Immunogenetics of Pigs. Information on swine immunogenetics has expanded recently (Lunney and Butler, 1998). Several different approaches have been used to examine the potential for using genetic approaches to improve animal disease resistance. It may be possible to predict the immunological potential of certain populations of pigs that may be more resistant to infectious diseases. These general immune resistance properties could be incorporated into commercial breeding operations. Theoretically, disease-resistant pigs, in well-managed facilities, help decrease the use of antimicrobials in swine herds.

Pig chromosomes are of special interest to farm animal cytogeneticists. The domestic pig (*Sus scrofa*) is cytogenetically the most widely studied farm animal (Chowdhary, 1998). This may be because of the relatively fewer chromosomes in the domestic pig ($2n = 38$) compared with other domesticated farm animals like cattle ($2n = 60$). The pig chromosomes are also readily distinguishable from each other, and it is relatively easy to identify most of the chromosomes even without the use of special staining methods. Techniques used to study the porcine genome have been reviewed (Chowdhary, 1998).

Genetics of Reproduction. The underlying genetic control of reproductive traits and methods of genetic improvement of these traits has been reviewed (Rothschild and Bidanel, 1998). A survey across breeds of swine demonstrates that considerable genetic variation exists for several reproductive measures. Average litter size varies among breeds from 4 to 16 piglets/litter for mature sows. Mean age at puberty varies from 3 to 7 months of age. This, along with genetic variability within breeds, suggests that substantial genetic improvement of reproductive performance in the pig is possible. Genetic differences for reproductive traits exist among and within breeds and lines. Differences among breeds and lines can be exploited most effectively through the use of crossbreeding. Whereas there has been much emphasis on the genetics of reducing backfat thickness, there is now much interest in the genetics of improving sow and boar reproduction (Rothschild and Bidanel, 1998). Experimental results have shown that the least heritable traits such as litter size could be selected successfully in certain circumstances. The use of powerful across-herd genetic evaluation techniques based on Best Linear Unbiased Prediction methodology has provided geneticists with the opportunity to substantially increase the efficiency of selection of these least heritable traits. As a consequence, litter size has become a major component of selection goals in maternal lines of pigs, and annual genetic trends of 0.1 to 0.3 piglet/litter have been obtained recently in some pig populations. Further gains in prolificacy, as well as in sexual maturity and mothering abilities, can be expected in the near future from the increasing use of prolific Chinese breeds or of synthetic lines developed through the use of these prolific breeds in crossbreeding plans. The use of marker genes will also contribute to more efficient use genetic improvement of reproductive traits, which are sex limited and often are expressed later in life.

Breeds of Pigs and Genetic Diversity. Pig production has been increasing in importance in both developing and developed countries. Pig numbers rank second only to poultry in terms of rate of increase: from 1960 to 1990 stocks increased by 45% and 201% in developed and developing countries, respectively. The increase is largely attributed to proliferation of a few breeds of pigs and the erosion of important genetic diversity in several indigenous breeds of pig. At least 20% of all known breeds of pigs are at risk of extinction (Hammond and Leitch, 1998). The greatest cause of genetic erosion is the growing trend to global reliance on one or a few modern breeds suited to high input-output needs of industrial agriculture. This is of major importance because about 50% of the total variation at the quantitative level is between-breed, the remainder being common to all breeds. Therefore a move to one breed would eliminate half this variation in the species, in addition to jeopardizing readily available gene combinations in other remaining unique genetic resources.

Animal genetic diversity allows farmers to select stocks or develop new breeds in response to changes in the environment, threats of disease, new knowledge of human nutrition requirements, changing market conditions, and societal needs, all of which are largely unpredictable. Animal genetic diversity is critical for achieving food security for the rapidly growing population, not only with respect to the local or national situation but also because countries are becoming increasingly interdependent for access to unique animal genetic resources. Furthermore, the lifting of trade barriers should create opportunities for developing countries to achieve more efficient and effective livestock sectors capable of increasing foreign exchange earnings and security for the world's majority. In addition, in developed countries consumer emphasis on product quality is increasing, markets are becoming more segmented, and efficiency of input resource use is being increasingly emphasized. These needs will intensify and should broaden efforts in the genetic development of animals for production, productivity, and product quality and should help sustain primary national and regional agrosystems.

A special action program for the global management of domestic animal genetic resources was begun by the Food and Agricultural Organization in 1992. Details of the program are described (Hammond and Leitch, 1998).

Genetics of Performance. Performance of an animal destined for market in a pork production system is defined by the efficiency with which it develops saleable product. That efficiency is largely determined by the costs associated with feed and time and by the amount of quality lean tissue produced. Genetic merit for market animal performance is improved in seedstock populations by performance testing and selection. For successful pork production, a breeding system must be implemented that optimizes market pig performance and reproductive efficiency. The genetics of performance traits have been reviewed (Clutter and Brascamp, 1998). In a typical selection program, an overall objective is defined and phenotypic measurements are chosen as criteria to estimate genetic merit for the selection objective. For objectives related to performance of the market pig, phenotypic measurements have included postweaning growth (days of age at an ideal market, typically 105 to 110 kg, or rate of gain from around 25 kg to market weight) and live animal backfat thickness at market weight, measured either with a ruler or more recently with an ultrasonic probe. Less frequently, phenotypic records may include individual feed intake and efficiency during the postweaning period and carcass information from relatives. A classical approach to this sort of multitrait selection involves derivation of a linear index of the phenotypic measurements with weightings that maximize its correlation with the selection objective (Clutter and Brascamp, 1998).

Performance and carcass traits in swine are affected by both heredity and environment. Heredity is the sum total of the genes and the combinations of genes that the offspring received from its parents. These are fixed at the moment of conception and cannot be changed thereafter. Environment includes all nonhereditary factors such as feed, management, and disease. The environmental effects can be controlled to a certain extent by the swine producer. Both heredity and environment must be optimum in order to produce swine efficiently. For example, the best feeding and management system possible will provide disappointing results if the animals produced do not have the genetic ability to perform well and to produce superior carcasses. On the other hand, a poor feeding and management system will also give disappointing results even if the swine produced are genetically superior.

The improvement of swine through breeding may be accomplished in two different ways. One way is to find the best animals for important traits when all are compared under similar conditions and then mate the best boars to the best sows. The second way is to cross unrelated strains or breeds to obtain heterosis, or hybrid vigor. The details of the different selection programs for purebred herds and commercial herds using crossbreeding systems are available in standard textbooks on the genetics of livestock improvement (Rothschild and Ruvinsky, 1998).

Breeding Stock Selection

Replacement breeding stock is a major expense in reproduction. It is also a major source of potential in improvement in productivity and quality of output through genetic improvement. It is an almost universal truth in North American production that the genetic improvement is gained through selection occurring off the farm in production systems designed for genetic selection. These systems have had the opportunity to use advanced selection methods and to respond more quickly to consumer demands. Moreover, they have had the scale to provide stock to allow the creation of large sow units.

Paternal genes are purchased as terminal boars or through semen purchases from local boar studs. Maternal lines are likewise often purchased as terminal line gilts. Alternatively, in larger production systems, parent lines are purchased from breeding stock suppliers, and the terminal line stock is produced in-house.

The role of the veterinarian is to aid in the selection of the breeding stock supplier. The criteria for selection of a supplier vary with the farm and the aims of the owners, but they include the following:

- *Familiarity and consistency of the genotype for the output buyers.* For sow units this will involve the buyer's ability to manage that genotype correctly. For meat packers this means that meat and carcass characteristics are expected to be of good quality. Unknown or unfamiliar genotypes are often disadvantaged because they are unknown for buyers and less likely to attain good contracts. Furthermore, inconsistencies with current supplies may be detrimental to processing. Meat-processing companies are starting to own or control the genotypes that enter their plants. One such example is Smithfield Foods, the largest pork producer in North America, which owns its genetic supplier, Northern Pig Development.
- *Freedom from specific pathogens.* The pyramidal and large-scale structure of modern pig production demands that new pathogens be avoided, since the cost is rapidly amplified and eradication is often difficult. This freedom involves current stock and the biosecurity methods to avoid new pathogen introductions.
- *Reliable and good productivity.* Not all productivity indexes can be superlative in the same genotype. Priorities for the farming system must be established. Prolificacy and durability of breeding stock along with feed efficiency; fast growth, and carcass characteristics are often the major characteristics of concern. It is also important to ascertain the priorities of future selection.
- *Long-term viability and improvement of the supplier.* It is costly and risky to change breeding stock suppliers because it allows a greater risk of new pathogens and creates a heterogeneous output.
- *Cost of product.* Costs vary between suppliers and can be a major cost of production. It is important to ensure that these added costs can be recouped through improved productivity or value of the output.

Sources of Breeding Stock

One of the major management decisions of commercial swine producers is selection of the source of breeding stock to be used in the breeding program. A major objective of both the producer and the veterinarian should be to introduce breeding stock with the greatest genetic potential for improving production efficiency. However, a major concern is the introduction of breeding stock that are latent carriers of pathogens able to spread to the home stock. The swine producer has three basic options for introducing breeding stock without introducing pathogens to the herd.

The first alternative is to maintain a closed herd except for the introduction of semen, embryos, or litters taken from their dams by cesarean section. This approach involves the least risk from the standpoint of disease introduction but often results in the lowest level of production efficiency of the three alternatives. The problem with the use of semen on a few selected crossbred sows is that the boars and gilts that will be produced are already crossbred and are probably related to many animals in the herd. There is often a major loss in potential heterosis for herds in which this procedure is attempted. If the commercial producer attempts to maintain a few purebred sows to prevent the loss of hybrid vigor, often the genetic level of these sows will be questionable. If these sows are bred artificially to superior boars, frequently there is little or no selection pressure placed on the progeny.

The second alternative is to purchase all breeding stock from a single supplier. This supplier should meet four basic criteria:

1. The health program of the supplier should satisfy the commercial producer and his veterinarian.
2. The selection and breeding program of the supplier should be planned to make near-maximum genetic progress for the economically important traits.
3. The supplier must have available for sale the breeds or crossbred combinations desired by the commercial producer so that maximum or near-maximum hybrid vigor may be attained by the producer.
4. The supplier must have enough boars available for sale so that the commercial producer may select boars with superior performance records. This approach appears safe from the herd health standpoint. Most of the genetic improvement is left to the supplier, who should be devoting a major portion of his time and resources toward continued genetic progress. Replacement gilts should continue to be selected from the commercial herd.

The third alternative is to use multiple suppliers of breeding stock. These suppliers would likely be two, three, or four purebred breeders of different breeds. If each of the breeders involved has a sound breeding and selection program, then this approach may allow the commercial producer to make optimum genetic progress. There are likely to be more problems with the introduction of disease by using this approach. Many commercial producers have been successful with this program by using careful introductory isolation and testing followed by a planned exposure program.

In Canada the commercial pork industry has shown a marked improvement in average carcass merit in the last few decades. This trend, stimulated and guided by the 1968 revision of carcass grading standards, has been accompanied by a 60% reduction in the number of commercial herds and a threefold increase in the average number of pigs marketed annually per unit. There has been steady growth in the use of systematic crossbreeding programs, and producer demand for boars with performance credentials has greatly intensified. This has fostered an increase in record of performance testing activity, given impetus to the evolution of swine AI programs, and encouraged the development of large closed-herd seed stock operations with self-contained performance test facilities. The central objective of performance testing programs, both private and public, is the genetic improvement of traits directly relevant to efficient lean meat production. Future production requirements are unlikely to alter this basic objective, but advances in the technology for live animal carcass evaluation and changing economic circumstances—specifically, changes in rations to accommodate the increasing competition for cereal grain supplies—will necessitate continuous review and revision of testing procedures.

Efficiency of production varies greatly among production units. It is not uncommon to find the amount of feed required to produce a unit of market weight to be as low as 3.3 to 3.7 for farms with excellent management and as high as 4.5 to 5.0 for farms with somewhat suboptimum management. Differences of this magnitude in production efficiency are not totally due to genetic differences; however, the practitioner should always be aware that performance never exceeds the genetic potential of the breeding stock used in a herd. Therefore the genetic potential should not be the weak link in preventing a production unit from attaining the efficiency of 3.3 units of feed/unit of live hog marketed.

Additional Information on Swine Improvement Programs

Additional information on swine improvement programs and systems is available on the Web through the Canadian Swine Improvement System (http://mark.asci.ncsu.edu/nsif/96proc/cSIS.htm) and the Review of Swine Genetics in the United States (http://mark.asci.ncsu.edu/nsif/95proc/review.htm).

Financial Planning

Swine practitioners are providing financial analysis of swine herd performance on an ongoing basis (Tubbs and Fuchs, 1996). Reasons for financial evaluation include new project proposals, sale of the swine operation, expansion of the herd, depopulation, producers' entering a network arrangement or a contract, intergenerational transfer of the enterprise, and financial difficulties. Three types of financial statements are used to monitor performance: balance sheet, income statement, and cash flow statement. Each of these statements provides information that is essential to the overall financial evaluation. The enterprise budget is another useful tool for analysis of the herd's financial status. It is a statement of planned economic activity for a given period of time. It identifies the likely sources of expected revenues and expected expenses. At the end of the period, the budget is compared with the income statement to determine how closely actual revenues and expenses have matched the projections and to assist in planning the next period's budget. Both the producer and the veterinarian are interested in the costs of production and how to decrease the costs of production and still maintain employee satisfaction, animal welfare, and sufficient profit. The costs of production are feed, labor, facilities and equipment, depreciation and interest costs, maintenance, veterinary services and animal health products, and administrative overhead. As competitiveness continues in the swine industry, the financial evaluation of the swine operation will be an absolute necessity.

Abattoir Surveillance of Market Pigs

Abattoir inspection data have been used in the surveillance of farm animal populations for occurrence of specific diseases as well as for tracing of affected herds as part of national disease control programs. The Danish Swine

Slaughter Inspection Data System provides surveillance of disease among Danish pigs (Willeberg et al, 1984). The system is unique to Scandinavia because the swine producers are strongly organized and supportive of their cooperatively managed slaughterhouses. The bacon industry of Denmark has developed excellent export-based production; maintaining a worldwide market for high-quality Danish pork is a common goal for the government and the swine producers. This has made it possible to introduce a national swine herd health management program to deal with current health problems in the national swine herd.

The keystones of the system are a centralized, computer-based accounting system for cooperative abattoirs and a uniform code list of diagnoses in the meat inspection regulations to specify the lesions causing partial or total condemnation of affected carcasses. Pigs shipped to market are identified by herd of origin through the use of a slap-tattoo. At slaughter, all lesions are examined and diagnosed by licensed qualified veterinarians. The diagnostic data are stored and processed on a central computer, from which data owners receive payment for the pigs with specifications of any deductions for partial or total condemnations. The routine reporting of all slaughter inspection findings for a particular swineherd has been very useful for the individual manager. The information obtained on a national basis is useful in identifying research priorities and providing an extension service to the farmers regarding the prevalent diseases. The data may also be used to conduct epidemiological investigations on farms with a high prevalence of diseases, such as enzootic pneumonia, and compare these farms with those with a lower incidence. A national file of approximately 60,000 herds that deliver pigs for slaughter is updated monthly with current figures for the number of pigs delivered and the number with lesions of the various categories. The updated file is processed to detect those herds for which one or more of the lesion rates exceed critical limits determined by different criteria. A herd file is flagged if the mean rates exceed the critical limits for any of the groups of lesions. The slaughterhouse sends a letter to the producer suggesting a visit to the farm to investigate the problem. If the producer responds favorably, the slaughterhouse arranges for a local practicing veterinarian, selected by the producer and the local extension swine specialist to meet with the producer at the farm. During the investigation and discussion at the farm, a recording form is completed with summary statements about the conditions found and recommendations are made to control the problem. The program currently covers 95% to 97% of all pigs slaughtered within the country. At the chosen level of discrimination, approximately 2.4% of herds are flagged each year and represent 14% to 17% of the pigs killed. There has been general acceptance of the principles and procedures of the scheme. However, producers have had a critical attitude regarding the problem-solving abilities of the veterinarians performing the herd visits.

The validity of the classification of lesions present at slaughter has been questioned. Examination of the data found high degrees of correlation between the occurrence of lesions at routine inspection and the recording of prior clinical episodes and detailed necropsy diagnoses. The meat inspection data have been used in several epidemiological studies, which have provided important information for the development of the national herd health program. For example, the data suggest that frequent problems are not independent, specific diseases but different manifestations of underlying unfavorable environmental and managerial herd factors (Willeberg et al, 1984).

The logistics of examination of swine at slaughter, the epidemiological considerations, and the significance of the findings have been described and are presented in the section dealing with monitoring disease in growing and finishing pigs ("Diseases of Growing and Finishing Pigs") (Straw et al, 1986a,b).

Losses resulting from death of pigs on arrival at the abattoir and condemnation of swine carcasses after slaughter can be substantial. Death of pigs during transport and lairage is a problem in some countries. The causes of rejection of whole carcasses include the pneumonia-pleurisy-peritonitis complex, abscesses, fever, and arthritis. Abscesses are the most common cause of rejection of parts of carcasses. The main reasons for rejection of liver, heart, and lungs were milk-spot, pericarditis, and pneumonia. In a survey of the causes of rejections of pig carcasses in seven abattoirs, which slaughtered 1.3 million pigs, 0.2% of whole carcasses and 2.0% of parts of carcasses were rejected.

Effect of Housing on Performance and Disease Incidence

Complete confinement of the swine herd during production has created many managerial and environmental problems that affect reproductive performance, growth performance, and incidence of disease (Donham, 1998). Inadequate housing and ventilation, poor sanitation and hygiene, and overcrowding are predisposing causes of disease and poor performance. The most economically important health and production problems are multifactorial in origin. The environment in buildings of the intensive pig industry can be associated with health hazards of people employed (Donham, 1998). Veterinarians need a working knowledge of the science of environmental design, control, and monitoring to facilitate their role as swine production and health management specialists (MacDougald, 1988). The various aspects of housing and ventilation must be examined at each visit to the farm. An agricultural engineer who is knowledgeable about housing and ventilation should be consulted when problems are suspected.

A checklist for inspection of such problems would include the following:

1. Sanitation and hygiene, and cleaning and disinfection practices
2. Comfort of animals in their pens
3. Quality of air and adequacy of ventilation
4. Stocking density and overcrowding
5. Quality of floor material and evidence of traumatic injuries resulting from floor surfaces
6. Adequacy of temperature in each section of the pig house
7. Manure disposal

Some of the identifiable risk factors that may interact with each other to affect performance and disease include herd size, herd immunity, feeding systems, quality of flooring, pen cleaning systems, manure storage and disposal systems, ventilation systems, lighting, pen design, and abnormal animal behavior. The major problems appear to be stocking rates and pen sizes, quality of floor surfaces, sanitation of pens, ventilation, and offensive odors from manure storage pits.

All-In, All-Out Systems

In large sow herds, a common practice is to divide the farrowing barn into smaller AIAO units for each week's farrowing group. The gestating sow units are usually housed in a central area, often with an estrus detection facility. Gestating sows may be confined and fed in groups or in individual stalls. Confinement in individual stalls allows for controlled individual feeding and more effective control of sow condition. Nursery units are also AIAO units, usually designed to hold one week's output of weaned pigs. If the nursery is

off-site, it may be designed to hold weanings from a number of sow units.

Ventilation and Air Quality

In most areas where pigs are raised in total confinement, a system of climate control with an effective ventilation system is necessary. The provision of an adequate ventilation system optimizes production, minimizes the spread of aerosol infections, and provides a reasonable working environment for employees. Effective ventilation systems for swine barns are notoriously difficult for an agricultural engineer to design and for the producer to operate and maintain. Many systems are incorrectly planned or used and are not maintained properly. High-low thermometers are often the first test to determine if the ventilation system is capable of maintaining the correct temperature. Effective climate control involves maintaining the temperature at a desirable level with the aid of supplemental heat and adequate insulation of walls and ceilings, achieving a relative humidity ranging from 50% to 75%, and providing satisfactory movement of air into and out of the building. There must be continuous removal of inside air and a continuous supply of fresh, outside air. For optimum animal health, supplemental heat may be required to permit continuous ventilation while an ambient temperature is maintained. The cost of energy for supplemental heat for swine barns in cold climates is a major economic consideration. Fully automated environmental control systems using microprocessors for the control of the climatic environment in swine buildings have been widely adopted by producers.

The ventilation needs for confined swine can be calculated from the size of the building, the number and ages of the pigs, the building materials used, and the outside ambient temperature. Standard formulas are available, and the assistance of an agricultural engineer should be sought. Guidelines that veterinary practitioners can use for monitoring and troubleshooting the environment of swine barns, especially for the weaned pig, have been described (MacDougald, 1988).

In weaned pigs the problem may be a lack of uniform growth in the absence of clinical or subclinical disease. Examination of the general environmental components includes checking the thermostats, the exhaust fans, the air inlets, the layout of the pens, and the manure disposal system. The temperatures in the pens can be monitored to determine the degree of fluctuations that occur over a 1- to 2-week period. A variety of thermometers is available for this purpose (MacDougald, 1988). Any air speed or wind chill reduces the effective temperature that a pig feels. Air speed and patterns in swine barns are easily determined by the use of smoke sticks. They indicate the overall air pattern in a room and are excellent aids to understanding the basics of inlets, air speed, and air pattern. Static pressure can be measured by static pressure manometers.

Dust and noxious gases are part of the environment of a confinement building, and although they cannot be eliminated, they can be controlled at a comfortable level with adequate ventilation. In swine confinement buildings, the gases of primary concern are ammonia, hydrogen sulfide, methane, and carbon dioxide. These gases are produced either directly or indirectly by the animals through respiration or from the manure and its decomposition. It is estimated that the gas of primary concern is carbon dioxide, most of which is produced by pig respiration. The anaerobic degradation of the stored manure causes the release of hydrogen sulfide, ammonia, and methane, which have some known physiological effects that can be controlled with adequate ventilation rates. Monitoring of air quality can be accomplished by comparing key production records with industry standards and by measuring and comparing relative humidity, ammonia, and air velocity at the pig and human level. Instrumentation can help to document environmental problems, and the assistance of an experienced agricultural engineer is desirable to interpret the findings. Carbon monoxide has also been documented as a cause of death in fetuses and newborn piglets. It occurs at toxic levels when there is an improperly operating fossil fuel heater in the barn and air exchanges are inadequate. Routine maintenance of all heaters should be encouraged.

The major health problems that have been epidemiologically associated with inadequate ventilation include enzootic pneumonia, AR, actinobacillus pleuropneumonia, tail biting and other behavioral abnormalities, and manure gas poisoning.

Floor Surfaces

The nature of floor surfaces used in swine barns has contributed to a variety of injuries to the feet and skin and possibly to the locomotor system of pigs. The lack of bedding, such as straw, and rough concrete surfaces can cause skin abrasions of the teats and carpal joints of nursing piglets and abrasions and fissures of the soles and hooves of older pigs (Svendsen et al, 1986). A wide variety of concrete floor surface finishes, plastic-coated expanded metal floors, concrete and metal slatted floors, and asphalt-covered surfacing have been used with varying success. Slatted floors reduce labor requirements but may increase claw injuries (Mouttotou et al, 1999).

Performance of growing-finishing pigs in terms of rate of gain and gain per unit of feed consumed generally has been comparable on partially and totally slatted floors. Where sizable differences in performance have occurred, factors other than slatted floors alone are usually involved. Among these factors are environmental temperature, space per pig, number of pigs per pen, management practices, variable spacing between or careless installation of slats, improper ratio of slat width to space width, insecurely fastened slats, and rough surface or jagged edges of slats. Frequently, the effects of these factors are difficult to assess.

Slatted Floors

More than any other factor, the adoption of slatted floors for swine housing has accelerated the trend to total confinement; with the introduction of partially or fully slatted floors, labor requirements were significantly reduced. Manure is generally stored under the slats, though some barns use under-slat scraping or flushing to remove manure daily to storage outside the barn. In flushing systems, effluent taken from the upper surface of the lagoon is recycled to the end of the swine building where it is used to flush new wastes into the lagoon. Noxious gases and odors formed from wastes can be irritating to both the animal and the animal attendants. The most important gases generated in a swine confinement unit are carbon dioxide, ammonia, hydrogen sulfide, and methane; a large group of trace organic compounds, such as amines, mercaptans, and skatoles, are generated as well.

Building Materials

The rapid intensification of the swine industry led to the use of many building materials that were attractive economically but undesirable for optimum swine production. The use of various floor materials and designs preceded research information, and the culling rates of breeding animals have

been high. This has necessitated the remodeling of older facilities and the building of new facilities after careful consideration of animal comfort and economic reality.

Handling Manure

The handling and disposal of swine manure is a major problem in total confinement production of swine. The daily accumulation of manure on solid floors may contribute to the spread of infectious diseases and may chill the pigs when the lying areas are soiled. In addition, it demands mechanical or hand scraping and cleaning. It is laborious and generally undesirable, because the frequency of cleaning that will maintain relatively acceptable sanitary conditions is prohibitive from a labor and cost standpoint where large numbers of animals are confined.

Cleaning and Disinfection of Swine Barns

Experience in swine herds has shown that increased losses and lowered productivity may occur if the rearing accommodations are not satisfactorily cleaned and disinfected between batches of pigs. Cleaning and disinfection routines are designed to remove most of the microbial population from pig pens during washing and cleaning procedures, followed by the destruction of accessible residual infections by chemical disinfectants, heat or steam, or fumigation. Farrowing, nursery, and growing-finishing facilities must be cleaned in conjunction with an AIAO policy. Breeding areas and gestating sow accommodations need only be swept clean unless herd-level disease problems dictate otherwise. The spread of pathogens in the breeding area could be encouraged to ensure that breeding stock develop an immunity to the agents associated with reproductive failure and neonatal diarrhea.

Cleaning and disinfection routines should follow the following pattern:

1. Remove bulk manure, litter, adherent dirt, and dust from floors, walls, and upper reaches, and dismantle equipment.
2. Soak and prewash pens and equipment with a suitable detergent. A high-pressure sprayer is the most effective and most common method used to clean confinement swine barns. The use of hot water will further speed up the cleaning process. Cleaning must remove all visible signs of dirt and feces. Allow drying after washing.
3. Apply the appropriate disinfectant to the floors, walls, equipment, and upper reaches, and allow drying. Disinfectants that are effective in the presence of organic matter are preferred.
4. Leave the pens vacant for 2 to 3 days if possible.

Pathogens persist in residual dust, porous walls, and floors, and thorough cleaning and disinfection routines using the appropriate products are needed to achieve any significant reduction in the number of these pathogens. The choice of building materials and surfaces that are easily cleaned and disinfected are advantageous in that they lower labor costs and improve sanitation (Madec et al, 1999).

Control of Flies in Swine Barns

The most commonly occurring biting flies of swine include the stable fly *(Stomoxys calcitrans)*, various species of horseflies and deerflies, mosquitoes, and biting gnats. The common housefly *(Musca domestica)* is the most prevalent nonbiting fly associated with swine and other livestock housing. Other nonbiting flies most often associated with swine include little houseflies (*Fannia* sp.), various species of blowflies, and moth flies (often known as pit flies).

Control of Biting Flies

Biting flies can be controlled using a program of regular spraying of the animals with insecticides such as synergized pyrethrins and dichlorvos. Fly baits are useful as a supplement to fly sprays. Larvicides applied directly to fly breeding sources are not normally eliminated by regular manure and sanitation management. Stirofos is available in a feed additive formulation as an oral larvicide. Control of mosquitoes depends on management of areas of standing water.

Control of Nonbiting Flies

The control of filth-breeding flies (houseflies, stable flies, little houseflies, dump flies) depends on sanitation. They are among the most difficult livestock pests to control. These flies develop in moist manure and wet, decaying organic matter of all kinds found around swine premises. All manure, spilled feed, wet straw, and decaying plant material should be removed twice a week to break the breeding cycle of flies. The increased resistance of flies to chemical insecticides emphasizes the need to consider alternative means to chemical control. Biological control techniques are being explored. Proper use of screens and fly traps are two methods of mechanical fly control that can be used, primarily in enclosed swine housing. Insecticides should be supplementary to sanitation and management measures aimed at preventing fly breeding. Residual sprays usually are the most effective and economical for controlling potentially heavy populations of adult flies. These sprays are applied when flies first appear in the spring. Generally, sprays continue to kill flies for up to 4 weeks with one treatment. The sprays are applied to fly resting surfaces, such as the framework of swine houses, ceilings, trusses, electric light wires and fixtures, outside walls, fences, and any other areas that attract flies. Space sprays, mists, and fogs with quick knockdown but no residual action are advantageous where immediate reduction of an adult fly population is necessary (Williams, 1992).

Housing the Sow from Weaning to Parturition

There has been almost universal adoption of individual confinement of pregnant sows and pubertal gilts in stalls. A major advantage of individual stalls is the ease with which individual feeding according to the conditions of the sow can be accomplished. This method also facilitates daily observation of individual animals for any early sign of illness (e.g., vaginal discharges, lameness, abortions, diarrhea) and makes treatment easier. Such observations and treatments are difficult in group breeding situations. However, because the pregnant sows are individually housed on concrete with no bedding and cannot huddle, they are particularly vulnerable to low house temperatures. It is therefore important that sows on restricted energy intakes, particularly those with energy reserves depleted by lactation, should be housed in the correct thermal environment. At 12° to 18° C, the animals are in conditions considerably below their lower critical temperature and require additional feed to achieve the projected live weight increase.

Alternative systems are being considered, including tethers, group housing with computer-controlled feeding stations, group systems with trickle feeders, and extensive housing on deep bedding (den Hartog et al, 1993). No one system is immediately better, but there are real differences in labor costs, welfare, health, and costs. Currently, European countries, particularly Great Britain, have eliminated the use of stalls and tethers and now support the outside housing (Hazas et al, 1998).

For small-sized swine producers with limited capital for new facilities, one successful alternative is low-cost housing (Friendship and Kains, 1998). In Ontario the most popular low-cost housing option is the hoop or tarpaulin (tarp) barn. These tarpaulin-covered, steel-arched structures are about one quarter to one third the cost of fully slatted, environmentally controlled finishing barns. In addition, hoop barns can be dismantled and moved or can be used for other farming purposes. Small producers using hoop barns have successfully created batch-farrowing systems that maximize crate use and sow performance. Batch farrowing can be implemented without compromising farm operations and profit.

Housing the Sow During Lactation

Considerable effort has been expended by the swine and building industries to develop the most suitable farrowing crate. The incidence of piglet crushing is still unacceptably high, but crates can be designed so that the sow is made to lower herself to her knees, before flopping over to the fully recumbent position, by narrowing the width between the bottom rails of the crate. Alternatively, hydraulic or adjustable arms restrict the sow's going down but allow the sow to arise easily. However, the most significant improvements in sow productivity have come through better management of farrowing houses rather than through the buildings themselves. More attention is being paid to sanitation, hygiene and efficiency of use of the farrowing crates. This includes leaving the crates vacant for at least a few days between sows and rational cross-fostering of piglets as necessary. The planned induction of parturition of batches of sows using the strategic administration of prostaglandins has also been a major advancement. Care of the sow includes cooling through air movement, and wetting ensures comfort during hot weather and improves feed intake. The ideal floor surface of the farrowing crate for the newborn piglet remains elusive. Many different perforated floor surfaces have been developed that are nonslip and nonabrasive for the piglets and that are also easy to clean after weaning of the piglets.

Housing the Young Pig from Weaning to 20-kg Live Weight

Early weaning at 3 weeks of age or younger has become commonplace. This trend has precipitated a demand for accommodations capable of housing piglets weighing less than 5 kg with no maternal protection, often with low feed intakes, and in groups matched for size rather than litter groups. The lower critical temperature of pigs weaned at 5 kg is about 27° C; consequently, weaner accommodations must be capable of maintaining temperatures of 30° C, especially in the immediate postweaning period when feed intake is low. All accommodations for young pigs require some form of supplementary heating if the required house temperature is to be maintained when the temperature difference between outside and inside is greater than 12° to 15° C. Housing problems that occur in weaner pens include overcrowding, insufficient feeder and water spaces, postweaning check, and the spread of infections.

Housing the Growing Pig from 30-kg Live Weight to Market

Housing for pigs from 30-kg live weight to market weight has not changed significantly compared with that for other classes of pigs. Pens with partially or fully slatted floors with no bedding holding 15 to 25 pigs are common. The urine and feces collect into a pit under the slatted floor and are removed as slurry on a regular basis. Considerable field research is being directed to the handling of the slurry.

Flow of Pigs Through the Unit

The flow of pigs through a farrow-to-finish operation must occur with optimum efficiency. There must be adequate space in each section of the operation, and a continuous breeding cycle must be established so that there is optimum use of space and a steady supply of pigs. The AIAO system should be used to minimize the incidence of infectious disease. In this system each unit of the swine enterprise is fully occupied by pigs for the necessary time, which is then followed by a complete depopulation of the unit, cleaning, disinfection, and a period of vacancy before being occupied by animals again.

Use of Antimicrobials as Growth Promotants and for Control of Infectious Disease

Antimicrobials are used extensively in swine feed as growth promotants and for the control of certain bacterial diseases (Prescott, 1997). Antimicrobials with in-feed, U.S. label indications for growth promotion and improvement of feed efficiency include sulfonamides, bacitracin, carbadox, tylosin, penicillin, lincomycin, tetracyclines, bambermycins, and virginiamycin. They are used to improve rate of gain-and-feed conversion in growing pigs and to control specific infectious diseases such as swine dysentery. Antimicrobials may be used in the rations of pigs from weaning until the end of the growing period. Prophylactic or therapeutic levels of certain antimicrobials are commonly used when outbreaks of disease occur. Examples of these diseases include *M. hyopneumoniae*, ileitis, and *A. pleuropneumoniae*. The use of antimicrobials in the feed of sows has improved reproductive performance in some situations.

The use of antimicrobials in the feed of food animals may result in the selection of antimicrobial-resistant bacteria that may be transferred to humans. Many expert scientific panels have been convened to review the scientific literature to consider the potential public health risks from using antimicrobials in the feed of food animals. These reports have concluded that, in general, antimicrobial use leads to selection for resistant bacteria, and that given certain circumstances, these bacteria may be transferred to humans. Most recent studies claim that there is a relationship between the use of antibiotics in food animals and the emergence of antibiotic-resistant bacteria and their transfer to humans (JETACAR, 1999; ACMSF, 1999). However, the risk of this occurrence has not been characterized and quantified. Nevertheless, there is increasing pressure on livestock producers not to use antimicrobials for growth promotion and for routine disease control, but to use them under the strict supervision of the veterinarian who has examined the animals and the circumstances requiring the use of antibiotics.

The conclusions and recommendations of the Advisory Committee on the Microbiological Safety of Food, "Report on microbial resistance in relation to food safety" (ACMSF, 1999) concluded that the aim must be to reduce the exposure of farm animal antibacterial populations to antibiotics by the following:

- Constraining the use of growth promoters
- Paying much greater attention to the question of resistance in the approval procedures for veterinary medicines and in postmarketing surveillance
- Stimulating the farming industry, its suppliers, and the veterinary profession to develop strategies for reducing the use of antibiotics for both therapy and prophylaxis

and confronting the difficulties caused by the veterinary use of fluoroquinolones
- Introducing tighter controls on medicated animal feedstuffs
- Improving the understanding of resistance in bacteria isolated from food animals and foodstuffs, and of ways in which the food chain contributes to human infections with antibiotic-resistant microorganisms

It is suggested that these strategies would reduce the chances both of acquisition of resistance by bacterial pathogens, and of transmissible resistance by other farm animal microflora. Also, importantly, there needs to be a greater emphasis on animal health management standards across the food-producing animal industry, including closer attention by veterinarians and producers on the threat of antibiotic resistance (ACMSF, 1999).

The U.S. FDA recently commissioned a risk assessment to estimate the risk to public health of antimicrobial use in food-animal production. The U.S. pork industry is emphasizing the need to adhere to science-based decision making. This is in contrast to some other countries where decisions are being made to withdraw antimicrobials without good scientific justification. For example, the Precautionary Principle in Europe is based on the notion that if someone raises a threat of harm, measures need to be taken to address the concern. The burden of proof of safety rests with the proponents of an activity or technology; it assumes a position of no risk. On December 14, 1998 the European Council of Agricultural Ministers voted to withdraw the feed additive use of bacitracin zinc, spiramycin, virginiamycin, and tylosin phosphate (Anonymous, 1998); three countries—Belgium, Portugal, and Spain—abstained. The ban was imposed as a precautionary measure to minimize the risk of development of resistant bacteria and to preserve the efficacy of certain antimicrobials used in human medicine.

As trade barriers fall, there is an increasing need to standardize the use of additives such as antimicrobials. Consequently, pressure to disallow subtherapeutic antimicrobials in Europe creates a need to address the situation in other countries. It remains to be seen if the desire to adhere to science-based decision making will prevail in the United States.

Growth Promotants in Swine Feeds

Growth promotants cause improvements in growth performance over and above many other means by which performance targets are met. Because the greatest expense in pig production is feed, any method by which the efficiency of utilization of feed is increased may be economically desirable. The types of growth promotants used in pig production include antimicrobials; trace elements, such as the organic and inorganic salts of copper; ionophore antibiotics; tiamulin, which is a semisynthetic derivative of an antibiotic; and probiotics.

The advantages and disadvantages of subtherapeutic antimicrobial use continue to be debated in the literature. In a recent review (Prescott, 1997) the advantages for the producer were described as greater uniformity of growth and reduction in morbidity. Average daily gain may increase by 10% to 23% and feed efficiency from 6% to 8%. For the consumer, the advantages are that the pork is produced at a reduced price, potentially contaminated with fewer bacteria and arguably produced with increased welfare for the pig. The disadvantages for the producer are the consumer and political pressures to avoid using growth promoters, the possible suppression of normal flora, and the possible failure of antimicrobial therapy resulting from resistance induced by subtherapeutic use. The disadvantages for the consumer are the possible tissue residues in pork and the possibility of infection with antimicrobial-resistant bacteria that emerged in pigs fed subtherapeutic antimicrobial. A World Health Organization (WHO) fact sheet states, "The widespread use of antimicrobials for disease control and growth promotion in animals has been paralleled by an increase in resistance in those bacteria (such as Salmonella and Campylobacter) that can spread from animals, often through food, to cause infections in humans" (WHO, 1998). There is increasing pressure from government organizations, such as WHO, and a host of citizen groups to eliminate subtherapeutic use of antimicrobials.

The antimicrobials and other growth promotants approved for use in swine feeds varies among countries. Each country publishes a brochure describing those products that are approved for use as growth promotants, their withdrawal periods, and their incompatibilities.

Strategic Medication of Feed and Water

Three major issues have increased the frequency of infectious disease, including (1) mixing of animals with different levels of immunity and microbial status, (2) increase of population size and stocking density, and (3) stressful situations caused by events such as transport and fighting after commingling. Mortality may be the tip of the iceberg in some disease situations, hence the practice of feed or water medication. Disease in these large and dense animal populations can be reduced and even prevented by prophylactic administration of antibiotics. The veterinarian must strive to balance the benefits of antimicrobial use with the risk of resistance and cost of the product. Having recognized a set of circumstances in which antimicrobial use may be beneficial, a decision to treat is made based on the following criteria:
- The cost of the particular disease
- The effect on well-being of the pigs
- What will likely happen if treatment is not provided (self resolving, staying the same, or getting worse)
- The cost of the proposed treatment
- The likelihood of resolving the problem with these changes and treatment

The most commonly used antimicrobials in the United States, listed in order of frequency, are tetracyclines, carbadox, bacitracin, tylosin, apramycin, and lincomycin (Dewey et al, 1999).

The specific treatment program will be based on the following:
- Presumptive diagnosis based on clinical signs and history
- Herd health history and performance records
- Prevalence and incidence of this disease
- Compliance of owner-staff
- Benefit:cost of treatment options
- Laboratory results (serology, postmortems with culture and sensitivity)
- Clinical experience
- Antibiotic options available

Mass medication of the feed and water supplies of feeder pigs is not without problems. In addition to the costs, it is not always possible to medicate feed supplies that are already in place on the farm, and the medication of water supplies is often difficult to perform selectively unless there is a double waterline in each pen, one of which can be turned off. Medication of the entire watering system may not be necessary and is more expensive. The withdrawal period for each feed additive must be followed to avoid drug residues in meat supplies. Tests to detect drug residues in pigs after slaughter are now available and are used for statistically valid random sampling of pork in abattoirs.

The American Association of Swine Veterinarians (AASV, 2000) issued a statement regarding the use of antimicrobials in swine production. It reiterated its commitment to the use of scientific knowledge and skills for the benefit of society (AASP, 2000). Culture and sensitivity results should be used to aid in the selection of antimicrobial. Therapeutic use should be confined to appropriate clinical indications. Therapeutic exposure should be limited to treating only for as long as needed for the desired clinical response and to treating only the ill or at-risk pigs, treating the fewest animals indicated. Judicious use of antimicrobials, when under the direction of a veterinarian, should meet all the requirements of a valid VCPR. Prescriptions, veterinary feed directive, and extra-label use of antimicrobials must meet all the requirements of a valid VCPR. Extra-label therapy must only be used where deemed appropriate and not expressly prohibited (chloramphenicol, clenbuterol, diethylstilbestrol, dimetradazol, ipronidazol, nitroimidazol, furazolidone and nitrofurazone [except for approved topical use], fluroquinolones, and glycopeptides [e.g., vancomycin]). Veterinarians should work with those responsible to use antimicrobials judiciously. Regimens for therapeutic antimicrobial use should be optimized using current pharmacological information and principles. Antimicrobials considered important in treating refractory infections in human or veterinary medicine should be used only after careful review and reasonable justification. Contamination of the environment with antimicrobials should be minimized whenever possible. Accurate records of treatment and outcome should be used to evaluate the therapeutic regimen.

In swine herds of today the veterinarian is responsible for making medical judgments, has sufficient knowledge of the animals to initiate at least a preliminary diagnosis, and is readily available in case of adverse reactions or failure of the treatment regimen. Veterinarians have a unique understanding of the broad array of production systems in which pigs are raised. Antibiotic use is a critical component and must be balanced with the needs of the farmer, the pig, and the public.

PRINCIPLES OF CONTROL OF INFECTIOUS DISEASE IN THE SWINE HERD

The presence of certain specific infectious diseases in a swine herd can have a serious limiting effect on efficient production. Some endemic infectious diseases can cause significant economic losses as a result of high mortality, suboptimum growth rate and feed efficiency, and high drug costs. The objectives of a disease control program are to improve animal performance, such as days-to-market and feed efficiency, to improve net profit, and, if possible, to eliminate the disease from the herd or control its prevalence at a low enough level that it does not significantly limit production economically. Some of the economically important infectious diseases of swine herds include the following:

- Enzootic pneumonia (*Mycoplasma* spp.)
- Porcine reproductive and respiratory syndrome (Lelystad virus)
- Multi-systemic postweaning syndrome *(Circovirus)*
- Pleuropneumonia *(A. pleuropneumoniae)*
- Swine dysentery *(Brachyspira hyodysenteriae)*
- AR (i.e., turbinate atrophy)
- Sarcoptic mange and other ectoparasitisms such as lice infestation
- TGE
- Neonatal piglet diarrhea (Enterotoxigenic *E. coli*)
- Porcine parvovirus (PPV) infections

In addition, certain infectious diseases are considered exotic to some countries whereas they occur sporadically in swine herds in other countries. These include the following:

- Aujeszky's disease (pseudorabies)
- Hog cholera (classical swine fever [CSF])
- Swine vesicular disease (SVD)
- Vesicular exanthema
- FMD

The veterinarian and the swine producer must decide which diseases should be controlled or eradicated in the herd based on the prevalence of the disease, the economic losses caused by the disease, and the probability that the disease can be controlled or eradicated. The diseases of concern vary from herd to herd and from country to country.

Epidemic Diseases of Swine

Several diseases of pigs are known as the important epidemic diseases. They are CSF (hog cholera), African swine fever (ASF), FMD, and SVD. These diseases are on the Office International des Epizooties (OIE) List A, which are defined as "transmissible diseases which have the potential for very serious and rapid spread, irrespective of national borders, which are of serious socioeconomic or public health consequence and which are of major importance in the international trade of animals and animal products" (Pedersen et al, 1996).

Outbreaks of the aforementioned diseases in meat-exporting countries are of major consequence because of export bans. When serious outbreaks of disease occur, the eradication measures required and the export ban have severe economic consequences. Therefore adequate prevention and control programs are of great importance to both government and private industry. The risks and consequences of introducing CSF into the Netherlands by feeding swill (garbage) to swine have been examined using risk simulation models (Horst et al, 1997). An outbreak of CSF in the Netherlands in 1997 caused estimated losses of $400 million (U.S. dollars), excluding losses from market disruptions (Horst et al, 1997). By April 1997, more than 120 farms were affected. High losses are due to government purchase and destruction of pigs from farms located within the protection zones where movement of pigs is prohibited. A decision support system for managing swine fever epidemics using an epidemiological program (EpiMan) has been described (Stark et al, 1998).

All outbreaks of List A diseases are immediately reported to the OIE and, in the European Community, to the European Commission. The outbreaks that occurred over a 10-year period are shown in Table 15-10. These diseases are important not only for the economic losses that occur on affected farms but for the major adverse economic consequences for international trade.

Classical Swine Fever (Hog Cholera)

CSF occurs in Asia, Central and South America, and parts of Europe and Africa. Many countries are now free of the disease. In August 2000 the European Commission banned the export of live pigs and porcine semen from England after the first outbreaks of CSF (hog cholera) since 1986 were confirmed on five farms in East Anglia (Anonymous, 2000). A large number of outbreaks of the disease have been confirmed in Germany, the Netherlands, Spain, and Italy in 1998.

The earliest record of hog cholera in the United States dates to 1883 in Ohio (Jordan, 1998). In the early 1890s, control was achieved using hyperimmune serum from pigs repeatedly vaccinated with the virus. In 1934 a vaccine was developed that provided 90% protection. The first

commercial license for modified live-virus vaccine production was issued by the USDA in 1951. In 1961 legislation was introduced to provide for a national eradication program. The use of vaccines was gradually phased out. The eradication program was designed in four phases: Phase 1, preparation; Phase 2, reduction of incidence; Phase 3, elimination of outbreaks; and Phase 4, protection of reinfection. Many outbreaks occurred during the eradication program because of breakdowns in regulations. Identification of the sources of infection was as important as identification of infected herds. The prime threats to herds were the addition of outside animals and neighborhood animals. Uncooked garbage accounted for some of the outbreaks. In January 1978, the United States was declared "hog-cholera free." The eradication of hog cholera was a major benefit to the swine industry. The key to eradication was a close working relationship with veterinarians and leaders in the industry. The compliance of the livestock producer was also a crucial factor to success. The ability to combat the introduction of foreign animal diseases to the United States was accomplished. Foreign markets were opened for breeding stock. It was truly a success story in animal disease eradication.

The recent outbreaks of CSF in Germany and Belgium illustrate some of the risk factors involved. Both epidemics were due to the movement of infected weaner pigs from a small breeding unit in one area to finishing units elsewhere in the country. The main risk factors are infected wild boars, densely populated pig areas, and long distance transport. The major factor in the resurgence of these diseases in areas previously considered free is the rapid development of the swine industry and the trade in live pigs that supplies it.

African Swine Fever

ASF is a highly contagious disease of domestic swine and European wild boar *(Sus scrofa)* caused by an isohedral, double-stranded DNA virus. The disease was first described in Kenya in 1921 with reported outbreaks of peracute disease accompanied by a high mortality and extensive hemorrhage of tissues; it was subsequently recognized in other countries of Africa, where it continues to be an economically devastating disease. In the late 1950s ASF appeared for the first time outside Africa, in the Iberian Peninsula. Depending on the infecting virus isolate, the clinical disease ranges from peracute to chronic, and recovered pigs may become healthy carriers. Currently there is no vaccine and the only effective control policy is based on identification and slaughter of infected pigs. It was present in four South American and Caribbean countries but has been eradicated.

Foot-and-Mouth Disease

FMD affects all ruminant species and swine. The epidemic in the United Kingdom in 2001 was first recognized in pigs at an abattoir. The pigs originated from a farm that allegedly had been feeding swill (table scraps from restaurants and other eating establishments). The epidemic began February 20, 2001; by May 2001, almost 2 million animals (cattle, sheep, pigs, goats) had been slaughtered and buried or burned as part of the eradication program. It also appeared that the disease had been present in sheep for several weeks before it was recognized in the swine herd. It is endemic in parts of Asia, African, the Middle East, and South America. A porcine strain of FMD may have been responsible for recent outbreaks in the swine population of Japan and Korea. Transmission of these diseases can be by direct contact between animals, from wild boars, and from the ingestion of feed (especially garbage fed to pigs) contaminated with the virus.

Many countries give high priority to preventing the introduction of highly contagious diseases such as CSF and FMD into their animal populations and have eradication policies in place to deal with outbreaks. The European Commission and its member states have directives in place to take action in the event of an outbreak of disease (Davies, 1994). The main provisions of these directives are:

1. If disease is suspected, an official investigation must follow.

2. When the presence of disease is confirmed, all susceptible stock on the holding must be slaughtered, the carcasses destroyed, and the site cleaned and disinfected.
3. A restriction zone of 3-km (protection) and 10-km (surveillance) radius must be established around each outbreak; within these the movement of susceptible animals is prohibited until all the herds have been screened.
4. Vaccine (CSF and FMD) can only be used under exceptional circumstances.

Swine Vesicular Disease

SVD has been recorded in Hong Kong, Japan, and several European countries. It is caused by an *Enterovirus* of the family Picornaviridae. The morbidity may be high, but mortality is low. There is no treatment and no vaccine available.

DISEASE CONTROL STRATEGIES

There is some variation in the terminology used to describe disease control strategies. Prevention, control, and eradication are terms commonly used to describe control strategies (Martin et al, 1987). In practice, the terms are commonly used interchangeably, and more than one strategy may be applied to reduce the prevalence of a particular infectious disease to a low level or to eliminate it from the herd.

Prevention is generally applied to those measures designed to exclude disease from an unaffected population. This applies to measures to exclude pathogens from certain geographic areas by quarantine or to protect a given population in an infected area by vaccination. Swine dysentery, enzootic pneumonia, sarcoptic mange, and AR can be prevented in swine herds through the use of certain strategies.

Control strategies are directed toward reducing the frequency of existing disease to levels that are biologically and economically tolerable or are otherwise of little consequence. The producer and the veterinarian may decide to tolerate presence of the disease because alternative methods of prevention or eradication may not be possible or are too costly. Control implies activities conducted at the population level. Piglet diarrhea caused by enterotoxigenic *E. coli* can be controlled at a low incidence in the herd; there are no techniques available for its eradication.

Eradication strategies are directed at the elimination of certain pathogens from a defined area, which may be at the level of the herd, the state, the country, or the world. In the strict sense of the word, "Eradication is the extinction of the pathogen that causes the infectious disease in question; and so long as a single member of the species (the pathogen) survives, then eradication has not been accomplished" (Done, 1985). For certain diseases, such as hog cholera and FMD, the country may have an eradication policy that includes slaughter and disposal of infected animals. Hog cholera, Aujeszky's disease, and SVD are examples of diseases that can be eradicated from herds and countries. Countries will sometimes introduce country-wide programs to eradicate certain diseases such as Aujeszky's disease. The literature commonly refers to the eradication of specific diseases, such as swine dysentery and sarcoptic mange, from swine herds, but these diseases would not necessarily be eradicated from the geographic area and could be reintroduced into a herd that had at one time eradicated them.

The tradition of farm animal disease control in the Nordic countries compared with the rest of Europe is interesting (Pedersen et al, 1996). All the Nordic countries were free of the OIE List A diseases in 1994. In contrast several of these diseases were present on the mainland of Europe. The explanation for this situation is complex but is probably based on the isolated geographic location, restrictive importation of animals and animal products, education and organization of farmers, and a long-standing tradition of solving animal disease problems by eradication when possible and economical. There is also a strong relationship between the expectations of consumers and those of farmers and veterinarians.

PRRS, TGE, and PRCV infections have never been reported in New Zealand (Motha et al, 1997). Passive surveillance for these diseases, as well as for other OIE List A and B diseases, is done routinely by the Ministry of Agriculture's animal health surveillance program. A serological survey of pig herds in 1996 for PRRS, TGE, and PRCV found no evidence of infections. Pseudorabies was first diagnosed in the North Island of New Zealand in 1976; it had never been reported in the South Island. An industry-funded eradication program was initiated in 1989 to eradicate the disease from the national pig herd. Through the use of a combination of serological surveys, abattoir surveillance, test and slaughter, depopulation, vaccination and movement restrictions, the disease was eradicated by 1997 (Pannett et al, 1999).

Diagnosis of Infectious Disease

Before any of the infectious diseases can be controlled or eradicated, there must be a reliable method of making a definitive etiological diagnosis. When the disease is already present, a diagnosis is necessary so that specific control or eradication procedures can be planned and carried out. A diagnostic test with high sensitivity and specificity is desirable so that the progress and success of the control program can be monitored with a surveillance system that will detect evidence of infection in a population and provide an estimate of its prevalence. Serology is becoming an increasingly important aid to monitor infectious diseases that potentially can enter a herd when new breeding stock is imported. Good serological tests are available for some of the major swine diseases and infections such as PRRS, PR, TGE, PPV, *A. pleuropneumoniae*, leptospirosis, *M. hyopneumoniae*, erysipelothrozoonosis, and swine dysentery. Enzyme immunoassays are being used more commonly for the diagnosis of several infectious diseases of pigs at the herd level. Diagnostic cytology is also used for the diagnosis of coccidiosis, *Clostridium perfringens* enterotoxemia, *E. coli* infection, swine dysentery, bacterial meningitis, and sarcoptic mange (Van Alstine et al, 1987). Another method of monitoring for disease is the examination of lungs and snouts of pigs from a herd at the slaughterhouse or the regular serum-antibody testing for specific pathogens, which is discussed in the section on slaughterhouse examination of lesions ("Diseases of Growing and Finishing Pigs").

Infectious Disease Control Strategies

Control of an infectious disease means reduction of the prevalence to the lowest level possible with the management techniques and economic resources available. One or more of the following strategies can be used.

Test and Removal of Infected Animals

The elimination of infection by test and removal (T&R) of positive animals can reduce the prevalence of infection in the herd. The process of T&R may be an efficacious strategy and is currently under investigation. Test and removal has been used successfully to eliminate Aujeszky's disease virus

and *A. pleuropneumoniae*. In herds infected with PRRSV, the primary focus of this strategy is to test all breeding animals, identify carriers, remove them from the herd, and prevent vertical transmission of PRRSV (Dee et al, 2000). Analysis of sera using ELISA for the detection of antibodies along with PCR for the detection of viral protein are used in combination to identify previously exposed, potentially infected animals. The detection of carriers is critical because of the ability of PRRSV to produce persistent infection.

In the case of a herd infected with PRRSV, the T&R program is recommended when the prevalence of infection in the herd is below 50%. This method requires testing of the entire breeding herd and immediate removal of all seropositive animals; 30 days after removal of seropositive animals, the herd is retested and, if necessary, at 30-day intervals until the entire herd tests are negative. Following a second negative test, the testing regimen may be changed to test only 25% of the herd every 4 months. Seropositive animals are identified and culled. The T&R method is superior to the vaccination system as a method of control. Valuable genetic material may be salvaged from breeding stock that are seropositive by using embryo transfer techniques. Embryos may be transferred safely to susceptible recipient gilts from sows that have recovered from infection, but not from sows that are in the active stages of infection. The virus does not penetrate the outer covering of the embryo, but it can become attached to it so that it may physically transfer to the uterus of the recipent. This transfer of infection may occur if the donor sow is in the active phase of infection.

Reduce the Prevalence of Disease by Early Recognition and Treatment

The common bacterial diseases like pleuropneumonia and swine dysentery are treated with antimicrobials. In many cases the disease affects many pigs over a short period, which necessitates the treatment of individual animals that are clinically affected and the mass medication of the feed, water supplies, or both in an attempt to treat subclinical infections before they cause clinical disease. This strategy will be beneficial in some cases and not in others, depending on the specific disease, adequacy of housing, ventilation, stocking density, and management expertise. In well-managed herds diseases like swine dysentery, pleuropneumonia, and enzootic pneumonia can be handled effectively by using strategic therapy; in poorly managed herds the results may be unsatisfactory. The principle of medicated early weaning is to initially control and then eradicate endemic infections such as *M. hyopneumoniae* and *S. hyodysenteriae* (Alexander, 1988). Reduction of the prevalence of the disease decreases the number of infective animals that can transmit the infection to susceptible animals. The strategic use of anthelmintics in pigs will effectively control internal parasites that cause economic losses as a result of mortality, morbidity, condemnation of organs at slaughter, decreased rates of gain, and suboptimum feed efficiency and carcass quality (Biehl, 1986). The control of the important ectoparasites, such as mange, requires regular administration of insecticides to all animals. As an example, sarcoptic mange is not easily controlled because the mites are hidden in burrows or beneath thick scabs of the skin, which are difficult to reach with an acaricide. Cure and control depends on adequate treatment of every pig, including the sows before farrowing—and, if necessary, retreatment 10 days later—and the weanlings and growing pigs before they enter the finishing pens. The boars must also be treated regularly. In addition, the administration of topical insecticides must be done carefully so that all areas of the skin are covered. A prefarrowing treatment of sows with ivermectin is highly effective in preventing transmission of mange mite to the piglets (Dalton and Ryan, 1988). Unfortunately, the prevalence of some of the commonly occurring diseases such as pleuropneumonia cannot be reduced reliably by treatment of affected pigs, because the infection cannot be totally eliminated from the lungs following treatment; therefore recovered pigs can act as reservoirs of the pathogen, and the disease will remain endemic in the herd. The selection of the most cost-effective antimicrobial and the development of drug-resistant strains can create problems.

Reduce Infection Pressure and Minimize the Opportunities for Transmission of the Infection

The AIAO system of managing a group of pigs at each stage of the production cycle is an effective method for the reduction of infection pressure. Groups of pigs are moved into a section of the barn, managed in that section or in pens as a group, moved to the next section as a group, and marketed as a group. The pens are cleaned and disinfected between groups of pigs. A combination of mass medication of the feed of all pigs in a herd, except the nursing piglets; cleaning and disinfection followed by a period of vacancy for 2 weeks; and placement of sows and their piglets in these newly cleaned pens led to the eradication of swine dysentery without depopulation (Wood and Lysons, 1988). The cleaning, washing, and disinfection of farrowing crates between successive sows is also an effective method of reducing infection pressure on newborn piglets. High population densities promote the rapid spread of infection, with a heavy attack rate of infection from infected to susceptible animals; therefore the crowding of pigs in pens must be avoided. The conventional method of rearing pigs, in which they had access to feces-contaminated surfaces, resulted in a high prevalence of gastrointestinal helminthiasis. Current systems of swine herd management have resulted in a very low prevalence of intestinal parasitism, because piglets do not become infected in early life. They are born in clean farrowing crates from sows that have not had ready access to pig manure or contaminated ground, which are sources of the common swine endoparasites. Feeding and watering systems must minimize fecal contamination. The successful treatment of diseased animals will also contribute to a reduction in infection pressure for noninfected animals.

Identify and Minimize the Risk Factors Associated with Infectious Diseases using Effective Management and Production Methods

Risk factors for infectious diseases are usually associated with the environment, the host, and the pathogens. Some commonly known examples of environmental risk factors include inadequate ventilation and wide temperature fluctuations in certain parts of the swine barn, particularly during very warm and very cold seasons; breakdowns in the ventilation system; and inadequate floor space per pig. Examples of host factors include the failure of newborn piglets to obtain sufficient colostrum from their dams, which is a major contributing factor to neonatal diarrhea, and the weaning of piglets too early (e.g., before 3 weeks of age), which may result in a high incidence of postweaning diarrhea associated with rotavirus and enterotoxigenic *E. coli*. Risk factors associated with pathogens include the ability of some pathogens to remain latent in animals that have recovered from disease or in the environment and thereby provide a source of infection for noninfected animals.

Enhance Herd Immunity from Natural Infection or by Vaccination

Under the extensive system of rearing pigs, herd immunity developed because pigs of all groups and ages, including the boar, mixed on a regular basis, and the common pathogens were spread between pigs. Under intensive conditions—in which the dry sows are kept separate from the lactating sows, the weanlings are kept separate from the growing-finishing pigs, and the boars are kept separately—herd immunity to the common pathogens may not develop to the same extent. In an attempt to stimulate herd immunity under these conditions, the feeding of some feces from the sows in the farrowing house to the sows in late pregnancy (e.g., 2 to 4 weeks before farrowing) has been recommended. However, the effectiveness of this technique has not been validated, and the unhygienic nature of the practice may make it questionable. Mixing newly introduced gilts to dry sows, cull sows, and finishing pigs is also recommended to naturally immunize them against the common pathogens, such as enteropathogenic *E. coli*, PPV, and TGE virus. Some diseases of swine can be controlled or prevented by vaccination. However, for the economically important endemic diseases such as enzootic pneumonia, pleuropneumonia caused by *A. pleuropneumoniae*, swine dysentery, sarcoptic mange, and AR, vaccines are either not available or those that are not efficacious.

Genetic Selection for Natural Disease Resistance

The term natural disease resistance refers to the inherent capacity of an animal to resist disease when exposed to pathogens, without prior exposure or immunization. Animals can defend themselves by at least three host defense mechanisms: the epithelial barrier, nonspecific immunity from cells of the immune system, and specific immunity from recovered natural infections or vaccination. The first defense barrier, the epithelium, provides receptor sites for the attachment of many pathogens. Genetically determined variation in the structure of a cellular receptor would cause some animals to be resistant to colonization by a specific pathogen. The classic example of such genetic variability is the resistance of certain pigs to the K881 strain of *E. coli* because of the absence of an appropriate receptor for attachment of the organism to intestinal epithelium. Swine-breeding programs used to increase the degree of natural resistance of the pigs will not completely prevent infectious diseases. Any form of resistance to any infectious disease is relative rather than absolute. However, the increased degree of natural resistance conferred by selective breeding would reduce morbidity and economic losses caused by infectious diseases. There are no documented practical recommendations available for the control of infectious diseases of pigs by genetic selection.

High-Health-Status Herds

In the early days of breeding-stock supply herds, the control of economically important endemic infectious diseases was attempted using the *specific pathogen free* (SPF) herd concept. Pigs were hysterectomy derived and, after a period of isolation, were placed in a nonsterile environment where they became infected with a range of microflora classed as normal. However, they were not infected with specific pathogens such as those that cause enzootic pneumonia and AR, and they were designated free of these diseases (Muirhead, 1989). Pigs from these herds were designated as SPF pigs.

After some years, the term *minimal disease* (MD) herds emerged and was used interchangeably with SPF, but MD became associated with the belief that the pigs were free of the major infectious diseases, although they were not. Muirhead proposed the use of the term *high-health-status herd*, which is a *"herd of recognized health status through the absence of the major infectious diseases."* The diseases would be defined for each particular herd by the consulting veterinarian. The purpose of the term is to ensure that each herd provides evidence of the continued absence of each disease. It is important to emphasize that the terminology does not describe the animals as being free of any infectious agent, but that the observations and tests indicate the disease to be absent. This is important in legal terms, because it would be impossible to claim freedom from a pathogen; at any point in time, the pig could unknowingly be in a period of incubation. The high-health-status designation allows the precise health profile of the herd to be described by the veterinarian. The interpretation of the health status will vary among herds, but it would be expected that most of the major infectious diseases would not be present. Diseases or infections that are absent in a high-health-status swine herd are listed in Box 15-4.

In some countries, FMD, ASF, swine fever, Aujeszky's disease, tuberculosis, and *B. suis* infection would not normally be present because of current national disease-eradication policies. For example, the swine population in Canada is free of the above diseases. However, enzootic pneumonia, AR, disease caused by *A. pleuropneumoniae*, swine dysentery, TGE, and sarcoptic mange are of major economic importance, and producers and veterinarians aim to eliminate these diseases from their herds.

The recognition of the presence or absence of the aforementioned diseases in a herd of pigs can be difficult, because reliable methods of diagnosis may not be available. A typical example is deciding if a particular herd is free of disease caused by *A. pleuropneumoniae*. Should the required standard be the complete absence of the organism on bacteriological and serological examinations or the identification of a herd with no history of disease on clinical or pathological grounds? (Muirhead, 1989). Pigs from such a herd would be capable of integrating safely into commercial herds without risking the introduction of pathogenic serotypes or disease. The criteria for demonstrating the absence of major infectious diseases in a high-health-status herd depend on the diagnostic tests that are available and

BOX 15-4

Foot-and-mouth disease

Glasser's disease
Streptococcal meningitis
Atrophic rhinitis
Disease caused by *Brucella suis*
Salmonella choleraesuis
Swine dysentery
Lice
Tuberculosis
Parvovirus

their sensitivity and specificity, the results of pathological examinations, the examination of organs at slaughter, and the herd life history, depending on the particular disease in question.

A high-health-status herd can be established when the herd is first populated using pigs purchased from donor herds that are free of the diseases in question or through depopulation and repopulation of an existing herd. The donor herd must be investigated by the producer and the veterinarian. The investigation should include the herd history; all veterinary reports; the animal health and production records, including growth and feed conversion rates; the results of specific tests performed; and a report written by the veterinarian of the donor herd declaring that certain diseases have not been present in the herd over a specified time.

Maintenance of the high-health-status herd is a challenge. The minimum objective in establishing a high-health-status herd is to maintain status quo for at least 2 years, reduce the days to slaughter by 10 to 21, and improve the feed conversion ratio by 0.1 to 0.4. Ideally, a farrowing rate of 90% should be attainable with a growing mortality of less than 2.5%. Enzootic pneumonia, for example, is one of the most difficult diseases to keep out of a herd that is initially free of the disease. Diseases can enter the herd through the air, the mechanical transfer of infected manure, or a carrier pig. The swine barn should be sited at least 500 m away from other pig farms.

Mechanical transfer of pathogens can occur through birds, dogs, cats, and other forms of wildlife. The feed trucks delivering feed to the farm may be a source of infection, but it is difficult to quantify the risk. The role of man as a mechanical transmitter of pathogens has been controversial. What period of time must elapse before a veterinarian who works in one herd enters another herd? It is recommended that the minimum requirement for a veterinarian or other personnel visiting a high-health-status herd would be no contact with pigs of another herd on the same day. All herds should provide boots and coveralls, and showering should be an option.

Genetic improvement of high-health-status herds can be done by importation of live pigs, AI, or embryo transplant (Muirhead, 1989). The introduced pig is the most common source of new infections in the herd. It can be purchased from an existing herd of known high health status or derived by hysterectomy. A veterinary certificate that states the herd of origin is free of the infection should be obtained. If the herd is free of enzootic pneumonia, incoming animals are placed in isolation for about 8 weeks, and sentinel pigs from the recipient herd should be moved in and slaughtered before the entry of the new breeding stock into the herd proper.

Importation of Breeding Stock into Breeding Units

A major problem in the establishment of new swine breeding units and introduction of replacement animals into existing herds is the source of the breeding stock. Clinically normal gilts and boars may be latent carriers of infectious agents, which may be shed and spread to resident nonimmune animals in the herd, causing an epidemic. This is particularly important in large herds of 250 to 500 sows, in which an epidemic can cause major economic losses. The larger the unit, the greater the investment and the loss if disease occurs. Outbreaks of infectious disease tend to be more serious, persist longer, and are more difficult to control in larger units. Some notable examples of diseases that can be introduced by carrier animals include TGE, enzootic pneumonia, Aujeszky's disease, swine dysentery, leptospirosis, and AR. This creates a conflict between the desire to prevent the introduction of infectious diseases and the need to introduce new genes in order to make genetic progress.

Until about 1960, the purebred breeder was the source of pedigreed gilts and boars. The only assurance that the purchaser had of obtaining breeding stock free of the endemic diseases was the statement made by the vendor that the herd was not recently affected with the diseases. This was not and still is not reliable. There is no totally reliable method for determining that imported breeding stock are not carriers of the diseases previously mentioned.

Government-sponsored, central performance test stations were popular from 1960 to 1975, and they emphasized the identification of select breeding stock by testing animals for highly heritable traits such as growth rate, feed conversion, and carcass quality. Disease control in these centers was less than desirable because test animals came from many sources and were housed together at the stations; following the test the boars would be purchased as breeding stock and be introduced into herds.

The need for high-quality breeding stock free of several common diseases soon became obvious and led to the development of multiple-herd breeding networks known as a breeding pyramid (Hammond and Leitch, 1998). In this network, *nucleus herds* supply breeding stock to *multiplier herds,* which in turn supply breeding stock to *commercial herds.* The nucleus herd is established from hysterectomy-derived piglets raised in isolation and known as SPF or MD pigs. In the simple pyramid system, the nucleus herd is a closed unit, and all replacements are hysterectomy-derived pigs. The health and disease security-system standards must be high. The multiplier herds supply breeding stock to the commercial herds, which in turn produce pigs for slaughter.

Theoretically, a 500-sow nucleus herd can provide replacements for 6000 grandparents in multiplier herds. Multiplier herds can provide replacements for 90,000 parents in commercial herds, which in turn can produce 1.5 million slaughter pigs/year.

Biosecurity and Health Monitoring: Application of the Principles to the Production System

Veterinarians can provide an important service in the swine industry by using a "systems approach" to health maintenance and disease monitoring. The following section sets out the design of a large production system, including the layout of buildings, animal flow, biosecurity protocols, and a disease monitoring and response plan. The intention is to describe the application of the principles outlined in this chapter to a large production system that is representative of the future of the swine industry.

Health Status of Breeding Stock

A critical component of any successful swine production system is the selection of a breeding stock source that has the highest level of health. Ideally, breeding stock should be free of the following pathogens: PRRSV, *M. hyopneumoniae,* pseudorabies virus, TGE virus, *A. pleuropneumoniae,* sarcoptic mange mites, toxigenic *Pasteurella multocida* type D, postweaning multisystemic wasting syndrome (Circovirus), swine influenza virus H1N1/H3N2, *B. hyodysenteriae,* and *S. choleraesuis.*

Veterinary communication and health status documentation must occur before purchase. A monitoring program should be in place within the source herd, and testing should take place weekly by the collection of a representative

sample of each pig population, using both serology and PCR when available. Proper sample sizes should be calculated according to population size, the desired level of confidence of the sampling protocol, and the sensitivity-specificity of each test used, according to published methods. Finally, diagnostic evaluation of tissues collected from clinically abnormal pigs should be carried out as needed.

Farm Size and Animal Flow Calculations

The proposed production model described in this section is provided in Figs. 15-10 and 15-11. The *basic production unit (BPU)* of the system comprises 33,000 sows. Each BPU contains a 130-boar AI center, an internal multiplication unit of 3000 sows, two −3000-sow P1 production-gilt development units, eight −3000-sow commercial units with wean-to-finish pig production facilities, a vehicle processing area, and a veterinary center. The 33,000-sow BPU can then be multiplied as often as necessary to achieve the total desired number of sows within the system, (e.g., 33,000 sow BPU × 6 units results in nearly 200,000 sows.

Replacement Stock Introduction

Grandparent replacements for the system enter the internal replacement unit as weaned piglets and are raised in facilities specifically designed for this purpose (Fig. 15-12, *A*). Based on production parameters of 2.3 litters/sow/year and a 9-pig weaning average/litter, the 3000 sow multiplication unit is capable of producing approximately 600 gilt piglets/week. Three hundred gilts are available for each of the two 3000 sow P1 production farms located within the BPU.

Parity 1 Production Farms

The purpose of each P1 unit is to raise, breed, gestate, and farrow gilts in order to wean P1 adult females into four commercial 3000 sow farms within the BPU. This process allows for the designation of labor and removes the gilt pool from the commercial component of the system. Production of each 3000 sow P1 production operation is based on 2.3 litters/sow/year, which is equivalent to 6900 farrowings/year, or 133 farrowings/week. Since this unit consists of only gilt farrowings, a conservative selection rate and farrowing rate is important to ensure sufficient gilts for mating. The use of a 70% gilt selection rate and a 70% gilt farrowing rate results in a gilt pool inventory of 270 females/week in order to produce approximately 135 weaned P1 sows for introduction into the commercial system.

Commercial Production Segment

Each of the four commercial farms within each BPU consists of 3000 sows. At a 45% annual replacement rate, 1350 P1 sows are required each year (26/week). Therefore, over all four units, 104 P1 sows are required each week, well within the projected weekly production level (n = 135) of the P1 farm. The value of a 3000-sow inventory is the production of approximately 1200 weaner pigs/week, allowing for all-in, all-out pig flow and stage depopulation of each wean-to-finish facility at the end of a 24-week period. This calculation is based on 2.3 litters/sow/year and a nine-pig/litter weaned average.

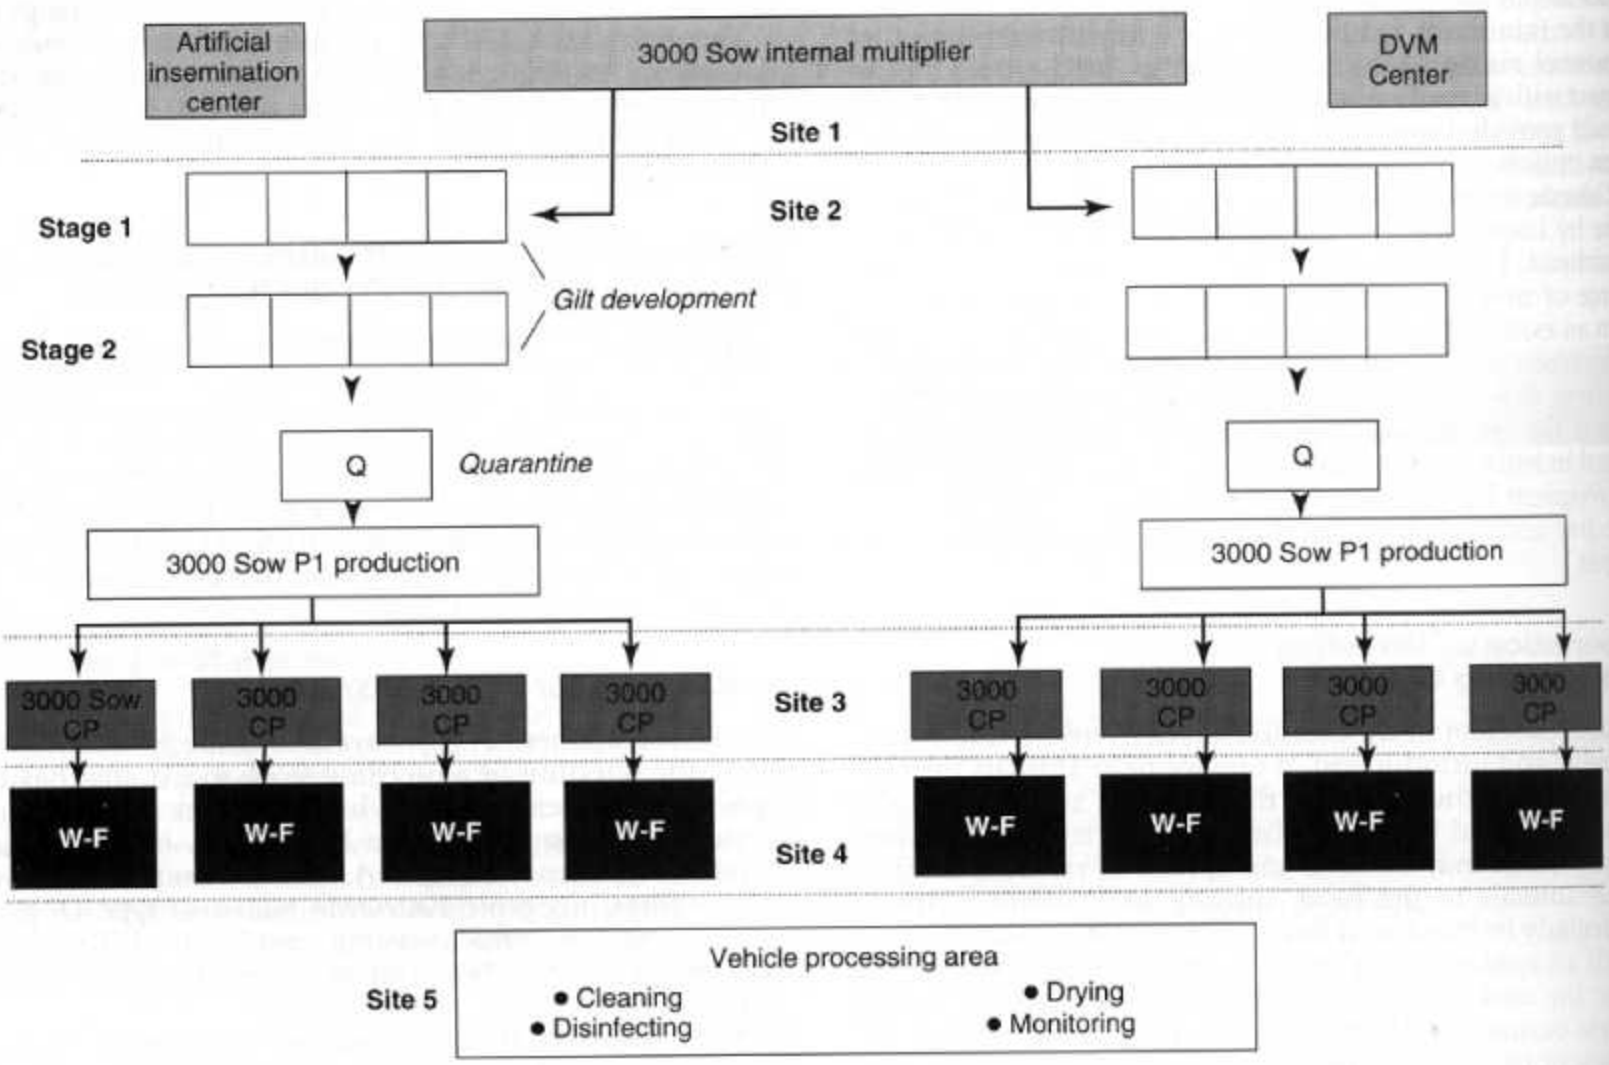

FIG. 15-10 Layout of the basic production unit consisting of 33,000 sows. *CP*, Commercial production; *DVM*, doctor of veterinary medicine; *W-F*, wean-to-finish.

Artificial Insemination Center

In combination with the BPU, an AI center of approximately 130 boars produces the sufficient number of doses of semen for the 33,000 sows at 2.5 doses/service and 2.3 litters/sow/year. Boar inventory is calculated based on an average of 30 doses/boar/week and 1500 doses/boar/year. According to the above calculations the BPU requires 190,000 doses/year; therefore 125 to 130 boars are housed in the AI center. Boars enter a quarantine center 60 days before introduction to the boar stud at a targeted age of 6 months.

Biosecurity Program: Breeding Herd

The facilities and the animal flow program for the quarantine of replacement breeding stock and the weaned P1 sows before entry into the commercial segment are illustrated in Fig. 15-12. Replacement stock initially enter a stage 1 quarantine, consisting of four rooms, each filled on a weekly basis (Fig. 15-12, *A*). A representative sample is collected from each room each week and tested according to the health assurance protocol. Although the entire facility will not operate on an "all-in" basis, it will operate "all-out"; therefore the oldest pigs reside in the facility for 4 weeks and the younger animals for 1 week, for testing purposes only.

Following completion of the 4-week stage 1 quarantine, the entire group moves to a wean-to-finish gilt developer containing four rooms to house four monthly groups. This facility will run all-in, all-out by room, but under a continuous flow airspace. After 16 weeks in this facility, each monthly group passes through a 30-day quarantine testing period before entry into the breeding herd of the internal multiplication unit. These animals complete their first gestation and lactation periods, thereby being classified as P1 sows. The point of health monitoring within this segment of the system occurs 7 days before weaning, before entering the P1 production farm's gilt pool area. A representative sample of P1 sows scheduled to be weaned the following week are tested. After completion of the lactation period, P1 sows are weaned into 1-week quarantines before entering the commercial production operation (Fig. 15-12, *B*).

To further reduce the risk of pathogen entry, breeding is done using AI. The AI center within a BPU is a separate site. Semen is distributed by a courier service to neutral delivery points located at the perimeter of the BPU. Vacuum tubes transport the delivered semen into the breeding area through an underground system. The AI center is monitored weekly through PCR testing of the semen and monthly serological evaluation of boars. Finally, biosecurity is further enhanced through the practice of a minimum of 48 hours free of swine contact and shower facilities for all personnel before their entry into the sow and boar centers.

Biosecurity Programs: Weaning to Finishing

For personnel movement between weaning-to-finishing facilities, the following protocol is in place: four such facilities compose a site, separated by a minimum of 100 m (Fig. 15-11). A "support building" containing a shower area, office, and wash area serves as the entry point for each site. The support building layout is shown in Fig. 15-13. Personnel enter the facility using a door on the contaminated side of the support building. This area also houses the site-specific loading chute for washing, disinfection, and storage. All equipment enters the noncontaminated side of the support building through fumigation rooms, and individuals enter using the shower protocol.

Following completion of the shower-in procedure, personnel put on clothing and footwear for movement to and between wean-to-finish facilities. Upon entry to each wean-to-finish building, a standard program of entry is in place consisting of a change of coveralls and boots, followed by a hand-face wash and use of a footbath before entry into the animal air space. This procedure is repeated between each facility on the site.

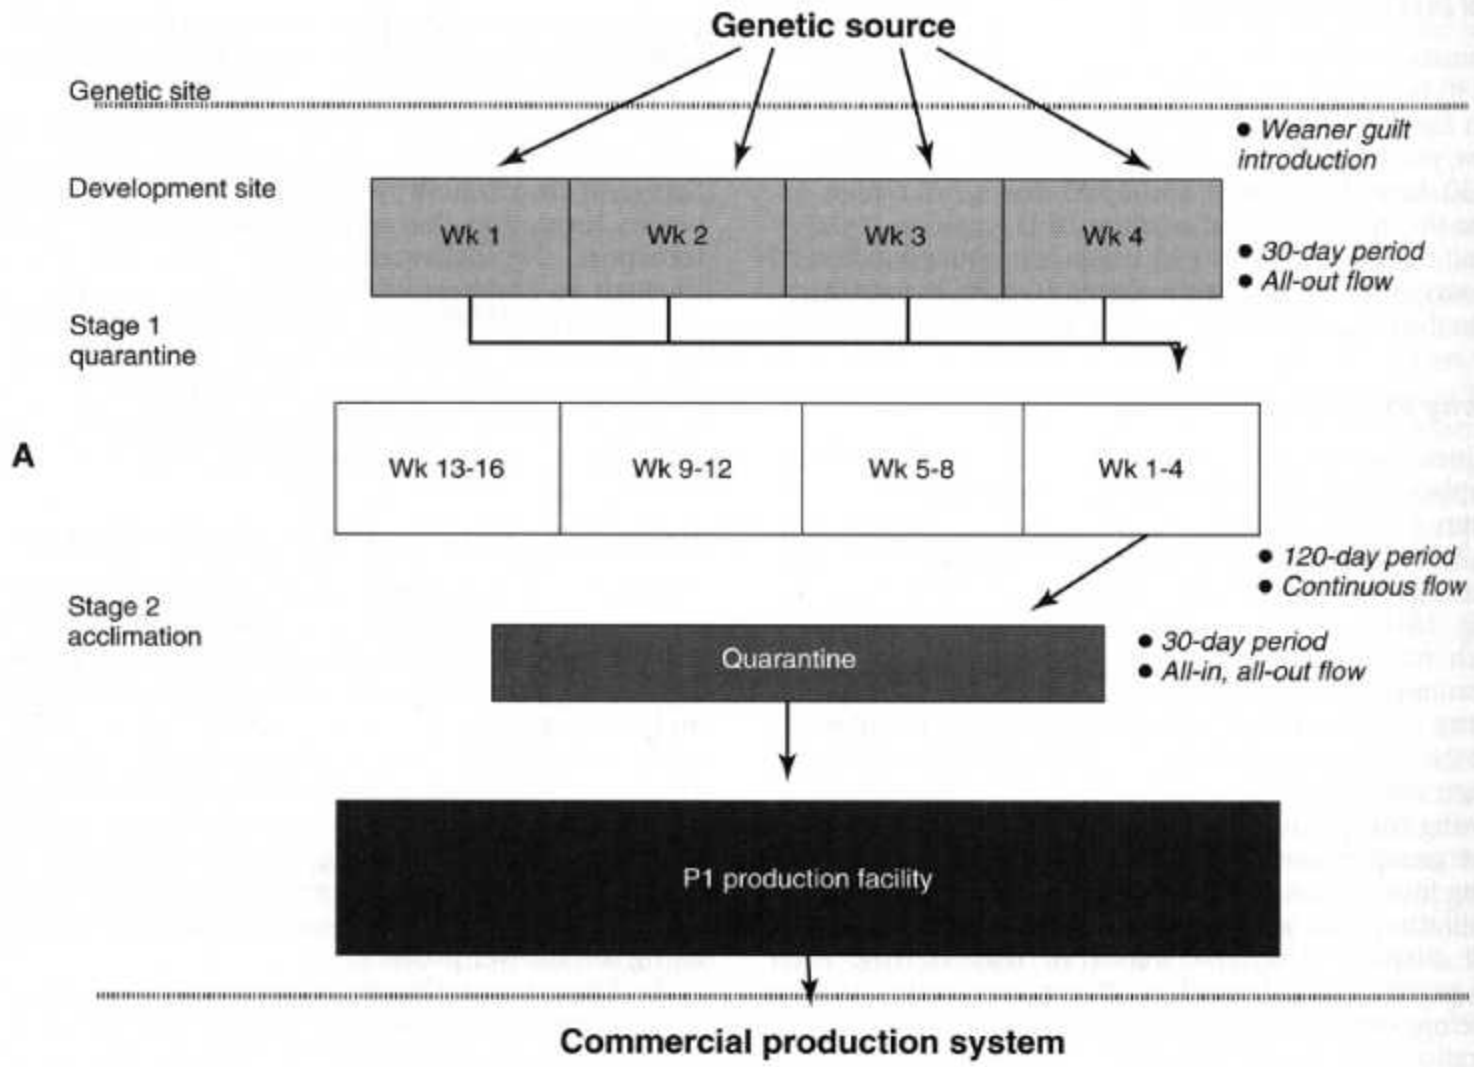

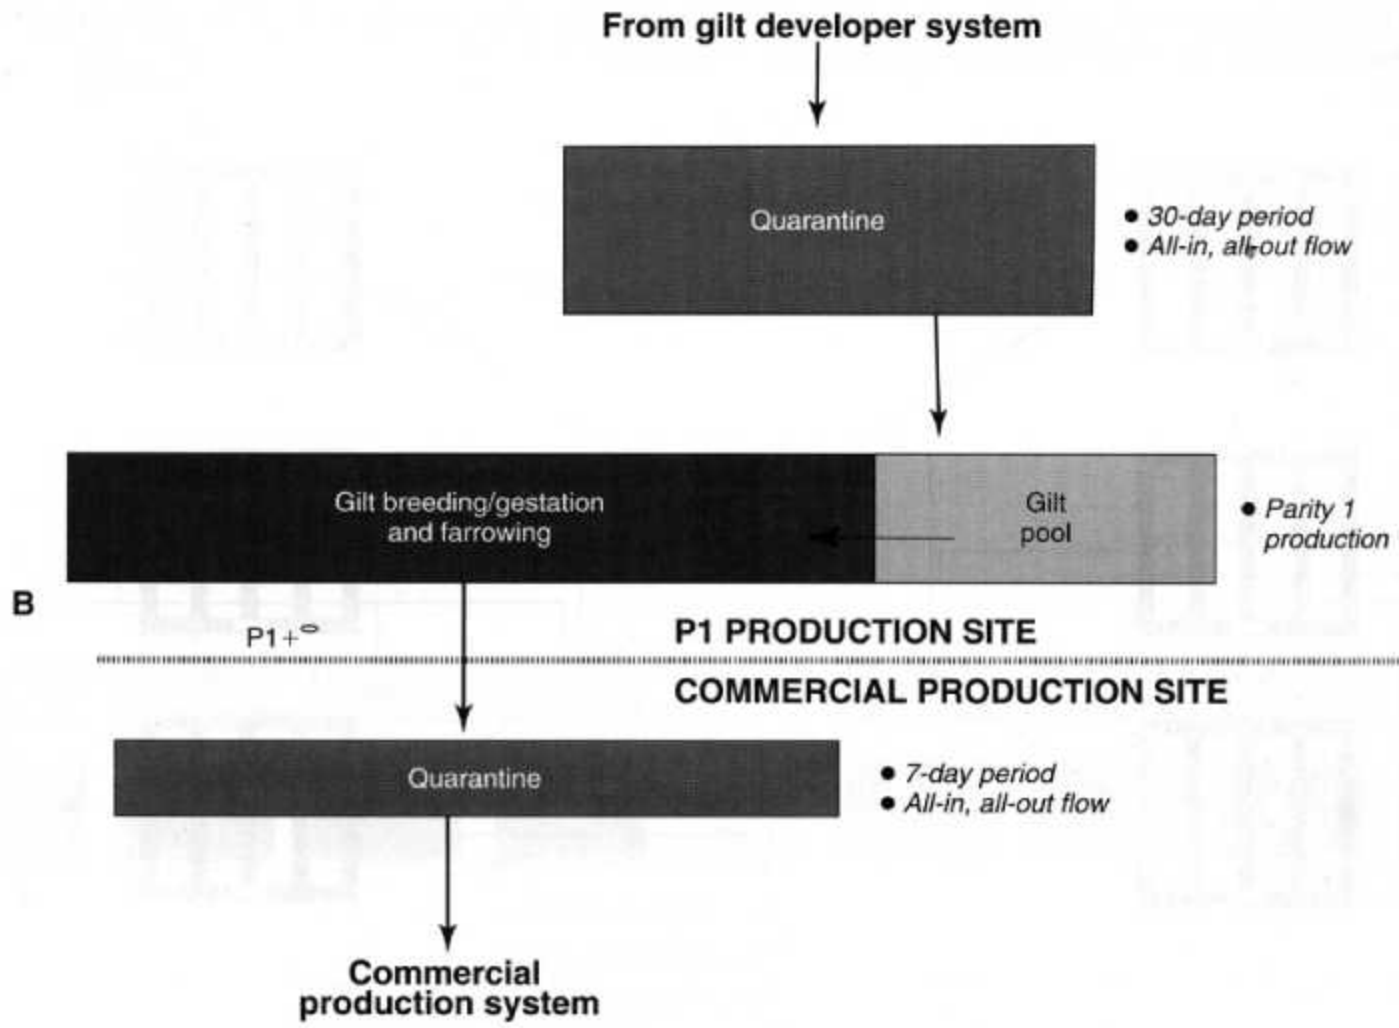

FIG. 15-12 **A,** Gilt development facility: layout and animal flow. **B,** Parity 1 production and commercial production facility layout and animal flow.

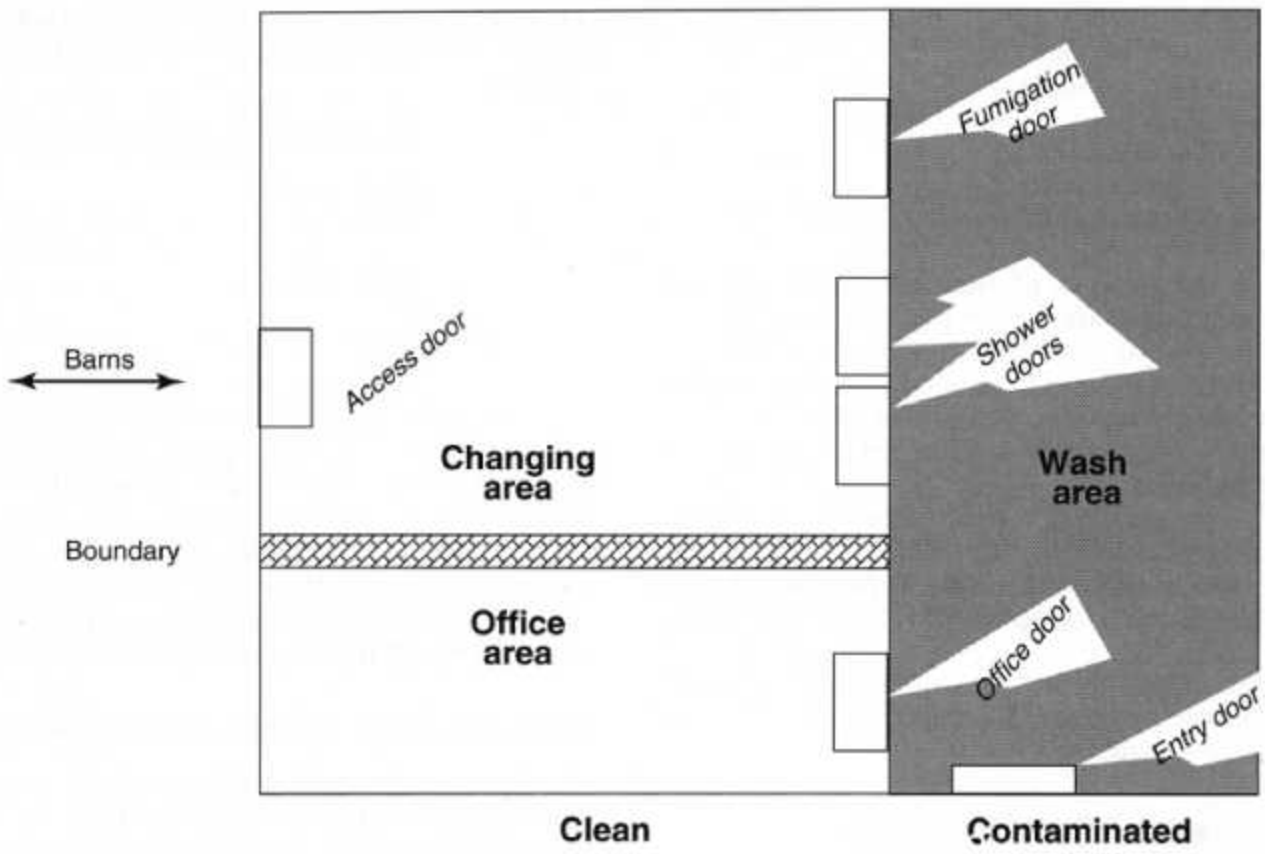

FIG. 15-13 Example of a farm office layout.

Laboratory and Monitoring Protocols

A central veterinary laboratory services the entire production system. The laboratory, located on a neutral site, contains a necropsy area, −70° C freezer, ELISA/PCR capabilities, and a bacteriology laboratory capable of aerobic and anaerobic culture. Testing of quarantine facilities proceeds as just described. All breeding herds are monitored through the weekly testing of piglets during the last week of lactation. Piglets should originate from randomly selected litters, with one piglet selected per litter in an effort to sample across parities. Monitoring the weaning-to-finishing population consists of testing a representative sample, at a calculated sample size equally distributed throughout all facilities each site, on a monthly basis.

EMERGENCY ACTION PLAN FOR HERD DISEASE INVESTIGATION

In addition to diagnostic monitoring, all farms within the BPU will be monitored for the onset of clinical abnormalities through the use of an emergency action plan (EAP). The purpose of the plan is to provide a standardized method for dealing with potential health concerns within each BPU. The EAP consists of four steps:

1. Early detection of an infectious disease
2. Quantification of its spread
3. Accurate diagnosis of its etiology
4. Rapid communication of its presence throughout the system

The EAP is designed so that veterinarians and farm managers can quantitatively assess the spread of peracute infection within specific pig populations. The EAP is based on two parts: *recognition of the problem* and *quantification of the problem*. An example of an EAP used in the industry today is outlined here.

Part 1: Recognition of the Problem

The first part of the EAP is based on the ability of farm personnel to recognize the early signs of an infectious disease process. The EAP divides a swine operation into three distinct populations:

- Breeding/gestation/lactation (B/G/L)
- Nursery (N)
- Finishing (F)

For the purpose of standardization across all farms, specific *clinical categories* have been established. The definition of each category is as follows:

- *Category 1:* inappetence (anorexia, fever)
- *Category 2:* respiratory (coughing)
- *Category 3:* intestinal (diarrhea with or without blood, vomiting)
- *Category 4:* systemic (septicemia, central nervous system, sudden death)

An understanding of these categories, and a daily regimen of monitoring to detect the clinical entities included in each category, must be communicated effectively during the employee training programs and consistently monitored during herd visits. The protocol of daily assessment is as follows:

Step 1. Each population is assessed daily, concentrating on attitude, consumption of feed, fecal consistency, and piglet quality. The following protocol is followed in each room:

1. Alleyway inspection
   - Examination of resting animals
   - Observation of clinical signs
2. Pen inspection
   - Examination of active animals
   - Observation of clinical signs
   - Inspection of water flow and feeder adjustment
   - Feed teasing

Feed teasing is the process of manually placing small handfuls of feed in random spots on a pen floor and observing the animal response. Normal, healthy animals frequently come forward to inspect the feed, whereas suspect animals typically remain inactive and uninterested.

Step 2. Rectal temperatures should be taken of any animal suspected of being ill.

Step 3. Each suspect animal is defined as a *Case*. For example, an anorexic sow is a *Case* within *Category 1*. A coughing finishing pig is a *Case* within *Category 2*, five nursery pigs demonstrating clinical signs of septicemia are 5 *Cases* within *Category 4*.

Step 4. After examination of each population, the number of cases within each category is relayed to the herd veterinarian for quantification.

Part 2: Quantification of the Problem

An example of problem quantification is as follows:

Step 1. The total number of cases over all four categories is calculated for each population. If multiple sites exist, each site represents a population. If a sufficient number of cases are detected in one finishing site, the EAP is activated, even if the other sites are clinically normal (Table 15-11).

TABLE 15-11

Criteria for Activation of Emergency Action Plan (EAP)

Population Inventory	Percent Level of Intervention	Required No. of Cases to Activate EAP
250	2.0	5 ± 1
500	1.5	8 ± 1
750	1.2	9 ± 1
1000	1.0	10 ± 1
1250	1.0	12 ± 1
1500	1.0	15 ± 1
1750	0.85	15 ± 3
2000	0.85	17 ± 3
2250	0.75	17 ± 3
2500	0.70	18 ± 3
2750	0.65	18 ± 3
3000	0.65	20 ± 5
3250	0.60	20 ± 5
3500	0.60	20 ± 5
3750	0.55	20 ± 5
4000	0.50	20 ± 5

Calculation: 1% Level = (1000 × 1%) = 10 ± 1 cases required to activate EAP.
Conclusion: EAP activated.

Step 2. An example of how to calculate the required number of cases-population for initiation of the EAP is as follows:

Population = B/G/L1000- sow inventory)

No. of Cases	
Category 1	16 (8 anorexic lactating sows)
Category 2	0
Category 3	0
Category 4	1 (sudden death)
Total	17

Obviously, the judgment of the veterinarian plays a major role in the decision making process. The veterinarian has the authority to activate the EAP even if the interference levels are not met if judgment dictates it is necessary. It is hoped that the protocol of daily assessment and a standardized method of quantifying clinical impact will heighten the sensitivity of disease detection and enhance effective communication between the farm and the veterinarian.

Protocol of Diagnostic Investigation

Should the EAP require activation, the protocol of diagnostic investigation (PDI) is implemented. In order to manage a disease outbreak, it is critical to obtain an accurate diagnosis, therefore sampling collection and handling is critical. Box 15-5 is an example of a PDI that follows a system-based approach.

Plan of Action After Detection of Disease

If the etiological agent of an infectious disease is conclusively detected, the BPU is designed for immediate action. If an individual weaning-to-finishing complex is infected, depopulation can be implemented. If infection is detected in the quarantine area through the introduction of infected seedstock, the quarantine is also depopulated. Should infection be detected during the 1-week quarantine period between the P1 production farm and the four commercial operations, the infected quarantine will be depopulated and any existing quarantined groups retested. Culling practices within the related commercial farm(s) will be reduced for that individual week of breedings, and plans within the P1 production farm to overbreed in order to compensate for lost production will be initiated.

If infection of the multiplication or P1 production breeding herd should take place, the flow and facility use of the replacement stock program will continue; however, the use of vaccination and acclimation procedures can be implemented immediately. Finally, the fact that the BPU is a "stand-alone" entity and does not rely on animal or personnel farms' other BPUs reduces the spread of infectious disease throughout the entire system of production.

Communication and Data Transfer

All sites within the BPU are electronically linked to the central veterinary laboratory office. Data from each farm, both production and diagnostic, are stored here in a centralized computer database. Results are summarized using the principles of SPC to detect irregularities in data over time throughout the system.

The inability to control diseases such as PRRS by relying solely on the principles and techniques of production has been frustrating. Therefore the advent of new systems and designs for the new millennium must stress the importance of health first, then assess its impact on production. Swine

BOX 15-5

System-Based Protocol of Diagnostic Investigation Approach

REPRODUCTIVE TRACT DISEASE

Serology

1. Collect sera from affected sows (n = 10)
2. Collect sera from nonaffected sows (n = 5)
3. Record ear tag identification and retest 2 to 3 weeks later
4. Test for the following pathogens:
   - Porcine reproductive and respiratory syndrome virus (PRRSV)
   - Aujeszky's disease virus (ADV)
   - Porcine parvovirus (PPV)
   - *Leptospira* sp.
   - Swine influenza virus (SIV)

Tests used are as follows:

PRRSV (ELISA); ADV (ELISA); PPV (hemagglutination inhibition; [HI]) *Leptospira* microscopic agglutination test (MAT); SIV (ELISA) (H1N1/H3N2).

Tissues (Abortion)

1. Collect fetal tissue from 3 to 5 litters, selecting 1 to 2 fetuses/litter.
2. Collect placental tissues from 3 to 5 affected sows.
3. Submit fresh and fixed (10% formalin) tissues.
4. Fetal samples to submit should include: brain, heart, lung, liver, spleen, kidney, stomach fluid, thoracic fluid.
5. Mummified fetuses should be submitted intact. A fetal crown–rump length of <17 cm indicates fetuses of <70 days gestational age.

Direct immunofluorescence for antigen to PRRSV, PPV, ADV, *Leptospira* sp., and SIV (H1N1,H3N2) should be requested, along with bacterial culture, virus isolation, and microscopic examination.

Tissues (Premature farrowings)

Collect 1 to 2 weak suckling piglets from 3 to 5 litters and euthanize. Tissue collection should mimic that described for aborted fetuses; however, it should also include alveolar macrophage lavage for PRRSV isolation.

RESPIRATORY DISEASE

Serology

Respiratory outbreaks should be assessed using the technique of cross sectional or serial testing. Cross-sectional testing consists of a random sampling of animals from different stages of production. Serial profiling consists of ear tagging of individual animals and retesting them over time. Cross-sectional profiling is advantageous because the results are generated much more quickly; however, serial testing demonstrates the presence or absence of seroconversion.

Outbreaks of pneumonia should be investigated based on the following protocol:

Breeding herd

Collect the following samples:

10 clinically affected sows

5 nonaffected sows

Record ear tag identification; retest 2 to 3 weeks later.

Tests

PRRSV (ELISA) *Mycoplasma hyopneumoniae* (ELISA), ADV (ELISA), SIV (H1N1/H3N2) (ELISA), or HI, porcine respiratory coronavirus blocking (ELISA), *Actinobacillus pleuropneumoniae* complement fixation (pooled antigen).

Nursery pigs

Collect the following samples:

Age (weeks)	No. of samples
4	10
6	10
8-10	10

Tests: as above

Finishing pigs

Collect the following samples:

Age (weeks)	No. of samples
10-12	10
14-16	10
18-20	10
22-24	10

Tests: as above

Tissues

Fresh and fixed tissues should be collected as previously described. Tissues collected should consist of lung, lymph nodes, tonsil, spleen, liver, and kidney. Direct immunofluorescence for PRRSV, ADV, SIV, and coronavirus should be conducted. Samples should also be assessed for PRRSV using immunohistochemistry. Attempts to isolate PRRSV should also be a part of the routine diagnostic workup; therefore alveolar macrophage lavage should be collected and tissues should be maintained at −40° C to maximize virus survival. Finally, bacterial culture and microscopic examination of fixed tissue are also required.

INTESTINAL TRACT DISEASE

Serology

Cross-sectional or serial testing is helpful for determining the epidemiology of the infection in the postweaning population. Serological profiling protocols for intestinal problems should consist of coronavirus differential for detection of seroconversion to transmissible gastroenteritis virus and immunofluorescence antibody (IFA) testing for *Lawsonia intracellularis*.

Tissues

Tissue samples are of primary importance in cases of intestinal disease. Frequently gross or microscopic exam is sufficient to determine the cause; however, bacterial culture of agents such as *Salmonella* sp. or *Serpulina hyodysenteriae* enhances the diagnostic process. Other techniques such as impression smears can be helpful for identifying *Isospora suis* merozoites or the large gram-positive rods typical of *Clostridium perfringens*. For further identification of this latter organism, toxin testing should be requested to identify the presence of toxin type A or C.

CENTRAL NERVOUS SYSTEM DISEASE

Outbreaks of nervous system disease are causes for concern, primarily because of the risk of ADV infection. Samples to collect include cerebrum, cerebellum, medulla oblongata, and tonsillar tissue. Fixed and fresh tissues should be collected, and bacterial culture, microscopic examination, and immunofluorescence testing is required. Cerebrospinal fluid can also be collected and is an excellent source of bacterial culture (e.g., *Streptococcus suis* or *Haemophilus parasuis*).

practitioners throughout the world are in an ideal position to lead the process of reeducating the global industry concerning the importance of health. Veterinarians must continue to develop new, creative strategies, first to understand the disease process, second to control its spread, and finally, to minimize its impact.

REPRODUCTIVE PERFORMANCE IN THE SWINE HERD

Reproductive performance has long been considered economically important to the swine producer. Present methods of intensified swine production have created an increased awareness of the influence of reproductive performance on overall production efficiency.

Sow Productivity

Reproductive efficiency of a sow herd is the result of many separate and interacting factors. Sow productivity is dependent on the number of piglets born live, the survival of pigs to weaning, the rebreeding interval, and the conception rate at first and any repeat service. Improved sow productivity is dependent on management during gestation; management at farrowing; management during lactation; management at weaning; management at mating, including the judicious use of hormonal therapy to induce estrus; and appropriate culling. The greatest improvement in the rate of pigs per sow per year results from increasing both the number of pigs born alive and their survival to weaning. Proper feeding of the sow during gestation and lactation is critical for maximum sow productivity. Managing the weaned sow properly to stimulate prompt return to estrus can shorten the farrowing interval and increase annual productivity.

Swine units have become larger and more specialized, and investment in buildings and equipment has increased greatly. Confinement production has placed increased demands on reproductive performance, created new problems to be solved in order to maximize reproductive efficiency, and made precise scheduling extremely important in the operation of an efficient swine production unit. Delays in breeding create major problems in efficient use of facilities and equipment.

The best indicator of reproductive efficiency in breeding herds is *the number of pigs weaned per mated female per year,* which depends on the *number of litters per mated female per year* and the *number of pigs weaned per sow.* It is optimized by the decrease of *nonproductive days, lactation length, number of stillbirths per litter,* and *preweaning mortality,* and by the increase in litter size.

Characteristics of High-Performing Herds

The productivity characteristics of high-performing commercial swine breeding herds have been compared with lower ranking herds (Koketsu et al, 1999; Koketsu, 2000). High-performing herds have shorter lactation durations and higher mean breeding female inventories than other herds. Large herd size likely makes it economically feasible to employ specialized workers, and shorter lactations enables herds to improve facility use. High-performing herds also have better reproductive efficiency and use farrowing facilities more effectively than other herds. High-performing herds had a higher percentage of sows bred by 7 days after weaning than did the remaining herds for all seasons and for all parities except for parity ≥6. Thus high productivity of the high-performing herds is attributable, in part, to better mating management. Higher percentages of multiple matings and sows bred by 7 days after weaning are associated with higher farrowing rate and greater litter size. The lower preweaning mortality rates for high-performing herds, compared with the remaining herds, suggested that these herds provided better piglet care during lactation and better farrowing facilities. Low preweaning mortality rate is associated with the use of supplemental heaters, non-concrete floors, and frequent cleaning and disinfection. In high-performing herds, lactation length was significantly associated with pigs weaned per sow but not associated with litters mated per female per year. High-performing commercial herds could increase pigs weaned per sow by improving preweaning mortality rate and number of pigs born alive, but number of litters per mated female per year was already maximum. For other herds, shortening lactation interval duration would likely decrease farrowing interval and improve efficiency of the reproductive cycle without reducing litter size. The study did not consider farm profitability, sustainability, or sow longevity.

The effects of within-farm variability in the number of females mated per week during a 52-week period on annual productivity have been examined (Koketsu et al, 1999). Increasing within-farm variability in number of females mated per week decreases annual reproductive efficiency, as determined on the basis of number of pigs weaned per mated female per year, farrowing rate, and farrowing interval, but not on number of pigs per litter. Farm managers should determine a target range for the number of females mated per week to prevent large week-to-week variations in breeding herd operations.

With the widespread use of three-site production, and especially all-in, all-out production, it became necessary to reevaluate the reproductive performance requirements in the production systems. The aim of reproductive units in the systems is to provide a low-cost consistent stream of quality progeny. The sow unit is essentially a fixed-cost part of the enterprise that aims to keep its customers' facilities full. The diagnostics of reproductive performance involves determining whether that aim is achieved efficiently.

Sow Longevity in Herd

Reproductive efficiency improves with herd life. Females with higher parities at the time of removal from the herd had weaned more pigs per year in the herd than did females with lower parities (Lucia, 1999). The initial reproductive cycles of young females are critical in determining herd life. Reducing the entry to first service interval would help to minimize the proportion of herd life spent in nonproductive days. Lifetime reproductive and financial performance is optimized among swine herds that have higher proportions of high-parity females (Lucia et al, 2000).

Breeding Records and Targets of Performance

Herd records provide the opportunity to monitor, diagnose, and provide guidance in correcting breeding herd problems. As in any production process, the aim of the breeding herd is to produce the required output in a timely and predictable manner. For instance, the target of a 500-sow herd may be to produce a group of 200 pigs with a minimum weight of 11 pounds and a maximum age of 26 days every week. In some ways, the sow herd can simply be viewed as an input similar to a feedmill to keep the growing pig facilities full. The breeding herd records allow the farm to do the following:

- Monitor activities on the farm to ensure that these targets can be met based on historical production parameters. This allows correct design of facilities and cashflows and assesses the risk of instability in output.

- Predict problems in the output. For instance, a decrease in conception rates can predict that the expected outcome is probably not going to be attained.
- Retrospectively diagnose problems in the design and management of the herd. It is this third area in which veterinarians spend most of their time examining, whereas the other two bullet points are predominately the efforts of the swine herdsman.

If the targets are not being achieved, several methods are available to reduce the analysis to the level of possible causal relationships. Some of the relationships can be elicited from normal herd records, whereas others must be based on discussion or further analysis. A basic methodology is as follows:

1. Are the pigs that come out of the farrowing crate meeting specifications? Lactational difficulty, infectious disease, and excessive competition among piglets may be found in records if they are kept in detail, but, in most cases, this involves the recollection of the farrowing room manager along with the observations of the swine veterinarian. Furthermore, mortality and morbidity records are almost invariably biased by the views of the record-keeper.
2. Is the sow herd inventory optimum for the facilities and the production methods? Often the sow herd inventory must be compared with the productivity of the herd and the facility capacities. Piglet inventories are also required to examine in detail exactly how the farrowing rooms are being managed and the amount of transfer between rooms. Nonetheless, it appears that many breeding herds, unless they are contractors, actually have a less than optimum breeding herd inventory.
3. What are the nonproductive sow days, on average, over the period of concern? Nonproductive sow days are, essentially, all the sow days in which the sows are not lactating or gestating. Thus nonproductive sow days contain the entry to mating interval for gilts, the mating to successful service interval, and the weaning to estrus interval in weaned sows as well as the weaning to removal interval in sows that are culled. With record-keeping systems such as PigCHAMP, these individual components can be defined and analyzed in more detail.
4. What is the average litter size over the time of concern? This is a more basic index than open sow days but does involve an accurate definition of stillbirths and sow inventory.

It is important to consider that there can be various biases in the indexes just described. First, many farms are reluctant to record gilts until they are successfully mated. This may then involve recording gilts only if they are mated. This will reduce the gilt inventory on the record-keeping system and decrease the actual capacity for additional sows in the gestational facility. Second, there may be a bias toward recording sows, not when they are actually culled, but when they are functionally no longer part of the herd. Thus, in some cases, the culling date is based on the culling decision instead of on the shipment date. In other cases, there may be a bias toward what is often called "retrospective culling" in which, when a sow returns, it is culled at its breeding date. Third, in some herds, to increase litter size, there are "phantom sows" (ones that are in the herd but not recorded) that can be used to inflate the reproductive performance while keeping the herd size artificially low.

The open sow days are directly inversely proportional to the litters per sow per year within the management scheme of a farm. Litter size and litters per sow per year vary by a number of factors to allow further analysis. The most common methods to further examine the data are by parity and by time. These two factors can create much of the description of the functional changes occurring in the herd. Parity affects both of these variables, and the treatment of individual parities often affects the breeding herd performance. For instance, second parity dip is often a function of excessively large litters on gilts. This can be examined by comparing the net foster number between parities on a parity report in PigCHAMP. Alternatively, graphing of litter size and various components of open days can be used on a calendar basis to show the effects of changes in management. For instance, if the weaning-to-culling interval increases after the introduction of a new breeding herd manager, this may be a sign for further investigation.

It should be emphasized that, especially in smaller herds, it is difficult to be certain of the trends based on the sample sizes available. Basing changes in production methods on 20 of the previous litters with a reduction in one pig per litter is probably unwise. Alternatively, if undesirable production practices are known to occur in the herd that should be changed to ensure continued success on the farm, this may be the justification to go forward with some of these.

Not all answers can be derived from reading herd records. The other way of using herd records to diagnose breeding problems is to make it a teaching moment board for further discussion with the producer. This is especially useful when production or other parameters are converted into graphs. This often jogs the memory of the farmer but also induces the farmer to open up and give more detail into the concerns and methods that are currently being used on the farm. It can also be used to give guidance and further analysis by either inducing more detailed production records or perhaps even creating an experimental protocol on that farm.

When a sow is moved into a farrowing crate or a farrowing pen, there is an expectation that the sow will farrow within a short time, producing a large number of pigs that are large, active, healthy, and able to convert the available colostrum and milk into rapid growth. It is expected that the sow will produce sufficient colostrum and milk and begin to ingest adequate amounts of feed and water to maintain herself and her progeny. The sow should have the ability to lie down in such a manner to protect the piglets. Preferably, all the sows within a group will farrow at the same time to allow efficient cross-fostering.

Measures of Reproductive Performance

The basic measure of success is the number of piglets weaned per week and secondarily the efficiency in achieving that flow of pigs. Secondary expected levels of efficiency include the following:

1. *Total number of services.* The number of services compared from week to week should be approximately equal to maximize continual flow through of the barn and thus utilization of the facilities. The number should exceed the target services per week to achieve the target number of pigs weaned per week.
2. *Percent repeat services.* A general rule of thumb is that if more than half the proportion of sows that do not farrow are bred again, culling based on poor reproductive performance should be emphasized. Sows are much more likely to return and tend to have smaller litters.
3. *Percent multiple matings.* If the level is below 85%, more time should be spent in the breeding room observing sows as they come into estrus to allow them to be bred more often.
4. *Weaning to first service interval and percent sows bred by 7 days.* To use the breeding room to its maximum, it is advantageous to have a 7-day turnover; the best sows are those that return within 7 days. Thus the weaning to first service interval on average should be below 7 days and percent sows bred by 7 days should be at least 85%.

5. *Average number of pigs born alive per litter.* With a normal parity distribution and the capabilities of most of the genetic stock and management procedures, an average number born alive of 10.5 to 11 can normally be attained.
6. *Average number of pigs born dead per litter.* To achieve a high average of pigs born alive per litter, the number of pigs born dead must be minimized with a percentage born dead being below 5% and the percentage of mummies being below 1%.
7. *Farrowing interval.* The farrowing interval should be below 150 days to allow for a large number of litters to be produced per sow per year. This can be compared against the potential farrowing interval, which is the average gestation length plus the average lactation length plus a 5-day weaning to breeding interval.
8. *Preweaning mortality.* This can be decreased to 10% through a rigorous monitoring of pigs. Preweaning mortality is closely related to the number of pigs born dead in many herds.
9. *Adjusted 21-day weight.* This is a good measure of the milking ability of the sows; if there is large variation, nutritional and other management factors should be examined closely. An aim is to produce 13-lb pigs at 21 days.
10. *Culling rate.* Most established herds should have a culling rate of at least 40% to maintain a constant herd profile for parity. This depends on a high average parity of culled sows. If either the average parity of culled sows is lower than 3, this should be examined closely and the age increased, or the culling rate accepted should increase to prevent receiving old sows.
11. *Sow mortality rate.* Sow mortality is a major cause of economic loss, since it involves unscheduled loss of sows, and often progeny; replacement costs for gilts are high.

For precise up-to-date indicators of herd performance, it is necessary to identify and extract specific data from those records related most closely to sensitive stages and events in the breeding cycle. The number of analyses and their frequency and detail depend on such factors as size of unit, degree of personal involvement by management, and overall production figures. A large herd with a poor production record, for example, may benefit from frequent and detailed record analysis, at least until the problems have been resolved. Sometimes it may be necessary to carry out in-depth analysis of data pertaining to a specific problem area to characterize it fully and, if possible, to identify any causal relationships.

Factors Influencing Reproductive Performance of Sow Productivity

The reproductive performance of sow productivity in a swine herd is dependent on several identifiable factors. The number of piglets weaned per sow per year is a function of the farrowing interval, the entry to farrowing interval for gilts, and the litter size at weaning.

The number of piglets weaned per sow per year can be increased by reducing the interval between farrowing or entry and conception and by reducing the lactation period. The length of gestation is almost constant, but it can be decreased by 2 to 4 days by the induction of parturition, although this is rarely recommended. Litter size can be enlarged by increasing ovulation and conception rates or by reducing losses in the perinatal and postnatal periods.

The major factors that affect reproductive performance in swine include the following:

1. Number of pigs born alive per litter
2. Pubertal development, first estrus, and anestrus in gilts
3. Weaning-to-estrus interval and delayed estrus in sows
4. Management and assessment of reproductive performance of boars
5. Mating management of gilts and sows
6. Pregnancy losses: failure to conceive, embryonic mortality, fetal death and abortion or fetal mummification, and stillbirths.
7. Perinatal mortality: low birth weight of piglets, small litters, low viability of piglets' disease, and lactational failure.

Number of Pigs Born Alive per Litter

The number of live-born pigs per litter is directly related to sow productivity. A reduction in live-born piglets per litter causes a reduction in pigs weaned per sow per year. During the past 50 years in the United States, the mean number of pigs weaned per litter has remained nearly constant at 7.4 pigs. With a preweaning mortality estimated at 18% of live-born litter size, an estimate of live-born litter size at 9.3 pigs/litter is much less than the estimated potential litter size of 10.5 to 11 pigs (Clark and Leman, 1987). The factors that influence litter size in pigs have been reviewed (Clark and Leman, 1986a,b). Surveys of swine farms in Ontario found that the herd-level variables associated with litter size included: the method of estrus detection, the number of matings per sow, the number of sows farrowing per week, the identity of the breeding manager, and the amount of time devoted to estrus detection and breeding sows (Dewey et al, 1995a).

The factors that influence litter size have been divided into two major categories (Clark and Leman, 1986a,b). The first category includes parity, age at conception of the first litter, number of matings per conception, season, previous lactation length, previous weaning-to-conception interval, and breed. These data are often recorded by commercial swine producers and are available for retrospective studies. The second category includes husbandry practices, nutrition, disease, and the contribution of the boar. Data for the measurement of the effects of these variables on litter size are not usually available in record-keeping systems.

Litter Size and Parity. Litter size is usually smallest in parity 1; increases to a maximum size in parities 3, 4, and 5; and then remains nearly constant or slowly declines as parity increases (Clark and Leman, 1986a,b). Age at conception, number of matings per conception, season of conception, and breed size have been associated with variation in parity 1 litter size, but the associations varied among herds (Clark et al, 1988). In some herds, as age at first conception increased, litter size increased slightly. On a herd basis, changing the breeding of gilts to their first observed heat can cause a reduction of one pig/litter compared with breeding them on the second or third heat.

Litter Size and Sow Management. The associations between litter size and specific sow-level management factors in a sampling of Ontario swine farms that used computerized recording systems showed a curvilinear relationship between litter size and parity; the largest litters were from sows in parities 3 through 10 (Dewey et al, 1995a,b). Natural matings resulted in one more pig/litter than did AI. Lactation length of 27 to 32 days and 33 to 40 days caused progressively larger litter sizes in subsequent farrowings than shorter lactation lengths. Litter size was highest at weaning-to-conception intervals of up to 4 days, decreased daily from 5 to 7 days (at which point it reached a plateau), until Day 11 when it increased again. The sow's current litter size was positively associated with her previous litter size.

Litter Size, Ovulation and Fertilization Rate, and Embryonic Mortality. Litter size is determined by ovulation rate, fertilization rate, and embryonic mortality. Despite a high ovulation rate of about 17, and fertilization rates from

90% to 95%, about 35% of fertilized ova and fetuses are reabsorbed or aborted during pregnancy. Average litter size at term is about 10 piglets; however, a significant number of litters are much smaller, and embryonic reabsorption accounts for more than one half of the total variation in this number in intensive swine herds. The majority (30%) of embryos dies within the first 40 days of gestation, followed by an additional reduction of 10% to 20% by term; embryonic mortality is a significant factor in determining litter size at farrowing. Pig fetuses require a certain initial length of the uterus to implant, develop, and survive. Length of uterus appears to be an important factor in limiting litter size as the number of ovulations increases (Wu and Dziuk, 1988). It is thought that there is limited capacity of the porcine uterus, and that as the fetus and placenta develop in gestation, some fetuses become crowded and die. An increase in the incidence of mummified fetuses in large litters is associated with uterine space per fetus below that needed for development and survival. A 12% fetal loss in late gestation can be associated with low uterine space per fetus. A longer uterus provides a greater space per fetus, a larger number of live fetuses, and a lower incidence of mummies. Average litter sizes can be increased substantially by reducing conceptus losses during early pregnancy through management practices such as restricted feed intake during the first weeks of pregnancy in order to maximize embryonic survival (Stone, 1987).

The effects of disease on litter size in pigs can be categorized into four major groups: (1) fertilization failure, (2) whole-litter loss, (3) small live-born litters with increased numbers of stillbirths and mummified fetuses, and (4) small live-born litters without increased numbers of stillbirths and mummified fetuses.

Litter Size and Nutrition. The influence of nutrition on ovulation rate has been reviewed extensively, and it has been established that increasing feed or energy intake before mating (e.g., flushing) increases ovulation rate (Aherne and Kirkwood, 1985). However, whereas higher ovulation rates in gilts are usually associated with an increased number of embryos, they are also associated with increased embryo mortality. Flushing in the prepubertal period does not enhance piglet production in gilts mated at puberty.

Although dietary manipulation has not been shown to have an effect on litter size, the absolute intake, particularly during farrowing and the weaning to estrus interval, has shown an effect. Low feed intake has been shown to decrease subsequent litter size, particularly if it occurs during late lactation (Zak et al, 1997).

Litter Size and Length of Lactation. Changing the length of the lactation of sows of parity greater than 1 can also result in a decrease in litter size (Mabry et al, 1996). There can be a difference of 0.2 piglet/litter between sows whose piglets are weaned at 20 days versus 15 days. In Ontario swine farms, litter size increased progressively at previous lactation lengths of 20, 25, 27, and 33 days (Dewey et al, 1994). Sows bred on Days 2 to 4 after weaning had essentially the same litter size. Litter size decreased progressively for sows bred on Days 5, 6, and 7 after weaning and then reached a plateau until it increased again for sows bred on Day 11 or later.

The reduction in litter size with earlier weaning is not caused by a reduction in ovulation rate but by increased losses of embryos, which suggests that the uterus requires a minimum period of time to fully recover from the previous pregnancy.

The length of lactation may influence subsequent litter size. A reduction of weaning age from Day 42 leads to a concomitant reduction in litter size (Clark and Leman, 1986a). The mechanism is associated with high plasma levels of estradiol after weaning. Estimates of optimum lactation length to achieve maximum reproductive efficiency range from 21 to 28 days. Some observations indicated that early weaning at 21 ± 3 days had no effect on subsequent litter size when the weaning-to-conception interval was longer than 14 days (Clark and Leman, 1986b). In those sows with weaning-to-conception intervals of less than 14 days, litter size was reduced by 0.1 pig for each day between the mean weaning ages of 21.9 and 27.5 days. Therefore the effects of lactation length on litter size are likely influenced by the weaning-to-conception interval. Investigations of the records of 11,929 litters from five commercial herds indicated that the preceding farrowing-to-conception interval had a positive effect on litter size from parity 3 to parity 7 sows (Clark and Leman, 1987). Live litter size per sow per year can be optimized if the farrowing-to-conception interval is manipulated by duration of lactation and culling to achieve a mean farrowing-to-conception interval of 35 days in parity 3 through parity 7 sows (Clark and Leman, 1987).

Litter Size and Number of Matings. Litter size may increase with increased matings per conception in some herds and not in others. The length of estrus in sows is about 66 hours, and ovulation occurs about 40 hours (range, 36 to 50 hours) after the start of estrus. A single mating at the optimum time during estrus would be expected to achieve maximum litter size. The optimum time is considered 12 hours before ovulation. Because there is no outward sign during the 66-hour estrus period to indicate when ovulation occurs, the pig's response to back pressure has been used to predict the time interval during which ovulation would be expected. Gilts exhibit the standing reflex only after direct exposure to the boar in the first and last 11-hour periods. During the middle 44-hour period, the gilts exhibited the standing reflex for the boar and for the inseminator. Litter size and conception rate were shown to be maximized when gilts were mated once by AI 22 or 33 hours into the estral period. Litter size was found to be reduced severely when insemination was performed 11 hours earlier or later (Clark and Leman, 1986a). Unless sows are mated during the optimum period, litter size is affected by the number of matings per estrus. The more matings per estrus, the greater the opportunity to mate the female during the 10- to 20-hour period before ovulation, which has been shown to maximize litter size. However, it has been shown that insemination during late estrus decreases litter size (Rozeboom et al, 1997).

One alternative that many farms use to ensure large weaned litter size is to farrow more sows than fit in the farrowing room and to cross-foster these extra litters onto the sows. This increases litter size and allows sows to be culled upon weaning at Day 0. If farrowing facilities are expensive, this may be a rational alternative in many cases. Litter size is controlled by many other factors at lower frequencies, such as infectious disease, zearalenone in the feed, and irregular feeding. Nonetheless, it is often difficult to determine the causes of small litter size, especially in short runs. Although shortcuts in swine husbandry can be taken, care in the factors mentioned is needed to maintain some assurance that litter size will remain acceptable.

Litter Size and Genetics. It is generally accepted that litter size cannot be increased through genetic selection because litter size has a heritability of about 0.1 and a coefficient of variation of about 0.25. However, intense selection based on several litter records indicates that prolificacy can be increased by exploiting within-population variability. There is some evidence that selection for components of litter size, namely ovulation rate and embryo survival, may have some potential. Even though rapid genetic responses in litter size are theoretically possible by conventional selection systems, the inclusion of litter size in selection has only moderate effects on overall economic gains because of the importance of growth rate and carcass traits. Based on the

genetic gains estimated from the analyses of several hundred litter records at an experimental station, it is proposed that litter weight at 21 days, alone or in combination with litter size at 21 days or the number of live-born piglets per litter in an index, can be used as the primary selection criterion to obtain genetic improvement in sow productivity traits. There is some heterosis effect on litter size. Genetic selection has had some increase on litter size through the choice of hyperprolific females (Ollivier, 1990). Some breeding stock suppliers have included a highly prolific Meishan line from China in their breeding stock development as well.

Pubertal Development, First Estrus, and Anestrus in Gilts

Maintenance of an optimum litter size at birth and an increase of the overall efficiency of the breeding herd offer two good opportunities for ensuring a productive swine unit. Because 30% to 40% of the sow herd is replaced by gilts each year, introduction of gilts into the breeding herd is an important aspect of herd productivity. The intensification of pig production has altered the physiological patterns and physiology of gilts, which has necessitated that producers establish gilt pools to increase the probability of cyclic gilts for breeding. However, the maintenance of large pools of gilts to have enough gilts in estrus at the right times causes increased feed, labor, and housing costs. Therefore every economical management effort must be made to improve gilt reproductive efficiency.

Pubertal Development. The attainment of puberty, continuation of regular estrous cycles, ovulation rate, and embryonic survival are the most important aspects of gilt reproduction. Effective early induction of puberty in the gilt has become important to swine producers, because it reduces the cost of gilt replacement in the breeding herd. The factors that influence sexual maturation, puberty, and reproductive efficiency in the gilt have been reviewed (Dyck, 1988b). Sexual development of the gilt involves the three distinct phases of sexual maturation, attainment of puberty, and pregnancy (Dyck, 1988b).

The developmental changes associated with sexual maturation are an orderly sequence of hormonal and anatomical changes that lead to puberty. A resting period follows this process until puberty. Extensive research on the occurrence of puberty—the point in time when the gilt commences regular estrous cycle activity—has shown that there is considerable variation in the mean age at puberty among breeds, breed crosses, lines within breeds, and locations. The variation in age at puberty remains constant with an SD of approximately 20 days for the western swine breeds. This translates into a range in age of 120 days with 68% of the gilts in estrus over a 40-day interval and 95% in estrus over an 80-day interval (Dyck, 1988a). Although it is not possible to substantially reduce age at puberty except by selection, puberty can be delayed by dietary intake restriction and by confinement housing with no movement or exposure to mature boars. Chronic feed restriction of gilts can cause cessation of estrous cycles in gilts. When gilts are moved and exposed to mature boars, they will be in estrus in a short period, if they have attained sexual maturity.

Pubertal or First Estrus. Pubertal estrus is expected in most gilts between 6 and 8 months of age. The natural range in the attainment of puberty is from 135 to 250 days; this range is due to various stimulatory and inhibitory influences, including genotype, nutritional status, environment, and the presence or absence of the boar (Hughes and Varley, 1980). With such a range, it is hardly surprising that the introduction of gilts into a breeding program in a herd is difficult to manage. The failure or delay of gilts reared under total confinement to exhibit a detectable estrus is one of the most common causes of inferior reproductive performance in swine.

The need to plan, predict, and control estrus in groups of cycling gilts has emerged from structural changes in the pig industry. The more the operation is out of phase with the sow-culling program, the greater the economic losses. If the breeding of gilts becomes erratic, overall production fluctuates 4 to 6 months later, with a major deleterious effect on cash flow. Conversely, if gilts are not available when needed, there is a propensity to keep sows that should be culled.

After the gilt attains puberty, it enters the next stage of the reproductive process, which includes conception, pregnancy, and parturition. To achieve the birth of a large, uniform litter of piglets, it is necessary to maximize ovulation rate, pregnancy rate, conception rate, and embryonic and fetal survival and growth, and to minimize death losses. Research on the many facets of pregnancy has resulted in development of nutritional and mating management procedures to maximize ovulation, pregnancy, and conception rates. The failure of gilts to continue to cycle at the desired time of breeding is associated largely with the time of year when they attain puberty. Anestrus in gilts is lowest when day length is increasing (e.g., winter and spring) and highest during the summer months when day length is decreasing. However, there has been little change in litter size at birth.

Anestrus in Gilts. The causes of anestrus include immaturity, the stress of confinement by tethering or individual stalls, the absence of a boar near the gilts, the breed of the gilt, and the failure of management to detect estrus behavior in the gilt. Gilts raised in confinement have delayed puberty and either quiet estrus or behavioral anestrus. Total confinement can reduce the proportion of gilts that attain puberty by 8 to 9 months of age by up to 50%; time of year may also affect the onset of puberty.

The proportion of gilts that do not show regular estrous cycles at 9 months of age ranges from 10% to 40%, and the line of the gilts is an important factor contributing to this percentage. Of noncyclic gilts slaughtered at 9 months of age, 55% were gilts with immature reproductive tracts, indicating delayed puberty; 45% were gilts with fully developed uteri and ovaries that had corpora lutea at different stages of development or preovulatory follicles and corpora albicans, indicating behavioral anestrus or an inability by herdsmen to detect estrus.

Various techniques have been used to stimulate the onset of regular estrous cycles in the gilt. These include daily exposure to a mature boar at the time of puberty, purposeful transportation of the gilts to stimulate the onset of estrus, and hormonal therapy. The exposure of prepubertal gilts to a boar advances the onset of first estrus. The timing of initial boar exposure has been shown to be of major importance; the gilt age at the start of boar exposure regulates the response obtained to a large extent. Boar exposure at a very young age (e.g., 3 to 4 months) or at a later age (e.g., 6 months or older) is inefficient. However, exposure of the boar to the gilts at about 160 days of age leads to the highest incidence of onset of regular estrous cycles. Continual boar contact with groups of gilts at this age results in 80% to 88% of the gilts ovulating within 17 days. The first estrus is usually followed by a second and third estrus at 18- to 21-day intervals. The gilts may then be bred on the second or third estrus for optimum ovulation rate. It is also known that olfaction plays an important role in porcine reproductive processes. Acceleration or delay of puberty can be affected by the presence or absence of mature boar odor.

The environmental stimulation of transportation has been considered as a possible technique for initiating estrus in gilts. It has been commonly observed that gilts come into

estrus a few days after being transported. However, controlled field trials indicate that the transportation was not a significant factor in inducing estrus in gilts (Stephens and Close, 1984). The close proximity to adult breeding stock was more important than transportation and relocation.

The role of nutrition as a factor influencing age at puberty has been studied extensively. In general, when the nutrient supply is adequate for commercially acceptable growth rates, there is no effect on age to puberty, but some suggest that a minimum adipose-to-lean tissue ratio is required for attainment of puberty (Kirkwood and Aherne, 1985).

Hormonal Induction of Estrus. Hormonal therapies to initiate the onset of estrus in gilts include the induction of ovulation with either pregnant mares' serum gonadotrophin (PMSG) or human chorionic gonadotropin (HCG), the imposition of a new estrus rhythm using HCG, the destruction of corpora lutea using either estrogens or progesterone, and the suppression of estrus and ovulation using either progesterone or analogs of progesterone (Kirkwood, 1999). The most promising method appears to be that of suppression of estrus and ovulation. Groups of randomly cycling gilts are treated with an agent to maintain all of the animals in a state of midcycle quiescence. Withdrawal of the treatment is followed by a rapid follicular phase, and the gilts come into heat all at the same time.

Allyl-trenbolone, a progestogenic compound, is an effective heat-synchronizing agent in gilts. The use of either allyl-trenbolone or gonadotropin (400 IU PMSG and 200 IU HCG) was effective in the control of estrus and ovulation in groups of prepubertal gilts (Varley et al, 1989). Evaluation of allyl-trenbolone fed during late lactation to primiparous and multiparous sows showed no significant benefit on their subsequent reproductive performance. Altrenogest, a synthetic progestogen, when fed for 10 days, can also effectively synchronize groups of gilts. A reliable synchronizing agent would provide considerable scope for planned mating of groups of gilts. The breeding of large numbers of gilts in a short period requires considerable planning of boar management to ensure that a sufficient number of highly fertile boars is available.

Anestrus resulting from inactive ovaries may be treated with a combination of 400 IU PMSG and 200 IU HCG. Approximately two thirds of the animals will exhibit estrus in 7 to 10 days, but the fertility level and number of pigs born alive are less than that for normally bred gilts. However, it may be useful as a temporary therapy when matings are needed for that week.

Weaning-to-Estrus Interval and Delayed Estrus in Sows

At the time of weaning after a 42-day lactation, the reproductive tract of the sow resembles that of a prepubertal gilt or anestrous sow (Dyck, 1983). From weaning to Day 6 (e.g., estrus) the ovarian vesicular follicle population changes from predominantly small follicles on the day of weaning to large preovulatory follicles, a few medium-sized follicles, and a large number of small follicles by Day 6 after weaning (Dyck, 1983).

The factors that affect the weaning-to-conception interval in sows include endocrine activity, uterine changes, genotype, parity of the sow, season of the year, and level of nutrition during the preceding lactation. Under ideal conditions the sow usually exhibits estrus within 7 days after her pigs have been weaned.

Postweaning anestrus in sows may be due to any one or a combination of the following:

- True anestrus resulting from failure of ovulation
- Silent estrus with normal ovarian activity
- Failure of the herdsperson to detect estrus because of mismanagement

The latter two causes are difficult if not impossible to differentiate. Slaughterhouse examinations of the ovaries of sows culled for anestrus reveal the presence of corpora lutea in about 50% of primiparous and 80% of multiparous sows, which indicates that silent estrus and failure to detect estrus are major causes of anestrus. The ovaries of postweaning anestrus sows are not inactive (Rojanasthien and Einarsson, 1988). Progesterone profiles of postweaning sows reveal that 90% of multiparous and 68% of primiparous sows resume ovarian activity within 10 days. Ovulation with overt estrus within 10 days occurs in 46% of primiparous sows and 54% of multiparous sows. Ovulation without detected heat may occur in 30% of all sows during the first 10 days after weaning.

The season of the year has a significant deleterious effect on return to the regular estrous cycle; this effect is more severe in primiparous sows than in multiparous sows. Postweaning anestrus is most common between July and October, which may be associated with the change in length of daylight. These observations have been recorded in the United Kingdom, Australia, and North America.

Underfeeding during lactation and after weaning, particularly in primiparous sows, is considered a significant cause of postweaning anestrus. Approximately 50% of primiparous sows fail to exhibit estrus within 1 week of weaning, whereas almost 80% of older sows are mated within this period. Inadequate nutrition of sows during their first lactation and the associated body weight and fat losses have been implicated as major factors affecting the incidence of postweaning anestrus. Lactating sows, particularly primiparous sows, are often unable to consume sufficient quantities of feed to satisfy their requirements for energy and protein. There is a critical level of energy intake during lactation, below which the weaning-to-estrus interval is adversely affected by low-energy intake, even when protein intake is adequate. However, protein intake during lactation may exert a greater influence on the interval between weaning and estrus in primiparous sows than does energy intake. The substantial nitrogen loss sustained by lactating sows with low protein intakes is the primary nutritional factor responsible for the prolonged weaning-to-estrus interval of primiparous sows. Age and body weight are also important; primiparous sows that are older and heavier at farrowing exhibit estrus earlier than younger sows, even when body weight losses during lactation are greater in the older sows.

Earlier weaning causes a reduced conception rate, increased cystic ovarian degeneration, and a net reduction in sow productivity. The weaning-to-breeding interval can influence ovulation rate (Deckert et al, 1997). The uterus requires 14 days to return to its normal size and weight after farrowing and an additional 10 days before it is ready to accept further implantation. Zero-weaning of sows (e.g., within a few hours of birth) causes an increase in the interval from farrowing to conception, a concomitant increase in the farrowing interval, an increased incidence of cystic ovarian degeneration, and a reduced conception rate compared with sows that have their pigs weaned 30 days after delivery.

Practical Recommendations for Management of Anestrus. The minimization of the mean interval from weaning to mating is of paramount importance if maximum sow productivity is to be achieved. As general guidelines, anestrus sows can be defined as problems if they do not show estrus before 7 days after weaning, and gilts can be defined as problems if they are not detected in heat and bred by 8 months of age. The most important management procedure to minimize the incidence of delayed estrus after weaning in sows is to move the sow to a breeding barn

specifically designed for housing sows from weaning until successful breeding and conception. After weaning, sows may be placed in individual stalls or in groups of four to six and observed carefully twice daily for the first 10 days after weaning. An intense surveillance system of heat detection in the recently weaned sow is necessary. Boar contact should begin within a few days after weaning to detect estrus in any of the sows. Sows in heat should be bred under supervision and a repeat service carried out in 12 to 24 hours. Bred sows should be identified and observed 18 to 21 days later for any returns to heat.

Hormonal therapy has been advocated for the treatment of sows with prolonged postweaning anestrus. PMSG at 400 IU combined with HCG at 200 IU may induce a fertile estrus within 7 days after treatment in about 66% of animals (Kirkwood et al, 1998). A comparison among exogenous estradiol benzoate, gonadotropin-releasing hormone (GnRH), PMSG, and HCG indicated that only PMSG was effective in inducing a fertile estrus in sows affected with persistent anestrus. Prostaglandin analogs in combination with GnRH are not as successful. A combination of estradiol benzoate and HCG is also ineffective.

The induction of ovulation and conception in lactating sows has been examined as a possible method of reducing the overall mean farrowing interval. Treatment with PMSG at 1500 IU, followed 96 hours later by HCG at 100 IU and followed 24 and 36 hours later by AI, will induce ovulation and conception as early as 15 days after farrowing. The conception rates, number of corpora lutea, and average number of embryos obtained were comparable to those obtained in a natural breeding program. The sow can be inseminated successfully without interruption of lactation or removal of piglets; pregnancy is thus concurrent with lactation, eliminating the need for early weaning and reducing the interval between successive farrowings. It is not possible to synchronize estrus in the pig with two doses of prostaglandins at a fixed interval as is possible in the cow.

Seasonal (Summer) Infertility. Seasonal or summer infertility occurs in swine herds in many parts of the world. In intensive herds in southern European countries, the United States, and Australia, seasonal infertility is induced by heat stress. This type of infertility is characterized by a decrease in farrowing rate and a delay in the return of sows to estrus after mating. There are increases in the number of sows showing irregular returns to estrus after service. Litter size is not adversely affected, but gilts and primiparous sows are most frequently affected. Depressed fertility in boars also occurs. It is thought that this type of infertility is caused by heat stress imposed more than 7 days after mating, which causes whole-litter loss and the return of the sow to estrus. In Britain and some other northern countries, there is an increase in sow abortions in the autumn, particularly in September and October. The lower levels of serum progesterone in pregnant sows in the autumn months may suggest a pathophysiological mechanism for this type of infertility. However, factors other than heat stress can cause reduced infertility in a swine herd at any time of the year. The effects of different photoperiods are controversial (Gooneratne and Thacker, 1990). These observations are important in the management of swine-breeding farms and in the diagnosis of reproductive problems. The provision of shade and the sprinkling of water on sows, gilts, and boars during the hottest periods of the year have been recommended and may be beneficial. The effects of seasonal infertility may be minimized by intensifying postservice estrus detection from 17 to 35 days after breeding, especially during the heat-stress periods. Early diagnosis of pregnancy should be made by 35 days after breeding so nonpregnant females either can be returned to the breeding area for surveillance or can be culled.

The fertility in sows mated during the low fertility summer season can be significantly improved by the addition of oxytocin (4 IU) to the seminal dose immediately before AI (Pena et al, 1998).

Practical Recommendations to Improve Breeding Herd Productivity. To improve breeding-herd productivity on swine farms, it is recommended that producers change their management systems to decrease lactation length, the percentage of gilts in the breeding-female inventory and female culling rate, and increase the percentage of multiple matings (King et al, 1998).

Management of Reproductive Performance of Boars and their Growth, Development, Selection, and Use

The prepubertal development of boars reared in herds exerts a major influence on the level of sexual behavior of the boar. Physical contact with other pigs is a critical aspect of the social environment, and producers should ensure that breeding boars are reared in an environment that allows physical contact with other pigs. The social environment after puberty also has a marked influence on the level of sexual behavior of the boar. A stimulus or stimuli from the female pig appears to be necessary to maintain the potential level of sexual behavior of the mature boar. The mature boar also requires stimulation from the presence of female pigs, regardless of their estrus stages, to maintain his potential level of sexual behavior. It appears that olfactory and, to a lesser extent, auditory stimuli are responsible for this effect. The development of the sexual behavior of the boar is dependent on the integration of androgens and estrogens, which act synergistically to maintain the growth and development of the accessory organs and secondary sexual characteristics (Booth, 1988). The pheromones, secreted by the testis and transported by the submaxillary gland to the saliva, facilitate the rigid standing reflex of the estrus pig so that the boar can more readily breed.

Boars should be purchased from reputable herds that will delineate the exact guarantee and the condition under which the boar will be replaced. Only boars older than 8 months of age should be guaranteed, and breeders should void the guarantee if the new owner does not follow recommended boar management practices. Before a new boar is delivered, it should be tested serologically for diseases such as leptospirosis, brucellosis, pseudorabies, and other endemic diseases that can be detected serologically (Lord et al, 1997). Ideally, newly introduced boars should be kept in isolation for at least 2 weeks, then mixed with nonpregnant breeding females about 1 month before use in breeding to promote the spread of infectious agents, such as parvovirus and porcine enteroviruses, well before breeding to ensure that immunization occurs. During this preconditioning period, boars should be test mated by exposure to females in heat. Boars should be purchased at least 6 weeks before the beginning of breeding to allow for a 2-week quarantine and a 4-week preconditioning period. They should be at least 8 months old before routine use.

Assessment of Reproductive Performance of Boars. There is little published validated information on methods for the assessment of reproductive performance of boars. Several studies indicate that a boar has an influence on subsequent litter size, whereas others could not document a consistent boar effect (Clark et al, 1989). A large number of litters are required to detect litter size differences attributable to boars, which precludes the use of litter size as a criterion for culling boars. Semen characteristics vary widely among the different ejaculates of each boar and have little association with litter size. The conception rate of sows bred

by boars varies considerably among boars but is confounded by variations in conception rate caused by matings per conception, season of the year, parity, nutrition of the sow, and duration of lactation. The identification of subfertile boars early in their reproductive life, so that they can be replaced early, has not been achieved.

The farrowing rate of the females bred by the boar has been evaluated as a measure of fertility of boars. The first 100 single-boar services of 140 boars were analyzed to determine if the farrowing rate from initial services could reliably predict the farrowing rate of subsequent services. The farrowing rate of less than 50 initial services of boars cannot be used as a reliable estimate of farrowing rate for subsequent services through 100 farrowings, and therefore it cannot be used as a management aid for culling subfertile boars. Boars should not be culled because of poor initial performance as measured by farrowing rate, which is influenced by parity, number of matings per estrus, and season of service. The results indicated that increased numbers of sows should be bred in the summer, more gilts than needed should be bred, sows of parity 8 or more should be culled, and all females should be mated at least twice per service to avoid reduced farrowing rates. Other workers feel that farrowing rate of first service is superior to percentage of returns to service as a method of monitoring performance of boars, provided the recorded farrowing dates are compatible with the recorded first service. The percentage of returns to first service provides information rapidly and may allow the identification of gross infertility in an individual boar. However, sows that do not conceive at first service may not be recorded because of failure to detect estrus, failure to record the fact, or anestrus.

The following indexes for the assessment of the reproductive performance of boars have been suggested:

- Ratio of boars to sows of 1:20
- Age at first breeding of 7 to 8 months
- Average number of services per week at 7 to 9 months of age of two/week
- Average number of services per week at 9 to 12 months of age of three to five/week
- Average number of services per week at older than 12 months of age of six/week
- First service conception rate of 90%
- Average interval to return to estrus of sows bred of 21 days
- Average litter size of 9.5
- Percent of litters with less than eight piglets of less than 15%
- Time since last service of less than 1 week

Boar-to-Sow Ratio. The number of boars required to achieve optimum fertility depends on the age of the boars, the size of the breeding pens, and the desired mating system. Ideally, young boars should not be used more than once daily. Because the mating of each female two or more times increases conception rate and litter size, there should be enough breeding boars to mate each female twice. The number of boars needed is equal to the maximum number of females in heat per day × 2.

Mating Systems. Double mating can significantly increase conception rate and subsequent litter size. Maximum conception rates are obtained when females are mated approximately 12 hours before ovulation. Much of the benefit gained from double mating may be the result of breeding nearer to the optimum time. Double mating can be achieved either by mating at 12- to 24-hour intervals with the same boar or with two different boars. In a hand-mating program, after the first mating, the female is served again, either later the same day or on the following morning. In the commonly used pen-mating system, double mating can be achieved by twice-daily boar rotation.

Culling of Boars. An effective culling policy for boars is part of a successful breeding management program, but the reasons for culling boars and an economic target value for an annual culling rate of boars has not been determined (D'Allaire and Leman, 1990). The estimated lifetime breeding expectancy of boars in a commercial swine herd varies from 12 to 24 months but can range from 0.3 to 38.5 months. In a study of boar culling in 84 herds in Minnesota over a period of 12 months, the annual culling rate was 59% and the proportions of reasons for culling were overweight boars (47%), reproductive problems (18%), leg problems (12%), death (7%), and other diseases (4%). The average breeding life was estimated at 20 months. Such a culling rate is considered too high, but there are few standards for comparison. The high rates of culling for overweight boars may reflect a feeding management problem, which indicates that the nutrition status and feeding program of the herds should be reviewed and corrected as necessary to improve the longevity of boars.

Artificial Insemination. AI has become an integral part of pig production, particularly in large herds. AI can be applied to swine production to increase the possibility of genetic improvement, disease control, and intensive management. The most critical problem in breeding sows artificially is determining the correct time to breed. Ovulation occurs approximately 40 hours after the beginning of standing heat, and the ova remain viable for only 1 to 2 hours. Therefore maximum conception is achieved when fresh spermatozoa are waiting to fertilize the ova as soon as they leave the ovary. Ideally, a sow should be inseminated early on the second day of standing heat to ensure that fresh, viable sperm are ready to fertilize the ova. However, with variation in sows and the fact that most producers only check for heat once daily, sows are usually bred on the first and second days of standing heat to ensure the maximum conception rate (Glossop, 1998).

A major constraint to the development of AI in swine is that boar semen freezes poorly, and prolongation of the viability of semen beyond the fourth day is a problem (Cosgrove, 1997). Long-term extenders are being developed that should allow the use of semen for more than 3 days and perhaps up to 9 days. The success of these long-term extenders will depend on the selection of boars with the best semen, with high suitability for long-term storage.

Boar ejaculate is characterized by its large volume (around 300 ml on average) and spermatozoa number (80 to 120 billion when semen is collected once a week), which corresponds to total sperm reserves and widely exceeds daily sperm production (10 to 20 billion spermatozoa/day). As a consequence, spermatozoa number per ejaculate steadily decreases when the boar is used or collected more than once per week, in spite of a slight increase in sperm production with ejaculatory frequency. Large amounts of spermatozoa and semen are necessary to ensure normal conception rate and prolificacy (50 ml of semen and 3 billion sperm are considered minimum requirements for AI). Frozen boar semen can be used successfully, but it leads to much lower conception rate and litter size than fresh semen so that its commercial use is currently very limited. These circumstances limit the use of either natural service (sow/boar ratio cannot exceed 12 to 15) or AI boars (which produce about 1000 semen doses per year) and consequently the dissemination capacity of favorable genes in breeding programs.

The technique of insemination is relatively standardized. During estrus, a sow is normally inseminated twice with 3 to 5 billion sperm in 40 to 80 ml of extender, although the later insemination is not as important if the first insemination is timed correctly.

Errors in insemination technique result in poor reproductive output, inefficient use of resources, or both. The choice of extender, boar usage rates, semen concentration, processing technique and insemination techniques are all in a tension between cost control and acceptable reproductive productivity.

The challenge for the veterinarian is mainly to assess the effect of insemination on farrowing rate and litter size. Swine producers now purchase semen from boar studs. These studs can have boar inventories as large as 300 boars. Semen is delivered 3 days a week or more, depending in part on the relative distance to the stud and the frequency of weaning.

Poor insemination technique or semen quality results in lower farrowing rates, more nonproductive sow days (NPSDs), and lower litter size. The specific faults may include the following:

- *Timing*. Excellent estrus detection is needed to make AI a useful technology. Inefficient detection results in late insemination or missed opportunities to mate sows. This causes lower litter size, farrowing rates, and more NPSDs. This problem is particularly acute in gilts, since estrus is more difficult to predict and detect (Soede et al, 1995).
- *Inseminator technique*. The inseminated sow needs to be stimulated adequately to induce contraction of the uterus to deliver the semen to the fallopian tubes. These contractions draw the extended semen from the bottle or sachet and are indicators of a successful insemination. Stimulation can include the presence of a boar or boar odors, backpressure, and kneading the flanks. Real differences can often be found among insemination technicians, and training and discipline in technique is important. In addition, adequate time should be given to employees to ensure good technique (Crabo and Dial, 1992).
- *Age and storage of semen*. As fresh semen ages, especially in less than optimum storage, the reproductive efficiency rapidly decreases. The exact expected parameters depend on the extender used, as do the storage conditions. In general, semen should not be used after 5 days of storage, and use after 3 days should be minimized.
- *Processing technique*. Boar stud management includes caring for the boar, collecting the semen, evaluating the ejaculate, and extending and packaging the semen. There are numerous errors that are possible, but most common problems are contamination of semen through contaminated equipment. This is in spite of the regular addition of broad-spectrum antibiotics in the extended semen. Viruses that exist in the ejaculate of infected boars are spread easily and thus disease control is imperative (Philpott, 1993).

AI is, as is any production technology, susceptible to error. However, it has been readily adopted as technique on swine farms. When AI is used correctly, productivity has increased and many costs have decreased.

Numerous diseases of swine can be transmitted by using fresh or frozen semen for AI. Information on this subject has been reviewed (Philpott, 1993). Contamination of semen with bacteria, mycoplasmas, rickettsiae, and viruses can occur within the boar, during collection, at processing, and during storage and transport. Infections of the reproductive organs of the boar can cause contamination of the semen. During collection of the semen, contamination may occur because of uncleanliness of the operator or the use of dirty equipment. Methods used to minimize bacterial contamination of semen include hygienic collecting and processing of semen, isolation of boars from certain pathogens, and the addition of antimicrobials to the semen. Many viruses have been isolated from semen, including PRRSV, Aujeszky's disease virus, PPV, enterovirus, adenovirus, reovirus, Japanese B encephalitis virus, apthovirus, SVD virus, and ASF virus. It is believed that there is a greater risk of infection from the introduction of an infected boar into a herd than from the use of fresh or frozen semen. AI permits breed improvement with the least risk of disease transmission.

Mating Management of Gilts and Sows

Maximum reproductive efficiency begins by breeding gilts at an early and predictable stage so that they farrow a good-sized litter at 10 to 11 months of age, nurse the pigs well, and maintain moderate body weight to ensure an early return to heat after weaning. They should proceed to produce good-sized litters approximately every 150 to 160 days up to about the sixth litter, with weaning programs at 4 weeks of age. Factors that influence the age at which gilts reach puberty include genotype, nutrition during the growth period, contact with boars, and stresses associated with transportation and commingling with other gilts. Gilts are usually selected at approximately 170 days of age, mixed with other gilts, and given short periods of supervised daily contact with a boar. Following this stimulation, groups of gilts will usually exhibit their first standing heat in 6 to 10 days. The second and third heats will usually follow in a synchronized fashion, and flushing (i.e., increasing the level of feeding 10 days before the breeding heat) can be done to increase the ovulation rate.

The factors that influence successful rebreeding of sows after weaning include the following:

Feeding. Sows should be fed a high level of feed from farrowing until mating to ensure that they come into heat as early as possible, preferably within 5 to 7 days. The feed intake must be reduced immediately after mating, because high feed intakes after mating increase embryonic loss, especially in gilts.

Housing. Following weaning, sows are usually housed in individual stalls or groups. There are advantages and disadvantages of both systems. In individual stalls, estrus detection may be more difficult than when sows are in groups. However, when sows are grouped, fighting can be a major problem. Fighting and riding during estrus leads to increased lameness and culling. Feed intake can be controlled more effectively in stalls than in groups, and feed intake can be reduced after mating. The housing system should allow for comfort; easy detection of heat; sight, smell, and sounds of the boar; easy movement of sows to the boar; and a good service area. It should also provide ease of movement and safety for herdspersons.

Parity. Sows are more difficult to breed successfully after their first lactation. This is usually associated with excessive weight loss of the gilt during her first pregnancy and lactation. As parity increases, the weaning-to-conception interval decreases. Excessive weight loss during the first lactation can be minimized by increasing feed intake during the lactation period or reducing litter size by cross-fostering.

Selection of a Farrowing Cycle. The complete reproductive cycle of mature swine involves mating, gestation, farrowing, lactating, weaning, and the interval to remating. Adequate facilities must be available to accommodate a number of animals at each of these stages. Farrowing time is relatively inflexible, and the parturition–nursing unit requires the greatest investment of capital. Therefore it is advisable to plan the entire reproductive program to optimize use of this facility. Batch farrowing allows better organization and more efficient use of facilities and labor and reduces disease problems in newborn piglets. In a batch-farrowing system, groups of females bred at about the same time move into a farrowing unit just before the first sow is due, remain in the unit until the youngest litter reaches weaning age, and then

are moved into the rebreeding area. The farrowing room is completely cleaned and sanitized before the next group moves in. The length of the farrowing cycle or time that the group occupies the farrowing room can be as short as 4 weeks with early weaning but is usually 5 to 6 weeks in most commercial practices.

In a herd that practices 4- to 5-week weaning, sows should be moved into the farrowing crates 3 to 4 days before they are due, and 1 or 2 days will be required for cleanup as the litters are weaned. Therefore the farrowing room will be tied up for 6 weeks with each batch. If 250 litters are expected, this requires 250 × 6, or 1500 crate-weeks, or a total of 28.8 crates. This could be organized with two farrowing rooms of 15 crates each operating with a farrowing every third week, or with three rooms of 10 crates each operating on a 2-week cycle. Both systems can spread the farrowing, weaning, cleanup, and rebreeding uniformly throughout the year.

In a 3-week cycle, 15 sows will be weaned; 12 of these should conceive the following week. The herdsperson should attempt to mate four or five gilts at the same time to maintain a batch of 15 pregnant animals. With a 2-week cycle, 8 of the 10 weaned animals should conceive the week after weaning, and about three additional gilts should be mated to maintain the batch number. Additional gilts must be mated if some of the group is culled before remating. The advantage of the 3-week cycle is that females that fail to conceive at first mating usually return during the period when the next group is being mated. However, working replacement gilts into the system is easier with a breeding every second week. Larger units with populations in excess of 125 sows should consider batch-farrowing a group of sows every week.

Whatever system is adopted, it should be organized to produce a uniform flow of batches through the mating, gestating, and farrowing areas and then back to the mating area for rebreeding. To achieve efficient breeding performance with batches over prolonged periods necessitates adequate housing, sound nutrition, and a disease control program that maintains the entire herd in continual good health. In addition, the operator must plan and execute a management routine that ensures prompt initiation of estrus after weaning, detection of estrus, high pregnancy rates, and large litters.

Predicting Number of Pigs Weaned Weekly. The even flow of pigs through a herd is important for several reasons. The producer must make optimum use of existing facilities to control the fixed costs of production. If there are excess number of pigs being produced with insufficient barn capacity, the pigs become crowded. Overcrowding can decrease feed intake and average daily gain and may increase the incidence of disease. A steady flow of pigs produced has become a high priority in segregated early-weaning production systems in which the nursery operator expects a given number of pigs per week to fill the nursery. Profits for the sow producers depend on production of a steady supply of pigs each week.

A spreadsheet can be used to predict the number of pigs weaned per week 19 weeks after the sows are mated (Dewey et al, 1997b). The prediction is based on 3-week rolling averages of sows served and 12-week rolling averages of litter size, preweaning mortality, and farrowing rate. It is possible to predict the number of pigs weaned per week as soon as the numbers of sows mated during a 3-week period are known.

Pregnancy Diagnosis. The recurrence of estrus following service is a traditionally accepted method of diagnosing nonpregnancy in sows (Almond and Dial, 1987). In large herds where sows are penned individually, the detection of heat can be difficult and unreliable. The commercial gain through the routine use of pregnancy diagnosis is dependent on the accuracy of the results, the overall fertility of the herd, and the costs of the test. It has been suggested that in higher performance herds with a consistent farrowing rate of 85%, ultrasonic pregnancy testing at about 1 month after the first service may be uneconomical, and that more attention should be given to improved detection of sows returning to estrus (Meredith, 1989). Returns to service are a more sensitive measure of fertility, because most nonpregnant sows will return in the first month and not reach the stage of pregnancy testing. Proponents of pregnancy testing argue that nonpregnant sows will be detected earlier, and the costs of barren sows will be reduced. However, the counterargument is that the cost of keeping a barren sow has been overestimated. The real question is how many empty days can be saved by pregnancy testing? In theory, nonpregnant sows can be identified by pregnancy testing at 1 month after service rather than waiting to be identified as a return-to-heat or a not-in-pig (NIP) sow later. However, in real practice, pregnancy testing will not be done routinely, and many sows will not be tested until they are well past the earliest day they could have been examined. When they are examined, it is unlikely that they will be culled if they are negative because most negatives will be false-negatives; culling a false-negative can be costly.

The principles, applications, and accuracy of pregnancy diagnosis in swine have been reviewed (Almond and Dial, 1987). There is no ideal technique available, and the method of choice varies with the requirements of the individual user. The available techniques include detection of estrus with boar exposure, estrus enhancement with estradiol-testosterone injections on Days 19 and 20 after breeding, laparoscopy, and serum concentrations of prostaglandins, progesterone, estrone sulfate, radiography, rectal palpation, vaginal biopsy, and ultrasound.

The ideal pregnancy test should be highly accurate (e.g., >95%) and should have low prevalences (e.g., <5%) of false-positive and false-negative results (Almond and Dial, 1987). The test should be safe, simple, and inexpensive and should provide results within a few minutes. It should be possible to conduct the test and receive the results before a nonconceiving animal is likely to return to estrus (e.g., <21 days). The test should be applicable to animals that are 1 week or more apart in gestation, so that a test can be conducted on all animals in a group at the same time. The test should also require a low investment of labor.

The most commonly used technique is the observation of the sow for failure to return to estrus after breeding. It is the oldest, most widely used, and most accurate method for predicting that sows will farrow (Almond and Dial, 1986). This method is based on the premise that pregnant sows rarely exhibit estrus during gestation, and that nonpregnant sows will return to estrus within 18 to 25 days after breeding. The test depends on the attendant making the observation of heat and using the standing reflex posture in response to back pressure; the test results are more conclusive if the sow's behavior is observed in the presence of a boar. Therefore the gestation facilities must be designed to allow daily fence-line contact between boars and sows. Daily estrus detection enables 98% accuracy in predicting farrowing rate if daily boar exposure for estrus detection is provided between 18 and 24 days after breeding. Although increased time and effort are required with this technique, the sow is reexposed to the boar soon after conception fails, thereby minimizing the weaning-to-conception interval. False-positive diagnosis may occur if the sow becomes pseudopregnant. Of sows that return to estrus after breeding, one group will return at a mean of 20 days and the other at 26 days (Glossop and

Foulkes, 1988). The first group represents failure of fertilization and the second group early embryonic death. The failure to detect heat at the first opportunity would lead to a second return at about 41 days.

The accuracies of the mechanical and endocrine tests have been compared with the return-to-estrus method (Almond and Dial, 1986). The overall accuracies of the techniques for diagnosing pregnancy were: returns to estrus, 98%; estrone sulfate, 92%; progesterone, 92%; Doppler with rectal probe, 86%; Doppler with abdominal probe, 86%; diode ruler, 73%; and oscilloscope, 86%. Estrus detection resulted in the lowest incidence of false-positive and false-negative diagnoses.

Mechanical ultrasound devices are used commonly by commercial swine producers for pregnancy diagnosis because they are easy to use, are commercially available, and are perceived as being highly accurate (Almond and Dial, 1987). The Doppler ultrasound device gives optimum results between 29 to 35 days of pregnancy, with an accuracy of more than 85% for pregnant animals and more than 95% for nonpregnant animals. There appear to be no significant differences between the accuracy of the Doppler fitted with the rectal probe and the Doppler fitted with the abdominal probe. With amplitude-depth ultrasound, the accuracy is more than 95% between 30 and 75 days of pregnancy. This method appears to have greater sensitivity but less specificity than the Doppler instruments. The ultrasonic linear scanning instrument (e.g., real-time, B-mode ultrasonography) is more than 95% accurate for determination of pregnancy between 22 to 24 days after breeding.

Rectal palpation is possible in sows but not in gilts, and it has an accuracy rate of about 94% when performed between 30 and 60 days of gestation. Rectal palpation is more than 94% accurate when performed at 28 to 30 days of pregnancy. Accuracy approaches 100% from 60 days to term. It is simple and quick, does not require expensive instruments or laboratory facilities, requires only minimal restraint, and is highly accurate. Sows are examined while standing in their gestation crates or pens or while tethered in the standing position. Where laboratory facilities are readily available, the vaginal biopsy technique is considered more efficient than the ultrasonic technique. Neither system allows routine detection of animals that have failed to conceive before the first anticipated return to service. False-positive results may occur because of embryonic or fetal death. The vaginal biopsy technique is highly accurate at between 18 and 22 days after mating.

An on-farm progesterone assay kit to determine pregnancy in sows claims an accuracy of 95% for pregnancy and 36% for nonpregnancy in sows sampled between 17 to 20 days after service (Glossop et al, 1989).

Pregnancy Losses

Reproductive losses can be grouped broadly into those that occur before breeding, such as those associated with anestrus in sows and gilts, and those associated with problems after breeding. Pregnancy loss is associated with failure of conception, embryonic mortality, fetal death and abortion or fetal mummification, pseudopregnancy, and diseases of the sow. A systematic and logical approach must be used when attempting to make a diagnosis of reproductive failure in a swine herd. The data required to monitor reproductive performance include: sow number; date of birth; date weaned; date bred; parity number; boar used; number of times bred and interservice interval; dates of rebreeding; dates of health events such as abortions, discharges, pregnancy test results, and treatments given; number of piglets born alive and dead; number of piglets mummified and their size; and litter scatter (e.g., the percentage of litters with less than nine total piglets alive and dead). Comparison of actual performance with the targets of performance at each stage of the reproductive pathway identifies the area that needs further epidemiological, clinical, and laboratory investigation.

The major categories of reproductive loss that occur after breeding are as follows:

Failure to Conceive. Failure to conceive is characterized by return to service 18 to 20 days after a normal mating or insemination and may be due to any of the following factors: (1) the spermatozoa fail to reach the ova; this may be the result of an abnormal uterus or occlusion of the oviducts; (2) death of ova postfertilization caused by inherent defects of the gametes, incompatibility between the gametes, or failure of the spermatozoa to penetrate the ova; insemination too early or too late in the estrus cycle or the use of boars with temporary infertility may also be causative factors; (3) death of the developing blastocysts within 12 days of fertilization is usually followed by the sow returning to estrus within the normal 21-day cycle; causes of blastocyst death include overfeeding, environmental stresses, and systemic illness. In the Australian experience, there is a relationship between high summer temperatures, which exceed 32° C, and an increase in the incidence of sows that exhibit delayed, irregular returns to estrus. In Britain, manifestations of seasonal reproductive inefficiency in large breeding units, mainly in animals bred during the months of July and August, include an increase in the returns to service, abortion, and sows remaining barren 95 days after service. Epidemics of endometritis can reduce the conception rate of gilts to about 11% compared with 82% in healthy gilts. Affected gilts have a profuse vulvar discharge that commences 6 days after estrus, and the disease usually resolves spontaneously after one or more estrous cycles. The bacterial species isolated are those that normally inhabit the lower urogenital tract, and it is thought they become opportunists at the onset of estrus. In some situations, medication of the prepuce of the boar, of the sow using long-acting oxytetracycline, and of the feed for 21 days was considered beneficial.

Zearalenone in the diets of gilts or sows may cause reproductive failure associated with uterine and ovarian abnormalities, reduced litter size, infertility, or pseudopregnancy.

Embryonic Mortality. Embryonic mortality is characterized by return to estrus more than 24 days after service. Embryonic loss between 14 and 40 days after fertilization is followed by resorption of the uterine contents. Causes include infections of the uterus occurring at mating or by transmission in semen.

Fetal Death and Abortion or Mummification. Damage or disease in fetuses from 35 days to term can produce various effects, including abnormality of tissue differentiation and function, distortion of body structure, and growth retardation. The onset of immune competence takes place at about 65 to 70 days of gestation, and after this time, antibody production and inflammatory processes can take place. Fetal death is followed by autolysis and then mummification or maceration, if sufficient time elapses before parturition or abortion. Bones of dead fetuses are not usually resorbed; therefore age of death, and sometimes even events that preceded death, can be determined by radiological examination.

The common causes of fetal death in swine are leptospirosis and infection with parvovirus and pseudorabies. Leptospirosis usually causes abortion without any significant illness of the sow. The diagnosis is made by serological examination of the sow and laboratory examination of the fetuses.

Parvovirus infection before 70 days of gestation in nonimmune gilts or sows will commonly cause mummified fetuses, which are carried to term with the net result of a small number of live piglets per litter. Parvovirus infection is widespread in the pig population, but the degree of reproductive failure depends on the number of susceptible females introduced into the breeding herd from outside sources. Maternal immunity must be established before conception occurs. In some surveys, parvovirus infection may account for up to 45% of fetal deaths in swine herds. Outbreaks of reproductive failure may occur after introduction of the infection into a susceptible herd. Severe fetal mummification can be expected in sows that become infected between 45 and 65 days of gestation.

Pseudorabies infection during gestation in nonimmune sows may cause fetal resorption, fetal mummification, and abortion. In some outbreaks, maternal illness occurs before the fetal deaths, whereas in others, there may be no significant illness in the dams. Diagnosis is dependent on examination of the fetuses and serological examination of the dams. Control of the disease may be achieved through the use of an eradication scheme of serological testing and the culling of positive animals or the use of vaccines in susceptible animals at least 2 weeks before breeding.

Other causes of fetal death that may occur sporadically include infections with enteroviruses, reoviruses, adenoviruses, and miscellaneous bacterial and fungal infections.

In some abortions, all of the embryos and fetuses are expelled without obvious abnormalities other than subcutaneous congestion, hemolysis, and early autolysis. On other occasions, however, some or all members of the litter may be diseased or long dead. Careful examination of aborted litters is therefore important not only because it enables distinction between maternal and embryonic failure but also because, in embryonic failure cases, it sheds light on what kinds of disease processes were involved. Radiography may once again be useful to ascertain the ages of the fetuses when they died and to detect abnormalities preceding death. Furthermore, if all fetuses in the litter are radiographed, it may be possible to determine whether all were affected simultaneously on a particular date, as in cases of maternal illness or transplacental toxemia, or whether a sequential process was involved with spread from fetus to fetus in utero, as in cases of certain intrauterine infections.

When fresh fetuses are available, as when pregnant sows are slaughtered specifically for the purpose or in instances in which stillbirths or early neonatal deaths are identified as the major problem, there may be a need for postmortem dissection and perhaps other detailed studies. First, however, the conceptual age of the litter must be ascertained from the service date, and then other quantitative information can be recorded and compared with appropriate standards (e.g., means and tolerance limits) for normal fetuses or piglets of that particular age. Such standards can be of special value in the assessment of the normality of fetal and newborn piglets.

Placentae should be examined when necessary, although recognition of pathological abnormalities presupposes familiarity with the normal placenta.

Stillbirths. Between 5% and 7% of piglets are born dead, and approximately 10% of these die before the act of parturition begins. Most stillbirths occur during the process of parturition because of anoxia caused by premature separation of the placenta or intrauterine rupture of the umbilical cord, which may be shortened. Prolonged parturition or uterine inertia in older sows may also be involved. The presence of meconium on the skin, in the mouth, and in the trachea of the piglet differentiates the type II anoxic intrapartum stillbirth from type I prepartum cases. Deaths that occur during the process of parturition (e.g., stillbirths) often result from fetal asphyxia. Sometimes, however, prior disease renders the fetus incapable of successful transition; therefore careful postmortem study may be needed to ascertain the exact mechanisms of stillbirth. Distinction between late fetal death, intrapartum death (e.g., stillbirth), and early neonatal death is not always easy when parturitions are not actually observed. However, late fetal deaths (i.e., those occurring 24 to 48 hours before term) usually show signs of early autolytic degeneration (e.g., cloudy cornea, subcutaneous and intraabdominal hemolysis, friable liver and kidneys), whereas evidence of lung expansion is seen in cases of neonatal death. Piglets asphyxiated in utero often have meconium and mucus in their tracheas and bronchi.

The majority of stillborn piglets are viable at the time of parturition. Only 10% to 20% of these stillborn piglets are type I. Stillbirths are most common in older sows, in large litters, and in the last piglets born in a litter. The longer the farrowing process, the more likely one or more piglets will be trapped in utero without adequate placental connection and will suffocate. The challenge is to save pigs in large litters in which stillborn piglets are most likely to occur. The risk factors that are associated with stillbirths and can be used to predict which sows will deliver stillbirths are older sows, a previous litter size of more than 12 piglets, and a record of previous stillbirths. If such high-risk farrowings are attended, and if proper guidelines on assisting sows during farrowing are followed, the incidence of stillbirths can be reduced. The induction of parturition with prostaglandins in high-risk sows allows scheduling of parturition during the working day so that adequate surveillance and assistance can be provided.

Perinatal Mortality Losses

Low-Birth-Weight Piglets, Small Litters, Low Viability, and Lactational Failure. Low-birth-weight piglets occur in most litters, especially those that are large and those born to older sows. They are usually associated with small areas of placentation that are established at the implantation phase, particularly where uterine overcrowding has also occurred.

Small litters are usually the result of an above-average degree of embryonic loss. It has been shown that pregnancy will not usually be maintained if four or less conceptuses are present in the uterus in the implantation phase or if one horn is devoid of developing blastocysts. Therefore, when two to five piglets are born, embryonic loss beyond the average has taken place. Reduced litter size may also occur in sows inseminated late or early in the estrous cycle or with the use of subfertile boars or semen that has been delayed in transit.

Low viability can be expected in underweight or overweight piglets or where the number of stillbirths in a litter is higher than normal. If, however, it occurs in apparently normal piglets, other factors are involved. Prenatal virus infection and vitamin A deficiency can be responsible for congenital malformation with subsequent low viability. Pregnancies that are terminated 2 or 3 days early, or those that end at Day 117 or later, also produce this effect. In-breeding, estrogenic mycotoxins, or nutritional inadequacies such as manganese or vitamin B_{12} deficiency may also be responsible for some reduction in viability.

The inherent weaknesses of all newborn piglets, namely the absence of subcutaneous fat, an undeveloped thermoregulating mechanism, and low glucose reserves, contribute to early perinatal loss, particularly if the environmental or nutritional conditions are also inadequate.

Infectious Agents Associated with Reproductive Failure in Swine. The following section reviews the major infectious agents capable of causing reproductive failure in swine.

An understanding of the general terminology of swine reproductive failure is essential for adequate consideration of the subject. The gestation period, or the period from conception to birth (approximately 114 days), can be divided into two sections: the embryonic period and the fetal period. The former usually includes the period from 10 to 30 days after conception, whereas the latter extends from 30 days to birth. The neonatal period consists of birth to 7 days of age.

Embryonic death refers to mortality of the conceptus before calcification of the skeleton that occurs at about 30 days' gestation. If embryonic death occurs before Day 12 of gestation, resorption of the embryos will take place and the sow will undergo a regular return to estrus. Pregnancy failure after Day 12 may cause delayed returns to estrus (e.g., greater than 25 days). Mummification occurs primarily in the fetal period after some calcification has taken place, approximately from Day 30 to 70 of gestation. Mummified fetuses are characterized by death, discoloration, and the resorption of fluids and then soft tissues. Stillbirths are fetuses that have matured fully in utero, but are born dead near the normal end of the gestation period. Stillborn piglets look normal, but their lungs have never inflated. There are two basic types of stillbirths: type I includes fetuses that die before the end of gestation, usually of infectious causes, and are prepartum deaths. Type II are piglets that die during parturition, usually of noninfectious causes, and are known as intrapartum deaths. Examples of the causes of this type of stillbirths are hypoxia resulting from umbilical rupture or impeded umbilical blood flow causing high carbon dioxide and low oxygen tension, high atmospheric carbon monoxide, and high temperatures in the farrowing house (>39° C) during Days 102 to 110 of gestation and prolonged parturition.

Abortion refers to the delivery of an immature fetus before the completion of the gestation period. The fetus is usually dead or dies shortly after birth. Early neonatal death refers to death or extreme weakness of the piglet within the first 7 days after birth. This condition is usually due to events occurring during gestation or soon after birth. Finally, embryos and fetuses may also undergo congenital malformations that are abnormalities in the size, shape, location, or structure of any part of the developing conceptus.

Porcine Reproductive and Respiratory Syndrome Virus (Blue-Eared Pig Disease, Mystery Swine Disease, and Swine Infertility and Respiratory Syndrome

During the late 1980s, outbreaks of a devastating new pig disease were reported in swine herds throughout the United States (Zimmerman et al, 1997). Clinical signs consisted of severe reproductive losses, extensive postweaning pneumonia, and suppression of growth. "Mystery swine disease" (MSD) was the name given to the syndrome, and it quickly spread throughout the major swine-producing areas of the United States. By 1990, MSD had occurred in 11 U.S. states, two provinces in Canada, and Germany. During the following year the disease was reported in the Netherlands, Belgium, Spain, and the United Kingdom (Done et al, 1996; Christianson and Joo, 1994; Meredith, 1999). Many etiological agents were proposed as the cause, including encephalomyocarditis virus, *Leptospira interrogans* serovar *bratislava*, PPV, porcine enterovirus, *Chlamydia psittaci*, and mycotoxins. In Quebec, Canada, a new subtype of influenza A virus was isolated from weaned pigs experiencing outbreaks of severe respiratory disease and was considered a potential etiological agent. Despite the intensive research efforts, the etiology of the disease complex remained unknown until 1991, when a viral agent was isolated (Wensvoort et al, 1991). It was possible to reproduce both the reproductive and respiratory disease and fulfill Koch's postulates. The virus was called Lelystad virus (LV) (Terpstra et al, 1991). The isolation of the etiological agent led to advances in diagnostic techniques, and soon evidence of the virus was found in Denmark, Malta, Luxembourg, Japan, Korea, Italy, Poland, and Russia. Finally, at the first international symposium held to discuss the latest information about the virus, it was officially designated as PRRSV.

The terms *mystery pig disease* and *blue-eared pig disease* were used because the etiology was unknown and the skin of the ears of affected pigs commonly appeared blue. The disease affected pregnant gilts and sows, unweaned and recently weaned pigs, and growing-finishing pigs. Outbreaks of late-term abortions, high numbers of stillbirths and mummified or weak newborn piglets, and respiratory disease in young unweaned and weaned pigs were common.

Etiology. Since its identification, rapid progress has been made on the characterization of PRRSV (Benfield et al, 1992). The virus was initially isolated on porcine alveolar macrophage cell lines (Wensvoort et al, 1991). It appears to be a positive strand RNA virus classified into the genus Arterivirus. It is spherical, enveloped, and ranges in size from 45 to 80 nm. Because of the presence of an envelope, rapid inactivation of PRRSV is possible following pretreatment with chloroform or ether. Disinfectants such as formaldehyde and phenol-based compounds appear effective at neutralization. The virus is stable under freezing conditions, retaining its infectivity for 4 months and up to 3 years when stored at 270° C. Infectivity is greatly reduced with increasing temperature (15 to 20 months at 220° C, 30 days at 4° C, 6 days at 20° C, and 15 to 20 minutes at 68° C). PRRSV is also sensitive to changes in pH, and infectivity is reduced over 90% at pH levels less than 5 and greater than 7.

The virus does not survive for long periods on fomites (Pirtle and Beran, 1996). Virus was not recovered after periods of exposure greater than 30 minutes to fecal slurry, porcine urine and saliva, plastic, stainless steel, rubber, wood shavings, straw, and alfalfa. Despite limited viability, the virus was recovered for up to 9 days from well water and up to 11 days for city water.

There are antigenic differences between strains of the virus. The amino acid sequences of open reading frames (ORFs) 2 to 7 of North American strains share only 55% to 79% homology with European strains, whereas those of Canadian and U.S. origin have greater than 90% homology (Benfield et al, 1992). Variation has also been reported between U.S. isolates. Analysis with PCR and molecular sequencing found up to 15% heterology between ORFs from U.S. isolates, with ORF 5 being the least conserved.

Epidemiology. The literature on the epidemiology of the disease has been reviewed (Albina, 1997; Zimmerman et al, 1997).

Occurrence. PRRS affects pregnant gilts and sows, unweaned and recently weaned pigs, and growing-finishing pigs. Outbreaks of late-term abortions, high numbers of stillbirths and mummified or weak newborn piglets, and respiratory disease in young unweaned and weaned pigs are common.

Prevalence of Infection. In endemic herds, 30% to 70% of pigs may be seropositive to the virus and about 60% of herds have some seropositive pigs. Although the seroprevalence may be high in herds in some regions, the incidence of clinical disease is lower and variable. Although the number of herds with the acute form of the disease has been decreasing, the infection may be endemic in many herds, characterized by increased mortality and suboptimum performance in nursery pigs, with active spreading of the virus mainly in nurseries. In endemically infected herds, subpopulations of infected animals may exist, consisting of a low prevalence (<10%) of seropositive animals in the breeding animals

and a high prevalence (>50%) of seropositive nursery piglets. The elimination of these susceptible subpopulations by exposing all members of a population to the virus is used as a control strategy in large herds in which there may be subpopulations of highly susceptible breeding females.

Morbidity and Mortality. The morbidity rate in young pigs may be up to 50%, and mortality in nursery piglets can reach 25%. Death is usually associated with secondary bacterial infections such as *S. choleraesuis, Str. suis, A. pleuropneumoniae,* and *H. parasuis*. Major losses occur in reproductive failure, but data for the magnitude of reproductive losses during an outbreak are not readily available. In general, the reproductive performance of positive herds is significantly lower than negative herds.

Risk Factors. The severity and duration of outbreaks following infection are variable. Some herds may be devastated by high production losses, whereas other herds may have almost no losses. Differences in morbidity and mortality may be due to dose of virus at exposure, differences in host susceptibility, differences in strain virulence, environmental or housing differences, or the production practices in the herd.

ANIMAL RISK FACTORS. Nursing piglets lacking maternal immunity, and young growing and finishing pigs and sows lacking acquired immunity from natural infection or vaccination are highly susceptible to infection and clinical disease. Severe disease appears to be more likely in large herds that have a large turnover of pigs and purchase replacements from other herds and do not use a quarantine system. Introduction of the virus to previously virus-naive herds may cause severe economic losses.

IMMUNE MECHANISMS. After natural infection most pigs are resistant to subsequent infection. Circulating antibodies to the virus are detectable within 14 to 21 days after infection based on indirect immunofluorescence test or ELISA (Albina et al, 1994), and 15kD protein is the most immunogenic of the viral proteins and may provide the antigenic basis for the development of improved diagnostic tests. Several structural and functionally distinct and specific antibodies to the virus are generated after infection or vaccination. Cell-mediated immune responses specific to the virus also occur (Molitor et al, 1997). The relative role of humoral and cell-mediated immunity in providing protection against disease is unknown.

A unique feature of infection is that viremia and circulating antibodies may exist together; the antibodies protect pigs from reinfection and reduce or eliminate shedding of the virus in the semen of boars. Sows are immune to further disease caused by the virus following recovery from acute infection. Following an outbreak of reproductive disease the level of performance will return to normal, suggesting that immunity develops following natural exposure. Protection against subsequent reproductive losses is of long duration in individual animals. However, cross-protection to different strains may not occur. Experimentally infected sows are protected against reproductive losses when challenged with homologous virus more than 300 days after initial exposure (Zimmerman et al, 1997). Extended studies against homologous infection found that the duration of protection was at least 604 days which is essentially life long protection (Lager et al, 1997a,b). Protective immunity was based on two criteria: the absence of transplacental transfer of challenge virus, and the apparent lack of virus replication in the dam 21 days after inoculation.

Piglets born from seropositive sows acquire *colostral antibodies,* which decline at highly variable rates from 3 to 8 weeks after birth (Houben et al, 1995). Passive immunity provides effective immunity for the piglets (Chung et al, 1997). However, loss of passive immunity at various ages results in susceptible pigs and infection, which results in persistence of the virus in pigs 6 to 9 weeks of age, these pigs are considered the major reservoir of the virus in farrow-finish herds. In the absence of natural infection, maternal antibodies become undetectable between 6 and 10 weeks of age (Houben et al, 1995). Some litters do not have maternal antibodies and may not have detectable antibodies until 4 weeks of age, and clinical disease may occur at 2 weeks of age (Albina et al, 1994). By 8 weeks of age, antibodies are usually detectable in all pigs and they persist for several months. However, there may be a large variation in the levels of antibodies in piglets at 10 to 12 weeks of age when they are moved to the finishing units (Houben et al, 1995). In longitudinal surveys the seroprevalence of the virus in the 4- to 5-week-old pigs was higher than in the 8- to 9-week-old pigs, and most pigs were negative when they entered the finishing units (Nodelijk et al, 1997). In herds in which the virus persists, sows do not suffer repeated reproductive losses, indicating that some form of protective immunity develops.

The virus has a predilection for immune cells, and disease manifestations can be linked directly to changes in the immune system (Molitor et al, 1997). The replication of the virus in the cells of the immune lineage, especially macrophages, may lead to immunosuppression and may predispose to secondary infections. Thus immunity to the virus may be a double-edged sword; the virus attacks the immune system, which may cause immunosuppression while inducing protective antibodies.

Antibody-dependent enhancement of infection may also occur because low levels of antibody enhance the ability of the virus to enter the pulmonary alveolar macrophage cells and replicate and destroy the cells. This may be important in sucking and nursery pigs exposed to the virus during a period of declining maternal antibody.

ENVIRONMENTAL AND MANAGEMENT RISK FACTORS. Housing of all age groups in one building, introduction of new animals, housing on slatted floors, storage of slurry under floors, exposure to transport vehicles and lack of disinfection procedures have been suggested as factors that increase the probability of herd infection. Lack of quarantine facilities for recently imported pigs is a major risk factor.

PATHOGEN RISK FACTORS. PPRS virus strains have many identical properties but some antigenic differences. Strains of the virus from the United States and Canada are antigenically similar and different from the European Lelystad virus isolate (Mardassi et al, 1994) There are serological differences between the European and American strains, and the antigenic and genomic differences between the North American and European isolates suggest the existence of two genotypes (Rossow, 1998). There are different genotypes and at least three minor genotypes within the major U.S. genotype. Genetic variations exist not only between European and U.S. strains but among the U.S. isolates, indicating the heterogeneous nature of the virus (Nelsen et al, 1999). Antigenic variation may affect the accuracy of diagnostic tests and the efficacy of vaccines.

Infection with the virus does not always lead to clinical disease, and the detection of high levels of serum antibody in many herds without history of clinical disease suggests that the consequences of natural and experimental infection depend on a complex of factors associated with host susceptibility and virus virulence (Rossow, 1998). The effects of the virus on reproductive performance are strain dependent. Strains of the virus cross the placenta when given to pregnant sows, and most sows will remain clinically normal and farrow normally. However, depending on the strain used, the number of late-term dead fetuses from gilts infected experimentally at 90 days' gestation may vary widely, and all gilts become viremic and develop antibody. There are also marked differences in pathogenicity for the respiratory tract between American strains of the virus compared with the Lelystad

virus when inoculated experimentally into caesarean-derived, colostrum-deprived, 4-week-old pigs (Halbur et al, 1995). Some strains cause severe lesions of the lymphoid and respiratory systems, which appear to be the major site of viral replication (Rossow, 1998). The difference in pathogenicity may explain the variation in severity of clinical disease observed in field outbreaks.

Field observations have suggested that the presence of the virus in a herd may increase the susceptibility of animals to other infections. However, studies with sequential infection of the virus followed by experimental inoculation with *H. parasuis, P. multocida,* or *A. pleuropneumoniae* have failed to demonstrate increased severity of disease (Solano et al, 1997). Similarly, infection with the virus did not increase the severity of experimental *M. hyopneumoniae* infection in young piglets. Based on diagnostic submissions, however, concurrent pulmonary bacterial infections may occur in up to 58% of cases in which the virus was also isolated (Zeman, 1996).

Methods of Transmission. The virus spreads rapidly within herds when infected pigs are housed in confinement. Up to 90% of sows may seroconvert within 3 months of the virus' being introduced into a closed breeding herd. The mode of spread is presumed to be by direct contact. The virus is present in nasal discharge, urine, and feces, and intranasal inoculation has been used to reproduce the disease experimentally. The virus is present in saliva and, considered in the context of the social behavior of pigs, may play an important role in transmission (Wills et al, 1995; Christopher-Hennings et al, 1995). Positive viral isolation has been made from tonsillar scrapings for up to 157 days after infection (Wills et al, 1997). Although these latter studies have not examined the ability of carrier pigs to shed virus under conditions of stress, one report has demonstrated recrudescence of viral shedding from offspring born of a dam that had been infected at Day 90 of gestation (Albina et al, 1994). Infected offspring remained seropositive for up to 15 weeks of life. At Week 22, 5 mg/kg of prednisolone acetate was administered to seropositive pigs for 5 consecutive days. Seronegative sentinels had been placed within fenceline contact for 9 weeks after initial exposure. All sentinels became infected within 2 to 5 weeks after treatment commenced.

The virus may persist in and circulate among different age groups and locations in a herd for several months despite the absence of clinical disease and may be transmitted by contact to replacement animals or to uninfected farms. Infected pigs may remain carriers of the virus for up to 15 weeks (Albina et al, 1994). Persistent and contact infection can be maintained in a nursery if uninfected pigs are continuously exposed to infected pigs. Pigs in the nursery become infected through contact with older infected pigs and not by *in utero* or postpartum exposure to infected sows (Stevenson et al, 1994). Long-term surveys of farrow-finish herds reveal that isolation rates of the virus reach their highest level of 70% to 100% of pigs 6 to 8 weeks of age, which coincided with the lowest level of maternal immunity (Chung et al, 1997). Large finishing enterprises, purchasing pigs of variable infection and immune status, provide ideal conditions for persistent virus circulation. Breeding herd subpopulations of infected pigs may exist and perpetuate and enhance the infection in a herd; the inability to control such subpopulations may reduce opportunities for successfully controlling the disease.

Infection may persist for an extended period of time because of the following: incomplete infection of the susceptible population during the acute phase; introduction of susceptible breeding stock; persistent viral infection in individual pigs with the potential of shedding virus under certain conditions, such as grouping for weaning or farrowing; rapid decline in passive immunity in young pigs; and variable periods of active immunity. Spread between herds is associated with the introduction of infected carrier pigs.

Infected boars may shed the virus in their semen for up to 40 days after experimental infection. After experimental infection of sexually mature boars, the virus was present in the semen 3 to 5 days after infection, and on days 13, 25, 27, and 43 (Swenson et al, 1994). A PCR assay can detect the virus in semen for up to 92 days after experimental infection. The insemination of gilts with semen from experimentally infected boars resulted in clinical signs of disease and failure to conceive. The use of the modified-live PRRSV vaccine in boars is controversial, because some boars may still shed wild-type virus in semen after challenge exposure 50 days after vaccination.

Exposure of pregnant gilts to either attenuated (vaccine) or virulent (field) strains of the virus can cause congenital infection (Mengeling et al, 1998). Vaccine and field strains can be transmitted postnatally from infected to noninfected littermates. Pigs infected with field strains have an inferior rate of survival and growth than do noninfected pigs. This suggests that use of attenuated virus vaccine during gestation is questionable. Attenuated PRRSV vaccines may have to be administered to naive gilts more than 30 days before conception to provide maximum protection throughout gestation (Mengeling et al, 1999).

The disease has occurred in PRRSV-seropositive herds in Denmark with no previous clinical evidence of PRRSV disease that were then vaccinated with a modified-live-virus vaccine licensed for use in pigs 3 to 18 weeks of age (Botner, 1997). Boars entering AI units were also vaccinated. After vaccination, a large number of herds experienced an increased number of abortions and stillborn piglets and an increasing mortality in the nursing period. The problems occurred mainly in herds without clinical signs among sows and with sows with low antibody titers in the period immediately before vaccination. The PRRSV was isolated from fetuses and identified as the vaccine virus. The evidence suggested that the vaccine virus had spread to nonvaccinated sows, followed by transplacental infection of the fetuses. Spread of the vaccine virus was also demonstrated in a nonvaccinated and previously virus-free breeding herd. Possible routes of transmission include introduction of vaccinated animals, use of semen from vaccinated AI boars, and aerosol transmission.

Airborne spread across regions and between countries is suspected. In Europe, during the winter of 1990 to 1991, the infection appeared to spread by the airborne route from Germany, across the Netherlands and into Belgium. Low temperatures, low sunlight, and high humidity may have facilitated airborne spread. Whereas aerosol transmission was once felt to be a definite method of transmission, the status of the potential for transmission of virus through aerosols is under debate (Torremorell et al, 1997). Initial observations from numerous European countries consider airborne spread a highly likely possibility, primarily if specific weather conditions such as high humidity, low temperatures, and low wind speeds exist. Transmission through aerosols may also be more likely if the surrounding area is densely populated with naive swine. Finally, although PRRSV appears to be closely related to lactate dehydrogenase elevating virus of mice, the ability of rodents to spread PRRSV has not been demonstrated under controlled conditions (Hooper et al, 1994). Airborne spread up to 20 km has been suggested, but most airborne spread is probably limited to less than 2 km.

Epidemiological investigations in Belgium attribute 70% of herd infections to local spread, 9% to purchase of infected pigs, 4% to other contacts, and in 18% of cases the source of infection could not be determined. There is no ev-

idence that rodents are susceptible to infection with the virus and are probably not a reservoir for the virus (Hooper et al, 1994).

Most spread between herds occurs by the introduction of unknown infected breeding stock into herds previously uninfected. Primary infections are common in multiplying herds that supply unknown infected replacement gilts to other farms.

The PRRSV is labile and does not survive for more than 1 day on solid fomites but for several days in well and city water (Pirtle and Beran, 1996). It may survive for several years in deep frozen tissues but for only 1 month at 4° C, 48 hr at 37° C, and less than 45 min at 56° C.

Pig meat does not retain detectable amounts of the virus, and it is unlikely that transmission through meat occurs.

Economic Importance. The export market for pork from a country can be seriously affected when a disease such as PRRS occurs. When the disease was recognized in the United States, countries such as Mexico, Japan, Canada, and South Korea banned the importation of pork from the United States or required certification that the swine originated from premises in which, within the 30 days before the issuance of the health certificate, no swine were introduced from a municipality in which a premises infected with the virus was located.

The economic losses may be high because of stillbirths, abortions, small litter sizes, birth of weak pigs (which increases preweaning mortality), and increased nonproductive days. In weaned pigs losses are associated with respiratory disease. In addition, there are the costs of control that may be high depending on the control strategies undertaken. Typically, about 20% loss in annual production can be expected from a severe outbreak.

Pathogenesis. Initially a viremia occurs with subsequent distribution and multiplication of the virus in multiple body systems and organs causing interstitial pneumonia, vasculitis, lymphadenopathy, myocarditis, and encephalitis (Rossow et al, 1995). The viremic period exists in the adult animal for 14 days, providing adequate time for transplacental transmission (Terpstra et al, 1991). Alveolar macrophages are primary targets for virus multiplication, but this does not fully explain the pathogenesis (Molitor et al, 1997). The effects of the virus on the immune system may explain the suspected immunosuppression and secondary infections that are recognized clinically but have not been reproduced experimentally.

Vascular lesions associated with PRRSV infection are analogous to those observed in horses with equine arteritis virus, also a member of the Arteriviridae (Cooper et al, 1997), and the renal lesions of equine viral arteritis infection correspond with those of PRRSV. Inflammatory infiltrates are seen at the junction of the renal cortex and medulla, with vascular changes associated with muscular tunics of small arterioles.

The characteristic lesions can be reproduced in conventional pigs at 1, 4, or 10 weeks of age, and the variation in severity of clinical disease can be attributed to differences in strain virulence (Halbur et al, 1995; Rossow et al, 1994). The effects of the virus on reproductive performance are also strain dependent (Mengeling et al, 1996). Some strains are of low pathogenicity, whereas others are highly pathogenic. The reproductive disease has been reproduced experimentally, and the effects on the fetus are dependent on the stage of gestation. Aerosol exposure of nonimmune pregnant gilts in late gestations (84 days) to the Lelystad virus causes clinical disease (Christianson et al, 1992). After an incubation period of 4 to 7 days, all sows were inappetent and listless for 6 to 9 days. Some sows develop blue ears, accompanied by abdominal respirations. Sows may farrow at Days 116 and 117 of gestation, giving birth to dead, mummified, and live piglets. Many of the live-born piglets are pale, listless, and weak, and some are in respiratory distress and exhibit varying degrees of splayleg or muscular tremors. The virus may be isolated from stillborn piglets or those born alive. Antibody is present in precolostral serum samples or ascitic fluids of piglets, which demonstrates transplacental passage of the virus.

The pathogenesis of PRRSV infection in the weaned pig has been studied extensively. Up to 40% of the mature populations of alveolar macrophages is destroyed by 7 days after infection, and the residual populations have reduced function (Pol et al, 1991). The release of interleukins from damaged cells causes inflammatory changes. As previously described, alveolar septae are infiltrated with macrophages, and cellular debris fill alveolar spaces. The severity of the clinical signs following infection appears to be highly correlated to the existing health status of the herd. Field observations indicate that PRRSV appears to predispose the respiratory system to coinfection with opportunistic bacterial agents (Galina, 1995). As previously described, it is common to isolate a myriad of bacterial pathogens from cases of respiratory disease, such as *H. parasuis, S. choleraesuis,* and *A. pleuropneumoniae.*

While PRRSV also predisposes pigs to *Str. suis* meningitis, it has been difficult to reproduce other relationships between PRRSV and other bacterial pathogens of the respiratory tract, under controlled conditions.

Clinical Findings. The severity of the clinical findings in acutely affected pigs can be extensive throughout the herd. All stages of the disease may occur on an infected farm, including abortions in the breeding herd and influenza-like signs in the finishing pigs. The following section reviews the clinical findings of PRRS infection in the different stages of production (Zimmerman et al, 1997; Done et al, 1996).

Breeding/Gestation. In adult animals there may be anorexia, lethargy, and depression. Pyrexia may be present (40° to 41° C), and sows may abort most commonly during the last trimester of gestation. The rate of abortion may exceed 10% during outbreaks of the acute form. Premature farrowings usually occur around 105 to 107 days of gestation. Clinical signs may appear in different groups of breeding animals each week, in contrast to infection with TGE virus or pseudorabies virus, in which large numbers of animals are anorexic at one time. This "rolling anorexia" may persist in a group of sows for up to 4 to 7 days. Farrowing rates may decrease from 20% to 40%. Occasionally, sows may vomit and lie in lateral recumbency. The mortality rate of sows may increase 3% to 5% during the acute infection, particularly in periparturient animals. There is usually an increase in repeat breeders, NIP sows and an inability to achieve the desired numbers of matings per female. A chronic form of PRRS can exist in the breeding herd. Typically, when nonimmune gilt replacements are introduced into an infected herd, there is an increase in stillbirths and an increase in preweaning mortality and conception failure. Although not as extreme as the acute outbreak, the problem may persist over a 1- to 2-year period (Dee and Joo, 1994b).

Farrowing. In farrowing sows there is a marked increase in the rate of stillbirths and mummified pigs. Stillbirth rates may increase up to 50% to 75%. The fetuses are brown, macerated, and appear to have died 5 to 7 days before parturition. Chronologically, a rise in stillbirths is preceded by an increase in abortions or early farrowings. Following the rise in stillbirths, a 20% to 30% increase in the rate of mummified fetuses may occur. Preweaning mortality levels can reach up to 60% to 80% within a farrowing group. Suckling piglets demonstrate "thumping," a unique pattern of rapid abdominal breathing with an open mouth. Sows

will usually be lethargic and agalactic, causing a high incidence of colostrum deprivation in piglets and a subsequent increase in the incidence of neonatal colibacillosis in the piglets throughout the farrowing groups.

POSTWEANING. Although the acute reproductive outbreak may be remarkable, it is usually of short duration (3 to 4 months). In contrast, postweaning abnormalities may persist for up to 1 to 2 years and cause significant economic loss. Average daily gain in the nursery pigs may be reduced up to 50% to 75%, and mortality levels frequently rise to 10% to 25%. The primary clinical entity in nursery piglets or growing-finishing pigs is an increased level of pneumonia, causing acute death loss or chronically slow growth. There may also be a sudden increase in the incidence of AR or postweaning colibacillosis. Samples submitted for laboratory diagnosis usually yield numerous bacterial and viral pathogens. Common isolates include the PRRSV, swine influenza virus, porcine respiratory coronavirus, *M. hyopneumoniae, P. multocida, Str. suis, H. parasuis, A. pleuropneumoniae,* and *S. choleraesuis*. The affected animals respond poorly to medication, causing a high level of frustration among producers and practitioners.

Because of the prevalence of other pathogens associated with the virus infection, gross lesions of PRRS may be obscured. In uncomplicated infection the gross appearance of the lung is one of a "fish flesh" consistency.

Necropsy Findings. The gross and microscopic lesions in the fetuses from sows experimentally infected oronasally with the virus at 90 days of gestation consist of hemorrhage of the umbilicus and necrotizing umbilical arteritis with periarterial hemorrhage (Lager and Halbur, 1996). Severe pulmonary lesions are present in fetuses inoculated in utero with the virus between 45 and 49 days of gestation. When sows are inoculated oronasally with the virus in midgestation, the virus does not readily cross the placenta but replicates in fetuses that are inoculated directly in midgestation. Thus the fetuses are more susceptible in late gestation than earlier in midgestation, or there is greater likelihood of transplacental infection during late gestation. Experimentally, the intrauterine inoculation of the virus into gilts on the day after natural breeding may have little or no effect on their reproductive performance.

In pigs that have died with respiratory disease, the lungs are heavy and consolidated. Histologically, there is a necrotizing interstitial pneumonia characterized by thickened alveolar septae, resulting from macrophage infiltration (Pol et al, 1991). Alveolar spaces also contain proteinaceous debris and degenerating cells in all lobes. In contrast to swine influenza virus infection or proliferative and necrotizing pneumonia, there is no involvement of the airways with PRRSV infection. Other lesions detected through microscopic examination include lymphoplasmacytic rhinitis, perivascular cuffing with mononuclear cells in the brain, mononuclear myocarditis, splenitis, and depletion of the thymic cortex, tonsilar crypts, and lymph nodes.

Diagnosis. The most important component of the control program is the proper use of diagnostic tests, to accurately determine the point of infection within the life of the pig (Mengeling et al, 1995; Botner, 1997). This information enhances the decision-making process regarding selection of the control strategy. New techniques, such as PCR have enhanced detection of viral antigen (Suarez et al, 1994). Samples suitable for analysis by PCR include serum, semen, and tissue. Positive PCR signals can be sequenced and samples of field virus can be differentiated from modified-live virus vaccine isolates. The use of PCR is valuable, particularly when investigating PRRS problems in lactation or nursery. This test is much more sensitive than virus isolation, and results are available in a shorter period (24 to 48 hours). Recent data have shown that shedding of PRRSV can be limited to gilt litters during lactation, and that shedding can occur at any time during the suckling period, resulting in infected piglets at 1 to 2 days of age (Dee and Philips, 1999). An example of a protocol to detect transmission of field-virus from sows to pigs during the lactation period is as follows:

- Collect sera from 5- to 7-day-old piglets, collecting 1 to 2 piglets/litter
- Sample across parities (6 piglets/parity)
- Pool sera 3:1 within each parity
- Example: Six parities are in lactation on a given sampling day

6 Parities × 6 Piglets sampled/Parity = 36 Samples

Samples pooled 3:1 = 12 Samples submitted

If virus shedding is occurring during lactation, the 5- to 7-day-old piglet has been shown to be a sensitive sample for the detection of PRRSV before weaning. During the sampling process, samples should be kept cool at all times and should be shipped to the diagnostic laboratory over night on ice. It is better to refrigerate samples than to freeze them. Serologic assays, such as the ELISA, are used for the detection of antibodies after exposure to virus. The IDEXX ELISA reports result in the form of a sample-to-positive (s/p) ratio, and s/p ratios of 0.4 or higher are considered positive. However, these data are only indicative of exposure to virus, not of protection. Cross-sectional sampling by stage of production can be useful to determine the point of infection in the life of the pig. Samples should be collected from the breeding herd across all parities, recently weaned pigs, 8- to 10-week-old nursery pigs, and 5- to 6-month-old finishing pigs. Testing by parity may indicate whether programs need to focus on a specific subpopulation within the herd, such as gilts. Unfortunately, diagnostic tests that differentiate antibodies because of natural infection from those induced following vaccination are not available at this time. Furthermore, it is also important to realize that PRRSV infection, without the presence of opportunistic pathogens such as *M. hyopneumoniae* or *Str. suis,* may have little impact on the health and performance of pigs. Therefore it is important to use clinical observations and production records in conjunction with diagnostic data to properly understand the status of the sampled population. Once the pattern of virus spread and the age in which the pig is infected is determined, intervention strategies can be initiated.

Treatment

ACUTELY INFECTED HERDS. Establishment of a cost-effective treatment program following an acute PRRS outbreak in a previously nonimmune herd is often futile and frustrating. The following section summarizes practical intervention strategies that have been reasonably successful.

- *Breeding/Gestation*: Because of the reproductive effects of PRRS on sows, pregnancy loss and conception failure are high. Therefore, in order to ensure adequate numbers of farrowings, overbreeding is recommended. Because boar libido may be reduced in some cases, AI should be used to ensure adequate numbers of viable sperm cells. Clinically affected animals with a fever may be treated with parenteral antibiotics. Antiinflammatory drugs such as fluxinin meglumine are sometimes used to reduce pyrexia and inflammation. Antibiotics in the feed such as tetracycline at 400 to 800 g/ton can be used to control secondary bacterial agents.
- *Lactation*: Similar to gestating animals, broad-spectrum antibiotics, and antiinflammatory products are indicated. Because of reduced feed intake, diets may be reformulated to contain higher levels of nutrients.
- *Suckling Pigs*: Castration or weaning should be delayed as long as possible. Needles used for injections should be

dipped in iodine between pigs following injections to avoid hematogenous viral spread. Cross-fostering pigs should be limited to the first 2 days of life. Following this period, litters should remain intact. The use of nurse sows should be avoided. Farrowing environments should be maintained at 28° to 30° C to keep pigs warm. Similar to a TGE outbreak, if preweaning mortality of the affected farrowing group is particularly high (>75%), it may be more advantageous to humanely destroy chronically infected survivors, or to transfer the entire group to a different weaning site in order to prevent these chronically infected pigs from entering the nursery and exacerbating the problem in this area. If an interruption in pig flow can be created between farrowing and nursery groups, pig-to-pig transmission may be minimized. Lactating sows should be treated with antibiotics, appetite stimulants, and antiinflammatories. Electrolyte solutions with vitamins should be provided to both sows and pigs.

- *Postweaning*: Besides parenteral antibiotic therapy, all-in, all-out pig flow is important. Thorough washing of the facility using water temperatures of 90° to 94° C along with disinfectants effective against PRRSV is recommended. Products such as formaldehyde-based disinfectants, or phenol-based compounds have proved effective against the virus. Autogenous bacterins for specific pathogens have also been used, as have oral or injectable immune stimulants (vitamin E/selenium), but results have been mixed.

Control. Following cessation of the acute infection, a control program must be recommended and implemented. The following section summarizes the major control strategies practiced in the industry today.

VACCINATION. Because of the necessity of cell-mediated immunity to control PRRS, modified-live virus vaccines appear to be more efficacious than killed preparations (Molitor et al, 1997). Although MLV products do shed in naïve populations, transmission has not been detected following revaccination (Dee and Philips, 1999). Diagnostic profiling is especially critical when vaccination is used to avoid immunizing pigs concurrently infected with field virus. It is important to develop farm-specific vaccination programs, based on individual farm diagnostic data, rather than to promote standardized protocols. Proper handling of modified-live virus vaccines is important to enhance efficacy. An adequate needle length ensures that intramuscular penetration is obtained. A 3.81-cm needle is required for adult breeding animals, whereas 2.54 cm is required for finishing pigs and 1.27 cm for weaners. The product must be rehydrated using the proper diluent and administered within 24 hours after hydration. Finally, use of a designated syringe, rinsed with only hot water and not disinfectant, is important as well.

GILT DEVELOPMENT. Gilt development is a very important component of a control program. Direct introduction of naïve or actively infected replacement stock enhances viral shedding and exacerbates PRRS problems (Dee and Joo, 1994a,b). Therefore it is critical to establish a gilt development program, consisting of quarantine and an acclimatization period, to properly develop replacement stock before entry to the herd (Dee, 1997). Changes in gilt development strategies in the United States include introducing gilts as weaners or 25-kg piglets, housing them in designated developer facilities, and establishing vaccination and acclimation protocols in an attempt to equalize the health level of this population to the existing breeding herd. Despite the use of cull sows or infected nursery pigs as sources of farm-specific viral strains, consistent induction of natural exposure can be frustrating, particularly in chronically infected herds, because of lack of active circulation of field virus. Therefore it is important to maintain the use of vaccination in gilt developer protocols to reduce the risk of developing naïve subpopulations. The purchase of gilts from PRRSV-negative sources enhances the importance of proper natural exposure to farm-specific strains before herd entry. If PRRSV-positive sources are employed, it is important to ensure that a change in source does not occur and that actively infected animals do not directly enter the recipient herd. For this reason, quarantine periods of 60 days or more are used, and quarantine facilities function on an AIAO basis.

NURSERY DEPOPULATION. ND is a cost-effective means to interrupt horizontal transmission of PRRSV from older, infected pigs to those recently weaned. Significant improvements in nursery pig daily gain, mortality, treatment cost, and profitability have been published, following implementation of ND (Dee et al, 1997a,b). Despite such improvement, reinfection of nurseries with PRRSV is a frequent event, often taking place 12 to 18 months after completion of the depopulation protocol. Therefore it has been speculated that the primary benefit of this strategy may be for the control of opportunistic pathogens, rather than PRRSV. ND consists of emptying, washing, and disinfecting all nursery rooms and allowing the facility to remain empty for a minimum of 2 days. Because of the poor viability of PRRSV outside of the pig, extended periods of downtime can be avoided, enhancing facility use and eliminating the virus from the nursery pig population (Pirtle and Beran, 1996). Disinfectants frequently recommended include phenol- or formaldehyde-based products to reduce survivability of the virus in the environment (Benfield et al, 1992). This strategy can also be applied to PRRSV-infected finishing populations.

ERADICATION. Eradication of PRRS is currently being evaluated (Dee and Molitor, 1998; Dee et al, 2000). Because of the ability of PRRSV to induce transplacental infection, or to be shed during lactation through saliva, milk, or colostrum, consistent production of noninfected piglets using segregated production and early weaning is not possible in the long term. The process of T&R may be an efficacious strategy and is currently under investigation. T&R has been used successfully to eliminate Aujeszky's disease virus and *A. pleuropneumoniae*. The primary focus of this strategy is to test all breeding animals, identify carriers, remove them from the herd, and prevent vertical transmission of PRRSV (Dee, 2000). Analysis of sera using ELISA for the detection of antibodies along with PCR for the detection of viral protein is used in combination to identify previously exposed, potentially infected animals. The detection of carriers is critical because of the ability of PRRSV to produce persistent infection (Wills et al, 1997). Although PRRSV persistence is not lifelong, infected sows pose the greatest risk for perpetuating virus transmission within an infected farm.

Eradication strategies using T&R have been applied to some farms in the United States with promising results (Dee and Molitor, 1998, Dee et al, 2000). These farms were originally infected with PRRSV 1 to 2 years before initiation of T&R. Before the initiation of T&R, ELISA seroprevalence of the breeding herd ranged from 6% to 12%. Herd size ranged from 200 to 1500 sows, and not all farms had employed PRRSV vaccination at any time after the initial outbreak. At this time, all farms have been declared PRRSV negative after completion of the protocol and a 12- to 24-month monitoring program. Carrier sows have been identified primarily as being parity 2 or older (6+ parities). Removed animals have tended to cluster in small groups or reside as single entities randomly located throughout the gestating population, but ELISA data from sow clusters appear to be distributed normally (Dee, 2000). This suggests that virus transmission in chronically infected farms occurs over short distances and

may be of low magnitude. In conclusion, although such strategies still require further testing, the PRRSV knowledge base continues to grow and expand, leading to a higher degree of successful control throughout the world. Eradication of the disease has been achieved in some Danish swine herds through the use of both total and partial depopulation (PD) (Andreasen et al, 1998).

Porcine Parvovirus. PPV causes reproductive failure, characterized by embryonic and fetal death, when susceptible sows and gilts are exposed to the virus during the first 56 to 70 days of gestation. Epidemics of PPV usually are characterized by an increased frequency of mummified fetuses and reduced litter size, but decreased conception and an increased frequency of stillborn or weak newborn piglets also occur. PPV infection is ubiquitous and enzootic in most swine herds.

The primary means of PPV infection is through the oral route. The virus can be transmitted by salivary or nasal secretions of infected pigs as well as through the feces. PPV is extremely thermostable and resistant to many common disinfectants, thus it is capable of surviving under farm conditions for long periods.

The major and usually only clinical response to PPV infection is reproductive failure. PPV is capable of crossing the placenta, and the damage caused by the disease depends primarily on the stage of gestation (in days) of the pig when infection occurs.

Conceptuses infected before 56 days undergo a wide spectrum of microscopic changes. Embryos die and are resorbed. The gilt may then return to estrus at the regular interval or experience a delayed return. Fetuses show stunted growth, increased prominence of blood vessels on the surface of the skin, edema hemorrhage, discoloration, and dehydration (mummification). In contrast, the litters of pregnant females infected after 56 days' gestation usually remain alive and show none of these signs. This is because transplacental crossing of PPV takes approximately 10 to 14 days, thereby infecting fetuses around 70 days. It has been established that at this period of gestation, porcine fetuses are capable of establishing immunocompetency and can survive the viral infection by using their own defense mechanism. The most efficient method of diagnosis of fetal infection is serology on fetal body cavity fluids by immunofluorescence (Waldvogel et al, 1995). Paired acute and convalescent gilt sera, if available, should be tested for PPV antibody.

Before development of commercial vaccines, control of PPV-induced reproductive failure was based on exposing replacement females to PPV by placing them in pens that might be contaminated with the virus, placing them in contact with older sows that might be infected, and feeding them feces or tissues from mummified fetuses. These procedures induced variable immunity because PPV was not always in the feces, tissues, or environment. When effective exposure to the virus was achieved, however, immunity probably persisted for the lifetime of the pig (Gardner et al, 1996).

Natural infection with PPV confers more effective immunity than vaccination and may be the preferred method of control. In many herds, however, females are not consistently exposed to virus before their first breeding, and veterinarians and producers must balance the costs of vaccination programs against the likely risks of reproductive failure when females are not vaccinated. For most herds in the United States, serologic screening for PPV before selection of a vaccination program is unlikely to be cost-effective, because vaccination is relatively inexpensive (Gardner et al, 1996).

Pseudorabies. Pseudorabies, or Aujeszky's disease, is caused by the pseudorabies virus or suid herpes virus 1 of the family Herpesviridae. The disease is widespread in pigs and causes heavy economic losses to swine industry worldwide (Miller et al, 1995). Pigs are the sole reservoir of infection and the only source of virus transmission and direct oronasal contact between infected and susceptible pigs is the primary method of transmission. The virus is widely present in feral swine, which do not exhibit any clinical abnormalities (Hahn et al, 1997; Romero et al, 1997). This seriously affects efforts to eradicate the virus from the domestic swine population. Aerosol spread between farms in an area is also considered possible. Substantial losses occur because of reproductive failure resulting from abortions, stillbirths, and mummification in sows; mortality of young pigs; and respiratory disease in older pigs. PRV infection in susceptible gilts produces mummified fetuses with average live litter sizes of 1.9 pigs. Sows may also delay farrowing up to 2 to 3 weeks and may suffer from impaired fertility and low conception rate in future breeding attempts.

Latent infection occurs in surviving pigs, and intermittent reactivation of the latent virus can result in excretion and spread to other susceptible pigs. The virus is primarily introduced into a herd through the inadvertent addition of infected carriers. Large herd size and frequent mixing of pigs increase the probability of exposure to an infected animal. Farrow-to-finish operations allow prolonged contact with infected animals. Indoor confinement increases population density and provides a contained environment for circulation of the virus in aerosols.

In most countries, vaccination is used to reduce clinical losses. In areas with a high prevalence of infection, vaccination is widely used to protect pigs against clinical disease. It can also limit the spread of virulent virus between animals or herds by decreasing the level of their excretion from vaccinated pigs. The control of pseudorabies is difficult and currently unreliable, because normal healthy pigs may be infected and shed the virus for up to several months.

The methods of control or eradication include *depopulation and repopulation, test and removal, segregation of progeny,* and *vaccination*. The selection of a strategy for the control or elimination of the disease depends on the source of the herd infection, the method of transmission of the virus, the survival of the virus in the environment, the sensitivity and specificity of the diagnostic test and the risk factors in the herd. The risk factors of the herd include the type of operation, the degree of herd isolation, the prevalence of infection, the value of the genetic material, the level of management expertise, and the availability of suitable virus-free replacement swine if depopulation and repopulation is chosen as a strategy (Siegel et al, 1999). Breeding stock producers favor eradication; farrow-finish producers who do not sell breeding stock or feeder pigs are generally more concerned with the reduction of losses from clinical pseudorabies infection than with eradication.

Depopulation-repopulation is the most expensive, segregation of progeny method the next least, and the T&R the most inexpensive per sow. The optimum alternative is to test and remove seropositive animals if the initial prevalence is <57%; otherwise vaccination of sows only is preferred. Vaccination may be recommended at lower prevalence rates as a conservative approach. Eradication by T&R combined with the use of gene-deleted vaccines is advantageous at any prevalence rate of infection. Depopulation and repopulation is not the best option under any circumstances.

In the United States the national pseudorabies eradication program was implemented in 1989 as a joint state-federal-industry sponsored program.

An epidemiological model projected future herd-herd disease transmission under alternative eradication or control programs over 20 years, from 1993 to 2012. With current eradication program funding in the United States, the

prevalence of infection would be 23% in high-risk states, 10% in moderate-risk states, and 1% in low-risk states. Increased funding for the eradication program would reduce the prevalence of infection substantially. Profitability for the average size farrow-finish herd was estimated to be $6/cwt of swine produced for virus-infected herds than for uninfected herds (Miller et al, 1995). Estimates of the value of economic welfare indicated that consumers would be the major beneficiaries of eradication because of reduced prices and increased consumption of pork (Miller et al, 1996). The details of the control programs are available (Radostits et al, 2000). A summary is set out here.

Determination of Prevalence of Infection. In large herds the virus must be eliminated from the growing-finishing pigs and the breeding herd. Large herds that are virus positive are infected in both groups; smaller herds are frequently infected in only the breeding herd. An initial step in eradication is to determine the prevalence of infection. Representative samples of finishing pigs older than 4 months and of breeding sows, gilts, and boars are tested. On the basis of the test results and the risk factors in the herd, a cost-effective plan can be devised for the individual herd.

Depopulation and Repopulation. When the prevalence of infection in the herd is over 50%, eradication can be achieved by depopulation and repopulation with virus-free breeding stock. However, depopulation is the most expensive method and is not compatible with the retention of valuable pedigree stock. The entire herd should be depopulated over a period of months as the animals reach market weight. After removal of the animals the entire premises are cleaned and disinfected. Repopulation should be delayed at least 30 days after the final disinfection, and swine should originate from a pseudorabies-free qualified herd and be isolated on the premises and retested 30 days after introduction. All herd additions should be isolated and tested 30 days after introduction.

Test and Removal. The T&R program is recommended when the prevalence of infection in the herd is below 50%. This method requires testing of the entire breeding herd and immediate removal of all seropositive animals; 30 days after removal of seropositive animals, the herd is retested (if necessary, at 30-day intervals) until all herd tests are negative. Following a second negative test, the testing regimen may be changed to test only 25% of the herd every 4 months. Seropositive animals are identified and culled. The T&R method is superior to the vaccination system as a method of control. Valuable genetic material may be salvaged from breeding stock that are seropositive through the use of embryo transfer techniques. Embryos may be transferred safely to susceptible recipient gilts from sows that have recovered from infection, but not from sows that are in the active stages of infection. The virus does not penetrate the outer covering of the embryo, but it can become attached to it so that it may physically transfer to the uterus of the recipent. This transfer of infection may occur if the donor sow is in the active phase of infection.

Offspring Segregation. The objective of this strategy is to raise a pseudorabies-negative breeding herd to replace the infected herd. Once the herd is diagnosed as pseudorabies infected, a regular schedule of vaccination is instituted. Gilts are vaccinated at first breeding, and both sows and gilts are vaccinated 2 to 4 weeks before farrowing to provide a high level of colostral immunity to their piglets. Offspring are removed at weaning and raised apart from the infected herd. At 4 months of age, and then again before breeding, the segregated replacements are tested for antibody. Since colostral immunity is no longer detectable by 4 months of age, any animals over 4 months of age that are seropositive are considered pseudorabies infected. As the gilts reach reproductive maturity, the old sow herd is replaced. Segregation between the infected sow herd and the clean gilt herd is maintained until all positive sows have been removed and the facilities disinfected. Groups of seronegative pigs are identified and combined into larger groups to establish a new herd. The original herd is gradually depopulated and the premises cleaned and disinfected. The new herd is then monitored on a regular basis. Herds that are not successful have been slow to adopt new technologies, particularly biosecurity and disease control procedures (Deen et al, 1995a,b).

Control Programs in Effect. A pseudorabies control program was introduced in England in 1983 when the infection was spreading rapidly. New legislation imposed restrictions on the movement of pigs when clinical signs of the disease were present in the herd. The first part of the eradication scheme involved testing all of those herds previously known to have pseudorabies. Within several months after the beginning of the eradication campaign, 417 herds had been slaughtered, involving 342,275 pigs, of which 72.5% were salvaged. Only 121 herds had been known to be previously infected, whereas the remaining 296 herds had been identified through tracebacks and reports of new cases. By 1985 it was concluded that the disease was well controlled in England with only 10 to 14 infected herds remaining. Farmers were compensated for all animals slaughtered and for consequential loss associated with the loss of stock. The cost of the eradication program was financed by a levy on all pigs normally marketed for slaughter in England. In 1995 England was free of Aujeszky's disease. In Northern Ireland pseudorabies is more widespread than it ever was in Britain before the eradication program. Because the infection rate is over 50%, an eradication program based on slaughter of infected herds would destroy the swine industry. Thus the control program in Northern Ireland is based on the use of vaccination, the culling of seropositive animals, and the gradual introduction of seronegative animals.

Pilot projects were conducted in Iowa, Illinois, Pennsylvania, Wisconsin, and North Carolina from 1984 to 1987. In the pilot projects, 97.5% of 116 herds that were initially pseudorabies positive were successfully cleared of infection. This indicated that eradication of pseudorabies virus from herds of swine can be achieved efficiently and is most effective when applied on an area basis. The introduction of the gene-deleted pseudorabies vaccines in the program was the technical breakthrough needed to be able to offer the national eradication program, since it was now possible to distinguish between naturally infected and vaccinated animals. The program consisted of five stages: Stage I: preparation; Stage II: control; Stage III: mandatory herd clean-up; Stage IV: surveillance; Stage V: free.

When an outbreak of the disease occurs in a susceptible herd, the mortality may be very high and the first consideration is to prevent spread to uninfected sows and litters and to pregnant sows from infected pigs. They should be attended by separate personnel, or adequate barriers to mechanical transmission of infection should be arranged. On affected premises cattle should be separated from pigs, and dogs and cats should be kept from the area. The affected herd should be quarantined, and all pigs sold off the farm should be for slaughter only.

Vaccination. Vaccination is used to reduce clinical disease when outbreaks occur or when the disease is endemic in the herd. An effective immunity develops after natural infection or vaccination, and piglets from immune sows are protected from clinical disease during the nursing period by colostral immunity. However, the *presence of circulating antibody does not prevent infection, the development of latency, or subsequent*

activation and excretion of the virus. But vaccination reduces viral shedding after natural infection. On farms in which the disease is endemic or outbreaks have occurred, vaccination of the sows and management procedures to reduce the spread of infection have markedly reduced preweaning mortality and reproductive failures. In field studies of large numbers of herds in which the sows were vaccinated three times annually, the reproduction ratio was below 0.66 (which is significantly below 1) and massive spread of the virus did not occur.

It is often virtually impossible to prevent the spread of infection in a susceptible herd, so vaccination of all pigs at risk, especially pregnant sows, is recommended, The vaccine reduces losses in infected herds, limits the spread of infection, and decreases the incidence in endemic areas. With a properly controlled and monitored vaccination and culling program in a breeding herd, it is possible to control clinical disease and reduce the infection pressure. All breeding stock present during an outbreak are subsequently vaccinated regularly until they are all culled, which removes the major sources of virulent virus. After this phase newly introduced gilts and boars are tested and monitored regularly. This is considered less costly than the test and slaughter policy. Additional details on vaccines and vaccination strategies are available (Radostits et al, 2000).

Hog Cholera Virus. Hog cholera virus is classified in the family Togaviridae, and its natural host is the pig. It can be transmitted through infected feces, nasal secretions, infected fomites (e.g., vehicles, boots, and garbage containing contaminated pork scraps). The virus is capable of crossing the placenta of pregnant sows, causing stillbirths, mummified fetuses, and small litters of weak "shaker" pigs. Hog cholera was eradicated from the United States in 1978. Outbreaks occur sporadically in other parts of the world (see earlier in this chapter).

Swine Influenza Virus (SIV). Swine influenza is a common and seasonal respiratory disease caused by Type A influenza virus. Whether swine influenza virus is capable of causing reproductive failure is undecided at the moment. Piglets from dams infected during pregnancy became ill shortly after birth and harbored chronic infections that reduced growth rate. Prenatal deaths were seen and virus was isolated from the placenta.

Leptospirosis. Leptospirosis is a worldwide cause of reproductive failure in pigs that manifests itself as abortions, mummifications, stillbirths, and weak neonates. Leptospirosis in pigs is mainly due to *L. interrogans* serovar *pomona*, which localizes in the kidney and is excreted in urine. Besides *pomona*, serovars *grippotyphosa, canicola,* and *icterohaemorrhagica* have been isolated from swine in the United States. The spirochetes enter the animal through contact of urine and breaks in the skin, mucous membranes, or conjunctiva. Animals may then establish themselves as shedders and serve as reservoirs of the bacteria. Wildlife (e.g., white tail deer, skunks, opossums, muskrats, rats and squirrels) and domestic dogs have been shown to harbor leptospira. Infected boars have also been incriminated as reservoirs by passing *L. pomona* through semen. In New Zealand leptospiral infection is apparent in piglets from 12 weeks of age (Bolt and Marshall, 1995). Spread occurs primarily because of mixing age groups.

The incubation period of leptospirosis in swine is 1 to 2 weeks, depending on the serovar and the age of the pig infected. Acute leptospirosis is manifested by anorexia, fever, and diarrhea for 1 to 3 days. Chronic infections cause no clinical signs, but bacteria are constantly shed and kidneys show gross lesions at necropsy. Leptospirosis infection is difficult to detect because it affects only a few animals at a time.

In pregnant swine, leptospires are capable of causing a septicemia and crossing the placenta, resulting in abortions, stillbirths, and weak neonates. When infections occur in the last half of gestation, the most characteristic lesions in stillbirths and neonates appear to be focal necrosis, edema, and bloody fluids in the body cavities, along with jaundice. Mild fever and inappetence are the only signs detectable in the sow.

Brucella suis. *Brucella suis* was initially recognized as a major swine pathogen in the 1920s; however, the effects of *B. suis* have diminished because of high standards of management and eradication procedures. *B. suis* can be divided into 9 biotypes, with types 1 and 3 being the primary problems, particularly type 1 because it is found worldwide. Transmission occurs through contact with infected swine through the alimentary tract (contaminated food and water, aborted fetuses) and the genital tract (contaminated semen).

The clinical manifestations of *B. suis* are abortion, infertility, orchitis, and lameness. Death is rare. Abortions may occur at any time during gestation, as early as 17 days after infection. The rate of abortion is highest in females infected through the genital tract. Early abortions are often overlooked in large herds. An indication of infection is a large number of sows returning to estrus 30 to 45 days after conception.

Stillbirths and weak neonates are observed, with mummification being uncommon. Aborted fetuses and the placentas are hemorrhagic, edematous, and autolyzed. *Brucella* is shed through vaginal discharge for up to 30 days after genital infection. Once infection has diminished, most sows regain their proper reproductive capacity following two to three cycles of sexual rest. Control programs for brucellosis have been successful in the United States, but endemic areas may still occur (Christianson, 1992).

Swine Erysipelas. Swine erysipelas (SE), caused by the bacteria *Erysipelothrix rhusiopathiae,* infects swine in three phases: acute, subacute, and chronic. Only acute SE is noted to cause reproductive failure. Infected animals are feverish, anorexic, and depressed and are covered with rhomboid, purple, uticarical lesions and skin necrosis at the ears and tail. SE reproductive failure is manifested by abortion, probably because of the septicemia and subsequent illness in the dam.

Fungal Agents. The ingestion of mold-contaminated feeds can have an adverse effect on swine reproduction. Molds such as *Penicillium, Aspergillus, Claviceps,* and *Fusarium* can produce chemical substances called mycotoxins, which can exist in corn, wheat, oats, barley, cottonseed, and peanut meal and soybeans. The ideal environment for the growth of the toxins occurs when the plants are subjected to cool, wet weather during flowering and a short drying season in the fall. Improper moisture contact during storage (greater than 13% to 14%) promotes mycotoxin formation.

The effects of mycotoxins produced by these various fungal species are diverse. Penicillin and *Aspergillus* are capable of producing ochratoxin, which causes renal necrosis. Aflatoxin, produced by *Aspergillus flavus,* causes reduced feed intake and growth. Ergot alkaloids, produced by *Claviceps purpura,* cause reproductive problems associated with failure of sows and gilts to nurse after farrowing. *Fusarium roseum* produces two mycotoxins—zearalenone and deoxynivalenone—with the former capable of mimicking the effects of estradiol and the latter causing decreased feed intake and vomiting.

Zearalenone has its most profound effects on prepubertal gilts. Low concentrations of the toxin cause hyperestrogenism, swollen vulvas, mammary development, and rectal and vaginal prolapse. In mature sows the toxin has been shown to cause pseudopregnancy, anestrus, weak neonates, stillbirths, and abortion.

The effect of zearalenone on the sexual development of boars has been examined, but no positive conclusions have been drawn. Studies have shown that the effects of the toxin are more severe on prepubertal boars. There is reduced testis development, and studies have shown decreased libido in prepubertal boars fed corn containing zearalenone. Recent studies on mature boars have shown no detrimental effects of the toxin on libido or sperm development. Further research is necessary.

Nutrition and Reproductive Performance in the Gilt and Sow

Prolificacy is the number of viable piglets produced per sow either per year or per breeding lifetime. Prolificacy is influenced by age at first successful mating, ovulation rate and embryo survival at each mating, number of piglets born alive, and the sow's ability to be remated successfully at regular intervals. The literature on nutrition and sow prolificacy has been reviewed (Aherne and Kirkwood, 1985). The protein and amino acid requirements for pregnancy and lactation in swine have also been reviewed (Speer, 1990). The effects of dietary salt during gestation and lactation on reproductive performance of sows have been examined. A decrease in salt concentration in sows' diets from 0.5% to 0.25% or 0.125% reduces birth weight, and a feeding of less than 0.5% salt for more than one reproductive cycle reduces litter sizes at birth and weaning.

The interaction of nutrition and reproductive performance in the gilt and sow are outlined and described here.

Gilt Nutrition. Gilts may constitute 30% to 40% of the breeding females of a herd; therefore the factors affecting gilt reproductive performance will have a significant impact on overall herd prolificacy (Aherne and Kirkwood, 1985).

Age at successful mating is largely dependent on age at puberty. Diets that meet recognized standards of energy and protein content have allowed gilts to express their potential in terms of age at puberty. Under normal conditions of feeding and management, nutrition will have a minimal influence on gilt prolificacy. However, to gain the advantages of a slightly younger age at puberty, maximum ovulation rate, and an adequate fat cover, gilts should be fed ad libitum up to the time of breeding. More feed or energy intake given before mating increases ovulation rate, but high-level feeding during rearing of gilts or in the premating period is also associated with an increased embryo mortality. An increased ovulation rate, combined with increased embryo mortality, therefore does not have a significant effect in final litter size at birth.

Under normal conditions of feeding and management, nutrition has a minimum influence on gilt prolificacy. However, to gain the advantage of slightly younger age at puberty, maximum ovulation rate, and an adequate fat cover, and to ensure against subsequent poor management, gilts should be fed ad libitum up to the time of breeding. Ad libitum feeding of gilts reduces age at puberty. Prepubertal flushing to increase ovulation rate does not lead to increased litter sizes from gilts mated at puberty (Kirkwood et al, 1988).

Pregnancy. Much research has centered on the influence of various levels of feed intake on the relationships between body weight and body condition changes during pregnancy and lactation, milk yield, and subsequent reproductive performance over several parities. The objective is to optimize long-term reproduction at the lowest possible cost.

Long-term reproductive performance is best served by minimizing fluctuations in live weight and fat reserves, thereby avoiding extremes of body condition and subsequent poor performance. This is achieved by small, controlled increases in sow body weight during pregnancy and by feeding according to appetite for restricted periods each day during lactation. Feeding of the sow during pregnancy should be based on requirements for optimum development of the sow and her fetuses. The young sow should receive sufficient feed to enable her to grow to mature size. If a sow has to produce a litter of 10 piglets and gain a total of 40 to 45 kg during pregnancy, the feed requirement for conceptus and maternal gain is about 30%, in addition to that for maintenance requirements. For each degree centrigrade below thermoneutrality (i.e., 18° to 20° C), about a 4% increase in maintenance requirements can be expected; changes in housing associated with increased activity of animals increase the maintenance requirement (Verstegen and den Hartog, 1989). Pregnant gilts and sows in gestation crates with unbedded concrete-slat floors during cold weather (i.e., 10° to 12° C) may have a lower critical temperature than expected and could benefit from additional feed, especially in late pregnancy when the critical temperature is lower than in early pregnancy. Additional feed in late gestation improves reproductive performance in sows. The cost of feeding an additional 31 kg of feed/sow during the last 23 days of gestation was more than offset by the value of the additional sow weight gain, 0.3 pig/litter at weaning, and 2.6 kg of total weaning weight. High-fiber feeds can be used during pregnancy, when energy requirements are relatively low.

Lactation. High-producing sows can easily yield 8 to 9 kg of milk/day when nursing 9 to 10 pigs during peak lactation. By weight, sow's milk has an average composition of 81.2% water, 6.8% fat, 5.5% lactose, 5.0% protein, and 1.0% ash. Peak milk production occurs between the second and fourth week of lactation. At the highest level of milk production, a lactating sow can yield 0.55 and 0.45 kg of milk fat and protein, respectively. As a result, the daily nutrient requirements for lactation are two to three times greater than during gestation. The energy requirements of the lactating sow are related to her body size and body reserves at the beginning of lactation, the number of pigs nursing, her milking ability, feed intake capacity, and other factors such as ambient temperature. If sows are not fed sufficiently during lactation, they use body stores of fat and protein. Sows mobilizing fat stores will lose body weight, which will subsequently be reflected in poor reproductive performance such as delayed estrus after weaning (Kirkwood et al, 1988). Excessive weight loss or backfat loss during lactation will adversely affect subsequent sow reproductive performance. The feeding of a high-energy diet during lactation can increase subsequent litter size, especially second litters. Sows should be fed at least to appetite during lactation, and a higher-energy–dense diet may be beneficial.

The lactating sow requires 5 to 7 kg of feed daily to maintain body weight and condition during lactation. However, even on ad libitum intake, sows fail to eat the required feed consumption and thus lose body weight and tissue. The problem is most acute in primiparous sows, and low feed intake during lactation is recognized as a major factor in postweaning anestrus and impaired reproductive performance. Older animals, those with high suckling load, and thin animals all tend to eat more, with maximum daily intake occurring at 4 to 5 weeks of lactation. Intakes are reduced at high environmental temperatures, but this can be alleviated by wet feeding and by offering a high-energy–dense diet or a high-protein diet. Other factors that influence voluntary feed intake are the breed of pig and the lighting pattern. The reduction in embryo survival after previous short lactation lengths or low-level feed intake during lactation may be due to a reduction in plasma gonadotropin levels or a reduced ovarian response to gonadotropin stimulation. Experimentally, the decrease in embryo number associated with a low level of feeding during lactation can be alleviated by the administration of GnRH.

The literature on the mineral nutrition of the sow has been reviewed (Mahan, 1990). The mineral requirements of the gilt and sow vary with the demands that occur during different phases of the reproductive cycle. Minerals are required for conception, maintenance of pregnancy, lactation, growth, and maintenance. The sow's mineral requirements are highest during late gestation and lactation, and minerals that are supplied from both the diet and tissue reserves contribute in meeting these nutritional needs. The sow is resilient to borderline mineral deficiencies, but longevity in the herd may be compromised under marginal conditions. The reproducing sow will deplete her pool of tissue minerals before litter size, congenital abnormalities of developing fetuses, or milk mineral composition are affected. Inadequate mineral nutrition, especially of calcium and phosphorus, may prolong the duration of parturition, causing an increase in the number of stillbirths, and cause skeletal abnormalities such as osteomalacia, which leads to pathological fractures in sows.

The recent NRC (1999) publication, *Nutrient Requirements of Swine*, lists the dietary mineral level and absolute daily intake of minerals for both gestation and lactation. The percentage values are interfaced with absolute calculations that assume an average daily feed intake of 1.9 kg during pregnancy and 5.3 kg during lactation to meet these needs. Gestation feed intakes are usually in line with these feeding standards, but lactation feed intakes may be less than 5.3 kg/day. Therefore, to meet the daily mineral needs as suggested by the NRC when a lower quantity of feed is consumed, a higher dietary concentration must be provided (Mahan, 1990).

Feed and water deprivation before weaning does not decrease the weaning-to-breeding interval of sows; feed deprivation can actually increase the weaning-to-breeding interval.

Nutrition of Sow after Weaning. The major objectives of nutrition during the period after weaning are to shorten the interval from weaning to breeding and maximize the ovulation and conception rates (Aherne and Kirkwood, 1985). Earlier recommendations included a drying-off period of at least 24 hours after weaning, during which the sow receives no feed or water. This was considered an effective method of shortening and synchronizing the interval to estrus. Recent evidence indicates no beneficial value of this practice. There is no benefit from high-level feeding after weaning, except possibly in primiparous sows or sows that lost a large amount of body weight and condition during the previous lactation. Soon after weaning, sows lose a considerable amount of weight because of water loss and depletion of body tissue, including protein.

Body Condition of Sows. Energy intake affects body weight and backfat changes during gestation and lactation, and these changes in body condition are associated with impaired reproductive performance. Observations of swine producers indicate that subtle changes in nutrition may not affect reproductive performance in commercial swine production systems. Sows gain weight and body condition during gestation and lose weight and body condition during lactation; the effects of these changes are reflected in subsequent reproductive performance. The production goal should be to determine the amount of feed intake that would result in minimum body weight changes from gestation through lactation and postweaning estrus, which would be commensurate with optimum reproductive performance and be profitable.

There are no significant relations between changes in body condition and rebreeding performance of sows. These results suggest that changes in body condition typically observed in sows housed in commercial production units may be too subtle to have an effect on reproductive performance (Esbenshade et al, 1986). The relationships between reproductive performance, body weight, and body condition, and differing body fatness at parturition, differing nutrition during lactation, and differing litter size have been examined (Yang et al, 1989). High-level feeding in lactation improved production and efficiency benefits in both primiparous and multiparous sows, whereas pregnancy feeding to attain a target of 20 mm rather than 12 mm of backfat at parturition was of benefit for primiparous sows. The timing of postweaning estrus in primiparous sows is not dependent on a minimal threshold of body fat. The interval to estrus is more closely related to metabolizable energy intake during lactation than to body-fat percentage (Johnston et al, 1989).

Formulation of Sow Diets. Swine producers continue to report a variety of problems associated with the performance of the gestating and lactating sow. The common problems are poor reproductive performance and reduced longevity of sows in the herd. Many swine producers do not regularly evaluate their feeding programs to check the accuracy of their diet formulations and mixing procedures. The nutrient content of feedstuffs can also vary considerably, depending on the source. Analysis of feed samples from the gestation and lactation diets of a large number of swine farms revealed that the percentage of samples failing to meet the nutrient levels specified by the NRC for crude protein, calcium, and phosphorus ranged from none to 24%, depending on the nutrient. More care is needed in formulating diets for the sow herd, and mixing and sampling errors must be minimized by using scales and following directions for proper mixing.

Housing of Sows During Gestation

Confinement housing of sows has become the predominant housing system because of its increased labor efficiency. Comparison of reproductive performance in sows housed during breeding and gestation with that in sows kept in outside lots, in a climate where ambient temperature reaches a minimum of −40° C in the winter and a maximum of 38° C in the summer, demonstrated that housing sows in outside lots had no effect on litter size at birth (Dyck et al, 1985). For sows kept outdoors, the litter size at weaning was larger and the culling rate was lower than for sows housed in confinement, which suggests that greater space per sow and cleaner air may be important factors in maintaining healthy sows.

A variety of housing systems have been used for nonlactating sows (Petherick and Blackshaw, 1986). They may be kept in groups outdoors in simple shelters, or in small groups indoors in pens with or without bedding, and facilities for group or individual feeding. Most gilts and sows are kept in individual stalls or cubicles throughout gestation. There are advantages and disadvantages with each system relative to the sow, the livestock attendant, the environment, and the cost. Keeping sows in groups is cheapest, but aggression among sows can be a problem. The providing of individual feeders, which eliminates fighting at feeding times, adds considerably to both the cost and the space requirement of the housing system. Individual housing in stalls or cubicles is relatively inexpensive and has the advantages of ease of handling and monitoring and the elimination of fighting. However, there is growing concern about the welfare aspects of the virtual lifelong restraint that these systems impose on sows. Individual housing of sows may be associated with certain stereotyped behaviors and may have an effect on reproductive performance, but these associations have not been defined clearly.

Farrowing Gilts and Sows

Periparturient Behavior of Sows. Periparturient behavior in swine can be divided into prepartum, parturient, and postpartum phases (Hurnik, 1985). In the last month of pregnancy, sows show an increased appetite, their movements become slower, and recumbency is more frequent. The mammary glands begin to enlarge about 3 weeks before parturition, and pregnant sows show increased responsiveness to the vocalization or visual appearance of piglets. During the last week of pregnancy, especially 3 to 4 days before parturition, the appetite decreases and the genitalia and mammary glands enlarge grossly. If liquid serous discharge can be expressed from the teats, farrowing will occur within 48 hours; if colostrum can be expressed, farrowing will occur within 24 hours. If given the opportunity, 1 day before farrowing, the sow will build a nest; if there is no opportunity, she will make movements with her legs indicating the desire to do so. Within the last several hours before farrowing, restlessness and an increased respiratory rate are obvious and the sow calms down. With approaching delivery, lateral recumbency is common and the sow enters the first stage of labor, which lasts from 1 to 2 hours and is accompanied by an increased respiratory rate, intervals of abdominal straining accompanied by vigorous tail switching, occasional grunting, and grinding of the teeth. Immediately before the expulsion of each piglet, tail switching and abdominal straining can be observed. Approximately 30% of piglets are delivered in posterior presentation, and in about 70% of cases, the umbilical cord remains intact until movement of the piglet or the sow effects breakage. Piglets are often fully surrounded by fetal membranes; in natural circumstances, they either free themselves by their own effort or suffocate. Approximately 70% of all mortalities result from suffocation, apnea, or other causes occur in piglets delivered in the latter part of the expulsion phase. The average interval between expulsions of two consecutive piglets is about 15 minutes. Duration of the second stage of labor is usually about 2 to 4 hours but may be as short as 30 minutes or as long as 10 hours. The third stage of labor may start during the delivery stage, but complete expulsion of the placenta generally occurs within 4 hours of the birth of the last piglet.

Postpartum Phase. In the postpartum phase, normal healthy piglets are active soon after birth. They may be apneic for 5 to 10 sec, but after a few light coughs and a short period of panting, regular breathing begins. Within a few minutes of freeing themselves from the placental membranes, they are able to walk, and within 30 minutes they usually succeed in finding a teat. During the first period of nursing, the levels of oxytocin are high, which provides for an extended period of milk letdown. The sow is almost continually available for sucking by the piglets, which makes colostrum available at practically any time during the expulsion and placental stages of labor. Cyclical nursing, the second period of nursing, starts to develop during the second half of the first day postpartum and is characterized by regular periods of milk letdown and socially synchronized suckling by the piglets. Sows seem to be actively involved in this process by controlling the approach of the piglets to the mammary gland. By the end of the second postpartum day, the nursing cycle of normal, healthy litters is fully stabilized. Cyclical nursing occurs at regular intervals of about 1 hour. A typical nursing cycle consists of several distinct phases such as assembly, nosing, slow sucking, true sucking, and departure. The sow-litter bond develops at the initiation of cyclical nursing, and thereafter the bond is strong. Any distress call of the piglets, alarm calls by adjacent sows, or appearance of unfamiliar objects, animals, or people triggers an immediate and sometimes aversive reaction.

Cross-fostering in swine is relatively easy to accomplish, if the alien piglets are introduced within 2 days postpartum. Any aggressiveness of the sow is usually diminished after sucking is initiated. Piglets develop a specific positional association with individual teats known as the teat order, which is characterized by consistency of teat choice on consecutive nursings. The development of teat specificity takes place over a period of 3 days in four phases: teat seeking, teat sampling, teat defense, and teat maintenance. Not being fully homeothermic, piglets experience a drop of about 2° C after birth and recover in about 1 day. A distinct behavioral characteristic of young piglets is the seeking of thermal comfort during resting by close aggregation to litter mates in areas of relative warmth, particularly during the first 2 weeks of life, when their physiological thermoregulation is still developing.

The foregoing knowledge is an important prerequisite for successful management of farrowing operations and more efficacious attainment of production potentials in swine. Traditionally, improvements in farrowing-house performance have been achieved by giving attention to basic hygiene and husbandry factors, and the accepted farrowing-house mortality has been 8% to 10%. However, many swine farms can get this mortality rate down to 5% with a better understanding of the needs of the farrowing and nursing sow. The factors that must be considered include: good records, pen layout, design of farrowing crates, bedding, stress factors, feeding systems, supervision of farrowing, fostering of piglets, and the education and training of the staff in the farrowing house.

Pregnant sows and gilts should be moved into the farrowing facility at least 6 days before the expected farrowing date. In a batch-farrowing system, a group is usually brought into the farrowing crates at least 1 week before the mean expected due date. This 1-week period allows for individual variations in gestational length, which will vary up to 4 days, and for an adequate period of adjustment to the farrowing crate. The farrowing crates should have been cleaned, disinfected, and left vacant for at least 3 days before pregnant sows are moved into them. In addition, all sows and gilts should be washed before entering the farrowing facilities. This removes gross fecal contamination of the skin and reduces the population of the bacterial flora of the skin, which aids in the control of bacterial diseases of the newborn piglet.

Dystocia and Perinatal Mortality. Parturition in the pig is relatively simple, and dystocia and uterine inertia are uncommon. The duration of farrowing is approximately 2 hours, and a piglet is born approximately every 15 minutes. Posterior presentations are common, but most piglets are born in a dorsosacral position. The most common cause of perinatal mortality is intrapartum death of piglets born in the last one third of the litter. Premature rupture of the umbilical cord is a major factor in the cause of intrapartum deaths, which may be related to prolonged farrowing times. In approximately 70% of intrapartum deaths, the piglets are alive at birth, although the clinical signs of viability are often limited only in the presence of a slow heartbeat, which gradually fades and ceases within several minutes of delivery. These piglets are in a state of hypercapnia and acidosis, and resuscitation may be possible.

Surveillance and supervision of farrowing to minimize perinatal mortality includes obstetric assistance of sows with dystocia, resuscitation of piglets that are almost dead as a result of intrapartum asphyxia, removal of placenta envelopes to prevent suffocation of piglets, placing of piglets under the heat lamp immediately after birth to prevent hypothermia and crushing by the sow, assessment of the sow's milking potential and interfrosting accordingly, identification of

piglets that did not suck early enough, clipping of all piglets' teeth, and treatment of piglets' navels with an antibacterial spray immediately after birth.

Induction of Parturition. Farrowing may be induced and synchronized in a group of sows by using a single injection of a prostaglandin or its analogs. A successful induction of parturition has practical application in commercial swine units operating a batch-farrowing system (Podany et al, 1987). Individual sows within groups weaned on the same day usually commence their postweaning estrus between 4 and 8 days later. If these animals are served over a 4- or 5-day period with a gestation period lasting between 114 and 118 days, the farrowings normally extend over about 10 days. With an induction treatment initiated just after the first natural farrowings, it should be possible to reduce the farrowing range for an individual group 5 or 6 days to maintain a better batch effect. This should increase the efficiency of use of the farrowing facility. A reduction of 2 to 3 days in the interval from first to last farrowing could allow more groups through the unit in a fixed time and give 1 or 2 extra days for cleaning and sanitation between groups. Concentrated farrowings would have other potential advantages: piglets could be transferred readily from larger to smaller litters, routine activities like iron injections or castrations could be carried out on more piglets at the same time, and the age range at weaning would be reduced. In addition, weekend and holidays farrowings could be avoided, which would minimize labor requirements during these periods.

Successful induced farrowings allow a high percentage of farrowings to occur at predetermined times, when maximum surveillance and supervision can be provided to minimize the incidence of perinatal mortality.

The prostaglandins are usually given 1 to 3 days before the expected farrowing date (e.g., Days 112, 113, or 114 of gestation). The response varies with the type of prostaglandin used, but in most cases more than 60%, and in some cases more than 90%, of treated sows commence farrowing between 18 and 36 hours after administration of the prostaglandin. The administration of oxytocin 6 hours after the prostaglandin induces the most rapid onset and the greatest synchrony of farrowing (Kirkwood and Aherne, 1998). The use of fenprostalene and oxytocin on Day 114 of pregnancy caused a reduction in the duration of farrowing compared with the prostaglandin alone (Stephens et al, 1988). Induction of parturition on Day 110 of gestation may be associated with a slight increase in perinatal piglet mortality compared with inductions on Days 112 and 113. It is essential to have reliable breeding records in order to induce farrowing 2 to 3 days before the expected natural farrowing date. New prostaglandin analogs are being made available and are as effective as cloprostenol.

Control of Diseases of Farrowing Gilts and Sows

Mastitis-Metritis-Agalactia Syndrome. The most important disease complex of the sow at the time of farrowing is mastitis-metritis-agalactia (MMA) syndrome, also known as lactation failure or periparturient hypogalactia syndrome. The details of the internal-medicine aspects of the disease are described (Radostits et al, 2000), and a review of the subject is available. While the etiology has been controversial, there is considerable clinical and laboratory evidence that toxemic mastitis, most commonly resulting from *E. coli*, is the predominant lesion, and the metritis is usually not present. It is suggested that the endotoxin suppresses the release of prolactin, which causes a decline in milk production.

Therapy includes the use of oxytocin, antimicrobials, and supplemental feeding of the piglets.

The prevention of MMA syndrome in the sow is crucial because of the effects of agalactia on the newborn piglets. It has been difficult to develop a rational approach to prevention, because the disease has been considered a complex syndrome caused by several different factors. However, the control of infectious mastitis would seem to be of major importance. Farrowing crates should be vacated, cleaned, disinfected, and left vacant for a few days before pregnant sows are transferred from the dry-sow barn and placed in the crates. Pregnant sows should be washed with soap and water before being placed in the crates. Farrowing crates must be kept clean and hosed down if necessary, particularly a few days before and after farrowing, to minimize the level of intramammary infection. In problem herds, it may be necessary to wash and disinfect the skin over the mammary glands immediately after farrowing.

Other causes of lactation failure include failure of the milk ejection reflex, psychogenic agalactia in nervous or aggressive sows, and failure of mammary development due to ergotism.

Antimicrobial agents used prophylactically appear to be successful in controlling some outbreaks of MMA. A sulfadimidine-trimethoprim-sulfathiazole combination fed to sows for 3 to 5 days before the expected farrowing date may reduce the incidence of MMA in problem herds.

The use of prostaglandins for the induction of parturition has not been associated with a consistent decrease in the incidence of MMA. Some field trials have shown a reduction in incidence, whereas others have had no effect.

Sow Hysteria. Some sows show aggressive behavior at parturition and attack their own piglets, resulting in wounding or death of the piglets. This behavior seems to be more common in gilts. Examination of the frequency, environmental influences, and heritability of aggressive behavior in a large number of litters indicated a heritability between 0.25 and 0.50, and selection against aggressive sows at parturition through the selection of boars and gilts from nonaggressive dams only slowly reduces the frequency of occurrence (van der Steen et al, 1988).

To minimize the stress on the sow of adjusting to the farrowing crate and facilities, the sow should be placed in the crates at least 1 week before the expected date of farrowing. The nature and composition of the diet fed to the sow while in the farrowing crate should not be changed. The only necessary change is to increase the daily intake compared with the intake during the dry period, beginning on the day after the sow has farrowed and continuing thereafter as lactation proceeds. The inclusion of bran at the rate of one third to one half of the total diet for 2 days before and after farrowing has been recommended to prevent constipation. In some herds, the use at all times of lucerne meal as 15% of the diet has been recommended. However, under intensified conditions, it may be impractical to prepare and provide these special diets on a regular basis. Although field observations suggest that a bulky diet at the time of farrowing minimizes the incidence of toxic agalactia, there is little scientific evidence to support the practice.

Pyelonephritis and Cystitis. Other diseases of the sow that may occur within a few days before or after farrowing include pyelonephritis and cystitis caused by *Eubacterium suis*. Cystitis and pyelonephritis resulting from *E. suis* may occur in several animals over a period of several months. The ubiquitous nature of the organism may make it difficult to eradicate from a herd. The use of modified and medicated early-weaning programs using antibiotics failed to eliminate *E. suis* from the male population (Dee et al, 1994).

Erysipelas. Epidemics of infectious disease are uncommon in sows raised in confinement, presumably because of age-dependent immunity and lack of exposure to pathogens

such as *Erysipelothrix insidiosa*, which may cause epidemics in nonvaccinated exposed animals.

Causes of Sow Mortality

Only a few large-scale studies of sow mortality have been published, and most are based on pigs submitted for necropsy examination. In a study of sow mortality in 75 Danish herds, an average mortality of 4.6% with a range from 0.4% to 11.4% was recorded (Christensen et al, 1995). Sow mortality rates reported from England, France, and Canada were 4.0%, 3.7%, and 3.3%, respectively. In a Danish study of sow mortality based on carcasses being submitted to a rendering plant and in which a clinical history was available, the distribution of likely causes of death or euthanasia was as follows: leg weakness (28.5%), diseases associated with late pregnancy and farrowing (20.9%), digestive tract disease (17.1%), urinary tract (13.1%), physical injuries (10.7%), and others (9.5%). In another group of sows submitted to the rendering plant with no known history, the distribution of likely causes was as follows: leg weakness (16.1%), diseases related to late pregnancy and farrowing (10.7%), diseases of the digestive tract (21.2%), urinary tract (15.2%), others (15.0%), and unknown causes (21.8%). The overall mortality rate was estimated to be 5% to 6%. Mortality rate increased with increasing herd size, and in herds with more than 100 sows the mortality rate was three times the mortality rate in herds with fewer than 50 sows (Christensen et al, 1995). The proportion of diseases of the digestive tract may have increased in the last 20 years. Gastric dilatation is particularly common and may be related to the intensification of production.

In a 1-year survey of 106 herds containing 2488 sows, the mortality rate was 4%. The major causes of death were complications of parturition, cystitis, nephritis, endocarditis, and acute hemorrhage. Bacterial infection was an important factor in 43% of the deaths.

The causes of death in sows examined in a diagnostic laboratory over a period of 8 years included the following: sudden death due to *Clostridium novyi* (31.6%), cystitis-pyelonephritis (20.0%), abdominal disease (gastric dilatation and torsion, gastric rupture, torsion of a lobe of the liver, and rupture and torsion of small and large intestines) (11.8%), perforated gastric ulcer (4.5%), splenic torsion (4.0%), heart failure (3.6%), septic pneumonia (3.8%), alimentary lymphosarcoma (2.7%), endometritis (2.2%), and no diagnosis (5.5%) (Duran, 1994).

In a study of sow mortality in herds in France, with an average mortality of 6.4%, the risk factors for high sow mortality included multiplier herds compared with commercial farrow-to-finish herds (Abiven et al, 1998). Farms in which dry sows were housed in individual stalls were at higher risk of experiencing a high mortality rate than farms with tethers for dry sows. Feeding lactating sows ad libitum was more risky for mortality than a feeding plan in which the maximum daily amount of feed provided to sows was lower than 8 kg and reached in early lactation. Providing of three meals a day instead of two to dry sows decreased the odds of high mortality. An average of weaning at 28 days or more and/or small average litter size at birth of 12 piglets or less were associated with higher odds of high sow mortality.

Housing and Space Requirements for Gilts and Sows in Confinement

Traditional Farrowing Pens. Before about 1960, a sow and her litter were kept in square or rectangular pens constructed in rows along a central feeding passage. These pens were commonly multipurpose; they could house a dry sow, a lactating sow and her litter, or perhaps a boar. Piglet mortality from crushing was a problem, and some pens had a protective rail along the walls to protect the piglets when the sow lay down. The pens were bedded with straw and cleaned daily. In some cases, a portable wooden farrowing crate was placed in the stall before farrowing and during lactation.

Advent of Farrowing Crates. Beginning around 1960, the farrowing crates were fixed to the floor in rows in farrowing rooms, and the sow was released twice daily to be fed. The farrowing crate had an infrared lamp–heated creep area for the piglets. From that beginning until the 1990s, many modifications of the farrowing crate have been developed, including the dry sow crate for housing the sows after weaning and during gestation. Tethering sows individually by the heartgirth or the neck was used for some years but soon fell into disfavor because of welfare issues. When pigs are kept extensively in an outdoor system with a large living space, their welfare is normally considered adequate.

Under current conditions, pigs are kept indoors during their entire life, and the number of pigs per unit is steadily increasing. Considerable progress has been made in the last 3 decades in the design of crates for pregnant and lactating sows. The requirements for a good breeding area include good contact, both physical and visual, between sows and boars; maintenance of a reasonable temperature range; feeding systems adequate to the system of management; ease of stock movement; ease of stock observation; and a well-designed service area. Boars are usually penned individually. Pregnant sows are commonly kept in individual stalls with straight or sloped sides and slatted floors in the rear and the feeder and waterer in the front. Farrowing houses are designed based on years of experience to produce a high survival rate in the piglets. The farrowing rooms are heated, and the creep areas of each farrowing crate have supplemental heat for the piglets.

Sow Crate Design and Comfort. The major concerns about sow crate design include the dimensions; the slope of the sides, which allows the sow to lie down and get up easily without injuring the piglets; the floor surface; the comfort of the creep area for the piglets; the ease of cleaning; the ease of removing the animal from the crate for breeding and other reasons; the welfare aspects of keeping animals in such confinement; and the effects of confinement on productivity.

The practice of confining sows in stalls or crates throughout gestation and lactation has become widespread in modern pig production. Surveys in the United Kingdom found that 87% of sows farrow in farrowing crates, and 75% of producers with large herds confine gestating sows in stalls (Baxter and Schwaller, 1983). Gestation crates of various dimensions, shapes, and fabrication materials are used widely (McFarlane et al, 1988). Gestation crates make it possible to feed pregnant sows and gilts individually; to keep them separated, which reduces fighting and thus injuries; to conserve building space and heat; and to facilitate waste handling. In most crates, however, sows and gilts can walk only a step or two and are unable to turn around.

Close confinement, which prevents the sow from turning around, has been a welfare issue over which much concern has been expressed. The Brambell Committee (Brambell, 1965) on farm-animal welfare concluded that "pregnant sows should not be kept without daily exercise in quarters which do not permit them to turn round." The Committee also stated that "an animal should at least have sufficient freedom of movement to be able without difficulty, to turn around, groom itself, get up, lie down and stretch its limbs." These animals might need to walk and turn around. Depriving them of opportunities to do so might affect their health, performance, and overall well-being. The Swedish code of recommendations for the welfare of animals was more

forceful, stating that "permanent tethering of pigs is forbidden" (Swedish Ministry of Agriculture, 1989).

The Farm Animal Welfare Council (1988) in the United Kingdom recommended that future trends in housing the dry sow should be away from the use of stalls and both girth and neck types of the tether system, and that the government should introduce legislation as a matter of urgency to prevent all further installations of units of these designs. The ban of permanent single housing of sows in Germany forbids neck tethering and states that after weaning, sows must be allowed free movement daily over a period of 4 weeks (Lehmann, 1990).

A symposium held in France in 1983 dealt with the welfare of confined sows. The four major topics discussed were productivity, physical health, behavior and physiology, and new approaches. Subjects discussed included the effects of confinement on productivity of sows and gilts, tethered versus loose sows, diseases and injuries affecting confined sows, ways to delineate the sow's welfare needs, an environmental model for the sow's physical and behavioral needs, and stereotyped behavior in tethered sows (Aumaitre and Dantzer, 1984).

The social space requirements of pigs is a concern. Pigs have social space requirements because of certain aspects of their sociality, and groups of pigs require more space than just the sum of the individuals' space requirements (Baxter, 1989). They do not appear to have personal space around their heads or bodies that other pigs are not permitted to enter, which regulates interindividual distances. Their tolerance of other pigs is dependent on what they are doing and, in particular, whether they are in possession of a resource that they want to defend. The social space requirements could be met by giving the pig as much space as necessary or by changing the pig's environment in such a way that the social space requirement is reduced to fit the existing space allocation. For example, this could be achieved by providing trough barriers to reduce aggression during feeding.

Animal Welfare Concerns. Welfare has been defined as a state of complete mental and physical health, in which the animal is in harmony with its environment. The welfare of animals relates to the degree to which they can adapt without suffering to the environments designed by humans. As long as a species remains within the limit of the environmental range to which it can adapt, its well-being is assumed (Stephens, 1989). It can be seen from these definitions that the mental state of the pig is vitally related to its welfare. Therefore the normal behavior of the pig and changes induced in that behavior by intensive husbandry methods are important indicators of the pig's well-being in such environments. When the pig undergoes behavioral changes in order to adapt to its environment, the nature of those changes depends on the stimulus. When the stimulus is simple, such as a change in ambient temperature, the response to the change in the environment is usually obvious and easy to interpret. For example, piglets reared in a group respond to a lowering of ambient temperature by huddling together. This reduces the surface area exposed to the environment, and the total energy expenditure of the piglets can be reduced by as much as 40%. However, the mental state of the pig is much more difficult to assess, particularly if the animals are producing the desired end product satisfactorily. The relations among environmental changes, abnormal behavior, and mental well-being are the subject of much investigation (Stephens, 1989).

The way in which farm-animal welfare is appraised has three faults: (1) welfare is not systematically analyzed; (2) welfare requirements are described in little detail; and (3) there is no published technical justification for the recommendations. An approach that can help to overcome these problems has been suggested (Baxter and Baxter, 1984). The method attempts to describe sow welfare as the sow perceives it, and then to translate each welfare element in quantifiable variables with defined boundaries of welfare acceptability. Such an approach would improve the depth of investigation of welfare requirements, give the codes of recommendations more consistency over time, and lead to greater longevity.

Sow Crate Design. Despite the widespread use of farrowing crates and the large and growing number of designs available, relatively little systematic investigation has focused on elucidating the effects of sow crate design on the animals that reside in them (Parfet et al, 1989). At the present time, there is no one sow-crate design that is better in all respects than others. However, research indicates that many factors must be considered in choosing a sow crate design, and that piglets are remarkably adept at coping with the environment with which they are provided (Parfet et al, 1989). It seems that crate dimensions tend to affect the behavior of both the sow and the piglets more so than side type, and space-restrictive crate dimensions are more important determinants of health and production (Parfet et al, 1989). The well-being of piglets depends on several factors, including social interactions, the care provided by the sow, and the general environment. The farrowing crate is a major part of the pig's immediate environment in modern swine-rearing systems. Its use has been associated with decreased piglet mortality because of crushing, but the mortality rate during the preweaning period still averages around 15%.

The effects of confinement of sows before breeding and during pregnancy and lactation are noteworthy (Baxter, 1987). Close confinement causes stress. When sows or gilts are confined by tethering for the first time, they demonstrate a panic reaction and undergo a period of intense physical activity directed at escaping from confinement, which lasts an average of 45 minutes. After the escape response, sows typically become very inactive or unresponsive; this state is best described as apathy. While sitting or standing, the sows adopt a hanging-head posture with their eyes half or fully closed and they lean against the bars of the stall. This period of unresponsiveness may last for up to 16 days. By about 10 weeks after tethering, sows will perform regular stereotyped behavior. Most of these stereotyped behaviors are nosing or mouthing activities, which are considered coping responses that help the sow to adapt to adverse aspects of confinement. These stereotyped behaviors can be eliminated and escape-related behaviors reinstated by administering naloxone, which specifically blocks naturally occurring opiates such as endorphins, which are believed to play an important role in any adaptation to stress (Baxter, 1989). The physiological, behavioral, and production responses of confined sows indicate that when sows are tethered individually or housed in pairs, they are in chronic stress compared with being kept in groups indoors or outdoors; however, there is no clear welfare advantage to housing dry, adult pigs in a more extensive natural environment (Barnett et al, 1985). Housing groups of adult gilts with a space allowance of 1 m^2/gilt compared with an allowance of 2 m^2 or 3 m^2 causes a significant elevation of plasma free-corticosteroid concentrations. Dry sows seem able to adapt to close confinement such as tethering, and there appears to be no disadvantage in terms of sow productivity (Parry, 1986). Confinement of sows in farrowing crates does appear to cause them some degree of stress and does seem to prolong the duration of gestation and farrowing interval (Backstrom et al, 1994), but this does not significantly increase the incidence of perinatal mortality or postnatal productivity. The confinement of sows can affect their health because of trauma or injuries. Field studies in Norway found the prevalence of claw lesions in sows is increased in

confined herds, compared with herds with loose-housing (Gjein and Larssen, 1995a,b,c)

Group Housing. Some commercial producers in North America are incorporating group housing of gestating sows into new, large, total confinement units. These group pens frequently have 40 to 80 animals/pen and straw bedding. These systems appear to provide more natural grazing, movement, and social activities. They may also stimulate increased intakes of fiber during late gestation. However, the disadvantages include increased labor input, increased environmental ammonia levels, and the need to handle manure in semisolid form. In addition to potential welfare benefits, these group facilities may be less expensive to build and maintain. It is likely that modifications in construction and management of these group-housing sow pens will resolve some of these disadvantages.

Modified Gestation Crates. Gilts kept in modified gestation crates that allow them to turn and walk do turn several times daily, but the turning does not seem to be motivated by any particular need (McFarlane et al, 1988). When outdoors, sows may walk nearly 2000 m/day. Sows in an indoor pen with eating, lying, and dunging areas close to one another walk an average of 200 m/day. In crates designed to allow walking, pregnant gilts walked 130 m/day (McFarlane et al, 1988), which may be related to the need to move to one end or another to turn.

Farrowing crate design may influence within-litter variance in piglet weights at 14 days of age. Within-litter variance can be significantly higher with horizontal-bar crates than with vertical-bar crates (Thompson and Fraser, 1986). It is suggested that the crate design did not influence the total intake of milk of the litter but did influence the evenness of its distribution to different litter mates. It is possible that the horizontal-bar crates make it more difficult for less competitive piglets to nurse.

In traditional, unconfined farrowing systems, straw plays an important role as a substrate for nest building by the sow. The nest provides both physical cushioning and thermal insulation for the newborn piglets, improving their chance of survival in a hostile environment. In modern farrowing systems, perforated floors are in common use; straw is not used routinely, which makes cleaning much easier; and heated farrowing houses and infrared lamps in the creep area provide the heat necessary for the piglets. The provision of straw in farrowing crates seems to have no effect on farrowing results or on piglet productivity.

Flooring in Farrowing Pens. Flooring in farrowing pens must satisfy a wide variety of criteria. Management considerations dictate that floors must be durable and easily cleaned, but the demands of management and the needs of the animal may conflict. Concrete floors, although durable and easily cleaned, are hard and abrasive. Perforated floors, designed to improve hygiene and save labor, are available in a variety of forms but are not suitable for farrowing pens. In any farrowing system, cleanliness is very important. When the sow is confined in a farrowing crate, she cannot maintain separate dunging and lying areas as she would if more space were available. Therefore she requires a floor that drains well and allows frequent manure removal. On the other hand, the piglets have a different requirement for voiding feces and urine. The incidence of knee and teat damage in suckling piglets varies widely among different floor types. Morbidity, mortality, and external injuries are greater in piglets housed in farrowing crates with a partly metal-slatted floor than on a solid floor with straw bedding (Vellenga et al, 1985). This association extends into the rearing period of the weaned piglets, in which morbidity, mortality, and external injuries were greater in piglets reared in the slatted-floor system.

The effects of the types of farrowing-crate floors on health and productivity of piglets and sows have been examined. The preweaning growth rate of piglets kept on raised, perforated floors was higher than that of piglets kept on mostly solid floors, but there were no differences among the different perforated-floor types studied. It is suggested that there is less heat loss in piglets raised on perforated floors than in those raised on concrete floors, and the perforations allow the liquid to drain; therefore the piglets are drier. The best floor for piglets may be a plastic-covered woven wire, which provides grip but is not abrasive. Injuries to the teats and knees of piglets occur more frequently on old cement or punched metal floors. On the other hand, the incidence of leg abrasions and teat injuries of sows may be greater on fully-perforated, plastic-covered floors, which may be slippery compared with different types of solid floors. Floors of plastic-covered expanded metal or concrete floors with concrete slats at the rear cause sows to move their hind feet a shorter distance and to make fewer foot movements while rising than did floors of fiberglass or perforated metal slats.

Comparison of Loose and Confined Housing. The health and welfare of pregnant sows in loose housing and confined housing systems in Norway have been compared. Vulval lesions were found in sows in loose housing and were related to biting by other sows (Gjein and Larssen, 1995a). The mean proportion of sows with body lesions was 13.1% in the loose-housed sows and 4.0% in the confined sows. Aggression between sows was the main cause of lesions in the loose-housed sows; decubitus ulcers were the main body lesions in confined sows. Sows in loose herds that were not feed additional roughage feed were at greater risk of body lesions. Claw lesions are common in sows kept in loose housing and confinement (Gjein and Larssen, 1995b). The mean herd prevalence proportion of sows with major claw lesions in loose-housing herds with partly slatted floors was about twice as high as in the herds with confined herds. The prevalence of claw lesions was lowest in sows kept in loose housing with deep straw litter (Gjein and Larssen, 1995c). The risk of lameness increased with higher claw lesion score and with the presence of claw infections (Gjein and Larssen, 1995d).

Decubitus Ulcers in Farrowing Gilts and Sows. Decubital ulcers commonly develop over bony prominences of the scapula, hip, mandible, tarsus, cubital joints (elbows), and carpus in sows housed on concrete and other hard floors. A high incidence occurs around the time of farrowing and early lactation, followed by rapid healing after weaning. It is considered a multifactorial disease and risk factors include floor type, moist skin from drip coolers, uninterrupted recumbency during parturition, reduced activity during lactation, and body condition (Davies et al, 1997). Factors such as floor type are important, but other physiological and behavioral factors of periparturient sows (e.g., body weight, body condition, and mobility of late-gestation sows; duration of farrowing; and patterns of recumbency) may be important. Ulcers on the shoulders occurred at the rate of 16% by Day 5 after farrowing; a peak incidence of 48% occurred by Day 12, and all ulcers had resolved by Day 68. The primary cause is unrelieved pressure or shearing forces that cause ischemia of the skin and subcutaneous tissues. Bony prominences with minimal soft-tissue covering are at greatest risk, because they have a high compressive stiffness to deforming loads. The lesions are transient, but the high prevalence may be an animal welfare concern. More field research including controlled studies of various floors is required.

Space Requirements for Gilts and Sows in Crates. The space necessary to allow a sow to stand up and lie down without touching the crate has been estimated (Curtis et al, 1989). The hypothetical 95th-percentile, 250-kg, North

American sow would require a crate approximately 220 cm long and 86 cm wide.

In the ideal farrowing crate, the sow should be able to stand up with ease, lie down without touching the crate, nurse her piglets comfortably, and be able to move away if she is squeezing a piglet; the floor should be self-cleaning or easily cleaned; the creep area should be attractive to and comfortable for the piglets, and the feeders and waterers for the sow should be easily accessible. The crate should allow the sow to perform prelying rooting and pawing behavior and to get any piglets in the danger zone awake and active before she lies down. The crate should also assist the sow in lying down under control and with a minimum of slipping. The dimensions of the crate should be easily adjustable for width, length, and height. The lower bars, which accommodate the sow when she is lying down and provide access of the sow's udder to the piglets, may be vertical, horizontal, or bowed (Curtis et al, 1989). Comparisons of different designs indicate that no one crate design combination is better in all respects than all others, but relatively small design differences can affect the health and performance of the animals. Raising the lower straight bar from 20 to 25 cm above the floor decreased knee lesions at 21 days after birth and increased piglet weight.

The slope of the sides of the farrowing crate has been examined. In the straight-rail crate the sides are spaced equally at the top and bottom. In the flared-rail crate the sides are narrow above and wider below. The finger crate has four straight horizontal bars spaced equally apart, with six prongs attached to the lowest bar and angled away from the sow, which allows the sow to lie down comfortably and provides good access of the piglets to the udder. In the Ottawa crate the sides are spaced well apart at the sow's standing height but are angled inward near the floor to restrict the sow's lying area and to prevent the sow from dropping suddenly onto one side.

Edinburgh Family Pens. The Edinburgh Family Pen System of Pig Production is an alternative system of pig production designed around the behavior and welfare of the pig (Kerr et al, 1988). The Family Pen System arose from the interpretation of observations made on a group of sows kept in 1.23-ha area of hill land, which involved detailed study of the animals to establish their behavior in a natural habitat. These studies identified those physical and social factors of the pig's environment that were judged important for social organization. Each unit was made up of four sows and their offspring housed in four pens, each of which comprised a nest area, activity area, peat area, and connecting feces corridors. The sows remain in the unit with a stable group composition for the whole of their breeding life. A familiar mature boar joins the group 2 to 3 weeks after farrowing. The sows suckle their piglets for 10 to 12 weeks. Estrus invariably occurs during lactation, and sows are successfully mated during lactation. Growing pigs remained in the unit with their dams until they reached slaughter weight, at which time they were sent directly from their pens to slaughter.

Outdoor Pig Production. The number of outdoor sow herds has increased significantly in the last decade in the United Kingdom, France, and Denmark (Mortensen et al, 1994). Productivity in outdoor systems is much more dependent on the climate than indoor production systems. This requires adjustment of management procedures to meet changing weather conditions. In Denmark the same average productivity can be achieved in outdoor sow herds as in indoor herds, although performance variation is greater in outdoor herds. In the most successful herds production performance was similar to that of the best indoor sow herds. The results indicate that outdoor production comprising gestation and lactation until weaning at 4 weeks is a realistic alternative to indoor production. Capital costs are approximately one third of that of indoor production.

Culling of Gilts and Sows

Culling Rates. The removal or culling of nonproductive sows and gilts and the introduction of replacement gilts are essential parts of maintaining herd productivity at a constant, high level. The reasons for culling sows and the rate of culling may be influenced by many factors, such as housing, genotype, management policies, time of year, disease, nutrition, market trends, and tax policies. Average annual culling rates range from 30% to 50%, with a high degree of variability among farms (D'Allaire et al, 1987). In many herds the culling rate has been suggested to be too high, causing an increased proportion of gilts in the breeding herd and therefore causing a lower-than-optimum mean litter size. In an Ontario study of 30 farrow-to-finish herds over a 2-year period, the culling rate of sows was high at 44%, with a wide herd-to-herd variation from 16% to 100%. Surveys have found that 50% to 67% of culled sows have had three or fewer litters before being culled; this indicates that many sows are removed before reaching maximum productivity, which occurs between the third and sixth parities. Conversely, herds with low culling rates may contain sows that have passed their most productive parities. Such herds may have a lower-than-optimum mean litter size and a high stillbirth rate.

The culling rate is a statistic that is often used and misused. The culling rate is defined as the number of sows shipped per year divided by the average number of bred gilts and sows in the herds. There is a need to carefully examine the reasons for culling and the year-to-year variation in culling rates (Christensen, 1997).

One of the aims in maintaining a sow herd should be to produce as many litters as possible between the second to fifth litters of a sow. These are the most productive litters, and they make the best use of farrowing facilities. Older sows tend to have large litter size but an increased number of stillbirths, more preweaning mortality, and lower weaning weights. In most herds the economically effective time to cull most sows is after they have had six litters, and only those sows that have had superlative litters should continue in the herd.

Nonetheless, many sows are culled before their sixth litter because of various problems such as infertility, poor legs, and poor mothering ability. These either increase the culling rate or force the producer to keep other sows above their sixth parity. Both these practices are counter-productive in providing sows to the farm in their most productive parities (Lucia, 1999; Lucia et al, 2000).

In herds with a high percentage of sows above the sixth parity, the culling rate may quickly be as high as 70% to 80%. This is counterproductive because high numbers of gilts' entering the farrowing room at the same time tends to increase problems with diseases such as preweaning diarrhea and pneumonia. It is much better to keep a consistent number of gilts going into the herd from year to year.

Evaluation of a culling program should include determination of the annual culling rate, average parity of females at culling, reasons for culling, and the interval from weaning or farrowing to culling (D'Allaire et al, 1987). The annual culling rate is defined as the number of females removed from the herd during the year divided by the average female inventory and multiplied by 100. The culling rate should include deaths, but they can be analyzed separately. A target annual culling rate of 39% (36% culling and 3% deaths) has been suggested. Comparisons of annual culling rates among

herds must take into account the inventory of gilts and sows. Gilts may be introduced into the inventory at different stages of their production cycle, which will have an effect on the culling rate if they are culled before or after they are bred. The culling rate is also influenced by other circumstances, such as a change in inventory, a change in culling policies, and the average length of lactation in the herd. There may be a sudden increase in culling rate if the producer suddenly realizes that the average age of the herd is increasing and begins to cull extensively in 1 year compared with a previous year. In the following year the culling rate may be down because a large proportion of the females are young. The average length of lactation for the herd may also influence the annual culling rate. Herds with short lactation periods tend to have a higher annual culling rate. This may be related to the increased probability of culling during each farrow-to-farrow interval; more farrowings per year lead to a higher annual probability of being culled.

Parity at Culling. Determination of the mean parity of sows at culling is the second step in evaluating the culling program. The average parity at culling varies from 2 to 4, but it can range from 2 to 8. Because the mean value can be influenced by extreme values, a parity distribution of culled sows is usually more informative.

Sows are culled when they are considered unsuitable for further production (D'Allaire et al, 1987). The reasons for culling can assist in identifying subclinical diseases or inadequacies in management. The most common reasons for culling, in order from highest to lowest frequency, are reproductive failure, old age, inadequate performance, locomotor disorders, and death and milking problems. In Denmark the likely causes of culling are leg weakness, problems related to farrowing and late pregnancy, disorders of the digestive system, disorders of the urinary system, and physical injuries. It has been mentioned that the proportion of disorders involving the gastrointestinal system has increased during the past 20 years (Christensen, 1997). Culling reasons can be analyzed according to two different rates: (1) the proportion of removals attributable to a specific reason (e.g., proportionate rate), and (2) a reason-specific annual culling rate. The proportionate rate is useful to indicate the relative importance of a given reason as part of total culling, and it helps in determining priorities for improvement in the herd. The reason-specific annual culling rate measures the risk of a sow being culled for that specific reason and indicates the extent of the problem. This is a more informative statistic, and it is not influenced by the number of sows culled for other reasons, as is the proportionate rate. Reason-specific annual culling rate is defined as the number of sows culled for a specific reason divided by the average female inventory.

Reasons for Culling. An investigation of culling patterns in 89 Minnesota swine breeding herds included 5918 sows and 1324 gilts for a total of 7242 culled females over a period of 12 consecutive months (D'Allaire et al, 1987). The definitions of the nine reasons for culling were as follows: reproductive failure included no observed puberty in gilts, no postweaning estrus, regular and irregular returns to estrus, negative pregnancy diagnosis, failure to farrow, and abortion. Inadequate performance included low numbers of pigs born alive or weaned, uneven litter, low piglet birth or weaning weight, and high preweaning mortality. Old age was a relative term and not defined clearly. Some producers culled sows as soon as the sixth or seventh parity and others only at the tenth. Locomotor problems included unsoundness, lameness, injury, abscess, downer-sow syndrome, and musculoskeletal disease. Death referred to an animal that died or was euthanized for humane reasons. Peripartum problems included dystocia; dead litter; metritis; prolapse of the vagina, uterus, or rectum; mastitis; and agalactia. Other diseases included those of all other body systems not included previously. Miscellaneous problems included the thin-sow syndrome, abnormal behavior, growth rate and carcass performance of market-pig progeny, abnormal piglets, market conditions, and no reasons. Transfer referred to an animal taken from the breeding herd and sold, leased, loaned, or given to another producer for breeding purposes.

Reproductive failure was the main reason for culling, varying from 20% to 50% of all removals. Failure to conceive accounted for 75% of all females culled for reproductive failure—80% for sows and 65% for gilts. Proportionally, culling as a result of anestrus was higher in gilts, accounting for 33% of all gilts culled for reproductive failure, which is twice as much as in sows. Culling for abortion accounted for only 4% of all those culled for reproductive failure. Inadequate performance accounted for 17% of all removals, and 70% of these sows had more than four litters. Old age accounted for 14% of all culls; the average age of these sows was 7.11 years. Death accounted for 12% of all removals and was the fourth most common reason for removal. Causes of death included the downer-sow syndrome, peripartum problems, difficult farrowings and prolapses, injuries, and various diseases. Locomotor diseases accounted for 9% of all removals. Peripartum diseases accounted for 7% of all removals. In general, the annual culling rate in these 89 herds was high, averaging 49%. The breeding life expectancy of sows was low at only 3.77 litters. The reasons for removal varied considerably among herds and among parities. Reproductive failure was of major importance, which indicates a need for increased awareness of the reproductive state of each breeding female at all times during the production cycle.

Lesions that could adversely affect production can be found in a large percentage of culled gilts and sows at slaughter. The prevalence of lesions of culled female swine at slaughter include foot lesions (59%), dermatitis (67%), and shoulder lesions (4.6%) (Ritter et al, 1999). Body condition scores were associated with the presence of dermatitis and shoulder lesions. Mean number of teats was 13.86 $\pm$ 0.02. Mean numbers of normal-appearing teats in the left and right rows were 6.57 $\pm$ 0.02 and 6.58 $\pm$ 0.02, respectively. Feet from 48% of the carcasses were condemned. Visceral lesions were present in 48.8% of the carcasses, of which 66% had liver spots and 43% had pneumonia. Knowledge of these lesions may assist in the health management programs in swine herds.

Environmental Factors and Culling. The relationships between management and environmental factors and annual sow culling rates in some swine herds have been examined (D'Allaire et al, 1989). With path-analysis techniques, only the type of flooring during gestation, the size of the herd, and the lactation length had a direct relationship with the annual culling rate. Producers' housing their sows in total confinement during gestation were most likely to keep them on partially or totally slatted floors, which were associated with a higher annual culling rate. Damaged slatted floors can increase foot and leg problems. Herds with an average weaning age of younger than 28 days were more likely to have a high annual culling rate. Sows kept in crates during the farrowing period were more likely to have a short lactation length, which was associated with a higher annual culling rate.

The relationships between other management and environmental factors and the annual culling rate were the result of common-cause associations. These factors included having the sows individually identified; using a more comprehensive recording system, mainly a hand-mating system; testing regularly for pregnancy; and housing sows in total confinement during the breeding period. Herds with more than 150 sows were more likely to have a high culling rate,

which may be a reflection of the various culling policies and the fact that managers and producers of large herds expect more productivity and better reproductive performance than those of smaller herds.

Criteria for Culling. The culling policy used has a major economic influence on the herd. Knowing when to cull a gilt or a sow that will be nonproductive is a major asset in ensuring continued high reproductive performance in the herd. The economics of culling strategies in swine herds has been examined using computer modelling to quantify the benefits of increased life span in herds and to optimize the decision to replace sows with poor reproductive and production performance (Dijkhuizen et al, 1986). The PorkCHOP computer program uses an index, known as the retention pay-off, that indicates the total extra profit that retention of a sow is expected to yield over her replacement, taking into account the risk of premature disposal. The index makes it possible to rank sows within the herd on potential future profitability and to know when to stop breeding if sows fail to conceive. The parity-specific default values that were used are considered typical of U.S. herds with continuous farrowing and standard management practices. They are as follows: an economic optimum herd life of 10 parities for average producing sows; an increase in income if the average parity at removal could be increased from 3.6 to 4.6; a significant financial loss per day of delay in conception; first-parity sows with a litter size of even 50% below average should not be culled on economic grounds; and average producing sows in the first, second, and third parity can fail to conceive at least three times before replacement becomes the more profitable alternative (Dijkhuizen et al, 1986). A comparison of the farmer's actual culling decisions and the computer model recommendations indicated that culling of older, poorly producing sows directly after weaning was the right decision economically. However, sows showing no heat were culled too early after weaning, and sows that failed to conceive were culled too late, from an economic standpoint (Dijkhuizen, 1989). Computer programs can now be used to assist producers in making economic culling decisions. It is expected that the computer will be of assistance to producers in making economic culling decisions.

Most purposeful culling occurs in sows from 3 and 5 years of age, when litter size begins to decline. Some criteria for culling include the following:

- Persistent anestrus in gilts older than 9 months of age. In some studies, up to 66% of gilts older than 9 months of age were culled for this reason.
- Persistent anestrus in sows lasting for more than 30 days after weaning.
- Failure to conceive after two successive matings.
- Chronic illness of any kind in which there is loss of appetite, persistent lameness, loss of body weight, and failure to respond to treatment.

CONTROL OF DISEASES OF THE PIGLET FROM BIRTH TO WEANING

An increase in the number of pigs produced per sow per year is a major means of improving efficiency of sow productivity. The number of pigs weaned per sow per year is a function of the number of piglets born alive and the number that survive to successful weaning. Preweaning mortality varies from 5% to 50%; in those herds with high levels of survivability, the producers are usually applying the principles of good management.

The basic requirements of the newborn piglet to ensure its survival and sound healthy growth are simple and well defined. Because both the number of pigs per litter in excess of sow nursing capacity and the occurrence of 15% to 20% of pigs with birth weights less than that needed for high percentage survival are common, management practices capable of supporting such piglets during the early postnatal period until weaning of the litter are essential. As the number of piglets born per litter increases, there is also an increase in the number of pigs that cannot be cared for well enough by the sow to ensure a concurrent increase in the number of piglets weaned per litter. By 3 or 4 days after delivery, each pig has selected a teat that it nurses exclusively, and therefore the maximum number of piglets reared by a sow is limited to the number of functional teats.

The factors that influence the number of pigs born alive, the number that survive to weaning, and their individual rate of gain include the process of parturition, the weight and vigor of the piglet at birth, the size of the litter, the parity of the sow, the lactation yield of the sow, the degree of warmth and comfort provided at birth, the adequacy of colostrum and milk, and the physical surroundings.

Birth weights within litters vary from less than 0.5 kg to more than 2.0 kg. Compared with heavier litter mates, low-birth-weight pigs often are born later in the birth order, take longer to first suck, and ingest smaller amounts of colostrum and milk. They are at a physical disadvantage in postnatal competition for available teats and frequently fail to achieve a regular and adequate suck. In addition, a greater surface area–to–body weight ratio combined with poor thermoregulatory control causes more rapid decreases in body temperature and, consequently, an increased risk of chilling, overlaying, and secondary infection. A strong positive correlation exists between birth weight, vigor, and neonatal survival. Under field conditions, preweaning survival rates of 25% to 45% are common in neonatal pigs weighing less than 907 g at birth. On the other hand, if low-birth-weight pigs are reared under optimum conditions, high survival rates are possible. In some surveys, birth weight was the most important determinant of a neonatal piglet's chance of survival (Gardner et al, 1989). Increases in birth weight category were associated with increasing odds of 7- and 21-day survival, with maximum survival obtained in the highest birth weight group, which consisted of pigs weighing more than 2 kg. Compared with piglets weighing less than 601 g at birth, for piglets weighing more than 2 kg at birth the odds ratio of survival was 349 (Gardner et al, 1989). In one large intensive piggery, of 238 litters born, 62% of all pigs with a birth weight of less than 800 g failed to reach weaning age. During the first few postnatal days, competition for nursing position is considerable, causing dissipation of energy and failure of adequate colostral and milk intake by many smaller pigs. In addition, average daily gain per piglet is highly variable among litters in the first and, to a lesser extent, the second week after birth, depending on the milk yield of the sow (Thompson and Fraser, 1988).

The sow is generally receptive to piglets other than her own, and she can, up to the limit of the number of functional teats, be used as a foster dam concurrently with or instead of nursing her natural litter. This attribute, to some extent, can adjust the inequity of number of piglets and number of functional teats, enhance the nutritional status and survivability of neonatal pigs, and increase sow efficiency. Early identification of litters with low initial gains might allow remedial action to be taken to reduce the problems of high mortality and low, variable gains later in lactation.

There is a 48-hour period in a pig's life when its odds of dying are up to one in three on some farms. It is the 48 hours after a sow begins to farrow a litter. Stillbirths and mortality during the first 2 days after farrowing can be added to create a rarely used statistic called *perinatal mortality* (PM).

Often PM can approach the one in three pigs born and, conversely, can be below 12%.

Infectious diseases are not usually a major contributor to perinatal mortality. Diseases caused by *E. coli* are usually controlled using sanitation and vaccines. A few diseases, such as pseudorabies and PRRS, may cause explosions of perinatal mortality, but rarely are their effects continuous.

There is often a sense of fatalism toward stillbirths and early mortality, with the attitude that "they were going to die anyway." This is usually not true, and although the solution is often not in a bottle of medication, there are distinct changes that can be made. The risk factors associated with high herds experiencing high perinatal mortality rates include the following:

- *Older sows.* In many genotypes, perinatal mortality may be higher in piglets born from sows in their fifth or greater parity. A common error is that sows are replaced one parity too late, when problems occur, rather than earlier, since perinatal mortality is usually predictable in older sows. An alternative strategy is to plan and schedule earlier replacement of stock, ensuring good replacement gilts are available.
- *Body condition of sows.* Fat sows have more problems in farrowing and lactation, leading to a higher incidence of perinatal mortality in their litters. Veterinarians can assist producers in monitoring the body condition scores and nutritional needs of pregnant sows.
- *Ambient temperature in farrowing crate.* Newborn piglets are quickly affected by chilling at birth. Lightweight piglets are susceptible to chilling and are often the "runts" that are found moribund in the corner of the farrowing crate in the morning. Chilling is prevented by using extra heat sources in the farrowing crate. One common method is to place two heat lamps on either side at the rear of the crate when the sow is farrowing unattended.
- *Care of newborn piglets.* Perinatal mortality rates can be reduced by taking the time to attend to details such as aiding in farrowing, removing fetal membranes from the noses of piglets, placing piglets near a teat, and cross-fostering. This demands either a large amount of time or the use of induced farrowing, which helps to synchronize and schedule farrowings so that assistance at farrowing can be provided.
- *Colostral intake.* If there are outbreaks of systemic infections such as coliform septicemic, there is a need to reexamine the handling of piglets at birth to ensure immunological competence. It is often useful to ensure colostral intake by manually extracting colostrum and feeding it to the piglets.
- *Infectious disease control.* Herds with inadequate attention to an AIAO farrowing cycle, inadequate sanitation and cleaning and washing of farrowing crates between sows have a higher incidence of acute infectious diarrhea in the piglets.

Magnitude and Causes of Preweaning Morbidity and Mortality

Morbidity and Mortality Data

On a worldwide basis preweaning losses range from 15% to 25% of piglets born alive.

More than 50% of preweaning losses occur during the perinatal period from birth to 3 days of age. The perinatal mortality rate is influenced by litter size, the age of the sow, the type of confinement of the pregnant sows, and the degree to which the farrowing is attended.

The NAHMS National Swine Survey in 1990 found that the most common cause of preweaning morbidity was acute undifferentiated diarrhea (42%) most of which occurred during the first 3 days of life (Tubbs et al, 1993). Management factors are responsible for the majority of preweaning piglet morbidity and mortality in the United States. The most common causes of mortality were trauma (43%), starvation (20%), unknown causes (13%), and diarrhea (10.8%).

A survey of perinatal mortality in 48 North American swine herds found that 6.8% of piglets were stillborn (Vaillancourt et al, 1994). Of piglets born alive, 3.9% died within 24 hours of birth. The highest perinatal mortality rates occurred in very small litters (less than 4 piglets) and very large litters (more than 17 piglets). Perinatal deaths increased as parity increased. The highest mortality percentage was recorded on Monday, which may be due to the recording of Sunday deaths on Monday. Over half of all perinatal mortality (51%) was attributed to only 13.2% of the litters, which supports earlier observations that 75% of all stillbirths occurred in only 25% of litters. It has also been observed that over 50% of stillborn piglets are from litters that had two or more stillborn piglets.

Risk Factors

The association between preweaning mortality and various facility factors was examined as part of a NAHMS survey (Yeske et al, 1994). Significant associations were found between preweaning mortality and flooring type, heat source, water delivery system, cleaning frequency, cleaning method, and duration of idle time between farrowing groups. Concrete floors are associated with an increased morbidity and mortality from diarrhea; wire floors are superior. A creep heat source such as heat lamps or radiant heat is considered better than under-floor heating. Longer idle times between farrowing and the cleaning of the farrowing area after every farrowing is recommended. In a survey of the management variables associated with reduced preweaning piglet mortality, those that reduce the exposure of suckling piglets to the pathogens of older pigs or previous occupants of the farrowing facilities were considered most effective (Bowman et al, 1996). In the same survey, there was no significant reduction in preweaning mortality associated with prefarrowing vaccination and the use of anthelmintics or insecticides, supplemental milk, or iron.

Causes of Mortality

The losses caused by crushing of the piglet by the dam and other fatal traumatic lesions constitute the largest mortality group among live-born pigs in most herds and contribute significantly to noninfectious losses. An average of 5% to 6% of live-born pigs die from traumatic injuries (Svendsen et al, 1986). Mortality caused by traumatic injuries varies greatly from herd to herd, and it is apparent that these losses are related to a large extent to housing systems and husbandry routines. During a 5-year study of the preweaning mortality in a Swedish Landrace herd of 100 sows, the distribution of deaths according to age was as follows: antepartum (14%), intrapartum (16%), day of birth (16%), Day 1 (15%), Day 2 (13%), Days 3 through 6 (12%), and Days 7 through 34 (14%). The causes of death and their percentages were as follows: antepartum (14%), intrapartum (16%), traumatized (22%), weak and undersized (11%); splayleg and splayweak (12%), starvation (4%), malformations and miscellaneous causes (6%), and infectious diseases (15%). Most traumatic injuries and risk situations, irrespective of the type of farrowing accommodation, occur within the first 24 to 36 hours after birth. Most traumatic injuries occur when the sow moves when standing up or lying down and when standing or walking. Most of these injuries are caused by the hindquarters and the hindlegs of the sow; therefore

30% of all traumatic injuries occur around the sow-feeding times in the morning and afternoon.

Starvation, crushing by the sow, and *stillbirths* were the three main causes of preweaning mortality in a Canadian study of 2388 piglets born over the second to fourth parity in 124 Yorkshire and 109 Yorkshire-by-Lacombe sow litters. The failure of piglets to obtain an adequate milk supply within a few days of birth, either as a result of agalactia or competition with larger and stronger piglets in the litter, was the primary factor contributing to piglet death and may account for in excess of 85% of the losses (Dyck and Swierstra, 1987). These losses can be minimized by cross-fostering of piglets shortly after parturition to equalize litter size and to reduce variation in piglet weight within the cross-fostered litter, or by artificial rearing of ill-thriving piglets and piglets from litters whose sow dies. Such practices can increase piglet survival to 95% of the piglets born alive. In a study of preweaning mortality in Ontario farrow-finish pig farms, stockmanship was an important modifier of environmental effects that were associated with mortality.

Information on neonatal piglet mortality in the United Kingdom reveals that the majority of losses occur by the end of the second day after birth. Mortality increased as litter size and the age of the sow increased and as birth weight decreased. In one study, five groups of primary factors were found to contribute to 88% of the deaths of 236 live-born piglets from one herd.

An analysis of piglet morality in a breeding herd kept outdoors in the United Kingdom found that, during a period of 8 months, the majority of deaths (72%) had occurred by the time the litter was first inspected, 27% of these piglets had uninflated lungs, and 53% of the piglets born alive had no food in their stomachs (Edwards et al, 1994). Of the stillborn pigs 17% were of Type I (events before birth) and 83% were of Type II (events after birth). At all ages crushing was the most common cause of death (72%) of liveborn piglets.

The timing and causes of piglet mortality have been examined in alternative and conventional farrowing systems (Marchant et al, 2000). In communal farrowing pens, sows were allowed to move freely and in the conventional crates they were restricted. More piglets were weaned from the conventional crates than from the open systems and the piglets grew more quickly. In the two open systems, 17% and 14% of the piglets born alive were crushed, compared with only 8% in the crates. Monitoring of sows and litters in detail in a communal pen system found that during the first 7 days, 75% of the liveborn mortality was due to crushing. The total of piglets dying per litter, including stillbirths, was significantly associated with the total litter size and the sow's parity. The percentage liveborn mortality was significantly associated with the parity and body length of the sows and with the within-litter variation in the birth weight of the piglets. Individual birth weight was closely associated with percentage survival. Only 28% of piglets weighing less than 1.1 kg at birth survived to 7 days of age. The alternative systems used in the experiments may have enabled the sow to express a greater range of maternal behavior, but only to the severe detriment of the welfare of the piglets. Piglet mortality was much higher than in conventional farrowing crates, and crushing in the open system was a major problem.

Infectious Diarrheas. The infectious diarrheas of newborn piglets are among the most common causes of preweaning mortality with mean incidence rates varying up to 50% (Svensmark et al, 1989a,b,c,d). However, the incidence of preweaning diarrhea in piglets continues to decrease. Some of this decrease is a result of recording criteria, but management factors have a major influence. Large, intensively managed herds now have a high level of hygiene, and the entire production system is under close, continuous control, including the use of supplemental iron and vaccination, especially for *E. coli* (Dewey et al, 1995c). The factors that affect the incidence of diarrhea in nursing piglets include the parity of the sow, the occurrence of the MMA complex in the sow, the litter size, the herd size, and the gilt proportion in the herd. In Danish swine herds, in addition to the diarrheas caused by enterotoxigenic *E. coli* and *Isospora suis,* rotavirus is considered to be a significant cause of diarrhea in piglets from 3 to 5 weeks of age. The type of mild diarrhea in 3-week old pigs known as steatorrhea or white scours may be associated with rotavirus infection, possibly in combination with *E. coli* and other agents (Svensmark et al, 1989c). In addition, litters that shed rotavirus during the suckling period had lower weight gains and higher incidence rates of respiratory diseases than virus-free litters. It is also suggested that piglets should not be weaned before either 3 weeks of age or a body weight of 6 to 7 kg has been reached.

During the first 3 days of life, enterotoxigenic *E. coli* is the most common causative agent associated with diarrhea in piglets. From 4 to 14 days of age, piglet diarrhea may be associated with various enteric pathogens. The common ones are the TGE virus, *I. suis,* and *C. perfringens* type C. Less common ones include other porcine coronaviruses, strongyloides, and, rarely, *Serpulina hyodysenteriae.*

The herd and litter level factors associated with morbidity and mortality resulting from diarrhea in piglets 1 to 3 days of age was examined in 29,843 litters from 708 herds monitored for production (Wittum et al, 1995). The average rate of diarrhea morbidity among 1- to 3-day-old piglets was approximately one new case/day in a herd with an inventory of 100 piglets. Diarrhea mortality averaged approximately one death every 10 days for the same size of herd. Both diarrhea morbidity and mortality were lower in herds that vaccinated sows against *E. coli.* The risk of diarrhea morbidity and mortality was higher among litters in which the sow experienced health problems within 3 days of farrowing. This suggests that the use of *E. coli* vaccines, along with careful observation of the postpartum sow for evidence of clinical disease, crossfostering piglets, and appropriate treatment, might reduce the occurrence of diarrhea in piglets from 1 to 3 days of age.

The herd and litter level factors associated with the morbidity and mortality resulting from diarrhea in piglets 4 to 14 days of age were examined in 29,843 litters from 708 herds (Dewey et al, 1995c). Diarrhea increased with herd size, sow health problems, deworming sows in the farrowing crate, and routine use of supplemental milk for piglets. Diarrhea decreased with AIAO farrowing rooms, washing of sows, TGE-free herd status, and vaccination of sows against *E. coli.* Diarrhea mortality increased with litter size, sow health problems, fostering of piglets at 4 to 14 days of age, and sow mange-lice treatment while in the farrowing crate. Diarrhea mortality decreased with fostering of piglets out of the litter at 1 to 3 days of age, use of supplemental iron, use of a hired manager in the farrowing facility, and *E. coli* vaccination. The factors not associated with diarrhea morbidity and mortality included vaccination of piglets, clipping of teeth, docking of tails, antibiotics fed to the sow, farrowing problems, operation type, supplemental creep feed, vaccination of sows against TGE or rotavirus, treatment of navels, facility type, and use of a consultant such as a veterinarian, nutritionist, or extension agent. Vaccination of sows for *E. coli* and fostering of piglets off sick sows are expected to decrease preweaning losses resulting from diarrhea in 4- to 14-day-old pigs.

Vaccination of pregnant sows against enterotoxigenic *E. coli* is effective in reducing morbidity and mortality resulting

from diarrhea in neonatal piglets (Wittum and Dewey, 1996). A partial budget analysis of vaccination of sows found that the swine producer who does not currently vaccinate sows against *E. coli* could expect to generate $5.51/sow in additional yearly profits by implementing a vaccination program. Losses attributable to piglet diarrhea would be reduced by nearly $10/sow/year. Investment in a sow *E. coli* vaccination program would expect to result in a 124% return on investment. Threshold analysis found that herd with diarrhea morbidity and mortality rates in 1- to 14-day-old piglets of at least 3.5% and 0.8%, respectively, could expect returns adequate to justify investment.

Hemorrhagic necrotic enteritis in piglets is caused by *C. perfringens* types C and A; although type C is most common (Songer and Glock, 1998). Type C infections can usually be controlled by vaccinating sows with a toxoid. The organism is susceptible to antibiotics, and prophylaxis of type C infections has been achieved by the use of feed grade bacitracin at 250 g/ton of feed, from 2 weeks prefarrowing and followed through lactation.

TGE in nursing pigs is characterized by high morbidity and mortality resulting from diarrhea. Clinical management of outbreaks requires implementation of a strict AIAO movement of pigs (especially in the nursery rooms), enhancing the immunity of pregnant animals by vaccination, improving the cleaning and washing activities of the farrowing and nursery rooms, and considering a partial depopulation protocol (Carpenter and Templeton, 1996). In Britain, serological evidence suggests that infection is widespread (Pritchard et al, 1999).

Porcine epidemic diarrhea is caused by a coronavirus CV777. Porcine epidemic diarrhea type I causes diarrhea and anorexia in adult pigs, and porcine epidemic diarrhea type II causes diarrhea in unweaned pigs (Pritchard et al, 1999). Herd outbreaks of porcine epidemic diarrhea can occur in finishing pigs and the disease is clinically indistinguishable from TGE.

Coccidiosis in nursing piglets is caused by *I. suis* and is characterized by a non-hemorrhagic diarrhea with low mortality. Experimentally, piglets inoculated with *I. suis* at 3 days of age develop more severe clinical disease than do older piglets (Koudela and Kucerova, 1999). Control depends on improved sanitation and chemotherapy with coccidiostats.

Staphylococcus hyicus (greasy pig disease, exudative epidermitis) is a bacterial infection of newborn piglets under 1 week of age that enters through skin wound, causing necrosis and exudation of serum. The skin becomes reddened then thickened, then brown with serum exudate, and finally brown and crusty. Death can occur within 2 to 3 days, but most affected pigs just have reduced growth rates. Prevention is through control of initiating factors. Treatment is by injectable antibiotics (most are efficacious) or by topical treatment with a mild disinfectant.

Control of Preweaning Mortality

Colostrum and Colostral Immunoglobulins

The newborn piglet requires an adequate intake of colostrum within a few hours after birth, a continued daily intake of milk, a warm environment of 30° to 34° C for at least the first 3 days of life, and protection from traumatic injuries such as crushing by the sow. Every economical effort must be made during the first 3 days of life to provide an optimum environment that will minimize crushing, chilling, starvation, and infectious disease.

The acquisition of an adequate level of colostral immunoglobulins is of vital importance. Some surveys indicate that piglets that fail to survive absorb only 10% to 50% as much immunoglobulin in the first 12 hours after birth as their age-matched surviving controls. Several factors can affect the levels of serum immunoglobulins achieved in the newborn piglet by 24 to 48 hours after birth. The concentration of immunoglobulins in the colostrum may vary from one sow to another by a factor of 10. The parity of the sow, the kind of feed used, the type of farming, the number of sows raised on the farm, and the level of management may affect the concentration of immunoglobulins in the colostrum of the sow.

Any factor that interferes with the movement of the piglet from its birthplace to the mammary gland will affect the time when the animal begins to suck colostrum and the amount that it ingests. The feet of the piglet may become stuck in a perforated floor in which the holes are too large, or solid floors may be too slippery and the piglet may become crushed by movements of the sow. The sow may refuse to allow the piglets to suck because of sow hysteria, agalactia, or other illness. Generalized weakness of the piglet may not allow it to compete successfully for a nipple during sucking. Exposure to cold may affect the amount of colostrum ingested by newborn piglets. Piglets are kept at an ambient temperature of 18° to 20° C.

The behavior of the sow and the piglets affects the amount of colostrum the piglets consume. The way the sow exposes her udder, the competition at the udder (especially in litters with large variation in birth weight), and the development of synchronized behavior in the piglets and in sow vocalization are all important features (Castren et al, 1989; De Passille and Rushen, 1989). The strategies of teat-seeking behavior of neonatal piglets and directing the teat-seeking behavior of piglets by farrowing crate design have been examined (Rohde and Gonyou, 1987; Parfet and Gonyou, 1990). Certain experimental designs of farrowing crates are being examined for their effectiveness in directing piglet movement and increasing the speed of movement from the posterior of the sow after birth to the udder.

The transfer of passive immunity to piglets from colostral immunoglobulins is essential to piglet survival in two ways: (1) during the first 24 hr of life, IgG and IgM, the major immunoglobulins of sow's colostrum, are absorbed directly from colostrum, providing systemic protection against infection, and (2) immunoglobulins in milk provide local protection (e.g., lactogenic immunity) in the small intestine until weaning. There are large individual animal variations in the concentrations of colostral immunoglobulins IgG, IgM, and IgA in the lacteal secretions of sows; most of these variations are associated with stage of lactation rather than any single physiological factor (Klobasa and Butler, 1987). Individual variation seems to be the largest influence. There is a rapid decrease in total Ig concentration during the first day after birth (e.g., 3.4%/hr), which means that it is possible that pigs born at the end of a prolonged parturition obtain colostrum with a lower Ig concentration at their first suck than that encountered by their earlier-born litter mates. However, this may only be a factor if pigs are born too weak to suck or are prevented from doing so by stronger pigs, because there is no difference in the serum concentration of maternal Ig between pigs sucking for the first time 4 hours after parturition than in those sucking immediately after birth. Much of the difference in IgG levels may result from differences between sows for colostrum produced at the time of farrowing. These sows may also have lower milk production. The behavior of the piglets can influence their IgG levels relative to those of litter mates. However, this effect is small; birth order, number of teats sucked, and the frequency of sucking bouts account for only a small proportion of the variation in IgG levels within litters. The changes in the concentrations of serum IgG, IgA, and IgM of sows throughout the reproductive cycle can be divided into four phases.

The major immunoglobulin component of sow milk is secretory immunoglobulin SIgA, which is synthesized locally within the mammary gland and forms a continuous defense, protecting the nursing piglet from disease caused by enteric pathogens (Salmon, 1989). This local protection provided by milk, in contrast to the systemic protection provided by colostrum, is called lactogenic immunity (Salmon, 1989). Most of the immunoglobulin in the milk of the sow is thought to originate from the immune system of the intestinal tract (Salmon, 1989).

There has been much interest in the routes of immunization of sows that will provide the optimum level of colostral and milk immunoglobulins for protection of piglets against the common systemic and enteric infections. The parenteral immunization of pregnant sows with diffusible antigens causes a systemic humoral immune response and the production of IgG and IgM. Stimulation of the immune system of the gut of young pigs will result in the production of intestinal IgA, which can protect weaned pigs from infectious enteric disease. In the sow, stimulation of the intestinal tract by oral vaccination will cause the production of both IgM and IgA. The IgA is transferred to the mammary gland and into the milk; this is known as the gut-mammary axis.

Preweaning Mortality Risk Factors

Several risk factors have been associated with preweaning piglet mortality.

Size of Litters. Large litters (e.g., over 12) are associated with undersized piglets, which are weak and more susceptible to crushing and starvation than heavier piglets. Mortality is usually higher in piglets born from sows that have had eight or more litters. Also, litters from large conventional herds or from herds with a high stocking density are expected to have a high risk of acquiring lameness in piglets. Mortality is also occasionally high in piglets born from gilts because of sow hysteria. There is also considerable variation in mortality rates between herds, which is probably a reflection of the level of management. The most significant variables associated with mortality are the use of AIAO pig flow in farrowing house and washing sows before farrowing. Other management variables that tended to reduce mortality are oxytocin injections, deworming, and vaccination for TGE, rotavirus, and erysipelas (Bowman et al, 1996).

Supervision at Farrowing. Because perinatal mortality (e.g., from birth to 3 days of age) accounts for approximately 60% of preweaning piglet mortality, the level of management and supervision at farrowing time and the quality and the environment of the facilities assume major importance. The frequency of stillbirths can be reduced by allowing sows in late pregnancy some daily exercise and by attendance at the time of farrowing to assist pigs that are hypoxemic and may be covered by placenta. Farrowing may be induced and synchronized to occur at a time during the day or week when maximum supervision is available. Piglets from large litters can be cross-fostered most successfully when done as soon after birth as possible to ensure one functional teat per piglet, thus securing sufficient colostrum for each suckling pig in the litter.

Infectious Disease Control. The common infectious diseases of newborn piglets can be controlled by a combination of batch-farrowing; regular cleaning and disinfection of the farrowing crates between sows; a closed-herd policy, which minimizes the introduction of infectious agents through carrier breeding stock; and vaccination of pregnant sows to stimulate the production of specific antibodies to transfer to the newborn through colostrum. The early recognition and treatment of postparturient diseases of the sow are also indicated to prevent the spread of infectious diseases to the piglets and to minimize starvation and hypoglycemia resulting from agalactia.

Drinking Water for Piglets. The provision of drinking water to newborn piglets is controversial. Piglets drink appreciable amounts of water on the first days after birth, especially if their milk intake is limited. Water use varies among litters, with an average of 46 ml/piglet over the first 4 days. It has been speculated that undernourished piglets, especially those housed in a warm environment, may be prone to dehydration in the first few days after farrowing. Water intake may help to prevent dehydration and to promote survival of piglets with low early milk intake.

Supplemental Heat for Piglets. An important environmental requirement of the piglet from birth to 3 days of age is supplemental heat to prevent chilling. This is usually provided most effectively and economically with heat lamps. The lower critical temperature of the newborn piglet is estimated to be about 34° C, and the highest proportion of piglet death loss as a result of chilling occurs during the first 72 hours after birth. In draft-free farrowing units with an ambient temperature of at least 21° C, the provision of supplemental heat beyond 3 days of age is usually not necessary. Supplemental heat from 3 to 21 days of age improves rate of gain compared with piglets with no supplemental heat, but it is not economically advantageous under ideal management conditions.

Low Birth Weight. The causes of low birth weight in piglets are difficult to identify retrospectively. It is not unusual to find litter mates differing by as much as 200% in body weight at birth. Possible influences on birth weight include maternal factors such as size of placental development in early gestation and the effect of nutrition on the sow during pregnancy. However, it is not yet possible to achieve uniformity in birth weight through feeding or by selection.

The most effective method to achieve uniformity in birth weight within litters is to batch-farrow and cross-foster piglets between simultaneously farrowed litters so that all the small piglets are allocated to one sow and the larger ones to another sow. Also, cross-fostering during the first few days of life is an effective method of accommodating the variation in rearing capacities of different sows. Rearing capacity is determined by the number of functional teats that are adequately exposed to the piglets in the crucial first days of life. Piglets in excess of the number of functional, exposed teats are transferred to sows with spare capacity. Cross-fostering should take place within 6 hours of farrowing for maximum benefit. Cross-fostering is used in 98% of commercial swine herds in the Midwestern United States and in Canada (Straw et al, 1998). Across all farms, a mean of 8.6% of piglets are cross-fostered.

Routine Procedures. Procedures that are performed routinely in piglets from birth to weaning at 3 weeks of age include clipping needle teeth after birth; docking tails at 2 to 3 days of age to prevent tail-biting; administration of iron dextran; castration at 3 to 5 days of age or at 10 to 14 days of age; providing creep-feed at 7 to 10 days of age, with increasing amounts up to weaning time; providing a water supply; and applying a method of identification of the litter or individual pigs. Castration performed at 3 days of age interferes with growth rate compared with castration at 10 days of age, but the difference is not significant at weaning (Kielly et al, 1999). Records should be kept of the birth date, the number of pigs born alive and dead, and the number of pigs that were treated and that died during the nursing period. If possible, necropsies should be done on each dead pig and the information recorded.

Farrowing Crate Design. As a result of the Swedish studies described in the "Causes of Mortality" section, a special unit for farrowing and neonatal pigs (the nursery unit) has evolved. Nursery units are constructed so that the stockperson has easy access to the piglets, and a local temperature close to the critical temperature of the newborn pig can be provided

(Svendsen et al, 1986). The unit has a room temperature of 22° C, and the sow, maintained in a farrowing crate, is kept on a totally perforated floor without straw bedding. The farrowing crates are clean and well insulated and have moveable heat lamps placed over the piglets parallel to the udder of the sow. The location of the heat lamps defines the location of the creep areas. This design minimizes the chances of piglets becoming chilled, which reduces the occurrence of traumatic injuries. This type of unit can be used with group farrowings, in which the sows are moved into the unit 2 to 3 days before farrowing and remain there for a period of no longer than 1 week after farrowing, at which time they can be moved to a more conventional type of accommodation.

The eliminative behavior of piglets should also be considered when designing the creep areas of farrowing crates. "Swine are probably the cleanest and most orderly of the farm animals when circumstances permit the expression of their normal patterns of elimination" (Whatson, 1985). Piglets do not eliminate where they sleep, nor do they lie where they eliminate. Neither the sow nor the siblings play a role in influencing where a piglet eliminates. Because there is no evidence that piglets have a preferred site of elimination but rather do not eliminate where they lie, it is not possible to predict where a piglet will eliminate based on where it last eliminated.

Prevention of Traumatic Injuries. The incidence of traumatic injuries to newborn piglets can be reduced by using farrowing crates designed to prevent the sow from lying down in one motion, and by the surveillance of sows to ensure that any evidence of sow hysteria, sow aggressiveness, and other illnesses of the farrowing sow are recognized and treated accordingly. Comparative behavior and production studies have shown that there are five main factors that are important for reducing losses resulting from traumatic injuries.

Fixation of the Sow. Farrowing crates require special design of the sides, which direct the movement of the sow when she lays down, and make possible the adjustment of the crate to the size of the sow and her litter. This type of rigid fixation is necessary for only the first few days after farrowing.

Flooring. The nature of the flooring should permit the sow to control the speed of her descent as she lays down and that provides a well-insulated, clean, comfortable, nonslippery surface for the piglet to reduce the occurrence of traumatic injuries. If straw bedding is used, the straw should be chopped into small pieces of about 1 in or less, so the piglets can easily push them out of the way when escaping from their dam.

Husbandry Routines. The litter from the area of the sow should be removed at sow feeding and dunging-out times during the first 2 to 3 days after farrowing. Group farrowing, which permits the adjustment of litter size and more intensive monitoring of the litters during the crucial 2 days after farrowing, contributes to a reduction in losses but will also increase the work of the attendants. Therefore the provision of a good working environment with low box walls and easy access to the sow and piglets is a necessity.

HEALTH MANAGEMENT AND PRODUCTION OF THE WEANED PIG

After weaning at 3 to 5 weeks of age and at 5 to 7 kg, the piglets are reared in groups in weaning or nursery pens until they are about 10 to 12 weeks of age weighing 20 to 25 kg. From the nursery pens they are moved into the growing and finishing pens. Major advances in the science of nutrition of the weaned pigs and our understanding of the pathogenesis of enteric disease of pigs have made it possible to wean pigs successfully and to control diseases such as postweaning diarrhea.

The weaning process and postweaning performance are the most critical events of a pig's life, secondary only to the problems associated with survival in the first few days of life. When pigs are weaned, they are stressed by the environmental, nutritional, and social changes to which they are exposed. Therefore every economical effort must be made to make the transition from the dam to the weaning pen as smooth as possible. This requires attention to the management of nutrition, housing, sanitation, and hygiene, as well as measurement of actual performance, including weight gain and feed efficiency.

The common diseases or causes of suboptimum performance that may cause high morbidity and significant economic loss within a few weeks after weaning are as follows:

- Postweaning multisystemic wasting syndrome *(Circovirus)* (Harding et al, 1998)
- Postweaning decrease in body weight gain, identified by postweaning check
- Coliform gastroenteritis, also known as postweaning *E. coli* diarrhea
- Postweaning diarrhea caused by porcine rotavirus
- Swine dysentery *(Brachspira hyodysenteriae)*
- Meningitis and septicemia caused by *S. suis* (MacInnes and Desrosiers, 1999)
- Ascariasis *(Ascaris suis)*
- Bacterial respiratory diseases:
  Bordetella bronchiseptica (rhinitis and pneumonia)
  P. multocida (pneumonia)
  M. hyopneumoniae (pneumonia)

Less common diseases that usually occur sporadically are as follows:

- Intestinal adenomatosis complex (*Lawsonia intracellularis)*
- Pityriasis rosea
- *H. parasuis*

The factors and procedures that are important for optimum health and production of the weaned pig are as follows:

- Optimum age at weaning and postweaning growth performance
- Method of weaning and mixing litters and control of agonistic behavior and behavioral vices
- Nutrition of the weaned pig
- Maintenance of systemic and intestinal immunity
- Therapeutic and subtherapeutic use of antimicrobials
- Housing and environment (the nursery)

Postweaning mortality from weaning to the beginning of the growing-finishing period ranges from 0.5% to 8.0% and may be higher. With good management the mortality rate can be kept down to 1% to 3%.

Optimum Age at Weaning and Postweaning Growth Performance

Under commercial conditions, the optimum age for weaning is between 3 and 4 weeks of age. Weaning at this age causes optimum subsequent reproductive performance of the sow. Weaning at an earlier age would not increase the number of litters per sow per year, because sows do not usually return to estrus until 30 days after farrowing. Early weaning at 2 to 3 weeks of age may also decrease cellular immunity compared with pigs weaned at 5 weeks of age.

The behavior of pigs weaned at 12 and 21 days of age from weaning to market has been examined experimentally (Gonyou et al, 1998). During the subsequent 48 hours, pigs weaned at 21 days of age spent more time eating than those weaned at 12 days of age. During the subsequent 6 weeks, pigs weaned at 12 days of age spent more time eating, drinking, nosing other pigs, and chewing on objects than did those weaned at 21 days of age. The delay in eating and the higher incidence of anomalous behaviors by earlier weaned pigs suggest that additional improvements in early weaning management are desirable.

Between 3 and 10 weeks of age, the average daily gain of weaned piglets fed an appropriate weaner ration under good management and adequate housing reaches 400 to 500 g/day. Postweaning performance can be increased by using complex diets containing several different energy and protein sources, but these diets are also more expensive and the increased gain may not always be economical.

The growth rate of pigs during the postweaning period should be monitored weekly, if possible. A practical method for weighing pigs on a weekly basis is not yet available, but performance must nevertheless be monitored if optimum performance is to be achieved.

Method of Weaning and Mixing Litters and Control of Agonistic Behavior and Behavioral Vices

The procedure of weaning should be performed with the least stress possible to the pigs. There are various ways to wean pigs. Some producers use split-litter techniques; some wean and group pigs by size. Under ideal conditions, the litters that are to be combined and moved into a weaner pen should be allowed to mix together before they are weaned. This is done by removing the partitions between the farrowing crates and allowing the litters to mix for 2 to 3 days before weaning. At weaning, the sows are removed, and the piglets are left in the farrowing crates for an additional few days. Familiar surroundings encourage the piglets to eat the dry feed and to drink water. Two to four litters then may be placed together in a weaner pen that has been cleaned previously, left vacant for a few days, and equipped with a fresh supply of feed and water. The entire group should be weighed when placed in the pen and again when moved out, and the amount of feed used in each pen recorded for determination of feed efficiency.

A common practice is to remove the sow and the piglets from the farrowing crate on the day of weaning and to place the piglets in the weaning pens immediately. When piglets from different litters are mixed in weaning pens, they fight to establish a new hierarchical dominance order. The introduction to a new environment and the separation from their own sows constitute severe stressors, which lead to elevated levels of circulating corticosteroids, depression of the immune system, and secretion of catecholamine.

The literature describing aggressive and agonistic interactions between domestic pigs has been reviewed (Petherick and Blackshaw, 1986). When unacquainted pigs are mixed together they display agonistic behaviors, which is a continuum of behaviors expressed in conflict situations and includes offense, defense, and submissive or escape components. The behavior may include contact, such as biting and pushing, or noncontact, such as threats in the form of body postures and gestures (Petherick and Blackshaw, 1986). Aggressive behavior is a component of agonistic behavior. Contact behaviors and threats are offensive in nature and are termed aggressive behaviors. These behaviors are also called fighting.

Tail biting, ear biting, ear chewing and ear sucking, belly rubbing, and fighting are all described as behavioral vices when observed in groups of pigs. When outbreaks of these vices occur, productivity may be markedly reduced. Tail biting can cause systemic infection and incurable abscesses. Poor ventilation, faulty nutrition, overcrowding, and boredom are among the suspected predisposing factors. However, there is no clear explanation of the etiology. Some observations suggest that behavioral vices could develop from the normal nosing behavior of pigs maintaining their hierarchy. Piglets still desiring oral stimulation may be rewarded by touching pig flesh. Presenting of pigs with a textured, mobile surface that provides stimulation to the sensitive nose and mouth region after weaning but before behavioral vices occur may prevent unsatisfied feeding behavior from being redirected toward other pigs. Attention to the environment, stocking rate, feed and water space, and the removal of particularly aggressive pigs also help to control the problem.

Over the first 6 weeks after birth, the main behavioral change in pigs consists of an increase in overall activity and in behavior associated with the ingestion of solid feed: feeding, drinking, rooting, and defecating.

During the first few days after weaning, there is a sudden increase in general activity and aggression, coupled with restless behavior when the animals lie down together. Pawing the floor is also common and may be a form of nest building for comfort. There is also a very rapid increase in feeding behavior during the first day after weaning, with a much slower rise in the frequency of defecation. It has been suggested that perhaps the combination of restless activity, the difficulty of lying together, and the stress of physiological adaptation to the new diet may lead to a state of fatigue and predispose to infectious diseases, which are common in the recently weaned pig. The importance of a consistently high ambient temperature for the early-weaned piglet is also recognized and may be a factor in postweaning behavior.

The mixing of unfamiliar pigs leads to aggressive interactions, which can result in wounds that may become infected. The effect of mixing on growth rate and feed efficiency has been contradictory (Petherick and Blackshaw, 1986). Mixing also causes increased competition for feed if feeding space is restricted, and the adverse effects of competition can be minimized by ad libitum feeding, providing barriers between pigs, and having regular feeding times. Competition for space may also result in aggression.

If aggressive behavior among pigs is minimized, the welfare and production of the pigs are improved. Aggression can be reduced by keeping the mixing of unfamiliar animals to a minimum. When unfamiliar pigs must be mixed, elimination of competition for resources such as feed and floor space helps to reduce aggression (Petherick and Blackshaw, 1986). Tranquilizers appear to be effective in reducing aggression, but they are expensive and impractical to use on a regular basis.

The effect of the method of weaning on the behavior of the sow has been examined (De Passile and Robert, 1989). During the 4 hours after weaning, sows may be more active and restless if they are moved away from their piglets to a different pen than if the piglets are moved away and the sow remains in the farrowing crate. The significance of these findings must be evaluated.

Swine producers should be encouraged to weigh pigs in and out of the weaner pens on a regular basis. This provides an excellent record of performance that can be evaluated; action can be taken when there is suboptimum performance. Producers are initially reluctant to weigh weaner pigs, but after seeing the results of a few batches, they commonly recognize the benefits of such a practice.

Nutrition of the Weaned Pig

Transition at Weaning

A major problem of early weaning at 3 weeks of age has been the nutrition of the weaner pig. At 3 weeks of age the piglet is still heavily dependent on sow's milk, which is highly digestible, and the digestive enzyme capacity of the piglet at this age is just beginning to adapt to digestion of nonmilk proteins and carbohydrates. Therefore a suddenly change in the diet of the nursing piglet at 3 weeks of age from sow's milk to a cereal-based diet without a period of

adjustment is an additional stressor. Sudden change in diet commonly causes an obvious depression in the rate of gain called the postweaning growth check. The postweaning growth check lasts from 7 to 14 days, depending on managerial and environmental factors, and it is characterized by little or no weight gain and low feed intake, frequently accompanied by diarrhea. The poor weight gains are largely a reflection of low feed intake and are not the result of inefficient feed conversion.

Early weaned pigs placed in an unfamiliar environment and offered an unfamiliar source of feed may not consume an amount sufficient to meet maintenance requirements (Bark et al, 1986). The reduction in feed intake is not related to physiological satiety mechanisms, because weaned pigs placed in a familiar environment consume 70% to 110% of the consumption levels observed in control pigs. The reduction in feed intake of pigs after weaning can be attributed to a reaction to an unfamiliar method of feed acquisition coupled with an unfamiliar source of feed (Bark et al, 1986). These factors can be minimized by management schemes that keep the pig eating through the weaning period. Experimentally, frequent liquid feeding is one method that can be used to accomplish this goal. A wasting-pig syndrome has been described in which, within 2 weeks after weaning, up to 7% of all weaners may exhibit a decrease in weight gain of more than 50% compared with piglets from the same origin, of the same age, and maintained in the same environment. Affected pigs have a prominent dorsal spine because of weight loss and impaired growth, and their hair appears longer than normal (Kyriakis and Andersson, 1989). Based on the suggestion that this syndrome may be associated with social stress after weaning in some pigs, amperozide, a psychotropic drug, has been used in an attempt to modify emotional behavior in response to the social stress, but it is too early to make any recommendations concerning its routine use.

Creep Feed and Postweaning Diarrhea

The relationships between the composition and amount of creep feed consumed by pigs before weaning, and the composition and consumption of the weaner diet after weaning as possible contributing factors to postweaning diarrhea and growth check, have been examined. Many factors interact at weaning time and culminate in these problems, including age at weaning, nutrient density of the diet, amount of feed intake, previous intake of creep feed, and factors that influence the proliferation of hemolytic *E. coli*. The inadequate ingestion of creep feed before weaning has been suggested to have a priming effect that causes a transient hypersensitivity to feed antigens in the immediate postweaning period, leading to an enteropathy and a predisposition to enteritis caused by *E. coli*. It had been suggested that total creep-feed intakes of at least 400 g/piglet before weaning were required for the development of mature intestines in order to minimize the incidence of postweaning diarrhea. The absorption of feed antigens by the intestine of pigs weaned at 3 weeks of age, with the subsequent development of an immunological response to dietary proteins in the intestines, has also been examined as a possible contributing factor in postweaning diarrhea (Wilson et al, 1989).

Recent evidence disputes the hypothesis that postweaning diarrhea occurs as a result of an intestinal hypersensitivity to weaner diets (Sarmiento et al, 1990). Weaning at 3 weeks of age causes large, rapid reductions in lactase activity at most sites along the small intestine; sucrase activity also decreases temporarily but then recovers. Minimum values of enzyme activities occur about 4 to 5 days after weaning. Similar changes occur whether or not creep feed is consumed before weaning. Continued consumption of creep feed by unweaned pigs up to 32 days of age led to small but significant reductions in lactase activity. The large loss of digestive enzyme activity in the brush borders of small intestines in weaned animals coincided with a reduced ability to absorb xylose and impairment of growth rate in otherwise healthy piglets. A loss of enzyme activity in this period could help to explain reduced growth rates, as well as the occurrence of a malabsorption syndrome. In weaned pigs, there is a marked increase in the depth of the small intestinal crypts and a marked reduction in the height of the villi, causing a reduction in the absorptive area of the small intestine. The pig has sufficient pancreatic and gastric enzyme activity so that performance should not be limited, except possibly during the period shortly after weaning. Attempts to reproduce an intestinal hypersensitivity response to weaner diets by feeding pigs small quantities of preweaning diets have been unsuccessful. When postweaning diarrhea occurred, it was associated with an earlier, more prolonged, and greater proliferation of enterotoxigenic *E. coli* in the small intestine than the diarrhea that occurred in healthy pigs after weaning. The greater proliferation in pigs that developed diarrhea could not be attributed to an excessive dietary intake after weaning or to a specific proliferation of rotaviruses. The underlying mechanism for the greater proliferation of hemolytic *E. coli* and the development of postweaning diarrhea in some pigs and not others in the same group are unclear.

The incidence of postweaning diarrhea in a herd is related to the age and weight at weaning and the size of litter (Svensmark et al, 1989a-d). In a survey of intensively managed Danish sow herds, the incidence of diarrhea increased with litter size at weaning. Litters weaned before 2 weeks of age had a twofold risk of developing diarrhea after weaning and a 2.4-fold higher mortality rate than did litters weaned at 6 to 7 weeks. Litters weaned at an individual piglet weight below 3 kg body weight had a threefold higher risk of developing diarrhea after weaning and a fivefold higher mortality rate than did pigs from litters weaned at 7- to 8-kg individual piglet weight (Svensmark et al, 1989d). Diarrhea after weaning was also associated with an increased incidence of diseases of the skin and respiratory tract.

The pathogenesis of *E. coli* postweaning diarrhea in weaned pigs is less well defined and appears to be more complicated than that of neonatal diarrhea. The apparent complexity of postweaning enterotoxigenic *E. coli* infections may be attributable to the effects of factors associated with weaning. These factors include the stress of weaning, cessation of lacteal immunity, selection for antibiotic-resistant enterotoxigenic *E. coli* by antibiotics in feed, and decreased gastric bactericidal activity caused by temporarily increased gastric pH. Other factors, such as reduction in ambient temperature and change in diet and preweaning exposure to diets fed at weaning, are associated epidemiologically with the development of *E. coli* diarrhea in weaned pigs. These factors have been described in the section on nutrition of the weaned pig. The inherited susceptibility of a herd to a particular strain of enterotoxigenic *E. coli* is also a determining factor.

The provision of high-energy, high-protein milk and milk by-products–based preweaner diets (e.g., creep feed), beginning when piglets are about 10 days of age, is used commonly to encourage piglets to eat dry feed early in life and through the weaning period. The concept is sound, and many creep feeds have been developed, all of which have as their primary purpose making the pig eat so that it becomes less dependent on sow's milk and weans onto a weaner diet with a minimum of nutritional stress. The major problem has been failure of the pig to eat a significant amount of the

dry diet before weaning. Therefore, after weaning, there is a period of 7 to 14 days before the pig adjusts to the diet. The use of phased feeding programs has been recommended. As animals reach specific weight ranges after weaning, dietary formulations are made to account for the evolving digestive capacity of the pigs and the availability and cost of the ingredients (Dee, 1999).

The presence of other stressors at weaning, such as the mixing of litters, crowding, uncomfortable weaner pens, and behavioral abnormalities such as fighting and tail biting, may exacerbate the effects of postweaning growth check because of inadequate feed intake.

A common practice among swine producers is to restrict feed intake during the early postweaning period to reduce the incidence of diarrhea in pigs. Some reports indicate a higher frequency of digestive disturbances in weaned pigs when fed ad libitum than when feed is restricted. However, restriction of feed intake significantly reduces performance. Diarrhea also reduces performance, but feed restriction reduces performance more than diarrhea. Restriction of feed intake by limiting weight of feed provided per day reduces the incidence and severity of postweaning diarrhea, but the overall performance of pigs until they reach 90-kg live weight may be unaffected by feed restriction or diarrhea. It is suggested that piglets weaned at 3 weeks of age be offered high-density diets ad libitum, but for pigs weaned at 4 weeks of age, there may be no advantage to higher-nutrient-density diets. Experimentally, strategic feed restriction during Days 3 to 8 after weaning, of pigs weaned at 5 weeks of age, reduced the occurrence of postweaning diarrhea and the proliferation of haemolytic *E. coli* without these problems when ad lib feeding was resumed (Rantzer et al, 1996). During the restrictive period the restricted-fed pigs had a lower diarrhea score, fewer number of antibiotic treatments, and a lower percentage of fecal haemolytic *E. coli* than the full-fed pigs. The performance of the full-fed pigs was suboptimum during the restrictive period as compared with the period after, which may be due to a peak in postweaning diarrhea and an increase in haemolytic *E. coli*. This suggests that a strategic feed restriction during the period of 3 to 8 days after weaning can reduce the proliferation of haemolytic *E. coli* and the occurrence of postweaning diarrhea for 14 days after weaning.

Water for Weaned Pigs

Weaned pigs must be provided with adequate supplies of water. A 6-kg weaned pig consumes about 103 g/kg live weight/day, and a 12-kg pig consumes about 246 g/kg live weight/day. Daily feed intake is the best predictor of water intake, and the relationship can be described by the following equation:

$$\text{Water intake (L/day)} = 0.149 + 3.053 \text{ Feed intake (kg/day)}$$

The reported ratios of water to feed intake have varied from 2:1 to 5:1. The pattern of water intake over the first 5 days after weaning also varies. In some cases, pigs will not consume water until Day 2, which may be explained by the piglets not finding the source of water when first introduced to the weaner pens. The presence of water from a leaking drinker may encourage drinking, and once drinking has commenced, consumption increases rapidly. Water deprivation of weaned pigs, as the result of a faulty watering system, can lead to salt poisoning (Marks and Carr, 1989). The pig is adaptable to restrictions of its water supply, but there are limits of adaptation. As pigs get heavier and ambient temperatures rise, attention to water flow rate becomes more important.

Maintenance of Systemic and Intestinal Immunity

During the first month of life, the piglet is dependent on the sow's colostrum and milk for both systemic and intestinal immunity. The intestine of the newborn piglet absorbs intact immunoglobulin molecules from ingested colostrum for 24 to 48 hours after birth, which provides a broad-spectrum of protection, primarily against systemic infection, for the first few weeks of life. Whereas colostrum provides the piglet with circulating immunoglobulins, the sow's milk provides secretory antibody (i.e., IgA), which becomes the predominant immunoglobulin in milk and provides passive intestinal immunity from a few days after birth until weaning. At about the time of weaning, piglets develop their own intestinal antibody, which can be extrastimulated by the use of oral vaccines administered in the feed (Bourne and Newby, 1981). The endogenous production of intestinal IgA begins to develop rapidly in the pig at about 3 weeks of age.

Therapeutic and Subtherapeutic Use of Antimicrobials

The advantages and disadvantages of using antimicrobials in animal and plant agriculture continue to be debated in the literature. The use of antibiotics as growth promotants in food animal production is highly controversial. The advantages for the producer are economic benefit resulting from greater uniformity of growth and reduction in morbidity. Typically, the improved performance is 4% to 8% in gain and feed efficiency. For the consumer the advantages are that the pork is produced at a reduced price, potentially contaminated with fewer bacteria, and arguably produced with increased welfare for the pig. The disadvantages for the producer are the consumer and political pressures to not use growth promoters, the possible suppression of normal flora, and the possible failure of antimicrobial therapy because of resistance induced by subtherapeutic use. The disadvantages for the consumer are the possible tissue residues in pork and the possibility of infection with antimicrobial-resistant bacteria that emerged in pigs fed subtherapeutic antimicrobials.

Growth-promoting concentrations of antimicrobial agents modify the microflora and their products within the gastrointestinal lumen and probably within the host's immediate environment. Growth promotion has been greatest with animals maintained under adverse managerial and environmental conditions. The antimicrobials and other growth promotants that are approved for use in swine feeds vary among countries. Each country publishes a brochure describing those products that are approved for use as growth promotants, their withdrawal periods, and their incompatibilities.

Antimicrobial Use and Resistance in Swine Herds

Some information is available on the use of antimicrobials in swine herds. They are used extensively in newly weaned pigs, a critical time for infections in young animals, and to a lesser extent in growing and finishing pigs, where their use may not be effective (Prescott, 1997). Raising pigs under intensified conditions has similarities to beef feedlots in which large numbers of animals are fed under intensified conditions.

A mail survey of swine herds in Ontario, Canada, in 1991, found that 86% of herds added antimicrobials to starter (weanling pig) rations, and only 29% added these drugs to finishing pig rations (Dunlop et al, 1998b). The most commonly used antimicrobials were tylosin, carbadox, and furazolidone in weanling pigs and tylosin, lincomycin, and tetracycline in finishing pig rations. Water medication of

growing-finishing pigs was practiced on 25% of farms; 80% of farms had injected at least some growing-finishing pigs with antimicrobials in the 12 months preceding the survey. Approximately 20% of herds that added antimicrobials to finishing rations did so for growth promotion purposes only, whereas others used them for the treatment of disease, prevention, control, or a combination of both. Among those not using antimicrobials in finishing rations, 83% did not consider they were necessary and 37% were concerned about the potential for residues in marketed pigs.

Antimicrobial use during swine production is associated with increased resistance to those antimicrobials among fecal *E. coli* of finishing pigs (Dunlop et al, 1998a). Antimicrobial treatment of groups of pigs has been shown to be more important than individual medication in increasing the risk of resistance among *E. coli*, but there was little evidence that group treatment practices increased the risk of resistance to gentamicin, which was used only for individual animal therapy. Antimicrobial use in starter rations was associated with resistance to ampicillin, carbadox, nitrofurantoin, sulfisoxazole, and tetracycline. Antimicrobial use in growing-finishing rations was significantly associated with resistance to ampicillin, spectinomycin, sulfisoxazole, and tetracycline. The results suggest that antimicrobial medication of rations of postweaning pigs selects for and maintains antimicrobial resistance among *E. coli* of finishing pigs. Similar studies indicate that patterns of antibiotic resistance are dependent on age of pig and level of antibiotic use (Mathew et al, 1998).

The prevalence of antimicrobial resistance among fecal *E. coli* of swine on farrow-finish-farms in Ontario were ampicillin (29%), carbadox (3.5%), gentamicin (0.6%), nitrofurantoin (27%), spectinomycin (28%), sulfisoxazole (38%), and tetracycline (71%) (Dunlop, 1998d). Between 30% and 76% of the variation in prevalence of resistance was explained by between-farm differences, indicating that farm-level factors may be important in explaining some of the variation.

Antimicrobial resistance was common on farms that did not medicate rations of postweaning pigs; the results indicate that antimicrobial use does increase the risk of resistance to the antimicrobials studied. The reduction of group medication with broad-spectrum antimicrobials of weanling and growing-finishing pigs might reduce the prevalence of resistant *E. coli* in market pigs. Thus antimicrobials should be used only when necessary, and the swine industry should continue to invest in the maintenance of a healthy population of pigs in which the need to treat with antimicrobials is reduced.

A survey of 34 farrow-finish swine herds in Ontario for individual and group antimicrobial drug use found that the rates of individual-pig treatment varied from 0 to 24.1 pigs treated/1000 pig-days, with a median of 5.29 (Dunlop et al, 1998c). Most individual treatments were given to piglets and sows at parturition, and penicillin was the most commonly used antimicrobial. Gentamicin was given to nursing piglets on some farms. Most herds either did not use any antimicrobials or used narrow-spectrum or broad-spectrum antimicrobials in the rations of postweaning pigs.

Information on the use of feed additives in swine herds was collected from 710 farms (Dewey et al, 1997a). Of all the feeds, about 79% contained feed additives used in the labeled manner. For all classes of pigs, the prevalence of labeled feed additive use was greater than 75%. Penicillin was used according to its label most often, followed by apramycin, bacitracin, tetracyclines, lincomycin, and tylosin. Carbadox had the highest prevalence of "off label" use. Of the 699 feeds that included feed additives in an off-label manner, about 57% included additives at greater than the recommended concentrations or were fed to an incorrect class of pig. About 56% of the feeds had "off-label" combinations of additives. Small farms were more likely to use rations with no feed additives than intermediate or large farms. Of those farms using feed additives, the odds of a small farm using all feed additives in the labeled manner was 7.7 times that of an intermediate or large farm. After controlling for herd size, producers who used a veterinary consultant were 2.1 times more likely to use feeds with feed additives.

Antimicrobial-resistant *E. coli* have been isolated from the fecal samples of veterinarians in different practice specialties (cattle, swine, poultry, or small animals) or in governmental veterinary medicine in the Netherlands (Bongers et al, 1995). The prevalence of *E. coli* isolates resistant to several antimicrobials was highest in cattle and poultry practitioners and lowest in swine practitioners. A significantly higher percentage of the isolates from cattle practitioners had a high level of resistance to ampicillin than did swine practitioners. A significantly higher percentage of the isolates from poultry practitioners had a high level of resistance to oxytetracycline than did the isolates from swine practitioners. The prevalence of antimicrobial resistance of *E. coli* isolates from veterinarians was relatively low compared with that of isolates from pig farmers, abattoir workers, and suburban residents. There was no resistance to carbadox in the fecal flora of participating veterinarians, but resistance was found in isolates from swine; this suggests that transfer by direct contact is unlikely.

The general aspects of using antimicrobials in the feed of pigs for the prevention of certain infectious diseases and for growth promotion, and the potential for the development of antimicrobial-resistant bacteria that may be transmissible to humans through the food chain, are described early in the chapter.

Housing and Environment (the Nursery)

The environment and housing factors that influence the performance of the early-weaned pig include temperature, humidity, air velocity, light, animal space, and hygiene. There has been much controversy about the optimum amount of floor space that should be allowed per pig, the best and most economical floor material, the ventilation system that will provide the best quality air, the optimum ambient temperature, the amount of feeder space per pig, and the feeding management. Weaning houses (e.g., nurseries) have now been designed and adapted to provide sufficient space and volume and a suitable environment for the weaned pig. In addition, reduction of labor requirements for piglet care has led to the design of weaner pens with wire mesh floors. However, wire mesh–floored cages favor an increase in radiative and convective heat losses, and, consequently, the critical temperature of the piglet is probably increased.

Air Temperature and Ventilation

The environment of the nursery is important and must include consideration of air exchange, humidity, dust levels, and temperature. The environmental temperature required at weaning varies with age. A range of 29° to 30° C has been recommended as a guideline when weaning age is 3 weeks or younger (Dee, 1999). This temperature should be maintained for the first week after weaning and gradually decreased as the pigs increase in size. The temperature should decrease at least 10° C during the 7- to 8-week nursery period, resulting in levels of 20° C to 21° C when the pigs weigh 20- to 25-kg body weight. Optimum air temperature for piglets weaned at 5 weeks is about 25° C. At lower

temperatures, growth rate and feed efficiency are reduced. Cold weather also increases pig mortality by affecting the immune system of the pig.

Because of the considerable magnitude of convective heat losses in piglets reared in batteries, air velocity is an important factor to consider in addition to air temperature. Weaned piglets are more comfortable, grow faster, and consume less feed in a draft-free environment. Proper ventilation rates are critical to providing fresh air for breathing and controlling humidity and residual gases. At levels of 50 ppm, atmospheric ammonia may affect lung clearance mechanisms. During the winter months, improperly adjusted propane heaters may lead to elevated carbon monoxide levels. There are no documented data on the optimum relative humidity for early-weaned piglets

The presence of bedding, such as straw or wood shavings, may help the piglets to create a microclimate that protects them from the adverse effects of climate and that considerably reduces heat losses. The provision of straw on a solid floor improves the welfare of weaned piglets. When straw is provided, piglets chew and root in it, which provides a form of recreation and may reduce chewing of penmates. Up to 25% of active behavior is straw-directed behavior. Any reduction in chewing of penmates may be beneficial, because serious tail and ear biting can cause great economic loss. The preference of weaned pigs for a bedded or concrete floor depends on temperature. Under warm conditions, straw is likely to benefit pigs because of its recreational value but not as a means of improving comfort in the resting area.

Rearing in complete darkness is considered favorable, since it reduces aggressiveness in animals of different litters that are mixed after early weaning.

All-In, All-Out Pig Flow

The AIAO management system is recommended for early weaned pigs. The weaner pens are depopulated, cleaned, disinfected, left vacant to dry for a few days, and then restocked with newly weaned pigs. Average daily gain and feed conversion are better in pigs reared in an AIAO system compared with those reared in the continuous system. The improvement is probably the result of the reduction of microbiological flora in the environment through cleaning and disinfection. Continuous occupation of weaner pens by successive litters of weaned pigs without cleaning and disinfection between litters causes a marked increase in the population of infectious diseases.

Stocking Density and Floor Space

As swine producers continue to intensify to increase productivity, the need to increase the density of nurseries to reduce building and operating costs per pig is important. An increase in the density of groups of weaned pigs to a crowded level decreases average daily gain, increases the ratio of feed/body weight gain, and promotes aggressiveness.

As floor space decreases from 0.25 to 0.17 to 0.13 m^2/pig, average daily gain decreases and continues to do so with each successive growth period. A depression in growth rate caused by overcrowding during the weaner phase affects subsequent growth rate throughout the growing period (Van Lunen, 1983). In weaner pigs reared at densities of 0.37, 0.18, and 0.12 m^2/pig on decks or floors, there were marked differences in rate of gain, days to market, and backfat thickness in favor of the lower density of 0.37 m^2/pig.

Decking has been an effective way of increasing nursery density. Properly designed double- and triple-deck environmentally controlled nurseries can provide the means of meeting the environmental needs of the pig during the critical postweaning period. The building and operating costs per pig can be reduced without adversely affecting pig performance. There are no significant behavioral problems, and the pigs usually remain clean because the feces pass through the expanded metal floors. Field trials suggest that 10 weaned pigs from 5- to 12-kg body weight may be housed per 1.2- × 1.2-m cage and that a maximum of eight pigs from 12 to 22 kg may be housed in the same size cage. Factors influencing the space requirement include the starting weight, length of time that pigs will be kept in the nursery, environmental conditions and the degree of environmental control, type of floor, amount of feeder space per pig, type of feeder, and number of pigs per pen. Space recommendations for optimum performance of weaned pigs with an initial weight of 5 to 11 kg range from a low of 0.09 m^2/pig to a high of approximately 0.28 m^2/pig. Piglets raised on perforated-sheet floors may experience a greater incidence of traumatic injuries on legs and feet than piglets kept on concrete floors, and piglets kept on mesh floors might have a greater incidence of injury than those kept on perforated floors.

Feeder-Space Allowance

Feeder-space allowance can affect weaner-pig performance. Pigs have a minimum feeder-space requirement below which daily feed intake is decreased, with a concomitant decrease in daily gain. However, an increase in feeder space above the minimum does not improve the daily feed intake and subsequent daily gain. Some studies show that three 15.2-cm sections of feeder space are adequate for 122- × 122-cm or 91- × 122-cm nursery pens when those pens contain 12 or fewer pigs (Lindemann et al, 1987). It may be advantageous to shorten trough length when possible to prevent fouling and wasting of feed resulting from urination and defecation in feeders that extend the total length of one side of the pen. When feed is supplied ad libitum, pigs are not required to eat as a group and therefore do not require enough trough space to accommodate all pigs at the same time.

TECHNOLOGIES USED TO IMPROVE THE HEALTH AND PERFORMANCE OF THE WEANED PIG

No other factor can affect the productivity and profitability of a swine farm as severely as exposure to an infectious disease(s). Bacterial and viral agents that affect weaned pigs are frequently spread laterally among populations of pigs with varying levels of immunity. Concurrent infection of multiple pathogens also can occur. One of the essential roles of the swine practitioner is to implement strategies to reduce the effect of such pathogens. The following review summarizes the published data health technologies commonly used to improve the performance of weaned pigs: AIAO pig flow, the F-10 system, multisite systems, whole herd depopulation-repopulation, and PD.

All-In, All-Out Pig Flow

AIAO pig flow has been documented to improve the performance of pigs (Clark et al, 1991; Scheidt et al, 1995). The ability to completely empty a room, building, or site prevents the continuous spread of pathogens from older to younger animals. AIAO has long been a practice in the poultry industry. Poultry barns are routinely emptied following delivery of the birds to the slaughterhouse, washed, disinfected, fumigated, and allowed to remain empty for a period of time to reduce microbial survival outside the host. This technology was initially adopted by the swine industry for the control of diarrhea before weaning. The effects of AIAO

on the postweaning pig performance have been studied extensively. Studies demonstrate that such practices improve average daily gain and feed efficiency and prevent mortality and the severity of respiratory disease in both the nursery and growing-finishing phase (Clark et al, 1991). AIAO can be practiced by room, building, or site. Data indicate that AIAO by site or airspace leads to better performance than if a single room is emptied (McManus, 1991). Although piglets ideally should be within a week of age of each other, 2 weeks' production can be housed together and still see benefits. Studies also indicate that despite an improvement in overall pig performance, AIAO does not appear to eliminate the disease (Clark et al, 1991). Implementation of AIAO does, however, cause a reduction in the prevalence of pneumonic lesions, as well as a reduced severity of intestinal diseases (e.g., ileitis). Conversion of large, continuous flow facilities to AIAO usually requires construction of walls to establish rooms of pigs within buildings. Each room must be individually ventilated. Another means of converting to AIAO pig flow may require the reorganization of farrowing schedules, causing larger "batches" of weaned pigs, completely filling a facility at one time. Although it does take prior planning, the effect of AIAO on postweaning performance appears to be well worthwhile.

F-10 System

F-10 stands for "farrowing to 10 weeks of age" and is a technology that has been successful for the improvement of weaned pig performance (Schuiteman, 1993). In this system, sows are weaned in the normal fashion, but the pigs remain in the farrowing crate until they are 10 weeks old. The farrowing crate is then modified and converted to a nursery pen. The advantage of such a system is that early removal of the sow prevents further spread of infectious agents from sows to weaners, a reduction of labor, and improved performance. Although little data are available, it appears that piglets raised under the F-10 system perform much better than those raised under conventional measures. Improvements in growth rate of 44% and a 50% reduction in mortality have been recorded (Schuiteman, 1993). The disadvantages of such a system may include a reduction in the utilization of farrowing crate space. Therefore the system may be applicable only to producers using batch or group farrowing schedules. Despite this limitation, pigs raised under the F-10 system appear to be capable of better performance than those in conventional nurseries.

Multisite Systems

Before the description of SEW, a brief review of the current production systems in the United States is presented here (Dial et al, 1992). The U.S. swine industry currently uses either one-, two-, or three-site production systems. One-site consists of breeding, gestation, and farrowing on one site, with the nursery and finishing on separate sites. Recommended distances between sites range from 1 to 3 km depending on the health status of the operation and the suspected airborne potential of various microorganisms. Two-site systems consist of breeding, gestation, and farrowing on one site, with nursery-finishing on another. The main premise of both systems is that the nursery must be located on a separate site away from the breeding herd (Dee et al, 1993). This is important to prevent the transmission of pathogens from the sow to her offspring. This theory has been the basis of SEW technology and is summarized in a later section.

Multisite production systems have many advantages for swine producers, besides the improvement of health status. If nursery and finishing facilities are relocated on other sites, existing facilities can be remodeled to expand the size of the breeding herd, usually with reduced investment. Nurseries can be remodeled into farrowing rooms, and finishing pens can house gestating sows. Frequently, swine producers network together and establish off-site weaning facilities to commingle pigs from several farms. The health status between the sow farms must be similar in order to prevent the exposure of susceptible pigs to new diseases. Three-site production can be costly and difficult for the majority of smaller commercial U.S. swine producers to use. It is usually reserved for breeding stock companies or large herds with 1200 or more sows. The two-site system is much easier to operate economically and appears to be just as effective. This technology in combination with the SEW program is beneficial to all types of procedures and leads to improved efficiency of the swine enterprise.

Segregated Early Weaning

SEW, performed to improve the efficiency of swine production, is a common practice in the commercial swine industry. The procedure is used to control infectious disease with the primary objective of improving productivity of the growing-finishing phase of production (Dritz et al, 1994). The procedure attempts to prevent and minimize the transfer of infectious diseases by segregating pigs at weaning. The pigs can be segregated by removing the sows to a centralized breeding and gestation facility and leaving the piglets on the site or by transporting the piglets from the farrowing site to another site. The movement of weaned pigs or sows prevents the vertical transmission of infectious diseases. The weaned pigs are placed in groups, and each group remains segregated by the use of AIAO production. The group segregation prevents the horizontal transmission of pathogens between groups.

SEW prevents vertical transmission of pathogens that do not cross the placenta. Vertical transmission of pseudorabies virus, TGE virus, *A. pleuropneumoniae, M. hyopneumoniae, Serpulina hyodysenteriae, B. bronchiseptica,* and toxigenic *Pasteurella* have been prevented by SEW. Respiratory infections caused by *A. pleuropneumoniae, M. hyopneumoniae, B. bronchiseptica,* and toxigenic *Pasteurella* have not been eliminated consistently by the use of traditional, on-site, disease-elimination programs. Vaccination and the strategic use of antimicrobials have been used traditionally for the control of these respiratory diseases but are unreliable.

SEW is a variation of *medicated early weaning* (Alexander et al, 1980). Further reports have indicated the ability to eliminate certain pathogens and improve weaned pig performance. A critical component of the program consists of hyperimmunization of the sow before farrowing to provide high levels of colostral antibodies against specific pathogens. This is important to reduce transmission of pathogens between sows and pigs during lactation. The pig is then injected with a series of antibiotics to eliminate specific bacteria before weaning. Finally, the pig is weaned at an early age to a separate site to prevent further transmission from the sow. Regarding the necessity of antibiotics, under controlled conditions, age-specific separation from the sow may be more important than medication (Clark et al, 1994). The relationship between weaning age and pathogen elimination has been examined (Clark et al, 1994). It currently appears impossible to eliminate certain pathogens with early weaning. *E. coli,* and *Str. suis* may be present in the pig shortly after birth (Day 1) because of colonization through contact with the mucosal surfaces, secretions, or excretions of the sow (Amass et al, 1996).

Transplacental transmission of PRRSV, *Leptospira* sp., or parvovirus may lead to the presence of these specific

pathogens immediately after parturition. The pathogens can be eliminated if certain weaning ages are met. Weaning age is critical to the success of SEW because the maternal immunity provided by colostrum decreases at different rates for different diseases (Dritz et al, 1994). Weaning pigs at 10 days of age or less appears to eliminate *H. parasuis, B. bronchiseptica, P. multocida,* and *M. hyopneumoniae*. The initial presence of these pathogens is not detected unless weaning ages reach 15 days or more. Similarly, *A. pleuropneumoniae* may be eliminated at 16 to 18 days of age. Finally, pseudorabies virus and TGE virus appear to be eliminated at 21 days of weaning.

On arrival at the nursery, weanlings are fed diets high in milk products and plasma proteins. It is critical to limit feed 5 to 7 times daily for the first week after weaning. Pigs are placed on a water-soluble antibiotic, selected on the basis of in vitro sensitivity testing. Four different diets are usually fed over the 8-week nursery period. Animals are housed in single stage nurseries with plastic coated flooring at 30° to 31° C and are sorted by size and sex.

The selection of vaccines and medications to use depends on the individual farm diagnostic data. It is recommended that nasal swabs be collected from sows and that two to three sick pigs from the nursery and finishing areas be submitted to the diagnostic laboratory for culture. Medication can be chosen based on the sensitivity patterns of bacterial isolates. Serology is also an important diagnostic aid to determine the exposure level of the breeding herd to specific pathogens that are targeted for eradication and assists with the development of vaccination programs for the breeding herd.

A. suis, H. parasuis, and *Str. suis* have emerged as important pathogens of swine, particularly in high health status herds (MacInnes and Desrosiers, 1999). They are considered opportunistic pathogens, and environmental and host risk factors need to be considered in the clinical management of these diseases. They have become known as the "suis-ide" diseases. They are early colonizers and, for that reason, are difficult to control by management procedures such as SEW. The efficacy of the vaccines and serodiagnostic testing are complicated by the presence of multiple serotypes, cross-reactive antigens, and absence of clear markers for virulence. Control is dependent on the use of antimicrobials for treatment of individual animals and strategic medication of the feed and water supplies, improvement of housing and management, and consideration of vaccines.

Some studies found no significant differences in average daily gain, feed:gain ratio, or average daily feed intake among pigs moved to offsite nurseries or in pigs maintained in a strictly sanitized environment compared with pigs reared in an onsite sanitized environment or in an environment where the sows are moved away from the pigs with the pigs remaining in the same crates in which they were farrowed (Fangman et al, 1996b). Production systems practicing good sanitation and conscientious biosecurity measures to establish a minimum pathogen exposure may not demonstrate significant performance results in nursery pigs moved offsite at an early age (<14 days). Weight at weaning may be a more important factor than age at weaning (if <21 days) in terms of subsequent growth performance (Fangman et al, 1996a). Site separation may not eliminate transmission of selected infectious agents. In some studies, pigs at all off-sites were culture positive for *Str. suis* and toxigenic *P. multocida*.

Comparison of the growth performance of segregated early-weaned pigs with conventionally weaned pigs through finishing found that SEW pigs weigh more at the end of the nursery phase, but they did not maintain that advantage through finishing (Drum et al, 1998). Also, vaccination may temporarily slow the growth of SEW nursery pigs, but the effect does not persist through finishing. A partial budget analysis can be used to predict how a change from conventional weaning to SEW, with a concomitant increase in the size of the breeding herd, affects profitability in a hypothetical herd (Drum and Marsh, 1999).

The use of antibiotics is not the most important factor for disease control in SEW programs (Dritz et al, 1996). Vertical transmission of *M. hyopneumoniae* was prevented by weaning pigs at 7 to 10 days of age and segregating them off-site, without the use of medication. Minimizing the use of antibiotics in disease-control protocols reduces the costs and the need for extra-label use of drugs. A low-cost, modified, medicated-early weaning program to eliminate *M. hyopneumoniae* has been examined (Dee, 1994). Pigs received a series of injections of oxytetracycline on Days 1, 7, and 14 of age. Pigs were weaned at 14 days of age to off-site nurseries. The organism was not detectable in tissues at slaughter and serologically. Performance was improved and is recommended as an effective low-cost program for improving the health and performance of growing pigs in a commercial herd.

Success of a SEW program depends on the commitment of the personnel managing and operating the system. A multiple-site operation requires discipline, coordination, and excellent management as the foundations of success. Strict AIAO pig flow is a necessary component of SEW.

Biosecurity and disease surveillance are important components of SEW. The suggested biosecurity measures for SEW include the following:

- Locate as far away from other pigs as possible; early-weaned pigs have are highly susceptible to infection
- Evaluate disease status of herd or origin
- Isolate all incoming breeding stock to prevent introduction of pathogens
- Maintain continuous disease surveillance by a veterinarian; this includes necropsies, serological testing, and abattoir surveillance
- Continuously evaluate of production records; feed intake and growth rate are sensitive nonspecific indicators of disease
- Educate animal attendants to recognize the early clinical signs of disease.
- Prohibit vehicles that have not been cleaned and disinfected from transporting pigs
- Use proper load out facilities that ensure a pig leaving the complex cannot return
- Use aggressive control procedures for rodents, flies, and stray animals
- Exclude all nonessential personnel from the farm
- Ensure that farm personnel have no contact with swine outside the herd
- Use pathogen-free feed sources
- Institute methods of feed delivery that closely control access of potentially contaminated trucks into the farm
- Dispose of dead animals promptly
- Use fences and locks to restrict entry of unauthorized personnel

Whole Herd Depopulation-Repopulation

Whole herd depopulation-repopulation has gained increased acceptance as a strategy to improve both health and genetic performance. Although the process can be very costly and extremely difficult psychologically, it is very effective at eliminating chronic, endemic diseases and at improving genetics at the same time. Reasons to repopulate the entire farm include poor growth rate, excessive numbers of nonmarketable or cull pigs, poor feed efficiency, and low heterosis (Dial et al, 1992). Diseases of the nursery pig are typically not severe enough to warrant whole herd depopulation.

A brief outline of the strategy is presented here. Before initiation of a depopulation program, prior planning is required. A careful evaluation of the current herd performance is necessary, including the identification of all significant disease entities currently in existence. Commonly encountered disease problems that lead to depopulation including pseudorabies, swine dysentery, *A. pleuropneumoniae*, and AR. Such chronic disease usually leads to excessive antibiotic use (Deen, 1992). It is important to establish the amount of antibiotics or vaccines that are being used to manage disease, in order to assess the potential economic benefits of a whole herd repopulation.

In addition to the assessment of current health problems, an evaluation should be made of the genetic status of the herd. Problems that indicate poor genetic performance include low live born litter size, low weaning weights, and excessive backfat at slaughter. Finally, because whole herd depopulation causes severe short-term capital losses, arrangements frequently must be made with a lending institution to provide an adequate level of working capital (Deen, 1992).

The timing of the depopulation is critical. Procedures should take into account the length of downtime required, season of the year, and predicted market prices. Ideally, to decrease downtime, facilities are rented to ensure a constant flow of pigs to market (Leman, 1992). At least 30 days of downtime are usually required on the home farm to allow for thorough cleaning and repairs and to reduce the survival of pathogens outside the host. Ideally, this should take place during periods of hot weather to take advantage of the bactericidal or virucidal effects of drying, heat, and ultraviolet radiation. The clean-up procedure is very involved and encompasses the washing of the entire swine complex, including a thorough cleaning of the pit. All equipment, including feeders, crates, pens, and ventilation equipment, needs to be washed thoroughly with hot (90° to 94° C), high-pressure water and disinfected (Leman, 1992). Pits should be emptied and slats lifted to obtain access to fecal material that has built up on the underside of the concrete (Leman, 1992). In addition, a rodent control program should be implemented and maintained, ideally, by a professional exterminator.

Improved performance is usually seen after repopulation (Leman, 1992). Improvements of 10% or more in growth rate, and a 5% to 10% improvement in feed efficiency, have been reported. Other benefits include a 10% to 20% increase in pounds marketed and a reduction in vaccination and medication costs. Problems frequently encountered during or after a repopulation consist of mismanagement of the offsite breeding project, reintroduction of a significant disease through the purchased stock, and the enhanced level of specific diseases such as greasy pig disease or parvovirus. Such diseases are thought to arise from a low level of immunity within the immature breeding population. Overall, whole herd depopulation and repopulation can produce both health and genetic benefits. However, because of its high level of economical and psychological stress, it is a technology that should be used only when other options have been exhausted.

Partial Depopulation

PD, in contrast to whole herd depopulation, involves the emptying of a single stage of production rather than removal of all pigs at one time. ND has been studied extensively and is a cost-effective means of interrupting horizontal transmission of PRRSV from older, infected pigs to those recently weaned (Dee and Joo 1994a). Significant improvements in nursery pig daily gain, mortality, treatment cost, and profitability have been recorded after implementation of nursery depopulation (Dee et al, 1997a,b). Despite such improvement, reinfection of nurseries with PRRSV is a frequent event, often taking place 12 to 18 months after completion of the depopulation protocol. Thus it is possible that the primary benefit of this strategy may be for the control of opportunistic pathogens, rather than control of the PRRSV. Nursery depopulation consists of emptying, washing, and disinfecting all nursery rooms and allowing the facility to remain empty for a minimum of 2 days. Because of the poor viability of PRRSV outside of the pig, extended periods of downtime can be avoided, enhancing facility use and eliminating the virus from the nursery pig population. Disinfectants frequently recommended include phenol- or formaldehyde-based products to reduce survivability of the virus in the environment (Pirtle and Beran, 1996). This strategy can also be applied to finishing populations.

HEALTH MANAGEMENT AND PRODUCTION OF THE GROWING AND FINISHING PIG

In farrow-to-finish herds, after rearing in the nursery, the pigs are transferred to the growing and finishing pens at about 25 kg of body weight, where they are fed until they reach market weight at about 100 kg of body weight and are (1) sold for pork, selected as breeding stock, and kept as herd replacements, or (2) sold as breeding stock to other farms.

Some feeder-pig enterprises purchase 20- to 25-kg pigs from a variety of sources and feed them until they reach market weight. These growing-finishing units may feed several hundreds or thousands of pigs annually and are commonly integrated with a feed company that supplies financing, feed, and professional veterinary consultation. The emphasis in these units is on producing body weight gains with the lowest possible cost per unit of gain.

The major objective during the feeding phase of pig production just described is to grow and finish the pig as rapidly as possible and to still obtain a lean pig that will yield the highest carcass score possible to obtain maximum economic returns. Because feed represents approximately 70% of the cost of production, obtaining maximum feed efficiency during the growing-finishing period is a major determinant of net profit, and the producer and veterinarian must think in terms of using whatever means are available to lower feed costs. The costs of production and profitability vary among herds. Using some Canadian data, 96% of the variation between herds is explained by days to market, mortality rate, total feed consumption, carcass weight, and incoming feeder-pig weight.

Causes of Economic Losses in Growing-Finishing Pig Production

Death losses of growing-finishing pigs are a major cause of economic loss. Published percentage mortality of growing-finishing pigs varies from 0.2% to 7.5% (Losinger et al, 1998b). It has been suggested that less than 2% mortality is excellent, and more than 4% is poor performance. Over a 6-month period, the mean mortality risk based on a 1995 NAHMS study of swine operations with 300 or more market pigs, was 2.3% ± 0.2% in the growing-finishing production phase (Losinger et al, 1998b). Mortality was 4% or higher in 13.5% ± 2.9% of growing-finishing operations, whereas mortality was 2% or less in 63.6% ± 5.3% of operations. Factors associated with a mortality of 4% or higher included a mean weaning age 28 days or less and not obtaining all growing-finishing pigs from farrowing units belonging to the operation. The decision to not provide growing-finishing pigs antibiotics or other agents in the feed or water for disease prevention or as growth promotants, and the ranking of producer organizations as very or extremely important

sources of antibiotic information, were associated with 2% or less mortality in the growing-finishing phase (Losinger et al, 1998b).

Respiratory disease is the leading cause of pigs during the growing-finishing phase of production (Losinger et al, 1998c). In herds with 300 or more market pigs, 61.7% of operations reported at least one death from respiratory disease. Mean mortality resulting from respiratory disease was 0.9% ± 0.1% of finishing pigs/operation. Risk factors associated with operations reporting 2% or higher mortality included having 3000 or more pigs enter the growing-finishing unit over a 6-month period; diagnosis of *Haemophilus* spp. or *A. pleuropneumoniae* infection in pigs in the previous 12 months; and keeping of pigs in the growing-finishing unit longer than 120 days (as compared to less than 100 days). With no farrowing facility, mean weaning age less than 28 days, and below 50% of finishing pigs on only solid concrete were associated with reports of 2% or higher mortality attributed to respiratory disease.

The estimates of feed-conversion ratio of finishing pigs in the United States range from 2.18 to 5.91 kg of feed fed for each kilogram of live-body weight gained during the growing-finishing phase, with a mean of 3.28 ± 0.52 (Losinger, 1998). The management factors associated with improved feed-conversion ratios include: three or more different rations fed during the growing-finishing phase; no rations mixed on the farm; and not giving chlortetracycline in feed or water as a disease preventive or growth promotant. The ratio was better in operations in which 3000 or more pigs entered the growing-finishing production phase during the 6-month period before the interview compared with those in which fewer than 3000 pigs entered.

Monitoring Growing Pig Production

Production Records

The details to be collected for growing-finishing pig records to be analyzed retrospectively are simple. Pigs are recorded as being located within a group or at a certain location over a time period. Feed is added to this group or location, and dead and culled pigs are removed. Finally, the pigs are marketed and the pigs are counted and weighed at entry and exit. Even more benefit may be gained when those weights are measured individually. From this information is gained estimates of average daily gain, feed conversion, mortality rates and cull rates. In addition to this information, carcass weights and characteristics can also be provided to provide estimates of the qualities of the end product.

Growing-finishing data are simple but involve varying amounts of labor. It is not the ability to collect grow-finish records but the utility in their collection that inhibits many farms from collecting the data. On many farms, the data collected are underutilized. In many cases a group of pigs is monitored and the describing characteristics are only calculated after all of the pigs leave the farm. These describing characteristics are usually limited to a few numbers such as average daily gain, feed conversion, mortality rate, and cull rate. If there is a problem, the numbers are not easily broken down to try to describe reasons by which they are inadequate. Greater detail is needed to provide adequate definition of problems and solutions in many cases. It is my experience that the most common measurement of pig performance in pursuing the aid of a veterinarian is usually sick or dead pigs, especially pigs that die suddenly. This reliance on mortality may lead to an overemphasis of factors that do not have an overall effect on profitability that is as great as some other factors:

- *Mortality and morbidity rates:* In addition to the pathological and clinical examination of affected pigs, an examination of the patterns of mortality is often useful. If the mortality can be graphed against the age of pig or the calendar date, patterns of mortality can be defined and precipitating circumstances are often seen. In many cases, mortality groups around seasonal changes in temperature or certain ages that may coincide with feed changes or increases in competition within the pen (Abiven et al, 1998).
- *Average daily gain:* It is best to graph average daily gain against the age of the pig and to compare average daily gain with and without the inclusion of mortality and culls. In many cases average daily gain does flatten out at approximately 70-kg live weight. This may reflect a number of combined occurrences, including respiratory disease and crowding as well as feed changes. The average daily gain is often best compared between barrows and gilts to ascertain that both genders are being affected equally (Dewey, 1993).
- *Feed efficiency:* Even though feed is the major cost in growing-finishing units, precise data on utilization of feed is often not available. Feed efficiency changes over the age of the pig with drastic changes occurring in certain genotypes. This is especially important to evaluate as increasing carcass size is considered. The use of collection pans under the slats is laborious but often exhibits a poor feeder-adjustment regime. Seasonal variations in feed efficiency are also important to monitor; the use of pig feed to keep them warm is expensive under most rearing regimes.
- *Average daily feed intake:* Although this index is relatively easy to monitor in all-in, all-out barns, it is just beginning to be used as an indirect measure for pig growth and pig health. The use of load cells under feed bins to obtain day-to-day measurements of feed disappearance has been introduced. This has been successful in predicting growing performance.
- *Facility throughput:* The number of pigs marketed per pig space per year is a good measure of the efficient use of the facility and the capital required. Clean-out strategies can be compared and monitored.
- *Feed costs per pig:* This index is a combination of feed costs and feed efficiency. It is a strong index to use to justify the minimization of feed costs and can be calculated relatively easily if other indexes are calculated.

Record-keeping in growing-finishing barns is evolving to allow rapid use of records along with prospective estimates of performance. This will continue to be important in the development of the growing-finishing industry. There are a variety of details that can be useful in diagnosing problems and potential performance on individual farms. They can include the following:

- *Gender*: It is well recognized that gender does have an effect on performance and should always be recorded to provide some guidance as to the expected performance of the pig or population of pigs.
- *Weight of culls and mortality:* This is important to accurately define calculations such as average daily gain and feed conversion. These pigs have contributed to the performance and should be included in many of the calculations.
- *Changes in pig weight over time:* In many cases, it is important to identify the time period during which suboptimum growth occurs. Recording a proportion of the pig's weights during incremental periods after the pigs enter the barn is useful in identifying problem areas and, more importantly, predicting the marketing schedule.
- *Weights of individual pigs:* In many cases, not only is the average pig weight important to identify—the distribution of weights is as well. It is important to differentiate in cases of suboptimum growth whether a proportion of pigs or the general population is affected. This can aid in

differentiation of causes and can identify strategies to alleviate the problems.

- *Carcass characteristics:* Since the objective is to produce a lean pork product with a minimum amount of feed, the marketable characteristics of the pigs are important to know. This analysis can identify methods of management, especially comparing groups or ages of pigs.
- *Feed disappearance and costs:* This variable is self explanatory but often poorly measured, especially when rations are mixed on-farm. Recording load cells should be considered in some of these applications.
- *Abattoir surveillance of lesions at slaughter:* If available and possible, every effort should be made to determine the nature and severity of lesions present in pigs sent to slaughter. The incidence and nature of the lesions may reflect the disease status in the herd and assist in the diagnosis, treatment, and control of clinical and subclinical disease. The relationship between the prevalence of lesions at slaughter and environmental factors in the herd is complex and extremely variable. The relation among certain diseases, their lesions at slaughter, and daily weight gain can be estimated.

Chronic diseases certainly have a negative effect on weight gain. Some environmental factors may be associated with certain diseases such as tail biting, but there may be no relation between certain infectious diseases and environmental factors that might be expected to be predisposing. This illustrates the complexity of relating managerial and environmental factors to disease.

The slaughter inspection system in Norway reveals that in bacon pigs, the thoracic cavity is the most commonly affected part of the body because of the frequent occurrence of pleuritis, pericarditis, and pneumonia. Arcoptic mange and ascariasis are also common. In culled sows sent to slaughter, there is a higher incidence of pyemia and abscesses than in bacon pigs. Pyemia and abscesses occur in bacon pigs, often in combination with tail lesions, severe pneumonia, and anemia. Pyemia is also associated with polyarthritis and lesions of the claws. There is a strong relation between serositides and pleurisy, pericarditis, and peritonitis, which suggests that these diseases may be caused by the same agent.

Other studies found a positive correlation among the rates of respiratory disease in feeder pigs, the incidence of clinical disease, the mortality, and the prevalence of lesions at slaughter (Willeberg et al, 1984). Meat inspection appears to be a more sensitive surveillance method for respiratory disease than clinical observation of the pigs. The monitoring of pigs at slaughter is an inexpensive method for obtaining extensive information on clinical incidence, prevalence at slaughter, seasonal and age incidence, efficacy of treatment, and, possibly, the effects of disease on live weight performance and carcass evaluation. It is a powerful tool for the clinico-epidemiological study of some of the common infectious diseases of growing and finishing pigs.

Examination of swine carcasses at slaughter is a valuable aid in several areas of health management. It can be used to detect the presence of subclinical disease or to assist in determining the causative agents of complex diseases. It can also be used to monitor the effectiveness of disease control and therapeutic strategies by comparing the prevalence and the severity of lesions at slaughter before and after implementation of a change between control and test groups (Straw et al, 1986a). Routine slaughter checks also provide a monitoring system to detect subclinical disease that may not have been observed clinically (Miller and Carlton, 1996).

Slaughter checks are valuable for monitoring the prevalence of disease over a wide geographic area and the variations of disease according to seasons. The five major reasons for condemnation of either portions or whole pork carcasses in 1 year were ascariasis, adhesions, abscesses, bruising, and arthritis. These lesions are associated with management-responsive diseases, which are diagnosed at slaughter and account for over 75% of all carcasses condemned.

The logistics of performing slaughter checks have been described (Straw et al, 1986a). The veterinarian must be well prepared for the examination, have the necessary equipment and recording forms, make appropriate arrangements with the producer and the abattoir, and plan which pigs and tissues will be examined and sampled. Careful consideration must be given to the selection of an appropriate number of animals from each different environment in the herd so that the findings will be representative of the real disease situation in the herd. Statistical analysis of the variability of pneumonia and turbinate atrophy suggests that 30 is the minimum number of animals necessary to accurately reflect the level of disease in the herd (Straw et al, 1986a). Positive identification of the pigs from the herd under study is essential. The seasonal variations in disease occurrence must be considered when selecting times of the year for slaughter examinations. When slaughter examinations are made only once or twice yearly, it is possible to miss peaks of disease that occur between the examination intervals. The practical diagnostic procedures used in slaughter checks have been described (Straw et al, 1986b). The speed at which the slaughter line moves varies considerably, and in some cases it moves so quickly that not every pig's lungs can be examined. Lungs are examined and scored primarily for pneumonia and pleuritis, the snouts are examined for turbinate atrophy, and the reproductive tracts can be examined for evidence of diseases of the ovaries and uterus. The stomach is examined for evidence of gastric ulcers, and the liver is examined for evidence of ascarid migration.

The value of a routine slaughterhouse check program for individual commercial producers was examined from seven herds over a period of 4 years in New York State (Straw et al, 1994). Quarterly checks were performed in February, May, August, and November. Pigs were examined for pneumonia, pleuritis, AR, and ascarid infestation. Pneumonia was most severe in pigs slaughtered in the spring, followed by, in descending order, the fall, winter, and summer. AR and ascarid lesions were most severe during the summer and least severe in pigs during the winter. In most cases, there was no evidence of a change in severity of respiratory disease in the herds over the 4-year period. The severity of pneumonia appeared to decrease in one herd whose facilities were extensively renovated. The severity of ascarid scarring decreased in two herds, which instituted control procedures. Commercial producers who made no changes in deworming practices or facilities gained no additional information from repeated slaughterchecks. Thus it is difficult to justify frequent slaughterchecks for most commercial producers unless the checks are accompanied by implementation of new control procedures. Seed stock producers could benefit from routine slaughterchecks as a means of verifying the health status of a herd for potential buyers.

In Finland, slaughterhouse data have been used in herd health management programs organized by cooperative slaughterhouses, and various aspects of the data have been examined using epidemiological studies (Tuovenin, 1994). Slaughterhouse data were compared between farms with high or low levels of condemnations and correlated with environmental and managemental factors in those herds. In feeder pigs units, partial carcass condemnations increased with increasing herd size, increasing stocking density, and increasing ammonia concentration (Tuovenin et al, 1992). Partial carcass condemnations were mainly due to arthritis (50%) and abscesses (35%) (Tuovenin et al, 1994c). The

provision of unsolicited advice to producers about the effects of partial carcass condemnations on average daily gain and production and their relationship to monitored environmental and management factors which was found to be unrewarding (Tuovenin et al, 1994a). It seems that advice can be offered only if requested by the producer and that producers with the greatest need for advice seldom request it. The prevalence and geographical variation of some economically important swine diseases in farrowing units, especially infectious diseases that could be transmitted to the finishing units with delivered growing pigs, was examined (Tuovenin et al, 1994d). Most finishing units received pigs that were infected with mange; the probability of importing pigs infected with the erysipelas pathogen was high. Based on serological studies many herds were positive for *A. pleuropneumoniae* and some for *M. hyopneumoniae.* In Finland, most market pigs are raised in AIAO finishing units. Given the prevalence of infectious diseases in farrowing units, the risk of spreading infectious diseases to finishing units is high. Feeder pigs from one farrowing unit can end up in several finishing units. A system of evaluating the health of farrowing units for freedom from clinical evidence of diseases such as AR, swine dysentery and mange, and seronegativity of colostrum samples for *M. hyopneumoniae* has been described and evaluated (Tuovenin et al, 1994b). The objective is to develop a health classification of multisource feeder pigs for finishing units. A premium price would be paid to the farrowing units to strive for health classification status. Most of the results favored health classification. The benefits were improved daily weight gain, decreased mortality, significant decrease in the incidence of lesions of pneumonia, and pleurisy at the slaughterhouse. Enzootic pneumonia, AR, and swine dysentery were effectively controlled. Enzootic pneumonia is controlled under this system by reducing the risk of infection. Such control procedures minimize the need for the use of prophylactic antimicrobials in the feed. Partial carcass condemnations were higher in the high classification group compared with the control group because of a higher incidence of joint infections.

A survey of the noninfectious factors associated with lung lesions in slaughter pigs from 150 randomly selected farrow-finish pig herds in Belgium found a median herd level prevalence of 24% for pneumonia, 16% for pleuritis, and 60% for lymphohistiocytic infiltration (Maes et al, 2001). Lesions of pneumonia were negatively correlated with lesions of pleuritis. The prevalence and severity of lesions of pneumonia were increased by a high frequency of purchasing gilts and by a slaughtering in January to February. The presence of a growing unit on the farm increased the severity of the pneumonia. The prevalence and the severity of lesions of pleuritis were higher when there were more pig herds in the municipality, when there were inadequate biosecurity measures, and when the slaughtering occurred in March to April. An increase in the airspace stocking density in the finishing unit also increased the prevalence of pleuritis. Pigs raised in pens with slatted floors were also at higher risk of more severe lesions of lymphohistiocytic infiltration.

Diseases of Growing and Finishing Pigs

The most economically important diseases of pigs during the growing-finishing period are infectious diseases of the respiratory and digestive tracts (Losinger et al, 1998b). Raising of pigs in total confinement has successfully controlled several soilborne infectious diseases, but pneumonia and enteritis still occur clinically and subclinically and cause major economic losses. Pigs affected with acute pneumonia are relatively easy to detect. The major problem, however, is the presence of the subclinical pneumonias, such as enzootic pneumonia caused by *Mycoplasma* spp. and pleuropneumonia caused by *A. pleuropneumoniae.* The important diseases of the pig during the growing-finishing period are those that are endemic and cause subclinical disease and those that cause epidemics of clinical disease. Box 15-6 lists the diseases that occur with an indication of how commonly they occur and whether they are usually endemic or cause epidemics.

Respiratory Diseases of Growing and Finishing Pigs

Respiratory diseases are common in swine herds worldwide and are clinically manifested primarily in growing and finishing pigs. The most prevalent are pneumonia, pleuropneumonia, pleuritis, and AR, often with multiple contributing infectious agents. An important risk factor in these diseases is that the primary source of the infections is an infected pig. The causes of economic loss are significant and due to reduced growth and feed efficiency. The economic losses are more severe if respiratory disease occurs early in life or is aggravated by other infectious diseases or an adverse environment. In general the morbidity of these diseases is high, although the mortality is variable depending on the causative agents involved and the level of management and adequacy of the environment in which the pigs are housed.

The effects of each of the diseases just described on growth rate are different on each farm, probably because of differing environments and variations in the virulence of serotypes. The presence of pleuropneumoniae in the herd warrants an evaluation of the epidemiological determinants on each farm, followed by recommendations based on an analysis of the conditions on each farm.

Outbreaks of acute respiratory disease in finishing pigs are a major problem in finishing barns, and their etiology is often unclear. A detailed clinical and diagnostic laboratory evaluation of affected pigs in 16 outbreaks of acute respiratory disease in finishing pigs led to a definitive diagnosis in only 12 (Loeffen et al, 1999). Seven were due to an infection with influenza virus and *A. pleuropneumoniae*. A combination of influenza virus and *A. pleuropneumoniae* may have caused one other outbreak, but no clear cause could be established for the other three outbreaks.

The animal welfare aspect has been examined, and public health concerns with regard to the syndrome have been raised. The use of antibiotics for the treatment of pneumonia in finishing pigs increases the risk of antibiotic residues in carcasses with lung lesions as compared with those without pathological abnormalities. In addition, the environmental factors causally related to respiratory disease in housed pigs may also be a source of health problems in people working on pig farms.

Various methods have been used to control respiratory disease in swine herds. The use of SPF herds has been effective as a method of eradication; however, many of these herds became reinfected at a later stage because of airborne disease transmission. Besides eradication, various control methods designed to reduce infection pressure within the herd, such as management and environmental changes, medication, and vaccination, have been applied with variable success.

Enzootic Pneumonia. Enzootic pneumonia is a bronchopneumonia primarily caused by *M. hyopneumoniae,* and secondary pathogens such as *P. multocida* are commonly the cause of secondary pneumonia. AR, characterized by turbinate atrophy, is caused by some strains of *B. bronchiseptica,* with or without the dermonecrotic toxin-producing strains of *P. multocida.* Pleuritis is associated with infections by *Mycoplasma hyorhinis, P. multocida, A. (Haemophilus) parasuis* and *A. (Haemophilus) pleuropneumoniae.* Pleuropneumo-

BOX 15-6

Diseases of Growing and Finishing Pigs

RESPIRATORY DISEASES

Common

Enzootic pneumonia caused by *Mycoplasma* spp.; commonly endemic
Pneumonic pasteurellosis caused by *Pasteurella* sp.; commonly a result of enzootic pneumonia
Pleuropneumonia caused by *Actinobacillus (Haemophilus) pleuropneumoniae*; endemic and epidemic

Less Common

Atrophic rhinitis (i.e., turbinate atrophy) caused by toxigenic isolates of *Pasteurella multocida* and *Bordetella bronchiseptica*; endemic
Swine influenza; sporadic
Glasser's disease; sporadic

GASTROINTESTINAL DISEASES

Common

Esophagogastric ulcers (e.g., gastric ulcers)
Intestinal helminthiasis; endemic
Ileitis caused by *Lawsonii intracellularis*
Ascariasis resulting from *Ascaris suis*

Less Common

Swine dysentery caused by *Brachyspira hyodysenteriae*; endemic and epidemic
Adenomatosis complex; endemic and sporadic acute clinical illness
Proliferative hemorrhagic enteropathy
Enteric salmonellosis; sporadic
Rectal strictures; sporadic

Rectal Prolapses

Predisposing causes of rectal prolapses include zearalenone toxicosis, chilling (and piling), and genotype. Treatment is usually through replacement and retention using a purse-string suture. It should be noted, however, that many rectal prolapses may be cannibalized and not noticed by the stockperson. Rectal prolapses may lead to rectal strictures.

Torsion of Abdominal Organs

Predisposing causes include agitation, overcrowding, whey rations, and engorgement. At necropsy, the main signs are hemoperitoneum, rotation of the spleen with stomach, enlargement of the spleen, and torsion of the root of the mesentery.

SEPTICEMIAS-SPORADIC

Streptococcus suis
Salmonellosis
Eryisipelas
Hog cholera
Pasteurellosis
Eperythrozoonosis

DISEASES OF THE NERVOUS SYSTEM

Pseudorabies
Str. suis

NUTRITIONAL DEFICIENCIES

Mulberry heart disease, hepatosis dietetica, exudative diathesis caused by vitamin E or selenium deficiency; sporadic
Osteodystrophy caused by absolute deficiency or relative imbalance of calcium and phosphorus; uncommon
Parakeratosis (e.g., zinc deficiency)

GENETIC DEFECTS

Porcine stress syndrome and pale soft exudative pork; common in some herds

BEHAVIORAL VICES—COMMON

Tail biting, ear chewing, flank biting

SKIN DISEASES

Greasy pig disease (*Staphylococcus hyicus*)
Sarcoptic mange

POISONINGS

Salt, arsenic, organophosphate
Selenium
Monensin toxicosis*
Mycotoxicosis (Fumonisins *[Fusarium moniliformis]*)† and vomitoxin

DISEASES OF THE FEET AND MUSCULOSKELETAL SYSTEM

Leg weakness, osteochondrosis; common
Sore feet, cracked feet, foot rot; less common
Erysipelas arthritis; common to sporadic
Mycoplasma arthritis; sporadic

*From Miskimins DW, Neiger RD: *J Vet Diagn Invest* 8:396-397, 1996.
†From Guzman RE, Casteel SW, Rottinghaus GE, Turk JR: *J Vet Diagn Invest* 9:216-218, 1997.

nia, a pulmonary necrosis accompanied by pleurisy, is a frequent consequence of infection with *A. (Haemophilus) pleuropneumoniae*. Acute forms of pleuropneumonia are associated with high-mortality fibrinohemorrhagic pneumonia, epistaxis, and blood-stained fluid in the pleural cavities and trachea.

M. hyopneumoniae is a problem mainly when in concert with secondary bacteria such as *P. multocida*. This pathogen is common among swine herds, although differences in the pathogenicities of strains occur. There are four capsular serotypes: A, B, D, and E; A and D are the most common types, with type D being associated with AR and type A with pneumonia. Both appear to require an initiating pathogen to allow colonization; *M. hyopneumoniae* is thought to be the major initiator for pneumonia, and *B. bronchiseptica* for AR. In AR, there is blockage of the tear ducts, twisted nose, turbinate atrophy, and poor growth rates. In acute pneumonia, clinical findings include dyspnea, productive coughing, some nasal discharge, and a fever of 104° to 106° F. Chronic cases show some productive coughing and poor growth.

Pleuritis occurs occasionally and causes a more severe reduction in growth rates. Both cause uneven growth and overall poor performance, with large amounts of money being spent on its control. It also limits the ability to move and mix pigs.

A comparison of the performance of pigs reared in AIAO production with pigs in continuous flow (CF) production during the growing-finishing phase found that lung lesions were less prevalent and severe in the AIAO system, even though the pigs may have been infected with *M. hyopneumoniae* and *P. multocida* but not exhibited signs of clinical disease when placed in the growing-finishing facility at 17- to 20-kg body weight (Scheidt et al, 1995). Antimicrobials were not added to the rations. The incidence of disease was much higher in the CF pigs than in the AIAO pigs. This illustrates that control of the environment and the population of pigs as a unit allows for improved performance of the pigs, even though they may be infected with the common pathogens causing respiratory disease in growing-finishing pigs.

The effect of enzootic pneumonia on the functional status of the pig has been evaluated by comparing average daily gain and feed efficiency in pigs with pneumonia against those without lesions of pneumonia (Morrison et al, 1986). Since the disease was first characterized, it has been accepted as a major cause of decreased productivity in finishing pigs being fed for market. There are many reports in the literature claiming that the economic losses are the result of mortality from secondary bacterial pneumonia, decreased rate of gain, and increased marketing of undersized or cull pigs. In pigs located at a central performance test station, the presence of lung lesions at slaughter was associated with a decrease in mean daily weight gain. For every 10% increase in the amount of lung tissue affected with pneumonia, mean daily weight gain decreased by 5.3% (Straw et al, 1983). Of the pigs examined at slaughter, 8.5% had no evidence of pneumonia, 52% had pneumonia in 1% to 5% of the lung, 22.5% had pneumonia in 6% to 10% of the lung, 8.5% had pneumonia in 11% to 15% of the lung, and 3.5% had pneumonia in 16% to 20% of the lung. There was involvement of more than 20% of the lung in 5% of the pigs.

These statistics illustrate the large percentage of pigs that may be affected with subclinical pneumonia and the potential for large economic losses as a result of suboptimum performance. The methods used to estimate the economic costs of pneumonia in swine herds include measurement of the growth rate and feed conversion, along with assessment of the severity of pneumonia in the herd, as determined by lesions present at slaughter (Straw et al, 1989). On average, mean daily gain decreased by 37.4 g for every 10% of the pig's lung affected by pneumonia. However, the results of many examinations of the association between enzootic pneumonia and performance have been inconsistent (Morrison et al, 1986). The effect that the lesions of enzootic pneumonia may have on performance depends on management and environmental conditions. Of 23 studies, 10 reported no significant effect, and the remaining 13 reported decreased average daily gain or increased feed:gain ratio by 5% to 25% and 4.6% to 25%, respectively. These variable results may occur because of the different experimental designs and techniques used. Inconsistent results may also be the result of the lung's ability to resolve pneumonia. As pigs increase in body weight above 40 kg, the prevalence of pneumonia decreases. Therefore, in the assessment of pneumonia in pigs at a slaughter weight of 100 kg, the older pigs may have been reduced in their gain; however, if pneumonic tissue has resolved, the pneumonia score may not reflect the true influence pneumonia has had on growth rate. *M. hyopneumoniae* causes a dry, nonproductive, "barking" cough in growing pigs. It predisposes pigs to secondary bacterial infections; independently, there is little effect on production, although it has been associated with decreased growth rates (Beskow et al, 1998).

Enzootic pneumonia in feeder-pig herds is more severe in herds that have inadequate facilities and in which pigs were purchased from auction marts, compared with herds that have good facilities and in which the pigs originated directly from breeding herds. In herds that obtained pigs directly from breeders, the management was considered acceptable and pigs had fewer clinical signs, the fewest pneumonic lesions, the best feed efficiency, and the lowest level and prevalence of the antibodies to TGE. The best evidence suggests that infection of the respiratory tract combined with environmental stressors such as inadequate ventilation and overcrowding causes clinical and subclinical pneumonia.

Actinobacillus Pleuropneumonia. *A. pleuropneumoniae* is the cause of actinobacillus pleuropneumonia. There are at least 13 distinct serotypes (1-12 with 5a and 5b). Certain serotypes are recognized in particular parts of the world, with serotypes 1 and 5 dominant in North America and serotypes 2, 3, and 9 in Western Europe. An excellent review of the taxonomy and bacteriology of the organism is available (Rycroft and Garside, 2000). The organism may cause disease independent of other respiratory pathogens and causes severe necrosis and hemorrhage in the lung of nonimmune pigs. In the acute form, pigs have labored breathing, are profoundly depressed, and die quickly. Lesions may be present throughout the lung but are most common in the upper lung. Necrotic, raised areas are commonly present with a fibrous exudate on the surface. In chronic cases, these necrotic areas become hardened and pleural tags develop. Mortality and morbidity rates can reach almost 100%. The laboratory diagnosis is usually obvious.

Antibiotic therapy, vaccination, and test-and-slaughter programs, either alone or in combination, have been used in attempts to control pleuropneumonia with varying degrees of success. Survivors of acute infection often develop chronic lung lesions and become carriers. The organism does not persist in the environment, and only pigs are known to be susceptible to infection; therefore elimination of the organism seems feasible. The infection is spread between herds by carrier pigs that harbor the organism in the nose, tonsils, or is sequestered in the lungs without any clinical sign. The spread of the disease is difficult to control because there is no reliable method to determine whether or not a pig herd is infected. The distribution of the serotypes varies from country to country, and the relative virulence of each serotype also varies (Vaillancourt et al, 1990). Three serological tests are available: namely, the modified complement fixation test, the ELISA test, and the 2-mercaptoethanol tube agglutination test. The immune response is serotype specific, but some serotypes share antigenic determinants with other serotypes. This may complicate both serodiagnostic and seroepidemiological work.

The disease occurs most commonly during the winter months in Canada, when the temperatures are cold for long periods and the adverse weather conditions commonly lead to poor ventilation of barns. Other important risk factors include increased traffic of pigs into the herd, purchasing of supplementary stock from sales barns rather than from herds known to have a low prevalence of the disease or from one breeder, and crowding of pigs.

The economic impact of the disease depends on the morbidity, mortality, treatment costs, and its effect on growth rate, feed efficiency, and carcass condemnations, all of which are dependent on the virulence of the serotype. In some herds the morbidity and case fatality from pneumonia can be high, whereas in others, the disease is subclinical and can

be identified only serologically and by the presence of lesions of pleuritis at slaughter. The effect of the disease on growth rate and feed efficiency varies from herd to herd and may be influenced by the level of management. In some herds, the incidence and severity of the disease can be controlled at acceptable levels by improvements in management and the treatment of clinically affected pigs.

Long-acting oxytetracycline IM may prevent experimental infection (Kiorpes et al, 1989) and may reduce mortality if used early in the course of the disease. However, the organism has developed resistance to certain antimicrobial agents. There is a high prevalence of resistance to ampicillin, penicillin, chloramphenicol, and tetracycline (Vaillancourt et al, 1988). When comparing the effectiveness of different treatments, the veterinarian must know exactly the virulence of the strains involved as well as their drug sensitivity. If this is not possible, eradication using depopulation and repopulation may be necessary.

A less inexpensive method of control is successive depopulation, in which seropositive sows are culled when their pigs are weaned at 3 weeks of age. These piglets, which are protected by colostral immunity and are unlikely to be infected, are then reared in isolation from potentially infected stock. During the period of elimination of the sows, the feed may be medicated for 6 to 12 months to inhibit the spread of the organism.

Pigs surviving a natural infection develop immunity and are protected against further infections of homologous or heterologous serotypes. However, the antigens that produce this solid protective immunity have not been identified clearly, and commercially available vaccines based on whole-killed bacteria do not provide complete protection. The success of the vaccines has been limited because of irregular efficacy, cost, short duration of immunity, and development of injection site granulomas. Piglets vaccinated with an inactivated tetravalent vaccine against serotypes 1, 2, 5, and 7 produced antibodies after the first injection and an anamnestic response after the second (Rousseau et al, 1988). This suggests that a second vaccination before sending piglets to the finishing unit should help to reduce the losses caused by pleuropneumonia.

Atrophic Rhinitis. The effect of atrophic rhinitis on growth rate and feed efficiency is inconclusive (Cowart et al, 1990; Scheidt et al, 1990). Turbinate atrophy assessed at the abattoir was not related to growth rate; however, in a few herds, pigs with severe turbinate atrophy had slower growth rates. In other studies the average reduction of growth rate in pigs with severe turbinate atrophy was 4.7% compared with pigs without it (Baalsrud, 1987). The difference was significant only in some herds. Pigs with moderate turbinate atrophy gained on average 1.1% less than unaffected pigs. There was no relationship on a herd basis between the reduction in growth rate and the percentage of pigs in the herd with the disease. The economic losses caused by atrophic rhinitis in a herd may be estimated on the basis of the number of pigs affected. As finishing pigs gain about 1 kg/day during the immediate preslaughter period and are slaughtered at approximately 100 kg of live weight, pigs with moderate atrophy need about 1 more day to compensate for the 1.1% reduced growth rate; those with severe atrophy require about 5 more days to reach normal slaughter weight.

The relationship between turbinate atrophy and pneumonia is variable. In some studies there was no difference in the prevalence of pneumonic lesions at slaughter among pigs with turbinate atrophy (Straw et al, 1983).

Whereas infectious atrophic rhinitis is caused by toxin-producing *P. multocida* types A and D and *B. bronchiseptica*, and the presence of the former can produce a severe progressive form of the disease, there is much variation in the severity of the conchal damage seen both within and between farms where both pathogens are present. The mere presence of the organisms is not a sufficient cause for the disease to occur. The aerial environment is considered an important part in the epidemiology and pathogenesis of the disease. Inflammation and colonization of the nasal mucosa occur in the young pig. Atmospheric ammonia, dust, and microbial concentrations in the farrowing house, as well as dust in the stage-one weaner house, play a significant role in the severity of the disease.

There are significant and positive correlations between the severity of conchal atrophy at commercial slaughter weights and the increased aerial concentrations of dust, bacterial counts, and ammonia in farrowing houses. The relationships between the dust concentrations in the first-stage weaner houses and the severity of the disease at slaughter were stronger and more numerous than the relationship with the farrowing houses. Some farms have a relatively low average snout score of conchal atrophy even though the toxigenic pathogens are present, which emphasizes that air quality has an important mediating role in the expression of clinical signs of the disease. Air quality can be influenced by the management and design of a building and the fixed equipment in it, and the severity of the disease can be influenced by manipulation and control of air quality.

Swine Influenza. Swine influenza is classically caused by virus type H1N1. The virus enters a herd and spreads rapidly by aerosol, with almost 100% morbidity with fever, dyspnea, and some coughing. Recovery occurs in 5 to 7 days with little or no mortality unless secondary infections occur. In comparison with other respiratory diseases, there are minimal clinical effects unless secondary infections occur.

Systemic Diseases. Several diseases, including those caused by *S. choleraesuis, A. suis, Str. suis,* and *H. parasuis,* can cause a bacteremia with localization in the lungs, resulting in pneumonia. This is particularly the case in the presence of preexisting lesions of *M. hyopneumoniae.*

Epidemiology of Respiratory Disease in Growing and Finishing Pigs

The risk factors that predispose to respiratory disease in growing-finishing pigs are complex and multifactorial. It is often difficult to interpret the significance of the presence of pathogens in the tissues of affected animals. The literature on the epidemiological investigation of the influence of environmental risk factors on respiratory diseases in swine has been reviewed (Stark, 2000). These factors can be categorized as characteristics of the herd, the management, the air quality, and the neighboring farms. The large number of factors associated with respiratory diseases and their interaction make it difficult to understand the epidemiology.

From a practical basis the factors can be divided into those affecting the presence of a causative agent known as infection pressure, and those that influence the susceptibility of the individual animal and consequently the establishment of the disease.

Infection Pressure. Nose-to-nose contact and airborne route are the most common routes of transmission. Transmission between animals requires (1) excretion by infected animals, (2) critical concentration, and (3) contact between susceptible animals and the causative agent. Because causative agents are easily introduced into a farm with live animals, the purchase policy of a farm is one of the most important risk factors. Generally, closed farms have the lowest risk, whereas exclusively finishing farms that purchase all their pigs are at highest risk, especially if they buy from several sources or from an auction market. The probability of purchasing infected pigs increases with

multiple sources, as the number of pigs purchased increases, and as frequency of purchasing increases (Stark, 2000). Finishing farms that purchase all of their stock are at greater risk than breeding farms, which are less likely to buy large numbers of animals from different sources.

Airborne transmission of infectious agents occurs from infected to noninfected animals within farms, and between neighboring farms if they are close enough. After their release from infected animals, infectious agents can exist as airborne or nonairborne particles. Certain management procedures can be used to reduce the concentration of infectious particles in the environment and to reduce the risk of a susceptible animals coming in contact with the agents. For airborne particles, the number of pigs sharing the same air space in a building, the stocking density, and the air volume available per pig are factors influencing aerosol levels. Ventilation also has a direct influence on aerosol levels and is associated with respiratory disease (Stark, 2000).

As herd size increases, the risk of respiratory disease increases. The presence of nearby swine farms with respiratory disease also increases the risk.

For nonairborne particles, other management factors are important. Production systems in which pigs are moved through the different production stages in batches (AIAO) compared with CF systems generally include cleaning and disinfecting steps that reduce pathogen concentrations. The literature on this subject indicates that it is highly advantageous for the control of respiratory disease.

Environmental Risk Factors and Susceptibility of the Pig. Several factors are considered to affect the susceptibility of pigs to respiratory disease (Stark, 2000). The microclimate of the environment is characterized by temperature, humidity, dust, gases, and airborne bacteria. Temperature and air drafts are the main sources of climatic stress. The immune response of pigs experimentally challenged with *A. pleuropneumoniae* may be affected by drafts and fluctuating temperatures. Air temperature and humidity have a close relationship to each other, but their combined effects to increase the susceptibility of pigs to respiratory disease are not clear. The survival of airborne respiratory pathogens depends on air humidity, and the number of respirable particles is also related to air humidity. Airborne gases, dust, and pathogens are also important components of the microclimate affecting susceptibility. Dust, ammonia, carbon dioxide, and microbes are correlated with the occurrence of pneumonia and pleuritis at slaughter. In behavioral studies, pigs exhibit distinct preference for fresh air compared with ammoniated air (100 ppm). This emphasizes the importance of environmental monitoring to ensure an optimum climate for pig production and a healthy environment for swine confinement-building workers.

Management risk factors influencing airborne particle concentrations include stocking density, ventilation, use of bedding, manure disposal, and method of feeding. Slatted floors and inadequate floor insulation (no bedding) may contribute to respiratory disease, but their effects have not been quantified. Similarly, the effects of floor feeding and access to drinking water may be involved but have not been evaluated. Changes in the weather may influence the occurrence of respiratory disease; it may be more common during cold wet seasons.

Host risk factors that may increase the susceptibility of pigs to respiratory disease include the immune status of the animals, the presence of other infectious diseases, nutritional deficiencies, and the presence of toxic factors such mycotoxins in the feed (Stark, 2000). The age of the pigs at weaning and birth weight may also be related to the severity of pneumonic lesions at slaughter. There also may be an association between the social status of the pig and its immune response (Hessing et al, 1994). Dominant pigs have significantly higher values in a lymphocyte proliferation assay than subdominant and subordinate pigs. Regrouping of pigs after weaning is an acute stressor.

A well-designed epidemiological analysis of the effect of environmental factors on the health of finishing pigs is recorded by Lindqvist (1974). Clinical inspections were made in 99 finishing herds involving 209,815 pigs delivered for slaughter over a 3-year period. The study attempted to answer several important questions about the role of housing and environment on the health and production of finishing pigs.

The average daily gain in pigs with severe pneumonia at slaughter was significantly lower than that in pigs without lung lesions at slaughter. There were no differences in growth rate between pigs with mild pneumonia as the sole pathological lesion and those without lung lesions at slaughter. The incidence of pleurisy and pericarditis was also lowest when pigs were housed in sections of less than 500 pigs, when production was strictly in batches, and when the total area was more than 0.7 m^2/pig. The incidence of pleurisy was highest during the warm period from May to October, and the average daily gain was lower in pigs with pleurisy than in those without pleural lesions at slaughter.

In an overall assessment of the results, it was concluded that health status generally appears to be better in barns with production strictly in batches, less than 500 pigs/section, space volume of at least 3 m^3/pig, a total area (e.g., lying area and area in dunging passage) of at least 0.7 m^2/pig, a solid manure-handling system in the house, and free access to drinking water. It also was concluded that, of the studied environmental factors, the system of rearing has the greatest influence on animal health.

It was evident that an assessment of health status based entirely on observations made at slaughter must be complemented by a veterinary assessment of the animals in their environment during the period of production if definite conclusions are to be drawn. If this is not done, essential information on the general clinical condition and behavior of the animals will be absent, as will be data on diseases that are not recorded at slaughter.

In another field study, a microcomputer-based environmental monitoring system was used to continuously monitor temperature, relative humidity, bacterial colony count of the air, and ventilation rate in commercial growing-finishing barns (Bauck et al, 1990). Significant differences existed among barns for daily maximum and minimum temperature, relative humidity, ventilation rate, and average bacterial colony-forming particle counts. There was no difference among farms in the average percentage of lung affected with pneumonia, average snout atrophy score, or growth rate of the test animals. It seems that further work is necessary to define measurable environmental parameters that may be responsible for variations in respiratory disease and productivity or that could be used as indicators of other environmental factors that affect disease and productivity (Bauck et al, 1990).

Factor analysis has been used to describe risk factors for respiratory disease on pig farms (Hurnik et al, 1994a). Factor analysis is a statistical technique for condensing the information from a large number of variables into a small set of uncorrelated new variables called factors that are weighted sums of the original variables. Under favorable conditions, each of the original variables is correlated highly with a single factor. These correlations induce a partition of the original variables into groups of correlated variables, each group being associated with a single factor. Subsequently these factors can be used as predictor vari-

ables in regression models. From the examination of 76 farms, 43 management variable were calculated. The 43 variables were condensed into 6 factors through factor analysis. The farm types that emerged were as follows: (1) smaller farms using extensive farming techniques: high volume and space per pig and straw as bedding, (2) a farm type using group flow, a system that used solid pen partitions, did not move pigs between pens, and a higher ratio of pigs to water spaces, (3) a farm type with room pig flow that was larger (pigs sold) than others in the study population, was farrow-to-finish, and had modern facilities, (4) farms that bought pigs from different sources, did not seek veterinary advice, and had slow-growing pigs, (5) a family farm type that primarily floor fed the pigs, and (6) an integral farm type that was larger than average, made its own feed, was closer in proximity to other farms, and had other farmers as primary visitors.

The results of the factor analysis can then be used in a regression analysis of enzootic pneumonia and pleuritis prevalence at slaughter (Hurnik et al, 1994b). Farms were dichotomized on enzootic pneumonia prevalence greater or less than 10%. Multiple source feeder barns (Farm Type 4) with low emphasis on disease entry and control had an odds ratio of 2.38 of having enzootic pneumonia. Family farms (Farm Type 5) using floor feeding methods had an odds ratio of 3.31. Integrated farms (Farm Type 6) had an odds ratio of 2.31, suggesting that farms that mill their own feed and are closer in proximity to other pig farms have a greater chance of having enzootic pneumonia. A linear regression of the prevalence estimates of enzootic pneumonia on positive farms revealed that only farms with multiple source feeder barns and floor-fed family farms were associated with a higher prevalence of enzootic pneumonia. Farms with extensive pig housing (Farm Type 1) were associated with a lower prevalence, suggesting that farms with ample pen space and air volume had fewer pigs with enzootic pneumonia. The odds of pleuritis were also lower on farms with extensively housed pigs. In summary, the study demonstrates that certain combinations of management risk factors found on the pig farms examined are associated with an increased overall risk of having enzootic pneumonia.

Simulation modelling can be used to predict the prevalence and severity of respiratory disease and the economic effects in relation to environmental factors. One such program is RESPIG, in which the air quality on a farm is classified into one of six categories; then the disease process is simulated along with its effect on feed intake, feed conversion, and growth (Turner et al, 1993).

In summary, the epidemiology of respiratory disease in growing and finishing pigs is complex, an investigation of respiratory disease requires a systematic identification and evaluation of the risk factors before recommendations can be made about which changes are necessary to control the disease and its effects on production. The critical aspects that should be examined include the following:

- *Hygiene:* Cleaning, disinfection, fly and rodent control, animal and person traffic, vehicles
- *Husbandry:* Climate, feeding, installations (pens effluent system, troughs, ventilation)
- *Management:* Stocking density, purchase policy, animal movements within a farm

Control of Respiratory Disease in Growing and Finishing Pigs

The control of respiratory disease in growing and finishing pigs depends on the prevention of infected animals being introduced into the herd and on the provision of adequate housing and ventilation. One environmental risk factor that may affect the health of growing pigs in intensive housing systems is the atmosphere, which includes air temperature, air movement, humidity, noxious gases, dust particles, and aerial bacteria (Jansen and Feddes, 1995). Other risk factors are related to the pens, including divisions in the pens, flooring, dunging facilities and disposal methods, feeder space allowance, and stocking density. Other factors include hygiene and the presence of pests as possible vectors.

If pneumonia is a major problem in a finishing barn, it may be possible to alter up to 20 environmental variables in an attempt to reduce the incidence of disease (Done, 1991).

1. A minimum of 250 to 300 pigs per barn (ideally 150).
2. Only 10 to 12 pigs in a pen, preferably with no mixing or moving.
3. More than 3 m^3 of air space/pig.
4. At least 0.7 m^2 of lying and dunging areas/pig with at least 0.5 m^2 for lying.
5. An AIAO policy should be operated.
6. Only one source of piglets to the finishing system.
7. The pens should be cleaned and disinfected between groups.
8. The number of air changes per hour should be increased.
9. A solid manure system is preferable.
10. If a slurry system is used, the slurry ideally should be removed daily to prevent accumulation of toxic gas.
11. The temperature fluctuations should be kept to a minimum.
12. Single span buildings are best because they help minimize cross infection.
13. Air should flow from the lying to the dunging area and then out the building.
14. Ammonia levels should be kept below 20 ppm and hydrogen sulfide below 10 ppm; other potential gas hazards should be reduced by segregating the pigs from the stored slurry.
15. Dust levels should be kept as close as possible to outside levels (1 mg/m^3) and not allowed to exceed 10 mg/m^3.
16. The level of respirable dust (0.5 to 2.5 μ) should be kept as low as possible by attention to feeding and bedding techniques.
17. Bacterial levels should be kept below 10^4 m^3 by attention to stocking densities and cleanliness; filters may become necessary.
18. Gram-negative organisms should be kept at low levels to reduce the aerial concentration of endotoxin, probably by efficient manure removal and cleanliness.
19. The pigs should have free access to drinking water.
20. Most important, attention should be paid to stocking densities, particularly during the winter months.

The principles of control of the major respiratory diseases of growing and finishing pigs are summarized here. The general control of respiratory disease depends on which respiratory disease is most prevalent in the herd. More than one of three common diseases may be present, which will require the development of a control strategy to meet the needs of the particular herd.

Enzootic Pneumonia. *M. hyopneumoniae* infects only pigs, and transmission requires close pig-to-pig contact. If transmission can be prevented, it is possible to limit or even eradicate the disease from a herd. There are thus two levels at which control can be practiced: *complete eradication* or *controlling the disease and its effects at a low level.*

The principles of control of enzootic pneumonia include the following strategies:

- Regular inspection of the herd for evidence of disease clinically and use of slaughter checks of lungs.
- Rigorous biosecurity of animals being introduced into the herd and control of visitors.

- Provision of adequate environmental conditions, including air quality, ventilation, temperature control, and stocking density.
- Use of the AIAO system of production, in which groups of pigs by age or stage of production are moved through the herd from the gestation barn, farrowing barn, nursery rooms, finishing units, and the pens previously occupied are cleaned, disinfected, and left vacant for several days before animals are reintroduced.

Eradication. This method of control is the most satisfactory and is probably mandatory for large breeding companies and herds supplying replacement stock to other herds and for large intensive farrow-to-finish enterprises. It is based on the principle that the source of infection for the young pig is the gilt or the sow, and this chain of infection must be interrupted to prevent infection.

SPECIFIC PATHOGEN FREE OR MINIMAL DISEASE PIGS. Several methods of eradication have been attempted, but the most satisfactory is repopulation with SPF pigs. The principle underlying this method is that the piglet in utero is free of infection with *M. hyopneumoniae.* If it is taken from the uterus at term by suitable sterile hysterectomy or hysterotomy techniques and reared artificially in an environment free of pigs, it will remain free of this infection. In practice this has been done in special units and the piglets have been used subsequently to repopulate existing farms where all pigs have been removed 30 days before the SPF pigs were introduced and a thorough cleaning program completed. This method was initially developed for the control of enzootic pneumonia and atrophic rhinitis. Moreover, if suitable precautions are taken and if the piglets are used to populate new units that have had no previous exposure to pigs, freedom from other important diseases such as internal and external parasitism, leptospirosis, brucellosis, swine dysentery, and others can be achieved. The progeny of these primary SPF herds can be used subsequently to repopulate other or secondary SPF herds known as minimal disease pigs.

Because of the cost and technical difficulty of this method, other methods of eradicating enzootic pneumonia have been attempted, but they are generally less satisfactory and have a higher failure rate. These include *"snatching" of pigs at birth* and *isolated farrowing*. In the former the piglets are caught and removed from the sow immediately at birth and reared as previously described or foster-suckled on SPF sows in another environment. Although enzootic pneumonia may be eliminated by this method, fecal contamination during parturition of the vulva and vagina and consequently of the piglet is common; this method is less satisfactory for disease control than removal by hysterectomy.

ISOLATED FARROWING. Isolated farrowing techniques have proved successful in small herds but have a high failure rate when practiced on a large scale. Older sows believed to be free of infection are farrowed in isolation in individual pens erected outside on pasture, and each sow and litter is kept as a separate unit. The litter is inspected clinically at regular intervals, and subsequently a proportion of the litter, usually excess males and gilts undesirable for breeding, are examined at slaughter for evidence of pneumonia. Any litters with clinical, pathological, or laboratory evidence of pneumonia are eliminated from the program. Litters that pass inspection are kept for repopulation of the herd. Because of the difficulties in detecting carrier pigs without lesions, eradication by methods using these principles frequently fails.

MINIMAL DISEASE HERDS. Minimal disease herds have been established in most countries with significant pig populations either by breeding companies or private purebred breeders. As a result there is, in most countries, a nucleus of enzootic pneumonia-free stock, which is a major swine-producing enterprise worldwide. The establishment of primary SPF herds is technically difficult and very costly and should not be undertaken lightly. There is also a considerable delay in cash flow between the time of initial population and buildup of herd numbers to the time when significant numbers of pigs are available for sale. Because of this, if eradication by repopulation is intended, it is preferable to purchase pregnant gilts from established primary SPF herds unless the maintenance of existing genetic lines dictates otherwise. Before recommending eradication by this method, the pig owner must understand the principles of this method of control and the restrictions that will need to apply if it is to be successful. Farrow-to-finish enterprises established by this method should be run as closed herds, and if further genetic material is required it should be introduced by hysterectomy techniques or by purchase from the initial source herd. The use of AI is an alternate method; however, isolation of *M. hyopneumoniae* from semen is recorded.

The problem of certifying and maintaining herds free of enzootic pneumonia is a major task.

Reinfection of herds. Reinfection of enzootic pneumonia-free pig herds occurs despite high standards of isolation and strict precautions, whereby complete protective clothing and showering routines are required for all visitors entering the unit. All visitors are debarred entry if they have been to a possible source of infection during the previous 48 hours and even up to 7 days. Also, the majority of breakdowns occur in herds that have not imported infected stock recently. In reinfected herds that imported stock, there was no concurrent evidence of breakdown in the parent herds, which supported the contention that the importation of infected pigs was an unlikely source of the infection. An epidemiological investigation of these reinfections suggests that close proximity of uninfected herds to infected herds may be an important factor. The organism does not survive for more than a few days under dry conditions; however, it can survive in diluted tap water and rainwater for 2 to 3 weeks, and it has been suggested that the organism may be transported in moist air and that airborne infection between piggeries is a possible method of transmission. Some preliminary estimates of risk indexes based on the proximity of other pig units has indicated that the most important factor was the reciprocal of the square of distance to the nearest other unit. The crucial distance for maximum survival was about 3.2 km.

Antimicrobial prophylaxis. Eradication of newborn piglets has been attempted by antimicrobial treatment with oxytetracycline on Days 1, 7, and 14, followed by weaning on Day 14 and a move to an offsite nursery. This is known as a low-cost, modified, medicated-early-weaning program. This can be followed by serological testing of the breeding herd and culling of positive reactors. Antibiotics are of questionable value, although tetracyclines, tiamulin, lincomycin, and tylocin have been used. Vaccines are being produced and have been shown to reduce the level of lesions at slaughter (Maes et al, 1999).

Low-level disease. The alternative to eradication is to limit the effects of the disease in those herds in which eradication is either not desirable or not feasible. The effects of the disease are generally less severe in nonintensive rearing situations and in small herds in which individual litters are reared separately and in which litters from older sows can be reared separately from other pigs. Where litters are grouped at weaning, a low stocking density with less than 25 pigs in initial pen groups and 100 pigs in a common air space may also reduce the severity.

Temperature, humidity, and ventilation also have an important influence on the disease. It is possible to determine an optimum air temperature zone for growing-finishing

pigs based on the measurement of behavioral and health-related problems. They are interrelated with stocking density and housing. The subject is too broad for full explanation here, and the requirements for pigs at different ages and under different housing situations may be found in standard texts on pig housing and production. The environmental risk factors associated with the incidence of enzootic pneumonia should be assessed in each circumstance. Some important environmental variables that should be assessed and modified include: the number of pigs per shed; the number of pigs per pen; the air space per pig; the floor space per pig; the cleaning and disinfection techniques used; the number of air changes per hour; the waste disposal system; the number of temperature fluctuations in a 24-hour period; the direction of the flow of air in the building; the concentrations of ammonia and hydrogen sulfide in the building; the dust levels; the feeding and watering systems; and whether or not the AIAO system is being used effectively.

Medication of breeding stock. The original medicated-early-weaning program was based on medication of the sows with tiamulin at the time of farrowing and the early weaning of the piglets to an off-site location. A variation of this method is to prevent the spread of infection by isolation of the breeding stock, strategic antimicrobial medication of the breeding stock, reintroduction of the breeding stock to the original but empty and disinfected gestation barn, separate rearing of the piglets before and after initiating the program, and regulation of flow of animals through the herd. Farrowing barns are emptied out when possible, and cleaned, disinfected and left empty. After weaning their piglets, sows are transferred to the dry sow barns. Sows about to farrow are treated with tiamulin and moved to the farrowing barn.

Source of feeder pigs. Where possible the purchase of weaners or pigs for finishing units should be from herds free of the disease or from a single source. Purchase through saleyards or the purchase of coughing or uneven litters is not advisable. When pigs from infected herds are purchased, it may be necessary to medicate the feed prophylactically with one of the tetracycline group of antibiotics or tylosin or spiramycin at 100 to 200 mg/kg of feed for a 2-week period after introduction. Medication of the feed of finishing pigs with tiamulin at 20 and 30 mg/kg of feed over an 8-week period on farms with histories of severe complicated enzootic pneumonia led to improved weight gains and feed efficiency, but the extent and severity of the lung lesions did not change. The level of 30 mg/kg in the feed was superior to the level of 20 mg/kg. Tiamulin at 100 mg/kg, combined with chlortetracycline at 300 mg/kg of feed for 7 days, was effective in herds with a history of enzootic pneumonia complicated by the presence of *P. multocida* and *A. pleuropneumoniae*.

Introduced pigs should be isolated from the rest of the herd and preferably reared as a batch through a house on the AIAO system. A high stocking density should be avoided, and internal parasites should be controlled.

Immunization. Vaccination with killed *M. hyopneumoniae* induces protection in pigs against experimental challenge exposure with the organism. A killed *M. hyopneumoniae* vaccine evaluated in a single herd reduced the prevalence of pneumonic lesions in slaughter pigs from 69% to 36% and the prevalence of pleuritis from 20% to 13%. There was a small decrease in the number of days to market. Other limited studies indicate that vaccination can reduce the severity of lung lesions detected at slaughter (4% to 6% compared with 12% in controls), improves feed efficiency and increases average daily gain during the finishing period. In other studies the average daily gain was not improved.

Actinobacillus Pleuropneumonia. There are two options for the control and prevention of porcine pleuropneumonia: (1) control at an economical level using good management combined with the possible use of vaccines, and (2) eradication of the infection from the herd. Determining which option to select requires careful consideration of the advantages and disadvantages of each option. With an understanding of the factors that result in clinical disease, it is possible to maintain an infected breeding herd and to produce pigs with a small risk of clinical disease.

Management. Control is difficult and unreliable because pigs that recover from clinical disease provide a source of future infection for finishing operations that purchase all of their introductions. The AIAO system of purchasing, feeding, and marketing pigs, with a thorough cleaning between groups of animals in a finishing operation, should be adopted. The disease is highly contagious, and control measures must be directed toward identifying and eliminating infected pigs into uninfected herds. When pigs are moved between herds, it is critically important that the herds be matched according to their infection status. Source herds for feeder animals are serotested, and then pigs of like immune status are commingled to produce a population that is immunologically compatible. By commingling only animals from seronegative herds, the risk of disease is greatly decreased and growth performance improved. The mixing of animals from herds known to be infected with homologous serotypes is also effective.

Every economical effort must be made to identify and isolate infected pigs and to exclude the importation of clinically normal but infected pigs into herds in which the infection is not present. This is a major challenge that is dependent on the availability of a highly sensitive and specific laboratory test. The acquisition of new breeding stock for herds free of the infection should include a period of quarantine and two serological tests 3 weeks apart. Only seronegative animals should be introduced into the herds. A seropositive animal should be considered a potential carrier. Field trials have shown that it is not possible to rear seronegative animals within a breeding and rearing herd heavily infected with serotype 2 of the organism. Neither medication of the sows and piglets with trimethoprim-sulfonamides nor a strictly applied AIAO system reduced the percentage of seropositive animals.

Management practices must emphasize the rearing of weaned pigs in pens separate from older stock, which are carriers of the organism. Large breeding herds and finishing units should subdivide the total herd into separate units, which minimizes the spread of infection. Early weaning and segregation of gilts from infected stock have been used to develop a seronegative herd.

Herds can be classified into one of three categories depending on their infection status:

- *Category 1:* Serologically positive for *A. pleuropneumoniae* without a history of clinical disease. A majority of herds are serologically positive but do not have clinically apparent disease. Good management and environmental quality control can minimize the incidence of clinical disease. Good ventilation, the use of AIAO management practices, and appropriate stocking densities are important.
- *Category 2:* Serologically negative and clinically free of *A. pleuropneumoniae*. These herds can be maintained free of infection with good biosecurity practices. New breeding stock must be obtained from herds free of infection. AI can be used to limit the introduction of live pigs. Pigs sold from these herds to herds with endemic infection are highly susceptible to infection.
- *Category 3:* History of clinical disease caused by *A. pleuropneumoniae*, which has been pathologically and microbio-

logically confirmed. In these herds, acute disease outbreaks occur most commonly in pigs 9 to 20 weeks of age. Pigs are usually protected by colostral immunity for the first 8 weeks of life. The severity of outbreaks can be reduced by mass medication of the feed, treatment of individual pigs, and good management practices to ensure adequate ventilation.

Eradication. Recurring outbreaks of pleuropneumonia is the most common reason for an eradication strategy. Eradication is achieved by depopulating the entire herd, followed by repopulation with animals from herds that are clinically and serologically negative. Eradication can be successful but the risk of introducing infections into the herd are high unless biosecurity measures are adopted and strictly implemented.

An alternative to depopulation is medicated early weaning in which pigs are weaned at 10 to 15 days of age, treated with antimicrobials, and reared in isolation. Transmission of infection between the sow and piglets does not occur before 11 days of age; about half of the piglets are infected at 16 days of age, and if weaned at 21 days of age most of the piglets are infected.

The early weaning program can be expanded to the three-site system of rearing. Adults and nursing piglets are housed in one site. At weaning, piglets are moved to the nursery barn for growth to 25 kg and then moved to a third site for the final growing period. The adults may be serologically positive for infection, but the nursery pigs and growing and finishing pigs are negative.

Age segregation, distance that prevents aerosol transmission, and adherence to strict biosecurity practices can reduce the prevalence of infection and the incidence of disease.

Vaccination. Natural or experimental infection with a serotype of *A. pleuropneumoniae* induces a strong immunity to both homologous and heterologous serotypes. Vaccination has been attempted to prevent pleuropneumonia in pigs. However, the protection obtained by parenteral vaccination is serotype specific, and vaccines must therefore contain the serotype existing in the swine population. The mortality rate is lower in vaccinated animals, but they are still carriers of the organism.

Serotype 8 is closely related to serotypes 3 and 6, and parenteral revaccination using a capsular extract or killed *A. pleuropneumoniae* serotype 8 provides a high degree of protection against challenge with serotypes 3 or 6. A tetravalent vaccine containing serotypes 1, 2, 5, and 7 stimulated titers to all four serotypes, and an anamnestic response was induced by a second vaccination This suggests that the serological and cross-protective properties of *A. pleuropneumoniae* serotypes should be identified before they are used as antigen in the complement fixation test and in vaccines.

Atrophic Rhinitis. Control of atrophic rhinitis can be attempted in at least four ways: *total eradication, reduction of infection pressure, mass medication with antimicrobials to reduce the severity and adverse effects of infection,* and *vaccination.*

Regardless of the method used, any effective control program must have a system for monitoring the incidence of clinical disease in the herd and the incidence and severity of turbinate lesions of the pigs sent to slaughter. Accurate and reliable methods for monitoring clinical disease are not available, but the incidence of acute rhinitis and facial deformities could be recorded regularly. At slaughter, snouts can be examined for lesions of turbinate atrophy and for assessing a mean snout score for each group of pigs slaughtered.

Total Eradication. Total eradication can only be achieved with confidence by complete depopulation for a 4-week period and repopulation with primary or purchased SPF stock. This approach has the added advantage of eliminating enzootic pneumonia, which may be a significant contributing factor to the economic importance of this disease. However, this method of control is extremely costly, and the economic importance of the disease would need to be carefully evaluated in relation to this cost before this method was instituted. Other techniques of obtaining pigs free of atrophic rhinitis, such as the isolated farrowing of older and presumed noncarrier sows with subsequent clinical and postmortem examinations of a proportion of the litters, have had a significant failure rate in the field and are not recommended. Eradication by repopulation with cesarean-derived stock may be essential in breeding nucleus herds in which a high generation turnover leads to a low herd sow age and a low herd level of immunity. The breakdown rate of herds established by this method can be significant, presumably because the initiating organisms are not solely confined to pigs.

Reduction of infection pressure. Reduction of infection pressure can be attempted. Infection of piglets occurs primarily either from carrier sows or from other infected piglets in the immediate environment, and severe atrophic rhinitis generally results from infection of piglets under 3 weeks of age. If these factors can be minimized, the incidence and severity of the disease can be reduced. An AIAO pig flow is one of the most effective methods for control of atrophic rhinitis. A change to an AIAO pig flow from continuous flow management can improve snout scores by 50%, lung scores by 55%, average daily gain by 0.14 lb, and days to market by 13 days.

Since severe lesions depend on infection of the piglet under 3 weeks of age, every attempt should be made to minimize the severity of the challenge to young piglets. It is a common observation that the effects of atrophic rhinitis are minimal under good systems of management and adequate ventilation, nondusty conditions, and good hygiene. The use of continual throughput farrowing houses and weaner houses allows a buildup of infection, with the presence of actively infected pigs that can provide a high-infection pressure on piglets born into or introduced into these areas. The use of AIAO systems of management in these areas is recommended, and young piglets should be kept in a separate area from older pigs.

Mass medication. The prophylactic use of antimicrobials reduces the incidence of the disease within the herd. Antimicrobials are used both within the breeding herd to reduce the prevalence of carriers, and in young suckling and weaner pigs to reduce the severity of the infection. The medication is begun about 2 weeks before farrowing, continued throughout lactation, and incorporated in the creep feed for the sucking pigs and the starter feeds for the weaned pigs. In this way there is continuous medication of the sow and the piglets during the most susceptible period. For the breeding herd, sulfamethazine at levels of 450 to 1000 mg/kg feed, with the higher levels being given to dry sows on restricted feeding, has been recommended. Sulfonamide resistance has proved a problem in some countries, but beneficial results may still be achieved with these levels. It is recommended that medication be continued for a 4- to 6-week period. Carbadox at 55 ppm in combination with sulfamethazine at 110 ppm is reported to be effective in clearing experimentally induced *B. bronchiseptica* infection; when used alone, it improved growth rate and feed efficiency in pigs with naturally occurring atrophic rhinitis. In the starter period, carbadox fed alone or in combination with sulfamethazine improved average daily gain in piglets from herds with naturally occurring atrophic rhinitis. Use of the medication, however, did not lead to a reduction of mean nasal lesion scores resulting from atrophic rhinitis. Sulfamethazine at 110 mg/kg of feed is more effective than sulfathiazole, at the same concentration, for the control of experimentally in-

duced atrophic rhinitis resulting from *B. bronchiseptica*. Sulfamethazine may also be incorporated in creep rations, and the use of tetracyclines (200 mg/kg of feed), tylosin (50 to 100 mg/kg of feed), and penicillin (200 mg/kg of feed) have also been suggested.

Medicated early weaning is recommended to obtain pigs free from pathogens, including *B. bronchiseptica*, that are endemic in the herd of origin. The sows are fed medicated feed from 5 days before to 5 days after weaning, and the piglets are dosed from birth to 10 days of age.

Vaccination. There has been considerable interest in the development of vaccines for the control and prevention of atrophic rhinitis resulting from *B. bronchiseptica*. Inactivated vaccines have been used to vaccinate the pregnant sow 4 to 6 weeks before farrowing and, in some cases, followed by vaccination of the piglets at 7 and 28 days of age. In general, the use of the vaccine in pregnant sows in herds in which the disease has been endemic has reduced the incidence of clinical atrophic rhinitis. However, the results from one study to another have been highly variable. Vaccination of the pregnant sow does lead to an increase in colostral antibody titer, which does improve the clearance rate of *B. bronchiseptica* in the piglets. However, it has been difficult to evaluate the efficacy of the *B. bronchiseptica* used alone, because the turbinate atrophy caused by infection of piglets with *B. bronchiseptica* experimentally or naturally heals and regenerates completely when they are reared to about 70 to 90 kg body weight in good housing conditions.

Gastrointestinal Diseases of Growing and Finishing Pigs

Unlike respiratory diseases, enteric diseases in growing pigs are usually due to a single agent, and the control is directly related to that agent. However, the occurrence and significance of gastrointestinal diseases in growing pigs has been decreasing with the use of AIAO production (Paul et al, 1997). In a recent U.S. study, enteric diseases accounted for 13.6% of mortality in growing-finishing pigs, and 9.5% in a U.K. study (Pearce, 1999). In addition, chronic enteric diseases have been suggested to increase feed costs by at least 50%.

Epidemiology. The epidemiology of enteric disease in growing-finishing pigs was examined using a mail questionnaire (Pearce, 1999). Enteric diseases causing diarrhea are a significant problem in growing-finishing pigs in the United Kingdom, with more than 50% of producers reporting a problem at some time during the previous 3 years. The survey found significant associations between several management factors and the occurrence of diarrheal disease in growing-finishing pigs (Pearce, 1999). All the important enteric pathogens of pigs are spread by the fecal-oral route, and control measures depend on reducing environmental contamination by adequate cleaning and disinfection between pens of pigs. Less than 40% of producers used disinfection as part of routine practice. The use of disinfectants in the preparation of pens between batches of pigs appeared to be protective (odds ratio of 0.3). Approximately 47% of producers used some form of isolation procedure for incoming breeding stock, which compares with 50% and 63% of producers in the United States who isolate new female and male breeding stock, respectively (USDA:APHIS:VS, 1995).

The use of slatted floors for finishing pigs was associated with a 3.6-fold increase in the risk of diarrheal disease. This may be due to inadequate cleaning of slatted floors and increased residual fecal contamination, which promotes the spread of disease between batches of pigs.

The use of a wet feeding system for finishing pigs was associated with a 5.9-fold increase in the risk of enteric disease, which may be related to less than satisfactory standards of hygiene.

The practice of tail-docking piglets was associated with an 8.6-fold increase in the risk of diarrhea in growing-finishing pigs. This may be due to a common link between poor environmental conditions and the increased levels of environmental stress known to be involved in mediating both the occurrence of tail biting (and the attempts to prevent it by tail-docking) and the incidence and severity of enteric diseases such as proliferative enteropathy.

Intestinal Spirochetal Infections. Intestinal spirochetes cause two well-recognized diseases in pigs: swine dysentery and intestinal spirochetosis. A third disease, spirochetal colitis, is less clearly defined but is caused by weakly β-hemolytic spirochetes other than those causing intestinal spirochetosis (Hampson and Trott, 1995).

Swine Dysentery. Swine dysentery is caused by *B. hyodysenteriae* and is characterized clinically by dysentery. The organism, found almost exclusively in pigs and rodents, proliferates in the large intestine, causing degradation of the surface and secretion of mucus and blood. Signs include diarrhea, sometimes involving blood with a rapid loss of condition, depression, and dehydration. Lesions are limited to the large intestine with necrotic debris coating its surface. There are dramatic reductions in weight, especially if left untreated, and mortality can occur in 1 to 2 days. Treatment is through antibacterial therapy via feed, water, or injection. Prevention is through sanitation and separation of affected pig. Elimination of the disease can be made through a combination of sanitation and medication (Harvey, 1997).

Intestinal Spirochetosis. Intestinal spirochetosis is caused by *Serpulina pilosicoli* sp. nov., which has a broad host range including human and nonhuman primates, pigs, dogs, commercial chickens, and various species of wild and zoo birds. The disease affects pigs between 4 and 20 weeks of age and is characterized clinically by mucus containing nonbloody diarrhea, poor feed conversion, and depressed growth rates. PCR assay can be used to differentiate *B. hyodysenteriae* from *Brachyspira pilosicoli*, both of which cause diarrhea in growing and finishing pigs (Barcellos et al, 2000). A detailed review of intestinal spirochetosis in swine is available (Hampson and Trott, 1995).

Porcine Proliferative Enteritis. *Lawsonia intracellularis* (ileitis, porcine proliferative enteritis, porcine intestinal adenomatosis [PIA]) causes proliferation and degradation, primarily of the mucosa of the ileum. It is found in all ages of pigs after weaning but is most common in 60- to 120-lb pigs. The disease is often sporadic but leads to poor performance in affected animals. The direct financial losses resulting from the disease are considered high (McOrist, 1997; McOrist et al, 1997). The use of PCR assays to detect the organism in intestinal mucosal samples is highly sensitive (Jordan et al, 1999). The test may be an appropriate monitoring tool for swine herds because it is a rapid procedure that could be applied to batch testing. Treatment and prevention is usually performed through the use of antibiotics, almost all of which are efficacious (McOrist et al, 1997). Continuous in-feed medication with chlortetracycline at 300 or 600 ppm can prevent disease in pigs challenged with *L. intracellularis* (McOrist et al, 1999).

Salmonellosis. *Salmonella* infections cause economic losses in the swine industry. In the United States, *S. choleraesuis* accounts for 90% of clinical cases of swine salmonellosis characterized by septicemia, pneumonia, hepatitis, and death. This disease is often a result of immunosuppressive factors such as chilling or PRRS. Most outbreaks also involve cases of sudden death with no diarrhea; these pigs characteristically have discolored ear and abdomen. Bloody diarrhea is a common sign in conditions that are more chronic. The

combination of mortality and depressed growth rate can be expensive and can affect 50% of a group by depressing growth rates and feed conversions. Antibiotic treatment is often unsuccessful. Prevention through the control of predisposing factors is preferred (Cole et al, 1994). *S. choleraesuis* is only rarely a zoonosis.

S. typhimurium primarily causes enterocolitis and is an important cause of human foodborne illness. Pigs leaving the farm are considered the main source of abattoir contamination by *Salmonella*. Pigs represent an important reservoir of *Salmonella* spp. and can spread the bacteria throughout the abattoir environment.

The prevalences of *Salmonella* spp. and *Y. enterocolitica* in finishing pigs examined at slaughterhouses in Canada ranged from 4.0% to 6.4% and from 18.8% to 23.0%, respectively (Letellier et al, 1999b). Overall, 24.6% of the animals tested were positive for one or both these pathogens. Only a small proportion of herds (2.8%) appeared to be contaminated by *Salmonella* spp. Other surveys of the prevalence of *Salmonella* contamination of pig carcasses found 28% in Greece, 17.5% in Canada, 21% in the Netherlands, and 27% in Belgium (Davies et al, 1999). In a sampling of a large number of pigs in an abattoir in the United Kingdom, salmonella was isolated from 7.0% of carcasses and 11.6% of samples of large intestinal contents (Davies et al, 1999). *S. typhimurium* DT 104 was found in 3.2% of the large intestinal samples. Sequential sampling during the slaughter process found 83% of the carcasses contaminated after bleeding, a percentage that was reduced to 5.7% after scalding eliminated after singeing. *Salmonella* infection was present in the pigs from 45% of farms and on a third of farms; *S. typhimurium* DT 104, a multiple antibiotic resistant strain, was present. The DT 104 strain and other multiresistant phage types have also been isolated from Danish pig herds, but the prevalence is low (Baggesen and Aarestrup, 1998).

Carrier pigs are positive for *Salmonella* in mesenteric lymph nodes, tonsils, colon, or feces, and development of control measures to reduce fecal or lymph node carriage of *Salmonella* in live animals would be an important step in the reduction of this pathogen in meat products. Pigs are a significant reservoir of foodborne pathogens such as *Salmonella* and *Yersiniacolitica*, and the mass production and rapid distribution of food poses a risk for widespread foodborne outbreaks resulting from these pathogens. The scalding and singeing processes used in the slaughter of swine, if properly conducted, can reduce the level of contamination of the surfaces of carcasses of salmonella to minimal levels before evisceration. The spillage of material from the intestinal tract, mainly as a result of intestinal perforation during evisceration, is the major source of carcass contamination.

On finishing pig farms previously identified as contaminated by *Salmonella*, sampling of the environment found the organism in fecal material in pens, doors, floors, ventilation units, dust, and farm accessories (Letellier et al, 1999a). The prevalence and distribution of *Salmonella* spp. in breeding herds supplying finishing pigs to finishing units was determined. The overall prevalence was estimated at 7.9%. Among the farms sampled, 70% were positive for *Salmonella* spp., and the distribution of infection was 15.9% in replacement sows and 21.9% in the finishing unit for gilts. The demonstration of vertical transmission of *Salmonella* spp. at different levels of integrated production system stresses the importance of reducing carriage in live animals by very strict and constant farm hygiene measures, starting at breeding farms, combined with other measures.

The management of manure and hygiene are very important in controlling salmonella infection in finishing units. Housing of finishing pigs on solid concrete floors with open-flush gutters increases the risk of salmonella shedding compared with housing on slatted concrete floors. Recycled lagoon water is commonly used to flush effluent from beneath slatted floors or from open-flush gutters. Compared with using fresh water for flushing, flushing with recycled effluent reduces total effluent output from a herd but provides a potential vehicle for transmitting organisms shed in feces or urine.

Although *Salmonella* can survive in liquid and solid pig manure for several months, *Salmonella* concentrations in fresh effluent are higher than in waste stored in anaerobic pits. Achievement of frequent and effective removal of feces from the flush gutters by increasing the frequency or volume of flushing with recycled liquids may be as effective in controlling *Salmonella* transmission as substituting recycled effluent with fresh water for flushing (Davies, 1998). Facilities should be designed to enable effective removal of fecal material from pens to control *Salmonella* in barns with open-flush gutters. When constructing facilities with open gutters, care should be taken to design gutter volume, gradient, and flush volume to ensure effective removal of feces from all pens.

On-farm initiatives in food safety, such as the HACCP, help reduce the risk of foodborne transmission of pathogens. Various treatments to reduce carriage of *Salmonella* in swine have been evaluated (Letellier et al, 2000). The use of some probiotics and prebiotics can alter the composition of the gut microflora to the benefit of the host (Letellier et al, 2000). A reduction of *Salmonella* in the colonization of mesenteric lymph nodes occurred with the use of bambermycins and a live attenuated vaccine (Letellier et al, 2000). The strategy of competitive exclusion cultures to enhance the colonization resistance of early-weaned pigs to *S. choleraesuis* has some potential based on some preliminary experimental work (Anderson et al, 1999).

Healthy pigs can carry *Salmonella* in their intestines and may shed this pathogen because of stresses incurred during transportation, contaminating trailer floors and bedding material. If not cleaned and sanitized between trips, trailers and bedding have the potential to infect other farms, the abattoir environment, or other animals with the organisms. *Salmonella* can be isolated from up to 80% of the bedding material in trailers. Up to 42% of trailer floor samples may be positive for *Salmonella* before washing, and 2.7% positive after washing and sanitizing. Neither distance traveled nor season of the year influences the number of *Salmonella*- or *E. coli*-positive pig trailers. Washing and sanitizing of pig-hauling trailers between loads to reduce or eliminate the incidence of *Salmonella* is effective (Rajkowski et al, 1998).

Feed and feed trucks may be sources of *Salmonella* contamination (Fedorka-Cray et al, 1997). The sample prevalence of *Salmonella* in feed trucks is low (0.7%), the overall contamination rate for feed trucks is much higher (22.7%), and thus feed could be a source of *Salmonella* contamination for swine herds.

It is possible to prevent *Salmonella* infection of pigs originating from a heavily contaminated herd by raising them at a distant, clean site (Nietfeld et al, 1998). Offsite growing-finishing strategies provide a management technique along with others such as all-in, all-out production and rigorous cleaning between groups of pigs to help control *Salmonella* infection. Prevention of environmental cycling of *Salmonella* spp. is an important component of a *preharvest food safety program*.

Esophagogastric ulceration. Ulceration of the esophagogastric region of the stomach is a common, widespread cause of mortality condition in finishing pigs worldwide. In some herds, mortality from ulcers can reach 1% or higher, with losses resulting from culling up to 3%. The prevalence of erosions in the pars esophagea of the stomach can range from 32% to 100% (Ayles et al, 1999).

Feeding finely ground pelleted feed to finishing pigs between 25- and 107-kg bodyweight can cause hyperkeratosis of the pars esophagea in 75% to 89% of the pigs with 11% of pigs with extensive erosions or ulceration. Pigs with extensive lesions gained 50 to 75 g/day less weight than pigs with no lesions in the pars esophagea (Elbers et al, 1995). Several factors involved in its pathogenesis have been recognized. The gastric ulceration characteristic of this problem occurs in the pars esophagea region of the stomach. This area often becomes hyperkeratotic and eroded, and such lesions are seen in many swine at slaughter with no apparent effects on productivity. A proportion of affected swine develops more severe erosions that lead to bleeding. Many of these cases are acute and severe and lead to death because of exsanguination into the digestive tract.

Mortality is generally acute and is usually diagnosed by the fact that the carcass is extremely pale, hence its vernacular description "bleach-out" (Friendship, 1997).

The feed manufacturing industry is faced with a difficult problem: on the one hand, finely ground feed is converted efficiently into growth, but on the other hand, it is associated with the erosion and ulceration of the pars esophagea. Pigs with slight ulcerative lesions of the pars esophagea grow significantly slower than pigs without such lesions. Mild gastric ulcers may cause pigs to take longer to reach market weight, causing an economic loss without clinical signs or mortality. A small dietary particle size has been associated with increased risk of gastric ulcers in pigs. A small particle size (approximately 500 to 600 μm) increases both the severity of and the incidence of gastric ulcers. Dietary melatonin supplementation increases the apparent digestibility of crude protein and dry matter of the diets and decreases the prevalence of ulcers, but it may not affect growth performance (Ayles et al, 1999).

Other factors that may be involved in esophagogastric lesions include the following:

- *Season*: There is an increase in lesions in the summer. This may be caused by temperature changes or concurrent changes in diet or management.
- *Nutritional deficiencies*: Suggested deficiencies have included vitamin E, selenium, and fiber.
- *Stress*: Overcrowding, mixing, and large variations in environmental temperature have been suggested as factors.
- *Disease*: Veterinarians have observed that many pigs that die from gastroesophageal ulcers also have large lung lesions, which are usually caused by enzootic pneumonia.
- *Genotype*: There appear to be differences between genetic lines in the incidence and severity of ulcers.
- *Age*: Farms report that mortality from ulcers occurs at distinct periods after entry into the finishing barn.

The majority of the factors just listed do not occur independently and thus the components of causation are difficult to measure. For instance, hot weather is associated with an increased use of fats in swine diets. Fats in swine diets during warm weather leads to an increased degradation of vitamin E. Also, the hot temperatures may induce greater mould and mycotoxin growth in swine feedstuffs.

Internal Parasites. Nearly all of the most common intestinal parasites of pigs are unevenly distributed among different age groups. *I. suis* and *Strongyloides ransomi* are most common in piglets, *Ascaris suum* and *Trichuris suis* in growing pigs, and *Esophagostomum* spp., *Hyostrongylus rubidus*, and *Eimeria* spp. in adult pigs (Roepstorff et al, 1998).

Surveys of market-age pigs have demonstrated *A. suis* prevalences of up to 60% based on adult parasites and typical liver lesions (Wagner and Polley, 1997). In Saskatchewan studies, sows are the most commonly treated age group, as they are in Australia and Denmark. Weanlings were the second most commonly treated age group, and the least commonly treated were the growing pigs. For anthelmintics to be used efficiently, treatment programs should be based on the epidemiology of the targeted parasites.

Locomotor Diseases of Growing and Finishing Pigs

Diseases of Feet and Legs. Diseases of the feet and legs can be a significant problem in modern intensive swine production systems. The major locomotor problems occur in adolescent and breeding pigs. In breeding stock, locomotor disease is usually only secondary in importance to reproductive inefficiency in the reasons for culling. Locomotor disease is one of the most common reasons for rejection of boars from breeding companies. Osteochondrosis, a noninfectious condition manifested as a failure of endochondral bone formation, is thought to be a principal predisposing cause of leg weakness in pigs approaching breeding age (Nakano et al, 1987). The lesions are most common in the distal humerus, the distal femur, and occasionally in the scapulohumeral and coxofemoral joints. Various factors such as rapid growth rate, lack of exercise, floor types, and dietary minerals and vitamins have been suggested and explored as important causative factors. However, there is no evidence linking any of these factors to the pathogenesis of the lesions. The effect of sow nutrition during lactation on the incidence of the disease in their progeny has been examined (Walker and Aherne, 1988). An increase in the mineral and vitamin intake above National Academy of Sciences–NRC recommendations has no effect on the size of toes, feet, and legs; the incidence and severity of horn and pad lesions; or the overall structural soundness and feedlot performance in crossbred boars from 35 to 330 days on test. Certain types of floors can cause foot lesions, but the effect does not extend to the knee and elbow joints. Osteochondrosis is frequently observed in growing swine fed under normal nutritional and management conditions. From 90% to 100% of pigs at 6 months of age have lesions of osteochondrosis of varying severity without any detrimental effect on growth rate or locomotor ability. These lesions are considered potential causes of lameness in young pigs and mature breeding stock. An advanced degree of osteochondrosis, however, leads to severe lameness, which affects breeding animals. The etiology of osteochondrosis is unclear.

The literature on floor surfaces and flooring materials for pigs has been reviewed (Kornegay and Lindemann, 1984). Differences in the incidence and severity of toe lesions have been reported for different floor surfaces. The lateral toes of the pig's foot, especially the hind foot, are larger, and because of their size they may be more susceptible to injury than are the medial toes (Kornegay and Lindemann, 1984). The desirable floor should satisfy the following requirements:

- The floor should not be the cause of injury—it should be of a nonslip, nonabrasive surface and should not have sharp, exposed, or protruding edges.
- It should not harbor bacteria and parasites by being impervious and readily cleaned.
- The floor should not contribute to stress or discomfort, which might be manifested by depressed growth and poor feed utilization.
- It should be thermally matched to the class of pigs housed on it.
- The floor materials should not deteriorate or deform during their planned life.
- Perforated floors should not retain feces and urine for periods of time, which would require some form of cleaning or scraping.
- Floors should comply with the above requirements at the lowest possible cost and should be comfortable to the pig, easy to keep clean, durable, and economical.

The different kinds of floors available for farrowing crates, weanling pigs, and growing-finishing pigs have been described (Kornegay and Lindemann, 1984). The footing and gait of pigs on different concrete surfaces have been examined. Some studies indicate a higher incidence of clinical disease and a higher mortality rate in pigs housed on punched metal floors than in those on plastic slats (Barrett et al, 1988).

Foot lesions in growing and finishing pigs may be caused by insufficient dietary levels of biotin. There is no requirement for supplemental biotin for weight gain, but a dietary requirement between 50 and 100 mg/kg of diet is indicated to prevent foot lesions.

Porcine Stress Syndrome (Malignant Hyperthermia). This is an autosomal recessive inherited muscle disease to which 10% to 20% of swine are susceptible (O'Brien, 1995). This syndrome can be initiated by a number of stressors including shipping, overcrowding, restraint, and farrowing. Affected pigs are rigid and have muscle tremors and labored breathing. Body temperatures may exceed 44° to 45° C (112° F), and death resulting from heart failure may occur in minutes. The postmortem diagnosis is made through the PSE quality of the muscle. Most susceptible pigs have been estimated to have some of these qualities in their meat at slaughter.

Skin Disease of Growing and Finishing Pigs

Sarcoptic Mange. Sarcoptic mange is an important disease of the skin of growing and finishing pigs but can affect pigs of all ages. It is caused by *Sarcoptes scabei* var *suis* and is characterized by intense pruritus. The mite infects only pigs, and direct contact between pigs is the principal mode of transmission. The presence of mange in a herd can affect growth rate, feed conversion, carcass value, and damage to facilities (from the effects of affected pigs scratching). There is a perception that mange in pigs is not a problem, and many producers either disregard the disease or do not use adequate control methods. Based on abattoir inspection of pigs, the prevalence of infection is widespread (Melancon, 1998). The Papular Dermatitis Lesion scoring system, as part of the Minnesota PigMON standardized swine slaughter monitoring system, was used to survey the presence of skin lesions on slaughtered pigs (Melancon, 1998). The overall prevalence of mange, defined as the percentage of lots of pigs with an average dermatitis score of 0.5 or greater during the evaluation period, was 43% for all lots. The overall prevalence of mange among pigs processed at individual plants ranged from 31% to 53%.

Studies performed in Australia, the United States, Canada, Europe, and Latin America evaluated the associations between *Sarcoptes* infestation and the severity of papular dermatitis at slaughter, using an ordinal scale for classifying carcasses (Cargill et al, 1997). The specificity of localized dermatitis ranges from 75% to 80%, and that of generalized dermatitis is highly specific (>98%).

Of greater importance than the difference in prevalence among the various locations is the fact that sarcoptic mange is still a persistent disease among herds, despite the availability of strategies for establishing mange-free herds such as SEW, herd depopulation and repopulation, and whole-herd treatment programs with effective insecticides. Effective mange-control programs are being either ignored or inadequately applied, which emphasizes the need for educational efforts to more fully elucidate the various effects of subclinical mange infestations.

Eradication programs consist of treating all animals at an interval of 14 days with ivermectin. Simultaneously, the pens are emptied, cleaned, and disinfected. This procedure is effective but laborious and time-consuming, and it may explain why eradication programs have not been done more commonly (Jacobson et al, 1999). The effectiveness of a herd eradication program can be evaluated using an ELISA. Blood samples are taken from all adults and from 20% of piglets aged 10 to 12 weeks, before initiating the control program, every third month during the first year and a final sampling 18 months after the treatments. After successful treatment, the antibodies continuously decline.

Sarcoptic mange was eradicated from a breeding herd using a combination of injectable ivermectin and in-feed ivermectin (Smets et al, 1999). Sows, replacement gilts, boars, and weaned piglets were treated with ivermectin (1% solution) by subcutaneous injection on Days 0 and 14, at a dose of 1 ml/33 kg body weight (equivalent to a minimum of 300 (g ivermectin/kg). Newborn piglets were given 0.27% solution subcutaneously on Days 0 and 14, at a dose of 1 ml/9 kg. Finishing pigs were treated with ivermectin oral powder (0.6%) in the feed over two periods of 7 consecutive days (Day 0 to Day 6 and Day 14 to Day 20). Finishing pigs from 25 to 40 kg were given 2 ppm in the feed, and animals from 40 to 100 kg were given 2.4 ppm. Before the treatment, 28% of ear scrapings of finishing pigs were positive for the presence of mites. Within 1 year after treatment adult animals were negative for mites and the scratching index, previously high, was very low. The feed consumption of the sows decreased by 5%; rebreeding decreased by 4.5%; average litter size increased 0.33 live piglets born/litter; and the farrowing index increased by 0.075 litters/sow/year. The production index increased by 1.34 more piglets weaned/sow/year. The costs of the treatment were recovered within 3 to 7 months.

MANAGEMENT OF ANIMAL HEALTH AND PRODUCTION DURING THE GROWING AND FINISHING PERIODS

The control of the economically important diseases and the management of production of pigs during the growing and finishing periods require a high level of animal-production management and the adoption of disease-control techniques designed for intensively reared animals. Those aspects of management that are most important include the following.

Specific Disease Eradication Policy

Certain diseases, such as enzootic pneumonia and swine dysentery, can be eradicated from the herd by the adoption of SPF or MD herd policy, in which the breeding stock are cesarean or hysterectomy derived. The piglets are not in contact with the sows and are reared in isolation until they reach puberty, when they are transferred to the breeding farm facilities. All breeding stock in the new herd are derived this way, and with strict security precautions, the herd remains free of specific pathogens. In addition test and cull strategies have been successful to eradicate pseudorabies from sow herds. Swine dysentery has also been eradicated by strategic medication of the herd.

In self-contained, purebred, or commercial farrow-to-finish enterprises, the common infectious respiratory and enteric diseases can be controlled satisfactorily by the adoption of techniques designed to prevent entry of disease into the herd and by the provision of an adequate housing system.

All-In, All-Out Production System

AIAO production of pigs during the growing-finishing phase is well established as means of reducing certain diseases and improving growth performance, including improvements in average daily gain, feed intake and feed conversion, de-

creased mortalities, decreased number of culls, and lesions of pneumonia and atrophic rhinitis detected at slaughter. A comparison of the performance of pigs in AIAO production with CF production during the growing-finishing phase found lung lesions that were less prevalent and severe in AIAO pigs (mean severity score, 3%) than in CF pigs (mean severity score, 15%) (Scheidt et al, 1995). The AIAO system is highly economical compared with the continuous flow system.

Every effort should be made to ensure that a previously cleaned and disinfected room or finishing barn is filled at one time with a group of pigs that are reared as a group throughout their growing and finishing periods. If possible, pigs moved from the weaner pens (e.g., nursery) should be maintained as a group and placed in a pen of the same group in the finishing barn. This "pen integrity" minimizes the stress associated with the change in feeding and environment. Some facilities are now maintained as "wean-to-finish" buildings where pigs are reared from weaning until marketing in the same pen (Jacobson, 1998).

Housing Environment and Floor Space Allowance

Confined housing for growing-finishing swine may be provided in the form of completely enclosed, modified open-front, and open-front buildings. Most enclosed buildings are insulated and have mechanical ventilation, auxiliary heat, and partially slatted or solid floors. Modified open-front or curtain-sided buildings rely on natural ventilation, do not have auxiliary heat, and may be open on one side, whereas open-front structures are generally insulated, open on one side, and have feeders and waterers located in outdoor concrete lots.

One of the basic requirements for housing of growing-finishing pigs is a warm, dry, and draft-free environment. Extremes of ambient temperature in the building, excessive air movement, and extremes of relative humidity can adversely affect rate of daily gain, feed consumption, and feed efficiency. In large, densely stocked barns for growing and finishing pigs, it is frequently suggested that the indoor climate causes unsatisfactory growth, respiratory disease, tail biting, and unfavorable hygiene, despite the indoor temperature being within the optimum range. Experimentally, different combinations of air velocities and temperatures can affect the behavior of growing and finishing pigs and lead to pigs' lying in dung areas, variable growth rates, and tail biting (Sallvik and Wallberg, 1984).

It has been estimated that the U.S. commercial swine industry is achieving only 65% to 75% of its genetic potential for growth because of limitations associated with the growing environment. Factors that potentially limit growth include physical (thermal, stocking density, feed and water access), social (pigs per pen, movement), and microbial (sanitation, segregation) conditions that may contribute to physiological and immunological stress. The influence of environment on the growth of commercial finishing pigs has been examined by comparing growth of pigs moved from the nursery to the environments of the adjoining commercial growing and finishing buildings or an unrestricting research environment (Holck et al, 1998). Liveweight, lean, and fat growth in pigs raised in a conventional commercial environment was reduced to 70% of that achieved under less limiting research conditions. Pigs in the unrestricted research environment had a higher average daily liveweight gain, fat-free lean gain, and fat gain compared with pigs raised in the commercial environment. The liveweight gain and lean growth advantage of the unrestricted research group of pigs were immediate and consistent at each measurement. The pigs in the unrestricted environment had lower serum levels of α-1-acid glycoprotein (AGP) and higher levels insulin-like growth factor-1 (IGF-1) compared with pigs in the commercial environment. This suggests that such biomarkers may be useful for monitoring a pig's response to its environment. There is need for field research to better understand the environmental factors limiting pig growth and evaluating cost-effective methods of intervention.

Floor surfaces in swine barns can influence foot health. Surveys indicate that 50% to 60% of pigs examined at slaughter may have foot lesions. Field trials to determine the effect of types of floor slats on performance and certain foot and leg characteristics of growing-finishing swine indicate the complex nature of the effect of floor surfaces. Lack of adequate exercise and hard flooring in confinement-rearing systems are suggested as major contributing factors to leg weakness and osteochondrosis in growing-finishing swine, especially young boars in performance test station. However, placement of affected animals in a pasture only slightly improves their gait. Shortening the length of the performance test period and increasing the opportunity for animal exercise may help to alleviate the problem. The genetic aspects of foot and leg soundness in swine have been examined, and the results are inconclusive.

The design of the pens should provide for adequate floor drainage, easy cleaning, ease of daily inspection of pigs, adequate ventilation, and effective manure disposal. The stocking rate should follow recommended guidelines, which are described below. The locations of the feeders, waterers, and dunging areas must reduce the fecal-oral route of infection. An adequate ventilation system is assumed to be necessary for the control and prevention of infectious respiratory disease.

The amount of floor-space allowance provided for weanling, growing, and finishing pigs can have a major impact on production during those phases of the pig's growth (Kornegay, 1986a; Kornegay and Notter, 1984). The literature on the effects of floor space and number of pigs per pen on performance (Kornegay and Notter, 1984) and stocking density for growing and finishing pigs (Kornegay, 1986b) have been reviewed. To maximize pork production from a given facility, the producer must be aware of the relationship between floor space per pig and individual performance. Individual performance includes daily body weight gain, daily feed intake, and body weight gain:feed intake ratio. Pen efficiency includes daily gain per daily feed intake per square unit of floor space. Within a given range, individual performance of weanling, growing, and finishing pigs decreases as area of floor space per pig is restricted. Insufficient space allowance may adversely affect individual pig performance and welfare, but high building costs encourage increasing stocking densities in commercial swine enterprise. Even though pig producers are very concerned with individual pig efficiency, the efficiency of a given facility is of more concern from an economic standpoint (Kornegay and Notter, 1984).

The floor-space requirements per pig are influenced by the number of pigs per pen, whether the floor is solid or fully or partially slatted, the temperature and air velocity, the pen design, disease control and sanitation level, the use of feed additives such as antimicrobials, the gender of the pigs, the pig behavior, and the use of decking to improve building efficiency (Kornegay and Notter, 1984).

Floor-space allowances have been studied in the United States and England, and similar results were obtained. Space allowance (Am^2) was defined in relation to liveweight (Mkg) of the pigs according to the equation $A = kM^{067}$, using values for the constant (k) of 0.024, 0.027, 0.030, and 0.034. For commercial recommendations, the calculated space allowance (m^2) would be $A = 0.030\ M^{067}$, or 0.6 m^2 for a

90-kg pig. This is appropriate as a guide to the minimum space requirement of 35- to 90-kg pigs when they are kept on fully slatted floors (Edwards and Armsby, 1988; Gonyou and Stricklin, 1998). The smallest space allowance constant of 0.024 is approximately the minimum lying-space allowance specified in current U.K. welfare codes (Ministry of Agriculture, Fisheries and Food, 1983).

The current U.S. floor space recommendations for pigs housed on partially or fully-slatted floors for which maximum daily gains would be expected are 0.38, 0.92, and 1.04 m^2/pig for weanling, growing, and finishing phases, respectively (Kornegay and Notter, 1984).

Pen efficiency (e.g., amount of pork produced per unit of feed in a given amount of floor space), represented by daily gain per daily feed intake per unit floor space, increased as stocking density increased (Kornegay and Notter, 1984). Therefore within reasonable limits, an increase in pig density (e.g., decreasing space per pig) would increase profits for the producer by spreading the costs of facilities over more pigs marketed. As a result, it is common for some producers to practice some degree of crowding in their confinement facilities. In summary, individual pig performance decreases as floor space per pig is reduced, with a much larger effect on feed intake than on feed efficiency. However, pen efficiency improves as floor space per pig is reduced. An increase in the number of pigs per pen with a constant space allowance per pig reduces individual pig performance slightly, but it has little effect on the pen's rate of feed conversion efficiency (Kornegay, 1986a). Smaller pen sizes provide more flexibility to ensure that all pigs in a pen are of uniform size and allow an individual pen to be kept fully stocked, which would lead to better feeding, resting, and dunging patterns (Kornegay, 1986a). An increase in the feeder space for weanling pigs would not overcome depressed daily feed intake caused by increased stocking density. Although the inclusion of antimicrobials in the diets of pigs can improve both the growth rate and the feed efficiency, the feeding of antimicrobials does not compensate for the adverse effects of insufficient space allowance (Zimmerman, 1986). The effects of the antimicrobials and the space allowances are independent.

In intensive pig production, unacquainted pigs are mixed together in pens, and this generally leads to vigorous fighting. An increase in numbers of long-lasting fights has led to decreased feed conversion efficiency, and decreased weight gains after mixing have been found for pigs fed at a restricted level but not for pigs fed ad libitum (Rundgren and Lofquist, 1989). It has been suggested that in group-fed pigs, the effects of fighting might interfere with feed intake because high-ranking pigs usually have more access to the feed trough. Experimentally, the effects of mixing pigs of a mean weight of 23 kg on agonistic behavior and performance indicate found decreased daily weight gains in the period between 23 and 100 kg body weight for barrows, but not for gilts. For gilts, feed conversion efficiency was negatively correlated with the number of attacks during the observation period (e.g., 80 minutes after mixing); for the barrows, feed conversion efficiency was negatively correlated with fighting injury scores (Rundgren and Lofquist, 1989).

Feeds and Feeding of Growing and Finishing Pigs

A comprehensive presentation of swine nutrition is beyond the scope of this book, but some important aspects are mentioned.

The nutrient requirements of the growing and finishing pig are sufficiently well known so that specific nutritional deficiencies should not occur. The qualitative and quantitative nutrient requirements and clinical signs of deficiency or toxicity are given in publication of the NRC (1998). Literature on recent advances in swine nutrition has been published. Veterinarians providing animal health and production management advice must become familiar with the above information and how it is used in order to formulate diets and to detect clinical and marginal nutrient deficiencies.

In a farrow-to-finish operation, feed costs for the growing-finishing phase of the production cycle accounts for 75% of the total feed costs, and 45% to 55% of total costs must be charged to finishing pigs (Kornegay, 1986a). Therefore feed costs per unit of quality pig marketed have a major impact on the cost of production. Feed costs can be reduced by making feed conversion better by improving genetics, improving diet formulation, reducing feed wastage, and providing a more desirable environment. The goal should be to maximize feed intake while minimizing feed costs per unit of pork produced. When swine producers are faced with very narrow profit margins as a result of low pig prices and high production costs, they are often tempted to reduce the amount of protein and mineral supplements they add to cereal grains to make the diet complete. This reduces feed costs, but it often leads to an increase in the overall costs of production by increasing the amount of feed required and the time required to produce a market pig. For example, lysine is the first limiting amino acid in pig diets. Since lysine and other amino acids are used primarily for muscle protein synthesis in growing-finishing pigs, a lysine deficiency would be expected to reduce the rate of growth, increase the amount of feed required per unit of weight gain, and reduce carcass muscling. It is uneconomical to feed below stated lysine requirements. Similarly, because phosphorus is an expensive mineral, adequate amounts may not be included in the diet. A marginal dietary deficiency of phosphorus depresses the growth rate and feed efficiency of pigs. A marginal deficiency of calcium does not influence growth rate or efficiency of gain, but a deficiency of either phosphorus or calcium reduces mineralization of bone, which can cause leg weakness, lameness, and pathologic fractures.

Most of the activity in nutritional research of the growing-finishing pig deals with refinements of specific nutrient requirements and the source, digestibility, and use of specific nutrients.

There is now much interest and research in the nutrition of the finishing pig to achieve the optimum carcass score within the genetic capability of the pig and to produce more lean pigs. As the pig grows, maintenance requirements and fat deposition rates increase, and the efficiency of conversion of feed into liveweight decreases. Pig growth above 90-kg liveweight is characterized by very rapid rates of fat deposition and a marked deterioration in feed efficiency. The relationship between liveweight, feed efficiency, and lean content is largely dependent on the lean-tissue growth potential of the animal. Any increase in the daily rate of gain of lean-tissue growth will cause a reduction in the amount of fat deposited in the carcass, an improvement in feed efficiency, and, therefore, an increase in the slaughter weight at which the unit of costs of production are minimized (Ellis and Horsfield, 1988). Consumer attitude surveys have shown that a low ratio of fat:lean tissue is demanded at the point of sale. However, although the consumer prefers lean pork, overlean carcasses may have unacceptably soft fat tissues. As pigs get leaner, the fat quality declines. The condition of PSE muscle, which causes excessive drip loss at retail sale and weight losses through the marketing chain, is most obviously associated with carcass leanness in certain breeds. The aspect of meat quality most often associated with carcass composition is PSE muscle, and the most important aspect of quality linked to carcass composition is eating quality. Therefore the challenge is to find the balance between the

desirable amount of lean and backfat and the optimum nutrition of the pig that causes the maximum margin of profit. The goal of producing a pig with a predetermined amount of carcass fat is not possible at this time. The processes of fat synthesis and fat mobilization are well defined in the pig at the various stages of its life, as are many of the factors that influence fat metabolism. A variety of feeding systems are available; each has advantages and disadvantages that vary from farm to farm, depending on the level of management, the type of housing, and the feed used.

The quantity and quality of protein should be maintained at full-feed rates if maximum response to limited feeding is to be obtained. Limited feeding can be done by the inclusion of high-fibrous feed ingredients to restrict energy intake or by limiting daily feed intake. The use of high-fibrous diets reduces feed conversion efficiency, which increases the cost of gain. In general, a decrease in dietary energy density leads to increased dry matter intake, but as a result of the lower density, daily intake of net energy is reduced, which influences pig performance and carcass characteristics. Restriction of the daily amount of diet has the potential for improving feed conversion ratios by reducing feed wastage, increasing digestibility of the feed, and lowering the energy required to produce a unit of gain (Kornegay, 1986a). The research on the efficiency of feed utilization in pigs has been reviewed briefly (Bereskin and Steele, 1988). Feed efficiency is one of the most important traits in pork production, because feed represents 60% to 80% of the cost of raising pigs, and breeding stock suppliers should consider the improvement of feed efficiency as a selection objective. Direct selection for feed efficiency has been less successful than expected, but selection for an index that combines growth rate and backfat as an estimate of lean tissue growth rate has been as effective, or more so, than direct selection for feed efficiency. The physiology of the controls of feeding in pigs has been reviewed. The factors that affect appetite of the pig will become more important in determining the efficiency of pig production. The dietary factors involved in feed intake regulation in growing pigs have been reviewed.

Antibiotics have played a major role in the growth and development of the pig industry for more than 30 years. Their efficiency in increasing growth rate, improving feed utilization, and reducing mortality from clinical disease is well documented. Because of consumer concern about drug residues in meat products, and the fact that the continuous use of antimicrobials may contribute to a reservoir of drug-resistant bacteria in animals that could be transferred to man, alternative methods of growth promotion are being examined.

Veterinarians specializing in swine health and production management are providing nutritional consultation to swine producers who mix and formulate their own rations on the farm. Homegrown or purchased grains are mixed with a purchased protein-mineral-vitamin concentrate mix. This requires a regular system of analysis of the feed grains used. A record of the total amount of feed used during the period is vital information for the assessment of feed efficiency from weaning to market.

On-farm feed production generally involves grinding and mixing grain that is produced and stored on the farm with concentrated commercial feed products. The purchase of complete feeds from a commercial feed mill offers the advantages of high quality assurance, convenience, and other services provided by the feed industry. However, the additional cost of this service and the necessary transportation may not be economical, and on-farm feed preparation has become popular as a result of the substantial reduction in feed costs. However, many producers are unaware of the increased management responsibility and the importance of quality control when preparing feed on the farm. Manufacturing feed on the farm requires additional labor, capital investment, and knowledge of nutrition to evaluate and purchase economical feed ingredients so that the diets can be formulated properly to meet the needs of the various classes of pigs in the herd. Quality control of on-farm mixed feeds is extremely important to minimize nutrient variation relative to final target levels. The addition of expensive major nutrients, such as protein and minerals, in excess of those required to meet the pig's nutrient requirement causes an unnecessary increase in the cost of pork production. Conversely, nutrient levels excessively below the pig's requirements increase the cost of pork production as a result of suboptimum pig performance. Surveys have revealed that many pig diets are not formulated or mixed correctly to meet the desired nutrient levels in the complete feed. The economic impact of these manufacturing errors is significant, and it is important to develop an on-farm program to improve quality control of the feed. The considerations for ensuring quality feed manufacturing include the following recommendations:

1. Obtain laboratory analyses for cereals and protein ingredients.
2. Formulate diets correctly. The nutrient levels for each ingredient must be obtained and the recommended nutrient levels for the class of pigs to be fed must be determined. Most nutrient recommendations are based on those published by the NRC with an added safety factor to account for biological variability.
3. Follow directions on commercially prepared ingredients.
4. Minimize errors when adding ingredients to the mixture. All bagged ingredients should be labeled properly and a checklist should be used to record each ingredient added to the mix.
5. Mix ingredients accurately. Accurate scales are needed for this step.
6. Premix ingredients with low inclusion rates. Feed ingredients with low inclusion rates (e.g., 1% to 2% of the total diet) should be premixed with grain or protein supplement before they are added to the complete mix. This facilitates even distribution of these ingredients.
7. Add ingredients to the mixer in the proper sequence. To facilitate satisfactory ingredient distribution in the mix, at least one half of the grain should be added first, followed by all premixed ingredients. Next, all of the protein sources should be added. Finally, the remaining grain should be added to complete the diet formulation specifications.
8. Allow enough time for adequate mixing. Mixing for 10 to 15 min in a vertical mixer and 5 to 8 min in a horizontal mixer provides satisfactory ingredient distribution in the final diet.
9. Avoid filling mixers beyond capacity.
10. Minimize segregation of ingredients.
11. Clean mixing equipment between batches.
12. Check mixing and formulation accuracy. Obtain representative feed samples, submit them to a laboratory for analysis, and compare the results with calculated levels of the diet formula.

Strategic Medication of Feed and Water of Growing and Finishing Pigs

When epidemics of infectious diseases occur during the growing-finishing periods, antimicrobials may be added to the feed and water supplies, initially at therapeutic levels for up to several days, then followed by prophylactic levels for a few weeks. They should be used selectively and strategically to control or eradicate specific infectious diseases. Routine indiscriminate use of antimicrobials should be avoided because of cost, the possible development of drug-resistant pathogens, and the false sense of security that develops in

the herdsperson. Swine dysentery can be eradicated from a herd by the judicious use of mass medication of the feed of the entire herd.

In swine feeder operations that purchase weaned pigs from a variety of sources, each with a different spectrum of diseases, the incidence of infectious disease of the respiratory and intestinal tracts is usually much higher than in self-contained herds, and there is no reliable method for control. The best that can be done is to provide the most comfortable environment that is economically possible, to treat individual sick pigs as they are detected, to submit dead pigs for necropsy, to mass medicate at strategic times if appropriate, and to practice the AIAO method of management.

The diagnosis must be as accurate as possible if mass medication of the feed and water is used as a method of treatment of the herd. Mass medication of the feed and water supplies of feeder pigs is not without problems. In addition to the costs, it is not always possible to medicate feed supplies that are already in place in storage on the farm, and the medication of water supplies is often difficult to do selectively unless there is a double waterline in each pen, one of which can be turned off. Medication of the entire watering system may not be necessary and is expensive. The withdrawal period for each feed additive must be followed to avoid drug residues in meat supplies. Tests to detect drug residues in pigs after slaughter are now available and are used for statistically valid random sampling of pork in abattoirs. The development of on-farm tests to detect residues in live animals before they leave the farm would assist producers in their drug-residue avoidance program.

The AASV has recently issued a statement reiterating its commitment to the use of scientific knowledge and skills for the benefit of society. Culture and sensitivity results should be used to aid in the selection of antimicrobial. Therapeutic use should be confined to appropriate clinical indications. Therapeutic exposure should be limited to treating only for so long as needed for the desired clinical response and should be limited to treating only the ill or at-risk pigs, treating the fewest animals indicated. Judicious use of antimicrobials, when under the direction of a veterinarian, should meet all the requirements of a valid VCPR. Prescriptions, veterinary feed directive, and extra-label use of antimicrobials must meet all the requirements of a valid VCPR. Extra-label therapy must only be used where deemed appropriate and not expressly prohibited (chloramphenicol, clenbuterol, diethylstilbesterol, dimetradazol, ipronidazol, nitroimidazol, furazolidone and nitrofurazone (except for approved topical use), fluoroquinolones, and glycopeptides (e.g., vancomycin). Veterinarians should work with those responsible for the use of antimicrobials to ensure that they are used judiciously. Regimens for therapeutic antimicrobial use should be optimized using current pharmacological information and principles. Antimicrobials considered important in treating refractory infections in human or veterinary medicine should be used only after careful review and reasonable justification. Contamination of the environment with antimicrobials should be minimized whenever possible. Accurate records of treatment and outcome should be used to evaluate the therapeutic regimen.

Vaccination and the Use of Anthelmintics and Insecticides

In herds that encounter epidemics of pneumonia from *M. hyopneumoniae,* vaccination of all pigs in the growing-finishing group may be indicated. Other vaccinations are now very uncommon.

Anthelmintics and insecticides should be used when indicated for the control of intestinal helminthiasis and skin diseases caused by arthropods. However, control of these diseases is accomplished most effectively by regular treatment of the adult stock, which minimizes spread to the weaned and growing pigs. Treatment of sows with an anthelminthic approximately 1 week before entry into the farrowing crate used in conjunction with good sanitation and AIAO production has been shown to adequately control roundworms.

Continuous Surveillance of Animal Health and Production

Pigs in the growing and finishing pens must be inspected visually twice daily for evidence of clinical disease. Dead pigs must be removed from the pen as soon as possible. A daily record of the number of pigs with clinical disease and the treatments given should be kept and reviewed by the veterinarian at each herd health visit. A monthly report should be prepared, and recommendations for specific action should be submitted to the producer. A record of the average days to market and the amount of feed used for a group of pigs or the total number of pigs over the entire feeding period is vital information.

Careful Handling and Transportation at Time of Shipping to Abattoir

Finished pigs identified for shipment to the abattoir must be handled as carefully as possible during sorting and loading to prevent PSS and PSE as well as other injuries. Overcrowding in the transport vehicle must be avoided, and in hot weather, the pigs should be transported during the cooler parts of the day. Prolonged time in the truck leads to higher mortality rates. Training of personnel of correct handling methods is important (Guise et al, 1994).

The handling facilities at the abattoir should be designed to minimize excitement and stress associated with the movement of animals during weighing, crowding, sorting, and killing (Grandin, 1993). Swine-handling facilities must be designed for a pig's shortened range of site and fear of unfamiliar circumstances. Pork quality may be defined as those factors associated with the appearance and palatability of fresh and processed pork. These factors include color, texture, firmness, and marbling of pork muscle. Several slaughter factors affect pork quality and are of concern to the meat packing and processing industry, the meat retailer, and the consumer. A major pork quality problem is PSE, which is associated with those factors that affect muscle pH and with the temperature during the slaughtering and chilling process. Stunning, bleeding, and chilling procedures, which slow down the glycolytic process and production of lactic acid, assist in maintaining normal pork quality.

Residue Avoidance in Pork

Consumers are concerned about the safety of the pork they eat and whether or not it contains chemicals from pesticides or drug residues from the use of drugs in the feed or for the treatment of pigs, and the possibility of the development of drug-resistant bacteria from the use of chemotherapeutics as growth promoters in the feed of swine. Regulatory authorities now regularly advise livestock producers about the incidence of drug residues. Residues of antimicrobials, anthelmintics, insecticides, and other therapeutic and prophylactic chemicals may be present in market pigs (e.g., barrows and gilts) if the producer fails to observe the withdrawal time for the drug

before slaughter or if these compounds have been added to the feed and water supplies unknowingly. The cause of the residue most frequently cited by the field investigators was failure to observe the withholding time for the drug. Other causes include cross-contamination on the farm or in the feed mill. Failure to clean the feeders when switching from medicated to nonmedicated feed and the clinging of sulfamethazine to the metal walls of milling and storage equipment are sources of the drug. Additional sources include accidental access of pigs to a source of medicated feed, recycling of waste water from lagoons, access to accumulated feces and urine in holding facilities, the unapproved use of the drug, extralabel use of drugs by veterinarians, and contamination of the watering system. Legally, the producer is responsible for the presence of residues in pork, and the veterinarian who prescribes drugs to swine for extralabel use becomes legally liable. A Food Animal Residue Avoidance Data Bank is now available to extension specialists, veterinarians, and other needing information on potential residue problems (Sundlof et al, 1986).

Drug-residue avoidance in pork can be achieved by giving special attention to those segments of the industry that lead to the majority of violations (Van Dresser and Wilcke, 1989). Guidelines for the proper use of drugs and growth promoters in feeds for swine are available. Veterinarians must become involved in educating the food-animal industry about drug withholding times. Educational efforts should emphasize the importance of record-keeping, including efforts to identify animals from their source to their entry into the food chain. To improve the knowledge base on drug residues, studies of the appropriateness of stated withdrawal periods should be conducted for a number of drug products used in food animals. This includes pharmacokinetic studies of the residues in pigs after extralabel use of drugs.

CHAPTER 16

Health and Production Management in Sheep Flocks

PHILIP R. SCOTT

WORLD SHEEP TRADE

The world has a sheep population of about 1.2 billion, occupying largely the difficult environments for agriculture, particularly the mountainous and semiarid areas (Marai and Owen, 1987). Sheep have also been associated with traditional subsistence systems, especially in developing countries, that have remained largely unchanged for centuries. Sheep provide meat, milk, and wool as main products for their keepers. Although there is still a major role for traditional systems as efficient converters of rangeland and by-products, circumstances are changing in many respects. This calls for a reassessment and modification of traditional sheep and sheep-keeping methods. Where good land and various other factors are favorable, sheep genotypes are capable of much higher productivity, although not always at a higher rate of efficiency and profitability.

The distribution of sheep throughout the world is unequal. In some countries the production and export of wool and sheep meat comprised a large part of the gross domestic product when there was a demand for wool, lamb, and mutton. Certain geographic factors and climatic characteristics favor the production of sheep, whereas others exclude the keeping of sheep (Fraser and Stamp, 1987). There are few sheep in either equatorial or subarctic regions, and many sheep on islands and in coastal regions. There is a close association between a 50- to 100-mm annual rainfall and the density of the sheep population.

Historical Considerations

The historical and commercial factors that influenced sheep production and population on a worldwide basis are interesting (Fraser and Stamp, 1987). In Europe, Britain, Spain, and the Balkan countries are the three main areas of sheep production. The countries of the European Economic Community have about 92 million sheep, of which France has about 11 million. Britain has about 37 million sheep and, historically, sheep have been important for Britain because they provided wool for clothing. The export of raw wool from England to Europe was once of primary importance to the country's wealth, preceding the development of a trade in manufactured woolens by some centuries. Lord Ernle wrote, "Wool was the chief source of the wealth of traders and of the revenues of the Crown. It controlled the foreign policy of England, supplied the sinews of our wars, built and adorned our churches and private houses" (Fraser and Stamp, 1987). The Lord Chancellor's sitting on a woolsack is a reminder that the wealth and majesty of England once rested on a solid and elastic foundation of sheep's wool. England then became a wool importer to meet the needs of the wool products manufacturing industry, which soon exceeded the relative importance and resources of the national sheep industry. The Industrial Revolution, the increase in manufacturing industries, and the growth of urban population led to an increase in purchasing power, affluence, and the consumption of meat. Roast beef was the traditional meat dish, but, because of increased demand and the lack of modern refrigeration, sheep became a source of meat. This was followed by the development of the English breeds of mutton sheep, which retain their preeminence throughout the world today. This diversion from the old short- and long-wooled flocks to the English breeds of mutton during the late eighteenth and early nineteenth centuries has helped maintain the viability of the sheep industry in Britain, in spite of the development of wool production in the Southern Hemisphere.

The merino breed of sheep, known for its fine wool, originated in Spain, which maintained a monopoly of production of merino wool for centuries. From the end of the eighteenth century, however, merino sheep spread to England and other European countries but most notably to South America, South Africa, Australia, New Zealand, and the United States. Spain lost its reputation for fine-wooled sheep to Australia.

The sheep in Italy and the Balkan countries are the triple-purpose breeds of sheep that produce wool, milk, and mutton. These are being replaced by specialized, dairy-type breeds; the seasonal migration of livestock and the people tending them, dependent on the use of natural grasslands, are giving way to modified systems of increased density. There are 40 million sheep in former East Germany, Poland, Hungary, Rumania, and Bulgaria. Larger, more specialized flocks are becoming more common in these countries.

In the Southern Hemisphere, there are four great and important areas of sheep concentration: Argentina and Uruguay in South America, South Africa, Australia, and New Zealand. Each of these countries has had much the same economic history related to sheep, beginning with the importation of the wool-producing merino sheep between the mid-eighteenth and mid-nineteenth centuries and the development of an export trade in wool, followed by diversification in the production of mutton and lamb with the introduction of refrigeration. These new centers of sheep production were favored by inexpensive and abundant land and favorable climatic conditions, and now contain about half of the world's population of sheep. The development of the sheep industry in the Southern Hemisphere led to a steady decline of wool production in industrialized European countries. Also, the export of frozen lamb to Britain and other European markets has caused some dramatic changes in the economy of the sheep industry, making it much more difficult to make a profit from sheep farming.

For many years, Australia was the world's largest sheep producing country, with total numbers ranging from 135 to

170 million. It is the largest producer and exporter of fine wools, but because of declining markets the sheep population in Australia has been decreasing, and it is now the second largest after the former Soviet Union, with 140 million. In 1991 the wool market in Australia collapsed, and the government was almost paying farmers to kill sheep in order to decrease the numbers. New Zealand imported its merino sheep from Australia in 1834, and, until the time of refrigeration, its major export was merino wool. In the early part of the twentieth century, New Zealand diversified quickly to lamb production in addition to wool, which has led to excellent fresh and frozen lamb for home consumption and export. In developing the lamb market, New Zealand did not sacrifice its wool market, which has changed from fine merino wool to a fairly coarse and crossbred wool that is used primarily in carpet manufacture.

The United States, India, and the former Soviet Union have sizable sheep populations. The sheep population of the United States decreased from 51 million in 1939 to 33 million in 1960 and to 13 million in 1976, a trend that appears to be permanent. Presently there are about 7 million ewes in the United States. The size of sheep flocks varies from a few kept by hobby farmers to several thousands by farmers who are in commercial sheep farming as a primary source of income. In the United States, in 1982, 50% of sheep farms had 1 to 25 head of sheep and lambs, 33% had 25 to 99, 15% had 100 to 999, 7.5% had 1000 to 2499, and 0.9% had 2500 or more. Small flocks are kept on many farms to use forage on small acreages that cannot be marketed. On western United States ranges, sheep consume forage that would otherwise have no economic value. Large flocks dominate in the western ranges, and, although only about 2% of producers have 1000 head or more, they produce about 70% of the sheep. The early settlers brought sheep with them, but improved breeds were not introduced until the nineteenth century. Merinos were introduced, and the sheep industry developed in the West because of cheap grazing and access to the large, undeveloped lands. American sheep of the western states still contain much merino breeding, even though wool in the American sheep industry has become a by-product of lamb. The merino is suited for the western states because of its close flocking instinct, which makes herding on open ranges much more practicable, and because the merino is the type of sheep suitable to semiarid climates. In the eastern states, sheep play a minor role in the economy of the mixed farm, and English mutton breeds prevail.

India and Pakistan together form a vast subcontinent of agricultural villages that might be expected to have a large concentration of sheep similar to the peasant communities of southeastern Europe. However, the hot and dry climate, although favorable to wool-bearing merinos, is not favorable to mutton and milk production. The former Soviet Union has the largest flock of sheep in the world, some 140 million. Before the Bolshevik Revolution, it supported a large sheep population consisting of triple-purpose, coarse-wooled sheep held by the peasantry and of the fine, merino-type breeds owned by the large landowners. Higher textile standards were achieved by large importations of fine-wooled breeds from Australia, and the adoption of artificial insemination (AI) on a wide scale was designed to accomplish this. Because of the harsh winters, both wool and sheepskins are of particular importance in providing clothing. During the World War II and early postwar years, both the sheep population and wool production suffered a severe recession, from which they have not recovered. Nevertheless, with its large sheep population, the former Soviet Union is second to Australia in the production of wool and is a leading importer of wool. Mutton production is being encouraged.

In North America, sheep are managed under a wide variety of conditions, including extensive range operations, semiconfinement, total confinement, and hobby farm systems. The degree of owner observation, individual animal identification, and systematic record keeping varies considerably in these systems and is sometimes inadequate. A primary task of the veterinarian in sheep practice is to educate producers about health and production aspects of sheep and the value of careful observation, identification, and record keeping for the improvement of flock health and productivity.

In Canada, in 1988, it was estimated that there were 365,000 breeding ewes and 330,000 lambs. Purebred flocks varying in size from 50 to 300 or more ewes, depending on the country, are kept for the production and sale of replacement rams and ewes for both the purebred industry and commercial breeders.

Sheep are kept under extensive and intensive conditions. For example, in Scotland, the stocking rate varies from one ewe to 2 to 3 hectares on uncultivated hill pastures to 12 or 16 ewes to a hectare of cultivated pastures. There has been a trend toward intensification of sheep farming with highly efficient systems dependent on high-quality forages and large inputs of concentrates to achieve production targets of 175% weaning rates with twin lambs reaching 40 kg by 14 weeks old. However, sheep use an extremely wide range of feed resources, and the utilization of vast areas of natural grasslands is one of the merits of the species. Thus grasslands continue to play an important role in sheep systems of all types. The area of grasslands in the United Kingdom, particularly that under 5 years old, continues to decline, whereas there has been a 30% increase in the national sheep flock, which now exceeds 23 million breeding ewes. The overall effect has been increased pressure on the grasslands (Johnson and Evans, 1986) with high stocking densities supported by high inputs of artificial fertilizers, particularly nitrogen, on short-term grass leys.

Lamb feedlots with capacities varying from a few hundred to tens of thousand head purchase lambs and finish them on a high-level grain diet. Approximately 6 million lambs are marketed for slaughter annually in the United States (Salman et al, 1988b).

The world sheep trade consists of wool, mutton, and lamb production. Wool is extremely variable and diverse in type and the wool manufacturing trade is complex because of the blending or mixing of wools during manufacture. A single piece of cloth may contain wool from several continents. Wool may be broadly classified into merino, crossbred, and carpet wool. About 90% of merino wool in the world is produced by Australia (the largest producer), South Africa, Argentina, and the former Soviet Union.

The crossbred wools, which are not necessarily from crossbred sheep, are produced in New Zealand, Argentina, Australia, and the former Soviet Union. The carpet wools are produced mainly in the former Soviet Union, China, India, and the Balkan States. All the industrialized countries of the world are importers of raw wool. Former West Germany is the largest user of wool per person. Most of the wool produced in Australia, New Zealand, and South Africa is sold at public auction by wool brokers who sell on behalf of the producer. The success of the world trade in wool depends on the success of the producer and woolen manufacturer in dealing with the competition of synthetic fibers used in the manufacture of human clothing and carpets. To promote the use of wool and to conduct research and development on the use of wool, the International Wool Secretariat (IWS) based in London, with offices in 30 countries, was established in 1937. The wool mark was introduced by the IWS in

1964 as a symbol of quality, which ensures the buyer that the product is manufactured from virgin wool. A set of quality control systems associated with the wool mark ensures that the product meets certain technical requirements, such as resistance to rubbing and snagging, fabric strength, and colors remaining fast to light and liquid. The wool blend mark introduced in 1971 indicates blended fabrics with a content of more than 55% wool.

The world trade in mutton and lamb is more limited than that of wool. The European Economic Community has only 6% of the world's sheep but produces 11% of the total sheep meat and contributes to one third of world trade. Australia and New Zealand account for 80% of world trade exports, and Britain, France, and Japan represent 40% of all sheep meat imports. At one time, New Zealand depended on the export of frozen lamb to Britain and France for a major portion of its gross national product. The consumption of lamb in Britain has traditionally been high, but consumption has been dropping, which has seriously affected agricultural prosperity of New Zealand. The predominant supplier of mutton is Australia, with Japan as the major importer.

Sheep dairying is a significant activity in the sheep industry (Dawe, 1990). Sheep milk is highly nutritious and is an important component of family sustenance for many millions of people in the favored environments of the world. The sheep dairy industry is concentrated in the more advanced countries of the Mediterranean basin. Sheep dairying is now a growing industry in Australia, Israel, and France. Sheep's milk is rarely used in the liquid form but is generally used for the production of cheese and yogurt. Sheep milk produces double the yield of cheese obtainable from cow or goat milk (Treacher, 1987). Sheep yogurt is finer, smoother, and about 50% more nutritious. Most flocks are hand milked, which is physically demanding and often done outdoors while exposed to the weather. In spite of the availability of effective milking machines, machine milking has not been widely adopted.

The sheep dairying industry has been described (Dawe, 1990; Mills, 1989). Animal health problems, particularly internal parasites, mastitis, and diseases of the feet, seriously limit the productivity of sheep dairy enterprises in Australia. An excellent review of these problems in dairy sheep has been published (Philbey, 1990). The intensive, pasture-based systems of sheep dairying favor the development of gastrointestinal nematodes. Acute mastitis causes death, and subacute mastitis causes loss of milk yield. Lameness caused by footrot is also a major cause of economic loss.

Potential for Sheep Production in Developing Countries

There is a large, untapped potential for improving the productivity of sheep and goats in developing countries (Johnson et al, 1986). This is explained on the basis of the substantial numbers of animals that already exist, the gap between average and best observed productivities, the opportunity to increase emphasis on market-oriented incentives, and the feasibility of realizing major increases with low costs of inputs (Nygaard and Amir, 1988; Johnson and Evans, 1986). In 1980 the lesser-developed countries accounted for 56% of the world's estimated 1.2 billion sheep and 96% of the 460 million goats. The importance of animals to people and the role of small ruminants in farm families in developing countries have been documented. They can obtain their nourishment from grasses and other fibrous forage, which people cannot use directly. In turn, humans are provided with an adequate supply and proper balance of energy, minerals, vitamins, and essential amino acids, which is necessary for human metabolism. Increasing the productivity of sheep and goats represents a hope for improving the living standards of undernourished poor people in the lesser-developed countries (Devendra, 1981). The nonfood contributions of ruminants, many of which cannot be determined precisely, are also substantial. However, at the present time, few research projects focus on livestock issues, and financial support is small. Reports have suggested that sheep play a crucial role in agricultural production, especially in western Asia and North Africa, but there is not much research effort and few new programs that promote production (Thomson et al, 1987).

To realize the potential just described, traditional farmers must place more emphasis on producing for the cash market and thus have more incentive to adopt new technology. Johnson et al (1986) have suggested that ensuring that appropriate new technologies are available for sheep producers in the lesser developed countries requires a six-step research effort: a description of the farming system, applied research on components of the farming system, linkage with international networks for basic research having widespread application, multidisciplinary experiments to examine interactions among system components, and on-farm validation and institutionalization of a dynamic system for technology innovations. This last step is especially important, but often overlooked (Johnson et al, 1986). The institutionalization of a dynamic system for the continued monitoring and improvement of on-farm technology—with effective, permanent lines of communication among farmers, researchers, extensionists, and support personnel such as veterinarians, bankers, and marketing specialists—is the most critical of all if the effort expended on the first five steps is to lead to permanent, ongoing improvements (Johnson et al, 1986).

The Small Ruminant Collaborative Research Support Program was established in the early 1980s to develop research projects oriented toward flock health and veterinary extension activities, and more recently toward infectious diseases, in countries such as Brazil, Kenya, Peru, Morocco, and Indonesia (Alexander et al, 1989). The first decade of animal health investigations in these countries has revealed that infectious and parasitic diseases continue to be a major constraint for small ruminant production. The economic value of small ruminants such as sheep and the low incomes of most owners limit the health care intervention that can be applied. The costs of anthelmintics and vaccines often prohibit owners from using these products to control the major diseases of sheep and goats.

The Small Ruminant Collaborative Research Support Program has also conducted research on the breeding and genetics of sheep and goats in participating countries (Bradford et al, 1989). The results indicate the importance of evaluating local breeds and provide evidence for opportunity for genetic improvement through breeding programs based on local genetic resources, as well as on the judicious introduction of breeds selected for specialized performance.

ECONOMICS OF SHEEP PRODUCTION

The economics of sheep production in the United Kingdom have been described (Nix, 1988) and are updated annually by the Meat and Livestock Committee (MLC, 1997). In terms of gross margin of profit, sheep production has been comparable with other livestock enterprises. Production data for 1996 reveal an average gross margin per hectare for a lowland spring lamb flock of £868 ($1200)/hectare. Since the introduction of sheep quotas based on breeding females, the sheep numbers in the United Kingdom have remained

static over the past 8 to 10 years. Many sheep farmers have a medium to large area of land (approximately 250 hectares) with a low income requirement; therefore a good profit can be generated. Such farmers usually like sheep, too. Two thirds of U.K. farmers own their land and have no mortgage. Sheep also have a low capital requirement compared with most of the alternatives. Little specialized machinery is required, and the feed requirements with March to April lambing follow the natural growth cycle of grass, although with increasing litter size, concentrate supplementation during late gestation is essential. Housing is not necessary except for short periods during lambing time, and usually old buildings, or multipurpose buildings, can be adapted suitably.

The major factors affecting gross margin per hectare are stocking rate, which accounts for 40% of contributions to sheep profitability, and lambing percentage, which accounts for 20%, although these data are generated from a relatively small population. Many low-ground sheep flocks in the United Kingdom wean in excess of 160 lambs/100 ewes mated. When such increased production figures are considered, the lambing percentage assumes a much greater role in affecting gross margin. A high lambing percentage necessitates high labor costs over 1 month (with extra care being given to every ewe at lambing and to every lamb after birth), increased concentrate feeding, and good quality forage. Thus it is essential to ensure high lamb survival rates and rapid growth rates such that these additional variable costs do not exceed the extra revenue obtained (Nix, 1988).

In northern Europe, especially Britain, wool is a by-product of intensive lamb production for meat. High meat prices and subsidies mean that wool accounts for less than 10% of income from sheep flocks (Ryder, 1987). Financial results produced for 1996 revealed that wool now accounts for less than 5% of the gross margin per ewe (MLC, 1997) and continues to decline still further. In southern Europe and parts of the Middle East, milk is the primary product of the ewe; this pushes wool (usually of the carpet type) into third place so that it often produces not more than 5% of income.

In North America the sheep industry consists primarily of large range flocks in the Western states managed extensively with minimal inputs, lambing once annually, and the production of pasture-fed lambs, which either are marketed or go into feedlots for short-term feeding. Wool is a by-product of these flocks. There are also some smaller, more intensively managed flocks in the Midwestern and Eastern states, which lamb more than once annually and produce heavy lambs, with wool as a by-product.

Sheep Industry Characteristics Affecting Animal Health and Production Management Services Veterinarians Provide

In many countries the sheep industry is similar to the beef industry in that many producers operate on a low-input, low-realization basis. Their enterprises are a way of life that has changed little in several generations, and they tend to resist change. Because the individual commercial sheep is of relatively low economic value compared with other food-producing animals, sheep producers have not asked for veterinary assistance to the same extent as cattle producers in the past. In New Zealand, with its large sheep population, the average number of veterinary hours per veterinarian spent annually in sheep practice is small; is less than the number of hours devoted to small animals, dairy cattle, and horses; and is about the same as that spent in beef cattle and goat practice (Boland and Morris, 1989). In contrast, in many European countries numerous flock advisory schemes have been operated by private practitioners. For many farmers sheep are the sole source of income, and veterinarians have endeavored to develop a working relationship with sheep producers, who traditionally perceive that veterinarians did not know much about sheep production (Wise, 1987).

Many large animal (rural) practices have provided the necessary veterinary services and animal health supplies such as anthelmintics and vaccines that sheep producers requested. These large animal practitioners have provided a major service by selling animal health supplies (dips, vaccines, anthelmintics) and by spending a large amount of time in giving advice on the use of these products in an animal health management and production program. In addition, veterinarians in diagnostic and research laboratories and industry veterinarians have made major contributions to the sheep industry.

Technology Transfer

Sheep producers have been traditionally slow to change their practices and techniques of management. However, since the 1980s, there has been an influx of new, younger, and more educated, innovative, and knowledgeable producers who recognize the importance of targets of health and production performance and who want to optimize production and maximize net income.

In sheep farming on extensive range, the risks of poor productivity or heavy losses are so large because of natural influences such as drought, flood, and poor feed supply, so high profitability is variable. The price of wool has also been extremely volatile until fairly recently, and this did not encourage financial investment in the wool enterprise. Sheep farms with intensive management on fertile ground in high-rainfall or irrigated areas have been more receptive to a high-input veterinary service. The availability of free government services in some countries has also restricted the development of private practitioner services.

Potential Market for Sheep Veterinary Practice

In some countries, there is a common assumption of responsibility for veterinary services to sheep flocks by government agencies, especially when strong government veterinary services are available. There are two consequences. Because no fee is involved, there may have been little incentive to carry out a study of the cost effectiveness of the animal health and production techniques that were being used. The lack of participation by practicing veterinarians in the sheep industry has led to much greater involvement of agriculturally trained animal husbandry advisors than in the cattle industries. This trend has been encouraged by the greater importance of production management compared with that of disease control in sheep than in the dairy cattle industries.

Some private practitioners are now providing consulting veterinary services to sheep farmers and incorporating the specialist consultants available from government agencies and universities, such as parasitologists, pathologists, epidemiologists, geneticists, economists, and agrologists (Bell, 1988; Watt, 1983a; Galloway and Grant, 1984). The cooperation among the veterinary practitioner and the government and university specialists provides opportunities for field research and development projects and meets the educational needs of the university to expose undergraduate and postgraduate students to production-oriented veterinary practice. Universities and government agencies provide encouragement, advice, and assistance to established veterinarians, who provide flock health management and production serv-

ices. The provision of flock health and production management services is a complex activity that requires decision making on the farm, often using many and different variables, which in turn requires that current knowledge and new information be sound and evaluated for applicability on individual farms. Thus the veterinarian and advisors must work together and assist the farmer with plans for the implementation of the health management and production methods to be used on the farm. Various sheep health schemes operate in the United Kingdom that involve the private veterinary practitioner in flock health management (Linklater, 1989).

The market for sheep veterinary practice in the United States is only about 4% of the total food-producing animal veterinary medical services (Wise, 1987). Sheep producers spend the least on animal health products and services. As a proportion of the total food animal veterinary service market, sheep practice represents the lowest proportion (about 4%) compared with beef practice (34%), dairy (47%), and swine (15%). Sheep practitioners have suggested that most of their revenue from sheep flocks comes from sick animal services, with a relatively high proportion of that revenue from laboratory and diagnostic services.

Although the total amount has been small, there has been some emphasis on disease prevention and control. This has occurred because of the nature of the veterinary services supplied to the sheep industry. Because of the low individual value of animals and the difficulty of making a clinical examination and diagnosis in a live sheep, the principal preoccupation has been with lethal diseases. The method developed to deal with this was to deliver several dead or badly affected sheep to a diagnostic laboratory. After a diagnosis was made, recommendations for clinical management of the problem were provided, but farm visits to evaluate the problem were not usually made. In the absence of repeated visits to farms to treat sick animals or to participate in disease eradication programs such as the brucellosis and tuberculosis eradication programs, which provided opportunities to get on cattle farms, the development of flock health programs has had no starting point.

The primary objective must be to devise ways of getting onto sheep farms regularly so that the veterinarian can develop familiarity with, and gain the confidence of, the sheep farmer. In New Zealand the major entry onto sheep farms has been through breeding soundness examinations of rams and *Brucella ovis* control. In Australia footrot eradication is providing a similar entry point. In both countries and in South Africa, testing for anthelmintic resistance is a regular and increasing activity, which is a routine annual procedure involving at least one visit. It is also noteworthy that, in New Zealand and Australia, veterinarians investigate flock problems on the farm and submit samples to the diagnostic laboratory as required. Thus considerable progress has been made in the provision of animal health veterinary services on the farm. In the United Kingdom, flock advisory visits during late gestation to monitor late gestation ewe nutrition has proved successful (Scott, 1989).

Having once provided some service to the producer and established a client-veterinarian relationship, it is still necessary to obtain full farmer cooperation. However, compared with the situation in dairy herds, there is great difficulty in ensuring that the regular submission of data by farmers is maintained. This is largely because of the infrequency of visits to the farms required in most programs. If these can be increased without jeopardizing the cost effectiveness of the program, the problem could be resolved. Failing this, the maintenance of telephone and mail contact and client meetings, with reminders of seasonal activities that should be carried out, help maintain enthusiasm.

Sheep Welfare

Aspects of intensive stock farming have become the focus for many animal welfare charities and organizations throughout the world. Sadly, public action has often achieved results in areas in which veterinary submissions to government agencies over many years have failed. Notable examples include public protests at ports that stopped the export of live calves and sheep from the United Kingdom to continental Europe. The banning of sow confinement systems during late gestation within countries of the European Community was the result of public opinion and protest. Public frustration, and that of many veterinarians, has been fueled by the lack of progress in many areas of concern and can be appreciated when reading much of the opinion emanating from various governing bodies. A recent Comment in the Veterinary Record (Anon, 1999) reports thus: "Anyone involved in attempting to achieve improvements in farm animal welfare at the practical level will be aware that progress is often slow and difficult to achieve. They will also be aware that the issues are complex and that well meaning but ill-thought out measures can all too easily have an effect opposite to the one intended."

The importance of animal welfare in sheep production systems was highlighted in the preface to the last edition of this book but has received relatively little attention (Scott et al, 1995a). Although attention to individual sheep cannot be provided in many remote rural areas throughout the world, the high economic value of many breeding ewes in European countries justifies veterinary attention for many procedures. Obstetrical problems are common and provide the veterinarian with opportunities to visit the farm and discuss aspects of production and flock health care in addition to the attention of individual sheep.

One area that has witnessed major advances in the welfare of individual sheep has been veterinary attention of ovine obstetrical problems, including vaginal and uterine prolapses (Scott et al, 1995a,b; Gessert and Scott, 1996) and dystocia cases (Scott and Gessert, 1996a; Scott and Gessert, 1997a,b). Extradural injection of 0.5 mg/kg B.W. of 2% lignocaine combined with 0.07 mg/kg xylazine injected at the sacrococcygeal site provides almost immediate caudal analgesia that lasts for up to 36 hours. This technique greatly facilitates correction of dystocia cases and replacement of vaginal and rectal prolapses. The provision of appropriate analgesia prevents tenesmus, thereby reducing the likelihood of recurrence of the prolapse and greatly improving prognosis. This technique is readily applicable in field situations; it indicates to the farmer and farm staff that there have been important advances in veterinary medicine and provides the opportunity to investigate other aspects of flock management during the farm visit. All too frequently dialogue between veterinary surgeons and their sheep clients has been limited to telephone advice on the use of a particular product; the client having made the diagnosis himself. An outline management system for the welfare of hill sheep in the Scottish highlands has recently been described (MacNab, 1997) and forms a useful blueprint for veterinarians. The visit to the farm to attend an obstetrical case affords the veterinarian the opportunity to look around and, where appropriate, offer advice, make suggestions, and ask questions. Such opportunities to extend and develop sheep flock health programs must be grasped firmly.

Education of the Species Specialist Veterinarian

In many veterinary colleges there is little instruction on sheep, especially in relation to flock health and production management. At the present time, if the veterinarian is to provide highly qualified advice on all aspects of sheep

health and production, the additional education and development of necessary skills may have to come from a combination of several years in practice and formal postgraduate courses that emphasize sheep production. These are available in some veterinary schools, such as the University of Melbourne's McKinnon project (Bell, 1988). In many countries specialized sheep veterinary organizations hold regular national and regional meetings and continuing education courses, which provide an excellent forum for exchange of practical information. In the United Kingdom the Sheep Veterinary Society boasts over 1000 active members. In the United States the Small Ruminant Organization organizes annual conferences and regional meetings.

It is possible for veterinary schools to provide a core elective program in which interested students could concentrate their studies in sheep health and production management during their clinical instruction years. This has not been possible in most schools because they have not had teaching practices large enough, with enough sheep work, to provide the opportunity for students to see a sheep specialty practice. The PEW National Veterinary Education Program in the United States has recommended that food-producing animal teaching centers be established in areas with a concentration of a certain species. Interested students could attend for an extended period of time during their undergraduate years to experience a species specialty practice. This would get around the necessity of every school attempting to provide clinical instruction in every domestic animal species. The development of a sheep farm advisory practice has been described (Bell, 1988).

Becoming a sheep specialist requires continual contact with good sheep farmers and astute observations of their sheep and management techniques, which provides a basis for self-directed learning. A major emphasis is on increasing and maintaining profitability of the sheep enterprises served by the veterinarian. A personal library of books, journals, and proceedings of seminars is a requirement that must be developed along with an effective information-management system that can find and retrieve information quickly. The availability of the Internet affords access to a vast amount of scientific information and allows active participation in specialist discussion groups, even for those veterinarians in remote areas. Communication with experts worldwide on a vast array of subjects allows the veterinarian to keep informed of the latest developments in sheep health and production. The veterinarian must be fully committed to advisory work, which cannot be combined with conventional emergency veterinary practice that provides service for dogs, cats, horses, cattle, and sheep at the same time. Certainly, a veterinarian can combine emergency service with health management service in one or two species, such as sheep and beef cattle, but this requires organization of the veterinarian's time to maximize efficiency.

The practitioner needs a certain amount of clinical experience before moving in the direction of sheep specialty practice. A considerable amount of out-of-hours work is necessary to retrieve the information required to solve flock problems and to provide advice to the producer. The veterinarian usually begins learning on the job by working with a group of sheep farmers who are interested in flock health management. It is with these initial clients that the veterinarian must endeavor to provide a successful service that in turn can produce a good reputation among sheep producers. Reports of flock health visits, along with recommendations for changes in health and production management, are a necessary part of developing an advisory service. Becoming computer-literate for the purpose of producing health and production reports and newsletters is a prerequisite. Additional subjects to be included in such a course are the following:

- Good understanding of sheep production, including the economics of sheep production and the use of partial budgeting
- Genetic management, including objective measurement methods and the handling of large numbers of sheep in a series of levels of differing excellence
- Grazing management: the economy of subdivision, selection of a level of grazing pressure, and selection of pasture species
- Nutrition: body condition scoring (BCS) and adjustment of rations accordingly, with feeding during periods of drought, ewe maintenance, and weaner management
- Reproduction management: times of breeding, duration of breeding period, concentration of lambing, and examination and selection of rams
- Management of lambing to ensure a high level of lamb survival
- Cost-effective control of serious diseases in the particular area
- Familiarity with the physical techniques of shearing, foot care, AI, ovum transplantation, culling of ewes, lamb and sheep necropsies, drenching, fleece appraisal, plunge and shower dipping, and many others

A sheep veterinary specialist certificate and diploma program is now available in the United Kingdom under the auspices of the Sheep Veterinary Society, a division of the British Veterinary Association.

Causes of Economic Losses in Sheep Flocks

There is little published literature on the causes of economic losses associated with disease or impaired productivity in sheep flocks. There have been surveys based on abattoir surveillance (Cuthbertson, 1983), but they have little validity except as indicators of change in prevalence from year to year or season to season. They reflect prevalence mostly in market sheep and are biased toward the young part of the population. Similarly, surveys carried out on material passing through diagnostic laboratories are biased toward fatal diseases and provide no indication of the real waste caused by nonfatal diseases such as footrot, many helminthiases, and nutritional deficiencies. They often do not provide the most basic of all epidemiological data, the size of the population at risk, and the number affected. Such surveys are common for particular sectors of the sheep population, especially lambs (see the "Perinatal Lamb Mortality" section). A survey of diseases diagnosed in adult and feeder sheep submitted to a diagnostic laboratory in Canada revealed that diseases of the respiratory and digestive tracts were most common (Moteane et al, 1979). Based on serological results, subclinical maedi-visna virus infection in sheep flocks can have a detrimental effect on productivity, such as conception rates and birth weights of lambs born to ewes infected with the virus (Dohoo et al, 1987).

A mail survey of diseases in 116 sheep flocks in Canada on the record of performance (ROP) over 1 year revealed a lambing percentage of 153% (1.53 lambs born alive/ewe lambing). This was below the rate observed in all flocks on the ROP program and substantially lower than the 179% lambing rate that can be achieved in some commercial flocks on an estrus synchronization program (Dohoo et al, 1985; Rawlings et al, 1983). Total lamb losses were estimated to be about 12%, but this was probably a conservative estimate. The major identified causes of lamb mortality were starvation, pneumonia, diarrhea, and accidents. Abortions occurred in about half of the flocks, but usually at a

BOX 16-1

Major Causes of Economic Loss

1. Reproductive inefficiency, including failure to conceive and failure to lamb normally with more than one lamb and with an optimum litter size for the environment and level of management.
2. Lamb mortality from birth to weaning. Most of this occurs in the first 2 days after birth.
3. Nutritional inadequacy of ewes during the various stages of the reproductive and wool-producing cycles. The most critical periods are the last 6 weeks of gestation and the first 3 weeks of lactation.
4. Diseases such as internal and external parasites, pregnancy toxemia, blowfly strike (in some countries), suboptimum growth rate in weaned lambs (weaner ill thrift), footrot, mastitis, prolapsed vagina, clostridial infections, and certain specific diseases, such as maedi-visna.
5. Insufficient long-term attention to the breeding program necessary to improve performance.

BOX 16-2

Veterinarian's Role in Flock Health and Production Management Service

Improvement of reproductive performance
Reduction of perinatal lamb mortality
Identification of suboptimum production or sources of loss
Formulation of cost-effective measures to achieve optimum productivity
Maintenance of optimum nutritional status of the flock
Ensuring that the parasite control program is correct (regular fecal egg counts) and monitoring that the chemicals used are effective
Control and possible eradication of specific diseases, such as footrot and *Brucella ovis* infection
Investigations of epidemics of disease
Transfer of new knowledge and technologies, which can improve the efficiency of production

low level, and abortion storms were uncommon. Pneumonia was the most common cause of mortality in ewes, and mastitis occurred frequently; this was often cited as a reason for culling (Dohoo et al, 1985). Prolapse of the vagina or uterus was also a common cause of mortality and a significant cause of culling. In the same survey, the average adjusted weight at 100 days of age was higher than in other types of flocks and the prevalence of diarrhea was lower (Dore et al, 1987). At the herd level, the incidence rates of pregnancy toxemia and vaginal prolapse were associated with heavier lambs, whereas the average daily weight gain between 50 and 100 days of age was lower in flocks affected with diarrhea and starvation. Lamb losses in Australia have ranged from 15% to 20% (Alexander, 1984) and 17% to 35% (Haughey, 1985), and an intensive study of losses in a large Scottish flock reported a total loss of 25.8%, of which 7.2% were stillbirths (Wiener et al, 1983). Further studies in the United Kingdom have reported perinatal mortality rates in excess of 15% (Barlow et al, 1987). In the United States perinatal losses ranged from 10% to 35% of the annual lamb crop (Rook et al, 1990).

Disease wastage in weaners and adult sheep varies from place to place, depending on climate and husbandry practices. An Australian report (Watt et al, 1981) estimated that 75% of ewes, 50% of weaners, and 85% of wether flocks were drenched for worms wastefully, insufficiently, or at the wrong time of the year. There was also a significant neglect of preventive procedures against blowfly strike and clostridial diseases, with more than 50% of susceptible sheep populations left unprotected. Wastage was also predicted in flocks in which a supplementary diet was fed to ewes to avoid pregnancy toxemia, because only 6.8% of ewes bore twins. The degree of susceptibility seemed to be much too low to warrant an across-the-flock feeding program. A New Zealand survey (Davis, 1979) reported a 5% annual rate of death in 24,000 sheep. The most common diseases were pregnancy toxemia, pneumonia, dystocia, blood poisoning, chronic facial eczema, and salmonellosis. In a similar survey covering 3000 adult sheep in Norway, the average loss was 2.7% annually, with most deaths occurring at pasture (Lutnaes, 1982). The most common causes were diseases of the nervous system, mastitis, trauma, metritis, and abortion. Data from MLC recorded flocks in the United Kingdom reveal annual ewe mortality rates from 4% for hill flocks and 5% for lowground flocks (MLC Yearbook, 1997).

In summary, there is general agreement that the major causes of economic loss are those listed in Box 16-1.

Opportunities for Improved Profitability

Because of the wide margins between the levels of sheep production that are economically possible and current levels, there are opportunities for improving the efficiency of production (Owen, 1987b). The best opportunities for the veterinarian to provide a flock health and production management service that can improve profitability in the sheep flock include those listed in Box 16-2.

NEED FOR HEALTH AND PRODUCTION MANAGEMENT

Traditionally, the sheep industry has not consulted veterinarians about flock health and production management. Producers themselves usually have undertaken most of the routine procedures and clinical work required, such as tail docking, castration, vaccination, drenching, obstetric assistance, and treatment of common diseases (e.g., pneumonia and diarrhea) because of the low economic value of individual sheep and a feeling of independence. Veterinarians were called to diagnose and treat sheep affected with diseases and problems that the producer could not or did not know how to manage. Thus veterinarians were consulted only occasionally, and a working relationship with the sheep producer did not develop. In some countries, government-financed agricultural advisors and veterinary sheep specialists began to provide advice on flock health and management, and these services developed into large advisory services that were supplied free to the farmer. The veterinary profession has not developed an expertise in flock health and production management that could be applied to sheep flocks in the business of sheep production because large animal practitioners have been busy with other relatively prosperous

aspects of large animal practice, such as dairy and beef cattle, swine, and companion animals. Consequently, the sheep industry has had the perception that veterinarians are not educated and trained to be useful sheep veterinary consultants.

A variety of new production methods in the sheep industry have provided efficient, profit-making opportunities in sheep production. In some areas, sheep production is becoming intensified successfully because of improved understanding of ruminant nutrition, improved grazing management, improved breeding methods, improved methods of monitoring performance, and providing of advice, better marketing, and effective parasite control (Pollott and Kilkenny, 1987). There is a need for wider dissemination of improved techniques that have been developed and already applied successfully on farms. Techniques are now available for the veterinarian interested in sheep production-oriented medicine to provide a completely integrated, planned health and production management service to sheep producers interested of making a living in sheep production.

A number of flock health programs have been described (Boundy, 1981; Quinlivan, 1981; Hindson, 1982). Flock health and production programs are aimed at applying the techniques of preventive medicine and animal production to commercial sheep enterprises (Galloway and Grant, 1984). They are designed to increase the productivity and profitability of the flock in the context of the objectives of the owners and to increase the welfare of the flock and individual sheep. Historically, the programs for sheep were based on the principles applied in dairy health management, but they emphasized both animal health and production management in the context of a whole-farm approach in assisting the farmer. Comprehensive descriptions of flock health and production programs developed in Australia have been published (Bell, 1983; Watt, 1983a).

The health and animal production components are closely related because adequate health is essential for animal production to be maximized, and because health depends to a large extent on nutrition, genotype, and animal management (Watt, 1983a). The health component in these programs is based on the control and prevention of disease through the application of appropriate measures at strategic times. The appropriate time depends on the epidemiology of the disease on a particular farm. For example, the strategic use of anthelmintics requires a clear understanding of the epidemiology of the parasites in question and an appreciation of what part of the life cycle is most vulnerable to the anthelmintic (Craig, 1998).

The animal production component is based on the information and techniques of the animal sciences, with particular emphasis on animal production from pasture. It attempts to use knowledge of nutrition, reproduction, genetics, and physiology to develop and improve the efficiency of animal production systems to which appropriate preventive medicine techniques can be applied (Watt, 1983a).

Sheep flock health and production management is concerned with the concepts and techniques of disciplines such as economics, agronomy, farm management, and sociology, because the measures recommended and used must be feasible, profitable, and in accord with the objectives of the farmer. The veterinarian acts as a consultant to the sheep farmer by attempting to identify suboptimum production or sources of economic loss, diagnose the causes, and formulate cost-effective measures to eliminate or reduce the losses or to achieve optimum productivity (Galloway and Grant, 1984). The veterinarian then discusses with management which aspects of the program are to be adopted, setting priorities according to cost-benefit ratios, but heavily influenced by the welfare considerations of the sheep and personal goals of the producer. The veterinarian provides advice about the application of new or different health and production methods, attempts to evaluate them in relation to the objectives of the farmer, and then reallocates resources according to current achievements (Blackburn and Cartwright, 1987). Monitoring and advising are conducted in a number of well-defined areas, including reproductive efficiency, internal and external parasite control, vaccination schedules for the control of infectious diseases, nutritional and metabolic disease control, genetic improvement, pasture use, and overall productivity. Contact with the farmer is essential and is maintained through telephone calls, newsletters, discussion groups, and farm visits to carry out the physical work necessary to obtain health and production information and to discuss past performance and future management. Reports are sent to the farmer after each visit, and annual reports are prepared. Recent recommendations made to U.K. government by the Farm Animal Welfare Council strongly advocate that every sheep farm must have a written flock health plan detailing strategic events, vaccination regimens, and treatment procedures. These flock plans will be devised and developed by the farmer's veterinarian who has expert knowledge of that particular farm. Such flock plans afford a great opportunity not only to increase flock health and productivity but also sheep welfare by ensuring that all situations are dealt with promptly and that, more importantly, prophylactic measures are adopted where appropriate.

Types of Flock Health Programs

West (1989) has defined a flock health program as a planned approach to a health or production problem and has described three levels of programs, as follows.

Type I: Simple Control Program

Simple control programs have been offered by veterinarians over many years. They are aimed at controlling or eradicating specific diseases such as *B. ovis* infection, footrot, or helminthiasis, or at the examination of rams for breeding soundness or pregnancy diagnosis of the ewes. In most cases, the veterinary work is task oriented, and some technical skill is required for success of the program. It is relatively easy to receive payment for the work done because the veterinarian is seen to have done something physical, such as examining the rams. There is a minimal requirement for records or writing reports, and in most cases the activity is initiated by the producer rather than the veterinarian.

Type II: Identification and Correction of Production-Limiting Disease Syndromes

Suboptimum reproductive performance, a high mortality rate in lambs, unthriftiness in lambs, ewe mortality, and intestinal parasitism are examples of production-limiting syndromes that must be investigated over time by using a systematic plan. They cannot be solved in one farm visit. These problems and their solutions must be considered part of the total enterprise and the contribution they make to overall farm productivity. The producer may bring these problems to the attention of the veterinarian during a routine visit while examining the rams for breeding soundness, or the veterinarian may recognize the problem while investigating another problem. Investigations of these production-limiting syndromes require sufficient time and in-depth knowl-

edge of sheep medicine and production to prepare reports and persuade the producer that future veterinary visits are required to follow the health and production indexes and to assess the action undertaken. Remuneration for this type of veterinary practice is not obtained as easily, because producers have been reluctant to pay for advice that is a larger part of this type of work compared with type I.

Type III: Whole-Farm Health Management Programs

A combination of types I and II leads to the whole-farm health management program. In this advanced stage the veterinarian acts as a consultant to the producer using the skills and knowledge of economics, partial farm budgets, sheep production and management, applied epidemiology, genetics, and nutrition. Computer programs, such as SheepMan, are now available to evaluate health and production data and to relate these figures to the financial aspects of the flock and farm. Progress is measured by economic improvement on the farm as a whole. In New Zealand, veterinary involvement on sheep farms is concentrated mainly on types I and II flock health programs, with only between 3% and 6% of time devoted to type III activity (West, 1989).

The most common task-oriented activities are ram breeding soundness and brucellosis control, which account for about 53% of all time involved with sheep and represent about 68% of income. Approximately 21% of veterinary time was devoted to troubleshooting that involved specific disease or problem investigation, defined as a type II activity. Advice given over the telephone accounted for 16% of time involved, but only represented about 0.7% to 2.5% of income. However, telephone consultation is often associated with the sale of animal health products, which accounts for a substantial part of the rural veterinary income in New Zealand.

Most veterinarians serving the sheep industry in New Zealand are involved in animal health and production management with an emphasis on types I and II programs. To be effective as a sheep consultant, veterinarians first must have expertise in types I and II programs and whole-farm flock health programs must be viewed as an extension of types I and II activities and not promoted in isolation. The examination of rams for breeding soundness and brucellosis control programs in New Zealand and footrot control in Australia have been the bases from which animal health programs have been initiated.

In Australia, there has been a significant increase in the involvement of veterinarians in the sheep industry (Plant, 1989). A broad cross section of veterinarians—including those from private practice, government advisory services, regulatory services, diagnostic laboratories, and research and development organizations such as universities, government, and commercial industries—are involved. A small but growing number of veterinarians are involved in whole-farm sheep veterinary advice, which includes providing advice on pasture production, stocking rates, time of lambing, flock structure, flock nutrition, shearing management and wool clip preparation, control of external and internal parasites, and breeding stock selection and management.

Beginning a Flock Health and Production Management Program

The increased intensification of sheep farming, coupled with increased capitalization of farms and greatly increased value of individual sheep, has created a need for a cost-effective flock health and production veterinary service. In most sheep-raising areas, preliminary surveys have revealed incomplete adoption of proven, cost-effective health and production techniques (Jelbart et al, 1984). A survey of Victorian sheep farmers indicated that a delay exists between publication of research findings and their communication to the farmer for consideration (Campbell et al, 1984).

In countries where departments of agriculture have traditionally provided on-farm veterinary advice to livestock owners, the initial problem that must be addressed when a flock health program is to be instituted is who should provide it. The situation in most countries has been a tendency to withdraw from free government services to private industry, and the trend is now veering sharply to private practitioners. This means that the costs of the programs are borne directly by farmers, and, if they and their advisors are to have mutual respect for each other's problems, the program must be cost effective and include a means of demonstrating its own economic efficiency.

When it actually comes down to starting a program and telling a sheep farmer that the program is available, there are difficulties compared with the situation in a dairy or beef herd, in which the veterinarian is likely to have been a frequent visitor. The veterinarian must use some persuasive initiative to be invited to the sheep farm to investigate a particular problem and to examine the overall health and production status of the flock. This helps develop a working relationship between the farmer and the veterinarian.

If a sheep farmer indicates an interest in a flock health and production veterinary service, the following steps are recommended for initiation of the program.

Create a Farm Profile

The veterinarian should visit the farm and collect the necessary information to generate a farm profile. This includes a full description of the farm; the numbers, types, and ages of animals; the management system used; the purpose of the flock, including the objectives of the farmer; the breeding programs used, health and production performance indexes within the last few years (lambing percentages, lamb mortality); disease prevention programs, including the use of anthelmintics and vaccines; the costs of veterinary services and animal health products within the past few years; and the costs of production, if available. All of this information is necessary for the establishment of a baseline in the flock and for the identification of obvious problems that are major causes of economic loss, which may be corrected easily.

Identify Immediate Concerns of Farmer

From the initial farm visit the veterinarian may identify certain health and production concerns that the farmer would like solved, and these should be examined as soon as possible followed by corrective action. This may include advice on the use of anthelmintics and vaccines and other routine procedures.

Formulation of Proposal

The veterinarian can prepare a proposal for consideration based on the farm profile. The proposal would include an analysis of the health and production of the flock and the areas of health and production that should be improved first. The veterinarian may wish to incorporate the observations and advice of other consultants; to do this, there must be full cooperation and communication so that the owner receives the same message from each consultant or, if different, a suitable explanation.

Application of the Program

If the farmer agrees to begin the program, the veterinarian may make several visits to the flock to examine the rams, to assess neonatal lamb losses, to do pregnancy diagnosis, to score the body condition of ewes, to examine the flock before breeding or after lambing, to make observations of the flock and management, and to establish a useful record-keeping system. The veterinarian can usually identify those areas of the flock that are most in need of attention and are most susceptible to immediate and economic correction. Most producers are interested in new advice dealing with parasite control, vaccination schedules, and the status of their rams, and in any methods that can increase the reproductive performance of their flocks. However, most farmers, at least initially, are not interested in modifying stocking rate or genetic improvement or in changing the time of lambing. Such changes involve relatively long-term modifications of management and may be risky.

Collaboration with Other Specialists

The veterinarian needs to consult with other specialists such as agronomists and parasitologists as the program is being developed. It is no longer possible for even a veterinary species specialist to be knowledgeable and skillful in every discipline of animal health and production, including the industry aspects of a particular species or class of animal.

Preparation of Reports

The collection of health and production data and the preparation and submission of reports to the farmer within a few days of each farm visit are vital to the success of the program. Farmers are interested in the veterinarian's observations and analysis of flock health and production, and they appreciate written reports. The time of the next visit should be discussed and confirmed with the producer before the veterinarian leaves the farm.

Communication

Once the veterinarian has begun to provide the service, regular communication by telephone, computer modem, fax machine, websites, newsletters, and personal visits is essential to the success of the program. Because veterinarians do not visit sheep farms on a regular basis, as in cattle practice, it is necessary to communicate with the sheep producer in other ways. Regular newsletters outlining new developments in health and production management are effective to keep producers informed. Communication and interaction by the Internet provides exciting opportunities for members of a particular flock health scheme.

Evaluation of the Service

The veterinarian must indicate a willingness to evaluate the cost effectiveness of the program as it is being developed. Farmers are interested in their costs of production and whether new health and production management techniques are cost effective.

FLOCK HEALTH AND PRODUCTION MANAGEMENT

Objectives

The principal goal of a sheep flock health and production management service is to provide individual sheep farmers with the advice and accompanying services that can best enable them to achieve their objectives. For the purposes of this discussion, it is assumed that economic efficiency is the farmer's sole objective. There are many other possible objectives, including economic efficiency to reduce income tax indebtedness and increase capital gain, but they do not appear to require veterinary advice.

It is necessary to point out a common error: the assumption that maximum physical production of wool or lamb is the final goal. This is often not the case, and data on production per hectare should be accompanied by an estimate of cost per unit of product produced.

Although a decision on the cost effectiveness of a simple technique is easy to make, a major difficulty arises when other implications of the technique must be considered. For example, a decision to start supplementary feeding of late pregnant ewes may have a significant effect on the birth weight of lambs and the milk supply of ewes. Lamb survival is likely to be improved as a result. Conversely, the expenditure may compete with another financial outlay such as a prelambing drench. Accordingly, a whole-farm approach is needed for every decision made about health maintenance and, because health and production are inextricably related to each other, to virtually all the decisions made on the farm.

Targets of Performance in Sheep Flocks

In addition to economic profitability, the performance of a sheep flock can be evaluated by comparing actual performance with targets of performance. Sheep producers are interested in achieving certain targets of health and production performance that are profitable and in identifying the causes of failure to reach those targets. A target of performance is one that can be achieved by using current management and production technology. The targets that can be achieved economically vary from flock to flock depending on the nature of the enterprise, the level of management provided, and the geographic area. Targets are determined by the collection of performance indexes in a representative cross section of flocks in the area. A range and an average for each index provide guidelines as to what is possible in similar flocks with similar objectives, feed supplies, environmental conditions, and management expertise. Such data are produced by the MLC in the United Kingdom featuring bottom, average, and top thirds for hill, upland, and lowground flocks. Typically, extensively managed flocks with minimal inputs do not have high performance indexes. Intensively managed flocks that are housed and lamb on an accelerated program or out of season have higher input costs and therefore must be more efficient and achieve higher targets of performance.

The targets in Box 16-3 are suggested as guidelines.

Which of the commonly used indexes is relevant varies with the particular circumstances. In extensively run flocks under ranch conditions, it is usually the survival rate—that is, the longevity—of the sheep that determines whether the enterprise is successful. In intensively managed flocks, survival is a prerequisite and the final decision depends on the rate of gain in body weight of growing sheep or the weight of wool (related to micron measurement of the fiber) produced. An exhaustive index of parameters used in performance recording in sheep has been prepared (Owen, 1971; Plant, 1981).

The indexes listed in Table 16-1 are relevant to southern Australian conditions in terms of work published and local experience. They are still theoretical even in this case, however, and no actual targets are quoted because they have not been tested against a large bank of data to determine that they are reliable in a practical way.

BOX 16-3

Targets of Performance

LAMBING RATE
This is the number of lambs born per ewe exposed to the ram per breeding period. The target is 1.5 to 2.0 (varies with breed and the purpose of the flock). The percentage of ewes with twins varies from 20% to 80%, depending on the breed of sheep and management.

ESTROUS CYCLING INDEX
This is the percentage of females bred in the first 17 days of breeding period. The target is 100%.

BREEDING INDEX
This is the percentage of females bred (marked by ram) per breeding period. The target is 100% for a two-cycle breeding season.

LENGTH OF BREEDING PERIOD
The target is 35 days.

RAM:EWE RATIO
This depends on the age of the ram, breeding environment (pen or field), ram behavior, and whether synchronized estrus is used. The ratios are ram lamb, 1:20; yearling ram, 1:25 to 30; and mature ram, 1:40. In New Zealand a common range is 1:80 to 1:100. For estrus-synchronized ewes or out-of-season breeding, the ratio is 1:5 to 10. In the United Kingdom 3 rams with 120-150 ewes is common practice.

PREGNANCY RATE
This is the percentage of females pregnant per female exposed to the ram per breeding period. The target is 98%.

ABORTION RATE
This is the percentage of females that abort. The target is less than 2%.

WEANING RATE
This is the number of lambs weaned per female exposed to the ram per breeding period. The target is 1.5 to 1.7.

EWES WEANING LAMBS
This is the percentage of ewes that wean at least one lamb. The target is more than 95%.

AVERAGE DAILY GAIN
This is measured from birth to weaning and adjusted for sex and multiple birth. The target is 0.3 to 0.5 kg/day (dependent on breed and management of the flock).

AGE AT FIRST BREEDING/LAMBING
The target is 7 to 12 mo for intensive systems. Under extensive conditions, most replacements are first bred at 18 mo.

CULLING RATE
The target is 20%. The reasons for culling should be age, not chronic disease such as mastitis and footrot.

EWE MORTALITY RATE
This is the percentage of ewes that die annually. The target is less than 2%.

PERINATAL LAMB MORTALITY RATE
This is the percentage of lambs born alive that die from birth to weaning. The target is less than 5%.

STILLBIRTH RATE
This is the percentage of lambs born dead. The target is less than 2%.

MEAT PRODUCTIVITY
This is the weight (in kilograms) of lamb sold per ewe per year exposed to the ram or per hectare of land.

WOOL PRODUCTIVITY
This is the grease wool yield per sheep in the flock or per hectare of land.

Management Efficiency

An assessment of the percentage application of recommended techniques is worthwhile. The assessment can be made by measuring the rate of occurrence of specific diseases. Specific targets are not supplied for most of the indexes presented because there is such great variation among countries and breeds. Actual targets need to be developed for each locality; these should be based on known performance in pilot flocks and on general local information, which is usually hard data from field research (much of this is regionally based). The absence of such information makes target development less reliable.

Special Productivity Targets

Meat Production

In terms of lamb, the common denominator in most countries, there should be an annual turnoff of 150% of lambs related to the ewe flock, and lambs should average 40 kg body weight at 14 to 20 weeks of age off pasture. As with wool, however, the range of normal values is wide and is influenced by many factors, especially, in optimum feed situations, by the genetic makeup of the sheep. The period taken to reach the desired weight is also critical, but insufficient data are available to give any worthwhile figure. Grain-fed Dorset lambs can reach 35 kg by 120 days, and Suffolk lambs can reach 45 kg by 120 days. Under pasture grazing systems, rapid growth is also important to ensure efficient use of pastures. The target in lamb feedlots in the United States is an entry weight of 33 to 36 kg, a daily gain of 250 g for 60 days, and a final weight of 47 kg. The targets in intensive lamb feeding units are not as well defined, but a daily gain on milk replacer of 250 to 300 g to reach 36 kg at 16 weeks at slaughter time is reasonably satisfactory. With grain supplementation of ewes at pasture, many lowground U.K. flocks sell 40 to 44 kg twin lambs by 14 to 16 weeks of age. Singleton lambs can exceed 40 kg by 11 weeks of age.

Wool Production

There is a large variation among and within breeds of sheep in the weight of fleece and the quality of wool produced. These differences are further magnified by the quality and quantity of feed available and by geographical location. Thus quoting of targets is almost meaningless. However, the alternative is to derive an optimum figure based on the mean of a large mass of data collected in a specific area. Under optimum conditions, classes of merino sheep are capable of producing the following weight of clean wool each year:

1. Fine-wooled merinos: 19-μ diameter wool, 70s spinning quality, 3 kg
2. Medium-wooled merinos (Peppin strain): 21 μ, 60s spinning quality, 4 kg
3. Strong-wooled merinos (South Australian): 22 to 24 μ, 58 to 60s spinning quality, 9.5 kg

Longevity

Those sheep that survive disease and culling for poor productivity achieve the ultimate goal of "cast for age." In practice, this often means culling for dental faults, such as excessive incisor tooth wear or loss ("broken mouth") or uneven molar teeth wear with sharp points. The sheep is then unable to graze efficiently and is rejected because of its inability to maintain weight or produce wool. The age at which the teeth fade varies, depending on diet—especially the calcium, phosphorus, and fluorine intakes—and on the degree of contamination of feed with soil debris. On moderately rough pasture composed of native plants, the age at which ewes are culled is somewhere around 6 to 7 years. Dental wear is distinct from broken mouth. In some districts in New Zealand, for example, the incisor teeth of sheep are worn to gum level by 3.5 to 4 years of age. The

TABLE 16-1

Indexes For Recording Performance In Sheep

Parameter	Definition	Target
Reproductive index* = $\frac{\text{Lambs born}}{\text{Ewes joined per breeding period}}$		
Cycling index	% ewes mated in first 14 days of breeding period	65%-70%
Mating index	% ewes mated in complete joining	>95%
	(or % ewes that do not mate)	<5%
Lambing rate	% ewes mated that lamb	>95%
Abortion rate	% pregnant ewes that abort	<2%
Ewe death rate	% ewes dead per annum	< 5%
Twinning rate	% ewes with twins	
	Merinos	10%-20%†
	Romneys	80%
Lamb survival index: marking percentage	% lambs marked (docking of tails and castration) to ewes joined	
	Merinos	80%-100%
	Romneys	110%-120%
	% ewes that lose all lambs born	10%-20%
Miscellaneous: mating management efficiency		
Average age of ewes at first joining		18 mo
Percentage of rams to ewes in mating groups		2%
Length of joining period (6 weeks in autumn, 9 weeks in spring)		6-9 wk
Meat production in mutton flocks as measured by:		
Average body weight at weaning (related to age at weaning)		—
No. of lambs (body condition score or weight and age) plus number of surplus adult sheep sold per hectare		—
Actual weight of lamb or mutton sold per hectare		—
Wool productivity — indicated by wool yield by weight (quality and price quoted) per hectare and/or per sheep stock unit		—
Longevity expressed as:		
Percentage of deaths and culls per year in age groups		—
Percentage increase in flock size minus the reproductive index		—
Percentage of sheep sold as surplus to static requirements minus the reproductive index		—

*This is the most informative index, but is often not measurable because of lack of surveillance at lambing.

†The lower figure is for maiden ewes. Unless otherwise specified, the indexes are for merinos in Australia (Plant JW: Field investigations into reproductive wastage in sheep. In Postgraduate Committee in Veterinary Science, Refresher Course for Veterinarians No. 58: Sheep, Sydney, 1981, University of Sydney) and are for illustration only.

precise cause and pathogenesis have not been defined, but they appear to be related to soil ingestion and the use of improved pasture and high rates of stocking. Broken mouth refers to the loss of incisor teeth as a consequence of periodontal disease.

NORMAL REPRODUCTIVE MANAGEMENT OF THE SHEEP FLOCK

The normal reproductive management cycle of sheep is summarized in Table 16-2. The ewe is seasonally polyestrous, with estrous cycles usually commencing in late summer and continuing through until late winter, unless pregnancy intervenes. The mating season of sheep occurs during the period of decreasing daylight. British breeds of sheep transported to the Southern Hemisphere alter their breeding season to correspond to the reversal of the seasons, so that transported ewes come into heat during the months corresponding to their homeland spring. During the breeding season, the ewe shows cycles of 16 to 17 days. Although methods of manipulation of the photoperiod to induce estrus in sheep have been known for many years, they are generally impractical, expensive, and cumbersome. However, in many countries, melatonin is being used to advance the breeding season by 6 to 8 weeks. The duration of estrus ranges from 1 to 1.5 days, with an average of about 35 hours. The ewe is a spontaneous ovulator, and ovulation occurs 24 to 26 hours after the onset of estrus. The presence of the ram can reduce the duration of behavioral estrus and advance the time of ovulation relative to the onset of estrus. The breeding activity of ewes can be stimulated by the sudden introduction of intact or teaser rams after complete absence of at least 1 month before the normal breeding season. This helps in the advancement of the breeding season, which can lead to a financial advantage by the earlier production of lambs than with regular production systems.

The behavioral signs displayed by the ewe during estrus are few and consist primarily of remaining close to the ram and standing to be mounted. Mature ewes display ram-seeking activity when they are in estrus, so that contact between the sexes is not necessarily completely dependent on

TABLE 16-2

Normal Reproductive Management Cycle of Sheep

Time of Cycle	Management Procedure	Body Condition Score (BCS)
6-8 Weeks before breeding	Ram breeding soundness examination Plan adequate ram power to support needed ram:ewe ratio Assess and adjust ram rations if too fat or thin	Ram, 4.0
3 Weeks before breeding	Ewe breeding soundness examination Increase nutrition if ewes too thin Teaser rams in for ram effect during transition Vaccinate ewe for *Campylobacter* and/or *Chlamydia*, if indicated Drench for parasites, if indicated Plan for hormonal induction of estrus, if indicated	Ewes, 3.0 to 3.5
Breeding season (48 hours to 42 days)	Change color of marking harness every 14 days Calculate cycling and breeding index Continue level of nutrition through breeding period and first 3 weeks postbreeding	Rams, decrease to 2.0 Ewes, static
End of breeding season	Remove rams and put in teasers with marking harness to help detect cycling nonpregnant ewes (in season only)	
12 Weeks after ram first in or 7 weeks after ram removed	Pregnancy test using real-time ultrasound Sort according to open (cull) singles and multiples for optimum nutrition to placentas and fetuses Calculate pregnancy rate	Ewes, static or down to 0.5
100 Days' gestation	Increase level of energy and protein in ration, particularly in ewes carrying multiples and thin ewes (BCS ewes) Observe for abortions (fetuses, red vaginal discharge) and investigate as indicated	Ewes, static
30 Days before first lambing expected	Vaccinate ewes for clostridial diseases Drench for parasites, if necessary Shear or crutch, if necessary BCS and sort thin ewes for higher level of nutrition Observe for pregnancy, toxemia, abortion Prepare for lambing (facilities, vaccines, feed)	Ewes, static
Lambing	Close observation (minimum 4× day) to decrease stillbirths and early neonatal losses (hypothermia or hypoglycemia) For details see "Perinatal Lamb Mortality" section	

the ram's activity. In ewe lambs, the behavioral signs of estrus are usually weak and the duration of estrus is shorter than in mature ewes. Ewe lambs usually make no effort to approach the ram and may be reluctant to accept the service when he makes his sexual advances. Rams may show preference for mature ewes, and, in extensive operations, it is sound management to mate ewe lambs and two-toothed ewes separately from older ewes in a confined mating area in order to use active rams of small to medium size and to maintain a high ram:ewe ratio. Thus the detection of estrus in ewes in the absence of rams is difficult, with the exception that occasionally the estrus ewe moves her tail vigorously as part of a display pattern when she is with the rams.

At the start of the breeding season in sheep, it is only after the end of the first ovarian cycle that behavioral estrus is exhibited by the animal. The initial ovulations of the season and the establishment of corpora lutea occur at a silent heat. The progesterone produced by these first corpora lutea plays an essential role in sensitizing hypothalamic receptors so that the ewe becomes capable of responding subsequently to minute quantities of ovarian estrogen and of exhibiting the behavioral signs of estrus. The ewe of many commercial sheep breeds shows a clear nonbreeding season, whereas the ram remains capable of reproduction throughout the year, with a reduction in sperm output during the nonbreeding season and reduced fertility during periods of temperature extremes. The length of pregnancy is approximately 147 days, with some breed variation.

The ram has an important influence on the reproductive performance of the ewe. Fertility is directly related to the number of services, the number of spermatozoa deposited in the ewes, and the time of breeding relative to ovulations. In natural breeding circumstances the ewe may be bred several times. Ewes may also be served by more than one ram during estrus, particularly if the ratio of rams to ewes is more than 1:100 (Fayez and Marai, 1987). There is also the potential of some ewes being ignored by some rams. Sexual behavior in a flock is determined by social interactions among the males, with dominant and subordinate rams. This can lead to reproductive failure if the ram or rams that occupy the top positions in the dominance rating have reduced or total infertility.

The sudden introduction of rams in the early transitional period can stimulate the breeding activity of the ewes, and the estrus induced is known as the ram effect. The exposure of ewes to the ram only needs to last for 48 hours, rather than the 16 to 24 days formerly advocated for the ram effect. This allows one ram to be moved among several groups of ewes. The efficiency of the ram effect is usually measured under field conditions by the proportion of ewes that display estrus 16 to 24 days after introduction of the rams. The advancement of the breeding season is often 2 to 3 weeks before the breed's normal commencement. This tends to synchronize the ewes over a 10-day period starting after the introduction of teaser rams or rams on the other side of the fence, which synchronizes the ewes and does not compromise the fertility of the rams with overbreeding of early-estrus ewes. The puberty of ewe lambs may also be advanced by the sudden introduction of rams and leads to a high degree of synchronization at first mating. The results are dependent on breed, season of the year, and BCS.

The ratio of rams to ewes varies widely. For mature rams, the ram:ewe ratio is usually 1:40 to 50. In many flocks three rams are placed with 120 to 150 ewes, with each group of rams rotated after 17 days. Ram:ewe ratios need to be adjusted if ram lambs are used, for out-of-season breeding, or for any form of synchronized breeding. Rams can serve 10 ewes a day over a 4-day period or 8 to 10 ewes in 24 hours under field conditions when allowed access to ewes in active estrus (Fayez and Marai, 1987). Some rams whose sexual motivation was maintained by the provision of fresh ewes have ejaculated 11 to 17 times/day with adequate sperm counts still recorded after 6 days, whereas in other rams the number of sperm per ejaculate was reduced below the level believed to be adequate for fertilization. Decreasing the number of ewes bred from 100 to 25/ram can lead to more rams serving each estrus ewe and in a greater proportion of ewes being covered during the first 2 weeks of breeding. When synchronization is practiced in a flock, short-term endurance of the ram becomes more important and the ram:ewe ratio must be increased. In conclusion, the increase in ram:ewe ratio is associated with an increase in the lambing rate and lambs born per ewe of the flock.

Two daily peaks of mating activity have been identified—from 0400 to 0800 hours and from 1600 to 2000 hours, coinciding with sunrise and sunset. A high proportion of ewes also exhibit the onset of estrus at sunrise and sunset. During estrus, the optimum time for a ram to inseminate is 9 to 12 hours after the onset of estrus.

Health and Production Management to Optimize Reproductive Performance

Breeding Program

The breeding program and methods used depend on the objectives and production goals of the producer, the geographical location of the flock, the size of the flock, the degree of intensification of production, the breeds being used, and the facilities available. If wool is the major production objective, as it is with Australian merino flocks, the sheep are raised under extensive conditions and lambing occurs annually. If the number of lambs that are reared to market age is the primary goal, increase of the number of lambs born annually per ewe becomes the production objective and influences the breeding methods used. In some countries, lambs are marketed at 16 to 30 kg, primarily at Christmas and Easter for an ethnic market. These lambs are usually sold before weaning and may have been creep fed while nursing. Lamb feedlots in North America purchase weaned lambs at 4 months of age and feed them until they weigh from 40 to 50 kg. British breeds and their crosses under traditional methods of British husbandry produce annually, on the average, 1.7 lambs and one fleece. The seasonality of the common breeds of sheep means that their breeding season is limited to the autumn months.

The number of lambs born each year can be increased by two methods: increasing the number of lambs born per lambing and increasing the number of lambings per ewe annually. The increase in number of lambs per lambing is achieved by selecting for multiple litters or by using fecund breeds of sheep, such as the Finnsheep, Blueface Leicester, Romanov, Arcott, or, more recently, the Booroola merino. An increase in the number of lambings per ewe annually may be achieved by selecting extended seasonal breeds of sheep in temperate climates and by managing them in specific frequent or accelerated lambing production systems. More frequent lambing can also be achieved by using exogenous hormone therapy to induce and synchronize estrus or by using photoperiod manipulation through lighting control and melatonin administration.

Time of Year for Breeding

A breeding period should be selected at which the serving capacity and fertility of rams and the occurrence of estrus and fertility of ewes are at their highest. This means avoiding hot months (because high environmental temperatures

reduce ram libido, semen quality, and ewe fertility). There is a distinct preference for autumn over spring because of greater fertility. However, the breeding period must also be compatible with good nutrition of the ewe during late pregnancy and with lambing occurring at a time when lamb survival is maximal. This means not only a time of mild weather, but also that the stressful situation of lambing should occur at a time that is nutritionally appropriate for a good start in life.

Length of Breeding Period

In autumn, 5 weeks is a sufficient breeding period in a well-managed flock. In a spring breeding program, 8 to 9 weeks is recommended.

Management of Ewe Flocks

The management of ewe flocks in regard to their reproductive performance must emphasize a strong culling program, good nutrition, and avoidance of debilitating disease. The culling program should be directed toward performance, age, udder health, and inherited defects.

Genetic Selection for Reproduction

There is considerable variation among breeds in their rates of reproduction, largely because of differences in ovulation rate, the main determinant of fecundity, and, to a lesser extent, fertility at various seasons of the year, or length of the breeding season and lamb survival (Fogarty, 1984). Fecundity (litter size) ranges from about 1 to 1.2 in many Australian merino flocks to more than 2.5 in breeds such as the Finnsheep, Blueface Leicester, Arcott, and Romanov. These differences in fecundity among breeds are mainly an expression of differences in ovulation rate (Dyrmundsson, 1987). Ovulation rate sets the upper limit to the number of offspring produced per pregnancy and accounts for an overwhelming proportion of the genetic variation in litter size, both among and within breeds of sheep. If within-breed selection is the only available option for genetic improvement of prolificacy, the annual rate of genetic improvement in litter size can be doubled when the ovulation rate is used as the selection criterion. In the Booroola merino, mean litter size and ovulation rate are 2.5 and 4.2, respectively, which exceed those values for other merino strains. The Booroola offers the opportunity for a quantum increase in fecundity in one generation compared with slower improvement from within-flock selection. Genes with similar magnitudes are segregating in the Cambridge, Icelandic, and Javanese breeds (Hanrahan, 1987; Owen, 1988). Genetic material from prolific breeds, such as the Finnsheep and the Romanov, in which high prolificacy is not apparently the result of a single gene, has been used in many countries to raise the prolificacy of local breeds or as the basis of new composite breeds (Hanrahan, 1987). Substantial heterosis or hybrid vigor is also expressed for reproduction when crossbreeding is practiced and has been used to maximum advantage in lowground sheep production systems in the United Kingdom.

Reproduction is a complex trait and includes the components of fertility, fecundity (which incorporates ovulation rate and embryo survival), and lamb survival (individual and maternal rearing ability). There is genetic variation in each component and therefore room for genetic improvement. Ewe fertility may be affected by age at puberty, breeding season, and postpartum breeding interval in accelerated lambing systems (Fogarty, 1984). There is considerable breed variation for age at puberty, and the number of estrous cycles in the first breeding season, which is largely determined by age at puberty, is moderately heritable at 0.3 (scale 0 to 1). This should respond to selection if the lamb ewes reach sufficient live weight to attain puberty in their first autumn-winter. Age at puberty is largely influenced by body weight.

There is considerable variation among and within breeds in the time of onset of estrus activity and duration of the breeding season. In the extreme, many tropical breeds do not exhibit a distinct breeding season. Onset and duration of the breeding season are affected by breed and age, nutrition, and postpartum interval, and they can be modified by artificial day length, melatonin, use of the ram effect, and exogenous hormones. Variable and limited estrus and ovulatory activity outside the autumn breeding season restricts flexibility of breeding time and limits the reproductive rate of breedings outside the normal breeding season. This restriction limits the scope for more intensive accelerated lambing systems.

Fecundity is largely a function of ovulation rate and embryonic survival. There is considerable variation among breeds, with fecundity ranging from 1.0 to 2.5. Genetic variation for fecundity also exists within breeds and can be exploited by selection (Fogarty, 1984; Nitter, 1987).

There is increasing evidence of genetic differences among and within breeds for neonatal lamb behaviors that affect survival (O'Connor and Lawrence, 1992; Dwyer et al, 1996) and maternal rearing ability that is independent of parity (O'Connor et al, 1992). Selection within a flock for twinning and culling ewes for failing to rear a lamb at any lambing can increase lamb survival (Fogarty, 1984).

Frequent Lambing Systems

Traditionally, sheep lamb only once yearly with a 12-month lambing interval. However, where lamb is the major product sold and wool is of little significance, it may prove advantageous to lamb more frequently. Because of the costs of production, sheep are underused if they lamb just once; however, this statement fails to acknowledge seasonal growth of pasture and other crops. The breeding period in many sheep is 30 to 50 days, gestation is 147 days, and the period from birth to weaning is 60 days, all of which indicates that the complete reproductive cycle should not be more than 8 months. Thus a sheep could theoretically lamb three times in 2 years, although few commercial farmers could operate such complex management and husbandry practices. Although computer modelling of the biological aspects of estrus and reproduction in sheep has determined that for breeds of sheep with long potential breeding seasons, it is advantageous to breed ewes more frequently (Dzakuma and Harris, 1989a,b), few flocks outside University department farms operate frequent lambing systems.

Frequent lambing is lambing at intervals more often than once annually. With a gestation period of 5 months, the minimum theoretical lambing interval would be 6 months, but such an interval has not been achieved consistently, even with the use of exogenous hormones, because the average time necessary for uterine involution is up to 2 months. Increasing the number of lambings per ewe annually may be achieved by selecting aseasonal breeds of sheep and managing them in specific, frequent, accelerated lambing production systems (Hogue, 1987).

The most suitable breeds for frequent lambing are those with a long-duration breeding season, along with high prolificacy, in order to achieve high annual production (Tempest, 1983). In the United Kingdom the Finn-Dorset (Finnish Landrace × Dorset Horn), and in France, the Romanov and Prealpe-du-Sud, have been successful in frequent lambing systems (Tempest, 1983). The Dorsets, the

Polydays, and the Arcotts have also done well in frequent lambing systems tested at Cornell University, in Idaho, and in Guelph, Ontario, respectively. Early weaning at 4 to 6 weeks of age is practiced, followed by controlled breeding techniques using vaginal pessaries of a progestogen for 12 days and by the administration of pregnant mare's serum gonadotropin at sponge withdrawal.

The ewes are scored for body condition at weaning, and a diet is provided as necessary for about 2 weeks to ensure that they have a score of 3 at breeding. At 48 hours after withdrawal of the vaginal sponge, fertile rams are introduced at a ratio of one ram to 10 to 12 ewes. The rams are removed after the synchronized estrus and reintroduced 14 days later to breed at the first repeat heats, after which they are finally removed (Tempest, 1983).

The success of frequent lambing is influenced in large part by the level and pattern of nutritional management throughout the cycle and the level of knowledge and expertise of the operators. The premating level of nutrition is maintained for the first month of gestation. In midpregnancy it is critical to restrict feed intake so that the ewe maintains her body weight while ensuring controlled mobilization of body fat for fetal growth (Mellor, 1983). In late pregnancy increased feeding is necessary to achieve high lamb birth weights; to meet the energy demands of large fetuses, twins, and triplets; to promote udder tissue development; to prevent excessive mobilization of body fat in the ewe; and to prevent pregnancy toxemia. At approximately 3 months of gestation, the ewes are pregnancy-tested using ultrasound technology and barren ewes are moved into the alternate subflock and sponge treated. With frequent lambing systems, extended lambing seasons must be minimized, and induction of lambing with corticosteroids to control lambing is recommended. Lactational management to meet the needs of the growth rate desired in the lambs requires attention to the ration. Maximum milk output from the ewe is closely related to the level and type of dietary crude protein (CP) and the amount of energy provided. The optimum level of dietary crude protein is about 170 g CP/kg dry matter (DM) with a protein source of low degradability, and the diet fed at three times the maintenance level in terms of energy (Tempest, 1983). This still leaves the ewe in negative energy balance, and she would mobilize her body fat reserves to supplement her energy requirements. In later lactation, it is necessary in the frequently bred ewe to avoid excessive depletion of body reserves before rebreeding and to begin drying up the ewe by encouraging a greater solid feed intake by the lambs before weaning.

The levels of production performance in frequent lambing indicate that up to 2.7 lambs/ewe annually in the flock are possible (Tempest, 1983). In addition to the increased reproductive efficiency that may be achieved with a frequent lambing system, there are some other advantages:

1. More uniform supply of lamb throughout the year, which is an advantage to processors and retail markets
2. Increased efficiency of the use of facilities, such as lambing barns and feeding pens
3. More uniform yearly labor requirement
4. Spreading the risk of bad storms or unfavorable markets throughout the year
5. Providing producers with a uniform cash flow throughout the year

Twice per Year. If all ewes in a flock would breed the month after lambing, they could be managed on a 6-month basis. The flock could be divided to provide additional lambing periods throughout the year, and a uniform and consistent level of production could be achieved (Hogue, 1987). However, few ewes achieve this level of production in temperate zones, and the system is considered impractical.

Three Lambings in 2 Years. In this system the flock is divided into two subflocks, with one or the other lambing every fourth month. Each ewe is given the opportunity to lamb every 8 months or, if that is not possible, at 12-month intervals. The breeding and lambing schedule can be depicted over 24 months (Table 16-3).

January, May, and September are lambing months, although the schedule could be shifted to other periods provided the proper intervals are maintained. Lambs are usually weaned the second month after birth, and the ewes are bred 1 month after weaning their lambs. Because all ewes have an opportunity to lamb for a 12-month interval if they do not conceive for the 8-month interval, any ewes that do breed the first time represent an increase in efficiency over the 12-month period (Hogue, 1987).

Four Lambings in 3 Years. This is planned around a 9-month lambing interval, with four lambing periods per year. Each ewe is placed with the ram the fourth month after lambing and every 3 months thereafter until bred. January, April, July, and October are the lambing months; May, August, November, and February are the breeding months. This system could be combined with twice-yearly lambing so that ewes would have an opportunity to lamb after 6-, 9-, or 12-month intervals.

STAR System. The STAR system was developed at Cornell and is based on the need of accelerated lambing to coincide with the biology of the sheep and to fit with the calendar year (Hogue, 1987). If breeding and lambing could be coin-

cident, overall management would be simplified. The STAR system solves these problems. With a gestation length of 146 days, half of a pregnancy is 73 days, which is exactly one fifth of the year. The calendar year contains exactly five sheep half-pregnancies, or five equal 73-day periods. Thus the annual calendar can be depicted in circular fashion and divided into five equal 73-day periods (Fig. 16-1). By breeding or lambing the first 30 days of a period, the remaining management tasks are immediately apparent. If a ewe lambs in period 1, she is bred in period 2 to lamb in period 4, to be bred in period 5, and so on. Each ewe can lamb five times in 3 years and complete the STAR. The five lambing periods per year have these advantages: (1) allow ewes to lamb five times in 3 years, which equals 1.67 lambings/ewe annually, (2) allow a uniform annual production of market lambs for a uniform supply and cash flow, (3) increase efficiency of utilization of facilities such as lambing areas, and (4) allow for the identification of ewes that not only breed out of season but breed following lambing in any season. The Cornell Dorset Horn (polled) flock has been managed on the STAR system for 4.5 years. Each year, more ewes lamb in the autumn and the average lambing interval decreases. The flock represents selected sheep because long-interval ewes are culled, sufficient STAR ewes have been identified to produce all breeding rams, and all lambs are sired by rams from STAR ewes. A comparison of the results of frequent lambing systems and a normal, once-yearly system is summarized in Table 16-4.

Prebreeding Management of Ewes

A breeding soundness examination is not possible in ewes, but BCS can be assessed, and examination of the udders can be performed whereby ewes with evidence of mastitis are culled. The incisor teeth of individual ewes should be examined for loss or uneven wear, which can adversely affect prehension and energy intake, even if they conceive and bear lambs. Investigations should be undertaken if more than 5% of ewes with normal dentition are found to have BCS below the target value. In most flocks, weaning lambs at 90 to 120 days allows 3 months for ewes to improve in body condition. It generally takes 6 to 8 weeks of good quality grazing to increase the BCS by one unit (five-point scale). Ewes in poor body condition have low estrus activity and conception rates (Grant et al, 1981).

The number of lambs born can be increased readily by increasing the ovulation rate. There are potential adverse economic consequences of multiple ovulations, including increased embryonic and early fetal losses (Dingwall et al, 1987) if ewe nutrition is not maintained for 4 to 6 weeks after the mating period. Ewe deaths may result from pregnancy toxemia if the flock is not managed correctly during late gestation, but such losses only occur in extensively managed flocks.

In merinos, the benefits of the extra lambs produced are offset by the reduced fleece weights of the breeding ewes and by the increased grazing pressure exerted by the lactating ewes and their lambs (White and Bowman, 1987) because

producers are not prepared to supply extra feed. However, in those sheep systems producing lambs, such producers definitely benefit from increased ovulation, implantation, and lambing rates. For wool-producing enterprises in southern Australia, the feeding of energy-based supplements to ewes before breeding to increase fecundity was evaluated using mathematical models of sheep production. Feeding supplements to ewes before breeding was concluded to be likely unprofitable (White and Bowman, 1987). While it has been speculated that too high a protein level in the flushing rations may contribute to early embryonic death, this phenomenon can be attributed more correctly to an energy deficit.

In flocks in which helminthiasis or fascioliasis is a problem, prebreeding and prelambing drenching with an effective anthelmintic may improve ewe fertility by 4% to 7% of lambs weaned (Mackay, 1980). Such preventive measures are fundamental to sheep health management schemes worldwide.

Nutrition of Ewes During Gestation and Early Lactation

The influence of nutrition on the reproductive performance of ewes has been a matter of concern to sheep farmers and sheep production research workers throughout the world (Gunn, 1983; Robinson, 1987). It is clear that the relationship between nutritional provision and nutrient requirements for optimum reproductive performance is seldom ideal because of the wide range of environmental conditions and the seasonality of breeding that most sheep breeds exhibit (Gunn, 1983). Prolonged periods of undernutrition during midpregnancy are partly the result of the decline in feed availability and quality over that stage of the reproductive cycle (Kelly et al, 1989).

Prolonged duration of moderate to severe undernutrition of ewes bearing twins in midpregnancy can reduce placental development causing significant reductions in lamb birth weight with increased mortality (Mellor et al, 1977; Rhind et al, 1980; Mellor, 1983). Considerable progress has been made in understanding the principles of nutrition of sheep and in defining their nutrient requirements for maintenance, pregnancy, and lactation (Russel, 1985).

The sensitivity of lamb birth weight, particularly in twins and triplets, to the ewe's plane of nutrition during late pregnancy is well known (Khalaf et al, 1979; Struber et al, 1979). It has been established that mortality rates are high in lambs with birth weights below the breed norm (Khalaf et al, 1979), and that after birth the absolute growth rates are lower in surviving light lambs than in heavier lambs of the same breed (Mellor, 1983). The plane of nutrition and the size of the placenta have been recognized as major determinants of the fetal growth rate. Fetal growth retardation in undernourished ewes has a placental component, and the factors that affect placental growth are relevant here.

The 21-week gestation can be divided into a number of periods to consider the effects of nutrition on reproduction within each period (Robinson, 1983). In the first month of gestation, embryonic loss is the main sequel to inadequate nutrition. During this period, it is generally recommended that the BCS of the ewe be maintained at 2.5 to 3.5 (scale of 1 to 5) to minimize embryonic and early fetal losses (Russel, 1985). This is followed by a period of 2 months in which there is rapid growth of the placenta, but during which growth of the fetus in absolute terms is still small. Over this period it is normal to advocate that losses in body weight should not exceed 5%. Finally, there is the phase from 90 days to parturition, in which gain in the mass of the fetus amounts to 85% of its birth weight; during this period nutrient intake must be increased.

Placental development in the pregnant ewe begins about 30 days after conception, the number of placentomes associated with each fetus is fixed at this time, and the total weight of the placentomes increases until about 90 days of gestation, after which there is little change (Mellor and Matheson, 1979). The factors that influence the ultimate size of the placenta and its weight include hormonal and nutritional factors, prolonged environmental heating of pregnant ewes, parity of ewes, and possibly genotype (Bell, 1984), but the most important determinant is nutrition of the ewe (Mellor and Murray, 1981). Moderately severe undernutrition during early pregnancy and midpregnancy significantly reduces placental weight at or near term and causes chronic intrauterine growth retardation.

The size of the placenta is a major determinant of fetal growth. In well-fed ewes, the fetal growth rate before 120

days of gestation is not correlated positively with placental weight, but fetal growth rate in the last 3 to 4 weeks of pregnancy is limited by the size of the placenta. Earlier placental influences on fetal growth are evident, however, when ewes are underfed. Placental weight and fetal growth rate are correlated positively during periods of maternal underfeeding, which starts before 90, at 95, or at 112 days of gestation (Mellor, 1983). During the first 90 days of pregnancy, placental growth is reduced when ewes are moderately underfed. Low-weight fetuses in ewes with placenta weights near the bottom of the normal range are affected with chronic and progressive hypoxemia and hypoglycemia, which affect fetal metabolism (Barlow et al, 1987). The consequences are fetal death during late pregnancy, fetal hypoxemia during parturition, premature birth, and a high perinatal mortality rate caused by hypoglycemia and hypothermia (Mellor, 1983; Barlow et al, 1987).

The extent to which ewes maintained on a fixed ration draw on their own body reserves in an attempt to meet the energy costs of pregnancy is determined by fetal weight (Mellor, 1983). In well-fed ewes, fetal growth rate remains constant until at least 120 days of gestation and decreases thereafter. However, its absolute growth rate increases markedly during the last 8 weeks of gestation, when fetal growth is most rapid, exceeding 100 g/day near birth. The growth rate among fetuses is highly variable, which accounts for birth weights ranging from 2 kg to over 7 kg. When ewes that have been well fed are severely underfed at any stage during the last 40 to 50 days of pregnancy, the fetal growth rate decreases within 3 days by 30% to 70%. This illustrates that the mobilization of maternal reserves is substantially less than fetal requirements and emphasizes the importance of ensuring a continuous supply of good-quality feed during late pregnancy. The larger the fetal burden, the more susceptible a ewe is to hypoglycemia during underfeeding.

Refeeding after severe underfeeding can reverse the reduced growth rate of fetuses, but the response depends on the duration of the underfeeding. If the period of underfeeding is 16 days or less, the growth rate increases when ewes are refed, but there is no change when refeeding occurs after 21 days of severe underfeeding. Moderate underfeeding of pregnant ewes for 85 days reduces the fetal growth rate irreversibly, and refeeding them in late pregnancy does not cause the fetal growth rate to increase but does prevent further decreases after 120 days.

The major consequences of prenatal growth retardation are on lamb survival. The neonatal mortality of lambs increases markedly in many environments as the birth weight falls below 3 to 3.5 kg (Khalaf et al, 1979). Compared with normal lambs, low-birth-weight animals have reduced insulation because of the smaller number of wool fibers, greater relative heat loss because of their larger surface area per unit of body weight, and a reduced capability to maintain heat production because of their lower fat and energy reserves. All these factors increase their susceptibility to environmental stress and reduce their ability to compete with normal-sized siblings. Underfeeding during pregnancy can also reduce available body lipids in lambs by about 47% and also decreases the lactose, lipid, and protein available in colostrum during the first 18 hours by about 50% (Mellor and Murray, 1985a,b). Newborn lambs have to draw on body reserves of glycogen in order to maintain heat production during the first 18 hours after birth, and thus depend heavily on colostrum intake and supplemental feeding to avoid hypoglycemia and hypothermia.

The effects of maternal nutrition on udder development and on the production and yield of colostrum and milk in ewes have also been examined (Mellor and Murray, 1985b; Mellor et al, 1987). In the last 30 days before birth, there is a marked increase in the rate of mammary tissue growth in the ewe. In well-fed ewes with one or two lambs, large volumes of colostrum accumulate in the mammary glands during the last few days of pregnancy and copious milk secretion begins soon after birth, with averages of 1800 to 2800 ml of colostrum and milk being produced during the first 18 hours (Mellor, 1987). Udder growth rates are proportional to fetal growth rates in that the greatest increase in udder weight occurs in the last 30 days of gestation and the weight of udder tissue is 30% to 40% of the total weight of the litter. Colostrum production is proportional to udder weight, and refeeding of ewes a few days before lambing fills the udder tissue present but does not increase udder tissue weight (Mellor, 1987). In underfed ewes, prenatal colostrum accumulation is reduced markedly, lactogenesis is delayed, and the total production of colostrum and milk during the first 18 hours averages about 1000 ml. Subsequently, in both types of ewe, milk production increases, reaching a peak about 1 to 2 weeks after birth. Underfeeding ewes beginning at 105 days of gestation can reduce the total yield of colostrum during the first 18 hours after birth by decreasing mammary tissue growth. Thus the prepartum accumulation of colostrum and its subsequent rates of secretion are reduced (Mellor et al, 1987). Improving the ewe's nutrition from 1 hour after birth can increase the secretion rates of colostrum between 10 and 18 hours (Mellor and Murray, 1985a,b).

The growth rate of lambs during the first few weeks of life is correlated positively with birth weight. Low planes of maternal nutrition during late pregnancy and early lactation are generally associated with low birth weights, milk yields, and postnatal growth rates, and high planes of nutrition with the opposite effects. A marked increase in the plane of maternal nutrition at birth can overcome the inhibitory effects on lactation and lamb growth rate of underfeeding in late pregnancy (Mellor, 1983).

At breeding time the aim is to achieve a body score of 3.0 to 3.5, which ensures maximum ovulation rate. For ewes with a BCS of 3.5 at breeding, it is desirable to allow them to lose no more than 5% of their body weight steadily, equivalent to approximately 0.5 to 1 unit of condition score during the second and third months of pregnancy. This mild degree of undernutrition enhances placental growth and establishes the basis for maximum fetal growth in the fourth and fifth months of pregnancy, the period during which the fetus achieves over 80% of its growth. During these final 2 months of pregnancy, there is a limit to the extent to which body fat reserves can be used, because excessive mobilization of depot fats as a consequence of inadequate dietary energy supply leads to pregnancy toxemia. In late gestation the optimum BCS ranges from 2.5 to 3.0. In contrast, early lactation is a period in which body fat can be safely used to meet some of the high energy demands of lactation. During this period, a loss of BCS of 1.0 (equivalent to 5 kg of fat for a 70-kg ewe at mating) is acceptable, and during lactation it ranges from 1.5 to 2.5. The replacement of the body fat that is used before the next breeding cycle is important in achieving a maximum ovulation rate and subsequently optimum reproductive performance (Robinson, 1983, 1987).

Winter shearing of pregnant ewes during the final 10 weeks of pregnancy has been shown to cause a significant increase in lamb birth weight. Shearing pregnant sheep at 8 weeks before lambing leads to a chronic increase in energy requirements, which are met by oxidizing body fat depots without risks of clinical ketosis (Symonds et al, 1986, 1988). Fetal growth is enhanced as a result of these metabolic adaptations.

The nutrient requirements for maintenance, breeding, pregnancy, and lactation of ewes have been catalogued (Agricultural Research Council, 1980, 1984; National Re-

search Council, 1985), and optimum feeding strategies for the breeding ewe can be formulated. The evaluation of the ewes' ration during late gestation by monitoring plasma concentrations of the ketone body 3-OH butyrate has been described with accurate guidelines provided (Russel, 1985), which have been used as the basis for flock nutritional advice during late gestation (Scott, 1988).

The achievement of optimum reproductive performance involves changing feeding strategies and adjusting the nutrient value of the diet as necessary throughout the reproductive cycle to meet the needs of the particular stage. The requirements for metabolizable energy begin to increase steadily above maintenance levels beginning at between 8 and 12 weeks of pregnancy and continuing into late pregnancy and lactation (Agricultural Research Council, 1980). During early lactation, when the energy requirements of prolific ewes exceed those required by the voluntary consumption of all but the highest-quality diets, the body fat reserves are used and then replenished toward the end of lactation, when milk yield declines, and in the period leading up to rebreeding (Robinson, 1987).

In contrast to the ability of the ewe, particularly in early lactation, to use body reserves when the intake of energy fails to meet her needs, there is little scope for sustaining production by drawing on body protein (Robinson, 1987). For example, lactating ewes can lose up to 7 kg of body fat during a 4-week period in early lactation, when energy intake is below requirements. For ewes on a low-protein intake, the maximum daily loss of protein was 26 g. Thus it is important to meet the protein needs of the ewe at all times during pregnancy, but especially during late pregnancy, for fetal growth, udder development, and colostrum production. The estimates for protein are also based on the important principle of distinguishing between the needs of the rumen microflora for rumen-degradable protein and of the host animal for additional undegraded dietary protein when rumen-degradable protein fails to meet those requirements; this represents the minimum protein needs of the animal. In practice the dietary allowances for late pregnancy and early lactation are higher than the sum of the rumen-degradable protein and undegradable protein.

The rapid growth of the fetus after 90 days of pregnancy requires an increased allowance of dietary energy, which can be met with concentrates if only hay is available. This is particularly true for ewes carrying twins or triplets. The daily dietary energy requirement of ewes of varying body weights and fetal number ranging from singletons to triplets has been described in conjunction with a monitoring program for dietary energy supply based on plasma concentration of the ketone body 3-OH butyrate (Russel, 1985). This system forms the basis of flock advisory visits made by veterinarians during late gestation in U.K. flocks. Correct nutrition during late gestation guarantees appropriate lamb birth weights despite litter size and sufficient accumulation of protective immunoglobulin in the udder.

Body Condition Scoring of Sheep. One relatively simple method of monitoring nutritional status is through BCS. BCS involves equating certain physical characteristics that are readily identifiable in ewes of different degrees of fatness with a particular score. A score is given on a scale of 1 to 5 according to the degree of fatness, which is defined by certain physical characteristics in the lumbar region. These are the prominences of the spinous processes of the lumbar vertebrae, the prominence of and the degree of fat cover over the transverse processes of the vertebrae, the extent of the muscular and fatty tissue below the transverse processes, and the fullness of the eye muscle and its degree of fat cover (in the angle between the spinous and transverse processes). The scale is defined in Box 16-4.

BOX 16-4

Body Condition Scoring of Sheep

SCORE 1
The spinous processes are felt to be prominent and sharp. The transverse processes are also sharp, the fingers pass easily under the ends, and it is possible to feel between each process. The eye muscle areas are shallow, with no fat cover.

SCORE 2
The spinous processes still feel prominent, but smooth, and individual processes can be felt only as fine corrugations. The transverse processes are smooth and rounded and it is possible to pass the fingers under the ends with a little pressure. The eye muscle areas are of moderate depth but have little fat cover.

SCORE 3
The spinous processes are detected only as small elevations; they are smooth and rounded, and individual bones can be felt only with pressure. The transverse processes are smooth and well covered and firm pressure is required to feel over the ends. The eye muscle areas are full and have a moderate degree of fat cover.

SCORE 4
The spinous processes can just be detected, with pressure, as a hard line between the fat-covered muscles in the area of the eye. The ends of the transverse processes cannot be felt. The eye muscle areas are full and have a thick covering of fat.

SCORE 5
The spinous processes cannot be detected, even with firm pressure, and there is a depression between the layers of fat in the position where the spinous processes normally would be felt. The transverse processes cannot be detected. The eye muscle areas are full, with thick fat cover. There may be large deposits of fat over the rump and tail.

In general, BCS of sheep is more useful and more readily undertaken than weighing. After training it can be repeated reliably by different operators on different farms. Ewe BCS and nutrition at mating are important factors affecting ovulation rate, and much of the variation among flocks in reproductive performance can be explained by nutrition before mating. Not only is it important to have ewes in good body condition, but it is also important to have the ewes on a rising plane of nutrition. Ewes with condition scores above 3 have a higher ovulation rate than ewes in condition score 2 or below (other factors being equal). Increase in condition score is beneficial, whereas loss is detrimental to the ovulation rate. To obtain a flushing response, a minimum period of 3 weeks' high-level feeding immediately before ram introduction is required. This is normally achieved by either providing good quality grazing or reducing the stocking density. This gives a 3-week carryover period during which time all of the ewes should be mated.

When investigating a problem of low lamb production, an important parameter to measure is the condition score of the ewes close at mating. The importance of feeding ewes during this period to achieve good condition scores and

some live weight gain cannot be overemphasized to sheep farmers.

Age of Ewes

The objective for age at first breeding of ewes for lamb production under intensive conditions is 9 months, but this trend has become much less popular in countries of the European Union since changes in farm subsidy payments. For most flocks under extensive conditions, the objective for age at first breeding of ewes is 18 to 19 months. Up to 6 years of age, the fertility index increases, so that there is a point in keeping ewes until at least this age if dentition and body condition are good. Other limiting factors are the increasing frequency with age of mastitis and appearance, in endemically infected countries, of certain viral conditions such as maedi-visna, scrapie, Johne's disease, and sheep pulmonary adenomatosis. Ewes are usually culled for age at 6 to 7 years. In merinos the fertility and lamb survival indexes reach their peak at about 7 years and the twinning index at about 8 years.

Control of Severe and Debilitating Diseases

Outbreaks of disease that have general systemic effects can be disastrous for a breeding program, and the control and prevention of common, serious diseases is part of an animal health management program. In southern hemisphere countries, if blowfly strike is likely, the sheep could be jetted before and during the breeding season. A decision on whether to administer anthelmintics should be based on history, clinical signs of parasitism, and fecal egg counts based on samples from 10 to 12 ewes. Suboptimum body condition or body weight gain may be the result of general or specific nutritional deficiencies, and the diagnosis and assessment of these should form part of the animal health plan. If ewes are affected by debilitating diseases, such as caseous lymphadenitis and chronic progressive pneumonia, their fertility is likely to be reduced greatly (Brown and Olander, 1987). Caseous lymphadenitis has been and continues to be a significant problem for the sheep industry in many countries. It is a common cause of the thin ewe syndrome (Gates et al, 1977), but not in the United Kingdom where the disease was first recognized in 1985. The control of other diseases that secondarily affect the fertility of sheep—and this includes most diseases—is presented in other texts (Radostits et al, 2000; Kimberling, 1988).

Estrous Synchronization and Induction of Out-of-Season Lambing

Hormonal Methods. Manipulating the estrous cycle of ewes involves techniques that artificially control the hormone status, either by the addition of extraneous hormones or by methods that can lead the ewe to alter her own hormone status, with the purpose of bringing groups of females into heat together in response to the treatment (Tempest and Minter, 1987). Whatever method is used, it must be simple and cheap, require minimal labor, have the same effect on all animals, and not interfere with sperm transport, reduce fertility, or have any side effects. Synchronization of estrus in sheep using progesterone sponges and pregnant mare serum gonadotropin (PMSG), regardless of the physiological state of the ewe or the time of year, is now a well-established technique (Tempest and Minter, 1987). However, because progestogen- and PMSG-treated ewes often have a variable response in terms of litter size with many ewes producing three or more lambs, and because mortality at and around birth is a major cause of lamb loss, adequate supervision at lambing time is a necessary management activity to ensure that the benefits of synchronized breeding are realized. Supervised care during the lambing period can be carried out more efficiently if the estrus-synchronized ewes are additionally induced to lamb in synchrony after injection of dexamethasone.

Manipulation of the progesterone status of the ewe is the principle behind control of estrus. The period of progesterone secretion can be reduced by the administration of prostaglandin, which causes regression of the corpus luteum and begins the return of the follicular phase and the return to estrus of all ewes treated from Days 4 to 14 of the cycle. Two injections 8 to 9 days apart cause cyclical ewes to be on heat 2 days after the second injection. However, because anestrus ewes do not possess an active corpus luteum, and because estrus control is desirable in anestrus ewes, prostaglandins are of no value in out-of-season breeding programs.

Lengthening the period of progesterone dominance is achieved by the extraneous administration of progesterone, which extends the luteal phase and suppresses follicular development so that, on synchronous removal of this negative feedback "blockade," the ewes rebound into a compact follicular phase followed by synchronized estrus. Polyurethane sponges impregnated with a synthetic progesterone are implanted intravaginally to release the progesterone through the vaginal wall. The technique involves the intravaginal administration by sponges of 30 mg flurogestone acetate or 60 mg medroxyprogesterone acetate for between 12 and 14 days to promote synchronized estrus in groups of ewes 2 days after sponge withdrawal. Follicle-stimulating hormone in the form of PMSG is necessary in seasonally anestrus ewes, either 2 days before or at sponge removal. Cyclic ewes normally exhibit estrus after sponge withdrawal without additional PMSG.

The interval from the end of progestogen treatment (sponge removal) to the onset of estrus is 36 hours, and from the onset of estrus to ovulation it is 21 to 26 hours, for a total of between 57 and 62 hours from sponge removal to ovulation. The general recommendation is to introduce the rams 48 hours after sponge removal, or for set-time AI at 56 hours (Tempest and Minter, 1987). Currently, in New Zealand, two intravaginal devices for providing progestogen therapy are being used: the polyurethane sponge impregnated with synthetic progestogen and the CIDR, a Silastic device impregnated with progesterone (Smith et al, 1989).

Ewes can be bred late in the breeding season so that they lamb in April and May to coincide with the plentiful supply of spring grass and to avoid the adverse weather conditions often encountered when lambing earlier. Passive immunization against steroid hormones can also be used to increase the ovulation rate in ewes that are bred in late November or December, when their ovulation rate and fertility are often below normal (Webster and Namaghi, 1990). Fecundin has been withdrawn from the market in the United Kingdom because of the highly variable response with a large percentage of ewes producing three or four lambs with an associated, very high, perinatal mortality rate. It is unlikely that this product will find application in many flock-breeding programs.

The hormone melatonin (Regulin) can be used to induce out-of-season breeding (Rajkumar et al, 1989), and more commonly to advance the breeding season by 1 month or so in pedigree flocks. Melatonin has also been used successfully to advance the breeding season of young ewes in the flock, producing a more compact lambing period. When appropriately timed, melatonin can advance the breeding season by about a month, and the majority of ewes lamb over a 2- to 3-week period (Haresign, 1990). It cannot overcome the seasonality of reproduction, however,

and is only effective during a limited period before the start of the natural breeding season. The ram effect forms an integral part of the melatonin treatment strategy. The objective is to bring the animals closer to the onset of a new breeding season with the hormone and then to use ram introduction at a defined interval after implantation, when the ewes should be responsive to the ram effect to promote a more synchronized mating pattern. It is important to ensure that ewes have been isolated from contact with rams for some time before implantation. Teasers can be used in combination with melatonin treatment, but the introduction of rams, whether entire or vasectomized, should not occur before 5 weeks after implantation (Haresign, 1990). Melatonin can also be implanted into or fed to yearling rams to prepare them for out-of-season breeding (Williams and Hanif, 1990).

The synchronization of estrus in ewes requires a different approach to ram management. A simple but effective paddock breeding system that is practical under most conditions can provide satisfactory results if the number of ewes per ram is restricted. The ewe:ram ratio can vary from 5:1 to 10:1. Conception rates were 87% to the first synchronized estrus with six ewes/ram, 73% to the first estrus with 12 ewes/ram, and 89% to the first and second synchronized estruses combined at 10 ewes/ram (Tempest, 1983).

Teaser Rams. The use of vasectomized teaser rams, although less versatile and less precise than the hormonal sponge, is helpful for shortening the lambing period and for encouraging ewes to start breeding a week or two earlier than they normally would during the transitional period (Henderson, 1985). Ewes that have been deprived of the sight, sound, and particularly the smell of rams for at least 4 to 6 weeks (late anestrus to early breeding season) respond to the presence of the male by ovulating within 3 or 4 days, but without any signs of behavioral (silent) estrus (Henderson, 1985). In a proportion of these ewes (40% to 60%), a true estrus with ovulation and a behavioral estrus occur after about 18 days after the introduction of teasers. In the rest of the flock the corpus luteum formed after the first silent estrus regresses prematurely, followed by a second silent estrus with ovulation and a corpus luteum that has a normal life span. These ewes therefore come into fertile estrus from around Day 23 after the introduction of teasers on Day 0. If fertile rams replace the teasers at about Day 14, the majority of ewes in the flock can be bred over an 8- to 10-day period from around Day 18 onward. Lambing can be reduced to 4 or 5 weeks, with the majority of lambing occurring over a 2- to 3-week period (Henderson, 1985).

The best teasers are rams of high libido that have had some previous breeding experience. Young mature rams that are to be culled for some reason are often ideal teasers. Males should be vasectomized well before the period of use and the vasa deferentes checked histologically. The vasectomized males must be double tagged for clear identification. Although vasectomized males can be tested for sterility by electroejaculation immediately before putting them with the ewes, this method is not fail-safe because some entire rams do not always ejaculate after such stimulation and a false-negative result may be obtained with potentially disastrous consequences.

Synchronization of Lambing

Because perinatal lamb losses constitute a major source of loss in sheep flocks, control of the time of lambing enabling maximum supervision would be beneficial. Several different corticosteroids have been used, but optimum treatment for an induced lambing is 16 mg of dexamethasone injected intramuscularly.

Parturition can be controlled using clenbuterol, which delays the onset of labor (Plant and Bowler, 1988), but this method has not proved popular. Ewes are selected for treatment on the basis of impending parturition—that is, filling of the teats, warmth in the udder, and swelling of the vulva. The drug delays parturition for at least 10 hours, which allows for the supervision of ewes at lambing to help reduce perinatal mortality. Advantages and disadvantages are weighed in Box 16-5.

Artificial Insemination

If it is desired to spread the influence of a sire or group of sires over a large population, AI of sheep has a significant part to play. Suitable techniques are available, and results with fresh semen are positive (Miller, 1981). Ewes are detected in estrus by teaser rams, usually vasectomized ones. Semen is generally collected by artificial vagina or, in some circumstances, by electrical stimulation. The semen is checked for quality by physical methods, diluted, and used immediately. Short-term storage for 24 hours at 2° to 5° C is used but is not universally favored.

The results are conflicting. Deep-frozen semen has a conception rate of about 50%, so it is unlikely to be used in ordinary circumstances. The application of nonsurgical AI in sheep has been inhibited by the anatomy of the ewe's cervix, in which the cervical canal is tortuous and narrow. For practical purposes this has limited the deposition of semen within the first fold of the cervix using a plastic pipette (Maxwell, 1984). Insemination is into the cervical canal, using a lighted speculum, with the ewe's hindquarters elevated and the forequarters downward to provide maximum viewability and to restrict movement. More recently pregnancy rates, comparable with laparoscopic insemination directly into the uterine horns, have been described for nonsurgical insemination methods that allow transcervical deposition of semen. Intrauterine insemination may be performed using a laparoscopic technique that locates the uterus, and the semen is injected directly into the uterine horns (Maxwell, 1984; El-Gaafary et al, 1987). Conception rates in ewes after intrauterine AI with ram semen can be compared with those results achieved after natural breeding. In general, it is recommended that not less than 100 × 106 spermatozoa per female be used for ewes at naturally occurring estrus and 200 × 106 for progestogen-treated ewes (El-Gaafary et al, 1987). If the semen has been frozen, the minimum number of motile sperm required is about 400 × 106 per female in vaginal insemination and only 25 to 40 × 106 in intrauterine insemination. The optimum time for insemination is midestrus, and two inseminations given at 12 to 14 and 23 to 25 hours after the onset of estrus have been recommended. In the fixed-time insemination method, estrus is not sought, and the timing of insemination is based on the time of sponge withdrawal in estrus-synchronized ewes that are inseminated 56 hours after sponge removal (El-Gaafary et al, 1987). Embryo transfer techniques have also been described (Wilmut, 1987) and are now offered commercially in many countries.

Pregnancy Diagnosis and Surveillance

Pregnancy Diagnosis. Knowing whether a ewe is pregnant has two principal advantages:

1. The identification of nonpregnant ewes makes for more efficient flock management, enables savings to be made on expensive prelambing feeding, and allows opportunities for increased financial returns by selling nonpregnant ewes when market prices are generally high. Information gained

BOX 16-5

Advantages and Disadvantages of Synchronized Breeding and Lambing

ADVANTAGES

1. Increased supervision of ewes in labor and then of newborn lambs reduces perinatal mortality. The majority of lamb deaths are caused by insufficient or delayed colostral intake, which are avoidable by supervision. Ensuring passive antibody transfer within the first 2 hours of life is critical not only as a source of energy but also to prevent development of bacteremia-septicemia, which constitute major causes of lamb losses in the form of bacterial polyarthritis, meningitis, enteritis, and specific diseases such as lamb dysentery.
2. Ewes can be fed in groups based on fetal number and stage of gestation-lactation.
3. Lambs can be weaned in even batches, replacements reared to adequate body weight for breeding, and slaughter lambs finished to specific requirements and timed to meet specific markets.
4. Ovulation can be predicted precisely, enabling the use of artificial insemination, the use of better rams (Sire Reference Schemes using Best Linear Unbiased Predictor [BLUP] analysis), and the development of embryo transfer for genetic improvement.
5. The use of resources such as buildings and especially labor can be planned, creating optimum use and avoiding excessive seasonal demands. This allows effective planning of part-time labor; 40% of the fixed costs of sheep production is labor, and 46% of the labor cost is directly associated with the management of lambing. In a 100-ewe flock, it is estimated that it requires 1.82 hours of labor at lambing time per ewe.
6. Flock health management programs can be planned to ensure optimum efficacy of disease prevention measures, such as vaccinations and anthelmintic treatments.
7. Early breeding of ewe lambs can be induced.
8. The forward planning that is possible by controlling the date of lambing some 5.5 months in advance must be attractive in large-scale systems of production.

DISADVANTAGES

1. The major disadvantages of synchronized breeding are cost and the need for more rams, until such time as an effective (non-surgical) sheep artificial insemination service unit can be developed commercially.
2. The ewe shows only single estrus, with no return to estrus if she does not conceive.
3. A major potential for problems is the premature induction of fetuses in the late stages of gestation, when it is building up its energy reserves. This entails a risk of weak and stillborn lambs. To avoid this problem requires accurate mating records and a high degree of management skill.
4. More skilled shepherding is required to cope with the potential flock problem of mismothering in a condensed lambing period.
5. More indoor lambing sheds and pens and more facilities for warming lambs are needed.
6. In general, more effort and careful planning and attention to details are required.

from pregnancy diagnosis should include the proportion of ewes pregnant with singles or multiples, the proportion of ewes in early and late pregnancy, the BCS of the ewe, and the condition of her udder at the time of the examination.

2. The determination of fetal numbers in pregnant ewes by ultrasonography has been undertaken routinely by many farmers in the United Kingdom and the United States over the past 10 years or so. The ability to determine fetal numbers between 45 to 90 days of gestation allows ewes to be fed during late pregnancy in relation to their nutrient requirements. Such feeding, in conjunction with late gestation sampling for 3-OH butyrate concentration (Russel, 1985) as part of a flock health plan, ensures appropriate lamb birth weights and increased survival potential of the lambs. Lamb mortality is closely related to birth weight (Barlow et al, 1987), with mortality rates in excess of 40% for low-birth-weight triplet lambs (Khalaf et al, 1979). Twin or triplet lambs from ewes fed as if they were pregnant with only one fetus have low birth weight and are likely to die because of excessive heat loss or exposure and poor immunoglobulin transfer predisposing to bacterial infections. In flocks in which all ewes are treated alike, those carrying more than the average number of lambs are also more likely to develop pregnancy toxemia in late pregnancy (Scott and Woodman, 1993; Scott et al, 1998). Although it is claimed that single lambs from ewes fed as if they were pregnant with multiple fetuses are at risk as a result of a prolonged and difficult birth, there are few data to support this supposition. Absolute fetal oversize is commonly encountered in purebred pedigree meat breeds, including the Texel and Suffolk breeds, but is much less common in commercial flocks where potential problems of extended duration second stage labor can be overcome by diligent supervision and timely intervention.

In any investigation of a suspected reproductive problem, the pregnancy status of the breeding ewes is an important piece of information. The following are considered necessary for pregnancy testing to be acceptable in sheep production (Bell, 1983):

1. Accurate (combined error rate of no more than 5% is necessary; this refers to ewes diagnosed pregnant but failing to lamb, and ewes diagnosed nonpregnant but subsequently lambed)
2. Fast (should be able to do about 1/min)
3. Labor efficient
4. Physically easy
5. Cost effective
6. Able to make a diagnosis in early pregnancy
7. Noninvasive

A wide range of ultrasonic, radiographic, manual, visual, surgical, biochemical, immunological, histological, and cytological techniques have been described for assessing pregnancy in ewes, and these techniques have been compared (Watt et al, 1984).

Ultrasonic Techniques. Numerous ultrasonic techniques are available for the pregnancy diagnosis of sheep (Watt et al, 1984), and the literature on the principles of ultrasonography in the pregnancy diagnosis of sheep have been reviewed (White and Russel, 1987). B-mode, real-time ultrasonic scanning is a rapid and accurate method for the diagnosis of pregnancy in sheep (Sprecher et al, 1989). After the user has had sufficient training to gain diagnostic expertise, 98% to 100% accuracy can be attained. Transabdominal ultrasonography should be conducted between 80 and 110 days after the beginning of breeding or 35 to 65 days after the end of a 45-day breeding period, ideally before 100 days or 14 weeks. This allows adequate time for different management regimens to be applied to nonpregnant, single-bearing, and multiple-bearing ewes during late pregnancy. During these gestational windows, the accuracy figures quoted as being acceptable are pregnant or not, 99%; empty, single, or multiple, 98%; and multiples defined as twins, triplets, or quadruplets, 96% to 97%. B-mode ultrasonography is able to discriminate fetal numbers during a 60-day window between 40 and 100 days of gestation. The predictive value for the diagnosis of a single versus multiple pregnancy is 90% to 100%. Ultrasonography is used most efficiently when a linear array or sector probe is placed in the inguinal region of a standing ewe (Sprecher et al, 1989).

If facilities and farm labor are adequate, rapid pregnancy diagnosis is a function of diagnostician experience, and not the rate at which ewes are brought to the operator for the examination. Ideally the ewes are restrained in a portable raised chute or race, which holds the ewe standing 880 mm above the ground (Watt et al, 1984). Rates of scanning vary from 80 to 150 or more ewes/hour, depending on expected litter size (White and Russel, 1987; Rowe and East, 1998). The experience of the operator is of great importance in ensuring accuracy. Prospective operators can be taught in a 1- to 3-day course. Newly trained operators are at first unable to scan successfully; their accuracy for determination of numbers of fetuses ranges from 70% to 100%. However, after a period of experience with the technique on approximately 500 ewes and an appraisal session with an experienced operator, the accuracy of the new operator is sufficiently high to be of commercial value to hill flocks and to low-ground flocks with limited housing (Logue et al, 1987).

Manual and Visual Procedures. Some manual or visual techniques are also possible, and their advantages and disadvantages have been reviewed (Watt, 1983b). In the pregnant ewe, after about 90 to 100 days of gestation, the udder is enlarged and a sticky secretion can be expressed from the teats. Abdominal distention is obvious in late pregnancy, and some experienced producers can divide ewes into early and late lambers on this basis. Because it is useful only for late pregnancy, it has limited application but is a useful adjunct to other methods.

Vasectomized rams with a paint-colored keel can be run with the ewes after removal of the rams to identify estrous ewes, which are then removed.

Surveillance of Pregnant Ewes. If the pregnant ewe flock is large enough, it is advantageous to divide it into groups with similar projected lambing dates. Vaccinations provided to pregnant ewes and directed at passive immunization of their lambs can also be given at a more exact time.

Pregnant ewes are especially subject to a number of problems for which special surveillance should be maintained (Box 16-6). During the last 6 to 7 weeks of pregnancy, the plane of nutrition of the ewes needs to be increasing, or at least maintained, to avoid pregnancy toxemia and also to promote lamb survival. As a general rule, ewes should gain 15 to 20 lb (7 to 9 kg) of body weight during this period.

BOX 16-6

Conditions of Pregnant Ewes that Require Special Surveillance

FAILURE TO CONCEIVE
If the rams are taken out of the flock before pregnancy is established in most ewes, this could lead to a serious drop in flock reproductive efficiency. Continuing to run vasectomized rams fitted with a harness and crayon markers with the ewes can detect estrus ewes.

ABORTION FROM ANY CAUSE
Because early abortion in many ewes may go unobserved, a single occurrence should stimulate close surveillance. This may be of particular importance if *Campylobacter fetus* ssp. *fetus* is the cause. Vaccination is recommended at the beginning of the outbreak to reduce the number of ewes aborting if the expected lambing is in more than 6 weeks. Alternatively, antibiotic therapy can be administered metaphylactically to reduce abortions.

PREGNANCY TOXEMIA
This is common during the last month of pregnancy, especially when the ewe is carrying three or more lambs* and the feed supply is declining.

HYPOCALCEMIA
Where the flock is not well supervised, hypocalcemia may cause deaths in late pregnant ewes that are suddenly moved onto fresh pasture, deprived of all feed during late pregnancy, transported, or run by dogs.†

More details on the nutrition of ewes during pregnancy are presented later in this chapter.

Prebreeding Management of Rams

The sheep industry is engaged in producing rams to be used as sires in other stud and commercial flocks. The following program can be used as a protocol when checking a ram for purchase and for maintaining ram fertility in a flock with a flock health program in operation.

Selection for Fertility

The known and suspected inherited defects of sheep are listed elsewhere. Those that are of particular importance to ram fertility are cryptorchidism and inguinal hernias. Of direct importance in fertility is the positive inheritance of twinning, a susceptibility to dystocia, and dental malapposition. It is probably wisest to select against testicular and scrotal abnormalities that are of unknown origin. For rapid genetic improvement, the average age of the ram flock should be kept as low as possible, which in pedigree flocks means the use of rams when 7 to 9 months old. However, the fertility of such young rams is often low and ewe numbers should be limited to only 15. In other age groups, com-

monly quoted figures are that 10% of rams are infertile at 4 years and 35% at 7 years.

Breeding Soundness Examination of Rams

Given 100% pregnancy rates, the maximum number of lambs produced by a flock of ewes is determined by the mean ovulation rate of the flock (Cameron, 1984). Various forms of reproductive wastage intervene to ensure that this potential lamb production is never achieved. The optimum use of rams involves keeping those sources of wastage that are attributable to rams to a minimum, using the least possible number of rams of the highest genetic merit (selection intensity). To achieve optimum breeding rates, the ability of the rams to breed and induce satisfactory lambing rates must be reliably predicted. The ram can contribute greatly to reproductive wastage by failing to inseminate all the available estrus ewes or by failing to achieve maximum lambing rates in those ewes that are inseminated. Unsatisfactory lambing rates in ewes that are bred can be the result of a low proportion of ewes that lamb (fertility), or a low number of lambs born per ewe lambing (prolificacy) (Cameron, 1984).

More attention should be given to the selection and breeding soundness examination of rams than has been done in the past (Buckrell, 1987). A standard breeding soundness examination developed after extensive field tests has been reported (Kimberling and Marsh, 1997). This routine examination can be undertaken quickly, yet accurately detects abnormalities of spermatogenesis and sperm storage and infection of the male reproductive system. The ram with superior reproductive ability can breed more ewes, which leads to an improved first conception rate, a lower early embryonic death rate, and an improved lambing rate with fewer weak or undersized lambs.

In surveys of the examinations of rams, approximately one third have recognizable abnormalities of the reproductive tract, with orchitis and atonic or hypoplastic testicles being most common (MacLaren, 1988). Most of these abnormalities are also detectable by careful clinical examination of the scrotum and its contents. Approximately one third of the rams have abnormalities of other body systems, with diseases of the feet being most common followed by broken mouth, broken horns, and pneumonia. It has been estimated that the proportion of infertile rams in the United Kingdom ranges from 3% to 10% (Barr, 1984). Generally, infertile rams do not constitute a serious problem in the flock, because rams of normal fertility are able to compensate for less fertile rams in the group. However, an individual ram assumes much greater significance if it is dominant and prevents other rams from working or, if on hill ground, it collects and protects a group of ewes. Breeding in small groups or hand mating may also result in problems when using individual rams. In a 5-year survey of one Scottish Blackface flock, the routine examination of all rams resulted in the elimination of a 17% level of infertility, with an increase of 2.3% in the lamb crop (Barr, 1984).

The details of examination of rams for breeding soundness have been published (Memon, 1983; Ott and Memon, 1980). The working efficiency of a ram depends on libido, ability to breed, and the production of semen of satisfactory quality and quantity. Ill health or lameness may profoundly affect each or all of these criteria. A complete breeding soundness examination of rams includes a clinical history of the group of rams, the general clinical examination of body systems other than the reproductive tract for evidence of clinical disease or other abnormalities, examination of the reproductive organs, semen evaluation, and the serving capacity test (Galloway, 1983). The purpose of a breeding soundness examination or ram fertility test is to identify those rams that are unsound for breeding, which can range from 15% to 25% of the average ram flock, and to identify those highly fertile rams that can be used most efficiently in the flock (DeBlockey, 1983, 1984).

Six to eight weeks before the breeding season begins, a physical examination should be made of all rams, followed by the bacteriological examination of semen in rams with abnormal palpatory findings. During the physical examination, the presence of other diseases such as pizzle rot (infectious posthitis), which may affect ram fertility, can be identified. These include local abscesses caused by *Corynebacterium pseudotuberculosis*, psoroptic and chorioptic mange, mycotic dermatitis of the scrotum, blowfly strike, and lice and ked infestation.

The rams need to be in good body condition (about 4.0) at the start of the mating season if they are to stand up to the intensive hard work of breeding 50 ewes in a 5-week period. In one report of 160 rams examined, only 37% were in ideal condition, 50% were in acceptable condition, and 12% were in poor reproductive condition (Galloway et al, 1981). Bad feet, poor body condition, and poor teeth are commonly found, with testicular degeneration, epididymitis, and preputial injury being the most common findings in the genitalia.

At the time of examination, the feet should be trimmed, anthelmintics administered if necessary, and blood samples taken for brucellosis testing. The rams should also be shorn, if required. All wool on the scrotum should be removed carefully. The ration should be adjusted if the ram is in poor condition. Legume hay, or other supplements with a high level of protein, should be avoided because it predisposes to pizzle rot.

Additional measures in some countries include shearing the rams twice a year with the aim of having about 3 cm of wool at breeding. Insufficient wool leads to lack of insulation. Unnecessary driving during the breeding season is to be avoided and, if possible, well-shaded paddocks should be provided. Fat, heavily wrinkled, and shorn rams are the most susceptible to infertility caused by heat stress. Conversely, extreme weather conditions in hill areas may lead to fine-wooled sire breeds, such as the Blueface Leicester, not searching out estrus ewes.

Reports on the reproductive behavior of rams (Fowler, 1984) and on the relationships among semen quality, quantity, and fertility of the flock have been reviewed (Cameron, 1984).

Clinical History of Rams. A full history of an individual ram or group of rams should be taken before the clinical examination. The breed, age, identification, origin, management, nutrition, illnesses, and previous reproductive performance should be recorded. A clinical history of a ram can assist in the interpretation of abnormal findings on clinical examination.

General Clinical Examination. Body systems other than the reproductive tract are examined for evidence of disease or abnormalities that might interfere with breeding or that might be a potential source of disease for the ewes or other rams. Each ear tag is identified, and the mouth, teeth, and eyes are examined. The BCS of each ram is recorded. Poor condition scores (score 2 or below) for the majority of rams in the stud indicates malnutrition or other management problems such as poor parasite control, which must be reviewed carefully. Individual rams in poor body condition may indicate a chronic infectious process such as caseous lymphadenitis, chronic respiratory disease, and other focal bacterial infections. The breech, the legs, and the feet are examined. All abnormalities are recorded and interpreted, if possible, and further diagnostic work performed, if required.

Examination of Reproductive Organs. Scrotal circumference is the most useful predictor of ram fertility and can be measured readily by farmers at breeding sales. Although there can be marked seasonal variations in the scrotal circumference of rams (Mickelsen et al, 1982), these measurements are used as guidelines approximately 2 months before commencement of the breeding season; thus consideration of the influence of season (Memon, 1983) should not prove problematic. Australian studies have indicated that the minimum scrotal circumference for a ram to be introduced to 50 ewes is 24 cm. In eastern Australia more than 95% of rams have a scrotal circumference larger than 30 cm, which is considered the optimum required for breeding 100 ewes (DeBlockey, 1983). The Society of Theriogenology has provided guidelines for optimum average scrotal circumference for rams according to varying body weights and breeds; the values range from about 24 to 40 cm, depending on the breed, age, and weight of the rams (Mickelsen et al, 1982). In the United Kingdom the scrotal circumference for adult rams is recommended to be 36 cm or greater, with 40 cm desirable in pedigree stud rams because of the high heritability of this trait. Similar selection criteria have been quoted by U.S. workers (Rowe, 1998).

Scrotal circumference is directly related to sperm concentration in semen, sperm motility, percentage of morphologically normal sperm, first-service conception rate, and lambing rate. Replacement ewes from rams with above-average testicular measurements have higher ovulation rates and reach puberty earlier.

The ram is restrained in the standing position, and the maximum scrotal circumference is measured with a cotton tape measure. The scrotum and its contents are carefully palpated. The head and tail of each epididymis are palpated for any swellings. The testicles must be freely mobile and feel firm and turgid but not hard. In general, rams without palpable abnormalities do not require semen collection and evaluation.

Epididymitis is a major cause of infertility in the ram in many countries where *Brucella ovis* and *Actinobacillus semini—Histophilus ovis* are the organisms of most importance (Cottrell, 1985). If there is clinical evidence of epididymitis, a semen evaluation, semen culture, and complement fixation test may be necessary to reach a diagnosis. Once a diagnosis of *B. ovis* infection is made, regular complement fixation tests are necessary to identify carriers in the flock and to eradicate the infection. Other organisms that have been associated with epididymitis in virgin lambs include *Actinobacillus* sp. and *Haemophilus somnus (Histophilus ovis, Haemophilus agni)* (Bulgin et al, 1990). Rams with palpable lesions of epididymitis usually produce semen of poor quality (Bagley et al, 1984), but some affected rams produce good-quality semen but can be identified readily by the presence of large numbers of white blood cells on microscopic semen examination through the use of negative phase contrast. Ultrasonographic examination of the scrotum, testicles, and epididymes can provide very useful information concerning gross lesions, but this examination may prove too involved for routine examination of large numbers of rams under field situations. The use of an autogenous, multivalent, adjuvant vaccine containing *Actinobacillus* sp., *H. somnus (H. ovis)*, and *B. ovis*, and long-term feeding of low dosages of antibiotics have been evaluated for the control of lamb epididymitis in large purebred flocks (Bulgin et al, 1990). There is some indication of a reduction in the incidence of clinically affected rams.

The penis is exteriorized to ensure that the urethral process is normal. The prepuce and the penis are examined for evidence of infectious balanoposthitis, which can cause reduced reproductive performance because of pain and scarring to the extent that the ram cannot protrude the penis (phimosis).

Serving Capacity Test. Many behavioral and physiological components interact during breeding, but the single most important factor affecting conception is the achievement of insemination. Serving capacity is defined as the number of services achieved by the ram in a specified breeding situation. It is highly variable among rams, ranging from 1 to 25 services in a 33-hour pasture breeding period (DeBlockey, 1983, 1984). It can be measured either in the breeding pasture or in a yard test designed to predict service ability in the breeding flock (Galloway, 1983). The higher the serving capacity of a ram or group of rams, the more ewes that become pregnant at each estrus. High-serving-capacity rams achieve a higher pregnancy at each estrus than medium- or low-serving-capacity rams because they mount more of the estrus ewes and actually breed more of the ewes they mount (DeBlockey, 1983, 1984). High-serving-capacity rams also achieve a higher fertilization rate because they serve more of their estrus ewes and serve each ewe more times than medium- and low-serving-capacity rams (DeBlockey, 1983). Ewes served once, twice, or three times have pregnancy rates of 64%, 76%, and 93%, respectively.

Mature ewe flocks bred by high-serving-capacity rams also have a higher proportion of lambs born in the first 17 days of lambing than when bred by the medium- and low-serving-capacity rams. Only about 50% of ewes bred to poor-serving-capacity rams lamb after a 6-week breeding period. High-serving-capacity rams are also more effective than lower-serving-capacity rams for the breeding of maiden ewes, which normally are timid, do not seek out rams, and have a shorter estrus period compared with mature ewes. The use of high-serving-capacity rams can also lead to an increase in the twinning rate (DeBlockey, 1983). However, published data relating to ram service capacity must be kept in context. Few farmers evaluate ram service capacity, because in most situations the pregnancy rate achieved after 17 days of the breeding season generally exceeds 90%. Palpable abnormalities of the testicles-epididymes and infectious disease such as virulent footrot are more important considerations.

In the yard test for serving capacity, ewes are restrained in service crates fixed around the perimeter of a large yard. In large flocks, 10 or 12 service crates are set up around the perimeter of a large yard and 10 to 12 rams are put in with the ewes. The rams to be tested are sexually stimulated by allowing them to watch other rams mounting the restrained ewes for about 10 minutes. The stimulated rams are then placed in the yard with the ewes and the number of services the rams achieve in 20 minutes is counted. Rams serving zero to one ewe are poor-serving-capacity rams and make up 5% to 10% of the flock. Medium-serving-capacity rams complete two or three services, and high-serving-capacity rams serve four or more times in 20 minutes.

DeBlockey (1983) has recommended testing the flock rams annually to detect and cull the 20% of unsound rams and to assign a mating potential based on serving capacity and scrotal circumference. Serving capacity testing has been evaluated primarily in adult rams of varying and unquantified experience. A large proportion of rams purchased from breeder flocks by commercial breeders, however, have their first breeding experience at 18 months of age (Purvis et al, 1984). The use of the test may not be economical in young rams, because rams initially sexually inactive may become active in a second test.

Semen Evaluation. Semen can be collected by either electroejaculation or artificial vagina, and standard methods for the evaluation of semen are available (Galloway, 1983).

The repeatability of samples collected by electroejaculation is low, and rams should not be condemned based on a single unsatisfactory test result. Semen collection by artificial vagina is the preferred method, but not all rams elect to serve the restrained ewe. The semen should be examined for motility and density, the details of which are available elsewhere. Where appropriate the ejaculate should be cultured and smeared for *B. ovis*.

Ram:Ewe Breeding Ratio. Sheep are usually bred in groups or flocks, and it is considered normal to breed 33 to 100 ewes/ram (Fowler, 1984). The use of 1.5% to 2.0% high-quality rams provides a safe guideline for the proportion of rams to be bred to ewes. The higher percentage of 2% of rams should be used for maiden ewes. Variations in this ratio can cause major changes in breeding behavior. As the number of ewes per ram increases, the total number of mounts and services are increased and more ewes are mounted and bred. However, the number of services per ewe decreases in both pen and pasture situations. The amount of time taken for the rams to serve all the estrus ewes increases, and the number of rams breeding each ewe tends to decrease. As the number of ewes per ram exceeds 100, there is increasing competition among ewes and there are reductions in the services and mounts per ewe, number of ewes served, and flock fertility. As the number of ewes per ram falls below 30, and as the number of rams in the syndicate increases, there is increasing competition among rams (Fowler, 1984).

A summary of the recommended ram:ewe ratio follows:

Ratio	Parameter
1:100	Prolific breeds, mature rams, or flat ground (merinos)
1:40-50	Mature rams, other breeds
1:30	Hill flocks, mature rams
1:25-30	Yearling rams
1:20	Ram lambs
1:5-10	Synchronized ewes; mature rams

In general, for optimum results, mature rams are used at a concentration of 2% to 2.5% of the total ewe population. Young rams in their first season breed fewer ewes, and a concentration of 4% is recommended. A similar concentration may be needed on sparsely populated farms to ensure that the rams can locate the ewes in estrus.

Monitoring Ram Performance

The efficiency of the rams can be gauged by the use of a ram marking (breeding or mating) harness. A number of different rams can be monitored in a flock by the use of colored crayons in the harness. The same device can be used to indicate different time periods by using crayons every 2 weeks. The lighter colors are used first, followed by the darker colors. In the first 3 weeks of breeding, the rams should be marking all ewes, but in the second 3 weeks, the numbers being bred should be less than 10%. A harness ensures identification of those rams that are working, the percentage of the offspring, and the identity of those ewes that are bred on the same day. It is of great practical value in flocks in which anestrus is likely. If identification of those ewes that are showing estrus but that are not to be bred is the objective, vasectomized rams may be used. Failure to mate may result from anestrus in the ewe or failure of the ram to perform. The technique is not likely to be applicable in the field unless plenty of labor is available, because the flock needs to be examined at least once each week to record raddling and to allow adjustment of the harness. Changing the colors avoids confusion about which marking is latest. Changing colors every 2 weeks is a little easier on the color range if a 6-week breeding period is contemplated.

If possible, the ewes that are marked as being served during a particular period should be kept as a group so that at pregnancy diagnosis, they are all at approximately the same stage of pregnancy. It is essential that ewes retain their identification and that an accurate record of events for each ewe be kept.

Ram Effect

The introduction of rams to anovular ewes induces ovulation in the ewes within 6 days; this is known as the ram effect (Pearce and Oldham, 1984). The presence of the rams increases the secretion of luteinizing hormone, which leads to the induction of ovulation, but the factors predisposing to the introduction of rams are not well understood. The effect occurs in seasonally and lactationally anovular ewes and can be used to induce puberty in ewe lambs. The ewes must be in the anovular transitional period and must have been isolated from rams visually and pheromonally for at least 1 month before they ovulate in response to the reintroduction of the rams. The effect is a powerful and inexpensive method for controlling the time of sheep breeding and is an integral part of the reproductive performance of flocks bred in the spring. The ram effect is applied on a practical basis by introducing vasectomized or epididymectomized rams with marking harnesses to anovular ewes in order to advance the onset of the breeding season. Breeders have reported improved lambing rates and prolificacy resulting from the introduction of teasers during programs of induction of estrus cycles in noncycling ewes using exogenous hormones.

Diagnosis and Management of Reproductive Inefficiency

Criteria

The low rate of reproduction in commercial sheep flocks is a prime target for a flock health management program. The rate of loss is high and has not improved significantly for many years. There are two parts to the problem:

1. Failure to produce one or more live lambs by every ewe bred, presented as reproductive inefficiency in this section
2. Loss of a full-term lamb in the perinatal period, presented in the next section as perinatal mortality

Because the subject is complex and because there is a great deal of information about it, it is necessary to discuss the problem in a structured way, related to the way in which it is encountered in the field. Therefore it is described from the point of view of a reproductive inefficiency problem brought to us by a farmer in the ordinary course of practice. The same technique is used for handling a problem that begins to develop in a flock under a flock health management program. The final aspect of this discussion is the flock health program that should be instituted to avoid wastage caused by disease, but at a cost less than the benefit derived. Such programs vary widely from place to place, and even from time to time, depending on the profitability of the sheep enterprise.

It is assumed that, as with other herd health management programs described elsewhere in this book, the program must automatically assess itself so that the benefits of its operation are continually under surveillance.

The major criteria for assessing reproductive efficiency in a sheep flock are the following:

1. Percentage of ewes exposed to the rams that lambed at term
2. Average number of lambs born alive or dead per ewe exposed to the rams during the breeding period
3. Number of lambs weaned per ewe exposed to the ram during the breeding period

These criteria are influenced by the following indexes of reproductive performance:

1. Breeding index: the percentage of ewes marked by the ram during the breeding season
2. Pregnancy rate: the percentage of ewes exposed to the rams that are pregnant at pregnancy diagnosis 80 to 100 days after the beginning of the breeding season
3. Lambs born alive: the number of lambs born alive per ewe exposed to the ram during the breeding period
4. Length of breeding season: the number of days over which the rams were allowed to breed the ewes
5. Observed abortion and stillbirth rates

If the problem is failure to produce a lamb at birth, the following modes of reproductive failure are then considered:

- Failure to breed (ewe or ram)
- Failure of conception (ewe or ram)
- Early embryonic death (ewe problem)
- Abortion
- Combinations of any of the above

In flocks in which complete records are kept and good field observations have been made, it is usually possible to make an accurate diagnosis quickly. The following is a discussion of techniques of assessment, a description of the individual errors encountered, and how to correct them.

Techniques of Appraisal

The diagnostic procedure for deciding in which mode the specific error lies in any problem of flock reproductive inefficiency has been described frequently (Fig. 16-2). A more detailed account, suitable for field research, is also available (Moule, 1965). Special techniques can enable the appropriate decisions to be made.

Farm Profile. This includes construction of a history of the problem plus a description of the managerial and physical resources that may be important in causing the problem. On a well-managed farm, good data are available that can be analyzed, as discussed below. In others, it may be necessary to use approximations from limited records. If neither are available, it may be necessary to create a data file prospectively by collecting data for 1 or more years. Suitable categories for analysis of the data are shown in Box 16-7.

Examination of the Flock

Breeding Soundness Examination of Rams. This topic is presented earlier, in the section dealing with the maintenance of reproductive efficiency in the flock.

Physical Examination of Ewes. The BCS of the ewes should be assessed at weaning and again about 2 months before breeding so that there is time to supplement their diet to regain condition, if necessary. Special attention should be paid to the presence of a group of thin ewes among a flock of better-conditioned ones; the presence of a high percentage of such ewes in the flock may indicate a heavy parasite infestation, old ewes, Johne's disease, poor dentition, or inadequate feed supply. The information on BCS of ewes is presented in the section dealing with the maintenance of reproductive efficiency in the flock.

Accurate Head Counts of Ewes and Lambs. These are basic and absolutely essential, especially at lambing. If they are carried out whenever the sheep are worked, irrespective of the reason, they provide a repeat monitoring of the size and composition of each flock. Because the data recording

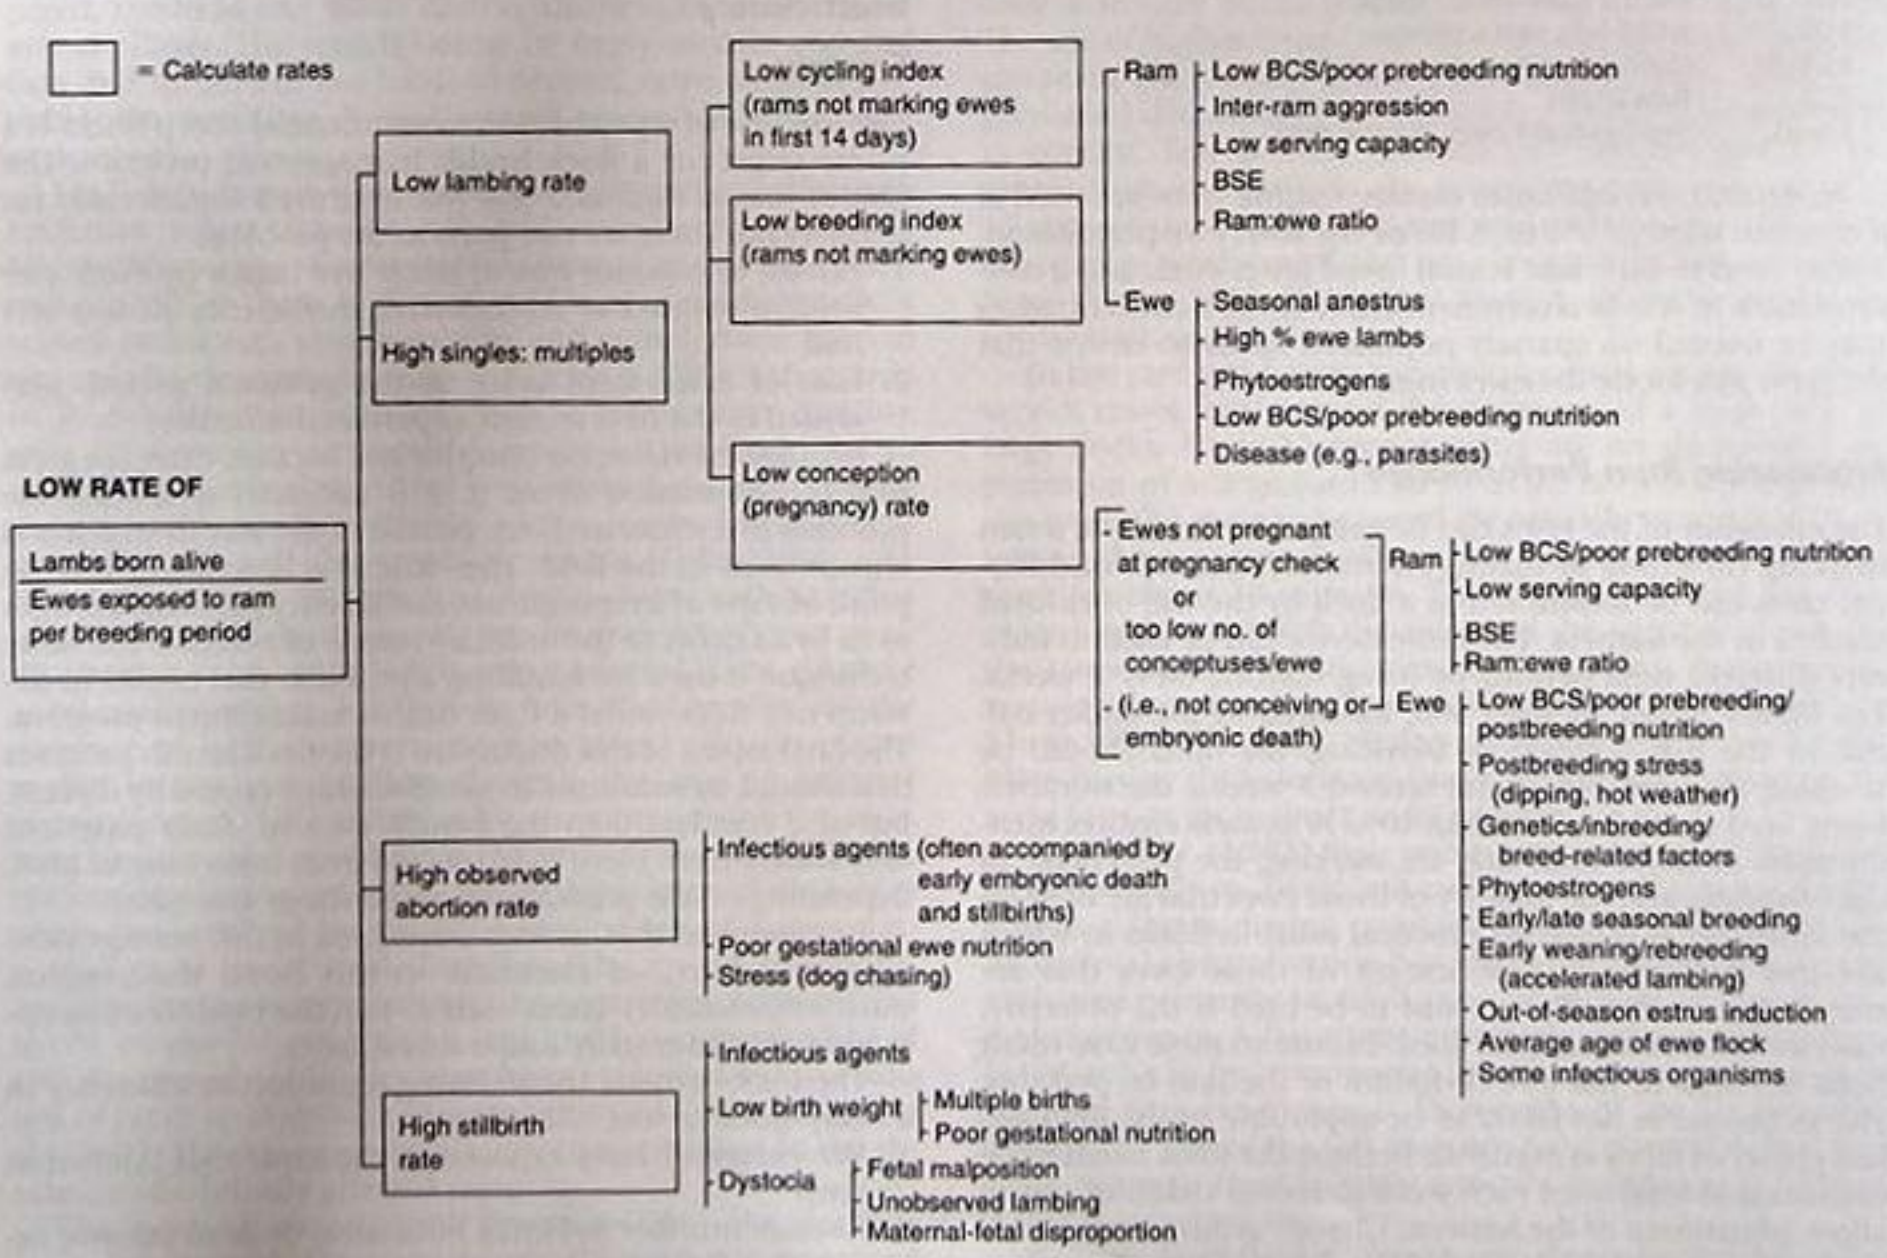

FIG. 16-2 Investigation of low rate of lambs born alive. *BCS,* Body condition score; *BSE,* body soundness examination.

and analysis on sheep farms must be based on flocks or subflocks, their accurate identification is essential at all times. The means of identifying the group may be by colored ear tag or by fleece brand.

Identification of Lactating and Nonlactating (Wet and Dry) Ewes. Under extensive flock management, the classification of ewes as soon as lambing is complete into groups indicating whether they have had lambs is known as the wet-dry classification but is more accurately referred to as lactating and nonlactating ewes. The latter classification is used here to avoid unnecessary confusion. If the classification of ewes can also include the year of birth of the ewe, which is easily achieved by a colored ear tag, the fate of the ewe can be decided on the spot. The recommended classifications are as follows:

1. Lactating ewes (wet-wet; ewes that have lambed and are now lactating). They have a lambing stain down the back of the udder. The udder is full and the teats are clean and large. Milk is readily expressed from the teats.
2. Nonlactating ewes (wet-dry ewes; ewes that have lambed but have lost their lamb[s]). A lambing stain is evident. The udder is at first large and full, but within a day the teats are dirty. Within a few days, involution of the udder begins but some secretions may be expressed for periods up to 2 months, with the secretion gradually becoming clearer and more viscous.
3. Nonpregnant ewes (dry-dry ewes; ewes that have not had a lamb this season). They have no lambing stain, are in good condition, and have no udder development with small teats.

Necropsy Examination. Necropsy examination is most valuable in attempting to determine the cause of death in newborn lambs. Such examination of infertile ewes is usually unrewarding.

Diagnosis of Mode of Reproductive Efficiency

The diagnosis of mode of reproductive efficiency is shown diagrammatically in Fig. 16-2. The scheme includes the use of techniques that may not always be available on commercial sheep farms. Without them, the questions cannot be answered. Because the questions also cannot be answered retrospectively, the investigation must be a prospective one. The modes of inefficiency—and thus their methods of detection—can be summarized (Box 16-8).

The failure of ewes to mate is not a common problem in adult merino ewes (Edey, 1969; Cannon and Bath, 1971), although it can occur (Restall et al, 1976). However, it is a significant occurrence in maiden ewes. The more common problem is a failure of fertilization or maintenance of the pregnancy.

Diagnosis of Failure to Breed. The decision to be made is between anestrus in the ewe or inability to breed by a ram.

Ewe Anestrus. During the natural breeding season, the most important single factor affecting the occurrence of estrus in ewes is nutrition. A dietary deficiency of total energy is manifested by a depression of ovulation rate or of fertilization and implantation. The result can be a decrease of the rate of mating to 70% for the first 2 weeks of the breeding season. The management response is to "flush" the ewe with supplementary feeding before the breeding period (Tassell, 1967a).

Determination of the nutritional status of sheep can probably best be done by BCS as described earlier. It should be emphasized that there is so much variation in body weight and fertility relationships among breeds and in different locations that any attempt to establish fixed standards would be futile. There is a special need to ensure adequate feeding of ewe lambs.

The occurrence of estrus also varies with the season, independent of nutritional status (Moule, 1965). This is most marked in merinos and merino crossbreeds, which come in heat regularly in autumn, although they breed in any season of the year in various geographic locations. Some breeds

GEOGRAPHIC ANALYSIS
Lamb-marking percentages on different farms

EWE FLOCK PERFORMANCE
As displayed by different age groups (e.g., ewe lambs versus mature ewes), indigenous versus introduced ewes (ewes brought in), nutritional status, culling policy (e.g., culling for age, lamb production, wool production), shearing, dipping, drenching program

RAM MANAGEMENT
Based on purchasing policy (age, origin, time of introduction to flock, shearing, dipping, drenching program), breeding policy (including number of rams/100 ewes, switching rams halfway, length of breeding period, time of year, prebreeding teasing, breeding as singles or as groups), culling policy (culling for age, fertility, serving capacity), breeding soundness examination history

BOX 16-8

Summary of Modes of Inefficiency

Failure of ewe to breed: no raddle mark is present from ram harness.
Failure of ram to breed: only some of the rams in the group have bred some of the ewes; both are identified by raddle marks from the harness. (Note that if all rams have low fertility, it is impossible to differentiate these first two modes.)
Failure of ram to inseminate: the mark of color unique to a particular ram is not seen, there is a reduced number, or single ram breeding groups are using the harness, with the subsequent ram successful.
Failure of conception: there are normal interestrus periods as indicated by ram harness marks, with different colors every 2 weeks. If out of season, this can only be assessed by a pregnancy test or by not lambing.
Early embryonic death: there are long interestrus periods as indicated by ram harness marks, with different colors every 2 weeks. When rams cease marking, conception may be assumed and rams are withdrawn. To determine that ewes do not return to estrus, vasectomized rams should be run with the ewes.
Abortion: the aborted fetus is picked up, the retained placenta is seen, and there is a bloody vulval discharge.
Stillbirth: lambs are born dead.
Neonatal mortality: see the "Perinatal Lamb Mortality" section.

such as the Blackface and Down types are seasonally anestrous, independent of nutritional status. There is also a seasonal influence on the number of ovulations occurring at one time, so that a higher proportion of twins is likely to occur in merino ewes bred in the autumn than in spring. The differences are significant, with the respective fertility indexes being 95% in autumn and 78% in spring.

Ram Impotence. Painful conditions of the hind feet of the ram may prevent proper mounting and interfere with successful breeding activity. Inter-ram aggression among rams that have not been socialized before breeding can contribute to a low breeding index. Poor nutritional status and an insufficient ram population may also reduce ram activity. The more important causes of ram infertility are discussed in the next section.

Diagnosis of Cause of Failure to Establish Pregnancy. This includes failure of fertilization and implantation and early embryonic death.

Ewe—Failure to Conceive. Except for the infectious diseases, which cause abortion and embryonic death and are discussed elsewhere, there are few known specific causes of failure to establish pregnancy, such as high ambient temperatures and genetic influences (Moule, 1965). Anatomical abnormalities of the reproductive tract of infertile ewes have been described (Dobson and Davies, 1989) but these conditions are not prevalent. Nutrition and fertility relationships are unclear. However, embryo survival is greatest in ewes fed a full maintenance diet. The ingestion of estrogenic substances in subterranean clover and other plants is the best-known cause of poisoning, which may result in a failure to establish pregnancy in 70% of ewes and cause further losses of lambs at parturition (Tassell, 1967b).

Ram—Failure to Impregnate. Rams contribute significantly to infertility in sheep flocks, largely because of infectious diseases that affect their reproductive tracts. In addition, there are environmental influences. Rams show highest libido in the autumn, and they may be relatively infertile in hot summers, especially if they are not acclimatized. Libido also tends to be low in late winter and spring, especially in British breeds of sheep. High environmental temperatures can also cause seminal degeneration. Because of the relative frequency of fertility breakdown in rams (5% to 10% is not remarkable in year-old rams and 35% may be impaired at 7 years), an examination of the rams before mating periods is desirable and recommended (Ott and Memon, 1980).

Further examination is necessary if a diagnosis of infertility is suspected or a more accurate evaluation is required. Collection of semen by electroejaculation is a standard procedure, and examination of the semen makes possible a judgment on semen quality and the probable state of fertility. The bacteriological examination of semen has considerable merit, and serological examination for *B. ovis* is a standard procedure. The specific diseases associated with ram infertility are presented in other books.

There are many other diseases that can, by their local or systemic effects, cause temporary or permanent infertility in rams, such as blowfly strike, parasitism, and footrot. During any physical examination of a ram, the presence of a local dermatitis—for example, that caused by mycotic dermatitis, or mange—would be noted as a possible cause of infertility and its prevention recommended. The scrotum is obviously important, but so are the feet, entropion, or infections of the eyes; a badly undershot jaw, preventing good prehension, can adversely affect body condition and reproductive efficiency in rams that have normal genitalia.

Diagnosis of the Cause of Abortion. Abortions in sheep are often unrecognized unless outbreaks occur or unless sheep are brought together in late pregnancy and aborted fetuses are seen in the yards. The clinical signs of abortion in flock include the following: (1) ewes separated from the remainder of the group and showing uterine discharges before the expected date of lambing, (2) aborted fetuses seen when pregnant ewes are yarded, (3) lambs or fetuses born still enclosed in the fetal membranes, and (4) in some flocks, there may be an increase in the number of dry ewes in the flock, with no apparent increase in perinatal mortality or evidence of abortion. In most cases, the ewe does not exhibit any signs of clinical illness before or after the abortion. However, abortion resulting from certain *Salmonella* serotypes often causes severe illness, often death. With early abortions, such as can occur with toxoplasmosis, there may be no clinical evidence of abortion, no vaginal discharges, and no evidence of fetal membranes; producers may interpret this as failure of the ewe to conceive except that the ewe has only one raddle mark.

Abortion in sheep refers to the expulsion of a fetus before it is capable of independent life, usually before 135 days of gestation. Parturient deaths are full-term lambs that were alive at the beginning of lambing but died during lambing. Surveys have indicated that in most flocks, up to 2% of pregnant ewes may abort and no specific agent can be determined. A higher rate should prompt an investigation because of the importance of infectious agents as causes of abortion in sheep (Dennis, 1975).

The common causes of infectious abortion in sheep are campylobacteriosis caused by *C. fetus* ssp. *fetus*, enzootic abortion of ewes caused by *Chlamydia psittaci*, toxoplasmosis caused by *Toxoplasma gondii*, and salmonellosis caused by *Salmonella abortus-ovis* and other types, such as *S. montevideo*, *S. typhimurium*, and *S. dublin*. Less common causes include *Listeria monocytogenes*, *Ehrlichia phagocytophilia* (tickborne fever), and *Coxiella burnetii* (Q fever). Viral disorders include border disease infection and Akabane disease as well as louping ill.

Enzootic abortion caused by *C. psittaci* is the most commonly diagnosed cause of abortion in sheep in the United Kingdom, based on material submitted to diagnostic laboratories (Aitken et al, 1990). Monitoring for serological and clinical evidence of the disease forms part of the ADAS Sheep and Goat Health Scheme and the Premium Health Scheme for Sheep of the Scottish Agricultural Colleges. Fresh placentas and lambs should be sent to the laboratory (with disposable gloves) because of the zoonotic nature of the disease. Transmission occurs at the time of abortion and ewes that have aborted should be tagged with the date of the abortion and isolated for a minimum of 6 weeks. All placentas not sent to the laboratory should be destroyed by burning. Ewes that have aborted should not be used to foster female lambs.

Oxytetracycline is effective against the organism, and the use of long-acting oxytetracycline 6 weeks before the expected lambing date can maintain pregnancy in some infected ewes. The disease can be controlled effectively through the use of a live attentuated strain of *C. psittaci* commercially available in Europe.

Toxoplasmosis as a cause of abortion in sheep is being recognized with increased frequency. It is commonly associated with cats, and spaying female kittens, while protecting the grain and other feed from contamination, and adding monensin to the ration of the ewes may prove helpful control measures. Effective control of toxoplasmosis in flocks is achieved by vaccination through the use of a live concentrated aqueous vaccine containing tachyzoites of the S48 strain of *T. gondii*.

Toxins have not been identified definitively as abortifacients, but the evidence against fungi growing on *Romulea bulbocodium* (onion weed), or the plant itself, is convincing.

BOX 16-9

Procedure for Investigating Abortion in a Flock of Sheep

1. Visit the flock, obtain as much history as possible pertaining to the abortion problem, and establish a case definition. Is this really an abortion problem or a stillbirth problem? Attempt to characterize the abortions according to time of gestation, number of fetuses per ewe, and whether abortions occurred in a cluster over a short time or were spread throughout the prelambing period. The pattern of distribution may indicate whether an acute infection occurred in a group of pregnant ewes in a short time. Determine the age group of ewes affected. The incidence of abortion may be higher in certain age groups (e.g., ewes carrying their second crop of lambs in the case of chlamydial abortion). A differential diagnosis list of possibilities should be created to guide the veterinarian in the pursuit of a specific causative diagnosis. The characteristics of the most common causes of abortion are available in standard textbooks of sheep medicine and other publications.*
2. Collect as many fetuses and fetal membranes as possible and submit them to a diagnostic laboratory. Necropsy often allows a field diagnosis to be made, which then can be confirmed by submitting appropriate specimens.
3. Based on the suspected infectious agent, perform serological testing of all ewes that are known to have aborted and on a percentage of ewes that have not aborted and are considered normal.

*Such as (1) Plant J: Abortion in sheep. In Postgraduate Committee in Veterinary Science, Refresher Course for Veterinarians No 141, Sheep Medicine, Sydney, 1990, University of Sydney, and (2) Linklater KA: New developments in health control: management and health control. In Marai IMF, Owen JB, editors: *New techniques in sheep production*, London, 1987, Butterworths.

Other fungal toxins (e.g., from *Claviceps purpurea* and *Aspergillus fumigatus*) are quoted as causes of abortion. Abortion caused by infection with fungi, as in cattle, is not recorded in sheep.

Investigation of Abortions in the Sheep Flock. A major problem with obtaining a specific causative diagnosis of abortion in sheep is the low rate of submissions of aborted material from the flock. As a consequence, 50% to 60% of abortions may not be diagnosed by the laboratory (Linklater, 1979) (Fig. 16-3).

The procedure in Box 16-9 is recommended for the investigation of abortion in a flock of sheep.

PERINATAL LAMB MORTALITY

Magnitude of the Problem

Perinatal lamb mortality is one of the major factors in the impairment of productivity on sheep-raising enterprises around the world (Gumbrell, 1980; Gumbrell and Saville, 1986). When lambs die shortly after birth, not only is the opportunity of the ewe to reproduce lost for a year, but perinatal deaths reduce the volume of lamb for sale and reduce the number of surplus sheep for sale by the enterprise. Death loss is one of the most important factors associated with productivity (Fiss et al, 1991). It also reduces the options for selection in breeding programs and for culling to increase flock productivity, and it decreases the options to adjust flock structure for flexibility in management (Alexander, 1984).

The extent of perinatal lamb mortality varies from about 5% to 70% but averages from 10% to 20%. In an Australian survey of merino breeders, 28% of flocks lost 15% to 24% of lambs, 18% lost 25% to 34%, and 5% lost 35% or more (Alexander, 1984). It is also suggested that lamb mortality based on marking percentages changed little during the previous century. In southern Queensland, where most lambs are born during the spring, field surveys of merino flocks found perinatal lamb mortality rates ranging from 9% to 20% (Jordan and LeFeuvre, 1989). A major cause of reproductive wastage in most years in that same area was the loss of lambs from birth to lamb marking (Jordan et al, 1989).

In the United Kingdom the annual perinatal lamb mortality rate has been quoted as 15% or greater by numerous studies (Whitelaw, 1976; Eales et al, 1983; Barlow et al, 1987), with some authors quoting figures as high as 25% (Hindson and Winter, 1990).

In a 10-year survey of a large sheep enterprise of 177,000 sheep in Peru, of which 40% were breeding ewes, mortality during the first 3 days of life was 3.6%, and for the period from 4 to 30 days mortality was 0.5% (Ameghino et al, 1984). Mortality averaged 4.3% for the first 30 days of life, which is substantially lower than that described in Australia, where lamb mortality is usually about 15% to 20%. The low rate for perinatal mortality in lambs in Peru may be attributed to the excellent management conditions under the pastoral-shepherd system employed on this cooperative. Management practices were designed to provide as high a level of health care, nutrition, parasite control, range management, and husbandry as technically possible. In Australia, by comparison, higher death losses occurred in commercial sheep enterprises under extensive management conditions. Weak lamb syndrome, accidents, injuries, and starvation were the leading causes of mortality. Approximately 86% of mortality occurred in the first 3 days of life when nutritional, environmental, and management factors leading to weak lambs and starvation accounted for about one third of total mortality. Infections (22%), accidents (22%), and stillbirths (16%) followed in order of importance. During the remainder of the first month of life,

deaths from infections predominated, accounting for 60% of mortality from 4 to 30 days.

In sheep flocks that are housed at lambing time, and in which surveillance of ewes and the provision of timely assistance in cases of dystocia are possible, neonatal mortality of lambs can be minimal. In fact, almost all lambs can survive if given adequate obstetric assistance, warmth, and colostrum and milk. But questions of economics, expected incidence of multiple births, likelihood of cold, wet, windy weather during lambing, and sheep farmers' diligence determine the measures taken toward attaining these objectives. When lambing under average conditions, the percentage of lambs surviving until weaning can be as low as 70% to 80%.

Dennis (1972b) has quoted an estimated loss of 20% of all lambs born in most countries before weaning. In Australia, 80% of these deaths occur during the first few days of life; the immediate and delayed parturient deaths are discussed below. A survey of range flocks in the United States showed that there is a mortality rate of 23.5% between birth and weaning, and that 73% of these deaths occur during the first 5 days of life (Safford and Hoversland, 1960). Over a 5-year period, on average, about 26% of lambs born at the University of Minnesota Agricultural Experiment Station died before weaning, with 72% dying in the postparturient period (Yapi et al, 1990). Surveys in Canada have indicated that lamb mortality is about 14% (Dore et al, 1987). In Zimbabwe, 15% of lambs were recorded as dying before 16 weeks of age, with 70% of losses being caused by managerial errors (McKenzie and Grant, 1976).

In southern Australia, the average estimated neonatal lamb loss in a predominantly merino population was 15% to 20% (Dennis, 1974), but losses as high as 70% of ewes losing all their lambs were recorded (Plant et al, 1976). English estimates of loss were 12% (Boundy, 1979), and Scottish estimates varied from 5% to 15% (Houston and Maddox, 1974) in milder climates but up to 20% to 25% in hill sheep, mostly from starvation and exposure (Watt, 1980). New Zealand studies (Gumbrell, 1980; Gumbrell and Saville, 1986) have shown that an average mortality of 8% to 10% of newborn lambs was composed of death from starvation in 39% and exposure in 28%; 76% of lambs had lesions caused by dystocia. Of these deaths, 6% occurred before parturition, 33% during parturition, and 61% after parturition. A Norwegian summary showed an overall death rate of 9.7% in housed flocks from birth to 5 months of age, with 46% of these deaths occurring in the perinatal period of days 1 to 28 (Lutnaes and Paus, 1981).

High losses are usually associated with single causes, but there is a core level of about 15% that has not been amenable to reduction without an input of labor or capital, which most producers regard as unacceptably high.

Patterns of Mortality

Alexander (1984) reviewed the patterns of neonatal lamb mortality that recur in many flocks. Most deaths occur in the first few days of life, which is a reflection of the transition from a dependent intrauterine life to an independent extrauterine life. Mortality is typically related to birth weight by a U-shaped curve in which mortality is lowest at a weight between 3 and 5 kg; however, the optimum weight for survival depends on the breed and body weight of the ewe because these birth weights are a generalization. Mortality usually increases with litter size, a relationship that is associated with a decline in birth weight as the litter size increases (Khalaf et al, 1979; Barlow et al, 1987).

The relationship between age and parity of the dam are not clear. Mortality can be as high as 33% in primiparous ewes and is minimal over the next four or five pregnancies before it rises again. Differences in mortality among various breeds and crosses, and even among strains of the same breed kept under comparable conditions, have been reported (Alexander, 1984). Inbreeding, both of the dam and lamb, can increase mortality (Wiener et al, 1983). Delayed birth can vary significantly among breeds (Woolliams et al, 1983a). There may be breed differences in the incidence of "weakly lamb" syndrome in spite of relatively low average birth weight (Woolliams et al, 1983b), and inbreeding can be associated with an increase in the incidence of infectious diseases (MacLeod et al, 1983). Losses of lambs from crossbred ewes are usually lower than from purebreds, and birth losses associated with dystocia in Australian Dorsets are invariably high. In a flock of English polled Dorset ewes, about half of ewes had difficulty in lambing and required assistance, and the overall perinatal mortality was 9%, but 55% of lambs died as a result of birth injuries and anoxia associated with dystocia (Wilsmore, 1986) indicating the important role of diligent supervision and timely intervention. Great care must be exercised not to rely on, or accept, all published data because many publications are based on relatively discrete sheep populations, often single flock studies performed over one season only. Veterinarians must collect reliable data from the best farms in their practice and use these performance results as realistic targets. These targets can be adjusted as improvements in flock performance result from the implementation of the flock health plan.

Relative Importance of the Individual Causes of Neonatal Mortality

The principal causes of neonatal mortality are those causing hypothermia in the lamb: excessive heat loss because of a high chilling factor in the environment, and low heat production caused by prolonged birth, immaturity, and starvation (Eales et al, 1982a; Alexander, 1984). However, it is not possible to provide general figures because individual causes have varying importance in different environments. Especially important is whether the sheep are housed and, if not, whether they are farmed intensively with close surveillance, or whether they are run under extensive pastoral conditions, where such surveillance is not possible.

One of the most exhaustive surveys of the causes of neonatal loss in sheep was completed in Australia (Dennis, 1974, 1975). Under those extensive conditions of sheep production, starvation, dystocia, predation, and exposure accounted for most of the deaths. Infectious diseases were a relatively minor cause of mortality. Even in housed ewes in the United Kingdom that were pastured after lambing, the losses were about 12%, most of them at birth and on the first day of life, with starvation and stillbirth representing almost half the deaths and neonatal infection the next largest category (Purvis et al, 1979). In northern Scotland, where the sheep run at pasture all year, the overall death rate has been recorded as 14.2%, again with stillbirths, starvation, and exposure as the most common causes, accounting for over 50% of deaths (Johnston et al, 1980). In New Zealand the most common cause of death in singles was dystocia caused by high birth weight; in multiples the most common cause was starvation and exposure as a result of lower birth weight. Many of these losses could be avoided by ultrasound determination of fetal number during midpregnancy and appropriate late gestation nutrition. Lambs of birth weight of 3.5 to 5.5 kg and from 4- to 5-year-old ewes survived best (Dalton et al, 1980). These data are invaluable to veterinarians when formulating a flock health plan with their clients to reduce neonatal losses. In Queensland (Australia), exposure to a high environmental temperature was a common cause, with small lambs (about 2.5 kg) being the most sus-

ceptible (Stephenson et al, 1980). In two highly prolific Booroola crossbred flocks and a Romney flock, dystocia was the predominant cause of death for single lambs, whereas for large litters, prenatal and prolonged birth causes were of increasing importance (Hinch et al, 1986). A study of a commercial lowland sheep flock in England over a 2-year period revealed that the major causes of lamb mortality were stillbirths, weak, underweight lambs, and climatic stress (Purvis et al, 1985).

In a 2-year survey of perinatal lamb mortality in 28 housed Michigan sheep flocks, the major causes of mortality were dystocia-stillbirth, starvation and hypothermia, pneumonia, and abortions, which accounted for 50% to 75% of perinatal losses (Rook et al, 1990).

In summary, the major causes of neonatal lamb mortality are low birth weight lambs that do not suck sufficient colostrum immediately after birth, which renders these lambs susceptible to cold exposure, hypothermia caused by cold exposure under adverse weather conditions, and various bacteraemic conditions. Birth injury alone, and as a predisposing factor to hypothermia and starvation, is reported as an important factor contributing to perinatal mortality in singleton lambs where there is poor flock supervision. Birth injury is not a major contributing factor to neonatal lamb losses in multigravid ewes managed under intensive conditions.

The numerous factors that jeopardize newborn lambs have been identified. It is evident that lamb survival depends on the integration and success of physiological activities in four crucial areas (Mellor, 1988):

1. Initiation and completion of the birth process
2. In utero preparation of the lamb to face the challenge of a free-living existence
3. Preparation of the ewe for her postnatal nutritive role
4. Establishment of a good ewe-lamb bond

A detailed clinical, biochemical, and pathological study of perinatal lambs in a commercial low ground flock in the Scottish borders with a history of substantial perinatal mortality revealed that placental insufficiency was involved in 24% of deaths, acute hypoxemia at birth in 35%, inadequate thermogenesis in 12%, and starvation in 12%. With only clinicopathological criteria, 37% of the lamb deaths were attributed to antenatal influences, which included immaturity, developmental anomalies, and degenerative or inflammatory changes; 33% of the deaths were the result of postnatal factors, which included (in declining order of frequency) starvation, enteritis, misadventure, pneumonia, navel infections, and septicemia (Barlow et al, 1987). No conclusions could be made from the pathological examinations alone in the remaining 30%, although almost half of these had low rectal temperatures after birth, with death being attributed to hypothermia. It is emphasized that antenatal influences can cause weaknesses in lambs that may lead to deaths, only a proportion of which are accompanied by morphological changes. These data highlight the importance of correct nutrition throughout pregnancy; unfortunately, detailed monitoring of flock nutrition during late gestation was not undertaken in this study (Barlow et al, 1987). Perinatal lamb losses as low as 3% can be achieved in well-managed flocks, indicating that the antenatal factors described above can be resolved by correct nutrition and management practices.

Causes of Perinatal Mortality

Classification

On any sheep farm, there are losses of lambs in utero, because of prolonged second stage labor, and in the neonatal period. When recommending a health management program to limit these losses, the veterinarian must know the important modes of loss on the particular farm. In sheep flocks it is common to find that more than one cause—and often a number of causes—contribute significantly to the total loss (Fig. 16-4).

Determination of the exact cause or causes of loss is usually difficult because the principal requirements—to observe closely, record carefully, and classify accurately—are not easy in the sheep-farming environment. A system of classification is illustrated in Fig. 16-5 based on an overall group of perinatal mortality (Dennis, 1972b) that included all deaths from late pregnancy to 28 days after parturition. The categories of the times of death are shown in Box 16-10.

Diagnosis of Specific Causes

On the basis of the history of the mortality and the gross changes at necropsy examination, it should be possible to categorize the cause as being either environmental or deriving from the characteristics of the lamb or ewe.

Environmental Factors. These include climate (inclement cold or hot weather), nutritional inadequacies or deficiencies (general inanition, iodine—goiter, copper—swayback, selenium-vitamin E—white muscle disease), predators, and infections (congenital or extrauterine, with or without immune deficiency).

Ewe Characteristics. These include breed, age, mothering capability and milk production, and dystocia.

Lamb Characteristics. These include lamb size (dystocia, undersized and weak), litter size, malpresentation, malposture, malposition, congenital defects, and lack of vigor (many causes).

Evaluation of Perinatal Mortality

A high perinatal death loss may be obvious, with a large number of dead lambs. In other extensive circumstances, it

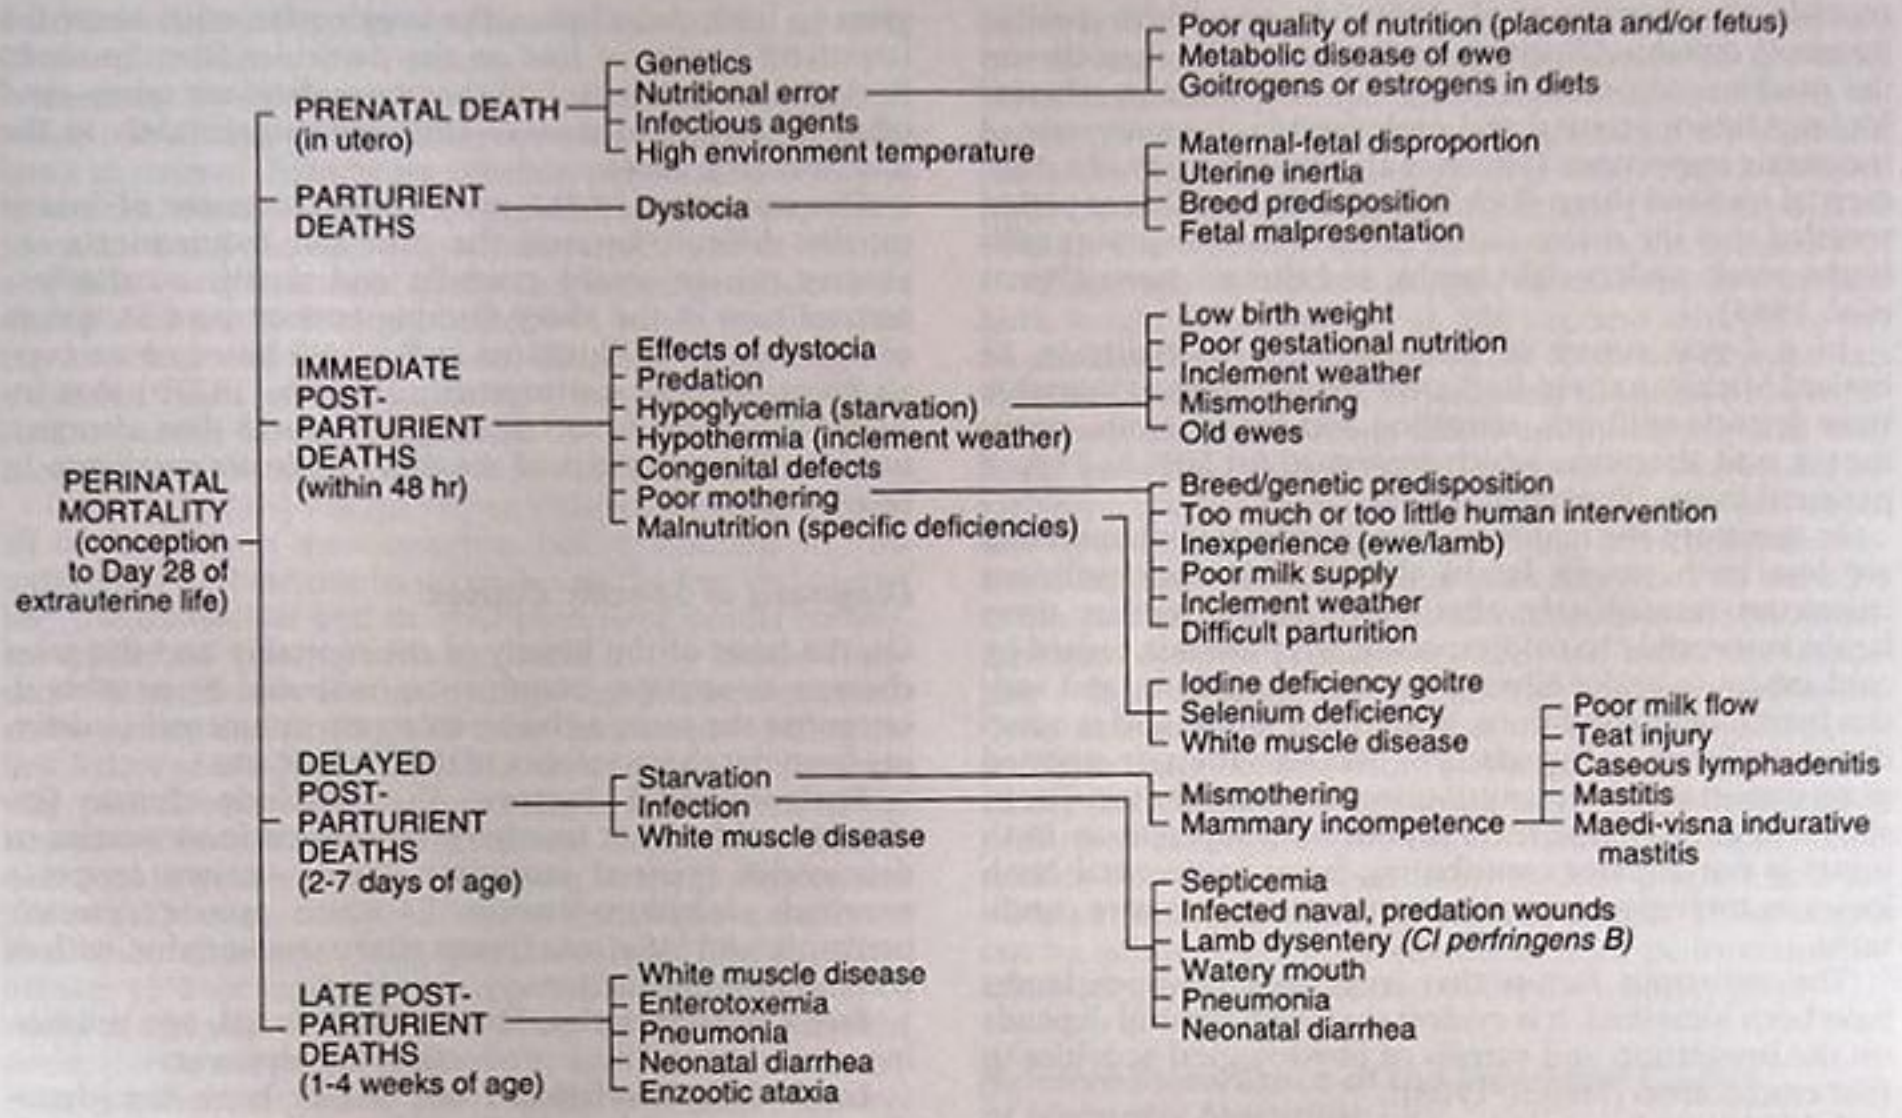

FIG. 16-5 Classification of perinatal deaths of lambs.

BOX 16-10

Categories of the Times of Death

FETAL DISEASES
These are diseases of the fetus during intrauterine life, such as prolonged gestation, congenital defects, infectious disease including toxoplasmosis, abortion, fetal death with resorption or mummification, and goitre.

PARTURIENT DISEASES
These are metabolic diseases associated with dystocia causing cerebral hypoxia and injury to the skeleton or soft tissues.

POSTNATAL DISEASES
These include the following: (1) early postnatal disease (within 48 hours of birth), such as malnutrition because of poor mothering, hypothermia from cold exposure, and infectious diseases such as omphalophlebitis and colibacillosis, (2) delayed postnatal disease (2 to 7 days of age), such as desertion by the dam; mammary incompetence resulting in starvation; increased susceptibility to bacterial infections including colibacillosis, meningitis, peritonitis, hepatic necrobacillosis, and polyarthritis; and lamb dysentery because of hypogammaglobulinemia, and (3) late postnatal disease (1 to 4 weeks of age), such as white muscle disease and enterotoxemia.

Failure to establish pregnancy, early embryonic death, and abortion are presented in the chapter.

may only become apparent as a high level of positive pregnancy diagnoses followed by a low lamb-marking percentage. Perinatal lamb losses are therefore often much greater than farmers realize, and the first objective is to determine the extent of the problem. This section on techniques is recommended as a guide to examining a problem in a flock (Plant, 1977) or to developing a monitoring system to include in a continuing flock health program.

As a general rule, under extensive conditions, it is recommended that losses of less than 15% of all lambs, or less than 10% of ewes losing all their lambs, are within the bounds of normality and are not economical to investigate in detail. It is unlikely that a cost-effective program could be mounted against the causes in these flocks. Under intensive and housed conditions, the perinatal mortality rate should not exceed about 5%, but few flocks ever achieve that level of performance (MLC Yearbook, 1997).

Analysis of Retrospective Data. Careful examination of past lambing records should be combined with a description of the management of the farm and its physical resources. This analysis can pay excellent dividends if there are good records. It provides an assessment of the size of the problem and indicates which phase of the lambing sequence is the location of the error. Suitable areas for analysis are shown in Box 16-11.

A simple system for recording the events associated with each lamb death in commercial flocks is shown in Fig. 16-6 (Eales et al, 1986b). This information is recorded for each lamb and then collated, summarized, and assessed, together with the clinical and necropsy data. The results can reveal the extent of lamb losses and provide an indication of the areas of management requiring improvement.

BOX 16-11

Analysis of Retrospective Data

Time of day, season, prevailing weather at lambing, reasons for timing
Geographic location of lambing paddocks or areas, shelter available
Size of ewe flocks, degree and frequency of supervision
Supplementary feeding during late pregnancy
Number of ewes requiring assistance at lambing
Quality of predator control
Tranquility of ewe flock under supervision
Use of pens for confining ewes and lambs
Vaccination program
Immediate postpartum care of ewes and lambs, including preventive treatments
Length of lambing season
Lambing percentage. Method of estimation should be as follows (ensure that nonpregnant ewes are included):

$$\frac{\text{Lambs born}}{\text{Ewes put to ram}} \times 100$$

Stillbirth rate and abortion rate (many causes of infectious abortion can result in stillbirths and weak lambs)
Losses at marking
Losses at weaning
Weaning policy, age, weight, amount of feed available

Special Examination of Flock to Decide Reproductive Efficiency at Lambing. The two recommended examinations are those for pregnancy diagnosis and those ewes not nursing lambs.

Observation of Flocks at Lambing. Differentiation between mismothering by ewes and lack of vigor in lambs as causes of death by starvation of lambs is important, but it can only be studied by the farmer through several observations of the flock during the day. Starvation from death or absence of the ewe or because of failure of lactation is usually clear-cut. The lambs, although still alive, are dejected, hunched up, gaunt, and hungry. In the United Kingdom demonstration of the empty abomasum by ultrasonography in lambs suffering from starvation has reinforced this problem area to farmers and shepherds in the lambing shed (Scott et al, 1997) without the need to undertake necropsies or laboratory measures to determine passive antibody transfer. Eventually, lambs suffering from starvation become comatose and hypothermic. Necropsy findings are confined to dehydration, loss of brown fat stores, and serous atrophy. Absence of perirenal and epicardial groove fat is indicative of starvation. Be aware that there may be milk in the abomasum if the lamb has been fed recently by esophageal feeder, but this milk will not have clotted and the remainder of the lower intestinal tract is empty.

When the cause of starvation is lack of vigor of the lamb, the signs and lesions of starvation are complicated by those of the primary cause, which may be infection (Scott and Gessert, 1996,b), dystocia, low birth weight, poor body fat stores, exposure to cold or heat, and congenital defects. They are accordingly more difficult to identify, and the only satisfactory way of identifying specific causes in lambs' dying of starvation is methodical observation and examination of the flock. When the cause of lack of vigor in lambs is undernutrition while in utero, it is necessary to identify this on the basis of low body weight at birth and an absence of placental lesions. The history of availability of feed and evidence of low BCS in the ewes is confirmatory evidence.

An accurate count of dead lambs is the only way to determine how many lambs have been lost. Ewes with twins may lose one and may not be noticed readily.

When a large number of lambs are dying over a short period, it requires some thought to devise a system of carrying out necropsy examinations in order to obtain significant results without prohibitive cost. First, it is necessary to conduct examinations to determine whether the lamb died of dystocia, hypothermia, starvation, predation, infection, or a new category that requires investigation. In other words, did the lamb die of a specific cause related to a proposed or existing control measure? Having categorized the death, it may be necessary to pursue a "new category" series of deaths to a more definite end. It is even more necessary, though, to examine a predetermined number of dead lambs to obtain a statistically meaningful result. This is not only a matter of numbers but a matter of selecting postmortem specimens in a random manner. It is easy to get a biased sample if it is left to the farmer to pick up the lambs selected for postmortem examination. If possible, the placentae should also be collected, because it is a better sample for evaluating for an infectious agent. When the farmer is bringing the lambs in, it is usually possible to have all of one day's pickup put into a waterproof bag and to bring the dated bags every third day. The bags must carry the date of pickup, information on weather, and so on.

A technique for a standardized postmortem examination has been described by McFarlane (1965, 1966) and is in general use. Its purpose is to establish whether the death was preparturient, parturient, or postparturient, and whether postparturient death was soon or late after birth.

The system depends on a number of critical "lesions" that suggest that particular lambs should be classified into one of 21 time categories relative to parturition. Thus lambs that have died intrauterine (e.g., preparturient deaths) show rapid autolysis of the subcapsular renal cortex. Postmortem discoloration and mummification occur at further time intervals. Parturient deaths are indicated by local edema of parts of the body jammed within the pelvis, in which circulation has been constricted; the lungs are aerated, and there is often hemorrhage from the liver. Postparturient deaths are divided into immediate, delayed, and late categories, and classification is made on the basis of aeration of lungs, the state of the umbilical artery, the degree of mobilization of body fat, the soles of the feet as an indication of whether the lamb has walked, and the presence of ingesta along the length of the gut. These findings are shown in Table 16-5. Severe cases of goiter are readily recognized at necropsy, but weighing the thyroid glands may be necessary to make a diagnosis in flocks in which hypothyroidism is suspected of being a contributory rather than a principal cause (Setchell et al, 1960).

Head Count of Ewes and Lambs at Marking (Docking). This provides an opportunity to segregate the lactating ewes from the ones that have not lambed. Ewes that have lambed, but have lost all their lambs, have enlarged udders containing secretions of various kinds, depending on when the lambs ceased to suck. Ewes that have not lambed have small, empty udders and no staining of the perineal wool. Detection of these ewes is greatly helped by a previous pregnancy diagnosis.

The valuable information that should be gained from a marking count includes marking percentage (e.g., of ewes bred), percentage of lambs to ewes present (the twinning index), and lambed ewes that have no lamb (loss of lambs from various causes).

FIG. 16-6 Record of events related to lamb deaths in commercial flocks. (Adapted from Eales FA, Small J, Gilmour JS: *Vet Rec* 118:227-230, 1986.)

Specific Environmental Causes of Lamb Deaths

Inclement Weather

Cold exposure resulting in hypothermia is a primary cause of lamb mortality when large numbers of lambs die during or soon after periods of low temperatures (lower than 5° C [41° F]) with wind and rain. The high mortality rates in newborn lambs resulting from the effects of cold exposure and starvation occur because many of these lambs are born during the late winter and early spring, when adverse conditions are most likely to occur. This is particularly true in the northern United States, Canada, and the United Kingdom (Eales and Small, 1986). Lambs are often born outdoors in unprotected pens designed to accommodate large numbers of ewes. Cold stressed lambs often become hypothermic because of excessive heat loss from exposure to inclement weather and poor heat production caused by either hypoxia during the birth process or starvation. Factors that further increase the susceptibility of lambs to hypothermia include poor mothering instincts of the dam; lambs from ewes in poor condition, from young or aged ewes, from multiple births, or from dystocias; and those with small birth weight and born prematurely. Breed differences, length of birth coat, wetting of the birth coat, and exposure to wind are additional factors that influence the susceptibility of newborn lambs to cold exposure. Cold-induced changes in lambs include physical weakness, depression, and poor nursing re-

*Thrombosis of umbilical artery indicates that lamb has survived birth process.
†Aerated state of lungs indicates that lamb has breathed.
‡Wear on soft sole of foot indicates that lamb has walked.
§Milk in the intestine and milk fat in the lymphatics of the gut indicate that the lamb has sucked.
‖Catabolism of the body fat (not white as normal, but yellow-brown gelatinous material) indicates lamb has mobilized fat to convert energy and suggests that nutritional stress has occurred.

sponse. The mortality rate was 40% in cold-stressed lambs and 10% in lambs kept at warmer temperatures (Olson et al, 1987).

Experimentally, wetness is the single most important factor determining whether lambs become hypothermic (McCutcheon et al, 1983a,b). Wet lambs suffer a reduction in coat insulation, primarily as a result of reduced coat depth, but this effect is small compared with the increase in evaporative heat loss that occurs as a result of wetting (McCutcheon et al, 1983a,b). Lambs exposed to experimental air movement from a fan produced more body heat than those in still air, and differences in resistance to cold stress between single and twin lambs were largely caused by the corresponding differences in body weight and coat depth.

In newborn lambs, as in piglets and infants, carbohydrate and lipids are the major energy substrates for heat production because protein catabolism is minimal during the first day after birth (Mellor and Cockburn, 1986). Liver glycogen concentrations increase markedly during the last few days before normal parturition. The amount of liver and skeletal muscle glycogen available in the newborn lamb at birth determines how long it can avoid hypoglycemia and hypothermia if not fed. The amount of lipid present in the newborn lamb can also affect the duration of the glycogen reserves. In growth-retarded lambs—either the result of poor placental function or inadequate late gestation dam nutrition—lipid availability is decreased and glycogen exhaustion occurs earlier than normal. Such lambs are highly susceptible to hypothermia that can be minimized by the early ingestion of colostrum, which is rich in lipid and extends the availability of glycogen.

Deaths from cold exposure are the result of excessive body cooling because of low temperatures, driving winds, and starvation. The starvation results indirectly either from poor mothering by the ewe or because the lamb is weak as a result of poor antepartum nutrition. At necropsy, the findings are not remarkable but are diagnostic. The lambs may have sucked, but there is little digestion, and the intestine on the recumbent side is flaccid. There are also subcutaneous hemorrhages of the limbs and depletion of brown fat stores. The weather history preceding the deaths is an important indicator.

The relative importance of environmental and maternal factors with regard to neonatal mortality is not easy to determine. The preponderance of evidence supports the view that inclement weather kills many lambs, probably more than would otherwise die. Those lambs that are susceptible have reduced vigor resulting from either poor preceding nutrition or poor mothering ability of the dam (Alexander and Peterson, 1961; Alexander 1962, 1964; Alexander et al, 1979). The vigor of the lamb, principally manifested as "sucking drive," is reduced by lack of reward, so that a vicious cycle is created if the ewe does not stand. Vigor is also greatly reduced by cold discomfort, giving inclement weather two points at which it influences lamb survival rates (Alexander and Williams, 1966). The lamb dies of hypothermia and inanition.

Nutritional Inadequacies

General Inanition. A total lack of colostrum and milk intake most commonly results because of inadequate nutrition of the pregnant ewe, but other factors including severe weather, too much human intervention at lambing time in nervous ewes, or lack of vigor of the lamb may be variably involved. Normal lambs are born with sufficient nutritional reserves to last for 1 to 4 days, so that deaths from starvation occur after this period. The starvation may be primary or secondary. Primary starvation results from absence of the

milk supply. Secondary starvation occurs when the lamb lacks sucking vigor because of another primary cause, including mismothering by the ewe, damage to the teats or udder (Hayman et al, 1955), and poor nutrition of the ewe (Bareham, 1976). Some aspects of poor mothering can be overcome by confining ewes and her lamb(s) in individual pens, which are widely used in North America and the United Kingdom.

The nutrition of the ewe, inasmuch as it determines her body condition and milk flow, has a considerable effect on her mothering tendency and energy supply to the lamb.

Another way in which nutrition of the ewe exerts its influence on lamb survival is through improved nutrition of the fetal lamb and its greater size and strength at birth (Khalaf et al, 1979). Overfeeding can also be harmful in that lambs are overweight and may develop dystocia, but this situation is unusual in prolific flocks. The widespread use of ultrasonography to determine fetal number during midgestation has resulted in more appropriate nutrition during late gestation, and absolute fetal oversize is an uncommon problem in most flocks. As a general guide, it is recommended that ewes should maintain their own body condition in late pregnancy and at the same time gain 15 to 20 lb in the 6 weeks before lambing. More accurate feeding strategies have been described (Russel, 1985) based on certain blood metabolites.

Later on in the lamb's life, nutrition of the ewe exerts still another effect. High-plane nutrition of the ewe leads to a high milk yield and the maintenance of a strong ewe-lamb bond. Ewes on a low plane of nutrition tend to reach the threshold milk yield, which leads to voluntary weaning much earlier. The growth rate of lambs and even their survival may be affected at this point (Arnold et al, 1978).

Specific Nutritional Deficiencies. Common deficiencies include iodine-deficient goitre, nutritional muscular dystrophy caused by selenium and vitamin E deficiencies, and congenital swayback and enzootic ataxia, caused by copper deficiency. White muscle disease can develop in utero (Hamliri et al, 1990). Cobalt deficiency in ewes may influence the growth rate of their lambs (Quirk and Norton, 1987; Fisher, 1990). Outbreaks of hypocalcemia can occur in late pregnant ewes that are fed a diet deficient in calcium and energy (Sweeney and Cudderford, 1987).

Orally Ingested Poisons

Plant poisons include *Veratrum californicum*, which causes brain defects and prolonged gestation, and *Astragalus* and *Oxytropis* sp., which cause limb contractures. *Brassica* sp. can be goitrogenic.

Infectious Diseases Causing Neonatal Lamb Mortality

Infectious diseases causing lamb mortality can be the result of congenitally acquired infections, such as *T. gondii*, *Chlamydia psittaci*, border disease virus, and *Listeria monocytogenes*. The bluetongue virus can cause hydranencephaly, prolonged gestation, and stillborn or weak lambs.

Postnatal infections include those found in Box 16-12.

In sheep, much more so than in cattle, the infections that cause abortion also cause fetal and neonatal deaths. They are more accurately identified as fetal-neonatal syndromes (Dennis, 1972b; Hartley, 1968).

The prevalence of neonatal infections varies. In New Zealand, up to 30% of total deaths, and in Scotland (Watt, 1980) 18% of total deaths, are attributed to infectious disease. Remember, however, that many shepherds in the United Kingdom routinely administer an oral antibiotic to lambs within the first 15 minutes of life to prevent watery mouth disease, as recommended (Eales et al, 1985). In Australia, a similar level of such infections—up to 30% of total lamb deaths—has been reported (Hartley and Boyes, 1964; Hughes et al, 1964; Haughey et al, 1967). In general, the tendency is to make little of the role of neonatal infections in causing lamb mortalities, because the mortality rate in flocks caused by these infections is often as low as 1%. This happens often, especially in merino flocks; more obvious reasons for lamb mortalities, such as deleterious climate and nutrition, are usually readily available.

Laboratory culture of every lamb in an investigation is neither possible nor advised. The recommended alternative is to culture from those carcasses that show lesions suggestive of congenital infection. These include subcutaneous tissue, usually blood-tinged, excess fluid and fibrin in body cavities, hepatomegaly, focal hepatic lesions, intestinal hyperemia, enlarged mesenteric lymph nodes, and bright yellow meconium.

The incidence of late postparturient deaths (1 to 4 weeks of age) in lambs is usually low, about 1.6% of all dead lambs (Hughes et al, 1971). In terms of late postparturient deaths, the infections represented only 3.3%. A much higher incidence is frequently reported, and the result largely depends on local conditions and the size of the sample. The infections recorded include the common pathogens of *Chlamydia*, *P. haemolytica*, *Fusobacterium necrophorum*, and *Clostridium* sp., but without emphasis on any particular agent. *B. ovis* has been identified as causing abortion in some sheep flocks and is suspected as a cause of perinatal lamb deaths through congenital infections in others (Haughey et al, 1968). Tetanus is one of the more common infections but is much less common now when routine vaccination is used. In lambs at pasture, especially under intensive management systems on lush pasture or creep grain-fed lambs, enterotoxemia caused by *C. perfringens* type D (pulpy kidney) may occur in outbreak form and routine vaccination of ewes before lambing is essential. When outbreaks of the disease occur in unvaccinated grain-fed lambs, the administration

BOX 16-12

Postnatal Infections

Septicemias: *Escherichia coli*, *Listeria monocytogenes*, *Salmonella* sp., *Pasteurella haemolytica*
Bacteremias with localization in joints, endocardium, and eyes caused by streptococci, especially *Streptococcus dysgalactiae*,* staphylococci, *Erysipelothrix rhusiopathiae*
Navel infections with a mixed bacterial flora
Diarrhea with dehydration: colibacillosis, rotavirus infection, and *Cryptosporidia parvum*
Pneumonia caused by *P. haemolytica*
Toxemias: gas gangrene of the navel, crow-picked eye† caused by *Clostridium septicum* or *Clostridium oedematiens*, lamb dysentery caused by *Clostridium perfringens* type B
Watery mouth disease‡ commonly associated with *E. coli* endotoxemia

of antitoxin may be indicated along with removal from grain for several days. Contagious ecthyma (Orf, contagious pustular dermatitis) may occur in unweaned lambs, especially when they are artificially reared. Vaccination provides variable protection and may cause widespread dissemination of the live virus, thereby worsening the situation.

Necropsy lesions that suggest postnatal infection are omphaloperitonitis; focal suppurative lesions in any solid viscera or skeleton; and pneumonia, arthritis, and enteritis. The specific infection with *C. perfringens* type B (lamb dysentery) characterized by a hemorrhagic enteritis is now uncommon because of routine vaccination. Clostridial infections of navels, predator-inflicted wounds, and docking wounds are also uncommon because of the awareness by farmers of the need for hygiene or prophylactic treatment at these times.

The clinical picture associated with neonatal infections, whether prenatal or postnatal, is likely to include a range of septicemia with sudden death or navel-ill accompanied by one or all of the following: meningitis, arthritis, endocarditis, and panophthalmitis. The most common is arthritis, either suppurative and caused by streptococcal or staphylococcal infections, or nonsuppurative and caused by *Erysipelothrix insidiosa*. These diseases are amenable to early and aggressive antibiotic treatment, but the prognosis is guarded if the condition has not been detected for 2 or more days. Hygiene at lambing to avoid umbilical infection and sterilization of instruments at tail docking and castration are appropriate preventive measures but rarely eliminate the problem. Recent studies (Watkins and Sharp, 1998) question whether the umbilicus is the primary portal of entry for *Streptococcus dysgalactiae* whereby only 16% of lambs with arthritis had omphalitis. Similarly, in lambs with meningitis the umbilicus was considered an unlikely portal of infection (Scott et al, 1994).

As in other species, there is a relationship among poor husbandry, failure of passive antibody transfer, and a high level of neonatal infection (Ducker and Fraser, 1973). Poor mothering by the ewe or interference with mothering by too much human intervention can predispose to neonatal infection by delaying passive antibody transfer.

Blowfly strike of navels or castration wounds can occur but are uncommon, because it is not usual to perform these operations during a dangerous period. In merinos it is a more common practice to carry out the Mules operation when docking and castrating, and the usual recommendations about hygiene to prevent infection through these wounds should be instituted. The welfare implications of this mutilation require urgent review.

Predation

Predatory birds and animals are responsible for much postmortem mutilation of carcasses and for some deaths of lambs weakened by other influences. Under extensive conditions, a wide range of animals and birds, including eagles, ravens, foxes, and feral pigs, are considered to cause significant losses (Smith, 1965a). In Australia, crows are a significant cause of loss, but their significance is much less than that of foxes; feral pigs are the worst of all, being capable of killing 80% of lambs born (Plant et al, 1978). In the United States (Dennis, 1980; Green and Woodruff, 1983/1984), more than 8% of all lambs born may die because of predation. Most deaths are caused by coyotes, which are credited with 93% of losses. The methods used for predator control included electric fencing, housing in barn at night, hunt predators, and guard dogs. The use of guard dogs to protect sheep from coyotes has been effective (Green and Woodruff, 1983/1984).

Determination that predatory injuries have occurred antemortem depends on the presence of hemorrhage in the region of the injury. Tissue disruption and broken bones may occur antemortem or postmortem. There may be mutilation, but hemorrhage is not present when the damage occurs after death. Deaths in this group should be classified as predation killing of a healthy animal or mutilation by a scavenger when the subject is ill or dead when first attacked.

Some information about the identity of the predator may be deduced from an inspection of the cadaver. Foxes and coyotes bite the neck, head, and face of lambs, causing extensive hemorrhage in the area and often crushing or tearing open the larynx. Death occurs as a result of suffocation or hemorrhage. Fang marks through the skin are accompanied by teeth marks, often more visible on the inside of the skin. Coyotes may eat part of the carcass, a hind leg of an older lamb, or the internal organs, heart, liver, and abomasum full of the milk of newborn lambs. Foxes favor the tongue, lower jaw, tail, and thigh. Dogs, which usually hunt in pairs, do not kill for food, and many lambs or sheep may be killed or mortally wounded in one attack. There are usually many bites anywhere on the body. Older sheep are torn about the flanks and thighs. Lambs are often crushed and the limbs stripped of flesh. Crows are poorly equipped to predate and are restricted to gaining access to the interior through the natural opening of an animal already attacked by another predator or already ill from another disease. Common targets are the tongue, eyes, anus, and umbilicus. Eagles and other avian predators and scavengers have the same predilection for tongues and eyes. Eagles usually leave talon marks along the back of a predated lamb.

Specific Ewe Causes

Breed of Sheep

The breed of sheep has an effect on the survival rate of lambs (Wiener et al, 1983). There are also apparent differences among families. The differences among strains of sheep within a breed, however, have not been shown to be significant (Lax and Turner, 1965; Arnold and Morgan, 1975). Among breeds, merinos are notoriously poor mothers, especially young ewes. Desertion of lambs at birth is common, and the lambs die of starvation. There is a great deal of difference in mothering traits among ewes, and ewes that are poor mothers often respond poorly to intensive lambing techniques (Hancock, 1996). Selection of the breed of sheep also determines the rate of twinning, and, because twins are much more sensitive to environmental insults in early life than singles, they are likely to have a much higher mortality rate. Selection for twinning, especially in merinos, should not be attempted unless intensive lambing facilities are available. The lower average birth rate of twins probably contributes to this higher mortality rate. Certainly, high- and low-weight singles have less chance of survival than those in the median zone (Purser and Young, 1964). The breeds of sheep that are good mothers include the Scottish Blackface, Charollais, Texel, Dorsets, Arcotts, Finnsheep, and Polyday and hybrid ewes.

Age of Ewe

There is a significantly higher survival rate in lambs from middle-aged merino ewes than those from either 2- or 7-year-old merino ewes. In part, this is the result of the better milk supply and mothering instincts of the middle-aged ewe, but there are other factors, such as the higher birth weights of the lambs, that favor the lamb of the middle-aged ewe. Deaths in lambs from young ewes is likely to be caused by dystocia, whereas in old ewes, death is more likely to be from starvation. Similar findings have been recorded for Norwegian sheep (Lutnaes, 1982).

Dystocia

The literature on the causes of dystocia in sheep is sparse and somewhat contradictory. Some early studies indicated that most cases of dystocia in ewes are caused by absolute fetal oversize exacerbated by overnutrition, but it was also considered genetically disposed by the presence of large heads, as in Dorset Horns, Southdowns (Dennis, 1970), and Romneys (Hartley and Kater, 1964). Some studies have indicated that the proportion of dystocias is 70% in Southdowns, 28% in Marshall Romneys, and as low as 4% in fine-wooled merinos (George, 1975). Correspondingly, the percentage of neonatal deaths that result from dystocia is lower (10% of all neonatal mortality) in merinos than for crossbreds (10% to 34%) and Dorset Horns (36%) (George, 1976). A recent study (Safir, 1991) reported only 0.5% of lamb losses attributable to dystocia in a flock with continuous supervision.

A large-scale farm-based survey by Gunn (1968) revealed an overall incidence of dystocia of 3.1% in 15,584 ewes from Scottish hill flocks. In that survey, 65% of assisted births involved postural abnormalities of the lambs, of which 42% involved the head only, 29% the head and one leg, 17% breech presentation, and 6% the forelegs only. Ellis (1958) reported similar results. In a survey of the causes of dystocia in sheep in western Wales, incomplete dilatation of the cervix (ring womb) was the most common primary cause, accounting for 26.8% of cases (Thomas, 1990). In this survey, ring womb had no breed, age, or condition score predisposition, but it was associated with a higher lambing percentage (ewes with ring womb produced 1.94 lambs/birth compared with the overall average of 1.67 lambs/birth). Many of the cases of ring womb were associated with simultaneous presentation of more than one lamb, thus altering the distribution of pressure on the cervix and probably influencing dilatation. Postural abnormalities (head deviation, flexed foreleg posture, breech presentation, and flexed hock posture) accounted for a total of 34.5% of the cases of dystocia. Fetomaternal disproportion accounted for only 3.0% of the dystocia cases, and the average BCS of the ewes with this dystocia was 3.4 compared with the overall average of 2.7. All cases of fetomaternal disproportion involved the birth of single lambs, with a significantly greater number in primiparous ewes. Fetomaternal disproportion was concluded to be essentially a management problem resulting from improper ram selection, especially with regard to primiparous ewes (Thomas, 1990).

The factors contributing to improved lamb survival in Marshall Romney sheep were identified and quantified over a period of 3 years in a flock of Marshall Romneys compared with a control flock of Romney sheep (Knight et al, 1988). The aim of the experiment was to identify major differences in the causes of lamb mortality and to determine the contributions of lamb birth weight and shape, ewe behavior, pelvic area, ram and ewe hemoglobin type, and gestation length to the differences in lamb survival (Knight et al, 1988). Marshall Romney ewes have been selected for many years for their ability to survive, to lamb unassisted, and to rear lambs with minimal shepherding under hard hill conditions (Knight et al, 1988). The factors that contributed to an increased survival rate in Marshall Romney sheep included a lower incidence of periparturient deaths from dystocia, of deaths from infections, and of starvation (Knight et al, 1988). The increased lamb survival in a Marshall Romney flock can result from contributions from both the ewe and the ram. More Marshall Romney ewes rear a lamb and more twin-bearing Marshall Romney ewes rear both lambs compared with control Romney ewes (Knight et al, 1988). The improved survival was also the result of a greater maternal pelvic opening and better maternal behavior in Marshall Romney sheep than the Romney breed. The optimum birth weight for survival was 4.6 kg, but skeletal size and shape influenced lamb survival independently of birth weight. The Marshall Romney ewes selected more sheltered lambing sites and had a stronger maternal bond, which was indicated by their response to the shepherd during tagging of the lambs. Ewes that stayed close to their lambs while they were tagged had a higher lamb survival, which is similar to observations in other genotypes.

In the long term, the positive approach to reducing the losses caused by dystocia depends on genetic selection against small pelvic diameters and large lambs or lamb heads. These criteria have been used effectively in a culling program to reduce greatly the occurrence of dystocia in Romney Marsh sheep (McSporran et al, 1977). In Dorset Horns (Fogarty and Thompson, 1974) a close relationship between pelvic size and dystocia has been observed, and in Australia a relationship between fetal size and dystocia has been observed in fine-wooled merinos and Cheviots (Whitelaw and Watchorn, 1975; Smith, 1977). If the pelvis is measured as an aid to selection, it is the internal measurement that is of importance; the external measurement is not a reliable guide (McSporran et al, 1979). However, the size of the fetus is also important, and there is little value in predicting the ease of lambing using only maternal pelvic size (Silva and Noakes, 1984). Death is usually the result of asphyxia, but this may also occur in births of long duration without obvious obstructions. Severe hypoxia during birth leads to a metabolic acidosis and depressed heat production capacity (Eales and Small, 1985). Occasionally, death is caused by rupture of the liver (Johnston and McLachlan, 1986).

Lambs dead of dystocia are characterized by localized edema of the head, tongue, and forelimbs in anterior presentations and of the perineum and tail in posterior or breech presentations (Hartley and Kater, 1964; Wilsmore, 1989). Lambs that survive a difficult birth may die subsequently of starvation because of poor mothering by the ewe. Others may die of injury incurred during parturition, including intracranial hemorrhage (Haughey, 1973). The injury to the central nervous system appears to be the critical factor rather than an indirect effect on food intake (Duff et al, 1982).

Mothering Capability

The mothering ability of the ewe, especially under breeds of sheep, has been discussed earlier. There are some other management points. Lambs are not discriminatory and suck any ewe. However, ewes are discriminatory and vary in their selectivity. Some ewes before lambing are receptive and actually search out and steal lambs from other ewes. Others are antagonistic to their lambs and desert them readily. This mothering trait may be innate and inherited. It may be interfered with by managerial factors such as too much human interference, prolonged parturition including dystocia, poor milk supply, and poor vigor of the lamb. The teat-seeking activities of lambs are subject to the same sorts of influences and may be absent or weak at birth. In normal lambs, there is a high level of teat-seeking activity at birth, but this declines rapidly to about 10% at 12 hours of age. It declines when the lamb is starved and when the weather is cold and the lamb is hypothermic, especially in the first few hours of life. Maternal behavior is likely to be interfered with by flocking behavior, in which the ewe tends to move to the rest of the flock rather than to her lamb. This tendency is likely to increase as the lamb gets older.

Udder Health, Milk Production, and Mastitis

At weaning and at birth, the udders of ewes should be examined to ensure that both glands are functional and the teat canals are patent. Significant losses can occur in ewes with teats damaged during shearing and glands destroyed by *Corynebacterium pseudotuberculosis* (Hayman et al, 1955), and in ewes with fibrosed udders (Kirk et al, 1980).

Mastitis is an economically important disease for sheep producers because of premature culling of ewes with udder abnormalities and of reduced growth rate and survival of lambs nursing ewes with mastitis (Hueston et al, 1989). The prevalence of defective udders may be as high as 12% in abattoir surveys of cull ewes (Madel, 1981) but the udder-teat lesions may have been the reason for premature culling. The most important variable affecting lamb growth is the milk yield of the ewe; the variation in milk yield can account for 56% of the variation in lamb growth rate (Jordan and Mayer, 1989). Surveys of ewes from 4 to 6 weeks after lambing revealed a prevalence of intramammary infection of 14% of ewes and 8% of glands (Watson et al, 1990). The prevalence is positively correlated with age; 2- and 6-year-old ewes had, respectively, 4.4% and 14.0% of glands infected. *S. aureus* was responsible for 40% of all intramammary infections (Watson et al, 1990). *P. haemolytica* is also an important cause of mastitis in sheep. Udder damage from mastitis can cause a decrease in milk yield to below the 500 ml/day considered necessary for adequate survival rates in lambs (Jordan and Mayer, 1989). Lamb growth rates during the first month after lambing can be reduced by as much as 20% by udder damage.

Infection of sheep flocks with the maedi-visna virus may be associated with a chronic indurative mastitis, which leads to suboptimum growth rates of lambs during the preweaning period (Van der Molen et al, 1985). Sheep flocks with a high prevalence of viral infection based on serological testing have a much higher incidence of indurated udders in the ewes and insufficient growth in their lambs than flocks that are seronegative for the virus (Van der Molen et al, 1985). The lesions of the udders of sheep from infected flocks are characterized by chronic interstitial indurative mastitis with abundant lymphoid proliferation.

The level of nutrition of ewes during late pregnancy and lactation influences lamb survival and growth rates of lambs (Jordan and Mayer, 1989). Ewes fed three levels of nutrition—110%, 90%, and 70% of maintenance requirements during the prenatal and postnatal periods—had daily milk yields of 1146, 1070, and 938 ml/day, with lamb growth rates of 178, 169, and 138 g/day, respectively. The live weights of the lambs at 4 to 6 weeks of age were 10.2, 9.6, and 8.6 kg, respectively. Lamb survival rates from ewes fed at 110%, 90%, and 70% of requirements were 89%, 75%, and 73%, respectively (Jordan and Mayer, 1989).

Subclinical mastitis in ewes leads to a marked decrease in the milk yield and decreases the growth rate of lambs between the 5th and 20th days after lambing, when they are highly dependent on milk (Fthenakis and Jones, 1990). Routine palpation of the udder at lambing, weaning, and breeding by a careful shepherd can be a useful screening procedure to detect gross abnormalities of the udders of ewes, which may warrant culling because they are unlikely to provide sufficient milk at the next lactation (Watson and Buswell, 1984). Intramammary infusion of affected udders with sodium cloxacillin at weaning may reduce the incidence of palpable lesions by breeding time. Similarly, subcutaneous injection of tilmicosin at weaning helps eliminate subclinical mastitis and prevent postweaning mastitis (Smith and Tice, 1996). Intramammary infusion of ewes with cephapirin benzathine at the end of lactation can reduce the incidence of new infections early in the next lactation and can reduce the persistence of existing infections (Hueston et al, 1989).

Acute and subacute mastitis are problems in sheep dairy enterprises. The literature on udder health and on the clinical and epidemiological aspects of mastitis, including control of the disease in sheep dairies, has been reviewed (Dawe, 1990; Philbey, 1990).

Specific Lamb Causes

A number of characteristics of lambs are associated with their increased susceptibility to disease.

Congenital Defects

The frequency of defects in newborn lambs appears to be much less than in cattle, and they are not usually recognized as a cause of significant mortality (e.g., an American survey recorded 9 of 36 listed inherited defects in 21,000 Rambouillet lambs born over a 15-year period) (Ercanbrack and Price, 1971). Another estimate was 2% congenital defects for lambs compared with 0.5% to 3% for calves (Hughes, 1972). However, higher figures have also been quoted (Priester et al, 1970). The nature, cause, and diagnosis of congenital defects in lambs have been reviewed (Dennis and Leipold, 1979).

Inherited Defects

The known or strongly suspected inherited defects are shown in Box 16-13.

The diseases against which control programs have been mounted are corticocerebellar atrophy, photosensitization, spider lamb syndrome, and entropion. Selection against the defect can be practiced, but the selection pressure for profitable traits is likely to be high. Accordingly, there is great difficulty in conducting a genetic control program in a single flock. On the other hand, participation in a group breeding scheme (see the later "Genetic Management" section) may make the program feasible.

Sporadic and Environmental Congenital Defects and Infections

The defects known to result from the effects of noxious items in the environment are shown in Box 16-14.

There is a long list of sporadic defects in sheep. These have been presented for New Zealand (Hartley and Kater, 1964) and Australian merinos (Dennis, 1965).

Twinning

Although the mortality among twins is higher than among singles, the difference may be obvious only under extensive conditions, if the general mortality rate is already high. There is also a behavior problem, especially with merino ewes, which are inclined to walk away from one of a pair of twins, especially if it lacks vigor for some reason. However, many of the separations and subsequent deaths from starvation are in robust lambs (Stevens et al, 1982).

Surgical Procedures

Given the absence of the rare disaster at castration, this operation does not significantly alter the survival rate. Excessive blood loss is rare in young animals, even with knife castration and tail docking. Internal bleeding, when the spermatic cords are removed by traction rather than being severed with a knife, can occur; it makes a dramatic postmortem picture,

BOX 16-13

Inherited Defects

Hereditary chondrodysplasia (spider lamb syndrome) in the Suffolk and Hampshire breeds (Rook et al, 1988)
Cerebellar abiotrophy (Scott et al, 1994)
Corticocerebellar atrophy (Stamp, 1967)
Clinically similar disease in border Leicesters characterized by lesions in neck muscles
Inherited goiter in merinos and possibly Polled Dorsets
Ceroid lipofuscinosis in South Hampshires
Generalized glycogenolysis of Corriedales
Globoid cell leukodystrophy of Polled Dorsets
Multiple tendon contracture in merinos
Osteogenesis imperfecta
Mandibular underdevelopment of merinos and Rambouillets
Epidermolysis bullosa in Suffolks and South Dorset Downs
Dermatosparaxia in merinos
Bilateral lip cleavage in Texels
Redfoot in Scottish Blackface
Inherited photosensitization in Corriedales and Southdowns
Atresia of gut segments
Entropion in several British breeds of fat sheep
Prolonged gestation and fetal giantism in Karakuls (also caused by poisoning with *Veratrum californicum* or *Salsola tuberculata*)
Hairy birth coat*
Cryptorchidism (Claxton and Yeates, 1972)
Scrotal anomalies*
Crooked legs*
Ventricular septal defect in Southdowns (Dennis, 1970)

*Genetic controllability has been reported.

BOX 16-14

Defects Resulting from Noxious Elements in the Environment

Hairy shakers or border disease caused by a virus
Congenital toxoplasmosis*
Brain deformity (porencephaly) caused by bluetongue virus
Arthrogryposis and hydrencephaly caused by Akabane virus infection
White muscle disease caused by vitamin E-selenium deficiency in the diet
Poisoning by weeds in pasture (e.g., *Veratrum californicum*, *Astragalus* and *Oxytropis* sp., *Lupinus sericeus*)
Poisoning by farm chemicals, especially parbendazole and cambendazole
Experimentally by high environmental temperatures
Enzootic ataxia (swayback) caused by copper deficiency in the diet
Goiter caused by a deficiency of iodine in the water supply or goitrogenic plants

but the overall importance of these losses is small. Strong rubber rings (elastrators) are commonly used for docking and castration and to avoid blood loss, but their use can lead to tetanus in unvaccinated flocks. The behavioral and cortisol responses of lambs to tail docking and castration during the first week after birth have been examined (Mellor and Murray, 1989).

Health Management to Optimize Perinatal Survival of Lambs

Principles of Preventing Neonatal Lambing Losses

An overall control program to suit all circumstances is difficult to propose because the relative importance of the causative factors varies so much from place to place, from farm to farm, and even within one farm from year to year. The management system may be intensive, indoors, or extensive, and the amount of care and the nature of the husbandry can vary considerably. However, the principles are similar. The major requirements for a high survival rate are birth weight near the optimum for the breed, good accumulation of protective immunoglobulins in the udder, easy birth, protection from cold, and maximum contact between ewes and lambs during the first 12 hours after birth to ensure adequate passive antibody transfer and development of the maternal bond. Almost all lambs survive if given adequate obstetric assistance, warmth, and food (Alexander, 1984); however, infectious diseases are not controlled so readily in intensive systems (Eales et al, 1985; Scott and Gessert, 1996b). In general terms, a program should at least give consideration to each of the following.

Close Supervision of Lambing. This can detect ewes with dystocia early during second stage labor and can provide assistance with the birth. This principle can be practiced by close examination of the ewes at pasture three times a day, by continuous supervision of groups of ewes indoors, or by any variation between these management practices. The farmer must be instructed in the technique of providing aseptic assistance with parturition where the introduction of disposable arm-length plastic gloves has proved very beneficial. The ewe's teats should be examined immediately after birth of the lambs to ensure that colostrum is present and that the teats are patent and not plugged with teat plugs. In indoor lambing sheds, it is empirically recommended that the navels of all lambs should be dipped in a tincture of iodine solution as soon after birth as possible and again 4 to 6 hours later. When this procedure is correctly undertaken, the umbilical remnant is dry and brittle by 36 hours old and provides an easy method for monitoring routine preventive measures on the farm.

Close Supervision of Ewe and Lamb Immediately After Birth. This helps ensure proper mothering. The amount of activity required varies with the mothering tendency of the ewe. The objective is to ensure that the lamb receives an adequate amount of colostrum in the first few hours after birth and then receives sufficient energy to maintain it through the sensitive first few days when it is susceptible to hypoglycemia. Lambs require 180 to 210 ml/kg body weight of colostrum during the first 18 hours after birth in order to provide sufficient energy for heat production and enough immunoglobulins (Mellor and Murray, 1986). Ewes that are well fed during late pregnancy produce more colostrum than their lambs need; those with singletons have

enough for a second lamb, but, in most underfed ewes, the lamb's requirements for colostrum exceed the ewe's production. Colostrum can be readily obtained and stored for subsequent use. Bovine colostrum is a good alternative source of immunoglobulin for lambs (Eales et al, 1982b). However, in some cases severe anemia occurs in lambs fed bovine colostrum because of the presence of immune complexes on lamb erythrocytes (Bernadina and Franken, 1985), but such cases are numerically unimportant compared with losses resulting from starvation and exposure. The risk from bovine colostrum-induced anemia can be reduced significantly by pooling colostrum from four or more cows and freezing aliquots for subsequent use.

In temperate areas where winter housing is practiced, ewes are confined to pens or buildings to provide protection from the environment. However, crowded conditions can sometimes lead to poor maternal behavior and lack of a ewe-lamb bond early enough. Ewes lambing in crowded conditions are often unable to isolate themselves from the flock and may be interfered with by other ewes, or their lambs may become separated and be deserted (Gonyou and Stookey, 1985). Under such intensive lambing environments ewes are confined in pens 1.3 × 1.3 m with their lambs for the first 24 to 36 hours to promote a good ewe-lamb bond.

There is a strong bond between mother and young in sheep, and it is usual for ewes to repel strange lambs once the bond with a newborn lamb has formed, within the first few hours after life (Gonyou, 1983/1984). As a result, lambs are normally fed exclusively by their dams, which is an obstacle to fostering orphan lambs or lambs born as multiples that are not being reared successfully by their dams. Fostering techniques have included ewe restraint, own-lamb odor transfer, and odor-masking agents (Alexander et al, 1987; Basiouni and Gonyou, 1988).

The fostering of alien lambs onto ewes can be facilitated by the use of restraint devices in pens 1.2 × 1.2 m, initiated 2 to 3 days after parturition and followed by a period of unrestrained cohabitation as a pair and subsequent exposure to groups of females (Price et al, 1984; Martin et al, 1987).

Odor specific to individual lambs enables ewes to discriminate between their own and alien lambs (Alexander and Stevens, 1982b). Many postpartum ewes adopt a single alien lamb in addition to their own if the alien lamb is wearing a jacket impregnated with own-lamb odor. Maternal acceptance of alien lambs is facilitated when own-lamb odor is transferred to alien young through the pelt of a dead lamb or on cloth jackets previously worn by the ewe's own offspring (Holmes et al, 1989). The transfer of odor from own to alien lambs with a cloth or hessian jacket leads to a relatively high acceptance rate of more than 90% when substituting a single alien lamb for a natural lamb (Alexander et al, 1985). Adoption rates are lower, about 70%, in "add-on" fostering, a procedure in which an alien lamb is placed in the care of a ewe in addition to her own single lamb (Alexander et al, 1985). Ewes bearing single lambs tend to accept only one lamb, whether or not odor transfer fostering techniques are used (Holmes et al, 1989). The use of nonspecific, strong-smelling substances to mask the odor of alien lambs is not successful (Alexander and Stevens, 1982a).

Fostering can be facilitated by the use of jackets soaked in birth fluids and by cervical stimulation (Basiouni and Gonyou, 1988). The use of washing of lambs combined with close confinement appears to be an effective method of fostering lambs onto ewes, especially within the first day or two after birth (Alexander et al, 1983). The traditional shepherd's method of draping the skin of the dead lamb over the foster lamb is almost 100% effective (Alexander et al, 1987).

It is important to avoid excessive, officious interference, especially with merino ewes and particularly with maiden ewes. A heavy-handed, bustling attentiveness may cause more disturbance of mothering than it prevents.

Provide Protection from Inclement Weather. This can be done by lambing in clement weather or by shedding or using other protective wind baffles. These include leaving rows of hay bales arranged to give shelter from prevailing winds and cutting swathes through a standing cereal crop or overgrown pasture (Egan et al, 1976). The provision of windbreaks around the edges of large paddocks has little value; the ewes and lambs are too far away to be protected. In effect, they need to get in among the protective material. In very hot climates the two critical needs are proximity to water and overhead shelter from the sun. Shedding may be performed in the shearing shed or in a shelter constructed especially for the purpose. The latter has obvious advantages, especially if the shed can be put to other uses in the lambing off season.

A system for the detection and treatment of hypothermia in newborn lambs can improve the survival rate (Eales et al, 1984; Eales et al, 1982c). Most lambs become hypothermic within 5 hours or at more than 12 hours after birth. Hypothermia in the first 5 hours of life is most commonly caused by a high rate of heat loss from the wet newborn lamb, whereas a depressed rate of heat production consequent to starvation is the most common cause in the older lamb. Twin and triplet lambs are more susceptible to hypothermia than singles because of lower body energy reserves; the ewe takes longer to lick dry two or three lambs, and the milk requirement of two or three lambs is higher than that of a single lamb and starvation is more likely.

The body temperature of any weak or suspect lamb is taken with an electronic thermometer (Eales et al, 1984). Lambs of any age with mild hypothermia (37° to 39° C [99° to 102° F]) (Table 16-6) are dried off if necessary to reduce heat loss, given ewe or cow colostrum by stomach tube, and placed in a sheltered pen with the ewe. Lambs less than 5 hours of age with severe hypothermia, lower than 37° C, are dried off and given an intraperitoneal injection of 20% glucose at a temperature of 39° C. A large lamb (more than 4.5 kg) is given 50 ml, a medium lamb (3 to 4.5 kg), 35 ml, and a lamb less than 3 kg, 25 ml. Hypothermic lambs are then placed in warming pens measuring 2 × 2 m made of horizontally laid straw bales, two bales high. The pen is divided into two chambers by a sheet of weld mesh on which the lambs lie. Warm air at 38° to 40° C (100° to 104° F) is blown into the lower chamber from a domestic heater, and a sheet of polythene fitted over the entire pen retains the heat. When the lamb's temperature reaches 37° C (99° F), it is removed from the warmer and immediately fed ewe or cow colostrum by stomach tube at a rate of 50 ml/kg. Any lamb that is vigorous and able to suck is returned to its ewe in a sheltered pen and monitored over the next several hours. Colostrum can be hand milked from the ewe after the administration of oxytocin.

Adequate Nutrition. In many prolific flocks, adequate nutrition necessitates supplementary feeding of ewes during late pregnancy. Alternatively, improved nutrition can be provided by moving them faster through a paddock rotation system, or even by advancing or delaying lambing by 4 or more weeks.

Surveillance for Dystocia and Shelter and Mothering Assistance. This requires a significant concentration of effort during the lambing period. Ewes getting close to lambing must be brought into an intensive care group and the ewes and lambs passed out of this group as soon as possible, but only when the dangers of starvation and exposure are

TABLE 16-6

Treatment of Hypothermic Lambs

Body Temperature	Age	Other Signs	Treatment
37°-39° C	Any age	—	Towel dry; tube 50 ml/kg warm colostrum; shelter with ewe
<37° C	<5 hr	—	Towel dry; warm box until temperature is 37° C; then tube 50 ml/kg colostrum; careful observation with ewe
< 37° C	>5 hr*	Head up	Hypoglycemic; stomach tube 50 ml/kg colostrum, then warm box to 37° C, stomach tube again; careful observation with ewe
< 37° C	>5 hr*	Comatose or convulsing	Intraperitoneal (IP) 20% warm glucose at 10 ml/kg body weight, then warm box to 37° C and stomach tube; careful observation with ewe

*Do not warm up lambs more than 5 hr of age without first treating for hypoglycemia (either by tubing with colostrum or IP glucose).

past. In shed lambing this is an obvious maneuver, but it can also be used in pasture lambing by a technique of "drifting" lambs and ewes away from the lambing group and into new rearing groups, which are watched less intensively.

Adequate Milk Supply. Measures to ensure an adequate supply of milk for the lambs when they come as singles or twins include prelambing inspection of the ewe's udders. A high incidence of caseous lymphadenitis, with lesions occurring in the supramammary lymph nodes, or of chronic mastitis can also have adverse effects on lamb survival. Udders surrounded by excessive wool, very pendulous udders, or grossly distended teats also reduce the availability of the milk supply. Ewes with any of these defects should be culled at the earliest opportunity. Observations of teat-seeking behavior of newborn lambs have revealed that they use surface texture and a degree of surface yield as cues for locating the teat (Billing and Vince, 1987a,b). There is a wide range of variation among breeds in several aspects of neonatal lamb behavior (Slee and Springbett, 1986). Those breeds with effective udder-seeking behavior tend to have a good resistance to hypothermia and low perinatal mortality. It is suggested that udder-seeking and early sucking behavior may be influenced genetically (Slee and Springbett, 1986). Finns and merinos have deficiencies in udder seeking and in resistance to hypothermia, and they are considered unsuitable for lambing outdoors in cold climates (Slee and Springbett, 1986).

Choice of Lambing Method Used. On a particular farm, this is largely dependent on the financial gains to be achieved. Managerial expertise is also important. For example, some farmers are excellent in their ability to identify ewes coming up to lambing. Unless there is reasonable expertise at this, the number of ewes that need to be under intensive surveillance at one time becomes so great that the shed required becomes too big to be financially practicable. Many of the problems of intensive lambing could be eliminated by an efficient system of estrous synchronization or batch lambing. An outdoor penning or indoor shedding system requires disinfection of pens between ewes to avoid cross-infection of neonatal infections, but this is rarely done under commercial conditions unless there is an existing infectious disease problem. Manual assistance to an ewe with dystocia requires hygienic precautions. Intensive lambing practices without the farmer appreciating the need for great care with these activities could lead to serious losses.

Ability as a Shepherd. This is the single most important factor in preventing lambing losses, but at present a more important restricting factor is the relative absence of people to work in this and other agricultural activities.

Financial Gain. This is the final criterion, but some factors need to be included in it. For example, if a particular farmer is anxious to increase the flock size without purchasing sheep, the value of twins is raised and the value of individual animals saved also rises. Because of the need to capitalize earning power when possible, the opportunity of increasing stocking rate must be kept in mind constantly, but the return to the new management technique must be set against its cost. The price of additional lambs has to be managed so that the cost of additional labor and the interest on the capital invested in a lambing shed are not greater than the value of the lambs provided. Thus the whole project becomes much more important when the prices of wool and mutton are high and all farmers are seeking to enlarge their flocks.

Availability of Capital. This may be as important as the availability of labor. Unless capital is available for shed construction or another similar device, it may be impossible to proceed.

Other Factors. Those that affect the time of lambing may have managerial and financial implications that outweigh inclemency of weather problems. For example, autumn breeding and spring lambing have the advantage of high fertility but the disadvantage of higher neonatal losses. The net effect of switching to spring breeding and autumn lambing may be nil in terms of lambs on the ground, but a seasonal poor supply of feed in early summer may mean that a high lambing percentage may be offset by a poorer growth rate in early lamb life. In North America, spring lambing coincides with higher market lamb prices.

Accurate Records. The overriding consideration in any flock health program is the need to know the forms of neonatal loss and their important causes. On some farms, it is not possible to do this because the necessary records are

not available. In most cases, a count is kept of lambs marked and lambs weaned, but it is usually necessary to run a surveillance year to accumulate data on which to base a decision that the reproductive loss is the result of poor fertility or high neonatal mortality. The records needed include the following:

- Careful, accurate pickup at least once daily of all dead lambs
- Careful, accurate necropsy examination of a large sample of dead lambs
- Accurate head count of ewes that lamb and the number of lambs born

This form of examination should be accompanied, as discussed earlier in the section on reproductive inefficiency, by a program including the use of a ram harness to mark ewes in estrus and pregnancy diagnosis. A complete examination is the only way of avoiding an error when both ends of the reproductive cycle have errors.

Specific Measures to Prevent Neonatal Lambing Losses

A completely successful program to cover all eventualities, without regard to cost effectiveness, is not likely to be a desirable objective. The following are programs of increasing sophistication and cost. The program likely to be chosen is the one most suited to the economic status and managerial system of the property (Beggs and Campion, 1966).

Extensive Lambing. Leaving the ewes to their own devices and examining them once daily at most is a time-honored and satisfactory method if sheep grazing systems are extensive. To do anything more than this would be financially impractical in most cases, because the usual mortality under this system of management is low. Predators are one of the main causes of loss, and shepherding during the day and corralling at night are about the only practical preventive measures. Changing the lambing date to avoid the inclement weather of late winter and early spring offers some attractions but has the serious disadvantage of missing the heightened fertility obtained by mating in early autumn. The net effect is likely to be no gain. Selection for more motherly ewes would be a worthwhile objective in a timid ewe flock, but care would be needed to avoid losing some of the fine wool characteristics. The use of sheltered paddocks and pastures with the best available feed are routine recommendations for lambing ewes and may be applicable here. The system has the advantage of avoiding excessive interference with the ewes.

Intensive Lambing at Pasture. In this system the ewes are run at pasture but at a high stocking rate with surveillance at least twice and preferable three times daily. This provides an opportunity for the early correction of dystocia and mismothering and allows a more accurate identification of lambs and their dams. The system is improved by having a series of small fields available as close as possible to the house to permit almost continuous observation. Maiden ewes should have the closest surveillance and if feed can be saved in the paddocks before lambing commences, this is an advantage. Shelter provided by putting out hay bales in rows or by cutting swathes in long pasture, especially phalaris or an oat crop, is much used by the sheep and is a great help (Egan et al, 1972). Lanes must be cut in the long grass or cereal crop; this enables the sheep to move about freely. Failure to do so can result in ewes and lambs being fatally separated. One advantage of this system is the number of lambs that can be salvaged that would otherwise die of starvation and exposure. These practices, however, require a vehicle for use as an ambulance, a makeshift nursery in a shearing shed, heat lamps and infrared lamps, hot water bottles, cartons, bottle-feeding equipment, and a supply of stored colostrum.

This system is the one most used and most recommended for areas with year-round pasture for average circumstances. It is possible to detect and correct dystocias and mismothering problems, but there is difficulty in catching the subjects, so that it is sometimes necessary to drive the particular group all the way to the nearest sheep yards. There is also the disadvantage that all the ewes must by inspected. There is no opportunity to separate the flock into ewes that are about to lamb within the next few days and those that are still distant from lambing. This wastes time, and, if the lambing percentage is good anyway, there is a tendency to dispense with the inspection, especially when other matters are pressing or when the weather is bad. However, these tend to be the times when the need is greatest. On the other hand, doubling the amount of time taken in the inspection may offer little improvement in the lambing percentage.

Drift Lambing. This technique is used to overcome the disadvantage of having to examine all the lambing ewes at every inspection. About six small paddocks are needed; the ewes that are reasonably close to lambing are put into the system each day and the nonpregnant ones moved on, leaving the ewes with recent lambs behind. Those left behind are watched to make sure that a firm ewe-lamb bond is established and that both the lambs and ewes are well. After 3 or 4 days they are moved out to other larger groups. The ewes are fairly easy to move in the autumn, when feed is inclined to be short and some supplementation is given by feeding out. In spring, when there is ample pasture available, the ewes are not easy to move. Drift lambing can be combined with shed lambing as an emergency program to be adopted when the weather is bad and losses are likely to be high. One thing is lacking in the drift system: protection from bad weather. The small size of the paddocks makes feeding, surveillance, and identification much easier.

Outdoor Pen Lambing. In this technique the ewes at the point of lambing are moved out of a set of drifting paddocks and into a set of individual pens. All ewes might go into a pen, or perhaps only the problem ones that present mismothering or dystocia difficulties. If all ewes go through, they might be put in individual pens before or after they have lambed. The former requires a sharp midwife-type eye; some farmers have it, some do not. A technique used to improve the accuracy of selection is to use a ram marking harness during the mating period and to separate the ewes into groups of 1-week's matings. These groups then can be moved up to the shed in rotation as their anticipated lambing date arrives. Those people who are good at selecting ewes that are close to their time are valuable, almost essential, for the efficient running of an intensive lambing operation. Experience is also valuable. Some of the points on which the selection of ewes is based are (1) relaxation of pelvic ligaments, as indicated by "falling in" of the tail and pin bones, (2) slackness of the vulva and surrounding skin, giving the vulvar lips a boxing glove shape, (3) bright red to purple vulva and posterior vagina, and (4) firmness and swelling of the udder with division of the udder into two halves evident, and the presence of colostrum. To be most effective in identifying these criteria, the tails of the ewes must have been docked and previously shorn.

For both outdoor and indoor pen lambing, it is usually safest to have a group pen into which the ewes go first (about 20 to a pen). From here, the individual ewes are selected for the lambing cubicles.

The number of cubicles required varies with the inefficiency of the operator in detecting impending parturition. An average operator can manage one cubicle per 20 ewes to lamb. A highly skilled person can manage one cubicle per 35

ewes. A common practice is to limit shed lambing to maiden ewes, in which the greatest losses occur and the most gains are to be made. As efficiency increases and more ewes can be handled through the shed, additional age groups are added.

Again, there is the disadvantage that inclement weather could still cause many deaths but, if the pens are carefully located or protection is provided against strong winds by natural or temporary artificial windbreaks, these losses can be reduced. The result is not as good as that obtained by providing a shed, but the capital cost of the latter is avoided. The costs and returns have been identified (Clarke, 1977); the profitability of shed lambing depends on the high value of sheep.

Shed or Indoor Lambing. Like outdoor pen lambing, this system provides an individual pen or crate for each ewe as she lambs. The ewe and lamb stay in the pen sufficiently long to ensure that the mothering bond is established and that the lamb has its quota of colostrum. Lambs lacking in vigor can receive special attention. They are then moved out to the flock, the pen is cleaned and possibly disinfected if there is any indication of need for it, and the next ewe is admitted. The provision of a shed is a considerable economic investment; it is generally used when lambs are born during cold, wet, and windy weather. One of its principal advantages is that it gives shelter to the workers when they are providing assistance to the animals. It is a great advantage if the shed can be used for several purposes; at the least it should be of the simplest and cheapest construction.

As soon as the lamb is born, it is kept under observation to make sure it stands and sucks. The udder and teats of the ewe must be examined to ensure the presence of colostrum and to remove any teat plugs. Lambs that are lacking in vigor profit from assistance with sucking and, if not successful, feeding of an appropriate volume of colostrum (50 ml/kg) by stomach tube. These lambs should be checked for progress about every 6 hours. If there is a limit to the number of ewes that can be handled through a shed, preference should be given to maiden ewes because they need more assistance than older ewes. One possible extension of a shed lambing program is the harvesting of the lambs at early weaning (e.g., 3 weeks) and artificially rearing them. The way is then clear for two crops of lambs each year and two uses of the shed. However, artificial rearing of lambs is costly and such lambs are prone to numerous problems, including abomasal bloat, and infectious diseases, namely cryptosporidiosis, coccidiosis, and respiratory disease.

General Provisions in All Lambing Systems

The systems just described are directed at the principal causes of loss at lambing: inclement weather, poor mothering, insufficient food supply, lack of assistance for ewes that are in trouble, and deaths caused by predators. All of these programs need to have specific provisions to control specific causes of loss, if and when they occur (Box 16-15).

Weather and Disease

In a Northern Ireland study, the occurrence of pleurisy and pneumonia in sheep slaughtered in the abattoir was correlated with the prevailing weather conditions. There was a strong correlation between lung condemnation because of pleurisy and pneumonia and inclement cold and rainy weather (McIlroy et al, 1989). Of the weather conditions such as rainfall, wind speed, temperature, and humidity, the most significant was wind speed (McIlroy et al, 1989). Both rain and wind reduce the insulating effect of the fleece and make the animals more susceptible to the effects of chilling, which can lead to pneumonia. This suggests that sheep should be protected from the extremes of both wind and rain. In the United Kingdom, housing of the ewe flock in winter can prevent pasture damage, reduce ewe and lamb losses, increase output, and improve working conditions for the shepherd (Linklater and Watson, 1983). The essentials for sheep housing have been described (Linklater, 1987). Wind chill in sheep can be estimated from meteorological records (Mount and Brown, 1983).

BOX 16-15

Provisions to Control Lambing Losses

- Specific nutritional deficiencies of iodine, copper, selenium, and vitamin E
- Congenital defects conditioned by inheritance
- Specific bacteriologic, chlamydial, and viral causes of abortion and neonatal death from intrauterine infection
- Similar infections occurring postnatally
- Ewes with defective udders
- High incidence of dystocia caused by the inheritance of large-headed lambs or very large lambs
- Other causes of ewe-induced lamb losses, particularly ring womb, uterine prolapse, and vaginal prolapse
- Factors that contribute to vaginal prolapse, including ring womb or dystocia, estrogens in the diet, multiple births, excessive body condition score of ewes, high-fiber diet, crowding at feeders, and idiopathic causes
- Trauma and blood loss resulting from dystocia, tail docking, and castration
- Protection against predators

PRODUCTION MANAGEMENT

Nutrition on Pasture

Good sheep management depends more than anything else on the judicious use of pasture. Pasture management is a science in itself and is not presented here. However, it is important to provide some indication of the types of factors to be considered in a pasture management program. Box 16-16 lists factors that influence the pasture as feed.

Animal Management: Using the Feed

There are many interactions among all the factors in Box 16-17, among them the uncontrollable variables of climate, environmental disasters, including fires, floods, and drought, and the site factors of geographic location. It is not possible to do much more than generalize about the subject without access to a computer simulation model, which enables the effect of variations in each of these variables to be tested. A good review of the subject has been published (White and Morley, 1982).

In general terms, pasture management for sheep requires that heavy spring and autumn growth be heavily stocked, saved as standing feed, or hayed. In poor growth periods the standing forage and hay are used to subsist the sheep through the period of undernutrition. Special attention is required in breeding sheep to provide optimum nutrition at the critical periods of breeding, late pregnancy, and lactation, especially the first few weeks. For lambs, the critical period is from weaning until the time of sale. These are the periods when supplementary feeding with grain or concen-

BOX 16-16

Pasture as Feed

Composition of the pasture: livestock graze preferentially, selecting, and consuming the species or individual plants or parts of plants that they like, such as grass over legumes, timothy or brome over orchard grass, white clover or perennial rye grass over most everything else, juvenile over mature plants, and leaves over stems, and only reverting to the less desirable species if they must
Use of fertilizers
Availability of irrigation
Subdivision of pastures: this requires sturdy fencing with provisions for securing it to the ground surface to keep out the coyotes and dogs
Pasture rotation systems
Forage conservation from pasture: hay and ensilage
Forage cropping
Supplementary feeding
Use of hay fields or stubble fields

BOX 16-17

Using the Feed

Stocking rates. The number, size, and shape of paddocks and the time that sheep spend in the paddocks are major factors in the development of an effective and controlled grazing system. The number of paddocks, their size, and the number of days of grazing depend on allowing sufficient regrowth time for each factor to regain grazeable maturity. The system must be designed to keep the forage healthy.

Movement of sheep from paddock to paddock and access to water. Grazing paddocks should be planned so that sheep can move from paddock to paddock with ease. This can be accomplished by having all paddocks connected to a single, central source of clean water. The water, salt, and minerals, together with any supplemental feed troughs, should be located in a fenced watering corral that is connected by gates or lanes to all paddocks. Ideally, handling facilities should be adjacent to this watering corral.

Composition of the grazing flock. Breeding versus dry sheep, date of breeding, date of weaning, date of marketing.

Disease control. Restraints on animal movement.

trates is most likely to be needed. On farms with mixed enterprises, grain growing is an advantage because of the stubble that becomes available, and beef cattle are also helpful in that they permit better management of the pasture, especially if it is overgrown.

By determining the BCS of a representative sample of sheep at strategic times during the reproductive cycle, it is possible to assess the nutritional status of the animals and to make the necessary adjustments in the ration, including supplementation at pasture to satisfy the nutrient requirements of the particular stage of the production or reproductive cycle. This was discussed in detail earlier.

Poisonings

Poisoning may be caused by fungi on grasses (e.g., facial eczema, possibly rye grass staggers). Toxic agents in pasture grass (e.g., phalaris, fescue, and *Panicum* sp.) may be present. In special circumstances, any lush grass may contain toxic amounts of nitrate (converted in the rumen into nitrite).

There is a long list of poisonous weeds that can affect sheep. Two important groups are the *Astragalus* sp., because of their palatability and extensive occurrence in North America, and plants containing pyrolizidine alkaloids and other hepatotoxic agents in Australia and South Africa.

Cyanide poisoning is no longer common because the common plant causes, especially sorghum and Johnson grass, are not grown much. Large areas of sheep country can be rendered unfarmable by the presence of subterranean clover and certain red clovers containing estrogens, or by a variety of plants containing high levels of oxalate. *Brassica* sp. are also used to extend pastures in temperate climates into December and have the potential to cause goiter.

Nutritional Deficiencies

Phosphorus, copper (primary or secondary resulting from a high molybdenum intake), cobalt, iodine, and selenium-vitamin E deficiencies are causes of naturally occurring diseases. Zinc deficiency has been produced experimentally. Vitamin D could be deficient in housed sheep, but this is unlikely in grazing animals. Animals on pasture during long droughts may become vitamin A deficient, but this is unlikely given the long hepatic storage of the vitamin.

Miscellaneous Dietary Diseases

A number of dietary diseases occur in sheep, and their prevention requires constant surveillance of the diet to ensure that the factors contributing to their occurrence are minimized. The details of control and prevention are presented in other texts. Bloat is much less common in pastured sheep than in cattle. Urolithiasis is a more common occurrence, especially in some areas where silica uroliths prevail, and calculi containing benzocoumarins occur on diets high in subterranean clover. Periodontitis and premature wear of sheep teeth achieve a high prevalence in some areas, especially New Zealand, and cause premature culling. Pregnancy toxemia commonly occurs because of an inability to maintain nutritional status in late pregnancy in a bad season. Hypocalcemia is also an important disease that occurs most commonly in the late pregnancy and less commonly in early lactation. It is rarely accompanied by hypomagnesemia.

Health Management in Lamb Feedlots

In the United States, approximately 6 million lambs are marketed for slaughter annually. Feedlot lambs originate from many different flocks of varying sizes and enter the feedlot weighing about 30 to 32 kg. They are fed in the feedlot for 45 to 60 days and marketed at 50 to 55 kg (100 to 120 lb). Average daily gains range from 0.2 to 0.3 kg. The diets are grain based, and a period of conditioning of 21 to 28 days to the high-level grain diets is commonplace to minimize the incidence of lactic acidosis and enterotoxemia. Systems of early weaning and finishing of lambs have been developed that have particular importance for intensive systems of frequent breeding or in systems in which ewes are milked for the sale of milk for processing (Orskov, 1987). The need for protein supplementation depends on the previous nutrition of the lambs. Those that have experienced a period of low-level nutrition or undernutrition have a greater requirement for undegraded dietary protein than

well-fed lambs at the same live weight. The nutritional and economic aspects of feeding lambs in feedlot conditions in Australia have been described (Hodge, 1983). Population mortality in lamb feedlots ranges from 1.5% to 3.0% (Pierson and Kimberling, 1981).

The consumer is demanding lean lamb rather than fat lamb, and production methods to increase lean and reduce fat in lambs have been reviewed (Glimp and Snowder, 1989). Crossbreeding and selection within a breed can increase the percentage of lean in the carcass. Selection for rate of gain should also improve the lean-to-fat ratio at a constant weight.

Reliable and useful data on disease prevalence in sheep feedlots are not readily available. The data that do exist are based on small numbers of sheep in small flocks, with mixed lots of age groups and no data on the numbers at risk (Moteane et al, 1979).

A survey of diseases and their associated costs in two Colorado feedlots in 1985 and 1986 revealed that the most prevalent diseases were pneumonia (4.9%, 13.0%), lactic acidosis (3.3%, 7.6%) enterotoxemia (3.1%, 1.49%), and transport tetany (0.48%, 2.4%), respectively, in each of the two feedlots (Salman et al, 1988b). Diseases with the highest average death loss causes in one feedlot were pneumonia, enterotoxemia, and acidosis; in the other lot, the highest average death loss causes were pneumonia, enterotoxemia, acidosis, and transport tetany. The prevalences of the other diseases in each feedlot were as follows: urolithiasis (0.50%, 0.35%), rectal prolapse (0.35%, 0.31%), salmonellosis (0.01%, zero), enteritis (0.10%, 0.02%), polioencephalomalacia (0.04%, none), tetanus (none, 0.01%), and other (0.57%, 0.60%). One feedlot had a lamb mortality of 2.2%, the other 3.1%. There was a large difference in the incidence of diseases between the two feedlots and in the expenditures for disease prevention (Salman et al, 1988b). This difference may have been the result of differences in management expertise, health management programs and schedules, and other factors that were not identified. This provides an opportunity for the veterinarian to examine the health management techniques used and to make changes to eliminate unnecessary costs.

Pierson (1970) has described a flock health management program in a lamb feedlot that reduced death losses from 4% to 1.5% in the first year. The greatest loss was associated with management and poorly designed corrals. A weekly visit of 2 to 4 hours was made during the feeding season of August to the following July. An accurate record of all health data was kept and updated at each visit. All newly arrived batches of lambs were examined closely for evidence of disease, a close watch was kept on lambs in the hospital area, and necropsies were performed on dead lambs whenever possible.

A suggested health management program for lamb feedlots emphasizes control of the common diseases such as lactic acidosis, enterotoxemia, and pneumonia. Each lamb is identified with a paint brand according to its group and sorted into groups according to size. At 48 hours after arrival, the lambs are vaccinated with *C. perfringens* toxoid. Each lamb is treated with levamisole, fenbendazole, or ivermectin. An implant of an anabolic agent is given. A booster dose of the toxoid is repeated in 2 to 3 weeks. Producers and veterinarians must adhere to the withdrawal times before the slaughter of treated lambs. The lambs are placed on the finishing ration by gradually increasing the level of concentrate in the self-feeding systems from 10% to 90% over a period of 21 to 28 days to avoid lactic acidosis and enterotoxemia. Antimicrobials may be added to the feed and water for the first 2 weeks to control the incidence of pneumonic pasteurellosis, but there is no evidence based on clinical trials that they are cost effective.

In such a program it is necessary to keep accurate records of the losses and expenditures related to health maintenance. If possible, body weights at entrance and sale, and the gain related to the weeks required to gain it, should be used in addition to deaths to indicate to the owner how well the health program is succeeding. Because the profitability of a feedlot depends on the efficiency with which the capital investment and the heavy recurring costs of labor are used, one of the two critical indexes is the speed with which lambs go through the lot. Thus inadequate feeding, climatic stress, and chronic disease become greatly important.

Among the important sources of loss are those that occur during transit to the lot. The lambs may become exhausted and go down to be trampled by the others so that they die of multiple injuries, exhaustion, or asphyxia. In hot weather, heat stroke may be an important cause of death. Most such problems can be prevented by avoiding overcrowding and by careful, easy-going transportation with regular stops where sheep are unloaded and offered feed and water.

Of the death losses, those caused by enterotoxemia are usually the greatest. Vaccination with *C. perfringens* type D toxoid as lambs go into the feedlot is almost mandatory (Pierson, 1967). Although this removes the bulk of the losses, some deaths can still occur during the first 10 days, and there would be an economic advantage in having the lambs vaccinated before they leave the home farm. The management technique of keeping the lambs on a low level of feed intake for the first 2 weeks in the feedlot may be necessary in a high-risk situation, but the effects are so unrewarding financially that a more positive approach is usually necessary. During their stay in the feedlot, the provision of a ration containing adequate roughage is an added protection against the disease occurring even in vaccinated lambs. Focal symmetric encephalomalacia is also a cause of significant loss, and a more intensive campaign against enterotoxemia should also reduce the occurrence of this manifestation of enterotoxemia.

Serious losses are sometimes caused by outbreaks of polioencephalomalacia. They present a problem, not only because of the ease with which they can be confused with outbreaks of enterotoxemia, but also because of uncertainty about the cause and prevention. A recent study has described an outbreak of polioencephalomalacia in fattening lambs fed a diet high in sulphur in which the high sulphur content resulted from the dietary components and not as the result of any mineral supplementation (Low et al, 1996). A routine preventive program would not appear to be necessary, but mass medication of the feed with thiamine may be necessary if cases occur.

To avoid the possibility of salt poisoning contributing to cases of a similar disease, it is essential that water be available at all times, especially when freezing disrupts supply. Salt, if provided, must be available at all times. An intermittent supply of salt combined with an intermittent water supply can cause salt poisoning.

Once in the feedlot, and with enterotoxemia under control, the other important causes of loss include pneumonia and septicemia caused by *P. haemolytica* and *Pasteurella trehalosi*. These diseases appear to be promoted readily by the stress of transport or by inclement weather. The metaphylactic administration of long-acting oxytetracycline has not proved cost effective during outbreaks of pneumonic pasteurellosis in lambs (Gilmour et al, 1988; Appleyard and Gilmour, 1990). In countries where psoroptic and other manges occur, dipping or spraying sheep as they enter the lot is almost obligatory. More recently, the introduction of effective ivermectins and milbemycins and related products allows control of psoroptic mange and gastrointestinal roundworms by a single subcutaneous injection.

During their stay in the lot, lambs are commonly affected by coccidiosis, which usually commences 2 to 3 weeks after they enter. Prevention depends on the hygienic arrangement of feeding and watering troughs to avoid their fecal contamination and early isolation and/or treatment of infected animals to prevent unnecessary contamination of the environment. The incorporation of a coccidiostat such as monensin, lasalocid, decoquinate, or amprolium is effective for the control of coccidiosis and improves the average daily gain. Internal parasitism is always a threat, and routine dosing with a broad-spectrum anthelmintic as the lambs enter the lot is recommended on the basis that it must be beneficial in almost every case. One of the problems arising when lambs do have diarrhea is their predisposition to blowfly strike (cutaneous myiasis) of the soiled area.

Because of the almost universal occurrence of wetness underfoot in outdoor feedlots and the high incidence of footrot in outside flocks, this disease is a major problem. Good drainage, the provision of roofing shelter, sandy soil, and mounds in the middle of the corrals all help, but severe outbreaks are inevitable. Although paring the feet and bathing are effective as a control program, because of the labor-intensive work they are hardly economical when 10,000 lambs are affected. The injection of large doses of either penicillin and streptomycin combination or oxytetracycline is expensive and much less effective when it is wet underfoot. The vaccines against footrot that are now available represent a more significant method of control but may prove cost prohibitive.

Urolithiasis can be a problem in lamb feedlots. Affected groups of castrated lambs usually come from well-defined geographic areas. The incidence seems to be higher in lambs fed diets with a calcium-phosphorus imbalance, usually a low level of calcium, and an inadequate water supply. The only generally applicable prophylaxis is the incorporation of 4% sodium chloride or ammonium chloride in the ration. Salt above this concentration unnecessarily depresses food intake. Other diseases likely to reduce effective weight gains are entropion and pinkeye (infectious keratoconjunctivitis). The former should have been dealt with at birth and certainly before the lambs enter the lot, and pinkeye is a summer disease although it may occur in an extended feeding season. There is no prevention other than early diagnosis and fast, effective treatment of early cases with intramuscular injection of long-acting oxytetracycline to prevent wider spread. Topical application of oxytetracycline ophthalmic powder is highly effective in the treatment of early lesions.

As well as traditional sheep feedlots, there are now those conditioning units in which sheep are held before being shipped overseas as live sheep, principally to Arab countries. They are, for the most part, adult male castrates with an emphasis on lean meat. Four- to five-year-old merino wethers are a common type of sheep for this trade in Australia (McAuliffe et al, 1978). The feeding program usually consists of hay, 0.4 to 1.0 kg/day, and pellets at the rate of 1.2 kg/day at the end of the period. The sheep are started on hay only, and the pellets are introduced and increased gradually to the full quota just before shipment. The death rate is claimed to be low (0.03%), where the principal causes of death are likely to be polioencephalomalacia and salmonellosis. A miscellaneous category includes clostridial infections and intoxications, trauma, transit tetany, toxemic jaundice, and urolithiasis.

Special Feeding Circumstances in the Sheep Flock

Survival Feeding and Management During Periods of Drought

During periods of drought, the veterinarian must provide advice on how to get through the drought with minimum dislocation to the farm as a business (Brightling, 1989). A major difficulty with costing a drought-feeding program is the uncertainty of the length of the drought. This can be overcome by estimating the probability of the drought breaking at various times and using these probability estimates to calculate an expected cost (Brightling, 1989). Sadly, the welfare of the sheep appears to be a secondary consideration.

For maximum economy and ease of handling, only grain is fed. Concentrate pellets may be used but add to the expense. Roughage is hard to handle economically, and in drought times is generally priced prohibitively. The sheep being fed grain are usually left in their paddocks and fed on the ground. In sandy country, where sand eating can cause heavy losses, troughs in the paddocks are necessary, or the sheep are yarded and fed in a feedlot system. Recommended amounts of feed are shown in Table 16-7. These are the amounts needed to support the sheep completely. They can be reduced if some natural feed is available.

TABLE 16-7

*Drought Feeding Table**

Class of Sheep	Wheat, Sorghum, Barley Grain	Oat Grain	Proprietary Sheet "Nuts"	Hay
Adult dry sheep including rams	350	400	450	750
Ewes in last 6 wk of pregnancy	450	550	600	900
Lactating ewes	650	750	800	1250
Lambs and weaners†	250	300	350	500

*Amounts in g/day/sheep.
†The amounts quoted are just adequate; a 33% increase would be safer.

Acidosis is always a threat, especially if sheep are put onto grain suddenly. All feeding changes should be made gradually; the grain should not be in amounts greater than those cited below, and it must be spread out so that all sheep can eat at the same time. Otherwise, the aggressive ones may get much more than their share. In the initial stages, it is important to feed every day to avoid acidosis, but, once the sheep are trained, better survival is obtained by intermittent feeding. A recommended regimen for dry sheep is to commence with 50 g/day, increasing to 350 g/day by Day 14. The feeding is then changed to every second day, and by Day 24 the sheep can be getting 1050 g (preferably 1400 g) every third day. Pregnant and lactating ewes get proportionally more (Table 16-7). Lactating ewes need some roughage, and 500 g/day would be a good investment. The economic advantage of knowing whether ewes are pregnant is most obvious during drought feeding.

In addition, there are a number of miscellaneous problems during drought feeding (Box 16-18).

Grazing on Lush Pasture or on Green Cereal Crop

Grazing on lush pasture or on green cereal crop are subject to two potential errors. On this type of feed, late pregnant and lactating ewes are likely to suffer a high prevalence of hypocalcemia, with or without hypomagnesemia. Little can be done to prevent the disease unless the sheep can be moved to a less lush feed, an unlikely prospect in a good spring. Most situations in which hypocalcemia is a probable hazard are dealt with by maintaining close surveillance and treating cases early. It is important to avoid sudden changes in feed or feeding practices in susceptible sheep.

In the northern hemisphere countries including areas of the United States and Europe, fall forage crops are becoming popular as means of extending the grazing season, which can be as short as 6 to 7 months compared to the 9-month grazing season in New Zealand, Australia. Fall annual crops include the winter grains (rye, wheat), and many *Brassica* sp. such as kale, rape, and turnip. *Brassica* sp. are easy to grow, are frost tolerant, and have a high carrying capacity (up to 1200 ewe grazing days/acre). Typically, the fall crops are grazed from late October to late November before a hard frost causes deterioration of the crop. Feed quality generally remains high throughout the feeding period, although the dry matter content increases with plant maturity.

Inadequate Diet in Late Pregnancy

This occurs commonly in low maintenance flocks because ewes are often mated to catch a spring or autumn flush when they are at the point of lambing. Failure of the appropriate rain to appear may lead to poor grass supply and the occurrence of pregnancy toxemia.

Genetic Improvement of Sheep Production

Sheep management systems have evolved over the centuries under conditions favoring the seasonal production of one or possibly two lambs. However, the productivity of the breeding flock can be improved through the use of breeds with special characteristics such as high prolificacy, rapid growth rate, milk production, and increased lean muscle mass. Further increases are possible through the use of specific crossbreeding schemes, selection within or between breeds, the

BOX 16-18

Problems During Drought Feeding

- The feed is usually simply spilled along a tortuous trail on the ground. Long-term feeding of the smaller grains on the ground may cause digestive upsets from the ingestion of surface soil. Troughing is preferable: 30 cm of double-sided trough for each three to four sheep.
- Drought feeding of parasitized sheep is poor economics, and all sheep should be dosed with a broad-spectrum anthelmintic before drought feeding commences.
- Lambs are a problem, especially if it is necessary to wean them early to save the ewe's life. They should not be weaned until they weigh at least 7 kg for merinos and 9 kg for crossbreds. At this weight, they should be about 6 weeks old. They should be fed roughage at all times; at the start at least 50% of the feed should be as chaffed roughage mixed with the grain. Vitamin A is probably best provided from the beginning; give 250,000 IU vitamin A at marking. A straight grain ration or poor hay is also low in protein, and the addition of 5 lb of linseed meal or 2 lb of meat meal/100 lb of grain is recommended. At this age, lambs need ample water, some good shelter from wind, and not too much space. A stocking rate of 600 to 800 lambs/acre is recommended. A hospital is needed for the weak ones.
- Lambing ewes should not have to compete too hard for their feed and, if possible, some roughage should always be available. Intermittent grain feeding then does not cause too much mismothering and desertion of lambs.
- Weaners and chronic "shy feeders" may not eat the grain and may die of starvation if they are not drafted off, driven up to the feed, and held on it. In any group on subsistence rations, there are some sheep that do not fare well. If losing them is to be avoided, they should be moved to a hospital group that is given special treatment.
- Sheep and cattle should not be fed together. The sheep are too exposed to traumatic injury.
- If urea is used, it should be fed with a carbohydrate-rich concentrate such as grain or molasses and given only when roughage is also fed. Feed no more than 10 g urea/head daily, and ensure that it is thoroughly mixed with feed.
- If the period of feeding is prolonged, the young sheep up to 1½ years of age need supplementation with vitamin A. Weaners at 3 months of age, if they have not had access to green feed, should receive 500,000 IU vitamin A, which should protect them for 6 months.
- Other specific nutritional problems that may be encountered are vitamin E deficiency, leading to cardiac and skeletal muscular dystrophy, and osteoporosis resulting from a high-phosphorus, low-calcium diet. Agalactia in ewes is also noted on purely grain diets. This can be corrected by the inclusion of some roughage in the diet.

mating of ewe lambs, and management techniques such as artificial photoperiod and hormonal treatments, which theoretically permit a lamb crop to be produced every 8 months or less (Ainsworth et al, 1985). Exploitation of higher productivity requires effective techniques for artificial rearing, an effective and simple recording system, adequate nutrition, and improved management procedures for control of predators, parasites, and disease. Although advances in research and technology in many of these areas have been comprehensively reviewed (Haresign, 1983; Treacher, 1987), a failure of technology transfer exists whereby perinatal ewe and lambs losses remain at unacceptable levels of 5% to 6% and 10% to 15%, respectively (MLC Yearbook, 1997), and as outlined elsewhere in this chapter.

All sheep breeding plans are intended to enhance the efficient production of one or more of the following products: wool, meat, milk, and pelts. The definition of the selection objectives is critically important for every sheep breeder because it determines the success of the sheep breeding enterprise. Every sheep producer is faced with a unique set of circumstances that can influence the choice of selection objectives. Different environments, different markets, access to different genotypes, and different personal goals lead sheep breeders to have a wide range of selection objectives (Robertson, 1983). The factors that should be considered in defining selection objectives and the variety of selection objectives that exist have been reviewed comprehensively (Robertson, 1983). In defining their selection objectives, sheep breeders should be prepared to assess their entire enterprise from its beginning in a systematically planned way. This includes a review of the resources available, a decision on the product desired (wool, meat, milk, pelt), consideration of adaptive traits (e.g., heat tolerance, parasite resistance, resistance to fleece rot, resistance to footrot), a long breeding season, consideration of the relative economic weightings of the products, a review of the genotypes available to obtain the optimum, and development of a breeding plan.

Increasing Prolificacy. Litter size or the number of lambs born per lambing is an important component of productivity in sheep, contributing more to the difference in total weight of lamb weaned per ewe than the growth rate of individual lambs (Bradford, 1985). It was traditionally thought, based on heritability estimates, that genetic variation in twinning rate or litter size was too low to justify trying to change it by genetic means. However, it is now generally accepted that genetic potential for mean litter size in sheep can be set at any desired level, from one to about three. Research interests are now centering on determining the levels of prolificacy that are optimum for different production environments, the most efficient means of achieving and maintaining those levels, and how to minimize variation around the mean (Bradford, 1985).

The optimum level of prolificacy is a function of environmental conditions and management systems. The optimum level is often not the maximum possible. Bradford (1985) suggested the mean values, shown in Box 16-19 for four different production environments, in terms of lambs born per mature (second or later lambing) ewe lambing. It is accepted that prolificacy is lower in first-lambing ewes, regardless of age at first lambing; it is generally uneconomical to delay breeding an ewe until she has achieved her full, mature reproduction potential.

The possibility of increasing litter size significantly can be achieved through the appropriate combination of breed resources, using prolific breeds of sheep, in one or two generations (Fogarty et al,1984a,b). However, the introduction of more productive genotypes into production systems is advantageous only if management is optimized to exploit the greater productivity. Ewes that give birth to and nurse triplets may produce 21% more milk/unit metabolic body weight, be 10% more efficient in the conversion of feed to milk, and produce 26% more kilograms of lamb/ewe in 42 days of lactation than ewes giving birth to and nursing twins (Loerch et al, 1985). This suggests that direct nursing stimulation of the mammary gland is responsible for the improvement in milk production observed when ewes nurse additional lambs. This aspect of husbandry practice must be considered carefully because overvigorous sucking by triplet lambs readily causes teat lesions and mastitis (Scott and Murphy, 1997). Feeding such ewes a moderate amount of undegradable supplemental protein such as roasted soybean meal or corn gluten may further stimulate milk production.

Despite the potential of new innovations and technologies, most have not been adopted to any great extent by the industry. The commercial failure of Fecundin highlights the gap between advances in reproductive biology and the ability of commercial sheep husbandry practices to cope with multiple litters, especially triplets.

Crossbreeding Programs. There are at least three possible methods available to effect genetic change in litter size in

BOX 16-19

Mean Values for Different Production Environments

EXTENSIVE LAMBING (GENERALLY ONCE A YEAR)

Forage is scarce and variable among seasons and years. Supplements are unavailable or uneconomic. The goal is single births. Twins are undesirable because the ewe will not have sufficient milk for the satisfactory growth of two lambs. Prolific sheep can be a serious liability under these conditions; the low birth weight of lambs, inclement weather, inadequate maternal care, and poor flock supervision combine to give a high lamb mortality.

If better forage is available, or there is potential for supplements, and seasonal rainfall supports forage for at least 3 or 4 months, the goal is twins from mature ewes but no higher multiples. Supplemental feed is often economically justified for ewes with twins but not for those with singles.

INTENSIVE LAMBING

Ewes are fed to meet nutrient requirements year round; there is supervised lambing with fostering of lambs, artificial rearing capability, or market for orphan lambs. This can occur on farms with good-quality pasture for 6 or more months of the year and with out-of-season accelerated lambing systems. The goal is a mean of 2 to 2.3 lambs/mature ewe/breeding period, with a maximum of 3.

Same management system as in the above example, except all lambs where there are more than 2/litter are reared artificially. Such a system is likely to involve confinement and accelerated lambing. The goal is the maximum number of viable lambs per ewe. A mean of 3 seems appropriate.

sheep: the introduction of inheritance from a prolific breed, selection within breeds, and the use of major genes, such as the Booroola. Genetic material from prolific breeds, such as the Finn, Blueface Leicester, and Romanov, in which high prolificacy is not apparently the result of a single gene, has been used in many countries to raise the prolificacy of local breeds or as the basis of new composite breeds (Hanrahan, 1987). Crossing the Finnish Landrace (Finn) or Romanov breeds with less prolific breeds increases the litter size by an additive effect (Hanrahan, 1987). The Cambridge breed is a highly prolific breed formed from foundation ewes selected on prolificacy records, and it represents genetic material from 11 British breeds (Hanrahan, 1987). The present Cambridge population has a litter size of about 2.8 for mature ewes, and up to 8 lambs/litter have been recorded; however, flock numbers are indeed small because of the level of supervision required to ensure neonatal survival and the poor carcass conformation with low returns. If prolific breeds are available, and the adaptability, performance, and product quality of the cross of local and prolific breeds giving the desired litter size are acceptable, it is the method of choice (Bradford, 1985). The reproductive performance in Finncross ewes under range conditions can be superior to purebreds in net reproductive rate and weight of lamb weaned over a period of several years (Ercanbrack and Knight, 1985).

The lifetime production efficiency of different crossbred ewes maintained on irrigated or dryland hill pastures in Oregon for 4 or 5 years of production has been examined (Saoud and Hohenboken, 1984). It is clear that the management system under which production occurs and the choice of breeds adapted both to management and to the physical conditions of the environment affect lifetime productivity. However, not all countries allow the importation of prolific breeds, and some prolific breeds lack some important traits for certain environments. For example, crosses carrying 50% Finn inheritance are unusually susceptible to pneumonia, have a high attrition rate, and tend to show summer anestrus characteristic of the Finn parent. The fleece and carcass traits may also limit their usefulness where there are stringent market requirements.

Crossbreeding programs using two maternal trait breeds (at least one of which is a prolific breed) to create an F1 dam line breed have been used extensively. These F1 breeds exhibit heterosis and tend to be superior to the average of their parents productively. These ewes, in a crossbreeding program, would be bred to a sire trait breed, and all offspring from this mating would be marketed for meat. This method of quickly improving the genetics of the flock is gaining in popularity to the point that some producers are creating enterprises out the production of superior F1 ewe replacements for sale to commercial flocks. A notable example of an F1 sheep is the Scottish Mule, which is a cross between the Blueface Leicester and the Scottish Blackface that forms the basis of lowground flocks in the United Kingdom. Finnish Landrace sheep are frequently used in crossbreeding programs to increase prolificacy. Many synthetic breeds stressing maternal traits such as prolificacy have been created in the last two decades through a multiway crossbreeding program and heavy phenotypic selection. Examples are the Arcott in Canada and Polpay in the United States, where litter size ranges from 2 to 2.8.

The second method is the use of major genes, such as the Booroola. The Booroola gene for high ovulation rate has stimulated much interest in the potential for increasing prolificacy. The Booroola merino is a highly prolific strain of sheep developed initially by two sheep breeders (Piper and Bindon, 1985). With a mean ovulation rate in 1982 of 4.2 (range of 1 to 10) and corresponding mean litter size of 2.5 (range of 1 to 7), the reproduction rate of the Booroola is different from that of any other merino and ranks among the most prolific breeds of sheep in the world (Piper and Bindon, 1985). The mean litter size of ewes heterozygous for the gene is approximately 1.0 lamb higher than in noncarrier ewes. The reproductive performance of a Booroola flock therefore depends on the proportion of the flock carrying the gene. Through repeated crossbreeding and heavy selection for prolificacy, the Booroola gene has been incorporated into other breeds (e.g., Dorset). Crossbred prolific ewes are bred back to the desired breed for several generations until the crossbreed has the phenotype of the selected breed while still carrying the Booroola gene.

The third method is selection within an adapted population. Selection requires recording in at least a nucleus flock. This method avoids the need for abrupt changes in inputs, such as supplemental feed and labor at lambing, and avoids abrupt changes in the product marketed. The factors favoring selection are lack of availability of prolific breeds or major prolificacy genes, and environmental or market requirements that make the prolific breeds or their crosses, or individuals carrying major genes for prolificacy, inferior to local breeds in total performance (Bradford, 1985).

Sheep meat production is dominated by two factors. First, there are the biological and agricultural considerations of resource use, in particular the efficiency with which feed is converted into lean meat. Second, there are marketing considerations, in particular the ability of sheep producers to adapt output to conform more closely with changing market demand. Progress in both factors is needed if sheep meat is to continue as an important component of the diet. Consumption of mutton and lamb in Britain has fallen from about 11 kg/person annually in the 1940s to about 7 kg/person annually in 1996.

Meat purchasers in attitude surveys have shown that they believe lamb lacks versatility and is too fatty and wasteful. Therefore the carcass is central to the various activities on which the improvement of meat is based. Carcass quality provides the primary measure of output and is a key selection criterion for genetic improvement (Kempster, 1983). Defined in terms of consumer requirements, the selection objectives for improved carcass quality would be for maximum lean, minimum bone, and optimum levels of fat. Most of the variation in body composition in live animals is associated with differences in the amount of fat in the body. As an animal increases in live weight or degree of maturity, the weight and proportion of fat in the body and carcass generally increase, with a reduction in the proportion of lean tissue. Thus carcasses with a higher proportion of lean could be produced without recourse to genetic improvement simply by slaughtering lambs at lighter weights (Simm, 1987). When breeds of different mature sizes are compared at the same live weight, the larger breeds generally grow faster and contain less fat and more protein and bone in the body and carcass than breeds of small mature size.

Genetic variation within and among breeds for growth and carcass composition indicates that breed substitution, crossbreeding, and selection within a breed can increase the percentage of lean in the carcass (Glimp and Snowder, 1989). Selection for rate of gain should improve the lean-to-fat ratio at a constant weight. Leaner carcasses of a given weight could be produced from a given production system by switching to a breed of larger mature size, other factors being equal. The genetic improvement of terminal sire breeds offers a permanent, cumulative, and relatively inexpensive method of improving the carcass composition of crossbred lambs. The carcass composition of lambs slaughtered at a given live weight may be improved by using a terminal sire of higher mature weight than that currently being

used. This may be achieved by breed substitution or within-breed selection. Further improvements may be possible by selecting for slower rates of maturation in fatness and for reduced fat content at maturity (Simm, 1987). The formation of new breeds to be used in breeding programs to improve carcass quality provides new opportunities to produce lean, tasty, well-presented lamb that sells at a premium (Fell, 1987). The Texel breed is gaining in popularity for this purpose. The selection of rams for leanness, measured ultrasonically and corrected for live weight, should increase lean percentage without increasing body size.

With regard to wool, most fleece characteristics are highly heritable, so improvements in weight and quality can be made through selective breeding. Considerable knowledge about the biology of wool production is available, but the way in which it is applied depends on the farming system. The factors that affect wool production include the level of nutrition, season of the year, physiological state of the animal (during pregnancy and lactation wool growth is depressed), and sex (entire males produce more than castrates, which produce more than females) (Doney, 1983). Only in low-cost extensive systems with low capital and labor inputs, such as in Australia, is it economical to produce wool as a primary product. In Britain, wool is a by-product of intensive lamb production for meat, and high meat prices and subsidies mean that wool accounted for less than 10% of the income of sheep flocks in 1986 (Ryder, 1987), and continues to fall to below 5% (MLC Yearbook, 1997). The major objectives of merino wool producers in Australia are a heavy, clean fleece weight, a specified mean fiber diameter, and whiteness. The merino is virtually the only breed in which it is economically viable to apply selective breeding solely to wool characteristics. Improvement programs for the specialized wool-producing breeds continue to aim to increase clean wool production while maintaining average fiber diameter. This requires the use of fleece measurement laboratories to determine yield and average fiber diameter of the ram replacements and ewes (McGuirk, 1983). Up until recently, it was generally accepted by research and extension workers that recommended breeding programs for improving wool production in the merino have been largely ignored by the merino industry.

Group breeding schemes have been developed in some countries to enable several small-scale breeders to combine into an effective breeding operation involving the screening of large numbers of females for use in a nucleus flock (Owen, 1987a). It is an efficient means by which native sheep flocks may be screened for superior females, and a vehicle for the efficient incorporation of foreign genetic material into adapted sheep breeds. Group breeding schemes commonly involve the cooperative action of 10 to 15 breeders who individually may possess only relatively small flocks. The most common form involves the initial screening of the female population in the members' flocks to establish a nucleus. This allows a two-way flow of genetic material between the member flocks and the nucleus. Breeding rams are transferred from the nucleus flock to the member flocks and, by continuous systematic screening of females in the member flocks, the nucleus is augmented.

Initially, ewes are donated to the nucleus flock, which is the property of the cooperative group of breeder members. In early December every year each member delivers to the nucleus his or her top-ranking 3-year-old ewe, as judged by the Meat and Livestock Commission index. This ewe, in lamb to a breeding in the member's own flock, remains on loan in the nucleus until she has lambed and the lambs are weaned. The ewe is then returned, and the lambs become the property of the cooperative group. Members are entitled to receive a yearling breeding ram from the nucleus for their own use. Replacements for the nucleus are selected on the basis of an index that is mainly weighted on prolificacy and ewe milking ability. Over a period of 5 years in the Lleyn sheep scheme in Wales, a high level of performance has been achieved in relation to ewe body size, lamb survival, and ewe-rearing ability (Owen, 1987a).

The major obstacle to the efficient improvement of sheep breeds is the difficulty of making accurate measurements on any but a tiny fraction of the population represented by any breed. The activities of many group breeding schemes, which rely on the intensive screening of base populations, are hindered by the difficulty of intensive recording, particularly for traits such as milk production (Owen, 1987a). The milk-producing ability in ewes can be measured by recording the milk yield on one day shortly after the lambs are weaned, at approximately 2 months of age. This allows the ewes in the flock to be ranked according to milk yield. A similar procedure can be used in the selection of rams. The ram lambs are presented for testing at weaning, and the lambs in any one flock are all weighed on the same day, with selection based on the ranking of lambs according to body weight. Lambs born to 2-year-old ewes, and those born early or late in the season, are separately identified by a paint mark so that selection does not unfairly discriminate against younger lambs and those with immature dams. Selected ram lambs then participate in a central performance test on winter grazing, ending at approximately 13 months of age (Owen, 1987b).

BASIC FLOCK HEALTH MANAGEMENT AND PRODUCTIVITY PROGRAM

A basic sample health program for the commercial breeding flock is presented here. It is based on the application of the practical and economical management strategies that can lead to the optimum levels of reproductive performance and lamb survival and to effective and cost-effective control of major diseases such as internal parasites, blowfly strike, clostridial infections, and footrot. To do this and still maintain maximum cost-effectiveness requires special care in avoiding overcapitalization and excessive use of labor in an effort to provide for all emergencies. This would be contrary to one of the principal needs of the sheep industry, which is to reduce the intensity of the permanent labor force employed and to cater to the peak needs for shearing, drenching, lambing, and other health and production tasks by the use of contract labor. It should be possible to provide for a health service by using, and even organizing and providing, such contract labor as part of the service. This consideration is of most importance to large flocks. In smaller flocks the profitable use of what is in effect a potential oversupply of labor may include the development of additional health maintenance techniques.

It would be unwise to commence a flock health program without experience and expertise in the control of the diseases that are the principal targets of the program and without the back-up services of labor and laboratory to support these activities. It is a job for experienced professionals, who must be paid professional standard rates. The program must be financially self-supporting (Quinlivan, 1981).

General Outline

The basis of a sheep flock health and production management program is the frequent and repeated encouragement of the farmer to adopt the recommended procedures that are essential to the maintenance of health, production, and welfare. Sheep producers can be encouraged to consider and adopt the veterinarian's recommendations by the develop-

ment of a client-veterinarian relationship that is directed toward the health and production of the flock. The relationship is fostered through regular contacts, which are essential to the overall strategy of the program. These include the following:

1. An initial farm profile to ensure that the farmer's objectives are understood. The primary objective is usually maximum profitability. Additional information must be obtained on the resources of the land, water, animals, labor, and money available to the enterprise. Discussion of the major problems should be combined with preliminary arrangements made for the data collection system. An analysis of the data of the previous 1 or 2 years is a great help in defining productivity and problems.
2. A system of timely checks and reminders adapted to the needs of each farm and sent by mail at times appropriate to the expected occurrence of the problem. For example, the farmer is advised to vaccinate now against enterotoxemia or to drench now for liver fluke or nematodiriasis.
3. Periodic solicitation from the farmer of data on performance in production and health maintenance tasks. This information is used to determine whether production targets are being achieved and whether recommended disease control procedures are being carried out. Failure to perform elicits a specific reminder of the need to do so.
4. A system of regular visits by the veterinarian, usually three or four each year, to carry out physical work and to discuss past performance and future recommendations. This personal contact is vital to provide for discussion about the value of the program.
5. An annual discussion by a small group of farmers (15 to 20 is a good number) on additions, deletions, and modifications of the program or its recommended techniques and targets to provide an opportunity for community discussion on difficulties encountered in achieving objectives.
6. Concentration on key issues, those that cause a lot of wastage in the flock, those that can be controlled with little expenditure, and those that are highly profitable. In most sheep-raising areas the same problems have the top priorities. These include reproductive efficiency, neonatal deaths, the need for genetic improvement, culling rate based on objective standardized measurement of body weight gains and fleece quality and yield, better management of pastures and their best use, including selective supplementary feeding, attainment of maiden ewes to optimum breeding weight at first mating, optimum BCS of adult ewes, feed levels at the end of pregnancy and early lactation, and restraint of the prevalence of infectious and other diseases to a level consonant with optimum profitability.

Programmed Visits

It is desirable to arrange two to five visits to each farm each year. If the major disease problems are identifiable, it is possible to arrange the visits at critical times in the proposed disease control programs including vaccination, foot paring and foot bathing, jetting for blowfly, lamb marking (docking and castration), and dipping for lice and ked infestations. A recommended program of visits is shown in Box 16-20 and Table 16-8.

Visits During Lambing

Visits during lambing time are of critical importance to ascertain how successfully the flock health plan is operating with particular reference to late gestation nutrition. It is essential that a large number (100 lambs or greater) of newborn lambs are weighed and these data analyzed with respect to litter size and dam parity. Blood samples should be collected from a representative number of lambs and total plasma protein concentration determined after centrifugation with a handheld refractometer. Plasma glucose concentration can be determined accurately with human test kits. These analyses are cheap and easy to perform on the farm and provide invaluable information that can be utilized immediately to reinforce aspects of management. These data can be compared with previous years to indicate trends. A large sample of lambed ewes should be condition scored and these data compared with values at breeding time and during mid-late gestation, thereby permitting assessment of nutrition throughout the entire gestation period. The experienced veterinarian will also detect early signs of disease problems, such as the first few cases of watery mouth disease

BOX 16-20

Farm Visits

PREBREEDING FARM VISIT
This is done 6 weeks before the beginning of the breeding season. The body condition scores of rams and ewes are determined and rations adjusted accordingly. Rams are examined for breeding soundness. Also, the ram-to-ewe breeding ratio, length of breeding season, advantages of pregnancy diagnosis, abortion control, clostridial vaccination program, and the previous year's health and production performance data can be discussed and reviewed.

MIDGESTATION FARM VISIT
This is done 7 weeks after the rams are removed. Pregnancy determination is carried out by real-time ultrasound examination. The ewes are scored for body condition and sorted according to the score and number of fetuses, and rations are adjusted accordingly. The breeding performance is reviewed.

PRELAMBING FARM VISIT
Facilities and supplies are examined for lambing, including the protocol for sick lambs, disease prevention measures for lambs such as vaccinations, storage of bovine colostrum or other supplements, and dipping of navels with iodine. Evaluation of the ration is of critical importance because of the major influence of late gestation nutrition on lamb birth weight and perinatal mortality in prolific flocks. The ration can be altered with respect to dietary current energy supply as outlined by Russel.* Collection of blood samples from a representative number of ewes and determination of the group mean serum 3-OH butyrate concentration form the basis of flock advisory visits in U.K. flocks where a lambing rate of 200% or greater is expected.† Any thin ewes detected at this time are separated into groups and the ration adjusted accordingly to ensure no further loss. Correct nutrition during late gestation is essential to ensure that ewes respond to the various vaccination regimens administered at this crucial time. Administration of a large amount of antigen to a debilitated ewe will not lead to adequate accumulation of protective immunoglobulin in the colostrum; rather such action may precipitate disease, including ovine pregnancy toxemia.

TABLE 16-8

Herd Health Program for Indoor March Lambing in a Temperature Climate

Reproductive Cycle Event	Month	Flock Health Visits	Body Condition Score (BCS)	Nutrition	Adults Management	Adult Disease Control	Lamb Management	Lamb Disease Control
	August	Visit 1, mid-August: Do rams breeding soundness examination, BCS, and *Brucella ovis* serology; advise on flushing nutrition, ram:ewe ratio, estrus synchronization, ram effect	Rams, 3.5-4.0	Increase ration to breeding rams mid-August	Cull unsuitable rams		Sell grass-fed lambs as they reach appropriate weight	Predator watch, monitor fecal egg count (FEC)
Mid-September: Teaser rams in	September		Ewes, 3.0-3.5	Increase ration to breeding ewes mid-September; sort thin ewes and feed extra	Ewes: check teeth and udder, cull unsuitable ewes, analyze store forages and formulate rations for all ages and production groups for year	Vaccinate for abortion diseases (*Chlamydia, Campylobacter*)		
October 5: rams in marking harnesses, change color every 14 days	October			Maintain ration until 3 weeks after rams removed (i.e., end of November)		Worm adults once housed with larvicidal drug, late November typically		
November 10: rams out, teaser rams in with marking harnesses	November							

Continued

TABLE 16-8—cont'd

Herd Health Program for Indoor March Lambing in a Temperature Climate—cont'd

Reproductive Cycle Event	Month	Flock Health Visits	Body Condition Score (BCS)	Nutrition	Adults Management	Adult Disease Control	Lamb Management	Lamb Disease Control
December 1: teaser rams out	December	Visit 2, late December: Do pregnancy checks and ewe BCS; advise on nutrition and sorting, vaccination, abortion	Ewes, 3.0-3.5 (sort ewes on BCS and no. of fetuses)	Maintenance ration for fetal and placental growth; late December—increase ration to thin ewes and ewes carrying multiples		Watch for abortions, submit fetuses, placentae for postmortem, contact vet for serology		
Mid-January: last trimester of gestation	January				Cull open ewes or move to next breeding group (accelerated lambing)			
	February	Visit 3, mid-February: do BCS on random ewes; advise on lambing facilities, supplies for preventive treatments		Increase ration to ewes with singles; watch for thin ewes	February 1: crutch or shear ewes and trim feet, sort ewes by due date or udder fill for closer observation	February 1: vaccinate ewes for clostridial diseases, watch for pregnancy toxemia, etc.		
March 1: lambing begins	March	Optional visit, midlambing, if neonatal mortality has been a problem in the past	Ewes, 3.0-3.5	Sort ewes by BCS and litter number and feed accordingly	As lamb: place in claiming pens (24-48 hr) strip teat plugs; check for adequate colostrum, mastitis	Watch for mastitis, dystocia, mismothering, indurative mastitis	At birth: claiming pens, dip navels; week 1—Tail-dock, castrate, watch nursing, save for postmortem stillborn and dead lambs	0.25 ml vitamin E-selenium injection at birth; tetanus antitoxin/Orf vaccination, as necessary, appropriate therapy hypothermic lambs; post-mortem dead lambs

Mid-April: Lambing finished	April					Indoors: optional worming after lambing complete before turning out to pasture		Housed lambs: coccidiostat in feed, watch for urolithiasis; pastured lambs: may need coccidiostat as well
Mid-May: lambs ready for weaning depending on management type	May	Visit 4, mid-May: review performance of past year and set goals for next year	Ewes, 2.0-2.5	Accelerated lambing: must have ewes weaned at BCS of 3.0	Weaning: check ewes for mastitis, cull based on reproductive and lamb performance	Worming: 3 weeks and 6-8 weeks after turned on pasture with larvicidal drug; optional—dry cow mastitis ointment at weaning (if high prevalence of mastitis)	Weaning: indoors—remove ewes from lambs; pasture wean onto safe pasture	Worming: pastured lambs only, wean at same time as adults
	June			At weaning decrease ration (no grain) so that slow increase to BCS of 3.5	Select teaser rams and vasectomize; foot trim and footrot treatment, as necessary		Select replacements based on performance; sell grain-fed lambs late May, early June	Vaccinate for clostridial diseases at 3 and 4 months; worm up to once/month on pasture
	July					Check fecal egg count in late July, worm if high		Predator watch on pasture

For lambing at other months of year, adjust reproductive cycle events.

(endotoxemia), polyarthritis, hepatic necrobacillosis, and omphalophlebitis-peritonitis not yet noted by the farmer. A visit at this time allows necropsies to be undertaken on a representative number of lambs. This farm visit should be undertaken about 1 week after the start of the lambing period, since many problems do not arise until one third to one half of the ewes have lambed.

Postlambing Farm Visit. The lambs are examined for performance, such as average daily gain, and for evidence of coccidiosis and internal parasites. The lamb weaning program is discussed, performance parameters reviewed for the past season, and goals set for the next season. Ewes are checked for mastitis and ewes selected for culling. In addition, when seasonally appropriate, the efficacy of parasite control (e.g., late summer), footrot control, and other flock-specific disease control programs (e.g., maedi-visna, abortion) should be reviewed.

Timing of Visits

Periodic visits by the supervising veterinarian to sheep farms using flock health programs need careful timing. The schedule needs to take into account other managerial activities on the farm so that visits do not conflict with them unnecessarily but take place when sheep would ordinarily be handled for other purposes. Whenever possible, the visits should not be simply for looking and advising. There is also an advantage in having the visits synchronized with a relevant farm activity, such as drenching or marking, which could be useful to observe.

Data Collection and Storage

Management Data

It is necessary to have some method of recording management details in order to provide information on the quality of animal management and the intensity with which the program's recommendations are applied. It is therefore necessary to record details of sheep groups and their numbers, age, and genetic composition without necessarily identifying each sheep. Also, management details such as supplementary feeding, BCS, fleece weights, numbers and dates of sales of sheep, and prices received for products all need to be recorded.

The best arrangement is to set up groups of sheep on an age basis and to retain them in these groups for as long as possible. The group is identified by ear marks or ear tag, and this is usually sufficient for the maintenance of adequate records. The difficulty arises when sheep from a number of groups are commingled. It is then necessary to identify a new group composed of the residues of a number of groups, each of which may have a different history.

An alternative or supplementary method is to group ewes on the basis of their breeding dates, so that they are all likely to be lambing at about the same time. As the ewes lamb, they are drifted off until the group is sufficiently large; a new group is then formed. The other method is to identify the ewes bred by using a mating indicator harness on the ram and removing the ewes from the original group as they are marked. Both techniques are inclined to confuse the original groups and their histories.

The basic requirements for collecting all information, managerial and disease related, is a structured diary with tear-off sheets that are filled in and sent to the veterinarian on a regular basis. This permits the record keeping to be monitored constantly and the data to be stored at a constant rate during the year. Each interim report should include a statement on the following:

- Climate, feed supply, and rainfall
- Management procedures, including sales, births, data on rams in and rams out, supplementary feeding, shearing, crutching, marking of lambs
- Preventive veterinary procedures (e.g., drenching for worms or flukes, jetting, dipping, vaccinations, examination of rams for breeding soundness)
- Deaths and illnesses, postmortem examinations conducted

A second document considered essential is the annual management profile, which records in detail the resources, management, and objectives for the farm. By these means, significant changes in these activities or aspirations are recorded.

If a cash flow report is to be provided, there needs to be additional information on prices obtained for wool and stock and prices paid for feed and other supplies.

No details on the types of forms used in the programs just mentioned are provided here because they are specific to the particular area, methods of husbandry, and economic status of the animal industry in question.

Because the amount of data is relatively small, there usually being only a few groups of sheep on each farm, the data can be handled manually. Manual handling is already necessary for much of the data because it is qualitative rather than quantitative information (e.g., the state of the pastures). Comparisons of results between farms and before and after on individual farms, including partial budget estimations of financial status, require a combination of descriptive, numerical, and financial data.

Health Data

Information on health matters, including deaths, necropsy results, illnesses, treatments, and prophylactic techniques, is recorded in the diary provided, and copies are forwarded periodically to the data laboratory. More detailed reports of work performed by veterinarians or the diagnostic laboratory are supplied to the data laboratory, and the information is coded and stored.

Ideally, a necropsy examination should be carried out on each sheep that dies, but in a pastoral economy that is run on extensive lines, it is impossible to do this. The best that can be done is to encourage the producer to submit as many cases as possible for necropsy. If outbreaks of disease occur, these should be investigated and appropriate measures taken.

Analysis of Data: Reporting to Farmers

The number of reports provided to the farmer each year depends on the amount of stimulation required by the farmer and the additional costs raised by each additional report. It is usual to supply a report after each visit—that is, two or four per year. One of these is an annual report containing a review of the entire performance of the flock for the past year. The others are interim reports covering the period since the previous report.

Annual Report

The annual report should include a report on all the indexes that have been monitored, including those relating to health and those dealing with production. It would also be simple to predict sheep numbers for each of the succeeding months based on numbers of ewes mated, breeding date, and anticipated fertility index. This would permit forward planning of feed supplies. Also included should be a list of the activities carried out in each group, together with its record of production.

In terms of timing, the logical occasion for an annual report is when lambs are weaned or marketed and the analysis of reproductive and growth performance is completed; thus, July 1 or January 1 is suitable, depending on whether the lambing is in the spring or autumn.

Interim Reports

Interim reports should be supplied after the prebreeding visit, the visit during late gestation, and the visit during lambing time. These reports are supplemented by error messages when examination of the records indicates that a recommended procedure has not been carried out, and reminders are sent out to advise farmers of specific tasks that should be carried out at specific times.

Interfarm Comparison

If an annual meeting of a study group of farmers is arranged, it is common practice to discuss a comparison among farms so that farmers know how their performance rates with others. Identities are masked by a code number and performance in each of the indexes is listed. There may be good reasons for a farmer not to even attempt to achieve one or more targets, and these often serve as good points around which to arrange a discussion.

Manual or Computer Analysis of Data

If the expense of the computer program can be borne, it is preferable because it is so error free, consistent, and successful at carrying out repetitious bookkeeping and examination of records. In comparison with dairy cattle, there are relatively few incidents to record, and a manual data processing system is adequate if there are only a few flocks. If there are a large number of sheep or if many additional procedures are used, however—such as individual identification, weighings, and use of a crayon marking breeding harness—the manipulation of record cards becomes tiresome. Many sheep producers have now written their own spreadsheets to track animals and produce action lists. These programs can be incorporated with Record of Performance data to analyze data and create reports of reproductive performance of the last breeding period.

Costs and Benefits of Sheep Health Management

Costs

The costs of a sheep flock health and production management program consist of the professional veterinary fees and the costs of animal health products such as vaccines, anthelmintics, insecticides, antimicrobials, and other drugs used in sheep production. Veterinary practices have had a major impact in the sheep industry through the professional advice they offer along with the provision of animal health products. The cost-effectiveness of these programs in the hands of experienced veterinarians who are advising average sheep producers is excellent. There are always a few farmers whose management and disease control is so good that the program offers them little financial gain, but they are recognizable early if a retrospective analysis of data is done at the time of the original farm profile. Some of these farmers decide not to continue, but most do in order to have insurance against error.

The professional fees for visits to the flock and for health management consultation and advice are best based on an hourly fee. However, some producers prefer to pay on a per breeding ewe-per year basis for health management services provided by the veterinarian. In addition to the time spent on the farm, the other tasks include arrangement of laboratory tests, answering of telephone calls for advice, analysis of data (often by computer), discussions with and arranging visits by other consultants, and preparation of reports, which are usually done in the veterinarian's office.

The time spent on the farm varies with the numbers of animals and problems to be assessed and corrected. A commercial flock of 2000 ewes would require at least four 3-hour farm visits annually. At $70/hr (U.S.), the costs of the on-farm professional services are about $840, or about 42 cents/ewe annually. For each farm visit, an additional 1 or 2 hours is necessary to analyze records, prepare reports, and make recommendations to the producer. This increases the annual professional fee to 56 to 70 cents/ewe. Transportation costs to the farm and the costs of animal health products such as anthelmintics, vaccines, antibiotics, and insecticides increase the total annual costs to $1.00 to $1.50/ewe.

In the United Kingdom flock size is generally smaller (averaging 500 ewes) but flocks over 2000 ewes are not uncommon. Increasingly, flock health schemes have become part of a welfare-based marketing exercise undertaken by large supermarket chains. Unfortunately, these health schemes are primarily concerned with food safety and accurate recording of treatments and sheep movements rather than with the major objectives of sheep welfare and productivity. Farm inspections are undertaken annually by lay people and not veterinarians and have not been well received by sheep producers. Standards demanded by membership at present can be achieved readily by almost every farmer, and a radical review of such schemes is overdue, but it would appear that the veterinary profession is unwilling to meet these challenges. Consequently, sheep health and production represents only a small proportion of food animal services in rural areas. The potential for veterinary services in the United Kingdom can be readily determined after reference to performance data produced by the industry. While the top third of lowland spring lambing flocks rear 160 lambs/100 ewes mated, the annual ewe mortality rate was 5% with 4% barren; lambs losses totalled 17/100 ewes mated (MLC Yearbook, 1997). These data relate to the top flocks and are unlikely to be representative of the majority of sheep producers; indeed perinatal lamb mortality rates in excess of 15% are widely quoted (Whitelaw, 1976; Eales et al, 1983; Barlow et al, 1987; Hindson and Winter, 1990) with the annual ewe mortality rate between 6% to 8%. These losses must be considered in context and are all the more disappointing because most flocks lamb indoors with 24-hour supervision, availability of highly efficacious vaccines against chlamydial abortion and toxoplasmosis, absence of predators, and routine administration of oral antibiotics to all lambs within 15 minutes of life (Eales, 1985).

Economic Benefits to the Sheep Producer

If the cost-effectiveness of the flock health program is to be assessed, the gross and net incomes must be determined. Failing this, the income can be estimated on the basis of yield multiplied by value. For wool, the total wool sold comes from bale weights and the yield per sheep from the bale weight divided by the number of sheep shorn. This figure is available from the shearing shed cut-out figures. The quality of wool can be determined by access to the objective measurements if they are used as a basis for the sale of the wool.

Body weights are harder to obtain, unless the lambs, hoggets, and wethers are sold to abattoirs on a weight basis or are weighed by the abattoir for its own purposes. The use of scales on the farm might be unreliable because of variations in gut fill that occur during the day, making the assessment of carcass weight from live weight a haphazard arrangement.

In many countries lambs are not only weighed but are also graded on conformation and fatness by the use of a grid classification at the slaughter plant (MLC Yearbook, 1997), providing the producer with accurate and reliable data on

which to base management decisions. Seasonal variation, indeed marked weekly fluctuations, in price may influence income, but most producers market lambs over a period of months; such fluctuations even out in the final financial assessment.

The publication of reference performance data (MLC Yearbooks) affords veterinarians and other livestock advisors accurate yardsticks to measure their clients' performance. One criticism is that these commercial flocks do not provide sufficiently high targets, and it can prove difficult to motivate those flockowners who exceed the "top third of producers." However, these data produced under commercial pressures are useful in the formulation of a flock health plan and should be readily consulted.

CONTROL OF OTHER ECONOMICALLY IMPORTANT DISEASES

The following diseases were chosen to be listed out of the large number that affect sheep because they are universally present, cause significant wastage, and must be included in a basic program. These are gastrointestinal helminthiasis, blowfly strike, clostridial diseases, footrot, and maedi-visna. They are only reviewed here because they are detailed in most textbooks of farm animal medicine (Radostits et al, 1994).

Gastrointestinal Helminthiasis

Gastrointestinal helminthiasis, especially that caused by nematodes, is a major health and production problem in sheep flocks and accounts for large economic losses. Economic loss results from clinical disease, suboptimum performance because of subclinical infection, and all the costs associated with the use of anthelmintics. Clinical disease can result in deaths, and subclinical disease reduces the growth rate of youngstock and reduces wool production. Helminth infections in sheep can also cause a reduction in birth weight of lambs, reduced fertility of ewes, and a reduced percentage of ewes rearing lambs to weaning. The use of anthelmintics without due regard for the epidemiological characteristics of the nematodes in a particular area is a major cause of economic loss. Furthermore, the development of anthelmintic resistance is also related to their use, and failure of anthelmintic effectiveness is a source of economic loss.

Principles of Control

Eradication of most helminth infections is not practical. Traditionally, most parasite control strategies were protective in orientation and were based almost entirely on the regular use of anthelmintics. The anthelmintics usually provided protection against serious clinical disease and mortality but frequently were not effective in preventing the exposure of animals to high levels of pasture infection. As a consequence, production losses still occurred because of reinfection in the interval between treatments. The principles of control of gastrointestinal helminthiasis in sheep are as follows:

1. Strategic, therapeutic, and prophylactic administration of anthelmintics.
2. Management techniques designed to prevent or limit contact between parasite and host (Brundson, 1980). The strategies include prevention of the buildup of dangerous numbers of larvae on pastures, and anticipation of the periods during which large numbers of larvae are likely to occur and removal of susceptible animals from heavily contaminated pastures before these periods. These aims can be achieved by using three interrelated approaches: grazing management, the use of anthelmintics, and dependence on the acquisition of immunity. The most efficient control requires the complete integration of all three facets (Brundson, 1980).

Much has been learned about the epidemiology of helminth disease in farm animals. This information can be used by the producer and veterinarian to develop the most effective and cost-effective strategies for the control of parasitic gastroenteritis in the sheep flock (Armour, 1980; Morley and Donald, 1980).

The most prevalent and important helminths in sheep are the trichostrongylids, *Haemonchus contortus, Teladorsagia circumcincta,* and *Trichostrongylus colubriformis.* These nematodes have a simple and direct life cycle. Eggs are passed in the feces, hatch, and develop through free-living L1, L2, and L3 stages within a week under optimum conditions. L3 is the infective stage, during which larvae migrate from the feces onto the herbage and are ingested by the grazing animal. After ingestion, they pass to the abomasum and intestines and develop into fourth-stage larvae within the glands lining the walls of these organs before emerging as egg-laying adult worms about 21 days after ingestion. Developing fourth-stage larvae cause damage to the lining of the abomasum and intestines, causing malabsorption, inappetence, unthriftiness, diarrhea, and anemia in the case of *Haemonchus* sp.

The helminths just described have developed adaptations to ensure transmission from one host generation to the next. These adaptations include hypobiosis and the periparturient rise in egg output by ewes, prolonged survival on eggs on pasture, and a long adult life span in some instances. Hypobiosis is a temporary but sometimes prolonged period of arrested development of the fourth stage of the larvae in the host. All the commonly occurring nematodes of sheep in North America are capable of hypobiosis, which occurs during the winter period. In the northern temperate United States, *H. contortus* overwinters almost exclusively in the hypobiotic state (Herd et al, 1984b). Maturation of the arrested larvae eventually occurs, which leads to an increase in the number of egg-laying worms; this in turn causes an increased fecal nematode egg output. In parturient ewes the increase in egg production may be marked; this is known as the "spring rise" or the periparturient rise in egg counts from 2 weeks before lambing until 8 weeks after lambing, regardless of the season (Herd et al, 1983). This sudden increase in egg production is the major source of pasture contamination early in the grazing season and is the prime source of infection for lambs. These lambs in turn can serve to augment pasture contamination, leading to heavy levels of pasture infectivity during late summer and fall (Gibbs, 1986).

Thus, under temperate conditions, the periparturient rise is a major source of contamination contributing to the summer peak of larvae on pasture. These larvae are mainly responsible for the first generation of worms that accumulate in lambs during the summer, because most of the larvae that overwinter disappear rapidly from the pasture during the early part of the summer before the lambs are grazing extensively.

The treatment of ewes in the spring early enough to remove arrested larvae has been highly successful in controlling the subsequent levels of parasitism in lambs. The strategic administration of anthelmintics to suppress the spring rise in egg production from ewes can reduce pasture contamination (Herd et al, 1984a). Prelambing treatments with levamisole or fenbendazole are effective in eliminating the hypobiotic stages of the worms and both the primary and secondary periparturient increases (Herd et al, 1983). Postlambing treatments may be too late to affect the periparturi-

ent rise. However, if the ewes lamb indoors, the anthelmintic can be given at lambing before they are turned out to grass.

It is now recognized that animals exposed to nematode infections develop immunity to the causal helminth. At the start of their second year at grass, yearling sheep have usually acquired an immunity to helminth infections. As a consequence, only a small proportion of the infective larvae that they ingest develops into adult worms and lay eggs, and those that do are probably expelled from the animal quickly. In the ewe there is a temporary relaxation of this immunity at the time of lambing, and during the course of early lactation this causes the periparturient spring rise in egg output. Because the development of immunity depends on exposure to infection, the application of anthelmintics may influence its development. The intensity and timing of anthelmintic administration must be arranged to effect acceptable control of the parasites and yet not depress the development of immunity (Gibson, 1980).

Sheep nematodes exhibit marked seasonal patterns of pasture infectivity. Sheep turned out to pasture in the spring in northern climates may be exposed to light infections from overwintered pasture L3 stages of *Teladosargia, Trichostrongylus,* and *Nematodirus* sp. (Smith and Fulton, 1989). By midsummer, sheep are commonly exposed to large numbers of second-generation L3 stages capable of causing disease. These infections originate from the maturation of the hypobiotic stages of the larvae that were present in the ewes and have now matured, and in part from the eggs shed by sheep infected early in the spring. The warm temperatures and rainfall of the summer provide ideal conditions for the explosive development of large numbers of infective L3 stages. These findings emphasize the need to attack first-generation helminths early in the year to prevent the escalation of second-generation worms in the summer months. The use of anthelmintics in late summer and fall, when the infectivity of the pasture is high, is usually ineffective over the long term because reinfection occurs quickly and the helminth load returns to pretreatment levels. For effective worm control, the timing of treatments must be related to the seasonal development of infective larvae on pasture.

Practical Control Strategies

The most important aspect of a program is education of the farmer regarding the principles behind parasite control. A survey of anthelmintic usage for sheep in New Zealand indicated that many farmers do not have an elementary understanding of the properties and limitations of anthelmintics (Brundson et al, 1983). Farmers may not fully realize the importance of dose rates and that most anthelmintics do not have a residual effect. This lack of knowledge is the collective failure of anthelmintic manufacturers, research workers, and veterinarians to communicate the appropriate information adequately to farmers (Brundson et al, 1983). Few farmers appear to have a clear idea of the purpose of prophylactic anthelmintic administration, which is to prevent contamination of pasture during epidemiologically important periods. They either treat youngstock regularly throughout the year as insurance against serious disease and to achieve peace of mind, or they treat protectively during the period of greatest risk or curatively after the appearance of ill thrift and/or onset of clinical disease. These methods are not cost-effective compared with the most cost-efficient method of integrated control, which requires forward planning of grazing management (Brundson et al, 1983). With a knowledge of the epidemiology of the helminths, a number of the following control strategies can be recommended.

Prelambing Treatment. A winter treatment of early-lambing ewes with levamisole or ivermectin at the time of housing eliminates arrested larvae and prevents maturation to adults and the periparturient rise (Herd, 1984, 1986). The treatment can be given any time around lambing, but it must be done before the ewes go out to spring pasture (Fig. 16-7). The major objective is to prevent ewes from contaminating spring pastures (McKellar et al, 1988). It is unlikely that many worm eggs shed within the barn before treatment develop to the infective L3 stage. Late-lambing ewes require a second treatment just before lambing if they have already grazed spring pasture contaminated with overwintered larvae. Both early- and late-lambing ewes that have been treated are best kept indoors or moved to clean pastures after treatment to avoid immediate infection. If pregnant ewes are housed from mid-pregnancy to lambing because of inclement weather, the use of levamisole during the last 10 weeks of pregnancy can improve the birth weight of lambs and increase the milk production of the ewes, thereby increasing the lambing percentage (Brown et al, 1984).

Administration of Anthelmintics and Movement to Safe Pastures. The movement of anthelmintic-treated sheep to a safe pasture extends the effectiveness of a single treatment and reduces reinfection. A safe pasture must not have been grazed by sheep for at least 3 months or more. Treatment removes the worm burden and protects a safe pasture from contamination. However, it must be remembered that some gastrointestinal ova and larvae can survive overwintering, and "safe pasture" is a relative concept. It is also important to note that, because of economic considerations, few producers can leave a pasture free of sheep for 3 months during the growing season unless alternated with cattle. This strategy requires some forward planning to secure the safe pastures and to make provisions for efficient use of the pasture after it becomes highly infective and cannot be grazed by susceptible sheep.

The production of safe pastures depends on the prevention of contamination during critical periods. Contamination is avoided by eliminating sheep grazing from certain areas of the farm for specified periods, which requires about 3 months or more. Contamination can also be reduced by dilution through the use of mixed grazing of sheep and cattle or alternate grazing. Alternate grazing of cattle and sheep also provides safe pastures because of the relative lack of cross infection between cattle and sheep. Pastures can be allowed to grow forage, which is then harvested for hay or silage. After harvesting, most of the previous year's overwintered larvae have died. Safe pastures can also be produced by the use of critical, strategic anthelmintic treatments when free-living development is minimal. The administration of anthelmintics during the dry summer period in Victoria, Australia, for example, produced safe grazing pastures for autumn and winter (Brundson, 1980). The weaning and treatment of lambs before grazing on clean pastures is also effective for the control of *H. contortus* because removal of the ewes as a source of contamination is effective in controlling hypobiosis (Tritschler et al, 1989).

The provision of ewes and their lambs with pastures relatively free of helminth infection (safe pastures) from lambing in spring until weaning is beneficial (Waller et al, 1987a; Fawcett and MacDonald, 1988). In southeastern Australia, ewes grazing safe pastures and drenched once before lambing produced more wool than did ewes on contaminated pastures (Waller et al, 1987b). An additional benefit was increased control of blowfly strike because of less fecal soiling of the breech in lambs.

Prophylactic Anthelmintic Administration in the Spring. This is given to sheep after they are turned out to spring pasture and become infected with the overwintered L3 stage on pasture. Treatments given at 3-week intervals starting 3 weeks after turnout usually kill newly ingested

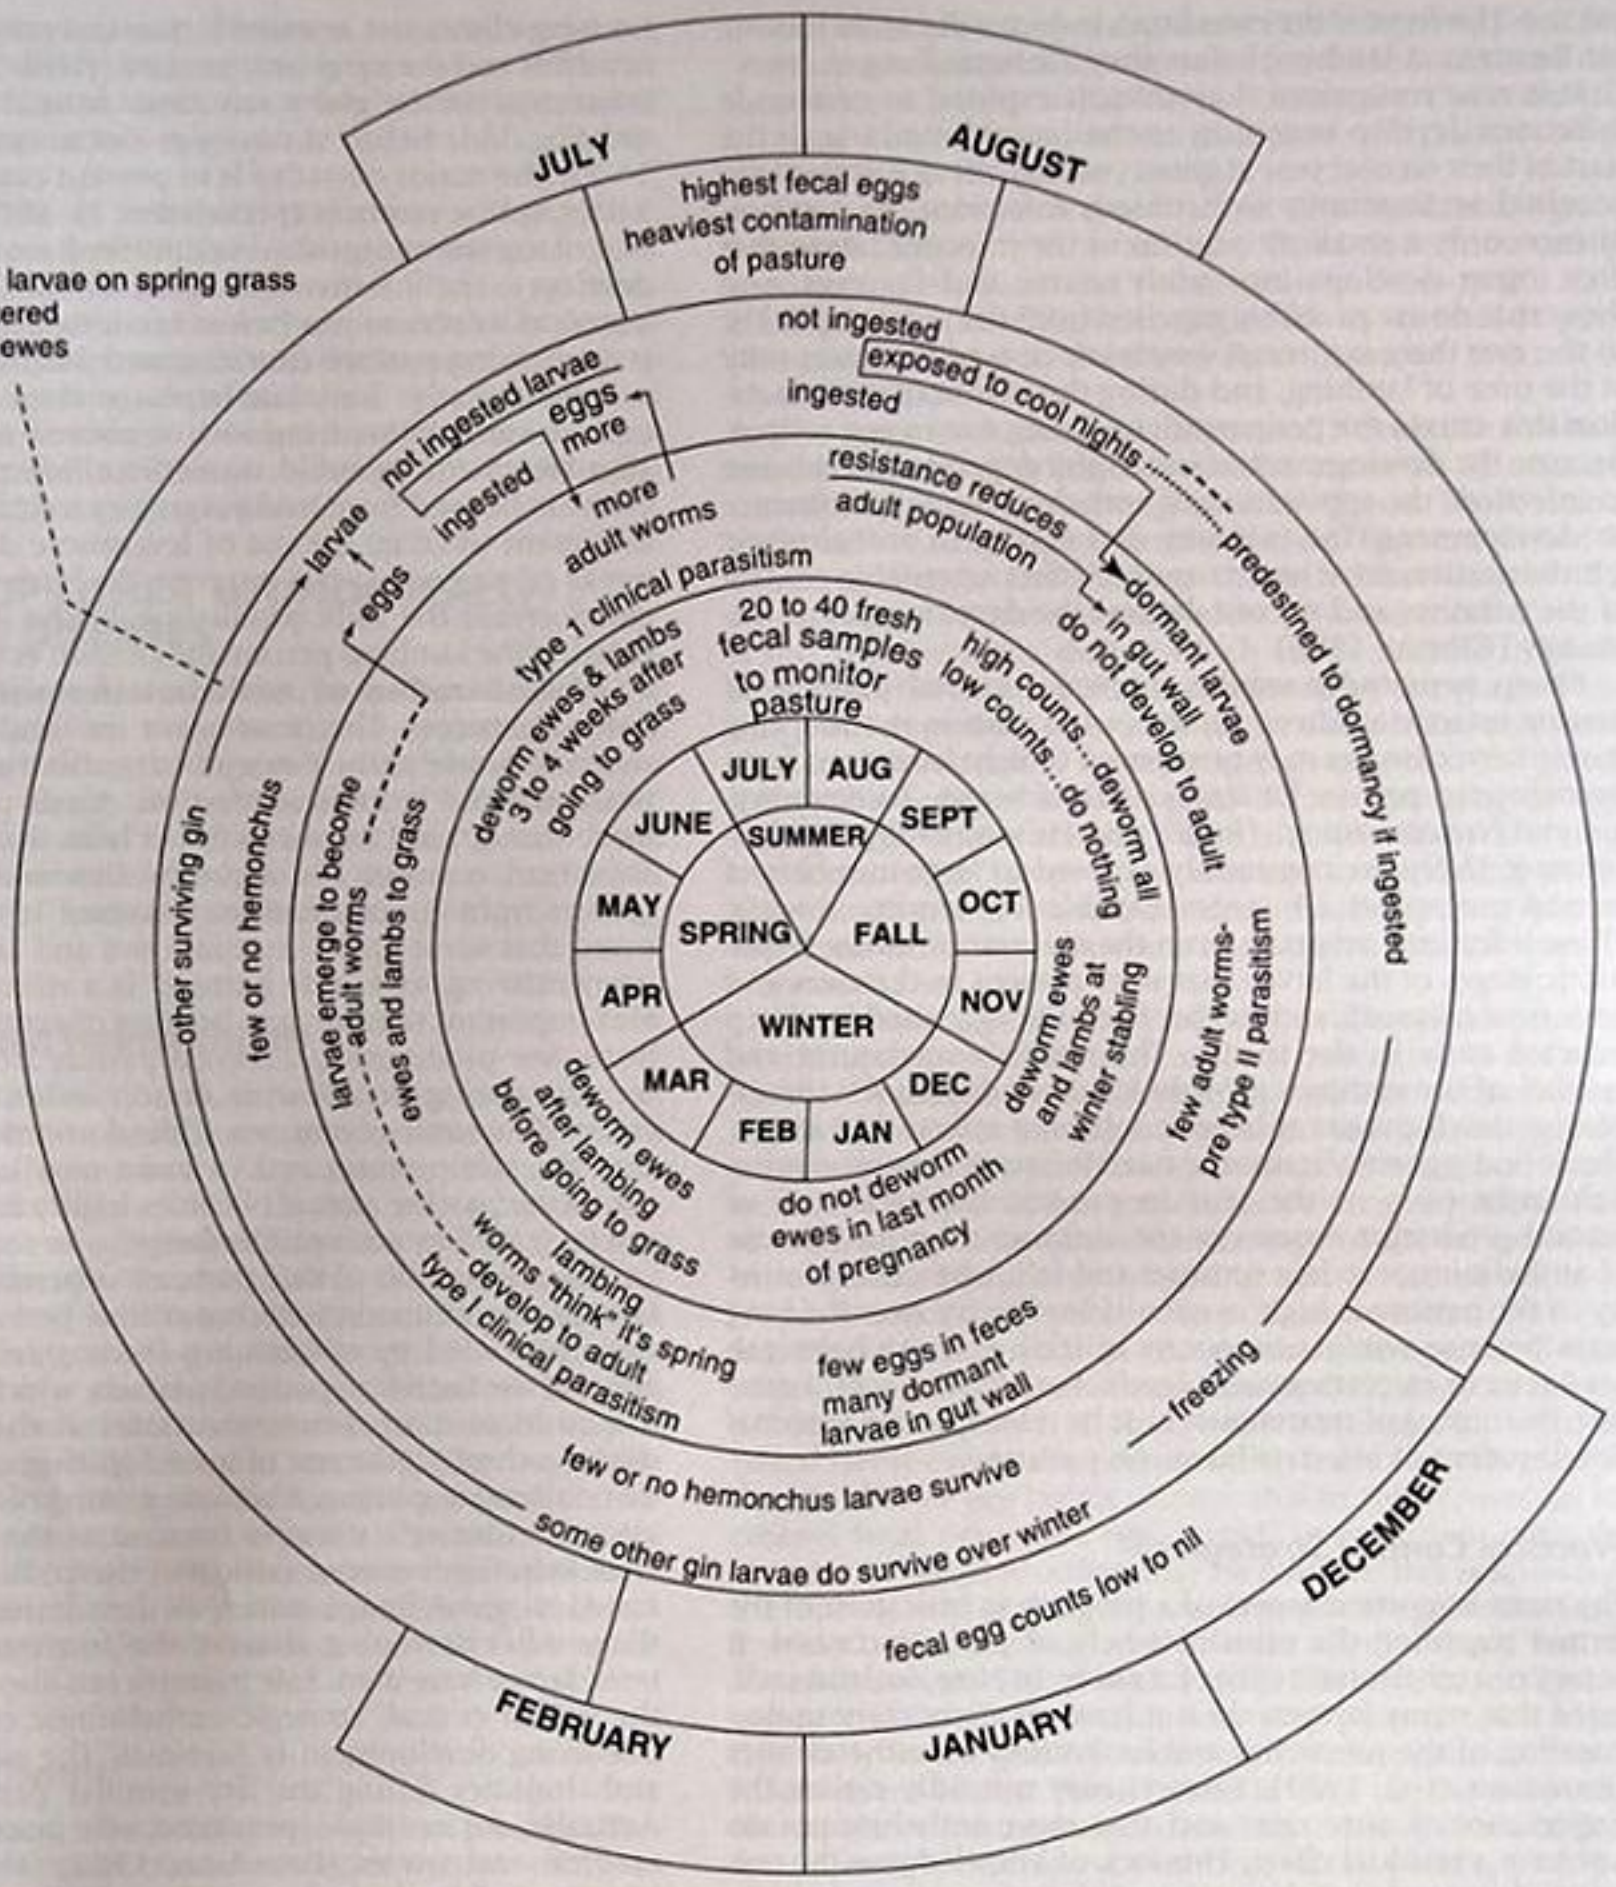

FIG. 16-7 Seasonal and monthly sheep deworming program. (Courtesy of JP Lautenslager.)

larvae before they mature and start contaminating pastures with large numbers of eggs. In the northern United States, four treatments at 3, 6, 9, and 12 weeks after spring turnout were just as effective as eight treatments at 3-week intervals in preventing the escalation of second-generation worms and achieving desirable weight gains (Herd, 1986). It is also important to give prophylactic treatments at no more than 3-week intervals; at monthly intervals, larvae ingested after treatment mature and pass eggs before the next treatment and cause pasture contamination. As temperatures increase in the summer, the remaining overwintered L3 stage larvae die off and there is relatively little new contamination with eggs (Herd, 1986).

Set-Stocking and Anthelmintic Administration. In many commercial flocks, lambing occurs on set-stocked permanent pastures contaminated with nematode eggs from sheep grazing in the previous autumn or winter. Set stocking is the practice of stocking a pasture with large numbers of animals for long periods of time. The pastures become heavily contaminated with infective larvae, and their numbers increase during wet seasons and decrease during the dry seasons. Anthelmintics are given frequently and regularly at times suggested by the epidemiological characteristics of the nematode; the objective is to maintain a low level of pasture contamination. Rotational grazing has been strongly recommended in the past but, on a practical basis, pastures cannot

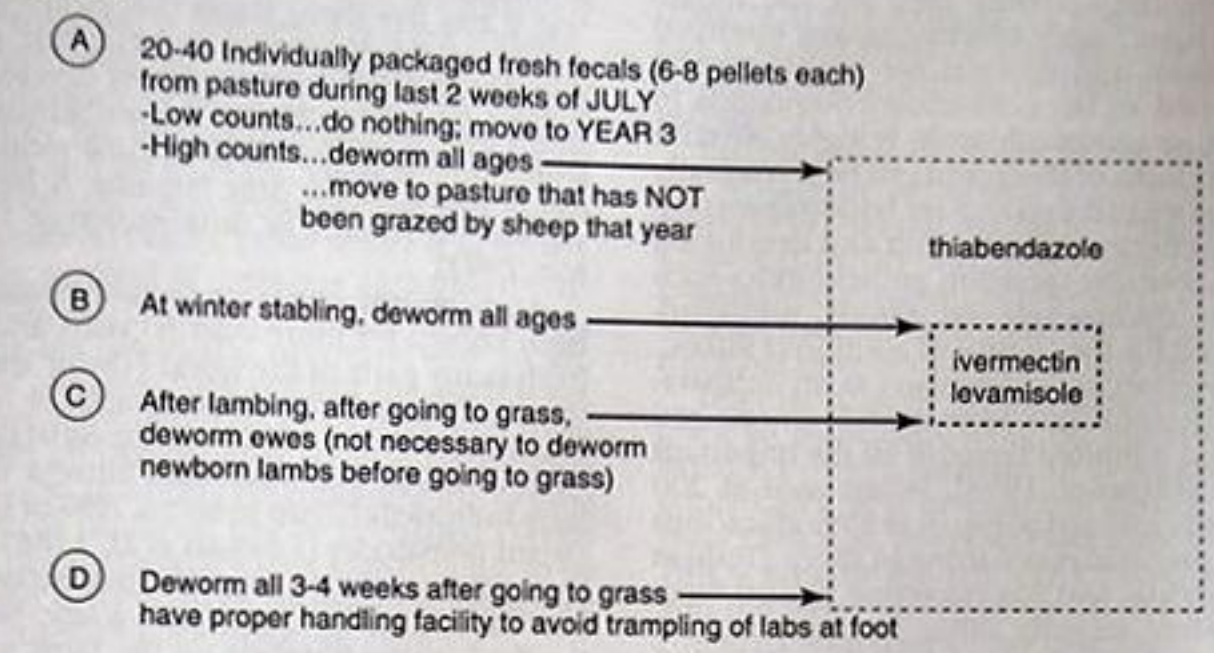

FIG. 16-8 Yearly sheep deworming program.

be spelled off until almost all larvae have died without damaging the pasture. For complete elimination of pasture infestation, an interval of 2 years between grazing is necessary but is not usually practical.

Clean grazing systems—which alternate cattle, sheep, and crops annually—have been described, but few farms have the correct ratios of livestock. Performance data of lambs reared on clean grazing systems are superior to those systems that attempt to control parasitism by chemoprophylaxis.

Choice and Use of Anthelmintics. The proper use of anthelmintics necessitates an understanding of the mode of action, the pharmacodynamics of the various drugs, and the factors that affect efficacy, because this information leads to the correct choice of the compound to be used in a particular circumstance. Arundel (1985) has pointed out that unfortunately, in practice, the compound is often selected without adequate consideration of the circumstances. Often, the choice of anthelmintic is made on the basis of the breadth of spectrum, narrow or broad, or price, without any effort being made to determine which parasites are present and causing the clinical condition or the effect of the routine use of broad-spectrum anthelmintics on the development of resistance.

A survey of the use of anthelmintics in New England indicated that sheep producers have a lack of awareness of the rationale for the use of anthelmintics (Tritschler et al, 1986). The administration of anthelmintics was commonly done when convenient and when other activities occurred, rather than with an epidemiological approach to the parasite. Only 27% of farms had a distinct drenching program for lambs, and less than 4% followed a grazing practice based on the control of the parasite. Producers were unaware of the side resistance (discussed later) among benzimidazoles in particular. About one third of producers had discontinued the use of an anthelmintic, most commonly thiabendazole, because they considered it to be ineffective. Excellent published material is available on the use of anthelmintics, their mode of action, the withholding periods to be used, and the problems of anthelmintic resistance (Gibson, 1980; Ministry of Agriculture, Fisheries and Food, 1984; Arundel, 1985).

The epidemiology of the major parasites of sheep is now well known for most areas, and the timing of treatments that can achieve maximum epidemiologic impact and minimum production losses has been determined (Fig. 16-8). If the best results are to be obtained, veterinarians and other advisers to the animal industries should understand the principles involved in the use of anthelmintics.

Broad-spectrum anthelmintics include the benzimidazoles and probenzimidazoles, the imidazothiazoles, the tetrahydropyrimidines, and the avermectins and milbemycins. Thiabendazole was the first of the benzimidazoles, followed by parbendazole, cambendazole, mebendazole, oxibendazole, fenbendazole, oxbendazole, and albendazole.

Most of the anthelmintics currently used are the broad-spectrum types, which are highly effective against intestinal nematodes. Thiophanate and febantel are probenzimidazoles that are converted to benzimidazole compounds in the body. Levamisole, an imidazothiazole, is highly effective against intestinal helminths of sheep and can be given orally or by injection. Morantel and pyrantel are tetrahydropyrimidines and are highly effective against adult and developing immature helminths. Narrow-spectrum anthelmintics such as the salicylanilides oxyclozanide, rafoxanide, nitroxynil, and brotianide are used for the control of adult liver flukes.

Ivermectin is an avermectin widely used as an antiparasitic agent. It is highly efficacious against adult worms and against developing and inhibited larvae of all the important nematodes of sheep (Marriner, 1986). When used at 200 μg/kg in experimentally infected sheep, it is 99% efficacious against the common nematodes occurring in sheep (Todd et al, 1985). It is not ovicidal and has no action against tapeworms and flukes. More recently other avermectins have been introduced, including abamectin, doramectin, and eprinomectin, and milbemycins such as milbemycin and moxidectin. In sheep, abomasal worms may be controlled for 5 weeks after moxidectin treatment (Bishop, 1998).

The following are several important factors influence the efficiency of anthelmintics used in sheep (Arundel, 1985).

Route of Administration and Dose. Most anthelmintics for sheep are given orally, and the operator must ensure that the drenching gun delivers the correct amount and that the animal swallows the product. Regular calibration of the drenching gun is recommended. Some products are given by injection. Producers may unintentionally underdose sheep, particularly adults, because they underestimate the body weight of the animals and because of variations in body weight within a group of sheep. Sheep must be weighed regularly and dosed on the basis of the heaviest in the group and not on the average body weight. It is important for the veterinarian to ensure that the producer understands the directions for use of the anthelmintic are fully understood.

Esophageal Groove Reflex. Some anthelmintics are more effective if delivered directly into the abomasum rather than the rumen; the reverse is also true.

Particle Size. Micronization provides greater surface area and leads to higher concentration in the fluids of the gastrointestinal tract, with more rapid absorption and greater effectiveness.

Anthelmintic Resistance To Nematodes. Anthelmintic resistance can be defined as a heritable change in the ability of individual parasites to survive the recommended therapeutic dose of an anthelmintic drug. Resistance is present when a greater frequency of individuals within a population is able to tolerate doses of a compound than in a normal population of the same species, and this resistance is heritable. Prichard et al (1980) and Waller (1986) have provided the following definitions of resistance. *Side resistance* exists if the resistance to a compound is the result of selection by another compound with a similar mode of action. Cross resistance resembles side resistance but involves compounds with different modes of action. *Multiple resistance* occurs when individuals are resistant to two or more different anthelmintic groups, either as a result of selection by each group independently or as a result of cross resistance. *Reversion* is a decrease in the frequency of resistant individuals in a population following removal of the selecting agent. *Counterselection* is reversion hastened by the use of an anthelmintic with a different mode of action to that which induced resistance. A synonymous, but less-favored term, is *back selection*. Selection pressure is determined not only by the dose of anthelmintic, but also by the proportion of the parasite population exposed to the drug. Selection pressure is high when anthelmintic treatment leaves few survivors and there are few, if any, free-living stages that escape exposure.

The establishment of anthelmintic resistance within a population follows a three-phase development. Initially the worms are susceptible to the anthelmintic, then heterozygous individuals gradually become more prevalent but clinical response to the drug remains. A homozygous resistant population follows as drug resistance is established (Jackson, 1993).

Anthelmintic resistance to gastrointestinal helminths has been known for more than 30 years and has been reported from many parts of the world (Taylor and Hunt, 1989). The literature on anthelmintic resistance in the United Kingdom (Taylor and Hunt, 1989) and in Australia (Hall, 1990) has been reviewed and discussed. Surveys in western Australia have indicated that up to about 70% of sheep flocks have resistant nematodes (Edwards et al, 1986). The factors related to resistance of one or more nematode genera to one or more anthelmintics include flock size, percentage of ewes in the flock, cattle numbers on the farm, main sheep production activity, grazing strategy, frequency of drenching, changes in the frequency of drenching, number of summer drenches, and the method of estimating dose rates (Edwards et al, 1986). Large-scale surveys of sheep farmers in Australia and New Zealand have revealed many misconceptions about the properties, limitations, and use of anthelmintics. Modern anthelmintics are safe and cheap, and originally they were effective. Nematode control programs often consisted merely of giving occasional anthelmintics according to traditional practices and beliefs, when sheep were yarded for some other reason, with little attention paid to the epidemiology of the parasites (Waller, 1986).

Frequent treatment at intervals close to the prepatent period of the parasite, such as monthly, is considered to be the most important factor in the development of a resistance problem. The most notable example is the resistance of *H. contortus*, which developed in chronological sequence to phenothiazine, the benzimidazoles and probenzimidazoles, and levamisole and morantel. In South Africa, strains of *H. contortus* have been identified that are resistant to the benzimidazoles, to the salicylanilides rafoxanide and clostanel, and to ivermectin (Taylor and Hunt, 1989). In Europe, resistance of sheep nematodes has been reported from several countries, including France, Germany, Holland, and Switzerland (Taylor and Hunt, 1989). Resistance to thiabendazole was seen in Australia in 1968 and is now known to be widespread in *H. contortus* almost worldwide (Cawthorne and Cheong, 1984). Because the benzimidazoles are related chemically, there is considerable cross resistance. Benzimidazole resistance in several gastrointestinal nematodes of sheep in New Zealand has now been reported (McKenna, 1989; West et al, 1989). The purchase and importation of sheep harboring resistant *Haemonchus* sp. may also be the explanation for the rapid appearance of anthelmintic resistance on one farm where previously the commonly used anthelmintics had been effective (West and Probert, 1989).

A diagnosis of anthelmintic resistance should not be made without good evidence. The most common cause of failure of parasitized sheep to thrive after treatment is the rapid reinfection that occurs when animals are placed, after treatment, on a heavily contaminated pasture. Another cause is an incorrect diagnosis when ill thrift is the result of nutritional inadequacies or other diseases. Tests for resistance include the egg count reduction test, in which there should be a reduction of more than 90% in the egg count if susceptible strains are present. The diagnostic value and interpretation of fecal egg counts in sheep have been evaluated (McKenna and Simpson, 1987). There is a good relationship between the egg count and the estimated flock worm burden

when 10 to 15 egg counts on randomly selected members are performed. The exception is during the late fall and winter months, when the larvae are in the hypobiotic state. A total worm count can also be done 10 days after routine treatment, followed by necropsy examination to determine which species remain and are resistant. There is good agreement between the fecal egg count reduction test and the reduction in worm numbers (Waller, 1986; Waller et al, 1990).

The most reliable method of assessing anthelmintic resistance is the experimental infection of groups of worm-free animals with third-stage larvae and treatment with an anthelmintic when the parasites have reached the adult stage. The animals are then slaughtered 10 to 14 days after treatment and their worm burden counted. By treating at different drug concentrations, an ED50 (the concentration of drug required to kill 50% of parasites) can be calculated (Taylor and Hunt, 1989). The selection of which anthelmintic to be used in the future may depend on an anthelmintic resistance test on the farm in question (Edwards et al, 1986).

If anthelmintic resistance is detected in a flock, a change to an unrelated anthelmintic group should be done (Taylor and Hunt, 1989). More importantly, the parasite control program that has been used should be investigated, and, if necessary and possible, the anthelmintics in use should be changed to ones less likely to select for resistance. Narrow-spectrum anthelmintics to replace broad-spectrum ones should be used only when required (Edwards et al, 1986). The strategic use of anthelmintics only at times of high incidence, and based on epidemiological information and disease forecast, can help delay the onset of resistance. Pasture and animal management for parasite control should be integrated as much as possible to reduce the dependence on anthelmintics. The alternation among the three groups of broad-spectrum anthelmintics, benzimidazoles, and probenzimidazoles; imidazothiazoles and tetrahydropyrimidines; and avermectins and milbemycins, at approximately yearly intervals has been recommended (Coles and Roush, 1992) and adopted by advisory agencies. Anthelmintics should also be used at dose rates that cause the highest economically feasible parasite kill in order to restrict genetic variability and render any resistance genes effectively recessive. The administration of mixtures of anthelmintics may be effective if multiple resistance exists (Anderson et al, 1991; Barnes et al, 1995), but success depends on the magnitude of resistance (Waller et al, 1990). The use of a combination of anthelmintics or of anthelmintics at dose rates exceeding the manufacturer's recommendations is not necessarily effective (Waller et al, 1990). When resistance to broad-spectrum anthelmintics develops, it may be necessary to use flukicidal drugs such as closantel against resistant blood-sucking nematodes such as *H. contortus*, which is done in the Wormkill program in Australia (Taylor and Hunt, 1989). Current evidence suggests that reversion does not occur (Hunt, 1997). Strategies for the control of anthelmintic-resistant nematodes in ruminants include reduced use of anthelmintics, use of a full dose, annual alternation of classes of anthelmintics as outlined above, and annual checking of the program by the veterinarian, with emphasis on the use of a fecal egg count reduction test as part of the health management program (Coles, 1988; Hunt, 1997; Craig, 1998). Larval development assays have also been described to evaluate compounds from egg hatching to third-stage larvae whereby the larvae are grown in a medium containing varying concentrations of anthelmintic (Amarante et al, 1997).

The basis for the control of parasitic gastroenteritis in sheep is a combination of the strategic administration of anthelmintics and reduction in the rate of reinfection by appropriate grazing management, such as movement to safe pastures. If safe pastures are not available, it is necessary to give repeated doses of anthelmintics during the most dangerous periods. The guidelines in Box 16-21 are recommended.

Fasting sheep overnight before drenching may increase the efficacy of benzimadole anthelmintics (Ali and Hennessy, 1995) but not ivermectin (Escudero et al, 1997) or levamisole (Charlier et al, 1997). Low-volume doses of a benzimidazole compound administered directly into the rumen increase their bioavailability (Hennessy et al, 1997), but this route has only been commercially exploited in cattle.

Internal parasite control programs differ markedly from place to place depending on the climate, with the major variable being *H. contortus*. In its absence, such as in a winter rainfall area, it is necessary to drench adult dry sheep only twice each year, breeding ewes three times and lambs twice. This is because the hot, dry summer is damaging to larvae, and the larval pickup is small. The same advice applies to countries with cold winter climates.

Adult dry sheep should be drenched at least once during the summer to eliminate the parasite at a time when pasture conditions are lethal to the larvae, and thus to clean the pasture of infection for the dangerous period ahead: the warm, moist autumn. The general recommendation is for two summer drenches: the first as soon as the pasture has dried off and the second in midsummer. A spring drenching can also be included with advantage. This disposes of any existing worm load so that the sheep can make best use of the spring flush of feed.

Breeding ewes get an additional drench either just before or within 3 weeks of lambing. The purpose is to avoid heavy contamination of the environment for the lambs and to enhance the ewe's milk supply.

Rams receive a prebreeding drench along with the other adult sheep in the summer drench program.

Lambs on pasture should be drenched at weaning to avoid their succumbing to the stress of weaning plus the burden of a parasite infestation. In lambs born in autumn into bad situations, or if there is any evidence of worm infestation, another drench may be given in midwinter while the lambs are still on the ewes. Lambs still on ewes should not need drenching when they are not yet grazing much.

The treatment of all purchased sheep (Barnes et al, 1995) is very important to prevent the introduction of resistant nematode strains.

This is a sample program that would be applicable in certain circumstances. It is not possible to make more specific recommendations. It presupposes that a broad-spectrum anthelmintic is used and that there is no problem of anthelmintic resistance in the resident worm population.

Summer Rainfall Areas. In this type of climate, the conditions on the pasture during the summer months are favorable for larval survival and pickup may be heavy. This is especially true for heavy egg layers such as *H. contortus*. One or two summer drenches cannot therefore prevent pasture contamination. For flocks that lamb in the spring, two drenches are given to the ewes at lambing, one before and one after the lambing period. Lambs are drenched at weaning and then monthly for 6 months. This intensity may be reduced if safe pasture is available after each drenching. Conversely, a heavier drenching program still may be necessary on heavily contaminated farms during seasons of hot, humid weather.

Monitoring Results of a Worm Control Program. The biggest problem with any worm control program is monitoring its efficacy. In completely standard climatic conditions, the recommended programs are guaranteed to be effective, but only if there is no anthelminitic resistance and if measures for the drenching program and use of rested pasture have been carried out conscientiously. The fecal egg

BOX 16-21

Guidelines for Administration of Anthelmintics

1. Treat ewes before lambing to kill the immature forms of the nematode, which are in the arrested stage of development.
2. After treatment of ewes before lambing, they and their lambs are placed onto safe pastures. When pasture with minimal larval contamination is available, it is beneficial to treat the ewes as they lamb and transfer them at this time in order to clean fields that have been free of sheep for at least 3 months. This should reduce the possibility of large numbers of parasites developing later in the season.
3. When sheep are housed over the winter, before lambing, and then turned out at lambing, the anthelmintic treatment may be given at the beginning of the housing period to reduce any production losses associated with inhibited larvae and adult parasites.
4. When pasture is set stocked and heavily contaminated, a number of anthelmintic treatments of the ewes are necessary over the lambing period. In Australia, where set stocking is common, anthelmintics may be administered to both old and young sheep up to 14 times annually, but this has led to the widespread development of anthelmintic resistance. This has necessitated new strategy schemes such as the Wormkill and Drenchplan systems, which are aimed at reducing the number of broad-spectrum anthelmintic treatments. In many areas of the northern United States and the United Kingdom, a common practice has been to give repeated treatments during late summer and autumn, when pasture contamination and infectivity are high and sheep are already affected with signs of clinical parasitism. Such treatment is only temporarily effective because of immediate reinfection from pasture. Treatment at three weekly intervals in the spring followed by movement to safe pasture after weaning has proved much more effective. Alternatively, a single or double treat-and-move program could be initiated in July, just before the expected increase in pasture contamination ("midsummer rise") occurs.*
5. Parasitic gastroenteritis in sucking lambs is rarely a problem (except for *Nematodirus battus* infestation on contaminated grazing in the United Kingdom), and delaying treatment until weaning with one or two treatments between weaning and autumn may provide adequate control in some countries. Weaned lambs set stocked on pasture may have to be treated at 3-week intervals on three occasions in May and June, and three times in August and September in the United Kingdom and Europe.† If clean pastures are available, treatment at weaning and movement onto the pasture may be sufficient ("dose and move"). If pregnant ewes are housed during the winter months, the anthelmintic can be given at the beginning of the housing period to reduce any production loss associated with inhibited larvae.
6. Ewes and rams are treated before breeding.

*Herd RP, Parker CF, McClure KE: *J Am Vet Med Assoc* 184:680-687, 1984a.

count reduction test and total worm count at necropsy described earlier are useful tests for assessing anthelmintic resistance. Fecal egg counts alone can be unreliable, but, because of their ease of performance, it is worthwhile to attempt a cautious interpretation of what the counts mean. The problem is created by older adult sheep that have developed a resistance to parasitic infestation so that there may be heavy infestations with immature larvae, which are not laying any eggs at all. The resistance to heavy helminth burdens may be of varying degree and may differ widely among sheep in the same flock. A simple way of overcoming this problem when interpreting fecal egg counts is to use only susceptible sheep as monitors. Weaners younger than 9 months old and ewes in early lactation are the obvious subjects. These sheep should have been drenched with an efficacious anthelmintic about 1 month previously. If the sheep were then grazed on a particular pasture for the ensuing month, their fecal egg burden should be an accurate indication of the infectivity status of that particular pasture. Individual sheep fecal egg counts are not necessary; bulked specimens containing fecal samples from 10 sheep each and two counts per flock are considered adequate for meaningful interpretation. The exercise might be carried out as the condition of the sheep dictates or at regular intervals (e.g., during veterinary visits plus other occasions).

It is possible, therefore, to assess the status of particular pastures, but the more common problem is to determine the parasitologic burden of a particular group of sheep. If the sheep are a susceptible group, they can be tested, preferably when larval pickup is at a high level (e.g., after autumn rain). If the sheep are likely to be partly immune, the testing is much less reliable. Some of the sheep may be passing significant egg loads, but many of them harbor only immature larvae and are passing few eggs.

Safe Grazing. The concept of a pasture carrying no infective nematode larvae is difficult to translate into reality in many sheep-rearing areas. Nowadays, it is customary to think of safe grazing as pasture on which sheep increase their worm load only slowly after going onto it, having had a prior effective anthelmintic drench. Unfortunately, any significant reduction of helminth larval burdens on pasture can only be relied on in hot summer weather, in which it takes 2 to 6 months of high subtropical temperatures. Paddocks that have been closed to sheep for some time, such as grains or forage crop stubbles and hay paddocks, are best suited as quarantine areas, but they are obviously limited in their availability. It is therefore usually necessary to limit their use to the susceptible groups—young sheep up to 18 months of age and ewes with lambs.

An alternate and moderately effective procedure for reducing pasture contamination is alternate grazing of paddocks by sheep and by cattle. Almost all helminths are species specific, so that cross transmission between sheep and cattle does not occur. The use of alternate grazing with resistant

sheep is much less reliable because these sheep, although they are resistant to the growth of helminths, can produce significant levels of contamination of pasture. Whichever decision is made about how to achieve the least parasitic risk to young sheep, it is often the quality of the feed in a paddock that determines whether it is used for grazing.

Fascioliasis (Liver Fluke)

Fascioliasis causes important economic losses in most regions of the world where cattle and sheep are raised. Heavily infected animals may die, but those less severely affected suffer a substantial reduction of growth and production (McIlroy et al, 1990). Losses caused by reduced production efficiency result in the greatest economic impact of the disease. Fascioliasis can be controlled effectively by strategic attacks on both snails and flukes. One of the most important methods of control used worldwide is the strategic use of modern flukicidal drugs. Because the administration of these drugs is expensive, any advice on the frequency and the most effective timing of their use must depend on the estimated annual risk of the disease forecast in any region (Morris and Meek, 1980).

The use of a computerized information retrieval system of abattoir and meteorological data to formulate a sophisticated mathematical model can accurately forecast the annual prevalence of fascioliasis (McIlroy et al, 1990), which enables the formulation of an effective control strategy.

A cost-benefit analysis of a control scheme, based on the prevention of snail infection by *Fasciola hepatica* by treating ewes grazed on fluke-infested riverine land with four treatments/ewe of triclabendazole, was compared with the costs of leaving the sheep untreated (Clarkson, 1989). On a farm with 1800 ewes, the total loss from failure to treat was estimated to be £8272 annually because of reductions in lamb carcass and fleece weight. In contrast, the cost of treatment would be only £864 annually.

Psoroptic Mange

Since reintroduction in 1973, psoroptic mange was controlled in the United Kingdom by twice-annual compulsory dipping during the spring and autumn, with fewer than 16 cases reported during 1988. Removal of these dipping controls in 1989 has lead to widespread infestation of the national flock (Lewis, 1997) with serious welfare as well as production consequences (Sargison et al, 1995; Bellworthy et al, 1997; Corke, 1997). The single subcutaneous injection of doramectin has proved highly effective in the treatment of psoroptic mange (Purnell, 1997) and forms the basis for disease control in the United Kingdom. Presently, there is no sheep scab eradication program operating in the United Kingdom.

Blowfly Strike

Sheep blowfly strike, cutaneous myiasis, or infection of sheep skin by fly maggots is the largest single cause of death and production loss to the sheep industry in Australia (Sandeman, 1989). An estimated 3 million sheep die each year of flystrike and its complications. Cutaneous myiasis is also reported to be a serious problem in Hungary (Farkas and Hall, 1998), as well as a major welfare concern worldwide (Groves, 1997). As many as 500,000 sheep are struck annually in the U.K. national flock of 30 million sheep (French et al, 1992). In North America and Europe, it is primarily a problem secondary to diarrhea in lambs with parasitic gastroenteritis and occasionally mycotic dermatitis. Blowfly strike is a preventable disease and continues to be a major disease whenever susceptible sheep are pastured in large groups, only because farmers fail to use available control techniques (Anderson, 1990). Merinos seem particularly susceptible to flystrike because of their fleece structure, but other breeds are also attacked. Although the merino fleece is slower to wet after rain than other breeds, once wet it remains so for longer, allowing bacterial growth and skin inflammation to create conditions for fly oviposition and maggot survival (Sandeman, 1989). In addition to wet wool, several skin conditions can predispose sheep to blowfly strike through the attraction of female flies to oviposit. Infected wounds, bacterial dermatitis, footrot, urine or fecal scalding, and sweating, especially around the horns in rams, can create ideal conditions for flystrike. Lambs and hoggets are the most susceptible age group both to infection and the pathogenic effects.

The only satisfactory way of dealing with the problem is to maintain a long-term strategy of reducing the susceptibility of the sheep and to combine this with a standby short-term emergency tactic that can deal with an infestation urgently and effectively. The indirect methods for controlling flystrike include timely shearing, breeding to reduce susceptibility, tail docking, crutching, the use of insecticides, and the control of nematodes and ectoparasites. The direct methods include blowfly bait bins and traps and the treatment of existing flystrikes. The details of flystrike as it occurs in Australia have been presented and reviewed (Anderson, 1990).

Mules Operation

It has been claimed that correct mulesing (or breeding for a plain breech) and tail docking (Yeo, 1981) are the long-term strategies that can effectively eliminate the greater part of the sheep's susceptibility to blowfly strike. This mutilation (mulesing) is performed on Merinos and other wool breeds such as the Columbia, with excessive wrinkling. It is usually not required in the meat breeds and has never been undertaken in European countries or in North America in any breed. The mutilation involves removal of the perianal skin to stop wool growth and, with tail docking, to reduce the possibility of urine or fecal staining on the breech. The mutilation is carried out without analgesia through the use of sharp shears on the skin wrinkles of the breech and tail, which are presented to the operator rump-down with the area exposed and accessible. The folds are removed by cutting with the shears (rather than a scalpel), using a scissors action, and making sure to start with sharp V cuts rather than blunt starts. The widest part of the denuded area should be just above the vulva. The mutilation must be performed in clean surroundings with disinfected instruments, and the lambs left undisturbed for 3 to 4 weeks to give the wounds time to heal. It is almost unbelievable that no careful study of costs and benefits appears to have been carried out for mulesing and prepuce dropping. Many veterinarians have expressed grave concern over mulesing.

Docking of the tail is claimed to be critical in the control of blowfly strike. The tail must be removed between the second and third vertebrae. A too-long tail means fouling and strike susceptibility in those flocks in which parasitic gastroenteritis is not effectively controlled. Too short of a tail means a high prevalence of skin carcinoma of the vulva.

Tail docking and mulesing, if properly performed over a period so that the flock is wrinkle-free on the breech, are claimed to reduce the size of the fly population as well as the chances of infections occurring in the less common sites of the back and the pizzle.

Because of the possible importance of the preputial area as a site of carryover infection in winter, two methods have been devised to reduce the susceptibility of this area. A

chemical ringing method creates a bare area of scar tissue around the prepuce and reduces the chances of wetting. The other technique, prepuce dropping, consists of severing the anterior attachment of the prepuce to the abdominal wall. This has a similar effect of reducing urine staining of wool.

The principal disadvantage of these techniques is that they are painful and unnecessarily mutilating. Although considerations of animal welfare must direct increasing attention to the long-term project of breeding less susceptible sheep with plain breeches, this does not appear to have a high priority with farmers nor veterinarians in Australia.

Timing Shearing Correctly

The less wool a sheep is carrying at the time of high risk, the less the chance of infestation. If the time of major fly infestation can be coincided with a prior shearing, much of the risk to heavy-wooled sheep can be avoided.

Avoiding Fleece Rot

Fleece rot has become prevalent and is conducive to blowfly body strike. Breeding to reduce susceptibility and development of a vaccine against it are strategies of potential prophylactic importance. Body strike is relatively uncommon, and outbreaks last for relatively short periods, but the disease is severe and heavy losses result (Watts and Merritt, 1981).

Control of Gastrointestinal Helminthiasis

Prevention of the diarrhea that accompanies trichostrongylosis in sheep helps to keep the perineum clean and less attractive to blowfly strike; it is the single most important factor in the prevention of cutaneous helminthiasis. Effective control of parasitic gastroenteritis has been outlined elsewhere in this chapter.

Chemical Treatment. Chemical treatment has been the major method of control since the 1950s and the introduction of the organophosphates (Sandeman, 1989). Fly resistance to organophosphates is now common, and protection lasts only 3 to 4 weeks. Newly introduced prophylactic drugs include cyromazine, a larval growth inhibitor (which protects for up to 12 weeks and is well established in the market), and synthetic pyrethroids, including cypermethrin, which inhibit oviposition. Organophosphorus compounds are still used for the treatment of fly strike, but there are serious human health considerations and great care must be exercised when handling these products. Organophosphorus compounds inhibit cholinesterase, thereby interfering with neuromuscular transmission. A major objective is to use a chemical to which the local blowfly larvae are least resistant. The practitioner must watch this carefully. Most areas with a local problem monitor the sensitivity of maggots continuously. Lucilia cuprina is the most prevalent fly in Australia (90% of strikes are by this fly) and the only one to be resistant (Wharton and Norris, 1980). Resistance has developed to all modern insecticides—including aldrin and dieldrin, carbamates, and organophosphates—but cyromazine is still effective (Anderson, 1990).

When the first sheep are struck, the rest must be jetted immediately (or some other effective means of application used). The machinery needs to be adequate to the task. Sheep handling facilities need to be able to handle the numbers quickly and the insecticide needs to be formulated so that it can be administered rapidly using the available equipment.

Other Approaches. The current control procedures described earlier are costly, are labor intensive, create fly resistance, and provoke concern from animal welfare activists and many veterinarians. Some new approaches are being explored. Genetic manipulation to produce and release sterile male flies similar to the program used for the control of the screwworm fly in the United States may show promise. The release of organisms that are pathogenic to the first instar larvae is also a possibility (Sandeman, 1989). Breeding for strains of sheep that are resistant to fleece rot is also being examined. A vaccine against *Pseudomonas aeruginosa*, a major cause of fleece rot, is currently being field tested, and initial results have suggested that the vaccine could control fleece rot initiated with the organism and natural flystrikes. A vaccine against the maggot antigens may also be possible.

Footrot

Footrot is one of the most important contagious diseases affecting the sheep and wool industry. No single completely satisfactory and cheap method of control has yet been found, and specific diagnosis continues to be difficult. However, much is known about the cause and epidemiology of the disease that can be applied toward effective control and eradication of the disease from a flock. In countries where footrot is a problem (e.g., Australia, New Zealand, and the United Kingdom), veterinary involvement has usually been restricted to research, to regulatory activities, and to extension (Egerton, 1989). Effective control of the disease depends on veterinary involvement directly on the farm.

Dichelobacter (Bacteroides; Fusobacterium) nodosus, the causative agent of footrot in sheep, is an obligate organism that cannot exist independently from ruminants' feet, and eradication requires only that all cases of footrot be recognized and removed. Therefore accurate recognition of the disease and differentiation from other diseases of the foot is necessary. Two clinical forms of footrot, virulent and benign, have been recognized for over 40 years (Stewart et al, 1986). The severity of the foot lesion is principally dependent on the particular infecting strain of *D. nodosus* (Winter, 1997), and such strains have been classified as virulent or benign. The organism possesses a spectrum of virulence for sheep, with a consequent disease continuum ranging from complete lack of effect, to mild interdigital skin lesions, to underrunning lesions in a varying proportion of feet, to severe necrotic separation of the horn of the hoof in the majority of feet (Stewart et al, 1986b). Recently, a particular virulent form of footrot has been described in the United Kingdom (Grogono-Thomas, 1997), where sloughing of the entire hoof capsule has been recorded (Winter, 1997).

Virulent or progressive footrot is characterized by extensive separation, which commences at the heel, extends centrifugally to the sole and toe, and frequently extends up the abaxial wall, with the formation of a foul-smelling, necrotic exudate. In benign or nonprogressive footrot (scald), occasional separation of the horn of the heel bulbs and posterior sole region occurs, but there is little accumulation of necrotic material under the separated horn. Benign footrot causes only mild lameness and rapidly regresses after topical treatment or after the onset of dry environmental conditions. Virulent footrot causes severe chronic lameness and tends to persist after the onset of dry conditions, unless intensive treatment is undertaken.

Footrot is a debilitating disease that can cause serious economic losses to the meat and wool industries of many sheep-producing countries. Field observations have suggested that some sheep flocks are less susceptible to footrot than others, and there is some circumstantial evidence for an inherited factor being involved (Bulgin et al, 1988). The progeny of Targhee rams are more resistant to footrot than those from footrot-susceptible rams (Bulgin et al, 1988). The genetic and phenotypic parameters for clinical foot

scald and footrot were investigated in a pedigree flock of New Zealand Romney sheep during outbreaks over a 6-year period (Skerman et al, 1988). Selection of the top 5% of progeny-tested sires for breeding could be expected to reduce the prevalence of footrot by approximately 45% per generation (Skerman et al, 1988). If the mechanism of resistance to footrot in sheep can be determined, a marker for the identification of resistant sheep might be found (Bulgin et al, 1988). The prospect of controlling such an important disease of sheep by genetic selection is attractive.

Footrot in sheep can be controlled at a low level of prevalence or eradicated from the flock. Vaccination alone reduces the prevalence in flocks and protects a high proportion of sheep at risk for a limited period (Egerton, 1986). Control is not an adequate long-term solution, however, and eradication should be the aim, but eradication is an expensive proposition and should not be attempted unless the producer and others involved appreciate all the costs, including labor, that are essential to success (Egerton, 1986). The strategy for eradication of the disease is based on the principles of eradication of infectious diseases, the epidemiology of footrot, and the selection of the most practical methods of eliminating virulent *D. nodosus* infection if neither depopulation of the flock nor the sale of affected animals is an option (Egerton, 1986). The important principles of eradication include diagnosis, reduction of the prevalence, elimination of infection, and surveillance. An accurate clinical diagnosis based on visual and manual examination is necessary. Careful examination of all feet of every sheep in the diseased flock is required, with extensive paring to expose and remove all pockets of infection. Sheep with overgrown and misshapen hooves should be examined carefully. The prevalence must be reduced to a level at which eradication becomes feasible. The elimination of infection from source animals is dependent on effective chemotherapy. After eradication of the disease from a flock, constant surveillance to prevent entry of the infection into the flock or the early detection of new cases and their elimination is necessary to maintain disease-free status.

The important epidemiological characteristics that are relevant to the eradication of footrot in sheep are shown in Box 16-22.

The traditional strategy for handling an outbreak of footrot in sheep was to adopt control measures to contain the disease until dry summer conditions were present, followed by an attempt at eradication. Commercial footrot vaccines containing representatives of the major serogroups of *D. nodosus* are now available as an aid in control and for the initial stages of eradication of footrot in sheep (Stewart et al, 1986a). The vaccines in use require water-in-oil adjuvant systems to achieve acceptable levels of efficacy and duration of immunity. The vaccines have the capability to prevent footrot and to accelerate healing. They can be used to control an outbreak of virulent footrot in previously unaffected sheep, which occurs when seasonal conditions favor transmission. The development of immunity takes about 3 to 4 weeks after vaccination, and it is unlikely that control of a new outbreak could be achieved without also running the animals through a foot bath of 5% formalin. The vaccine is also effective for control after transmission has ceased. Vaccination at this time is primarily for the therapeutic effect and to prime the sheep for a rapid response to future doses of vaccine (Egerton, 1986). The vaccine accelerates healing and reduces the prevalence to a level at which eradication, either by disposal or individual chemotherapy, is feasible. If eradication has not been completed because of unfavorable conditions, and if continued control is the option, revaccination can provide continued protection. If only control of the disease is the objective, annual revaccination can maintain the prevalence at a low level. Vaccines cannot eradicate the infection from the flock.

Chemotherapy with and without foot paring has been a long-standing option for the clinical management of footrot in sheep. Topical treatment with 10% zinc sulfate solution or a 5% formalin foot-bath is an effective method. Zinc sulfate foot bathing is highly effective for the treatment of footrot in sheep (Winter, 1997), except in those animals that have lesions located beneath the hard horn of the toe or beneath the hard horn of the outside wall in the vicinity of the toe. These feet must be pared and retreated for a cure to result. After paring, the sheep stand in a 10% zinc sulfate solution for at least 30 minutes, and then twice more, 1 week apart, with no further paring. Thorough inspection of the feet and foot paring were traditionally deemed necessary for the effective control and eradication of footrot. Examination of all feet and paring before treatment with a foot bath of zinc sulfate or vaccination have revealed that paring is highly effective (Plant and Claxton, 1986).

An economic evaluation of various treatments for footrot in sheep, by decision analysis, revealed that of 32 treatment regimens tested, the use of 10% zinc sulfate applied to the feet of affected sheep was the most cost-effective, regardless of the prevalence of the disease or its impact on productivity (Salman et al, 1988a). Parenteral treatment with antibiotics, especially streptomycin-penicillin combination or 10% oxytetracycline (Winter, 1997), is also effective. In some areas the use of formalin is decreasing because it is believed to not penetrate the hoof wall as much as previously thought; it is perceived by producers to be painful when splashed on the skin of the legs and the udder; producers find it unpleasant to use; it is considered a carcinogen; and zinc sulfate is cheaper, safer, and more effective.

The strategy for the eradication of footrot is shown in Box 16-23.

BOX 16-22

Epidemiological Aspects of Eradication of Footrot

The carrier sheep is the only significant source of the organism and infection is often introduced on to the farm with the puchase of carrier sheep. The organism survives on pastures, mud, and soil for only a limited time. Keeping pastures free of sheep for no less than 2 weeks during peak transmission periods ensures that they are clean (Stewart et al, 1986a). Infected sheep must be identified by careful examination and trimming of all feet, and the infection eliminated by treatment or culling from the flock.

Transmission of infection is at its highest peak during wet seasons. Eradication should only be attempted in dry periods after the pastures have dried and transmission is no longer occurring. In Australia, midsummer to early autumn is often a good time for an eradication program.

Clostridial Diseases

Enterotoxemia, botulism, tetanus, blackleg, black disease, malignant edema, and focal symmetric encephalomalacia can be significant causes of loss in sheep flocks, usually as massive outbreaks. Perhaps because they are easily controlled by vaccination and do not specifically require changes in management, they are generally kept under

BOX 16-23

Strategy for the Eradication of Footrot

1. Eradication should be attempted only during a dry period.
2. The feet of all sheep are examined and affected sheep are segregated. Clean sheep are put through a foot bath of 5% formalin or 10% zinc sulfate and placed in clean fields.
3. Affected sheep are treated by paring of the feet, foot bathing with zinc sulfate or formalin, and treated with an antibiotic parenterally or vaccinated. Foot bathing must be repeated weekly for at least three treatments. Sheep that do not respond must be retreated intensively or culled. Those with grossly misshapen feet should be culled. Foot bathing may have to be continued throughout the summer months so that the infection is eliminated. This strategy should reduce the prevalence of the disease in the flock.
4. Constant surveillance is necessary to ensure that no affected sheep have been classified as unaffected and to determine response to treatment. Surveillance must be maintained until no cases of footrot are found in the treated or untreated sheep. Absolute eradication can be declared when there are no cases in the flock during a subsequent period of weather favorable for transmission.*

*Egerton JR: Control and eradication of ovine footrot. In Stewart DJ, Pearson JE, McKern NM, Emery DL, editors: Footrot in ruminants, Proceedings of a Workshop, 1985, Melbourne, 1986, Australian Wool Corporation.

control. It is usually because vaccination programs are allowed to lapse or because the diseases occur out of season or in normally free areas that outbreaks occur.

Maedi-Visna

Maedi-visna, or ovine progressive pneumonia, is a slow virus disease of sheep characterized by chronic interstitial pneumonia, encephalitis, chronic arthritis, and chronic indurative mastitis, usually observed clinically in sheep 2 years of age and older (Watt et al, 1994; Watt et al, 1995). Both forms of the disease progress slowly and are inevitably fatal. In many cases the disease is subclinical, but infected sheep are carriers of the virus for their entire lives and propagate the infection. The disease can be an important cause of economic loss in sheep flocks because of adult mortality resulting from chronic pneumonia and unthriftiness and the increased incidence of culling ewes before the end of their productive life. Infection can lead to reduced conception rates, lower lamb birth weights, and lower lamb weights at 25 to 50 days of age (Dohoo et al, 1987). The disease is prevalent in sheep populations of many countries, especially southern European countries, where serologic evidence has suggested that up to 90% of flocks may be infected. The virus is transmitted from the infected ewe to her lambs through the ingestion of colostrum and milk. Infection of the mammary gland associated with the disease may account for the lactogenic route of spread and for the chronic mastitis that is common in infected sheep. Infected sheep can be detected with serologic tests such as the agar gel immunodiffusion (AGID) test and the enzyme-linked immunosorbent assay (ELISA) test.

Two practical methods for control of the disease have been used. In one method, colostrum-deprived lambs are reared artificially in isolation. In the other, routine serologic testing and subsequent culling of seropositive reactors and their progeny is carried out until the prevalence of seropositive sheep decreases gradually and a seronegative flock is achieved. Under field-type Canadian farming conditions and good management, the disease can be eliminated by the two control programs (Williams-Fulton and Simard, 1989). The test and cull program is more practical, but the first method of rearing colostrum-deprived lambs in isolation to develop a seronegative flock is more effective.

A summary of the control procedures used in the management of other common disease entities in sheep is presented in Table 16-9.

SHEEP HEALTH ACCREDITATION SCHEMES

National health schemes have been established in the United Kingdom to provide data on the health status of specific flocks of sheep (Linklater, 1989). The accreditation scheme for the control of maedi-visna in sheep has approximately 3500 members, almost exclusively pedigree ram breeders. It is based on a system of blood testing and isolation to identify flocks that are free of infection and, once they are decreed to be free, to maintain them as such. The health status is monitored by periodic blood testing, and there are strict rules regarding movement of animals, presentation of animals at sales, and isolation from animals not within the scheme. The major benefit of the scheme is the certification of animals for sale purposes; exports of live sheep from the United Kingdom have been banned since the recognition of bovine spongiform encephalopathy.

The Scottish Veterinary Investigation Service has developed another health scheme for sheep aimed specifically at the commercial sheep producer (Premium Health Scheme [Synge, 1996]). Its purpose is to establish a register of sheep flocks of a high health status based on freedom from enzootic abortion and on vaccination immunity to the clostridial diseases and pasteurellosis. The flock is monitored for enzootic abortion by submitting all aborted fetuses, along with placentae, for examination by a veterinary diagnostic laboratory for evidence of chlamydial infection, the blood sampling of all aborted and barren ewes, the blood sampling of a statistically derived portion of the flock between 1 and 3 months after lambing, and the blood testing of all purchased female animals if they do not come from an accredited flock. Vaccination against enzootic abortion is not permitted because it affects the results of the serologic tests. For the vaccination program, lambs destined for sale must all receive two doses of a multiple-antigen clostridial vaccine, according to the manufacturers' recommendations, with the second dose being given at least 2 weeks before the sale. All lambs must also receive two doses of *Pasteurella* vaccine before the sale.

The breeding stock presented for sale from these flocks are certified by farmers who testify that they have abided by the rules of the scheme and have vaccinated the animals as instructed, by the veterinarian who testifies that the appropriate number of ewes in the flock have been sampled, and by the veterinary investigation officer who testifies that evidence of enzootic abortion has not been found. The advantages of the scheme are that the risk of spreading enzootic abortion is reduced because all abortions are being monitored, ewe lambs sold for breeding are fully vaccinated for clostridial diseases and pasteurellosis, and each producer receives a certificate of full accreditation for the flock, which is

TABLE 16-9

Summary and Control Procdures Used in Some Disease of Sheep

Disease of Production Procedure	Monitoring Technique(s)	Prophylactic Techniques			
		Management	Vaccination	Medication	Other
Anthrax	Sudden death is the only manifestation	Hygienic disposal of carcasses and other infected material	Excellent results; annual in enzootic areas	—	—
Black disease	Sudden death is the only manifestation	Fluke control as prevention	Excellent results with two vaccinations	—	—
Bluetongue	Clinical evidence of oral and coronet lesions; seroconversions indicate presence of one or more serotypes	Prevent introduction of virus into country	Many vaccines available	—	—
Botulism	Clinical cases of flaccid paralysis in groups of sheep on contaminated food or water	Avoid use of feed or water containing carcasses	Excellent results with type-specific toxoid for enzootic area	—	—
Brucellosis	Serologic testing—complement fixation test, plus physical palpation epididymitis	Run some groups separately: vaccinate and test and slaughter positive reactors	Vaccination effective	—	—
Caseous lymphadenitis	Observe enlarged lymph nodes at shearing	Cull affected sheep; disinfect shearing and marking tools after each sheep	Vaccine available and reduces severity but does not prevent disease	—	—
Coccidiosis	Growth rate, fecal oocytes	Prevent crowding, fecal contamination of feed and water	—	Coccidiostats in feed	—
Contagious ecthyma	Observe lesions on mouth, udder, coronets	Isolate affected sheep; avoid abrasive material in environment	Very effective live virus vaccine	—	Very bad outbreaks in lambs or ewes
Copper poisoning	Clinical cases of hemoglobinuria, icterus, and death	Careful use of copper medication for mistakes in feed/mineral supplementation	—	Penicillamine orally or ammonium molybdate in water	Production disease caused by overstretching lamb's potential
Enterotoxemia	Sudden death of lambs, usually	High feed and good body condition of sheep predispose—reduce them	Effective with two vaccinations	*Clostridium perfringens* type D antitoxin provides temporary protection	—
Fluke infestation	Report from abattoirs, fluke egg counts in feces	Control of snails in pasture water	—	Strategic dosing with effective flukicide	—

Continued

TABLE 16-9—cont'd

Summary and Control Procdures Used in Some Disease of Sheep—cont'd

Disease of Production Procedure	Monitoring Technique(s)	Prophylactic Techniques			
		Management	Vaccination	Medication	Other
Hypocalcemia	Serum calcium and magnesium values may predict, but not a practical exercise; observe cases of recumbency and death	Avoid sudden changes of environment or feed or transport in late pregnant or lactating ewes	—	—	—
Jaagsiekte (pulmonary adenomatosis)	Chronic fatal pneumonia, sporadic cases	Slaughter of clinical cases or slaughter of all sheep in country	—	—	—
Johne's disease	Emaciation, soft feces, wool shedding; serologic tests, necropsy lesions best	Slaughter of positive reactors with eradication as aim	Vaccination possible and effective but not practical unless prevalence high	—	—
Listeriosis	Clinical cases of abortion, septicemia in lambs, circling in adults	Reduce access to ensilage; very cold weather predisposes	Cost-effective vaccine available	Therapy not prophylactic	—
Louping-ill	Clinical cases of incoordination, tremor, paralysis; serologic detection possible	Control of vector ticks by dipping program	Excellent vaccine available	—	—
Lumpy wool	Clinical cases very evident with lumpy discolored wool	Isolate affected animals, avoid grooming and other gear spread of infection	—	Antibacterial dip after shearing	Disease disappears in dry weather
Maedi-visna	Observe chronic pneumonia, indurative mastitis, or encephalitis cases; serologic identification possible	Slaughter of serologically positive sheep; isolate lambs at birth with no colostrum; avoid shed lambing	—	—	Complete slaughter of whole flock advised if prevalence high (?)
Malignant edema	Found dead	Hygiene at lambing, castrating, docking, shearing; disinfect wounds	Highly effective	—	—
Mastitis	Clinical cases and gangrenous mastitis (high % not gangrenous)	Cull affected ewes; change pastures and bedding grounds	None available	Therapy not prophylactic	Dry cow mastitis ointment at time of weaning if prevalence high
Nasal bots	Clinical rhinitis and sneezing	—	—	Strategic organophosphate treatment effective, and ivermectin at any stage of life cycle	—
Nutritional deficiency of: Calcium	Bendability and ease of fracture of bones	Improved general nutrition and provision of specific nutritional deficiency	—		—
Cobalt	Poor weight gain; urine concentration			Reticular "bullet"	

Copper	Poor weight gain; blood copper or ceruloplasmin level			Depot injection	
Iodine	Birth of goitrous lambs			Depot injection iodine	
Selenium	Blood levels of glutathionine peroxidase/whole blood selenium			Reticular "bullet"	
Pasteurellosis	Clinical cases of septicemia and pneumonia	Avoid environmental and feed stress	Vaccines used but efficiency not proven	Feeding tetracyclines common in feedlots or long-acting tetracycline at time of risk	—
Pediculosis	Frequent inspection of fleece of live sheep	Avoid spread by inert objects; maintain good body condition (body score)	—	Strategic dip or spray application	—
Pinkeye	Observe signs of blindness, eyelid spasm, conjunctivitis	Avoid close confinement, long grass, flies	—	Long-acting tetracyclines and/or local treatment of severely affected eyes	—
Pizzle rot	Scabs at preputial orifice; swollen prepuce	Reduced protein in diet; ring shear around prepuce	—	Implant of testosterone in wethers	—
Poisoning pasture plants	Many clinical syndromes represented, especially incoordination	Careful surveillance of pasture area for poisonous plants and elimination	—	—	—
Weeds, trees, arsenic	Clinical cases of abdominal pain, diarrhea, high mortality	Access to dipping fluids must be prevented	—	—	Use insecticides other than arsenicals
Polioencephalomalacia	Clinical cases of blindness, opisthotonos, nystagmus, tonic convulsions	Ensure adequate roughage in diet, and adequate continuous water supply; check pasture for equisetum	—	Dietary supplement with thiamine	—
Pregnancy toxemia	Observe late pregnant ewes with blindness, convulsions, recumbency, ketonuria	Ensure high caloric intake in last third of pregnancy plane of nutrition needs to rise	—	Propylene glycol supplementation of diet effective, but impractical	—
Scrapie	Pruritus, incoordination, paralysis; very long incubation period	Slaughter clinical cases; also slaughter contact sheep or goats in free area, particularly of dam line	—	—	Inheritance a significant factor in cause; selection aids control
Squamous cell carcinoma	Tumors on vulva, ear at high level of prevalence	Leave tail docked at correct length; suggested that susceptibility may be inherited	—	—	Correct length of tail left at docking
Tetanus	Clinical cases of fatal tetanic convulsions	Hygiene at birth, docking, castration, mulesing, shearing	Excellent results; vaccinate ewes annually before lambing	—	—
Urolithiasis	Clinical cases of urolithiasis	Ensure adequate fresh water; balance calcium: phosphorus and adequate vitamin A	—	Add salt or ammonium chloride to diet	—
Weaner ill-thrift	Failure to make adequate weight gains in presence of adequate feed	Gentle handling of young sheep at weaning	—	Copper, cobalt, selenium, vitamin D supplementation	Check for parasite load (fecal egg count)

issued by the Scottish Veterinary Investigation Service on completion of 2 years' testing with no evidence of enzootic abortion in the flock. Market research has indicated that buyers pay a substantial premium for breeding stock that has participated in these schemes (Linklater, 1989), although the recent introduction of a highly efficacious chlamydial vaccine questions whether this premium will be maintained. The establishment of a naive flock must be considered carefully because of the ease of disease transmission in areas with a high sheep density.

Health accreditation schemes exist for ovine brucellosis in all sheep-raising states of Australia and in New Zealand. In addition, there is a scheme for footrot control in New South Wales (Plant, 1989). An accreditation scheme either can be totally voluntary, in which a service is provided to interested producers, or it may be part of an overall campaign in which voluntary accreditation may progress to compulsory eradication as disease frequency decreases. All the brucellosis schemes are similar. The major objectives are to supply brucellosis-free rams for sale to sheep breeders and to control the spread of infection by marking rams and urging owners to sell them for slaughter. A major goal is to eradicate ovine brucellosis from most major stud flocks. The main benefits to the participants are increased flock fertility and higher sale prices. Owners organize testing of the rams through their private veterinary practitioner, and diagnostic laboratories of the Department of Agriculture provide the laboratory service and coordinate the scheme. Initial accreditation of the flock is for 12 months and, after 3 years of accreditation, retesting is undertaken every few years thereafter. Indicators of progress include the number of accredited flocks compared with the total number of registered flocks, the number of registered rams supplied against the number of ram replacements needed, the number of breakdowns in accredited flocks per year, and the percentage of flocks seeking accreditation that had positive rams on initial testing. In New Zealand, the ovine brucellosis eradication scheme has been enlarged to include commercial flocks and stud flocks. The scheme has eliminated the spread of infection from ram breeding flocks to commercial flocks.

The footrot scheme in New South Wales commenced in 1989. The main aim was to improve the productivity and welfare of sheep and goats by the progressive eradication of virulent and intermediate footrot. Strategies for control include detection of infected flocks through surveillance, particularly of high-risk groups, and implementation of treatment and preventive measures for footrot (Plant, 1989).

Health accreditation schemes are a form of disease control with voluntary participation by producers. Planning for such schemes needs to be comprehensive and should include a clear statement of objectives and a comparison of likely benefits and costs. The schemes should be largely self-funding, with the assistance of some public monies. Such health schemes are good examples of the integration of government and private veterinary services for the benefit of the wider community. The strategies for control must take into account the transmission cycle of the agent and the role of reservoirs. The unit of interest in assessing progress is the flock rather than the individual animal and progress indicators should be used to assess the level and rate of progress in achievement of objectives.

CONTROL OF INTERNATIONAL SPREAD OF INFECTIOUS DISEASES OF SHEEP

Many infectious diseases of sheep can be spread from one country to another by the importation of infected sheep. Prevention of the introduction of these diseases requires strict import and export controls by the veterinary authorities of the exporting and importing countries (Watson, 1984). National protection against the importation of animal disease depends on a strong, well-organized, and centrally controlled veterinary service in the exporting country, which should have an efficient system of disease reporting along with good testing systems to certify animals free of disease before they are exported. The importing country depends heavily on certification by the exporting country that the animals being exported are free of the infection, and that the disease has not existed in the flock of origin for certain periods of time before export. The importing country also needs an efficient, centrally controlled veterinary authority that can test imported animals in quarantine and that has procedures for isolating and monitoring animals on the farms of destination (Watson, 1984).

The infectious diseases of sheep that are of concern in international trade include bluetongue, contagious agalactia, *Brucella ovis*, maedi-visna, scrapie, foot-and-mouth disease, sheep-pox, and infection caused by *Brucella melitensis*. Serologic and other diagnostic tests are available for some of these diseases, such as bluetongue and maedi-visna, but for others (e.g., scrapie) there is no diagnostic test; certification is dependent on the flock of origin being certified free of the disease for a certain number of years (Watson, 1984). The international expansion of trade to meet the mounting pressure of agricultural interests for improved breeds depends on an extension of national flock eradication programs and on the establishment of flocks with superior health status for diseases such as maedi-visna and scrapie.

objectives of, 774-777, 775*b*, 776*t*
programmed visits and, 818*b*, 818-822, 819*t*821*t*
sheep industry characteristics affecting, 768
survival feeding during periods of drought and, 813*t*, 813-814, 814*b*
swine herd, 670-682
abattoir surveillance of market pigs in, 676-677
advances and changes in, 638-639
all-in
all-out pig flow and, 734-735
all-out production system and, 752-753
causes of economic losses in growing-finishing pig production, 737-738
cleaning and disinfection of swine barns in, 679
continuous surveillance in, 756
control of flies in, 679
diseases of growing and finishing pigs and, 740, 741*b*
effect of housing on performance and disease incidence in, 677-679
emergency farm visits in, 670
F-10 system and, 735
feeds and feeding of growing and finishing pigs in, 754-755
financial planning in, 676
flow of pigs through unit and, 680
genetics and selection of breeding stock in, 673*t*, 673-676
housing and environment in nursery and, 733-734
housing environment and floor space allowance and, 753-754
housing growing pig from 30-kg live weight to market and, 680
housing young pig from weaning to 20-kg live weight and, 680
maintenance of systemic and intestinal immunity in, 732
method of weaning and mixing litters in, 730
monitoring growing pig production in, 738-740
multisite systems and, 735
nutrition of weaned pig and, 730-732
nutritional advice in, 670-673
optimum age at weaning and postweaning growth performance in, 729-730
partial depopulation and, 737
regular farm visits in, 670, 671-672*b*
residue avoidance in pork and, 756-757
segregated early weaning and, 735-736
sow housing during lactation and, 680
sow housing from weaning to parturition and, 679-680
specific disease eradication policy and, 752
strategic medication of feed and water in, 755-756
Health and production management—cont'd
swine herd—cont'd
subclinical disease and, 654
therapeutic and subtherapeutic use of antimicrobials in, 732-733
use of antimicrobials in, 680-682
vaccination and use of anthelmintics and insecticides in, 756
veterinarian role in, 654-656, 655*b*
whole herd depopulation-repopulation and, 736-737
targets of animal health and performance and, 4-5, 5*f*
Health management feedback cycle, 238, 238*f*, 367*f*
Heat for piglet, 728
Heat stress, reduced fertility and, 270*t*
Heating requirements
of calf barn, 345
of veal housing facility, 364
Heavy condition, body scoring and, 463*b*
Heavy grain feeding programs, 584
Heavy veal, 360
Heel erosion, 494, 496
Heifer
dairy
common and sporadic diseases and control procedures in, 223*t*, 251
housing for, 489-490
internal parasitism and, 499
lameness and, 497
nutrition for, 469-470, 471*t*, 472*f*
objectives of raising, 365
risk for infectious disease in, 160
selection of, 304
health management programs for, 365-388
economics of, 388-390, 389*t*
feed bunks in, 370-375, 371*t*, 373*t*, 374-380*f*
genetic selection and numbers of replacements in, 387*b*, 387-388, 388*t*
health and disease management in, 383-387, 385*b*
housing in, 375-378, 376*b*, 381*t*
nutrient intake and feeding in, 366-370, 368*t*, 369*t*, 370*t*
reproductive performance and, 378-383
hormonal implants for, 615-616, 616*b*
pregnancy in feedlot heifer, 613-614, 614*t*
selection for artificial insemination, 564
spayed, 614-615
Heifer growing operations, 213-214
Height
recommendations for Holstein heifer, 471*t*
suggested range for breeding age heifers, 373*t*
Helminthiasis, 148*b*
in dairy cow, 223*t*, 225*t*
in sheep, 824-831, 826*f*, 827*f*, 830*b*, 832
Hemicellulolytic bacteria, 437*b*
Hemoglobinuria, postparturient, 222*t*, 467*t*
Hemolytic-uremic syndrome, 155
Hemophilosis, 601
Hemophilus, 226*t*
Hemorrhagic necrotic enteritis, 727
Hepatic lipidosis, 468-469
Herd average cow predicted transmitting ability, 321*t*, 321-322
Herd expansion, 306
Herd health calendar, 26*t*, 533, 535*f*, 535*t*
Herd health program
animal health and production data and information systems in, 24-26, 25*f*, 26*f*
artificial insemination and, 564-565
beef cattle, 510-511
marketing of, 530-534, 531*t*, 532*b*, 532*t*, 534*t*, 535*f*, 535*t*
veterinary resources in, 574-575, 575*b*
components of, 27-38
activities during farm visit in, 28-30
animal health technicians and, 37-38
animal welfare and animal rights in, 31-32
antimicrobial resistance and, 35-37
clinical research in, 37
consultation by telephone in, 30
drug residue avoidance in, 31
environmental management in, 37
environmental toxicology and ecosystem health in, 33

Herd health program—cont'd
components of—cont'd
food safety in, 33-35
frequency of herd visits in, 28
investigation of outbreaks of disease and crisis management in, 30
meetings with participating producers in, 30-31
prevention of zoonoses in, 32-33
provision of drugs and vaccines in, 31
costs and benefits of, 38-41
current status of, 12-18
animal health economics and, 16-18
costs of production and, 18
market in U.S. for veterinary services and, 12-15
market studies and, 15-16
marketing strategies and, 16
factors affecting development of, 41-43
feedlot cattle, 590-617
backgrounding and, 611
benefits of, 630
castration and dehorning and, 613
disease surveillance in, 592*f*, 592-594, 593*f*, 594*b*
environmental pollution and, 608
feedlot facilities and, 608
growth-promoting agents and, 615
growth-promoting feed additives and, 616-617
hormonal implants and, 615-616, 616*b*
implementation of, 591
individual identification and, 612-613
nutritional advice in, 597-598
objectives of, 585
origin and purchase of cattle and, 609-610, 610*b*
pregnant heifers and, 613-614, 614*t*
preimmunization and preconditioning and, 610-611
processing of nonpreconditioned cattle and, 611-612, 612*b*
record keeping and, 594-596, 595*f*
relationship between veterinarian and feedlot personnel, 590-591
spayed heifers and, 614-615
transportation of cattle and, 608-609
treatment protocols in, 594
undifferentiated bovine respiratory disease and, 600-608, 603*t*, 606*b*
vaccination and, 613
vaccination protocols in, 596-597
objectives of, 4-5, 5*f*
requirements for, 19-27
animal health and production data and information systems in, 24-26, 25*f*, 26*f*
competent veterinarian in, 20-21
data analysis in, 26-27
general advice in, 27
periodic reports to producer in, 27
postgraduate certificate programs in, 21-24
progressive livestock producer in, 19*f*, 19-20, 20*f*
swine herd, 670-682
abattoir surveillance of market pigs in, 676-677
all-in
all-out pig flow and, 734-735
all-out production system and, 752-753

Vitamins
in dairy cow's diet, 448, 454-455, 455*t*
injection of, 617
supplementation during dry period, 341
Volatile fatty acids, 436, 443-444
Voluntary cull, 301-304
Voluntary waiting period, 276, 279
Vulvitis, 270*t*

W
Walking areas and surfaces, 486-488
in farrowing pen, 721, 729
lameness and, 496, 498
locomotor diseases of growing and finishing pigs and, 751-752
of swine barn, 678
risk for infectious disease and, 161-162
Warble fly infestation, 225*t*
Warm barn, 479-482
Waste days, 281
Water
antimicrobials in, 681-682
consumption in dairy heifer, 371, 371*t*
for dairy herd, 442-443, 486, 486*f*, 487*t*
for piglets, 728
for weaned pigs, 732
sampling for livestock use, 200
strategic medication of, 755-756
Waterer, 486
Wean-to-finish swine production unit, 648
Weaner ill-thrift, 837*t*
Weaning
of beef calf, 533, 544-545, 545*t*
of dairy calf, 358-359
housing recommendations after, 377, 381*t*
nutrition from birth to, 353-354
of pig
mixing litters and, 730nutrition of sow after weaning, 716
optimum age at weaning and postweaning growth performance in, 729-730
prediction of, 703
Weaning—cont'd
of pig—cont'd
segregated early weaning and, 735-736
weaning-to-estrus interval and delayed estrus in sows and, 699-700
Weaning pen, 346
Weaning percent, 520*b*
Weather
perinatal lamb mortality and, 800-801, 807, 808*t*, 810
risk for infectious disease and, 161
Weaver, 320
Weende system for feed analysis, 456, 457*f*
Weight
body condition scoring and, 462, 463*b*
dystocia and, 537
lameness and, 497
nutrient requirements and, 440*t*
recommendations for Holstein heifer, 471*t*
suggested range for breeding age heifers, 373*t*, 546*t*
Welfare of animal, 3, 31-32
beef cattle and, 571-574, 573*b*, 574*b*
culling and, 292
in beef feedlot, 630
pig production and, 647-648, 720
sheep production and, 769
veal calves and, 361-362
Western veal, 360
Wet ewe, 793
Wheat, 453
Wheat midds, 454
Whey
in milk replacers, 357
newborn calf and, 354
White line disease, 467*t*, 493, 494
Whole cottonseeds, 454
Whole milk for dairy calf, 355
Whole swine herd depopulation-repopulation, 736-737
Wildlife vectors
control of, 172
vaccination of, 180
Win Episcope 2.0, 202
Winter
barn categories and temperatures in, 479-480
consequences of mismanaged ventilation in, 480
lamb mortality and, 800-801
minimum continuous ventilation in, 479
Winter dysentery, 160, 224*t*
Wool, 765, 768
crossbreeding and, 817
productivity targets for, 776
World sheep trade, 765-767
Worm infestation, 499-502, 502*b*
Written report in investigation of disease outbreaks and suboptimal productivity, 193, 208

Y
Yard test for serving capacity, 790
Year-round calving herd, 260
Yearling heifer facilities, 378
Yearly reproductive summary, 284-285
Yeast additives, 455-456
Yersiniosis, 155
Youngstock management in dairy herd, 246

Z
Z-test confidence interval, 57*f*, 57-58, 96, 97
Zearalenone, 714-715
Zeranol, 616*b*
Zinc
for beef cattle, 529, 529*t*
in dairy rations, 451*t*
in milk replacers, 356*t*
requirements for dairy cow, 441*t*
Zoonoses, 155-156
in dairy calves, 340-341
prevention of, 32-33
