Preface

Disease Mechanisms is a textbook designed to explain, in understandable language, how individual organs and organ systems are affected by disease processes. It defines the principles upon which surgical procedures are based and is therefore an ideal companion volume for CURRENT TECHNIQUES IN SMALL ANIMAL SURGERY. It not only helps the Practicing Veterinarian better understand the function of specific organs effected by disease; it also helps explain it and the selected surgical treatment to an ever more demanding

Downloaded From Vet-eBooks.com

client. It will be enormously helpful to the veterinary student, intern and resident studying for boards. This book assembled the most qualified experts in the fields of surgery and pathophysiology to present the mechanisms by which disease affects each organ system in practical and understandable terms. This book is an update of the highly successful second edition which was sold out and is no longer available. This book is also very helpful for the veterinary Technician because of its practical focus, consistent presentation and clear explanation of disease mechanisms in all body regions. One of the reasons the previous editions of this book were so extremely successful is because the

Downloaded From Vet-eBooks.com

practicing veterinarian can use it effectively for client information. In other words this book served as the veterinarians “second opinion” backing up his information to the client.

I know you will enjoy reading this book and learning the wealth of usable knowledge which will help you in all future cases. I believe that it will become the number one reference in your library.

M. Joseph Bojrab DVM, MS, PhD.

Acknowledgements

I would like to thank Dr. Eric Monnet and all of his residents for their many hours of hard work to ensure the accuracy and completeness of these manuscripts. It is due to them that this book is one of the most outstanding works on disease mechanisms every published.

Dr. M. Joseph Bojrab

Dedication

I would like to dedicate this book to my 94 year old Mother Julia Bojrab. She is still sharp as a tack and drives herself around Ft. Wayne, IN. She has been an inspiration for all 3 of her children to work hard, be the best you can be and be kind to others. Everyone is a creature of God. Thank you Mom!

Chapter 1

The Systemic Inflammatory Response Syndrome

Tim Hackett

Inflammation is good. A protective series of events, the inflammatory response is – under normal circumstances – an amazing dance. Infectious agents, external stimuli, even intrinsic disease can stimulate a cascade of events resulting in inflammation. The four signs of inflammation were recorded in Latin by Cornelius Celsus in first century

Downloaded From Vet-eBooks.com

Rome: *Rubor* (redness), *calor* (heat), *tumor* (swelling), and *dolor* (pain). It was understood later that the increased circulation, fever, and swelling were the results of potentially beneficial physiologic responses. In the 19th century, Rudolf Virchow added a fifth sign of inflammation: *Functio laesa* (loss of function), a suggestion that the temporary loss of function may be an adaptive response to limit use and allow healing.

This response is due to locally produced mediators that recruit and activate cells of the immune system (***recognition, release,*** and ***recruitment***). As these defenders arrive, they recruit and activate other

Downloaded From Vet-eBooks.com

proteins and chemical messengers. Some of these messengers are pyrogens. Others act on local vasculature, increasing circulation; the cause of redness. Circulation to the area brings oxygen, nutrients, and primarily neutrophilic cellular infiltrate. Some factors increase vascular permeability; the cause of local swelling. Increased permeability allows agents of the immune system to enter damaged tissues. As these cellular, chemical, and protein messengers stimulate the proinflammatory cascade, a simultaneous anti-inflammatory cascade acts to limit the process to the affected area. If it all works, the infection is vanquished, the damaged

Downloaded From Vet-eBooks.com

tissues heal, the inflammatory response is confined to the local area, and the organism survives (***removal, resolution,*** and ***restoration***).

When the inflammatory stimulus is extensive, or for other reasons the proinflammatory forces are not contained, this protective process can lead to systemic manifestations. When the inflammatory cascade results in systemic signs of infla mmation the process is called the **systemic inflammatory response syndrome** (SIRS). Clinical criteria of SIRS in veterinary patients are listed in Table 1-1. SIRS can be caused by invasion of normally sterile host tissues by microorganisms. **Septicemia** occurs

Downloaded From Vet-eBooks.com

when bacteria are found in the blood stream. When the systemic inflammatory response is associated with bacterial infection of normally sterile host tissues, the process is called **sepsis**. **Septic shock** is a state of inadequate oxygen delivery and organ dysfunction. Unlike other causes of circulatory shock, septic shock is characterized by hypotension often unresponsive to fluid and vasoactive therapies. While infection is a common cause of SIRS, there are many noninfectious causes. Any stimulus that initiates the production and release of circulating inflammatory mediators can cause systemic inflammatory changes. Examples of noninfectious causes of SIRS include pancreatitis,

Downloaded From Vet-eBooks.com

heat stroke, multiple trauma, rattlesnake envenomation, and neoplasia.

SIRS can occur preoperatively and may, in fact, be an indication for emergency surgery. SIRS can also result from the trauma of surgery itself. The inclusion criteria for SIRS have been criticized as being too sensitive and insufficiently specific. This is especially true in surgical patients. SIRS may also be mimicked by certain events that are commonplace in the immediate postoperative period. These signs will likely subside in the hours following surgery and are not caused by underlying physiologic derangements.

Downloaded From Vet-eBooks.com

Table 1-1. Definitions Related to the Inflammatory Response and Related Disorders.

Definitions

Infection: Microbial invasion characterized by an inflammatory response to the presence of microorganisms or to the invasion of normally sterile host tissue by those organisms.

Systemic Inflammatory Response (SIRS): The systemic response to infection characterized by two or more of the following criteria:

1) Temperature > 103.5° or < 100°

Downloaded From Vet-eBooks.com

F

2) Heart rate > 160 bpm (dogs) and > 250 bpm (cats)

3) Respiratory rate > 20 bpm or $PaCO_2$ < 32 (28 at high altitude)

4) White blood cell count > 12,000 cells/ µl, < 4,000 cells/µl or < > 10% bands

Sepsis: The systemic response to confirmed infection characterized by two or more of the criteria above.

Septic shock: Sepsis with hypotension, despite adequate fluid resuscitation, along with the presence of perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or acute changes in mental

Downloaded From Vet-eBooks.com

status.

Multiple Organ Dysfunction Syndrome (MODS): The presence of altered organ function in the acutely ill patient such that homeostasis cannot be maintained without intervention. Examples include hepatic, renal, and cardiac failure, stupor and coma, acute respiratory distress syndrome (ARDS), cardiac arrhythmias, and disseminated intravascular coagulopathy (DIC).

Compensatory Anti-inflammatory Response Syndrome (CARS): A severe reaction of anti-inflammatory mediators characterized by immune system depression.

Downloaded From Vet-eBooks.com

Epidemiology

In the United States it is estimated that 750,000 patients suffer annually from sepsis and septic shock. Sixty percent of people suffering from severe sepsis and septic shock will develop circulatory shock with hypotension and organ failure. Traditionally, septic shock has been closely associated with gram-negative bacteria. The incidence of gram-negative sepsis in the United States has steadily increased. The endotoxin produced by gram-negative bacteria has long been known to cause many of the signs associated with SIRS. Since the late 1980s, however, the incidence of gram-positive and fungal sepsis has increased. Reasons given for

Downloaded From Vet-eBooks.com

the increased incidence include an aging of the population and a rise in the incidence of geriatric diseases. With better medical care, patients live longer and succumb to the effects of chronic organ failure.

The incidence of sepsis in veterinary medicine also appears to be increasing. As in people, this may be a result of good preventative medicine and better medical care. Pets surviving into their golden years face chronic dysfunction of vital organs. When these animals present with surgical disease they may not have the physiologic reserve to mount an appropriate inflammatory response. Septicemia is found in critically ill veterinary patients. One

Downloaded From Vet-eBooks.com

study of 100 critically ill dogs and cats found 49 had bacteremia (positive blood cultures). Bacteremic patients in this study also had an increased mortality rate.

Patients with SIRS may experience dysfunction of one or more organ systems. This process is termed the **multiple organ dsyfunction syndrome (MODS).** Human patients with sepsis experience dysfunction of at least one organ, with multiple organ dysfunction occurring in 30% of such patients. MODS can also be found in more than 30% of trauma patients, 24% of patients with acute pancreatitis, and 33% of burn victims. A massive inflammatory reaction

Downloaded From Vet-eBooks.com

resulting from systemic cytokine release is the common pathway underlying multiple organ dysfunction. Despite the availability of more potent antibiotic and sophisticated critical care, mortality rates from sepsis still range from 20% to 75%.

Pathophysiology

Several factors have been identified that increase the risk of SIRS. These include the presence of infectious diseases or debilitating conditions (trauma, neoplasia, diabetes mellitus), immunosuppression (viral diseases, chemotherapy or other immunosuppressive treatments), advanced age, and malnutrition.

Downloaded From Vet-eBooks.com

Invasive therapeutic and diagnostic procedures can also increase the risk of acquiring a serious infection. Indwelling vascular and urinary catheters or chest tubes can let pathogens past natural protective mechanisms. General anesthesia can depress normal defenses directly by inhibiting the reticuloendothelial system. Anesthesia can also result in systemic hypotension, further depressing host defenses. A controlled inflammatory response can increase the risk of developing an exaggerated response to a second event. Called the “two hit” phenomenon this is of particular concern to the veterinary surgeon who may unwittingly supply the second “hit” when the patient is

Downloaded From Vet-eBooks.com

taken to surgery.

Surgical Stress and the Neurohormonal Response

Tissue injury is injury whether the cause is the front end of an automobile or the surgeon's knife. The neurohormonal response to tissue injury begins with adrenocorticotropin release by the anterior pituitary gland. The anterior pituitary also secretes growth hormone, prolactin, and endorphin. Arginine vasopressin is released by the posterior pituitary while the adrenal gland responds with cortisol and epinephrine. This fight-or-flight response is basic to survival and results in a variety of physiologic

Downloaded From Vet-eBooks.com

effects including tachycardia, tachyarrhythmias, hypertension, myocardial ischemia, congestive heart failure, hypokalemia, hypomagnesemia, hyperglycemia, altered immune function, and hypercoagulability.

Biochemical Mediators of SIRS

Mediators of the inflammatory response include endotoxin, cytokines, complement, kinins, endorphins, and myocardial depressant factor. These products contribute to hemodynamic changes, cardiopulmonary dysfunction, and multiple organ dysfunction associated with SIRS. Cellular

Downloaded From Vet-eBooks.com

messengers initiate a complex signaling sequence involving the release of secondary mediators (Figure 1-1). Surface receptors on macrophages recognize a variety of pathogens. While acquired immunity helps to fight a previously encountered pathogen, there are primitive, innate Toll-like receptors (TLRs) conserved across species that can also mount an immune response. Secondary mediators include platelet activating factor and metabolites of the arachidonic acid, cyclooxygenase, and lipoxygenase pathways. Induction of inducible nitric oxide synthetase, endothelial tissue factor expression, microvascular coagulation, and cell-adhesion molecule up-regulation are also

Downloaded From Vet-eBooks.com

considered secondary events.

Intercellular Communication

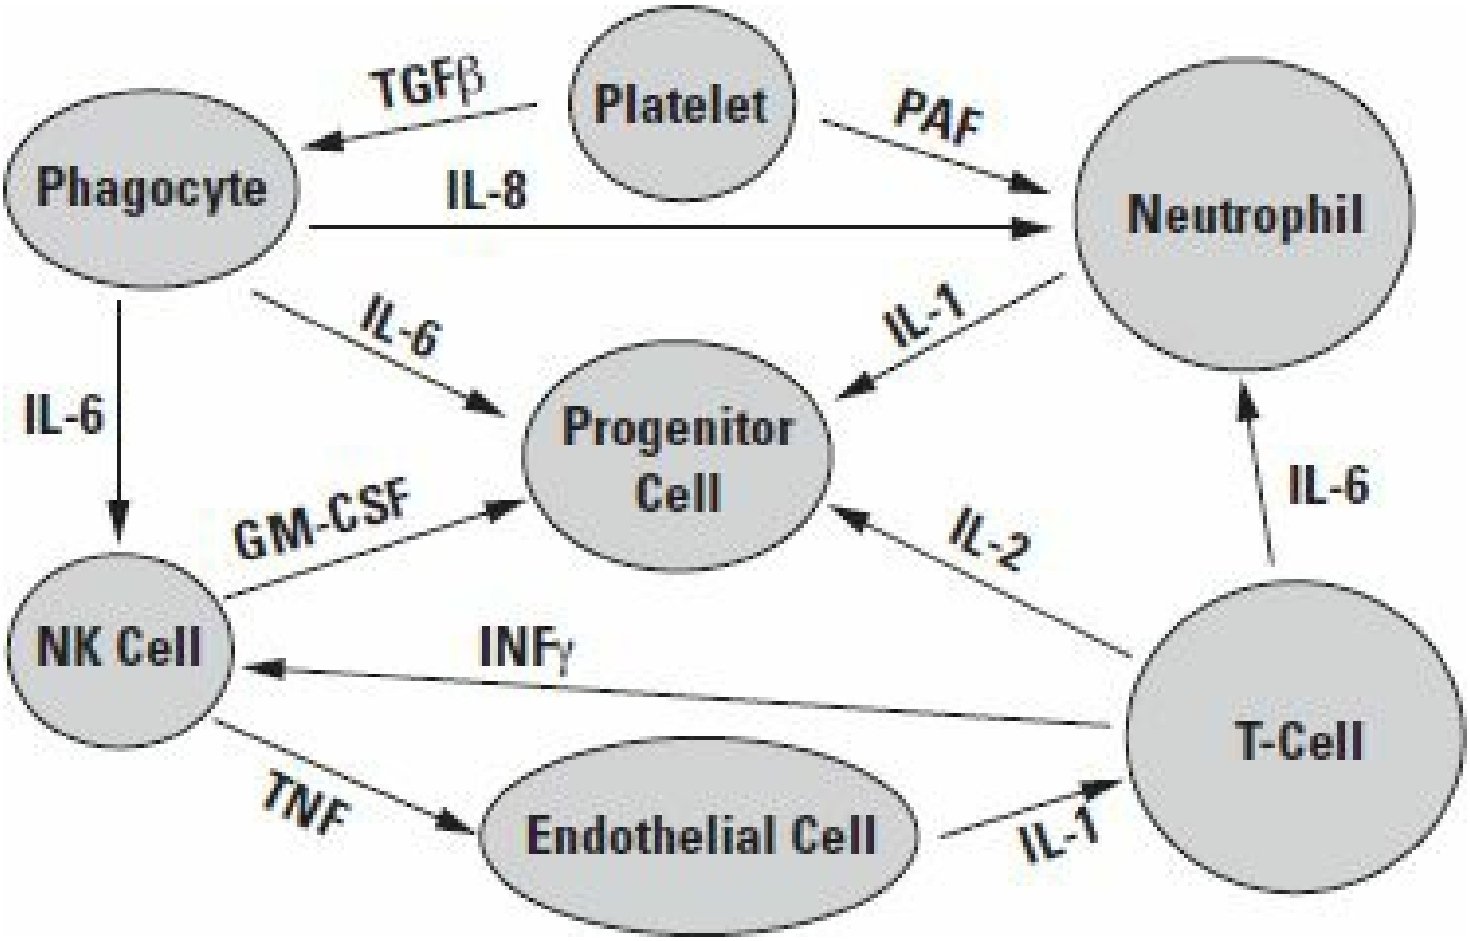

Figure 1-1. Some of the cells and mediators involved in the inflammatory response. Direction of the arrow indicates which cells activate other cells of the immune system and the mediators involved. GM-CSF = Granulocyte monocyte-colony stimulating factor, IL = Interleukin, INF = Interferon, NK = Natural killer

Downloaded From Vet-eBooks.com

cell, PAF = Platelet activating factor, TGF = Tissue growth factor, TNF = Tumor necrosis factor.

The substance most extensively investigated has been endotoxin, the lipopolysaccharide (LPS) moiety of the gram-negative bacterial cell wall. Endotoxin is detectable in the serum of nearly half the patients with septic shock. When endotoxin is given to experimental animals or to normal human volunteers, it can produce the same cardiovascular abnormalities as those seen in human septic shock. These and other observations lent support to the hypothesis that endotoxin represented the "Final Common Pathway" of sepsis. However, recent experiments have proven that endotoxin is not essential to the

Downloaded From Vet-eBooks.com

development of SIRS. Studies in dogs have demonstrated that *Staphylococcus aureus*, an organism without endotoxin, produces the same cardiovascular abnormalities as does *E. coli*.

LPS is delivered to immune cells and the CD14 cell surface receptor. Acute phase proteins and specific LPS binding proteins play a roll in presenting the LPS to the macrophage. Along with a Toll-like receptor, the LPS binding to the CD14 receptor signals the activation of the nuclear transcription factor NF-Kb, a transcription factor for many of the proinflammatory cellular glycoproteins or **cytokines**.

Downloaded From Vet-eBooks.com

Cytokines, released from activated white blood cells, include tumor necrosis factor (TNF) alpha; interleukin (IL)-1, IL-6, IL-8; and platelet activating factor (PAF) (Figure 1-2). TNF is detectable in the serum of septic shock patients, as well as in healthy animals given endotoxin. TNF is now thought to be one of the primary mediators because the levels peak very early in sepsis and SIRS. TNF given experimentally to healthy animals produces fever, hypotension, anorexia, leukopenia, increased capillary permeability, and granulocyte colony-stimulating factor release.

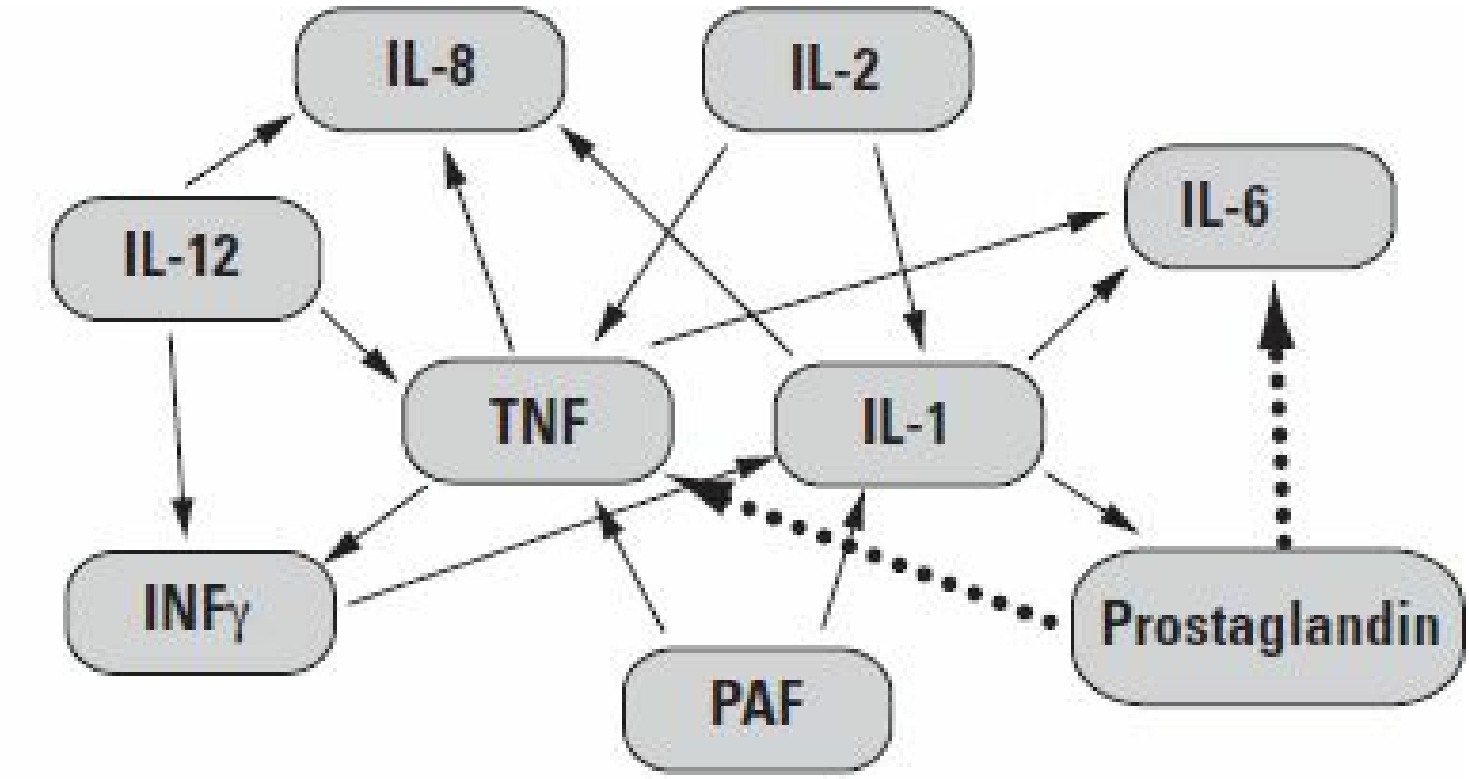
Resolution occurs when soluble

Downloaded From Vet-eBooks.com

receptors contain TNF, and IL-1 or specific anti-inflammatory cytokines (IL-4, IL-10, IL-11, IL-13, and some of the colony-stimulating factors) counteract the effects of proinflammatory cytokines (Figure 1-2). Other mechanisms include an intracellular suppressor of cytokine signaling and elimination of circulating cytokines through normal systemic metabolic pathways.

Pro-Inflammatory Cytokine Interactions

Downloaded From Vet-eBooks.com



Anti-Inflammatory Cytokine Interactions

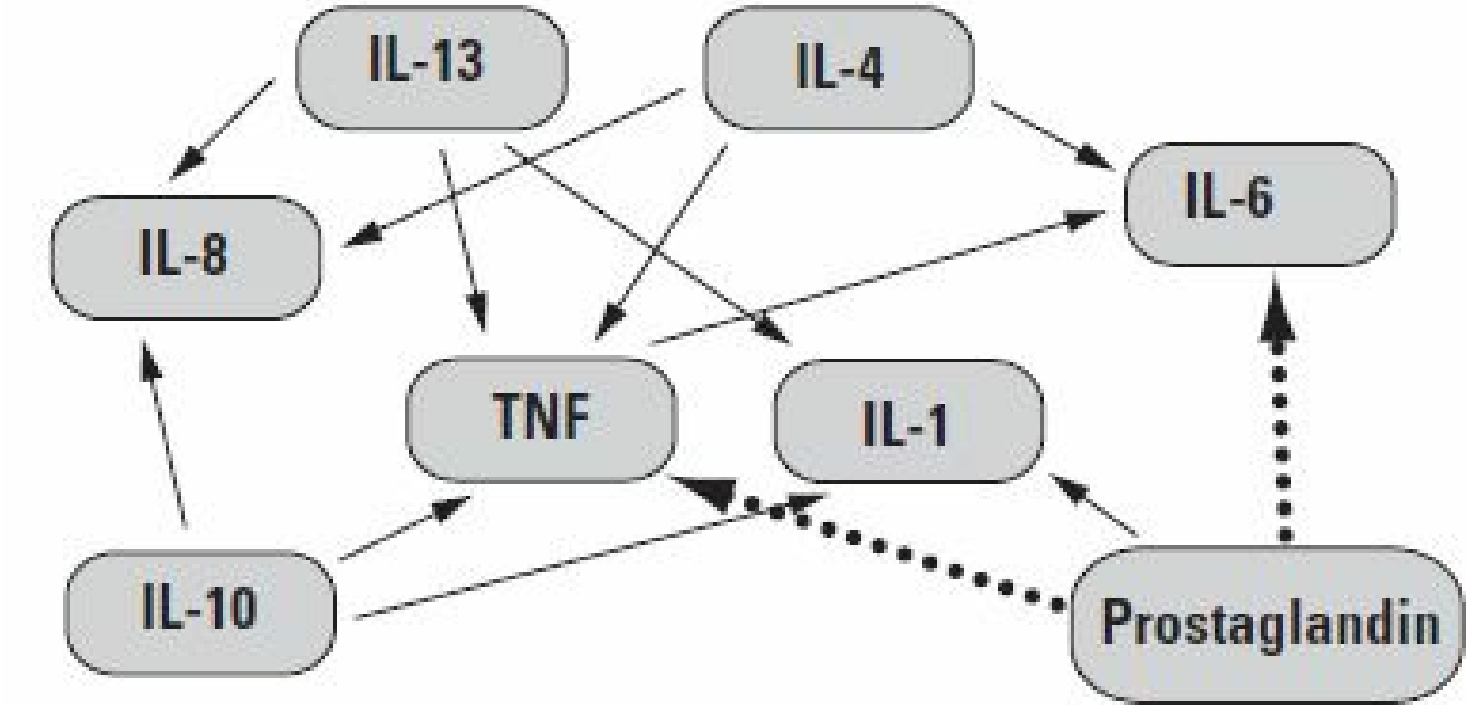


Figure 1-2. Pro- and anti-inflammatory cytokine-cytokine interactions. Arrow direction indicates

Downloaded From Vet-eBooks.com

which cytokines activate (in proinflammatory cascade) or inhibit (in the anti-inflammatory cascade) other cytokines. Dashed lines indicate stimulating and suppressing functions. GM-CSF = Granulocyte monocyte-colony stimulating factor, IL = Interleukin, INF = Interferon, PAF = Platelet activating factor, TGF = Tissue growth factor, TNF = Tumor necrosis factor.

Clinical Features

SIRS becomes detrimental with arterial hypotension and evidence of inadequate perfusion in the setting of a systemic insult. Patients with SIRS experience three types of circulatory shock. Hypovolemia as a result of increased vascular permeability and fluid loss into the tissues, distributive shock because of inappropriate vasodilatation and shunting of blood

Downloaded From Vet-eBooks.com

from vital areas, and a cardiogenic component due to depressed cardiac function. Many features, such as tachycardia, depressed mentation, and oliguria, are nonspecific: presentations vary from hypothermia with cold extremities and weak pulses to hyperthermia with warm extremities and bounding pulses. Cardiovascular instability may last from hours to days, but typically it will respond to therapy within 1 to 4 days in patients destined to survive the acute phase of the illness. An early change in septic shock and uncompensated SIRS is altered blood flow regulation. The coagulation cascade may also play a role in this response. Overexpression of proinflammatory cytokines is thought

Downloaded From Vet-eBooks.com

to upset the balance toward procoagulation. Decreased circulating levels of protein C and antithrombin are found in patients with severe sepsis and septic shock. Capillaries become blocked with activated white blood cells and microthrombi. Systemic release of inflammatory mediators also contributes to inappropriate shunting of blood around important vascular beds. Many systems are affected, and signs of progressive multiple organ system dysfunction may begin to appear.

Diagnosis

Suspicion of infectious causes of SIRS requires that diagnostic material be

Downloaded From Vet-eBooks.com

collected early while appropriate therapy and monitoring are instituted. SIRS is not a diagnosis but a syndrome with multiple causes. Possible causes must be excluded through history, physical examination, and diagnostic testing. Patients should be expected to do better if the source of the inflammation can be quickly identified and removed or drained. This means surgical disease should be ruled out first. Imaging of the abdomen may reveal mass lesions, organomegally, or local fluid accumulation. Loss of abdominal detail on plain radiographs would suggest abdominal fluid. Ultrasound may be more sensitive for abnormal fluid and useful for sampling. Radiographs of the chest and

Downloaded From Vet-eBooks.com

echocardiography help to evaluate the heart and lungs. When fluid is suspected in the chest or abdomen, sterile collection (either thoracocentesis, abdominocentesis, or diagnostic peritoneal lavage) for fluid analysis should be performed. It should be noted that abdominocentesis alone is relatively insensitive and a diagnostic peritoneal lavage with 10 to 20 ml/kg of sterile physiologic crystalloid fluid can increase sensitivity. Nonsurgical infectious and noninfectious causes of SIRS require intensive reassessment of therapy. Where (as with bacterial culture) a positive diagnosis may take days, therapy should be directed at likely pathogens. Areas of particular concern

Downloaded From Vet-eBooks.com

include the urinary tract, reproductive tract, abdominal cavity, respiratory tract, teeth and gums, and the heart valves. A thorough physical examination is performed with attention to oral examination, cardiac and thoracic auscultation, and abdominal palpation. Blood samples are drawn for CBC, serum biochemical profile, coagulation testing, rickettsial, fungal, and immune testing if indicated. Urine is collected for analysis and culture. Blood cultures should be taken from the jugular vein after surgically preparing the skin. Because blood cultures can have a relatively low yield, multiple samples should be taken 15 minutes to 1 hour apart, ideally during peak rises in body

Downloaded From Vet-eBooks.com

temperature. Antibiotic administration should be withheld until samples are collected but no significant delay should occur in starting therapy. If interstitial changes in the lung fields and clinical findings support possible pulmonary disease, bronchoscopy or a transtracheal wash may provide samples for a diagnosis.

Treatment/Monitoring

Standard sepsis treatment strategies include volume support to maintain cardiac output, the use of antibiotics to kill invading bacteria, surgical procedures to eradicate the nidus of infection, and intensive life-support procedures such as dialysis, mechanical

Downloaded From Vet-eBooks.com

ventilation, and the use of vasoactive drugs. Despite these approaches the mortality rate from septic shock is high, ranging form 25% to 75%. In addition, the incidence of sepsis syndrome in hospitals in the United States increased 139% between 1979 and 1987. This increase may be caused by several medical trends: improved life-support technology that keeps patients who have a high risk for infection alive at the extremes of age; increased use of invasive medical procedures; advances in cancer chemotherapy and immunotherapy; and the prevalence of acquired immunodeficiency syndrome. The increasing incidence of sepsis and its high mortality rate have charged the

Downloaded From Vet-eBooks.com

search for additional therapies.

Advances in cytokine biology have stimulated research to mitigate the biologic activity of cytokines on target cells. Binding cytokines with neutralizing molecules in circulation and blocking the interaction between cytokines and their cell-surface receptors in the target tissues are the two strategies employed. Repeating experiments performed on anti-endotoxin antibody, researchers used anti-TNF antibodies with significant success in protecting mice against lethal doses of endotoxin. However to date no convincing studies exist that anti-TNF antibodies are effective in clinical SIRS. The same can be said for

Downloaded From Vet-eBooks.com

similar work with other proinflammatory cytokines. All of these studies have failed to take into account the natural anti-inflammatory counterpart to these cytokines and other mediators. Interleukin-4, 10, 11, and 13 as well as the colony-stimulating factors and natural receptor antagonists are induced by TNF, IL-1, and other proinflammatory compounds. These anti-inflammatory mediators suppress many of the inflammatory effects of TNF and cytokines. New therapies for sepsis and SIRS should be directed at restoring homeostasis and not simply suppressing inflammation.

The management of patients with life-

Downloaded From Vet-eBooks.com

threatening infections and systemic inflammation still largely consists of hemodynamic and pulmonary support, appropriate antibiotics, and timely surgical intervention. Despite the exponential growth in our understanding of the basic biology of inflammation, our arsenal does not yet include a magic bullet to normalize the mediators of the proinflammatory and anti-inflammatory response.

Downloaded From Vet-eBooks.com

Chapter 2

Shock

Tim Hackett

Oxygen delivery to tissues is one of the primary functions of the cardiopulmonary system and of primary importance to the patient manifesting signs of circulatory failure. Oxygen delivery is a function of cardiac output and oxygen content of arterial blood (Figure 2-1). In health, blood flow (cardiac output) is adjusted to meet the oxygen demands of the individual. This occurs primarily

Downloaded From Vet-eBooks.com

through changes in heart rate and vasomotor control of perfusion to maintain oxygenation of active tissues. Many acute disease states result in inadequate oxygen delivery to the tissues and tissue hypoxia. Initially, this drop in oxygen delivery can be overcome by compensatory increases in oxygen delivery variables and increases in oxygen extraction. When these mechanisms fail to restore oxygen homeostasis, global tissue hypoxia (shock) results.[1] If the defect in the transport of oxygen to the vital tissues can be identified and corrected while the patient is undergoing supportive care, recovery is possible. Failure to correct poor perfusion will lead to decreased oxygen consumption

Downloaded From Vet-eBooks.com

in the tissues, organ dysfunction, and death.

DO_2 (oxygen delivery) = CaO_2 (oxygen content) x CO (cardiac output)

CO = Heart rate x Stroke volume

CaO_2 = Hgb x SaO_2 x 1.34 + (PaO_2 x 0.003)

Figure 2-1. Variables determining oxygen delivery. SaO_2 = Arterial oxygen saturation; Hgb = Hemoglobin concentration; PaO_2 = Partial pressure of oxygen in arterial blood. Each gram of hemoglobin carries 1.34 ml of oxygen when fully saturated. Dissolved oxygen is equal to 0.003 ml of O_2 per 100 ml of blood per mm of Hg PO_2.

Classification of Shock

Shock may be classified in many ways,

Downloaded From Vet-eBooks.com

including by common pathway or specific cause. It is helpful to think of shock in terms of broad categories before further defining the type of shock within each category. The broadest classification system includes three major and exceedingly different causes of shock: cardiogenic shock, hypovolemic shock, and distributive shock.[2] Each results in reduced oxygen delivery to tissues through low blood flow or uneven distribution of flow. In practice, each primary event can lead to a cascade of complex physiologic problems, neurohormonal compensations, and activation of various biochemical mediators and inflammatory responses integral to the shock syndromes. A single patient may

Downloaded From Vet-eBooks.com

have several pathologic processes simultaneously resulting in reduced perfusion of tissues.

Hypovolemic Shock

The primary defect in hypovolemic shock is an inadequate circulating volume. This can be from sudden massive blood loss as in surgery or trauma, or fluid loss from vomiting, diarrhea, or renal disease. Neurohormonal pathways detecting a drop in blood pressure will stimulate the renin-angiotensin-aldosterone system to conserve water through the action of antidiuretic hormone. Stimulation of the sympathetic nervous system leads to epinephrine and

Downloaded From Vet-eBooks.com

norepinephrine release from the adrenal gland. These hormones increase vascular tone in an attempt to shunt circulation from the periphery to vital tissue beds and result in cool extremities and prolonged capillary refill time. Myocardial contractility is also increased through their action. As the patient begins to decompensate, tachycardia is a common finding, allowing maintenance of oxygen delivery in the face of diminished stroke volume. Concurrently, fluid shifts from interstitial fluid reserves in an attempt to preserve vital perfusion of the brain, heart, and kidneys while stealing supplies from other organs and tissues such as skeletal muscle and the gastrointestinal tract.[3]

Downloaded From Vet-eBooks.com

Cardiogenic Shock

Cardiogenic shock occurs when the pumping function of the heart is severely impaired, leading to circulatory failure. As with hypovolemic shock, the patient will be tachycardic, weak, oliguric, have cool extremities and weak pulses. The patient with cardiac failure may also have evidence of primary cardiac disease such as an auscultable murmur, ascites, jugular venous distention, pulmonary edema, or cardiac arrhythmias. The primary defect in oxygen delivery is a reduced cardiac output.[4]

CO = Heart Rate x Stroke Volume

Downloaded From Vet-eBooks.com

Stroke volume is determined by preload, afterload, and contractility. Within limits, cardiac output increases as heart rate increases. High heart rates will eventually decrease cardiac output by impairing cardiac filling and subsequent stroke volume. Tachycardia may be the result of cardiac arrhythmia or simply a physiologic response to low volume. Specific antiarrhythmic therapy and correction of underlying causes of tachycardia should be used to normalize heart rate. Clinically significant bradyarrhythmias are less common. Hyperkalemia or decompensated shock (especially in the feline) can result in clinical bradycardia. Specific arrhythmias include sick sinus syndrome, second-

Downloaded From Vet-eBooks.com

and third-degree atrioventricular block. It is uncommon for these slow heart rates to require emergency treatment. Often these patients have already compensated with increased stroke volume and can be referred for pacemaker treatment.[5]

Stroke volume is dependent on three determinants of cardiac function: preload, afterload, and contractility. With congestive heart failure, the pump is failing because of decreased contractility. The body attempts to compensate by increasing preload (sodium and fluid retention). Normally, the heart is able to pump the fluid presented to it through increased stretch of myocardial muscle fiber,

Downloaded From Vet-eBooks.com

resulting in increased contractility. Therefore, by increasing preload, the heart will increase stroke volume. In cardiac failure, the excess fluid cannot be moved and it accumulates downstream of the failing ventricle. This results in pulmonary edema in left-ventricular failure and ascites, pleural effusion, and hepatic congestion in right-ventricular failure.[6]

Maximize stroke volume (and cardiac output) by recognizing and treating the primary defect. In congestive failure, preload can be optimized by monitoring central venous pressure, administering diuretics such as furosemide, and venodilators such as nitroglycerine. With obstructive

Downloaded From Vet-eBooks.com

failure, as is seen with pericardial effusion, removal of even a small amount of pericardial fluid will relieve the pressure on the right ventricle and allow more normal filling.[7] Cardiac output can also be enhanced by decreasing afterload with calcium channel blockers or ACE inhibitors. These are especially useful in treating failure caused by mitral insufficiency where contractility may be normal to increased but a portion of the cardiac output is going backwards into the left atrium instead of out and into systemic circulation. In documented myocardial failure, contractility can be enhanced with positive inotropic drugs such as dobutamine, digoxin, or pimobendan.[8]

Downloaded From Vet-eBooks.com

Distributive Shock

Distributive shock is probably the most challenging of the shock syndromes and one of the most difficult to reverse. The primary defect with distributive shock is an abnormal systemic vasomotor response leading to peripheral vasodilation and maldistribution of blood flow.[9] Increases in vascular permeability can further exacerbate this shock syndrome. Both peripheral vasodilation and increased vascular permeability result in decreased perfusion of vital tissues. The many causes of distributive shock are summarized in Table 2-1.

Downloaded From Vet-eBooks.com

Table 2-1. Causes of Distributive Shock

Sepsis and endotoxemia
Metabolic (renal or hepatic failure or severe acid base imbalances
Toxic (anesthetic overdose, heavy metal toxicosis)
Endocrinologic (adrenocortical insufficiency, diabetic ketoacidosis)
Neurogenic (cerebral and spinal disease)

Components of other forms of shock may contribute to poor tissue

Downloaded From Vet-eBooks.com

oxygenation in distributive shock. Fluid loss into body cavities and interstitial spaces results in relative hypovolemia. The release of inflammatory mediators in septic shock can depress the myocardium, resulting in a cardiogenic component. Therapy must be directed at the underlying systemic defect. In sepsis, therapy consists of drainage and control of the infected focus. Because systemic inflammation resulting from sepsis and other inflammatory disease can affect oxygen delivery in many vital tissues, serial monitoring of many variables becomes necessary to treat the variety of problems an individual may face.[10]

Downloaded From Vet-eBooks.com

Treatment and Monitoring

Treatment of shock should be directed at the primary problem(s) while correcting the fluid deficit. Crystalloid fluids can be used initially to restore circulating volume. Crystalloids improve cardiac output and should not be withheld for fear of diluting the red blood cell mass.[11] Oxygen delivery is a function not only of oxygen content, but also of cardiac output. Improved stroke volume should offset the initial drop in packed cell volume as the patient's true level of anemia becomes apparent. If signs of shock persist as the patient becomes more anemic, a hemoglobin-containing fluid (whole blood, packed red blood cells, or

Downloaded From Vet-eBooks.com

Oxyglobin®) should be administered.[12,13]

With a treatment goal of improving oxygen delivery to the tissues, we can increase cardiac output by increasing stroke volume (appropriate fluids). Oxygen content can be increased by increasing the hemoglobin concentration (hemoglobin transfusion) and by increasing oxygen saturation (oxygen supplementation).

Volumes of fluid for resuscitation should be tailored to the individual patient. It has long been recommended that the initial goal with crystalloid fluids is to give a blood volume (approximately 90 ml/kg dog, 60

Downloaded From Vet-eBooks.com

ml/kg cat) in an hour.[14] This is often more than enough fluid, and in extremely debilitated patients may lead to fluid overload (pulmonary and cerebral edema).[15] Patients with systemic inflammatory conditions may also be prone to vascular leakage. Excessive fluids can affect electrolytes, dilute clotting factors, and lead to accumulations of fluid in interstitial spaces and body cavities. It may be more practical to titrate this dose in smaller increments. Smaller boluses of 22 ml/kg in dogs or 10 ml/kg in cats (approximately 25% of the total shock volume) of crystalloid fluids should be given intravenously followed by repeated doses if the patient's clinical signs fail to improve.[16] Endpoints of

Downloaded From Vet-eBooks.com

resuscitation should be evaluated closely and the rapid administration of fluids should be discontinued when the patient is improving.[17] Questions to ask: Are the pulses stronger? Slower? Is the patient more alert? If the answer is "no," more fluids are administered while alternate mechanisms of shock are investigated.

Following the administration of a bolus of 25% shock dose of crystalloid fluids, the packed cell volume and total solids should be compared to pre-fluid values. If a patient receiving large quantities of crystalloids becomes anemic or hypoproteinemic, the fluid should be switched to an appropriate colloid such as whole blood, packed red blood cells,

Downloaded From Vet-eBooks.com

plasma, or a synthetic colloid. If the total solids drop to less than 50% of pretreatment values, a colloid should be considered for further resuscitation. If the PCV has dropped precipitously, administer whole blood and search for the source of blood loss. Often, in traumatic hemorrhage, correction of blood loss volume and pressure facilitates repeated hemorrhage in areas of vascular trauma, while simultaneously diluting available clotting factors. Therefore, close attention during initial fluid resuscitation is important.

Heart and respiratory rates are useful objective variables to monitor in critical patients. Capillary refill,

Downloaded From Vet-eBooks.com

peripheral pulse quality, and mentation are subjective but still valuable parameters to help assess perfusion when used by experienced professionals. Blood pressure and pulse oximetry are gaining wider use in veterinary medicine and may provide additional information on cardiopulmonary function so long as limitations of the equipment are understood.

Blood pressure is the lateral force per unit area of vascular wall. Blood flow is the amount of motion provided by blood pressure working against vascular resistance. Throughout the cardiac cycle, the blood pressure oscillates about a mean pressure. Pulse

Downloaded From Vet-eBooks.com

pressure, which determines pulse quality or strength, is the difference between systolic and diastolic pressure. Systolic pressure is determined by stroke volume, peak rate of ejection, and arterial compliance. Diastolic pressure is a function of end-systolic arterial pressure, diastolic duration, peripheral vascular resistance, and blood volume.[18]

Indirect blood pressure measurement involves the occlusion of a peripheral artery by inflation of a pneumatic cuff. The closing and opening of the artery is detected through palpation, auscultation, or oscillometric or ultrasonic means. Diastolic pressure, which is much more important in the

Downloaded From Vet-eBooks.com

critically ill animal, unfortunately is much more difficult to establish. Limitations to the use of indirect blood pressure monitoring include the expense of the equipment and the inability to reliably detect blood pressure in smaller animals or those critically ill patients with low-pressure readings.

Oscillometric indirect blood pressure measurement senses amplitude of oscillations in a pressurized cuff. These oscillations are produced by changes in arterial diameter caused by changes in pulse pressure. A sudden increase in the amplitude of oscillations corresponds to systolic pressure and a low point of maximum oscillations

Downloaded From Vet-eBooks.com

corresponds to the diastolic pressure. The mean arterial pressure is measured directly as the lowest cuff pressure at which the oscillations are at their highest amplitude. Appropriate cuff size should be 40% of limb circumference. If the cuff is too narrow it may lead to a falsely high blood pressure. If it is too wide the blood pressure will be falsely low.[18, 19]

Ultrasonic pulse detectors use ultrasound kinetoarteriography to detect arterial wall motion using ultrasonic waves to amplify the sound of pulsating blood. Gradual deflation of cuff pressure allows blood flow as pressures drop below systolic blood pressure. Systolic pressure is recorded

Downloaded From Vet-eBooks.com

as the first audible sound as blood begins to flow through the artery.[18] Diastolic pressure is much more subjective and is recorded when the sound quality changes dramatically and becomes muffled. The advantage of ultrasonic sphygmomanometry is its adaptability to many animals. Also, the equipment is relatively inexpensive. Disadvantages and limitations are similar to those of the oscillometric devices. Because determination of actual pressure cutoff points is operator dependent, fluctuation in reported values can be greater. Mean arterial pressure cannot be determined directly by this method but can be calculated if systolic and diastolic pressures are recorded.

Downloaded From Vet-eBooks.com

Pulse oximetry allows the estimation of arterial oxyhemoglobin saturation by transmitting light through a skin fold and sensing the difference between light absorption during pulsation (arterial flow) and background absorption. Although oxyhemoglobin (SaO_2) saturation is not directly related to arterial PO_2, it provides information about tissue delivery of oxygen. The advantage of measuring SaO_2 is the continuous, immediate noninvasive estimate of oxygenation. Disadvantages include the difficulty in maintaining the transducer in small conscious patients, interference in pigmented skin, and the inability to detect adequate signals with certain diseases (low cardiac output states,

Downloaded From Vet-eBooks.com

icterus, anemia, and hypothermia).[20]

An important clinical question is how to determine when the shock state is controlled. With goal-directed therapy, fluid rates can be lowered to deficit replacement, maintenance volumes, and ongoing losses when clinical signs of shock resolve. It is important to note that traditional endpoints of resuscitation (capillary refill time, heart rate, peripheral pulse quality, blood pressure, level of mentation, and urine output) may be normal in early, compensated shock and altered only when the patient decompensates. However, the opposite is also a problem: In animals in which the above endpoints are successfully

Downloaded From Vet-eBooks.com

corrected but that still have ongoing evidence of tissue hypoxia, more sensitive markers of oxygen transport must be evaluated.[17]

Intensive oxygen transport monitoring gives greater importance to detecting oxygen delivery. Researchers in the 1980s hypothesized that oxygen delivery and oxygen consumption were the best means of assessing adequate tissue oxygenation. Their research led to the idea that supranormal oxygen delivery in acute perioperative shock would lead to reduced mortality.[21]

This led to the routine use of pulmonary artery catheters and measurement of variables such as

Downloaded From Vet-eBooks.com

cardiac index (cardiac output standardized to body weight), central venous pressure, and pulmonary capillary wedge pressure. By sampling mixed venous (pulmonary arterial) blood and comparing it with arterial blood, oxygen extraction and utilization could be measured and monitored. Unfortunately many studies performed since have led to conflicting results and routine placement of pulmonary artery catheters has been associated with technical problems and catastrophic complications.[22] Even so, decreases in oxygen utilization have been shown to negatively affect prognosis in patients that fail to achieve normal oxygen utilization within 12 hours of resuscitation.[23] For

Downloaded From Vet-eBooks.com

this reason, alternative means to assess patients' relative oxygen debt continue to be investigated. Blood lactate, serum base excess (or deficit), gastric tonometry, and organ-specific cellular oxygen utilization techniques have provided new means to assess oxygen debt.[17]

Lactate is produced from pyruvate (via lactate dehydrogenase) during periods of tissue hypoxia. Normally less than 2 mmol/L, arterial lactate climbs with anaerobic metabolism. Tissue hypoxia causes lactate levels to climb beyond the ability of normal clearance mechanisms.[24] While it can indicate poor perfusion, tissue hypoxia, and lactic acidosis, lactate can be normal

Downloaded From Vet-eBooks.com

during periods of deranged cardiac output (before clearance mechanisms have become saturated). Hemorrhagic shock in a canine model found lactic acidosis more predictive of the severity of oxygen debt than blood pressure or cardiac output.[25] Lactate can be used to monitor resuscitative efforts, as levels should drop quickly with improved perfusion. Lactate measurement has limitations because other forms of lactic acidosis exist that are not specific for global oxygen debt. An example of this occurs with sepsis and catecholamine administration in which altered lactate metabolism can overestimate the severity of tissue hypoxia.[24]

Downloaded From Vet-eBooks.com

Determination of base deficit has been favored over that of blood lactate in human critical care. Base deficit is calculated by most blood gas analysis equipment as the amount of a base required to titrate a set volume of the patient's blood to a normal pH (7.40). Base deficit is a measure of the amount of excess fixed acid (metabolic acidosis) in the patient. Clinical and experimental studies have shown that high base deficit is inversely related to outcome.[26, 27] Compared with lactate, mean arterial blood pressure, and cardiac output in another canine model of hemorrhagic shock, base deficit correlated the most closely with oxygen debt and mortality.[27]

Downloaded From Vet-eBooks.com

Although technically demanding, direct analysis of organ-specific oxygenation is becoming available. Gastric tonometry allows the measurement of gastric pH and with it, evaluation of gastric perfusion.[28] Transcellular probes applied to skin, inserted into muscle, or attached directly to the surface of organs can evaluate tissue oxygenation of specific vascular beds. These newer techniques may take some of the subjective guesswork out of treating shock. Each deserves objective evaluation and further research in evaluation of the ability to monitor the effectiveness of shock therapy.

Conclusions

Downloaded From Vet-eBooks.com

New technology is providing interesting new choices in the diagnosis and management of shock. Each intervention deserves investigation and, if proven practical and effective, will help clinicians manage this devastating syndrome. In the meantime, circulatory shock needs multimodal treatment with a basic goal: to improve oxygen delivery (DO_2) (Table 2-2). Improved oxygen delivery is achieved by optimizing oxygen content (CaO_2) and increasing oxygen saturation (SaO_2). If the packed cell volume is limiting DO_2, we can increase hemoglobin concentration with whole blood transfusion, packed red blood cell transfusion, or hemoglobin-based oxygen-carrying

Downloaded From Vet-eBooks.com

fluids (HBOC). We may also improve DO_2 by optimizing cardiac output (CO). This is done by optimizing heart rate (monitor pulse rate, quality, electrocardiogram), treating specific arrhythmias, and optimizing stroke volume. The goal of shock stabilization is to give the clinician time to treat the primary problem and improve the chance of a successful outcome.

Table 2-2. Monitoring Variables, Goals, and Therapeutic Interventions used to Address Impaired Oxygen Delivery and Circulatory Shock.

Downloaded From Vet-eBooks.com

Physiologic Variable	Optimal Values	Therapeutic Interventions
Systolic arterial pressure	> 90 mmHg	Fluids, vasoactive/inotropic
Mean arterial pressure	> 70 mmHg	Fluids, vasoactive/inotropic
Central venous pressure	< 3 cm H_2O – normal 5-10 cm H_2O when loading	Fluids when low, diuretics and venodilators when high
Urine output	> 1 ml/kg/hr	Fluids, diuretics, dopamine
Blood glucose	70-200 gm/dL	Nutrition, dextrose if low Regular Insulin if high
Total serum solids	3.5-5.5 gm/dL	Plasma, colloids, nutrition
Albumin	> 1.5 g/dL	Plasma, 25% HSA, nutrition
Arterial blood gasses	PaO2 > 70 mmHg	Supplemental oxygen
	PaCO2 < 35 mmHg	Ventilatory support
	HCO3 14-24	Fluids, bicarbonate
	pH 7.35-7.45	Fluids, ventilator therapy, bicarbonate
	Base deficit -2 to 2 mEq/L	Fluids, vasoactive/inotropic
	Lactate < 2 mmol/L	Fluids, vasoactive/inotropic
Heart rate	70-150 BPM	Fluids, analgesics, antiarrhythmics

Chapter 3

Transfusion Medicine

Elizabeth Rozanski
Mark P. Rondeau

Over the last 25 years, blood transfusions given to ill or injured patients in veterinary medicine have evolved from a relatively rare occurrence to a routine and frequently life-saving practice.[1-6] It is impossible to contemplate a successful surgeon and surgery team not having a strong knowledge base in transfusion medicine and easy access to blood

Downloaded From Vet-eBooks.com

products. The purposes of this chapter are to outline the physiology of blood and plasma, and to describe blood groups, methods of collection, blood components, indications for transfusion, methods of administration and monitoring during transfusions, and transfusion reactions.

Physiology of Blood and Plasma

The purpose of red blood cells is efficiently to carry oxygen to support oxygen delivery to the tissues. Red blood cells are highly evolved to be exceedingly efficient at oxygen transport by saturation of the hemoglobin (Hb) molecule with oxygen

Downloaded From Vet-eBooks.com

absorbed at the interface between the alveolar and pulmonary capillaries. Oxygenated hemoglobin contains approximately 1.34 ml of oxygen per gram of Hb. The oxygen content of the blood is dependant primarily on the oxygen saturation of Hb, but also, to a far lesser extent, on the dissolved partial pressure of oxygen. The oxygen content of blood can be calculated (Table 3-1).

Table 3-1. Calculation of the Oxygen Content of Blood. This Formula may be used for Arterial or Venous Blood. Each mg of

Downloaded From Vet-eBooks.com

Hemoglobin may carry 1.34 grams of Oxygen.

Oxygen content = [Hemoglobin (g/dl) x % saturation x 1.34] + [PaO_2 (in mm Hg) x 0.003]

For example = (15 x 0.98 x 1.34) + (100 x 0.003) = 20 ml O_2/g Hb/dl

However, the oxygen content alone is only part of the equation of successful oxygen delivery. Oxygen delivery to the tissues is also dependant on cardiac output (CO) which is the product of stroke volume (SV) and heart rate. Thus, in an anemic animal the attempt to improve oxygen delivery by increasing cardiac output is by

Downloaded From Vet-eBooks.com

increasing rate and/or stroke volume. This can result in tachycardia and "bounding pulses." Bounding pulses associated with anemia are a result of a greater pulse pressure (systolic – diastolic), which is usually associated with either increased systolic pressures because of increased stroke volume or from diastolic run-off if concurrent hypovolemia is present. Tachycardia becomes an important branch in decision-making about a transfused pet. In some cases, dogs will have a normal heart rate while resting, but develop a marked tachycardia (e.g., 80 bpm to 180 bpm) upon standing or being encouraged to walk, because oxygen delivery to the tissues is limited and the cardiovascular system attempts

Downloaded From Vet-eBooks.com

to compensate for tissue hypoxemia.

The cellular components of the blood also include white blood cells and platelets. White blood cells have a variety of roles, primarily involving modulation of the immune response and defense against infection. Because of the limited survival times of white blood cells, low white blood cell counts are not treated with transfusion and, in some cases, removal of the white cells (leukoreduction) has been advocated as a method of limiting immune response associated with transfusion.[7]

Platelets are involved in primary hemostasis. Thrombocytopenia is

Downloaded From Vet-eBooks.com

common in animals with anemia. Platelet-rich plasma or platelet concentrates may be transfused in dogs. However, if thrombocytopenia is secondary to immune-mediated destruction, the transfused platelets will be destroyed within a matter of minutes.[8] The plasma component of blood acts to reduce overall viscosity in addition to containing plasma proteins (albumin and globulin), antithrombin, electrolytes and glucose, pro- and anticoagulant factors, hormones, and a multitude of other factors.

Blood Groups and Blood Type

Dogs have many different blood

Downloaded From Vet-eBooks.com

groups, which are defined by glycolipid and glycoprotein antigens found on the red blood cell surface.[9] These are named dog erythrocyte antigens (DEA). Up to 9 antigens have been recognized within this system (DEA 1.1, 1.2, 1.3, 3, 4, 5, 6, 7, and 8). Not all antigens are considered equally important in regard to their ability to trigger a transfusion reaction. DEA 1.1 is the most likely to trigger an acute hemolytic transfusion reaction in dogs. Forty to 50 % of dogs are positive for DEA 1.1. A DEA 1.1-negative dog that has been previously sensitized with DEA 1.1 positive red blood cells may develop an acute hemolytic transfusion reaction on subsequent exposure to DEA 1.1-positive red blood cells. DEA

Downloaded From Vet-eBooks.com

1.2 is also capable of eliciting an acute reaction in sensitized dogs. DEA 4 is the most prevalent of canine blood types, occurring in up to 98% of dogs. While it was previously believed that DEA 4 did not play a role in transfusion reactions, severe hemolytic reactions have been described.[10] Fortunately, transfusion reactions are rare in dogs that have not previously been transfused or that have had puppies. Dogs are unlikely to have preformed antibodies against other determinants. It has been suggested that some DEA 7-negative dogs have preformed antibodies against the DEA 7 antigen, although the antibody is weak. Sensitized DEA 7-negative dogs that are transfused with DEA 7-positive

Downloaded From Vet-eBooks.com

blood experience a delayed transfusion reaction where the transfused red blood cells are lost in 72 hours. Blood typing of both the recipient and the donor dog can be performed at a variety of laboratories and also with commercial blood typing cards (Appendix 3-1). Although blood typing of a recipient dog prior to transfusion is ideal, in an emergency situation it is unlikely that a transfusion will result in a reaction for the first-time recipient, because of the lack of preformed antibodies. Blood typing of both the donors and the recipients helps to maintain a better blood bank by controlling the resources. Blood typing antisera are available for DEA 1.1, 1.2, 3, 4, 5, and 7, although most

Downloaded From Vet-eBooks.com

commercial blood banks and laboratories type for DEA 1.1 only, as it is the most antigenic. In an animal that has been previously transfused or in which the transfusion history is unknown, cross-matching prior to the initial transfusion is prudent to reduce the risk of a reaction.

The cat blood group system has classically been made up of A, B, and AB types;[2,11] however, the existence of a new red blood cell antigen (MIK) has been described in a domestic short hair cat.[12] Cats, unlike dogs, have naturally occurring alloantibodies to blood groups other than their own, even without previous transfusion. Type A is the overwhelmingly prevalent type in

Downloaded From Vet-eBooks.com

domestic mixed-breed cats in the United States. Some purebred cats (notably the Devon Rex and British Shorthair) have a high incidence of type B blood. If a cat with type A is given type B blood, the transfusion will typically be hemolyzed within 48 hours; however, if a cat with type B is given type A blood, a fatal transfusion reaction is likely to occur. Thus, **all** recipient cats should be typed or cross-matched prior to transfusion. In cats requiring multiple transfusions, cross-matching may be warranted each time, particularly in cats that have had prior transfusion reactions.

Blood Collection and

Downloaded From Vet-eBooks.com

Processing

Although historically in veterinary medicine, fresh whole blood was collected as needed from either clinic animals or pets belonging to the staff of veterinary hospitals, this is considered antiquated and is not advised if it is possible to avoid. Blood banking is commonly performed in the larger veterinary hospitals. Several large commercial blood banks for animals also exist (Appendix 3-1). The purpose of a blood bank is to provide a readily available source of packed red blood cells or plasma for use in hospitalized patients. Most veterinary blood banks rely on client and staff-owned animals. Pre-donation

Downloaded From Vet-eBooks.com

screening is strongly recommended for the donors. Typically, screening involves a physical examination, a complete blood count, and chemistry profile. Species-specific screening for cats includes testing for feline leukemia and feline immunodeficiency viruses, and for dogs, heartworm testing. In some geographic locations, testing for exposure to tick-borne diseases such as Erhlichia is also recommended. The American College of Veterinary Internal Medicine has published a consensus statement concerning the recommended pre-testing of animal donors.[13]

The ideal feline donor is a large (more than 8- to 10-pound) well mannered

Downloaded From Vet-eBooks.com

adult cat. Most if not all cats require some sedation for donation. Frequently used sedatives include ketamine, narcotics, and diazepam. Feline blood donors should be carefully ausculted prior to sedation, as occult cardiomyopathies are not rare and could contribute to morbidity or mortality for the donor cat. Approximately 50 ml of whole blood may be collected from a donor cat. Blood may be collected as frequently as every 4 weeks, although with pet cats the donation interval is typically 2 to 3 months. The blood may be anticoagulated with heparin if it is to be used immediately, or with citrate-phosphate-dextrose-adenine (CPDA-1) for storage. Cat blood is often

Downloaded From Vet-eBooks.com

transfused as either fresh or stored whole blood, although interest has been growing in the use of components in cats as well (Figure 3-1).

Figure 3-1. A cat following collection of one unit of fresh whole blood.

The canine blood donor is typically a

Downloaded From Vet-eBooks.com

large breed (more than than 50 pounds) well mannered adult dog. Unlike cats, typically dogs do not require any sedation (Figure 3-2). Approximately 1 unit (450 ml) may be collected from each donor. Generally, canine blood is collected into bags containing CPDA-1 designed for human blood donation. Canine blood is almost always divided into components to best utilize the available resources.[3] The different blood products that are available include fresh and stored whole blood, packed red blood cells, platelet-rich plasma, fresh frozen plasma, stored frozen plasma, cryoprecipate, and cryo-poor plasma. (Table 3-2) The most widely used components are packed red blood cells

Downloaded From Vet-eBooks.com

and fresh frozen plasma. The blood components are prepared by separating and processing the units after collection.

Figure 3-2. A golden retriever donating a unit of blood.

Fresh whole blood (FWB) contains red

Downloaded From Vet-eBooks.com

blood cells, platelets, leukocytes and plasma. Fresh whole blood is blood that is transfused within 8 hours of collection. The primary indications for transfusion with fresh whole blood include hemorrhage (resulting in loss of both red cells and plasma), thrombocytopenia with active hemorrhage, and lack of other available blood components. If a freshly collected unit of whole blood is not to be used within 8 hours, it should be separated into components or refrigerated at 4°C. Whole blood may be stored for up to 35 days, depending on the anticoagulant-preservative used. Stored whole blood contains viable red blood cells and plasma proteins such as albumin and globulin

Downloaded From Vet-eBooks.com

(although labile coagulation factors V and VIII will lose their activity). The primary indication for the use of stored whole blood is hemorrhage or the lack of other readily available components.

Table 3-2. Characteristics of Blood and Blood Components Available for Transfusion for Dogs.

Product	Contents	Advantages	Disadvantages
Fresh whole blood	Red blood cells, white cells, platelets and plasma	No processing, replaces shed blood	Potential waste of resources, volume overload, short shelf life (8 hours)
Stored whole blood	Red blood cells and plasma	No processing	Potential waste of resources, volume overload
Fresh frozen plasma	Clotting factors, including V, VIII, von Willebrand factor, albumin and antithrombin	Rich in clotting factors, useful in some coagulopathies	Limited source of albumin, stable for 1 year; if thawed and not used, may be re-frozen as stored plasma
Stored plasma	Some clotting factors (II, VII, IX, X), albumin, antithrombin	Useful in some coagulopathies (e.g., anticoagulant rodenticide), source of plasma proteins	Stable for 5 years
Cryoprecipitate	Concentrated form of clotting factors (specifically VIII, von Willebrand factor and fibrinogen)	Useful if volume overload from fresh frozen plasma a concern; cryo-poor component may be used for albumin and other plasma proteins	Extra step to prepare from fresh frozen plasma

Downloaded From Vet-eBooks.com

Commonly, individual units of canine whole blood are processed into components. The red cell portion of the unit is called packed red blood cells (pRBC). Packed red blood cells are prepared by spinning a unit of fresh whole blood at 4°C at 5000 rpm for 15 minutes and removing the majority of the plasma. A unit of pRBC may be stored for approximately 35 days at 4°C, depending on the anticoagulant-preservative used. The average hematocrit of a unit of pRBC is 70 to 80%. Typically, a unit of packed red cells is re-suspended in saline (0.9%) prior to transfusion. The ammonia levels will increase in stored red cells and the glucose level (because of the preservatives) will be high (> 500

Downloaded From Vet-eBooks.com

mg/dl).[14] However, the clinical significance of this effect is unknown at this time, and packed red blood cells are indicated to provide oxygen-carrying support to anemic animals requiring such support regardless of underlying cause. In a patient with suspected severe hepatic encephalopathy, it may be prudent to avoid packed cells at the end of their shelf life.

Plasma may be classified as fresh frozen plasma, stored plasma, platelet-rich plasma, cryoprecipate, or cryo-poor plasma, depending on how the unit of whole blood is processed. The types of plasma differ in their relative number and efficacy of the clotting

Downloaded From Vet-eBooks.com

factors. Fresh frozen plasma (FFP) is prepared by separating a unit of fresh whole blood within 6 hours of collection. Fresh frozen plasma is a good source of all the clotting factors including V, VIII, and von Willebrand factor. Fresh frozen plasma is stable for up to 1 year if stored at -40°C. After 1 year, the more labile factor activity is diminished and the unit is termed stored plasma. Stored plasma may also be produced at any point from a unit of stored whole blood or if FFP is inadvertently thawed and then refrozen. Stored plasma has adequate amounts of factors II, VII, IX, and X (the vitamin K-dependant factors), and also albumin.

Downloaded From Vet-eBooks.com

Platelet-rich plasma may be made by centrifugation of fresh whole blood at lower than normal speeds (2000 rpm). Platelet concentrates have also been described in dogs. Practically, transfusions of platelet-rich plasma or platelet concentrates is rarely performed in veterinary medicine because of the technical requirements for preparation of the products.[15,16]

Cryoprecipitate may be prepared by thawing and centrifuging partially thawed fresh frozen plasma. Cryoprecipate is rich in clotting factors VIII, von Willebrand factor, and fibrinogen. It also contains clotting factors IX, XI, and XIII. It is stable for 1 year after the initial collection of the

Downloaded From Vet-eBooks.com

plasma. The cryo-poor component may also be used for some clotting factors and albumin. Cryoprecipitate was initially created for use in people with congenital coagulopathies requiring multiple transfusions in whom volume overload with plasma products was a concern.

Indications for Transfusion

Indications for transfusion are plentiful in injured or ill animals. It is helpful to divide the indications for transfusion into absolutely indicated and potentially indicated. Transfusions carry the risk of reaction or possibly even disease transmission and certainly can add extra expense.

Downloaded From Vet-eBooks.com

Transfusions are considered primarily indicated to treat anemia and coagulopathy. In surgical patients, transfusions may be particularly warranted prior to anesthesia to improve the oxygen-carrying capacity and decrease the potential for anesthetic complications.

Anemia

Anemia should be divided into normovolemic anemia and hypovolemic anemia. Animals that are anemic with a normal volume status typically have either nonregenerative or hemolytic anemias. In these animals the anemia may have been long-standing and/or accompanied by a

Downloaded From Vet-eBooks.com

relative increase in plasma volume. Normovolemic anemic patients appear relatively bright, have normal to slightly elevated total solids, and have pale rather than white mucous membranes.

Normovolemic anemic patients require slow administration of packed red cells to avoid volume overload. In comparison, hypovolemic anemic patients have typically suffered from catastrophic blood loss within the last 12 to 24 hours. These patients are very weak, have rapid and faint pulses, and mucous membranes that appear more pale than their hematocrit might suggest. Their total solids are almost invariably low. These patients require

Downloaded From Vet-eBooks.com

aggressive volume resuscitation as well as blood transfusion. It is not uncommon to find that the post transfusion hematocrit may be lower that the starting point as a result of dilution of the circulating volume with crystalloids or colloids. It is crucial for the clinician to remember that oxygen delivery may be improved dramatically by increasing blood volume (and thereby letting cardiac output improve) even in the face of a lower number for the hematocrit. Massive transfusion, defined as one entire blood volume (90 ml/kg over 24 hours or half a blood volume over 3 hours) has been described in dogs.[17]

Packed red cells are usually transfused

Downloaded From Vet-eBooks.com

at either a dose of 1 ml per pound of body weight x the desired increase in hematocrit (Table 3-3) or simply in increments of 1/4, 1/2, or 1 unit. Each unit of packed red cells contains approximately 225 to 250 ml.

Table 3-3. Calculation of the Volume of Blood to Transfuse. This formula assumes lack of active Hemorrhage and stable Intravascular Volume. In Hemorrhaging Animals, Blood should be Transfused to an acceptable

Desired PCV

Hematocrit of transfusate- Assume 75% for packed red blood cells (pRBCs)

Each 1 ml/ pound of body weight (2.2 ml/kg) will raise the PCV by 1%: e.g., in a 44 # dog, PCV is 15%, you want to make it 25%.

10 (% increase) x 44 (bw) = 440 ml of packed red cell required.

Coagulopathy

Blood or plasma transfusions are also

Downloaded From Vet-eBooks.com

considered indicated to treat coagulopathy from decreased coagulation factors. (Tables 3-4 and 3-5) This may be inherited or acquired. Coagulopathy may be a difficult term to completely define. The normal coagulation system has a relatively large pool of circulating inactive coagulation factors, which are available if massive hemorrhage ensues. The methods of routinely assessing coagulation (prothrombin time, activated partial thromboplastin time, activated clotting time) typically rely on the detection of the formation of a fibrin clot. By the time these assays are abnormal, much of the coagulation ability is lost. Inherited coagulopathies that may benefit from

Downloaded From Vet-eBooks.com

plasma transfusion include hemophilia A or B, von Willebrand disease, and other specific coagulation factor deficiencies. Acquired coagulopathies are common in critically ill animals and include anticoagulant rodenticide toxicities, liver failure, and possibly disseminated intravascular coagulation (DIC). Coagulopathy is markedly worsened by hypothermia and acidosis. Plasma is usually given at a dose of 8 to15 ml/kg, repeated every 12 hours as needed until normalization of the coagulation times. Plasma is also commonly transfused at 1/4, 1/2, or full unit volumes. A full unit of plasma is approximately 225 to 250 ml.

times

Inherited coagulopathy and planned surgical intervention (Evaluate on a case by case basis)

Very small [< 5 kg (11 lbs)] patient with profound hypoproteinemia

---

Other Indications

Transfusions are also potentially indicated with therapy of sepsis/multiple organ dysfunction syndrome, pancreatitis, hypoalbuminemia, and DIC without associated laboratory-proven coagulopathy. It appears commonplace among clinicians to want to give plasma when animals appear critically

Downloaded From Vet-eBooks.com

ill. However, it is prudent to try to determine what the end-point of transfusion is (i.e., normalization of a specific laboratory parameter versus cardiovascular parameter versus other). Correction of an albumin deficit is usually impractical in all but very small patients as much of the patient's albumin is actually extravascular.

Thrombocytopenia

In patients with severe thrombocytopenia that require surgical intervention, attention to meticulous hemostasis is mandatory. In these specific cases, transfusion with platelets in the form of fresh whole blood, platelet-rich plasma, or platelet

Downloaded From Vet-eBooks.com

concentrates may be appropriate. Practically, it is essential that the surgical team recognizes the time constraints (45-60 minutes) of either collection of fresh whole blood and/or processing into platelet-rich plasma or platelet concentrates.

Thus, while transfusions may be beneficial for a variety of reasons, it is wise to carefully consider the predicted benefit in each patient and post-transfusion to try to assess whether that benefit was reached.

Transfusion Administration and Reactions

Transfusions of both plasma and pRBC

Downloaded From Vet-eBooks.com

should be completed within 4 hours. Transfusions should be administered through filters and may be allow to either flow in by gravity or through the use of specific fluid pumps. If concurrent fluid therapy is warranted, the transfusate should not be allowed to mix with a crystalloid solution that contains calcium (e.g., lactated Ringer's solution) as the calcium may interfere with the action of the anticoagulant citrate.

Complications are possible with blood transfusions and deserve mention. (Table 3-6) Transfusion reactions occur from time to time, but the actual incidence is not well established in dogs and cats. Studies in dogs have

Downloaded From Vet-eBooks.com

reported transfusion reactions occurring in 2.9 to 13% of cases, with the majority of reactions being mild.[6,18] Transfusion reactions are usually classified as immune- or nonimmune-mediated and acute (within 48 hours) or delayed. Immunologic reactions may include hemolysis or hypersensitivity reactions (such as urticaria or facial swelling). Nonimmunologic reactions may include circulatory overload, bacterial contamination, hyperammonemia, or infectious disease transmission. It is important to monitor the patient carefully for any signs of problems (vomiting, fever, hemoglobinuria/hemoglobinemia).

Delayed transfusion reactions, when

Downloaded From Vet-eBooks.com

they occur, are likely due to the development of alloantibodies.[19] Rarely, transfusion-related acute lung injury (TRALI) may occur, although the syndrome has been much better described in people.[20]

Table 3-6. Clinical signs Associated with Acute and Delayed Transfusion Reactions.

(e.g., intravascular hemolysis)

Cardiovascular collapse

Delayed reaction

Bilirubinemia and bilirubinuria (e.g., Extravascular hemolysis)

Development of a positive Coombs test

Shortened transfusate survival

The standard monitoring during a transfusion should include measurement of temperature, pulse, and respiration every 15 minutes for the first hour, then hourly, and monitoring for increased respiratory effort, vomiting, pigmentuia or signs of facial swelling. The most life-threatening type of transfusion

Downloaded From Vet-eBooks.com

reaction is the acute hemolytic transfusion reaction. This occurs most commonly when a previously sensitized DEA 1.1-or 1.2-negative recipient is given DEA 1.1- or 1.2-positive blood. The severity of these reactions varies, but the reactions are most severe when complement is activated by IgM antibody. The release of vasoactive mediators during an acute hemolytic transfusion reaction can lead to shock, DIC, and multiple organ failure. Diagnosis of an acute hemolytic transfusion reaction is usually based on suspicious clinical findings such as development of hemoglobinuria, hemoglobinemia, and fever shortly after blood transfusion in an animal that may have been

Downloaded From Vet-eBooks.com

transfused 4 or more days earlier. If an acute hemolytic transfusion reaction is suspected, the transfusion should be stopped immediately and supportive care to maintain vital organ perfusion should begin. Supportive care may include IV fluid administration, furosemide, dopamine, or mannitol to prevent or treat acute renal failure. It may include fresh frozen plasma administration if DIC is suspected. Monitoring should include careful measurement of systemic arterial pressure, central venous pressure, and urine output.

Delayed hemolytic transfusion reactions may occur 3 to 21 days after a blood transfusion. These reactions

Downloaded From Vet-eBooks.com

usually involve extravascular hemolysis and are mediated by IgG antibody. These reactions are typically mild. Fever is common, and anorexia or icterus has been reported.[18] A positive Coombs test provides strong support for the suspicion of a delayed hemolytic reaction in a patient that was previously Coombs negative. Specific treatment is not usually required. The lifespan of transfused red blood cells may be shortened, resulting in the need for further transfusion.

Conclusions

Transfusion medicine represents a vital adjuvant to clinical practice. Basic tenets of transfusion medicine include

Downloaded From Vet-eBooks.com

knowledge of benefits and risks surrounding transfusion and concepts associated with practical transfusion. For surgical patients in particular, careful planning is advisable to avoid emergent crisis.

Chapter 4

Hemostasis and Disseminated Intravascular Coagulation

Daniel L. Chan

Overview of Hemostasis

Hemostasis is a complex but elegant process of forming blood clots to seal injured vessels and degrading such clots after they have served their purpose. The various reactions that comprise hemostasis are traditionally conceptionalized as having three distinct phases: primary hemostasis,

Downloaded From Vet-eBooks.com

secondary hemostasis, and fibrinolysis. Primary hemostasis involves the formation of a platelet plug. Secondary hemostasis begins with cross-linking of fibrin strands and stabilization of the platelet plug to form a mature clot. The degradation of the mature clot describes the process of fibrinolysis. While this over-simplified scheme is useful in the evaluation of coagulation, especially in relation to typical laboratory coagulation tests, it is important to realize that *in vivo*, coagulation likely proceeds in a different manner. More recently, a new "cell-based" model of coagulation has been proposed to better explain the process of coagulation that occurs in the body.[1,2] The purpose of this

Downloaded From Vet-eBooks.com

review is to outline the classical approach to coagulation, introduce newer concepts in coagulation, and describe perturbations in coagulation that may culminate in disseminated intravascular coagulation (DIC). A discussion of coagulation tests, their interpretation and rational therapy of coagulation disorders completes this overview of hemostasis.

Primary Hemostasis

The inciting events leading to activation of coagulation are endothelial damage and subsequent exposure of collagen on the subendothelial surface. One of the mechanisms by which platelets adhere

Downloaded From Vet-eBooks.com

to the subendothelium is mediated by von Willebrand factor (VWF). A key event is the bridging between exposed collagen and various platelet surface glycoprotein receptors via VWF. Following adhesion, platelets release substances including adenosine diphosphate (ADP), serotonin, and platelet activating factor (PAF), which serve to activate platelets. This is followed by aggregation forming the temporary hemostatic plug. The formation of this temporary plug is referred to as primary hemostasis and is degraded within minutes. Concomitant with platelet aggregation, platelets release a large number of procoagulants and clotting factors, providing an optimum

Downloaded From Vet-eBooks.com

environment for activating the coagulation cascade and, thereby, initiation of secondary hemostasis.

Secondary Hemostasis

Stabilization of the temporary platelet plug with cross-linked fibrin strands derived from serine proteases constitutes secondary hemostasis. Traditionally, this process was thought to be composed of intrinsic, extrinsic, and common pathways (Figure 4-1). Similarly to activation of primary hemostasis, an irregular vascular surface is the contact stimulus necessary for activating factor XII into factor XIIa, which initiates the intrinsic (factors XI, IX, VIII) pathway. The

Downloaded From Vet-eBooks.com

extrinsic pathway is initiated by the release of tissue factor (TF), a transmembrane glycoprotein present in most nonendothelial cell membranes (e.g., fibroblasts, vascular smooth muscle cells, monocytes). Tissue factor complexes with factor VII, and subsequently activates factors IX and X. Once factor X is activated, the common pathway of coagulation is initiated. Activated factors X and V culminate the conversion of prothrombin to thrombin, and finally thrombin converts fibrinogen into fibrin. Thrombin is also responsible for activating factor XIII which serves to cross-link fibrin strands and stabilize the clot, increasing its resistance to proteolytic degradation. Although the

Downloaded From Vet-eBooks.com

different pathways were once viewed as discrete events, it is now recognized that direct interactions occur between the pathways; the TF:factor VIIa complex (extrinsic pathway) also activates factors IX and X (intrinsic pathway). Nevertheless, the traditional scheme of secondary hemostasis offers a way to interpret common coagulation tests such as the prothrombin time (PT) and activated partial thromboplastin time (aPTT).

Downloaded From Vet-eBooks.com

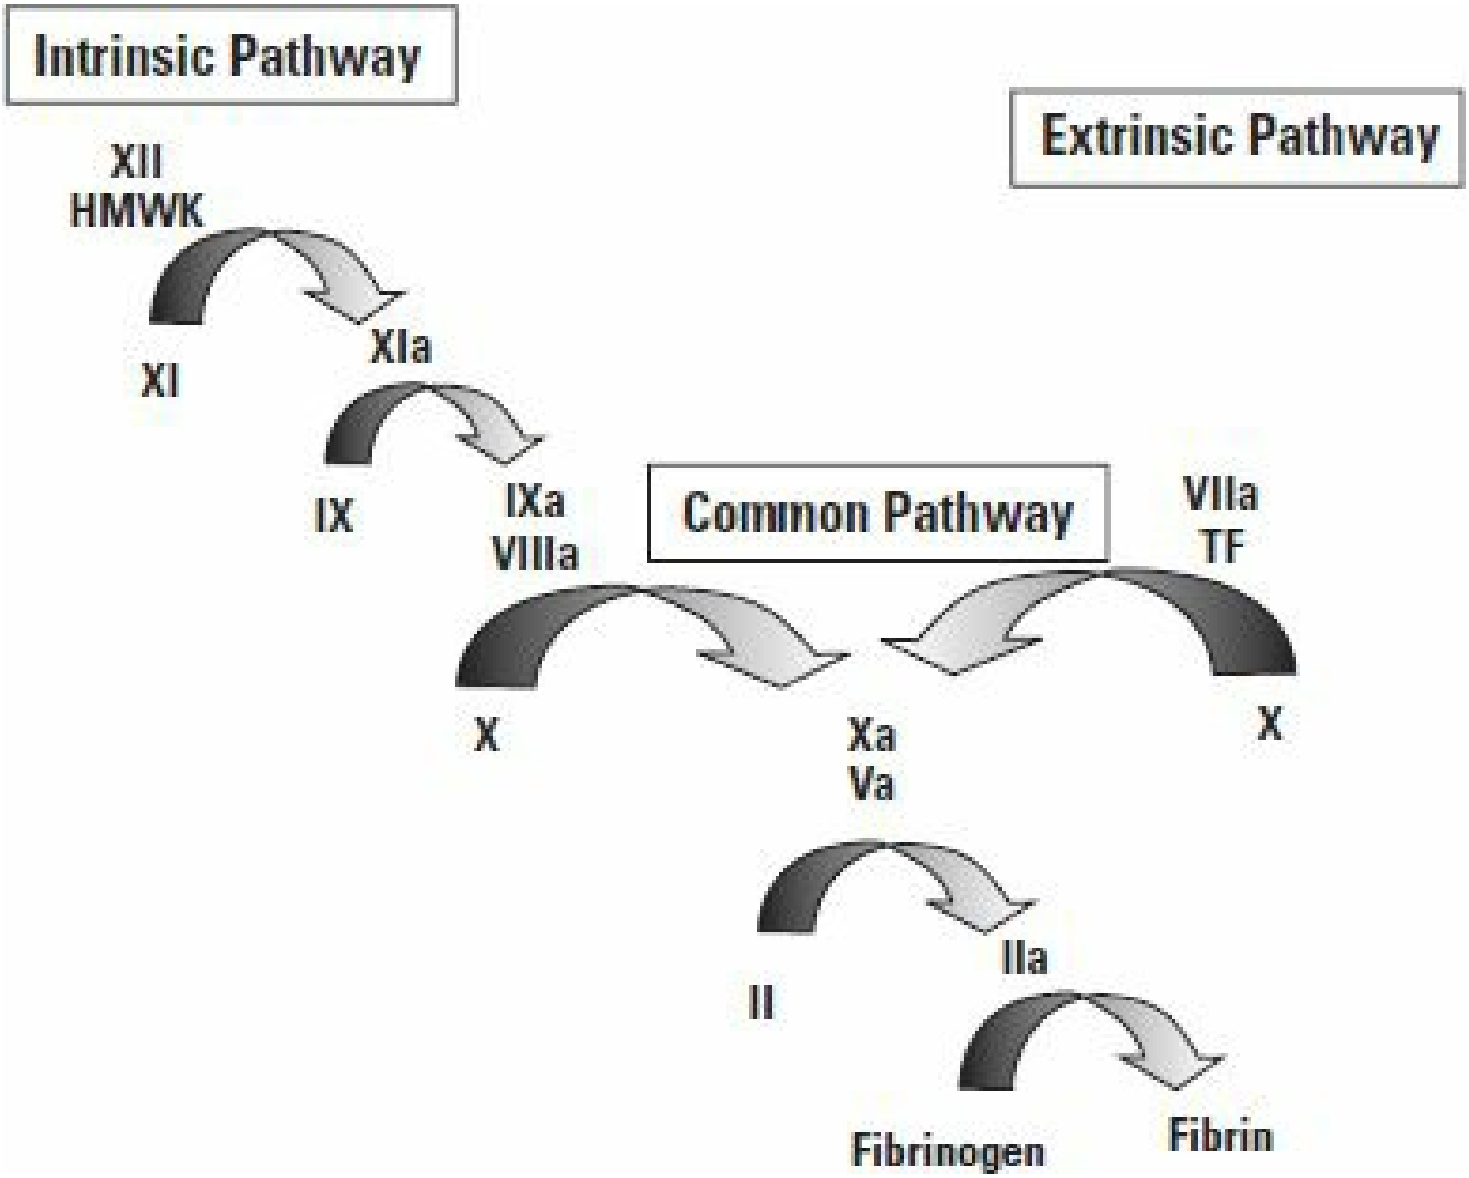

Figure 4-1. Classic coagulation cascade depicting reactions involved in the intrinsic, extrinsic, and common pathways, culminating in the production of the fibrin clot. HMWK = High molecular weight kalikrein, TF = tissue factor.

Fibrinolysis

Downloaded From Vet-eBooks.com

Once the hemostatic plug has served its purpose it must be degraded and removed from the intravascular space. In addition to lysing fibrin and fibrinogen, plasmin biodegrades factors V, VIII, IX, and XI. Plasminogen, a proenzyme, is activated into plasmin by either factor XIIa or by a variety of poorly defined tissue factors. Several tissue activators of plasminogen have been recognized, including streptokinase, urokinase, and tissue plasminogen activator, and they may be used therapeutically in patients with thromboembolic disorders. The fibrinolytic system also has built-in inhibitory mechanisms that have a net procoagulant effect. Inhibitors of fibrinolysis include alpha-2

Downloaded From Vet-eBooks.com

antiplasmin, alpha-2 macroglobulin and tissue plasminogen activator inhibitors 1 and 2. Plasmin biodegrades fibrinogen and fibrin-generating fibrin(ogen) degradation products (FDPs) that can be detected in plasma of dogs and cats. These FDPs also exert profound inhibitory effects on platelet function, contributing to the petechia and ecchymoses noted in patients with DIC.

New Model of Coagulation

Although the classic coagulation cascade is a convenient scheme that allows clinical assessment of coagulation status, it fails to explain why patients with severe congenital

Downloaded From Vet-eBooks.com

factor XII or XI deficiency do not exhibit significant bleeding disorders. In addition, it does not adequately explain why patients with deficiencies in factor VII but with intact intrinsic factors suffer from pronounced bleeding tendencies. It became apparent that coagulation in vivo must proceed differently from that demonstrated *in vitro*. A new model of coagulation emphasizes the role played by platelets and TF-bearing cells; hence it is referred to as the cell-based model of hemostasis (Figure 4-2).[1,2] This model is described as having three phases: initiation, amplification, and propagation (Figure 4-3).[1]

Downloaded From Vet-eBooks.com

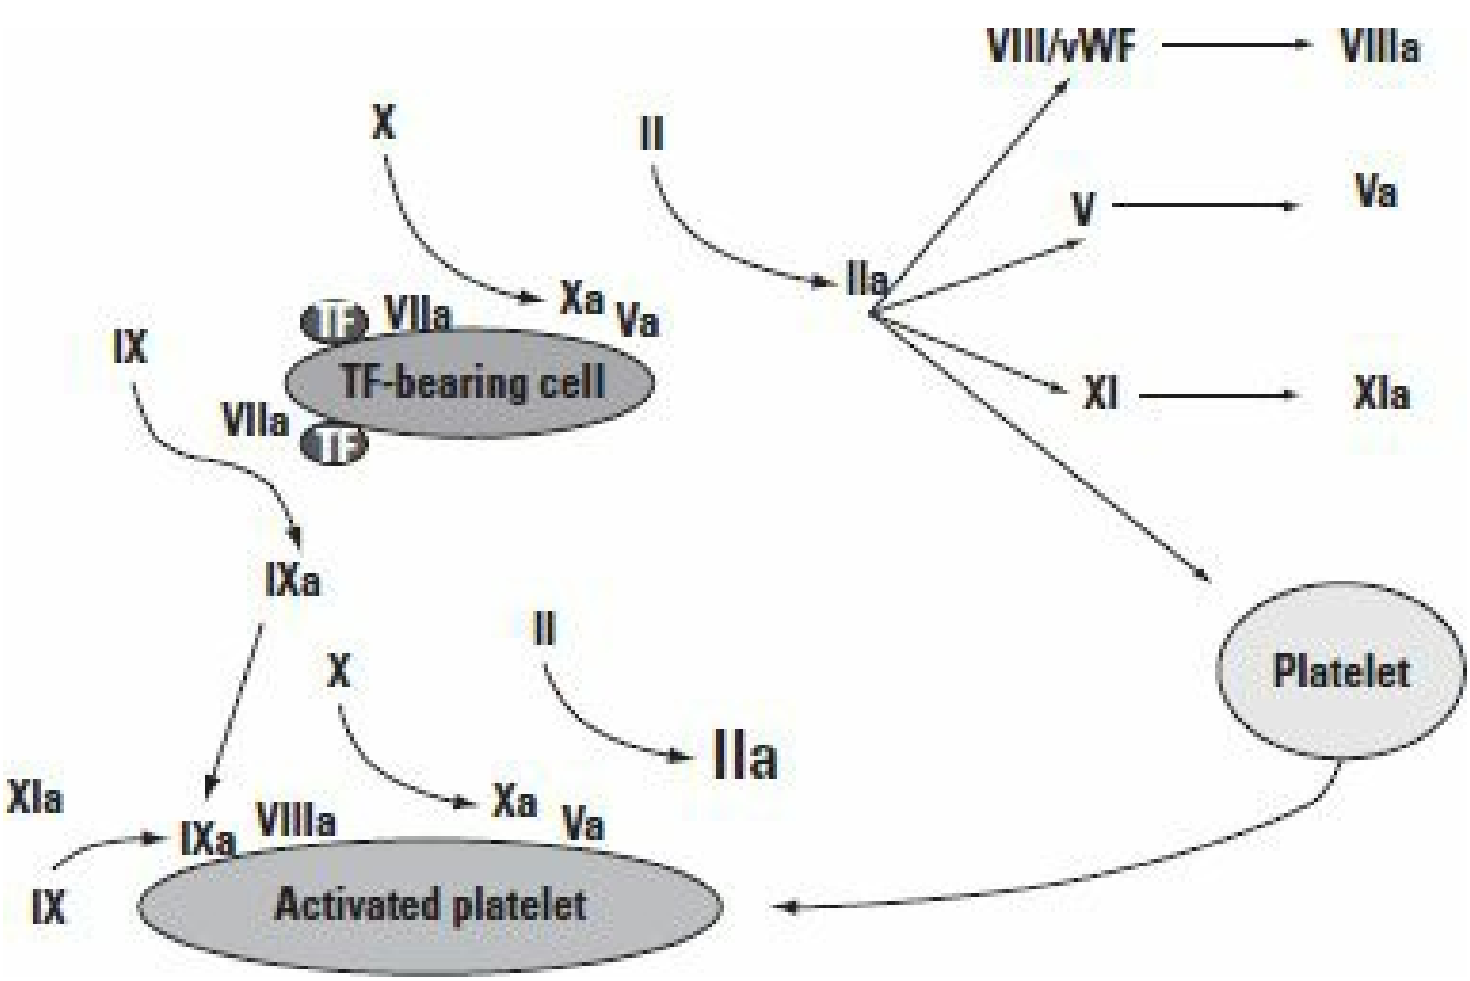

Figure 4-2. Cell-based model of coagulation. Tissue factor (TF)-bearing cells first activate factor VII into VIIa. The TF:VIIa complex converts X and IX into Xa and IXa, respectively. Xa combines with Va and generates a small amount of thrombin, which activates platelets and other coagulation factors. The surface of activated platelets then becomes the site of major thrombin generation necessary for fibrin formation. vWF = von Willebrand factor, TF = tissue factor.

During the *initiation phase*, vascular

Downloaded From Vet-eBooks.com

injury exposes TF expressed on TF-bearing cells such as fibroblasts, smooth muscle cells, and monocytes. Factor VII becomes activated when complexed with TF. This complex proceeds to activate small amounts of factors IX and X. Activated factor X combines and activates factor V on the surface of the TF-bearing cell to produce a prothrombinase complex that generates thrombin. The small amount of thrombin generated is insufficient to catalyze fibrin generation and is limited to the vicinity of the TF-bearing cell. However, this small amount of thrombin serves as a priming mechanism for subsequent hemostatic events (see Figure 4-2).

Downloaded From Vet-eBooks.com

Platelet activation is central to the *amplification phase*, which sets the stage for subsequent large-scale generation of thrombin. The thrombin generated in the initiation phase stimulates release of factor V from circulating platelets, disengages factor VIII from VWF, and activates factors V, VIII, and XI on the platelet surface. Activated platelets also express receptors and binding sites for activated clotting factors. Uncoupled VWF can now mediate additional platelet adhesion and aggregation. The importance of the amplification phase is that platelets that were not directly stimulated by the inciting vessel-wall injury are recruited to participate in active coagulation.

Downloaded From Vet-eBooks.com

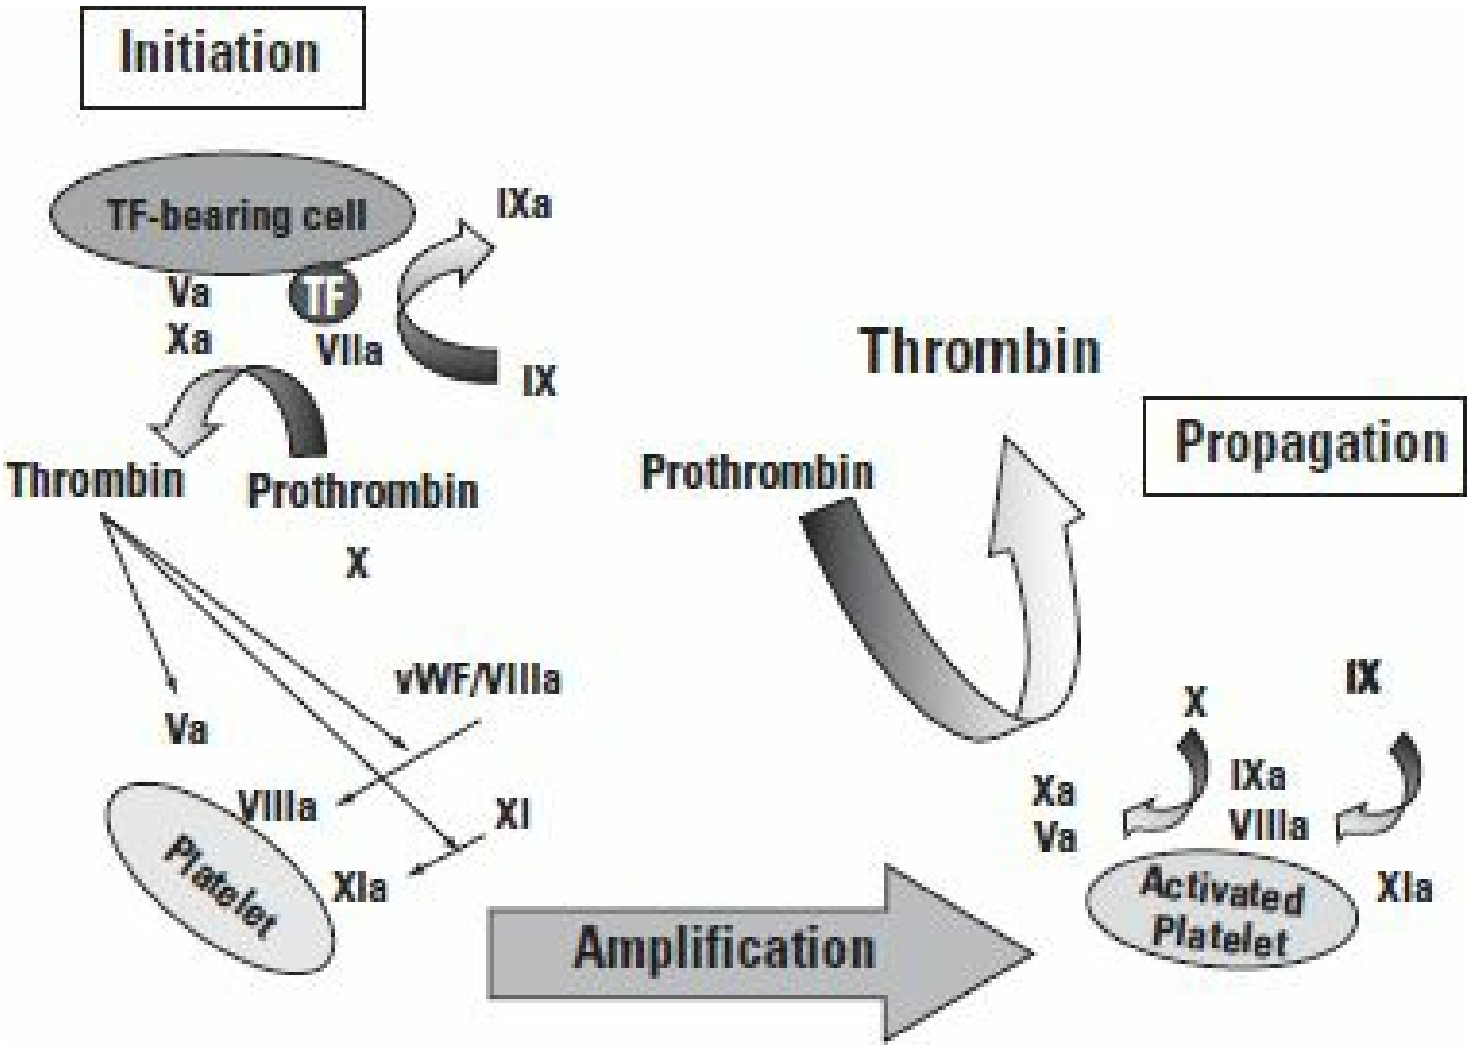

Figure 4-3. Stages of the cell-based model of coagulation. Initiation occurs on TF-bearing cells and results in the production of a small amount of thrombin. Thrombin produced by the initiation stage, activates platelets and other coagulation factors. Propagation occurs on the surface of activated platelets and results in the production of significant amounts of thrombin required for fibrin formation.

The *propagation phase* is typified by the

Downloaded From Vet-eBooks.com

production of thrombin and fibrin from their inactive precursors (see Figure 4-3). Activated factor XI produced in the amplification phase converts more factor IX into activated factor IX. Activated factor IX combines with its cofactor VIIIa to form the “tenase complex” (IXa/VIIIa). The tenase complex then recruits additional factor X from solution yielding more Xa on the surface of the platelet. Activated factor X, binds to activated factor V to form the “prothrombinase complex” that leads to a burst of thrombin generation of sufficient magnitude to clot fibrinogen and to the generation of the hemostatic plug.

Once the bleeding is abated, the

Downloaded From Vet-eBooks.com

clotting process must be limited to avoid thrombotic occlusion of adjacent normal areas of the vasculature. This may be thought of as a *termination phase*. The protein C/protein S/thrombomodulin system is an important mechanism confining coagulation to the site of injury.[3] Some of the thrombin generated during coagulation can diffuse away from the site of vascular injury. When thrombin reaches an intact endothelial cell, it binds to thrombomodulin (TM) expressed on the endothelial surface. The endothelial thrombin/TM complex then activates protein C, which binds to its cofactor protein S and inactivates any factors Va and VIIIa. This system illustrates the anticoagulant tendencies

Downloaded From Vet-eBooks.com

of the intact endothelium.

Disseminated Intravascular Coagulation

Rather than a disease, DIC is the pathologic consequence of many different disorders. It is characterized by an acute, generalized, widespread activation of coagulation, resulting in thromboembolic complications because of intravascular formation of fibrin, as well as diffuse hemorrhage, because of the consumption of platelets and coagulation factors.[4-6] Widespread fibrin deposition is associated with the genesis of multiple organ failure and poor outcome.[4-8] The clinical situation with simultaneous thrombosis and

Downloaded From Vet-eBooks.com

bleeding poses a difficult problem for the clinician in that replenishment of clotting factors with plasma does not attenuate the risk for thrombosis.

As DIC is always secondary to an underlying disorder, rational therapy should always be targeted at the primary disease. Common diseases associated with DIC are listed in Table 4-1. Disease processes characterized by capillary stasis, loss of vascular integrity, red cell hemolysis, inappropriate particulate matter in blood, or necrotic tissue release of tissue thromboplastin into the vasculature can produce this life-threatening complication.

Downloaded From Vet-eBooks.com

Table 4-1. Common Disorders that may be Associated with DIC in Animals

Sepsis/severe infection
Severe trauma
Malignancy
Heat stroke
Severe burns
Severe hepatic failure
Pancreatitis
Hemolytic transfusion reactions
Adverse drug reactions
Immune-mediated hemolytic anemia

Downloaded From Vet-eBooks.com

The pathogenesis of DIC in patients with severe infections may involve exposure to specific cell membrane components of microorganisms (e.g., lipopolysaccharides) or bacterial exotoxins. A generalized systemic inflammatory response ensues, characterized by the elevation of several cytokines. Cytokines, produced mainly by activated mononuclear cells and endothelial cells are partially responsible for the derangement of the coagulation system in DIC.[4-9] Neutrophil activation leads to platelet activation and decrease in antithrombin activity. Disturbances in the antithrombogenic functions of the endothelium induce adherence of platelets and granulocytes through the

Downloaded From Vet-eBooks.com

expression of cell adhesion molecules, such as P-, E-, and L-selectins, endothelial leukocyte-adhesion molecules (ELAM), such as ELAM-1, and intercellular adhesion molecule-1 (ICAM-1).[4-8] During this excessive intravascular coagulation, platelets are consumed in large quantities, causing thrombocytopenia. Tissue factor, which is exposed following injury to the endothelium and by activated monocytes, triggers the initiation of the coagulation cascade on the local endothelial surface. Local generation of thrombin leads to the formation of thrombi. In this process of self-perpetuating coagulation, coagulation factors are consumed. Once the fibrinolytic system is activated,

Downloaded From Vet-eBooks.com

inactivation of clotting factors, and impaired platelet function follows. Fibrin degradation products, produced by clot lysis, are strong inhibitors of platelet function. Antithrombin, along with proteins C and S, are soon depleted in attempts to halt intravascular coagulation. The fibrinolytic system becomes inhibited by the release of plasminogen activator inhibitor 1 (PAI-1). PAI-1 release is chiefly mediated by TNF, endotoxin, IL-1, and IL-6. This imbalance between the systems fosters fibrin deposition. The formation of fibrin within the microcirculation leads to hemolytic anemia as the red blood cells are sheared by the fibrin strands. As a result, fragmented red blood cells

Downloaded From Vet-eBooks.com

or schistocytes are found in circulation.

Assessment of Coagulation

Prothrombin time (PT) is the primary laboratory test to evaluate the status of the extrinsic pathway. For this test, blood is collected into tubes containing citrate, which binds calcium and halts coagulation. A thromboplastin reagent (source of TF) and calcium are added to initiate coagulation. The time to fibrin formation is measured in seconds and prolongation greater than 25% as compared with normal is considered significant. The PT is prolonged by deficiencies in factors II, V, VII, and X. Typically, prolongation in PT indicates that factor activity must be depleted to

Downloaded From Vet-eBooks.com

less than 30%.

The activated partial thromboplastin time (APTT) primarily reflects the integrity of the intrinsic pathway. As with measurement of PT, coagulation is halted by collecting blood into citrated tubes. An activator (e.g., kaolin, celite, propyl gallate) is added, supplying negatively charged particles similar to basement membranes to activate the contact group (i.e., factors XII, XI). Partial thromboplastin (source of phospholipids surfaces) and calcium are then added and the time to fibrin formation is recorded in seconds. Prolongations in APTT occur if factor activity of factors VIII, IX, X, XI, and XII decrease below 30%. Severe

Downloaded From Vet-eBooks.com

depression in factor activity of factors II and V and depletion of fibrinogen will also prolonged the APTT.

Activated clotting time (ACT) is a coarse assessment of the intrinsic pathway. Tubes containing diatomaceous earth provide a contact activator. Platelets supplied by whole blood, provide phopholipid membranes needed to support coagulation reaction. While normal reference ranges for PT and APTT depend on the particular reagents used, it is generally accepted that the normal ACT for dogs is 60 to 110 seconds and for cats 50 to 75 seconds.

Plasmin-mediated degradation of

fibrinogen and fibrin produces several fragments (fragments X, Y, D, and E) collectively referred to as FDPs. The measurement of FDPs can be semi-quantitatively evaluated via agglutination techniques and is used as an indicator of active fibrinolysis. It is important to note that FDPs are produced from lysis of both cross-linked and non-cross-linked fibrin. As such, elevation in FDP concentration is merely an indicator of increased generation of fibrin and increased fibrinolysis. Kits to evaluate dimers of D fragments (D-dimers) are commercially available and are becoming more commonly used.[10,11] D-dimers are more specific for fibrinolysis (particularly of cross-linked

fibrin), however, it does not distinguish between physiologic or pathologic fibrinolysis.

Diagnosis of DIC

The association between the development of DIC and poor outcome is the impetus for early diagnosis; however, therapy should be directed at the primary disease rather than at coagulation abnormalities. Despite the desire to identify afflicted patients, currently no consensus exists in definitively diagnosing DIC. Several criteria have been proposed, and many include abnormalities in any three coagulation parameters (prolongation in PT, APTT, decrease in platelet

count, elevated FDPs or D-dimers, depleted fibrinogen or AT).[12,13] In people, DIC scores and algorithms have also been proposed but are not widely recognized.[6,14] Various veterinary publications have each defined their criteria slightly differently, making development of similar schemes impossible.[10,12,13] Moreover, abnormalities in coagulation parameters are not specific enough for DIC and can be encountered in many disorders with vastly different prognoses.

In the CBC, schistocytes are indicative of mechanical damage to red cell membranes from microvascular fibrin strands. Whereas the presence of

schistocytes is suggestive of DIC, they are only recognized in approximately 10% of patients with DIC.[12,13] Platelet counts can be variable in DIC because some inflammatory states can cause a reactive thrombocytosis and, therefore, it is more important to perform daily blood smears and manual platelet counts, as a drop in the platelet count often precedes other signs of DIC. In the future, increased platelet factor 4 and beta-thrombomodulin measurements could become pathognomonic for platelet destruction in DIC.[4-7] Dysfunctional platelets, resulting in thrombocytopathia, are caused by FDPs coating platelet membranes, which causes the release of platelet procoagulant materials.

Therapy for DIC

As DIC is a reflection of complete dysregulation of hemostasis, reversal can occur only if the primary stimulus is eliminated. However, as elimination of the initiating cause of DIC is almost never immediately possible, focus of therapy has traditionally been directed at halting further intravascular coagulation (administration of plasma, heparin, aspirin), promotion of capillary blood flow (aggressive fluid therapy), and supporting target organs at risk for hemorrhage, microthrombi, or ischemia (maintenance of perfusion and oxygenation, correction of acid-base status).[3-7] Despite these generic recommendations, no studies exist supporting the use of such therapies at

ameliorating or reversing DIC.[7] The most commonly employed therapies include administration of plasma and heparin, yet improvement in outcome has not been demonstrated in either people or animals with these approaches.[2,15,16] There is even a suggestion that while heparin does improve AT activity, it does so at the expense of potent anti-inflammatory properties of AT, making recommendations for heparin therapy questionable in patients with DIC.[2,15,16] In the future, strategies directed at inhibiting TF-mediated activation of coagulation or restoration of physiologic anticoagulant systems may prove beneficial.[7]

Conclusions

As hemostatic disorders are commonly encountered in critically ill patients, many of which require surgical intervention, an understanding of coagulation, its assessment, and relationship to disease pathogenesis is crucial for the clinician. Since surgical removal of tumors may be the most effective way to treat DIC, the presence of coagulation abnormalities alone does not preclude surgical interventions. Interpretation of coagulation tests must be done in the context of clinical situations so as to guide the most appropriate course of action. Discordant results of coagulation tests with clinical

assessment of clinical or surgical bleeding may reflect differences between the processes of coagulation *in vitro* and those encountered *in vivo*. In spite of the progress in the understanding of coagulation, therapeutic decisions are still controversial and should be individualized on the basis and severity of the coagulation abnormality.

Chapter 5

Metabolism and Nutrition of the Surgical Patient

Elisa M. Mazzaferro

During states of health, the body's neuroendocrine system is in a constant state of flux in order to maintain homeostasis. Alterations in host substrate metabolism and endocrine pathways have been documented in both human and veterinary patients with critical illness and neoplasia.[1-6] In general, stressors such as injury, neoplasia, infection, anesthesia, and

surgery can adversely influence the body's physiologic adaptive mechanisms and disturb homeostasis (Figure 5-1). The changes observed in metabolic pathways are intimately related to changes in the body's hormonal axes, including suppression of thyroid hormone activity and host release of glucocounterregulatory hormones, including cortisol and glucagon. Activation of the hypothalamic-pituitary-adrenal axis, thyroid axis, renin-angiotensin-aldosterone system, and release of proinflammatory cytokines during states of illness and injury can lead to protein and calorie depletion, negative nitrogen balance, organ dysfunction, suppressed immunity, delayed wound

healing, changes in resting energy requirements, and increased morbidity and mortality.[7-8] Nutritional intervention is one modality that should be considered in all cases of critically ill and surgical patients to help restore homeostasis and aid in the healing and recovery process.

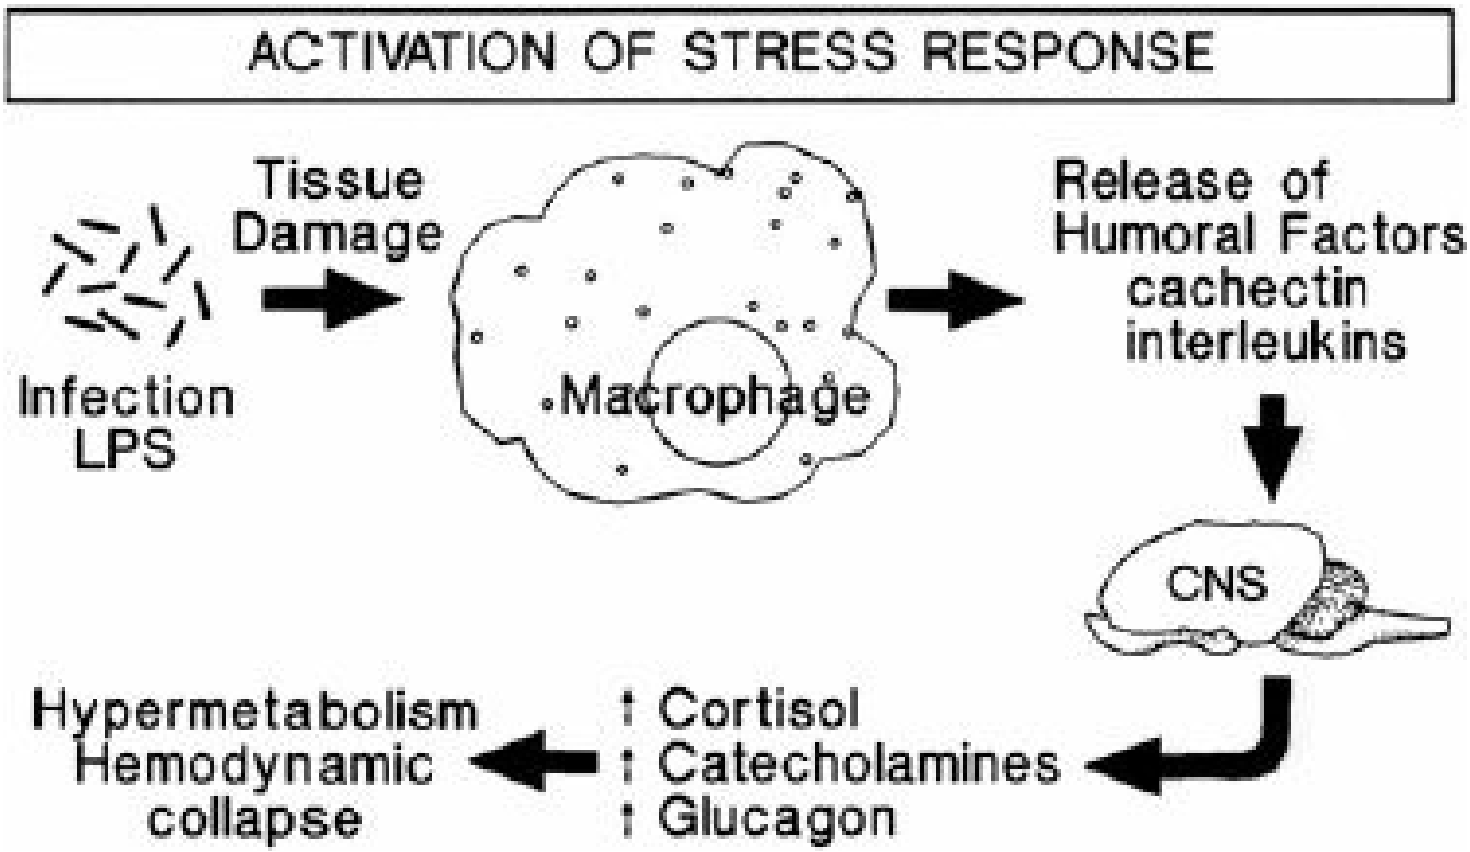

Figure 5-1. Activation of the stress response.

Stressed Versus Non-Stressed Starvation

In healthy patients, starvation occurs as a result of lack of available nutrients. This differs greatly from the "stressed starvation" that occurs in the face of illness and injury.

During non-stressed starvation, adaptations occur that favor utilization of fat for energy, sparing carbohydrate for glucose-dependent tissues and diverting host amino acids and protein to healing processes.[5,9] In healthy animals, hepatic glycogenolysis initially is utilized to maintain a state of euglycemia.[10] In dogs, hepatic glycogen becomes depleted within 48

to 72 hours,[11] and physiologic adaptations are utilized to break down muscle protein and provide gluconeogenic precursors such as alanine and glutamine for gluconeogenesis.[10,12] During non-stressed starvation, pyruvate becomes transaminated and is transported to the liver as alanine, where it becomes deaminated to pyruvate for gluconeogenesis. The kidney and the gastrointestinal tract also contribute alanine for gluconeogenesis, sparing muscle protein for other purposes. Skeletal muscle stores of alanine can become depleted during prolonged stressed starvation and can lead to dyshomeostasis and loss of function.[13] Obviously, continued proteolysis can

result in lack of available amino acids for *de novo* protein synthesis and wound healing.

As starvation becomes more prolonged, down-regulation of the patient's metabolic rate and muscle proteolysis occurs, and the body adapts by reverting to lipolysis and fat oxidation for energy purposes. Muscle lactate, rather than muscle amino acids, are shuttled to the liver for gluconeogenesis by the Cori cycle (Figure 5-2) Although energy is formed in this process, it is largely an inefficient process by which the body maintains euglycemia.

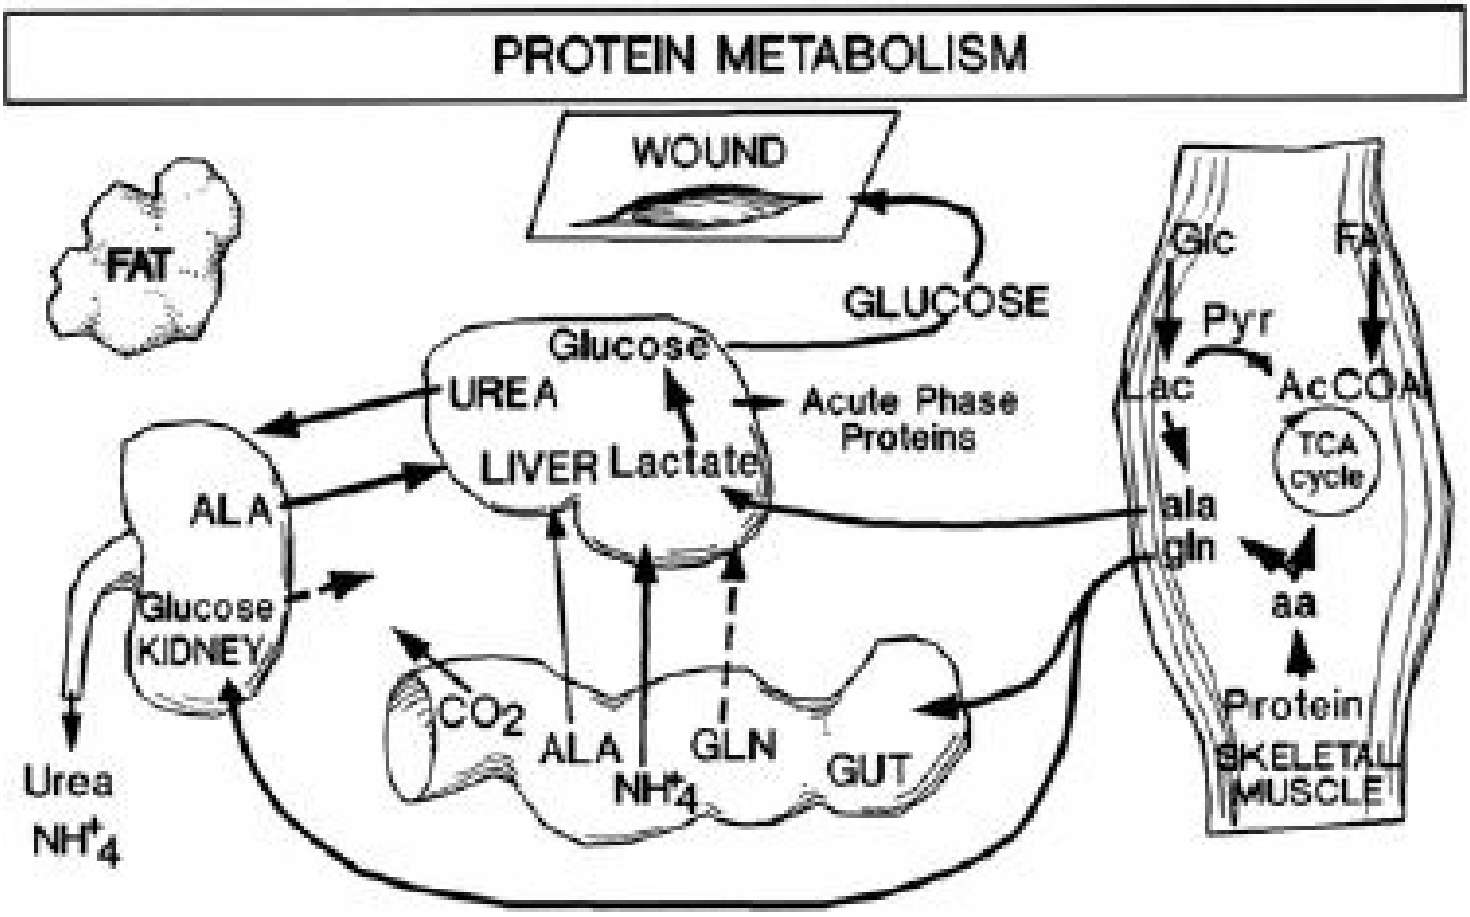

Figure 5-2. Protein metabolism.

Stressed Starvation

Lack of adequate nutrient intake is of particular importance in surgical patients and those with a variety of illnesses due to maladaptive responses that occur. Inadequate nutrient intake is common in veterinary patients

during the pre- and post-operative periods. Many animals either cannot, or will not, voluntarily consume their nutritional requirements as a result of nausea, pain, facial masses or trauma, or anxiety. Food is often withheld in preparation for anesthesia and surgery. Sometimes, inadequate food orders can contribute to a decrease in nutrient intake, even in the realm of a hospital environment.[14] Suppression of resting energy expenditure occurs because of down–regulation of the hypothalamic-pituitary-adrenal axis. However, the release of proinflammatory cytokine mediators, including interleukin-1, interleukin-2, interleukin-10, and tumor necrosis factor (TNF), combined with the

glucocounterregulatory hormones cortisol and glucagon has been implicated to play a role in the catabolic stress response.[15-17] Continued proteolysis in ongoing starvation leads to negative nitrogen balance.

During a variety of stressors, including anesthesia and surgery, activation of the sympathetic nervous system leads to the release of the catecholamine norepinephrine from peripheral nervous tissue and epinephrine from the adrenal medulla.[10] Activation of the hypothalamic-pituitary-adrenal axis leads to the release of cortisol from the adrenal cortex. Epinephrine indirectly stimulates hepatic

glycogenolysis and gluconeogenesis. The actions of epinephrine also inhibit insulin release and promote the release of glucagon. An increase in glucagon relative to insulin helps to promote glycogenolysis, gluconeogenesis, and ureagenesis. Gluconeogenesis from muscle amino acids proceeds unchecked, and nitrogen utilization is increased relative to intake. Accelerated protein catabolism in stressed patients and urinary nitrogen loss contributes to protein-calorie malnutrition.[17] Negative nitrogen balance is characteristic of a catabolic state.

During stress, muscle protein appears to be the primary source of energy

used for fuel, with approximately 25% of calories obtained from utilization of endogenous proteins.[15] In addition to endogenous nitrogen, amino acids are shuttled into the production of hepatic acute-phase protein synthesis during stress and illness. In canine surgical and critically ill patients, accelerated urinary nitrogen loss can occur even in the presence of enteral and parenteral nutritional supplementation.[16] As a result of diminished structure and functional protein synthesis, depressed immune function, impaired wound healing, and cardiorespiratory dysfunction can occur (Table 5-1).[18-20]

Table 5-1. Adverse

Consequences of Malnutrition

Decreased protein synthesis

Delayed wound healing

Hypoalbuminemia

Increased risk of surgical site dehiscence

Enterocyte atrophy with increased bacterial translocation and nutrient malabsorption

Cardiac myocyte atrophy, decreased cardiac output, ventricular dysrhythmias

Respiratory muscle fatigue, hypercapnia, respiratory acidosis

Immune system suppression, increased

risk of sepsis

Impaired carbohydrate utilization can also occur during critical illness. Any stressor, including surgery and anesthesia, that results in the release of glucocounterregulatory hormones, namely epinephrine, cortisol, and glucagon, can lead to impaired carbohydrate metabolism and inefficient glucose utilization. Glucocounterregulatory hormone release during illness can increase the synthesis of pyruvate carboxylase and phosphoenolpyruvate carboxylase, enzymes that favor the conversion of three-carbon intermediates to glucose.[21] As a result, glucose entry into the tricarboxylic acid (TCA) cycle

is limited, and favors the shuttling of glucose through other pathways, including the Cori cycle or glucose-alanine shuttle (Figure 5-3).[21]

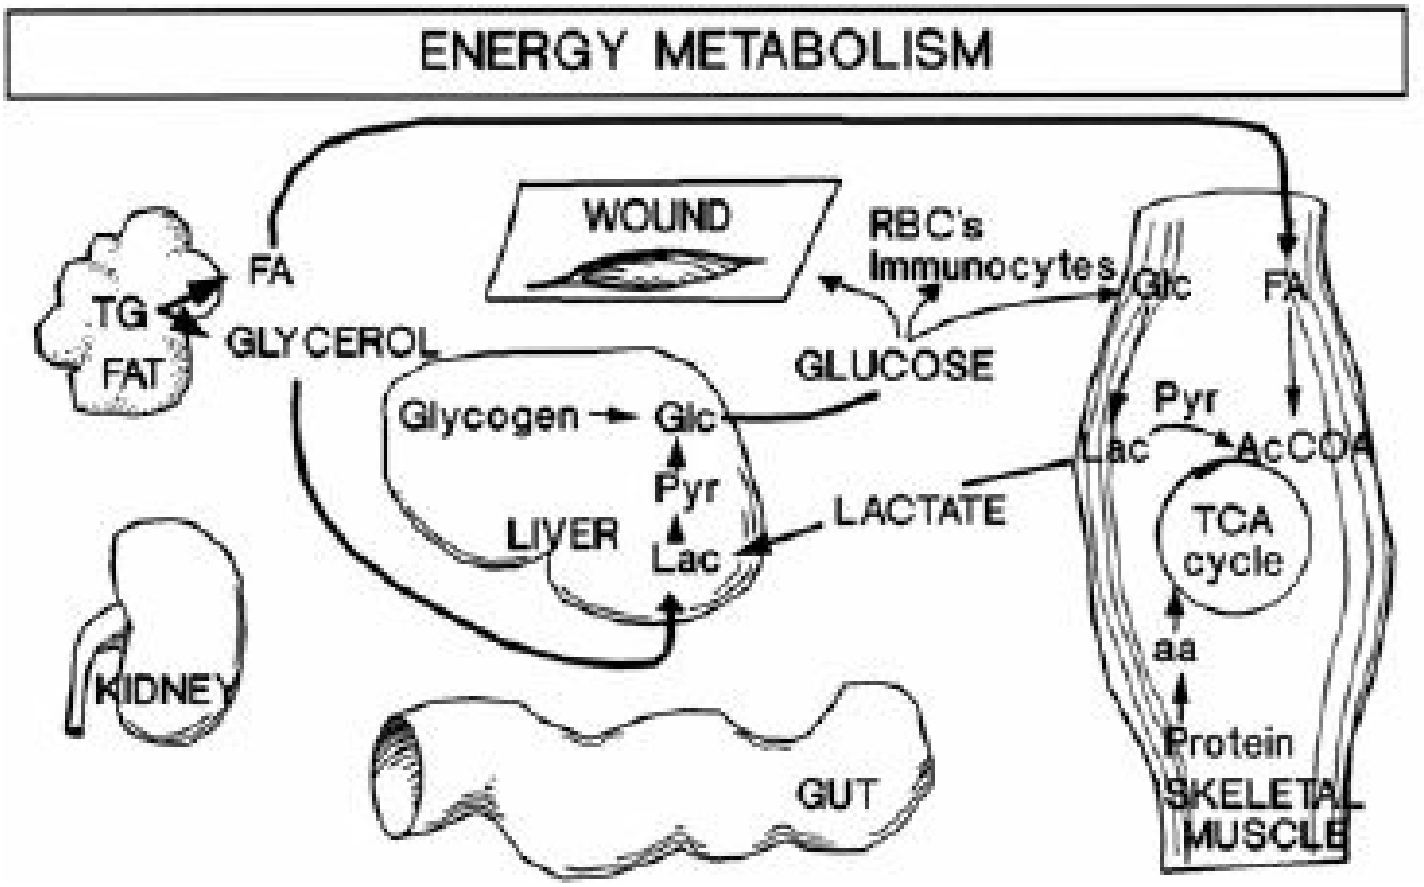

Figure 5-3. Energy metabolism.

Lipid Metabolism

Endogenous catecholamines released

during stress promote lipolysis by increasing hormone-sensitive lipase in adipose tissue. Glycerol and free fatty acids are utilized as alternate energy sources, thus sparing endogenous amino acids for other purposes. Fatty acids are oxidized in the liver to the ketone bodies beta-hydroxybutyrate, acetone, and acetoacetate that can be utilized for energy purposes by some tissues, including the brain.[22] Glycerol released during lipolysis can also serve as a gluconeogenic precursor, further sparing muscle amino acids. In non-stressed starvation, lipolysis is a primary means by which euglycemia is achieved. However, during stress, peripheral insulin resistance can lead to catabolism in the face of lipolysis

and hyperglycemia.

Resting Energy Expenditure

A patient's resting energy expenditure (REE) is the amount or number of calories (Kcal) expended by an animal in a post-absorptive state while resting in a thermoneutral environment.[8] Values used for REE and basal energy requirements (BER) in small animal patients have largely been obtained from healthy animals or extrapolated from those obtained from human subjects.[23-24] In human medicine, the precise measurement of resting energy expenditure has become fairly routine using bed-side indirect calorimetry units. In veterinary patients, relatively

few studies have used similar methods to determine energy expenditure in small animal patients.[23-27] It was previously thought that all human and veterinary patients with illness and injury, including surgically induced trauma, were in a hypermetabolic state, and therefore required caloric intake in excess of their basal requirements.[25] This assumption led to the routine arbitrary use of an illness/injury/infection multiplication factor to apply to a patient's REE to determine the patient's actual daily caloric requirements. Indirect calorimetry analyses conducted in over 106 dogs with a variety of illnesses documented no significant increase in their resting energy expenditure

compared with that of healthy controls.[23] Surgery and anesthesia, too, failed to increase a dog's REE.[25-27] In fact, research has demonstrated that an individual dog's REE can differ depending on the type, duration, and degree of illness; the REE may be increased, decreased, or normal.[28] Depending on the time that an individual patient's REE is measured, nutritional support may over- or underestimate caloric requirements throughout the course of illness and healing. Oversupplementation of calories, particularly in the form of carbohydrates, can lead to carbon dioxide retention and respiratory muscle fatigue. Oversupplementation of carbohydrates in human patients

has been thought to contribute to impaired ability to wean from mechanical ventilation.[29] If, however, the patient's REE is measured at a time-point at which the patient is hypometabolic, nutritional support may underestimate the patient's changing caloric needs and may actually contribute to malnutrition. The most recent recommendations by veterinary nutritionists describe feeding veterinary patients at least 50% and no more than 100% of their calculated REE, in anticipation that the patient's actual energy needs will change over the course of disease and recovery.[30] In general, the formula: [(30 x Body weight in kg) + 70] = Kcal/day is used to calculate a

patient's resting energy expenditure for nutritional support purposes.

The Hypothalamic-Pituitary-Thyroid Axis

The hypothalamic-pituitary-thyroid axis plays an important role in numerous cellular functions during states of health, including cellular oxygen consumption, basal energy metabolism, growth and development, regulation of cardiovascular indices, and regulation of carbohydrate and lipid metabolism.[31] During health, the hypothalamus secretes thyrotropin-releasing hormone (TRH) into the median eminence of the pituitary. The pituitary gland, in turn, releases

thyroid-stimulating hormone (TSH), which stimulates the thyroid glands to produce and secrete the thyroid hormones thyroxine (T4) and triiodothyronine (T3). Triiodothyronine is the active form of thyroid hormone. Approximately 10 to 20% of T3 in circulation is released directly from the thyroid glands, and 80 to 90% is a result of conversion of T4 to T3 by enzymatic activity in the peripheral tissues. Both T4 and T3 feed back to the hypothalamus and pituitary gland to suppress further thyroid stimulation.

Down-regulation of the thyroid axis has been documented in a variety of systemic illnesses and injury in

veterinary patients, including hyperadrenocorticism, pneumonia, sepsis, diabetes mellitus, renal and hepatic disease, and neoplasia.[32-33] During periods of stress and healing, down-regulation of thyroid hormone metabolism may be a teleological adaptive mechanism by which energy expenditure and protein loss decrease in order to allow healing to occur. During non-stressed starvation, T3 levels decline within 3 days of decreased nutrient intake.[34] Glucocorticoid release during stress is a primary mediator of inducing euthyroid sick syndrome in human and nonhuman animals. Euthyroid sick syndrome is characterized by impaired release of thyrotropin-releasing

hormone from the hypothalamus, decreased pituitary responsiveness to TRH, decreased TSH release from the pituitary gland, and decreased level of thyroid-binding proteins in circulation. Complicating factors include decreased conversion of T4 to T3 owing to impaired monoiodinase enzyme activity, and decreased affinity of T3 for peripheral receptors. Euthyroid sick syndrome can be distinguished from true hypothyroidism by the presence of normal to low endogenous TSH in the presence of low T4. In true hypothyroidism, the lack of negative feedback of T4 to the pituitary gland results in elevated eTSH levels in the presence of low T4. Supplementation of thyroid hormone in euthyroid sick

syndrome is ineffective at increasing patient survival.

In dogs, euthyroid sick syndrome has been documented in both acute[2] and chronic illnesses.[35-38] In one study, 67% of dogs admitted to a veterinary critical care unit displayed derangements of the thyroid axis, including decreased T3 and T4 concentrations.[2] Similarly, an increase in euthyroid sick syndrome was observed in surgical patients in the postoperative period compared with the same animals preoperatively.[32] In humans, severely decreased thyroid hormone function has been associated with an increase in morbidity and mortality.[1,39] Improvement of clinical

condition was associated with similar improvements in thyroid axis function.

Nutritional Support and Glutamine

Nutritional support in surgical patients should be proactive, and ideally should aim to meet the patient's ongoing needs and prevent endogenous protein catabolism.[40] In every patient, a daily nutritional assessment should be considered. Is the patient able to eat? Is vomiting or diarrhea present that can increase nutrient loss or prevent nutrient absorption? Is there excessive loss of protein in the urine or from wound exudates? Is the animal third spacing fluid and protein? Based on

the answers to these questions, the route and amount of nutritional support can be decided. In all cases, enteral nutrition is preferred, whenever possible. If enteral nutrition is impossible, parenteral nutrition should be implemented. Both enteral and parenteral nutritional support should provide not only a source of protein, carbohydrate, and lipids, but should also provide other nutrients that can become depleted during the course of illness. As a general rule, protein should compose 30 to 45% of a cat's diet and 15 to 30% of a dog's diet on an as fed dry matter basis.[41] Carbohydrates should be less than 50% of a cat's diet and approximately 50% of a dog's diet on an as fed dry matter

basis.[41] Fat should constitute 10 to 30% of a cat's and 10 to 20% of a dog's diet on an as fed dry matter basis.[41] Enteral products formulated specifically for use in critically ill patients are available (Clinicare, Abbott Animal Health, North Chicago, IL; Maximum Calorie, The Iams Company, Dayton, OH; A/D, Hill's Pet Nutrition, Topeka, Kansas) and are an excellent source of calories, protein, and fat in ratios that are highly digestible for veterinary patients with critical illness or in the post-surgical period. A complete review of parenteral nutrition is located elsewhere in this text.

Glutamine

Glutamine is a nonessential amino acids that is required for numerous physiologic processes throughout the body, including normal enterocytes function, nucleic acid and protein synthesis, renal ammoniagenesis, carbohydrate metabolism and gluconeogenesis, and cellular immune function. Although glutamine is abundant in host tissues, demand quickly exceeds the body's synthetic capacity during states of illness, and the nutrient becomes "conditionally essential" in critically ill and surgical patients. Glutamine depletion has been associated with negative nitrogen balance, enterocyte atrophy, suppressed cellular immune function, and increased risk of bacterial

translocation and sepsis. Glutamine supplementation in human enteral and parenteral formulations has been shown to increase muscle protein synthesis, peripheral leukocyte numbers, and overall nitrogen balance.[42] Although limited studies have been performed in veterinary patients, stable glutamine dipeptides are available in commercial enteral nutrition formulations (Clinicare, Abbott Animal Health, North Chicago, IL) and may help promote gastrointestinal health during the pre- and post-surgical periods.

Omega-3 Fatty Acids

The ratio of omega-3 to omega-6

polyunsaturated fatty acids has been implicated in playing a role in inflammatory conditions both in human and veterinary patients.[43] Omega-3 fatty acids are derived from alpha-linolenic acid, and omega-6 fatty acids are derived from linoleic acid. Both fatty acids are essential nutrients in cats and dogs. Breakdown of omega-3 and omega-6 fatty acids by cyclooxygenase and lipooxygenase ultimately results in the production of mediators of inflammation, namely, eicosanoids, prostaglandins, leukotrienes, and thromboxanes.[43] In general, proinflammatory mediators are the breakdown products of omega-6 fatty acids, whereas breakdown of omega-3 fatty acids, namely,

eicosapentaenoic acid, produces anti-inflammatory mediators.[43] Fish oil supplementation, a potent source of omega-3 polyunsaturated fatty acids, may be beneficial in decreasing proinflammatory conditions in some species.

Chapter 6

Enteral Nutrition

Elisa M. Mazzaferro

Nutritional support should be considered in any patient that is unable or unwilling to eat enough quantity to fulfill the caloric and nutrient requirements. Nutrient depletion is associated with increased patient morbidity and mortality.[1] Many veterinary patients have oral trauma, ulcers, or mass lesions that preclude them from prehending and swallowing food. In other cases, the

patient may voluntarily eat, but has a disease process that causes severe vomiting or diarrhea and, therefore, the nutrients that are ingested do not have adequate time for digestion and absorption.[2] In one study, only 84% of dogs and 68% of hospitalized cats voluntarily consumed their resting energy requirements.[3] In another study, many patients were withheld from food prior to surgery, or had feeding orders during the postoperative period that led to inadequate offering and thus consumption of calories and other nutrients.[4]

Inappetance, whether voluntary or not in the situation of stress and illness,

can lead to protein calorie malnutrition and negative nitrogen balance. Depending on the patient's overall condition, primary disease process, and anticipated length of time of inappetance, some form of nutritional support should be implemented as soon as possible. In general, if a patient has sustained a 10% decrease in body weight, has increased nutrient losses secondary to vomiting, diarrhea, renal disease, or wound exudates, or if oral intake has been or is anticipated to be diminished or ceased for more than 3 to 5 days, enteral support should be initiated.[5-6] The overall goals of nutritional support in any patient should be to replenish caloric intake and nutrients, reverse

negative nitrogen balance, prevent tissue catabolism, decrease the incidence of complications, quicken recovery, and improve overall survival.[2] Enteral nutrition is preferred over parenteral nutrition for a variety of reasons including it being more cost-effective and physiologic, and for maintenance of gastrointestinal health and function, decreased incidence of bacterial translocation, and improved clinical outcome. Unless a specific contraindication exists to prevent some form of enteral nutrition, any portion of the gastrointestinal tract that is functioning should be utilized.[7]

Gastrointestinal Health

In addition to its important role in nutrient digestion and absorption, the gastrointestinal tract serves as a physical and immunologic barrier between the enteric bacteria and the relatively sterile environment of the rest of the body.[8] In critically ill and post-surgical patients, normal gastrointestinal protective defense mechanisms can be impaired by the use of glucocorticoids, immunosuppressive drugs, parenteral nutrition, and bowel rest.[8] The presence of luminal nutrients stimulates a complex cascade of events that serves to maintain enterocyte health, gastrointestinal barrier function, gastrointestinal immunity, and overall patient health. The cells

lining the intestinal tract, enterocytes, derive approximately half their nutrient requirements from intraluminal substrates.[2] Research has documented that the presence of luminal nutrients is the single most important stimulus for intestinal mucosal growth and maintenance of barrier function.[9] Once ingested, the presence of substrates within the lumen of the gastrointestinal tract stimulates mesenteric blood flow and digestive enzyme and hormone secretion. Enteral nutrients stimulate the secretion of cholecystokinin and biliary flow.[10] Physical contact of fiber with mucosal cells directly stimulates mucosal cell proliferation. Fermentable fiber is metabolized to the short-chain

fatty acid butyrate within the large intestine and provides a key substrate fuel for colonocyte health that exerts trophic effects on the gastrointestinal tract.[11-12]

As gastrointestinal nutrients are absorbed, mucin secretion is stimulated. Mucin functions to lubricate the ingesta and neutralize bacterial toxins and hydrogen ions.[8] Additionally, luminal nutrients stimulate the excretion of biliary secretory IgA, an important defense mechanism against bacterial adherence and endotoxin binding to the intestinal mucosa.[2,8,13] Without luminal nutrients, even patients receiving parenteral nutritional support undergo

intestinal villous atrophy and mucosal atrophy. Luminal nutrition has been shown to maintain villous height and thus improve intestinal absorptive capacity and gastrointestinal barrier function.[10]

Benefits of Enteral Nutrition in the Critically Ill Surgical Patient

Within 24 hours of lack of enteral intake, enterocytes undergo atrophy and demonstrate decreased ability for digestion and absorption of nutrients.[14-15] The administration of enteral nutrition early after experimentally induced burn injury and abdominal surgeries has been

shown to decrease bacterial translocation and improve clinical outcome.[16-17] In human patients undergoing small intestinal and colonic resection, early enteral nutrition maintained gastrointestinal mucosal integrity, improved wound healing, and had a lower incidence of complications.[18-21] Enteral administration of a liquid diet within 12 hours of admission caused a significant increase in weight gain and earlier return to function in canine patients with parvoviral enteritis.[22] Early enteral nutrition provided to canine and feline patients admitted to a university critical care unit was associated with a significantly increased rate of survival compared

with patients that received parenteral nutrition alone.[23] The reported benefits of reduced complication rate, decreased length of hospital stay, and improved overall outcome have now led to the recommendation that enteral nutrition should be provided early in the course of illness, unless specific contraindications exist for using the gastrointestinal tract.[18]

Consequences of Inappetance and Parenteral Nutrition

The absence of luminal nutrients during courses of anorexia and administration of parenteral nutrition can result in intestinal villous atrophy,

a decrease in enterocyte mass, impaired gastrointestinal barrier function, decreased biliary release of secretory IgA, and suppression of brush border enzyme activity necessary for nutrient breakdown and absorption.[24-25] The consequences of mucosal atrophy are increased gastrointestinal permeability and decreased mesenteric immunity. Bacterial translocation, with stimulation of mesenteric proinflammatory cytokine release, can lead to systemic inflammatory response syndrome, and contribute to multiple organ dysfunction (MODS) in critical patients.[26]

Nutritional Assessment

A patient's nutritional status should be documented ideally within 24 hours of admission to the hospital and then carefully evaluated on a regular basis in order to meet nutritional needs and monitor response to therapy. A variety of factors is typically used to determine a patient's nutritional status, and includes overall body condition, the presence or absence of muscle wasting, total protein and serum albumin concentrations, white blood cell count, and serum acute-phase protein concentrations.[7] Factors other than malnutrition such as fluid therapy, hepatic dysfunction, and increased protein loss can alter normal values; for this reason, the use of a specific indicator by itself when determining a

patient's overall nutritional status is largely subjective.

Body condition score (BCS) is one method of evaluating a patient's general nutritional status. Various scales are used to determine overall BCS. This author uses a scale of 1 to 5, with 1 being cachexic and 5 being obese. A score of 3 is optimal. Negative nitrogen balance can occur in any patient with injury and illness. For this reason, even a morbidly obese patient should have caloric needs met based on their metabolic body size, not ideal body weight, while recovering from illness. To determine a patient's resting energy expenditure, use the formula: $(30 \times BW_{kg}) + 70 = Kcal/day$, where

BWkg is the patient's body weight in kilograms and Kcal/day is the number of kilocalories per day required. In general, if caloric intake is optimal based on metabolic body size, a patient's protein and other nutrient requirements will be met, if veterinary formulas are administered. A more in depth description and discussion of metabolic nutrient requirements are discussed in, Chapter 5, Metabolism and Nutrition of the Surgical Patient.

Consideration of the individual patient's disease processes and ability to tolerate various forms of enteral feeding is necessary to determine a nutritional plan. First, optimal proportions of specific fuel sources in

the form of carbohydrate, lipid, and protein should be determined.[27] Next, a specific diet and proposed means of nutrient delivery should be chosen.[27] Once nutritional support is initiated, the patient's response and tolerance to enteral feeding should be evaluated on a daily basis, at minimum. Changes to the nutritional plan should be made if complications occur or voluntary intake resumes. Once the patient's primary disease process has been treated, a plan should be formulated to transition the patient back to voluntary oral nutrient intake or to some form of indwelling feeding tube after discharge from the hospital.

Enteral Feeding Formulas

The type of enteral formula to administer should be considered based on the patient's clinical disease and ability to tolerate the type and route of feeding, the nutrient profile and specific disease or species requirements, and the individual patient's response to treatment, as well as on the cost and availability of the dietary formulation, its ease of storage and resistance to bacterial contamination and growth.[5-7,28] If a patient is going to require nutritional support for longer than 2 days, an indwelling feeding tube should be considered to minimize stress and potential trauma to the

nasopharyngeal region.[2,6] The chosen diet should be balanced to provide the patient's carbohydrate, protein, lipid, and micronutrient requirements, and should be formulated to flow through an appropriately sized feeding tube without difficulty or risk of obstruction.[27] The ideal dietary formulation for tube feeding should be well tolerated, easily digested and absorbed, inexpensive, and have a long shelf life with minimal risk of bacterial contamination.[29] In general, if a feeding tube is less than 14 Fr in size, a liquid diet should be chosen. Blenderized soft food is appropriate for large (> 14 Fr) tubes, whenever possible.[30]

Blenderized Diets

Blenderized diets are an appropriate means of feeding through large-bore (esophagostomy and gastrostomy) feeding tubes. Soft food is usually higher in protein and fat, and lower in carbohydrate than liquid diets, and is generally well tolerated by the patient. Hill's P/D can be mixed with water (1/2 cup of P/D with 3/4 cup of water, blenderized then strained) to form a well balanced, calorie-dense diet that can be fed through esophagostomy and gastrostomy tubes. More recently, Hill's Pet Nutrition and the Iams Company have developed A/D and Maximum Calorie diets, respectively. Both diets are extremely palatable and do not require dilution with water or

blending. An added benefit of the Maximum Calorie diet is its change in form by heating. The product can be warmed in the microwave, which changes its consistency to a liquid gruel that can be administered through feeding tubes without dilution.

Liquid Diets

A variety of liquid enteral products is available for use in veterinary and human patients (Table 6-1). Liquid enteral formulations are often associated with the development of diarrhea.[7] In some cases, the osmolality of the fluid causes osmotic diarrhea. In other cases, a lack of adequate fiber or fat in the diet results

in diarrhea. Supplementing with fiber or fat can slow gastric emptying time and the rate of nutrient passage through the intestines and can improve fecal consistency.[7] In general, the nutrient density of most liquid formulations used for tube feeding approaches 1 Kcal/ml. Approximately 30% of the calories should be provided as protein, 34% of calories as carbohydrate, and 36% of calories provided as lipid.[27] The addition of lipid and carbohydrates to a liquid diet improves feces consistency and decreases the incidence of diarrhea.[7] Many products developed for human use contain less than 20% of calories as protein and, therefore, are insufficient to meet canine and feline

requirements.[5] Specific nutrients such as taurine are also not present in adequate quantities in human formulations. For these reasons, products developed specifically for veterinary use are preferred, whenever possible. While the caloric density is important in determining the volume of liquid to administer as continuous or bolus feeding, the type of diet can further contribute to a patient's ability to assimilate and absorb the nutrients provided. Two broad categories of enteral diets are currently available, and are classified based on the predigestion of carbohydrates and proteins present.

Table 6-1. Enteral Products Formulated for Human and Veterinary use.[14,31]

Veterinary Diets Liquid Diets	Manufacturer	Caloric Density	Osmolality mOsm/kg	% Content

*** Suitable for short-term use in veterinary patients.**

Monomeric Diets

Monomeric diets, or elemental diets, contain crystalline amino acids or

dipeptides as a nitrogen source, dextrose or other simple sugars or oligosaccharides as a carbohydrate source, and are generally lower in fat. Fats are provided as long- or medium-chain triglycerides that require no digestion by pancreatic or brush border enzymes prior to absorption.[14] Hydrolysates of proteins provide amino acids as mono-, di- and oligopeptides.[14] It is thought that the digestion of di- and tripeptides and crystalline amino acids requires less fuel and energy than that of intact proteins and is thus more desirable in patients with impaired nutrient assimilation.[14,31] Because the nutrients are predigested, monomeric diets have a high osmolality (400 – 700

mOsm/kg) that often results in diarrhea.[5] Dilution of a monomeric diet with water sometimes can decrease the incidence of diarrhea by decreasing the solutions osmolality. However, dilution also decreases the caloric density of the diet, and requires administration of larger volumes to meet the patient's needs. It may not be physically possible to provide adequate caloric and nutrient intake when dilution is necessary to avoid diarrhea.

More recently, evidence suggests that administration of monomeric diets and elemental nutrition may influence gastrointestinal tract integrity. One study that investigated the use of a monomeric diet in cats with

experimentally induced enterocolitis demonstrated that monomeric diets may contribute to gastrointestinal atrophy and increased morbidity even in the presence of gut-specific nutrients. Administration of intact nutrients, or a polymeric diet, helped retain gastrointestinal mucosal integrity.[5] For this reason, a polymeric diet is preferred over monomeric diets whenever possible. A monomeric diet should be offered only if a patient fails to tolerate the polymeric diets that are available.[31]

Polymeric Diets

Polymeric diets contain intact protein, intact carbohydrate, and lipids. In

general, they contain a higher percent of calories as fat than do monomeric diets. Protein is provided as casein, soy, and egg albumin.[30] Proteins are provided primarily intact and require digestion by gastric hydrochloric acid and pancreatic enzymes prior to absorption and nutrient assimilation.[14] Intact lipids provided are usually of vegetable origin, such as corn oil, and are largely composed of long-chain triglycerides.[14] Lipids are digested into chylomicrons by pancreatic and enteric lipase prior to absorption.[29] Most polymeric diets are isoosmolar (300 – 450 mOsm/kg) and are better tolerated with fewer complications of diarrhea compared with monomeric diets.[31] Human products that have a

caloric density greater than 1 Kcal/ml can be relatively hyperosmolar (600 – 700 mOsm/kg), and are often associated with diarrhea.[5]

Specific Nutrients

Glutamine

Glutamine is a nonessential amino acid that becomes "conditionally essential" during stress and critical illness. During nutrient depletion, intestinal glutaminase activity is upregulated, and glutamine utilization increases. Glutamine is extracted from luminal nutrients and from blood flow to the intestinal basement membrane to provide fuel for the gastrointestinal tract. Glutamine serves as an

important substrate for the synthesis of protein and nucleic acids, glutathione, and gastrointestinal mucus.[32] Glutamine also is absolutely necessary for mesenteric immune function, glutathione synthesis, and nitrogen transport.[10,32] Glutamine depletion has been associated with gastrointestinal mucosal atrophy, increased permeability, depressed mesenteric immune function, and bacterial translocation. Enteral supplementation with glutamine-enriched formulas has been shown to ameliorate the negative consequences of depletion listed above.[32]

Arginine

Arginine is an essential amino acid for dogs and cats.[11] Arginine is known to stimulate the release of various anabolic hormones, including prolactin, insulin, and growth hormone. Arginine is also essential in mediating microvascular function and serving as a precursor for nitric oxide, and is an important vasodilatory substance.[10] Supplementation with arginine is thought to improve nitrogen balance by promoting nitrogen retention and to improve immune function and wound healing.[8] Veterinary nutritional supplements should contain arginine at a minimum of 146 mg arginine/100 Kcal for dogs and 250 mg arginine/100 Kcal for adult cats.[31] Most veterinary products

contain arginine in sufficient quantities to meet the needs of critically ill patients, however, they do not meet the requirements necessary to promote improved immune function.[11]

Starch

A wide variety of carbohydrate sources is available in enteral formulations. In many products, carbohydrate is provided as corn starch or as mono- or disaccharides in elemental form. Mono- and disaccharides increase the relative osmolality of the preparation and may be associated with diarrhea.

Fiber

The addition of soluble and insoluble fiber to enteral diet formulations serves a dual purpose. Insoluble fiber such as lignin, cellulose, and hemicellulose is present in human formulations (Metamucil Regular or Psyllium fiber 10 – 13 g/100 Kcal) and stimulates enterocyte and goblet cell proliferation when in direct contact within the gut lumen.[31] Fiber can provide a barrier function and limit bacterial adherence and translocation. Additionally, soluble fiber such as pectin is fermented by enteric anaerobic bacteria to the short-chain fatty acid butyrate, acetate, and propionate.[14] Short-chain fatty acids enhance colonocyte health and decrease the incidence of diarrhea.

Over-the-counter products that contain psyllium and pectin (1 gram/100 Kcal) can be administered in large-bore feeding tubes in combination with veterinary enteral formulations to decrease the incidence of diarrhea.[14] Oral fiber slows the rate of gastric emptying, and may help improve nutrient assimilation.

Fatty Acids

Enteral diets contain fats as medium- or long-chain triglycerides. Interest has been increased in providing varying proportions of the essential fatty acids linoleic (omega-3) and linolenic (omega-6) when dealing with inflammatory disease states. Omega-3

fatty acids are found in large quantities in flaxseed, canola, and fish oils. Omega-6 fatty acids are present in vegetable oils.[11] Essential long-chain fatty acids are precursors for arachidonic acid synthesis. Dogs can synthesize arachidonic acid from linoleic (omega-6) acid, and can synthesize eicosapentaenoic acid from α-linolenic (omega-3) acid. Cats are deficient in the enzymes necessary for arachidonic acid and eicosapentaenoic acid synthesis, and thus require both in their diets. Arachidonic acid is metabolized by cyclooxygenase enzymes to various pro- and anti-inflammatory mediators, including prostaglandins, thromboxanes, and leukotrienes. Collectively known as

eicosanoids, these substances play an important role in mediating immune function, inflammation, platelet function and aggregation, and vascular tone.[11] Increasing the ratio of omega-3 to omega-6 fatty acids in the diet can promote the preferential substitution of linoleic acid into the phospholipid bilayer of cells and result in the production of less inflammatory cytokines. This can help decrease overall inflammation that is thought to contribute to the adverse consequences of systemic inflammatory response syndrome.

Protein

Protein in dietary supplements is

typically provided as intact protein, crystalline amino acid, or as hydrolysates of protein. Di- and oligopeptide formulations have a higher osmolality than intact proteins and can cause diarrhea. Intact protein requires digestion by gastric hydrochloric acid and pancreatic enzyme activities. Crystalline amino acids can be absorbed in an energy-consuming active transport process. Di- and oligopeptides, in contrast, are absorbed in passive transport and do not consume energy in the process.[14]

Protein requirements for small animal patients differ across species and across disease states. In general, dogs require 3 to 4 grams of protein/100

Kcal, whereas cats require 4 to 6 grams protein/100 Kcal. Lower concentrations of protein are advisable if hepatic or renal dysfunction is present. Higher quantities of protein should be considered in cases of severe protein loss, including burns, excessive wound exudates, or protein-losing enteropathy or nephropathy. The concentration of protein in relation to caloric density should be considered when choosing an enteral formula appropriate for an individual patient. Protein concentration ranges from less than 5 g/100 Kcal to 15 g/100 Kcal.[14] The protein content of many human enteral nutrition products is deficient and should not be used for long-term nutritional support in small animal

patients.[11] In general, if a patient's caloric requirements are met with a veterinary enteral product, its protein requirements will be met as well, unless excessive ongoing nitrogen loss occurs.[30]

Feeding Options and Considerations

Although enteral nutrition is preferred whenever possible, it is not a suitable mode of nutritional support for all small animal patients. Ideally, it is best to evaluate the patient's status at the time of presentation, or at the latest within 24 hours of admission. The nutritional status should be carefully assessed and the patient's individual

needs determined prior to the onset of any complications. The anticipated time of enteral nutritional support and time to resume normal voluntary oral intake should be considered.[5] Animals that are poor anesthetic candidates, have coagulation defects, are recumbent or comatose, and cannot protect their airway will have increased risk of aspiration pneumonia, hemorrhage, or death if an indwelling tube is placed under general anesthesia.[5] Other contraindications to enteral feeding include gastrointestinal obstruction and severe malabsorptive syndromes.[8] Postoperatively, gastric ileus may be present for more than 5 days. In such cases, postgastric feeding in the form

of duodenal or jejunal tubes should be considered.

Appetite Stimulation

If an animal is physically able to prehend food and does not have esophageal dysfunction or stricture or gastrointestinal obstruction, oral feeding may be possible if an animal is willing to eat and responds to appetite stimulants. Forcefeeding is extremely stressful for animal and caretaker alike and should be avoided. It is difficult to provide adequate calories to meet an animal's resting energy requirements. In some cases, the animal will associate the mere presence of a caregiver with the stress of

forcefeeding and reactively and spontaneously vomit. This reverse Pavlovian response negates the goal of providing enteral nutrition and can lead to aspiration pneumonia, esophagitis, and further debilitation. Appetite stimulants that have been used with some success include benzodiazepene tranquilizers (Diazepam 0.05 – 0.5 mg/kg IV once daily to cats) and serotonin antagonists (2 mg/cat PO bid).[31,33] In some cases, warming a liquid diet or adding a small amount of spice to it can enhance odor and palatability.[33] Positive reinforcement and encouragement may entice a patient to eat. If voluntary feeding is not successful in meeting the patient's

nutritional requirements, some form of involuntary feeding in the form of feeding tube or parenteral administration should be implemented.[3]

Nasoesophageal and Nasogastric Tubes

Nasogastric (NG) and nasoesophageal (NE) feeding tubes should be considered for short-term (< 1 week) administration of enteral nutrition.[5] Nasoesophageal and nasogastric tubes can be placed efficiently without anesthesia or sedation, in most cases.[2] Contraindications to nasoenteral feeding tube placement include facial or head trauma, impaired neurologic

status (moribund or comatose patient without an intact gag reflex), or esophageal disorders including megaesophagus, masses, or stricture.[2]

The placement of nasoenteral feeding tubes has been discussed elsewhere.[5,34–37] Both silicone and polyvinylchloride tubes (Argyle Infant Feeding Tubes, Sherwood Medical, Inc; Sovereign Feeding Tube, Monoject,) are available for use. Because polyvinylchloride tubes can harden within days of exposure to hydrochloric acid, silicone tubes are preferable.[2] A 5 to 8 French tube can be placed in cats and small dogs that weigh less than 10 kg, while larger (8 to 10 Fr) tubes can be placed in larger dogs. Early studies

documented that patients, in general, tolerated the NE or NG tube with mild to moderate coughing or sneezing as a common complaint. Gastroesophageal reflux can occur if the tip of the tube passes through the lower esophageal sphincter; however, gastric suctioning may be helpful in animals with severe ileus, to decrease gastric distention and vomiting.[22] In one study, 63% of patients demonstrated no complication with the nasogastric tube feeding, and 61% of patients maintained body weight while hospitalized.[7] Some animals were able to eat with the tube in place.[27,37] Administration of liquid enteral diets allowed maintenance of serum albumin, commonly used as a nutritional marker, in hospitalized

small animal patients.[7] The most common complications observed were tube dislodgement, vomiting, and diarrhea, which may have been secondary to the patient's primary disease process(es), owing to the enteral feeding tube, or owing to dietary intolerance. In many patients, diarrhea was treated successfully by changing to a different dietary formulation.[7] More serious complications of nasoenteral feeding include epistaxis, rhinitis, vomiting, esophageal stricture, nasopleural intubation with pneumothorax, and aspiration pneumonitis.[5] Mechanical disruption of the tube by clogging is common, because of the small diameter necessary to bypass the nasal meatus.

Sometimes, debris clogged within the tube can be dissolved with the use of pancreatic enzyme solutions or carbonated beverage products such as Coca Cola®.

Esophagostomy Tubes

Esophagostomy tubes are an excellent means of providing enteral nutritional support in a patient with full use and function of the gastrointestinal tract.[28,38] Several methods for esophagostomy tube placement have been described.[28,34,38,39–43] Advantages of esophagostomy tubes include their ease of placement, low risk of complication compared with other indwelling feeding tubes, low cost, lack

of need for specialized equipment, immediate use, and positive owner and patient tolerance and use.[28] A recent study investigated the use of esophagostomy versus percutaneous endoscopic gastrostomy tubes, and found that 92% of clients with animals with E-tubes were comfortable and satisfied with their use, versus only 71% of clients whose animals had G-tubes placed.[28] Minor complications associated with E-tube use and placement included vomiting, inadvertent tube removal, patient scratching at the tube, and tube obstruction.[28] More serious complications that have been described, but are uncommon, include hemorrhage during tube placement,

cellulitis, and mediastinal placement with pleuritis.

Gastrostomy Tubes

Percutaneous gastrostomy tubes can be placed with or without the assistance of an endoscope. Several techniques have been described.[33,44–46] Gastrostomy tubes are indicated in any patient that has a nonfunctional or injured esophagus, but still has normal gastric function. Gastric tubes are generally well tolerated by clients and animals alike.[34] Complications of gastric tubes include inadvertent tube removal, peritonitis, cellulitis, stoma site infection and pressure necrosis.[5,34] Disadvantages of a gastrostomy tube

over esophagostomy tube include the need to wait a minimum of 12 to 24 hours prior to tube use to allow a seal to form, and the need to wait a minimum of 7 to 10 days prior to tube removal.

Jejunostomy Tubes

In general, jejunostomy tubes are well tolerated and provide an effective means of providing nutritional support if only a portion of the gastrointestinal tract is functional. Various methods for placement of jejunostomy tubes have been described.[47–50] Placement of a jejunostomy tube is indicated in patients with upper gastrointestinal obstruction or resection, gastroparesis,

pancreatitis, and recurrent aspiration pneumonia.[5] Following placement of the jejunostomy tube, feeding should be initiated after 6 to 12 hours if peristalsis is present.[5] Without a reservoir to allow nutrients to slowly trickle into the gastrointestinal tract, intermittent bolus feeding through a jejunostomy tube is often associated with the development of diarrhea.[6] For this reason, continuous feeding is preferred. Providing a patient's nutrient requirements should be started slowly and then ramped up to full caloric intake over a period of 48 hours. A J-tube should ideally remain in place for a minimum of 7 to 10 days before removal, to decrease the risk of peritonitis. Complications associated

with J-tube placement and feeding include orad migration of the tube, abdominal cramping with diarrhea, tube obstruction, focal cellulitis, and tube dislodgement with peritonitis.

Metabolic Complications Associated with Enteral Feeding

Enteral feeding has been associated with a variety of metabolic complications, including hypo- and hyperglycemia, uremia, vitamin and trace mineral deficiencies, and fluid and electrolyte imbalances.[5-10] Overfeeding with resultant vomiting and diarrhea is common. Whenever gastric function is marginal, it is best

to aspirate and measure the residual volume in the stomach before the next feeding, to avoid gastric overdistention. If more than one third the volume of the previous feeding is still present, the scheduled feeding should be delayed to allow more time for the stomach to empty. Vomiting can increase the risk of aspiration pneumonia and should be prevented, whenever possible.[10]

Initiating Feeding

Enteral nutritional supplementation should be initiated gradually in the inappetant patient. Caution must be exercised when initiating enteral feeding support to a patient that has

had inadequate fluid resuscitation. Research has indicated that administration of enteral nutrition to a patient with hypotension and intravascular fluid volume depletion can result in increased gastrointestinal work-load and oxygen consumption with impaired oxygen delivery, causing further compromise to the gut barrier.[11,51] If the stomach is functional, bolus meal feeding through an esophagostomy or gastrostomy tube can be administered as 6 small meals in a 24-hour period. Trickle feeding via constant-rate infusion is another method of administering liquid diets through nasoesophageal, nasogastric, and jejunostomy tubes. In some cases, a jejunostomy tube can be placed

through a gastrostomy tube until the stomach and duodenum can tolerate feeding. Whether nutritional support is administered as a bolus or as a constant-rate infusion, approximately on quarter to on third of the patient's daily caloric requirements should be fed on the first day. Initially, nutrient boluses should equal 5 to 10 ml/kg until the patient is able to tolerate a larger volume.[31] The volume and caloric density should slowly be increased to full feeding over a period of 48 hours, to avoid oversupplementation and refeeding syndrome. Feeding should cease if clinical signs of salivation, retching, or vomiting occur.[31] The patient's acid-base and electrolyte status should be

carefully monitored for hypokalemia, hypophosphatemia, and hyperglycemia during this time.

Refeeding Syndrome

Refeeding syndrome is an uncommon complication that occurs in dogs and cats when overzealous nutritional supplementation is administered to a patient that has been anorexic for a long period. Upon reintroduction of nutrients, insulin release drives potassium and phosphorus intracellularly with glucose.[52] A rapid decrease in serum potassium can result in cardiac dysrhythmias and muscle fasciculations. Hypophosphatemia (< 1 mg/dL) can result in severe red blood

cell hemolysis.[53–54] Supplementation with phosphorus as potassium phosphate (0.03 – 0.12 mMol/kg/hour IV CRI or 100 mg/100 Kcal energy/day as oral supplement) and potassium chloride (not to exceed 0.5 mEq/kg/hour) or potassium gluconate (2 – 4 mEq/100 Kcal/day as oral supplement) may be necessary to alleviate clinical signs associated with hypophosphatemia and hypokalemia.[55] If clinical and metabolic signs of refeeding syndrome occur, enteral feeding should be decreased until electrolyte abnormalities have been normalized.

Gastric Atony

Gastric atony is a common complication observed in inappetant and post-surgical patients. Narcotic drugs administered to provide analgesia in the postoperative period often contribute to delayed gastric emptying, ileus, gastroesophageal reflux, and vomiting.[56] Empiric therapy with prokinetic agents can potentially decrease some of the complications associated with gastric atony in some patients.[56] Metoclopramide, a dopaminergic and 5-hydroxytryptamine (5-HT) receptor agonist-antagonist, functions as a central antiemetic and gastric promotility drug. Administration of metoclopramide (1 – 2 mg/kg/day IV CRI or 0.2 – 0.4 mg/kg SQ tid) has

been shown to increase lower esophageal tone, increase the force of gastric contractions, and cause pyloric relaxation to promote gastric emptying.[56] The combined effects of metoclopramide serve to decrease vomiting and gastroesophageal reflux.

Chapter 7

Parenteral Nutrition

Elisa M. Mazzaferro

Too frequently, veterinary patients do not receive their daily nutritional requirements as a result of inadequate nutrient intake.[1] Advancements in veterinary nutrition and critical care have directed us to provide more aggressive nutritional support to critically ill small animal patients. A lack of essential nutrients and energy can contribute to increased patient morbidity, impaired wound healing,

immunosuppression, and increased mortality. The goals of nutritional support are to treat and prevent malnutrition during times of critical illness until the patient is able to assimilate enteral nutrients alone.[2] Although the gold standard for administration of nutritional support is to utilize and feed whatever portion of the gastrointestinal tract is functional, some animals either cannot or will not voluntarily eat, or cannot digest or absorb nutrients provided enterally because of severe vomiting, ileus, inflammation, or surgical resection of the gastrointestinal tract.[2,3] The use of enteral nutrition may be contraindicated or impossible in such cases, and alternate forms of nutrition

become absolutely necessary.

Parenteral nutrition is the provision of nutrients by any method other than the gastrointestinal tract.[4] Parenteral nutrition usually contains some form of carbohydrate in the form of dextrose, lipid, and a protein source in addition to vitamins and minerals (Table 7-1). Various phrases have been used to describe the type and method of parenteral nutrition. The term “total parenteral nutrition” (TPN) has frequently been used to indicate the provision of all of a patient’s essential nutritional requirements via intravenous, intraperitoneal, or intraosseous route.[5,6] Because we rarely are able to provide every

essential macro- and micronutrient to veterinary patients, the term TPN is actually a misnomer that should be abandoned.[4] Another recommendation was to simply use the terminology "Parenteral Nutrition (PN)" to be more accurate.[6]

Parenteral nutrition has also been named based on its route of administration. Solutions with an osmolality greater than 600 to 800 mOsm/L are typically infused via central venous catheters to prevent thrombophlebitis.[7] Such solutions have been called "central parenteral nutrition."[4] Interest has been renewed in the infusion of solutions with lower osmolalities into peripheral veins. This

is termed “peripheral parenteral nutrition” or “partial parenteral nutrition” (PPN). Peripheral parenteral nutrition should be considered when short-term nutritional support is required, or as a bridge between parenteral and enteral nutrition as a patient becomes able to tolerate enteral feedings.

Table 7-1. Parenteral Nutrition Components

Name	Osmolality (mOsm/L)	pH	Manufacturer
10% Amino acid (Travasol)	998	6.0	Baxter Healthcare Corporation
Aminosyn	850	4.5-6.0	Abbott Pharmaceuticals
Procalamine	735	6.8	McGaw, Inc.
5% Dextrose	252-310	3.2-6.5	Abbott Pharmaceuticals
50% Dextrose	2530	4.2	Abbott Pharmaceuticals
20% Amino Acid (Aminosyn)	260	8.3	Abbott Pharmaceuticals

Parenteral Nutrients

In the past, the administration of

parenteral nutrition in veterinary patients has been limited, largely because of the perceived increased expense, risk of potential complications including sepsis, and lack of technical expertise required for the placement and maintenance of central venous catheters.[7,8] Advancements in veterinary critical care have largely made parenteral nutrition a more viable option for critically ill small animal patients.[8] Parenteral nutrition can be formulated in-house or by commercial pharmacies by compounding a mixture of amino acids, dextrose, lipids, and vitamins.[7] "Three-in-One" mixtures can also be purchased from commercial sources. Ideally, parenteral nutrition solutions

should be formulated and mixed under strict aseptic conditions, either in a compounding machine or in a laminar flow hood. In private practice, however, such techniques are often not possible. Mixing should occur, instead, in a surgical suite or low-traffic area, with the personnel wearing a surgical cap, mask, and sterile gloves.

Proteins

Essential and nonessential crystalline amino acid solutions (3.5%, 8.5%, and 15%) are available as a protein source for veterinary parenteral nutrition formulations. Most commonly, an 8.5% solution is used for small animal patients.[6] Amino acid solutions have a

high osmolarity (300 – 1400 mOsm/L) and a relatively acidic pH (5.3 – 6.5).6,9,10 It has been recommended that amino acid solutions with concentrations greater than 3.5% should not be administered through a peripheral vein because of the high osmolality.[10] Commercial products containing varying amounts of glucose and electrolytes are also commercially available.[6] The amount of protein in parenteral formulations is usually calculated relative to the amount of nonprotein calories required by each patient. Protein requirements range from 1 to 6 grams of protein/100 Kcal nonprotein energy in small animal patients.6 In dogs, approximately 2 to 3 grams of protein/100 Kcal

nonprotein calories should be administered on a daily basis. In cats, the value is slightly higher, at 4g protein/100 Kcal.[6] In patients with hepatic or renal insufficiency, smaller amounts of protein should be provided; in patients with large amounts of protein loss, larger portions should be considered. Because most amino acid solutions do not contain the amino acid taurine, taurine supplementation should be considered if parenteral nutrition is required for long-term management of feline patients.[2]

Lipids

Lipid emulsions are often a combination of soybean and safflower

oil, and linoleic and linolenic acids.[6] Lipid sources for parenteral nutrition administration are available as 10 to 20% solutions, and are used to provide 40 to 60% of the patient's daily nonprotein calorie requirements.[11] Lipids traditionally supply essential fatty acids and provide a source of calories in an isotonic fluid. Because lipid emulsions typically have a lower osmolality (260 – 310 mOsm/L)[6,9,10] than amino acid solutions, lipids can be administered by peripheral catheters with minimal risk of causing thrombophlebitis.

Dextrose

Carbohydrate sources are typically

provided as dextrose (2.5%-70%) in parenteral nutrition formulations. Most commonly, 50% dextrose is combined with lipid and amino acid solutions for a patient's daily nutritional needs. The exact ratio of dextrose to lipid to meet a patient's caloric requirements is a topic of debate. During states of stressed starvation, glucocounterregulatory hormones such as cortisol and epinephrine promote a state of insulin resistance. The body is unable to utilize carbohydrate sources for energy, and hyperglycemia develops. In humans, hyperglycemia secondary to oversupplementation of carbohydrates has been shown to increase patient morbidity, respiratory failure, and

mortality. In small animal patients, dextrose as provided in parenteral nutrition formulations should not exceed 50% of total daily caloric requirements.

Electrolytes

Electrolyte abnormalities are a common complication of critical illness and parenteral nutrition administration. The most common electrolyte abnormalities observed are hypokalemia and hyperphosphatemia. Following a period of prolonged anorexia and malnutrition, infusion of supplemental dextrose alone or in combination with amino acids and lipids can stimulate insulin release,

driving glucose, potassium, and phosphorus intracellularly. Provision of nutrients and the production of high-energy-containing compounds such as adenosine triphosphate (ATP) can deplete a patient's phosphorus stores, resulting in hypophosphatemia. Measuring a patient's levels of potassium and phosphorus is necessary in order to determine the appropriate amount of potassium and phosphorus supplementation. In most cases, adding 20 to 40 mEq/L of potassium chloride, or a mixture of potassium chloride with potassium phosphate (0.01 – 0.03 mmol/kg/hour) may be necessary to maintain normokalemia and normophosphatemia. Ten milliliters of 10% calcium gluconate

solution can be administered in each liter of parenteral nutrition.[10]

Vitamins

Most patients do not require fat- and water-soluble vitamin supplementation unless the anorexia and weight loss have been prolonged or if nutrient absorption has been diminished because of excessive diarrhea or steatorrhea.[6] A weekly dose of Vitamin K1 (0.5 mg/kg) has been suggested at the onset of parenteral nutrition.[2,6] Other fat-soluble vitamins (A,D, and E) can be administered as a repository solution (1 ml IM, Schering-Plough Animal Healthcorp, Kenilworth, NJ) and will provide a sufficient store for

approximately 3 months.[6] B-complex vitamins can be provided as a combination preparation in the parenteral solution (1 ml/100 Kcal or 3 ml/10 kg/day).[2] Because some B-vitamins degrade when exposed to light, the parenteral nutrition solution should be covered to prevent degradation of labile substances.

Formulating Parenteral Nutrition Solutions

Before actually formulating a patient's daily parenteral nutrition, one must first calculate the daily energy requirements (resting energy expenditure, REE), then determine what percent of the REE will be

provided as carbohydrate (dextrose) and what percent will be provided as lipid. Veterinary studies have documented that critically ill small animal patients actually require basal energy requirements,[12] and are not "hypermetabolic" as previously suggested. A linear equation to calculate a patient's daily caloric requirements or resting energy expenditure (REE) is:

$$\mathbf{REE = (30 \times Body\ weight_{kg}) + 70 = Kcal/day}$$

Once the REE is calculated, the amount of calories provided by fat as lipid emulsion and of carbohydrate as dextrose is then calculated. Finally, the

REE is divided by 100, to provide a multiplication factor for the amount of protein to add to the mixture. In order to determine the amount of each solution to add to the total mixture, one must know the concentration of lipid, dextrose, and amino acid in each component solution. The volume of each component is added together and the sum divided by 24 hours, to yield a rate of ml/hour to administer the parenteral nutrition. An example of step-by-step calculation of parenteral nutrition formula for a canine and a feline patient is located in Table 7-2. Once a bag of parenteral nutrition has been formulated, it can be refrigerated for up to 48 hours. The parenteral nutrition should be administered at

room temperature. Each bag should be administered over a period of 24 hours, then discarded.

Total Nutrient Admixture

A simple method of providing the patient's total daily nutritional and fluid requirements is to combine the parenteral nutrition within a Lactated Ringer's or other isotonic fluid (Normosol-R, Plasmalyte-A) bag. First, the volume of each parenteral nutrition component is determined. Next, the patient's total daily fluid requirement is determined. The volume of the parenteral nutrition is adjusted to meet the patient's daily fluid requirements by adding an isotonic

fluid such as Lactated Ringer's, Plasmalyte-M, or Normosol-R into the bag of parenteral nutrition. The additions are made in a sterile manner, then the fluid is infused into a dedicated line. The advantages of administering a TNA solution are that the patient requires just one dedicated catheter, one fluid administration set, and one fluid pump.[4]

Central Catheter Placement

Infusion of a hyperosmolar substance into a peripheral vein is often associated with the development of thrombophlebitis. It is recommended, therefore, that parenteral nutrition solutions with an osmolality greater

than 600 mOsm/L should be infused into a central venous catheter. In small animal patients, central venous catheters can be placed into the jugular, medial saphenous, and lateral saphenous veins with relative ease. Several single- and multiple-lumen catheter types are available. Polyurethane and silicone catheters are less irritating to the vessels and, therefore, are recommended over Teflon catheters.[6] A complete description of through-the needle and over-the-wire catheter placement is beyond the scope of this text. One of the most important concepts to remember when placing a central venous catheter is to maintain sterility at all times, to prevent catheter-related

sepsis. First, the fur over the proposed site of catheter insertion should be clipped. Next, the clipped area should be aseptically scrubbed as with any surgical site. The area should be draped with sterile field towels to avoid contamination of the site. Wearing gloves, the practitioner can insert the catheter according to manufacturer's instructions, then secure it in place. The catheter entrance site should be covered with an antimicrobial ointment, then bandaged. The bandage should be labeled with the time and date of catheter placement, initials of the person who placed the catheter, and the date of bandaging. Once the catheter has been successfully placed

and bandaged, the parenteral nutrition can be connected. The line should be labeled as a dedicated line and not be used for any purpose other than administration of the nutritional support. The line should not be disconnected for any reason except to change fluid/nutrition bags every 24 hours, even when taking the patient for a walk outside. The bandage should be changed and the catheter entrance site examined every 24 hours. Signs of phlebitis include erythema and pain at the catheter site, pain upon infusion into the vessel, and ropiness or hardening of the vessel on external palpation. In several retrospective studies regarding the use of central venous catheters for infusion of

parenteral nutrition, catheter occlusion and kinking were among the most common complications observed.[13,14,15]

Partial Parenteral Nutrition

Partial parenteral nutrition is the provision of a portion of a patient's daily nutritional requirements. Partial parenteral nutrition should be used only in cases where nutritional support is anticipated for less than 5 days, or during a transition period when a patient is consuming only a portion of the daily nutritional requirements enterally. The osmolality of partial parenteral nutrition formulations is usually lower than 600 mOsm/L, and therefore, they can be administered

through a peripheral vein. Because amino acid solutions are hyperosmolar, peripheral parenteral solutions typically contain small amounts of amino acid and provide a portion of the patient's caloric requirements as a mixture of dextrose and isoosmolar lipid solutions. Because of volume and osmolality constraints, peripheral parenteral nutrition only provides a portion of a patient's daily nutrient needs.[13,16]

Table 7-2. Step-wise Approach to Calculating Parenteral Nutrition Formulation

1. Calculate the patient's daily resting energy requirement (REE in Kcal/day) REE $= (30 \times BW_{kg}) + 70$
2. Calculate the patient's carbohydrate source, providing 20% of REE as dextrose.
3. Calculate the patient's lipid requirement, providing 80% of REE as lipid.
4. Calculate the patient's daily protein requirement (3 g/100 Kcal for dogs and 4 g/100 Kcal for cats)
5. Use the following guidelines to determine the volume of each parenteral nutrition component required.
   5% dextrose $=$ 0.17 Kcal/ml

50% dextrose = 1.7 Kcal/ml
20% lipid = 2 Kcal/ml
8.5% amino acid = 0.085 g/ml
3% amino acid = 0.03 g/ml

6. Add the volume of dextrose, lipid, and amino acid solution together to yield a daily volume to be administered.
7. Divide the volume obtained in Step 7 by 24 hours, to yield a ml/hour rate of infusion.

OR

8. Determine the patient's daily fluid requirement.
9. Subtract the volume obtained in Step 6 from the volume obtained in Step 8.

10. Add the volume obtained in Step 9 as an isotonic solution to the parenteral nutrition (components in Step 6) to obtain a daily fluid and nutrition solution.
11. Divide the total volume of Step 10 by 24 hours, to yield a fluid rate per hour.

Example of Calculating Parenteral Nutrition for a 30 kg dog:

1. Calculate the patient's daily REE.
   (30 x 30) + 70 = 970 Kcal/day
2. Calculate the daily carbohydrate source.
   20% = 0.2 x 970 Kcal/day = 194 Kcal/day carbohydrate (dextrose)

3. Calculate the daily lipid source.
   80% = 0.8 x 970 Kcal/day = 776 Kcal/day lipid
4. Calculate the daily protein requirement (4 g protein/100 Kcal in dogs)
   970 Kcal/day x 4 g protein/100 Kcal = 38.8 g protein/day
5. 50% dextrose = 1.7 Kcal/ml
   194 Kcal x 1 ml/1.7 Kcal = 114 ml of 50% dextrose/day
   20% lipid = 2 Kcal/ml
   776 Kcal x 1 ml/2 Kcal = 388 ml 20% lipid
   38.8 g protein/day x 1 ml/0.085 g protein = 456.5 ml/day 8.5% protein

6. Add the volume of dextrose, lipid, and protein required.

114 ml 50% dextrose
388 ml 20% lipid
+ 456.5 ml 8.5% amino acid
= 958.5 ml/day

7. a. Divide the above volume by 24 to yield ml/hour rate of administration.
958.5 ml/day ÷ 24 hours = 39.9 ≈ 40 ml/hour

OR

7. b. Determine the patient's daily fluid requirement (60 ml/kg/day)
60 ml/kg/day x 30 kg = 1800 ml/day

8. Subtract the parenteral nutrition volume from daily fluid requirement.

1800 ml/day – 985.5 ml/day = 814.5 ml

9. Add 814.5 ml of an isotonic fluid such as Normosol-R to the parenteral nutrition, to create a total nutrient admixture (TNA)
10. 1800 ml ÷ 24 hours = 75 ml/hour of total nutrient admixture.

Complications of Parenteral Nutrition

One of the most common reasons for not implementing parenteral nutritional support in critically ill veterinary patients is the perception of numerous complications. Several studies have been published

investigating the use of parenteral nutrition in veterinary patients. Complications associated with parenteral nutrition administration can be categorized as mechanical, metabolic, or septic (Table 7-3).[3,13] Mechanical complications are most common and are typically associated with catheter dislodgement, kinks, and clogging.[3,13,14,15] Metabolic complications include transient hyperglycemia, hypokalemia, hyperlipidemia, hypophosphatemia, hyperbilirubinemia, hyponatremia, and hypochloremia.[3,13,14,15] In one study,[14] hyperglycemia at 24 hours after onset of PN infusion was associated with increased risk of mortality. In human patients,

persistent hyperglycemia can contribute to respiratory fatigue and increased patient mortality. Administration of 10 units of regular insulin per liter of parenteral nutrition can decrease the hyperglycemia associated with PN administration.[3]

Lack of enteral nutrition can promote disuse atrophy of enterocytes and promote bacterial translocation and sepsis. In several veterinary studies, septic complications during administration of parenteral nutrition were few and were associated with the patient's primary disease process or to disruption of the patient's designated infusion line.[3,13,14,15]

Table 7-3. Mechanical and Metabolic Complications Associated with Parenteral Nutrition

Mechanical Complications
Catheter occlusion
Catheter malfunction
Line disconnection
Line or catheter breakage
Thrombus formation
Inability to re-catheterize patient
Metabolic Complications
Hyperammonemia
Hyperglycemia
Hyperkalemia

Hypokalemia

Hypomagnesemia

Hypochloremia

Hyponatremia

Hypophosphatemia

Elevated BUN

Conclusions

Parenteral nutrition should be considered in any patient that cannot tolerate enteral feeding. Nutritional plans should be formulated based on individual patient requirements, disease processes, anticipated length of required nutritional support, and risk of complications. The risks of increased patient morbidity and mortality and of

delayed wound healing greatly exceed the perceived risks of increased patient expense and mechanical, metabolic, or septic complications. With increased use and technical proficiency, placement of dedicated central venous catheters and administration of parenteral nutrition can become commonplace in all veterinary hospitals, provided that aseptic techniques are strictly adhered to.

Chapter 8

The Physiology of Pain and Principles for its Treatment

James S. Gaynor

Why is the Control of Pain Important?

The alleviation of pain is important for physiologic and ethical reasons.[1] Briefly, pain can induce a stress response in patients that is associated with elevations in ACTH, cortisol, antidiuretic hormone (ADH), catecholamines, aldosterone, renin,

angiotensin II, and glucose, along with decreases in insulin and testosterone. These changes can result in a general catabolic state with muscle protein catabolism and lipolysis, in addition to retention of water and sodium and excretion of potassium.[2] A prolonged stress response can decrease the rate of healing. In addition, the stress response can have adverse effects on the cardiovascular and pulmonary systems, fluid homeostasis, and gastrointestinal tract function.[2,3]

Veterinarians have an ethical obligation to treat animal pain. Most under-treatment of animal pain is probably a result of lack of adequate knowledge and not a lack of concern.

Outward show of concern for the pet and family is important to demonstrate a bond-centered approach to cancer therapy and pain management. Most owners who are willing to undergo the emotional stress and financial commitment to pet care have already shown they have a strong attachment to their pet. It is important for the veterinarian to foster good communication surrounding primary therapy and pain treatment and at the same time to demonstrate empathy for the owner. This fosters the doctor-client-patient relationship and will help build goodwill both within and outside of the practice.

Definitions

Having a working understanding of the terminology surrounding pain and analgesia is important. By knowing the terminology, practitioners can speak intelligently and accurately to one another when discussing their patients. Table 8-1 provides definitions, arranged alphabetically, that are commonly used when discussing pain.

Table 8-1. Definitions

- Acupuncture – The practice of inserting needles at certain points in the skin to achieve specific effects such as pain relief.
- Acute pain – Pain that follows some

bodily injury, disappears with healing, and tends to be self limiting.

- Allodynia – Pain caused by a stimulus that does not normally cause pain.
- Analgesia –The loss of sensitivity to pain.
- Anesthesia – Total or partial loss of sensation.
- Breakthrough pain – A transient flare-up of pain in the chronic pain setting, which can occur even when chronic pain is under control.
- Chronic pain – Pain that lasts several weeks to months and persists beyond the expected healing time when nonmalignant in origin.

- Cancer pain – Pain that can be acute, chronic, or intermittent and is related to the disease itself or to the treatment.
- Epidural – The space above the dura mater.
- Hyperalgesia – An increased response to a stimulation that is normally painful (a heightened sense of pain) either at the site of injury or in surrounding undamaged tissue. Stimulated nociceptors respond to noxious stimuli more vigorously and at a lower threshold.
- Local anesthesia – The temporary loss of sensation in a defined part of the body without loss of consciousness.

- Multi-modal analgesia – The use of multiple drugs with different actions to produce optimal analgesia.
- Neuropathic pain – Pain that originates from injury or involvement of the peripheral or central nervous system and is described as burning or shooting, possibly associated with motor, sensory, or autonomic deficits.
- Opioid – A drug that is related naturally or synthetically to morphine.
- Pain – an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such

damage.

- Preemptive analgesia – The administration of an analgesic drug prior to stimulation to prevent sensitization of neurons and wind-up (see below), thus improving postoperative analgesia.
- Regional anesthesia – The loss of sensation in part of the body by interrupting the sensory nerves conducting impulses from that region of the body.
- Somatic pain – Pain that originates from damage to bones, joints, muscle, or skin and is described in humans as localized, constant, sharp, aching, and throbbing.

- Wind-up – Sensitization of nociceptors, and peripheral and central pain pathways in response to a barrage of afferent nociceptive impulses resulting in expanded receptive fields and an increased rate of discharge.

Mechanisms of Pain

Textbook chapters and multiple review papers are dedicated to describing the mechanisms of nociception, transduction, modulations, and the perception of pain.[4-7] The following section provides an overview of what are considered the most important aspects of the mechanisms of pain. It is important to note that these concepts

may change over time as we develop a better understanding on a basic science level and an improved interpretation of these aspects in the whole animal.

The detection of tissue damage by specialized receptors in the periphery is referred to as nociception. These peripheral receptors, nociceptors, can be found in the skin, mucosa, deep fascia, connective tissue of visceral organs, ligaments, muscles, tendons, articular capsules, periosteum, and arterial vessel walls. Nociceptors are the distal end of the axons of first order neurons in the pain pathway. They are responsible for detecting and transmitting the location, quality, and duration of the stimulus. Nociception

occurs when the free nerve endings are activated on the distal terminals of A-delta and C nociceptors. The term nociception is used for the activity occurring from the periphery through the spinal cord to the brain. Pain, which is a conscious experience, requires integration with higher brain centers. Thermal, mechanical, chemical, and electrical stimuli may activate most nociceptors. Some, however, only respond to thermal or mechanical stimuli. The ability of a nociceptor to respond to a specific stimulus has been elucidated on a molecular basis. The cell bodies of the C fibers contain several unique molecules, which may be useful in the production of analgesic drugs in the

future. These molecules include TTX-R, a tetrodotoxin-resistant Na^+ channel; VR-1, the vanilloid receptor that is targeted by capsaicin; P2X3, a subtype of purinergic receptor; and DRASIC, an acid-sensing ion channel.[8-18] Once activated via the nociceptors, the nerve signal is propagated to the central nervous system via C fibers or A-delta fibers.

A-delta are small (1-6 μm) diameter myelinated fibers. They conduct at relatively high speeds, 5 to 25 m/sec. C fibers are smaller (< 1 μm) diameter unmyelinated nerves with slower conduction velocity, typically less than 2 m/sec. The primary afferent nociceptors contain a variety of

neurotransmitters, including glutamate, substance P, and calcitonin gene-related peptide. Glutamate is an excitatory amino acid, which acts upon several receptor subtypes to mediate rapid depolarization of dorsal horn neurons via an influx of Na^+ and an efflux of K^+. Substance P also activates subpopulations of dorsal horn neurons. Substance P can contribute to some of the long-term changes produced by persistent injury, as can the N_Methyl_D_Asparte (NMDA) receptor. The NMDA receptor gates Ca^{++} in addition to Na^+ and K^+ and can alter long-term dorsal horn processing.

The propagated stimulus from the periphery enters the spinal cord via the

dorsal roots of the spinal nerves where the first synapse takes place. The spinal nerves then innervate the different laminae of the gray matter of the dorsal horn of the spinal cord. The laminae are distinct layers of cells that form columns extending the length of the spinal cord. Laminae I, II, V, and VI are locations where incoming A-delta and C fibers typically synapse.

Local inhibitory interneurons and descending inhibitory pathways with origins in the brain stem, both in the dorsal horn, help regulate dorsal horn nociception. Most inhibitory interneurons use glycine or gaba (gamma-aminobutyric acid) as their neurotransmitters. These inhibit the

firing of dorsal horn neurons. Enkephalin and dynorphin also have inhibitory effects in some interneurons by causing hyperpolarization via increased K^+ conductance. Norepinephrine and serotonin have antinociceptive effects in the descending inhibitory pathways.

The second order neurons receive input from primary afferent fibers. These are located in the dorsal column nuclei and transmit signals to the higher centers of the brain via multiple parallel pathways including, but not restricted to, the spinothalamic, spinoreticular, spinocervicothalamic, neospinothalamic, and paleospinothalamic tracts. The

importance of the various tracts is likely to have species-specific importance. The spinothalamic and spinocervicothalamic tracts seem to play an important role in conveying nociceptive input in domestic species.

The spinothalamic tract has neurons that originate in lamina I and ascend to the thalamus. The spinoreticular tract has origins deeper in the dorsal and ventral horns, with neurons coming from laminae VII and VIII. These axons project to reticular formations at all levels of the brainstem.

The sensation of pain is produced in the lateral thalamocortical system of

the lateral thalamus and the primary and secondary somatosensory aspects of the cerebral cortex. Aversive reactions to noxious stimuli occur owing to projections to the medial thalamus, which sends projections to the limbic structures.

The gate control theory is a description of the physiologic mechanism of pain. Briefly, it states that sensory input is modulated by ascending and descending mechanisms in the central nervous system. In essence, the spinal cord acts like a gate, which increases or decreases the effect of the neural input before being processed by the brain, evoking pain perception and response.[19]

Traditional Chinese Medicine Aspects of Pain and Acupuncture Therapy

From a traditional Chinese medicine (TCM) perspective, pain can be a result of an excess condition leading to the obstruction of the circulation of Qi and blood. Examples of excess conditions contributing to pain include invasion of exterior pathogenic factors, interior cold or heat, stagnation of Qi or blood, obstruction by phlegm, and retention of food. Pain can also be caused by deficiency conditions such as deficiency of Qi and blood and consumption of body fluids from Yin deficiency. These conditions cause malnourishment of the channels, and

hence, pain. Stagnation of Qi causes distention with distending pain and no fixed location. Stasis of blood causes a severe boring pain in a small defined area.[20]

The principles behind acupuncture therapy are the restoration of a balance in the body. Acupuncture needles placed in appropriate proximal, local, and distal locations can help resolve the underlying causes of pain. This ultimately restores Qi and blood circulation to normal. With no obstruction, there is no pain.

Acupuncture Pain Relief

Acupuncture can be used a pain

relieving modality, often when conventional therapy does not work. It is also useful in conjunction with other therapy to allow lower doses of drugs that may have significant side effects. While some practitioners have difficulty accepting acupuncture because of traditional Chinese medical explanations, which may be scientifically untenable, it is important to remember that there exists well documented physiologic theory and evidence for its clinical effects.[21,22] In general acupuncture analgesia is extremely useful for pelvic, radius/ulna, and femoral bone pain as well as cutaneous discomfort secondary to radiation therapy. Acupuncture also helps alleviate nausea associated with

chemotherapy and some analgesics, as well as promoting general well being.

Physiology of Acupuncture Pain Therapy

Placement of needles at specific acupuncture points can relieve pain through several different mechanisms. First, acupuncture may decrease muscle spasms when inserted into trigger points. Lack of spasms will increase comfort considerably. Acupuncture can also induce release of a variety of neurotransmitters, which can affect the processing of the pain impulse. This effect can be enhanced with specific types of electrical stimulation. Proper needle placement

and low-frequency electrical stimulation (2-6 Hz) induces central release of endorphins and enkephalins, which may induce analgesia by inhibiting the transmission of nociceptive impulses from their origin to the brain and increasing the descending inhibition back to the periphery.[23] This type of stimulation usually produces analgesia in 10 to 20 minutes and is considered cumulative, meaning that subsequent treatments produce better and better analgesia. The analgesia produced by low-frequency stimulation can be abolished by the opioid antagonist naloxone.[24-26] High-frequency electrical stimulation (100-200 Hz) induces release of serotonin, epinephrine, and

norepinephrine, inducing noncumulative analgesia.[27-28] As opposed to low-frequency-induced analgesia, analgesia from high-frequency stimulation is not affected by naloxone.[29] High-frequency-induced analgesia has its major effect by increasing descending inhibition of spinal tracts. For postoperative analgesia, low-frequency stimulation is most efficacious.

Approach to Pain Management in the Small Animal Patient

Drug treatment is the cornerstone of pain management. It is effective and affordable for most patients and

owners. The general approach to pain management should follow the principles outlined further on. Individuals may suffer different side effects within the same category of drugs; therefore, if possible, it may be best to substitute drugs within a category before switching therapies. It is always best to try to keep dosage scheduling as simple as possible. The more complicated the regimen, the more likely that noncompliance will occur. Mild to moderate pain should be treated with a non-opioid such as a nonsteroidal anti-inflammatory drug (NSAID) or acetaminophen. As pain increases, some type of opioid should be added to the regimen. As pain becomes more severe, increase the dose

of the opioid. Drugs should be given on a regular basis, not just as needed, as pain becomes moderate to severe. Continuous analgesia will facilitate maintaining patient comfort. Additional doses of analgesics may then be administered as pain is intermittently more severe. Adjuvant drugs may be administered to help with specific types of pain and anxiety.

Principles of Pain Management

Three simple principles may be followed to avoid acute and chronic pain. The first principle is that pain control is good medicine. This follows from the earlier description of the

physiologic importance of avoiding pain. Once again, prevention and alleviation of pain keep normal patients reasonably healthy, prevent sick patients from developing unnecessary complications, and can preempt catastrophic events in critically ill patients. In the simplest sense, pain control helps patients heal more quickly and more effectively.

The second principle of pain management is the concept of preventative analgesia. This concept implies the provision of pain control before a potentially nociceptive or painful stimulus is induced. Problem pain is frequently associated with pathophysiologic changes that occur at

the level of the spinal cord and brain. These changes frequently involve the activation of NMDA receptors, resulting in central neuronal hypersensitization, commonly referred to as wind-up. As wind-up develops, the central neurons begin to exaggerate the stimulus, which enters the spinal cord, making the stimulus that eventually makes it to the higher centers of the brain of greater intensity than its peripheral origination, thus resulting in worsening pain. This can result in any of the NSAIDs or other analgesics having a tapering effect over time, even though the origin of the pain has not worsened.

The third principle of pain control is to

use drugs in a multimodal manner. This is simply the implementation of drugs or techniques that work at different levels of the nociceptive pathways and via different mechanisms. This means using some combination of opioids, nonsteroidal anti-inflammatory drugs, alpha-2 agonists, NMDA-antagonists, and local anesthetics.

Assessment of Pain

Assessment of pain in animals can be difficult and frustrating. Understanding types of pain and their causes can be helpful. Often veterinarians need to rely on the experience in humans to help define

the pain in animals. Technicians and other staff members are usually the ones who experience the postoperative period more than the doctors. Pain assessment typically is delegated to these staff members. Recognition and assessment of pain is the first and probably the most difficult step in providing analgesia to dogs and cats. It is often easiest to assume an animal is in pain if a person undergoing similar trauma or surgery would be in pain. A patient usually tolerates mild pain without a problem and does not exhibit any behavioral changes. Patients with mild pain often are not treated. Patients experiencing moderate pain usually exhibit changes in behavior, appetite, activity,

positioning, or posture, at least in the absence of human interaction. These patients also tend to respond significantly to palpation of the painful area. Severe pain can be thought of as intolerable, and is often manifested as unprovoked crying, whimpering, or howling associated with violent thrashing. Nonspecific physiologic responses to pain include elevated heart rate and blood pressure, abnormal cardiac rhythm, panting, salivation, dilated pupils, and unhandleable behavior. It is important to remember that differences in variables will occur among individuals, breeds, and species.

Classification as to origin of pain is

also important because some drugs have greater efficacy for different types of pain. Somatic pain originates from damage to bones, joints, muscles, or skin and is described in humans as localized, constant, sharp, aching, and throbbing. Visceral pain arises from stretching, distension, or inflammation of the viscera, and is described as deep, cramping, aching, or gnawing, without good localization. Neuropathic pain originates from injury or involvement of the peripheral or central nervous system and is described as burning or shooting, possibly associated with motor, sensory, or autonomic deficits.

Assessment of pain can be accomplished systematically with a

pain scoring scale.[30-31] The objective of a pain scoring system is to place a quantitative value on a specific variable, add up the variables and compare the total to some predetermined assessment of pain. There are many different pain score scales and no one is perfect. Some investigators have also used a visual analog scale (VAS) in animals. A VAS would need to be validated for several people at each practice to assure consistent scoring.

Failure to assess pain initially and throughout the course of treatment is a leading factor of under-treatment. Pain should be assessed early with the goal of characterizing the pain as to

location, intensity, and probable etiology. Client engagement in this process helps determine aggravating and relieving factors. After a good assessment is performed, goals for pain control can be set with the client.

Nonopioids

Nonopioid analgesics include drugs such as carprofen, meloxicam, tepoxalin, etodolac, deracoxib, firocoxib, acetaminophen, aspirin, ketoprofen, and etodolac (Table 8-2). All except acetaminophen are considered nonsteroidal anti-inflammatory drugs (NSAID). Despite the low anti-inflammatory activity of acetaminophen, it possesses beneficial

analgesic effects, minimal risk of bleeding in thrombocytopenic patients, decreased gastrointestinal effects, and synergism with opioid analgesics, such as codeine. Acetaminophen should be avoided in cats because of their inadequate cytochrome P-450-dependent hydroxylation.[32]

Table 8-2. Commonly used Nonopioid Analgesics

Drug	Dog Dose	Cat Dose
Acetaminophen (Tylenol®)	10 mg/kg PO q 12 hrs	CI
Carprofen (Rimadyl®)	4 mg/kg PO q 24 hrs	Uknown oral dosing
Carprofen	4.0 mg/kg IV,IM,SQ q 24 hr	1-3 mg/kg SQ ONCE
Meloxicam (Metacam®)	0.2 mg/kg PO q 24 hrs ONCE then 0.1 mg/kg PO q 24 hrs	Variable#: 0.1 mg/kg PO q 24 hrs x 4 days, then 0.05 mg/kg PO x 4 days; then 0.05 mg/cat PO x 4 days, then 0.
Meloxicam (Metacam®)	0.2 mg/kg SQ	0.2-0.3 mg/kg SQ
Tepoxalin (Zubrin®)	10 mg/kg PO q 24 hrs	UK
Deracoxib (Deramax®)	1-2 mg/kg PO q 24 hrs	UK
Firocoxib (Previcox®)	5 mg/kg PO q 24 hrs	UK
Ketoprofen (Ketofen®)	2.0 mg/kg PO for 1st 24 hrs then 1.0 mg/kg PO q 24 hrs	2.0 mg/kg PO for 1st 24 hrs then 1.0 mg/kg PO q 24 hrs
Ketoprofen	2.0 mg/kg IV, SC, IM q 24 hr	2.0 mg/kg SC q 24 hr
Etodolac (Etogesic®)	10-15 mg/kg q 24 hrs	UK
Piroxicam (Feldene®)	0.3 mg/kg q 24 hrs for 2 days then 0.3 mg/kg q 48 hrs	0.3 mg/kg q 48 hrs
Misoprostal *(Cytotec®)	2-5 μg/kg PO q 8 hrs	UK

CI = Contraindicated for use in cats; UK = unknown dose

 # Oral dosing for meloxicam long term in cats has not been well established via pharmacokinetics, but clinical efficacy is based on variable dosing regimens

***Synthetic prostaglandin E used to increase the protective effects of endogenous prostaglandins ($PGE_{2\alpha}$) and nonselective cyclooxygenase inhibition to help prevent GI ulceration.**

Mild to moderate pain, especially that arising from intrathoracic masses,

intraabdominal masses, minor fractures, mild soft tissue injuries, and bone metastases, can be relieved with NSAIDs. When pain increases, NSAIDs have an opioid-sparing effect so that better analgesia can be achieved with lower doses of opioids. NSAIDs have central analgesic and peripheral anti-inflammatory effects mediated via inhibition of cyclooxygenase. The choice of NSAID ultimately depends on available species information, clinical response, and tolerance of side effects. Most NSAIDs have been formally investigated only in dogs, leaving anecdotal information for use in cats. The most common side effect of NSAID administration in dogs is gastric irritation and bleeding owing to loss of

gastric acid inhibition and of cytoprotective mucus production normally promoted by prostaglandins. Other side effects include renal failure and hepatic dysfunction that may lead to failure.[33] NSAIDs that are more selective for inhibition of cyclooxygenase-2 (COX-2) seem to have fewer gastrointestinal effects and potentially fewer renal effects.[34,35] Therefore, more selective COX-2 inhibitors, such as carprofen, meloxicam, deracoxib, tepoxalin, firocoxib, and etodolac, should be considered priority NSAIDs in pain patients. A blood chemistry panel should be performed prior to initiating NSAID therapy. If evidence exists of liver or renal disease, dehydration or

hypotension, another approach to therapy should be considered. Therapy with NSAIDs, which are non-specific cyclooxygenase inhibitors, may also inhibit platelet function, leading to bleeding and oozing. Therapy with these NSAIDs should be stopped if this occurs. If clinical effectiveness is not achieved with one NSAID, it should be discontinued and another started 4 to 7 days later to avoid additive or synergistic cyclooxygenase inhibition effects. Aspirin should be avoided in dogs because of the increased possibility of gastrointestinal bleeding, even with buffered formulations.[36,37] Administering misoprostol can help provide gastrointestinal protection during the switchover period.

Opioids

Opioids are the major class of analgesics used in the management of moderate to severe pain. They are reasonably effective, predictable, and have low risk associated with them. The most common parenteral opioids used in small animals are morphine, oxymorphone, fentanyl, codeine, meperidine, buprenorphine, and butorphanol (Table 8-3). Parenteral opioids should be used in the perioperative period and should be discontinued when a patient can be switched to oral medication. Common oral opioids include morphine and codeine with or without acetaminophen. An opioid-like oral

drug that is becoming more commonly administered is tramadol.

As a patient's pain increases, the required dose of opioid also increases. Veterinarians may be reluctant to administer high doses of opioids for fear of adverse side effects. It is important to remember that veterinarians have an ethical obligation to benefit the patient by alleviating pain. Opioids can be administered while managing side effects to maximally help the patient. Side effects of opioid administration include diarrhea and vomiting initially, constipation with long-term use, sedation, and dysphoria. The initial gastrointestinal effects occur most

frequently with the first injection in the perioperative period and usually do not occur with subsequent dosing. These effects usually do not occur with oral dosing. When sending a patient home with oral medications, it is important to discuss with the owner that dosing is highly individual. It is possible that a given dose may be perfect, or it does not provide enough analgesia, induces sedation, or induces dysphoria or excitement. Adjusting of the dose requires excellent doctor-client interaction. Bradycardia is also possible after opioid administration, but is most common if opioids are administered parenterally. If bradycardia occurs, an anticholinergic, such as atropine or glycopyrrolate,

should be administered, rather than discontinuing the opioid.

Opioids are classified as full mu-receptor agonists, partial agonists, and kappa agonist--mu antagonists. Examples of the full mu-receptor agonists include morphine, oxymorphone, fentanyl, codeine, and meperidine. In normal, healthy animals, opioids may produce sedation, which is usually acceptable, or dysphoria, an exaggerated unrest, which usually is undesirable. Full mu agonists induce the best analgesia in a dose-dependent manner and are not limited by a ceiling effect. As pain increases, larger doses may be administered. Morphine should be the

most commonly used opioid for severe pain. It is available in multiple injectable and oral formulations, including short-duration tablets and liquids and sustained release tablets. Oral morphine may be the most effective method for providing longer term analgesia to dogs with moderate to severe pain. Patients receiving analgesics at set dosing intervals should also be provided with some short-duration opioid for breakthrough pain. While the pharmacokinetics of oral morphine in dogs are variable, the clinical efficacy seems to be highly reliable.[38,39]

Oxymorphone is only available as an injectable analgesic and may induce

panting, by changing the temperature set point in the brain.[40] This usually is not an issue, except when attempting thoracic or abdominal radiography. Hydromorphone, like oxymorphone, is a pure mu-receptor agonist and can induce the same degree of analgesia as morphine. Meperidine is short acting in animals, limiting its use as an analgesic in patients with severe pain. Codeine is available alone or with acetaminophen, allowing some flexibility in choice of oral medications. Fentanyl is an injectable drug that is potent and equally effective as morphine. All of the previously mentioned parenteral opioids may be administered by intermittent intravenous,

intramuscular, or subcutaneous routes. A problem with this type of intermittent dosing is that patients often develop pain before their subsequent dose, then are extremely sedate after dosing. An alternate dosing regimen would use continuous infusion of an opioid. Fentanyl, morphine, hydromorphone, and oxymorphone are appropriate drugs for continuous infusion. Fentanyl may be especially suited to continuous infusion therapy because it is short acting. This enables the practitioner to alter the dose as necessary from minute to minute to achieve good analgesia and potentially minimal sedation if desired.

Buprenorphine is an example of a partial mu agonist. It does not produce the same degree of analgesia as does morphine and has a ceiling effect. The advantage of buprenorphine is that it has a long duration of action, 6 to12 hours. It also has a long time to onset, approximately 40 minutes, even when given intravenously. Buprenorphine is a unique drug in that larger doses may actually produce less analgesia owing to a bell-shaped dose-response curve. Tapering the dose to the individual maybe difficult. If an animal does not have adequate analgesia after receiving buprenorphine, dosing with a morphine-like drug may not produce any results because of buprenorphine's strong affinity for mu-opioid receptors.

Buprenorphine is not easily reversible. Experimentally, it takes 1000 times the normal dose of naloxone to reverse it in a normal dog.[41-43] Because of the inherent lack of maximal analgesia compared with morphine, buprenorphine should be used only for mild to moderate pain.

Buprenorphine can also be administered transmucosally in cats (Table 8-3). Owing to the pH of a cat's mouth, buccal buprenorphine has good uptake, resulting in pharmacokinetics that parallel intravenous administration.[44-46] Cats can usually tolerate 2 days of administration of buccal buprenorphine before developing unacceptable sedation.

Another group of opioids that are available are the kappa agonist--mu antagonists, of which butorphanol is an example. Butorphanol may reverse the effects of drugs like morphine, a pure mu agonist, but provides analgesia and sedation of its own. Butorphanol is also reversible with naloxone and nalmefene. Butorphanol cannot induce the same maximal analgesia as morphine, having a ceiling effect at moderate doses of pain. Even in large parenteral doses, butorphanol produces analgesia of short duration in dogs.[47] These last two properties may limit butorphanol's utility for treatment of severe pain.

Tramadol is an opioid-like drug that

also inhibits serotonin reuptake.[48] Tramadol is a useful adjunct to NSAID therapy in patients with moderate pain. The pharmacokinetics seem to indicate the need for large doses administered frequently in dogs, although the clinical experience may indicate otherwise (Table 8-3).

Table 8-3. Commonly used Opioid Analgesics

Drug	Dog Dose (mg/kg) and Route	Duration in Dogs (hrs)	Cat Dose (mg/kg) and Route	Duration in Cats (hrs)
Morphine	0.5-2.2 SQ, IM	3-4	0.25-0.5 SQ, IM	3-4
Morphine	0.1-0.2 IV	1	0.05-0.1	1
Morphine: liquid; immediate release tablets	1.0-4.0 PO	4-6	0.5-1.0	4-6

NAD: Not applicable to dogs due to oral pH

**** Duration is dependent upon infusion duration;**

CI= Contraindicated in cats

An alternative to oral opioids for

providing multiple-day analgesia is through transdermal fentanyl patches (Table 8-3). Fentanyl patches require 12 to 24 hours to take effect and last 2 to 4 days. Additional analgesia must be provided during the first 0.5 to 1 day after patch placement. One problem with transdermal fentanyl is related to unreliable plasma levels in dogs,[49-51] probably related to failure of patch application or inappropriate dosing. Fentanyl patches may not provide enough analgesia for severe pain,[52] but they allow lower doses of additional drugs. Fentanyl patches are expensive and should not be the first approach to chronic therapy. Transdermal fentanyl is most appropriate in those patients that do not tolerate oral medication.

Epidural opioids, especially morphine (Table 8-3), have been used as a method for perioperative analgesia. With placement of an epidural catheter, epidural opioids can be administered for days to weeks. Epidurals are discussed later in this chapter.

The appropriate dose of an opioid is that dose which produces analgesia with the fewest side effects. The need for increased doses often reflects progression of disease. Long-term use may produce opioid tolerance, increasing doses or frequency to achieve equivalent results. As previously mentioned, veterinarians should not be afraid of increasing

doses in patients and should remember the need for analgesia. A distinct advantage of using opioids for pain control is that they are reversible with naloxone or nalmefene if unacceptable side effects occur. Prolonged use may produce constipation. Oral laxatives can help alleviate this problem.

Alpha-2 Agonists

Medetomidine and xylazine are two alpha-2 agonists approved for use in small animals in the United States (Table 8-4). They are non-controlled parenteral agents that provide excellent visceral analgesia, but only for 20 minutes to 2 hours.[53] Their effects can be nearly completely

reversed with yohimbine or atipamezole, respectively. Xylazine and medetomidine should not be the first or sole choice in providing analgesia perioperatively to patients in moderate to severe pain because they greatly reduce cardiac function and, potentially, oxygenation.[54-56] Xylazine and medetomidine have synergistic effects with opioids. This effect,which can be achieved with microdoses, is useful postoperatively for inducing additional analgesia and alleviating dysphoria.

Ketamine

Ketamine has been used for many years as an induction agent to general

anesthesia in normal and compromised patients (Table 8-4). It has been well established that ketamine provides reasonable somatic but poor visceral analgesia.[57] Recently, ketamine has been identified as a NMDA receptor antagonist. N-methyl-D-aspartate receptors are believed to play a role in the processes leading up to central sensitization and wind-up. As an NMDA receptor antagonist, ketamine reduces postoperative pain and cumulative opioid requirements for a variety of procedures in humans and dogs.[58-59] This is accomplished with doses that are much smaller than those for anesthesia. As such, it is uncommon for patients to develop behavioral or cardiovascular effects. Micro-dose

ketamine appears to provide beneficial effects for a variety of surgical procedures, limb amputations, and major fracture repairs. When used in this manner, ketamine should be administered as a bolus (0.5 mg/kg IV) followed by an infusion (10 μg/kg/min) prior to and during surgical stimulation. A lower infusion rate (2 μg/kg/min) may be beneficial for the first 24 hours postoperatively and an even lower rate (1 μg/kg/min) for the next 24 hours. In the absence of an infusion pump, ketamine can be mixed in a bag of crystalloid solutions for administration during anesthesia. Using anesthesia fluid administration rates of 10 ml/kg/hr, 60 mg (0.6 ml) of ketamine should be added to a 1 liter

bag of crystalloid fluids to deliver ketamine at 10 µg/kg/min.

Table 8-4. Adjunct Drugs to Management of Pain

Drug	Route	Dose
Acepromazine	IV	0.005-0.03 mg/kg
Acepromazine	SQ, IM	0.02-0.05 mg/kg
Diazepam /Midazolam (Versed®)	IV	0.1-0.2 mg/kg
Xylazine	IV	0.05-0.1 mg/kg
Xylazine	IM	0.2 mg/kg
Medetomidine (Domitor®)	IV	0.001 mg/kg
Medetomidine	IM	0.002 mg/kg
Amitriptyline (dog) (Elavil®)	PO	1-2 mg/kg q 12-24 hrs
Amitriptyline (cat)	PO	2.5-12.5 mg /cat q 24 hrs
Imipramine (dog) (Tofranil®)	PO	0.5-1.0 mg/kg q 8 hrs
Imipramine (cat)	PO	2.5-5 mg/kg q 12 hrs
Clomipramine (Comicalm®)	PO	2-4 mg/kg PO q 24 hrs
Ketamine	IV	0.5 mg/kg bolus followed by 0.6 mg/kg/hr during surgical stimulation followed by 0.12 mg/kg/hr for 24 hrs

Doses are the same for dogs and cats unless otherwise described

Tranquilizers

A concern that frequently arises with pain management is concurrent

tranquilization and sedation. Most of the drugs used by veterinarians usually produce concurrent sedation. As mentioned previously, opioids have the greatest potential of producing dysphoria, instead of sedation. Dysphoria becomes more likely when cats are administered higher than necessary doses of opioids and when a patient is already experiencing high anxiety in the hospital. Dysphoric patients can sometimes be treated simply by petting and soothing, or by helping the patient change positions. Low-dose acepromazine, both IV and/or IM is reasonable drug therapy for dysphoria (Table 8-4). While acepromazine does not treat pain, it calms anxious patients very well and

also makes them care less about their pain. For patients in which acepromazine is contraindicated, those with bleeding and seizure disorders, the benzodiazepines, diazepam and midazolam, often calm patients (Table 8-4). Benzodiazepines should not be used by themselves in most alert patients as they frequently cause excitement. Combined with opioids, sedation usually results. In patients that are hemodynamically stable, a microdose of medetomidine, IV, also can decrease dysphoria and increase analgesia.

Patients that develop dysphoria after oral analgesic medications often respond well to oral acepromazine or

diazepam. It is important to discern whether the opioid dose is effective before changing the analgesia regimen.

Tricyclic Antidepressants

Tricyclic antidepressants, such as amitriptyline, imipramine, and clomipramine block the re-uptake of serotonin and norepinephrine in the central nervous system. They also have antihistamine effects. These drugs have been used in humans for the treatment of chronic and neuropathic pain at doses considerably lower than those used to treat depression.[60] Veterinarians have not used tricyclic antidepressants in this manner for

long, but they appear to induce similar analgesic properties and enhance opioid analgesia as they do in humans (Table 8-4).

Local Anesthetics

The use of local and regional anesthetic techniques in small animals was common in the early 20th century. Interest has increased in these techniques, probably owing to their ability to provide preemptive analgesia and decrease wind-up. Local anesthetic techniques can be used instead of general anesthesia in selected cases or, more commonly, in combination.

The most commonly used local

anesthetics include lidocaine and bupivacaine (Table 8-5). Lidocaine has a short onset (< 1 min) and lasts approximately 60 to 90 minutes. Doses of 1.5 to 2.0 mg/kg are safe in dogs and cats. Signs of toxicity are manifested as neurologic changes, including seizures. Bupivacaine takes approximately 20 minutes to take effect, but may last for 5 to 8 hours. Whereas lidocaine has antidysrhythmic effects at low to moderate intravenous doses, bupivacaine has cardiotoxic effects when administered intravascularly. Inadvertent IV administration can result in death.[61-64] Epinephrine may be added to bupivacaine in a 1:200,000 dilution to cause local vasoconstriction and

prolonged duration. Epinephrine should not be used for peripheral blocks because collateral circulation may not be available to provide adequate perfusion to distal tissues. Combinations of lidocaine and bupivacaine are often used to achieve quick onset and long duration. This is especially necessary when using local anesthetics interpleurally. Because of its long onset, bupivacaine causes stinging and discomfort. Lidocaine administered concurrently limits the discomfort to a period of seconds.

Local anesthetics have numerous uses. They are often used epidurally to produce either better analgesia in low doses or anesthesia for caudal

procedures in higher doses. They may be used interpleurally for thoracic and cranial abdominal pain. Intercostal nerve blocks are easily performed for lateral thoracotomy pain. Brachial plexus infiltration provides anesthesia for procedures distal to the elbow. Maxillary, infraorbital, mandibular, and mental nerve blocks are commonly used for procedures involving the face and mouth. Local infiltration is common for procedures involving the ear. Ring blocks have also been used for distal limb and digit amputations. Many of these techniques have been well described.[65]

Epidurals

Epidural administration of drugs requires additional skill and expertise that may not be available in all clinical settings. With epidural administration, a needle is placed on the dorsal midline and advanced at the lumbosacral junction through the ligamentum flavum until one encounters a loss of resistance. This technique has been well described.[65,66] Epidural morphine is commonly administered in the perioperative period to provide analgesia, but not anesthesia, for the abdomen or more caudally. In some instances, analgesia may be effective for the thorax and forelimb. This analgesia may last up to 24 hours.[67] Local anesthetics may also be administered epidurally as a low

dose to augment epidural morphine-induce analgesia or at a higher dose to produce anesthesia.

Table 8-5. Doses of Local Anesthetic

Type of Block	Lidocaine (mg/kg)	Bupivacaine (mg/kg)
Epidural anesthesia to L2	2.0	1.5-2.0
Epidural anesthesia to T5	4.0-6.0	2.0
Epidural analgesia (administered with epidural morphine)	0.5-0.2	0.03-0.1
Interpleural	1.5 (given with bupivacaine)	1.5 (given with lidocaine)
Miscellaneous nerve blocks	1.5-2.0 maximum*	1.5-2.0 maximum*

***The maximum dose should be divided among all blocks to be performed**

A catheter can also be placed in the epidural space for severe pain that may be intractable in the caudal portion of the body. Maintenance of this catheter requires veterinarian and client vigilance to assure cleanliness

and prevent infection migrating to the spinal cord. With proper care, an epidural catheter can remain in place for days to weeks.

Conclusion

The understanding of pain and its alleviation is a constantly evolving science. While we know more now than ever before, new information changes our approach to patients almost daily. Veterinarians have a physiologic and ethical obligation to treat pain to help assure optimal well being of their patients. The current understanding of pain medicine allows veterinarians to effectively treat the vast majority of patients with acute

painand a large number of patients with chronic pain. While chronic pain may be more of a challenge, no patient should be euthanized because of pain if the owners have the means to explore multiple modalities.

Chapter 9

Principles of Metastasis

Susan E. Lana

In spite of the advances made in diagnostic approaches, surgical techniques, adjuvant chemotherapy, and radiation therapy, metastasis to distant sites remains the leading cause of cancer related death.[1-3] Unfortunately these metastatic foci can also be resistant to conventional therapies.[4] A significant amount of research has focused on the biologic and molecular events involved in this

process, however much remains unknown. The purpose of this chapter is to provide an overview of the complex process of metastasis.

Metastatic Cascade

The process of metastasis is a series of sequential events or steps that must be completed for successful dissemination of a tumor to occur.[5] The metastatic cancer cell has often been referred to as the decathlete of cells for its ability to leave the primary tumor, enter the circulation, evade host defenses and physical stress, exit the vasculature and recognize an appropriate distant organ where it must interact in a sometimes hostile environment, divide, and

continue to grow.[6] Because of theses multiple complex steps one can imagine that metastasis is a highly inefficient process. In fact, experimental models have shown that less than 0.01% of cells injected intravenously actually form viable tumor foci.[5] Additionally, the process of metastasis is not random and each step can be rate limiting, with failure to succeed at any point resulting in disruption of the process.

Several steps in this process, often referred to as the metastatic cascade, are discussed in the following.

Angiogenesis

As a tumor grows beyond a size that can be sustained by simple diffusion of nutrients from the immediate environment, hypoxic areas arise and the tumor initiates development of its own blood supply. This is usually the result of increased production of pro-angiogenic factors such as basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), and platelet-derived growth factor (PDGF) either by the tumor or the surrounding host cells in response to tumor signals.[8,9] At the same time, suppression occurs of anti-angiogenic factors such as interferon alpha, thrombospondin, and endogenous protease inhibitors.[5] New vessel growth from existing vasculature has

been believed to be the end result of this imbalance of factors; however, evidence is increasing to support the hypothesis that circulating endothelial progenitor cells (CEPs) derived from the bone marrow also play a significant role in tumor angiogenesis.[10] Regardless of the source, vascularization of tumor foci greatly increases the potential for metastasis.

Detachment

Cells must detach from the primary mass to start the journey to a distant location. To do this, down regulation occurs in cell-to-cell adhesion molecules such as E-cadherin as well as

alterations in how the cell interacts with the extracellular matrix (ECM).[11] Change in cell mobility is also required and is associated with altered cytoskeletal elements in response to tumor-derived factors acting in an autocrine fashion, as well as host-secreted factors. Tumor cells may also secrete proteases that facilitate detachment.[5]

Invasion

Once a cell separates from the primary tumor and enters the ECM it must gain access to the vasculature. Degradative proteolytic enzymes are produced by the tumor or host support cells to facilitate this process. These include

cathepsins, matrix metalloproteinases, and plasminogen activators. An increase in these enzymes has been associated with greater metastatic potential in several tumor types.[12] Tumor cells that bind to basement membrane components such as laminin or fibronectin also have a metastatic advantage.

Survival in the Circulation

At this point tumor cells must avoid host immune defenses and are susceptible to destruction by immune effector cells such as lymphocytes, monocytes, and natural killer cells. Other reasons for circulatory death include mechanical stresses associated

with turbulent flow and high oxygen tension leading to toxicity. The host may also trigger apoptosis of tumor cells in the circulation through a variety of signals.[11]

Arrest and Extravasation

Cells or aggregates of cells (emboli) must stop at a distant vascular bed to begin the extravasation process. This arrest can be facilitated by the mechanical size of the emboli compared with the capillary or, more likely, is mediated by tumor cell attachment to specific cell surface markers such as E-selectin or CD-44. Arrest can also occur when endothelial cells are damaged and the basement

membrane is exposed.[5] Cells can then attach to basement membrane components such as laminin, type IV collagen, and other proteoglycans similar to the process that occurs during invasion into the vascular space. These interactions are facilitated by cell surface adhesion molecules such as integrens.[11]

Organ Specificity

Clinical as well as experimental observations have shown that certain tumors tend to metastasize to certain locations preferentially. This is exemplified in Paget's "seed and soil" hypothesis, which was proposed to explain the apparent non-random

pattern of tumor spread observed in visceral organs and bones.[4] This theory states that specific interactions between the metastasizing tumor cells and the target organ environment must occur and be favorable in order for tumor foci to survive and grow. Another theory of organ preference is based on hemodymanic factors such as the number of metastases that occur in an organ is related to the number of tumor cells delivered there by the flow of blood. In reality the theories are not mutually exclusive.[11] Rodent models demonstrating organ preference of metastatic cells are well documented in the literature. An example of this also exists in a clinical observation of ovarian cancer patients who have

peritoneovenous shunts placed to palliate ascites build up. Ovarian cancer cells will readily grow in ascetic fluid and on peritoneal and organ surfaces. They rarely, however, spread beyond the abdominal cavity. When a shunt is placed, millions of tumor cells are dumped into the venous circulation, theoretically increasing the chance of hematogenous metastasis. Clinical observations at the time of patient death by Tarin and colleagues, however, did not show any increase in metastasis outside the abdominal cavity, supporting the need for the appropriate "soil" to ensure metastatic cell growth.[4,13] Our understanding of the tumor-host microenvironment has increased. Each organ likely has a

unique set of growth factors, differentially expressed endothelial receptors and cell surface receptors that allow for unique cross talk with available metastasizing cells, encouraging or discouraging tumor growth.[4] One example of this cross talk is the finding that chemokine receptors may play a role in organ specificity. It has been shown in vitro that breast cancer cells have a high expression of CXCR4 and CCR7 and that the ligands for these receptors are highly expressed in organs where breast cancer preferentially spreads, including the lung and liver. Additionally, blocking the specific receptor ligand interaction can decrease metastasis experimentally.[14]

New Considerations

Disseminated Tumor Cells and Tumor Dormancy

The use of sensitive immunocytochemical stains and PCR strategies has allowed for the detection of disseminated tumor cells in sites such as the bone marrow where clinically evident macrometastases rarely occur. One example of this has been reported in 550 breast tumor patients where 30 to 40% of cells taken from the bone marrow had markers specific for epithelial tumors compared with 1% of the 200 non-cancer bearing individuals sampled. The presence of these cells also predicted a worse prognosis.[15]

Additional studies have shown that 20 to 40% of patients with carcinomas from various primary sites have cells detectable in the bone marrow even with no evidence of lymph node or distant organ metastasis.[3] The implications of the discovery of these cells may indicate that the bone marrow may be a reservoir for malignant cells either to remain dormant or to adapt prior to establishing metastatic foci in other organs.

Genetic and phenotypic profiling of these cells compared with the primary tumor has shown significant differences, supporting the theory that these cells change and develop unique

characteristics after leaving the primary tumor, perhaps even early in tumor development.[3] This theory proposes that cells neither proliferate or die, instead remain quiescent. These cells are probably resistant to traditional chemotherapeutics that typically target dividing cells.[1] The dormancy of cells can be reflected in the lag time that exists between the removal of a primary tumor and the development of detectable metastatic foci. Detection of disseminated cancer cells early in the course of disease might help guide therapy by predicting which patients actually need adjuvant therapy post-surgical excision of the primary tumor. For example 90% of breast cancer patients without lymph

node metastasis will have adjuvant therapy recommended, whereas only 20 to 25% of those individuals will likely develop metastasis within the first 10 years, indicating that some patients may be overtreated.[16]

Therapeutic considerations also need to be given to these disseminated cells especially when targeted therapies become routinely incorporated into cancer treatment. If the primary tumor expresses one target and the disseminated cells another, one subpopulation may go untreated.

Gene Expression Profiling and the Metastatic

Phenotype

In longstanding models of metastasis it has been believed that, within any given tumor, a small subpopulation of cells develop and are genetically altered to acquire the advantages needed to become metastatic.[2] This implies that the ability to metastasize happens late in tumor progression. Several studies have challenged this, including ones in breast cancer using microarray platforms to profile gene expression. These studies have shown that the differences in gene expression of the primary tumor can predict whether the tumor will spread or remain localized. In one study by Van De Vijver et al, tumors from 295 early-stage breast cancer patients were

screened using a 70-gene prognosis profile dividing the population into poor and good gene signature groups. Patients with a poor signature (n = 180) had a 10-year survival of 55% compared with 94% for those in the good signature group (n = 115). Additionally the probability of remaining metastasis free was 51% in the poor prognosis group compared with 85% in the good prognosis group. Even in multivariate analysis, the gene profile status remained a strong independent factor at predicting disease outcome.[17] The authors of this study concluded that gene profiling was potentially a more powerful predictive tool than standard clinical and histopathologic criteria. The

genetic background of the host may also influence the efficiency of the metastatic process, with certain individuals having the genetic profile that favorably supports tumor spread. If these individuals can be reliably identified, investigation of cancer preventative measures might be warranted.[18,19]

Conclusion

As more is learned about the process of metastasis, it is clear that many unanswered questions exist and that new technologies will help elucidate the intricacies of this complex process. From a therapeutic standpoint, it is also evident that not only must the

metastatic tumor cell be targeted, but so must the host-produced factors that promote tumor cell growth, survival, invasion, and metastasis.

Chapter 10

Organ Transplantation – The Rejection Response

Clare R. Gregory
Andrew E. Kyles
Margo Mehl

In the late 1800s and early 1900s, surgeons gained the technical ability to transplant organs and tissues from one animal to another. It soon became evident that, following transplantation, the organ would rapidly become ischemic and necrotic.

In 1923, Dr. Carl Williamson, at the Mayo Clinic, demonstrated that cells of the immune system were responsible for the death of transplanted tissues and organs. This discovery set the stage for the study of immune-mediated rejection and the development of effective immunosuppressive strategies.[1]

Transplantation of organs and tissues in veterinary medicine is becoming more common. Corneal transplantation is performed to replace diseased or scarred corneas. Corneoscleral transplantation is performed for the treatment of canine epibulbar melanomas. Allogeneic bone marrow transplantation has been

performed in cats to aid in the treatment of lymphohematopoietic neoplasias, aplastic anemias, and feline retrovirus infections. In the dog and cat, for the treatment of acute and chronic renal failure, kidney transplantation is performed at university hospitals and private practices. Feline renal transplant patients have now survived for over 13 years with normal renal function.

Nomenclature

A graft is tissue or an organ used in a transplant procedure. An autograft is tissue or an organ that is removed from and then transplanted on or into the same individual. A common

example is a cancellous bone graft used to speed fracture healing. Autografts do not incite a rejection response. An isograft is tissue or an organ transplanted between two genetically identical individuals; identical twins or closely inbred individuals. An allograft is tissue or an organ transplanted between genetically nonidentical members of the same species. Virtually all renal transplants performed in clinical veterinary medicine are allografts. A xenograft is tissue or an organ transplanted between members of different species.

Mechanism of the Immune

Response to an Allograft[2-4]

Rejection of the transplanted tissue or organ is determined by T-cell (lymphocyte) recognition of differences in the composition of cell surface glycoproteins between graft and host tissues. These glycoproteins are termed histocompatibility antigens or histocompatibility molecules. The histocompatibility antigens that incite the most vigorous rejection response are encoded by genes of the major histocompatibility complex (MHC).

A MHC is found in all vertebrates. In dogs, this cluster of genes on a single chromosome is termed the dog leukocyte antigen (DLA); in cats it is

termed the feline leukocyte antigen (FLA). Polymorphism, or the presence of many different variations of the same gene (alleles) at a single location, or locus, is characteristic of the MHC. Each individual will have two, one on each paired chromosome, of many possible alleles at each locus in his or her MHC. This variation in the genetic makeup of the MHC results in the production of a tremendous variety of cell surface histocompatibility antigens. This variety ensures that the host T-cells will recognize virtually all tissue and organ allografts as foreign, resulting in a rejection response.

The genes of the MHC are closely linked, and the genetic information

inherited from each parent on a single chromosome is transferred as a block. This group of genes is termed the MHC haplotype; each offspring receives one haplotype from each parent. The genes of each haplotype are expressed codominantly; therefore, cell surface histocompatibility derived from each parent will be present in the offspring. This basic understanding of the genetics of the MHC is important clinically, particularly in a species like the dog, in which it is difficult to immunosuppress or control the rejection response. Because each offspring inherits one haplotype from each parent and each haplotype is expressed codominantly, 25% of littermates have the possibility of

being MHC identical, 50% might share one haplotype, and 25% will not share a haplotype. Without the administration of immunosuppressive agents, renal allografts from MHC-nonmatched dogs survive approximately 10 days, renal allografts from dogs matched for one haplotype survive approximately 24 days, and MHC-matched allografts survive for 150 days or more. In the latter group, the rejection response can be more readily controlled using immunosuppressive agents; therefore, selection of MHC-identical littermates as donor/recipient pairs can greatly enhance the chance of long-term graft survival.

The fact that allograft survival is not indefinite when a dog receives a kidney from an MHC-identical donor demonstrates that the MHC is not the only genetic region coding for histocompatibility antigens. Minor histocompatibility genes have been isolated in mice and human beings and probably code for changes in peptide structure in endogenous proteins that allow recognition by host T-cells, but do not affect their physiologic function. Fortunately, the rejection response produced by minor histocompatibility differences is relatively easy to prevent using immunosuppressive agents.

It is important to understand that the

MHC-encoded cell surface glycoproteins, or transplantation antigens, did not evolve to prevent the transplantation of genetically dissimilar tissue and organs, but rather to protect the host from invasion by viruses, fungi, nematodes, and other parasites. To do so effectively, the immune system must distinguish between antigens against which an immune response would be beneficial (pathogenic or allogeneic) or harmful (host or self). In the thymus, during fetal development, T-cells are propagated or destroyed based on their ability to recognize MHC glycoproteins as “self” or “nonself.” The interaction between MHC glycoproteins and T-cells, in the presence of antigen, results

in a series of transmembrane and cytosolic chemical reactions that result in T-cell cytotoxic activity and the production and/or release of cytokines. Cytokines (interleukins [ILs], tumor necrosis factor [TNF], and others) result in the further activation of T-cells, B-cells, macrophages, and other immunoreactive cells.

The cell surface glycoproteins of the MHC are divided into two major classifications: Class I and II. Class I glycoproteins or molecules are expressed on all nucleated cells. Class I molecules have a folded region that holds and presents antigens from virus-infected, tumor, and allogeneic cells to antigen-responsive cytotoxic ($CD8^+$) T-

cells. The linkage of the T cell receptor – CD8 complex on the surface of cytotoxic T-cells with the class I molecule-antigen complex of allograft or antigen-presenting cells (monocytes, macrophages, Langerhans cells of the epidermis, and dendritic cells of lymphoid organs) results in the proliferation and differentiation of a clone of cytotoxic T cells specific for that class I-antigen combination. Thus, the cytotoxic activity of T-cells is both antigen specific and class I restricted.

Class II molecules are only constitutively expressed on the surface of cells that are essential for immune responses. These include B-cells (lymphocytes), thymic epithelial cells,

and the cells listed above that present antigen to T-cells. T cells, vascular endothelial cells, smooth muscle cells, and others can express class II antigens when activated by cytokines such as interferon-γ (INF-γ). The function of class II molecules is similar to that of class I. Antigen-sensitive T helper cells ($CD4^+$) recognize the class II-antigen complexes on allogeneic or antigen-presenting cells. The linkage of the CD4-T-cell receptor complex with the class II-antigen complex results in the proliferation and differentiation of a clone of T helper cells specific for that class II-antigen complex. Activated T helper cells begin the cascade of events responsible for acute allograft rejection by the release of cytokines (IL-2, IL-3,

IL-4, IL-5, IL-6, INF-γ, TNFs, granulocyte macrophage colony stimulating factor [GM-CSF], and others) that propagate an inflammatory response, activate cytotoxic cells, and promote antibody formation.

In addition to their role as antigen-presenting molecules, it is believed that foreign class I and class II molecules, in the absence of antigen, may stimulate alloreactive T cells and serve as the stimuli for rejection reactions. Also, rejection may be initiated following T-cell recognition of class I or II - minor histocompatibility antigen complexes.

The allograft rejection response begins with the migration of antigen-presenting cells of the host or donor organ to T-cell areas of secondary lymphoid organs. These T cells circulate between lymphoid tissues, regulated by chemokine and sphingosine-1 phosphate receptors. T-cell activation by allogeneic or antigen-presenting cells requires cell contact and cell surface molecule interaction. Cell surface molecules that interact are termed “ligand-receptor pairs.” A ligand is any molecule that forms a complex with another molecule. Antigen presentation through class I or class II molecules can be split into four stages that produce three signals needed to stimulate the

rejection reaction: adhesion, antigen-specific activation, co-stimulation, and cytokine signaling (Figure 10-1). Association of the antigen-presenting cells and T cells first involves nonspecific, reversible binding through adhesion molecules such as LFA-1and ICAM. When the T-cell receptor complex is presented with an alloantigen, a conformational change occurs in the adhesion molecules that results in tighter binding and prolonged cell to cell contact. The first signal of the rejection response is provided by the class I/antigen-CD8/T-cell receptor ligand-receptor pair and the class II/antigen-CD4/T-cell receptor ligand-receptor pair (CD3 complex) (Figure 10-2). The specific

MHC/peptide – T-cell receptor interaction, although necessary, is not sufficient to fully activate the T cell. A second signal is required, otherwise the T cell becomes unresponsive. The second signal, also termed co-stimulation, is of critical importance (Figure 10-3). Two of the most potent co-stimulatory molecules expressed on antigen-presenting cells are B7-1 (CD80) and B7-2(CD86). They are ligands for the T-cell molecules CD 28 and CTLA-4. CD28 is the main co-stimulatory ligand expressed on naïve T cells. CD28 stimulation has been shown to prolong and augment the production of IL-2 and other cytokines and is probably important in preventing the induction of tolerance.

CTLA-4, the alternative ligand for B-7 is an inhibitory receptor, limiting T-cell activation, and resulting in less IL-2 production. CD28, which is constitutively expressed, initially interacts with B7, producing signal 2 that leads to T-cell activation. The upregulation of CTLA-4, which has a higher affinity to B7 than CD28, limits the degree of activation. Signals 1 and 2 activate 3 signal transduction pathways: the calcium-calcineurin pathway, the RAS-mitogen-activated pathway (MAP), and the nuclear factor-kB pathway. These pathways activate transcription factors that bind to regulatory proteins in enhancer regions of specific genes involved in proliferation and differentiation,

including cytokines such as IL-2, cytokine receptors such as IL-2R (CD25), and receptors involved in co-stimulation such as CD40L (CD154). Interleukin and other cytokines produce signal 3 via activation of the mammalian target of rapamycin (mTOR) pathway. This pathway is the trigger for cell proliferation (see Figure 10-2).

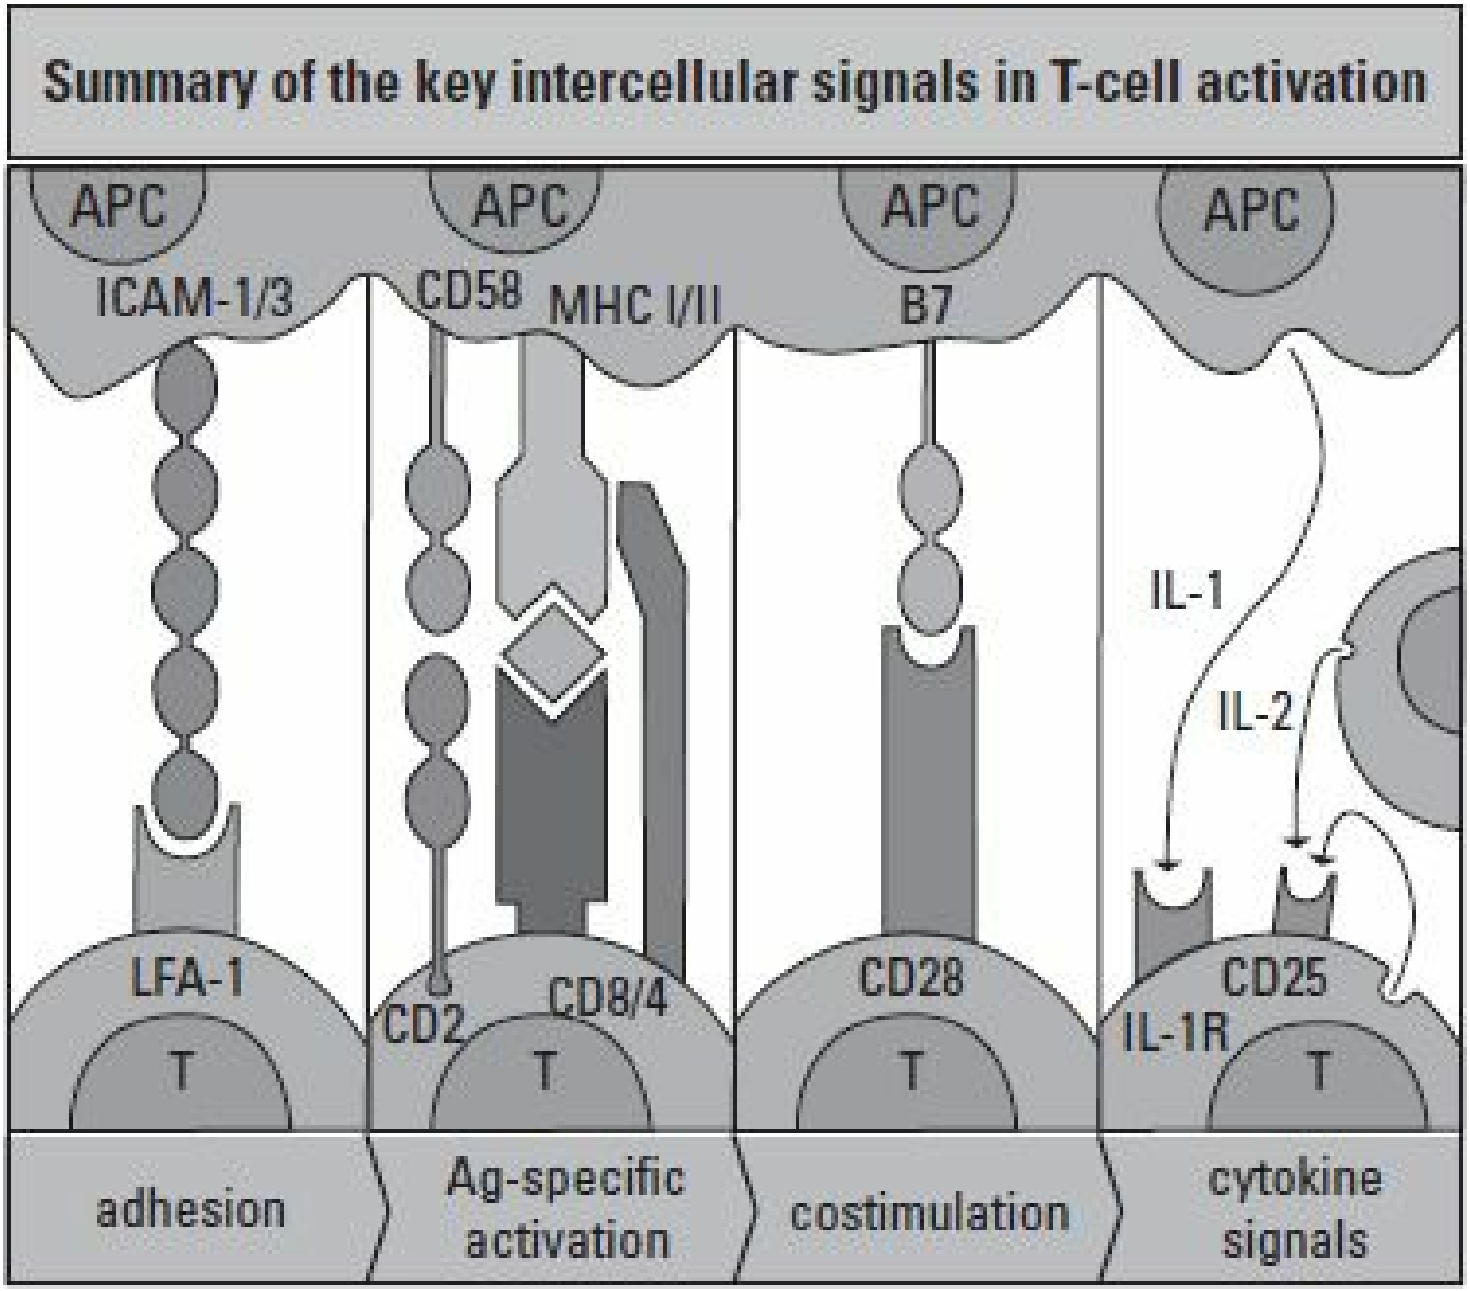

Figure 10-1. Association of APCs and T cells first involves non-specific, reversible binding through adhesion molecules, such as the LFA-1/ICAM interaction. Recognition of the peptide antigen in the MHC molecule by the TCR, which provides the specificity of the interaction, results in prolonged cell-cell contact. A second signal (co-stimulation) is necessary for the T cell to respond efficiently,

otherwise tolerance may result. Activation results in upregulation of cytokines and their receptors, which boost the activatory signals and help to decide the cell fate.

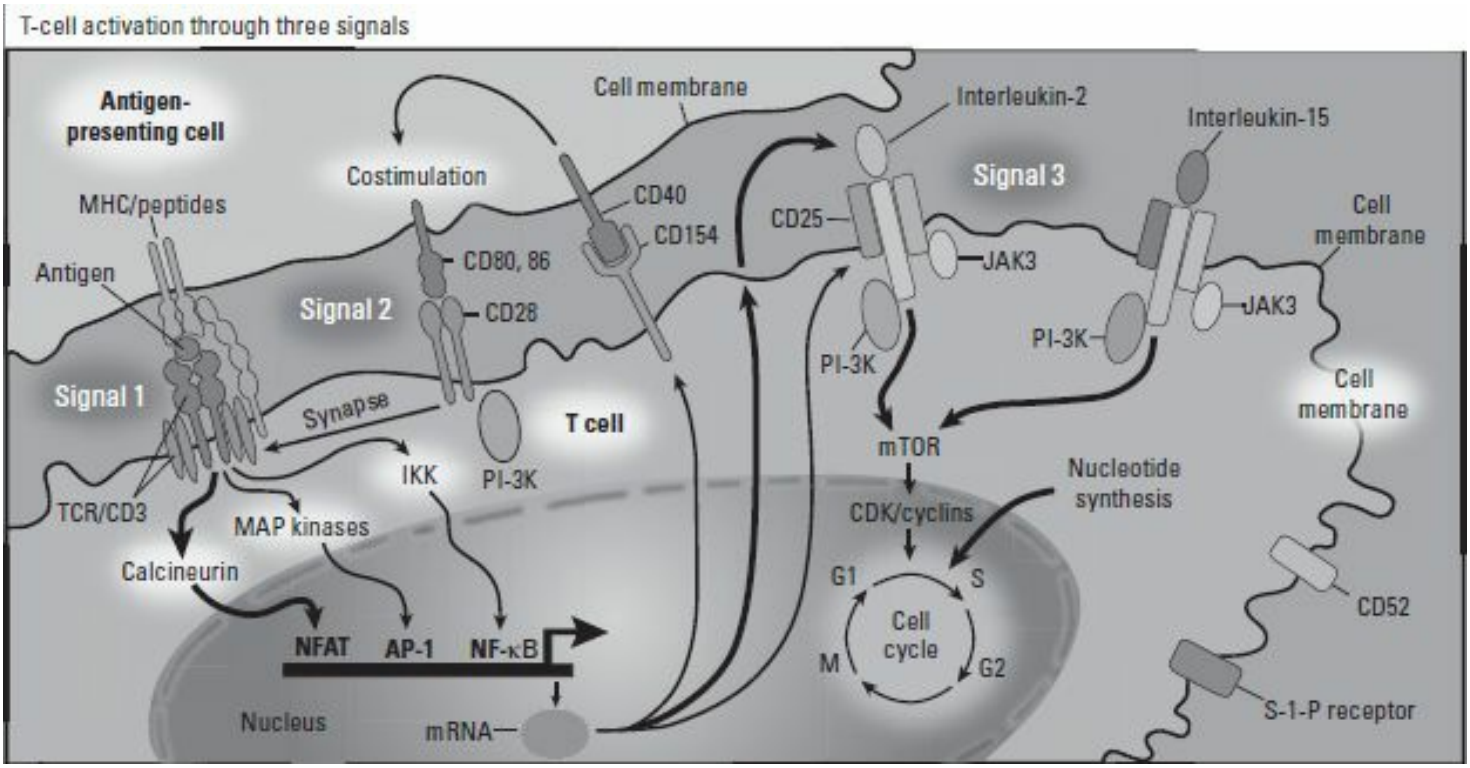

Figure 10-2. T-cell activation through three signals.

Proliferation and differentiation lead to a large number of effector T cells. The primary mechanism of the destruction of an allograft is by generation of T cells that leave the

lymph nodes, migrate to the allograft, and are cytotoxic for the cells of the graft. Graft-cell lysis is accomplished through the direct action of T cytotoxic cells, including release of secretory granules containing granzyme B and perforin and by the induction of apoptosis, and by the activation of cascading enzyme systems, including the complement, clotting, and the kinin pathways. Other cellular mediators such as plasma cells, macrophages, platelets, and polymorphonuclear leukocytes also migrate into the allograft and have both a direct and indirect role in allograft rejection. B cells are activated when antigen engages their antigen receptors, usually in lymphoid follicles

or in extrafollicular sites, such as the red pulp of the spleen or in the transplant, producing alloantibody against donor MHC antigens. Alloantibody targets capillary endothelium and fixes complement that results in cell lysis, thrombosis, and ischemia.

The severity of the immune response to allografts differs greatly between dogs and cats. Dogs mount a virulent rejection response, and without immunosuppression, a MHC-mismatched renal allograft is destroyed in 6 to 8 days. In cats, a MHC-mismatched renal allograft will function for approximately 23 days.

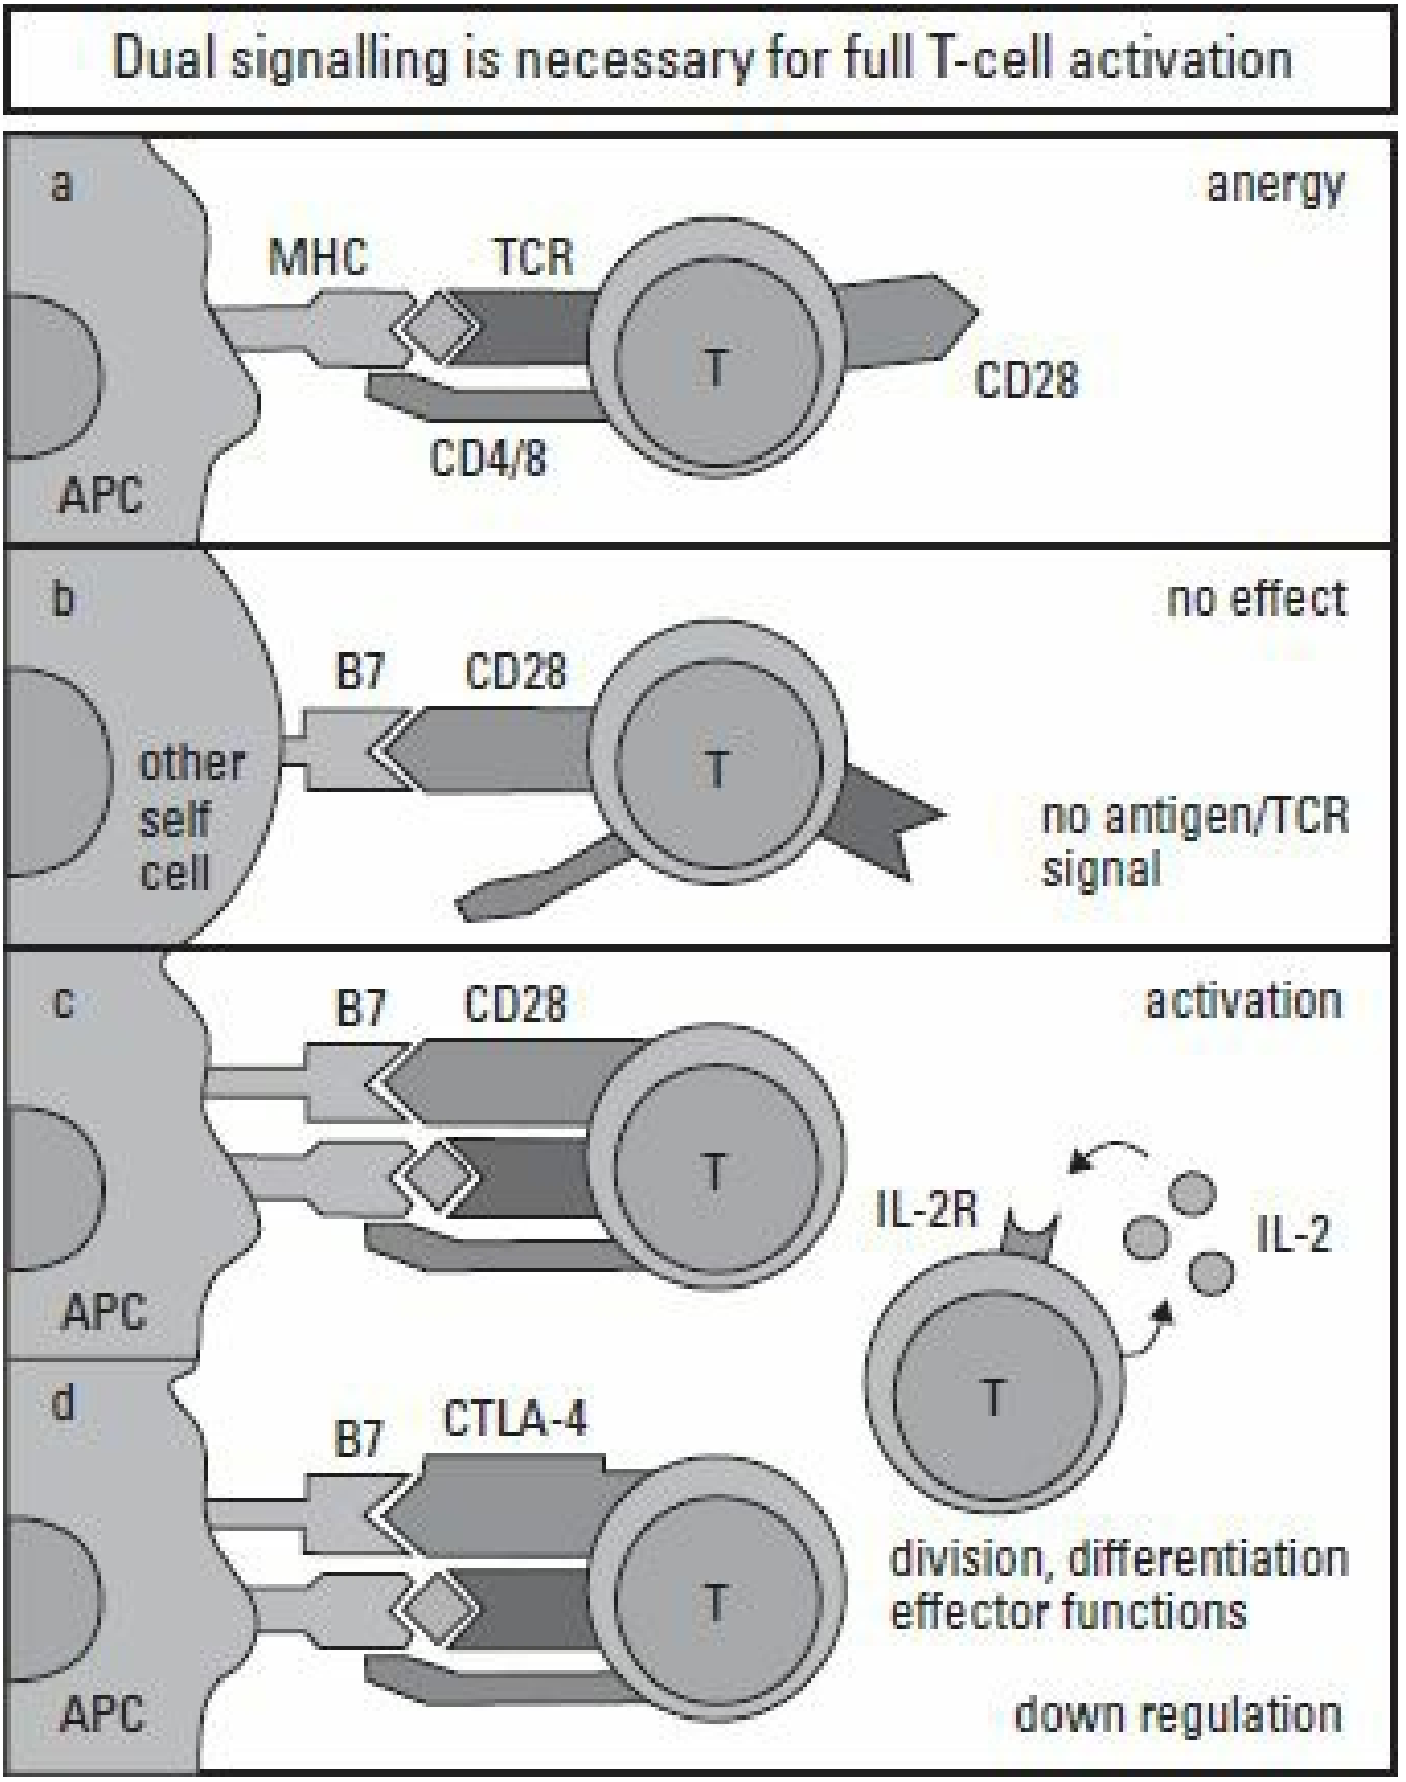

Figure 10-3. A T cell requires signals from both the T-

cell receptor and CD28 for activation.

(a) In the absence of co-stimulatory molecules inactivation or anergy results. This situation would prevail in order to tolerize T cells not removed by central tolerance to self anti96ns expressed on peripheral tissues.

(b) In the absence of an antigen-specific signal (wrong peptide for example) there is no effect on the T cell.

(c) Co-reception of both signals, from the surface of a professional APC, activates the T cell to produce IL-2 and its receptor. The cell divides and differentiates into an effector T cell, which no longer requires signal 2 for its effector function.

(d) At the termination of the immune response, CTLA-4 replaces CD28 and downregulates T-cell function.

The Tempo of Rejection

Three overlapping types of organ rejection are recognized clinically. Hyperacute rejection is an accelerated

form of rejection that is associated with naturally occurring or preformed circulating antibody in the serum of the recipient that reacts with donor cells, particularly the endothelium of blood vessel walls as described above. In hyperacute allograft rejection, the recipient has been sensitized to the allograft MHC antigens by previous blood transfusions, pregnancy, or transplantation. Preexisting antibody can be identified before transplantation by lymphocyte cross-match, which involves testing leukocytes of the potential donor with serum of the recipient in the presence of complement. If preexisting antibody is present in the serum, the host leukocytes will be lysed. In addition,

antibodies against the donor's blood type (erythroid cell surface antigens) can cause hyperacute rejection. The donor and recipient should be tested for blood type compatibility and a blood cross match should be performed prior to transplantation.

Acute allograft rejection typically occurs 7 to 21 days after transplantation or when effective immunosuppression is terminated. Pathologic studies of the rejected organ reveal a predominant pattern of mononuclear leukocyte infiltration in the tissue.

Chronic rejection is characterized by gradual loss of organ function over

months to years, often without any clinically recognized rejection episode. Chronic rejection is a major cause of death of all human organ transplant recipients and the primary cause of death for heart transplant recipients. Kidneys undergoing chronic rejection show severe narrowing of numerous arteries and thickening of the glomerular capillary basement membrane. Heart transplants show progressive thickening of the coronary arteries caused mainly by smooth muscle cell proliferation and migration. Occlusion of coronary artery blood flow results in diminished function of the cardiac muscle, and, eventually, in myocardial infarction. The factors causing chronic rejection

are multiple and appear to produce chronic inflammation and injury via both immune and nonimmune mechanisms.[5] Factors that have been implicated in the development of chronic rejection in human beings include donor age, donor race, HLA mismatches, ischemia time, reperfusion injury to the allograft, viral infections, hyperlipidemia, hypertension, acute and subacute rejection, and drug toxicity. Many peptide growth factors, including transforming growth factor β, platelet-derived growth factor, and the fibroblast growth factors, have been shown to be upregulated in chronically rejecting organs. Growth factors have been shown *in vitro* and *in vivo* to promote fibroplasia, collagen

synthesis, and smooth muscle cell proliferation and migration. Currently, growth factor inhibitors, coenzyme A reductase inhibitors, antiviral strategies, and changes in organ procurement and preparation are being investigated to reduce the incidence and severity of chronic rejection.

Chapter 11

Organ Transplantation – Immunosuppressive Agents

Clare R. Gregory
Andrew E. Kyles
Margo Mehl

Modification of the Rejection Response[1,2]

Transplanted organs are rejected by a process that occurs when the host's immune system recognizes the grafted tissue as foreign and mounts a

response. Modification of this rejection response or altering the immune system's ability to respond to the grafted tissue can be produced in a number of ways including reducing the immune system's exposure to antigens, depleting the number of lymphocytes, suppressing antibody formation, and altering cellular function, such as blocking activation of lymphocytes. The most direct from of immunomodulation is to reduce the exposure of the host immune system to alloantigens. In organ transplantation, this is accomplished by matching the donor and recipient for MHC antigens. Transplantation antigens can also be hidden from allosensitive T cells. Prior to implantation into the peritoneal

cavity, pancreatic islet cells can be encapsulated in fenestrated plastic spheres that prohibit T cells from coming into contact with the islet cells.

Lymphocyte populations can be depleted by the administration of cytotoxic drugs, antilymphocyte serum, lymphocytopheresis, or by irradiation of lymphoid organs. Organs of the immune system, in particular the spleen and thymus, can be surgically removed. Splenectomy results in impairment of phagocytic functions and a reduced production of antibodies.

Antibody formation may be suppressed by cytotoxic drugs or lymphoid

irradiation of B cells and plasma cells. Destruction of T cells indirectly decreases antibody production by decreasing the effects of T-cell-derived cytokines on B cells. Antibodies and cytokines can be directly eliminated from the host by plasmapheresis.

Alteration of cellular function, directly or indirectly, without generalized cytotoxicity has been in the forefront of immunologic research for the past two decades. Cyclosporine was the first antirejection agent that specifically altered T-cell function. A number of antibodies have been developed that inhibit cell surface molecules involved in T-cell activation and/or T-cell-mediated cytotoxicity. OKT3 is a

murine monoclonal antibody directed against the human CD3/T-cell receptor complex on the cell surface of T cells. Within minutes of administration, a marked decrease occurs in the number of circulating T cells. Gradually, these cells reappear but have internalized the CD3/T-cell receptor complex from the cell surface. Without this receptor complex, T cells cannot respond to the class I or class II antigen complex on the surface of allogeneic or antigen-presenting cells. Other antibodies have been directed against cytokines and cytokine receptors. Anti-IL-2 receptor antibodies are now available for human transplant patients and have been safely used to reduce the incidence and severity of acute

rejection episodes. Anti-tumor necrosis factor, anti-INF-γ antibodies and others have been shown to increase allograft survival in animal models.

Antibodies have also been directed against the accessory cell-adhesion molecules, resulting in reduction of T cell binding and activation. Interference with the binding of LFA-1 on T cells and with ICAM-1 on allogeneic or antigen-presenting cells has prolonged allograft survival in rodent and primate models.

The antibodies used against T-cell receptors, cytokines, and adhesion molecules are usually murine in origin. Mice are challenged with the foreign

glycoprotiens and produce antibody that is collected and administered to another animal or human being facing a rejection response. In most cases, the organ recipient will form antibodies against the murine antibody that eventually neutralize its effect. To reduce this problem in human transplantation, the new anti-IL-2 receptor antibodies have taken the active portion of the mouse antibody (antigen binding or Fab portion) and combined it in various ways to human antibody (Fc and variable regions) to produce antibodies of lower or nil antigenicity (Zenapax, Roche, Nutley, NJ; Simulect, Novartis, East Hanover, NJ).

Other schemes of specific immunosuppression are under investigation; for example, the generation of T-cell-specific antibody/toxin complexes. As T-cell activation and the factors involved in signal transduction are better understood, agents are being directed against the molecular events that occur in the cell membrane and in the cytosol following T-cell antigen recognition.

Immunosuppressive Agents[1,2]

Over the last half of the 20th century, immunosuppressive agents evolved

from nonspecific cytotoxic drugs to agents that target specific enzyme pathways that catalyze reactions required for normal immune function. Much of our current knowledge of T-cell function was provided by research performed to understand the mechanism of action of cyclosporine. As each element of antigen recognition, T-cell activation, cytokine synthesis, and T-cell-dependent cytolysis are unraveled, investigators are devising more specific, less toxic and more efficacious agents for interrupting the immune response. This is termed rational drug development and replaces the selection of potential immunosuppressive agents based on their ability to lyse or inhibit the

activation of T and B cells *in vitro*. Although specific immunosuppression using naturally induced and genetically engineered antibodies, soluble receptor fragments, and other biological methods are available for therapy of human diseases, most are not applicable or available for use in the treatment of animal diseases. For the foreseeable future, in clinical veterinary medicine, immunosuppression will continue to be accomplished using chemotherapies. As the new immunosuppressive agents become more readily available and clinicians become familiar with their indications, effects, and side effects, immunosuppression should become more specific, effective, and safe.

Myelotoxic Agents

The major effect of cyclophosphamide results from alkylation of deoxyribonucleic acid (DNA) during the S phase of the cell cycle. The alterations in DNA structure can be lethal to the cell or may produce miscoding errors that inhibit cell replication of DNA transcription. Cyclophosphamide produces T- and B-cell lymphopenia and suppresses both T-cell activity and antibody production. Cyclophosphamide is administered to dogs for the treatment of corticosteroid-resistant autoimmune hemolytic anemia, corticosteroid-resistant thrombocytopenia, rheumatoid arthritis, and polymyositis

(in conjunction with corticosteroids). Cyclophosphamide is administered to cats for the treatment of autoimmune hemolytic anemia and rheumatoid arthritis. Myelosuppression, gastroenteritis, alopecia, and hemorrhagic cystitis are the major complications associated with cyclophosphamide therapy.

Azathioprine is a purine analog that is metabolized to ribonucleotide monophosphates. Poor conversion to diphosphates and triphosphates leads to an intracellular accumulation of monophosphates that produces a feed-back inhibition of enzymes required for the biosynthesis of purine nucleotides. The triphosphate analogs that do form

become incorporated into DNA and result in ribonucleic acid (RNA) miscoding and faulty transcription. Azathioprine has a greater effect on humoral than on cell-mediated immunity. For the treatment of immune-mediated diseases in dogs, azathioprine is generally administered in conjunction with corticosteroids and/or cyclophosphamide. Azathioprine has been used for the treatment of autoimmune thrombocytopenia, autoimmune hemolytic anemia, autoimmune skin diseases, chronic hepatitis, myasthenia gravis, immune-mediated glomerulopathy, chronic atrophic gastritis, systemic lupus erythematosus, and inflammatory bowel disease.

Although myelotoxic in cats, azathioprine has been used for the treatment of feline autoimmune skin diseases. Azathioprine and prednisolone, when administered at maximally tolerated levels, do not effectively suppress the rejection response against canine MHC-nonmatched renal allografts. However, when administered on an every other day schedule (1 to 5 mg/kg) with cyclosporine, azathioprine has been used to successfully maintain both canine MHC-matched and MHC-mismatched renal allografts. When administered at a dose of 0.3 mg/kg every third day, adjusting the dosage to maintain a white blood cell count of at least 3000 cells/μl, azathioprine has

been used in combination with cyclosporine to reverse or control renal allograft rejection in cats. The primary complication encountered with the administration of azathioprine is bone marrow suppression that can result in leukopenia, anemia, and thrombocytopenia. Acute pancreatitis and hepatotoxicity may also occur.

Methotrexate competitively inhibits folic acid reductase necessary for the reduction of dihydrofolate to tetrahydrofolate and affects the production of both purines and pyrimidines. The effects of methotrexate occur during the S-phase of the cell cycle. Methotrexate is used primarily as an antineoplastic agent in

dogs and cats for lymphomas, carcinomas, and sarcomas. In human medicine, methotrexate is administered for the treatment of rheumatoid arthritis and psoriasis. Gastrointestinal toxicity is the most common complication encountered with the administration of methotrexate.

Glucocorticoids

Glucocorticoids, and in particular, prednisolone, have both direct and indirect effects on the immune response. Glucocorticoids stabilize the cell membrane of endothelial cells and inhibit the production of local chemotactic factors, thus decreasing infiltration of neutrophils, monocytes,

and lymphocytes. In allogeneic tissues, the secretion of destructive proteolytic enzymes such as collagenase, elastase, and plasminogen activator is inhibited. Glucocorticoids also inhibit the release of arachidonic acid from membrane phospholipids. This prevents the synthesis of prostaglandins, thromboxanes, and leukotrienes, which are major mediators of inflammation. Glucocorticoids redistribute monocytes and lymphocytes from the peripheral circulation to the lymphatics and bone marrow. This affects primarily T cells. T-cell activation and cytotoxicity are also reduced. Glucocorticoids suppress cytokine activity and alter macrophage function. Owing to their general efficacy and low cost, prednisolone or

prednisone are considered to be the first line immunosuppressive agents for the treatment of immune-mediated and chronic inflammatory diseases in dogs and cats. Autoimmune hemolytic anemia and thrombocytopenia, autoimmune and allergic skin diseases, myasthenia gravis, allergic pneumonitis and bronchitis, immune-mediated arthritis, and systemic lupus erythematosus are just some of the indications for corticosteroid therapy in animals. Prednisolone at a dose of 0.25 to 2 mg/kg/day, has been used in both dogs and cats to slow allograft rejection; administered as a single agent, however, prednisolone is not capable of preventing allograft rejection. Although inexpensive and

often effective, the chronic use of corticosteroids in both human beings and animals can result in severe complications, usually manifested as signs of hyperadrenocorticism. This complication, in addition to the fact that corticosteroids suppress multiple elements of the immune response, has led to the search for steroid-sparing immunosuppressive protocols.

Calcinurin Inhibitors

Cyclosporine is bound in the cytosol of lymphocytes by cyclophilins (cyclosporine-binding proteins). The cyclosporine-cyclophilin complexes associate with calcium-dependent calcineurin/calmodulin complexes to

impede calcium-dependent signal transduction. Transcription factors that promote cytokine gene activation are either direct or indirect substrates of calcineurin's serine/threonine phosphatase activity. This enzymatic activity is reduced by association of the cyclosporine-cyclophilin bimolecular complex with calcineurin. Via this mechanism of action, cyclosporine inhibits early T-cell activation (Go phase of the cell cycle) and prevents synthesis of several cytokines, in particular, IL-2. Without stimulation by IL-2, further T-cell proliferation is inhibited, and T-cell cytotoxic activity is reduced. Cyclosporine may also exert an immunosuppressive effect as it stimulates mammalian cells to secrete

transforming growth factor beta (TGF-β) protein. TGF-β is a potent inhibitor of IL-2-stimulated T-cell proliferation and generation of antigen-specific cytotoxic lymphocytes. Cyclosporine is not cytotoxic or myelotoxic, and is specific for lymphocytes. This specificity spares other rapidly dividing cells, and allows nonspecific host defense mechanisms to continue to function.

Cyclosporine is gaining wide use in veterinary medicine. Combination cyclosporine and prednisolone immunosuppression has maintained normal function of MHC-nonmatched feline renal allografts for over 13 years. Cyclosporine in combination

with azathioprine and prednisolone, or with azathioprine, prednisolone, and antithymocyte serum has been used to maintain MHC-nonmatched canine renal allografts. Bone marrow transplantation has been successfully performed in cats using cyclosporine immunosuppression.

Cyclosporine has also been used to control corticosteroid-resistant autoimmune hemolytic anemia and thrombocytopenia in dogs. Cyclosporine is available in an ophthalmic preparation (Optimmune, Schering-Plough, Kenilworth, NJ) for the control of keratoconjunctivitis sicca in dogs. Recently, cyclosporine was found to significantly reduce the size

and depth of perianal fistulas in dogs. Most dogs did not require further therapy, either medical or surgical, after 6 to 8 weeks of therapy.

Cyclosporine is available in two oral formulations: Sandimmune and Neoral (Sandoz, East Hanover, NJ). Both contain cyclosporine in a concentration of 100 mg/ml, but the two solutions are not biologically equivalent. Sandimmune consists of an olive oil base and absorption of cyclosporine requires emulsification of the agent by bile salts and digestion by pancreatic enzymes. Absorption percentage can be as little as 4% and tremendous variation exists in dose/trough whole blood

concentrations among individuals of the same species. Neoral is a microemulsion preconcentrate of cyclosporine that becomes a microemulsion when in contact with gastrointestinal fluids. The microemulsion is directly absorbed through the gut epithelium, resulting in more sustained and consistent blood concentrations of the drug. When converting to Neoral from Sandimmune, most feline renal transplant recipients have had a reduction in dose level necessary to maintain the same trough whole blood concentrations. In addition, feline renal transplant patients were administered Sandimmune at 10 to 15 mg/kg/24 hours to initiate

immunosuppression at the time of surgery. To achieve the same trough whole blood concentrations of cyclosporine (approximately 500 ng/ml), Neoral is administered at 4 to 6 mg/kg/24 hours. Owing to a more complete absorption that results in a more sustained and predictable blood concentration, Neoral appears be a more effective immunosuppressant than Sandimmune. In addition, it is more economical to use.

To achieve immunosuppression with cyclosporine in dogs, the authors recommend attaining a 12-hour whole blood trough (measured just before the next oral dose) concentration of at least 500 ng/ml. Using Sandimmune,

this will require an oral dose of 10 to 25 mg/kg/24 hours divided into 2 doses. Neoral can be initiated at 6 to 10 mg/kg/24 hours divided into 2 doses. With either formulation, gastrointestinal inflammation will increase the dose requirements, and blood concentrations of the agent must be measured starting 24 to 48 hours after initiation of therapy to assure that adequate blood concentrations are achieved. Blood concentrations of cyclosporine should be measured at periodic intervals during the time of therapy.

To reduce the cost of cyclosporine necessary to treat medium- to large-size dogs, ketoconazole can be

administered at 10 mg/kg/24 hours in addition to the cyclosporine. Ketoconazole interferes with the hepatic metabolism of cyclosporine, and will reduce the dose requirement of cyclosporine by as much as 60%. Possible toxic effects with the coadministration of these agents include hepatitis and cataract formation.

To achieve immunosuppression with cyclosporine in cats, the authors recommend attaining a 12-hour whole blood trough concentration of 250 to 500 ng/ml. Using Sandimmune, this will require an oral dose of 4 to 15 mg/kg/24 hours divided into 2 doses. Neoral can be initiated at 1 to 5

mg/kg/24 hours divided into 2 doses. Again, it is imperative to measure blood concentrations 24 to 48 hours after initiation of therapy to ensure that adequate blood concentrations have been achieved. Blood concentrations must also be measured periodically during the time of therapy.

Whole blood or plasma concentrations of cyclosporine can be determined by high-pressure liquid chromatography, fluorescence polarization immunoassay, and specific monoclonal antibody radioimmunoassay. Most medical centers that serve human patients perform cyclosporine assays and will serve veterinary needs.

Based on pharmacokinetic studies in the cat, trough whole blood concentrations of cyclosporine may not correlate well with drug exposure.[3] The whole blood concentration measured at 2 hours after administration of the drug may correlate better with drug exposure and give a better index for drug dosage and change in dose. The blood concentration of cyclosporine measured 2 hours after administration, or C_2, is recommended for therapeutic drug monitoring in human renal transplant patients.[3]

Unlike the situation in human beings, cyclosporine does not appear to be hepatotoxic in dogs and cats unless extremely high blood levels are

maintained (> 3000 ng/ml). Although not as frequently encountered in human beings, cyclosporine can be nephrotoxic in the cat. Nephrotoxicity in the cat does not seem to be related to the concentration of the drug in the whole blood; it can occur at relatively low drug concentrations. Cats with extremely high concentrations in whole blood may show no nephrotoxicity at all. Whole blood concentrations of cyclosporine greater than 1000 ng/ml can cause inappetance in cats. If concentrations of 1000 ng/ml are maintained for several weeks or months, opportunistic bacterial and fungal infections can occur. As in human beings, cyclosporine can promote the development of neoplasia,

particularly lymphomas, in cats and dogs. The administration of high levels (1 to 2 mg/kg/24 hours) of prednisolone with cyclosporine increases the likelihood of tumor formation. As in humans, cyclosporine has resulted in a marked increase in hair growth in several of our feline renal transplant recipients.

Cyclosporine has a distinctly unpleasant taste to both humans and animals. It is necessary to administer the drug in gelatin capsules. Novartis supplies capsules containing 25 mg or 100 mg of cyclosporine. For most cats, these capsules contain far too much drug. The authors place the oral solution in #0 or #1 gelatin capsules.

Some cats require only a small dose of cyclosporine: 1 to 3 mg/dose. Measuring and administering this small amount (0.10 to 0.03 ml) of drug is difficult and imprecise. Sandimmune can be diluted and stored in olive oil. Neoral can be diluted in any oral solution, including tap water, but because it is a microemulsion concentrate, it must be administered immediately after it is diluted.

Cyclosporine is also available in an intravenous solution (Sandimmune IV) that must be diluted in 0.9% sodium chloride or 5% dextrose in water. The authors administer a dose of 6 mg/kg over 4 hours in the calculated maintenance fluid requirement.

Intravenous cyclosporine is administered to control organ rejection episodes, an acute hemolytic crisis, or during periods when a patient cannot tolerate oral medications.

Tacrolimus (FK506, Prograf, Fujisawa USA, Dearfield, IL), although structurally different from cyclosporine, shares a similar mechanism of action. Tacrolimus binds in the cytosol of lymphocytes with an immunophilin, FK-binding protein (FKBP). As with the cyclosporine-cyclophilin complex, the tacrolimus-FKBP complex binds to calcineurin and inhibits its phosphatase activity. This directly and indirectly inhibits *de novo* expression of nuclear regulatory

proteins and T-cell activation genes. The transcription of cytokines (IL-2, -3,-4, -5, IFN-γ, TNF-α, and GM-CSF) responsible for lymphocyte activation is suppressed as is the expression of IL-2 and IL-7 receptors. Tacrolimus, *in vitro*, is 50 to 100 times more potent an inhibitor of lymphocyte activation than cyclosporine. Tacrolimus also inhibits B-cell proliferation and production of antibody by unknown mechanisms. Tacrolimus decreases hepatic injury associated with ischemia/reperfusion injury, perhaps by inhibiting production of TNF and IL-6 by hepatocytes, and stimulates hepatic regeneration following liver injury.

Experimentally, allograft recipients

from many species have been treated successfully with tacrolimus with doses several times less than for cyclosporine. Tacrolimus has prolonged the survival of renal, liver, pancreas, heart, lung, and vascularized limb grafts in rodents, dogs, and nonhuman primates. In human organ recipients, tacrolimus is superior to cyclosporine for the reversal of ongoing rejection. Tacrolimus also seems to have a greater steroid-sparing effect over Sandimmune but may not be superior to Neoral. The toxicity of tacrolimus is similar to that of cyclosporine in human beings.

Little, if any, use of tacrolimus has been applied clinically to veterinary

patients. Experimentally, tacrolimus was shown to significantly prolong MHC-mismatched renal allograft survival in cats without serious side-effects.[4] Based on its effectiveness in other experimental animal trials, tacrolimus could be effective in controlling a wide range of immune-mediated conditions. Owing to its inhibition of antibody synthesis, in addition to T-cell proliferation, tacrolimus may be particularly effective in controlling immune-mediated anemia, thrombocytopenia, and arthritis.

Despite the potential benefits of tacrolimus for treating diseases in dogs, a major concern is the possible

toxicity of the drug. A dose of 0.16 mg/kg/intramuscularly/day and 1.0 mg/kg/orally/day has been reported to be effective in prolonging renal allograft survival in beagle dogs. Side effects included anorexia, vasculitis, and intestinal intussusception. In a study using mongrel dogs, the same doses were not effective in prolonging renal allograft survival and most of the dogs developed severe vasculitis leading to fatal myocardial infarction, hepatic failure, and intussusception. Combination therapy with cyclosporine appears to have an additive effect with less toxicity. Blood concentrations of tacrolimus are assayed at human medical centers using monoclonal immunoassays. The

effective serum trough concentration of tacrolimus in dogs is approximately 0.1 to 0.4 ng/ml; about 100 times lower than that of cyclosporine. Trough levels of 2.0 ng/ml or greater can result in death.

Inhibitors of Cytokine and Growth Factor Action

Sirolimus (rapamycin, Rapamune, Wyeth-Ayerst, Philadelphia, PA) is a macrocyclic antibiotic with a structure similar to tacrolimus that also binds in the cell cytosol to FKBP. However, sirolimus and tacrolimus affect different and distinct sites in the signal transduction pathway. The immunosuppressive activity of

sirolimus appears to be a consequence in part of the sirolimus-FKBP complex blocking the activation of the mammalian target of rapamycin, (mTOR).[5] mTOR is a serine/threonine protein kinase and is involved in the regulation of cell proliferation through the initiation of gene translation in response to amino acids, growth factors, cytokines, and mitogens. The kinase activity of additional cell cycle regulatory proteins, cyclin-dependent kinase-2 and -4, is also inhibited by sirolimus. Sirolimus blocks IL-2 and other growth factor-mediated signal transduction (signal 3 of the allograft rejection response) and the calcium-independent CD28/B7 (CD80/CD86) costimulatory pathway. Whereas

cyclosporine and tacrolimus block T-cell cycle progression at the G0 to G1 stage, sirolimus prevents cells from progressing from G1 to the S phase. Sirolimus blocks T-cell activation by IL-2, -4, and -6 and stimulation of B-cell proliferation by lipopolysaccaride. Sirolimus directly inhibits B cell immunoglobulin synthesis caused by interleukins. Sirolimus has been shown to prevent acute, accelerated, and chronic rejection of skin, heart, renal, islet, and small bowel allografts in rodent, rabbit, dog, pig, and nonhuman primate graft recipients. It has also been shown to be efficacious in models of autoimmunity; insulin-dependent diabetes, and systemic lupus erythematosus.

Sirolimus' antagonism of cytokine and growth factor action is not limited to cells of the immune system. Growth factor (PDGF, FGF)-induced proliferation of fibroblasts, endothelial cells, hepatocytes, and smooth muscle cells is inhibited by sirolimus. Sirolimus has been very effective in preventing intimal smooth muscle proliferation (arteriosclerosis) following mechanical or immune-mediated arterial injury. In human clinical trials, supplementation of cyclosporine-based protocols is associated with a reduction in acute renal allograft rejection; however, the combination of the two drugs increases the risk of nephrotoxicity, hemolytic-uremic syndrome, and hypertension.[5] Other reported side effects include

hyperlipidemia, thrombocytopenia, delayed wound healing, delayed graft function, mouth ulcers, pneumonitis, and interstitial lung disease. Everolimus, another inhibitor of mTOR, is a derivative of sirolimus.

Mycophenolate mofetil (RS-61443, mycophenolic acid, Cellcept, Roche Laboratories, Palo Alto, CA) is a prodrug hydrolyzed by liver esterases to mycophenolic acid. Mycophenolic acid is cytostatic for lymphocytes owing to its inhibition of inosine monophosphate dehydrogenase (IMPDH), an enzyme necessary for *de novo* purine biosynthesis. Mycophenolic acid is a relatively selective inhibitor of T- and B-cell

proliferation during the S phase of the cell cycle via its ability to prevent guanosine and deoxyguanosine biosynthesis. Mycophenolic acid has been shown to reduce allograft rejection in multiple animal models, being most effective when combined with cyclosporine, tacrolimus, and/or sirolimus. Mycophenolic acid was developed, in part, as a nonmyelotoxic replacement for azathioprine in human allograft patients. Early clinical trials in human renal allograft recipients showed a decrease in biopsy-proven acute rejection episodes in patients receiving mycophenolic acid in place of azathioprine. At therapeutic doses, mycophenolic acid can be toxic to animals. The primary dose-limiting

effects are anemia and weight loss in rats; leukopenia, diarrhea, and anorexia in monkeys; and gastrointestinal hemorrhage, anorexia, and diarrhea in dogs. To reduce the toxic effects, the dose can be lowered or mycophenolic acid can be given in combination with other immunosuppressive agents. Mycophenolic acid can also inhibit growth factor-induced smooth muscle and fibroblast proliferation. Sirolimus and mycophenolic acid, in combination, are extremely effective in preventing arterial intimal smooth muscle proliferation following mechanical injury. This has marked implications for the control of chronic allograft rejection.

Leflunomide (Hoechst AG, Wiesbaden, Germany) is a synthetic organic isoxazole that the intestinal mucosa metabolizes to the active form, A77 1726. Leflunomide mediates at least part of its antiproliferative activity during the S phase of the cell cycle by inhibiting the *de novo* pathway of pyrimidine biosynthesis. The target of A77 1726 in this pathway is the enzyme dihydroorotate dehydrogenase. At higher concentrations, leflunomide is also an inhibitor of tyrosine kinases associated with growth factor receptors. In addition to T and B lymphocytes, leflunomide also has an antiproliferative effect on smooth muscle cells and fibroblasts, which is also owing to inhibition of the

pyrimidine biosynthetic pathway in these cells. Leflunomide is currently approved for the treatment of rheumatoid arthritis in human beings. It has been shown to be an effective disease-modifying antirheumatic drug free from the side effects commonly associated with currently approved immunosuppressants. In addition to its efficacy in humans and animal models with autoimmune diseases, leflunomide has been found to control acute, ongoing, and chronic allograft rejection of the kidney, skin, heart, vessels, lung, and composite grafts in small and large animal models. Leflunomide has been used to successfully treat steroid-resistant autoimmune hemolytic anemia and

systemic histiocytosis in dogs. In combination with cyclosporine, leflunomide has completely prevented the rejection of canine MHC-nonmatched renal allografts in both experimental and clinical studies.

At doses used in humans, leflunomide causes gastrointestinal toxicity in dogs because of the accumulation of a metabolite, trimethylfluoroanaline (TMFA). Fortunately, the canine lymphocyte is far more sensitive than the human lymphocyte to the effects of the active agent, A77 1726, and much lower oral doses are equally effective in achieving immunosuppression. The authors currently recommend a dose of 4 mg/kg/24 hours orally, and adjust

the dose as needed to obtain a 24-hour serum trough concentration of 20 μg/ml. Early studies in the cat suggest that TMFA does not present the toxicity problem encountered in dogs; however, cats metabolize the drug much slower and require approximately half the oral dose to achieve effective blood concentrations. Both cats and dogs with diminished renal function may be subject to TMFA toxicity, as it is excreted by the kidneys. Leflunomide is marketed under the trade name, Arava. Owing to the short half-life of the drug in dogs, as compared with that in human beings, the use of leflunomide in dogs is very expensive.

Leflunomide analogs are currently being developed for transplantation applications. A combination of cyclosporine and FK778, a leflunomide analog, significantly prolonged MHC-mismatched canine renal allograft survival.[5]

Experimental Compounds

FTY 720 is derived from myriocin, a fungus-derived sphingosine analogue.6 After phosphorylation, FTY 720 engages lymphocyte sphingosine-1-phosphate receptors and profoundly alters lymphocyte traffic, acting as a functional sphingosine-1-phosphate antagonist. FTY 720 sequesters naïve and activated CD4+ and CD8+ T cells

and B cells from the blood into lymph nodes and Peyer's patches, without affecting their functional properties. Importantly, FTY 720 does not impair cellular or humoral immunity to systemic viral infection, and it does not affect T- cell activation, expansion/proliferation, or immunologic memory.

FTY 720 synergizes effectively with inhibitors of T-cell activation and proliferation to prevent allograft rejection in a wide range of animal models. In combination with subtherapeutic concentrations of cyclosporine, FTY 720 has been shown to delay or prevent the rejection of skin, heart, small bowel, liver, and

kidney allografts in rats, dogs, and nonhuman primates.[7] Similar results have been seen when FTY 720 is combined with rapamycin and tacrolimus. FTY 720 is extensively metabolized in the liver via cytochrome enzymes that are not involved in the metabolism of cyclosporine, rapamycin, or tacrolimus and, therefore, variations in drug concentrations when these agents are co-administered are unlikely to occur. In Phase I and II clinical trials in human renal transplant patients, FTY 720 was well tolerated and did not cause any significant toxicity, allograft loss, or increase in infection rates or other complications such as diabetes. The pharmacokinetic profile of FTY

720 was characterized by linear dose-proportional exposure over a wide range of doses, only moderate inter-patient variability, and a prolonged elimination half-life (89-150 hours). These factors suggest that FTY 720 will be administered once daily, without the need for monitoring blood concentrations or dose titration.[7] Human renal transplant patients experienced a significant reduction in peripheral blood lymphocyte counts by up to 85%. It is hoped that FTY 720 may be useful in the future design of more effective and less toxic immunosuppressive regimens for prevention of allograft rejection.

Combination Therapy

Most of the currently used or soon to be available immunosuppressant agents have differing mechanisms of action and are effective at different stages of the cell cycle. Experimentally and clinically, combining agents often results in more effective immunosuppression with fewer drug-induced side effects. In human transplant patients, cyclosporine and tacrolimus are currently considered to be the first line immunosuppressive agents. To increase their effectiveness and decrease toxicity, azathioprine, sirolimus, prednisolone, and/or mycophenolic acid are added to antirejection protocols. Few of the new

non-myelotoxic agents have been used in veterinary patients, but many published experimental animal trials investigating autoimmune disease and organ transplantation provide indications and insight into their use. Based on experimental and clinical experience in canine MHC-nonmatched organ transplantation, the combination of cyclosporine and leflunomide or cyclosporine with azathioprine are extremely effective in preventing renal allograft rejection.

Chapter 12

Antimicrobial Prophylaxis

Dianne Dunning

Perioperative prophylactic antimicrobial therapy may be defined as the administration of antibiotics in the absence of infection, prior to surgery. The words antimicrobial and antibiotic are often used interchangeably; however, they are not equivalent. An antimicrobial is a general term that refers to a group of drugs that includes antibiotics, antifungals, antiprotozoals, and

antivirals; whereas an antibiotic is a drug that is used to treat bacterial infections.[1] The general goal of this form of antimicrobial therapy is to reduce the number of viable bacteria present at the time of surgical incision to a level that normal host defenses can handle, thereby preventing postoperative surgical site infection (SSI).[2-9] Despite the widespread use and availability of antibiotics, however, postoperative wound infections or SSIs still continue to be a problem in people and animals.[9-17] Although the principles of antimicrobial prophylaxis in surgery have been clearly established, many reports continue to describe inappropriate drug selection and use.[2-

[4,10,18,19] Strict adherence to the recommended guidelines and avoidance of invalid indications or use of drugs with too broad a spectrum of activity should be eliminated to reduce risk of resistance and treatment failure.

Sources of Contamination

Even with appropriate hair removal, skin preparation, and aseptic technique, all surgical wounds are contaminated.[20] The skin and hair of animals provide the principal source of bacterial contamination entering the surgical wound and it is estimated that 20% of normal canine skin flora remains in situ, deep within the hair

follicles, even after appropriate skin preparation.[1,9,11,13,16,20-22] Common bacteria residing on normal canine skin after preoperative preparation include (in order of descending prevalence): *Staphylococcus intermedius, coagulase-negative Staphylococcus spp, Bacillus spp., Acinetobacter spp., and Staphylococcus aureus*.[22] Clinical studies in the dog have revealed that the skin begins to reinstate its inherent bacteria colonies 90 minutes after aseptic preparation, turning a clean procedure into a clean contaminated surgery (Table 12-1).[1] It is also contraindicated to clip surgical sites any time before anesthetic induction, as they are 3 times as likely to develop infection owing to

superficial skin infection resulting from superficial abrasions and cuts.[11] The risk of infection is the same whether or not the surgical site is clipped 4 hours or more before the induction of anesthesia.[11] Although the risk of SSI is not greater for most noninfected, properly performed gastrointestinal and urogenital procedures, the number and species of bacteria vary and must be considered when selecting an antimicrobial agent.[4,11,21] Each segment of normal bowel, beginning at the stomach, has an incrementally increasing load of bacterial colonies, culminating with the colon and rectum, and the most common pathogens encountered in the gastrointestinal tract are coliforms and anaerobes.

Although hematogenous sources of infection are uncommon, prolonged indwelling venous catheter sites should be inspected, as they pose a source of distant infection that may increase the risk of SSI if undetected. Multiple risk factors for the development of vascular catheter-related infection and bacteria have been identified, which include prolonged duration of catheterization (> 3 days), frequent manipulation of catheters and intravenous lines, improper aseptic insertion and maintenance, the use of transparent plastic dressing, contaminated skin-preparation solution, the location of the catheter, and the use of multilumen catheters.[16,21,23-25] Exogenous sources of bacteria are also infrequent, but

they still should be considered when dealing with a SSI.[6,16,20] Commonly reported exogenous sources of bacteria in people and animals include: surgical equipment, the operating room, and personnel.[13,26,27]

A recent prospective study of postoperative SSIs in dogs and cats revealed "infection/inflammation" and "infected" rate of 5.8% and 3%, respectively.[13] In this particular study, a wound was classified as "infected" if purulent drainage, an abscess, or a fistula was recorded, and a wound was classified as "infected/inflamed" when more than 3 of the following signs were present simultaneously: redness, swelling, pain, heat, serous discharge,

and wound dehiscence.[13] These infection rates and definitions are in close agreement with previous studies in dogs and cats and also compare favorably to epidemiologic studies in people.[8,9,11,16,28]

Table 12-1. National Research Council Wound Classification Criteria

Classification	Criteria
Clean	Nontraumatic No inflammation encountered No break in technique

	Respiratory, gastrointestinal, genitourinary tracts not entered
Clean contaminated	Gastrointestinal or respiratory tracts entered with no significant spillage
	Oropharynx or vaginal vault entered
	Genitourinary or biliary tract entered in the absence of infection
	Minor error in aseptic

	technique
Contaminated	Major error(s) in aseptic technique Gross spillage from the gastrointestinal tract Traumatic wound $<$ 4 hours after event Genitourinary or biliary tract entered in the presence of infection
Dirty	Acute bacterial inflammation encountered

	Penetration into necrotic or abscessed tissue
	Traumatic wound with gross fecal or foreign body contamination and devitalized tissue (> 4 hours after event)

Indications

SSIs usually develop within 30 days of a procedure and within 1 year of implant application.[21] To develop a SSI, two main conditions must be present: a bacterial inoculum (> 10^5

bacteria/gram of tissue) and an environment to support bacterial growth and nutrition. In most cases, the mere presence of bacteria is less important than the level of bacterial growth, as all contaminated wounds do not necessarily become infected.[20] A strong correlation exists, however, between wound contamination and SSI rates, with the rate of infection predictably increasing with increasing wound contamination.[8,9,13,17]

Classically, the four categories of wound contamination are the following: clean, clean contaminated, contaminated, and dirty (Table 12-1). Although the classification of wound type is important, it is insufficient by

itself to accurately predict infection rates, because of the wide variety of presenting complaints and procedures it encompasses.[8,9,13,17] One prospective study revealed the three major risk factors for increasing the probability of surgical wounds becoming infected: the duration of surgery, increasing number of personnel in the operating room (particularly a problem in teaching hospitals), and a dirty surgical site classification.[13] Risk factors identified for a wound to become "infected/inflamed" include: a prolonged duration of anesthesia, admission to a postoperative intensive care unit, the presence of wound drainage, increasing patient weight, and a dirty surgical site

classification.[13] For both “infected” and “infected/inflamed” wounds, antimicrobial prophylaxis was a protective factor, decreasing the rate of infection 6 to 7 times.[13] Additional risk factors from previously reported veterinary epidemiologic studies include: prior irradiation of the surgical site, chronologic age of the animal (dogs older than 8 years), sex (intact males), presence of a concurrent endocrinopathy, existence of distant sites of active infection, presence of abnormal body condition scores, administration of propofol as a part of the anesthetic protocol, the contamination of the surgical wound with more than 10^5 organisms/gram of tissue, excessive use of electrocautery,

presence of foreign material and debris, use of braided or multifilament suture material, and presence of a contaminated surgical suction tip.[11,14,16,22,29-32]

In 1941, the American Society of Anesthetists, the forerunner of the American Society of Anesthesiologists (ASA), began to classify patients according to their preoperative physical status.[33] The ASA Physical Status Classification System was initially created with 6 classes, and then a seventh class was added. The modern ASA classification consists of 5 categories and was adopted in 1961 (Table 12-2).[34] Over the years, many clinical studies have utilized the ASA

classification system to stratify patients for morbidity and mortality analysis associated with surgery and anesthesia. In people and in dogs, an ASA classification grade greater than 3 has been shown to be associated with an increased risk of SSI. However, this classification system was meant only to categorize physical status for the purpose of audit and statistical analysis. It was never intended to represent perioperative risk of morbidity for any individual patient, because, as with the surgical wound classification system, many other factors such as the surgical procedure, patient preparation, variability of surgeons and equipment used in different institutions can also affect

outcome.[34]

Table 12-2. The ASA Physical Status Classification System.

Classification	Criteria
P1	A normal healthy patient
P2	A patient with mild systemic disease
P3	A patient with severe systemic disease
P4	A patient with severe systemic disease that is

	a constant threat to life
P5	A moribund patient who is not expected to survive without the operation
P6	A declared brain-dead patient whose organs are being removed for donor purposes

Pharmacologic Principles[1,35]

The key factors that determine a drug's delivery to the surgical site include: the absorption, distribution, and elimination characteristics of the selected antimicrobial agent (Figure 12-1). The disposition of most drugs is split between the central compartment of the vascular system and the tissue compartment, which are composed of less perfused areas, including the interstitial fluid which baths the surgical wound. The concentration of the antimicrobial agent in the interstitial fluid is critical to effective drug efficacy, as most antimicrobials penetrate tissues well but perform poorly in formed tissue exudates and clots.

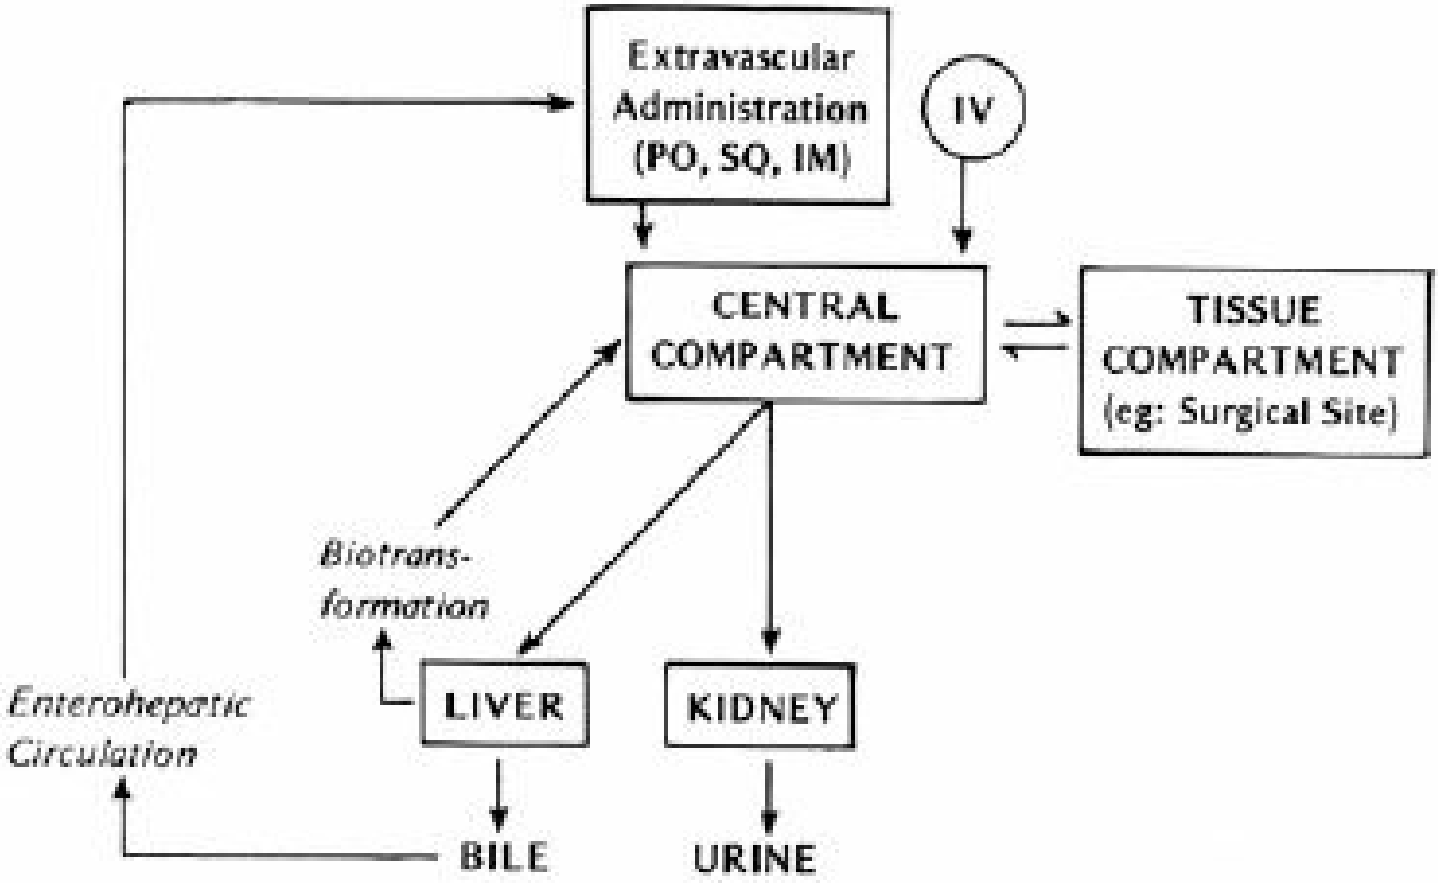

Figure 12-1. Schematic diagram of a drug's disposition in the body. PO, Per os; SQ, subcutaneous; IM, intramuscular; IV, intravenous.

Plotting the amount of intravenously administered drug in the central and tissue compartments as a function of time (Figure 12-2) clarifies the rationale for the general recommendations for perioperative

antimicrobial prophylaxis. In the alpha phase, the drug is distributed from the central compartment to the peripheral or tissue compartment. When both compartments are at equilibrium, the beta phase ensues, with the onset of drug elimination. Peak tissue concentrations of the antimicrobials are only achieved once the distribution phase is complete. Therefore, for efficacious antimicrobial prophylaxis, antimicrobial administration should be initiated prior to the surgical incision at the start of the elimination phase, or within 30 minutes to an hour when using a cephalosporin or similar β-lactam antibiotic.

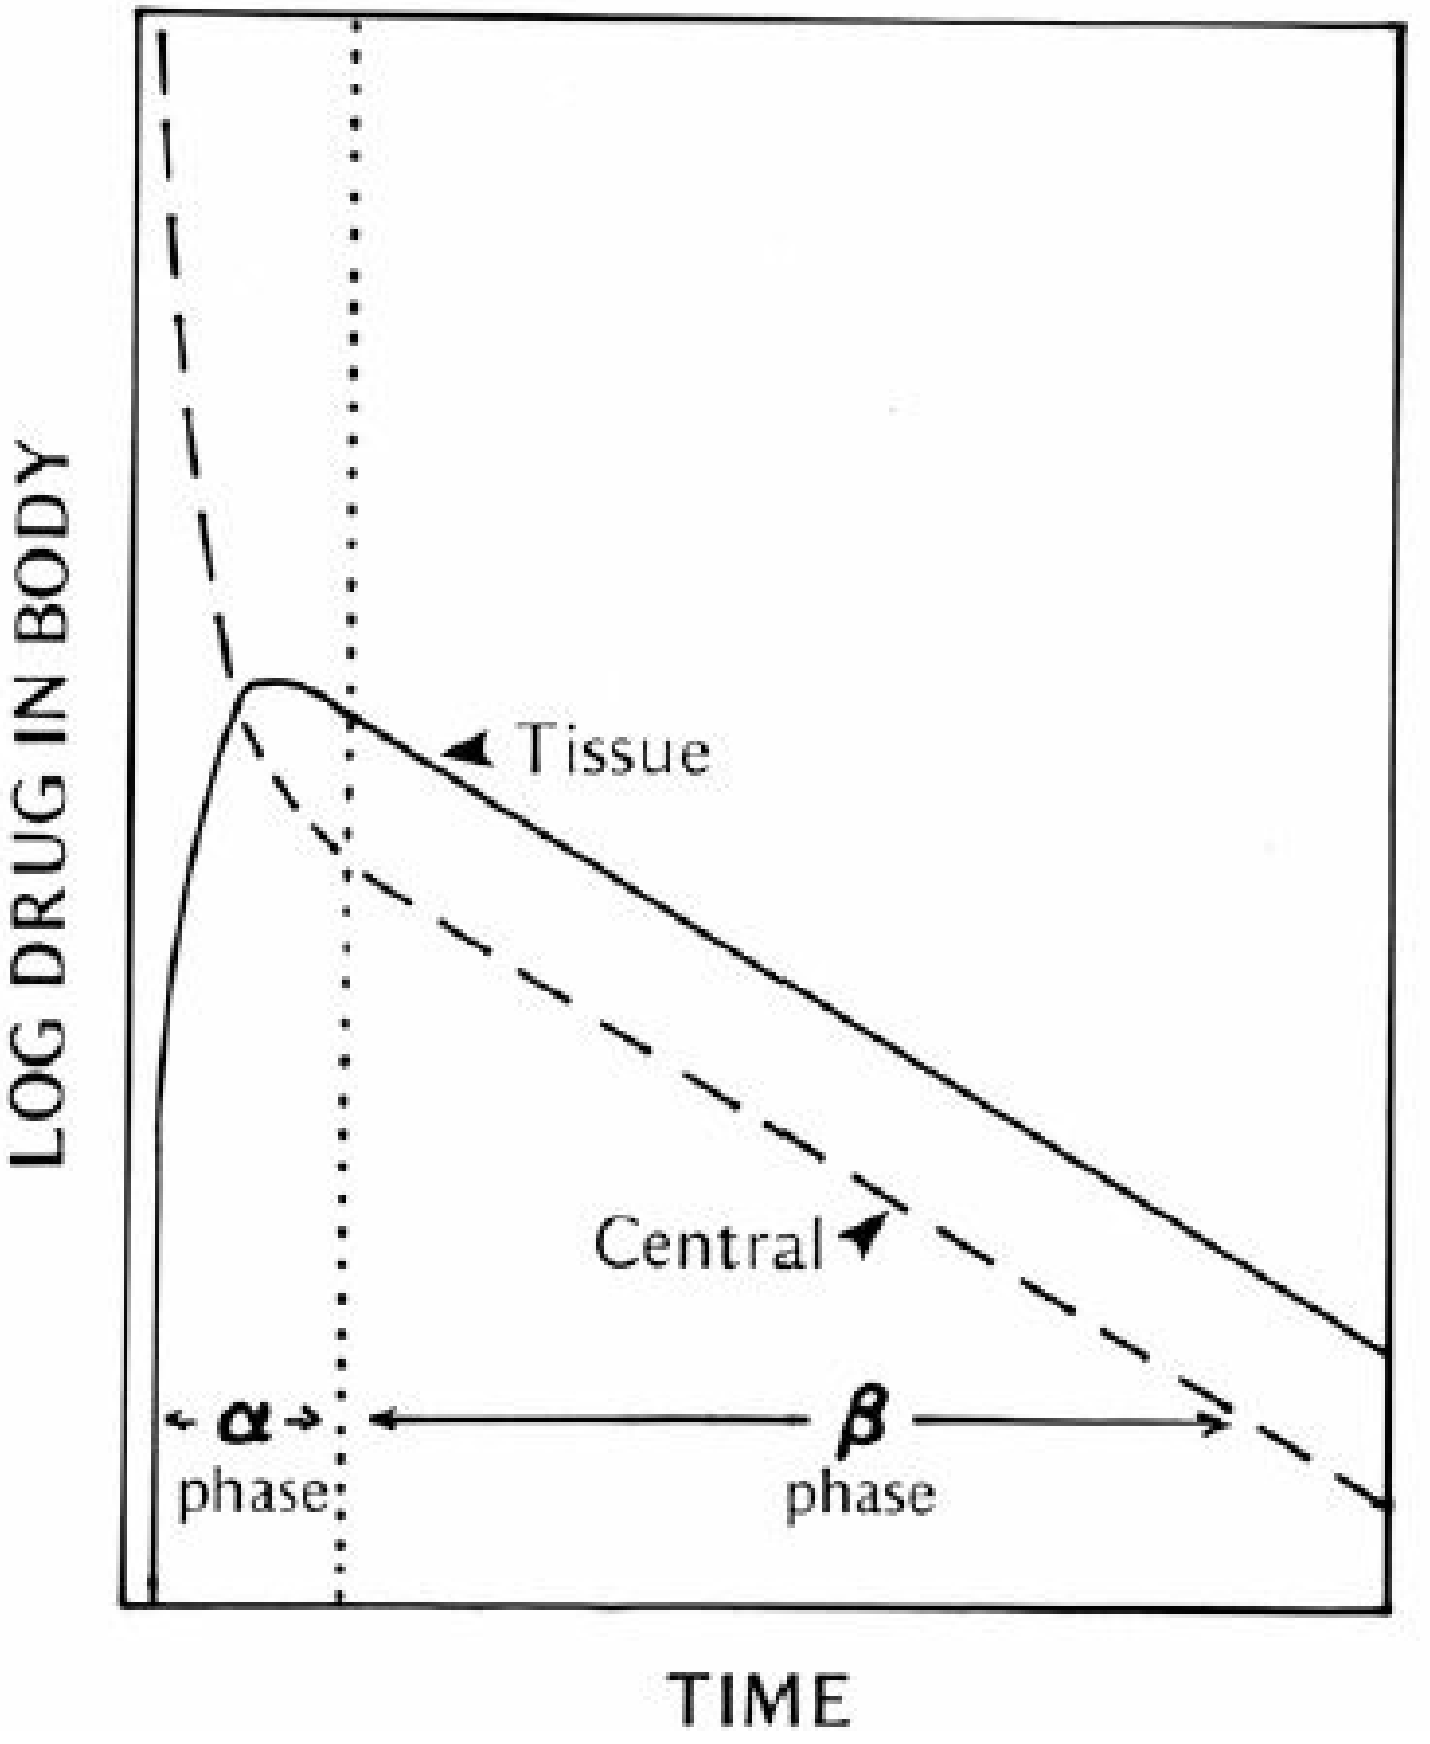

Figure 12-2. Plot of the amount of intravenously

administered drug in the central and tissue compartments as a function of time. α, Distribution; β, elimination.

Following intravenous administration, an antimicrobial must reach a certain concentration to have an antimicrobial effect. The minimum inhibitory concentration (MIC) is defined as the lowest concentration that inhibits visible bacterial growth. Practically, the MIC represents the minimum concentration necessary for an antimicrobial to have an inhibitory effect in the plasma or tissues of the animal. The minimum bacteriocidal concentration (MBC) is defined as the lowest concentration that kills 99.9% of the bacteria and is sometimes also referred to as the minimal lethal

concentration (MLC). If a drug has a low MBC to MIC ratio (< 4-6) it is referred to as a bacteriocidal drug, because it can be administered in safe doses to achieve high effect or bacterial kill. If a drug has a high MBC to MIC ratio (> 6) it is referred to as a bacteriostatic drug, because safe doses may not be possible to achieve a 99.9 % kill of the bacteria encountered. Depending on the dose administered, a drug may be both bacteriocidal and bacteriostatic. For purposes of perioperative prophylaxis, it is preferred that an antimicrobial be bacteriocidal rather than bacteriostatic to achieve greatest drug efficacy during the operative period.

The recommended dose of an antimicrobial is based on MIC studies performed in animal models of infection. Bacteriocidal antimicrobials are to be administered at 4 to 8 times the MIC for maximal drug efficiency; whereas bacteriostatic antimicrobials are administered at 1 time the MIC throughout the dosing period. Dosing recommendations are also based in part on efficacy studies where antimicrobials were classed as either a concentration or a time-dependent drug. Concentration-dependent drug efficacy (such as aminoglycosides or fluoroquinolones) relies upon achieving one peak concentration above the MIC for successful therapy. After achieving that peak, it is

acceptable to allow the drug concentration to fall below the MIC for 8 to 12 hours over a 24-hour period. This is in contrast to time-dependent drug efficacy (such as β-lactams), which is reliant not only on achieving but on maintaining those peak concentrations above the MIC for successful drug therapy throughout the dosing interval.

General Recommendations (Table 12-3)

Timing of Antimicrobial First Dose

The goal of perioperative antimicrobial prophylaxis is to achieve serum and tissue drug concentrations for the

duration of the operation that exceed the MIC for organisms likely to be encountered during the operation. Landmark experimental studies in the early 1960s revealed that surgical incision contaminated with *Staphylococcus aureus* could not be distinguished from incisions that had not been contaminated when antimicrobial agents were administered before the incision.[36] Furthermore, in 1976, Stone et al demonstrated that the lowest SSI rates in patients undergoing gastrointestinal, biliary, and colon operations occurred when antimicrobial agents were administered within 1 hour before incision.[37] Administration of the first

antimicrobial dose after surgery resulted in SSI rates almost identical to those in patients who did not receive prophylaxis.[370]

Ideally, based on numerous clinical and experimental studies in people and animals, the antimicrobial agent should be administered as near to the incision time as possible to achieve low SSI rates.[28,36-39] Although research in people has demonstrated that administration of the antimicrobial agent at the time of anesthetic induction is safe and results in adequate serum and tissue drug levels at the time of incision, in veterinary medicine we must take into account the time needed after induction for

clipping and surgical preparation, which can be far more extensive and time consuming than in humans. If significant preoperative patient preparation is necessary, the initial dose of an antimicrobial should be delayed past anesthetic induction to more closely approximate 1 hour prior to the start of surgery to ensure appropriate drug concentrations in the peripheral compartments.[4,11,19,30,39] It is also advisable to deliver the entire antimicrobial dose 1 hour prior to applying a tourniquet to ensure local tissue concentrations distad to the vascular occlusion.[4]

Table 12-3. Summary of

General Principals of Antimicrobial Selection

General Principal	Recommendation
Antibiotic timing	Infusion of the first antimicrobial dose should begin 60 minutes prior to the start of surgery
Duration of prophylaxis	Perioperative prophylactic antimicrobials should be discontinued after wound closure at the end of the surgical procedure
Antimicrobial dosing	The initial antimicrobial dose should be based on the animal's ideal weight. Administration should be repeated intraoperatively if the operation is continuing two half-lives after the first dose to ensure adequate antimicrobial levels until wound closure.
Screening for β-lactam allergy	Generally unnecessary, as sensitivity not widely documented in dogs and cats.[46] Clindamycin, vancomycin, or metronidazole are feasible options if β-lactam allergy suspected.

Duration of Antimicrobial Prophylaxis

The majority of published evidence demonstrates that antimicrobial prophylaxis after wound closure is unnecessary, and most studies comparing single- with multiple-dose prophylaxis have not shown benefit of additional doses.[3,5,8,31,40] The optimal

duration of antimicrobial prophylaxis in veterinary surgery is unknown. In people, antimicrobial therapy is often continued for 24 hours beyond surgical wound closure, despite concerns regarding superinfection or selection for antimicrobial resistant pathogens.

Selection of an Antimicrobial Drug[1]

For most routine perioperative prophylaxis, the antimicrobial agents of choice are cephalosporins owing to their efficacy, safety, and cost effectiveness. Cephalosporins belong to the β-lactam family of antimicrobials, which also include the penicillins. Similar to other β-lactam

antimicrobials, cephalosporins alter cell wall formation by interfering with bacterial peptidoglycan synthesis by inhibiting the final transpeptidation necessary for cross-links of the cell wall.

Cephalosporins are grouped into “generations” by their antimicrobial properties. The original cephalosporins were designated first generation with more extended-spectrum cephalosporin drugs being developed and sequentially classified as second, third, and fourth. In general, each new generation of cephalosporins has significantly greater gram-negative antimicrobial properties than its predecessor, however, the expense of

the cephalosporin also usually increases with the generation bracket.

Specifically, most first generation cephalosporins have a spectrum of activity that includes penicillinase-producing, methicillin-susceptible staphylococci and streptococci. First generation cephalosporins also exhibit activity against *Staphylococci* spp., *Streptococci* spp., *Escherichia coli*, *Klebsiella* spp., and *Proteus mirabilis*, but they do not display effectiveness against anaerobic bacteria, *Pseudomonas, Enterococcus* spp., other *Proteus*, or *Serratia*. Second generation cephalosporins display a greater gram-negative spectrum while retaining some activity against gram-positive

cocci and, therefore, are the antimicrobial of choice for most enteric and abdominal procedures. Second generation cephalosporins may also be active against some anaerobic bacteria as well as some strains of *Enterobacter, E. coli, Klebsiella, Proteus,* and *Serratia* that are resistant to first generation cephalosporins. Third generation cephalosporins exhibit a broad spectrum of activity against gram-negative bacteria but display less activity against *Staphylococci* and *Streptococci* species. The newest or fourth generation cephalosporins have a greater spectrum of activity against gram-positive organisms than the third generation cephalosporins. They also are useful and have a greater

resistance to β-lactamases than the third generation cephalosporins.

In conclusion, SSIs in people and animals are the most common cause of postoperative morbidity and mortality because they often necessitate additional intervention and expense and prolong hospitalization.[7,9,10,12-17,28,30,41-45] Before considering whether antimicrobial agents are indicated, it is imperative that a surgeon consider the type of surgery to be performed, its expected duration, the potential pathogens that may be encountered, and the immunocompetence of the animal. While antimicrobial agents are an essential tool used to limit the incidence of SSIs and their associated

complications, they do not replace good surgical technique, including gentle tissue handling, appropriate suture materials and patterns, and adequate preoperative planning.

Chapter 13

Perineal Hernia

G. P. Dupré
H. N. Brissot

Perineal hernia (PH) results from weakness of muscles of the pelvic diaphragm. It occurs most likely in older male dogs, where its prevalence ranges from 0.1 to 0.4% from different hospital admisions.[1,2] It has also been described in cats, but one study describes only 40 cases in 12 years in three major American referral centers.[3] Some cases have also been mentioned

in the female dog.

Clinical signs include straining to defecate and, less frequently, straining to urinate. Some other signs such as fecal incontinence, urinary incontinence, and flatulence have also been mentioned.[1-17]

The clinical diagnosis is based on appearance of a perineal swelling, most often right-sided or bilateral. A rectal examination demonstrates the presence of accumulated feces in an abnormally enlarged rectum. When the rectum is empty, the hernia may be difficult to diagnose. In these cases, the ability to push the finger through an enlarged rectum toward the

sacrotuberous ligament demonstrates the loss of muscular support to the rectum wall and thus is diagnostic for perineal hernia.[1,4,5] Occasionally, an acute soft-tissue swelling increases the perineal deformation unilaterally. In these cases, a perineal cystocentesis usually confirms the diagnosis of an associated retroflexed bladder.[1,15] In most cases, besides the rectal wall deformity, periprostatic fat, omentum, digestive loops, or prostate may fill the perineal cavity.[1,2,18]

Causal Factors for Perineal Hernia

Predisposition

Breeds

Although breed over-representation has been mentioned for the Boston terrier, Pekingese, Boxer, Collies, and Old English sheepdogs,[1,2,12] this predisposition was not found in two other retrospective studies,[16,17] where Yorkshire terriers, Cotons, Bichons, German Shepherds, and Mixed-breeds have been the most common breeds encountered.

Male/Female

Perineal hernia occurs almost exclusively in male dogs. Some authors have shown that the levator ani muscle is larger and stronger in the female compared with the male dog to support

parturition, thus explaining the low number of perineal hernias in the female.[19] However, when the weight of the pelvic diaphragm muscles was compared in some predisposed breeds (Corgie, Boxer)[1,2] to the weight of the same muscles in the Greyhound, no significant difference was found.[19] Therefore, based solely on the muscle weight, it is difficult to understand why perineal hernia occurs rarely in female dogs.[2]

Age

Perineal hernia occurs most commonly in dogs from 7 to 9 years of age.[1,5,12] Whether the age is associated with muscle weakness, prostatic disease, or

any other underlying disease remains unknown.[15,20,21]

Side of the Hernias

Among different studies, 60% of perineal hernias were unilateral and 40% bilateral.[5,10-17] Among the unilateral hernias, almost 70% were right-sided. Studies have failed to demonstrate a relative weakness of the pelvic diaphragm muscles of the right side. On rectal examination of unilateral hernias, a contralateral weakness is often encountered. Failure to recognize this weakness and to reconstruct adequately this contralateral side makes it prone to future hernia.[17]

Increased Abdominal and Perineal Pressure

Chronic constipation resulting from bad feeding habits is usually associated with increased defecating efforts, which in turn, can increase abdominal and perineal pressure.[17,18,22,23] In cats, most cases were bilateral and associated with chronic constipation, megacolon, stranguria, or perineal urethrostomy surgery.[3] Increased abdominal pressure during coughing could be one predisposing factor in female dogs and in older male dogs prone to cardiac insufficiency.

Muscular Weakness and

Atrophy

Perineal herniation commonly occurs between the external anal sphincter and the levator ani muscle and, more rarely, between the levator ani muscle and the coccygeal muscles. Frequently, the cranial remnants of the levator ani can be found close to the external anal sphincter or to the external coccygeal muscle. In severe cases, muscle atrophy will involve not only the levator ani muscle but also the external coccygeus, the internal obturator muscle, and the external anal sphincter.[1,2,18,24] Biopsy specimens of the levator ani muscle fibers of dogs suffering from perineal hernia have shown atrophy of neurologic origin,[24] but it remains unclear whether this atrophy is an

expression of aging, neurologic disease, or excessive pressure.

Hormonal Imbalance

Androgen

Perineal hernias have frequently been associated with testicular tumors (2% of sertolinomas, 15% of interstitial tumors, 19% of seminomas, and 11% of mixed tumors),[25] which suggested an association between hormonal imbalance and pelvic diaphragm muscle atrophy. Currently, no influence of the androgen concentration has been demonstrated, although, in the rat, androgen receptors have been found in the

levator ani muscle. Similar studies in the canine have failed to demonstrate any relation between testosterone levels and muscular fiber size.[19,26,27] In one study, the recurrence rate in castrated animals was 2.7 times less than in intact animals.[2] This is one of the reasons why castration is recommended as an adjunct therapy for perineal hernia.

Role of Prostate

The presence of relaxin in the canine prostate was evidenced and the hypothesis of relaxin being involved in perineal hernia formation in male dogs was tested. Based on preliminary results, relaxin of prostatic origin

leaking from periprostatic cysts, usually seen in the perineum of affected dogs, is a possible factor in local connective tissue weakening and subsequently in perineal hernia formation.[28]

Different studies confirm that dogs with perineal hernia are prone to concurrent prostatic disease (range 10 to 51%)[12,14-17,29,30] In one study where ultrasonographic prostatic assessment was performed before any perineal hernia surgery, prostatic lesions were present in 17 dogs (41%); in 8 dogs (19.5%), prostatic disease had to be specifically treated surgically.[15] In another study on 41 bilateral or complicated hernias, 9 prostatic

surgeries (omentalization or perineal cyst resection) were performed.[17] Given the high frequency of prostatic disease associated with perineal hernia, an ultrasound evaluation of the prostate is recommended prior to surgery. It remains unclear whether both diseases occur in the same type of patients (breed, age, and sex) or if a significant correlation does exist.[15-17,21]

Pathogenesis

Deterioration of the levator ani muscle results in a progressive loss of rectal wall support. The fissure between the external anal sphincter muscle and the pubocaudal part of the levator ani muscle progressively enlarges.

Retroperitoneal fat naturally progresses through this fissure. The loss of muscular support and the progression of defecating efforts increase the chances of the rectum to progressively fill this new space into the perineal cavity. Then, because of lack of continuity of the rectum with the anus, feces cannot be expelled and defecating efforts even increase. Secondary rectal dilation occurs.[1,12,15,17,21] During this process, continual straining to defecate progressively enlarges the rectal dilatation and further weakens the pelvic diaphragm muscles.[17] Finally, persistent straining associated with a huge rectal dilatation and hernia can even promote secondary herniation of

the prostate and retroflexion of the bladder into the perineal cavity.

Rectal Diseases

Rectal lesions associated with perineal hernia have previously been characterized as deviation (a change in rectal orientation from the midline), sacculation (enlargement not associated with tearing of the muscular wall), or diverticulum (protrusion of rectal mucosa through the muscular layers of the rectal wall).[12,14,17,21] Because differentiation between rectal deviation, sacculation, and diverticulum appears difficult clinically or radiographically,[12,13,21] a grading for the rectal dilatation was

proposed.[17] In this study, a simple deviation with no dilatation was a grade 1, a mild rectal dilatation (asymmetric dilatation with fecal accumulation without visible perineal deformation) was a grade 2, and a severe rectal dilatation (asymmetric dilatation with a visible bulge of the perineum and a large amount of fecal accumulation and impaction) was a grade 3.

Bladder Retroflexion

Bladder retroflexion occurred in 12 to 29% of dogs.[8,6,10,12,15-17,29,31] In cases of retroflexion, the bladder rotates at least 180° around its neck. Although this finding was not statistically

significant in all studies,[17] perineal hernias with bladder retroflexion carried a higher mortality rate (30%) and a worse prognosis than those without.[6,10,12] Following retroflexion, several complications can be encountered. Acute renal failure can occur secondary to complete urethral occlusion, bladder necrosis owing to occlusion of the urogenital arteries,[12] and overall, partial, total, temporary, or definitive loss of urinary continence can occur.[12,17]

Perineal Hernia Grading

In order to propose guidelines for surgical treatment, some authors have graded perineal hernias as unilateral,

bilateral, and complicated. A perineal hernia was defined as complicated if it met the following criteria: recurrence of PH, unilateral PH with a severe (grade 3) rectal dilatation, PH with a concurrent surgical prostatic disease, and PH with retroflexed bladder.[15,16,17]

Considerations for Treatment

Closure of the Pelvic Diaphragm

Current approaches to treatment of perineal hernia rely on closure of the pelvic diaphragm. Because muscle appositional techniques resulted in excessive tension on the external anal

sphincter, muscle transposition techniques were developed using the superficial gluteal muscle,[7,8] internal obturator muscle,[8-12] semitendinosus muscle flap,[32] or a combination of internal obturator muscle with superficial gluteal muscle flap.[13] Filling the defect with stainless steel, polypropylene mesh,[33,34] porcine intestinal submucosa,[35,36] and with fascia lata have been suggested.[37] Presently, the internal obturator flap with tenotomy is the most popular and seemingly the most appropriate technique for most cases of herniorraphy. In cases of severe muscle loss, we have successfully used the superficial gluteal muscle flap or the fascia lata free flaps.

Laparotomy in the Treatment of Perineal Hernia

Besides rupture of the pelvic diaphragm, rectal disease, bladder retroflexion, and prostatic disease often occur concurrently.[6,12,14-17,21,29-31] They contribute to the severity of perineal hernia, and may even discourage further treatment. After a report by Bilbrey et al in 1990,[29] some authors studied the incidence of rectal, prostatic, and bladder diseases associated with perineal hernia.[14-17,20] Since 1993 they have developed a "2-step protocol," where laparotomy was performed as the initial stage of repair in bilateral or complicated perineal hernia (recurrence of perineal hernia,

unilateral perineal hernia with a grade 3 rectal dilatation, perineal hernia with a concurrent surgical prostatic disease, and perineal hernia with retroflexed bladder). During laparotomy, colopexy and cysto- or vas deferens-pexy and, if needed, prostatic surgery, are performed, and a perineal herniorraphy using an internal obturator muscle flap transposition[15-17] is performed 2 to 7 days later. Results compare favorably with those of previous studies.[6,9-13] Satisfactory results using colopexy and cysto- or vas deferens-pexy as sole or adjunctive treatment for perineal hernia have also been reported by others.[14,29,31]

Rationale For A Two-Step Protocol

Colopexy resolves rectal dilatation or deviation, vas deferens-pexy stabilizes the prostate, and cystopexy prevents abnormal motion of the bladder so that the perineal space becomes free of viscera after the abdominal surgery. At subsequent herniorraphy, perineal inflammation has resolved and the hernia is empty, which allows improved observation of important local anatomic structures such as the pelvic diaphragm muscles, pudendal and caudal rectal nerves and artery, internal obturator muscle and tendon, and rectal wall. This facilitates hernia repair (Figure 13-1).[15,17] Then

guidelines for perineal repair can be proposed (Table 13-1).

Prognosis, Complication Rates and Causes

Prognosis and complication rates have been published. They depend on the severity of the hernia, associated disease, surgeon's experience, and surgical techniques (Table 13-2).

Colo-Recto-Anal Abnormalities

Preoperatively, external anal sphincter mechanism incompetence is rare. However, chronic distension of the rectal wall and chronic straining may

weaken the external sphincter fibers. Whenever incompetence is suspected, electromyography of the external sphincter should be recommended prior to surgery. Although postoperative fecal incontinence and rectal prolapse have been described respectively in 3 to 15%[10,12,30] and 7 to 42%[10,12] of dogs with PH, none of the dogs sustaining a laparotomy as a first-step procedure experienced this complication.[17] When recorded, persistent postoperative tenesmus has been reported to occur in to 2 to 50% of dogs.[10,12,17] Causes of persistent postoperative tenesmus have not been determined, although rectal deformation associated with persistent rectocolitis has been suggested.[12] Colonic or rectal motility disorders can

also be associated with long-term straining.[22,23] This could explain poor rectal emptying in some patients with good perineal reconstruction.[17]

Urinary Dribbling

Postoperative urinary incontinence has been described in 4 to 8% of dogs with perineal hernia.[6,10,12,14,17] Suggested mechanisms involve acute traction on the hypogastric and pelvic nerves or secondary deterioration of the detrusor muscle owing to retroflexion.[6,12,30] In one study,[17] 15 dogs (36%) presented with urine dribbling after surgery; 8 resolved within the first 6 months, but 7 (17%) had permanent dribbling. Possible associations between prostatic

disease, bladder malposition as well as vas deferens- or cystopexy and urine dribbling remain to be determined.

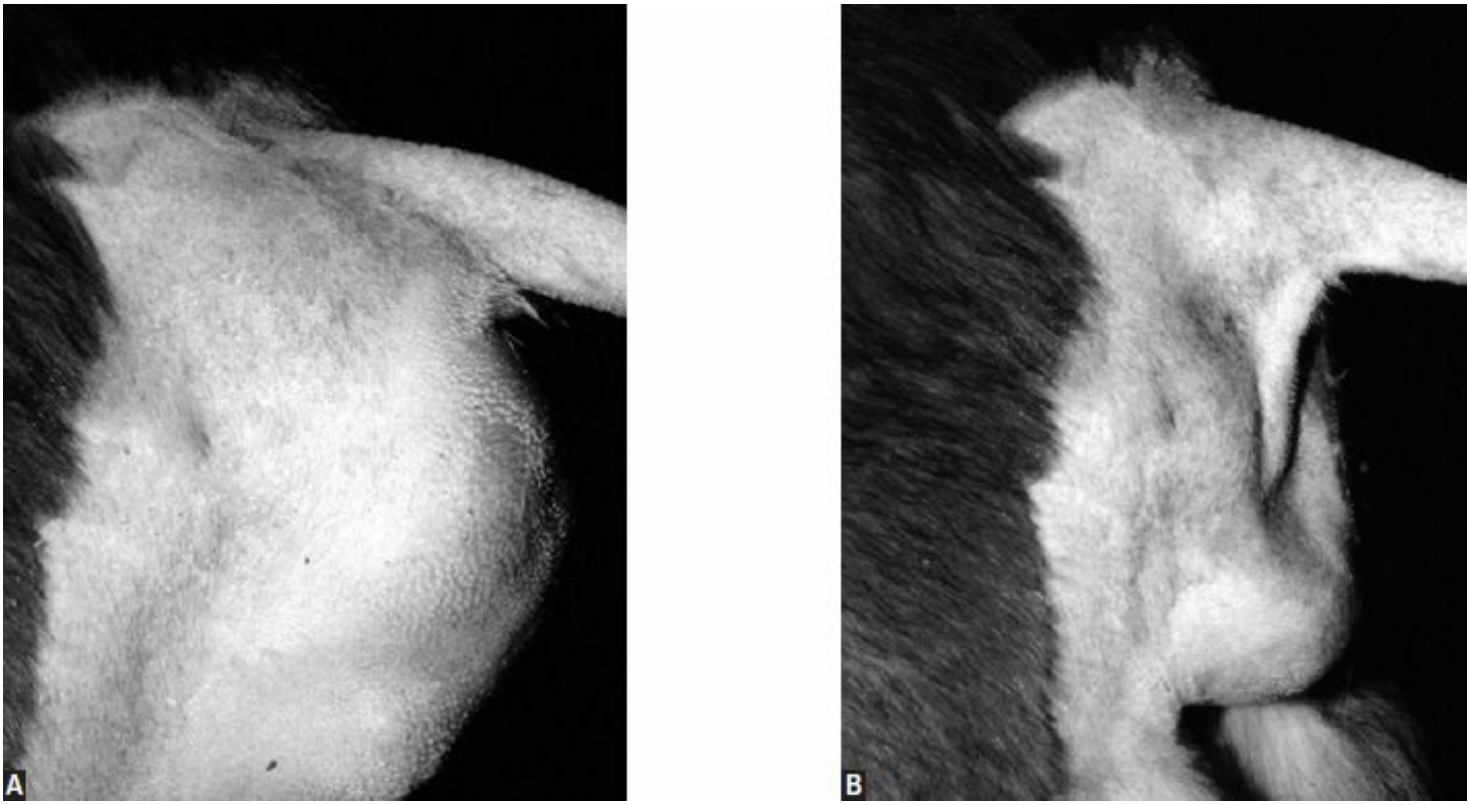

Figure 13-1. A 7-year-old mixed-breed dog with left perineal hernia and grade 3 rectal disease. Note the appearance of the perineum before (A) and after (B) colo- and cystopexy.

Perineal Wound Infection

Perineal wound infection is the most

common complication described after perineal hernia repair, ranging from 5 to 45%.[9-13,17,30] Absorbable monofilament suture material, perioperative antibiotics, and anal closure are used to decrease the risks of postoperative infection.[10,12,30,38] Although laparoscopic colo- and vas deferens-pexy have been suggested,[39] these have been discouraged by some authors because of the high rate of septic complications at the colopexy site.[16,17]

Table 13-1. Current Guidelines for Perineal Hernia Repair[15-17]

1- Upon admission: Is the bladder in

place?

If bladder retroflexion is suspected, catheterization is mandatory. In case of impossible catheterization, a perineal cystocentesis must be performed. Then the bladder can be manually reduced and catheterization becomes possible. Diuresis is monitored.

2- Complete physical exam and blood work

Given the age of the patients, concurrent diseases are not rare, particularly renal or cardiac diseases. In addition, some patients can be debilitated by tenesmus and anorexia. Preoperative enteral feeding may be

necessary.

3- Diagnosis of associated lesions

After manual rectal emptying, grading of rectal disease is provided and prostatic ultrasonography is performed.

4- One- or two-step protocol

Candidates for a laparotomy before perineal herniorraphy include those with:

- retroflexion of the bladder
- surgical prostatic disease
- bilateral hernia
- recurrence
- unilateral hernia with grade 3 rectal disease

During laparotomy, only patients suffering from vesical retroflexion undergo a cystopexy, but colopexy, vas deferens-pexy, prostatic biopsies, and castration are done on all. In all other cases, a perineal herniorraphy and neutering are accomplished as the sole surgical treatment.

5- Medical care

When a laparotomy has been the first step, herniorraphy can be delayed for about 48 hours, during which rectal emptying and enteral feeding (no residue) can be accomplished. In some debilitated patients the herniorraphy can be delayed even further.

6- Perineal herniorraphy

Herniorraphy is the last step of this protocol. It usually involves an internal obturator flap, but a superficial gluteal muscle or fascia lata free flaps can also be added.

Table 13-2. Signalment, Description of Associated Lesions, Surgical procedures, Postoperative functional outcome and Recurrence rate published for Dogs suffering from Perineal Hernias.[9-12,14,17]

Chapter 14

Abdominal Hernias

Daniel D. Smeak

An abdominal hernia is a defect or opening in the wall of the abdominal cavity (external abdominal hernia) or within a compartment of the peritoneal space (internal abdominal hernia). Under certain clinical conditions, the defect allows protrusion (herniation) of an abdominal structure. Organs or tissue located in the immediate vicinity are usually found within the defect. However, predicting

the organ involved may be difficult because freely movable organs with long vascular pedicles may travel considerable distances to occupy the hernia. It is important to understand that the defect itself may not be the most important clinical problem presenting to the veterinarian for treatment. Instead, it is the cause and effect of vital structure entrapment within the confines of the defect (hernial ring) or concurrent organ damage from trauma, which often dictates whether prompt and aggressive medical or surgical treatment is needed. Frequency and types of complications, success of surgical repair, and ultimately, final outcome are often dependent on the

initial condition of the patient and the organ involvement.[1-3] Whether an uncomplicated hernia defect requires surgery depends on the surgeon's estimate of the risk of future organ displacement. The causes of an abdominal hernia should also be determined so proper decisions can be made to help prevent perpetuation of the defect in offspring and to reduce the risk of incisional breakdown (dehiscence) or recurrence.

Hernia Classification and Terminology

Abdominal hernias are described in many ways depending on the nature of the herniation or defect, the location or

anatomy of the hernia, the etiology, and most importantly, the condition of the structures protruding through the hernia and the functional alterations resulting from this protrusion.

The abdominal wall is composed of multilaminar arrangements of muscles, their aponeuroses, strong fascia, fat, and either skin or peritoneum. Generally speaking, the abdominal wall functions as a barrier to contain (limit movement) and offer protection for vital abdominal organs. Several normal anatomic openings lined with peritoneum penetrate the external abdominal wall, providing nourishment to the fetus (umbilical aperture), passageway and

neurovascular supply for the testicles (inguinal canal), and neurovascular supply to the rear limbs (femoral canal).[4]

"True" hernias are generally formed from a **congenital** (present at birth) weakness or absence of tissues surrounding the normal abdominal apertures. More rarely, true hernias include midline abdominal wall fusion defects. This weakness or lack of a barrier leads to enlargement of the opening (hernial ring) and eventual organ protrusion. True hernias have a complete lining or sac of peritoneum (hernial sac) surrounding the contents. Congenital defects in the ventral midline of the abdominal wall, so

called “ventral hernias or substernal hernias,” often associated with internal hernias (diaphragmatic), are also considered true hernias because peritoneum usually covers the hernia contents. This slippery peritoneal lining helps reduce adhesion formation of herniated organs or tissue to periabdominal tissue so these hernias are frequently **reducible** (contents freely move from within the hernial sac to the abdomen) and often pose no immediate threat to the patient.

“False” hernias allow protrusion of organs outside the normal apertures of the abdominal wall. False hernias initially do not contain a complete peritoneal sac. Generally, these hernias

are **acquired**, caused either by accidental trauma to the abdomen (traumatic hernias) or following breakdown of a surgical approach to the abdomen (incisional hernia). One recent report described a dog with a traumatic abdominal hernia caused by a fractured 12th rib penetrating through the paracostal musculature, resulting in liver herniation; this was termed an **"auto-penetrating hernia."**[5] Owing to the lack of a peritoneal covering, false hernias often lead to development of organ adhesion to surrounding periabdominal tissues causing complications such as **incarceration** (hernial contents become trapped or irreducible). In contrast to true hernias, contents of

false hernias are exposed to local tissue inflammation and may sustain constriction of blood supply as the hernial rings contract during healing. When vascular supply to the contents within a true or false hernia is compromised it is said to be **strangulated**, and this is a surgical emergency.

Causes and Pathophysiology

The etiology of a hernia may be from a single obvious defect, such as trauma, or, more commonly, from multiple predisposing factors. Hernias may be the result of either congenital or acquired factors. Congenital defects result when injury or altered

development of the fetus occurs as a result of various factors (developmental) or from genetic mechanisms that are transmissible from generation to generation (hereditary). Developmental hernias may be caused by lack or excess of some necessary substance (vitamin, protein) or by a toxin, resulting in abnormal fetal development. As investigation continues into causes of congenital hernias, more and more "developmental" hernias may be found, in some way to be caused by as yet unknown genetic influences. Therefore, until genetic causal factors have been eliminated for specific congenital abdominal hernias, it is prudent for the veterinarian to advise

sterilization of affected patients.

Developmental Hernias

Congenital inguinal and umbilical hernias have well explained developmental causes. Male dogs develop congenital inguinal hernias more often than do females.[1] This is believed to be a result of delayed inguinal ring narrowing because of late testicular descent in dogs.[1,6,7] Congenital umbilical hernias result from failure or delayed fusion of the lateral folds (principally tissues forming the rectus abdominis muscle and fascia) at the umbilicus after normal return of the midgut (6th week of gestation) from the umbilical cord in

the fetus.[8] Omphalocele congenitalis is a congenital defect formed when loops of intestine are delayed in their transit from the umbilical cord into the abdominal cavity. Gastroschisis is another congenital abnormality appearing similar to omphaloceles, except that the abdominal wall defect is paramedian.[9] Spontaneously occurring femoral and scrotal hernias seen in adult dogs are thought to be caused by an underlying congenital weakness of the musculofascial tissues surrounding the respective abdominal apertures. Factors such as trauma and increased intraabdominal pressure, from obesity or chronic straining from constipation for example, may then trigger hernia occurrence later in life.[3]

Hernias are often found in patients with other congenital defects. Cranioventral abdominal hernias, incomplete caudal sternal fusion, and umbilical defects with concomitant diaphragmatic hernias of various types have been described in puppies.[10] Successive breedings of a Laborador retriever and American foxhound with these defects created ratios of affected offspring suggesting an autosomal recessive mechanism.[11] Another investigation describing diaphragmatic, cardiac, and abdominal wall defects in a litter of cocker spaniel dogs, similar to thoracoabdominal ectopic cordis syndrome, however, suggested a developmental cause.[12] Cardiac malposition in humans may

cause a mesodermal defect resulting in partial or complete failure of septum transversum development and subsequent supraumbilical fusion failure.[8,13] Congenital heart defects and portosystemic shunts may be associated with supraumbilical defects.[14] Defects associated with caudal ventral midline (infraumbilical) hernias include exstrophy of the bladder, hypospadius, and imperforate anus.[8,15] In addition, dogs with umbilical hernias often have cryptorchidism as well as other congenital defects.[16,17] These findings confirm the need to examine patients with congenital hernias closely for other important developmental problems before attempting surgical

repair.[2]

Heritable Hernias

Many congenital umbilical and inguinal hernias are thought to be caused by hereditary influences. Heritable inguinal hernias have only been documented, however, in the golden retriever, cocker spaniel, and dachshund.[18] In man, persistence of the process vaginalis (opening into the evaginated peritoneum surrounding the testicle) and enlarged inguinal rings have a similar familial tendency. Although most umbilical hernias appear to be inherited, no definitive information has been presented regarding the mode or pattern of

inheritance affecting the fibrosis and union of the abdominal aponeuroses. Results of one study indicated that this defect is probably the result of a polygenic threshold character, possibly involving a major gene whose expression is mediated by the breed background.[19,20] Umbilical hernias have also been associated with fucosidiosis, an inherited neurovisceral lysosomal storage disease. Of 31 English springer spaniels diagnosed with fucosidiosis, 10 had umbilical hernias and 1 had a scrotal hernia. This disease is believed to be inherited in an autosomal recessive manner.[21] Neutering should be recommended for all small animals with congenital inguinal or umbilical hernias until

conclusive evidence is demonstrated regarding the heritable nature of this disease process.[6]

Hernias Caused by Metabolic and Hormonal Imbalance

Certain pathophysiologic conditions predispose to acquired abdominal herniation. Inguinal hernias are most commonly seen in older intact female dogs.[1] These hernias occur as a result of multiple factors including obesity, decreased connective tissue strength, and increased intraabdominal pressure. Obesity causes increased intraabdominal pressure, forcing fat through abdominal wall apertures and further dilating the hernial rings.[22]

Onset of hernia occurrence is often associated with estrus or pregnancy, suggesting hormonal imbalance as a contributing cause.[23] Estrogen production is considered to have a close relationship with development of inguinal hernias. Sex hormones may change the strength or character of the connective tissue, weakening or enlarging the inguinal rings.[24] Experimentally, sex hormone imbalance has been directly linked to formation of inguinal hernia in male and female mice.[25] Ovariohysterectomy, therefore, is recommended to reduce the incidence of acquired inguinal hernias; this procedure may help to prevent recurrence following repair.

Supporting structures of the abdominal wall may also become weak or stretch owing to nutritional or metabolic problems (for example, hyperadrenocortism or diabetes mellitus). Accumulation of fat around the round ligament may dilate the vaginal processes and inguinal canal, allowing herniation.[26] Maintenance of normal body weight and eliminating hormonal or metabolic disturbances should help reduce the incidence of acquired nontraumatic abdominal hernias.

Traumatic Hernias

It has been proposed that the contents of acute traumatic hernias may be

more prone to adhesion formation to extra abdominal structures and to incarceration because such hernias lack a complete serosa lined hernial sac. Traumatic hernias may undergo organ strangulation owing to swelling caused by acute inflammation or from hernial ring contraction during healing.[22] However, adhesion formation, incarceration, and strangulation have not been found to be common sequelae of traumatic hernias in retrospective studies. The important cause of organ damage may be from the trauma itself, rather than from the hernia. None of the contents of 21 traumatic hernias in one retrospective study demonstrated any evidence of vascular obstruction from incarceration during abdominal

exploration; although 2 dogs had evidence of traumatic intestinal devitalization.[27] One dog developed organ compromise as a result of mesenteric avulsion in a recent report of 36 traumatic body wall hernias in dogs and cats.[5]

Most abdominal hernias are caused by blunt trauma (automobile accidents, kicks, falls). Of 21 consecutively studied traumatic abdominal hernias, 17 were caused by blunt trauma (automobile accident) and 4 by penetrating trauma (dog fight).[27] Hernias can occur in a variety of locations, often dictated by the mode of trauma.[22,28] The most common areas of herniation caused by blunt trauma

in one study were in the ventrolateral caudal abdominal (inguinal or prepubic areas) and paracostal regions.[27] In a more recent study, 28 of 36 dogs and cats with abdominal hernias were caused by bite wounds.[5] The lateral paralumbar site was the most common hernia location in dogs in Shaw's study,[5] whereas the ventral body wall and femoral sites were more common in cats. All pubic ligament ruptures in this study were caused by vehicular trauma.

Hernia location depends on various factors, including the local direction of the traumatic force and intraabdominal pressure changes. Blunt trauma, applied while abdominal

muscles are contracted but the glottis is open, thus limiting increase in intraabdominal pressure, may result in traction or avulsion type injury to tissues with minimal elasticity (muscle attachments to bone).[22,27] Common hernias resulting from avulsion forces are the prepubic (ruptured cranial pubic ligament), inguinal, and dorsolateral hernias (muscle avulsion from transverse processes of lumbar vertebrae termed paralumbar or lateral hernias).[27,29] Rupture of the cranial pubic ligament is often associated with concurrent inguinal ligament damage (a traumatic femoral or inguinal hernia may result). A sudden increase in intraabdominal pressure may cause rupture in the weakest area of the

abdominal wall. Paracostal hernias occur when the origin of the external oblique abdominal and transverse abdominal muscles avulse from their rib or costal cartilage origin, or they are caused by a broken rib lacerating adjacent musculature (autopenetrating hernia).[5] Abdominal viscera herniate laterally into the subcutaneous tissues in paracostal and paralumbar hernias. Paracostal hernias frequently occur with diaphragmatic rupture, presumably as a result of similar initiating forces. Direct local trauma caused by a blunt object (shoe, fence post) results in separation (tearing) of the wall at the location of impact.[30]

Blunt trauma may cause widespread

crush, rupture, or avulsion damage to intraabdominal organs. Up to 75%of traumatized small animal patients with abdominal hernias have other significant injuries; most are orthopedic and usually involve the pelvis. In decreasing order of frequency, the respiratory, gastrointestinal, and genitourinary systems are also injured.[27] In a recent study, over 50% of patients with traumatic hernias suffered injury to other structures. One quarter had more than one associated injury. One third of the hernias had associated body cavity injuries including diaphragmatic hernia, kidney avulsion, bladder rupture, and mesenteric avulsion. In addition, 9 of 36 animals had

concurrent orthopedic injuries.[5] A thorough examination of patients with traumatic hernias is imperative to assess for significant associated injuries.

Abdominal hernias may rarely occur through a fracture defect (sacroiliac luxation, pubic or symphyseal fracture).[31,32] In addition to the fracture, severe damage to underlying soft tissue structures, such as ligaments and mesenteric attachments, is required to allow organ herniation.[28] Traumatic body wall hernias may also result from shearing forces that are distributed over boney projections of the pelvis or caudal thorax rib cage. These forces result in the tearing of

muscles or tendons from their boney attachments.[33]

Sharp trauma (bite wounds, gunshot, knife stabs) may cause herniation anywhere in the abdominal wall. Animal fight wounds are more apt to cause multiple hernias located in the dorsal or lateral abdominal wall.[5,27] Tears, perforation, and laceration of intraabdominal structures occur frequently with sharp trauma. Shaw reported that nearly 25% of animals with perforating abdominal wall trauma had evidence of intestinal damage requiring resection and anastomosis.[5] Therefore, patients with penetrating abdominal trauma and herniation should undergo emergency

abdominal exploration after stabilization.[34,35]

Incisional Hernias

Incisional hernia incidence is reported to be between 1% and 11% in humans, and is as great as 16% in large animals, depending on the surgical approach to the abdomen, predisposing factors, and overall status of the patient.[36,37,38] Incisional hernia in small animals is less common. Sequelae to incisional hernia often are extremely serious and costly (e.g., total abdominal wound dehiscence in humans is associated with a 15 to 20% mortality rate).[24,39]

Predisposing causes of acute and chronic incisional hernia vary, appear interrelated, and occur at different times after surgery. Acute incisional hernias generally occur within the first 7 days after surgery, whereas chronic hernias are noted weeks to years postoperatively. Reported risk factors for acute incisional hernia include increased intraabdominal pressure because of pain, entrapped fat between hernia edges, inappropriate suture material use, infection, chronic steroid treatment, and poor postoperative care.[40] Technical error in surgery is the most common cause of **acute** wound disruption.[3,39] Factors associated with **chronic** incisional hernia in humans include obesity,

hypoproteinemia, cardiopulmonary complications, abdominal distention, skin wound dehiscence, and deep fascial infection. Local wound complications, especially deep infection, are considered the most important predisposing causes of chronic incisional hernias.[37,41]

Incisional hernias result from either excessive forces acting on the abdominal incision or poor holding strength of the sutured wound.

Excessive Forces on the Incision

Forces disrupting the abdominal incision are mainly derived from

excessive intraabdominal pressure or muscle tension. Experimentally created abdominal wounds healing under increased tension were less resistant to rupturing compared with wounds under normal tension, at 15 days.[42] Vigorous uncontrolled activity or violent coughing or straining postoperatively certainly predispose to wound breakdown. Increased intraabdominal pressure is observed in such conditions as obesity, abdominal effusions, pregnancy, or organ distention because of ileus or obstruction; all these problems increase incisional hernia risk.[39,42]

The gravity dependent ventral midline and paramedian approaches pose a

greater risk for incisional herniation. Experimentally created transverse abdominal incisions in rabbits offer better security against dehiscence than ventral midline incisions because the suture/tissue interface is stronger in this area.[42] "Grid incisions" or those that involve muscle splitting, such as the flank approach, may be less susceptible to incisional hernia because wound edges are drawn together with muscle contraction.

Poor Holding Strength of the Wound

The choice of suture material for abdominal closure is rarely the sole cause of incisional hernia, provided the

appropriate size is used.[39,42] Choice of suture type may be critical in patients that have prolonged wound healing or are severely catabolic and when wound infection is present, particularly when an unpredictable, rapidly absorbable suture such as chromic gut is used.[39]

A tied suture is only as strong as its knot. The nature of disruptive forces produced by normal physical activity applied to sutures and their knots remains unknown. An *in vitro* knot testing study found that suture materials placed in an interrupted pattern, except polydioxanone and monofilament nylon, were secure with three square throws. Square knots used

to begin or end a continuous pattern require an additional one or two square throws, respectively, to be secure. Granny knots, loose asymmetrical square knots, and loosely tied square knots were not as secure as snug square knots for most suture materials tested.[43]

Whether suture is placed in an interrupted or continuous pattern or the abdomen is closed in a single or double layer has little significance in incisional hernia formation, provided the strength holding layer is incorporated.[42,43,44] Of 52 human patients with acute incisional hernia, 88% of the disruptions contained intact sutures that had pulled through tissue,

whereas only 12% had broken sutures. The problem with most of the closures was inclusion of too little rather than too much tissue.[39] The holding power of abdominal wounds closed in a single layer was stronger than that of double layer closures in one experimental study involving rabbits.[42] Interrupted suture patterns are the more secure choice in situations where wound edges have questionable viability or strength or if other predisposing incisional hernia factors are present.

Successful, lasting abdominal wall closures must include the external rectus fascia. Identifying this layer before attempting closure is critical. Sutures should incorporate at least 5

mm of healthy fascia to ensure adequate anchorage.

Prevention of incisional dehiscence is best afforded by preventing excessive continual intraabdominal pressure (reducing coughing, straining) or abdominal distention, and preventing local wound complications (infection, seroma). Necrosis within a suture loop caused by excessive tightening should be prevented. Meticulous surgical technique placing sutures in strong tissue with adequate tissue bites using proper knot tying will reduce the incidence/occurrence/development of most acute wound dehiscences.

Causes of Hernia Recurrence

Overall, abdominal hernia recurrence appears to be much less frequent in small animals compared with humans. Abdominal hernia repair breakdown in humans ranges from less than 1% to 20%, depending on the cause and type of hernia and patient variables. Most hernia recurrences stem from infection, extreme tension on the repair, incorporating tissues with poor strength in the repair, poor anatomic reconstruction, or more obvious technical failure such as inappropriate suture type or size. Overall, it appears that the choice of suture material is less important than the technique and placement of sutures for prevention of hernia recurrence. The prime etiologic

factor in late hernia recurrence is tension on the suture line, which is the cause of suture or tissue disruption. Increased intraabdominal pressure from vomiting, coughing, or straining to urinate or defecate greatly increases the risk of dehiscence. Severe obesity triples the risk of hernia recurrence in humans owing to increased intraabdominal pressure.[3]

High sac ligation to help reduce hernia recurrence, popularized by Marcy in some of the earliest reports of successful hernia repair, was until recently a universally accepted goal of hernia repair technique.[45] It is now known that the peritoneum lining the hernia sac is relatively weak and

regenerates rapidly. Healing of large serosal defects is usually complete in less than one week.[46] Clinical and experimental studies have shown that the risk of incisional disruption is no greater if the peritoneum is not sutured at laparotomy or herniorrhaphy. Because of these findings, many surgeons now believe that high hernial sac ligation does not prevent recurrence, provided the other aspects of the repair are properly performed.[47] Suturing the peritoneum may cause deleterious effects such as local ischemia, delayed healing, increased postoperative pain, and adhesion formation.[48]

When a hernia recurs many times, it is

unwise to always assume that the prior surgeon and surgical procedure were inadequate. Underlying tissue weakness may be responsible for the failure. In one recent experimental study, progressive fascial wound failure decreased the fidelity of subsequent incisional hernia repair, compared with identically sized acute abdominal wall defect repairs. The mechanism appears to include decreased fascial wound strength and decreased tissue compliance after herniorrhapy.[49] Mesh reconstruction of these complicated recurrent hernias is now routinely recommended in humans because defects of any size can be repaired without tension. In addition, polypropylene mesh sets up a

scaffolding that, in turn, induces the synthesis of collagen.[50] A biologic approach to combat acute wound failure is gaining more attention in human surgery. Treatment of experimentally created abdominal fascial incisions with growth factors in one study prevented development of incisional hernias in the rat model. TGF-beta stimulated fascial macrophage and fibroblast chemotaxis as well as collagen production.[51]

Sequelae to Organ Herniation and Trauma

Most abdominal wall defects can be reconstructed easily and successfully if the previously described surgical

principles are observed. The overall success of a hernial repair (and often the prognosis for the patient), however, relies heavily on how the surgeon manages the sequelae to organ herniation or internal damage from trauma, which tend to impair normal body function. The severity of the functional alteration depends on the cause, location, and content of the hernia. Important, often life-threatening sequelae can be attributed to space-occupying effects or the condition termed “loss of domain,” incarceration, or strangulation. The condition of the animal at presentation, concurrent injuries to distant structures, as well as organ compromise owing to the trauma must

also be factored when attempting to predict patient outcome.[5]

Space-Occupying Effects

"Loss of domain" occurs when the abdominal cavity has become accustomed to a small intraabdominal volume so reduction of the hernia contents and primary closure of the defect are impossible. This is most commonly associated with closure of large chronic hernias. Repair of the abdominal wall and forcing the herniated contents back into the abdomen often result in excessive tension on the repair (increasing recurrence risk). Even more deleterious are acute pulmonary complications

(caused by restriction of diaphragm function) and poor organ perfusion. High intraabdominal pressure has been documented in a series of client-owned dogs undergoing abdominal surgery, necessitating surgical decompression; one case was following hernia repair.[52]

Several techniques have been employed in human patients to reduce this “loss of domain” complication, using a tissue expansion principle.[53,54] Progressive pneumoperitoneum and tissue expansion using inflatable silastic expanders function to gradually expand the abdominal wall in much the same way that pregnancy does. Staged reduction of open congenital abdominal defects with a silastic sac

has achieved excellent results with little mortality in infants. Most adult human patients with “loss of domain” are repaired using prosthetic materials to help span the defect to avoid tension and hernia recurrence, as well as postoperative complications.[54,55]

Other examples of space-occupying effects occur when organs herniate into the pleural or pericardial spaces. The negative pressure in the pleural space tends to draw abdominal organs into the chest. Organs herniating into the chest or pericardial sac reduce lung expansion and cardiac function, respectively, creating problems with patient management particularly at anesthetic induction. Severity of

compromise depends on the volume and rate of expansion of the space-occupying herniated tissue. For example, a herniated liver lobe, spleen, or omentum rarely causes major problems for the patient unless strangulation occurs, so most are surgically repaired on an elective basis. A rapidly expanding herniated stomach, on the other hand, causes severe progressive respiratory distress and is a surgical emergency.

Incarceration

Incarceration of organs such as the intestine, uterus, or bladder most often alters normal function because of luminal obstruction. Incarcerated

organs are irreducible and can become (within hours) lethal strangulated obstructions. The severity and onset of the clinical signs related to the incarcerated obstruction often depends on the contents of the hernia and size of the defect. Abdominal defects with small-sized, rather inelastic hernial rings, such as scrotal or femoral hernias, are at high risk for incarceration and strangulation.[1]

Incarceration of the uterus is often associated with inguinal hernias or large umbilical hernias. An irreducible viable, nongravid uterus within a hernia rarely causes clinical problems, however, incarceration of a pyometra or gravid uterus may lead to severe

systemic alterations. Toxemia, resulting from obstructed drainage of an infected uterus or from uterine rupture, and dystocia are sequelae of uterine incarceration. Emergency surgical resection of the diseased uterus or caesarian section is given first priority following aggressive patient stabilization with appropriate fluid and antibiotic therapy. Surgical repair of the hernia is attempted only if the patient's vital parameters are stable following uterine surgery; otherwise repair is performed under more controlled conditions.

Small intestine may become incarcerated within any hernia, but it is my clinical impression that the risk

is greatest when the hernial ring approximates the size of the bowel. Smaller hernias rarely allow intestinal protrusion. Larger hernias rarely trap or obstruct bowel unless they are caused by acute trauma or the entrapped intestines undergo torsion. Intermittent intestinal dysfunction may occur, however, even if intestines are reducible within the hernia. Once signs of intestinal obstruction occur (acute abdominal pain, vomiting, depression, anorexia) early intestinal decompression is warranted. Electrolyte, acid-base, and body fluid imbalances associated with the particular level of intestinal obstruction are corrected without delay before surgery. Adhesions, if present,

are broken down and an incision is made in the hernial ring to help reduce the intestines and relieve the obstruction.

The urinary bladder may become obstructed in incarcerated perineal, ventral, inguinal, and traumatic pubic hernias. As urine flow becomes partially obstructed within the hernia, the bladder progressively distends, further obstructing outflow. Complete obstruction causes severe metabolic consequences such as azotemia, hyperkalemia, and metabolic acidosis, and eventually causes bladder-wall necrosis. Death results within 2 to 3 days if the obstruction is not relieved. Immediate bladder decompression and

diversion of urine flow via needle cystocentesis, catheterization, or tube cystostomy are imperative. Diuresis is established with appropriate intravenous fluids following bladder decompression. If kidney function is not impaired, azotemia and electrolyte abnormalities usually normalize within 24 hours, after which surgical reduction of the bladder and hernia repair are attempted.

Strangulation

A strangulated hernia implies that the hernial contents are incarcerated and undergoing devitalization from arrested circulation. The arrested circulation may be from venous or

arterial occlusion, or from a combination of the two. Early venous obstruction results in reversible organ engorgement, but eventually arterial stagnation occurs from back pressure at the capillary beds. Arterial stagnation or obstruction causes rapid organ necrosis if collateral blood supply is insufficient, resulting in organ rupture. Generally, venous obstruction occurs early in most strangulated hernias, but by the time surgical decompression is attempted, irreversible arterial stagnation has occurred.

Strangulation occurs from several mechanisms such as constriction of the blood supply at the hernial rings or

from allowing organs more freedom of movement, resulting in torsion of a vascular pedicle. Organs with long, freely movable vascular pedicles (e.g., uterus, omentum, spleen, intestine, testicle) are more prone to torsion. Incarceration of a hollow viscus organ favors strangulation because increasing intraluminal pressure further obstructs venous outflow from the organ and opposes circulatory pressure. Traumatic hernias are more prone to incarceration and strangulation because organs are held within the hernia by adhesions, and the hernia ring eventually narrows from contraction during wound healing. Pleural effusions resulting from entrapped, compromised liver

lobes in chronic diaphragmatic hernias are an example of this process. Decompression of ascites in humans with reducible umbilical hernias may result in rapid incarceration and strangulation. Decompression apparently reduces tension on the hernial margins, acutely narrowing the defect.

The threat of complication and death is 50% higher in human patients with incarcerated or strangulated hernias versus hernias containing reducible viable tissue. Early diagnosis and surgical correction of incarcerated hernias, therefore, is critical to prevent life-threatening sequelae relating to organ devitalization. Sequelae of

hernia strangulation vary, depending on the organ involved and chronicity. Strangulated umbilical, inguinal, femoral, and prepubic hernia most often contain falciform ligament or omentum, uterus, prostatic fat, and urinary bladder, respectively.[12] The clinical course is affected by the degree of vascular compromise, volume of body fluids lost from obstruction or sequestration, and absorption of bacteria and toxins. Strangulated contaminated hollow viscus organs may result in significant blood, protein, and fluid loss, and often rupture, causing toxemia and septicemia. Bacteria migrate transmurally through devitalized intestine even before evidence of gross

spillage occurs.[56] Before overt signs of infection or contamination occur, vasoactive substances such as arachadonic acid metabolites (cytokines, leukotrienes, kinins) from tissue and blood cell autolysis cause redistribution of body fluids and severe cardiopulmonary effects.[57]

Strangulated viscera within external abdominal hernias (when compared with intraabdominal strangulated viscera) are more isolated from the vascular system. Liberated vasoactive substances are not absorbed as quickly through the subcutanous tissue as the permeable peritoneal lining, and thus, external strangulated hernias may have a more delayed onset of clinical

signs and shock. Initial management of patients with strangulated hernias include aggressive restoration of tissue perfusion, pain management, acid-base, and electrolyte balance, appropriate antimicrobial and shock therapy if infection and toxemia are present, and lastly, emergency surgical correction. Ventral midline celiotomy is the preferred approach to most strangulated hernias because it allows complete abdominal exploration, and the affected organ can be isolated with surgical towels to avoid further soilage of the peritoneum. Manual reduction of strangulated organs should not be attempted. Severely compromised patients often decompensate and die under anesthesia during attempts at

surgical reduction and repair of strangulated hernias; this is thought to be caused by rapid release of vasoactive substances into the circulation from necrotic strangulated organs during surgical reduction. *En bloc* resection of the herniated devitalized tissue, releasing the constricting ring only after the vascular supply is occluded, may help reduce this fatal complication.[2]

Conclusion

Successful management of an abdominal hernia not only requires observation of sound surgical principles (anatomic closure of the defect without tension, incorporating

strong tissue with meticulous technique) but a solid understanding of the disease mechanisms reviewed in this chapter. Attempts at hernia repair without searching and correcting for the underlying cause or the pathophysiologic consequences or effects associated with organ herniation often lead to hernia recurrence, severe postoperative complications, or death.[58]

Chapter 15

Diaphragmatic Hernia

Geraldine B. Hunt

Anatomy

The diaphragm separates the abdominal and thoracic cavities and assists in ventilation. The muscular costal, sternal, and lumbar parts of the diaphragm surround a strong central tendon.[1] The costal and sternal muscles insert on the abaxial border of the central tendon, and the lumbar muscles insert on its axial border. The central

tendon is approximately Y shaped, with each arm of the Y extending dorsally from the central region up to the 13th rib. The paired lumbar muscles form the diaphragmatic crura. The right crus is larger than the left. Each crus has a bifurcate tendon arising from the bodies of the third and fourth lumbar vertebrae, medial to the psoas minor muscles. The sternal muscle is unpaired and is continuous with the left and right costal muscles. It originates from the xiphoid cartilage, transverse fascia, and the eighth costal cartilages and extends forward to insert dorsally on the body of the central tendon.

The aorta, azygos and hemiazygos

veins, and lumbar cistern of the thoracic duct pass through the aortic hiatus.

The thoracic surface of the diaphragm is adjacent to the lungs and is covered by endothelial fascia and pleura, the pleura being continuous with that of the mediastinum. The mediastinal attachment to the diaphragm is median dorsal to the esophagus. Ventral to the esophagus it deflects to the left in a wide semicircle across the left diaphragmatic costal muscles and returns to the midline at the sternum. A pleural reflection (plica vena cava), caudal to the heart around the caudal vena cava, is attached to the diaphragm on the right side. The plica

vena cava and the mediastinum form a pouch cranial to the diaphragmatic central tendon that is occupied by the accessory lung lobe. Organs involved in diaphragmatic hernias may occasionally occupy this pouch, rather than the main part of the thoracic cavity. Motor innervation to the diaphragm is by the phrenic nerves.[1,2]

Embryology

Embryogenesis of the diaphragm is complex. The transverse septum is the initial incomplete partition between the pericardial and peritoneal cavities. This septum becomes the central tendon of the diaphragm. The dorsal mesentery of the esophagus develops

simultaneously with the transverse septum and produces the median portion of the diaphragm. In adults, this mesentery forms the diaphragmatic crura, including the esophageal hiatus and aortic hiatus. The pleuroperitoneal folds develop along the lateral body walls and migrate medially, where they close the pleuroperitoneal canals by fusion with the esophageal mesentery and dorsal portion of the transverse septum, thereby completing the diaphragmatic partition. Finally, as the pleural cavities enlarge, myoblasts from the body wall invade the peripheral border of the diaphragm to form the costal muscles. Failure of development or fusion of any of the aforementioned

structures may lead to formation of a pleuroperitoneal or peritoneopericardial hernia.[3]

Physiology

The diaphragm contracts during inspiration, pushing caudally on the viscera and displacing the abdominal wall outward.[4,5] At the same time, contraction of the diaphragmatic costal muscles expands the caudal thorax. The diaphragm plays a critical role in the maintenance of negative intrapleural pressure by resisting movement of abdominal viscera into the thorax during inspiration.

Types of Hernias

True diaphragmatic hernias are rare with the exception of hiatal hernias. Herniated viscera in false diaphragmatic hernias (traumatic or congenital) are not contained within a sac but lie free within the pleural cavity or pericardial sac. With peritoneopericardial hernias, the peritoneum is continuous with the visceral layer of the pericardium.

Traumatic Diaphragmatic Hernia

Following trauma, the diaphragmatic costal muscles are more often disrupted than the central tendon, whereas the stronger crural muscles are seldom damaged.[6] Despite early claims to the

contrary, left to right distribution is probably uniform in dogs and cats, with sporadic cases having bilateral or multiple tears.[6-10] Tears are oriented circumferentially in about 40% of dogs, radially in 40%, or both in 20%. Cats had a preponderance of circumferential tears (59%) and fewer radial tears (18%) in one report.[9] In another series, tears were left-sided in 44% of cats, right-sided in 38%, ventral in 15%, and multiple in only 1 cat (23%).[8] In humans, the liver protects the right side of the diaphragm, and left-sided rupture of the tendon is 8 times more frequent than right-sided rupture.[11] In dogs and cats, the liver contacts both sides of the diaphragm and its protective effect is

not as marked. The liver is found in the thoracic cavity in over 80% of cases with diaphragmatic hernia.[6] The small intestine, stomach, spleen, omentum, pancreas, colon, cecum, and uterus may be involved, in descending order of frequency. Herniation of a gravid uterus has been reported in a dog.[12] Herniation of a kidney, leading to urothorax has been reported in a cat.[13] Which organs occupy a hernia depend on various factors, including the site of the diaphragmatic tear, proximity of the organs, and range of movement of supporting ligaments or mesentery. The liver, small intestine, and pancreas tend to herniate through right-sided tears, whereas the stomach, spleen, and small intestine more commonly

herniate through left-sided tears (Figures 15-1 and 15-2).

Figure 15-1. Lateral radiograph from a 9-year-old male neutered cat with a chronic diaphragmatic hernia.

A

B

Figure 15-2. Intraoperative photographs of a chronic ventral diaphragmatic hernia in a cat. A: Herniated viscera is covered by omentum. B: Retraction of the omentum shows herniation of small intestine. C: Reduction of intestine reveals herniation of the quadrate lobe of the liver. The malleable retractor is indicating the gallbladder. Herniation and/or torsion of

the liver lobes may lead to temporary or permanent signs of biliary and hepatocellular dysfunction such as obstructive jaundice, ascites, and hepatic encephalopathy.

Congenital Pleuroperitoneal Hernia

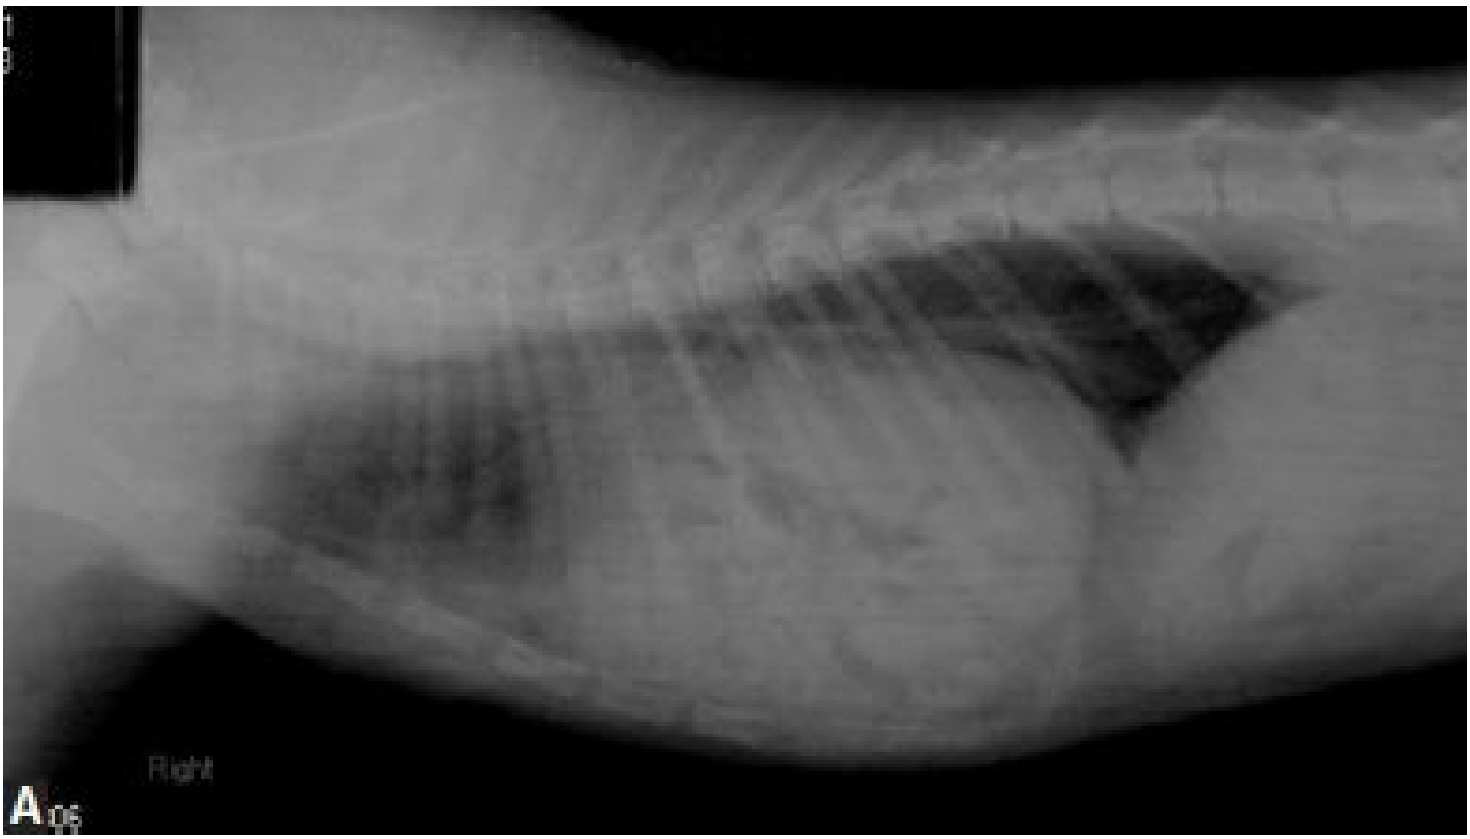
Canine congenital pleuroperitoneal hernias are rare, and usually take the form of a defect in the dorsolateral diaphragm, with or without central tendon involvement.[14] The intermediate part of the left lumbar muscle of the crus may be absent, leaving a defect of 1 to 2 cm in diameter, or the defect may be more extensive with both crura and parts of the central tendon absent. An autosomal recessive mode of

inheritance of the defect was proposed in a series of related dogs.[14] Congenital pleuroperitoneal hernias have also been diagnosed in cats.[15]

Congenital Peritoneopericardial Hernia

Peritoneopericardial hernias commonly contain omentum, liver lobes, gallbladder, and small intestine, as a result of a simple communication between the peritoneal and pericardial cavities (Figure 15-3). Stomach, colon, falciform ligament, and spleen have also been reported. Cystic lesions in the pericardium have been reported in animals with small peritoneopericardial hernias and

pathologic changes of the omentum or liver.[16,17]



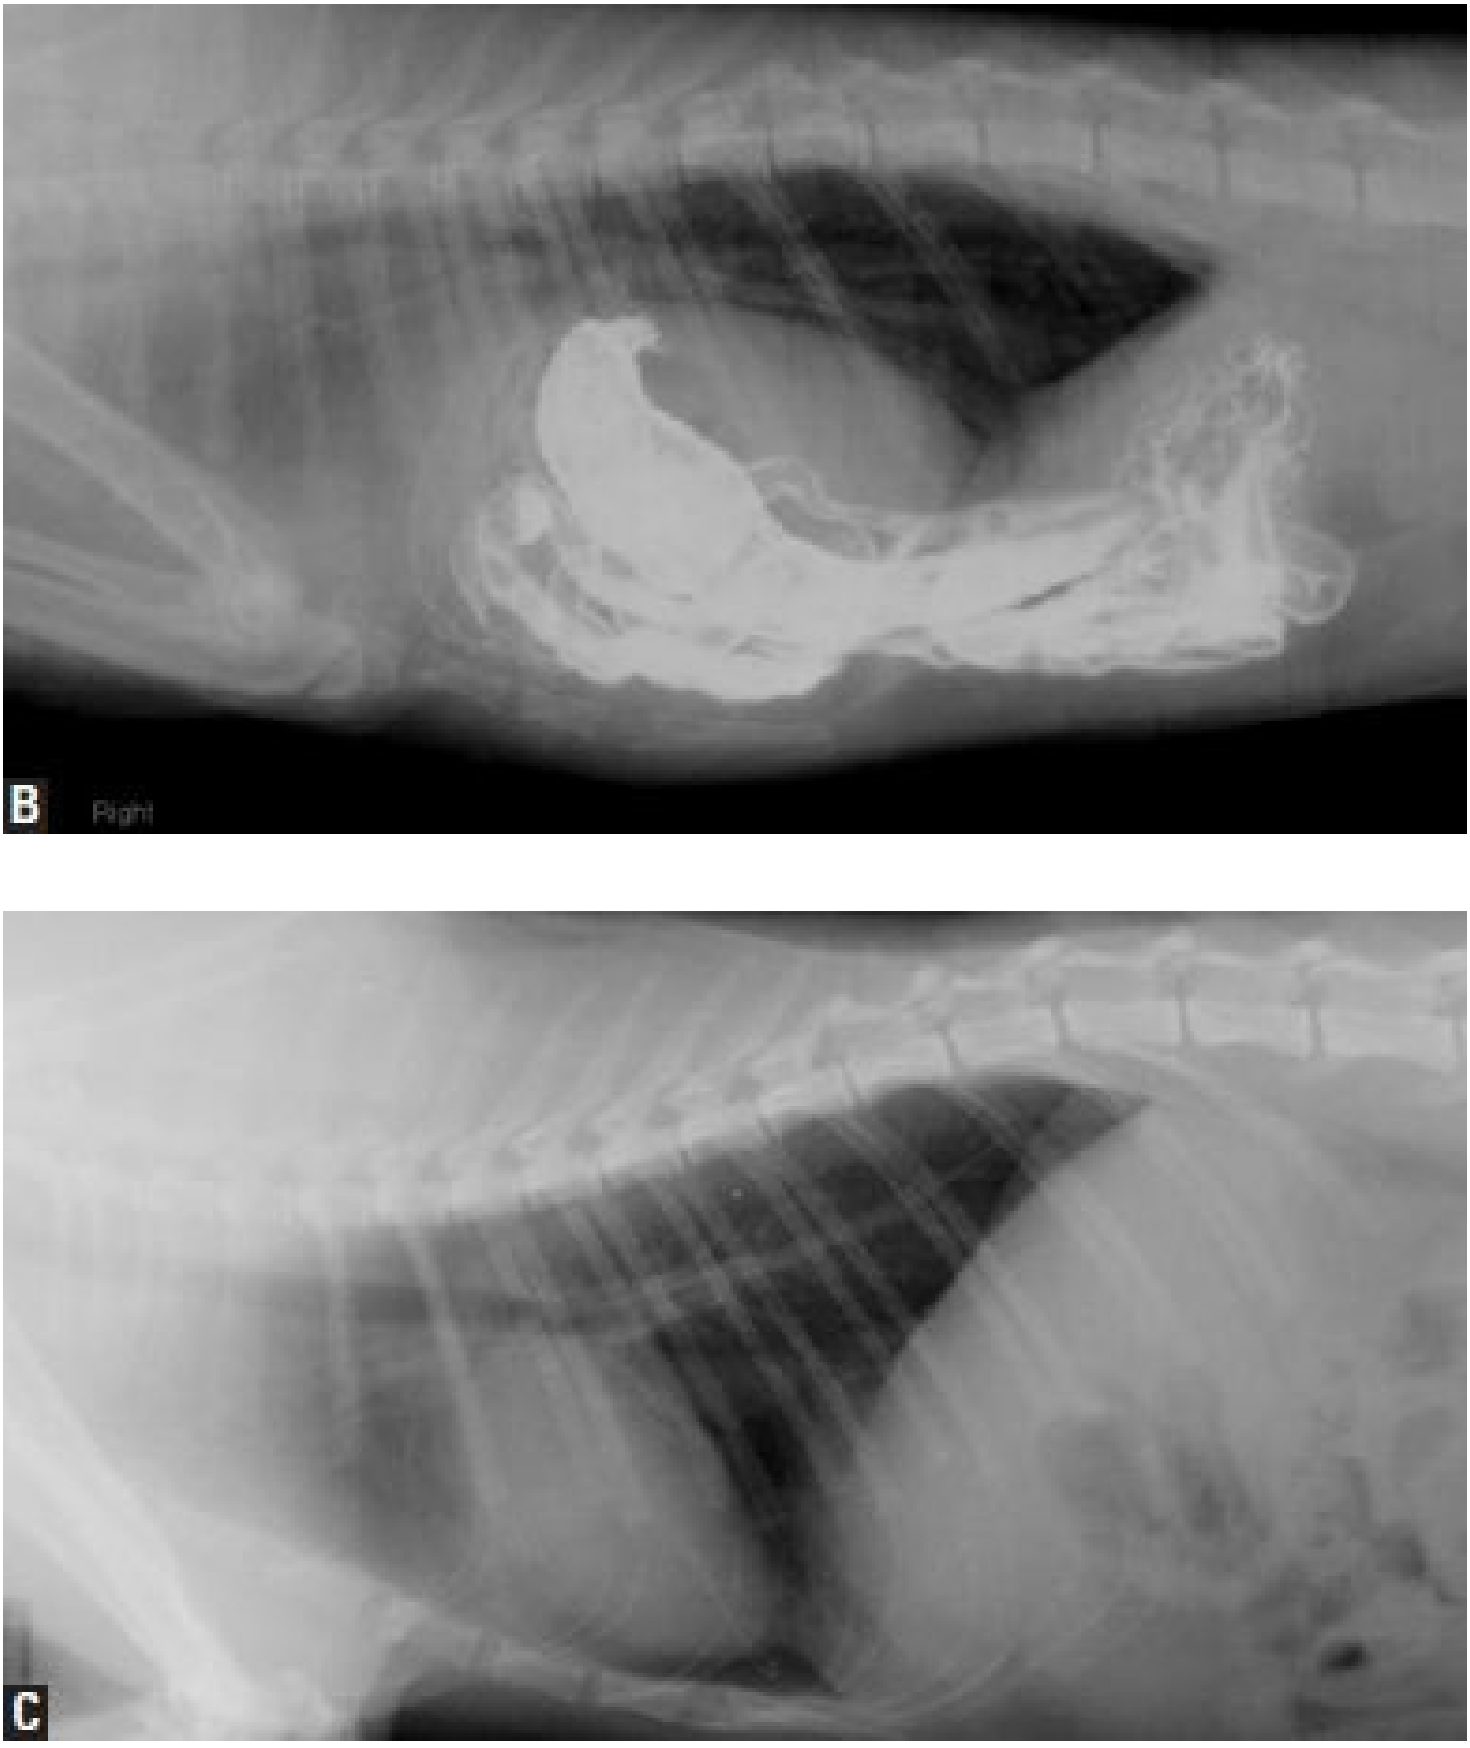


Figure15-3. Thoracic radiographs of a 5-month-old male cat with peritoneopericardial hernia. The cat

presented with vomiting, decreased exercise tolerance, and hyperpnea. A: Plain radiographs (lateral and ventrodorsal views). Note the enlarged, rounded cardiac silhouette and the marked lung collapse. B: Contrast radiographs of the same cat after oral administration of barium sulfate. Small intestine and colon are present within the pericardial sac. Distention of gut with gas or ingesta, or effusion from herniated structures may lead to pericardial tamponade. C: Plain radiographs 2 months after surgical correction. The lungs were expanded gently over a period of 24 hours to avoid pulmonary reexpansion syndrome.

Causes of Hernias

Up to 85% of diaphragmatic hernias in small animals are traumatic in origin, 5 to 10% are congenital, and the rest are of unknown etiology.[6,7,18]

Pleuroperitoneal and peritoneopericardial hernias result

from failure of development of the transverse septum and inappropriate patency of the pleuroperitoneal canals, with failure of ingrowth of myoblasts to form the muscular crura.[3] Breed predispositions for peritoneopericardial hernias have been reported for the Weimeraner,[19] domestic longhair, and Himalayan cat.[20]

Injury to the diaphragm, causing traumatic diaphragmatic hernia, can be either direct or indirect in origin. Blunt force trauma is the most common cause of diaphragmatic hernias in dogs and cats. Direct injuries from thoracoabdominal stab and gunshot wounds are a frequent cause of

diaphragmatic injury in humans[21] but are rarely encountered in veterinary patients. Iatrogenic injury of the diaphragm has been reported with thoracocentesis, poorly positioned chest drains, or by extension of a midline celiotomy incision lateral to the xiphoid process.

Blunt force trauma likely to cause diaphragmatic hernia in animals includes motor vehicle trauma and falling from heights. Male dogs 1 to 3 years old are at significantly greater risk for traumatic diaphragmatic hernia, as a consequence of their increased risk of motor vehicle trauma. The mechanism of diaphragmatic rupture in these instances is probably

the sudden increase in intraabdominal pressure at the same time as forced exhalation. Severe injuries of the thoracic cavity and organs have been reported in more than 39% of dogs and cats with musculoskeletal trauma.[22,23] Pulmonary contusions, pleural effusion, hemothorax, pneumothorax, and rib fractures are the most common of these injuries. Between 2% and 5% of animals with fractures have a diaphragmatic hernia.[22,24] Sudden exposure to elevated gravitational forces has been reported to cause diaphragmatic rupture in humans, but is unlikely to be a precipitating factor in veterinary patients. Diaphragmatic hernias have also been reported as a complication of parturition and

excessive coughing in humans. Diaphragmatic hernias have been reported occasionally in animals with increased intraabdominal pressure but no obvious precipitating traumatic event.

Pathophysiology

Regardless of the etiology of the diaphragmatic defect, clinical signs related to diaphragmatic hernia are largely associated with the following: failure of the thoracic bellows to produce adequate negative inspiratory pressure, a mass effect from the abdominal organs present within the thorax or pericardium, and incarceration or strangulation of the

herniated structures. Respiratory manifestations of diaphragmatic hernia may be further exacerbated by the presence of a pleuroperitoneal effusion or dilation of the gastrointestinal tract. Because of the nature of automobile trauma, multisystem injury and shock are potential complications in traumatic diaphragmatic hernia.

Respiratory Consequences of Diaphragmatic Hernia

Dyspnea and tachypnea are the most common clinical signs in diaphragmatic hernias. In addition to diaphragmatic dysfunction, rupture of the diaphragm causes loss of parietal

pleural contact with the lungs and impairs the animal's ability to generate negative intrathoracic pressure. Pressures in the thoracic and abdominal cavities equalize and abdominal and thoracic wall muscles take over ventilation. Pain, rib fractures, and flail chest may limit thoracic expansion in patients with polytrauma. Pulmonary atelectasis following herniation of abdominal organs results in hypoventilation, ventilation/perfusion mismatch, and hypoxia. Dyspnea can also result from pleural effusion.[25] Effusions are commonly reported in association with diaphragmatic hernias, and result from obstruction to lymphatic drainage, inflammation of herniated or displaced

organs, and leakage of bile, urine, and feces. Although in most cases the effusion is present in both the peritoneal and pleural cavity, in some instances abdominal organs seal the diaphragmatic defect and the effusion may be restricted to the pleural cavity.[13,26] Gastric tympany should be considered as a cause of respiratory compromise in cases where breathing deteriorates rapidly, particularly in animals known to have a diaphragmatic hernia.

Cardiovascular Consequences of Diaphragmatic Hernia

Cardiovascular abnormalities most commonly result from peritoneopericardial hernias. Pressure of herniated viscera within the pericardial sac may cause cardiac tamponade and right-sided congestive heart failure as a result of compression of the thin-walled right atrium and ventricle. Hypotension, tachycardia, venous distension, ascites, and pleural effusion (including chylothorax) may be seen. Concomitant cardiac defects in animals with congenital disease may produce a variety of hemodynamic effects.

Gastrointestinal Consequences of

Diaphragmatic Hernia

The main effects of diaphragmatic hernias on the abdominal viscera are incarceration, obstruction, and strangulation. These effects result from pressure applied by the edge of the diaphragmatic tear as the organs pass over it, from formation of fibrous adhesions and strictures, or from malpositioning or torsion.

Incarceration of the stomach and intestine in a diaphragmatic hernia may result in partial or complete obstruction. Gastric tympany may cause rapid interference with cardiorespiratory function by compression of the caudal vena cava and lungs, and can be rapidly fatal.

Recurrent vomiting, leading to dehydration, acid-base and electrolyte derangements, altered cardiac electrical conduction, and muscle weakness, was reported as a consequence of gastric outflow and duodenal obstruction in one dog.[27] Severe compromise of blood supply can also induce ischemic necrosis, intestinal perforation, and abscessation. In some instances, viscera may rupture, leading to bile peritonitis and pleuritis, fecal contamination of the body cavities, and uropleuritis.

Hepatic Consequences of Diaphragmatic Hernia

The liver may be injured at the time of diaphragmatic injury, or one or more lobes of the liver may herniate into the thoracic cavity. The latter may occur in both traumatic and congenital diaphragmatic hernia. Disease resulting from liver lobe herniation occurs as a result of hepatic congestion, hepatic necrosis, liver lobe torsion, or obstruction to biliary flow. A pressure gradient of up to 12 mm Hg normally exists across the hepatic sinusoids, between the portal vein and the hepatic vein. The caudal vena cava and hepatic veins are thin-walled, low-pressure vessels and are easily compressed. When the liver herniates or undergoes torsion, compression of these vessels results in occlusion to

hepatic venous outflow. A rise in pressure in the hepatic veins or caudal vena cava relative to the intrahepatic sinusoidal pressure results in hepatic congestion, dilation of hepatic lymphatic vessels, and extravasation of copious quantities of high-protein hepatic lymph. Rapid accumulation of hydrothorax, ascites, or a combination may result. Hydrothorax and ascites develop in about 30% of animals with liver herniation.[6,7,10] The fluid typically is a modified serosanguineous transudate. In addition to fluid extravasation, the liver may undergo severe and sometimes irreversible changes (Figure 15-4). Hepatonodular myelolipomatosis has been reported in a cat with herniation of liver lobes into

a peritoneopericardial hernia.[28] Diaphragmatic rupture with concomitant biliary tract injury, bile peritonitis, and bile pleuritis has been reported in dogs. Two cats with chronic diaphragmatic hernia were presented mainly for icterus resulting from extrahepatic biliary obstruction.[29] Although not yet reported in the setting of diaphragmatic hernias, bacterial proliferation (particularly of anaerobic organisms) is known to occur in devitalized liver, leading to sepsis and death.

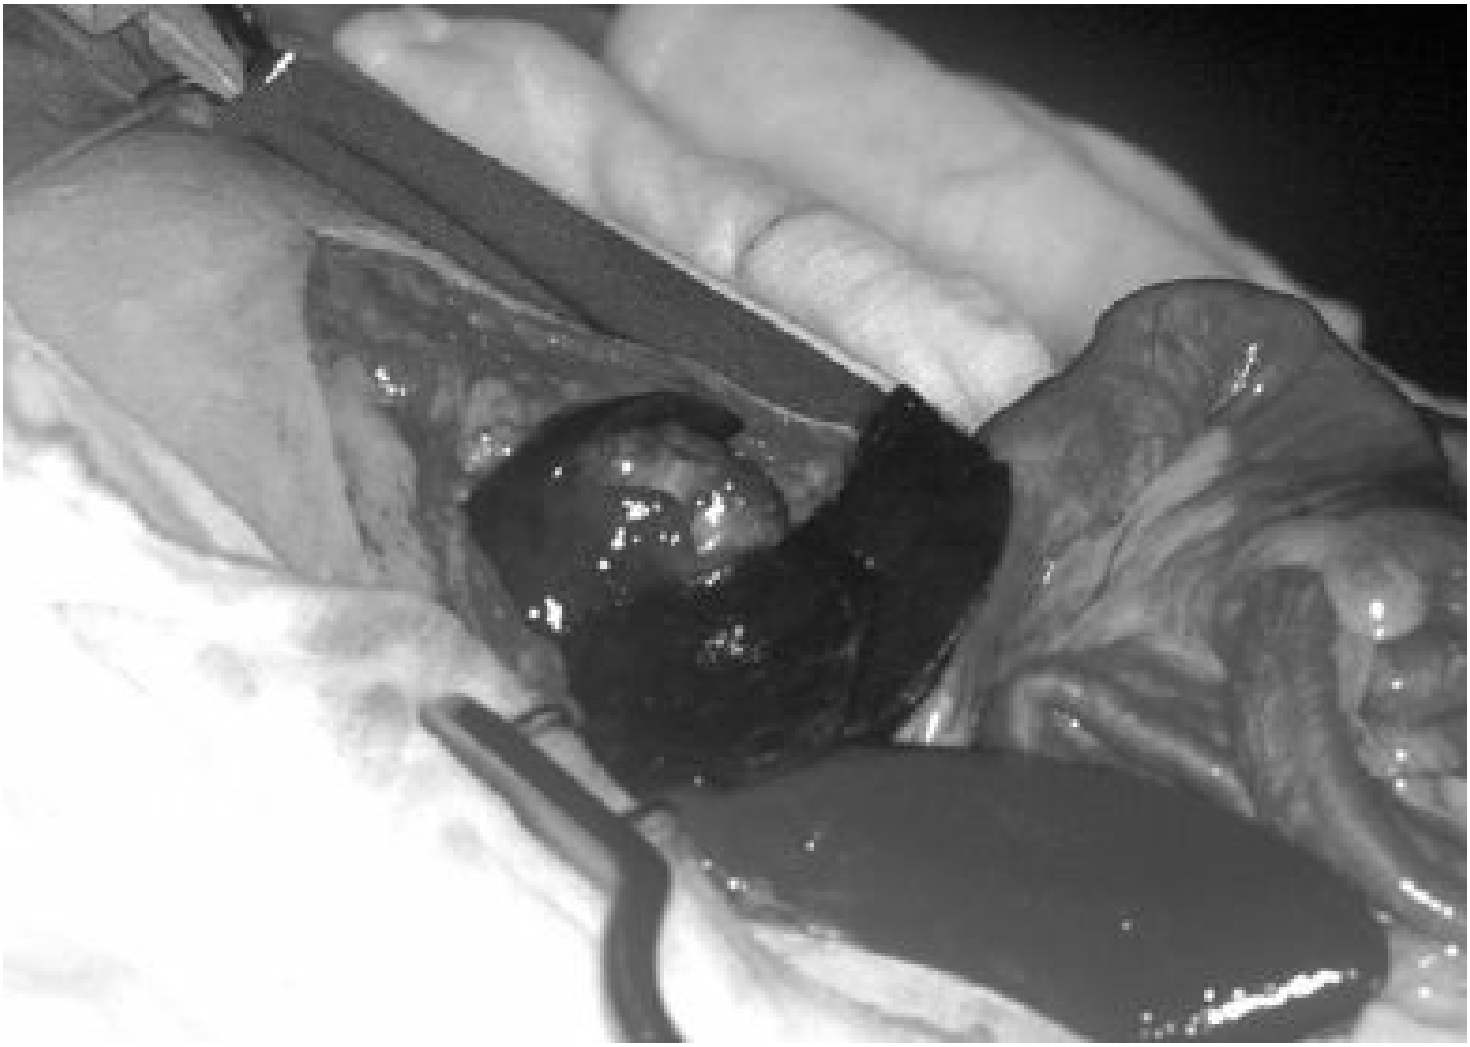

Figure 15-4. Darkened and fibrotic liver lobes (arrow) that have been reduced from a chronic diaphragmatic hernia in a cat. No clinical signs of hepatic dysfunction were present, but a preoperative biochemistry panel revealed markedly elevated activities of serum alanine aminotransferase and alkaline phosphatase. The nonherniated portion of the liver has undergone hyperplasia (open arrow). The discolored liver lobes were assessed as being viable despite the chronic changes and they were not resected. The cat made a complete recovery.

Pleural Effusion

Pleural effusion occasionally results from damage to viscera other than the liver. Hemothorax, chylothorax, urothorax, pneumothorax, and pyothorax have been reported. Pleural effusion may also occur as a result of right-sided congestive heart failure in animals with cardiac tamponade.

Mortality associated with Diaphragmatic Hernia

Prior studies have indicated that approximately 15% of animals die before presentation for anesthesia and surgical correction of traumatic diaphragmatic hernia. Preoperative deaths are due to hypoventilation,

shock, multiorgan failure, and cardiac dysrhythmias. Restraint for examination, radiography, and pleural or peritoneal drainage may cause decompensation of critically compromised patients. Mortality may also result in animals with chronic hernias from sudden dilation of the stomach or intestine with ingesta or gas. The effect of acute gaseous distension of the stomach is equivalent to a tension pneumothorax. Emergency decompression of the stomach with a hypodermic needle or stomach tube may be required.

Anesthetic induction is a critical phase of management, and any undue delay in intubation and controlling

ventilation can cause death. Induction of anesthesia and surgical intervention in patients that have not been adequately stabilized is likely to be the main reason for the poor outcomes observed previously in animals sent to surgery within 24 hours of injury.[9,36] More recent studies indicate that survival rate is between 80% and 94% and prognosis should be equally good for patients operated on within the first 24 hours, as long as appropriate adjunctive treatment is given.[8,37,38]

Postoperative complications that result in death fall into two groups and may result from the hernia, the surgical procedure, or the underlying traumatic event. In the first 24 hours after

surgery, death is caused by hemothorax, pneumothorax, pulmonary edema, shock, pleural effusion, and sudden cardiac arrest. Deaths occurring later after surgery tend to be a result of rupture, obstruction, or strangulation of the gastrointestinal tract, secondary changes in herniated organs, or diseases unrelated to hernia.

Mortality may occur in up to 14% of dogs and cats undergoing surgery for peritoneopericardial hernia.[19,20,30] Mortality has resulted from cardiac arrest and persistence of preoperative signs such as chylothorax and vomiting. One animal developed ascites and signs of hepatic

encephalopathy as a result of hepatic cirrhosis, presumably as a result of hepatic ischemia during herniation.[19] The author has also encountered this complication in an Australian cattle dog with a chronic diaphragmatic hernia.[15]

Complications of Diaphragmatic Hernia Repair

Complications reported after repair of diaphragmatic hernias result from changes to diaphragmatic function, physical impingement on structures passing through or near the diaphragm, changes in pleural and peritoneal pressure, and pulmonary

reinflation.

Pulmonary dysfunction and edema are perhaps the most serious complications directly related to surgical repair of diaphragmatic hernias. Pulmonary reexpansion syndrome is a well described entity in humans and was first reported in a cat following diaphragmatic hernia repair in 1978.[39] Pulmonary reexpansion injury is commonly reported in humans following evacuation of pneumothorax, sometimes after just a few hours of lung collapse. It has since been identified as a major risk in many studies of small animal patients with diaphragmatic hernia. Pulmonary injury may result from barotrauma

owing to overly zealous reinflation. Reexpansion pulmonary edema results from increased permeability of the pulmonary capillary bed. Experimental studies suggest that an inflammatory response follows mechanical injury to the alveolar-capillary membrane and is complicated by reperfusion injury. Reexpansion injury may be avoided by ensuring slow reexpansion by evacuation of air from the thorax using a negative pressure less than minus 10 mm Hg. Lungs should be reinflated slowly over a period of 12 to 24 hours.[40] Reexpansion injury is not just a complication of diaphragmatic hernia repair but may potentially occur in any animal undergoing pulmonary reexpansion after chronic

lung collapse, for instance following drainage of pleural effusion or resection of a large space-occupying lesion of the thorax.

Hiatal hernia is a recognized complication of diaphragmatic hernia repair. Proposed mechanisms by which this occurs include physical damage to the esophageal hiatus, abnormal tension on the central tendon of the diaphragm and hence the hiatus, increases in intraabdominal pressure as a result of loss of abdominal domain following chronic diaphragmatic hernia, and alterations in vagal activity as a result of surgical trauma and organ repositioning.

Loss of abdominal domain is not, strictly speaking, a complication of diaphragmatic hernia repair, but it is a complicating factor that may impact the success of surgery. Loss of abdominal domain refers to reduction in the capacity of the abdominal cavity as a result of abdominal myofascial retraction in the presence of chronically reduced volume of abdominal contents. Muscles of the abdominal wall contract and lose the capacity to stretch immediately back to their original length. The fascial sheaths undergo remodeling. Muscles may also undergo fibrosis and retraction if they were damaged at the time of the original trauma. Therefore, following repositioning of herniated

organs, direct closure of the celiotomy incision may be impossible, or may result in dangerously elevated intraabdominal pressures. Development of hiatal hernias subsequent to repair of chronic diaphragmatic hernias is likely to result, at least in part, from elevated intraabdominal pressure secondary to loss of domain. Strategies for overcoming the restrictions imposed by loss of domain include myofascial releasing incisions and mesh expansion.[41] The author has used relaxing incisions of the external rectus sheath parallel to the celiotomy incision to assist abdominal closure following repair of chronic diaphragmatic hernia in small animal

patients.

Development of ascites immediately after surgery may signal an elevation in hepatic venous drainage pressure caused by repositioning the liver during herniorrhaphy or by chronic liver disease.

Gastric ulceration was a postoperative complication in two dogs that had chronic traumatic diaphragmatic hernia with intrathoracic adhesions to incarcerated liver.[42]

Hyperthermia was reported as a complication of peritoneopericardial hernia repair in 54% of cats in one study.[20] The authors speculated that

this may be a result of hepatic manipulation and reperfusion. Hyperthermia has also been reported as a consequence of other major hepatic manipulations such as intrahepatic shunt attenuation in dogs and repair of hepatic injuries in humans.

Prognosis

Traumatic Diaphragmatic Hernia

The overall survival rate for animals diagnosed as having diaphragmatic hernias in the published literature is 52 to 94%. Two significant peaks in mortality were noted in a previous review. Survival rates for 40 dogs

operated on within 24 hours was 67% and for 8 dogs operated on after 1 year was 37%.[18,36,43] Death in the early group was due entirely to shock and trauma and in the late group was largely unrelated to the hernia. By delaying surgery until 1 to 3 weeks after trauma, survival rates were greater than 90%. More recent reports, however, suggest that prognosis is equally good for animals operated on early, as long as the patient is stabilized appropriately prior to surgery, and following repair of chronic hernias.[8,37]

Recurrence rates of traumatic hernia, initially repaired with interrupted sutures of polyglactin 910 through an

intercostal exposure, have been reported as 4% for dogs and 5% for cats.[44] Recurrence, in man and animals, is usually a result of a combination of tissue weakness and loss of abdominal domain, leading to elevated intraabdominal pressures.

Congenital Diaphragmatic Hernia

A surgical success rate of greater than 80% has been reported for repair of peritoneopericardial hernia in dogs and cats.[19,20,30]

Chapter 16

Peritonitis

Jamie R. Bellah

Peritonitis is a clinical syndrome characterized by an inflammatory response to irritation of parietal serous membranes that line the abdominal cavity and the visceral membranes that cover the abdominal viscera, and it is a common initiator of the systemic inflammatory response syndrome.[1] It is most commonly secondary to diseases or trauma that result in bacterial contamination of the abdominal cavity

in both dogs and cats. Introduction of microbes by any means can induce septic peritonitis, whereas nonseptic inflammation, or aseptic peritonitis, may be induced by neoplastic invasion, blood, urine extravasation, bile leakage, and irritating acid by-products of pancreatitis.[2-4] The latter nonseptic conditions may become septic (i.e., bowel obstruction) if damage to bowel allows transmural movement of bacteria.[3] Primary peritonitis is not common in small animals and is usually attributed to corona viral infection causing feline infectious peritonitis in cats, or to hematogenous infection if the source of peritonitis is not known in either dogs or cats.[5] The surface area of these

inflamed membranes can be as much as 150% percent of the surface area of total body surface area,[6] so disorders that affect the abdominal cavity in either a generalized or local region can have a profound affect on the clinical health of the dog or cat.

Anatomy

The peritoneum is a serous membrane made up of mesenchymal cells supported by a stroma of collagenous and elastic fibers, called the transverse fascia.[6] Other cells and substances populate this stroma and include macrophages, lymphocytes, mast cells, adipose cells, and glycosaminoglycans. Special lymphatic collecting vessels

and lacunae, especially common on the visceral surface of the diaphragm, are responsible for clearing fluid and particles from the peritoneal cavity,[6,7] but are also capable of increasing in diameter during peritonitis.[8] The peritoneal cavity normally has a small amount of serous fluid that serves a lubricating purpose. This fluid is produced by the mesenchymal cells.[6] The peritoneal membrane has been characterized as a semipermeable membrane that is capable of absorptive and exudative functions.[2] Circulation of normal peritoneal fluid occurs caudal to cranial (toward the diaphragm). Investigative dye studies show clearance times varying from 19 to 72 minutes, depending on a cranial

or caudal location of the dye injection, respectively.[6,9] After absorption by diaphragmatic lymphatics, lymph is carried to mediastinal lymph nodes, to the thoracic duct, and finally to the systemic circulation. Omental lymphatics provide a route for drainage and aggregations of cells ("milky spots"), which include neutrophils, macrophages, and lymphocytes that are important to defense mechanisms. Peritoneal-associated lymphoid tissues are also capable of immunoglobulin production.[6]

The peritoneal cavity has a normal positive pressure, which varies from 1.5 to 5.5 mm Hg, which can be

measured indirectly using a transurethral urinary bladder catheter. Increases in peritoneal pressure can result in decreased abdominal compartment compliance, which can cause cardiovascular, respiratory, and abdominal organ dysfunction. Peritoneal pressures greater than 15 mm Hg can be associated with tachycardia, hypertension, increased systemic vascular resistance, decreased cardiac output, decreased mesenteric blood flow, decreased intestinal mucosal blood flow, and increased bacterial translocation.[6] Intraabdominal pressures are increased after ovariohysterectomy and other causes of abdominal distention. Abdominal pressures greater than 22

mm Hg may require surgical decompression, especially in oliguric animals.[10]

Cytologic characteristics of normal peritoneal fluid include mostly macrophages, mesothelial cells and lymphocytes, and a protein content of less than 3 g/dl. Peritoneal fluid lacks fibrinogen, does not clot, and has antibacterial activity as a result of its complement and opsonizing fibronectin components.[6]

Etiology of Secondary Peritonitis

Gastrointestinal microorganisms gain access to the peritoneal cavity by

leakage from perforation or other loss of bowel integrity and are the most common cause of secondary peritonitis.[6,11] Peritonitis may follow abdominal surgery and, when postoperative peritonitis occurs, the mortality rate is high.[11] Recently, preoperative peritonitis has been shown to be a risk factor for developing anastomotic leakage.[12] Bacteria and inflammatory cells produce collagenases, which decrease the collagen content of the intestinal wall and impair the strength of the anastomosis.[12] Gram-negative aerobes and anaerobes with an admixture of fluid and ingesta from the bowel result in initiation of inflammation from bacterial, chemical, and foreign

materials. Leakage from bowel may occur from mechanical perforation, neoplastic invasion, foreign materials, sharp and blunt trauma, vascular disruption causing ischemia and necrosis, dehiscence of surgical incisions, and drug-induced lesions such as corticosteroid-induced ulceration or colonic perforation. Gastrointestinal perforation typically results in a plural population of bacteria within peritoneal fluids. A factor that determines the number and type of bacteria that escape into the peritoneal cavity is which region of gastrointestinal tract perforates. The more distally the site of perforation is located, the higher are the total bacteria count and the percentage of

anaerobic microorganisms, as well as the incidence of mortality.[6] Two bacteria predominate with intestinal perforation: E. coli and *Bacteroides fragilus*. The aerobic and anaerobic characteristics of these organisms are thought to be synergistic. Endotoxin produced by E. coli is commonly integral in early mortality, and concomitant infection with *Bacteroides fragilis* is thought to enhance the lethal potential of E. coli.[13,14] Alpha-hemolysin, an exotoxin produced by E. coli, is thought to promote infection within the peritoneal cavity, as it is toxic to mammalian cells, and it alters the character of intraperitoneal fluid by lysing red blood cells and having detrimental effects on peritoneal

leukocytes.[14,15] This exotoxin enhances the ability to recover E. coli and *Bacteroides fragilis* from peritoneal fluid, and it increases mortality.[14]

Rupture of a septic organ such as the pancreas, prostate, uterus, gallbladder, or urinary bladder, and rupture of intraabdominal abscesses (i.e., liver) usually result in single population of bacteria. The fluid content varies depending on the septic organ that ruptures. Peritoneal dialysis is commonly complicated by septic peritonitis, usually a result of tubing contamination during fluid exchanges or gastrointestinal perforation.[16] Peritonitis is rarely secondary to parasitic infections. *Toxoplasma gondii*

infection in cats, *Porocephalus crotali*, and mesocetoides species in dogs have been identified.[17-19]

Secondary peritonitis that occurs in the absence of an infectious pathogen is termed aseptic peritonitis. Chemical agents (usually endogenous such as urine or bile), foreign materials such as starch or surgical sponges, mechanical irritation, and neoplasia may result in aseptic peritonitis. Surgical exposure and manipulation, including exposure to air during surgery or laparoscopic inflammation will cause peritoneal inflammation. Granulomatous peritonitis may result from glove powders, including starch, from talcum powder, and from silicone-based

powders. Hypersensitivity to starch or corn is the proposed mechanism.[6] Sterile urine and bile within the peritoneal cavity does not result in significant inflammation of the peritoneum unless bacteria gain access to the fluid.[17,20,21] Sterile bile effusions have been reported for as long as 30 days.[21] Uroperitoneum usually has a more significant metabolic impact on the health of the animal; bacterial contamination from urine is not common. Sterile urine may remain in the peritoneal cavity for long periods without peritonitis if it is sterile.[22] If uroperitoneum is contaminated by bacteria, the need to correct the problem surgically is more urgent, whereas if the urine is sterile, urine

diversion via peritoneal drainage can be performed until the patient is stable. Other chemicals that are iatrogenically placed into the abdominal cavity, such as antibiotics, barium, povidone-iodine solutions, and iodinated contrast agents cause varying degrees of peritoneal inflammation.[6]

Sclerosing encapsulating peritonitis, a chronic condition that results in the abdominal organs being encased in "cocoon-like" layers of collagenous connective tissue, has been reported in small animals.[6] This condition is nonseptic, with peritoneal fluid containing red blood cells, macrophages with phagocytized red

cells, and fibroblasts. The etiology of this condition is uncertain.[23,24]

Inflammation of Peritonitis

The peritoneum utilizes immunologic mechanisms, absorptive function, and the ability to localize infectious processes to defend its surfaces. When peritoneal contamination or injury occurs, an immediate inflammatory response occurs beginning with activation of complement (C3a and C5a), and the influx of neutrophils. Mast cells and basophils degranulate, promoting vascular permeability and the elaboration of opsonins and complement. Opsonization of organisms, cell lysis and clearance of

immune complexes is potentiated by complement. Phagocytosis is enhanced, and immunoglobulins are produced by peritoneum-associated lymphoid tissues.[25] Mast cells, neutrophils, macrophages, lymphocytes, and mesenchymal cells participate in release of cytokines, which results in further cell recruitments. Prostaglandin synthesis results from arachidonic acid metabolism stimulated by interleukin 1β and tumor necrosis factor-α. Such cytokines, with interleukin 8, enhance neutrophil emigration. The elevation of proinflammatory cytokines, such as tumor necrosis factor-α, and interleukins 8 and 6 are proportional to the severity of the clinical response.[6] Exudation of peritoneal fluid results

from increased permeability of peritoneal capillary networks caused by mast cell histamines and prostaglandins. This peritoneal fluid exudation provides a large volume of fluid containing complement, immunoglobulins, clotting factors, and fibrin. Fibrin clearance is decreased because the fibrinolytic system is inactivated by inflammation, and clumps of fibrin can occlude peritoneal lacunae. Bacteria may be protected from the inflammatory response in regions of fibrin deposit; however, fibrin deposits are prerequisite to fibrous adhesion formation, which help localize regions of infection.[6,26]

The consequence of exudation of fluid

from the vascular space into the peritoneal cavity is hypovolemia and hypoproteinemia. Hypovolemia and hypoproteinemia are exacerbated when ileus occurs secondary to sympathoadrenergic reflex inhibition[27] and fluid becomes sequestered in the bowel lumen. Translocation of bacteria is enhanced when intestinal motility is altered; therefore, in nonseptic types of peritonitis the associated ileus may allow transmural bacterial contamination of the peritoneal cavity.[6] Ileus may also occur from conditions such as ischemia or chronic distention from obstruction. As the volume of fluid in the peritoneal cavity continues to increase, loss of diaphragmatic compliance occurs and

ventilation is compromised. When severe, hypoxemia and respiratory acidosis can result. Increasing volumes of peritoneal fluid eventually increase intraabdominal pressure, which may reduce venous return from abdominal capacitance vessels and negatively impact cardiac output. Acute renal failure will eventually result from decreased renal perfusion. Septic peritonitis has been associated with septic hepatopathy; intrahepatic cholestasis, icterus, and elevation of serum bile acids and liver enzymes.[28] Disseminated intravascular coagulation resulting in microembolization of parenchymal organ blood supply exacerbates insults to major organs from hypovolemia and hypoxia.

Multiorgan dysfunction syndrome (MODS) may result from cell dysfunction and is mediated by cytokines.

Sepsis commonly occurs when peritonitis is secondary to bacterial contamination. Secondary effects of the bacterial pathogens and their by-products complicate the metabolic alterations already described. Experimentation has shown sepsis to be associated with a marked increase in peripheral oxygen demand, elevated levels of plasma insulin, glucagon, and catecholamines (the hyperdynamic state).[29,30] Endotoxin potentiates levels of proinflammatory cytokines, complement, and products of

arachidonic acid metabolism, by stimulation of the innate immune response.[6] Anaerobic organisms produce exoenyzmes that make them particularly invasive to tissue, causing necrosis, suppuration, adhesion, and abscess formation.[6]

Substances that Potentiate Peritonitis

Substances that augment or potentiate local or systemic inflammatory responses in peritonitis or that worsen the prognosis for recovery in bacterial peritonitis are termed adjuvants of peritonitis.[29] Bile salts, gastric mucin, hemoglobin, and barium are recognized as adjuvants that enhance

the virulence of contaminating bacteria.[6,31] Phagocytosis is inhibited by gastric mucin because of a heparin-like anticomplement effect and by hemoglobin, which disrupts phagocytic cell chemotaxis. Hemoglobin also interferes with phagocytosis, intracellular killing,[29] and lymphatic clearing mechanisms.[26,32] Bile salts lyse red blood cells and release hemoglobin and alter cellular adhesion mechanisms by lowering surface tension.[33] Another adjuvant effect is related to peritoneal fluid volume. Experimentally, incremental increases in volumes of fluid injected intraperitoneally while keeping the bacterial inoculums unchanged resulted in slowed bacterial clearance, increased bacterial

proliferation, and increased mortality.[34] Barium and intestinal-content contamination resulted in a higher mortality rate than intestinal content contamination alone in an experimental study.[35] Despite this finding, barium is still used in upper gastrointestinal studies because it provides better radiographic detail. If leakage occurs, immediate exploratory surgery is performed to resolve the gastrointestinal perforation and to remove extravasated barium and foreign material by thorough lavage.

Clinical Signs of Peritonitis

It is common to think of clinical signs referable to peritonitis as acutely

painful with vomiting, fever, and shock, but peritonitis in dogs and cats can present with a wide variation in clinical signs.[6] Anorexia, vomiting, malaise, depression, fever, weakness, and an abdominal pain response are common. Fever is not always present and rectal temperature can vary from hypothermic to hyperthermic. Fever may occur in either septic or aseptic peritonitis.[36] Dogs generally exhibit an abdominal pain response, however one third of cats with peritonitis do not exhibit an abdominal pain response.[37] Abdominal pain may be exhibited by a "praying position," which may provide pain relief in some dogs (also not a consistent observation). Varying degrees of abdominal fluid

accumulation may or may not be detectable during physical examination. Large volumes of effusion may cause respiratory compromise. Sequestration of fluid in the peritoneal cavity and the intestinal lumen from ileus can quickly result in marked dehydration when accompanied by vomiting. In cats and dogs, peritoneal effusions have been associated with hyponatremia and hyperkalemia in the presence of normal adrenal gland function.[38] Auscultation of the abdomen may reveal the absence of borborygmi, consistent with ileus. Vital signs that may be suggestive of a hyperdynamic systemic inflammatory response syndrome include injected (brick red)

mucous membranes, rapid capillary refill time, tachycardia, strong quick pulses, and pyrexia. As peritonitis progresses and hypovolemia worsens, tachycardia becomes severe with weak pulses, prolonged capillary refill time, pale membranes, and hypothermia (hypovolemic shock). In cats, bradycardia and hypothermia, pale mucous membranes, signs of diffuse abdominal pain, weak pulses, anemia, hypoalbuminemia, and icterus are indicative of severe sepsis.[39] Clinical signs may also reflect the organ system involved: icterus with septic cholecystitis and perforation; a vaginal discharge with ruptured pyometra; dysuria or pyuria with prostatic abscessation or septic prostatitis.

Purulent drainage associated with abdominal pain after gastrointestinal surgery can be associated with dehiscence and leakage of bowel content.

Diagnosis

Many diagnostic tests contribute to and support the diagnosis of peritonitis, but cytologic examination of peritoneal fluid is the most important examination. The finding of degenerative neutrophils with intracellular bacteria is diagnostic for septic peritonitis. Culture (and susceptibility test) confirms bacterial infection.[40] A recent study recommended culturing nonseptic

fluid, as lack of cytologic evidence for sepsis did not mean bacteria would not be cultured.[41] Often the volume of peritoneal fluid makes obtaining peritoneal fluid by abdominocentesis relatively simple, but ultrasound can guide aspiration when the fluid volume is low. In the absence of ultrasound guidance, a “four-quadrant” tap may be done. Diagnostic peritoneal lavage may also be used to “wash” peritoneal surfaces and collect fluid for examination; it is indicated when septic peritonitis is suspected despite low volumes or absence of abdominal fluid.[6] Exploration of the abdominal cavity is indicated if cytologic examination reveals degenerative or toxic neutrophils with phagocytized

bacteria, free bacteria (be careful of stain contaminants), or plant material. Abdominal fluid obtained after uncomplicated gastrointestinal anastomosis surgery typically had nondegenerate neutrophils.[42] Neutrophil counts vary widely; cytologic characteristics are considered the most important criteria and should be used in conjunction with peripheral white blood cell counts. Peripheral blood WBC can vary from neutrophilia to neutropenia when neutrophilic consumption exceeds bone marrow production.[36] Culture of aerobic and anaerobic organisms and susceptibility testing is done.

Peritoneal fluid and serum in septic

peritonitis have been compared, as bacterial isolation is not temporally realistic versus cytologic diagnosis. In this study, a presurgical white blood cell count of more than 2000 cells/dl and postsurgical white blood cell count of more than 9000 cells/dl was indicative of peritonitis in general. When blood and peritoneal fluid glucose were compared, a concentration difference of more than 20 mg/dl differentiated septic peritoneal effusions from nonseptic effusions in dogs and cats.[40] Lactate production occurs as a result of neutrophilic glycolysis and bacterial metabolites from an anaerobic microenvironment in peritoneal fluid with a resultant decrease in the pH of

peritoneal fluid.[43] Septic effusions in cats were found to have a lower pH, but dogs did not show this trend.[40] Differences in blood to fluid pH were found to be insignificant in dogs and cats, blood to fluid glucose significant in dogs and cats, and blood to fluid lactate insignificant because of low numbers. Although not statistically significant, a blood to fluid lactate difference of less than -2.0 mmol/L was 100% sensitive and specific for septic peritoneal effusion in 7 dogs.[40] Blood to fluid glucose difference was more sensitive than glucose alone.[40] Another investigation in 19 dogs and 18 cats, showed dogs with septic peritoneal effusions to have peritoneal fluid lactate concentrations of more

than 2.5 mmol/L and to have peritoneal fluid lactate concentrations that were higher than blood lactate concentrations (a negative blood to peritoneal fluid lactate difference); however, similar tests were not found to be accurate in cats.[43] It has been hypothesized that, because cats are deficient in glucokinase, they may have a tendency toward anaerobic metabolism with higher concentrations of lactate in peripheral blood.[43]

Suspicion of peritoneal fluid may occur during physical examination if a fluid wave is palpable and survey radiographs of the abdomen demonstrate loss of serosal detail (a ground glass appearance). In the

absence of recent abdominal surgery, the appearance of free air in the abdominal cavity is indicative of gastrointestinal rupture.[41] Studies have shown gastrointestinal perforation to be the cause in 77% of 34 animals with pneumoperitoneum,[41] and in 74% of 54 animals with pneumoperitoneum but without history of penetrating trauma.[44] Residual free air can occur after abdominal surgery for as long as 30 days,[41] or from diagnostic procedures that utilize gas or air. Emphasematous change within abdominal organs may show air density as well, and be associated with peritonitis.[6] Ultrasonographic examination can reveal fluid and may be able to localize the potential source

of leakage if a parenchymal organ is the source of septic purulent fluid. Corrugated small intestine was noted in 4 of 24 dogs with peritonitis, but was more commonly associated with pancreatitis (12 of 24 dogs).[45] Pleural effusion may occur concomitant with peritonitis and is considered a poor prognostic sign.[46] Imaging techniques such as CT and MRI may provide additional information prior to exploratory surgery, but ultrasonography provides a simple, practical, and widely available tool.

Complete blood count, serum chemistry evaluation, and coagulation profiles are preferentially done to assess the severity of disease. Biochemical

analysis of peritoneal fluid can be helpful if uroperitoneum or bile leakage is suspected. Creatinine levels in peritoneal fluid greater than serum levels support a diagnosis of uroperitoneum; however, in icteric animals, reagent-based tests for bilirubin (i.e., urine reagent strips) are not accurate.[47] Determination of bilirubin concentration has been shown to be 100% effective in diagnosing bile leakage prior to exploratory surgery. It was consistently two and one-half times the serum concentration of bilirubin when bile leakage was occurring.[21] Hypoglycemia is often present during sepsis.[36] A glucose concentration in peritoneal fluid of less than 50 mg/dl was 100% specific for

bacterial peritonitis when 55 cases of nonseptic abdominal effusion were compared with 16 cases of septic abdominal effusion.[48]

Management of Septic Peritonitis

When making a diagnosis of septic peritonitis supportive treatment is initiated typically with aggressive intravenous fluid resuscitation to restore hydration and to improve perfusion. Intravenous crystalloids are administered initially with the goal of achieving a urine output of 1 to 2 ml/kg/hour with a central venous pressure between 0 and 5 cm H_2O. Monitoring of central venous pressure

can help tailor fluid therapy to achieve volume expansion and avoid fluid overload. Synthetic colloid administration or blood products may be appropriate, depending on the results of blood and serum evaluations. As fluid resuscitation progresses, serial testing of CVP, serum albumin, colloid osmotic pressure, acid base status, electroplytes, coagulation parameters, and blood pressure aid therapeutic decisions. Preoperative analysis can help to relate cardiovascular parameters to the effects of fluid administration. Fluid rates of 10 to 12 ml/kg/hour may be required to assure maintenance of blood pressure after surgery.[6] Antimicrobial therapy is initiated as soon as peritoneal fluid

specimens are cultured and generally involves a combination of an aminoglycoside and a parenteral drug that is effective against anaerobes; however, this greatly depends on individual clinician's preference.[6] Administration of ntimicrobials, such as cefoxitin, that have broad spectrum and good activity against anaerobes, simplifies initial antimicrobial therapy. Antimicrobial therapy may be altered as soon as susceptibility tests are returned. Exploration and resolution of the source of bacterial contamination are required for successful treatment of septic peritonitis. Thorough lavage of the peritoneal cavity to dilute contaminants is believed to be important by most surgeons, but a

recent investigation questions if evidence-based support exists for lavage.[49] Antimicrobials are not used in the lavage fluid during surgery as parenteral antimicrobials reach sufficient (therapeutic) levels in peritoneal fluid during peritonitis,[50] and adverse affects such as chemical irritation, adhesions, and delayed anastomotic healing are avoided.[51] In addition, use of antimicrobials in lavage fluids has not been shown to provide significant benefit over lavage alone. After correcting the source of bacterial contamination and thorough lavage, consideration is given to providing a gastric or enteral route of alimentation, so nutritional support can be provided in the early

postoperative period. Corticosteroid and nonsteroidal use in septic peritonitis is controversial and is not routinely done, as there is no proven benefit.[36]

Drainage of the inflamed peritoneal cavity is the decision that seems most controversial. Closure of the abdominal cavity without drainage, sump drains for continued drainage (with or without intermittent lavage), open peritoneal drainage, and vacuum-assisted peritoneal drainage are used currently, although the latter technique is in its infancy in both human and veterinary medicine.[52-55] Open drainage allows the fluid to be removed from the abdomen in as little

as 6 hours, whereas sump drainage requires 24 to 48 hours.[6] A retrospective investigation of 36 dogs and 6 cats, comparing open peritoneal drainage and primary closure techniques, found an overall survival rate of 71% with no significant difference in survival between groups. Iin the open drainage group, however, patients received more plasma and blood, more animals had jejunostomy tubes and longer intensive care unit hospitalization (a mean of 6 days versus 3.5 days for the primary closure group).[55] Prospective clinical trials comparing closed and open drainage techniques are not available in the veterinary literature.

Primary closure of the abdominal incision after exploration for septic peritonitis has been reported to have a mortality rate of 46%.[53] Although prospective comparison of open and closed methods of treating septic peritonitis has not been done, retrospective comparison of mortality rates in individual studies shows mortality rates to be similar, with gastrointestinal leakage being the most common cause and having the highest mortality.[52] A prospective randomized study that categorized septic peritonitis as gastrointestinal, biliary, and nonbiliary nongastrointestinal (i.e., uterus, prostate, renal) such that large numbers of animals managed by open and closed methods in each category

would contribute to determination of when open peritoneal drainage is warranted and when primary closure is sufficient. In the author's opinion, septic peritonitis that originates from parenchymal organs such as the uterus, prostate, and kidney tends to have peritoneal contamination that is easily removed and diluted by large volume lavage. In situations of gastrointestinal content leakage, the decision for open peritoneal drainage is made based on judging the adequacy of lavage to dilute and remove foreign material and exudates and the extent of surface involvement (local or diffuse).

Septic peritonitis treated by primary closure and abdominal drains has not

achieved strong support because drainage has been ineffective and because it benefits only a local region of the peritoneal cavity, undergoes premature partial occlusion by omentum, and can be complicated by ascending nosocomial infection. Bacterial contamination via an abdominal drain has been shown to occur in as little as 24 hours.[56] Sump drains allow better drainage than nonsump drains but also allow potential contamination because air is pulled into the peritoneal cavity if not filtered. Sump-Penrose drains were completely encased by omentum and omental adhesions in 96 hours in normal dogs.[54] Both the sump-Penrose drains and open peritoneal drainage in

normal dogs caused a local inflammatory response.[54] Intermittent peritoneal lavage with a Parker peritoneal dialysis cannula has also been used, and an average of 91.4% of the infused lavage volume was recovered. Closed suction drains have also been used successfully to treat generalized peritonitis in dogs and cats without clinically important complications.[57,58]

Open peritoneal drainage has resulted in mortality rates varying from 22% to 48%.[52, 54, 55] Open peritoneal drainage provides the best and most complete drainage of the peritoneal cavity, essentially leaving it as an open wound or abscess would be treated and

maintaining a microenvironment within the cavity less favorable to anaerobic bacteria. The efficacy of open peritoneal drainage is reported to be due to enhanced removal of bacteria, foreign material, and exudates (including inflammatory mediators).[59] Gross appearance of the wound, cytologic examination of the fluid, and the condition of the patient are factors that contribute to the optimum timing of abdominal closure. Reexploration of the abdomen may be performed if degenerative neutrophilic inflammation or bacterial contamination persists or returns. Bacterial culture is done prior to closing the abdomen; in previous studies, as high as 40% of cases had

different bacteria isolated at closure than at initial exploration.[6] The most common complications of open peritoneal drainage include hypoproteinemia, hypoalbuminemia, anemia, and nosocomial infection.[6] Open peritoneal drainage in humans has been shown to have significantly more complications and no advantage over a primary closure technique when compared in a prospective clinical trial.[60] A study of 239 patients showed 31% mortality with closed technique and 44% mortality with open techniques.[61] The suggestion has been made that open peritoneal drainage is possibly enhanced by the animal's posture.[6]

Vacuum-assisted closure (VAC) is a new technique in both human and veterinary medicine and has application in acute and chronic wounds.[62,63] Vacuum-assisted peritoneal drainage is in its infancy, but is currently being evaluated in human patients and in a few veterinary centers. The technique has been shown to accelerate wound healing by increasing local blood flow, by reducing bacterial load, and by stimulating growth of granulation tissue.[64] In humans, use of temporary vacuum-assisted closure is being used for local and for generalized peritonitis. Techniques have been developed for using VAC to treat anastomotic leakage after rectal

resection.[64] Vacuum-assisted wound closure has been reported to augment open abdominal wall repairs where human acellular dermal matrix is used to close open abdomens that cannot be closed by local tissue mobilization.[65] Use of VAC has also been successful in managing post-laparotomy wound dehiscence where compromised wound healing was thought to play a complicating role.[66] Technique modifications are being developed to allow treatment of local intraabdominal infections without dissemination of infection to other areas of the abdominal cavity.[67]

Supportive Care

Septic peritonitis results in massive protein and electrolyte losses in an animal that is unlikely to eat soon after surgery. Failure to provide nutritional support results in protein-energy malnutrition, which depletes energy stores, delays wound healing, impairs immunocompetance, and can result in weakness and eventually organ failure.[68] Early enteral nutrition is beneficial to enterocytes and also has been shown to decrease bacterial mural translocation, preserve or increase gastrointestinal blood flow, prevent ulceration, increase IgA concentration and stimulate other immune system defenses, and enhance wound repair;[68] therefore, a judgment as to what technique to use is

important during surgery. Jejunostomy tubes allow direct infusion (as continuous rate infusion) of special diets into the small intestine; however, the complication rate with this technique is high, varying from 17.5% to 42%.[6] Esophagostomy tube placement and gastrostomy tube placement are alternatives to jejunostomy. Other noninvasive tube placement techniques include nasoesophageal and nasoenteric feeding tubes. Parenteral nutrition may be done in lieu of enteral feeding techniques and is capable of maintaining serum protein concentrations. Transfusion therapy is important to overall management as indicated by results of serial

examination of hematocrit, albumin, and coagulation parameters, and management of pain with analgesics before and after surgery.

Prognosis

Survival rates for generalized peritonitis have varied from 52% to 79%. As has been noted,[6] more recent survival rates are improved and are likely related to improved diagnosis and preoperative and postoperative management. Septic bile peritonitis has been shown to be particularly lethal; only 27% of animals survived in one retrospective investigation.[21] In the same investigation, all six animals with sterile bile leakage survived.[21]

Part III

Cardiovascular

Chapter 17

Pericardial Disease

Eric Monnet

“The major function of most organs is readily apparent and requires no deep knowledge of biology or physiology. However, whether or not the pericardium serves an important function or not has been debated over the years and the debate continues.”[1]

The pericardium is composed of two layers: the visceral pericardium and the parietal pericardium. The visceral

pericardium is a serous membrane composed of mesothelial cells adherent to the epicardium. The parietal pericardium is fibrous and acellular. It contains collagen and elastin fibers. Collagen fibers are wavy when the pericardium is at low stretch. When the pericardium is stretched, the collagen fibers straighten, resulting in increased stiffness of the tissue.[2]

The parietal pericardium has ligamentous attachments to the diaphragm and the sternum. Therefore, the pericardium maintains the heart in its normal anatomic position in the chest by its attachment to the sternum. The pericardium provides a barrier against infection and provides

lubrication between the parietal and visceral layers.[2] The pericardium is well innervated, including mechano- and chemoreceptors.[2] These nerve endings likely participate in reflexes resulting from irritation of the pericardium, epicardium, or both. An intact pericardium protects against atrial rupture in dogs with mitral insufficiency and myocardial hemorrhage induced by acute right-sided heart failure.

The pericardium also restrains cardiac filling and enhances diastolic ventricular coupling (Figure 17-1). The force exerted on the surface of the heart by the pericardium can significantly limit filling.[3-5] This effect

is mostly important with high filling of the left and right ventricles. Under normal conditions, the contact pressure between the pericardium and the epicardium is 2 to 4 mm Hg.[3,4] With a left ventricular filling pressure of 25 mm Hg, the contact pressure has been estimated at 10 mm Hg.[3,4] By this mechanism, the pericardium prevents cardiac overdistention and helps balance the output of the right and left ventricles. The pericardium contributes to diastolic interaction (transmission of intracavitary filling pressure across the septum).[2,6] A portion of the right ventricular diastolic pressure is transmitted to the left ventricle across the interventricular septum and contributes to left ventricular end-

diastolic pressure. If the cardiac volume increases, the pericardium contributes even more to the diastolic interaction.

The pericardium provides a gliding surface to accommodate heart motion. The pericardial cavity is filled with a variable amount of pericardial fluid. The volume of pericardial fluid present in normal dogs ranges from 1 to 15 ml (0.25 ml/kg). This fluid is an ultrafiltrate of serum containing between 1.7 and 3.5 g/dl of protein and having a colloid osmotic pressure approximately 25% that of serum. The pericardial fluid contains phospholipids that serve to lubricate the heart.[7,8] Because the pericardium is

noncompliant and has a small reserve volume, intrapericardial pressure rises rapidly when the volume of its contents increases acutely (see Figure 17-1). Chronic stretching of the pericardium results in hypertrophy and augmentation of the pericardial volume.

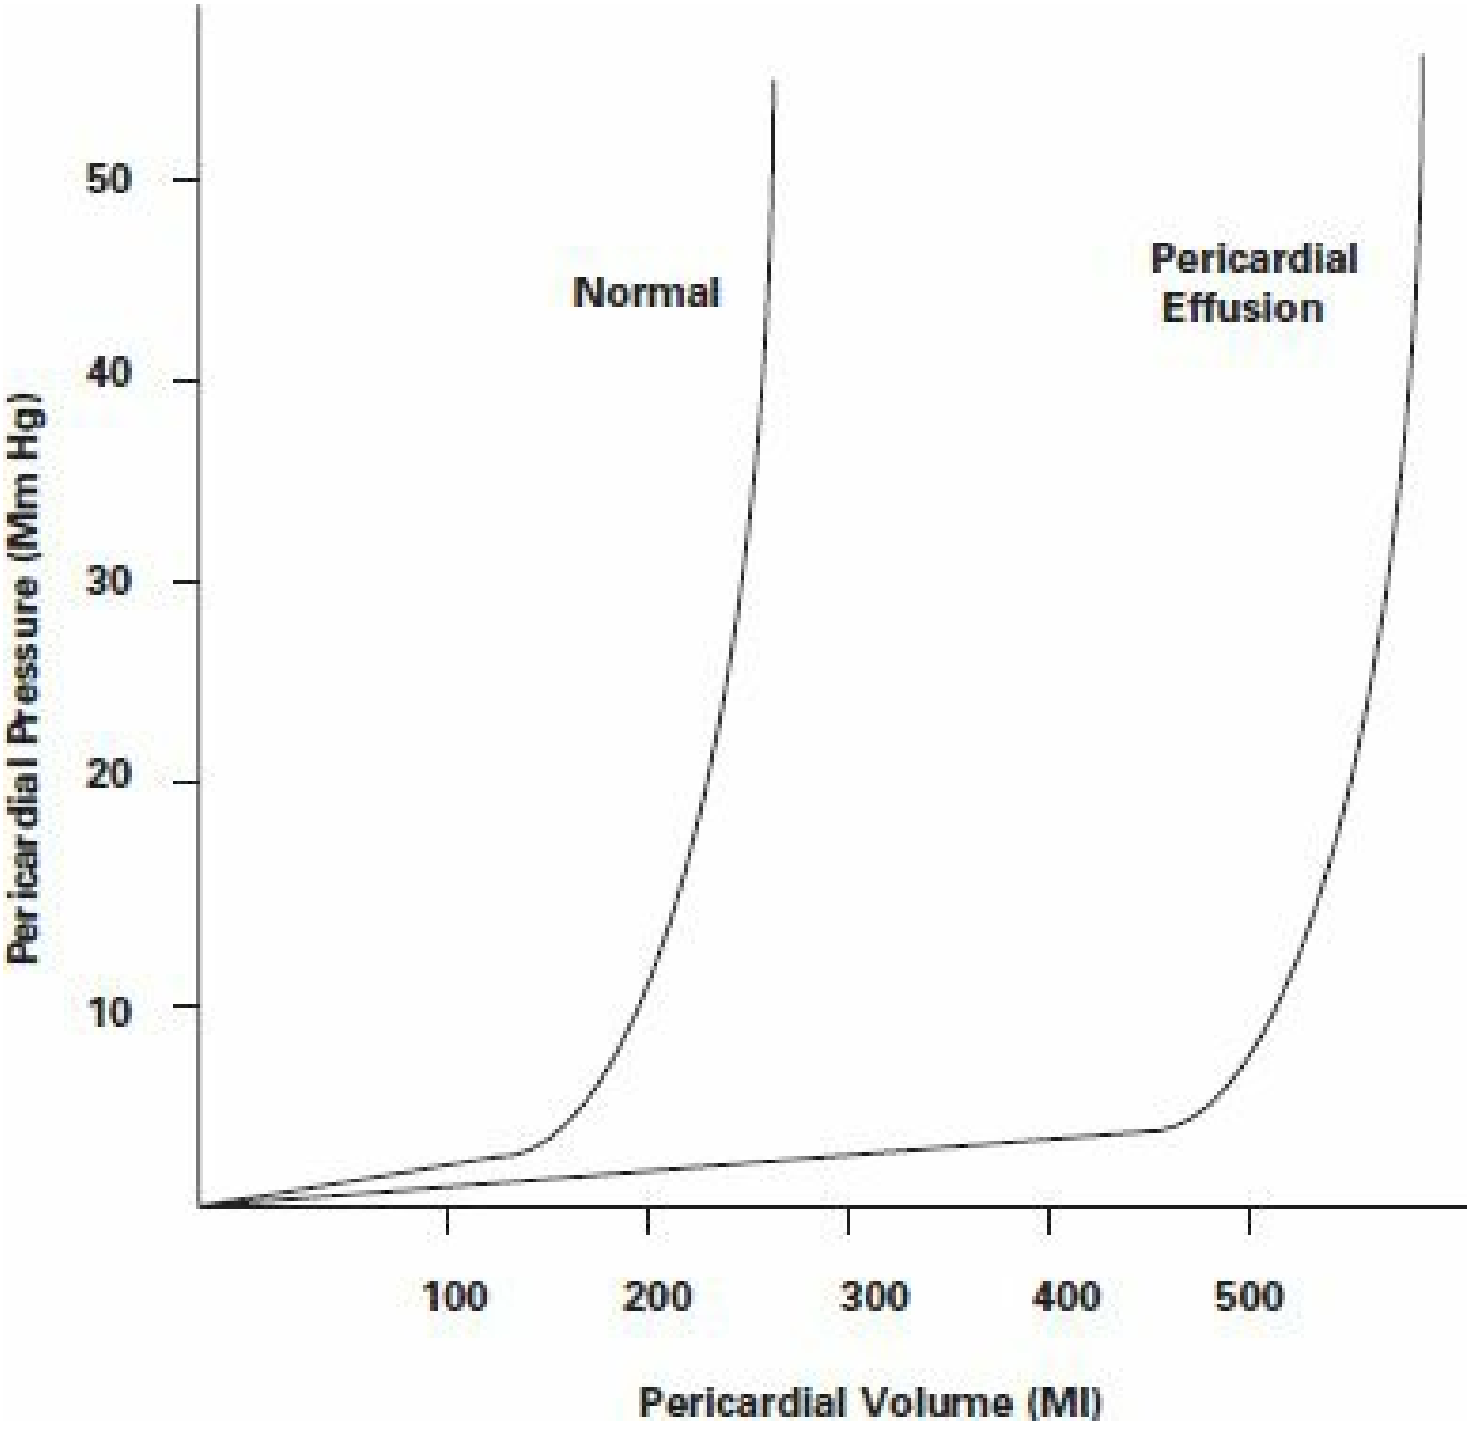

Figure 17-1. Pressure-volume relationship of the pericardium.

Congenital Pericardial

Disease

Absence of Pericardium and Pericardial Defects

Absence of the pericardium is rare in dogs and cats. It does not precipitate clinical signs and is usually detected only at necropsy. Partial pericardial defects occur and represent a risk for cardiac herniation. Right atrial herniation through partial pericardial defects has been reported in dogs.[9,10]

Pericardial Cysts

Pericardial cysts have been described mostly in companion animals less than 3 years of age. Cysts are either

unilocular or multilocular masses. On histologic analysis, they are thought to be cystic hematomas because they do not have an epithelial lining. In some cases, cysts were associated with a peritoneopericardial diaphramatic hernia. In other cases, cysts were on a stalk at the apex of the pericardium. This suggests that pericardial cysts result from entrapment of omentum, falciform ligament, or liver in the pericardium during development.[11-14] Dogs with pericardial cysts may show no clinical signs or may present with signs related to cardiac tamponade.

Acquired Pericardial Diseases

Pericardial Rupture

Traumatic rupture of the pericardium has been reported rarely in dogs.[10] Rupture of the pericardium after trauma (e.g., automobile accident or blunt thoracic trauma) likely occurs more frequently than it is diagnosed because it usually does not cause clinical signs. However, when the pericardium contracts around the herniated heart during healing, a stricture can develop that compresses the vena cava, causing a Budd Chiari syndrome with ascites and hepatomegaly, caval syndrome with swelling of the head and neck, or both.

Pericardial Effusion

Pericardial effusions are categorized by the clinical pathologic characteristics of the fluid. A transudate occurs secondary to congestive heart failure, peritoneopericardial diaphragmatic hernia, hypoalbuminemia, or increased vascular permeability.[15-22] An exudate results from infectious on noninfectious pericarditis.[17,23,24] Acute pericarditis is not associated with pericardial effusion.[2] Pericarditis has been associated with feline cardiomyopathy and feline infectious peritonitis.[17,25-28] Fungal pericarditis is unusual, with the exception of *Coccidioides immitis* in dogs living in the southwestern United States.[17,29] Renal failure can induce epicarditis and pericardial effusion in dogs.[30] Hemorrhagic pericardial

effusion results from trauma, rupture of the left atrium secondary to mitral valve disease, intoxication with an anticoagulant, and neoplasia, or it may be idiopathic.[31-38] Idiopathic pericardial effusion is the most common cause of acute or chronic non-neoplastic hemorrhagic pericardial effusion in the dog.[15,16,20,29,37,38] Neoplasia of the heart, heart base, or pericardium is the second most common cause of hemorrhagic pericardial effusion in dogs. Hemangiosarcoma of the right atrium is the most common neoplasia. This tumor is often multicentric, involving the spleen or liver at the time of pericardial effusion. Chemodectoma is the second most common cardiac

tumor and is most commonly seen in brachycephalic dogs. Mesothelioma of the pericardium is another cause of a hemorrhagic pericardial effusion.[15,18,20,22,23,27,37,39-43]

Cardiac Tamponade

The pericardium is fairly noncompliant, and pericardial pressure begins to rise after 5 to 60 ml of fluid accumulate within the pericardium (see Figure 17-1). The capacitance of the pericardium is influenced by the rate of fluid accumulation. Hypertrophy of the pericardium by slow stretching allows augmentation of pericardial volume and rightward shift of the pressure-volume curve of the pericardium. As a

result, the pericardium can accumulate a larger volume of fluid before pressure begins to rise. However, beyond a certain point, pressure increases quickly with a small additional increase in volume. When the pericardium is thickened, as is the case with constrictive pericardial disease, a minor increase in volume causes a significant increase in pericardial pressure.[44-50]

The compensatory response to a pericardial effusion is an adrenergic stimulation and a parasympathetic withdrawal. It induces tachycardia and increased contractility.[2,51] Patients on beta-blocker therapy may not be able to show this response. Elevation in

pericardial pressure increases diastolic pressure within the heart, which in turn reduces stroke volume. High pericardial pressure exerts its main effect on the right heart by impeding diastolic filling. The effect on the left side is secondary to decreased pulmonary venous return.[51-55] Because part of the vena cava is in the pericardial sac, increased pericardial pressure will directly affect blood flow in the vena cava. Pericardial pressure first equilibrates with right ventricular filling pressure (right-sided heart tamponade) and then with left ventricular filling pressure (left-sided heart tamponade). Right- and left-sided atrial and ventricular diastolic pressures raise and equilibrate at a

pressure equivalent to the pressure in the pericardial sac (between 15 and 20 mm Hg). Cardiac output is significantly compromised and systemic venous pressure is elevated.[36,44-47,49,50] The small end-diastolic volume accounts for the small stroke volume. Compensatory mechanisms induce an augmentation in contractility, and a reduction of end-systolic volume, but not enough to normalize the stroke volume. Tachycardia is common as a reflex to maintain cardiac output. Also during cardiac tamponade, the flow of blood from the right atrium to the right ventricle is significantly reduced. Therefore, the y descent on the central venous pressure tracing is absent. Y

descent is observed when the tricuspid valve opens. At this time no blood is leaving the heart, and because the right ventricle is fixed with a small volume, the y descent is lost. During cardiac tamponade, a transfer of blood volume occurs into the systemic circulation, resulting in a reduction of the pulmonary vascularity on thoracic radiographs.[56]

Decreased cardiac output results in activation of the renin-angiotensin-aldosterone system, causing retention of sodium and water. Activation of the sympathetic nervous system results in positive inotropic and chronotropic effects and vasoconstriction. Atrial natriuretic factor is not increased

during cardiac tamponade to counteract the above effects because the atrium is still supported by the pericardium, which limits its dilation. As a result, cardiac tamponade is associated with increases in systemic venous and portal pressures, causing jugular distention and fluid transudation from systemic capillary beds to produce peripheral edema, liver congestion, and ascites.[36,44-47,49,50]

Arterial pressures may vary paradoxically with respiration during severe cardiac tamponade. During inspiration, pericardial pressure and right ventricular pressure decrease. Venous return to the right atrium and

ventricle are increased. However, because the volume is limited by the pericardium, there is a leftward shift of the septum. Left ventricular end-diastolic volume is decreased, resulting in a reduction of cardiac output and arterial pressure during inspiration. This phenomenon, known as pulsus paradoxicus, is not a pathognomonic sign of cardiac tamponade. It can also occur with obstructive lung disease, restrictive cardiomyopathy, or hypovolemic shock.[36,44-47,49,50]

Constrictive Pericarditis

Constrictive pericarditis compromises cardiac filling by causing a non-distensible, thickened, and fibrotic

pericardium. This condition has been reported in dogs aged from 3 to 10 years old.[57-59]

Chronic pericarditis resulting from any etiology can cause constrictive pericarditis. Chronic idiopathic pericardial effusion, neoplasia, foreign material (e.g., bullets), and infection (coccidiomycosis) are most commonly reported in cases with constrictive pericarditis.[58,59] In most cases, the parietal pericardium is more severely affected than the visceral pericardium. The parietal pericardium can be up to 8 mm thick. In some cases, the visceral and parietal pericardium are both affected, with severe adhesions between them. Pericardial fluid may be

present, and if so, the condition is called effusive-constrictive pericarditis. Mesothelial proliferation, inflammation, and fibrosis are common findings on histopathology.[58-60]

Constrictive pericarditis affects late diastole. Early ventricular filling is normal and proceeds rapidly until the limit of pericardial distendibility is reached. The thickened, non-compliant pericardium abruptly limits ventricular filling in mid to late diastole. The atrial and ventricular pressure tracings classically show a rapid y descent followed by an abrupt rise to an elevated diastolic plateau. This is referred as the “square root sign” and is

considered diagnostic for pericardial constriction (Figure 17-2). If a small amount of pericardial fluid is present, the rapid y descent is absent.

Figure 17-2. Constrictive pericarditis. Right ventricular pressure tracing showing the "square root sign" and an elevated end-diastolic pressure (8 mm Hg).

Pulmonary capillary wedge pressure, right ventricular diastolic pressures, right atrial, and left ventricular diastolic pressures are all elevated and equal with constrictive pericarditis. If localized fibrosis is affecting one cardiac chamber more than another, this hemodynamic occurrence may not be found. Also, if the patient is volume contracted from diuretics or other causes, volume loading with a crystalloid solution might be required to demonstrate these classic hemodynamic changes. As the condition worsens, cardiac output declines. Central venous pressure does not decrease during inspiration as normal because negative intrathoracic pressure during inspiration is not

transmitted to the cardiac chambers. Changes of intrathoracic pressure are still transmitted to the pulmonary vasculature during respiration. During inspiration, the pressure gradient between the left atrium and the pulmonary circulation is reduced, resulting in less left atrial and ventricular filling. It results in an augmentation of right ventricular filling and deviation of the septum toward the left ventricle. The opposite occurs during expiration.[2,54] Augmentation of systemic venous pressure during inspiration with constrictive pericarditis is referred to as Kussmaul's sign.[2,60] High central venous pressure and reduced cardiac output result in compensatory

retention of sodium and water by the kidney. Inhibition of the atrial natriuretic peptide (atrium cannot dilate) also contributes to the sodium retention. It further exacerbates increases in systemic, central venous, and left-sided filling pressures.

Chapter 18

Perioperative Cardiac Arrhythmias

Janice McIntosh Bright

For every affection…that is attended with either pain or pleasure, hope or fear, is the cause of an agitation whose influence extends to the heart.
--- Sir William Harvey, 1628

That emotion and stress may affect the heart was recognized by William Harvey over three centuries ago. Stresses encountered by surgical

patients predispose them to a variety of cardiac rhythm disturbances. Because these rhythm disturbances can contribute to morbidity and mortality, it is important to anticipate and avoid them when possible. When not possible, early recognition and intervention are usually advantageous. Monitoring heart rate and rhythm during and after surgery is, consequently, of utmost importance. Anesthesiologists and surgeons must be aware of normal variations of rate and rhythm in healthy anesthetized animals. In addition, they must be familiar with specific pathologic arrhythmias and appropriate treatment interventions for clinically significant rhythm perturbations. This

chapter provides an overview of the identification and management of common perioperative arrhythmias. Other sources should be consulted for a discussion of arrhythmogenic properties of various preanesthetic and anesthetic agents.[1]

Risk Factors

Animals with a history of arrhythmia are at increased risk for recurrence or exacerbation of the arrhythmia during the perioperative period. Similarly, patients with preexisting structural heart disease are at risk of developing significant intraoperative and postoperative cardiac rate and rhythm abnormalities. The preoperative

assessment of these animals should, therefore, include a complete cardiac evaluation, including Doppler/echocardiography, electrocardiography (ECG), thoracic radiographs, and blood pressure measurement. The data obtained from this evaluation is critical for choosing the safest anesthetic protocol and the most appropriate antiarrhythmic agents. A preoperative ECG in cats older than seven years of age is helpful for detecting the presence of left anterior fascicular block, which is a silent ECG abnormality often associated with myocardial disease in this species.

In people, risk factors identified for

development of supraventricular tachyarrhythmias include advancing age, a previous history of supraventricular arrhythmia, type of surgery (intraabdominal, intrathoracic, or major vascular surgery), and preexisting congestive heart failure or chronic lung disease.[2] Risk factors for development of supraventricular arrhythmia in dogs during the perioperative period include atrial enlargement and a history of previous supraventricular ectopy. Furthermore, giant breeds and Labrador retrievers are predisposed.

Perioperative ventricular arrhythmias are strongly associated with underlying myocardial dysfunction or contusion,

splenic surgeries, pheochromocytoma, hyperthyroidism, and surgery to correct gastric dilation/volvulus. Patients with preoperative ventricular tachyarrhythmias are also at high risk for intraoperative and postoperative ventricular ectopy. Animals receiving β-adrenergic antagonists preoperatively may develop either supraventricular or ventricular tachyarrhythmias associated with β-blocker withdrawal if these agents have been recently and abruptly discontinued.

An important bradyarrhythmia that must be anticipated preoperatively is the development of increasing severity of atrioventricular (AV) block in

animals with conduction system disease. Bradyarrhythmias resulting from enhanced vagal tone occur frequently in animals with upper airway obstruction, those undergoing surgery of the cervical spine, and animals with increased intracranial pressure.

General Approach for Management of Perioperative Arrhythmias

Abnormalities of cardiac rate and rhythm that occur while the patient is anesthetized are often the result of alterations in depth of anesthesia. Arrhythmias may also occur under anesthesia as a result of autonomic

imbalance and catecholamine release; direct effects of anesthetic agents including analgesics, muscle relaxants, and reversal agents; hypothermia (and rarely hyperthermia); and mechanical stimulation secondary to invasive procedures and surgical manipulation. All of these factors must be considered and specific interventions taken to alleviate the causative mechanism(s). Other factors involved in arrhythmogenesis during the intraoperative period include electrolyte abnormalities, acid-base disturbances, volume depletion, release of toxic metabolites, and myocardial ischemia. Again, these factors must be specifically treated to appropriately manage the resulting arrhythmias.

Although cardiac arrhythmias are common in the postoperative period, most are clinically benign, such as sinus bradycardia, sinus pauses, accelerated idioventricular rhythm, isorhythmic AV dissociation, and isolated ventricular premature contractions (VPCs). Tachycardia in the immediate postoperative period may reflect the sympathetic activation associated with recovery. However, in addition to anesthetic emergence, both supraventricular and ventricular tachyarrhythmias in the postoperative period may reflect hypoxemia, hypercarbia, acidosis, toxemia, hypovolemia, blood loss, electrolyte imbalances, fear, pain, or a combination of these factors. Residual

effects of anesthetic agents such as ketamine may also play a role. Again, treatment should be directed at identification and reversal of underlying causative factors; however, antiarrhythmic therapy may be needed when the primary cause of a potentially fatal arrhythmia cannot be identified or quickly corrected. In summary, the following general approach for management of perioperative arrhythmias is proffered:

1) Have a precise ECG diagnosis for the arrhythmia, if possible.

2) Specifically treat noncardiac causes (e.g., electrolyte abnormalities, hypothermia, acidosis, hypovolemia, hypoxemia, pain, fear) before using an antiarrhythmic medication unless

hemodynamic or electrical instability are present.
3) Consider discontinuing drugs that may be causing or contributing to the arrhythmia.

Identification and Management of Common Perioperative Tachyarrhythmias

Sinus Tachycardia

Post-anesthetic sinus tachycardia (canine > 180 beats/minute; feline > 240 beats/minute) may often result from the anesthetic agents used, including atropine, glycopyrrolate, ketamine, or adrenergic agonists. Sinus

tachycardia in the perioperative period is rarely, if ever, a true cardiac arrhythmia, but, rather, a reflection of increased sympathetic tone, which may arise from a wide variety of pathologic and/or physiologic causes. Physiologic causes include excitement, stress, and fear. Pathologic causes include pain, hypovolemia, anemia, acidosis, hypoxemia, fever, hyperthermia, toxemia, cardiac failure, hypercapnia, hypotension, acute hemorrhage, and hyperthyroidism.

Treatment of sinus tachycardia should be directed at identification and correction of the underlying cause of the heightened adrenergic tone. Antiarrhythmic agents are rarely

indicated and are often detrimental.

Atrial Fibrillation and Atrial Flutter

Atrial fibrillation and atrial flutter are common postoperative arrhythmias in human patients,[3] but development of either of these arrhythmias postoperatively is less common in dogs and extremely rare in cats. When atrial fibrillation and atrial flutter are noted in animals in the perioperative setting, these arrhythmias are usually present preoperatively. Nonetheless, both arrhythmias are clinically important because both may decrease cardiac output secondary to inappropriately fast heart rates that reduce stroke

volume. Furthermore, atrial fibrillation abolishes the atrial contribution to ventricular filling and may, thereby, decrease cardiac output by as much as 39% while increasing left atrial pressure by as much as 9.5 mm Hg in otherwise healthy dogs.[4]

On ECG, atrial fibrillation is recognized by absence of P waves and completely irregular R-R intervals (Figure 18-1). Rapid, irregular fibrillatory waves that vary in size, shape, and timing are often visible. The QRS complexes are normal unless an intraventricular conduction abnormality is also present (e.g., right or left bundle branch block). The ventricular rate will depend on

conduction velocity and refractoriness of the AV node and may be normal in dogs without structural heart disease. However, heart rate is typically very rapid in dogs and cats with heart failure as well as those with high circulating levels of catecholamines. In animals with atrial fibrillation that have been receiving oral medication for rate control, the heart rate often drops significantly following induction of anesthesia.

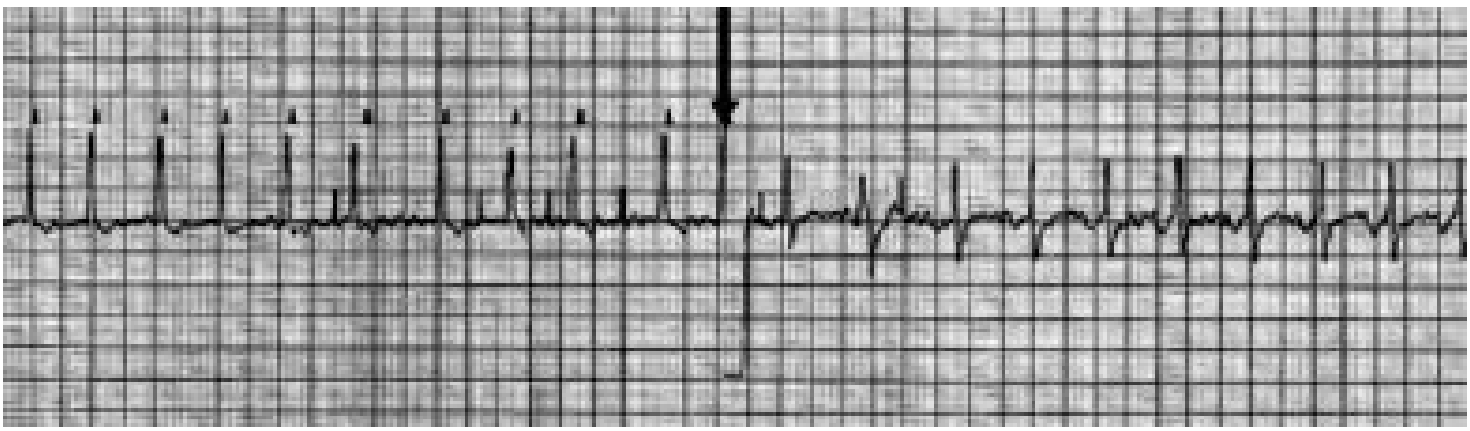

Figure 18-1. An ECG rhythm strip recorded during direct current (DC) cardioversion of atrial fibrillation

in a dog with laryngeal paralysis. Atrial fibrillation is recognized as the underlying cardiac rhythm in the initial portion of the ECG by absence of P waves and completely irregular R-R intervals. Fibrillatory waves are present in the baseline. Prior to delivery of the synchronized electrical shock (at large arrow), the cardioversion device identifies QRS complexes with small arrows. As a result of the shock, normal sinus rhythm is restored. (lead II; 25 mm/s)

Management of atrial fibrillation is initially aimed at controlling heart rate. Intravenous calcium channel blockers or β-blockers are effective for slowing conduction through the AV node and can rapidly provide control of the ventricular response in patients with atrial fibrillation (Table 18-1). These drugs may be administered by bolus injection but require maintenance infusions or follow-up

oral dosing to maintain adequate rate control. When continuous infusions are administered, blood pressure and heart rate should be closely monitored because these medications may cause hypotension and bradycardia. Because of the negative inotropic effects of β-blockers or calcium channel blockers, patients with myocardial systolic dysfunction may develop congestive heart failure or worsening of congestive heart failure after administration of these agents. Oral digoxin is used extensively for chronic heart rate control in dogs with atrial fibrillation because this drug will increase parasympathetic tone to the AV node with a resultant slowing of AV nodal conduction. However, in the

postoperative period, sympathetic tone is often excessive, rendering this drug less effective in this setting. Furthermore, digoxin toxicity can cause nearly every known cardiac rhythm disturbance, and animals receiving digoxin may develop digoxin-induced arrhythmias in the perioperative setting if hypovolemia, hypoalbuminemia, or electrolyte depletion is induced by surgery or anesthesia.

Restoration of sinus rhythm with a synchronized direct current shock (DC cardioversion) has several advantages over heart rate control for management of atrial fibrillation in animals needing surgery. The

cardioversion may be done immediately after induction of anesthesia, obviating the need to administer negative inotropic agents for rate control. Also, restoring sinus rhythm immediately after induction of anesthesia will improve cardiac performance and reduce ventricular filling pressures throughout the remainder of the anesthetic period and recovery.

Although similar to atrial fibrillation, atrial flutter is less common in veterinary patients. With atrial flutter the ECG recorded will show rapid, organized atrial activation with an abnormally rapid ventricular rate unless the patient is receiving

medication to control heart rate or unless AV conduction block is also present. Unlike atrial fibrillation, the ventricular rate is usually regular. Although a “saw-toothed” pattern of flutter waves is typically described, this pattern of atrial activation may be difficult to appreciate when 2:1 AV conduction is present, and the arrhythmia may, therefore, be difficult to distinguish from other types of supraventricular arrhythmia. With administration of calcium channel blockers or β-blockers, or with induction of anesthesia, the flutter waves usually become easily visible. Management of atrial flutter is similar to management of atrial fibrillation, although rate control is often more

difficult. DC cardioversion of atrial flutter is usually achieved at lower energy levels than those needed for cardioversion of atrial fibrillation.

Occasionally, atrial fibrillation and atrial flutter will develop in the postoperative period as a result of autonomic imbalance. This is recognized most frequently in patients that have had surgery on or trauma to the cervical spine. In this situation, the arrhythmias are often self-limiting with no treatment required (Figure 18-2).

Table 18-1. Drugs used for Acute Management of Tachyarrhythmias

Drug	Dose	Comments
Calcium channel blockers		
Diltiazem	Dog, Cat: 0.25 mg/kg IV bolus (may be repeated once after 3 minutes); then 2-6 μg/kg/min PRN	monitor for hypotension & bradycardia; may exacerbate congestive heart failure in animals with impaired myocardial function
Verapamil	Dog: 0.05 mg/kg IV (slow bolus) q 15-20 min PRN (up to 0.15 mg/kg total dose)	(Same as diltiazem)
Beta-blockers		
Esmolol	Dog, Cat: 50-100 μg/kg IV bolus q 5 min PRN (up to 500 μg/kg max); 50-200 μg/kg/min infusion	ultrashort acting; monitor for hypotension & bradycardia; may exacerbate congestive heart failure; reduced efficacy if β-agonists administered
Propranolol	Dog, Cat: 0.01-0.1 mg/kg IV (slow bolus)	monitor for hypotension & bradycardia; may exacerbate congestive heart failure; reduced efficacy if β-agonists administered; may induce bronchospasm
Digoxin	Dog: 0.0025 mg/kg IV bolus; repeat hourly 3-4 times up to 0.01 mg/kg	vagomimetic; toxicity enhanced by cachexia, renal dysfunction hypokalemia, hyponatremia, hypercalcemia, hyperthyroidism, hypoxemia, myocardial failure; many drug interactions
Lidocaine (without epinephrine)	Dog: 2-4 mg/kg IV bolus over 5 min (administer 2 mg/kg boluses slowly); then 40-80 μg/kg/min IV infusion Cat: 0.25-1.0 mg/kg IV bolus over 5 min (or 1 mg boluses, max of 4 mg, over 5 min); then 10-40 μg/kg/min IV infusion	serum [K^+] and serum [Mg^{++}] must be normal for max efficacy
Procainamide	Dog: 6-10 mg/kg slowly IV bolus to effect; then 25-50 μg/kg/min IV infusion Cat: (No data available for parenteral dosing)	serum [K^+] and serum [Mg^{++}] must be normal for max efficacy
Amiodarone	Dog: 2.5-5.0 mg/kg IV bolus over 2-5 min	Avoid preparations with polysorbate 80 and benzyl alcohol

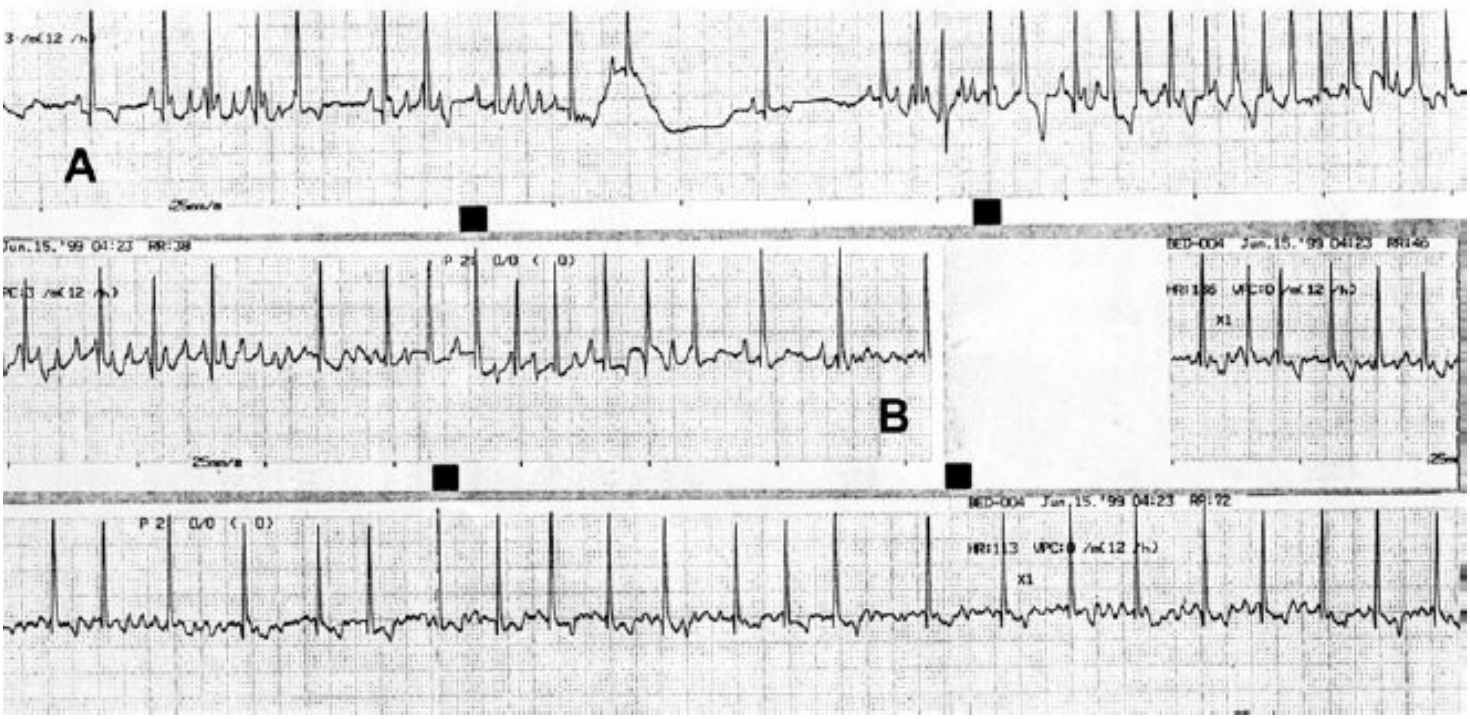

Figure 18-2. Continuous ECG rhythm strips obtained from a Labrador retriever during the early postoperative period following hemilaminectomy. Initially, the rhythm strip (A) shows sinus arrhythmia with brief paroxysms of atrial flutter. Ultimately (B), the rhythm degenerates to atrial fibrillation. This dog spontaneously converted to sinus rhythm within 24 hours, suggesting that the arrhythmias resulted from autonomic imbalance caused by surgical manipulation and stress. (lead II; 25 mm/s)

Paroxysmal Supraventricular Tachycardias

Although the term supraventricular tachycardia (SVT) in its broadest sense refers to any tachycardia originating above the ventricles, this term is generally reserved to describe supraventricular tachyarrhythmias other than sinus tachycardia, atrial fibrillation, or atrial flutter.

Paroxysmal SVT owing to impulse reentry in the AV node, impulse reentry within atrial tissue, or impulse reentry via an accessory atrioventricular conduction pathway has a similar ECG appearance, namely a rapid tachycardia with narrow (normal) QRS complexes (Figure 18-3). The QRS complexes will be abnormally wide, however, if there is

intraventricular conduction delay such as right or left bundle branch block or when conduction from atria to ventricles occurs over an accessory conduction pathway. Regardless of the anatomic location of the reentry pathway, any of these SVTs may occur in the perioperative setting, causing a very rapid heart rate with hypotension. SVTs may occur in any age group and often are not associated with structural heart disease. These tachycardias are usually associated with enhanced adrenergic tone as well as with triggers such as premature atrial contractions or premature ventricular contractions. When paroxysmal, these SVTs begin and terminate abruptly (lack of gradual

rate acceleration and deceleration).

The specific type of paroxysmal SVT can theoretically be identified from a multiple lead ECG (including chest leads) by evaluating P' wave morphology and timing. However, P' waves may be extremely difficult to identify with certainty during a rapid SVT. Furthermore, during anesthetic induction, surgery, or in the immediate recovery period, available ECG monitoring equipment is often not conducive to examination of multiple-lead ECG recordings. While vagal maneuvers may be helpful both diagnostically and therapeutically, many animals do not respond to them. Furthermore, aggressive vagal

maneuvers may, on occasion, produce ventricular fibrillation. Therefore, administration of intravenous antiarrhythmic agents is generally a safer, more effective means of differentiating and treating SVTs. Ideally, blood pressure and ECG monitoring are done as antiarrhythmic agents are administered. Diltiazem is the drug of choice for initial treatment because of its ability to rapidly slow the ventricular response to atrial tachyarrhythmias, and for terminating most AV nodal and AV reciprocating tachycardias (see Table 18-1). Diltiazem has a negative inotropic effect and must be used cautiously in animals with myocardial failure; however, diltiazem has a less potent

negative inotropic effect than verapamil or esmolol.[5] Although adenosine is used to terminate SVT in human patients, this agent does not appear to be effective for this purpose in dogs. Procainamide, a class IA antiarrhythmic, may also be administered intravenously for management for supraventricular tachyarrhythmias in dogs (see Table 18-1). This agent is most appropriately used after administering diltiazem and is useful for terminating atrial reentrant tachycardias and atrioventricular reentrant tachycardias.

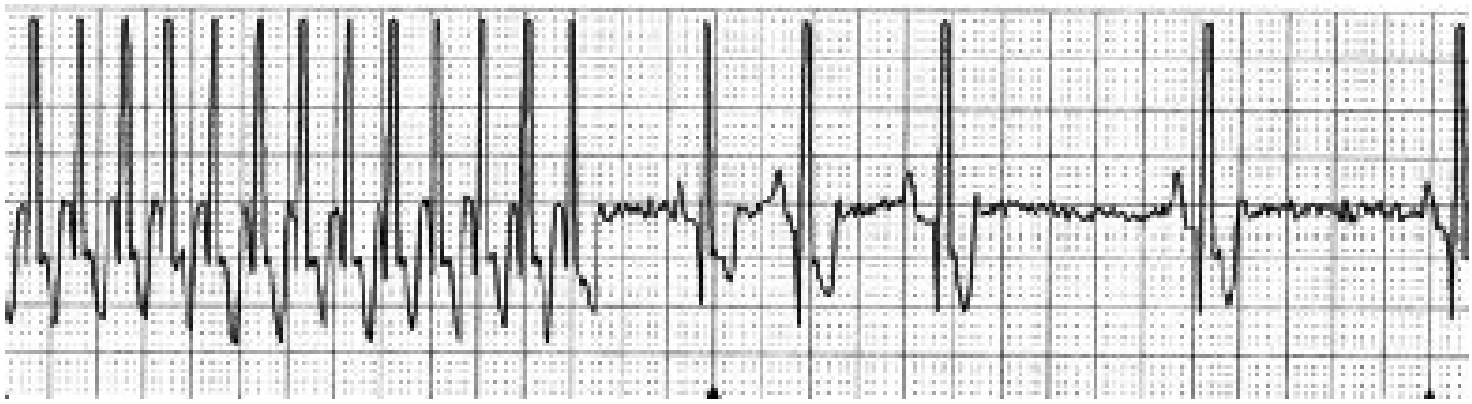

Figure 18-3. A lead II ECG rhythm strip obtained from a 1–year-old golden retriever. The ECG shows supraventricular tachycardia with a rate of 300 beats/minute. Abrupt conversion to sinus rhythm resulted from intravenous administration of diltiazem (0.25 mg/kg). Note that the QRS complexes during the arrhythmia are normal and identical to those during sinus rhythm. (lead II; 25 mm/s)

Ventricular Tachyarrhythmias

Perioperative ventricular ectopy may include relatively benign conditions such as ventricular premature contractions (VPCs) and accelerated

idioventricular rhythm or potentially lethal arrhythmias such as sustained ventricular tachycardia (VT) and ventricular fibrillation (VF). The appearance of ventricular ectopy of any type should prompt measures to eliminate inciting factors such as hypoxemia, hypercarbia, electrolyte deficiencies, drug toxicities, and catecholamine excess. Antiarrhythmic therapy is indicated when the inciting cause cannot be identified or immediately reversed and the arrhythmia is responsible for hemodynamic compromise. Antiarrhythmic treatment is also indicated in animals at risk for sudden death triggered by fatal electrical instability.[6,7] In one postoperative

study of 230 consecutive human patients with frequent VPCs or VT, adverse outcomes were not associated with the arrhythmias.[8] The adverse effects of ventricular arrhythmias in veterinary surgical patients has also been questioned, and the empiric use of antiarrhythmic agents has been challenged.[6,7] The decision that a ventricular arrhythmia is dangerous and should be suppressed with antiarrhythmic medication is based on the presence of weakness, syncope, hypotension, pallor, or exacerbation of heart failure directly attributable to the arrhythmia. Ventricular tachycardias vary in rate, morphology, and duration, and rate is generally the most important determinant of

hemodynamic consequences. In general, the slower the rate of VT, the more benign the arrhythmia will be. In absence of clinical signs linked to the arrhythmia, the following characteristics of VT justify suppression with antiarrhythmic agents: rapid VT (rate appreciably greater than underlying sinus rate), sustained VT (> 30 seconds), VT with a short coupling interval to preceding sinus complex, and polymorphic VT. Furthermore, because of the known tendency for sudden death from ventricular ectopy, suppression of VPCs and VT is justified in boxers, Doberman pinschers, German shepherds, dogs with subaortic stenosis, and animals with significant

myocardial dysfunction.

Ventricular premature contractions (VPCs) are identified on the ECG as wide QRS complexes that differ from the sinus complexes and occur prematurely (Figure 18-4). VPCs are frequently followed by a compensatory pause caused by retrograde conduction of the VPC into the His-Purkinje system with either block of the subsequent sinus beat or with retrograde conduction to the atrium resetting the sinus node. Ventricular ectopic complexes are classified as monomorphic or polymorphic according to whether the QRS complexes are uniform or variable. Ventricular tachycardia is defined as

three or more consecutive ventricular premature beats (see Figure 18-4). VPCs may be difficult to distinguish from aberrantly conducted supraventricular beats; however, the presence of P waves that are not associated with QRS complexes or the presence of fusion beats indicates ventricular ectopy. It is also helpful to recall that ventricular tachycardia occurs much more frequently than supraventricular tachycardia with aberrancy. Ventricular tachycardia, particularly VT that is rapid, sustained, and polymorphic, may degenerate to ventricular fibrillation which is a rapid, chaotic, wide complex rhythm with absence of adequate cardiac output.

Ventricular tachycardia resulting in hemodynamic compromise (hypoperfusion or hypotension) should be treated immediately with DC cardioversion. Antiarrhythmic therapy can be administered to prevent a recurrence or as the initial therapy to terminate the VT in hemodynamically stable patients at risk for progression to hemodynamic instability. For veterinary patients, the antiarrhythmic agent of choice for immediate suppression of ventricular ectopy is lidocaine. This agent is highly effective with few side effects[3] (see Table 18-1). If lidocaine is not effective, substitution or addition of intravenous procainamide may provide arrhythmia suppression. Procainamide

administration is particularly appealing when the ECG diagnosis of a wide complex tachycardia is uncertain. For refractory ventricular arrhythmias during the perioperative period, β-adrenergic blockers are often effective, particularly when combined with a class IA or IB antiarrhythmic agent, because the β-blockade antagonizes increased circulating catecholamines caused by stress. Regardless of the underlying mechanism of the ventricular arrhythmia, increased sympathetic tone can trigger the arrhythmia. Furthermore, adrenergic stimulation can render many antiarrhythmic drugs ineffective. Similarly, most antiarrhythmic agents are ineffective in the presence of

hypokalemia or hypomagnesemia.

Amiodarone is now available for intravenous treatment of life-threatening VT and is recommended as a first line treatment for pulseless VT in people.[9] However, the most readily available intravenous preparation of amiodarone (Cordarone, Wyeth Laboratories Inc, Philadelphia, PA) contains polysorbate 80 and benzyl alcohol, both of which cause severe hypotension in dogs.[10,11] A newer aqueous formulation of amiodarone (Amio-Aqueous, Academic Pharmaceuticals Inc, Lake Bluff, IL) does not contain these agents and is better suited for dogs. Ventricular fibrillation should be managed by

immediate DC defibrillation.

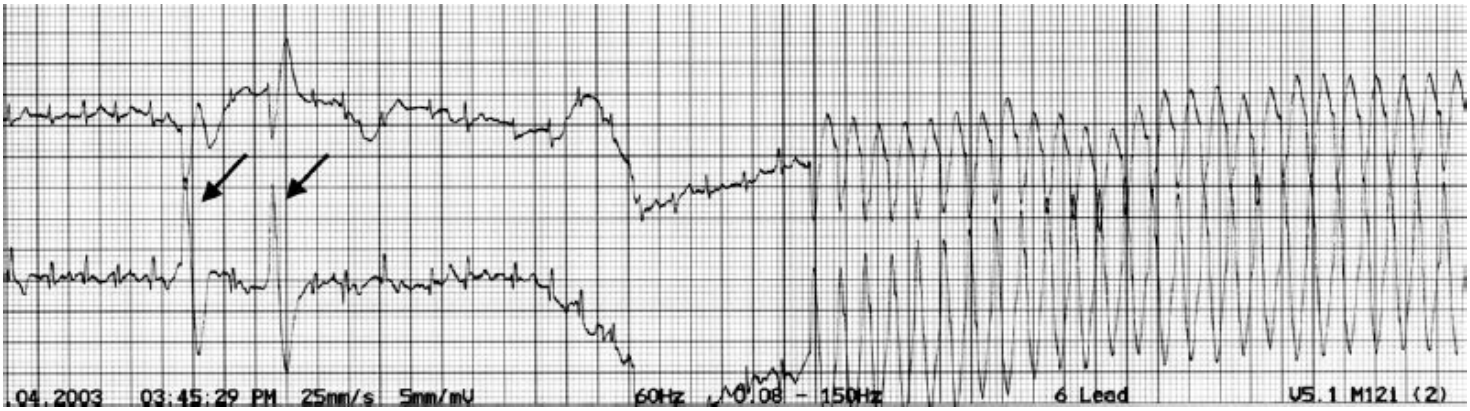

Figure 18-4. Simultaneous ECG rhythm strips recorded from a 7-year-old Irish wolfhound presented for collapse. Initial narrow complex, irregular rhythm consistent with atrial fibrillation is interrupted by isolated ventricular premature contractions (arrows). However, the rhythm abruptly deteriorates to sustained ventricular tachycardia with a dangerously rapid rate of 350 beats/minute. (lead AVL (top strip) and lead AVF (bottom strip); 25 mm/s; 5 mm/mV)

Accelerated Idioventricular Rhythm

Accelerated idioventricular rhythm develops frequently in dogs and cats

during the intraoperative and postoperative periods. This arrhythmia is actually slow ventricular tachycardia, ventricular tachycardia at a rate slower than the sinus rate in a normal animal. Therefore, by heart rate criteria alone, this rhythm is not a tachycardia. Yet, because the ectopic ventricular focus responsible for the arrhythmia is depolarizing at a rate faster than a normal ventricular escape focus can depolarize, this rhythm is truly a ventricular tachycardia. Nonetheless, because the rate is slow, this form of VT is often referred to as accelerated idioventricular rhythm. The clinical importance of this terminology is that an accelerated idioventricular rhythm is usually benign whereas rapid

VT is often malignant. The specific rates at which accelerated idioventricular rhythm becomes “true” ventricular tachycardia have not been precisely defined for dogs and cats. However, heart rates exceeding 180 beats/minute in dogs with VT and heart rates greater than 240 beats/minute in cats are most likely to be harmful.

Accelerated idioventricular rhythm often occurs in the perioperative setting in animals without underlying cardiac disease. This arrhythmia is frequent in dogs after gastric dilation/volvulus surgery, in dogs following splenic surgery, and in dogs with any type of abdominal disease

(e.g., pancreatitis, prostatitis, enteritis, colitis). Accelerated idioventricular rhythm is also common in dogs with neurologic disease and with trauma.[12] Accelerated idioventricular rhythm in animals without underlying primary cardiac disease is nearly always benign, and antiarrhythmic treatment, in most cases, is unjustified.

On ECG, accelerated idioventricular rhythm is recognized as intermittent ventricular tachycardia that has a rate similar to or slightly greater than the sinus rate. The ventricular rhythm competes for the cardiac rhythm, meaning that the ventricular rhythm is apparent when the sinus rate slows or during sinus pauses (Figure 18-5).

Although accelerated idioventricular rhythm usually has a uniform morphology, multiform ventricular complexes may occasionally be present.

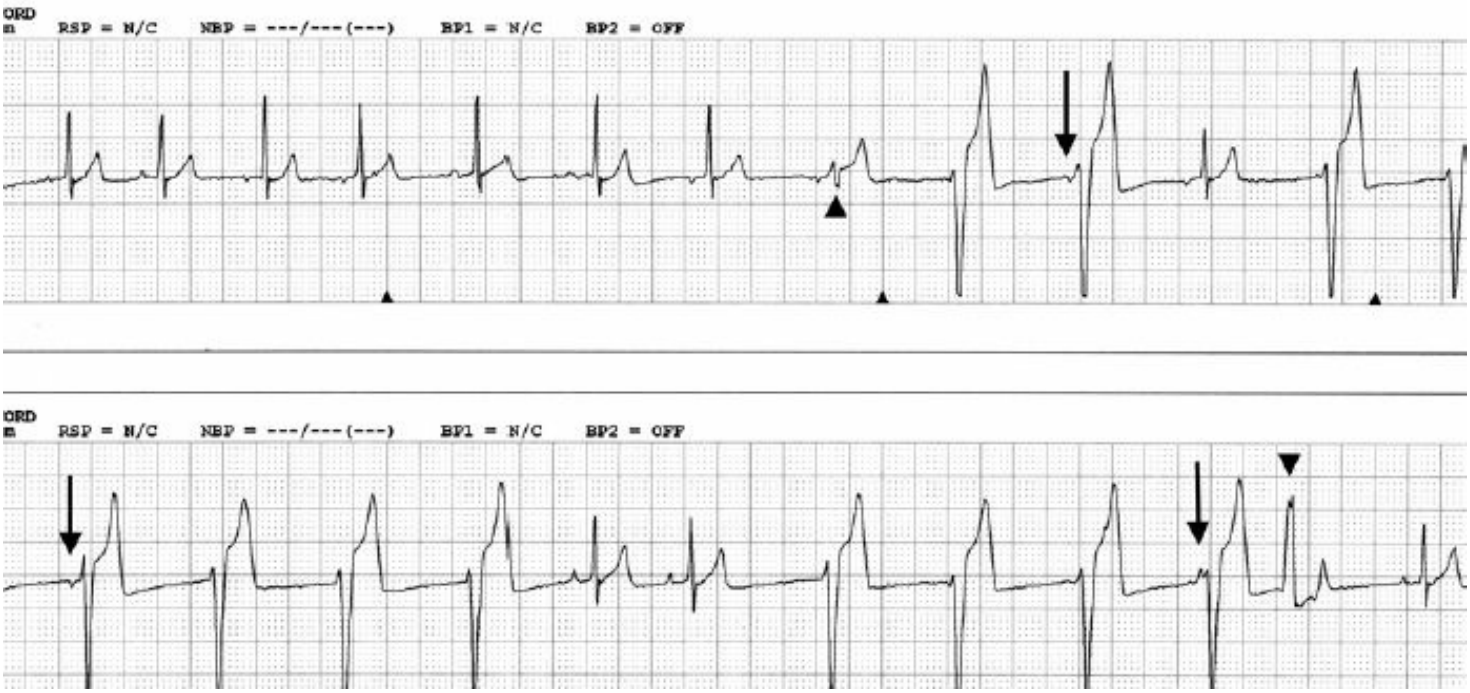

Figure 18-5A. ECG rhythm strips recorded after splenectomy from a canine patient. A sinus arrhythmia is present with wandering pacemaker during which the sinus rate varies from 83 to 107 beats/minute. The sinus arrhythmia is usurped intermittently by a wide QRS complex rhythm with a regular rate of 79 beats/minute. This wide complex rhythm is a slow ventricular tachycardia referred to as

accelerated idioventricular rhythm. The idioventricular rhythm is evident only when the sinus rate drops below the ventricular ectopic rate. P waves unassociated with the QRS complexes are visible intermittently during the ventricular rhythm (arrows). Occasional fusion beats are present (arrow heads). (lead II; 25 mm/s)

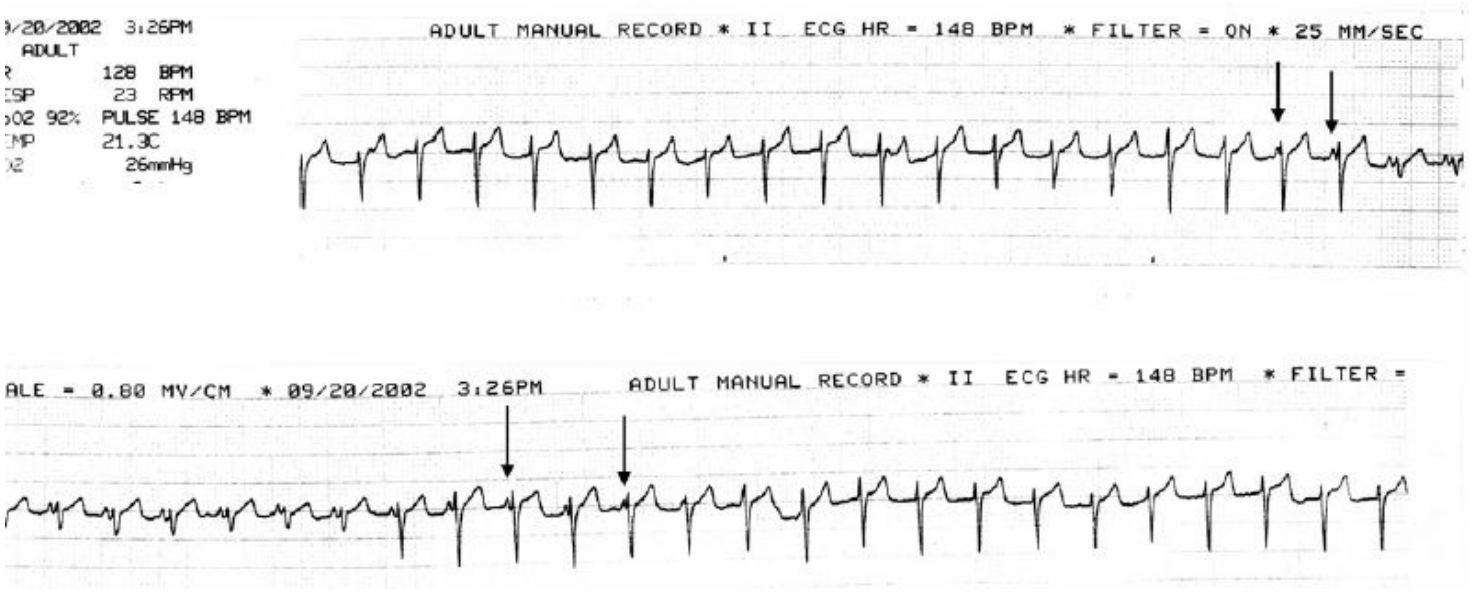

Figure 18-5B. ECG rhythm strip recorded from an anesthetized cat showing accelerated idioventricular rhythm. The cat was undergoing a subtotal colectomy. Initially a wide complex rhythm is seen with a regular rate of 142 beats/minute, during which P waves, unassociated with QRS complexes, are intermittently seen (arrows). Between the episodes of idioventricular rhythm is sinus rhythm with a similar rate (142 beats/minute). The accelerated idioventricular

rhythm competes with the sinus rate as the dominant rhythm. (lead II; 25 mm/s)

Identification and Management of Perioperative Bradyarrhythmias

Bradyarrhythmias seldom cause significant problems in the perioperative period, and antiarrhythmic treatment is rarely indicated. Patients with symptomatic bradycardia resulting from disease of the cardiac pacing or conduction system should be evaluated for permanent pacemaker implantation prior to elective surgery. For patients with AV block or sinus node

dysfunction without clinical signs or for those needing emergency surgery, temporary transvenous or transcutaneous pacing should be available. In the intraoperative and postoperative settings, bradycardia may signify a potentially serious underlying problem that requires specific intervention such as hypoxemia, hypothermia, surgical manipulation of the autonomic nervous system, excessive anesthetic depth, cardiac ischemia, hyperkalemia, increased intrathoracic pressure associated with pneumothorax, or drug toxicity (e.g., from opioids, α2-adrenergic agonists, digoxin, β-adrenergic antagonists, calcium channel blockers, halothane, or

vagomimetic agents)[2,13,14] Profound sinus bradycardia and asystole have been described in association with spinal anesthesia in humans.[2]

Sinus bradycardia (sinus rhythm with rate < 60 beats/minute in dogs), sinus arrhythmia, and sinus pauses are common in healthy large and giant breed dogs with strong vagal tone. These physiologic, vagally mediated arrhythmias are often observed in dogs in the perioperative setting, particularly during sleep. Vagally mediated rate and rhythm alterations may also be associated with enhanced vagal tone caused by chronic airway diseases (particularly upper airway obstruction), chronic gastrointestinal

diseases, increased intraocular pressure, increased intracranial pressure, and cervical spinal injuries or surgery.[14]

High-grade second-degree AV block and complete (third-degree) AV block often reflect intracardiac disease, and animals with these arrhythmias may require temporary or permanent heart rate support. Second-degree AV block is recognized on ECG by the presence of intermittent nonconducted P waves; whereas with complete AV block, the atrial and ventricular activity are completely dissociated, and the ventricular rate is slower than the atrial rate. Causes of high-grade AV conduction block in dogs and cats

include degenerative disease of the conduction system, primary or secondary myocardial diseases, trauma, endocarditis, neoplasia, drug toxicity, and surgery or catheters within the heart. Transient third-degree AV block is occasionally due to vagal surges caused by pain, hypoxemia, or suctioning.[2]

Other than correcting reversible underlying causes, treatment of bradycardia is needed only if the rate is slow enough to cause hypoperfusion. Atropine may be administered intravenously at a dose of 0.02 to 0.04 mg/kg IV or IM. Intravenous infusion of isoproterenol (0.01-2.0 μg/kg/min) or dopamine (5-8 μg/kg/min) may also

be considered. Temporary pacing for bradycardia may be performed transcutaneously in anesthetized patients; however, not all patients can be effectively paced in this manner because of high chest wall impedance. The discomfort induced by this pacing method limits its use to anesthetized or comatose patients. Transvenous pacing is more reliable and may be utilized as a bridge to permanent pacing in conscious or unconscious patients. However, temporary transvenous pacing is associated with risks including sepsis and sudden death from lead displacement. It should be recognized that any type of temporary pacing may produce pacemaker dependence.

Arrhythmias Associated with Specific Surgical Procedures

Instrumentation and Monitoring

Tracheal intubation may be associated with tachyarrhythmias caused by reflex sympathetic stimulation, and anxious patients with high adrenergic tone are particularly susceptible. Pretreatment with opioids, lidocaine, or β-blockers will reduce the cardiovascular responses to intubation.[1] Transient supraventricular or ventricular tachyarrhythmias have also been noted during placement of central venous pressure (CVP) monitoring catheters as

the guidewire is passed into the right atrium or right ventricle.[1,15] Similar arrhythmias may occur from catheters passed through the right side of the heart into the pulmonary artery. Usually, these arrhythmias are transient and insignificant, but ventricular fibrillation has been reported.[16] Complete AV block has also occurred with guide-wire insertion during CVP cannulation.[17] To avoid these potential arrhythmias, it is recommended that guide-wire insertion be limited to the length necessary to reach the junction of the cranial vena cava with the right atrium. It is also important to monitor the patient's ECG or pulse and to have resuscitative drugs and equipment readily available

during insertion of central venous or pulmonary artery catheters.

Acute Gastric Dilation and Gastric Dilation with Volvulus

A high incidence of ventricular arrhythmias (VT and VPCs) has been noted in dogs during and after surgery for acute gastric dilation (AGD) and gastric dilation with volvulus (GDV).[18] Continuous ECG monitoring is, therefore, recommended, and management of ventricular arrhythmias should be considered when formulating the anesthetic plan. The cause of ventricular ectopy associated

with gastric dilation most likely is multifactorial. Ischemia almost certainly plays an important role.[19] Release of myocardial depressant factors from the pancreas has also been implicated.[20] Reperfusion injury is known to occur with GDV and will produce cardiac compromise and irritability.[21] Finally, the acid-base and electrolyte abnormalities in affected dogs undoubtedly play a contributing role. Ventricular ectopy in dogs with AGD and GDV rarely produces hemodynamic instability, and the value of antiarrhythmic treatment is unproven.[22] However, dogs with polymorphic VT, frequent pulse deficits, rapid VT, underlying heart disease, or hypotension associated with

the arrhythmia should receive antiarrhythmic agents. Spontaneous resolution of the arrhythmia typically occurs within a few days with successful treatment of the underlying disease.

Splenectomy

Ventricular arrhythmias are also common in dogs undergoing splenectomy for neoplasia, torsion, or immune-mediated disease.[23,24] These arrhythmias may occur in the pre-, intra-, and postoperative periods, but arrhythmias most commonly develop 5 to 12 hours after surgery.[24] Therefore, continuous ECG monitoring throughout the perioperative period is advised.

Proposed causes of the ventricular ectopy include release of emboli during manipulation of the spleen, arterial hypotension, anemia, free radical-induced myocardial damage, transient ischemia, and the effect of myocardial depressant factors.[23-25] Treatment should consist of restoring normal blood volume and red cell mass, treatment of hypotension, and correction of metabolic abnormalities. As with gastric dilation/volvulus, the ventricular arrhythmias associated with splenectomy are usually hemodynamically stable, and contribution of the ventricular ectopy to postoperative death is unlikely.[6] Monitoring cardiac rhythm and arterial blood pressure without administration

of antiarrhythmic medication is a reasonable course of action in many patients. However, dogs with polymorphic VT, frequent pulse deficits, rapid VT, underlying heart disease, or hypotension associated with the arrhythmia should receive antiarrhythmic agents. In most dogs, ventricular arrhythmias associated with splenectomy resolve without antiarrhythmic treatment within 2 to 3 days following successful treatment of the underlying noncardiac abnormalities.

Thoracic Surgery

Cardiac surgical procedures frequently result in arrhythmias owing to direct

stimulation of the myocardium. VPCs are a common manifestation of surgical manipulation or incision of the myocardium, and ventricular ectopy in this setting should be suppressed to prevent unstable VT or VF.[14] Preventive measures include discontinuing arrhythmogenic drugs (e.g., digoxin) in the preoperative period if possible; reversing electrolyte depletion caused by chronic diuretic administration; avoiding the use of halothane; and administration of lidocaine prior to and during manipulation, incision, or suturing of the myocardium.

Arrhythmias also occur frequently during thoracic surgeries that do not

directly involve the heart. The etiology of these arrhythmias typically includes one or several factors including increased pulmonary vascular resistance, mediastinal shift, autonomic imbalance (vagal surges and release of catecholamines), hypoxemia, electrolyte and acid-base imbalance, and preexisting cardiac disease.[26]

Pheochromocytoma

Pheochromocytomas are functional tumors of the adrenal medulla that produce norepinephrine, epinephrine, and occasionally, dopamine. Large amounts of catecholamines may be released into the central circulation as

a result of intraoperative tumor manipulation. This catecholamine release may cause or aggravate potentially fatal tachyarrhythmias. Direct monitoring of the ECG, arterial blood pressure, and central venous pressure throughout the perioperative period is advised. Supraventricular and ventricular tachycardias should be suppressed with intravenous administration of a β-adrenergic blocking agent such as esmolol or propranolol (Table 18-1). In addition, intravenous administration of phentolamine to control hypertension may indirectly mitigate ventricular tachyarrhythmias. Administration of lidocaine immediately prior to tracheal intubation has also been suggested.[27]

Thyroidectomy

Functional thyroid tumors (adenomatous thyroid hyperplasia) are common in older cats. In one series of 85 cats undergoing thyroidectomy, 10% had tachyarrhythmias during surgery.[28] When surgery on cats with this condition is necessary, intraoperative and postoperative cardiovascular complications, including supraventricular and ventricular tachyarrhythmias, can be minimized by medical induction of a euthyroid state prior to surgery. If this is not possible, recommendations for minimizing arrhythmia include administration of acepromazine prior to induction, avoidance of anticholinergic agents and α2-

adrenergic agonists, and avoidance of halothane.[27]

Chapter 19

Pathophysiology of Congenital Heart Defects

E. Christopher Orton

Congenital heart defects are morphologic disorders of the heart and great vessels that are present at birth. Strong breed predilections for congenital heart defects suggest a genetic basis for most defects. Congenital heart defects result in a variety of pathophysiologic alterations that eventually can lead to progressive heart failure, cardiac arrhythmias, and

sudden cardiac death, debilitating hypoxemia, or combinations of these adverse outcomes.

Patent Ductus Arteriosus

The ductus arteriosus is a vascular conduit between the pulmonary artery and descending aorta that diverts pulmonary flow away from the fetal lung circulation. Soon after birth, expansion of the fetal lung lowers pulmonary vascular resistance and reverses flow through the ductus. Oxygenated blood is detected by the vascular endothelium of the ductus arteriosus, and this, in turn, inhibits the release of the vasodilating prostaglandin that keeps the ductus

patent. The vascular smooth muscle of the ductus arteriosus contracts and functionally closes the ductus within a few hours of birth.

Patent ductus arteriosus (PDA) results from a persistence of the ductus arteriosus after birth. Incomplete development of the medial layer of the ductus arteriosus wall has been implicated in the pathogenesis of PDA in dogs.[1] PDA allows a high-flow left-to-right shunt that overloads the volume in the left atrium and ventricle and overcirculates the lungs. The resultant chronic volume overload induces progressive dilation of the left ventricle with or without wall thickening. Secondary functional

mitral regurgitation (MR) and overload-induced systolic dysfunction eventually contribute to the progression of heart failure as PDA becomes long standing. The overload is so overwhelming that most animals will succumb to progressive left-sided congestive heart failure within the first year of life. Closure of PDA is indicated for the vast majority of animals with this defect and is generally undertaken with curative intent unless secondary changes are advanced.

On occasion, increased pulmonary vascular resistance can elevate pulmonary artery pressures sufficiently to reverse flow through a PDA. Suprasystemic pulmonary hypertension

results either from a failure of transition of the pulmonary circulation to extrauterine life or progressive pulmonary vascular remodeling caused by chronic pulmonary overcirculation. In the former case, right-to-left or "reverse" PDA is present from birth. In the latter, it typically develops in the first 8 months of life. Regardless of the inciting mechanism, the right-to-left shunt through a PDA causes selective hypoxemia to the caudal portions of the circulation and is responsible for the hallmark sign of differential cyanosis. Clinical consequences of the chronic hypoxemia include moderate to severe activity intolerance, pelvic limb weakness, and progressive polycythemia. Closure of right-to-left

or “reverse” PDA causes severe acute cor pulmonale and is contraindicated.

Pulmonic Stenosis

Pulmonic stenosis (PS) in dogs is most often valvular, although supravalvular and subvalvular defects occur, either as isolated defects or in combination. Valvular PS represents a spectrum of abnormalities ranging from *simple commissural fusion*, consisting of incomplete separation of the valve leaflet commissurae, to valve *dysplasia*, characterized by varying degrees of narrowing of the valve annulus and/or thickening and immobility of the valve leaflets. In severe cases of PS, secondary hypertrophy of the right

ventricular outflow tract (RVOT) can contribute to PS severity by causing dynamic obstruction to ventricular ejection of blood.

Chronic pressure overload caused by PS induces thickening of the right ventricular wall without chamber dilation (i.e., concentric hypertrophy). Right atrial dilation occurs as diastolic filling pressures increase in response to poor ventricular compliance and decreased cardiac output. If primary or secondary tricuspid regurgitation (TR) accompanies PS, then right ventricle dilation may accompany the ventricular wall thickening. Despite its relative importance as a congenital defect, the natural history of untreated

PS in animals is not well documented. Dogs with mild to moderate PS may tolerate the defect relatively well for many years. Dogs with severe PS are likely at risk for both sudden cardiac death and progressive right-sided heart failure. Right-sided heart failure can manifest as either congestion behind the right heart (i.e., ascites) or low output failure, or both. Catheter-based or surgical procedures are generally recommended for dogs with moderate to severe PS to lessen the severity of RVOT obstruction, and decrease the risk for sudden death or heart failure.

Some dogs with PS, particularly English bulldogs and boxers, may have an accompanying anomalous left

coronary artery. In dogs with this defect, the left coronary artery originates from the right coronary ostia and may course across the right ventricular outflow tract. As a result, the left circumflex coronary artery is at risk for injury during surgical or catheter-based treatments for PS.

Double-Chambered Right Ventricle

Double-chambered right ventricle (DCRV) is an uncommon congenital heart defect of dogs characterized by a fibromuscular diaphragm at the junction of the inflow and outflow portions of the right ventricle.[2] The defect obstructs flow through the mid-

portion of the ventricle and causes hypertrophy of the proximal portion of the right ventricle, giving it a “double-chambered” appearance. The pathophysiology and natural history of DCRV are thought to be similar to those of PS.

Subvalvular Aortic Stenosis

Subvalvular aortic stenosis (SAS) is a common congenital defect in certain large and giant breed dogs. The typical defect consists of a discrete subvalvular fibrous membrane located millimeters below the aortic valve leaflets. The membrane traverses the ventricular septum and reflects onto the septal mitral valve leaflet. The defect can be

associated with varying degrees of muscular septal hypertrophy and diffuse fibrosis of the left ventricular outflow tract (LVOT) that can contribute to outflow obstruction. The defect is often accompanied by varying degrees of aortic insufficiency. Mitral regurgitation may also be present if the fibrous membrane restricts motion of the septal mitral valve leaflet.

Subvalvular aortic stenosis causes a pressure gradient across the LVOT during left ventricular ejection that, in turn, increases left ventricular systolic pressure. The accompanying increase in ventricular systolic wall stress causes cardiomyocyte hypertrophy, leading to concentric thickening of the

left ventricular wall and interventricular septum. Intramural coronary arterial pathology characterized by intimal hyperplasia and medial degeneration has been documented in dogs with SAS.[3] Myocardial oxygen demand is increased by the combination of high systolic wall stress (i.e., afterload) and cardiac hypertrophy. Myocardial oxygen delivery is impaired by abnormal coronary arteries. The resultant mismatch between oxygen demand and delivery causes myocardial ischemia that is exacerbated by activity or exercise. Myocardial ischemia is thought to be the cause of malignant ventricular tachycardia and sudden cardiac death.

Median age at sudden death has been reported to be 18 months in dogs with untreated SAS.[4] Chronic β-adrenergic blockade therapy may reduce, but does not eliminate, the risk of sudden death.[5] Surgical intervention has not been shown to decrease the risk of sudden death in dogs with SAS.[5] Dogs that avoid early sudden death may develop left-sided congestive heart failure late in life.

Ventricular Septal Defect

Ventricular septal defect (VSD) is a congenital defect that occurs in dogs and cats. The defect allows left-to-right systolic shunt flow from the left to the right ventricle. The magnitude of the

pathophysiologic change depends on the size of the defect. Small defects do not allow for equilibration of left and right ventricular systolic pressures and are termed “restrictive.” Such defects are associated with low shunt flow. Large defects allow equilibration of ventricular systolic pressures and are associated with high shunt flow. Left-to-right shunt flow causes volume overload of the left heart and pulmonary circulation. The most common anatomic location for VSD in animals is high in the septum behind the septal leaflet of the tricuspid valve. Such defects, termed *perimembranous* VSD, typically spare the right ventricle from volume overload because shunt flow is ejected directly into the RVOT.

Defects located low in the muscular septum may result in volume overload of both sides of the heart. On occasion, VSD occurs dorsal to the supraventricular crest (crista supraventricularis) in the RVOT. Such defects, termed *supracristal* VSD, are associated with a high incidence of aortic valve leaflet prolapse and concurrent aortic insufficiency. Surgical closure of VSD can be undertaken with the aid of cardiopulmonary bypass with curative intent. Pulmonary artery banding is a palliative surgical procedure intended to decrease shunt flow.

Restrictive VSD is generally well tolerated by both dogs and cats. Large

hemodynamically significant defects cause progressive left-sided chamber dilation and congestive heart failure similar to PDA. High shunt flow also can trigger progressive pulmonary vascular remodeling, increased pulmonary vascular resistance, and increased pulmonary arterial pressures. If pulmonary artery pressures reach suprasystemic levels (i.e., exceed systemic arterial pressures), shunt flow reverses and becomes intermittently or continuously right-to-left. This condition, termed Eisenmenger's syndrome, is associated with varying degrees of hypoxemia and polycythemia.

Atrial Septal Defect

Various forms of atrial septal defect (ASD) or atrioventricular septal defect (AVSD) have been described in dogs and cats. Atrial septal defects (ASD) are classified as sinus venosus defects, coronary sinus ASD, ostium secundum (fossa ovalis type) ASD, or patent foramen ovale. Sinus venosus defects are situated cranial and dorsal in the atrial septum at the junction of the cranial vena cava and are frequently associated with anomalous pulmonary venous return. Coronary sinus ASD or unroofed coronary sinus results from an incomplete separation between the coronary sinus and the left atrium; this is often due to the persistence of the

left cranial vena cava. Other types of ASD occur directly in the septum primum or the septum secundum, or both. Ostium secundum ASD (fossa ovalis type) occurs in the mid-dorsal portion of the atrial septum. Patent foramen ovale is usually an acquired defect secondary to pressure or volume overload of the right heart. Atrioventricular septal defects represent a spectrum of malformations that involve the septum primum, the inlet portion of ventricular septum, and the atrioventricular valves. Ostium primum ASD is currently classified as a partial AVSD. The defect is characterized by an ostium primum defect and a malformed mitral valve. The mitral valve defect consists of a

cleft in the septal leaflet that changes the valve into a trileaflet structure. This malformation usually causes significant mitral regurgitation. Complete AVSD consists of an ostium primum defect above, a VSD below, and a single AV valve that is common to the right and left ventricle. The complete form of AV septal defect was formally termed an endocardial cushion defect.

Atrial septal defects share a common pathophysiology regardless of type. Left-to-right shunt through the defect causes volume overload of the right side of the heart. The right atrium and ventricle dilate in response to chronic volume overload. Increases in right

ventricular diastolic pressure lead to progressive right-sided congestive heart failure. As right atrial pressures become elevated, bidirectional shunt and hypoxemia can complicate the clinical picture.

Tetralogy of Fallot

Tetralogy of Fallot (TF) is a complex congenital heart defect consisting of PS, VSD, an overriding aorta, and right ventricular hypertrophy. The defect occurs in both dogs and cats. The pathophysiology and natural history of TF depend on the magnitude of its two primary defects: PS and VSD. Animals with severe pulmonic stenosis and a large VSD will have significant right-

to-left shunt resulting in severe hypoxemia. The clinical consequence is moderate to severe cyanosis at rest, profound activity intolerance, and progressive polycythemia. A shortened life span is expected owing to complications related to chronic hypoxemia, polycythemia, and sudden cardiac death. Animals with less severe pulmonic stenosis or restrictive VSD may tolerate the defect to varying degrees. Total correction of TF can be undertaken with the aid of cardiopulmonary bypass with curative intent.[5]

Tricuspid Valve Dysplasia

Tricuspid valve dysplasia (TVD) is a

congenital malformation of the tricuspid valve that occurs in several large breeds of dog including Labrador retrievers, golden retrievers, and German shepherds. A spectrum of pathologic lesions has been associated with TVD, including shortening, thickening, or notching of leaflets; fusion, absence, or elongation of chordae tendineae; and malformation of papillary muscles. Tricuspid regurgitation (TR) is the most common hemodynamic manifestation, although tricuspid stenosis is possible. Tricuspid regurgitation results from restrictive motion of the valve leaflets and severe progressive dilation of the valve annulus. Severe TR causes volume overload of the right heart and

eventual right-sided congestive heart failure. The age at onset of heart failure varies widely among individual dogs. Right-sided congestive heart failure is generally preceded by severe right atrial and ventricular dilation. Pulmonic stenosis or pulmonary hypertension will accelerate the course toward heart failure. Atrial fibrillation is a common late sequela that contributes to progression toward heart failure.

Chapter 20

Heart Failure

E. Christopher Orton

Heart failure is a clinical syndrome that represents a final common pathway of severe and progressive cardiac insufficiency. Heart failure is present when cardiac output is inadequate despite adequate diastolic filling pressures or when adequate cardiac output can only be maintained at the expense of elevated diastolic filling pressures. Heart failure results from the combined effects of acute or

chronic cardiac insufficiency and compensatory neuroendocrine mechanisms. Heart failure manifests as either multiple organ dysfunction secondary to low cardiac output (termed *low output heart failure or forward heart failure*) or congestion of organs behind the heart (termed *congestive heart failure or backward heart failure*), or both. Congestion can occur behind the left heart, resulting in pulmonary edema or pleural effusion; or behind the right heart, resulting in ascites, peripheral edema, or pleural effusion; or both, resulting in any combination of the these.

Importance of the Frank-

Starling Relationship

Cardiac output (ml/min) is the total effective flow coming from the heart and is the product of *stroke volume* and *heart rate*. Stroke volume is a function of the degree of myocardial fiber shortening in the ventricle. The stretch or load on myocardial fibers just prior to contraction profoundly influences the degree of myocardial fiber shortening. This load or stretch prior to contraction is termed *preload*. Within limits, an increase in preload increases myocardial fiber shortening and stroke volume. *Diastolic filling pressures* in the heart reflect the amount of stretch or preload on the ventricle prior to contraction and, in turn, are an

important determinant of cardiac output. The *Frank-Starling curve* describes the direct relationship between cardiac output and diastolic filling pressures (i.e., preload) in the heart (Figure 20-1).

Cardiac output and diastolic filling pressures are not only functionally related, but are the physiologic parameters directly responsible for the two adverse manifestations of heart failure: namely, inadequate perfusion and congestion. The absolute amount of cardiac output is less important than the adequacy of tissue perfusion (i.e., how well cardiac output is meeting the metabolic needs of the patient). Initially, low cardiac output narrows

the cardiac reserve, i.e., the ability to increase cardiac output during activity or exercise. The clinical manifestation is exercise or activity intolerance. Eventually, cardiac output can become low enough that it fails to meet the metabolic needs of organ systems and tissues even at rest. At this point, the patient is in low output heart failure. Multiple organ and tissue dysfunction are apparent. The patient is “cold” rather than “warm.” While diastolic filling pressure exerts a positive influence on cardiac output, it also is the effective down stream pressure that resists venous return to the heart. Congestion occurs when diastolic filling pressure elevates capillary hydrostatic pressure to the point where

a net efflux of water from capillaries to the interstitial space occurs. The result is edema of the organs and tissues behind the failing heart. The patient is "wet" rather than "dry."

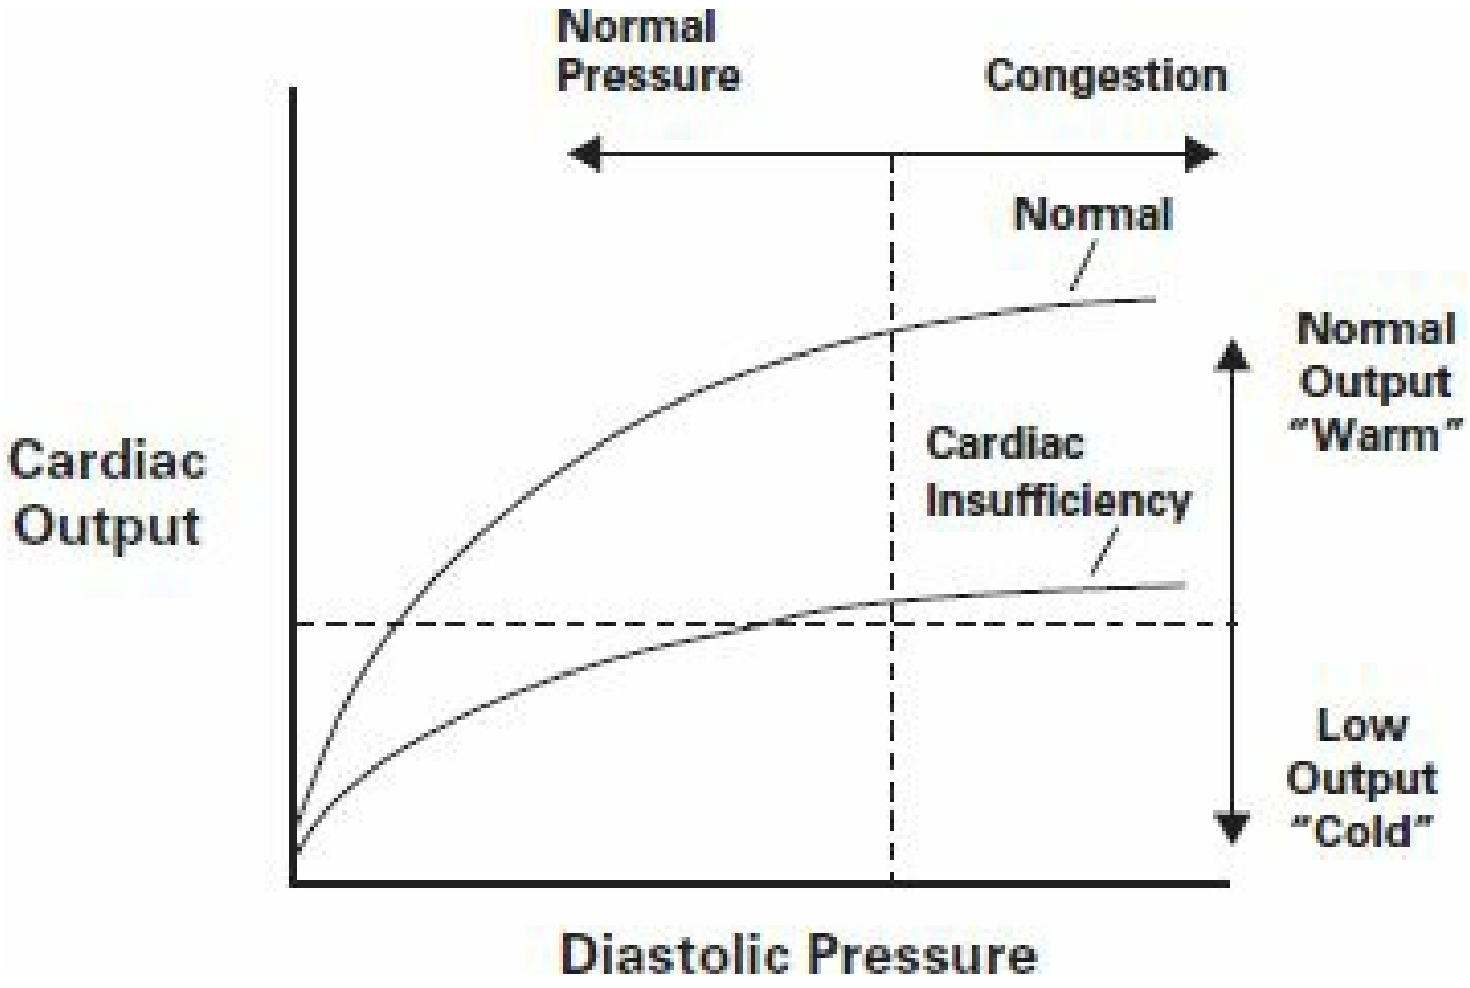

Figure 20-1. The Frank-Starling curve describes the direct relationship between cardiac output and diastolic filling pressures in the heart. When cardiac function is normal (upper curve), cardiac output will

be adequate at normal diastolic pressures. The patient will remain "warm" and "dry" over a wide range of cardiac outputs. When cardiac insufficiency is present (lower curve), then cardiac output may be inadequate at normal diastolic pressures or cardiac output will only be adequate when diastolic filling pressures are high. In the former case, the patient is in *low output heart failure* or "cold." In the latter case, the patient is in *congestive heart failure* or "wet."

Causes of Cardiac Insufficiency

Most causes of cardiac insufficiency in small animals are chronic and insidiously progressive. Cardiac insufficiency is caused by one or a combination of four basic mechanisms: *primary myocardial failure, hemodynamic overload, diastolic dysfunction,* or *cardiac*

arrhythmias. From a physiologic standpoint, primary myocardial failure is a loss of systolic function associated with a decrease in cardiac contractility or an inotropic state. The most common example of primary myocardial failure in dogs is heritable dilated cardiomyopathy. Myocardial infarction is a rare cause of primary myocardial failure in animals. Hemodynamic overload results when structural defects in the heart cause it to have to do excessive work. Excess cardiac work results from the heart having to pump a high volume of blood (i.e., *volume overload*) or against a high systolic pressure (i.e., *pressure overload*) in order to maintain an adequate cardiac output. Causes of

volume overload include valve insufficiency (mitral regurgitation, tricuspid regurgitation, aortic insufficiency) and congenital left-to-right shunts (patent ductus arteriosus, ventricular septal defect, atrial septal defect). Causes of pressure overload include semilunar valve stenosis (subvalvular aortic stenosis, pulmonic stenosis) or hypertension (e.g., pulmonary hypertension). Diastolic dysfunction results from myocardial or pericardial disorders that decrease ventricular diastolic compliance (i.e., change in the pressure-volume relationship of the ventricle during diastole). Causes of diastolic dysfunction include hypertrophic cardiomyopathy, restrictive

cardiomyopathy, pericardial effusion, and constrictive pericarditis. Cardiac arrhythmias can cause or contribute to heart failure by impairing cardiac output by either tachycardia or bradycardia. Tachyarrhythmias that cause or contribute to heart failure include chronic atrial fibrillation, atrial flutter, and sustained supraventricular tachycardias. Bradyarrhythmias that can cause or contribute to heart failure include third-degree atrioventricular block and persistent atrial standstill.

Response to Cardiac Insufficency

Progression of heart disease can be arbitrarily divided into three phases.

The first phase of heart disease occurs when an initiating cardiac injury or insufficiency is present. If the initiating cardiac insufficiency is acute and overwhelming, then *low output heart failure* may immediately ensue. More often in veterinary patients, the cardiac insufficiency is not initially overwhelming or lethal, but rather slowly progressive. The presence of heart disease may be signaled only by the presence of physical findings such as abnormal heart sounds or murmurs and not associated with overt symptoms of heart failure other than possible activity or exercise intolerance.

The second phase of heart disease is

hallmarked by activation of the *neuroendocrine response* to cardiac insufficiency (Table 20-1). This neuroendocrine response ensures that blood pressure and cardiac output are maintained principally through the retention of vascular blood volume and the constriction of arteries and veins. *Cardiac hypertrophy* generally begins during this phase, particularly when the initiating cardiac insufficiency results from hemodynamic overload. The type of cardiac hypertrophy depends on the nature of the cardiac insufficiency (Figure 20-2). During this phase, clinical evidence of cardiac insufficiency in the form of cardiomegaly occurs, although overt signs of heart failure are still not

present. Symptoms would still be associated mostly with reduced activity or exercise capacity.

Although the neuroendocrine response is initially adaptive, ultimately this response becomes maladaptive. This is the third phase of heart failure. During this phase, the neuroendocrine response "overcompensates," producing high diastolic filling pressures and congestion in the form of tissue and organ edema. Inappropriate arterioconstriction is also present during this phase and may actually contribute to poor tissue perfusion. This state is termed *congestive heart failure*. It is possible in advanced cases of cardiac insufficiency for both

congestive heart failure and low output heart failure to be present.

Table 20-1. Adaptive and Maladaptive Responses to Cardiac Insufficiency

Mechanism	Activating Stimuli	Physiologic Effects	Adaptive Consequences	Maladaptive Consequences
Epinephrine Norepinephrine	baroreceptors angiotensin II	vasoconstriction increase heart rate increase contractility	increase blood pressure increase cardiac output	decrease tissue perfusion tachyarrhythmias $beta_1$ down-regulation cardiomyocyte dysfunction cardiomyocyte apoptosis globoid ventricular dilation
Renin-Angiotensin	decreased RBF decreased [Na^+] sympathetic activation	vasoconstriction	increase blood pressure	decrease tissue perfusion cardiomyocyte dysfunction cardiac remodeling
Aldosterone	increased [K^+] angiotensin II	Na^+ retention (blood volume expansion)	increase cardiac output (preload)	venous congestion
Vasopressin	angiotensin II increased osmolality	water retention (blood volume expansion) vasoconstriction	increase cardiac output (preload) increase blood pressure	venous congestion dilutional hyponatremia decrease
Naturetic Peptides	angiotensin II atrial stretch increased [Na^+]	vasodilation naturesis	increase tissue perfusion decrease venous congestion	
Endothelin	vasopressin angiotensin II epinephrine, norepinephrine	intense vasoconstriction	increase blood pressure	decrease tissue perfusion cardiac remodeling
Cardiac Hypertrophy	systolic wall stress (pressure overload) diastolic wall stress (volume overload) angiotensin II epinephrine, norepinephrine endothelin	cardiac wall thickening cardiac chamber dilation	decrease afterload (wall thickening) increase cardiac mass (contractility)	increase afterload (chamber dilation) increase myocardial oxygen demand

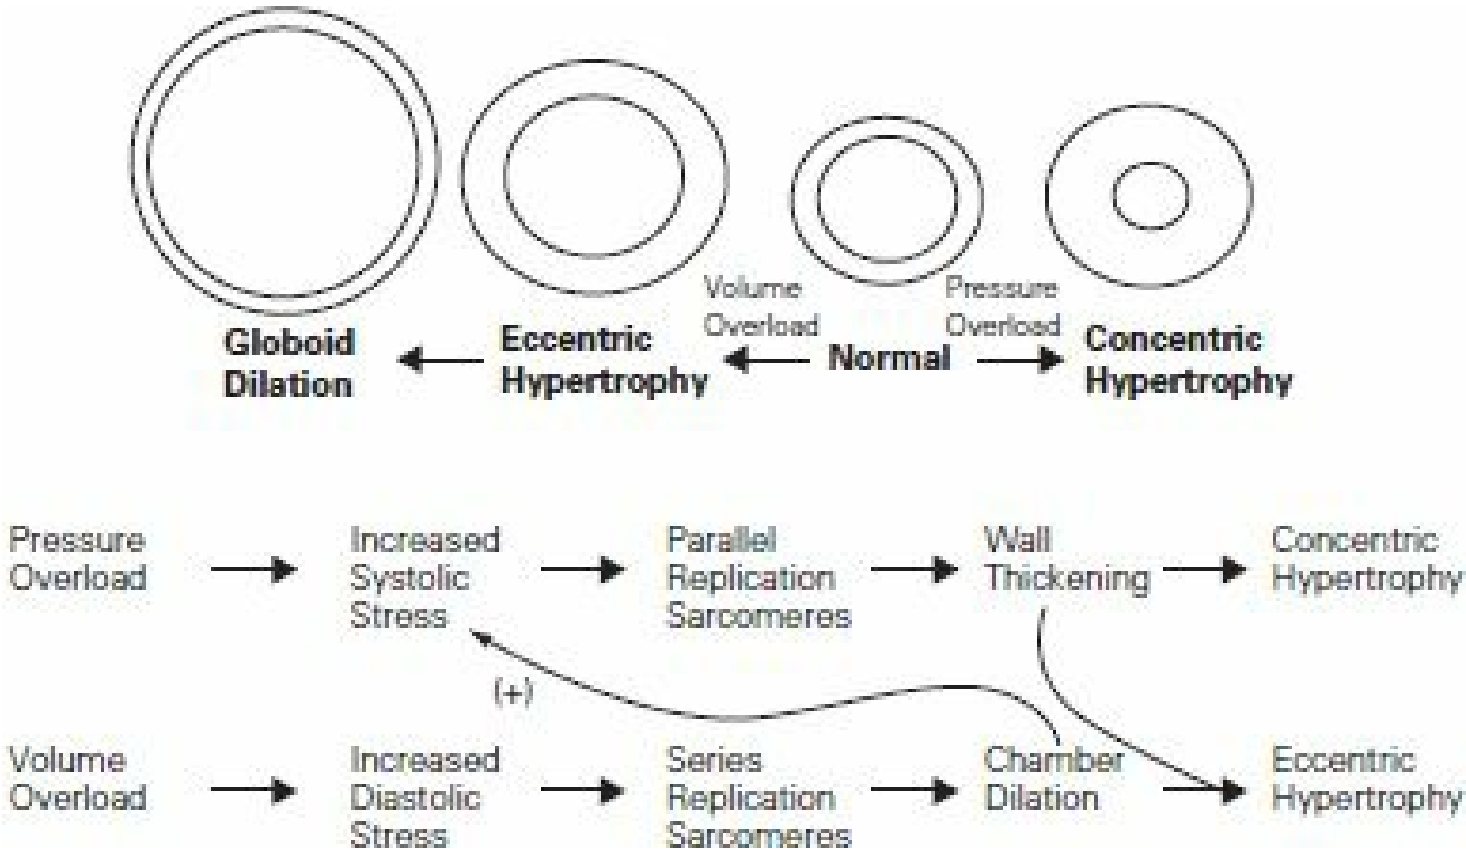

Figure 20-2. Cardiac hypertrophy is initially an adaptive response to hemodynamic overload in the heart. Pressure overload initiates a hypertrophic response that consists primarily of parallel replication of sarcomeres resulting in wall thickening. This pattern, termed *concentric hypertrophy*, normalizes afterload and thereby reduces the effect of pressure overload on the ventricle. Volume overload initiates a hypertrophic response that consists of both parallel and series replication of sarcomeres resulting in chamber dilation and wall thickening. This pattern, termed *eccentric hypertrophy*, increases the stroke volume capacity of the ventricle without increasing

afterload. In advanced states of cardiac insufficiency, cardiac hypertrophy consists primarily of chamber dilation without wall thickening. This response, termed *globoid ventricular dilation*, is maladaptive because it places the ventricle at a mechanical disadvantage from the standpoint of afterload.

Neuroendocrine Theory of Heart Failure Progression

It has long been recognized that, regardless of the initiating cause of cardiac insufficiency, deleterious changes in the myocardium in the form of progressive systolic dysfunction will eventually contribute to the progression of heart failure. According to the neuroendocrine hypothesis, endogenous neuroendocrine systems activated by cardiac insufficiency are

not only responsible for the deleterious hemodynamic derangements of heart failure, but also directly mediate progressive myocardial deterioration.[1-3] This myocardial deterioration takes the form of intrinsic loss of myocardial fiber contractility and, for many causes of heart failure, *globoid ventricular chamber dilation*. Several changes at the cellular and molecular level have been implicated in the loss of myocardial contractility, including down-regulation of beta-receptors, reversion of the cardiomyocyte to a less contractile fetal phenotype, and cardiomyocyte apoptosis. While some degree of ventricular dilation can be adaptive by increasing stroke volume capacity, particularly for volume

overload, excessive ventricular chamber dilation places the ventricle at a substantial mechanical disadvantage from the standpoint of afterload, particularly when it is accompanied by thinning of the ventricular walls. In this regard, severe globoid dilation of the heart is considered a maladaptive response that contributes to heart failure progression. Evidence strongly implicates endocrine, paracrine, and autocrine mediators such as angiotensin II, aldosterone, catecholamines, endothelin, inflammatory cytokines, and peptide growth factors as mediators of or contributors to these deleterious myocardial effects. This understanding

forms the current rationale for “cardioprotective” therapeutic strategies intended to slow progression toward heart failure. Drugs demonstrated to have a cardioprotective effect include angiotensin-converting enzyme inhibitors and beta-adrenergic antagonists.[2]

Chapter 21

Thromboembolic Disease and Hypercoagulable States

Daniel L. Chan

Thromboembolic Disease

The formation of blood clots to seal injured vessels is an essential protective mechanism in animals and is referred to as coagulation. Once these clots have served their purpose, they are degraded by various enzymatic processes (fibrinolysis). The body also has in place several

mechanisms to prevent the aberrant formation of blood clots (anticoagulation). Together, these processes form the complex but elegant system of hemostasis. Abnormalities in any of the components of hemostasis can result in thromboembolic disease with serious consequences. In fact, thromboembolic disease is one of the leading causes of death among critically ill people.[1,2]

As a point of clarification, the term “thrombus” refers to an aggregation of platelets and other blood components that causes partial or complete vascular obstruction. An “embolus” is a clot or other plug (e.g., fat or fibrocartilaginous material) that breaks

off from an originating site and lodges in a distant vessel. Thromboembolic disease encompasses all types of thrombi and emboli.

Hypercoagulable or prothrombotic states are clinical conditions that predispose affected patients to blood clot emboli. The pathophysiology of thrombosis depends on three major factors: alterations in the vessel wall (endothelial injury), impairment of blood flow (blood stasis), and in abnormalities within the coagulation system (hypercoagulability). The interactions of these three processes culminating in thromboembolic disease are known as Virchow's triad.

Vascular injury leads to the exposure of subendothelial vessel wall components, such as collagen, resulting in platelet adhesion and activation of the contact phase of the coagulation system. Vascular integrity may be damaged with venipuncture, intravenous catheter placement, infectious and inflammatory vasculitis, and neoplastic invasion of vessels. Blood stasis favors thrombosis by retarding the removal of activated coagulation factors and by causing local hypoxia and vascular injury. Stasis can result from hypovolemia, shock, cardiac insufficiency, blood vessel compression, or immobility. Vascular obstruction by implants, foreign bodies, or neoplasms may induce local

thrombosis as well. Cardiac chamber enlargement or vascular aneurysm leads to focal sludging of flow and thrombus formation. Hyperviscosity, as occurs with dehydration, polycythemia, leukemia, hyperglobulinemia, and hyperfibrinogenemia, also results in stasis.

Whereas vascular stasis and injury are prothrombotic, true hypercoagulability refers to a quantitative or qualitative change in the coagulation system. In the simplest sense, the coagulation system is composed of procoagulants (platelets and coagulation factors), anticoagulants (protein C, protein S, antithrombin, heparin cofactor II), and the fibrinolytic system. Any imbalance

in these processes may result in excessive bleeding or hypercoagulation, depending on the nature of the imbalance. Hypercoagulation can result from platelet hyperaggregability, excessive activation or decreased removal of coagulation factors, deficiencies of natural anticoagulants, or defective fibrinolysis.

In regard to platelets, there appears to be no correlation between thrombocytosis and hypercoagulation. Hyperaggregability of platelets, however, can increase thromboembolic risk. Platelet aggregation is finely controlled by interactions between the platelets themselves and the vascular

endothelium. Additionally, platelets produce and release various proaggregating substances, including thromboxane A_2, adenosine diphosphate (ADP), and prostaglandins G_2 and H_2. The endothelium in turn, releases several inhibitors of platelet aggregation, namely prostacyclin (PGI_2), ADPase, and nitric oxide. Disturbances in the balance between platelets and the endothelium can lead to thrombosis.

Increased activation of coagulation factors (by vascular injury or inflammatory mediators) or decreased removal of factors from areas of injury (owing to stasis or decreased activity of the reticuloendothelial system) may

contribute to thrombosis. Whether increased levels of individual clotting factors alone heighten the trend toward a hypercoagulable state remains controversial, but elevated fibrinogen levels, and elevations of factors VIII and XII as seen with hyperadrenocorticism, have been incriminated in people.[3-5]

The mechanisms for triggering coagulation are offset by equally powerful mechanisms for controlling it. Three principal mechanisms are involved in this regulation: antithrombin (AT), protein C, and the fibrinolytic system. Protein C is a small (56,000 daltons) vitamin K-dependent serine protease that is synthesized in

the liver. It circulates in plasma as an inactive protein, but is activated by thrombin complexed with thrombomodulin. Activated protein C (APC) then exerts its anticoagulant effect by inactivating membrane-bound factors Va and VIIIa (the amplifiers of coagulation). APC also encourages fibrinolysis by neutralizing plasminogen activator activity. Both actions of protein C are greatly enhanced by protein S.

Antithrombin is a serine protease inhibitor of low molecular weight (58,000 daltons) that is synthesized in the liver and endothelial cells. It is one of the most important inhibitors and effective modulators of hemostasis. AT

functions as an inactivator of coagulation factors IIa, IXa, Xa, XIa, and XIIa. This effect occurs too slowly to be physiologically relevant unless heparin binds to AT, causing AT to undergo a conformational change that increases its anticoagulant activity by 1000-fold. Natural heparin-like substances (e.g., sulfated aminoglycans and heparin sulphates) are present on endothelial surfaces and are the major contributors to the anticoagulant properties of the endothelium. Heparin cofactor II (HC II) is a glycoprotein with a molecular mass of 64,000 daltons. It acts as an inhibitor of thrombin, with its action also accelerated by heparin.

AT deficiency is well described in dogs.[6,7] Acquired deficiencies occur because of decreased production, excessive losses, or consumption. Decreased hepatic production of AT occurs with hepatopathies, but thrombosis generally does not result because concomitant clotting factor deficiencies favor hemorrhage. A similar situation occurs with generalized protein loss, such as protein-losing enteropathies. However, there have been cases of thrombosis with protein-losing enteropathies.[8] In contrast, the increased glomerular permeability that accompanies protein-losing nephropathies (e.g., glomerulonephritis and amyloidosis) permits selective loss of lower

molecular weight proteins, and consistently results in hypercoagulability.[6,7] AT is smaller than albumin (69,000 daltons) and procoagulant proteins, creating sufficient imbalance to favor a hypercoagulable state. Disseminated intravascular coagulation (DIC) is a situation of increased AT consumption. Measurement of AT activity has been helpful in detecting patients with DIC, and some authors have used it to guide therapy.[9]

The fibrinolytic system is extremely complex, and remains the least completely understood. Evidence is growing that fibrinolysis is exceedingly important in hypercoagulation.[10]

Persistence of thrombi is abnormal and implies defective fibrinolysis. More recently, various degrees of hypofibrinolysis have been confirmed in many types of hypercoagulable states.[10,11]

In its simplest form, the fibrinolytic system consists of plasminogen and its activators, which convert plasminogen to plasmin. Plasmin is responsible for dissolution of the fibrin clot. The two physiologic plasminogen activators are tissue-type plasminogen activator (t-PA) and urokinase (UK). T-PA is released from intact endothelium in its active form, whereas UK is released as an inactive zymogen (pro-UK, which is converted to UK by kallikrein. Both t-

PA and UK are inhibited by plasminogen activator inhibitor (PAI-1), the major inhibitor of the system. Other inhibitors include: histidine-rich glycoprotein, which interferes with the binding of plasminogen to fibrin; α2-antiplasmin, which inhibits plasmin; and C1-inhibitor, which inactivates kallikrein. Alpha2-macroglobulins are scavenging protease inhibitors that intervene in situations in which antiplasmin is markedly decreased (i.e., thrombolytic therapy). Hypofibrinolysis and resultant thrombosis can occur because of decreases in plasminogen, t-PA, or UK, or because of increases in circulating inhibitors. Increased levels of PAI-1 are by far the most frequent cause of

ineffective fibrinolysis in people.[10]

Thrombosis associated with the development of antiphospholipid antibodies ("lupus-type anticoagulants") is common in people but has only been described in one dog with hemolytic anemia.[12] The exact mechanism by which lupus-type anticoagulants cause thrombosis is unclear, but these antibodies may develop secondarily to autoimmune disease, neoplasia, infectious or inflammatory diseases, or drug reactions. Defects of platelet function, dysfibrinolysis, plasminogen deficiency, dysfibrinogenemia, and t-PA deficiency may also lead to thrombosis in people, but have not yet

been described in veterinary patients.

Specific Prothrombotic Disorders

Nephrotic Syndrome

Glomerular damage leads to leakage of small molecular weight proteins from blood. Because all of the major inhibitors of coagulation are proteins smaller than albumin, significant protein loss will result in acquired coagulation inhibitor deficiency. Antithrombin deficiency is well documented in protein-losing glomerulonephropathies.[6,7] The hypercoagulable state results from retention of high molecular weight hemostatic factors and selective loss of

hemostatic regulators. Underlying inflammation also contributes to the hypercoagulable state by increasing production of acute-phase proteins that play a role in hemostatic reactions, e.g., fibrinogen, factor VIII, and α2-macroglobulin.[6,7] Hypoalbuminemia contributes to hypercoagulability owiing to the development of platelet hyperreactivity.[7] Pulmonary thromboembolism (PTE) is the most common manifestation of hypercoagulability in this disorder.[6]

Immune-Mediated Hemolytic Anemia (IMHA)

PTE is also a common complication of IMHA, occurring in up to 35% of IMHA

patients.[13-19] The mechanism is incompletely understood but it has been suggested that endothelial exposure to anti-erythrocyte antibodies and the subsequent complement-mediated damage triggers thrombosis.[13-16] Other hypotheses include increased activity of clotting factors, decreased activity of anticoagulants, defective thrombolysis, increased platelet reactivity, and the presence of antiphospholipid antibodies.[16] In complement-mediated erythrolysis, a significant amount of thromboplastin may be released into the circulation. Other factors implicated in the development of PTE include the release of inflammatory cytokines, the use of corticosteroids,

frequent venipuncture and catheterization, and patient inactivity, resulting in sluggish blood flow.[19]

Cardiac Disease

Arterial thromboembolism (ATE) occurs commonly in cats with cardiac disease, especially cats with hypertrophic cardiomyopathy.[20-24] ATE has also been reported in dogs, but the incidence is much lower.[25,26] Unlike other hypercoagulable states where the lesions center within veins, the thrombosis associated with cardiac disease affects arteries. Moderate to severe left atrial enlargement and swirling echocardiographic densities in the left atrium ("smoke") are

considered risk factors for ATE.[22] The pathophysiology of ATE is thought to involve severe dilatation of the left atrium (resulting in stasis of blood flow), endothelial damage leading to platelet activation, increased platelet reactivity, and a number of as-of-yet unidentified factors.[21,22,24]

Hyperadrenocorticism

Patients with endogenous or exogenous glucocorticoid excess may develop venous, pulmonary, or arterial thrombosis. The mechanism of hypercoagulability associated with hyperadrenocorticism is incompletely understood. Contributing factors may include increased activity of

coagulation factors (factors VIII, V, and prothrombin), which have been documented in dogs with hyperadrenocorticism, or the occurrence of secondary hypertension.[3] The presence of hyperadrenocorticism alone probably does not confer a high risk for thromboembolic complications necessitating prophylactic therapy. However, the presence of other concomitant risk factors may require anticoagulation.

Pancreatitis

The relationship between inflammatory conditions and the predisposition for developing thromboembolic events is well known.

Proinflammatory cytokines such as TNF-α and IL-1 play a role in activating the coagulation system but are not the only contributors. In the case of severe pancreatitis, proteolytic enzymes that leak into the circulation are removed by the reticuloendothelial system once bound to α-macroglobulins.[27] Depletion of plasma α-macroglobulins or the inability of the reticuloendothelial system to remove bound proteases leads to activation of many plasma proteins, including those of the coagulation cascade and fibrinolytic system.[27] Athough the depletion of α-macroglobulins in patients with pancreatitis has been used to justify the use of fresh frozen plasma (FFP) transfusions, no

veterinary trial has demonstrated an improvement in AT activity following transfusions.[15,28] A benefit to the course or outcome in human patients with severe pancreatitis by the administration of FFP has similarly not been demonstrated.[29,30]

Sepsis

In septic patients, several mechanisms exist by which thromboembolic events can occur. Generalized inflammation and circulation of cytokines are thought to activate the coagulation system. Furthermore, endotoxins and exotoxins released by microbes can contribute to thrombosis by causing direct endothelial damage, stimulating

tissue factor (TF) expression, and activating clotting factors and platelets.[31] The progression of a hypercoagulable state to fulminant DIC occurs with concomitant dysfunction of the natural anticoagulant system. Depletion of AT, protein C, and protein S, and reduced plasmin activity, are key players in this progression. A more detailed discussion of DIC is found elsewhere. (See Chapter on Hemostasis and Disseminated Intravascular Coagulation). Necrotizing fasciitis is another important condition that exemplifies the relationship between infections and coagulation. Microorganisms can possess unique cell membrane components that elicit

specific prothrombotic tendencies that result in the thrombosis of regional vessels and contribute to the extensive tissue necrosis and sloughing of muscle and skin seen with this condition.[32] In fact, the rapidity and extent of tissue destruction is more consistent with microvascular thrombosis and resultant ischemia than with direct microbial destruction of tissue.[31]

Orthopedic Surgery

The occurrence of PTE stemming from deep venous thrombosis in patients requiring orthopedic surgery is well documented in people, but this has not been described in the veterinary literature. However, the occurrence of

thromboembolic events during or after total hip replacement in dogs has been described.[33-36] In the unique context of cemented total hip replacement, a marked increase occurs in proximal intramedullary pressure within the femur during femoral stem implantation. As cement intrudes into the cancellous bone, it dislodges particles of fat and bone, which enter the circulation and migrate to the right heart and pulmonary circulation.[35,36] This has been documented in studies using transesophageal echocardiography, capnography, pulmonary scintigraphy, and histologic evaluation.[33-36] Despite the fact that some form of thromboembolism occurs frequently in dogs undergoing total hip

replacement, clinically significant abnormalities or fatalities remain rare. The pathophysiology of thromboembolism associated with total hip replacement differs from other diseases in that there is no direct perturbation of the coagulation system; therefore, preventative and therapeutic interventions should not involve the use of anticoagulants or antithrombotics. Nevertheless, a discussion of this phenomenon is important because the clinical manifestations (e.g., respiratory distress and sudden death) are identical to PTE caused by hypercoagulability. Techniques to reduce the risk of thromboembolic complications include controlling the

rise in intramedullary pressure during implant insertion, use of vacuum drainage in the proximal femur, and meticulous, copious, pulsatile lavage of the bone-cement interface to remove embolic substrate.[35,36]

Laboratory Diagnosis of Hypercoagulation

The detection of hypercoagulability is extremely difficult in clinical practice. Little correlation exists between thrombocytosis, shortened coagulation times (decreased prothrombin time (PT), and activated partial thromboplastin time (aPTT)) and a prothrombotic tendency. Fibrin degradation products (FDP) are

generated by the dissolution of fibrin by plasmin, and therefore, increased concentrations only indirectly imply thrombus formation.

Assessing risk for thromboembolic complications involves the recognition of predisposing conditions and populations rather than any single clinicopathologic abnormality. A list of predisposing conditions can be found in Table 21-1. Some authors have attempted to devise a predictive scheme based on the patient's plasma AT concentrations, but this algorithm has neither been validated nor is the AT assay widely available.[9] Such a scheme recommends AT supplementation and heparin therapy

when AT activity levels fall below 60%. Other tests that have been developed include screening for elevations in the by-product of prothrombin activation (fragments F1 and F2) or fibrinogen cleavage (fibropeptides A and B), and increased concentrations of thrombin: AT complex.[36-39] Again, these markers indicate that thrombin has been generated rather than the likelihood of thromboembolism. Newer assays for D-dimers (a more specific indicator of cross-linked fibrin generation) are currently considered the best clinical test for diagnosing the presence of active coagulation.[40-42] Because of its high specificity, this semi-quantitative test may be best used to rule out cases

of suspected PTE.[40] D-dimer concentrations > 2000 ng/dL had a 98.5% specificity in a heterogeneous population of dogs, and no dog with a confirmed embolus had a negative d-dimer test.[41] Thromboelastography, a global in vitro test of coagulation, is perhaps the best tool for assessing hypercoagulability, but remains a research tool optimally suited to characterize the degree of hypercoagulability seen with specific diseases.[43,44]

Table 21-1. Disorders that have been Associated with Thromboembolic Disease in Animals

Sepsis/severe infection

Severe trauma

Malignancy

Heat stroke

Severe burns

Pancreatitis

Immune-mediated hemolytic anemia

Protein-losing glomerulonephropathy

Protein-losing enteropathies

Hyperadrenocorticism

Exogenous glucocorticoid therapy

Vascular disease (heartworm infestation)

Anticoagulant and

Antithrombotic Therapy

Unfractionated heparin is probably the most commonly employed form of anticoagulant therapy used in animals. The mechanism of action centers around the potentiation of AT, leading to the inactivation of factors IIa, Xa, IXa, XIa, and XIIa. Of these, the inactivation of IIa (thrombin) and Xa are considered the most important. Whereas heparin appears to increase tissue-type plasminogen activator (t-PA) activity, it does not appear to enhance fibrinolysis; however this subject remains highly controversial.[45] Various dosing schemes have been proposed and range from intermittent subcutaneous injections of 50 to 300

units/kg every 8 hours to continuous intravenous infusions of 5 to 20 units/kg/hour. It is important to realize that these dosing schemes are largely anecdotally derived, and studies to determine optimal dosing in patients with hypercoagulable tendencies have not been performed. Regardless of the dosing scheme, a common recommendation is to prolong the APTT by 1.5 to 2.5 times the baseline. Some limitations of monitoring heparin therapy via clotting times do exist, however, in that manipulation of the APTT does not necessarily decrease the risk of a thromboembolic event. Furthermore, considerable variation occurs in APTT sensitivity to heparin using different

coagulometers.

One of the major concerns with heparin therapy is that it can lead to overt coagulopathy and major hemorrhage. Individual variation in the ability to metabolize heparin and changes in coagulation status in the course of many diseases explain the development of bleeding tendencies in previously hypercoagulable individuals. Although protamine sulfate is considered a reversal agent for heparin, few indications exist for its use given its side effects and the short half-life of heparin, particularly in hypercoagulable individuals. Another concern with the use of unfractionated heparin is that it can

eliminate the important anti-inflammatory effects of AT, potentially limiting its use in critically ill patients.[46-49]

Given concerns over the possible complications of using unfractionated heparin, interest has been increased in the use of low molecular weight heparin (LMWH). Major advantages of LMWH include improved bioavailability, predictable renal clearance, predictable antithrombotic responses, more tempered effects on coagulation factors (mainly Xa), and supposedly prolonged half-life. However, several studies have shown that maintenance of a desirable anti-Xa activity level in both dogs and cats

requires more frequent administration than the once daily dosing recommended for human patients.[50,51] A dose of 150 to 200 units/kg subcutaneously every 8 to 12 hours, in cats and dogs, respectively has been anecdotally reported with dalteparin.[20,50,51] Monitoring of APTT during LMWH therapy is not effective and may require assaying anti-Xa activity, which is not readily available. Because of the reduced risk of hemorrhage with LMWH, some authors have used it empirically without specific monitoring. However, further studies are needed to determine the optimal use of LMWH in dogs and cats, especially given the high cost of LMWH.

Coumarin-based anticoagulants (e.g., warfarin) block the g-carboxylation of several glutamate residues in factors II, VII, IX, and X, as well as the endogenous anticoagulant proteins C and S. The blockade results in incomplete molecules that are biologically inactive (unable to undergo calcium-mediated binding of prothrombin to platelet phospholipids), and are collectively known as PIVKA, or *proteins* induced by vitamin K antagonism or absence. The anticoagulant prevents the conversion of inactive vitamin K epoxide back to its active hydroquinone form that is required for proper clotting-factor synthesis. Therapy using coumadin should be

carefully titrated against the PT, with the optimal goal of prolonging it to 1.5 to 2 times the patient's baseline PT. Recommended dose ranges are from 0.05 to 0.1 mg/kg PO SID for 3 days, then every other day to every third day, depending on individual response. Therapy should be recommended only in patients in which monitoring will be consistently and reliably performed.

Aspirin antagonizes thromboxane A_2, which is responsible for allowing platelets to alter their shape, release their granules, and aggregate. Aspirin is a mild platelet inhibitor that slightly attenuates aggregation responses to ADP and collagen but does not inhibit thrombin- or PAF-induced aggregation

responses. Aspirin inhibits synthesis of thromboxane A_2 by irreversible acetylation of cyclooxygenase. Because the anuclear platelet cannot synthesize new proteins, it cannot manufacture any new enzyme during its 10-day lifetime. The typical dose of aspirin used as an anti-inflammatory agent may actually be procoagulant and, therefore, the use of an ultra-low dose has been recommended, which has been reported as 0.5 mg/kg/day PO.[52,53]

Fibrinolytic Agents

Although the practice is controversial, in the situation of a life-threatening thromboembolism, fibrinolytic drugs

may be used to rapidly lyse thrombi and restore perfusion. This is accomplished by the ability of these agents to catalyze the formation of plasmin from its precursor plasminogen. These drugs create a generalized thrombolytic state when administered intravenously. Thus, both protective homeostatic thrombi and pathologic thromboemboli are broken down. In people, to reduce the nonselective systemic effects of fibrinolytic agents, intra-arterial administration has been used.[54] Given the high rate of complications, considerable cost, difficulty in obtaining these products, and high mortality of affected patients, experience with these treatment

modalities is limited in veterinary medicine.

The use of streptokinase has been reported sporadically in the veterinary literature.[55-58] Streptokinase combines with a proactivator of inactive plasminogen, and this enzymatic complex catalyzes the conversion of inactive plasminogen to active plasmin, which degrades fibrin into fibrin degradation products. Since streptokinase does not have an affinity for fibrin-bound plasminogen, it can induce a state of systemic fibrinolysis and lead to significant hemorrhage. The dose in cats has been reported as a loading dose of 90,000 units per cat in 20 to 30 minutes, followed by a

maintenance dose of 45,000 units per hour for 3 hours.[23] In dogs, dosage protocols include loading doses of 90,000 units intravenously administered slowly, followed by maintenance doses of 45,000 units per hour intravenous infusion over various periods of time, ranging from 30 minutes to 12 hours.[56,57] In one successfully treated case of arterial thromboembolism, a total of 8 streptokinase infusions were administered over a 50-hour period.[57]

Another potent thrombolytic agent is tissue-type plasminogen activator (t-PA), which is relatively clot-specific owing to its relative low affinity for circulating plasminogen and high

affinity for cross-linked fibrin. In people, t-PA has been used for lysis of thrombi involved with acute myocardial infarction, PTE, and peripheral vascular thrombosis.[54] The clinical use of t-PA for the treatment of PTE in dogs and cats has not been reported. Only a few reports exist of successful thrombolysis in dogs using t-PA.[8,59] The cost and difficulty in obtaining this drug has precluded further evaluation of this treatment modality as a practical option. In cats, a total dose of 1 to 10 mg/kg administered as a 0.25 to 1 mg/kg/hour infusion has been reported, although the mortality rate associated with this therapy was 50%.[24]

The clinical use of urokinase in veterinary medicine is limited but has been reported in both cats and dogs with various types of thromboembolism.[26,60] The greatest experience is in cats with ATE, where the success rate was similar to that of other thrombolytic agents, but the complications were less severe and less common.[60] The one possible advantage suggested by the limited data available is that complications associated with UK therapy, as compared with other thrombolytics, may be less frequent and less severe; however, more studies are warranted to address this issue.

Conclusion

The occurrence of thromboembolic disease can have devastating consequences. Recognition of high-risk populations is important because timely intervention can be essential in the successful management of these cases, and preventative measures may be employed to decrease the likelihood of thromboembolic events. Knowledge of the pathophysiology involved in the development of thrombi in the context of different diseases can help in raising the index of suspicion in particular cases and in devising effective therapeutic strategies. Further research in the area of antithrombotics and anticoagulants is needed to determine optimal use of these agents in high-risk populations.

Chapter 22

Periodontal and Endodontic Disease

Alexander M. Reiter
Colin E. Harvey

Periodontal and endodontic diseases are common in small animal practice and are similar in several ways:

- The basic pathology is inflammation resulting in bone resorption.
- The cause is most commonly contamination by oral flora.
- The end result of the pathologic

process is loss of the tooth, permitting the adjacent tissues to recover from the chronic infection.

The major difference between periodontal and endodontic diseases is the location of the primary lesion.

Periodontal disease is centered in the periodontium (gingiva, periodontal ligament, alveolar bone, cementum), spreading along the periodontal space toward the root apex and causing loss of alveolar bone as it progresses. If allowed to continue to develop, it will eventually affect the periapical region of the tooth root, leading to retrograde pulpal infection. Thus, endodontic disease can occur as a result of severe

periodontal disease.

Endodontic disease is centered in the pulp cavity, as a result of inflammation or necrosis of the pulp inside the tooth. The pathology spreads outward through foramina at the root apex or other areas of the root surface to involve the periodontal ligament and alveolar bone. If allowed to continue to develop, it will eventually affect more coronal areas of the periodontium. Thus, periodontal disease can occur as a result of severe endodontic disease.

Periodontal and endodontic disease may co-exist in the same tooth. It is often possible to recognize

radiographically which condition was first to appear. When the condition starts as periodontal disease, subsequently spreading to involve the periapical region of the tooth root, it is referred to as *periodontal-endodontic lesion*. When the condition is primarily centered at the periapical region of the tooth root, secondarily affecting the mid- or coronal tooth-supporting alveolar bone and causing a fistula through the gingival attachment into the oral cavity, it is referred to as *endodontic-periodontal lesion*. Regardless of what came first, treatment must include both aspects of the disease (although many teeth with "perio-endo" or "endo-perio" lesions are so severely affected that extraction

often is the only practical treatment option).

Periodontal Disease

Periodontal disease is the most common disease occurring in domestic dogs and cats and is defined as plaque-induced pathology of any part of the tissues that hold the tooth in the mouth - the gingiva, periodontal ligament, alveolar bone, and cementum. When accumulation of plaque is prevented by effective oral hygiene, periodontal disease does not develop.1 Local severity and systemic impact on the rest of the body are reasons that companion animals should receive an oral examination every time they are

seen by a veterinarian. Periodontal disease is often separated into two clinical conditions.

Gingivitis is an inflammation of the gingiva, presenting clinically as reddening and edema initially at the gingival margin and progressing to visible ulceration and spontaneous bleeding. Gingivitis is reversible if dental plaque is removed by home or professional oral hygiene procedures.

Periodontitis is an inflammation and destruction of the non-gingival periodontal tissues and can be thought of as "alveolar bone osteomyelytis." It is diagnosed clinically as "loss of attachment" (i.e., the connective tissue

attachment between the root and the alveolar bone no longer extends to the level of the cementoenamel junction [CEJ] of the tooth), which is recognized:

- Because gingival recession exposes part of the root.
- When a gently applied blunt-tipped probe can be passed between the tooth root and the gingiva into a periodontal pocket apical to the CEJ.
- Radiographically as horizontal or vertical alveolar bone loss.

Anatomy, Pathophysiology, and Oral Environment

The *gingiva* provides a thick protective

cap to the alveolar margin (the tip of the alveolar bone closest to the crown). The marginal gingiva abuts the tooth crown and is not attached to bone but held in place by the hemidesmosomal attachment of the sulcular epithelium to the enamel surface. The *periodontal* ligament holds the tooth in the jaw by means of fibers and provides a shock-absorbing effect to prevent fracture of teeth during forceful occlusal action. The *alveolar bone* surrounding the roots has the most rapid turn-over of any bone in the body. The alveolar margin is the critical area in development of periodontitis.

Evaporation causes the salivary fluid to become deposited as a glycoprotein

layer (the *pellicle*) on the tooth crowns, entrapping bacteria. *Plaque* is the developing biofilm on the surface of the teeth. The salivary fluid in which the teeth are bathed has antibacterial properties (lysozyme, lactoferrins, IgA with specific antibodies), and the combination of this antibacterial activity and daily occlusal scrubbing works well to keep the plaque from getting out of hand under "normal" conditions. Excellent long-term oral health is easy to achieve if daily oral hygiene is impeccable.[1] When oral hygiene is less than optimal and plaque is allowed to accumulate, it becomes thicker and more complex, and the protective components in oral fluids have less effect on the microbial

inhabitants in the deeper layers. *Calculus* forms when calcium carbonate and other calcium salts in salivary fluid crystallize on the tooth surface, mineralizing the soft plaque into a hard material. Following dental scaling, it takes 2 to 3 days for plaque to become sufficiently mineralized to form calculus that resists being readily wiped off by dental abrasion. Calcium salts are more likely to be deposited on plaque in an alkaline environment. The mouths of dogs and cats are slightly alkaline (oral fluid in humans is usually slightly acidic). Thus, dogs and cats are more prone to deposition of calculus than are humans.[2]

Plaque Development and Periodontal Infection

When occlusal scrubbing is insufficient or infrequent, plaque thickens and matures. In the deeper part of plaque, the oxygen is strangled out of the fluid as a result of metabolism of aerobic organisms, and an anaerobic environment is established. This is unique to the plaque on teeth because of the lack of vascularity of the enamel surface on which plaque forms. Gingivitis and periodontitis are referred to as "bacterial infections," but several hundred bacterial species have been identified to date in normal and diseased mouths of dogs and cats.[3] Plaque development on a clean tooth

surface following dental scaling follows a predictable pattern:

1. Colonization of the pellicle by aerobic cocci.
2. Adhesion of aerobic rods on the sticky and irregular surface provided by the growing coccal layer.
3. The aerobic cocci and rods multiply, and as they do so, the oxygen gradient in the thickening plaque changes so that at its deepest point oxygen is no longer available. The occasional obligate anaerobes caught deep in plaque can now grow. Plaque maturation to the point where it will support anaerobic organisms takes about 24 hours in the dog.

4. The biochemical environment changes, as plaque continues to mature, and is enriched by products of gingival inflammation. The mixture of microbial detritus and products of inflammation forms a physical and chemical environment that allows spirochetes and other organisms with complex growth requirements to thrive.
5. A “climax biofilm community” results - a semi-stable state in balance with available nutrients and oxygen, made more complex in the case of plaque by the presence of calculus, which provides protected spaces in an anoxic and nutrientrich

environment.

Periodontopathogens are bacteria that are the putative cause of gingivitis and periodontitis. They (a) are cultured more commonly from diseased individuals than from nondiseased individuals and from diseased areas of the mouth than from healthy areas in the same individual; (b) produce toxins or tissue-destructive enzymes such as matrix metalloproteinases; (c) show cytotoxic effects on tissue culture; and (d) reveal other "virulent factors." DNA probe technology has allowed recognition of a group referred to as *pathogen-related oral spirochetes* (PROS) in dogs as well as in humans.[4] Carnivore and human oral floras have

many similarities, but also some important differences. The gram-negative anaerobic rod *Porphyromonas gingivalis* is considered to be the key human periodontopathogen. A catalase-positive form of *P. gingivalis* is found commonly in canine and feline periodontal specimens and is recognized as a distinct species - *Porphyromonas gulae*.[5] Other recognized canine and feline *Porphyromonas* organisms include *P. cangingivalis, P. canoris, P. cansulci, P. crevioricanis,* and *P. gingivicanis*.[6]

Progression of Periodontal Disease

As with bacterial infections in any

other tissue, the initial effect is inflammation (gingivitis). Neutrophils are attracted to the site, move onto the epithelial surface through large intercellular spaces of the sulcular epithelium, and engulf, ingest, and digest the plaque bacteria. When a pathogenic plaque mixture is present, many neutrophils become over-full and burst, and some retire into the adjacent tissue before they burst; bursting neutrophils release bacterial toxins and destructive enzymes, including matrix metalloproteinases (e.g., collagenase) within tissue, causing breakdown of connective tissue integrity. The bursting neutrophils also release pro-inflammatory cytokines (e.g., IL-1β, IL-6, PGE2 and TNF-α) that propagate the

inflammatory response. The sulcular epithelial layer ulcerates, exposing the more vulnerable connective tissue to direct bacterial invasion. As the destructive inflammatory-infective mixture descends deeper into the tissue, inflammation-induced resorption nibbles away the alveolar bone to produce periodontitis. Continuing bone loss causes instability of the attachment and mobility of the tooth, which is pushed against the remaining bone during chewing. This further enhances alveolar bone resorption by squeezing the blood vessels adjacent to the tooth. In an aging toy-breed dog with severe periodontitis, only a match-stick of mandibular bone may be present

adjacent to the roots of the large first molar tooth, and pathologic fracture of the mandible is possible (Figure 22-1). If the process continues for long enough, the eventual result is loss of the tooth. This is actually a defense mechanism - finally, the remaining tissues can recover because the presence of the constant overwhelming plaque bacterial burden has been removed.

In the (usually long) period between the initial gingivitis and the final exfoliation of the tooth, bacteria adjacent to capillaries are squeezed into the vascular space, causing bacteremia. Bacteremia secondary to periodontal disease occurs daily in

patients with gingivitis and active periodontitis, and it is normally rapidly cleared by the reticuloendothelial system in otherwise healthy patients.[7] Bacteremia is accompanied by chronic body-wide release of inflammatory mediators, immune complexes, and bacterial and cellular degradation by-products that may produce direct or immune-mediated distant organ pathology. The long-term consequences of these intravascular effects are the subject of ongoing investigations. It is known that an association exists between severity of periodontal disease and distant organ abnormalities in both humans (Table 22-1)[8] and dogs.[9,10] Circulatory markers of systemic

inflammation are increased in dogs with more severe periodontal disease; they decrease following periodontal treatment.[11] Studies are underway to determine whether the cause (plaque → gingivitis/periodontitis → bacteremia/systemic inflammation) and effect (distant organ damage) hypothesis is correct.

A

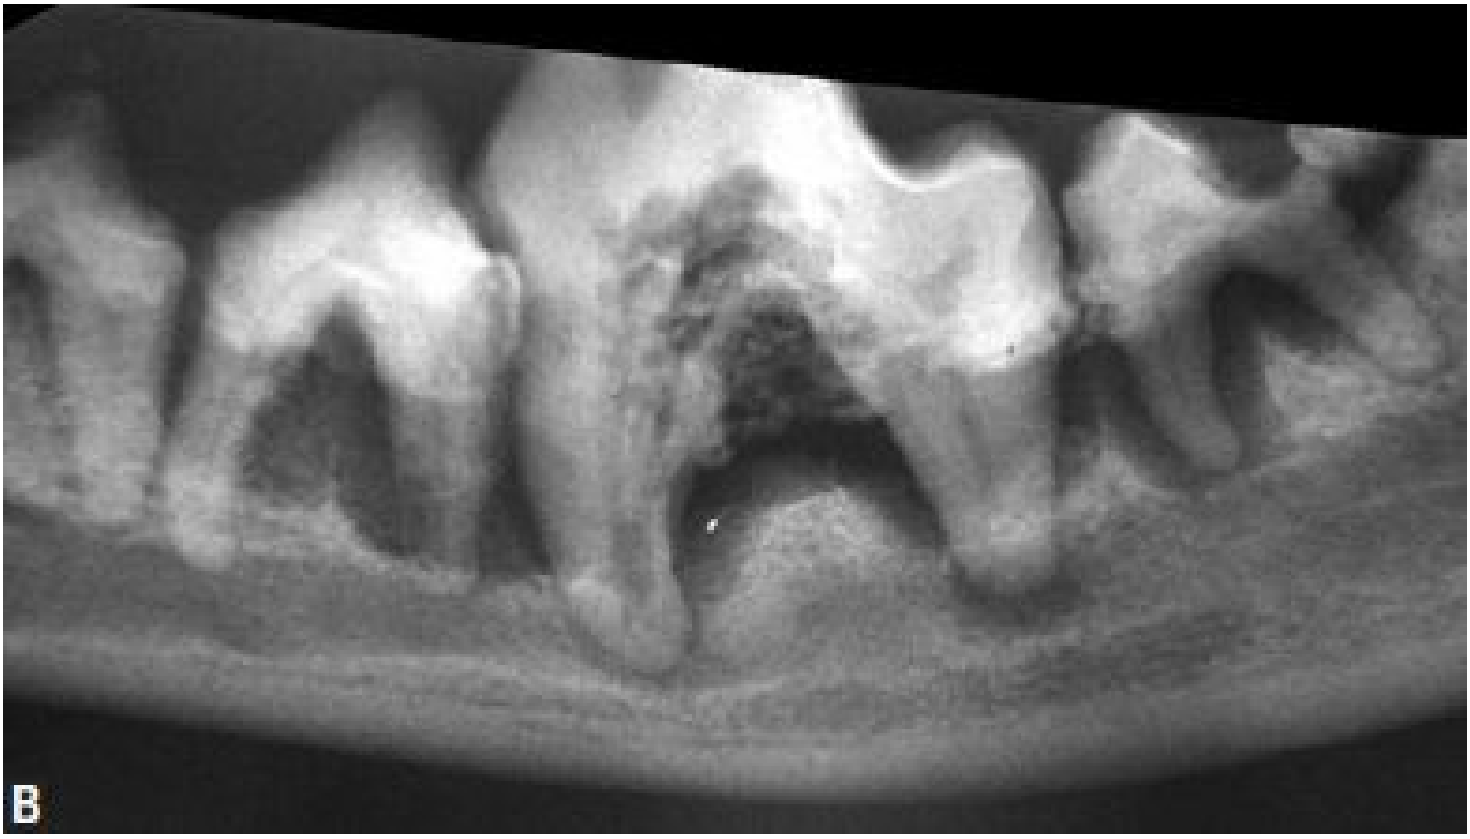

Figure 22-1. Dog with severe periodontitis. (A) Excessive plaque and calculus accumulation at mandibular incisor, canine, and premolar teeth. (B) Dental radiograph of left mandibular premolars and molars showing advanced loss of alveolar bone; the mandible is at risk of pathologic fracture.

Prevention and Therapy

Prevention is primarily directed at removing or reducing subsequent accumulation of plaque and calculus, or at suppressing the tissue-destructive effects of the inflammatory response. Professional supra- and subgingival scaling as needed, followed by daily tooth brushing, is the "gold standard" for prevention. Products that enhance dietary abrasion or chemically suppress plaque or calculus deposition are recognized by the Seal of Acceptance system of the Veterinary Oral Health Council (www.VOHC.org). Systemic antibiotic treatment is not indicated for periodontal patients except in very limited circumstances.[12] A trivalent *Porphyromonas* bacterin for use as a periodontal disease preventive

in dogs is under development.[13] Treatment with anti-inflammatory drugs has been shown experimentally to have a protective effect on alveolar bone in dogs.[14] Anti-osteoclastic drugs such as bisphosphonates also retard alveolar bone loss experimentally in dogs.[15] Use of these pharmacologic agents long-term in veterinary patients has not been investigated and thus cannot be recommended at this time.

In some patients, several different types of procedures may be indicatedwith the patient under anesthesia. It is useful to differentiate between *preventive* and *treatment* procedures, both of which fit under the term periodontal *management*.[2]

Frequent home oral hygiene and professional dental scaling are the primary preventive procedures. Professional scaling under anesthesia is necessary when accumulation of calculus is moderate. Gingivitis and mild or moderate periodontitis (periodontal pockets of up to 5 mm) can be managed effectively by scaling followed by frequent (daily) oral hygiene in an otherwise healthy dog or cat.

When periodontitis is extensive, or when complicating factors exist such as systemic illness, preventive procedures alone are insufficient. The most commonly indicated periodontal treatment in dogs and cats is

extraction – it is also the most reliable means of preventing further local deep-seated periodontal infection and its systemic consequences. Some severely affected teeth can be successfully retained in the mouth by a combination of scaling, periodontal surgery, and conscientiously applied oral home hygiene.

Endodontic Disease

Endodontics refers to the branch of dentistry concerned with the anatomy, physiology, and pathology of the dentin, dental pulp, and periapical region and with the treatment of endodontic disease.[16] The periapical region of the tooth root becomes

involved when bacteria invade the pulp, rendering it partially to totally necrotic. Exposed pulp in germ-free rats remains vital and relatively uninflamed, and the exposed site is repaired with reparative dentin. Thus, without bacteria and their by-products, periapical disease of endodontic origin does not occur.

Endodontic Anatomy

The pulp is a soft tissue with highly differentiated *odontoblasts* arranged peripherally in direct contact with the dentin. Because of the close relationship between odontoblasts and dentin, they are considered a functional entity and referred to as the

pulp-dentin complex.[17] The pulp also consists of loose connective tissue, intercellular substance, blood and lymph vessels, nerves, and fibers. The pulp connects with periapical tissues through the apex in each root. Root development in dogs and cats results in the formation of several *apical foramina*, in ground sections appearing as *apical delta*. *Secondary, accessory, lateral, and furcation canals* also may connect pulp tissue with periodontal ligament.[18,19] Endodontic success is influenced by obturation of all these canals. If bacteria from progressing periodontal disease reach and involve these canals, pulp involvement will result. Some epithelial cells persist within the periodontal ligament during

tooth development, the *epithelial rests of Malassez*, forming a net-like structure around the tooth root.[20]

Arterioles enter through the apical foramina and pass centrally through the pulp, giving off lateral branches that divide further into capillaries. Minor vessels may enter through secondary, accessory, lateral, and furcation canals but do not provide sufficient collateral circulation. Venous return is collected by a network of capillaries that unite to form *venules* coursing down the central portion of the pulp. The blood supply diminishes with age, rendering a pulp more susceptible to irreversible damage. Inflammation in a localized coronal

zone does not cause immediate strangulation of apical vessels and death of the pulp, as it is confined by a combination of ground substance and a unique blood supply. *Arteriovenous shunts* redistribute the blood and prevent buildup of unsustainable pressure in the rigid environment.[17,20] Autonomic and sensory nerve fibers enter the pulp with the vessels through the apical foramina. Individual axons branch into many terminal filaments, which may enter the dentinal tubules. The autonomic nerve supply consists of sympathetic fibers that control microcirculation. The two types of sensory fibers are *myelinated A fibers* and *unmyelinated C fibers*. The faster-conducting A fibers are responsible for

sharp, localized pain owing to rapid movement of fluid in dentinal tubules, resulting in mechanical distortion of tissue in the pulp-dentin border and stimulation of A fibers. Stimulation of the slower-conducting C fibers gives rise to the duller, throbbing, less-localized pain.[17,20]

The primary role of the pulp is to produce dentin by mature odontoblasts, which are incapable of further division and, if damaged, may be replaced from undifferentiated mesenchymal cells. The odontoblast cell bodies are separated from mineralized dentin by an unmineralized *predentin* layer. *Primary dentin* is formed during tooth

development. *Secondary dentin* is formed physiologically after the tooth is fully developed. Its formation continues throughout life, enabling the vital pulp to partially compensate for the loss of enamel or dentin caused by mechanical trauma or disease. Teeth of young adult animals have a fairly wide pulp cavity, whereas in old animals the pulp cavity is usually narrow. The narrower the pulp cavity, the thicker are the dentinal walls, and thus the stronger and more aged is the tooth. Comparing the radiographic appearance of the pulp cavity between ipsi- and contralateral teeth is an effective means of determining pulp vitality in teeth with suspected endodontic pathology. *Tertiary dentin*

(reparative dentin) is formed in response to trauma or disease.[17,20]

Dentin consists of thousands of dentinal tubules radiating outward from the dental pulp to the enamel in the crown and cementum in the root. The tubules contain the long, narrow odontoblastic processes and are filled with *dentinal fluid*. A pressure gradient between the pulp and oral cavity accounts for the outward flow of fluid. Exposure of tubules from tooth fracture or cavity preparation results in outward movement of fluid to the exposed dentin surface. *Peritubular dentin* lines the tubules and is laid down by the odontoblastic process; *intertubular dentin* is found between

tubules. Partial or complete occlusion of tubules may occur as a result of aging or in response to stimuli such as mechanical wear or caries. When tubules become filled with mineral deposits, the dentin becomes sclerotic and less permeable, shielding the pulp from irritation. *Dentinal sclerosis* gives aged teeth a characteristic translucency, and clinically the dentin appears glassy.[17,20]

Causes of Endodontic Disease

Rapid tooth wear removes enamel and dentin faster than odontoblasts can form dentin. The pulp may be exposed or eventually succumb to prolonged

chronic inflammation. Causes of tooth wear include *abrasion* (tooth wear caused by contact of a tooth with a non-dental material), attrition (tooth wear caused by tooth-by-tooth contact in malocclusion), and *erosion* (demineralization of the tooth surface because of acids). *Caries* is the most common cause of endodontic disease in humans but is rather uncommon in dogs and has not yet been reported to occur in cats. It results from demineralization of the tooth surface by acids that are formed during fermentation of highly refined carbohydrates by cariogenic bacteria. Although the most common responses to caries are dentin sclerosis and formation of reparative dentin, the

formation of a *dead tract* in dentin is not considered to be a defensive reaction. It is an area in dentin with tubules devoid of odontoblast processes, providing a channel for bacteria to reach the pulp.[20]

Crown infraction is an incomplete fracture of enamel without loss of tooth structure. Though these fractures are weak points through which bacteria and by-products can challenge the pulp, rarely do they result in permanent pulp damage. An *uncomplicated crown fracture* is a fracture of enamel only or enamel and dentin without pulp exposure. If enamel is involved only, the consequences are minimal; if dentin is

exposed, a pathway exists for stimuli to pass through dentinal tubules to the pulp, resulting in formation of sclerotic and reparative dentin, chronic pulpitis, or pulp necrosis. A *complicated crown fracture* is a fracture of enamel and dentin with pulp exposure. If left untreated, this always results in pulp necrosis. This fracture is common in canine teeth of dogs and cats owing to motor-vehicle trauma, falls from great heights, kicks, and hits. Military, police, and prison dogs are more prone to fracture of canine teeth if their distal tooth surfaces are weakened by wear from chewing on cage bars (cage biter teeth). Fractures of carnassial teeth in dogs are frequently caused by chewing on hard objects (e.g., nylon

bones, cow hooves, large ice cubes). Resorption initiating on external root surfaces and progressing into root and/or crown dentin are often the cause of crown fracture in cats, with root fragments remaining in the alveoli. A *crown-root fracture* is a fracture of enamel, dentin, and cementum. The pulp may or may not be involved. If a crown-root fracture cannot be made into an uncomplicated crown fracture by periodontal surgery and/or orthodontic extrusion, the tooth should be extracted. A *root fracture* is a fracture of cementum and dentin, usually with pulp exposure. The coronal segment is displaced and pulp necrosis may result, but generally the apical segment is not displaced and

has an intact blood supply. Apical root and midroot fractures have a good to fair prognosis (root canal therapy and splinting of the coronal segment), while coronal root fractures have a poor prognosis.[20]

In *concussion* and *subluxation*, the tooth shows normal or slightly increased mobility and sensitivity to percussion, but no displacement. The tooth should be monitored radiographically to determine pulp vitality. *Luxation* refers to clinically or radiographically evident displacement of the tooth within its alveolus. Lateral and extrusive luxation occur most commonly and are often associated with fracture of the alveolus. Intrusive

luxation is a rare complication associated with trauma that forced a tooth with periodontal disease into the nasal cavity, resulting in chronic rhinitis and nasal discharge. Surgical exposure through an intra-oral approach is required to remove the tooth. *Avulsion (exarticulation)* refers to complete extrusive luxation. The teeth most commonly avulsed in dogs are the incisors and canine teeth. The success of reimplantation of an avulsed tooth is greatly influenced by the length of time that the tooth is out of the alveolar socket. Luxated and avulsed teeth require repositioning, stabilization, and root canal therapy owing to the likely loss of blood supply to the pulp.[20]

Thermal injury causing pulp hyperemia, pulpitis, or pulp necrosis is caused by poor dental scaling and polishing techniques (insufficient cooling water, too much pressure on the working tip, prolonged scaling/polishing at the same location), restorative cavity and crown margin preparations; and careless use of thermocautery, diathermy, electrosurgery and laser units near teeth, and electric cord injuries. *Anachoresis* refers to infection of pulp tissue in a state of hyperemia by hematogenic invasion of bacteria through apical and non-apical ramifications. Progression of pulp hyperemia to pulpitis in the presence of bacteria ultimately results in pulp necrosis. Other causes of endodontic

disease include *external tooth resorption*, progressive *internal tooth resorption*, severe *periodontitis*, *use of local anesthetics that contain a vasoconstrictor*, excessive *root planing*, unbased *restorations*, and rapid *orthodontic tooth movement*. Tooth resorption is common in cats, but infrequent in dogs. Periodontally diseased teeth have narrower root canal widths compared with healthy teeth owing to deposition of reparative dentin along the dentinal walls. Bacterial infection of the pulp is possible in areas devoid of cementum and through lateral, accessory, secondary, and furcation canals if exposed to oral fluids.[20]

Clinical Signs

Evaluation of the endodontic patient requires assessment of previous trauma and chewing history and inspection and palpation of intra- and extraoral tissues, focusing on tooth discoloration, crown defects, intra- and extraoral swellings, and sinus tract formation. Reduced biting pressure during play or aggression training and reluctance to eat hard or fibrous food may be noted. To relieve discomfort during late signs of abscess development, the animal may attempt to contact cool or cold surfaces and liquids. Regional lymphadenopathy and fever develop as the abscess reaches an acute stage. In cooperative patients, the occlusal surface of several healthy teeth and the

suspect tooth can be percussed with a finger or the handle of a dental mirror. Hyperreaction indicates that the infection extended beyond the pulp into the periapical region. The pressure build-up in this small space from edema and inflammation will yield pain on percussion. Endodontic disease may result in crown discoloration (pink, red, purple, gray, or brown). Progressive tooth discoloration and/or radiographic changes can reasonably be interpreted as indicative of pulp necrosis. One study revealed that over 90% of teeth with crown discoloration are nonvital.[21] Transillumination of normal and suspect teeth reveals vital teeth to be rather translucent, whereas nonvital teeth tend to appear more

opaque. Crown integrity is evaluated with a fine dental explorer. The tip of the explorer will find irregularities in the crown surface or catch in an open pulp chamber. Recent pulp exposures reveal bleeding pulp, whereas old pulp exposures show black debris and necrotic pulp tissue. Tooth mobility is directly proportional to the integrity of the attachment of the root. The degree of depressibility of the tooth within its alveolus should also be tested by pressing the tooth into its alveolus and watching for any vertical movement. The pressure exerted by purulent exudate in the periapical region may cause some transient tooth mobility. Crown-root and root fractures often result in mobility of a crown segment.

Before incipient swelling becomes clinically evident, it may be detected by gentle palpation with the index finger. Swelling and sinus tracts originating from endodontically diseased maxillary fourth premolar teeth in dogs and cats often are located ventral to the medial canthus of the eye. Intraoral sinus tracts are commonly draining at the mucogingival junction. Swellings and sinus tracts owing to endodontic disease often have a history of responsiveness to antibiotics and recurrence when antibiotic therapy is discontinued. Sinus tracts can be traced with a gutta-percha cone, and a radiograph is obtained to locate their source.[16]

Pathophysiology and Radiographic Signs

A reversible pulpitis is pulp inflammation to the extent that thermal stimuli (usually cold) cause a quick, sharp, hypersensitive response that subsides as soon as the stimulus is removed. If the irritant is removed, the inflamed pulp will revert to an uninflamed state that is asymptomatic. An *irreversible pulpitis* may be acute, subacute, or chronic, partial or total, infected or sterile. The acutely inflamed pulp is symptomatic; the chronically inflamed pulp is usually asymptomatic. A symptomatic irreversible pulpitis elicits prolonged episodes of pain. A thickening of the

apical periodontal ligament may become evident on radiographs in the advanced stage of disease. A reddish cauliflower-like growth of pulp tissue through an open pulp chamber is one variation of asymptomatic irreversible pulpitis and attributed to a low-grade chronic irritation of the pulp and the generous vascularity characteristically found in young animals. *Pulp necrosis* results from an untreated irreversible pulpitis, a traumatic injury, or any event that causes long-term interruption of the blood supply to the pulp, and may be partial or total. Total necrosis before it affects the periodontal ligament is asymptomatic. Protein breakdown products, bacteria and endotoxins will eventually spread

beyond the apical foramina into the periapical region, leading to thickening of the periodontal ligament and manifesting as tenderness to percussion and chewing.[20]

Acute apical periodontitis is a painful inflammation around the apex before the bone begins to resorb and results from an extension of pulpal disease into the periapical tissue, an overextension of endodontic instruments or materials, or occlusal trauma such as bruxism. It may occur around vital and nonvital teeth. The apical periodontal ligament may be within normal limits or only slightly widened on dental radiographs because of edema. An *acute apical*

abscess is a painful, purulent exudate around the apex. The periodontal ligament may be within normal limits or only slightly thickened on dental radiographs with a relatively normal (or slightly thickened) lamina dura because the fulminating infection has rapidly spread beyond the confines of the cortical plate before bone demineralization can be detected radiographically. Presenting signs include rapid onset of slight to severe swelling (cellulitis spreading into fascial planes), moderate to severe pain, and slight increase in tooth mobility; fever and general malaise are present in more advanced cases. *Chronic apical periodontitis (granuloma)* is generally asymptomatic and

manifests radiographically. Bacteria and endotoxins, cascading out into the periapical region from a necrotic pulp, cause extensive demineralization of cancellous and cortical bone and large or small, diffuse or circumscribed, radiographically evident lesions. Slight tenderness may be evident on percussion and/or palpation testing. A sinus tract may yield frank suppuration. As pressure from pus is relieved by drainage, the sinus tract may close temporarily; if pressure from pus builds up again, the sinus tract returns. Epithelial rests of Malassez may respond to the stimulus in the apical periodontal ligament by proliferating to wall off the irritants coming through the apical foramina,

creating a *periapical cyst*. A *phoenix abscess* is an acute exacerbation of chronic apical periodontitis, and symptoms identical to those present with an acute apical abscess will appear (Figure 22-2).[20]

Periapical osteosclerosis is excessive bone mineralization around the apex of a vital tooth caused by low-grade pulp irritation; this condition is asymptomatic and benign and does not require endodontic therapy. *Condensing osteitis (focal sclerosing osteomyelytis)* is excessive bone mineralization around the apex of a non-vital tooth caused by long-standing and low-toxic exudation from an infected pulp, resulting in mild irritation and circumscribed

proliferation of the periapical bone. *Acute osteomyelytis* can arise directly from an endodontic infection. Live bacteria pass the apex and multiply in the marrow spaces and soft tissue of the bone, resulting in localized or wide-spread infection of the bone; if untreated, the acute form may progress to a chronic form, eventually leading to bone necrosis. *Calcification of pulp tissue* includes diffuse mineralization (often a pathologic process related to various forms of injury) or pulp stones *(denticles)* that form around epithelial cells remnants. Perhaps the greatest endodontic significance of pulp calcification is that it may hinder root canal shaping.[20]

Endodontic Treatment

Vital pulp therapy is primarily utilized

for “recent” tooth fractures or after intentional surgical crown reduction to preserve pulp vitality and increase strength of the tooth by allowing continued dentin formation. If the pulp is exposed for longer periods of time or has become necrotic, *standard root canal therapy* is performed and includes accessing the pulp cavity, debriding, shaping, disinfecting and obturating (filling) the root canal, and access restoration. An *apexification procedure* is a type of root canal therapy that is performed to stimulate the formation of a closed apex with hard tissue when a necrotic pulp is present in an incompletely developed permanent tooth in young animals or in teeth of adult animals that have “open” apices

owing to apical root resorption. *Surgical root canal therapy* is performed when standard root canal therapy has failed or will likely fail in teeth with advanced periapical disease. This includes access through oral mucosa or skin, alveolectomy, apicoectomy and retrograde filling. Extraction is the treatment of choice for teeth fractured through the long axis of the tooth root(s) and teeth with advanced root resorption.

Chapter 23

Palate Defect

Alexander M. Reiter

Embryology

During embryogenesis the paired maxillary processes, the paired mandibular processes, and the median frontonasal process surround the primitive oral cavity. *Medial and lateral nasal processes* originate from the *frontonasal process* and extend on each side of the olfactory placodes. In contrast to humans, where the upper

lip is formed by the maxillary and nasal processes, in dogs and cats the upper lip and the primary palate are both formed by the midline fusion of the maxillary processes.[1]

At this stage of the development, the choanae open at the caudal end of the primary palate. Later, the lateral palatine processes move toward the midline and fuse with the downwardly growing nasal septum that originates from the nasal process. This constitutes the secondary palate which will ossify *(hard palate)*, except in the caudal part where it will form the *soft palate*.[2]

Anatomy

The upper lip and most rostral hard

palate supported by the palatine processes of the incisive bones constitute the *primary palate*. The hard palate that is supported by the palatine processes of the maxillary bones and the horizontal laminae of the palatine bones together with the soft palate constitute the *secondary palate*.[3] The junction of the hard and soft palate is at the level of the first maxillary molar teeth. The incisive bones carry the incisor teeth. The maxillary bones carry the canine, premolar, and molar teeth. The palatine bones do not contain teeth.

Cornified stratified squamous epithelium covers the oral surface of the hard and soft palates. The oral

mucosa covering the hard palate is developed into 6 to 10 transverse ridges and depressions *(palatine rugae)*.[4] The mucosa ends abruptly laterally at its junction with the short palatal free gingiva and has a thick tough connective tissue support, the mucoperiosteum, which is continuous with the periodontal ligaments of the maxillary teeth.[5] The *incisive papilla* is located on the midline rostral to the first transverse ridge and just caudal to the maxillary first incisor teeth. On either side of this papilla are the *incisive ducts* that extend caudodorsally through the palatine fissures into the floor of the nasal fossae. This duct communicates with the *vomeronasal organ*.[3]

Unless stretched, the oral surface of the soft palate is thrown into many fine longitudinal folds and a few larger transverse ones, evidence of the mobility and slight elasticity of the soft palate. The oral mucosa of the soft palate is also richly endowed with palatine glands and lymphoid tissue. Dogs and cats possess several tonsil-like structures, but only the *palatine tonsils* are conspicuous as large, ovoid, discrete bodies, each partly concealed in its own tonsillar fossa by a tonsillar fold derived from the soft palate caudal to the palatoglossal folds.[3] Efferent lymphatics depart for the medial retropharyngeal lymph node.

The free edge of the soft palate curves

laterally to form the left and right *palatopharyngeal arches*, which pass caudally and merge with the walls of the pharynx to create a large caudoventrally directed central hole – the intrapharyngeal ostium. The three parts of the pharynx (nasopharynx above, oropharynx below, and laryngopharynx behind) meet at this ostium, and a pair of palatopharyngeal muscles within the arches serves as its sphincter.[3] No uvula is present. There is no palatoglossal arch in the dog and cat comparable to that structure in humans, as they lack the palatoglossal muscle that forms the basis of the human arch. When the tongue is forcibly withdrawn from the mouth and moved to one side, a fold is

developed on the opposite side, running from the body of the tongue to the initial part of the soft palate. Although this fold is not formed by muscle as in humans, is seems feasible to regard it as the *palatoglossal fold*, which distinguishes it from the palatoglossal arch of humans.[3] The minor palatine artery, infraorbital artery, and a common trunk that gives rise to the sphenopalatine and major palatine arteries are branches of the *maxillary artery* (Figure 23-1).[3,6] At its most caudal aspect the maxillary bone forms a small pointed spur, the pterygoid process. This process and the palatine bone form a notch or foramen, through which the *minor palatine artery* passes, which is the main

blood supply to the soft palate.

The muscles of the soft palate consist of the paired *intrinsic palatine muscles* and the end ramifications of the paired *tensor and levator veli palatini muscles*.[3,7] The fibers of the palatine muscles are longitudinal and shorten the relatively long soft palate of the dog. Lateral radiographs in brachycephalic dogs reveal that their soft palate is thickened, suggesting that these animals have sustained contractions of their palatine muscles to maintain a patent airway. The tensor and levator veli palatini muscles stretch and lift the soft palate, respectively, with the aponeurosis of the tensor also serving as a structural support for the palate.

The insertion of the tensor veli palatini muscle passes over the ventral edge of the hamular process of the pterygoid bone to reach rostrally in the soft palate. The main sensory supply to the soft palate is the minor palatine branch of the maxillary nerve (derived from the trigeminal nerve). The tensor veli palatini muscle is also supplied by a branch of the trigeminal nerve, while the levator veli palatini muscle is innervated by the facial nerve. Nerves from the pharyngeal plexus (derived from glossopharyngeal and vagus nerves) supply the palatopharyngeal muscles.[3]

The lateral surface of the palatine bone forms the medial wall of the

pterygopalatine fossa. There is one large opening, the maxillary foramen for the infraorbital artery, and two smaller openings, the sphenopalatine foramen for the sphenopalatine artery and the caudal palatine foramen for the major palatine artery. The *infraorbital artery* runs in the infraorbital canal and emerges at the *infraorbital foramen*. The *sphenopalatine artery* extends to the nasal cavity. The *major palatine artery* passes through the palatine canal with a delicate vein and relatively large satellite nerve and emerges again at the *major palatine foramen* that is located near the transverse palatine suture between the median palatine suture and the maxillary fourth premolar tooth, from where it runs

rostrally in the *palatine sulcus* to the *palatine fissures*. This artery is the most important vascular structure of the palatal mucosa and needs to be preserved during surgical procedures. Within the palatine canal the nerve and artery divide so that one or more *accessory palatine arteries* and nerves emerge on the horizontal process of the palatine bone through *minor palatine foramina* situated caudal to the major palatine foramen.[3]

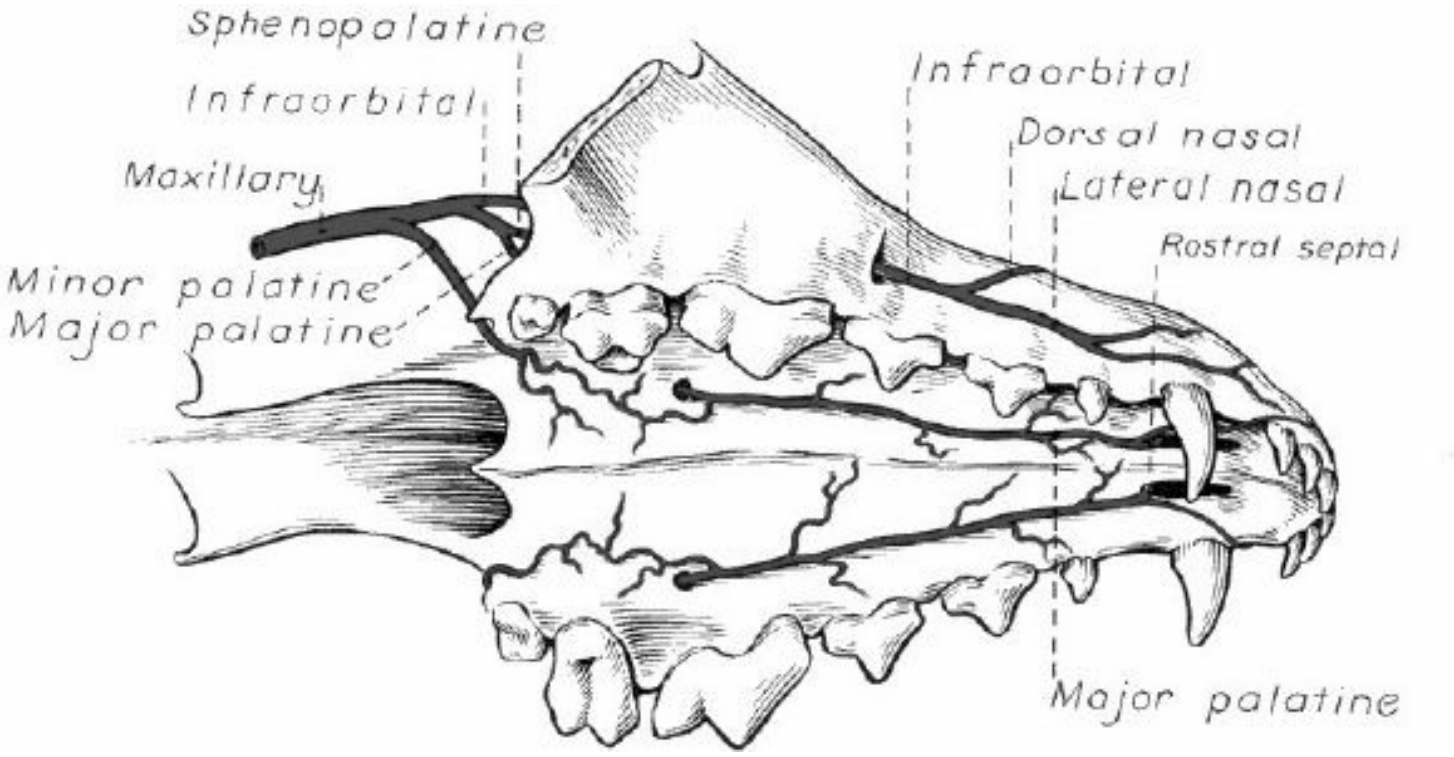

Figure 23-1. Terminal branches of the maxillary artery. (From Evans H (ed): Miller's Anatomy of the Dog, 3rd ed. Philadelphia: WB Saunders, 1993.)

A small rostral septal branch of the major palatine artery passes through the palatine fissure dorsomedially and anastomoses with a branch of the sphenopalatine artery, which supplies the mucosa on the nasal side of the hard palate and the nasal septum. A small artery extends rostrolaterally

and passes through the interdental space between the canine and third incisor teeth, anastomosing with the lateral nasal artery. The most rostral aspect of the major palatine artery branches profusely and anastomoses with its fellow. At the anastomosis a small vessel runs dorsally through the *incisive foramen* near the interincisive suture in the incisive canal, joining the right and left lateral nasal arteries. The main channel draining the area of the hard palate runs caudally in the soft tissue of the hard palate as a spongy, poorly developed venous plexus. The plexus continues in the soft palate, where it lies dorsal to the palatine glands and lateral to the palatine muscles. It empties into the maxillary

vein caudal to the temporomandibular joint, ventrolateral to the tympanic bulla. The lymphatics go to the medial retropharyngeal lymph nodes.[3]

Etiology

Congenital defects of formation of the lip and palatal structures have been reported in both dogs and cats and may be inherited or result from an insult during fetal development.[5] A wide variety of dog and cat breeds have been affected. Brachycephalic dog breeds have been reported to be at higher risk. Growth of the palatine portions of facial bones must compete successfully with growth of the skull width to achieve midline closure of the

palate. Broad-headed fetuses have a greater tendency to develop a cleft palate. The sporadic nature of these conditions and the wide range of dog and cat breeds that are affected suggest that in many cases the cause is an intrauterine insult rather than inheritance,[5] although all types of clefts, from partial unilateral to complete bilateral, have been produced in dogs in mating trials. As in children, unilateral harelips in dogs are almost always on the left side, and cleft lips may be associated with abnormalities of the secondary palate. According to the stage of development and the severity of the cause, other physical or neurologic abnormalities may be present. Clefts can occur if the

intrauterine insult (trauma, stress, corticosteroids, antimitotic drugs, nutritional, hormonal, viral, and toxic factors) occurs at a specific time in fetal development (25th to 28th day in dogs).[2]

Acquired palate defects result from chronic infections (severe periodontal disease), trauma (e.g., high-rise syndrome, electric cord and gunshot injury, dog bites and foreign body penetration, and pressure wounds secondary to malocclusion), neoplasia, and surgical and radiation therapy (Table 23-1).[5] In all cases, the cause of the defect must be removed prior to repair. The most common cause of oronasal fistula is loss of incisive

and/or maxillary bone associated with severe periodontal disease or tooth extraction. Traumatic cleft palate is commonly seen in cats after high-rise trauma. The defect that develops from electric cord injury is due to thermal necrosis of the soft and hard tissues of the palate.

Pathophysiology

Whereas the hard palate forms a rigid partition between the oral and nasal cavities, the soft palate forms a valve. When elevated during swallowing, it closes off the nasopharynx, and when depressed during nose breathing, it closes off the oropharynx.[3] During swallowing, it works with the

epiglottis, which closes off the distal airway, to allow a bolus of ingesta to cross the respiratory tract. Thus, the palate allows independent functioning of the respiratory and digestive systems and is especially important during the neonatal period, when sucking requires an airtight oral cavity.[5]

Dog bites

Foreign body penetration

Pressure wounds secondary to malocclusion

- Neoplasia
- Previous surgery
- Radiation therapy

Congenital palate defects manifest either as cleft lip or cleft palate. Defects of the primary palate are

obvious at birth as an abnormal fissure in the upper lip *(harelip)* and/or a cleft of the most rostral hard palate (Figure 23-2A). Affected animals must be examined for coexisting clefts of the secondary palate. Except for being externally visible, clefts of the primary palate rarely result in clinical signs beyond local rhinitis, and repair may be performed for esthetic reasons. Clefts of the secondary palate *(cleft hard and/or soft palate)* are more common and more serious, although they are rarely visible externally. They are almost always along the midline and are usually associated with a midline soft palate abnormality (Figure 23-2B). Soft palate defects without hard palate defects may occur

in the midline or may be unilateral.[8] The prognosis for congenital absence of the soft palate, as opposed to cleft soft palate, is poor because restoration of a palatopharyngeal sphincteric ring and normal swallowing function may not be achieved despite careful planning and meticulous surgical technique.[9,10] Clefts of the secondary palate frequently go unnoticed until a neonate demonstrates clinical signs, including failure to create negative pressure for nursing, nasal discharge (drainage of milk from the nares during or after nursing), coughing, gagging, sneezing, nasal reflux, tonsillitis, rhinitis, laryngotracheitis, aspiration pneumonia, poor weight gain, and general unthriftiness. Early

diagnosis is important so that these secondary problems can be avoided. The prognosis without surgical repair is guarded because of the risk of aspiration.

An acute oronasal fistula following tooth extraction is diagnosed by direct visualization of the nasal cavity and hemorrhage at the nostril. Clinical signs of a chronic oronasal fistula include sneezing and ipsilateral nasal discharge. A defect in the area of a missing tooth that communicates with the nasal cavity may be noted on oral examination.[5] Patients with large acquired palate defects may show similar clinical signs as those with congenital defects of the secondary

palate (Figure 23-3). The further caudal and the larger a defect, the more severe become the clinical signs.

Chapter 24

Salivary Gland

Dianne Dunning

Diseases of the salivary glands and ducts are uncommon in the dog and cat, with a reported overall incidence of 0.17 to 0.3%.[1-3] Reported conditions involving the salivary glands include rupture, inflammation, dilation, necrosis, fistula, a foreign body, autoimmune disease, calculi, and neoplasia.[1,2,4-11] The onset of many of these conditions is frequently insidious, with vague findings on physical

examination.[12] Definitive diagnosis often necessitates fine-needle aspiration and cytology, radiology, ancillary imaging, biopsy, and exploratory surgery. Complete knowledge of the anatomy of the head and neck, accurate dissection, removal of the affected glands and duct systems, and drainage may be necessary to successfully treat many of the conditions outlined in this chapter.

Anatomy and Function

The four major salivary glands in the dog and cat are the paired parotid, mandibular, sublingual, and zygomatic glands.[13] The parotid gland is a triangular bilobar gland located at the

base of the horizontal ear canal. The parotid duct runs rostrally along the lateral surface of the masseter muscle between the dorsal and ventral buccal branches of the facial nerve and opens into the oral vestibule at the level of the 3rd-4th and 2nd cheek tooth in the dog and cat, respectively. Secretion from the gland is primarily thin and serous, with a mucous component also present in the dog. Sympathetic innervation is provided by the external carotid plexus of nerves, which travel in tandem with the parotid artery. Fibers of the auriculotemporal branch of the trigeminal nerve give parasympathetic input. The parotid artery is the main blood supply to this gland. Venous drainage is via the

superficial temporal and great auricular veins.

Often mistaken as an enlarged lymph node on cervical palpation, the mandibular gland is located directly beneath the bifurcation of the external jugular vein, lying caudoventrally to the parotid gland, between the linguofacial and maxillary veins. It is an ovoid, capsulated gland that is fused to the monostomatic part of the sublingual gland. The mandibular duct travels rostrally, medial to the digastricus muscle to empty at the sublingual caruncle on the floor of the oral cavity. Secretion from this gland is mixed, both serous and mucous. Sympathetic never fibers reach the

gland by means of a perivascular plexus around the glandular artery. Parasymphathetic innervation is provided by the chorda tympani of the facial nerve. The main artery supplying blood is the glandular branch of the facial artery, which enters the gland medially and in close association with the mandibular duct. Entering the dorsal part of the deep surface are one or two branches of the caudal auricular artery. The chief vein draining the gland terminates into the lingual vein. A second smaller vein drains the caudal portion of the gland and terminates in the facial, maxillary, or lingual veins.

The sublingual salivary gland is

composed of both a monostomatic and a polystomatic component. The monostomatic portion is compact with a fibrous capsule that is contiguous with the rostral border of the mandibular gland. Its duct opens into the oral vestibule near the sublingual caruncle. The diffuse polystomatic part of the sublingual salivary gland spreads into tissues ventral to the floor of the oral cavity and drains via several ducts opening into the oral cavity on either side of the frenulum of the tongue. Similar to that of the mandibular gland, innervation is provided by perivascular plexus around the glandular artery and the corda tympani of the facial nerve. Blood supply to the monostomatic

portion is provided by the facial artery; the sublingual artery supplies the small polystomatic part of the sublingual gland. Small satellite veins accompany the facial and sublingual arteries to drain the gland.

The zygomatic gland is seated deep to the zygomatic arch, on the dorsolateral surface of the medial pterygoid muscle, forming most of the orbital floor. It has both major and minor ducts that open into the vestibule opposite to the maxillary molar. The zygomatic gland is a mixed salivary gland, ovoid in shape, and is innervated by the glossopharyngeal nerve. Several ducts drain this small gland, but the major zygomatic duct opening is opposite the

last maxillary molar. The minor duct openings are difficult to visualize with the naked eye, opening just caudal to the major duct. The first branch of the infraorbital artery provides blood supply to the gland. Venous drainage terminates into the deep facial vein on the lateral surface of the gland.

In addition to these primary glands, smaller, variable glands are present in the soft palate, lips, tongue, and cheeks and are collectively referred to as buccal glands. These glands drain into the oral cavity via numerous small ducts; the secretion is mixed serous and mucous in character.

Secretion of saliva is under control of

the autonomic nervous system, which controls both the volume and type of saliva secreted.[14] Salivary secretions serve many functions in the dog and cat, some of which are to lubricate and bind masticated food into a consumable bolus, to solubilize dry food, to flush the oral cavity from debris, to prevent overgrowth of oral microbial population, to initiate starch digestion, and to provide evaporative cooling and maintain core body temperature homeostasis.[14]

Specific Disease Conditions

Salivary Mucocele (Sialocele)

Mucoceles are the most common

salivary gland disorder of dogs, but are less frequent in the cat.[3,15,16] A mucocele, or sialocele, is defined as the accumulation of saliva in the subcutaneous tissue adjacent to the gland or duct. Unlike a cyst, a mucocele does not have an epithelial lining.[3,6,9,15,17-19] True brachial and zygomatic cysts have been reported in both the dog and cat, but these are rare.[18,19] The exact pathogenesis underlying mucolele formation is usually unknown, but trauma, foreign bodies, and infrequently, sialoliths have been implicated.[3,6,9,12,15,17] A case report of a mucocele associated with dirofilariasis has been reported in the dog.[17] Poodles, dachshunds, Australian silky terriers, and Siamese cats may be

predisposed.[3,15]

Although a mucocele may arise from any one the salivary glands or their associated ducts, the sublingual and mandibular glands are most frequently implicated.[9,12,15,20] Clinical signs are dependent on the site of saliva accumulation. The most commonly reported clinical sign associated with mucocele formation is the appearance of a soft, fluctuant, painless mass that must be differentiated from abscesses, tumors, and other retention cysts of the neck.[9,12,15,20] Saliva will generally accumulate in a gravity-dependent site, within the cranial cervical or intermandibular region, but it can also appear within the oral cavity under the

base of the tongue. The accumulations are referred to as ranulas.[9,12,15,20] A less common site is in the pharyngeal wall, which can obstruct airways and cause significant life-threatening dyspnea and heat stroke.[9,12,15,20]

In the initial phases of accumulation, the soft tissue surrounding saliva is inflamed and may be painful on palpation.[9,12,15,20] This stage is short-lived and usually not detected.[9,12,15,20] Once established, the slowly enlarging saliva-filled mass is non-painful; however, secondary infection should be suspected if the mass is persistently painful or a fever is noted.[9,12,15,20] Additional differentials for the swelling in this area include abscesses,

neoplasia, and other retention cysts of the neck.[9,12,15,20] A complete oral exam should be performed in the event of a ranula, particularly if oral bleeding is noted.[12,18] Diagnosis of a mucocele is confirmed via paracentesis of a golden-brown or blood-tinged viscous fluid that typically does not need further analysis. If any question exists regarding the identity of the fluid, a mucus-specific stain, such as a periodic acid-Schiff will confirm the diagnosis.[12,15,20]

Definitive treatment requires surgical removal of the affected gland and duct.[15,20] Positioning the animal in dorsal recumbency usually delineates the affected side, as origin of the saliva

is typically unilateral and most often originates from the mandibular sublingual gland complex. If the mucocele appears to be bilateral, exploration of the site of swelling will demarcate the side that is affected. The salivary glands may be removed bilaterally without any detrimental effects to saliva production, if any uncertainty remains as to the origin of the saliva acummulation.[12,15,20] Treatment limited to lancing and draining or periodic aspiration risks infection, does not address the primary problem, and is contraindicated. A retrospective review of mucoceles in the dog revealed a 42% recurrence rate when treatment was limited to surgical drainage.[15] Aspiration and drainage

are indicated with pharyngeal mucoceles, but only as an emergency palliative procedure to relieve dyspnea until the animal can be anesthetized and the offending glands and the redundant tissue blocking the airway removed. If a ranula is present, marsupialization may be necessary in addition to glandular removal and drainage. Treated appropriately, mucocele recurrence is uncommon (less than 5%), unless the glandular tissue is not fully removed.[12,20]

Sialoadentitis

Inflammation of the salivary gland, or sialoadentitis, is an incidental finding frequently noted at necropsy in the

dog that rarely manifests as a clinical problem. Blunt trauma, mucoceles, penetrating bite wounds, foreign body migration, invasive tumor infiltration, and systemic viral infection have been reported to cause inflammation of the salivary gland.[3,4,12,20,21] Sialodentitis has been reported with rabies, distemper, and paramyxovirus.[3,4,12] Clinical signs are characterized by pyrexia, lethargy, and painful, swollen salivary glands.[3,4,12] Severe inflammation can result in abscessation and rupture of the gland into the oral cavity or through the skin, with fistula formation.[3,4,12] Sialodentitis of the zygomatic gland frequently results in exopthalmos, retrobulbar swelling, divergent

strabismus, and trismus.[3,4,12] Mild sialodentitis requires no treatment, and recovery is usually rapid and complete. A salivary abscess necessitates surgical drainage or removal of the gland and therapeutic antibiotics.[3,4,12]

Fistula

Salivary fistulas are typically the result of penetrating injury or abscessation of the salivary gland.[3,12] The transcutaneous flow of saliva prevents second intention healing. Definitive treatment entails dissection of the fistulous tract and salivary gland removal. In people, botulinum toxin A, injected into the involved gland with ultrasound guidance, has been

successfully employed to abate the flow of saliva and allow wound healing via second intention, while preserving the gland in situ.[22,23]

Sialolithiasis

Salivary calculi or sialolithiasis is a rare condition; only two cases have been reported in the dog.[8,24] Clinically, these dogs present with a painful swelling and rupture of the affected parotid gland owing to obstruction of saliva outflow.[8,24] Diagnosis is made by palpation of the sialolith within the duct, skull radiographs, ultrasound and/or sialography.[8,24] Treatment entails removal of the calculi, with cannulation and lavage of the duct to

remove any residual debris.[8,24] Healing is via second intention and closure of the duct in not necessary. Sialolith composition is usually calcium phosphate or calcium carbonate.[8,24]

Immune-Mediated Disease[25-28]

Immune-immediated disease localized to the salivary gland is rarely recognized in the dog and cat. Keratoconjunctivitis sicca and xerostoma (Sjögren syndrome) have been reported in the dog and are seen in association with other autoimmune diseases, such as rheumatoid arthritis, systemic lupus erythematosus, and polymyositis.

Necrotizing Sialometaplasia

In people, necrotizing sialometaplasia is a benign, mildly painful, self-limiting disease characterized by ischemic necrosis of the palatine gland with secondary proliferation (metaplasia) of the salivary duct.[5,29,30] Histologic changes in humans are difficult to differentiate from neoplasia and include: lobular necrosis of salivary tissue, squamous metaplasia conforming to duct and/or acinar outlines, preservation of salivary lobular morphology, variable inflammation, and granulation tissue.[5,29,30] In contrast, clinical signs in the dog and cat are characterized by severe acute retropharyngeal pain accompanied by enlarged, hard

mandibular salivary glands, anorexia, gagging, and vomiting.[3,5,11,12,30] The underlying pathobiology is unclear; however, traumatic ischemia is suspected to be the cause of the vasculitis and thrombosis.[5,29,30] It has also been hypothesized that this syndrome may be an unusual form of limbic epilepsy.[31] Treatment consists of surgical excision of the affected gland and multimodal pain management or the short-term administration of anticonvulsants for their antiemetic properties.[5,29,30] The milder disease in humans is self-limiting; in some cases, facial or pharyngeal pain is more extensive.[5,29,30,32] The prognosis is guarded in the dog, as some animals continue to experience severe pain and

vomiting, despite surgical excision and supportive care.[5,29,30] The prognosis in cats is more favorable for complete recovery.[5,29,30]

Neoplasia

Salivary gland neoplasia, like all other salivary gland disease, is rare, with an overall incidence of 0.17%.[1,2] Within the realm of salivary gland disease, however, neoplasia represents a relatively frequent condition, with 30% of all salivary gland biopsies being classified as neoplastic on histopathology.[2,3] Siamese cats are at higher risk than other breeds of cat, but there does not appear to be a breed predilection in the dog, as previously

reported.[2,18] The glands most commonly affected are the parotid and mandibular salivary glands, accounting for approximately 80% of all the neoplastic cases reported (Table 24-1).[1,2,18] Clinical signs of salivary gland neoplasia include a mass affect in the region of the gland, dysphagia, weight loss, exophthalmos, and halitosis.[1,2] The most common histopathologic type of tumor was simple adenocarcinoma in both the dog and cat.[2] Other reported histopathologic tumor types include squamous cell carcinoma, mucoepidermoid carcinoma, anaplastic carcinoma, and complex carcinoma.[2] Adenomas are rarely reported and comprise only 5% of all salivary

tumors. Fibrosarcomas, lipomas, mast cell tumors, and lymphomas may also incorporate salivary gland tissue by direct extension and invasion.[1,2]

In general, cats are diagnosed at a later stage of disease than dogs.[1,2] A retrospective study reviewing salivary gland neoplasia in the dog and cat revealed that early diagnosis significantly improved survival times in dogs but not in cats.[2] In this study, cats seemed to have a more aggressive disease, with over half the feline patients having nodal involvement, distant metastases, or both at the time of diagnosis.[2] Furthermore, clinical staging was prognostic in dogs, but not in cats.[2] The median survival times for

dogs and cats reported in this multi-institutional study was 550 days and 516 days, respectively.[2] Local infiltration and metastasis to regional lymph nodes and lungs was common, as was local recurrence after surgical excision.[2] Radiotherapy, with or without surgery, offered the best prognosis.[2]

Table 24-1. Distribution of Salivary Gland Tumors in the Dog and Cat.

Gland	Dog	Cat
Mandibular	30%	59%
Parotid	50%	19%
Sublingual and minor glands	12%	6%
Zygomatic	4%	3%
Indeterminate	4%	13%

Chapter 25

Swallowing Disorders

Andrew E. Kyles

Swallowing is a coordinated process consisting of three phases – oropharyngeal, esophageal, and gastroesophageal.[1] Swallowing disorders can be caused by a mechanical or anatomic lesion either intrinsic to the ailmentary tract or by compression from adjacent structures, by a functional or neurologic disturbance, or secondary to pain (Table 25-1).[2] The interruption to the

normal coordinated sequence of swallowing may involve one or more of the contributing structures, including the muscles of the tongue, hyoid apparatus, soft palate, pharyngeal muscles, cranial esophageal sphincter, esophagus, and gastroesophageal junction.[2]

Oropharyngeal Phase

The oropharyngeal phase of swallowing involves the prehension of food and formation of a bolus in the mouth and passage of the bolus into the cranial cervical esophagus. The oropharyngeal phase is subdivided into oral, pharyngeal, and cricopharyngeal stages.[1] These stages occur in rapid

succession and can only be reliably differentiated by careful analysis of fluoroscopic studies. The oral stage is a voluntary process involving prehension and mastication of food, the formation of a bolus at the back of the tongue, and the delivery of the bolus into the pharynx. The pharyngeal stage is the first step of the involuntary phase of swallowing and is initiated by the delivery of a food bolus into the oropharynx. Pharyngeal constrictor muscles propel the bolus aborally to the cricopharynx. Contraction of the palatal and pharyngeal muscles closes the nasopharynx and prevents nasal reflux, while the epiglottis and adduction of the vocal folds close the

larynx and prevent laryngotracheal aspiration. No obvious thickening occurs of the esophageal wall at the pharyngoesophageal junction to form a true cranial (or upper) esophageal sphincter. However, the cricopharyngeus and thyropharyngeus muscles and associated elastic tissue serve the function of a cranial esophageal sphincter. The cricopharyngeal stage of swallowing involves the relaxation of the cricopharyngeus and thyropharyngeus muscles and the delivery of the bolus into the cranial cervical esophagus. The oropharyngeal phase of swallowing is coordinated by cranial nerves V (trigeminal), VII (facial), IX (glossopharyngeal), X (vagus), and XII

(hypoglossal).

Oral dysphagia is caused by abnormalities in prehension or interference in the voluntary process of bolus formation at the base of the tongue. The tongue plays the dominant role during the oral phase of swallowing, milking fluid aborally against the hard and soft palates. Food should be maintained in midline; oral dysphagia often results in lateral deviation of food into the buccal folds and loss of food from the mouth. The diagnosis can normally be made on the basis of the history, physical examination, and evaluation of swallowing. Fluoroscopy is not usually required for diagnosis. When

performed, the dynamic study will show a reduced ability to form a bolus, with normal transport of the bolus after it reaches the oropharynx. Many animals with oral dysphagia learn to compensate by modifying their eating behavior.

Table 25-1. Causes of Dysphagia

Mechanical or Anatomic Lesions

- Pharyngeal inflammation (abscess, inflammatory polyp, oral eosinophilic granuloma)
- Foreign body obstruction (oral, pharyngeal, nasopharyngeal, proximal esophagus)

Acute oropharyngeal penetrating injuries

Neoplasia

Retropharyngeal lymphadenopathy

Sialocele

Necrotizing sialometaplasia

Mandibular fracture

Lingual frenulum disorder

Cricopharyngeal achalasia

TMJ disorder (luxation, fracture, ankalosis, malformation)

Craniomandibular osteopathy

Congenital (cleft palate, narrowed intrapharyngeal opening)

Pharyngeal trauma

Functional or Neurologic Disorders

- Myasthenia gravis (focal or generalized)
- Acute polyradiculitis
- Masticatory myositis
- Tick paralysis
- Botulism
- Polymyositis
- Muscular dystrophy Sensory neuropathy
- Rabies
- Trigeminal paralysis or neuritis
- Neuropathies of cranial nerves VII, IX, X, or XII
- CNS disorders (brain stem lesion)

Dysautonomia

Pain

Stomatitis/glossitis/pharyngitis (FIV, FeLV, immune-mediated disease, uremic glossitis, ingestion of a caustic substance)

Tooth-related problem (tooth root abscess, fracture, periodontitis)

Trauma

Electrical cord burns

Retrobulbar abscess

Pharyngeal and cricopharyngeal dysphagia produce similar clinical signs. Affected animals are able to prehend and chew normally; these

actions are followed by several, partially successful attempts to swallow. The animals then become anxious, gag, and expel the food from their mouth by forward motion of the tongue. The cycle is then repeated until the entire meal is swallowed. The animals may have an associated nasal discharge and coughing caused by aspiration of food material into the nasal cavities and trachea. Homogenized food is usually easier to swallow than chunks; although, oddly, water may be more difficult to swallow than food.[3]

Fluoroscopic examination of swallowing is needed to differentiate pharyngeal and cricopharyngeal

dysphagias. In pharyngeal dysphagia, fluoroscopy demonstrates the absence of a strong aboral pharyngeal peristaltic contraction, resulting in incomplete bolus transport across the pharynx.[4] Associated reflux of contrast medium into the nasopharynx and laryngotracheal aspiration may occur. Cranial esophageal sphincter relaxation is proportionate to the size and consistency of the bolus delivered; therefore, pharyngeal dysphagia may result in a less pronounced relaxation of the sphincter compared with that in a normal animal. The deficient relaxation of the cricopharyngeal sphincter could result in an erroneous diagnosis of cricopharyngeal dysphagia. However, cricopharyngeal

dysphagia is associated with vigorous contraction of the pharyngeal muscles, which causes distortion of the cricopharynx and/or transient pharyngeal outpouchings.[4]

Cricopharyngeal dysphagia is characterized by either cricopharyngeal asynchrony or achalasia. Cricopharyngeal asynchrony is caused by an incoordination between contraction in the dorsal cranial and middle pharyngeal constrictor muscles (hyopharyngeus, pteryopharyngeus and palatopharyngeus muscles) and relaxation of the cranial esophageal sphincter. In dogs with cricopharyngeal asynchrony, the time

interval between onset of swallowing (closure of the epiglottis) and maximum pharyngeal contraction is normal, but the time to opening of the cranial esophageal sphincter is significantly prolonged.[5] Cricopharyngeal achalasia is a lack of relaxation of the cranial esophageal sphincter during the cricopharyngeal stage of swallowing. It is observed less commonly than asynchrony.[6] With both conditions, movement of the bolus into the caudal pharynx by movement of the tongue and pharyngeal constriction is normal. A thin stream of contrast medium may pass through the cranial esophageal sphincter. When the bolus of food in the cranial cervical esophagus is sufficient, primary

esophageal peristalsis is initiated, and the food passes normally into the stomach. The food that does not pass through the cranial esophageal sphincter is expelled through the mouth, sometimes accompanied by nasal reflux and laryngotracheal aspiration.

Surgical management of cricopharyngeal dysphagia may be indicated. Surgery consists of a cricopharyngeal myotomy (incision of the cricopharyngeus muscle on dorsal midline of the larynx, sometimes accompanied by a partial or complete incision of the thyropharyngeus muscle) or myectomy. It is crucial to differentiate between pharyngeal and

cricopharyngeal dysphagia as surgery can exacerbate signs of pharyngeal dysphagia.[2] Although it has been reported that surgery results in an immediate and continued resolution of all signs of dysphagia and nasal regurgitation in dogs with cricopharyngeal dysphagia,[7] one study reported poor long-term results.[8] In the latter study, complete, long-term resolution of signs occurred in one dog, transient complete resolution (with recurrence of dysphagia at 2 to 36 weeks after surgery) occurred in 3 dogs, a permanent, partial resolution occurred in 3 dogs, and no improvement was noted after surgery in 6 dogs. The reason for this disparity may reflect a lack of long-term follow-

up in some earlier reports. In individual cases, there may be a failure to transect all the bands of the cricopharyngeus muscle, an incorrect initial diagnosis, or concurrent pharyngeal or esophageal dysfunction.[9] A poor outcome may be seen in older dogs, dogs with concurrent aspiration pneumonia or malnutrition that is not addressed prior to surgery, or where cricopharyngeal dysphagia is complicated by other anatomic or functional conditions, such as myasthenia gravis, laryngeal paralysis, or esophageal stricture.[8]

Esophageal Phase

Esophageal disorders are relatively

common in the dog and cat. The entire length of the canine esophagus is composed of striated muscle, whereas the caudal one third to half of the feline esophagus is composed of smooth muscle. During normal swallowing, a food bolus is delivered to the cranial cervical esophagus through the relaxed cricopharynx. The bolus initiates a primary peristaltic wave in the esophagus, which propels the bolus aborally to the gastroesophageal junction. The transit time for the bolus from the cervical esophagus to the stomach is approximately 3 to 4 seconds.[3] Initiation of a primary peristaltic wave depends on the presence of a sufficiently large bolus distending the

cervical esophagus; several swallows may be needed to produce a bolus that initiates a primary peristaltic wave. If the primary peristaltic wave fails to propel the bolus through the gastroesophageal junction, esophageal distention results in the generation of a secondary peristaltic wave. In normal animals, no significant amount of food should be retained in the esophagus at the end of eating.

The hallmark clinical sign of esophageal-phase dysfunction is regurgitation.[3] Regurgitation is the passive, retrograde expulsion of esophageal or gastric contents. Regurgitation, as distinct from vomiting, is characterized by minimal

retching, minimal abdominal or thoracic muscle contraction, and the expulsion of a mucus-covered, sausage-shaped mass of food with a neutral or alkaline pH. Regurgitation may occur minutes to hours after eating. Other clinical signs may include weight loss accompanied by an increased appetite and signs of aspiration pneumonia.

Definitive diagnosis of esophageal-phase dysfunction is usually made by radiographic examination. Most esophageal-phase problems can be diagnosed by plain radiography or radiography following administration of a barium meal or liquid contrast medium.

The causes of esophageal-phase dysfunction can be broadly divided into mechanical or anatomic lesions, functional or neurologic disorders, and inflammatory conditions. Mechanical obstruction of the esophagus can result from the presence of a luminal or mural lesion or from compression from adjacent structures. Causes of mechanical obstruction include esophageal foreign bodies, strictures, neoplasms, vascular ring anomalies, hiatal hernias, and gastroesophageal intussusceptions. The presence of a mechanical obstruction results in a variable degree of obstruction of the esophagus. Esophageal obstruction results in the accumulation of food and secretions proximal to the obstruction

and distention of the esophagus. Esophageal distention disrupts normal neuromuscular function and decreases peristalsis. The extent of distention of the esophagus proximal to the obstruction is the major determinant of long-term prognosis after successful relief of the obstruction.

Esophageal foreign bodies are a common problem in dogs and are occasionally diagnosed in cats. The most common foreign bodies in dogs are ingested bones. Esophageal foreign bodies most commonly lodge at the thoracic inlet, heart base, and caudal esophagus where extraesophageal structures restrict esophageal dilation.[9] Esophageal foreign bodies cause

mechanical obstruction of the esophagus and can result in pressure necrosis and perforation of the esophageal wall.

Esophageal strictures are uncommon in dogs and cats. Acquired esophageal strictures are more common than congenital strictures. Acquired strictures result from severe, circumferential esophageal injury extending into the muscular layer of the esophageal wall. The damaged esophagus heals by fibrosis and wound contracture, resulting in a narrowed esophageal lumen and obstruction. The most common cause of acquired esophageal strictures in dogs and cats is esophageal reflux during anesthesia;

other causes include chronic vomiting, ingestion of corrosive substances, thermal burns, radiation injury, foreign body ingestion, and surgery. The reader is referred to Chapter 26 for more information on vascular ring anomalies and to Chapter 27 for more information on hiatal hernias.

Causes of functional or neurologic disorders of the esophagus include congenital megaesophagus, acquired megaesophagus, and dysautonomia.

Esophagitis can be acute or chronic. Causes of esophagitis in dogs and cats include swallowing caustic substances, esophageal foreign bodies, and gastroesophageal reflux.

Gastroesophageal Phase

Dogs have an increase in thickness of the circumferential striated muscle layer at the gastroesophageal junction, which correlates with the accepted location of the high-pressure zone at the gastroeosphageal junction and may represent the anatomically ill-defined caudal (or lower or cardiac) esophageal sphincter.[10] Other proposed anatomic contributors to the lower esophageal high-pressure zone include the diaphragmatic crural muscles, the angle at which the esophagus and stomach meet and the folds of the gastroesophageal mucosa. It has also been suggested that the intraabdominal portion of the

esophagus is subjected to higher pressure than the intrathoracic portion, although one anatomic study found that the intraabdominal portion of the esophagus in dogs could not be consistently demonstrated.[10]

The gastroesophageal phase is the final component of normal swallowing. As the peristaltic wave carries the bolus along the esophagus, the myenteric plexus mediates relaxation of the esophagus ahead of the bolus, permitting the passage of the bolus down the esophagus and through the gastroesophageal junction into the stomach. On fluoroscopic contrast examinations in normal dogs, the bolus of food will occasionally stop in front

of the gastroesophageal junction and then enter the stomach with the following bolus. Reflux of food from the stomach into the distal esophagus also occurs occasionally; refluxed food is then carried by a secondary peristaltic wave through the gastroesophageal junction into the stomach.[3] In normal dogs, no food remains in the esophagus after completion of a meal.

Esophageal achalasia is a disease described in humans in whom a failure occurs of reflex relaxation of the gastroesophageal sphincter during swallowing. On thoracic radiographs in dogs with megaesophagus, the caudal thoracic esophagus narrows as

it approaches the diaphragm and this "stenotic" appearance should not be misinterpreted as esophageal achalasia. Myotomy of the gastroesophageal sphincter is not recommended in cases of megaesophagus. In a single case report of a dog with apparent esophaghageal achalasia that responded to myotomy, the diagnosis was established by fluoroscopic contrast studies and was not confirmed by manometry.[11]

Gastroesophageal reflux is a disorder involving reflux of gastrointestinal contents into the esophagus. The severity of the resulting esophagitis depends on the frequency and composition of the refluxed material.

The combination of gastric acid, pepsin, trypsin, and bile acids can produce severe esophagitis. Gastroesophageal reflux is poorly documented in dogs and cats, and is probably under-diagnosed.[12] It is associated with chronic vomiting, disorders of gastric emptying, hiatal hernia, and anesthesia-induced decreases in the pressure of the lower esophageal high-pressure zone.[12] The reader is referred to Chapter 27 for more information on hiatal hernias.

Chapter 26

Vascular Ring Anomalies

Andrew E. Kyles

Vascular ring anomalies are developmental abnormalities of the great vessels that result in a complete or incomplete ring of vessels encircling the trachea and esophagus. Congenital anomalies of the great vessels have been reported in 20% of dogs, but most variants are not clinically significant.[1] The most common vascular ring anomaly in both human beings and dogs is aberrant right subclavian

artery, although this is frequently not associated with clinical signs.[1] The most common clinical vascular ring anomaly is persistent right aortic arch (PRAA) with a left ligamentum arteriosum, an anomaly that accounts for 95% of canine clinical cases.[2] A patent ductus arteriosus is present in approximately 10% of dogs with a PRAA. Dogs with vascular ring anomalies may also have a persistent left cranial vena cava or left hemiazygous vein, which, although not clinically significant, may complicate the surgical approach.

Embryology of the Great Vessels

In the embryo, the paired dorsal and ventral aortas are separated by the foregut and pulmonary bud. The six pairs of aortic arches, corresponding to the six brachial arches, connect the dorsal and ventral aortas, and encircle the foregut. As the embryo develops, selective involution and reconnection of the vessels results in the formation of the definitive cardiovascular system and the release of the esophagus and trachea.

During normal embryonic development, the ventral aortas fuse caudally to form the heart and the dorsal aortas fuse caudally to form the descending aorta. The first, second and fifth aortic arches involute early in

development. The paired ventral aortas between the third and fourth arches develop into the common carotid arteries and the corresponding sections of the dorsal aortas between the third and fourth arches disappear. The paired ventral aortas that served as the origin of the first two aortic arches develop into the external carotid arteries and the third aortic arches and the cranial dorsal aortas form the internal carotid arteries.

The left ventral aortic root of the fourth arch and the fourth left aortic arch develop into the adult aortic arch, which connects to the fused caudal dorsal aortas that form the adult descending aorta. The right ventral

aortic root of the fourth arch becomes the brachiocephalic trunk and the right fourth aortic arch forms the right subclavian artery. The left subclavian artery arises from the left seventh intersegmental artery. The sixth aortic arches form the pulmonary arteries. The left aortic arch retains a connection to the fused dorsal aortas that serves as the left ductus arteriosus in the embryo and becomes the left ligamentum arteriosum after birth. The right ductus arteriosum involutes to release the esophagus and trachea.

Abnormal development of the third aortic arches will not produce a vascular ring anomaly, whereas abnormal development of the fourth

and sixth aortic arches can produce a vascular ring anomaly. Complete vascular rings are formed when the right and left portions of the sixth aortic arches are retained, whereas abnormal development of the fourth aortic arches can result in an aberrant right or left subclavian artery and an incomplete vascular ring.

Types of Vascular Ring Anomalies

Several types of vascular ring anomalies have been described in dogs.

Persistent Right Aortic Arch

Persistent right aortic arch and left

ligamentum arteriosum: The most common clinical vascular ring anomaly in which the aortic arch develops from the fourth right aortic arch and the ligamentum areteriosum connects the left pulmonary artery to the descending aorta, forming a complete ring around the esophagus.

Persistent right aortic arch, right ligamentum arteriosum, and aberrant left subclavian artery: The aberrant left subclavian artery courses over the esophagus and passes ventrally toward the ventral thoracic inlet.[3] The aberrant left subclavian artery can cause esophageal obstruction because it acts as a band, causing an incomplete vascular ring.

Persistent right aortic arch, left ligamentum arteriosum, and aberrant left subclavian artery: This anomaly forms two strictures, a complete vascular ring associated with the left ligamentum arteriosum and a more cranial incomplete vascular ring caused by the aberrant subclavian artery.[4]

Persistent right aortic arch and right ligamentum arteriosum: This is the mirror image of normal anatomy and does not result in the formation of a vascular ring. However, this anomaly has been associated with cranial thoracic esophageal dilation and regurgitation.[5] In dogs with a PRAA and left ligamentum arteriosum,

fibrous, periesophageal bands are often present under the ligamanetum arteriosum; it was speculated that, although the left ligamentum arteriosum had involuted, similar bands may have been present.

Double Aortic Arch

Double aortic arch: This results from the persistence of both the right and left fourth aortic arches.[6] This anomaly can result in significant tracheal stenosis.

Left Aortic Arch

Left aortic arch and right ligamentum arteriosum: This is the mirror image of

PRAA with a left ligamentum arteriosum.[7] Although it is uncommon, it is of particular significance because it cannot be corrected via a left lateral thoracotomy.

Left aortic arch, left ligamentum arteriosum, and aberrant right subclavian artery: This represents normal anatomy of the aortic arch and ligamentum arteriosum, with an aberrant right subclavian artery that passes dorsal to the esophagus, causing an incomplete vascular ring.[8]

Left aortic arch, right ligamentum arteriosum, and aberrant right subclavian artery: This anomaly forms two strictures, a complete vascular ring

associated with the right ligamentum arteriosum and a more cranial incomplete vascular ring caused by the aberrant subclavian artery.[9]

Vascular ring anomalies are reported less frequently in cats. Vascular ring anaomalies that have been described in the cat include PRAA and left ligamentum arteriosum,[10] left aortic arch and right ligamentum arteriosum,[11] double aortic arch[12] and PRAA, right ligamentum arteriosum and aberrant left subclavian artery.[13]

Diagnosis

Vascular ring anomalies are reported in a variety of breeds; German shepherds and Irish setters have an

increased risk compared with the general population.[14] The condition can affect multiple animals in the same litter; breeding of affected animals should be strongly discouraged. Most affected animals are considered normal until weaning, with the development of postprandial regurgitation after the introduction of solid food. In one study, 20% and 80% of dogs were diagnosed before 2 and 6 months of age, respectively,[14] though some animals are not diagnosed until later in life.

Clinical signs of vascular ring anomalies are caused primarily by a partial esophageal obstruction. The usual presenting complaint is

regurgitation of undigested food. Affected animals are often smaller than their littermates and appear malnourished despite a ravenous appetite. Respiratory signs can develop secondary to aspiration pneumonia or tracheal compression in animals with a double aortic arch. Signs of cardiac disease are uncommon, except for an association between vascular ring anomalies and patent ductus arteriosus.

The diagnosis of a vascular ring anomaly can be confirmed by survey and positive-contrast radiography. On survey radiographs, the esophagus cranial to the heart may be dilated with air, fluid, or ingesta. On the

ventrodorsal projection, it may be possible to identify the descending aorta on the right side of the esophagus in animals with a PRAA. Radiographic signs of aspiration pneumonia may be present. Positive-contrast radiography will confirm the presence of esophageal obstruction at the level of the base of the heart, with dilation of the esophagus cranial to the obstruction; the esophagus caudal to the obstruction is usually undilated. Angiography is rarely performed, but can be used to help determine the type of vascular malformation. Endoscopy can be used to rule out other causes of esophageal obstruction and may show a right-sided aortic pulse in animals with a PRAA.

Treatment

Long-term medical management is generally unrewarding as the degree of esophageal dilation usually increases with age. Preoperative medical management should be used in malnourished animals and patients with aspiration pneumonia. The aim of surgery is to divide the vascular ring by transecting the ligamentum arteriosum and the periesophageal fibrous bands that form under it. Aberrant subclavian arteries are ligated and divided. With double aortic arches, one branch is usually dominant, and the contralateral branch can be divided and oversewn.

Prognosis

The most common problem after surgery is persistent regurgitation. A loss of normal neuromuscular function occurs in the dilated section of the esophagus cranial to the vascular ring, and, although some reduction in esophageal dilation and improvement in motility can be expected following surgery, normal esophageal motility will not be regained. Factors that may affect prognosis include the degree of esophageal constriction and dilation, the severity of debilitation, the presence and severity of aspiration pneumonia before correction, and the medical management before and after surgery.[15]

The prognosis for surgical correction of vascular ring anomalies has improved. In 1981, Shires and Lui reported an excellent outcome (no regurgitation) in 9% of dogs, a good outcome (intermittent regurgitation) in 67%, and a poor outcome in 25%.[14] In 1997, Muldoon et al., using a similar classification scheme, reported the outcome as excellent in 92% and good in 8%.[16]

Chapter 27

Hiatal Hernia

Geraldine B. Hunt

Hiatal hernias occur when abdominal contents protrude through the esophageal hiatus of the diaphragm into the thorax. Hiatal hernias are classified into two main types, sliding (or axial) and paraesophageal, according to the position of the gastroesophageal junction.[1,2] In dogs and cats, the most common type is the sliding hernia, in which the esophagus, esophagogastric junction, and part of

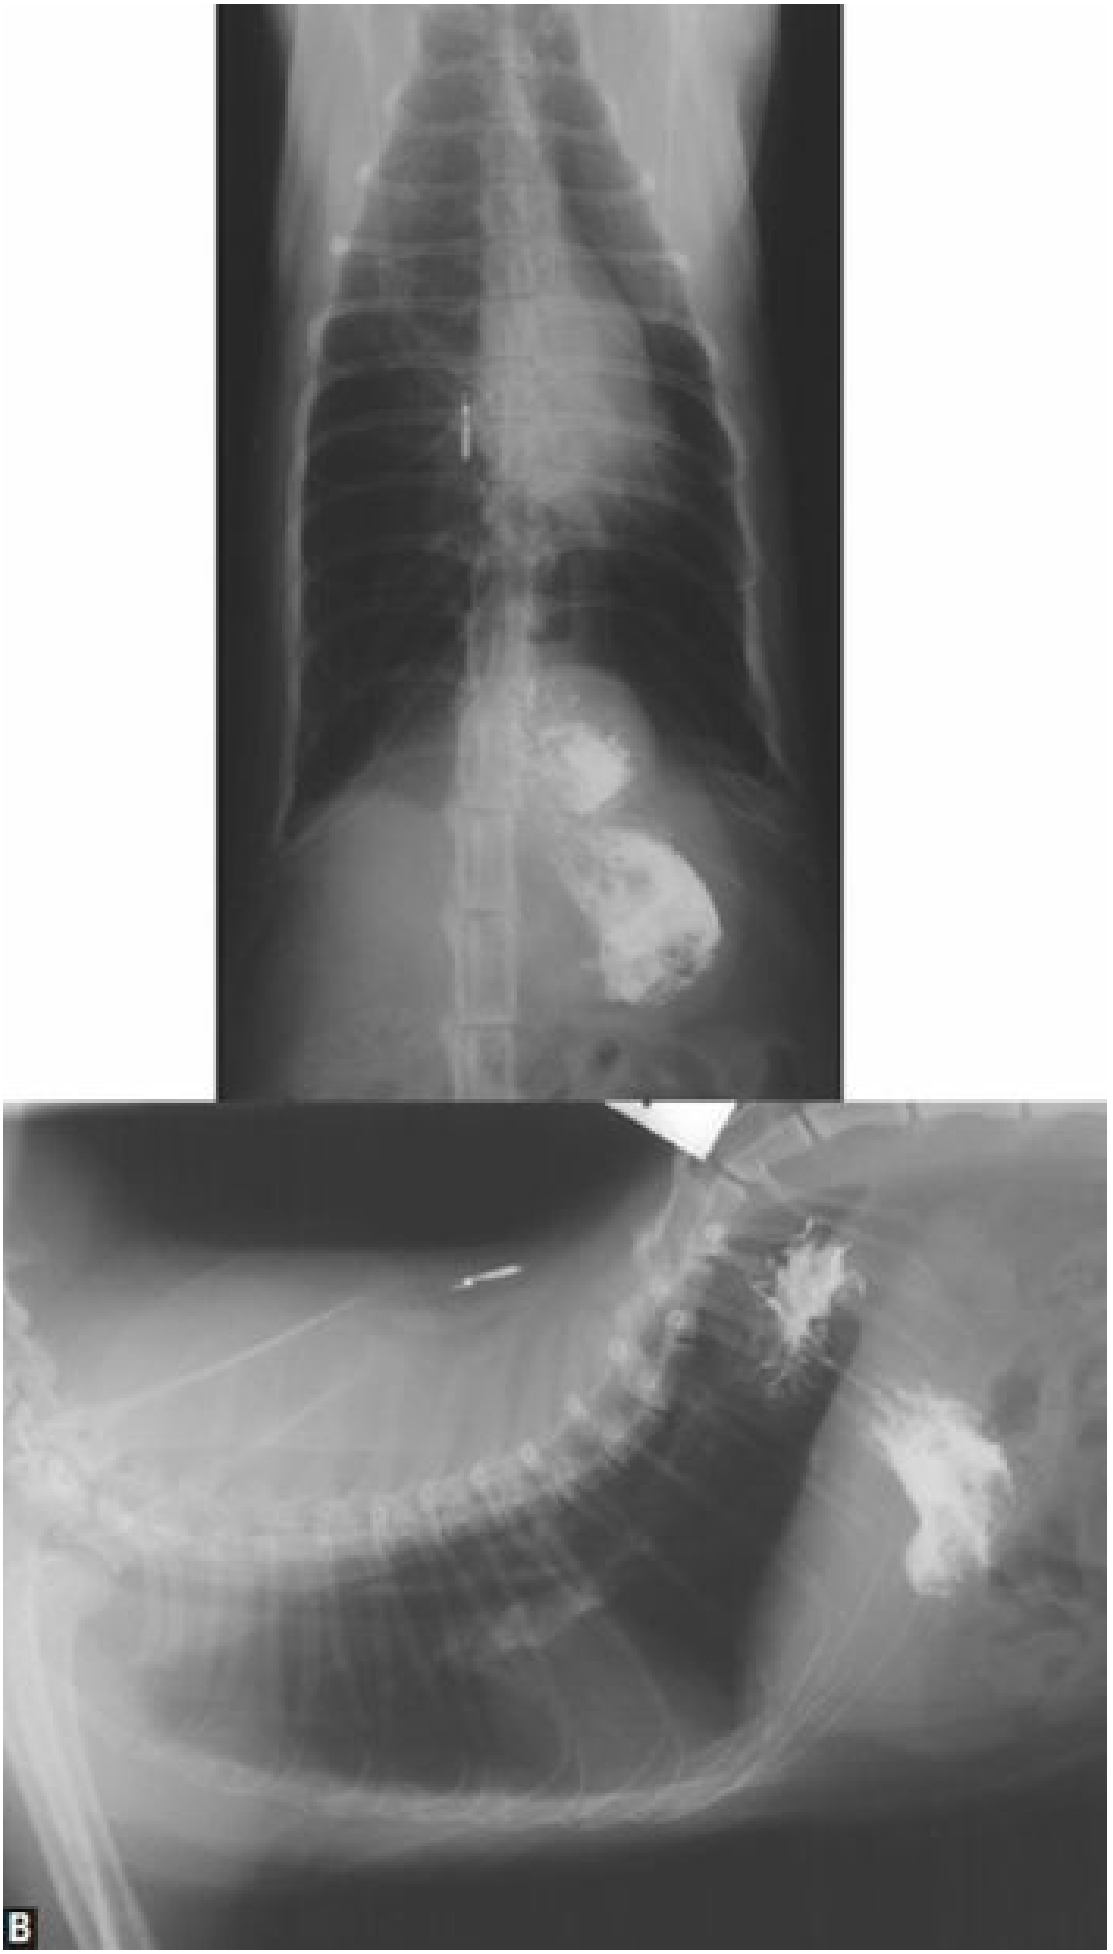
the stomach move through the esophageal hiatus into the thoracic cavity.[3-5] This is also described as Type 1 (Figure 27-1). Paraesophageal (Type 2) hiatal hernia has been described infrequently and involves movement of the fundus of the stomach in a rolling fashion through a defect in the esophageal hiatus while the gastroesophageal junction remains fixed in its normal position. Type 2 hernias have been reported only sporadically in dogs, and never in cats.[3,6] In cases where a combination of the above two abnormalities occur, the hernia is classified as Type 3. In extreme cases, other abdominal organs may accompany the stomach in the thorax, in which case the hernia is

classified as Type 4 (Figure 27-2).[7] Hiatal hernias may be fixed or dynamic, with herniated tissues moving in and out of the thorax according to changes in position and pleural pressure. Hence, clinical or radiographic signs may not always be present, and dynamic studies may be required to confirm a diagnosis.

Hiatal hernias may be diagnosed at any age. A distinction has been made between congenital and acquired sliding hiatal hernias in dogs, based on age of diagnosis.[2] However, reported case series demonstrate that acquired posttraumatic hiatal hernias can occur in animals as young as a few months.

A

Figure 27-1A. Lateral and ventrodorsal radiographs of a 14-month-old Burmese cat with lordosis. A type 1 hiatal hernia was diagnosed coincidentally.



B

Figure 27-1B. Administration of barium paste reveals cranial malpositioning of the stomach through the diaphragmatic hiatus. This cat did show evidence of clinical signs associated with its hiatal hernia.

Figure 27-2. Lateral and ventrodorsal radiographs of a 10-week-old domestic shorthaired kitten with dyspnea. A large hiatal hernia is present, possibly incorporating other abdominal organs in addition to the stomach. A few days after these radiographs were taken, the kitten suffered a sudden deterioration in its respiratory function and died. Postmortem examination was not performed.

Anatomy and Physiology of the Diaphragmatic Hiatus and Gastroesophageal Junction

The diaphragm is a musculotendinous partition that separates the abdominal and thoracic organs, assists in ventilation, and has a role in the movement of lymphatic fluid. The diaphragm is composed of a strong

central tendinous section and three separate muscles: the costal, sternal, and lumbar parts. The right crus is larger than the left. A tendon attaches each crus to the bodies of the third and fourth lumbar vertebrae, medial to the psoas minor muscles. Motor innervation of the diaphragm is from the phrenic nerves.[8]

Gastroesophageal reflux is normally controlled by a zone of increased pressure, the lower esophageal sphincter of the terminal esophagus.[9] At this point, the muscular layer is the thickest of the entire esophageal length. No anatomic or histologic differentiation exists between this zone and the rest of the esophagus. A

complex arrangement of transverse, oblique, and longitudinal muscle fibers blends with the muscular layers of the stomach. A section of inner, transverse fibers blends with the inner muscular fibers of the stomach. Dorsal longitudinal fibers of the outer layer continue on the dorsal wall of the stomach. Oblique, inner fibers pass external to the transverse fibers to blend with longitudinal fibers of the stomach wall.[10] The lower esophageal sphincter (esophageal high-pressure zone) is traditionally considered to be part of the intraabdominal esophagus, situated between the diaphragmatic hiatus and the gastroesophageal junction. It has been contended that the intraabdominal esophagus is

subjected to higher extraluminal pressures, increasing its resistance to gastroesophageal reflux. However, some anatomic studies challenge this concept by suggesting that in many canines there is little or no intraabdominal esophagus.[11] It has also been proposed that extrinsic influences imposed by diaphragmatic tone and the anatomic arrangement of the esophagus, hiatus, and stomach support the action of the increased pressure zone. Primary incompetence of the lower esophageal sphincter has not been demonstrated in dogs and cats.[28] Pratschke et al[12] demonstrated significant differences in the barrier pressure at the gastroesophageal junction in anesthetized dogs

positioned in ventral versus lateral recumbency. Hence, the intrinsic muscular activity of the lower esophagus, exertion of extraluminal compression by surrounding structures such as the diaphragm, and geometric relationship of the cardia and esophagus seem most likely to work in concert to moderate gastroesophageal reflux.

Clinical Signs

In congenital hiatal hernias, clinical signs may be observed immediately after weaning onto solid food and are usually seen before the animal is 1 year of age. Acquired hiatal hernias can occur at any age and are most

often associated with abdominal trauma. In some instances, animals with a congenital predisposition toward hiatal hernia may develop signs following development of an exacerbating problem such as upper respiratory tract obstruction or diaphragmatic dysfunction. In other individuals, such as the cat shown in Figure 27-1, hiatal hernias may be diagnosed incidentally during investigation for other problems. Clinical signs result from esophagitis, esophageal dysfunction, and the mass effect of herniated organs within the thorax. They include hypersalivation, regurgitation of frothy saliva and/or food, vomiting, dysphagia, dyspnea, and exercise intolerance.[2-4] The

severity of disease may range from minor, with discomfort from mild esophagitis, to life-threatening, with cachexia, dehydration, and aspiration pneumonia. It is likely that, in contrast to humans in whom mild reflux esophagitis may be detected as a result of the patient's complaining of heartburn, most animals presenting for management of hiatal hernias will be diagnosed as a result of relatively severe clinical signs, such as hypersalivation, regurgitation, or dyspnea.

Predisposition to Hiatal Hernia

Breed

Multiple case reports and case series indicate that Chinese shar-peis appear to have a breed predisposition to the disease.[6,13,14] Hiatal hernias have also been described in a range of brachycephalic breeds. No breed predispositions have been reported in cats.

Upper Respiratory Obstruction

Evidence is growing that upper respiratory tract obstruction exacerbates the clinical signs associated with hiatal hernias.[15-19] A case-control study of bulldogs

demonstrated that hiatal hernias were associated with the more severe manifestations of brachycephalic syndrome.[16] Single case reports have described complete remission of clinical signs associated with a sliding hiatal hernia in a Labrador-cross after surgical treatment of laryngeal paralysis,[15] and resolution of clinical signs and radiographic signs of a hiatal hernia following surgical correction of congenital stenosis of the soft palate in a dachshund.[17] A review of 30 dogs with brachycephalic obstructive airway syndrome revealed evidence of esophagitis in 25 and sliding hiatal hernias in 13.[18] Marked improvement in esophagitis and herniation followed surgical correction of the upper airway

problems. Esophagitis (among other gastrointestinal tract lesions) was found in a substantial proportion of brachycephalic dogs with upper respiratory syndrome in another study.[19] Proposed mechanisms for exacerbation of hiatal hernias and gastroesophageal reflux by respiratory tract disease include increased force of ventilation, exaggerated negative pleural pressures, and aerophagia leading to gastric distention. Conversely, a strong association between gastroesophageal reflux and chronic respiratory and otolaryngeal disease has been identified in people, with speculation that gastroesophageal reflux may exacerbate airway disease by mechanisms including direct

stimulation of the respiratory mucosa, aspiration pneumonia, and reflex bronchoconstriction.[20,21]

Other Disease Processes

Hiatal hernias may also occur as a result of other diseases that interfere with normal diaphragmatic function. Symptoms of hiatal hernias have been repeatedly observed following surgery for diaphragmatic hernias in cats and dogs.[3,4,22,23] Proposed mechanisms by which diaphragmatic hernia repair might predispose animals to clinical signs of hiatal hernias include physical damage to the diaphragmatic hiatus, abnormal tension on the central tendon of the diaphragm and hence the

hiatus, increases in intraabdominal pressure as a result of loss of abdominal domain following chronic diaphragmatic hernia, and alterations in vagal activity as a result of surgical trauma and organ repositioning.

Four cases of hiatal hernias associated with generalized tetanus have been reported in dogs.[24-26] Proposed mechanisms relate to abnormal neuromuscular function of the diaphragm, distal esophagus, and abdominal musculature, causing diaphragmatic spasm or esophageal dysmotility with a subsequent tendency to herniation.

Regardless of the observations that

clinical signs did not appear until after a precipitating event, it has not been possible to rule out the possibility of a preexisting predisposition to hiatal hernias in these patients.

Obesity

Excessive body weight has been reported as a significant factor predisposing both to hiatal hernia and esophagitis as a result of gastroesophageal reflux disease in humans. Obesity is considered to exacerbate the signs of hiatal hernias owing to an increase in intraabdominal pressure, increasing the likelihood of organ herniation and gastroesophageal reflux.[27]

Consequences of Hiatal Hernia

In humans, clinical signs associated with hiatal hernias do not result from the major anatomic abnormality (laxity of the esophageal hiatus of the diaphragm) but secondary to the events that occur as a result of movement of the gastroesophageal junction and axial displacement of the lower esophageal sphincter from the esophageal hiatus.[28]

Gastroesophageal Reflux

Gastroesophageal reflux is the major consequence of hiatal hernia,[29,30] causing esophagitis, esophageal

dysmotility, airway contamination, and pneumonia.[3,4] Gastroesophageal reflux occurs as a normal event in humans when lower esophageal sphincter pressure falls below 4 mm Hg31, but regurgitated material is usually cleared promptly by esophageal peristalsis.[32,33] Increased exposure to gastric acid, increased acidity of gastric contents, reduced passage of saliva through the esophagus, and failure of normal esophageal clearance result in esophagitis. Esophagitis caused by reflux of acidic gastric contents induces vomiting, regurgitation, and hypersalivation. Severe esophagitis may progress to esophageal stricture.[34,35] In extreme cases,

esophagitis may extend transmurally, resulting in fibrous adhesion between the esophagus and surrounding structures (such as the diaphragmatic hiatus), thereby reducing the elastic ability of the esophagus to stretch. This condition is termed "shortened esophagus syndrome" and carries a poor prognosis when addressed using normal surgical techniques.[3,36]

Regurgitation

Abnormal and decreased esophageal motility may be primary or secondary to hiatal hernia and reflux esophagitis. Up to 60% of patients with hiatal hernias have signs of megaesophagus on plain or contrast radiographs.[3,16,37]

Dysphagia in humans seems to result from obstruction to passage of a swallowed bolus by diaphragmatic impingement on the herniated stomach.[38]

Dyspnea

Dyspnea may occur in animals with hiatal hernias as a result of an intrathoracic mass effect (gastric distention in Types 1 to 4 or herniated organs in Type 4 hernia, Figure 27-2), failure of the thoracic bellows in animals with diaphragmatic dysfunction, or aspiration of gastric contents leading to bronchospasm or aspiration pneumonia.

Prognosis

Hiatal Hernia

Reflux esophagitis may be treated effectively with a variety of medical agents. However, surgery is indicated in animals with severe gastroesophageal reflux leading to chronic esophagitis, regurgitation, and airway disease. After surgical correction of hiatal hernia by use of an anatomic restoration technique, and with attention to exacerbating problems such as brachycephalic disease, uniformly good results may be expected.

Chapter 28

Pathopysiology Associated with Gastric Dilation-Volvulus Syndrome

Daniel J Brockman

Gastric dilatation – volvulus syndrome (GDVs) includes acute gastric dilation (GD), acute gastric dilation with gastric volvulus (GDV), and chronic gastric volvulus (cGV).[1] Although the overall prevalence of this disease in the population at risk is low, animals affected by GD and GDV are commonly

presented as emergencies, so this remains an important syndrome for any clinician involved in emergency practice. Treatment protocols based on best current evidence regarding the pathophysiology resulting from GD and GDV, has resulted in good survival rates.[2-4] It is likely that any future improvements in the treatment of this condition will be as a direct result of a better understanding of the disease mechanisms involved. The most profound functional changes that occur are associated with GD and GDV and vary according to the extent of gastric dilation, the degree of gastric rotation, and the duration of each. Although it is often helpful to consider the pathophysiology on the basis of an

organ or body system, the changes that occur are complex and interdependent. For the body as a whole, the consequences of GDVs are reduced oxygen delivery to tissues. These changes can be so mild that they are barely evident or they can be so severe that they result in irreversible "sepsis syndrome," either through uncontrolled infection (sepsis) or noninfectious systemic inflammatory response syndrome (SIRS).[5] The author will begin this review by describing the pathoanatomy of GDVs followed by a description of the effects this pathoanatomy has on body systems and organs based on data derived from experimental creation of GD or GDV. Data from clinical studies will be

presented as confirmation, or otherwise, that each process is actually happening in dogs affected by GDVs. Again, however, it is important to remember that these processes are interdependent; no process or system can really be considered in isolation of other organs or systems. This is particularly germane to clinical treatment where a "global approach" to the patient aimed at optimizing oxygen delivery to tissues will yield the best clinical results in terms of overall outcome.

Pathoanatomy

Dilation of a normally positioned stomach, results in a 90- degree

counter-clockwise gastric rotation around the gastroesophageal junction.[6] The majority of dogs affected with GDVs undergo simultaneous dilation and clockwise rotation (between 180 and 360 degrees) of the stomach about the gastroesophageal junction.[2-4] It has been suggested that gastric malposition must be present before gastric dilation results in classic GDV.[6] What conditions or factors trigger gastric rotation and whether it preceded gastric volvulus or vice versa, in an individual, are rarely clear at the time of diagnosis. From a pathophysiologic perspective, GD and GDV can create similar systemic effects, but evidence exists that the deleterious effects to the blood supply of local organs (stomach

and spleen) are greater when volvulus has occurred.[6,7]

Splenic displacement has been documented in many patients with GDVs[2,6] and is considered inevitable because of its close anatomic association with the greater curvature of the stomach. The magnitude of displacement should, in theory, have a direct relationship with the degree of splenic vascular compromise.

Experimental Models of GDV

Attempts to precisely recreate the pathoanatomy of dogs with naturally occurring GDV have failed. In addition,

all of the experimental models of this disease require general anesthesia, abolishing any conscious influence (such as release of endogenous catecholamines and cortisol) over events in these dogs. It seems that it is impossible to rotate the stomach of an otherwise normal dog and dilate it with air and have it remain in that state without additional “devices.” Passi et al[8] ligated the thoracic esophagus around an orogastric tube, via thoracotomy, and ligated the pylorus through a right subcostal laparotomy. They inflated the stomach to a mean pressure of 25 +/- 11 mm Hg to create a model of GD. Merkley et al[9] used the experimental model of GD that was predominant at that time,

using an intragastric balloon inflated to 80mm Hg. Orton and Muir[10] argued that such high intragastric pressures (80 mm Hg) should not be used because the intragastric pressure in dogs with naturally occurring disease varied from 9 to 62 mm Hg. They favored, therefore, using an intragastric balloon inflated to a pressure of 30 mm Hg.[10,11] In addition, these workers created a small celiotomy to allow concurrent rotation of the dilated stomach to create GDV. Subsequently, models of GDV have involved umbilical tape ligatures placed at the gastroesophageal junction and at the pylorus, in such a way that branches of the vagus nerve and the gastric vasculature are not

compromised, to create an air-tight seal. The stomach is then inflated via a Foley catheter in the pyloric antrum, to a pressure of 30 mm Hg and the stomach is sutured in a rotated position to create GDV.[7,12-14] The length of time that these models of GD or GDV were maintained varied between 90 and 180 minutes. In addition to these models of GD and GDV, Lantz et al[7] studied the effect of gastric volvulus alone by suturing the nondistended stomach in position after rotating it 360 degrees. All models of GD or GDV that required celiotomy for their creation had the celiotomy closed before any measurements were made.

In summary, none of these models

perfectly recreate the natural disease. In addition, anesthetic drug protocols have varied from model to model, which could have a significant effect on results. Because of the careful use of control animals, however, experiments using these models have provided a valuable insight into the events that follow GD and GDV.

Circulatory Pathophysiology

Passi et al[8] using their acute GD model, demonstrated that caudal vena cava flow rates fell rapidly from 51 ml $kg^{-1}min^{-1}$to between 0-9 ml $kg^{-1}min^{-1}$ within 31 minutes. Cranial caval flow rates fell from 28.9 ml $kg^{-1}min^{-1}$ to 24 ml kg-1min^{-1} during this time. Mean

arterial pressure (MAP), during the same period, fell from 112 mm Hg to 90 mm Hg, and it took only a further 30 minutes for MAP to fall below 50 mm Hg. Pretreatment with lactated Ringer's solution (50 ml/kg), bilateral cervical vagotomy, and sympathectomy did not prevent the onset of these hemodynamic changes. Of 16 dogs, 12 required additional lactated Ringer's following gastric decompression to restore normal hemodynamics. These workers concluded that mechanical obstruction of the cava was responsible for an acute decrease in venous return, leading to systemic arterial hypotension, and that fluid administration was required to return

these dogs to their predilation hemodynamic state. Orton and Muir[10,11] confirmed the earlier findings of Passi[8] and added further information regarding a fall in the maximum rate of left ventricular pressure change over time (dp/dt_{max}), increased heart rate, decreased cardiac output, and presumed neurohormonal reflex alterations in total peripheral resistance. Wingfield et al[15] provided angiographic evidence of caudal venous attenuation and obstruction in their model of acute gastric dilation. Barnes et al[16] provided indirect evidence of mechanical obstruction secondary to changes in intraabdominal pressure in an experiment that investigated the

hemodynamic response to elevations in intraabdominal pressure (IAP). They documented hemodynamic changes similar to those that had been documented following experimental GD by increasing intraabdominal pressure to 40 mm Hg, alone. Together, the above experiments have demonstrated that acute gastric dilation, using intragastric pressures equivalent to those seen in dogs with natural disease, cause mechanical obstruction to the caudal vena cava with predictable consequences with respect to cardiac output. In addition, acute increases in IAP alone can be detrimental to blood flow through the low-pressure vascular systems (caudal cava and portal vein). Finally, because

simply decompressing the stomach was not always enough to return hemodynamics to control levels, data from these experiments contained the clue that additional factors were mediating prolonged systemic hypotension in animals recovering from GD and GDV.

Impaired myocardial contractility has also been cited as a contributing factor in the poor circulatory status of dogs with GD and GDV. Such an influence could be secondary to an imbalance to the cardioinhibitory (e.g., myocardial depressant factor [MDF] or vagal mediated) and cardiostimulatory (circulating catecholamines) influences over myocardial function. In addition,

myocardial ischemia could directly influence myocardial performance in these hypotensive patients. Orton and Muir[11] failed to detect cardioactive substances in their acute model of GDV, but they commented that, if MDF was being released by the pancreas, it could remain sequestered in the portal circulation until gastric decompression and mechanical release of the splanchnic circulation had occurred. Horne et al[17] investigated the direct effect of experimental GDV on myocardial blood flow and myocardial oxygen extraction in addition to more global changes in hemodynamic indices. They documented reduced myocardial blood flow (50% below control level) increased heart rate

(similar to what has been previously described) and corresponding increase in myocardial oxygen extraction (30% above controls). Of the 8 experimental dogs, 6 developed subendocardial necrosis. Unfortunately, the long-term effects of MDF and the myocardial ischemia were not determined by either investigation.

Clinical evidence:
Good objective clinical data regarding the circulatory status of dogs with GDVs before fluid resuscitation is not contained in any of the large reports of this condition.[2-4] One small prospective study by Wagner et al[19] evaluated cardiopulmonary variables in 6 dogs that underwent gastropexy without

partial gastrectomy for GDV. Unfortunately, 4 of these 6 dogs had intravenous fluid therapy before any measurements were made and all had intraoperative fluid therapy "according to the perceived needs of the patient, made by the attending clinician and anaesthetist." Wagner et al[19] concluded that not all dogs with naturally occurring GDVs have severe circulatory derangements. The study population did not include any dogs that required partial gastric resection -- creating study population bias -- and with so many uncontrolled variables, such as degree of gastric distention and fluid administration, and the small sample size, it is hard to interpret these data as being sound scientific evidence.

Other evidence of the degree of systemic hypoperfusion was provided indirectly by De Papp et al[4] who retrospectively evaluated venous plasma lactate concentration as a predictor of gastric necrosis and survival in 102 dogs. In this study, the dogs with gastric necrosis were compared with dogs that did not have gastric necrosis, and mean venous plasma lactate concentrations were 6.6 mmol/L and 3.3 mmol/L, respectively. Originally, these workers hypothesized that the gastrointestinal tract was the source of the lactate; but ultimately they concluded that any ischemic tissue in the body could contribute to the venous plasma lactate concentration, especially if the sample was retrieved

prior to gastric decompression and release of the splanchnic (portal venous) reservoir of gut-derived lactate. These authors suggested that high lactate was more likely to reflect systemic hypoperfusion than gut production alone and, as such, should be considered a marker of disease severity rather than a direct indicator of gastric-wall ischemia. In addition, dogs with naturally occurring GDVs frequently have rupture of the short gastric vessels and hemoperitoneum, both of which can affect regional organ blood flow (see later) and systemic hemodynamic parameters.

The prevalence of cardiac arrhythmias in dogs recovering from GDVs has been

well documented.[2,3,19] Evidence of myocyte injury in the form of serum cardiac troponin I (cTI) and cardiac troponin T (cTT) has been demonstrated in dogs clinically affected with GDVs.[20] In the same study, 10 of 16 dogs that died had arrhythmias; all 16 had detectable cTI and CTT, but, it was not reported how many of the dogs that died did so as a direct result of a fatal arrhythmia.[20] In 4 of 5 dogs necropsied, myocardial necrosis was evident. In the absence of the identification of a direct myocardial depressant factor, another cardiotoxic element, or electrolyte derangements in the plasma of dogs affected with GDVs, reduced coronary blood flow and increased myocardial

oxygen demand could be considered as a reflection of the systemic hypotension and hypoperfusion. Because coronary blood flow occurs predominantly during diastole, low diastolic pressures, in particular, would reduce coronary blood flow. Because diastolic pressure depends on systemic vascular resistance, perturbations of this in addition to total intravascular volume could have a detrimental effect on myocardial oxygen delivery.

In emergency practice, the clinician must rely on subjective indicators of perfusion such as mucous membrane color, capillary refill time, and pulse rate and quality. It would be an error to ignore these basic physiologic

parameters when assessing the circulatory status of any patient.

Respiratory Pathophysiology

The effects of increasing gastric volume or increasing intraabdominal pressure on total thoracic volume and diaphragmatic excursions have been studied infrequently in an experimental setting.[15] These effects include a decrease in total thoracic volume, decreased diaphragmatic excursions, and partial lung lobe collapse (causing ventilation-perfusion mismatching), all resulting in hypoventilation and hypoxia. Compensatory mechanisms such a

tachypnea and alterations in the lateral thoracic dimensions preserve lung function initially. Ultimately, the pulmonary blood flow falls secondary to systemic hypovolemia, magnifying the effect of ventilation-perfusion mismatching.

Clinical evidence:
No firm clinical evidence exists that these mechanisms occur in dogs clinically affected by GDVs, but anecdotal evidence of respiratory compromise abounds. It is understandable to anyone involved in emergency practice why objective documentation of this respiratory impairment has not been acquired. Improved pulmonary function,

however, must remain one of the potential benefits of gastric decompression.

Dogs clinically affected by GDVs often make frequent attempts to vomit, and regurgitate any oral intake of fluid or food. This might place them at risk for aspiration pneumonia. Aspiration pneumonia is a finding that has been reported as a postoperative complication in several studies of this disease.[2,3] Aspiration of pharyngeal contents can have an acute and a longer term effect on pulmonary gas exchange and should be considered as one of the potential causes of poor lung performance in these animals.

Gastrointestinal, Hepatic, and Splenic Pathopysiology

The effect of 360-degree rotation of the blood supply of the nondistended dog stomach was investigated by Lantz et al.[7] These workers concluded that gastric venous obstruction contributed to mucosal and submucosal edema throughout the stomach, and that stretching of the short gastric arteries along the greater curvature of the stomach exacerbated the ischemic injury at that site. Davidson et al[13] demonstrated reduced blood flow to all tissues except liver and heart ventricles after experimental GDV lasting 270 minutes. In this experiment, pancreatic and jejunal blood flow were among

those measured. The implication of the results of the two aforementioned experiments, is that gastric dilation causes reduced gastrointestinal blood flow either by direct compression of the portal vein or via reduced cardiac output. The compromise to gastric blood flow is worsened by gastric rotation and compression (or avulsion) of the short gastric and splenic arteries. It is important also to realize that the perfusion pressure in the gastric wall arterioles and capillaries must exceed the compressive force applied to these vessels by the tension in the gastric wall in order for blood to flow. The potential for gastric necrosis is, therefore, influenced by several factors: degree of gastric rotation,

duration of rotation, intragastric pressure (gastric wall tension), systemic arterial pressure, and compression or injury to the short gastric branches of the splenic artery.

Increased levels of circulating endotoxin along with histologic evidence of intestinal villus injury were demonstrated by Davidson et al[13] in their experimental GDV group. The finding of high level of circulating endotoxin could indicate increased production of bacterial lipopolysaccharide (LPS) in the gut or increased permeability to LPS. Peycke et al[21] investigated the effect of experimental GDV on adenosine triphosphate (ATP) and conductance of

the canine gastric and jejunal mucosa They concluded that the jejunal mucosa showed more profound changes and that the conductance values and ATP levels in jejunal mucosa were suggestive of cell-membrane dysfunction. These experiments could be taken as evidence for intestinal mucosal barrier compromise secondary to GDVs, resulting in systemic release of both bacterial products (e.g., LPS) and, potentially, whole bacteria.

Histologic evidence of hepatocellular damage following experimental GDV was provided by Davidson et al.[13] Several mechanisms could be responsible for this injury: ischemia-reperfusion injury, damage caused by

endotoxin, and hypoxic damage. Alterations in hepatic function have not been assessed in experimental models of GDV but, in theory, acute diminution of hepatic function could have serious consequences. The effect of experimental GDV on the spleen has not been reported in detail.

Clinical evidence:
Gastric necrosis following naturally occurring GDVs has a predictable pattern, with the gastric fundus most commonly affected.[22] In clinical studies of this disease, rupture of the short gastric vessels and hemoperitoneum is often recorded, demonstrating that the natural disease causes changes that experimental models have not

included, such as blood loss and irretrievable vascular compromise. In addition to necrosis of the fundus, necrosis at the cardia has been reported,[2] suggesting that twisting of the cardia can also directly affect local tissue integrity, probably by direct vascular occlusion. The reported prevalence of gastric necrosis in patients with naturally occurring GDV is between 10% and 30% in most studies.[2-4,22] This fact may give an indirect indication of the prevalence of "severe" disease among affected dogs, since the survival rate for dogs that do not require partial gastric resection as part of their treatment approached 100% in one study.[4] The intermediate-term effects of the gastric-wall insult

are uncertain. Perhaps the abnormalities in gastric myoelectrical activity reported by Stampley et al14 and Hall et al[23] in dogs recovering from GDV and gastropexy represent these effects. Postoperative gastrointestinal ileus is an occasional complication in clinical patients recovering from GDVs, but the potential causes of this include anesthetic drug use, analgesic drugs, anxiety, and disease-related gastrointestinal compromise, so it is not possible to identify a single cause and effect relationship.

Splenic vascular compromise (vessel avulsion, intravascular thrombosis, infarction) occurs in approximately

16% of dogs that survive and 40% of dogs that die following acute GDVs.[2] Again, perhaps the presence of splenic complications implies more "severe" disease.

Although elevations in serum alkaline phosphatase and alanine aminotransferase have been documented in dogs recovering from GDVs, there is no clinical evidence of either acute or chronic hepatic dysfunction in these dogs.

Ischemia-Reperfusion Injury, Sepsis, Sirs, and Ards

(See Chapters 1 and 2)

Experimental evidence that ischemia-

reperfusion injury occurs in dogs with acute GDVs was provided by Badylak et al[12] and Lantz et al.[25] Ischemia-reperfusion mediated production of reactive oxygen species directly through lipid peroxidation and indirectly through neutrophil activation will fuel the genesis of local and systemic inflammation. Endotoxin is a potent mediator of inflammation and has been demonstrated to be released in experimental models of GDVs.[13] Hypoperfusion and direct ischemic damage to many organs could also result in activation of neutrophils, monocytes, macrophages, and platelets, all of which contribute cytokines to the inflammatory cascade. In addition, inflammation associated

with bacterial infection will feed local and systemic inflammation. Together these factors can trigger systemic inflammatory response syndrome (SIRS).

Clinical evidence:
High levels of circulating endotoxin have not been demonstrated in clinical patients with GDVs, nor have indicators of lipid peroxidation been measured from tissues of clinical patients. Large studies of GDVs do not frequently cite massive bacterial infections in dogs that die following treatment.[2-4] The most commonly cited causes of death are euthanasia because of massive gastric necrosis, and continued cardiovascular instability

characterized by hypotension, despite appropriate resuscitation attempts, followed by multiple organ failure, notably pulmonary.[2,3] Such findings could be interpreted as circumstantial evidence, at least, that SIRS is a consequence for animals severely affected by GDVs.

Clinical Indicators of Disease Severity

Several preoperative clinical parameters that have been studied might best be considered indicators of the severity of disease in dogs suffering acute GDV rather than being a direct cause of morbidity or mortality. Such parameters include plasma lactate,[4]

abnormal haemostatic profiles,[25] and the presence of cardiac arrhythmias.[3,19] Venous plasma lactate is considered an indicator of the degree of circulatory system compromise. Of course, other clinical data (pulse rate, capillary refill time, mucous membrane colour, packed cell volume, plasma protein levels) can also aid in the clinical evaluation of circulatory status. High lactate was associated with increased chance of having gastric necrosis in one study.[4] This study did not imply cause and effect, simply statistical association between a measure of perfusion status (plasma lactate) and the presence of gastric necrosis, an event influenced by many factors. It would seem, however, that high

plasma lactate pre-resuscitation and, perhaps more importantly, elevated plasma lactate that is refractory to treatment, should be considered an indicator of severe disease.

The presence of abnormal laboratory hemostatic profiles in dogs clinically affected with GDV was associated with increased chance of gastric necrosis, in another study.[25] The authors of this study implied that microthrombi that either caused or resulted from the abnormal coagulation status in these dogs accelerated the demise of the gastric wall by local vessel occlusion.[25] Although it is difficult to determine whether stasis precedes thrombus formation in gastric-wall arterioles and

capillaries or vice versa in dogs with GDV, abnormalities of hemostasis and evidence of disseminated intravascular coagulation (DIC) should be considered as clear evidence of severe disease.

The presence of cardiac arrhythmias was a negative prognostic indicator in one study[3] but was not thought to influence overall outcome in another.[2] Given that the majority of experimental and clinical evidence so far points to myocardial ischemia as a key factor in the development of cardiac arrhythmias, it would seem that dogs that have the most severely compromised circulation are going to be most likely to develop arrhythmias. Again, in this scenario, the presence of

cardiac arrhythmias could be considered an indicator of disease severity.

The three parameters mentioned in this section are representative of many that could be considered in a similar way. Indeed, intraoperative findings such as gastric necrosis and splenic complications could also be considered markers of disease severity, as could postoperative findings such as intractable hypotension, intractable elevation in plasma lactate, fall in the partial pressure of oxygen in arterial blood, and intractable arrhythmias. The sensitivity of each with respect to the severity of disease is unknown and, given the potential complexity of the

pathophysiologic events in these patients, the author would caution against using any single numberor event as a reason for withdrawing treatment from any patient. Rather, the patient should be considered as a whole in respect of clinical decision making.

Chapter 29

The Gastric Mucosal Barrier: Why the Stomach does not Digest Itself

Colin F. Burrows

Ever since René Antoine Ferchault de Réamur, the 18th century man of many sciences, showed that juice secreted by the stomach could digest meat, philosophers, physiologists, and physicians alike have been puzzled by the question: why does the stomach not digest itself? One answer, of course, is

that it sometimes does. Under certain circumstances, gastric juice can produce ulcers and even destroy most of the stomach lining. Normally, however, the stomach wall staunchly resists attack; as Claude Bernard observed, it behaves as if it were made of porcelain.[1,2]

Gastric juice contains hydrochloric acid, one of the most corrosive acids known. At the concentration secreted by the parietal cells in the gastric mucosa, gastric acid is capable of dissolving zinc and is deadly to cells. Yet in the stomach, hydrochloric acid ordinarily acts only to perform the useful functions of killing ingested bacteria, softening fibrous foods, and

promoting pepsin production.[2] The corrosive juice is prevented from attacking the stomach wall by a complex physicochemical barrier termed the *gastric mucosal barrier* (GMB). The GMB was first defined by Davenport as "that property of the gastric mucosa which impedes diffusion of acid from the lumen into the mucosa and impedes diffusion of sodium ions from the mucosal space into the lumen."[3,4] The barrier cannot be defined on a strictly anatomic basis, but is rather a collection of interdependent physical and chemical processes that act in concert to protect the gastric mucosa against secreted acid and pepsin.[5,6] It is now generally agreed that the barrier has eight basic

components: (1) epithelial cell tight junctions, (2) the ability of the gastric epithelial cells to change shape – a process called restitution, (3) mucosal bicarbonate (HCO_3^-) secretion, (4) the hydrophobic apical membrane of the gastric epithelial cells, (5) gastric mucosal blood flow and local acid-base balance, (6) gastric mucus production and secretion, (7) the protective and regulatory effect of mucosal prostaglandins, and (8) the basal lamina.[7-9]

In the normal stomach the gastric mucosa is under a continuous state of physical and chemical siege. It is exposed daily, not only to the potential ravages of acid and pepsin, but also to

a wide variety of potentially damaging agents that include certain foods, a range of temperatures, hyperosmolar and abrasive substances, chemical damage from refluxed bile and pancreatic juice, as well as to bacterial toxins and a variety of potentially damaging drugs.[10] Some damage is inevitable under these circumstances, yet the gastric mucosa normally retains its integrity even under these attacks. The balance between normal gastric mucosal physiologic damage and repair is a dynamic process involving a variety of complex mechanisms. Clinically, however, when this process breaks down, acute gastric mucosal injury results, often with the accompanying signs of acute gastric

disease. If the process is severe or ongoing, progression to chronic gastric disease is the almost inevitable sequel.

Although the mechanisms of disruption of the gastric mucosal barrier can vary widely, the end result is the same, namely erosion of the gastric mucosa, which allows acid to diffuse back into the submucosa and to initiate an inflammatory response. Mucosal epithelial erosion, hemorrhage, gastritis, and overt ulceration may develop if the process remains unchecked. Barrier disruption occurs to some extent in virtually every type of gastric disease as well as under a variety of sometimes less well appreciated circumstances such as

neurologic disease, stress, hypotension, sepsis, and protein-calorie malnutrition. An appreciation of the mechanisms of acid secretion as well as barrier disruption and repair, therefore, are important for most clinicians, as is an understanding of approaches that enhance the repair process.

Gastric Acid Secretion

The mammalian stomach is a specialized organ of the digestive tract that serves to store and process food for subsequent intestinal absorption. One of its features, considered to be the hallmark of gastric function, is its ability to secrete acid. In most species

this is a continuous process that varies in intensity in response to a variety of exogenous and endogenous stimuli. In the dog, however, and possibly in the cat, animals that ancestrally, at least, can go for days without eating, acid secretion is more variable, with the distinct possibility that little or no basal acid secretion occurs in these species.[11]

The gastric mucosa consists of a variety of cell types, predominantly mucus-filled tall columnar epithelial cells, which form a single protective layer. The secretory unit of the gastric mucosa is the gastric (or oxyntic) gland, of which the normal human stomach has been estimated to contain

approximately one billion. These contain parietal (acid-producing and secreting) cells, chief (pepsinogen-producing and secreting) cells, mucous neck cells, and a variety of endocrine cells. Mucous neck cells are relatively few in number and are scattered among the parietal cells. Parietal cells are located mainly in the isthmus and neck region of the gland, whereas chief cells are located at its base (Figure 29-1).[12] Adjacent to the parietal cells are histamine-secreting enterochromaffin-like (ECL) cells and somatostatin-secreting "D cells." The surface epithelial cells have a life span of about three days and are replaced by division of cells just below the opening of the gastric glands. Immediately

below the surface epithelial cell layer is a rich network of blood vessels, nerves, and lymphatics supported by a connective tissue matrix, which collectively form the submucosa.

The stomach secretes hydrogen ions, sodium, chloride, pepsinogen, lipase, and varying quantities of mucus into its lumen. Hydrogen ions are secreted into the lumen of the gastric gland in exchange for potassium by an energy-dependent exchange enzyme in the mucosal surface of the parietal cell called the hydrogen potassium-adenosine triphosphatase (H^+K^+ -ATPase) pump (Figure 29-2).[13] During acid secretion, the H^+K^+ -ATPase secretes H^+ ions into the lumen of the

gland in exchange for K^+ ions, which have previously moved out of the cell down their concentration gradient. Simultaneously, chloride ions move from the cell into the lumen down an electrochemical gradient. Water moves out of the cell in response to the subsequent osmotic gradient, to form hydrochloric acid. This acid then flows from the glands through pores in the overlying mucus, which acts to prevent back-diffusion of acid from the lumen.[14]

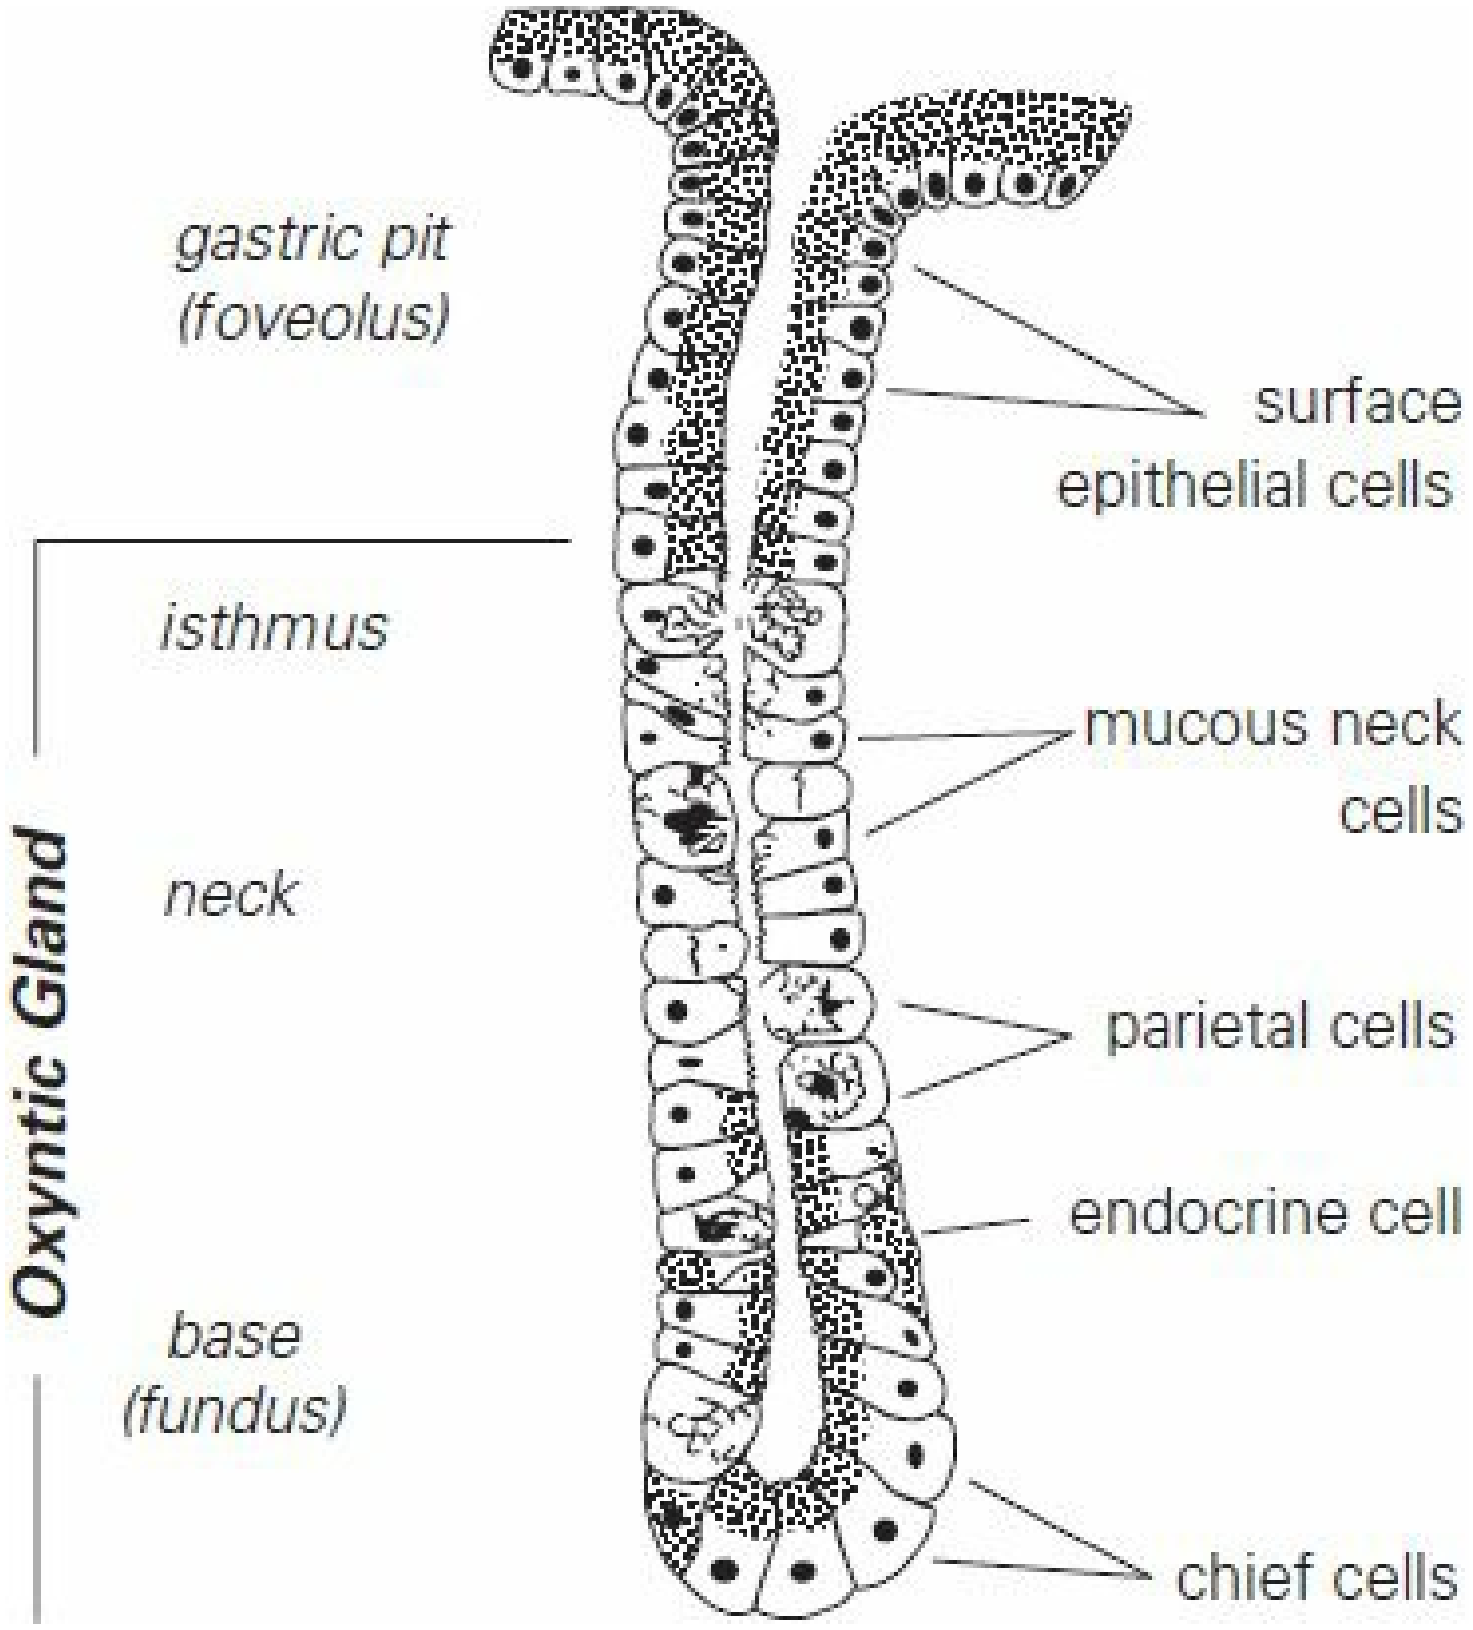

Figure 29-1. Diagram of tubular gastric (oxyntic) gland in the body of the mammalian stomach. (From I to S: Functional gastric morphology. *In* Physiology of

the Gastrointestinal Tract, 2nd ed. Johnson LR (ed). Philadelphia: Lippincott Williams & Wilkins, 1987, with permission.)

Acid secretion can be stimulated by the binding of acetylcholine or histamine to specific receptors in the serosal membrane of the parietal cell. Gastrin, another important stimulus of acid secretion, is believed to bind to receptors on the ECL cells and to stimulate them to release histamine (Figure 29-3). It can, however, also stimulate the parietal cell directly via CCK-B(2) receptor. When gastrin, acetylcholine, or histamine bind with the cell, a variety of second messengers are stimulated that increase intracellular cyclic AMP (gastrin and histamine) or calcium (acetylcholine)

concentration. These in turn stimulate acid secretion.

Gastric acid secretion is divided into four phases: basal, cephalic, gastric, and intestinal. The basal state, as has been mentioned, may be minimal in carnivores although it can be augmented by sepsis[15] and possibly by a variety of other stressful events. The cephalic phase of gastric secretion is activated by the thought (in man), sight, and smell of food via vagal impulses conducted from the brain to muscarinic receptors in the gastric mucosa. During the gastric phase of secretion, which accounts for 40 to 50% of the response to a meal, acid secretion is stimulated by both

chemical and physical factors that include gastric distention and ingested protein. Amino acids in the duodenum are mainly responsible for initiation of the intestinal phase, primarily through stimulation of gastrin release.

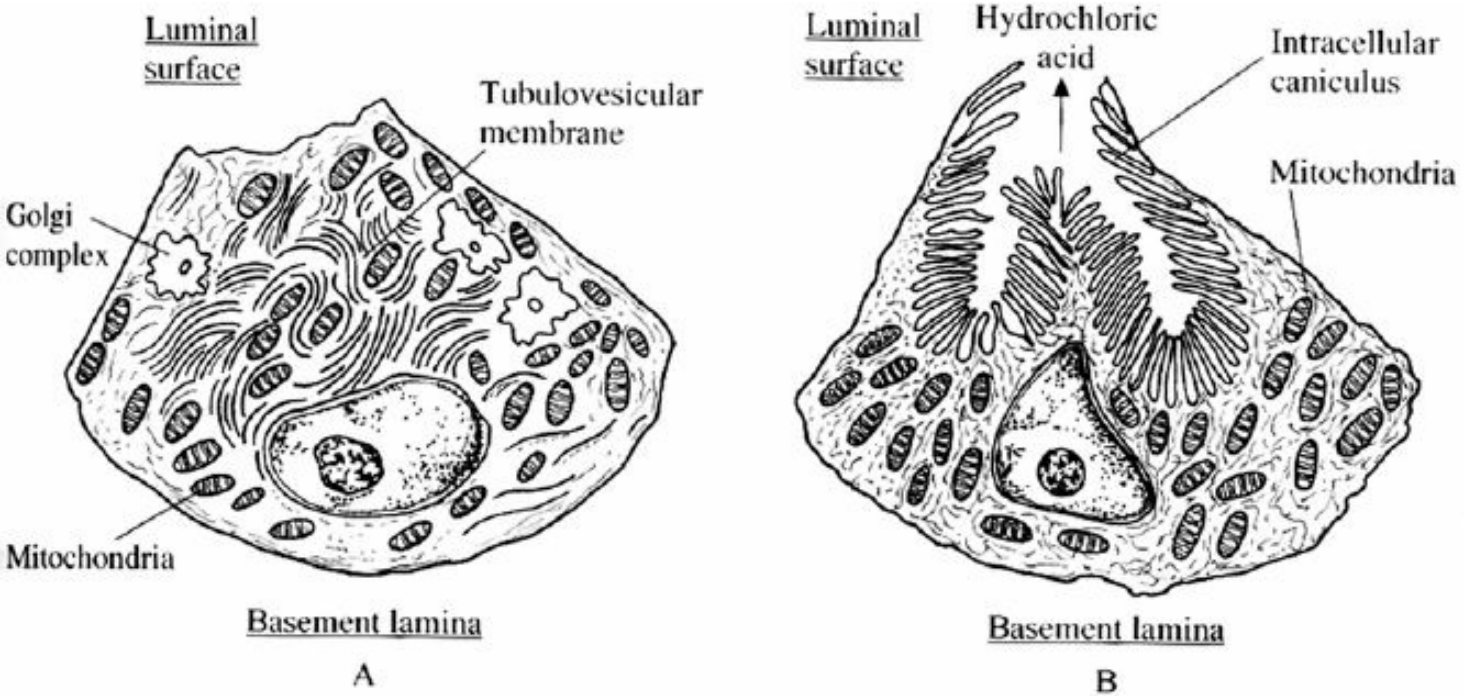

Figure 29-2. A. Non-secreting parietal cell. The cytoplasm is replete with tubulovesicular membranes, which contain H+K+-ATPase. B.Acid-secreting parietal cell. The tubulovesicular membrane has fused with the apical plasma membrane to form a secretory canalicular membrane with numerous microvilli.

H+K+-ATPase is inserted into the membrane so that the cell can secrete acid. (From the BSAVA Manual of Canine and Feline Gastroenterology. Thomas DA, Simpson JW, Hall EJ (eds)., 1996, with permission.)

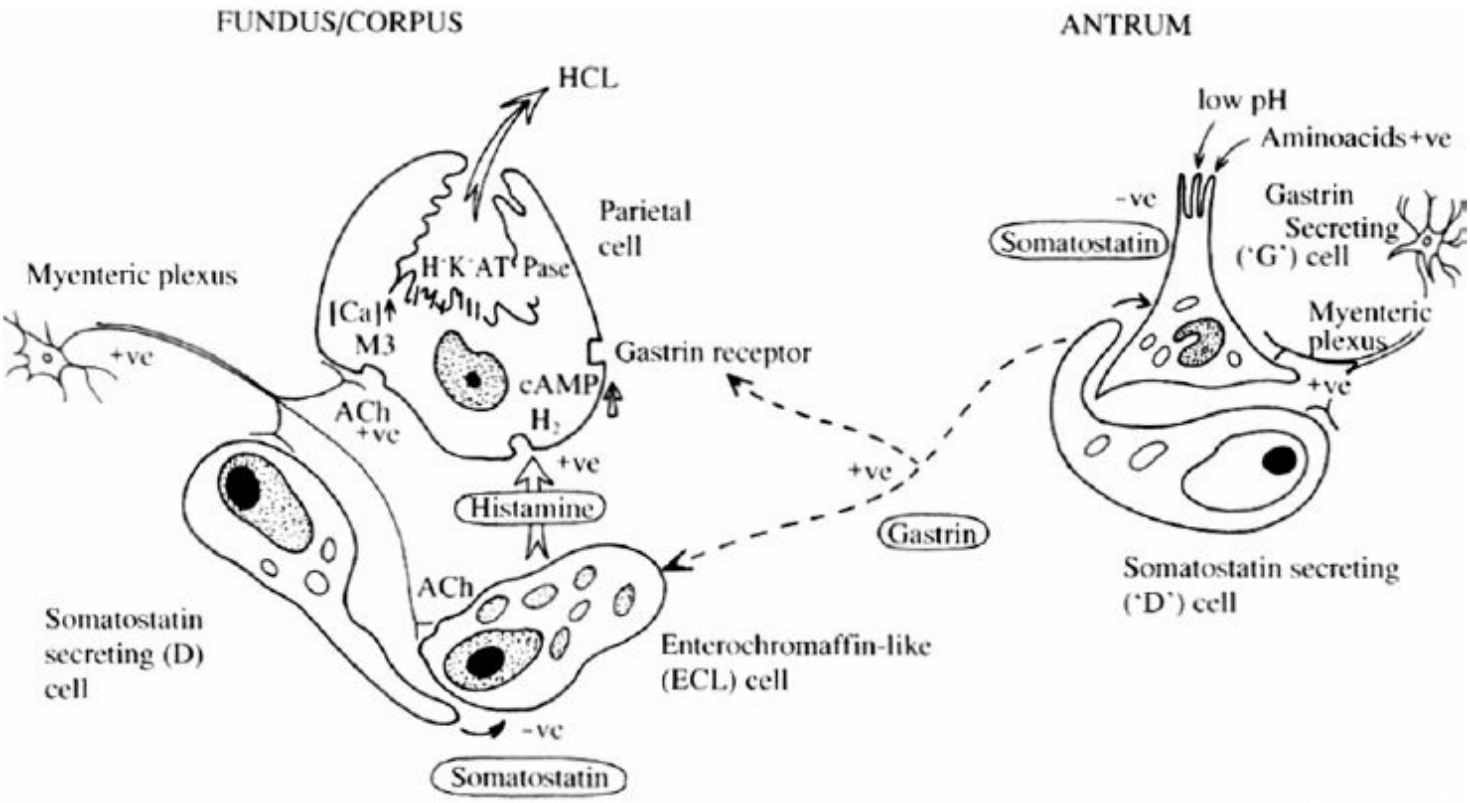

Figure 29-3. Current concept of the role of the enterochromaffin-like (ECL) cell, gastrin- (G) and somatostatin-secreting (D) cells in the peripheral regulation of acid secretion by parietal cells. Nervous stimulation from the CNS causes release of acetylcholine from the myenteric plexus. This binds with a muscarinic M3 receptor on the parietal cell, which results in an increase in intracellular calcium concentration. Calcium in turn stimulates insertion of

H^+K^+-ATPase into the canaliculi membrane. Release of histamine is brought about by either gastrin or acetylcholine binding to receptors on the ECL cell. Histamine binds with H2 receptors on the parietal cell, which increases intracellular cAMP. This activates H^+K^+-ATPase in the membrane. Gastrin also probably reacts directly with the parietal cell in the dog. Somatostatin released from D cells in the gastric mucosa inhibits both histamine and gastrin release. (From the BSAVA Manual of Canine and Feline Gastroenterology. Thomas DA, Simpson JW, Hall EJ (eds)., 1996, with permission .)

After a meal, acid secretion is modulated by a negative feedback mechanism in which antral acidification inhibits further release of gastrin, possibly via the inhibitory effect of somatostatin.[12] The relative importance of and exact relationship between histamine, gastrin, and acetylcholine receptors in the

stimulation of acid secretion is unclear. The two main activating receptors on the parietal cell are a histamine (H_2) receptor and a muscarinic (M_3) receptor. It is believed that the activity of the M_3 receptor is regulated by acetylcholine released from nerve fibers, whereas activity of the H_2 receptor depends on histamine released locally from the ECL cell. Release of histamine from the ECL cell results from the binding of either gastrin or acetylcholine to receptors in the ECL cell wall.[16]

Acetylcholine and histamine are also the major stimuli for pepsinogen secretion by chief cells, although secretin also stimulates its release.

Pepsinogen is always secreted in parallel with acid and is converted to pepsin, its active form, by acid at a pH of about 1.5 as well as by previously converted pepsin. Stimulation of mucus secretion from the mucus neck cells also appears to be under the control of acetylcholine. This mucus is more viscid than mucus released by rupture of the surface epithelial cells. An acid-stable lipase is released from the chief cells and mucous-producing cells that is responsible for the digestion of up to 30% of dietary fat.[17,18]

Hydrogen ion secretion is accompanied by the passive secretion of chloride from the parietal cell and by the production of an equivalent amount of

HCO_3^-. This is secreted from the base of the cell into the interstitium from where it is picked up by mucosal capillary vessels and carried to the systemic circulation.

Gastric secretion is inhibited by a low intraluminal pH, which inhibits gastrin secretion.[16] Secretion is also inhibited by hydrochloric acid, fatty acids, and hyperosmolar solutions contacting receptors in the duodenal mucosa. These negative feedback mechanisms ensure that acid secretion is proportional to need. Somatostatin secreted from D cells, adjacent to the parietal cells, is one of the principal inhibitors of acid secretion. D cells are also found in the gastric mucosa

adjacent to the ECL cells where secreted somatostatin inhibits gastrin release (Figure 29-3). Prostaglandins, which are secreted by a variety of mucosal cells, also exert a tonic inhibitory effect on acid secretion by decreasing cyclic AMP production in the parietal cell.[16]

Components of the Barrier

Gastric Epithelial Cell Tight Junction

The stomach is lined by a layer of columnar epithelial cells, which form very tight junctions with each other and constitute the main anatomic portion of the gastric mucosal barrier.[19] These cells, however, are not

completely impervious to luminal H^+ nor to diffusion of tissue Na^+. Small quantities of Na^+ and H^+ normally diffuse in both directions across the mucosa, with any H^+ that diffuses into the mucosa being neutralized by tissue buffers. Gastric mucosal cells are formed by division from mucus neck cells and have a life span of about 3 days, after which time they are sloughed into the lumen and replaced by lateral migration of younger cells from the neck of the oxyntic gland.[8] Mucus neck cells are located in the neck and isthmus region of gastric glands (Figure 29-1). Cells in the mucosal proliferative zone in the isthmus are responsible for the constant replacement of gastric

epithelium in both health and disease.[20]

Restitution

Studies of the mechanisms of gastric repair after mucosal damage by such substances as alcohol, salicylates, and bile salts revealed that, in areas of relatively superficial cell disruption not extending deep into the mucosa, much of the damage is repaired within minutes. This is accomplished by a process called restitution, which occurs by migration of still viable epithelial cells from areas adjacent to or just beneath the injured surface cells.[13] After the necrotic surface cells exfoliate, the viable mucus cells in the

upper gastric pits immediately flatten, extend finger-like projections called lamellipodia, and migrate across the exposed basal lamina to restore an intact cell layer over shallow defects (Figure 29-4). However, deeper lesions or ulcers require new cells to fill in the defect. The process of restitution occurs within minutes of injury and before the appearance of an extensive inflammatory response or cell proliferation.[9,19] The response is evoked, at lease in part, in response to hyperemia invoked by a capsaicin-sensitive emergency neural response system.[21] If gastric acid remains in contact with the mucosa, damage is ongoing, the basal lamina is destroyed along with the mucosa, and the

substratum necessary for restitution is removed. This can result in persistent macroscopic lesions that may bleed, invoke a classic inflammatory response, and become clinically significant.

Figure 29-4. Low-power scanning electron micrograph of ethanol-disrupted rat gastric epithelium with much of the interpit basal lamina exposed. Many mucus cells from the gastric pits (GP)

have lamellipodia (arrows) extending onto the basal lamina (x 1500). (From Lacy ER, Ito S: Rapid epithelial restitution of the rat gastric mucosa after ethanol injury. Lab Invest 51:573-583, 1984 with permission from Lippincott Williams & Wilkins.)

The shed surface cells are believed to play an important role in protecting the mucosa from further injury and to facilitate the process of re-epithelialization.[22] When traumatized, the apical plasma membrane of the shed cells ruptures, spilling mucoid contents and contributing to a gelatinous mass that contains mucus, cellular debris, necrotic tissue, and trapped alkaline exudate from damaged capillaries. It is believed that this layer may provide a protective microenvironment for reconstitution.[23]

Each of these responses to superficial injury, namely formation of a protective mucoid layer, flow of alkaline mucosal fluid that may act to dilute luminal noxious agents, and rapid restitution of superficial epithelial cells appears to help prevent the formation of deeper hemorrhagic lesions and subsequent pathology.[23] Indeed, factors that facilitate or impair these early mucosal defense mechanisms are now believed to be of far greater importance in the development and repair of gastric damage than is the integrity of the classic gastric mucosal barrier itself.[23]

Bicarbonate Secretion

Under normal circumstances HCO_3^-, produced as a by-product of H^+ secretion, is present in abundance in the gastric mucosa. Some of this HCO_3^- is taken up by mucosal cells by means of a prostaglandin-dependent pump mechanism in exchange for chloride. The HCO_3^- is transported across the cell and secreted with mucus into the lumen. At one time it was believed that secreted HCO_3^- was trapped in the surface mucus where it neutralized H^+ back-diffusing from the lumen.[24-26] Until recently, epithelial HCO_3^- secretion was accepted as the most important defense mechanism against acid.[26] This theory has been called into question by more recent work that

shows the surface pH is kept constant at a pH of about 4 by dual secretion of HCO_3^- and acid as needed into a surface unstirred layer.[27] In the mouse at least, pH control at the protective surface pH gradient is regulated by cyclooxygenase-1 (COX-1).[28]

Gastric Epithelial Cell Membrane

The luminal surface of gastric epithelial cells contains a layer of surface-active phospholipids that confers a degree of hydrophobicity to the cell surface.[29] Phosphatidyl-cholines are present in high concentrations in the luminal membrane of gastric mucosal cells and

are oriented so that the hydrophobic end of the molecule is at the exterior surface. These hydrophobic molecules are believed to render the cell resistant to any acid that permeates the mucus layer. When the lipid layer is damaged however, the route is opened for acid to permeate into the cell and begin destruction.

A number of lipid-soluble nonionized substances can easily disrupt the membrane and penetrate the epithelial cells to initiate gastric mucosal damage. Bile salts, for example, have been shown to disrupt the mucosal barrier and initiate cell damage,[30] whereas lipid-soluble bile acids are taken up directly into the cell to cause

mucosal injury from within the cell.[31] Reflux of bile into the stomach is a normal physiologic event in most species; however, it is usually quickly cleared so that no lasting damage is done to the gastric mucosa.[32] If normal clearance mechanisms fail, prolonged contact ensures membrane damage and development of gastritis.[33] Part of the damage caused by refluxed intestinal content is also caused by lysolecithin, a potent membrane-toxic phospholipid formed by the action of pancreatic phospholipase on biliary lecithin in the duodenal lumen.[34] Prolonged reflux of upper intestinal content causes extensive mucosal damage and chronic gastritis.[35] In endotoxemia, exposure of the stomach

to bile causes macroscopic injury to the gastric mucosa.[36,37]

Aspirin has long been recognized as a substance that disrupts the mucosal barrier and causes extensive mucosal damage.[38] In humans, for example, ingestion of a single aspirin tablet results in the loss of between 0.5 and 2.0 ml of blood.[39] In some susceptible individuals much larger blood volumes may be lost and severe mucosal lesions may develop. The same situation can occur in the dog.[40] The mechanisms of aspirin damage are complex, but the most important is through a pH-dependent effect on mucosal hydrophobicity. At a pH of less than 3.5 to 4.0, acid is in its lipid-soluble

form and disrupts the cell membrane. At a higher pH, aspirin is lipid-insoluble and little or no direct damage is done.[41] Another important effect is the inhibitory effect of aspirin and other NSAIDs on cyclooxygenase (see further on).

Gastric Mucosal Blood Flow and Local Acid-Base Balance

An adequate mucosal blood flow is critical for barrier integrity. If mucosal blood flow is decreased, gastric mucosal erosions and hemorrhage almost inevitably develop.[42] It was once thought that mucosal damage developed because of tissue hypoxia, but microanatomic and physiologic

studies have shown that delivery of HCO_3^- to the mucosa and the prevention of local acidosis are much more important.

Anatomic studies have shown that the gastric arteries supply an arterial network in the submucosa from which arterioles penetrate the muscularis mucosae to supply the mucosal capillaries with blood (Figure 29-5). These capillaries run both in between and parallel to the oxyntic glands and are interconnected by short capillaries parallel with the mucosal surface. These capillaries form short loops around the mouth of the gastric gland before joining the collecting veins, which penetrate the muscularis

mucosae vertically to form an extensive network of veins at the submucosal level.[7] Bicarbonate, produced as a by-product of H^+ synthesis in the parietal cells, escapes to be picked up by the vertically flowing capillaries, which are especially fenestrated at the mucosal surface to facilitate HCO_3^- flux. A small proportion of HCO_3^- escapes while the rest is carried to the systemic circulation (Figure 29-6).[43,44]

The epithelial cell membrane is not totally impervious to H^+ ions, which diffuse through the intact gastric mucosa in relatively small amounts. Mucosal HCO_3^-, however, normally neutralizes this acid to maintain a

normal tissue acid-base balance. If the barrier is damaged, H^+ diffusion increases and HCO_3^- buffers are reduced.[9] When tissue buffers are exhausted, the tissues become acidotic and submucosal damage develops.

In that it carries HCO_3^- to the mucosa to maintain normal tissue acid-base balance, gastric mucosal blood flow is critical to the prevention of gastric lesions. Systemic acid-base balance is also important in that with acidosis less HCO_3^- is available for mucosal protection. This is one of the reasons advanced for the development of gastric lesions in critically ill or hypotensive individuals. It has been shown, for example, that intravenous

sodium HCO_3^- not only prevents the decreases in gastric intramural pH induced by hemorrhagic shock but also prevents mucosal ulceration.[45] Plasma HCO_3^- concentration also plays a key role in mucosal resistance to ulceration in experimentally induced canine gastric dilatation.[46] It has also been observed that the absolute amount of H^+ that diffuses into the tissue from the luminal solution is less important in causing ulceration than the ability of the tissue to dispose of influxing H^+ by neutralization with mucosal HCO_3^-.[47]

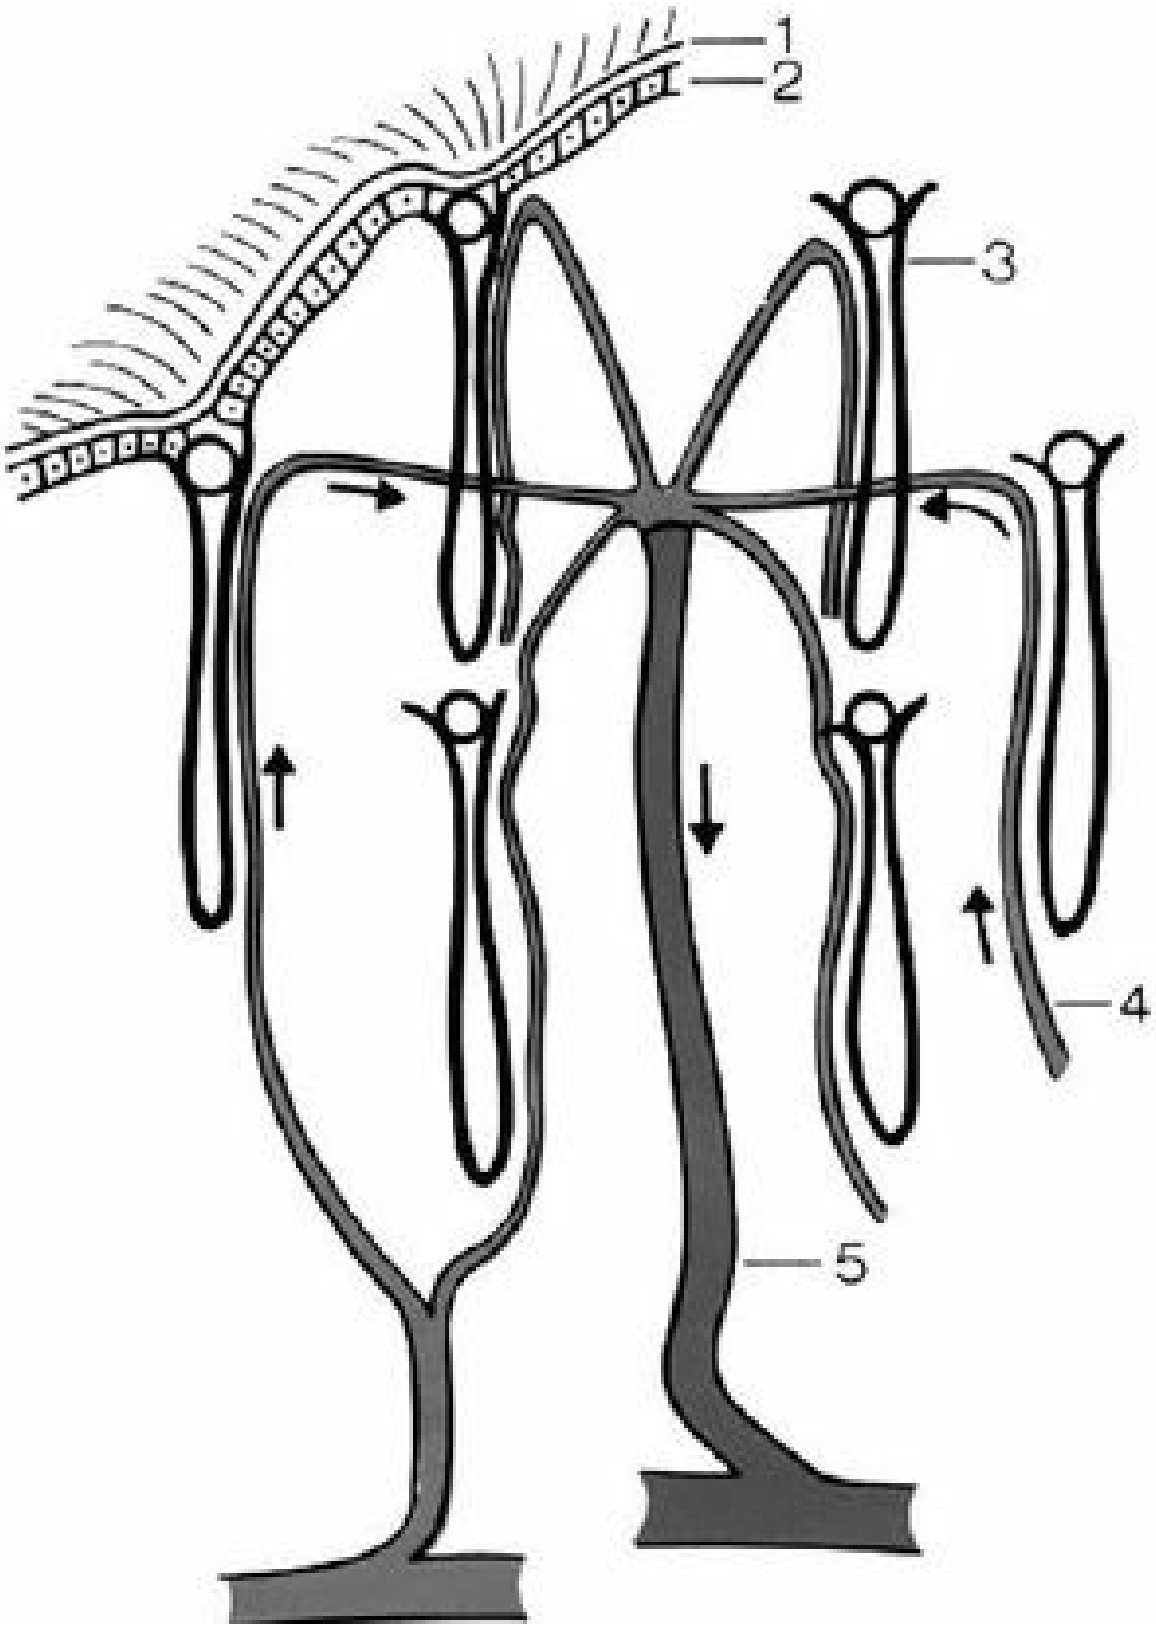

Figure 29-5. Three-dimensional view in the blood supply to the gastric mucosa. (From Miederer SE: The gastric mucosal barrier Hepato-gastroenterology

33:88-91, 1986, with permission of IASG.)

Gastric mucosal blood flow is regulated by constriction and dilation of submucosal arterioles. Smooth muscle in these arterioles constricts to inhibit mucosal blood flow under a variety of conditions, including hypotension, stress, and sepsis as well as in response to a variety of vasoconstricting drugs.[48,49] Prostaglandins, beta-adrenergic agents, and gastrin all increase mucosal blood flow and, thereby, reduce gastric mucosal damage. This is one of the mechanisms by which prostaglandins are thought to exert cytoprotection (see further on).[50]

Gastric Mucus and Mucus Secretion

The gastric mucosa is covered by a variable layer of mucus between 5 and 200 μm thick that is believed to play a multifactorial role in mucosal defense. Composed of various mucopolysaccharides, glycoproteins, and water, mucus is secreted by the mucus neck cells in the parietal glands and by the gastric epithelial cells themselves. Mucus occurs in two physical forms: water soluble and water insoluble. The water insoluble form is produced by the mucus neck cells and consists of a thin layer of stable gel that firmly adheres to the gastric mucosal surface. Adherent

mucus is impermeable to large proteins and thus protects the mucosa against peptic proteolysis. Water-soluble mucus comes from the surface epithelial cells, is less viscous, and acts as a lubricant to prevent mechanical damage to the mucosa. The adherent insoluble mucus provides a stable unstirred layer that traps secreted HCO_3^- to cause an alkaline interface between the surface and the lumen. Microelectrode studies showed a pH gradient within the mucus gel that varied somewhat among species and experimental conditions. The gradient peaks around 6.6 to 7.0 near the apical membrane.[9] More recent work has shown that this gradient may be only a part-time defender of the gastric

epithelium, however, present only when the luminal pH is 3 or below.[51,52] The ability of mucus to form a pH gradient by trapping HCO_3^- at the epithelial cell surface (Figure 29-7) provides a mechanism that is believed to reduce acid diffusion into the mucosa by neutralization with concomitant production of carbon dioxide and water.[53]

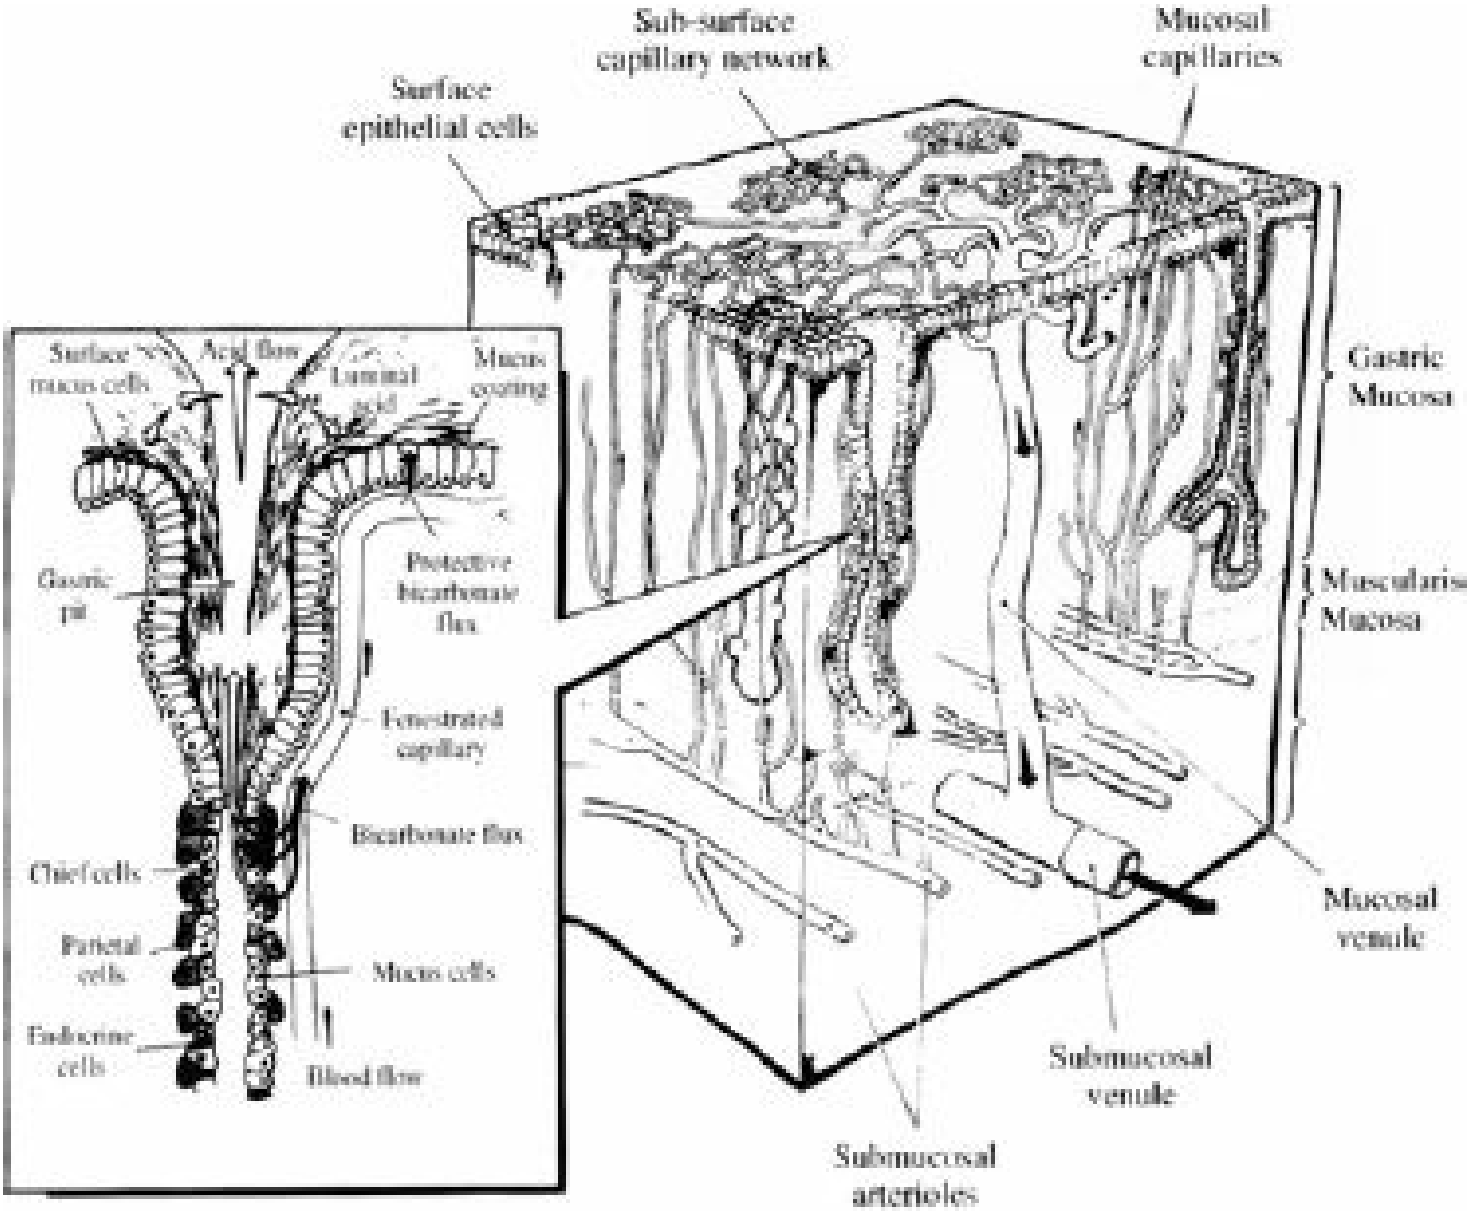

Figure 29-6. Schematic diagram of the vascular organization in oxyntic mucosa (right) and the proposed mechanism for vascular transport of bicarbonate toward the surface mucus cells from deeper within the mucosa (inset left). (From Gannon B, et al: Mucosal microvascular architecture of the fundus and body of the human stomach. Gastroenterology 86:866-875, 1984, with permis-sion of WB Saunders).

The neural emergency response system enhances mucus production after gastric injury. Mucus flows copiously out of the gastric glands and spreads over the mucosal surface to form a protective cap over the damaged area and restituting cells beneath.[21] Much of the mucus cap, however, comes from mucus in the disintegrating damaged epithelial cells themselves. Viscous mucus produced by the mucus neck cells in the upper regions of the gastric glands forms strands of thicker mucus that hold the cap in place. This facilitation of repair, by holding a HCO_3^- -rich cap over damaged areas while epithelial integrity is reestablished, is believed to be one of the most important functions of gastric

mucus.[54]

Various agents such as E-type prostaglandins, calcium, and glucagon

stimulate both gastric mucus and HCO_3^- secretion, whereas compounds such as NSAIDs and bile salts decrease them.

Prostaglandins and Cytoprotection

Prostaglandins are found in high concentrations in the gastric mucosa and gastric juice and have been shown to protect the gastric and duodenal mucosa against injury, a function that has been termed cytoprotection.[54] Prostaglandins are found in a variety of cells in the gastric mucosa including mast cells, macrophages, and endothelial cells and are synthesized locally from arachidonic acid via the

action of cyclooxygenase. Since Vane in 1971 showed that acetylsalicylic acid inhibits the cyclooxygenase system and thus the synthesis of prostaglandins, and hypothesized that this explained not only the therapeutic effects of acetylsalicylic acid but also its gastric side effects, there has been a tremendous amount of interest in the effect of prostaglandins on the stomach.[55] Prostaglandins promote mucosal defense through a variety of actions (Table 29-1), most important of which are the inhibition of acid output, augmentation of HCO_3^- and mucus secretion, and regulation of mucosal blood flow.[56,57] The wide range of effects of prostaglandins listed in Table 29-1 demonstrates their overall

importance in gastric mucosal protection. Their synthesis can also be stimulated by a variety of mild irritants, with subsequent protection against more severe damage.[56] A deficiency of prostaglandins can result in a mucosa that looks and functions normally but that is more susceptible to injury.[56]

Given the wide range of beneficial effects of prostaglandins, it is no wonder that exogenous stimulation by the synthetic prostaglandin misoprostol offers some protection against NSAID-induced mucosal damage. Various other compounds have also been shown to exert a protective effect, at least in part,

through stimulation of endogenous prostaglandin synthesis. These include sucralfate, arachidonic and linoleic acids, cimetidine, bismuth, and possibly, aluminum-containing antacids.[8,56] The hormone gastrin and salivary epidermal growth factor also have cytoprotective effects through a trophic effect on the gastric mucosa.[58] Even milk, the oldest ulcer remedy, has been shown to contain large quantities of PGE_2 and to protect against stress ulcers in rats.[59]

Basal Membrane

Destruction of the surface epithelial cells leaves the basement membrane exposed. This is permeable to alkaline proteinaceous tissue fluid, which exudes as part of the repair process. The basal membrane is the final barrier, however, and is essential as a surface for the spread of epithelial lamellipodia and associated reconstitution. Its destruction, which is heralded by the appearance of red blood cells on the mucosal surface,

leaves the path open for erosion and ulcer formation and invokes the inflammatory process.[7]

The Response to Injury and Gastric Disease

One of the basic tenets of gastric pathophysiology has long been that a break in the gastric mucosal barrier results in increased gastric mucosal permeability to hydrogen ions and loss of sodium ions into the lumen. Back-diffusion of acid into the mucosa has a variety of consequences, including the stimulation of parietal and chief cells to secrete more acid and pepsinogen.[23] This acid diffuses across the broken barrier, repeating the cycle and

exhausting intracellular and tissue buffers. Nerve endings are stimulated, invoking the neural emergency response system, which induces local smooth muscle contraction, and in humans at least, is associated with pain.[21] The decrease in mucosal pH also stimulates mucosal mast cells to release histamine and initiate an inflammatory response. This histamine stimulates the parietal cells to secrete even more acid and dilates precapillary sphincters, which increase mucosal blood flow through a prostaglandin-mediated response. Histamine is also believed to increase capillary permeability and to allow plasma protein and fluid to escape into the interstitium to cause local edema.

Rapid diffusion of acid into the mucosa can break down capillary walls and trigger hemorrhage (Figure 29-8). Events so far can be considered a virtually normal physiologic event because tiny superficial hemorrhages are sometimes seen during digestion of a meal. These, however, are transient and are quickly repaired. The same processes also occur in disease, but if the insult is non-physiologic, if it is widespread or ongoing, then the normal repair processes are inadequate, and gastritis, possibly with gastric hemorrhage and the signs of gastric disease, develops.

The gastric mucosal barrier is disrupted in virtually all types of gastric disease

(Table 29-2) as well as in a variety of other and perhaps less well appreciated situations (Table 29-3). Of concern in the development of overt gastric disease in this latter group are factors that may delay or impair either epithelial cell restitution or the repair process. Corticosteroids have been shown to delay epithelial cell renewal and, in high doses, to cause mucosal damage.[60-62]

Gastric mucosal injury is well documented in a variety of clinical situations in humans. It occurs for example, during severe stress, hypotension, sepsis, and uremia, as well as with severe burns, intracranial lesions, and bile reflux. It also occurs

after ingestion of certain agents such as alcohol, aspirin, or other NSAIDs.[8,48] Superficial erosions or ulcerations that develop in individuals who are victims of shock, trauma, burns, or sepsis, and especially, peritonitis are called stress ulcers (Table 29-4).[10] These are located primarily in the fundic mucosa and are superimposed on a background of erosive gastritis. It has been estimated that approximately 5% of patients who are the victims of shock, trauma, burns, and sepsis have major gastrointestinal hemorrhage during the course of their illness. Risk factors for gastric hemorrhage include hypotension, continued sepsis, jaundice, renal disease, and hypoxia.[63-65] Specific mechanisms for barrier

disruption and inhibition of the normal restitution and repair processes in these patients are unclear, but it is believed that mucosal ischemia with subsequent local acidosis is most important.[10]

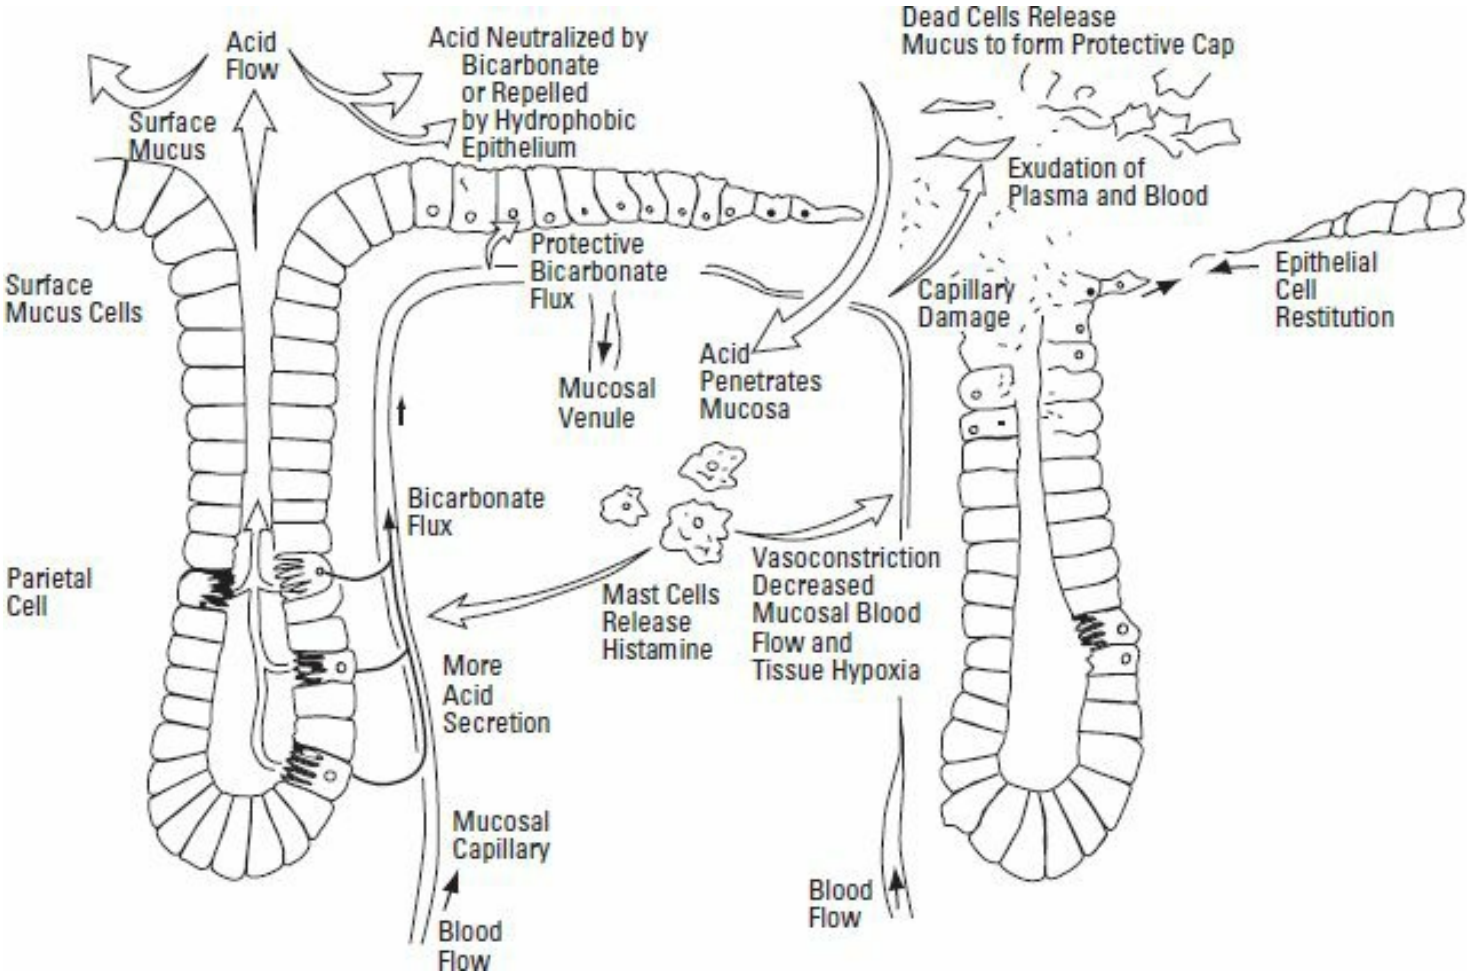

Figure 29-8. The normal gastric mucosal barrier (left) and the broken gastric mucosal barrier (right). The normal stomach is prevented from autodigestion by a

variety of physical and chemi-cal defense mechanisms. Acid production in the parietal cells results in concomitant production of bicarbonate. The acid diffuses out of the cell into the mucosa where it is picked up by the uniquely arranged capillaries that flow beside each gastric gland and carry the acid to the surface. The acid then diffuses out of the vessels into the mucosa and the surface epithelial cells. It diffuses from the epithelial cells into the lumen where it is trapped in surface mucus secreted by mucus neck cells. Acid that diffuses back into the mucosa is thus neutralized by the bicarbonate. The biocarbonate maintains the surface of the cells at a pH of about 7 in contrast to the pH in the lumen, which can be as low as 2.5. The epithelial cells also contain a high proportion of hydro-phobic phospholipids in the apical surfaces that also acts to repel acid. The cells have tight junctions that prevent intracellular acid flow. The mucosal blood flow also maintains good tissue oxygenation and local acid-base balance. Mucosal blood flow is under the influence of prosta-glandins, particularly PGE2, which is produced by a variety of mucosal cell types. When the mucosa is damaged, mucosal cells rupture and release mucus that forms a protective cap. This cap protects

undamaged cells at the periphery of the lesion that change shape and cover the lesion by growing over the basement membrane, a process called restitution. Acid in the mucosa over-whelms local buffering capacities and causes cell death and the release of histamine from mucosal mast cells. Histamine augments acid secretion from parietal cells and causes constriction of smooth muscles in blood vessel walls that diminishes mucosal blood flow and exacerbates tissue damage. Mucosal blood flow can also be disturbed by stress-induced submucosal vasoconstric-tion. This process also removes tissue buffer capacity and disrupts the barrier. (From Burrows CF: Vomiting and regurgitation in the dog. Viewpoints in Veterinary Medicine, 1990, with permis-sion of ALPO Pet Center, ALPO Petfoods Inc., Pennsylvania.)

Gastric mucosal injury and ulceration under such circumstances are less well documented in veterinary medicine, although clinical impression and anecdotal reports suggest that they may be much more widespread than is generally realized. Gastric hemorrhage occurred in 90% of dogs undergoing spinal surgery combined with administration of methylprednisolone sodium succinate.[66] In the dog, ulcers have been associated with peritonitis and liver disease,[67] with protein-calorie malnutrition,[68] and gastric

erosions and hemorrhage with hypoadrenocorticism.[69] Gastroscopy in animals with such diverse conditions as peritonitis, hypoxia, pneumonia, chronic vomiting, systemic mastocytosis, liver disease, pyometra, feline infectious peritonitis, carcinomatosis, pancreatitis, and antral mucosal hypertrophy has revealed the presence of often severe and yet clinically unsuspected erosive gastritis with hemorrhage or frank ulceration (Burrows, unpublished observations).

Aspirin and other NSAIDs are notorious for the damage they cause to the mucosal barrier. This damage is achieved in a variety of ways,

including damaging the mucosal cell membrane and enhancing mucosal cell permeability; inhibiting active mucosal ion transport; producing changes in mucosal blood flow; decreasing mucus production; and inhibiting prostaglandin synthesis.[70] Of all of these, the impact on prostaglandin synthesis through the inhibition of COX may be the most important. After Vane[55] showed that NSAIDs inhibited COX, the next great step in our understanding came in the early 1990s with the demonstration that COX had two isoforms: COX-1, which was constitutively expressed; and COX-2, which was inducible.[71] COX-2 is rapidly up-regulated at inflammatory sites and is responsible for the

formation of pro-inflammatory prostanoids. COX-1 is responsible for the production of physiologically relevant prostanoids such as those in the stomach and platelets. Pharmacology defined the selectivity of existing NSAIDs on these COX enzymes and played a key role in producing a new generation of COX-2-selective drugs. These drugs would, it was hoped, have much reduced toxic side effects, particularly on the stomach.[71] COX-2, however, also has a physiologic role, being involved, for example, in the maintenance of fluid balance by the kidney. The COX-1 and -2 models, however, did not fully explain the antipyretic and analgesic effects and non-anti-inflammatory effects of

acetaminophen. This might be explained by a variant of COX-2 now named COX-3.[72,73] The proposed pathways are shown in Figure 29-9. Different NSAIDs have different effects on the gastric mucosa but are most severe when the drugs are administered orally. Parenteral NSAIDs also have an effect, however. Much of the local effect perhaps can be attributed to the action of some NSAIDs, especially aspirin, in the acid milieu of the stomach to damage the hydrophobic lipid layer,[41] whereas the systemic effect is a result of the inhibition of COX.

Although all NSAIDs cause gastric mucosal damage, there is a wide interspecies susceptibility to specific drugs that may be associated with varying susceptibility of COX to different NSAIDs and to different metabolic pathways (Table 29-5). Aspirin, flunixine, and phenylbutazone for example, seem relatively well tolerated in the dog, although aspirin at a dose needed to obtain analgesic blood levels still causes gastric hemorrhage.[74] Wide individual susceptibility also exists. Flunixine, for example, appears to be relatively well tolerated over the short term in most dogs but caused severe ulceration after only 2 days of treatment in an apparently susceptible patient

(Burrows, unpublished observations). These drugs, therefore, should always be used with caution because we currently have no means of identifying susceptible individuals. Other NSAIDs should never be used in veterinary medicine. Indomethacin and naproxen for example, cause severe, often fatal gastric and duodenal ulceration and hemorrhage in the dog.[75-78]

Facilitation of Barrier Repair

One of the basic tenets of medicine is that, in order to diagnose a disease, one has first to suspect it. The purpose of this chapter is to alert the reader to the possibility that gastric mucosal

disease may be present not only in a variety of gastric diseases (Table 29-2) but also in a wide range of other disorders (Table 29-3). Recognition and appropriate treatment of barrier disruption may well reduce patient morbidity and mortality.

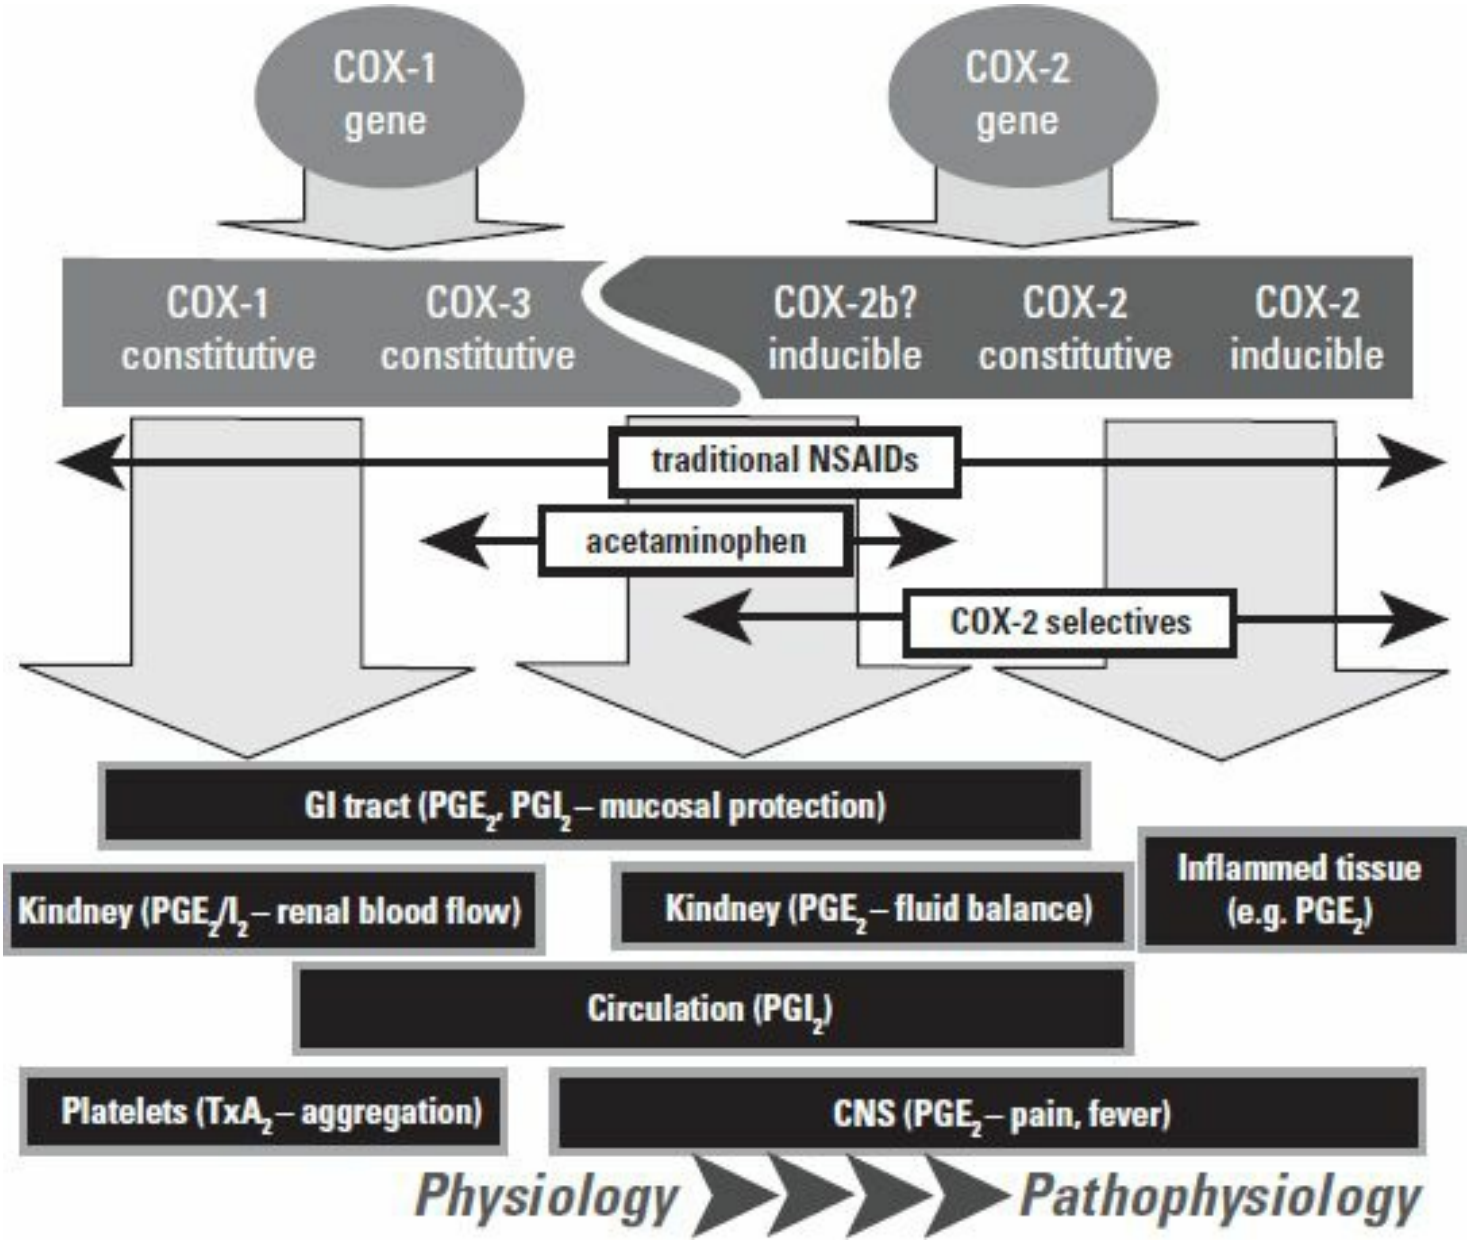

Figure 29-9. Current concept of the differing and overlapping roles of COX-1, COX-2, and proposed COX-3. Two distinct genes for COX-1 and -2 may give rise to a number of constitutive and inducible COX proteins with overlapping functions. Considering prostanoid production by a COX continuum may help us appreciate which enzymes underlie prostanoid production in different tissues as well as the actions of

traditional NSAIDs, newer COX-2-selective drugs, and acetaminophen (COX-3 or COX-2b). (From Warner TD, Mitchell JA: Proc Natl Acad Sci 99(21):13371-13373, 2002, with permission. Copyright 2002 National Academy of Sciences, USA.)

Table 29-5. Drugs that Affect the Gastric Mucosal Barrier

Negatively	Positively
Corticosteroids	Misoprostol
Aspirin	Sucralfate

Indomethacin	Omeprazole
Flunixine	Bismuth sub-salts

Phenylbutazone	Aluminum salts
Alcohol	Linoleic and arachidonic acids

In dealing with the broken barrier, one first has to identify and, if possible, treat the underlying disease. All other actions are of secondary but nevertheless still considerable importance. Much of the mucosal damage comes from secreted acid, and one of the most important therapeutic approaches is to reduce acid output. This can be accomplished, at least to some extent, by dietary manipulation and, more importantly, by antisecretory drugs. Mucosal repair is also facilitated by a variety of

cytoprotectants that protect the damaged mucosa from further acid damage.

As in most species, food is a potent stimulus to gastric secretion in the dog and cat. Since these species have little or no basal acid output, however, mucosal repair in many acute diseases may be facilitated by withholding food for 24 to 48 hours. Afterward, avoiding high-protein meals and providing frequent feedings in small quantities to reduce acid output may also be useful. This constitutes only supportive care, however, and most patients require additional antisecretory or cytoprotective drug therapy.

Antisecretory Drugs

The old maxim "no acid no ulcer"[79] is as true today as it ever was. A variety of substances can be used to reduce acid output but most widely used are the H_2 receptor antagonists and proton pump inhibitors (PPIs). Cimetidine, famotidine, and ranitidine are most widely used H_2 receptor antagonists in veterinary medicine. These drugs combine with the histamine receptors on parietal cells to inhibit histamine-stimulated secretion. They inhibit not only the acid secretory response to histamine, but also the response to cholinergic agents, gastrin, food, and vagal stimulation.[12] Their use should perhaps be routine as prophylaxis

against mucosal injury in critically ill or stressed patients (Tables 29-3 and 29-4). Cimetidine is ineffective against aspirin-induced mucosal injury in the dog,[80] probably because in partly reducing acid synthesis, cimetidine also reduces HCO_3^- production and subsequent mucosal buffering.[70] Famotidine at a twice-daily dose appears to be the most effective drug in this class at reducing gastric acid secretion in the dog.[81]

The PPIs (e.g., omeprazole, pantoprazole, lansasoprole, esomeprazole) block the Na^+H^+-ATPase in the parietal cell in its secretory state. They are the most effective of the available drug classes

in blocking acid secretion and are indicated in a spectrum of severe gastric diseases.[82] One study has shown that pantoprazole and omeprazole are effective in reducing acid secretion in dogs. Twice-daily dosing of omeprazole was the only regimen tested, however, that approached the potential therapeutic efficacy for acid-related disease when assessed by criteria used for human patients.[81] Omeprazole given once daily lessened aspirin-induced gastritis in the dog.[83] No data have been published for cats.

Cytoprotectants

Cytoprotection is defined as protection against gastric mucosal injury by a

mechanism other than inhibition or neutralization of acid secretion.[84] Cytoprotective drugs include the synthetic prostaglandins, sucralfate, aluminum-containing antacids, bismuth compounds, and carbenoxolone (Table 29-5). It is possible that cimetidine also exerts some of its protective effect through this mechanism. In general, cytoprotective drugs promote the mechanisms responsible for maintaining a normal barrier, including increased mucus and HCO_3^- secretion, increased mucosal blood flow, promotion of apical cell restitution, phospholipid synthesis, and maintenance of vascular permeability to HCO_3^-.

Misoprostol and sucralfate are the most widely used cytoprotectants. Misoprostol, a synthetic prostaglandin that is effective when given orally, reduces the gastric mucosal side effects of NSAIDs. Sucralfate is a complex polymer of sucrose with multiple substitutions of aluminum sulfate. At a pH of less than 4.0 in the stomach, this compound undergoes a change in chemical configuration, develops a positive change, and binds electrochemically with negatively charged proteins leaking from the damaged mucosa.[85] In so doing, it forms a protective barrier over the damaged mucosa. The drug appears to be most useful in veterinary patients with gastric mucosal disease and was

shown to be effective in lessening aspirin-induced gastritis.[83] It binds cimetidine, however, and the two drugs should not be given orally at the same time. Cimetidine, sucralfate, and misoprostol were ineffective in prophylaxis of gastrointestinal bleeding in dogs undergoing spinal surgery after having received methylprednisolone sodium succinate.[66] Omeprazole or pantoprazole may be more effective in these patients.

In conclusion, it should be appreciated that barrier disruption can occur under a wide variety of disease conditions. It should be considered as a complicating factor in most, if not all, critically ill

patients. Mucosal protection therefore should be a routine part of therapy in such patients.

Chapter 30

Gastric Outflow Obstruction

Ronald M Bright

Anatomy and Physiology

The stomach is an unequal dilatation of the foregut, which extends as a J-shaped loop from below the esophagus and diaphragm in the upper left abdominal quadrant to the duodenum in the upper right quadrant.[1] The greater curvature of the stomach, facing caudally, is located mostly to the left of the midline. The lesser

curvature faces cranially and is accentuated when the stomach is empty. The distal stomach is somewhat immobilized by the hepatogastric and hepatoduodenal ligaments. Within these structures are the common bile duct, the hepatic ducts, and the portal vein.

The stomach is divisible into four parts. The cardia is immediately distal to the gastroesophageal junction below the diaphragm. It blends into the fundus, which provides receptacle and storage functions and, along with the body, is the most expandable portion of the stomach. The cardia, body, and fundus comprise approximately two thirds of the proximal stomach. The fundus and

body are histologically indistinguishable from each other. The pyloric antrum forms the remaining third of the stomach and leads into the pyloric sphincter. The mucosa of the body and fundus is rugose. The mucosa-submucosa are loosely attached to the underlying muscle, making it somewhat mobile. The antral mucosa contains fewer rugal folds and is flatter. The mucosa-submucosa are more firmly attached to the underlying muscle. When the stomach is empty, the rugal folds are most distinct.

The muscle layers of the stomach contain an outer layer of longitudinally arranged muscle fibers, an oblique layer, and deep to this are

circularly arranged muscle fibers. The latter are plentiful in the antrum because of its important function of grinding, retropulsing, and emptying of gastric contents. The pylorus is a thickened continuation of the circular smooth muscle, which, along with its mucosal lining, forms an intraluminal bulge that can be palpated. The pylorus is considered a true antatomic sphincter owing to these abundant circular muscle fibers that encircle it.[2]

The blood supply to the stomach is by way of the celiac artery and some of its branches. The left and right gastroepiploic arteries primarily nourish the greater curvature, whereas the lesser curvature is supplied by the

right and left gastric arteries, which eventually anastomose. Venous drainage is accomplished by the gastrosplenic and gastroduodenal veins emptying into the portal vein.

The proximal stomach serves a reservoir function and expands greatly in response to liquid and food. “Receptive relaxation” of the fundus and body of the stomach is induced when the animal swallows, resulting in decreased motor activity and pressure.[2] Gastric accommodation follows as pressure begins to increase within the fundus.

The primary role of the fundus is to empty liquids without allowing any

modest change in the pressure within the fundus to raise intragastric pressure. Partial or complete removal of the fundus will raise the intragastric pressure more readily, however, resulting in an increased rate of emptying of liquids. This has no effect on the rate of emptying solids.[3]

The distal stomach is primarily responsible for grinding, filtering, and propelling solid food until it reaches a particle size of 1 to 2 mm in diameter. Even after antrectomy, up to 60% of emptied particles are smaller than 1 mm.[3]

In the fed state, peristaltic waves occur at a rate of 4 to 5 per minute, which

helps propel the food toward the pylorus. The pylorus, as a "gate-keeper," is responsible for keeping material in the stomach until it reaches the appropriate particle size.[4] When the smaller particles begin to move aborally, the pylorus is partially relaxed and emptying occurs. Near the end of each antral contraction, the pylorus closes, forcing the larger particles to be retropulsed back into the antrum and body of the stomach so grinding can continue.

In the fasted state, the stomach and intestine alternate between quiescent time and short times of intense myoelectrical activity.[5] This results in vigorous aboral contractions and forms

the migrating motor complexes, which extend through the entire intestinal tract. In the dog, this occurs every 2 to 3 hours. This is the period when nondigestable materials and cellular debris move out of the stomach. Antral contractions are stronger during the fed state and when relaxation of the pylorus is at its maximum.

The pylorus, besides regulating the size of particles that leave the stomach, is also responsible for limiting the amount of duodenogastric reflux.[4,6,7] It is known in dogs that bile, pancreatic juice, and intestinal contents have a deleterious effect on the gastric mucosa.[7] The amount of duodenal material inside the stomach depends

on the rate and volume of duodenogastric reflux and the rate at which regurgitated material is removed from the stomach. Duodenogastric reflux is a common phenomenon and is not affected by the type of meal.[6] However, if gastric emptying is delayed, the reflux rate is stimulated, which may result in an erosive gastritis or ulcer formation.[6,7]

Similarly, when surgery of the pyloric sphincter or resection of the pylorus has occurred, the reflux of bile and pancreatic and intestinal secretions may increase. These secretions may be innocuous in some animals, but in others, reflux gastritis or bilious vomiting may occur. This is termed

postoperative alkaline reflux gastritis.[8]

Gastric outflow obstruction is most often caused by mural, mucosal, and luminal abnormalities. Foreign bodies can produce either partial or complete obstruction as can inflammatory diseases caused by eosinophilic gastritis, fungal gastritis, chronic gastric ulcer disease, and neoplasia, most notably, adenocarcinoma. Suture-induced granuloma following pyloric surgery has also been reported.[9] Gastric volvulus, seen primarily in large or giant breeds, can result in outflow problems as well.

Vomiting is the most frequent sign seen with gastric outlet problems. The

normal stomach is usually empty within 8 to 10 hours after eating. Vomiting after this time suggests a gastric retention disorder.[4]

The content of the vomitus may be bile and mucus when vomiting occurs on an empty stomach. This may suggest a duodenogastric reflux problem or gastric hypomotility. Conversely, in the absence of bile, the presence of nondigested material 12 to 24 hours after eating would suggest an outflow obstruction problem.[4]

Pyloric Stenosis (Congenital)

This condition is primarily seen in

brachycephalic breeds and in the Siamese cat. This stenosis results from hypertrophy of the circular smooth muscle of the pylorus. Signs are usually not seen in the first 6 to 8 weeks of age. They appear when the animals are weaned and begin to take solid food. The difficulty of emptying solid food is the hallmark of this disease. Gastrin and its effects on the smooth muscle of the pylorus have been implicated but the mode of inheritance and exact pathogenesis are unknown.[5] Pentagastrin, a gastrin analogue, has been given to pregnant animals, resulting in pyloric stenosis in the neonate as a result of hypertrophy of the muscle. Surgery is necessary to correct this problem. Pyloromyotomy

carries little risk and is accompanied by good results.[10,11]

Acquired Antral Pyloric Gastropathy

The acquired form of antral pyloric stenosis usually results from dramatic hypertrophic changes to the mucosa and, occasionally, to the circular smooth muscle as well. Type I hypertrophy involves the muscle; type II, the combination of muscle and mucosa; and type III, the mucosa.[7] Benign inflammatory infiltrates are commonly seen on biopsy samples. Grossly, these masses can resemble polyps. They can be smooth-surfaced or slightly lobulated. Some are

somewhat sessile and can be single or multiple and confined to the antrum.

This acquired form of hypertrophy is typically seen in middle-aged small breeds, in which progressive vomiting is the most common clinical manifestation. The vomiting can be delayed up to 24 hours after eating, and it is not uncommon to see the absence of bile and undigested food in the vomitus. Melena and/or hematemesis would indicate erosive gastritis or ulcer disease that can also contribute to gastric emptying delays.

The treatment of choice is some type of pyloroplasty with resection of the hypertrophied polypoid-like masses

(Figure 30-1).[10] The prognosis following surgery is good, with early return to normal gastric emptying. Any hypomotility that persists will usually respond to short-term use of a prokinetic agent.

Bilious vomiting following surgery may indicate an excessive amount of duodenogastric reflux caused by the pyloric operation. Sucralfate (Carafate, Hoechst Marion Roussel), systemic antacids and feeding a small meal before bedtime may be necessary on a short-term basis or indefinitely.

Figure 30-1. This intraoperative photo demonstrates the polypoid-type masses that are often seen in cases of antral mucosal hypertrophy.

Neoplasia

Gastric neoplasia is rare in the dog and no cause is known. Adenocarcinoma is the most common malignant tumor in

dogs and it can manifest as an ulcerated mass, polypoid in appearance or scirrhous in nature.[12] Other gastric tumors include lymphosarcoma, (most common in cats), leiomyoma/sarcoma, and adenomatous polyps.[12]

Any of the gastric tumors can cause partial or complete gastric outflow obstruction (Figure 30-2). They can also result in gastric ulceration or altered gastric motility.

As is typical of any mass obstructing gastric outflow, progressive vomiting is the predominant sign. Hematemesis and melena are commonly seen with adenocarcinomas owing to their

frequent ulceration.

Foreign Bodies

Foreign bodies are the most common cause of gastric outlet obstruction in dogs and cats. Vomiting is the sign most often observed and, if the foreign body is sharp-edged, hematemesis may be seen. Many foreign bodies can pass through the pylorus during the interdigestive period owing to the migrating motor complexes. Ideally, foreign bodies can be retrieved by means of endoscopy, with surgery serving as a viable option if this is not possible.

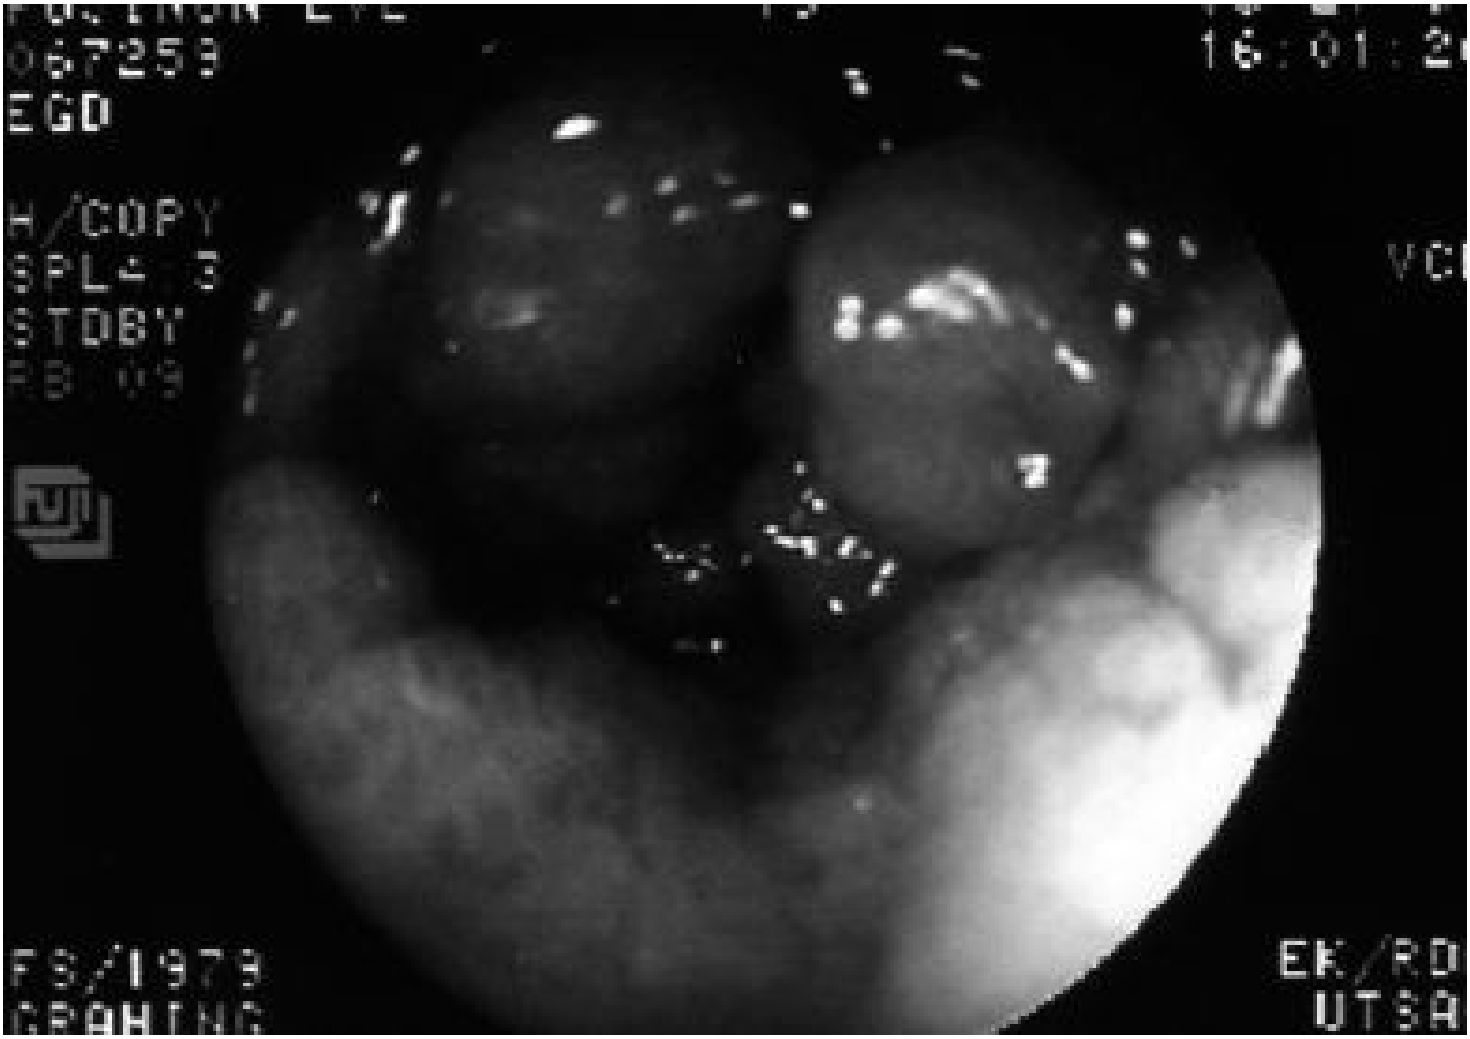

Figure 30-2. These multiple masses were diagnosed as adenocarcinoma based on biopsies taken endoscopically. Gastric outlet obstruction was almost complete in this case.

Miscellaneous

Other causes of chronic intermittent vomiting include granulomatous conditions caused by Phythium and

rarely, eosinophilic gastritis.[5] Fungal diseases are most commonly seen in the Gulf Coast states, affecting primarily male large-breed and younger dogs. The granulomas that form in the submucosa and muscularis mucosae are caused by the penetration of ingested spores that eventually enter the lymphatics.[5]

Eosinophilic gastritis can stimulate a large amount of granulation tissue to be formed anywhere in the stomach. If this lesion is large enough and present in the antrum, it can cause serious gastric emptying problems. This disease may be immune-stimulated.[13] These granulomas, when viewed grossly with endoscopy or during

surgery, are indistinguishable from neoplastic lesions.

Extraluminal lesions can encroach on the antrum and, therefore, interfere with gastric emptying. Ultrasonography is usually helpful in distinguishing these lesions from intraluminal ones. Depending on the origin of the mass, systemic involvement may also occur.

Important causes of gastric emptying problems that can be confused with some type of mechanical obstruction are motility disorders. This is not well documented in dogs and cats and the diagnosis is usually made based on delayed gastric emptying in the

absence of an obstructive lesion.[13]

Trichobezoars in cats may be caused by the lack of migrating motor complexes. Emptying of any type of foreign material in the stomach of a cat, therefore, may be impaired.[13]

Hypomotility disorder may occur in dogs that have survived an acute gastric-dilatation-volvulus episode. This may be associated with a large and flaccid stomach, which has been observed during acute gastric-dilatation-volvulus surgery. The vomiting associated with this is presumed to be related to delayed gastric emptying because response to a prokinetic agent is favorable. Long-

term use of a prokinetic agent may be necessary in some instances.

Metabolic problems, although not as well documented in animals as in people, may delay gastric emptying. These include hypokalemia, diabetes mellitus, hypothyroidism, uremia, and hepatic encephalopathy.[13]

Perioperative Considerations

Regardless of the cause of gastric outflow obstruction, serious metabolic consequences can result from chronic and frequent vomiting that may accompany a gastric emptying disorder. Dehydration and metabolic

alkalosis with its accompanying electrolyte imbalances (hypochloremia, hypokalemia) should be corrected when possible before any surgical intervention.

A large, distended, fluid-filled stomach can present a serious risk to any animal undergoing anesthesia and/or surgery. These animals are at a greater risk of gastroesophageal reflux that could lead to an aspiration pneumonia or reflux esophagitis. Immediately after induction of anesthesia, an orogastric tube with a suction device attached should be passed into the stomach to remove it contents. In addition, a prokinetic agent and systemic antacid can be used during

the perioperative period to decrease the risk of potential problems related to reflux of gastric contents.

Chapter 31

Pancreatitis

Craig B. Webb
Jacqueline C. Whittemore

The diagnosis of severe acute pancreatitis carries with it a mortality rate of up to 50% in humans.[1] Although alcohol consumption and biliary disease (the two most common causes of pancreatitis in humans) are uncommon in veterinary patients, the underlying cellular pathophysiology is likely to be similar between species, and starts with premature activation of

digestive enzymes within pancreatic acinar cells. Despite extensive research into the inflammatory mediators that promulgate the systemic effects of pancreatic inflammation, advances in treatment of the disease beyond pancreatic rest and nonspecific supportive care have been minimal. Pancreatitis in veterinary patients remains predominantly a medical disease unless a specific mass (e.g., a tumor, pseudocyst, or abscess) or structural defect (i.e., biliary obstruction) can be identified.

Physiology

The exocrine pancreas produces zymogens, pancreatic secretory trypsin

inhibitor (PSTI), and active enzymes (lipase, amylase, and the pro-coenzyme, procolipase). The zymogens include trypsinogen, chymotrypsinogens, kallikreinogen, proelastases, procarboxypeptidases, and prophospholipase A_2. Zymogen granule secretion is the result of both neural and humoral mechanisms. Secretin and cholecystokinin (CCK) are believed to be the most important humoral mediators in stimulating zymogen secretion in dogs and cats. Trypsin is the only enzyme capable of activating itself and the other zymogens. This activation is largely controlled by the local calcium concentration. At a low calcium concentration, as is found within

acinar cells, calcium binding protects the trypsinogen activation peptide from exposure. Increased calcium concentration, as is found in the pancreatic ducts and intestine, increases the sensitivity of trypsinogen to activation by trypsin. The lysosomal granules within exocrine pancreatic cells contain proteases, including cathepsin B, which can activate zymogens on contact.

Protective mechanisms that decrease the risk of premature zymogen activation include the inclusion of PSTI with zymogens, the segregation of zymogens within lipid structures, and the maintenance of high alkaline ductular flushing. Ductular PSTI

protects the pancreas by binding to the active site on trypsin to prevent further zymogen activation.[2] Alkalinity is maintained by bicarbonate secretion through the cystic fibrosis transmembrane conductance regulator (CFTR).[3] The association of pancreatitis with CFTR mutations in humans emphasizes the importance of ductular bicarbonate secretion as a protective mechanism.[3] Duodenal brush border cells produce enterokinase, a strong protease that is responsible for zymogen activation within the intestinal lumen. This site-specific production of enterokinase helps ensure activation of zymogens within the intestinal lumen while limiting the risk of zymogen activation

within the pancreas. Muscle sphincters in the pancreatic ducts help prevent reflux of enterokinase and duodenal contents into the pancreas, which is particularly important as enterokinase is not inactivated by PSTI and does not form complexes with anti-proteases.

Low levels of circulating exocrine pancreatic enzymes are commonly present in plasma and are cleared through the kidney. Circulating zymogens are bound by circulating enzyme inhibitors, α1-antitrypsin and α2-macroglobulin, which decrease their activity and increase monocyte-macrophage clearance, respectively.

Pathophysiology

Pancreatitis is a multifactorial process that eventually culminates in inappropriate activation of zymogens within the pancreatic parenchyma. In most patients, this is likely the result of abnormal fusion of lysosomal and zymogen granules within the acinar cells. A small subset of veterinary cases, like a large percentage of human cases, may be a result of inappropriate duodenal reflux into the pancreas.[4] The conversion of trypsinogen to trypsin starts a self-perpetuating cascade of zymogen activation with resulting auto-digestion of the pancreas and surrounding tissues. Endothelial membrane damage and increased capillary permeability lead to pancreatic edema, decreased

microvascular circulation, increased free radical accumulation, and local ischemia.

As proteolytic enzymes propagate, they may overwhelm circulating anti-proteases and activate inflammatory cascades. The result may be refractory hypotensive and vasoactive shock, disseminated intravascular coagulation (DIC), multiple organ dysfunction syndrome (MODS), and death.[5] Pancreatic abscessation and pseudocysts may form in severe cases. Pancreatic pseudocysts are collections of pancreatic secretions that form secondary to fibrosis or inflammation.[6] Pancreatic abscessation may also occur and is usually sterile.[7] Both may

require surgical intervention for successful outcomes.

In humans, defects in the trypsinogen, PSTI, and CFTR genes are associated with hereditary pancreatitis.[2] It is currently unknown whether there are specific hereditary causes of pancreatitis in dogs or cats, although terriers, miniature Schnauzers, and Siamese cats are over-represented.

Classification

Pancreatitis can be classified as either acute or chronic, and either form may be mild or severe. Acute pancreatitis is a completely reversible condition, despite the fact that this is often the more severe manifestation of the

disease. In the cat, acute pancreatitis is further delineated as either acute necrotizing or acute suppurative disease.

Chronic pancreatitis entails irreversible histopathologic changes, including fibrosis and acinar atrophy with lymphoplasmacytic inflammation, although this form is often mild and subtle in its clinical presentation. Mild pancreatitis is associated with minimal systemic effects and low mortality. The pancreas may be edematous or show mild interstitial changes but the condition is rarely associated with necrosis of acinar cells. Severe pancreatitis is often associated with extensive pancreatic necrosis,

hemorrhagic changes or suppurative inflammation, multiple organ involvement, and a poor prognosis.

Etiology and Examination Findings

Known or suspected risk factors for canine pancreatitis include breed (terriers, miniature Schnauzers), age (older than 5 years), concurrent endocrine disease (diabetes mellitus, hyperadrenocorticism, hypothyroidism, and hypertriglyceridemia), hypercalcemia, obesity, gastrointestinal disease, drugs (sulfonamides, azathioprine, L-asparaginase, estrogen, furosemide, potassium bromide, salicylates,

tetracyclines, thiazide diuretics, and vinca alkaloids), toxins (cholinesterase inhibitor insecticides, cholinergic agonists, and zinc), epilepsy, infection, ischemia, and blunt abdominal trauma.[8] Glucocorticoids are no longer considered a risk factor for development of pancreatitis in humans; little support exists for an association between glucocorticoids and pancreatitis in either dogs or cats. Risk factors in cats include breed (Siamese), age (older than 7 years), trauma, and concurrent disease (hepatic lipidosis or diabetes mellitus).[4,9-11] Triaditis refers to concurrent inflammatory bowel disease (IBD), cholangiohepatitis, and pancreatitis. Feline cases may be

caused by feline infectious peritonitis, toxoplasmosis, and liver or pancreatic flukes (*Erythremia procyonis, Amphimerus pseudofelineus,* or *Opisthorchis felineus*).[4,12]

Clinical signs in dogs include weakness, anorexia, vomiting, diarrhea, abdominal pain, fever, and collapse. Signs in cats include lethargy, anorexia, dehydration, and jaundice. Vomiting and diarrhea are uncommonly associated with feline pancreatitis; mild weight loss or atypical behavior may be the only clinical signs in this species. Findings on physical examination include dehydration, abdominal pain, icterus, tachycardia, tachypnea, fever or

hypothermia, or the presence of an abdominal mass. In some animals, particularly cats, physical examination may be unremarkable.

Sequelae

The inappropriate activation and release of digestive enzymes have a number of systemic consequences. Direct injury to the pancreatic parenchyma results in cellular necrosis and the progression of the disease from edematous to hemorrhagic and/or necrotic pancreatitis. A variety of cascades are activated that cause systemic dissemination of the deleterious consequences of pancreatic inflammation. These include the

kinin/coagulation cascades, the fibrinolytic, and the complement systems. A variety of inflammatory mediators are released that can quickly turn pancreatitis into a condition affecting multiple systems; free radicals released from neutrophils and macrophages also contribute to the adverse systemic consequences. Vascular injury leads to increased capillary permeability and activation of vasoactive amines. Effects can be significant fluid and protein loss, decreased blood flow to vital tissues, dehydration, hypovolemia, and shock. Plasma protease inhibitors are consumed; protease digestion of clotting factors may worsen shock and lead to DIC. In humans the cardiac

system is particularly susceptible to the systemic signals set in motion by pancreatitis. Renal, pulmonary, and hepatic changes are the result of direct contact with digestive enzymes or secondary to altered blood flow and oxygen delivery. Hepatocellular necrosis, bile duct obstruction, pulmonary edema, acute renal failure and tubular degeneration, fibrosis, and clotting disorders are all recognized sequelae of pancreatitis in human patients.

Chapter 32

Pathophysiology of Hepatocellular Diseases

Pierre M. Amsellem
David C. Twedt

The liver is the largest solid organ and is involved in many critical metabolic functions of the body. It is important in metabolism, having a central role in synthesis, detoxification, excretion, and storage as well as host defensive mechanisms. The liver is also unique because of its dual blood supply

derived from the portal vein and hepatic artery. The portal blood with its low oxygen tension provides approximately 70% to 75% of the hepatic blood flow to the liver. Disruption of liver function or circulation can have serious consequences to the patient. Lastly, the liver has the unique ability to regenerate. For example, following removal of one lobe, the liver will quickly regenerate to its original size. When dealing with the surgical patient, it is critical to understand basic liver function and to recognize conditions affecting the liver.

Identification of Liver

Disease

The clinical history and physical examination may provide some insight to the presence of liver disease, but generally, the diagnosis of liver disease or circulatory disorders of the liver largely depends on combined information obtained from clinical findings, laboratory testing, ultrasonography, and histopathologic evaluation. Identification of abnormal liver enzymes or liver function tests such as bile acids, albumin, glucose, ammonia, and bilirubin indicate that the liver should be first investigated. It is important to point out, however, that the liver is also frequently a so-called “innocent by-stander,” being

affected by many non-hepatic metabolic or systemic disorders. Such hepatic changes are often referred to as reactive hepatopathies and rarely do they significantly alter hepatic function. Examples include certain drugs, endocrine disease, cardiovascular conditions, or intraabdominal disorders such as pancreatitis or inflammatory bowel disease.[1] Consequently, non-hepatic conditions and drug-associated liver dysfunction should be excluded first in the diagnostic work up before a primary investigation of the liver begins.

Radiographs will reveal liver size and shape and may aid in detecting other

intraabdominal disorders. Ultrasonography is useful to detect parenchymal, biliary, and vascular abnormalities.[2] Hepatic cells for cytologic investigation are frequently obtained during ultrasonography using fine-needle aspiration; they may provide some useful information about the liver. Cytologic evaluation, however, is limited in the amount of information it can give. The best cytologic correlation with histopathologic findings is found with hepatic neoplasia and diffuse vacuolar disease.[3]

The definitive diagnosis of biliary or parenchymal disorders generally requires histopathologic evaluation.

Histopathologic samples are obtained by needle biopsy, laparoscopy, or surgery. Each technique has certain advantages but also inherent limitations. For example, a needle biopsy is the least invasive but a core needle biopsy sample only represents one fifty-thousandth of the entire liver. It is recommended that at least 3 core biopsies of 16 g each be obtained from the liver to get an adequate quantity of tissue for interpretation.[4] The diagnostic accuracy of a needle biopsy is highest with diffuse hepatic disease. Laparoscopic or surgical wedge biopsies can be visually directed and provide larger pieces of tissue for examination. Laparoscopy is considered to be minimally invasive,

but it is limited in that it is difficult to view the entire liver surface. The advantage over needle biopsies is that larger and more diagnostic samples are obtained when compared with the smaller needle biopsies.[5] Surgery, although more invasive, allows one to evaluate all liver lobes and obtain large samples with good hemostasis. In the appropriate clinical situations, liver culture and or hepatic copper analysis should be obtained on a liver biopsy sample.

Metabolic Considerations

Response to Injury

The liver can respond to an injury in only a limited number of ways.

Reversible hepatocyte injury includes hepatocellular swelling, steroid-induced hepatopathy (in dogs only), and steatosis or lipidosis.[6] Hepatocellular swelling (hydropic degeneration) is the first manifestation of almost all forms of injury to cells and occurs when the cells are incapable of maintaining ionic and fluid homeostasis and accumulate water. Excessive corticosteroids will induce hepatocyte vacuolar changes owing to abnormal hepatic glycogen accumulation in dogs, but not cats. Lipidosis with hepatocyte accumulation of triglycerides occurs from abnormalities in fat metabolism or mobilization.

Nonreversible hepatocyte death occurs by either apoptosis or necrosis.[6] Hepatocytes may be killed by various insults, including hypoxia, toxins, drugs, microorganisms, immunologic events, and severe metabolic disturbances. The response following destruction of hepatic parenchyma results in inflammation, regeneration of parenchyma, fibrosis, and ductular proliferation.[6] The degree of clinical liver disease is dependent on the extent of hepatic damage and the ability of the liver to maintain normal functions. The liver has a great reserve capacity, and liver disease must be much advanced before clinical signs occur. Because the liver is involved in so many functions, no one test will

determine the liver's overall function. When approximately 60% of the liver function is lost, function tests start to become abnormal, and when approximately 80% of liver function is lost, clinical evidence of liver failure usually becomes apparent.[7]

With persistent parenchymal damage (chronic hepatitis) or extensive loss of hepatocytes (massive hepatic necrosis) fibrosis can become extensive. In cirrhosis, collagen becomes deposited in the sinusoids, resulting in altered permeability, the formation of intrahepatic portovenous shunts, and regenerative parenchymal nodules. Impaired hepatic perfusion then results in portal hypertension.[8]

The liver has the special ability to regenerate when a loss of hepatocyte numbers occurs and as long as the reticulin framework remains intact. Following partial hepatectomy, hyperplasia and hypertrophy of the remaining cells occurs. This process is known as “liver regeneration.”[9-11] However, regeneration may be a misnomer because the resected lobes never grow back. Potential stimuli for liver regeneration include cytokines and growth factors produced by the hepatocytes but also circulating substances (insulin, norepinephrin, or glucagon).[9-11] These stimuli induce changes in gene expression in hepatocytes, leading to mitotic proliferation of all cells composing the

intact organ, including hepatocytes, biliary epithelial cells, and endothelial cells.[9,10]

In healthy dogs, 70% hepatectomy is well tolerated,[12] whereas 84% hepatectomy is usually fatal.[13] The cause of death remains unclear with extensive hepatectomies. It has been postulated that portal hypertension may occur because the reduced portal vasculature is insufficient to accommodate a constant volume of portal blood.[13] Secondary bacterial translocation and death may then ensue.[13] The decreased number of hepatic Küpffer cells after extensive hepatectomy may reduce clearance of bacteria by the liver and possibly lead

to sepsis.[14] Changes in laboratory values following extensive hepatectomy have been studied in dogs. Following 70 % hepatectomy in healthy dogs, a small, transient increase in serum alkaline phosphatase, total bilirubin, and transaminases occurs.[12] Monitoring of blood glucose and supplementation of intravenous fluids with dextrose is recommended following extensive hepatectomy.[15] A small transient decrease in serum albumin occurs concurrently.[12] The result of ammonia-tolerance testing is normal following 40% hepatectomy but abnormal after 60% hepatectomy.[7] In one study in healthy dogs, 91% of the liver mass returned 6 weeks following 70 %

hepatectomy.[12] Finally, the potential for regeneration after repeated sublethal partial hepatectomies has been studied in rats.[16] Twelve sequential partial hepatectomies were performed and complete regeneration occurred each time,[16] suggesting that the clonogenic potential of the liver may be endless.

Only when the normal hepatic stroma becomes disrupted from either collapse or from collagen deposition does hepatocyte regeneration become disorganized and regeneration result in nodular formation. Regenerative nodules in cirrhosis lose their ability to carry on normal hepatic function.[8]

Risk of Sepsis

The liver of healthy dogs may normally harbor various bacteria.[17] The portal vein of normal dogs often carries gastrointestinal bacteria, which are then normally cleared by the liver. Bacteria are phagocyted by reticuloendothelial cells referred to as Kupffer cells and then either killed or excreted into the bile. Immunoglobulin A production in the liver and bile also contributes to the protection against infectious agents. Impairment of these protective mechanisms may predispose to sepsis or resident bacterial colonization. Acute portal hypertension from loss of normal parenchymal function may allow for translocation of gastrointestinal

organisms. Congenital or acquired portosystemic shunts allows gastrointestinal endotoxins or bacteria to bypass the liver, often leading to systemic enterotoxemia or bacteriemia.[18] Animals with intrahepatic or extrahepatic cholestasis,[19] hepatic ischemia, hepatic trauma, or portosystemic shunts may be at risk of sepsis and should be routinely treated with antibiotics perioperatively. The need for postoperative antibiotic is also based on the underlying disease and the condition of the animal.[15] Surgical resolution of biliary obstruction may result in release of bacteria into the biliary tract,[20] and postoperative antibiotic therapy has been

recommended in those cases.[20] Antibiotics used should be non-hepatotoxic, have wide distribution in the hepatic tissue and biliary tract, and be bactericidal and effective against the gastrointestinal flora. Ideally, the antibiotic selection should be based on the results of bile or liver culture and sensitivity testing. Recommended empiric perioperative antibiotics include the use of second-generation cephalosporins or possibly a combination of penicillin and fluoroquinolone. In some cases, when anaerobic infections are suspected, metronidazole (Flagyl, Pharmacia) or clindamycin (Antirobe, Pfizer) may also be used.[21] Because metronidazole requires hepatic metabolism, it is

recommended that lower doses be used with hepatic disease.

Risk of Hemorrhage

The liver plays a central role in hemostasis. The liver produces all coagulation factors except factor VIII, von Willebrand's factor, calcium, and tissue thromboplastin.[20] It also regulates anticoagulant and fibrinolytic mechanisms.[20] Studies in animals having liver disease found laboratory evidence of abnormal coagulation in 93% dogs and 82% of cats evaluated.[22,23] Mechanisms involved in coagulopathies occur from decreased factor synthesis, vitamin K deficiency,[24] excessive factor

consumption, or inadequate clearance of activated factors. Thrombocytopenia and thrombocytopathies have also been reported in association with liver disease.[20] Disseminated intravascular coagulation (DIC) may also be initiated by liver disease because of release of thromboplastic substances by damaged hepatocytes, reduced clearance of intestinal bacterial endotoxins, decreased antithrombin III concentrations, stasis of mesenteric blood flow, and reduced clearance of activated clotting factors and fibrin degradation products.[25] As DIC progresses, fibrin degradation products (FDPs) accumulate, interfering with fibrin polymerization and platelet function.[20] Although mild

coagulopathies are common in association with liver disease, clinical evidence of hemorrhage is uncommon.[20,26] In a large study in dogs, significant hemorrhage following ultrasound-guided liver biopsy occurred only when moderate thrombocytopenia was present.[27] Recommended testing in animals with liver disease should include a platelet count, prothrombin time (PT), and activated partial thromboplastin time (APTT). Buccal mucosal bleeding time should also be evaluated in animals with suspected platelet dysfunction. If DIC is suspected, fibrinogen, D-dimers, and FDP concentrations and antithrombin III activity are also measured. In cats with liver disease, measurement of

protein invoked by vitamin K absence (PIVKA) is reported to be more sensitive than PT or APTT to detect coagulopathies.[24]

Risk of Gastrointestinal Ulcerations

Liver disease has been associated with ulcerations in both animals and humans. Blood loss from gastrointestinal ulceration not only results in anemia and protein loss but also precipitates hepatic encephalopathy in advanced liver disease or portosystemic shunting.[20] In one study, dogs with liver disease made up 28% of animals with identified gastroduodenal

ulcerations.[28] Gastroduodenal ulcerations occur if the normal mucosal protective mechanisms are disrupted. Factors that reduce epithelial cell turnover, affect quality or quantity of gastric mucus production, or decrease gastrointestinal blood flow may induce gastrointestinal ulcerations. The duodenum is the most common site of ulceration in dogs with liver disease.[28] With severe liver disease, negative nitrogen balance and hypoalbuminemia also occur, resulting in decreased turnover of epithelial cells.[20] Portal hypertension also reduces gastrointestinal blood flow.[29-31] The role of gastrin in the pathogenesis of gastroduodenal ulceration secondary to liver disease

remains unclear.[20] Because the gastric pH may actually be high in humans with cirrhosis, the prophylactic use of H-2 receptor antagonists in those patients is controversial.[20] Sucralfate (Carafate, Aventis) may be useful prophylactically because it provides cytoprotection and may increase gastric blood flow in cirrhotic animals.[32] Anti-inflammatories (steroidal and nonsteroidal) should be used cautiously in animals with severe liver disease because they may further disrupt mucosal defense mechanisms.[31] Some H-2 receptor antagonists drugs (i.e., cimetidine, Tagamet, SK-Beecham) and the proton pump inhibitors (i.e., omeprazole, Prilosec, Astrazeneca) require hepatic

metabolism and are contraindicated in animals with liver disease. Ranitidine is a safe antacid in animals with liver disease because of its minimal involvement in hepatic metabolism.

Hepatic Encephalopathy and Portal Hypertension

These important complications of liver disease will be discussed in detail in the vascular anomalies chapter (Chapter 34).

Classification of Liver Disease

The basic classifications of liver disease in the dog and cat can be divided

simply into one of four large categories: parenchymal, biliary, or circulatory disorders, and neoplasia.

Parenchymal Disorders

Damage involving hepatocytes is the hallmark of most of these disorders. The parenchymal disorders can be grouped into those causing reversible hepatocellular injury (cell swelling, steroid-induced hepatopathy, and steatosis), hepatic amyloidosis, hepatocellular death (apoptosis and necrosis), and acute and chronic hepatitis and cirrhosis. Hepatocellular death is a nonreversible injury most often associated with acute and chronic hepatitis, sometimes leading to

cirrhosis.

Acute hepatitis is generally secondary to a hypoxic or toxic injury, infectious agents, or metabolic derangements.[33] Damage can be random, zonal, or diffuse throughout the liver. Diffuse or massive liver necrosis can lead to liver failure. Hepatic failure is complicated by the consequences of the loss of normal regulatory functions of synthesis, excretion, and metabolism. In these situations, recovery is possible if the patient can be maintained on life-support measures, if the reticulin framework remains intact, and if the liver retains it ability to regenerate. Metabolic consequences include hepatic encephalopathy,

coagulopathies, cerebral edema, sepsis, and gastrointestinal ulceration.[34]

Chronic hepatitis may result secondary to infections, toxins, drugs, and immune mechanisms.[35-37] Many breeds of dogs also have primary metabolic defects in copper metabolism with hepatic copper accumulation causing hepatocyte death. In most clinical situations, the etiology is never determined. Hepatocellular necrosis results in production of cytokines that recruit inflammatory cells locally. In most cases, the inflammatory changes originate in the portal areas but expand into the parenchyma. Inflammation also becomes a stimulus for collagen deposition. If the reticulin

framework is destroyed, regeneration becomes disorganized, sinusoidal circulation becomes permanently altered, and the hepatocyte regeneration develops as nodules. Cirrhosis is the end-stage of chronic hepatitis and is defined as a diffuse process characterized by fibrosis of the liver, the conversion of normal liver architecture into structurally abnormal nodules, and the presence of altered vascular circulation with portal-central vein anastomoses.[8]

In addition to the consequences listed with acute liver failure, portal hypertension results from the failure of the portal blood to adequately perfuse the sinusoids. The result of portal

hypertension is the development of acquired portosystemic shunting and ascites. Portal collaterals become visible as multiple, tortuous vessels, particularly in the mediastinum along the esophagus, originating from the cardia of the stomach (cardioesophageal anastomoses), in the omentum between the spleen and the left dorsal abdominal wall cranial to the kidney (splenorenal anastomoses), and in the mesocolon and mesorectum (mesenteric anastomoses).[38,39]

Hepatic Biliary Disorders

The biliary disorders can be grouped into cystic disorders and cholangitis. Biliary cysts result from congenital

defects in the development of the biliary tree.[40,41] They may be solitary or multiple, of variable size, and are characterized by dilatation of segments of the bile ducts. They are frequently associated with polycystic kidney disease especially in Persian cats. Cysts rarely have connection with the remaining biliary system and are often incidental findings on ultrasound, through palpation, or at surgery. Large cysts may be drained. Occasionally, they require surgical removal.

Cholangitis results from inflammation centered on the bile ducts within the liver. This condition is most commonly observed in cats. An acute neutrophilic (suppurative) cholangitis is thought to

result secondary to enteric bacteria ascending the biliary system.[42] The extrahepatic biliary system can also be involved. Cholangitis can become chronic associated with mixed inflammatory infiltrates, bile duct proliferation, and variable fibrosis.[43] Chronic cholangitis is also reported to have an association with chronic pancreatitis and inflammatory bowel disease in cats. Liver flukes also produce bile ductal dilation and chronic cholangitis.

Hepatic Neoplasia

Liver tumors are divided into primary, metastatic, and hemolymphatic neoplasia.[44] In cats, hemolymphatic

tumors are most common; whereas metastatic neoplasms are the most common form of liver tumors in dogs.[45] Primary liver tumors comprise less than 1% of findings in all canine and feline necropsies.[46,47] Malignant primary tumors are more common in dogs than in cats.[46,48] Primary liver neoplasms are categorized according to their histologic origin into hepatocellular, biliary, mesenchymal, and neuroectodermal.[46] They may also be divided into massive, nodular, and diffuse forms according to their distribution within the liver.[46] Biliary tumors are discussed in the biliary diseases chapter.

Most dogs and cats with primary liver

tumors are 10-years old or older. The exception is in animals with carcinoids, which affect dogs at an average age of 8 years.[46,48] Clinical signs include anorexia, lethargy, vomiting, weight loss, polyuro-polydypsia, diarrhea, jaundice, and abdominal distension.[46,49] An abdominal mass may be palpated in 50% to 80% of cases.[44,49] Other reported findings include seizures associated with hypoglycemia or hepatic encephalopathy and, rarely, exercise-induced weakness owing to myasthenia gravis.[46,50] At the time of diagnosis of primary liver tumor, 28% of animals are asymptomatic.[49]

Laboratory findings are nonspecific

and may include thrombocytosis, elevation of liver enzymes, and less commonly, hyperbilirubinemia or hypoglycemia.[45,46,48,51,52] In one study in cats, azotemia was the most common laboratory finding.[53] Thoracic radiographs should be performed to rule out lung metastasis, reported to occur in 14% of cases.[54,55] Abdominal ultrasonography allows confirmation of the hepatic origin of an abdominal mass and evaluation of other abdominal organs for metastasis (peritoneum, lymph nodes), and may help define the relation of the lesion to other abdominal structures such as the caudal vena cava and the gallbladder,[56,57] but it cannot differentiate neoplasia from benign

nodular hyperplasia.[58] Fine-needle aspirate or core biopsies can be obtained with ultrasonographic guidance. Prior evaluation of hemostasis is advised as many large hepatic masses may be highly vascular and hemorrhage is a possible complication. MRI has also been proposed as a means to differentiate benign from malignant hepatic nodules in dogs.[59]

Hepatocellular tumors include hepatocellular adenoma, hepatocellular carcinoma, and hepatoblastoma. Hepatocellular adenoma is the most common hepatocellular tumor in cats and rarely has any clinical significance;[48]

however, significant hemorrhage and hypoglycemia have been reported.[51] Prognosis is then based on tumor resectability. Hepatocellular carcinoma is the most common primary liver neoplasm in dogs.[44,46] The left liver lobes are most commonly involved.[46,56,60] Massive form is the most common HCC observed in dogs.[44,46,60] They are often resectable, rarely metastasize, and carry a good long-term prognosis after successful surgery.[56] Massive right-sided tumors may have a worse prognosis because of higher intraoperative mortality rate.[56] Nodular or diffuse forms of HCC are less common and carry a poor prognosis because they are rarely resectable and often metastasize.[56,60]

Metastases to the lungs, peritoneum, and peritoneal lymph nodes are most common, but metastases to the kidneys, spleen, adrenal glands, gastrointestinal tract, and bone marrow have also been reported.[60] Prognosis is related to resectability and the presence of metastasis.56 Adjuvant therapies such as radiation or chemotherapy are uncommonly used because of poor efficacy.[56]

Carcinoid neoplasms are rare primary liver tumors in dogs and cats.[46,60,61] Carcinoids originate from neuroectodermal hepatic cells. These cells are also classified as enterochromaffin or APUD cells (they are capable of amine precursor uptake

and decarboxylation). Prognosis is poor because of diffuse liver involvement and high rate of metastasis.[60]

Mesenchymal tumors or sarcomas are rare primary hepatic tumors in dogs and cats.[44,46,48,56,62] A poor prognosis has been suggested because of early metastasis.[44,46] A combination of surgical resection and adjuvant chemotherapy is recommended.[54,63]

Hepatic nodular hyperplasia (ENH) is a common necropsy finding in dogs.[64,65] It has been reported to occur in 70% of dogs older than 6 and 100% of dogs over 14 years.[64] The etiology of ENH is unknown. In dogs, ENH is

not thought to be a preneoplastic lesion.[65] Macroscopically, superficial, multifocal, well-circumscribed, pinkish to pinkish-tan nodules may be seen;[64,65] however, deeper nodules, within the parenchyma are not visible.[64] In a post-mortem study, nodule sizes ranged from 0.1 to 5 cm in diameter.[65] Microscopically, well differentiated hyperplastic hepatocytes with increased mitotic activity may be seen.[64,65] The lobular architecture is maintained.[64,65] In affected animals, clinical signs are often lacking.[66] Laboratory findings may include mild to severe increase in serum alkaline phosphatase (up to 14 times normal) and, less commonly, increase in serum alanine aminotransferase.[66]

Ultrasonographic findings are nonspecific.[58,67] Hyperplastic nodules may be hyperechoic, isoechoic, or hypoechoic to the surrounding parenchyma.[58] ENH is clinically significant because it may easily be confused with primary or metastatic hepatic neoplasia on abdominal ultrasound or at surgery. Histopathologic study is required to differentiate ENH from neoplasia. However, even microscopically, it may be impossible to differentiate ENH from hepatocellular adenoma;[65] and large samples (wedge rather that needle biopsies) may be required to differentiate ENH from hepatocellular adenocarcinoma.[66]

Other Hepatic Conditions

Liver Torsion

Liver lobe torsion is a rare condition that has been reported in man, rabbits, pigs, horses, dogs, and in one cat.[68-80] The affected lobe rotates around its vascular pedicle causing congestion, cholestasis, and ischemic necrosis.[75-77] Clostridial proliferation may then occur,[73,77,81] occasionally leading to abscessation of the affected lobe.[69] As clostridial toxins and inflammatory mediators are liberated, septic shock and death may follow.[73,77] The left lateral liver lobe is most commonly affected in small animals, but torsion of the quadrate, caudate, and right medial lobes has also been

reported.[69,73,75-77,80,82] Factors that cause stretching or rupture of the supporting ligaments of the liver may predispose to liver lobe torsion.[73,77] Congenital absence of the triangular ligaments, chronic gastric dilatation, traumatic diaphragmatic hernia, and tear of the hepatogastric ligament of the lesser omentum have been reported as possible causes.[73,76-78] Hepatic masses may also predispose to lobe torsion.[76] Liver lobe torsion has also been reported following routine ovariohysterectomy.[80] Clinical signs range from low-grade abdominal pain, anorexia, lethargy, vomiting, and ascites to acute abdominal crisis and death.[76] Occasionally a cranial abdominal mass can be palpated.[75]

Intermittent clinical signs with intermittent lobe torsion have been described in a child.[83] Diagnostic findings may include an inflammatory leukogram, increased ALT, alkaline phosphatase (ALP), and total bilirubin.[69,76] Abdominal radiographs and ultrasound may reveal a cranial abdominal mass, but definitive diagnosis is often made at surgery or necropsy.[69,76] Preoperative management should include intravenous fluids and antibiotics directed against Clostridium sp. (e.g., ampicillin, Fort Dodge).[81] Immediate surgical intervention with liver lobectomy is indicated.[76] Derotation of the affected lobe is generally avoided because it may lead to systemic release

of clostridial exotoxins.[69] The resected lobe should be submitted for cytologic and histopathologic studies and both anaerobic and aerobic bacterial cultures. Antibiotic therapy is continued postoperatively based on results of bacteriologic culture. Prognosis appears to be good if prompt surgical intervention is performed.[68,75,76]

Hepatic Abscesses

Hepatic abscesses are uncommonly reported in humans, dogs, and cats.[69,75,82,84-91] Abscesses may be single or multiple and are associated with high mortality rates in both humans and animals.[82,85] Underlying

pathologies in humans include liver trauma, ascending infection from the biliary tract, malignant obstruction of the biliary tract, extension from an adjacent abdominal abscess, and hematogenous spread.[85] Hematogenous spread may be divided into systemic hematogenous (secondary for example to pneumonia, endocarditis, or otitis media) and portal spread from abdominal septic focus (e.g., inflammatory bowel disease, or pancreatitis).[85,88,89] Immunocompromised individuals are also predisposed.[85] In newborn puppies it may occur secondary to ascending omphalophlebitis.[87] In adult dogs and cats, hepatic abscess formation has been associated with

diabetes mellitus,[86,90] liver lobe torsion,[69] ascending biliary tract infection,[91] and hepatic neoplasia.[90] In most cases, however, the underlying cause remains unknown.[82,90,91] Clinical signs often are nonspecific and include lethargy, anorexia, and fever.[82,85,90,91] Abdominal pain, jaundice, vomiting, and diarrhea are reported less frequently.[82,90,91] Laboratory findings may include an inflammatory leukogram, mild non-regenerative anemia, and increase in liver enzyme activities.[82,90,91] Hyperbilirubinemia may indicate sepsis or hepatic dysfunction. Hyperbilirubinemia may also be associated with primary biliary obstruction. Disseminated intravascular coagulation has been

suspected in both dogs and cats.[82,91] Imaging modalities include abdominal radiographs, ultrasound, computed tomography, and scintigraphy.[85] In humans, the use of WBC-labeled scintigraphy may help differentiate an abscess from a metastatic lesion.[85] Ultrasound-guided or intraoperative aspiration and cytologic evaluation confirm the diagnosis.[82,85,90,91] If ultrasound-guided aspirate is chosen, a surgeon should be available if hemorrhage or contamination of the abdominal cavity occurs.[85] E. coli is the most common bacteria isolated but multiorganism infections are common and anaerobic infections have been reported.[82,85,90,91] Treatment consists of appropriate antibiotic therapy

combined with drainage techniques or abscess resection.[85] However, antibiotic therapy alone may be adequate in selected cases, especially when multiple small abscesses are present.[92] Bactericidal antibiotics that are distributed in the liver should be used based on bacteriologic sensitivity results. While awaiting sensitivity results, a four-quadrant antibiotic therapy is recommended. Quinolones in combination with clindamycin have been recommended.[85] Drainage procedures may be surgical or ultrasound-guided. In humans, ultrasound-guided drainage for 11 to19 days with an in situ catheter is the modality of choice and has a high success rate (70-90%).[85] This technique

fails in 10% to 30% of cases, and surgical intervention is then required.[85] Repeated ultrasound-guided drainage has also been successful in 10 of 14 dogs.[90] Resolution after ultrasound-guided drainage and alcohol injection has also been reported.[93] Surgical intervention may consist of drainage or abscess resection with partial or complete lobectomy.[82,90,91] Intraoperative identification of parenchymal abscesses may be difficult; however, the use of intraoperative ultrasound may help localize the abscess. Laparotomy allows thorough inspection of abdominal viscera and treatment of the primary disease. If the animal is stable, biopsies of the liver and

intestinal tract are indicated to identify an underlying cause. Laparoscopic drainage has also been reported in humans.[94] Regardless of the modality of treatment, frequent ultrasonographic monitoring is indicated.[85] Antibiotic therapy should be continued for at least 2 weeks after ultrasonographic imaging indicates resolution of the abscess.[82] Prognosis is guarded, especially in debilitated animals with septic shock.[82,85,90,91] However, with early diagnosis and treatment, long-term successful outcomes are common in patients who survive the perioperative period.[82,85,90,91]

Hepatic Trauma

Following blunt or penetrating injury, disruption of hepatobiliary structures may occur. Isolated hepatic injuries are uncommonly recognized in small animals. In humans, capsular lacerations, parenchymal fractures, and subscapular hematomas are most common.[95,96] Trauma to the major vascular structures is uncommon.[95,96] In humans, peritoneal lavage, ultrasound, and computed tomography are used to identify and classify hepatic injuries and their severity.[95,96] Conservative management, with intravenous fluids and blood products is advocated in hemodynamically stable patients.[54,96] Heart rate, blood pressure, and packed cell volume

(PCV) should be monitored to evaluate the need for surgical intervention. PCV should not be used as sole monitor during acute hemorrhage.[97] Indeed, acute hemorrhage results in splenic contraction and loss of both plasma and red cells.[97] Thus, PCV may remain normal in an animal that is bleeding heavily.[97] Abdominal exploration may be necessary to control severe hemorrhage.

Chapter 33

Extrahepatic Biliary Obstruction

Michael D. King
Robert A. Martin

Anatomy

The intrahepatic portion of the biliary system originates where bile, produced by sheets of liver cells surrounded by blood sinuses, is discharged into minute bile canaliculi that lie between these cells.[1] Interlobular ducts are formed from the unification of the

canaliculi and lie between the lobules in the interstitial tissue. The interlobular ducts unite further to form lobar or bile ducts that exit the liver parenchyma as a variable number of hepatic ducts, beginning the extrahepatic portion of the biliary system. Usually there are four such ducts, two originating from the central division of the liver (quadrate and right medial lobes), and one each from the right (right lateral lobe and caudate process of the caudate lobe) and left (left lateral and medial lobes, papillary process of the caudate lobe) divisions.

The gallbladder is a pear-shaped structure, located within a fossa

formed between the right medial and quadrate lobes of the liver. It is divided into a fundus, body, and neck and connects with the bile duct via the cystic duct. Its function is to store and concentrate bile and secrete a mucoid substance for lubrication and protection. The cystic duct extends from the neck of the gallbladder to the site of its junction with the first hepatic duct from the central liver division. From this level distally to the duodenum the main excretory channel that receives bile from the hepatic ducts from the left and right liver divisions is the bile duct.[1]

The free portion of the canine bile duct is approximately 5 cm long and 2.5

mm in diameter and courses through the lesser omentum to the duodenum within the hepatoduodenal ligament.[1] The intramural portion of the bile duct enters the mesenteric wall of the duodenum and courses obliquely for an additional 1.5 to 2 cm before terminating at the major duodenal papilla, separate from the ventral pancreatic duct. A double layer of smooth muscle (sphincter of Oddi) exists around the intramural portion of the bile duct, resulting in the discharge of bile being largely dependent on activity of the duodenum itself.[1]

An auxiliary retroportal network of bile ducts is reported to exist in dogs.[2] These additional ducts connect the

intrahepatic lobar ducts of adjacent liver lobes to allow for continued drainage of bile when primary pathways are obstructed.

Specific features of note in the cat include the flexuosity of the feline cystic duct, and the existence of double or even triple gallbladders on occasion.[3,4] Additionally, the terminal intramural portion of the bile duct usually merges with the major pancreatic duct to empty into the duodenum through a common ampulla.[3-5]

Bile Formation, Flow, and Pathophysiologic

Alterations

Bile is a slightly alkaline, isotonic solution that consists of water, inorganic electrolytes, and organic solutes such as bile acids, cholesterol, phospholipids, and bilirubin.[5,6] Primary bile is produced in the canaliculi as a result of several different active transport processes, with secretion of bile salts the most important factor in promoting bile flow.[7] This active transport of solutes by the hepatocytes is accompanied by passive water flow.[5]

Bile acids are produced from cholesterol, conjugated by hepatocytes, and secreted continuously into canaliculi. They are essential for the

emulsification and absorption of fat from the small intestine.[6,8] The term bile acid refers to the molecular form in which the carboxylic acid side chain is nonionized; while the term bile salt refers to the ionized configuration. At physiologic pH the ionized bile salt form predominates.[5] More than 90% of the solutes within bile consist of bile acids and can represent a concentration 10^5-fold greater than serum bile acid concentrations.[5] They are maintained in solution in bile by formation of micelles, so an isosmotic balance is maintained with plasma. The rate of bile acid production is determined by the amount delivered to the liver for resecretion via enterohepatic circulation. With biliary

obstruction, a decrease in bile acid production results from the increased plasma levels of bile acids.

Cholesterol is synthesized primarily in the liver, with the rate of synthesis related inversely to its level of dietary intake. Synthesis of bile acids from cholesterol with excretion through the gastrointestinal tract represents the major method of excretion of cholesterol from the body. Although not water-soluble, cholesterol exists in normal bile in the form of micelles. Because lipid solubility is the major determining factor for absorption of solutes by the gallbladder mucosa, cholesterol is present within bile in lower quantities than water-soluble

compounds such as conjugated bile acids and bilirubin.[5]

Bilirubin, the major pigment in bile, is a product of hemoprotein degradation, two thirds of which is estimated to come from erythrocyte breakdown.[5] The unconjugated bilirubin is poorly water-soluble and binds to plasma proteins (predominantly albumin) for transport within the vascular space. Only a very small amount of unconjugated bilirubin remains unbound to plasma proteins because of albumin's high binding affinity for it, and this minimizes its renal filtration and excretion. Protein-bound unconjugated bilirubin is transported to liver for conversion by hepatocytes

into a water-soluble form. The bilirubin is conjugated with glucuronic acid to diglucuronide in the smooth endoplasmic reticulum of the hepatocytes. Conjugated bilirubin is then either excreted into the bile canaliculi or removed from the body via renal filtration. More than two thirds of the bilirubin present within the liver at any time is unconjugated, yet less than 3% of bilirubin excreted within the bile is in this form.[5,9] This illustrates the importance of enzymatic presence and function as the rate-limiting steps in bilirubin conjugation.[5] Once excreted into the intestinal tract, the conjugated bilirubin undergoes bacterial deconjugation, with conversion to urobilinogen, some of

which is resorbed through the enterohepatic circulation. The majority of this is returned to the liver, and a small portion is excreted in the urine. The remaining urobilinogen in the intestinal tract is further converted to stercobilin, which imparts normal fecal color.[9] Feces absent of normal color are termed acholic. This occurs from either a lack of bilirubin present within the intestinal tract (biliary obstruction) or a deficiency in intestinal bacterial activity.[5] Since only a small amount of bilirubin is needed for normal fecal pigmentation, complete cessation of bilirubin excretion is usually required for the formation of acholic feces. This is not seen until 7 to 10 days after complete blockage of the biliary

system, when jaundice is also readily apparent.[5,9]

Biliary obstruction can occur in a variety of disease processes (Table 33-1). With biliary obstruction, bilirubin conjugation occurs normally but secretion in the bile is inhibited. Regurgitation of conjugated bile back into the plasma then occurs, causing hyperbilirubinemia. While the majority remains protein-bound in plasma, it has a less profound binding affinity when compared with unconjugated bilirubin. The liver maintains a high reserve capacity for bilirubin excretion, capable of increasing up to 30 to 60 times above normal.[5] Because of this reserve, dogs must regurgitate

considerable amounts of bilirubin into the bloodstream before a significant increase in plasma levels occurs. The dog's renal threshold for bilirubin is low, with active excretion within the renal tubules possible. The renal threshold in cats is 9 times greater than that in the dog, and because of this, any bilirubin in the urine of cats should be considered abnormal.10 In cases of bile duct obstruction, renal filtration and excretion become essential.[5]

Table 33-1. Causes of Extrahepatic Biliary Obstruction

Congenital

Biliary atresia

Choledochal cysts

Acquired

Luminal

Inspissated bile

Parasites (flukes)

Stones (choleliths, choledocholiths)

Blood clots

Cholangitis (infectious, sclerosing)

Neoplasia (biliary carcinoma)

Cholecystitis

Stricture

Hematoma

Extraluminal

- Pancreatitis (chronic fibrosing, acute)
- Neoplasia (pancreatic, lymph node, gastrointestinal)
- Abscess
- Duodenal foreign body
- Diaphragmatic hernia
- Perforating ulcer (gastric, duodenal)

Intra- or extrahepatic obstruction of the biliary system is the most common cause of conjugated hyperbilirubinemia (Table 33-1). However, nearly all hepatic diseases associated with hyperbilirubinemia consist of a mixture of conjugated and unconjugated

bilirubinemia; differentiation is unlikely to be clinically useful.[9] Serum bilirubin levels over 0.3 mg/dl in the cat and 0.6 mg/dl in the dog are considered abnormal; at higher values, jaundice becomes visible clinically as yellow-stained tissues (serum levels > 2.0 mg/dl) or in serum (serum levels > 1.5 mg/dl).[9]

Flow of bile within the canine biliary system is dependent on pressure gradients because no valves are present. The increased pressure of the intramural component of the bile duct results in direction of the bile flow from the liver into the cystic duct and the gallbladder. The capacity of the gallbladder is about 1 ml per kg

bodyweight; however, a much greater volume of bile can be accommodated by the gallbladder by mucosal absorption of water and electrolytes.[5] Active transport of sodium through the gallbladder epithelium is followed by passive transport of chloride, water, and other soluble constituents. Thus, bile is concentrated between 5- and 20-fold while in the gallbladder and this prevents a rise in pressure within the biliary system.[5,8]

The gallbladder does not simply fill continuously during fasting; rather, partial emptying occurs intermittently; approximately 75% of the bile excreted from the liver is released directly into the duodenum in this way.[5] The

gallbladder has emptied 50% or more of its bile into the intestinal tract within 30 minutes following a meal.[4] The presence of chyme in the duodenum stimulates the release of cholecystokinin from duodenal mucosa as the primary regulator of gallbladder emptying. Cholecystokinin causes contraction of the gallbladder as well as relaxation of the terminal bile duct (sphincter of Oddi). In addition, vagal parasympathetic stimulation and, even more importantly, the presence of duodenal peristalsis itself contributes to relaxation of the smooth muscle surrounding the intramural bile duct, resulting in bile being expelled into the intestine with intermittent spurts[1,5,8] Obstruction of the bile duct increases

intraductal pressure proximal to the obstruction, causing vascular dilatation. With increasing pressure bile flow decreases; at pressures of approximately 30 mm Hg it stops.[11] This increased hydrostatic pressure produces characteristic morphologic alterations to the liver.

Morphologic Alterations of the Liver

Soon after obstruction, intrahepatic cholestasis is followed by bile duct dilation and edema with inflammatory cell infiltration of portal areas. These changes occur from both initial increased hydrostatic pressure and toxic effects of bile leakage into

periportal areas. In any disease process where cholestasis occurs there is the potential for hepatocellular damage. Bile acid retention causes injury to organelles, hydropic degeneration of hepatocellular tissue, and destruction of the cytochrome P-450 system.[5,7] In cases of chronic severe cholestasis, hepatocytes undergo degenerative necrosis and cirrhosis can occur.[5,7,12] An increase occurs in both fibroblast and hepatocyte collagen synthesis, with a concomitant reduction in hepatic collagenase activity, which results in fibrosis.[7,10]

Following bile duct obstruction, proliferation of both hepatocellular and preexisting biliary epithelial cells

occurs, resulting in a new tortuous periportal ductal system. With prolonged duct obstruction, metaplasia of hepatocytes can occur and further contribute to the neo-duct network. Increased hydrostatic pressure in obstructed ducts is necessary for this proliferation, and once obstruction is relieved, additional bile ducts may regress.[5]

Physiologic Alterations of Digestion

Efficient digestion of fats in the intestinal tract largely depends on the presence and function of bile salts and the phospholipid lecithin.[5,8] Bile salts and lecithin act to first emulsify

ingested lipids into smaller particles, and then to form micelles around monoglycerides and free fatty acids derived from pancreatic lipase activity. This allows for continued digestion of remaining fat globules and for efficient transport of the monoglycerides and free fatty acids to the intestinal epithelium. Bile salts and lecithin perform a similar transportation role in digestion of dietary cholesterol. Although intestinal absorption of free fatty acids can occur without bile salt micelles, absorption of cholesterol cannot, making the presence of bile even more critical.[8] The most important cause of clinically significant bile acid deficiency is extrahepatic biliary obstruction.

Steatorrhea, weight loss, and acholic feces may result.

In situations of decreased intestinal absorption of fats, there is concurrent malabsorption of fat-soluble vitamins (A,D, E, and K), vitamin K being the most clinically significant.[7-9] The formation of functionally active forms of five important clotting factors (prothrombin, factors VII, IX, X, and protein C) is dependent on vitamin K, with its deficiency leading to potential blood dyscrasias. Because factor VII has the shortest half-life of these clotting factors, prothrombin time will usually be prolonged before partial thromboplastin time.[13] Vitamin K is continually produced by intestinal

bacteria and clinical manifestation of deficiency is uncommon, except in cases of impaired fat absorption.[5,8,10,13]

Diversion of bile from the duodenum (extrahepatic biliary obstruction or surgical diversion via cholecystojejunostomy) not only affects fat digestion but also results in increased gastric acid secretion, with duodenal ulceration as a frequent sequela.[5,14] It is theorized that decreased absorption of fat in the duodenum results in a decrease in cholecystokinin activation (a competitive gastrin inhibitor), causing increased serum gastrin levels and subsequent peptic ulceration.[14] Also, hormonal inhibition of gastric acid

secretion may be decreased in cases of biliary obstruction or surgical diversion of bile away from the duodenum.[14] Finally, neutralization of gastric acid is decreased in the absence of bile, which can lead to duodenal ulceration.

Cholelithiasis

Cholelithiasis is uncommon in animals and is often an asymptomatic incidental finding, usually at necropsy. Clinical signs are seen when biliary stones are associated with cholecystitis, biliary obstruction, or gallbladder rupture.[15] The incidence of cholelithiasis in dogs is reported at less than 1% of patients with biliary disease;[16] only a few cases have been

reported in cats.[10,17] In animals, bile pigment stones predominate, in contrast to the cholesterol-based stones seen in people.[5] Choleliths seen in dogs and cats also tend to be lower in calcium than are human stones because of the efficiency of the gallbladder in resorbing free calcium from bile.[5]

Biliary stasis has been theorized as a potential cause of cholelith formation in animals because this is a common element seen in clinical disease. In contrast to humans, abnormal cholesterol metabolism does not seem to be a significant component of canine and feline choleliths.[5,15,18] Trauma, cholecystitis, dietary alterations, and parasitic or bacterial

infections have also been proposed as predisposing factors.[10,15] Bile stasis results in pigment sludge formation with mucin-bilirubin particles present in the gallbladder. As the mucin component increases, sludge particles precipitate as stones.[5]

Both bile stasis and biliary infection are commonly seen in disease associated with cholelithiasis in animals; however, infection is not thought to be a necessary component of stone formation because choleliths occur frequently in the absence of infection. Also, the relatively high incidence of stones seen as an incidental finding at necropsy suggests clinical disease arises only when the

biliary system containing stones becomes obstructed or infected. However, suppurative cholecystitis is inherently lithogenic because of prostaglandin-mediated inflammatory processes, increased mucin production, and the presence of bacterial enzymes.[5]

Although the gallbladder is the most common site of choledocholith formation, stones can form primarily within the bile duct.[11,19] This usually requires an abnormality that produces bile stasis such as partial obstruction and marked dilatation.[11]

Surgical Considerations

Preoperative Considerations

A vitamin K deficiency and subsequent coagulopathy can occur with complete bile duct obstruction over a period of weeks, but is unlikely in most clinical cases in the dog and cat.[5,9] Hemostasis testing is recommended, however, in patients with potentially chronic obstruction, most commonly by determination of prothrombin and partial thromboplastin times.[10,20] Prolonged partial thromboplastin time has been identified as a poor prognostic indicator in dogs undergoing extrahepatic biliary surgery.[21] The more specific test for potential vitamin K deficiency is that for "proteins induced by vitamin K absence or antagonists" (PIVKA).[5,22]

This test evaluates the occurrence of both depleted vitamin K-dependent coagulation factors and build-up of PIVKA. PIVKA are circulating nonfunctional precursor forms of vitamin K-dependent proteins that are normally stored in the liver but accumulate and spill into the circulation when a vitamin K deficiency occurs. Results are expressed in seconds, with marked elevations in PIVKA time warranting treatment. Parenteral administration of vitamin K1 can correct the coagulopathy in these cases,[10,20] with an initial loading dose of 5 mg/kg bodyweight, followed by a 2.5 mg/kg bodyweight daily dose divided every 8 hours until the biliary obstruction has been relieved and

coagulation times returned to normal.[22] Altough tests for PIVKA are sensitive and can detect early evidence of vitamin K deficiency, they are not as widely used clinically as other coagulation profile assessments.[22]

In addition to administration of vitamin K, patients with evidence of coagulopathies may require transfusion of whole fresh blood or fresh frozen plasma to replenish coagulation factors or packed red blood cells if they are anemic. It may take up to 12 hours for vitamin K administration to significantly decrease the prothrombin time and subsequently decrease bleeding.[22]

Antibiotics should be administered perioperatively when surgery is performed for biliary obstruction. Although normal bile is sterile, in situations of impaired bile flow, positive cultures have been frequently reported in people.[5] Hepatocellular damage secondary to biliary obstruction may decrease the effectiveness of the Kupffer cells in removing bacteria and bacterial endotoxins from the liver.[5] Empirical preoperative administration of broad spectrum intravenous antibiotics is recommended and should be active against enteric organisms commonly detected in biliary obstruction (Escherichia coli, Klebsiella, Proteus, Streptococcus, Pseudomonas, and

Clostridium species). Examples include cephalosporins, or potentiated ampicillin, and fluoroquinolones plus metronidazole. These should be continued postoperatively depending on surgical findings, patient condition, and results of bacterial culture and antibiotic sensitivity testing of bile.

It has been well established that bilirubin is damaging to cells, with unconjugated bilirubin more toxic than the conjugated form because of its increased lipid affinity. However, the high binding affinity of unconjugated bilirubin with albumin reduces widespread tissue distribution and, therefore, limits its deleterious effects.[5] Free unconjugated bilirubin crosses the

blood-brain barrier, causing neurotoxicity; this has been shown to result in hypotensive shock and death in dogs.[5] Additionally, hyperbilirubinemia is associated with renal failure in dogs and cats, theorized to be caused by direct cellular toxicity, hypotensive ischemia, or absorption of bacterial endotoxins.[5,21] Hypotension is commonly seen in cases of biliary obstruction and has been identified as a poor prognostic indicator. This is thought to be a result of a combination of the toxic effects of bilirubin and the development of systemic inflammatory response syndrome (SIRS).[21] Both preoperative and intraoperative efforts to monitor and maintain systemic

blood pressure are essential in these patients.

Intraoperative Considerations

Liver biopsy should be performed routinely during surgery for extrahepatic biliary obstruction, including cases of cholelithiasis. Histopathologic evaluation of the liver provides information on the severity and progression of structural liver alterations and may prove beneficial in the diagnosis, prognosis, and long-term management of the patient postoperatively. A biopsy taken from the margin of a liver lobe (guillotine method) or from a more centrally

located region of a lobe (biopsy punch technique) should be representative of the generalized parenchymal changes associated with extrahepatic biliary obstruction. Intraoperative culture of bile is essential to appropriately direct antimicrobial therapy in the postoperative period, as well as to provide prognostic information. The presence of septic bile peritonitis (traumatic rupture, cholecystitis, or extrahepatic biliary obstruction) is a negative prognostic indicator with 50% to 75% mortality in dogs, compared with less than 15% mortality for those patients with a nonseptic effusion.[21]

Cholecystectomy is preferred over

cholecystotomy for stone removal. Secondary changes to the gallbladder that result from the presence of stones or concurrent infection include mucosal hyperplasia, inflammation, and necrosis. Removing the gallbladder eliminates a reservoir for subsequent stone formation and minimizes potential risks of dehiscence or increased morbidity that might occur with cholecystotomy.

Determination of patency of the remaining extrahepatic biliary tract is vital to surgical outcome. A duodenotomy created over the major duodenal papilla allows retrograde cannulation of the bile duct when patency cannot be determined from

cannulation through the cystic duct. In cases of biliary obstruction or stricture unrelated to stones, a bile flow diversion procedure should be employed when the obstruction cannot be relieved. Furthermore, in extremely ill patients, temporary external biliary decompression using a cholecystostomy tube or intermittent percutaneous aspiration of the gallbladder should be considered until improved patient homeostasis can be achieved.[23] A definitive but more complicated diversion technique can be used when the patient's condition improves.

When bile diversion is required, cholecystoduodenostomy is the procedure of choice for the dog and

cat. A wide anastomotic stoma (2.5 to 4 cm) can be created to reduce the possibility of postoperative stricture and secondary cholangitis. Bile that is redirected into the duodenum maintains normal digestion and intestinal homeostasis.

Chapter 34

Portosystemic Vascular Anomalies

Karen Tobias

Portosystemic shunts (PSS) are vascular anomalies that connect the portal system or its tributaries to the systemic circulation.[1-3] Portosystemic shunts may be congenital, in which case they are often singular, or they may be acquired secondary to portal hypertension. Blood shunting through the PSS bypasses the liver, circumventing extraction and

detoxification processes normally performed by the hepatocytes. Clinical effects of shunts vary depending on the amount of blood shunted; in severe cases, PSS eventually results in death of the affected animal.[4] To understand the development and effects of PSS, a review of hepatic vascular anatomy and embryology is necessary.

Anatomy of the Hepatic Vasculature and Abdominal Venous Drainage

The portal vein provides up to 80% of blood flow and 50% of the oxygen content to the liver, with the remainder supplied by the hepatic artery. The portal vein is formed by

the confluence of the cranial mesenteric vein, which drains the small intestines, and the caudal mesenteric vein, which drains the colon and proximal rectum. Cranially, the portal vein is joined by the splenic vein, which receives blood from the stomach (via the left gastric vein); the spleen; and, in dogs, the gastroduodenal vein, which drains portions of the pancreas, duodenum, and stomach.[2,3,5] The portal vein then bifurcates into the right and left portal veins. Branches of the right portal vein supply the right lateral liver lobe and the caudate process of the caudate lobe. The larger left portal vein gives off a central branch to the right medial liver lobe and a small papillary branch to the

papillary process of the caudate lobe before dividing into quadrate, left medial, and left lateral branches.[5] In the cat, the portal vein divides into right, central, and left branches.[6] Within the liver lobes, blood flows through the portal venules and percolates through the hepatic sinusoids, mixing with blood from hepatic arterioles. It then collects within the central veins and is transported to the caudal vena cava via the hepatic veins.

Embryologic Development of the Portal System

The veins of the abdominal cavity are derived from the umbilical, vitelline,

and caudal cardinal veins of the embryo.[7] The paired vitelline veins form the left hepatic vein, hepatic sinusoids, the hepatic portion of the caudal vena cava, and prehepatic portal vein and its tributaries. Portions of the vitelline and umbilical veins combine to form the ductus venosus and the left branch of the portal vein. The nonportal abdominal drainage, such as the renal and gonadal veins, is derived from the fetal cardinal venous system. The caudal cardinal veins also form the prehepatic caudal vena cava (caudal to the liver) and the azygos vein. In a normal animal, the only communication between the cardinal and vitelline systems is where the prehepatic and intrahepatic segments

of the caudal vena cava join. Congenital extrahepatic portocaval and portoazygos shunts are developmental anomalies that result in abnormal, functional communication between these two systems.[7] Numerous nonfunctional portocaval and portoazygos communications are normally present in the fetus; these may become functional if chronic portal hypertension develops.[7] In rare instances, extrahepatic congenital PSS may result from persistence of the umbilical vein.[8]

Circulation through the ductus venosus permits at least 50% of the oxygenated blood from the placenta to reach the fetal heart without traversing hepatic

sinusoids.[9-11] In most mammals it undergoes functional closure in the first 2 to 6 days after birth and structural closure within a few weeks.[9,10,12,13] The cause of functional closure of the ductus venosus is controversial.[13-15] Decreased portal blood flow and pressure and cessation of umbilical placental flow result in retraction and narrowing at the ductus origin.[10] In newborn puppies, no anatomic sphincter is evident, and the ductus appears to narrow uniformly after birth.[7,10,14,15] Ductus flow is not detectable by Doppler ultrasonography in 50% of Irish wolfhound puppies 4 days after birth and in 100% 9 days after birth.[13] Connective tissue proliferation at the junction of the

ductus venosus and umbilical portal sinus in dogs expands to the termination of the ductus at the left hepatic vein, resulting in structural closure within 3 weeks after birth. Persistence of the fetal ductus venosus results in a left-sided intrahepatic PSS. If the ductus venosus remains patent in dogs, it may be secondary to underdevelopment or atresia of the hepatic portal system rather than a failure of primary closure mechanisms.[11] Etiology of central and right-sided shunts has not been determined and it is unknown whether these represent anomalous ductus venosus or other developmental errors.

Congenital Portosystemic Shunts

Etiology

Congenital PSS are reported in 0.18% of all dogs and 0.05% of mixed-breed dogs.

Because Yorkshire terriers, Irish wolfhounds, and a variety of other breeds are at increased risk for PSS, an underlying hereditary cause is suspected.[16,17] Familial relationships have been noted in Irish wolfhounds with PSS, and incidence of the disease has been reduced by breeding outside of these lines.[18] In Yorkshire and Cairn terriers, inheritance is not simple dominant, simple recessive, or sex-

linked.[17,19] In humans, a recessive mode of inheritance is suspected for familial patent ductus venosus.[20] Inheritance of PSS in dogs is autosomal and most likely polygenic, or monogenic with variable expression or incomplete penetrance.[17,19] Genetic predispositions have also been noted in other portal vascular diseases, including muscular portal venular hypertrophy with secondary acquired portosystemic shunting in Cocker spaniels and congenital portal hypoplasia (also known as hepatic microvascular dysplasia or HMD) in Cairn terriers.[21,22] Breeding of dogs with HMD can result in offspring with PSS, suggesting that the diseases may be related.

Clinical Signs

Neurologic, urinary, and gastrointestinal signs are reported in animals with congenital PSS. General clinical signs of animals with congenital shunts include small stature, poor hair coat, weight loss, fever, and anesthetic or tranquilizer intolerance.[2,3,23-26] Poor growth may be a result of decreased serum insulin-like growth factors (IGFs), which are anabolic and mitogenic polypeptide hormones that are responsible for prenatal tissue growth and postnatal development.[27]

Because of decreased urea production and increased ammonia excretion, animals can present with polyuria,

pollakiuria, stranguria, and other clinical signs of urinary tract dysfunction and infection. Polydypsia and polyuria may also result from alterations in portal vein osmoreceptors, decreased renal medullary concentration gradient, potassium depletion, stimulation of thirst centers owing to hepatic encephalopathy, medullary solute washout, decreased responsiveness to ADH, shift in intrarenal blood flow from cortical to juxtaglomerular nephrons, and increased endogenous cortisol concentrations.[23] Animals with PSS may develop renomegaly secondary to increased glomerular filtration rate or changes in renal metabolic function or blood flow.[28]

Hepatic Encephalopathy

Pathophysiology

The most common clinical signs in dogs and cats with PSS are neurologic abnormalities associated with hepatic encephalopathy.[2,3,23,25,26] Clinical signs include depression, dementia, stupor, and coma. Muscle tremors, motor abnormalities, and focal and generalized seizures have also been reported.[2,29] The metabolic cause of hepatic encephalopathy is unknown, but is probably dependent on several factors, including alterations in amino acid neurotransmitters γ-amino butyric acid (GABA), glutamate, and glutamine; accumulation of cerebral toxins; and dysfunction of

astrocytes.[29-46] Toxins that have been implicated in hepatic encephalopathy include ammonia, mercaptans, short-chain fatty acids, indoles, skatols, aromatic amino acids (AAA), and biogenic amines. None of these factors alone will consistently initiate an encephalopathic coma experimentally, but any may play a part in its development. Other metabolic alterations associated with portal blood shunting and impaired hepatic function include increases in blood levels of epinephrine, adrenocorticotropin, α-melanotropin, and cortisol.[46-49] Consequences of these increases on neurologic function of animals with PSS has not yet been thoroughly evaluated.

Ammonia

Ammonia is a side product of degradation of glutamine by glutaminase in the brain, small intestines, kidneys, and other tissues.[33] Ammonia produced by the small intestines is reabsorbed and transported through the portal system to the liver where 80 to 90% is transformed into urea via the Krebs-Hensleit urea cycle or used in the conversion of glutamate to glutamine.[29,32] Most urea is excreted by the kidneys into the urine; however, 20 to 25% is released into the intestinal lumen where urea and remaining amino acids, amines, and purines are degraded into ammonia by

urease-producing coliforms and anaerobes within the colon. In the kidneys, a small portion of the ammonia produced during renal glutamine metabolism is reabsorbed and carried into the systemic circulation via the renal veins. Within skeletal muscle, ammonia is metabolized through glutamine synthesis; this process is coupled with the use of branched-chain amino acids for energy production.[32]

Because the brain lacks several enzymes of the urea cycle, ammonia must be removed by glutamine synthesis through amidation of glutamate in the astrocytes. Increased ammonia concentrations in the

cerebrospinal fluid may cause neurotoxicity as a result of disturbances in cerebral energy metabolism, alteration in excitatory and inhibitory mechanisms, and interference with neuronal membrane transport and receptor function.[34-36] Structurally, hyperammonemia induces myelin splitting and brain vacuolation, preferentially within the white matter. Histologically, animals with hepatic encephalopathy develop Alzheimer type II cells and polymicrocavitation, particularly in the brainstem, cerebellar nuclei, and the border between grey and white matter.[34,39,50]

In people with acute liver failure, venous ammonia concentrations often

increase with the severity of clinical signs, and arterial ammonia concentrations greater than 150 μmol/L predict a greater likelihood of dying from brain herniation.[35,51] In animals, the correlation between blood ammonia concentration and degree of encephalopathy is poor. Brain to blood concentration ratios in acute liver failure, however, may be 4 to 8 times normal because of increased ammonia uptake in the brain.[36] Mercaptans and short-chain fatty acids, products of bacterial activity in the intestines, may reduce ammonia metabolism or act synergistically with ammonia to increase inhibitory neurotransmission.[33]

Glutamine

In the brain, astrocytes are critical for ammonia metabolism, regulation of the extracellular environment, neuronal excitability, and neurotransmission. Accumulation of intracellular glutamine secondary to hyperammonemia causes osmotic stress and astrocyte swelling. This upregulates expression of peripheral benzodiazepine receptors, affects multiple ion channels and amino acid transport, alters receptor densities and neurotransmitter processing, induces deposition of glycogen and inhibition of glycogenolysis, and increases synthesis of neurosteroids that are potent modulators of neuronal GABA

receptor activity.[35,36] Cerebrospinal fluid (CSF) concentrations of glutamine are significantly higher in dogs with PSS compared with healthy dogs fed a low-protein diet.[37]

Glutamate

The mammalian brain has four types of excitatory receptors that are defined by agonist selectivity, including N-methyl-D-aspartate (NMDA), α-[3H]amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA), kainite, and L-2-amino-4-phosphonobutyrate (L-AP4).[38] A fifth receptor subtype is linked to phophoinositol metabolism. L-Glutamate, the most important

excitatory neurotransmitter, acts preferentially at AMPA and kainite sites. Effects of L-aspartate, another excitatory neurotransmitter, are thought to be mediated predominantly through the NMDA receptor. In dogs with congenital PSS and hepatic encephalopathy, glutamate concentrations are increased 65% in the CSF.[30,39] Kainate-receptor density and low-affinity AMPA sites are reduced, however, which may result in decreased excitatory neurotransmission and, therefore, a predominance of inhibitory neurotransmission.[38]

Gamma-Aminobutyric Acid (GABA)

Gamma-aminobutyric acid, the most important inhibitory neurotransmitter, is produced by enteric bacteria and is usually metabolized by the liver. Binding of GABA to its receptors increases chloride flow into the neuron, resulting in membrane hyperpolarization and inhibition of neurotransmission. The GABA receptor also has binding sites for barbiturates, benzodiazepines, and benzodiazepine-like substances called ligands. The majority of studies have found no significant alteration in brain GABA-receptor density or affinity in animal models of hepatic encephalopathy, and GABA concentrations are within normal range in dogs with congenital PSS.[30,38,39] Some researchers suggest,

however, that ammonia may enhance selective binding of GABA to receptors, increase synaptic availability of GABA by inhibiting synaptic uptake, and upregulate peripheral-type benzodiazepine receptor release of neurosteroids that are potent agonists of GABA receptors, thus increasing inhibitory neurotransmission.[40]

Peripheral-type Benzodiazepine Receptors

Because GABA receptors contain binding sites for endogenous benzodiazepine receptor ligands, benzodiazepines were originally speculated to produce central nervous system (CNS) depression in animals

with hepatic encephalopathy.[26] Although dogs with congenital PSS have increased concentrations of endogenous benzodiazepine receptor ligands in peripheral and portal blood, they do not have increased benzodiazepine binding activity in the CSF, and infusion of the benzodiazepine receptor antagonist flumazenil has little effect in reversing clinical and neurophysiologic dysfunction of dogs with chronic hepatic encephalopathy.[41,52] However, administration of sarmazenil, a drug that has both antagonistic and partial inverse-agonistic activity, results in significant improvement in electroencephalographic activity and clinical grade of dogs with hepatic

encephalopathy.[41,42] Sarmazenil is thought to negatively modulate GABAergic tone by counteracting the actions of ammonia and neurosteroids on the GABA receptor, potentially balancing the effects of decreased excitatory glutamatergic neurotransmission.[42]

Unlike central receptors, peripheral-type benzodiazepine receptors have increased density and expression in hepatic encephalopathy models.[39] Ammonia is thought to upregulate these receptors, enhancing the production and release of neurosteroids that are potent agonists of the GABA receptor complex.[34,39,40] Manganese also increases expression

of peripheral-type benzodiazepine receptors, resulting in increased inhibitory activity.[39]

Amino Acid Imbalances

Aromatic amino acids (phenylalanine, tyrosine, and tryptophan) are normally metabolized by the liver; whereas branched-chain amino acids (valine, leucine, and isoleucine) are used as energy sources in skeletal muscle and as substrates for CNS synthesis of the excitatory neurotransmitters norepinephrine and dopamine.[30,33,43,46] Dogs with PSS have significant increases in plasma concentrations of aromatic amino acids (AAA) owing to reduced hepatic

clearance. Additionally, peripheral concentrations of branched-chain amino acids (BCAA) are significantly decreased in response to hyperammonemia, hyperinsulinemia, and hyperglucagonemia, resulting in a reduction of the peripheral BCAA:AAA ratio to 1.5 or less (normal is greater than 3.0).[30,33,43,46] Hyperinsulinemia decreases the rate of release of BCAA and stimulates the rate of utilization of BCAA by muscle and adipose tissue and incorporation of BCAA into proteins.[43] Because all amino acids compete for the same transport system into the brain, decrease in peripheral concentrations of BCAA means more AAA are transported into the CNS, resulting in reduction of CSF

BCAA/AAA ratio to 0.5 (normal, 2.3).[30,43,46] Increased AAA may result in increased concentrations of inhibitory neurotransmitters and formation of weak or false neurotransmitters that disrupt normal synaptic impulse transmission.[37,46,53] Tryptophan hydroxylation is the rate-limiting step in CNS serotonin synthesis; therefore, increased CSF tryptophan could increase serotonin concentrations and thus inhibitory neurotransmission.[37] Increased tryptophan in the brain may result in increased amounts of its oxidative product quinolinic acid. Quinolinic acid is a known excitotoxin that acts at the NMDA receptor, causing irreversible damage to neurons.[44]

Precipitating Factors

Factors that may increase the chance of an encephalopathic episode include protein overload, zinc deficiency, arginine deficiency in cats, hypokalemia, alkalosis, hypovolemia, gastrointestinal hemorrhage, infection, azotemia, and constipation.[2-4,29,32,39,42,45,53] Blood that has been stored for 24 hours contains 170 µg of ammonia/dl; ammonia concentrations increase further with longer storage.[29] Diuretic agents promote hypokalemia, which increases renal ammonia production and alkalosis, increasing the availability of diffusible ammonia.[29]

Treatment

Medical management of animals with PSS-associated hepatic encephalopathy includes correction of fluid, electrolyte, and glucose imbalances and reduction of precipitating factors.[3,24,28,54] Reduction of total protein intake is more beneficial than altering the content of dietary amino acids; however, severe protein restriction may result in loss of skeletal muscle mass and subsequent reduction in ammonia metabolism.[46,55] Depletion of zinc can precipitate hepatic encephalopathy, and supplementation may improve psychomotor function in mildly affected patients.[56,57]

Lactulose is a poorly absorbed

synthetic disaccharide that is hydrolyzed by colonic bacteria to short-chain fatty acids, lactic acid, and hydrogen. Proposed effects of lactulose include decreased colonic pH with subsequent entrapment of ammonium; inhibition of protein and amino acid metabolism, thereby reducing formation of ammonia and amino acid-derived short-chain fatty acids; decreased intestinal transit time; and increased fecal nitrogen excretion.[56] Nonabsorbable disaccharides have not consistently been shown to reduce or prevent signs of hepatic encephalopathy in human clinical trials, but are still used frequently in people and animals with hepatic encephalopathy.[58,59] Administration of

nonpathogenic lactic acid bacteria may provide benefits similar to lactulose and may increase the proportion of non-urease-producing bacteria in the intestines.[60] Oral administration of antibiotics will also decrease colonic bacterial populations.

Other medications that improve clinical status of people with hepatic encephalopathy include arginine, sodium phenylacetate, sodium benzoate, L-ornithine L-aspartate, methionine sulfoximine, and sodium benzoate, which decrease ammonia production or increase ammonia metabolism.[35,36,44] L-ornithine L-aspartate (LOLA) may provide substrate to the liver for enhancing the

residual urea cycle and serve as a substrate for ammonia detoxification in the muscles.[35,61] Administration of LOLA reduces brain edema in animals with acute liver failure.[32] Methionine sufloximine, an inhibitor of glutamine synthetase, prevents uptake of nonpolar amino acids, including tryptophan, by the CNS, ameliorating signs of hepatic encephalopathy in rats with surgically induced PSS.[37] Mild hypothermia may also be useful to reduce blood-brain ammonia transfer.[34]

Laboratory Abnormalities

Hemograms

Abnormalities on hemograms of

animals with PSS include anemia, microcytosis, hypoproteinemia, and leukocytosis.[2,3,23] Other reported hemographic abnormalities include target cell formation, poikilocytosis, and hypochromasia. Potential causes of anemia include decreased red blood cell production because of poor nutritional status, low erythropoietin levels, decreased transferrin production and subsequent poor iron utilization, and abnormal cholesterol and lipid metabolism; decreased survival of red blood cells; dilution from increased extracellular fluid and plasma volume and total body water; or chronic loss from parasites or a coagulopathy.[2,3,23,28] Additionally, hematocrits may be considered low

according to adult laboratory reference ranges but may be within normal limits for pediatric patients.[62] Microcytosis is thought to occur because of a problem with iron transport or utilization rather than an absolute iron deficiency. Dogs with congenital PSS have decreased serum iron concentrations and normal or decreased total iron binding capacity.[63,64] Some naturally affected animals and those with surgically created portocaval shunts may have accumulation of stainable iron in the liver.[63,64]

Presence of leukocytosis is variable and may occur in response to stress, hypercortisolemia, or infection.

Inadequate clearance of bacteria and endotoxins from the portal system may play a role in development of leukocytosis; however, significant differences in concentration of endotoxins and in rates of positive portal blood cultures have not been found when comparing normal dogs with those with congenital PSS.[65,66] Recurrent bacterial infections, fever, leukocytosis, and hypergammaglobulinemia may occur with reticuloendothelial impairment, because 90% of reticuloendothelial function in dogs occurs within the liver.[67] Dogs with PSS have significantly impaired reticuloendothelial function secondary to a reduction in effective liver blood

flow. Reticuloendothelial activity increases in the spleen and lung, but only partially compensates for the hepatic reductions.[67] Severity of preoperative leukocytosis is correlated with postoperative outcome.[68]

Serum Chemistry

In dogs with congenital PSS, decreased blood urea nitrogen and albumin and increased partial thromboplastin time are primarily the result of decreased hepatic production of proteins.[23,69] Hypoalbuminemia may also occur secondary to intestinal loss or fluid retention.[64] Decreased creatinine may occur with hepatic insufficiency or reduced muscle mass; the level of

creatinine is also naturally lower in young patients.[28] Potential causes of hypoglycemia include decreased hepatic glycogen stores, increased insulin concentrations, decreased responsiveness to glucagon and insulin, and abnormal balance of counter-regulatory hormones (cortisol and epinephrine).[23,70] Dogs with congenital PSS have hyperinsulinemia and hyperglucagonemia secondary to insulin hypersecretion, insulin resistance, and decreased hepatic degradation of these hormones. Hypoglycemia is uncommon in cats with PSS, possibly because of their tendency to develop stress-induced hyperglycemia during sampling.[23]

Increases in alanine aminotransferase concentrations occur with hepatocellular necrosis and increased membrane permeability, possibly as a result of poor hepatic perfusion and cell hypoxia.[23,64] Because cholestasis is not a prominent feature of PSS, an elevation in serum alkaline phosphatase concentrations in young animals may actually be of osseous origin.[23]

Urinalysis

Low specific gravity may be secondary to polyuria/polydipsia or to alterations in the renal medullary concentration gradient from deficits in urea.[23] Chronic hypercortisolism induces

inadequate osmoregulation of release of ADH and, thus, polyuria.[70] Animals with congenital PSS may have hematuria, pyuria, and proteinuria, and clinical signs of urinary tract infections secondary to urolithiasis or inflammation from urate crystal or calculus that form because of increased ammonia excretion.[2,23,24] Renal urate calculi may dissolve after shunt ligation.[71]

Bile Acids

Bile acids are synthesized in the liver from cholesterol. Within the liver they are conjugated to taurine (cats and dogs) or glycine (dogs) to increase their water solubility and enable

micelle formation. Conjugated bile acids are excreted across the hepatocyte canalicular membrane into bile. Cholecystokinin, which is released in response to ingestion of a meal, stimulates gallbladder contraction and release of bile acids into the duodenum.[72] At least 95% of intestinal bile acids are actively reabsorbed in the ileum and are transported by portal blood back to the liver (the "enterohepatic cycle"), with the remainder lost in the feces.[72-74] At the sinusoidal surface of the hepatocyte, bile acid uptake relies on a sodium-coupled transporter. Serum bile acid concentrations increase in conditions that affect hepatocellular uptake, such as cholestasis or primary hepatic

disease, or conditions that alter vascular flow to the liver, such as PSS. They are not significantly affected by dehydration, hypovolemia, or passive hepatic congestion. Effects of lipemia and hemolysis on spectrophotometric sample analysis of bile acids are unpredictable; theoretically they can overestimate bile acids by scattering light and increasing spectrophotometric absorption. However, lipemia may decrease bile acids by volume displacement of serum, and hemolysis can reduce bile acid recovery.[75] Falsely lowered results may occur with delayed absorption from prolonged intestinal transit time, lack of gallbladder contraction because of inadequate food intake or delayed

gastric emptying, or malabsorption/maldigestion with subsequent decrease of enterohepatic recirculation. Postprandial bile acid concentrations are less than fasting in 20% of animals because of spontaneous interdigestive gallbladder contraction or with prolongation of gastric emptying or intestinal transit times.[4,23,76]

Increases in postprandial bile acids that were mild (> 31 μmol/L) or moderate to severe (> 80 μmol/L) were reported in 79% and 34% of Maltese dogs, respectively.[75] Most had normal ammonia tolerance tests, and bile acids were significantly lower when measured by high-performance

liquid chromatography, indicating that bile acids measured spectrophotometrically in Maltese may be increased by some other cross-reacting substance.[75]

Plasma Ammonia Concentration

In dogs with PSS, sensitivity of postprandial ammonia is 91%[6] hours after feeding, compared with 81% before feeding; ammonia tolerance test is recommended to increase sensitivity.[77] Plasma ammonia levels may be normal in dogs with PSS after prolonged fasting or with effective medical treatment.[23] Because erythrocytes contain 2 to 3 times the

amount of ammonia in plasma, improper sample cooling, hemolysis, incomplete plasma separation, or delays in sample analysis falsely increase ammonia values. Concentrations of ammonia measured with tabletop analyzers can be falsely increased if ammonia-based cleaners are used nearby or if ammonia-rich skin oils contaminate the apparatus.

Histology

Hepatic histologic changes in animals with PSS include generalized congestion of central veins and sinusoids, lobular collapse, bile duct proliferation, hypoplasia of intrahepatic portal tributaries, Kupffer

cell hyperplasia, and proliferation of small vessels and lymphatics.[54] In dogs with surgically created PSS, direct infusion of insulin into the intrahepatic portal vein reduces atrophy, preserves hepatocyte ultrastructure, and increases cell renewal, indicating the first pass effect of insulin may be necessary for liver development.[70] Dogs with PSS have increased fragility of intracellular organelles, increased endoplasmic reticular and lysosomal enzymes, and increases in the biliary canalicular component of alkaline phosphatase activity.[78] Increased hepatic iron stores can be seen in some dogs with congenital PSS but this is not a consistent finding.[63,64] Histopathologic changes in the livers of

dogs with congenital PSS are identical to those in dogs with primary hypoplasia of the intrahepatic portal venous system (HMD), reduced portal perfusion for any reason (e.g., portal vein thrombosis), and congenital arterioportal fistula; therefore, histopathology alone may not differentiate among these diseases.[22,54,79,80]

Surgery

Surgical options include acute ligation with suture; gradual occlusion with ameroid constrictors, cellophane banding, or hydraulic occluders; or embolization with coils.[2,3,81-86] When suture ligation is performed, portal

and central venous pressures are measured to determine the acceptable degree of attenuation, because[32] 60% of animals cannot tolerate complete acute occlusion.[3,68,81-85,87,88]

Normal intraoperative portal pressures range from 6 to 15 cm H_2O (6-10 mm Hg); portal pressures in animals with PSS range from 0 to 12 cm H_2O.[2,3,87] Acute ligation of single PSS in animals with poorly developed or nonexpansile intrahepatic portal vasculature results in large increases in portal pressure and decreases in central venous pressure. Central venous pressure is an indirect measurement of right atrial pressure and cardiac preload. It is controlled by the tone of capacitance

vessels and the intrathoracic pressure when right ventricular function is adequate and blood volume is stable. Because blood flow is proportional to the fourth power of vessel radius, small decreases in portal vessel size result in large decreases in venous return and central venous pressure.[87] Increases in portal pressure are caused by increased resistance to blood flow in the hepatic vascular bed. Mild increases in portal pressure accompanied by large decreases in central venous pressure and subjective evidence of portal hypertension during shunt occlusion suggest splanchnic venous compliance has increased and splanchnic pooling has occurred.[87,89] Portal pressure measurements can vary with depth of

anesthesia, administration of inotropes, catheter position, abdominal viscera position, abdominal bandages, temperature, hydration status, phase of respiration, degree of splanchnic compliance, and other systemic factors.[89]

Multiple Acquired Portosystemic Shunts

Multiple acquired PSS are tortuous vessels that connect the portal system with tributaries of the caudal vena cava, most frequently the left renal or gonadal veins. They are thought to originate from pre-existing nonfunctional communications between the portal vein and the

systemic circulation, secondary to portal hypertension from severe liver fibrosis, neoplasia, portal atresia, or congestion.[90,91] Animals with multiple acquired shunts often have neurologic and urinary tract signs similar to animals with congenital shunts.[90] Because of underlying portal hypertension and, in some cases, severe hypoalbuminemia, animals with multiple acquired shunts often develop ascites. Bleeding dyscrasias from decreased hepatic production of coagulation factors may also occur, resulting in prolonged bleeding of wounds and hematoma formation at venipuncture sites. Blood work results vary with the underlying cause but often include hypoalbuminemia,

decreased blood urea nitrogen concentrations, increased liver enzymes, and increased bilirubin if cholestasis is present.

Hepatic Arteriovenous Fistulas

Hepatic arteriovenous (AV) fistulas are anomalous connections between the hepatic artery and the portal or hepatic vein. They are most often caused by congenital failure of embryologic vascular systems to differentiate into capillary, arterial, or venous structures; they may also occur as a result of trauma or surgery.[92-97] In animals with hepatic AV fistulas, high arterial pressure flow into the portal

system results in retrograde portal flow, with subsequent intrahepatic portal hypoplasia, and portal hypertension with subsequent development of multiple acquired PSS. Clinical signs of hepatic arteriovenous fistula are associated with hepatic insufficiency (diarrhea, vomiting, neurologic abnormalities), portal hypertension (ascites), and decreased arterial blood volume (tachycardia, water-hammer pulses with decreased diastolic pressure, ventricular failure). On physical examination, a systolic cardiac murmur may be noted. Many dogs have water-hammer pulses and an auscultable continuous machinery-type murmur with the point of maximum intensity on the abdominal

wall over or near the affected lobe.[96] Biochemical and hemogram abnormalities are similar to those of animals with PSS. Diagnosis of hepatic arteriovenous fistulas is made with Doppler ultrasonography. The presence of an extremely dilated and tortuous portal branch in a liver lobe is considered pathognomonic.[94,95,97] Ascites, hepatofugal blood flow in the portal vein, and multiple acquired shunts may also be noted. On exploratory laparotomy, affected liver lobes have multiple large, tortuous vessels; acquired extrahepatic shunts around the left renal and gonadal veins are also evident. Histologically, the fistulas consist of numerous thick-walled arteries and markedly dilated

veins. The arteries and veins may contain smooth muscle hyperplasia, and hepatic lobules are atrophied, especially near the fistulas. Proliferation of bile ductules and thick-walled hepatic arterioles are found in the portal triads; portal veins in the triads may be reduced in size or absent.[98] Surgical ligation of the hepatic arteriovenous fistula or resection of the affected liver lobe will decrease clinical signs caused by arteriovenous shunting in 57% of dogs.[3,96] Animals are pretreated with glycopyrrolate or atropine to prevent reflex bradycardia (Branham reflex) with closure of the fistula.

Chapter 35

Intestinal Obstruction

Gary W. Ellison

By definition, intestinal obstruction implies the failure of ingesta or intestinal secretions to move in a normal aboral direction.[1] Obstructions are typically classified by their duration, their severity, and their location. Partial or incomplete obstruction is incomplete occlusion of the bowel lumen that allows limited passage of fluid or gas. Complete obstruction is total occlusion of the

intestinal lumen, with failure of gas or fluid to pass the point of obstruction. Blockage in the duodenum or upper jejunum constitutes a high intestinal obstruction; blockage in the midjejunal area constitutes a midintestinal obstruction; and blockage in the distal jejunum, ileum, or ileocecal junction constitutes a low intestinal obstruction.

In terms of pathophysiologic changes, obstructions are usually best described as either simple mechanical or strangulating.[1] Simple mechanical obstruction is partial or complete obstruction of the bowel lumen, but the blood supply to the intestinal wall is usually not impaired. Conversely, with strangulation obstruction, the

circulation to the involved segment of intestine is impaired, and usually complete obstruction is present.

Etiology of Simple Mechanical Obstruction

The causes of mechanical obstruction can be subdivided into three general categories: intraluminal mechanical obstruction, intramural mechanical obstruction, and extramural mechanical obstruction (Figure 35-1).[2]

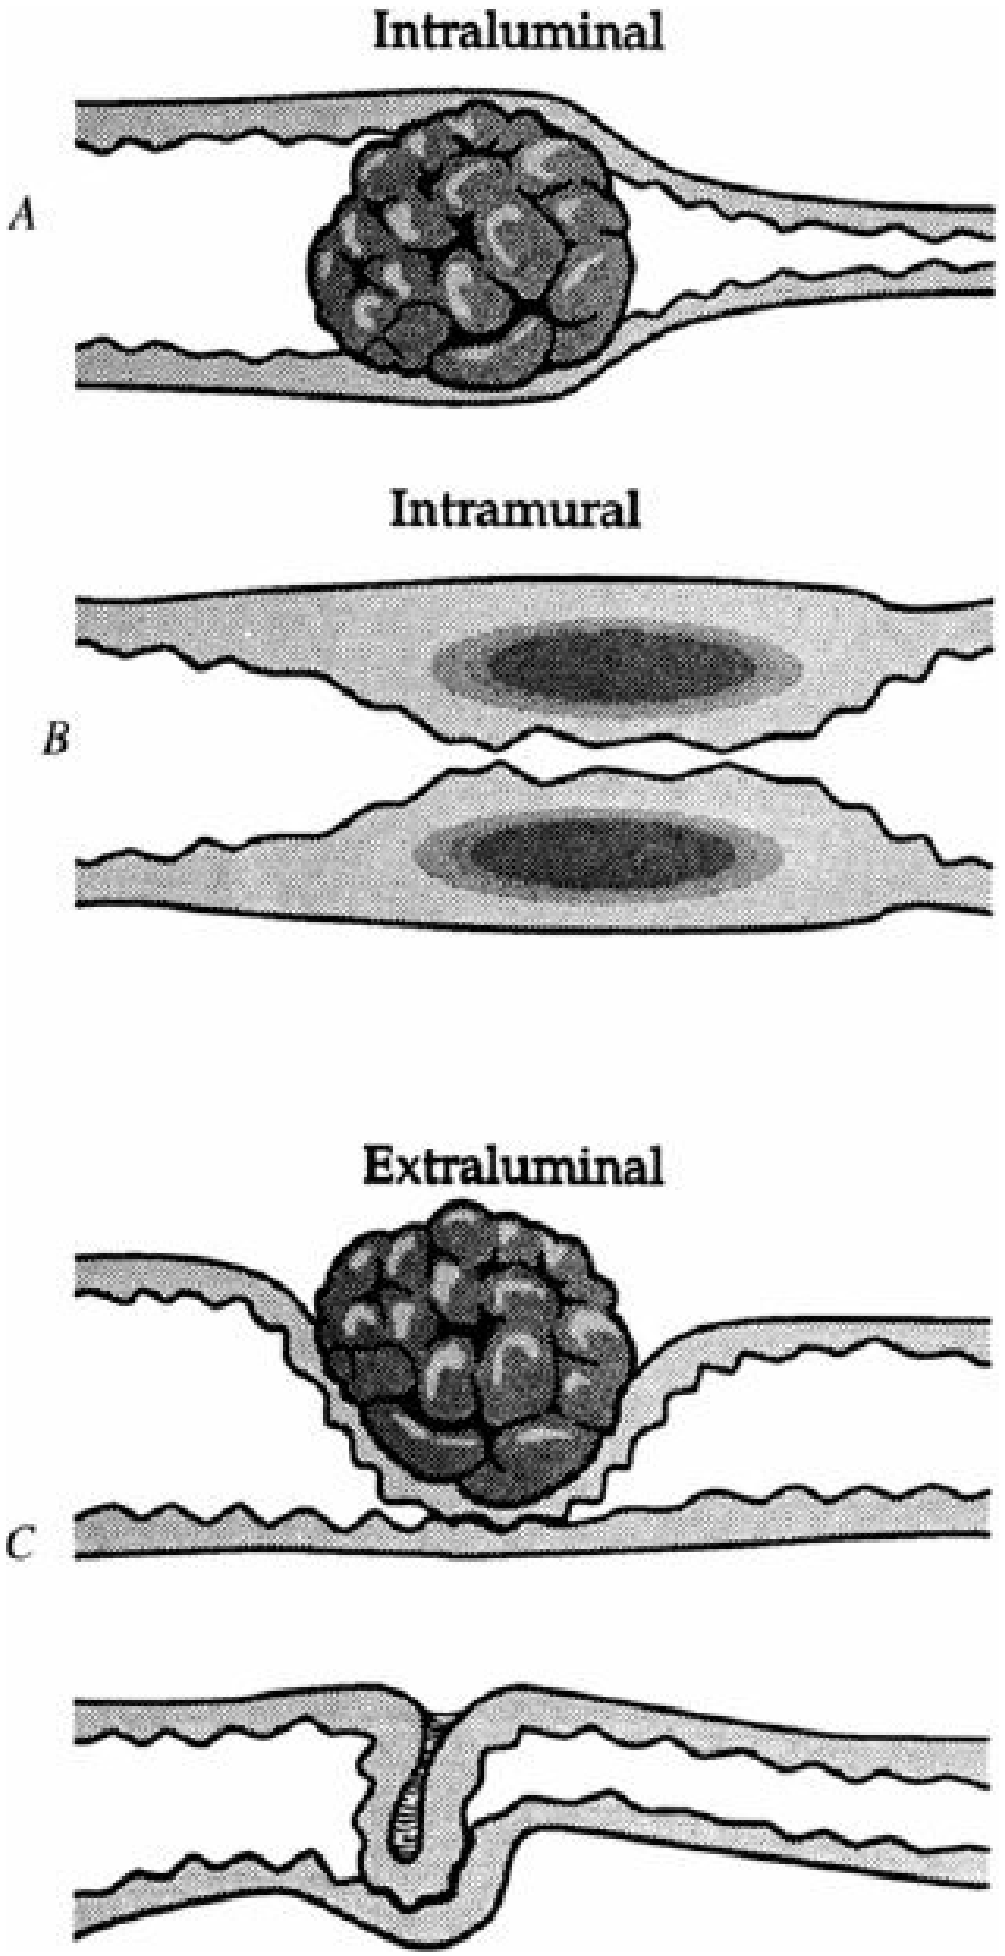
Intraluminal mechanical obstruction is the most common type in small animals. The oropharyngeal opening is larger than any other orifice in the alimentary tract and foreign bodies

such as bones, balls, or corncobs can traverse the esophagus and stomach and become lodged in the smaller-diameter intestine. Large intraluminal foreign bodies often cause signs consistent with complete luminal obstruction, although slow aboral passage of the foreign body may occur. Polypoid intestinal masses or linear foreign bodies such as string may cause partial or incomplete luminal obstruction. In cats, benign adenomatous polyps of the upper duodenum can cause intermittent hematotemesis.[3] The trailing end of linear foreign bodies often becomes anchored over the base of the tongue or in the pyloric antrum. Normal intestinal peristalsis moves the foreign

body distally, but because it is fixed proximally the bowel plicates itself along the length of the foreign body.[4]

Intramural mechanical obstruction is most commonly caused by intestinal wall neoplasia or fungal granulomas. Intestinal neoplasms such as adenocarcinoma, leiomyoma, leiomyosarcoma, fibrosarcoma, and lymphosarcoma commonly invade the muscular layer of the intestinal wall. These tumors not only compromise lumen diameter, they also reduce the pliability of the intestinal wall at that point, reducing its distensibility and likening the occurrence of intussusception. In the Southeastern United States, intestinal granulomas

caused by the algae Pythium species is a common cause of intestinal obstruction. This obligate organism creates mural thickening and fibrosis that interferes with normal intestinal absorption and also prevents normal intestinal distention. Both intestinal neoplasms and fungal granulomas tend to cause incomplete mechanical obstruction. Onset of clinical signs is often delayed or insidious.[4]



Intraluminal
A

Figure 35-1. Types of mechanical obstruction. A. An intraluminal obstruction caused by a foreign body. B. An intramural obstruction created by neoplasia or granuloma. C. An extra-mural obstruction caused by an extramural mass (top) or kinking of the bowel wall to adhesions (below).

Extraluminal small intestinal obstruction resulting from adhesions is a potential sequela of elective abdominal surgery. Because of this, there is increasing emphasis on minimally invasive laparoscopy techniques in human and veterinary medicine. Most experimental and clinical studies in people found a reduction of adhesions with laparoscopy versus laparotomy.[5] Although adhesions do occur in the dog and cat abdomen following laparotomy, functional obstruction is

less common. Studies of intestinal transit times after planned enteroplication techniques for intussusception in dogs have shown that no delay occurs in actual transit time when planned adhesions are created.[6] Clinical signs relating to extraluminal obstruction in small animals are more often a result of compression because of pancreatic abscess or neoplasia or translocation of the bowel through rents in the mesentery or through hernias in the diaphragm, umbilicus, or inguinal or femoral triangle region. These latter translocations usually lead to strangulation obstruction.

Pathophysiology of Mechanical Obstruction

Accumulation of Gas and Fluid

Complete intraluminal mechanical obstruction results in distention of the bowel proximal (oral) to the obstruction, owing to accumulation of gas and fluid (Figure 35-2). The gas accumulating proximal (oral) to the obstruction consists of swallowed air (72%) and gas formed in the body (28%).[1] Of the gas formed in the body, it is estimated that approximately 70% is gas that diffuses from the blood into the bowel lumen, and a smaller percentage (30%) results from

intramural decomposition of food material by bacteria. The gas in the distended bowel is composed principally of nitrogen (70%), oxygen (10% to 12%), and hydrogen (1% to 3%), which mimics those percentages seen in atmospheric air. Additionally, small amounts of carbon dioxide (6% to 9%) can be formed from neutralization of bicarbonate in the bowel lumen. Organic gases such as methane (1%) or hydrogen sulfide (1% to 10%) when present are the result of low-level bacterial fermentation.[1]

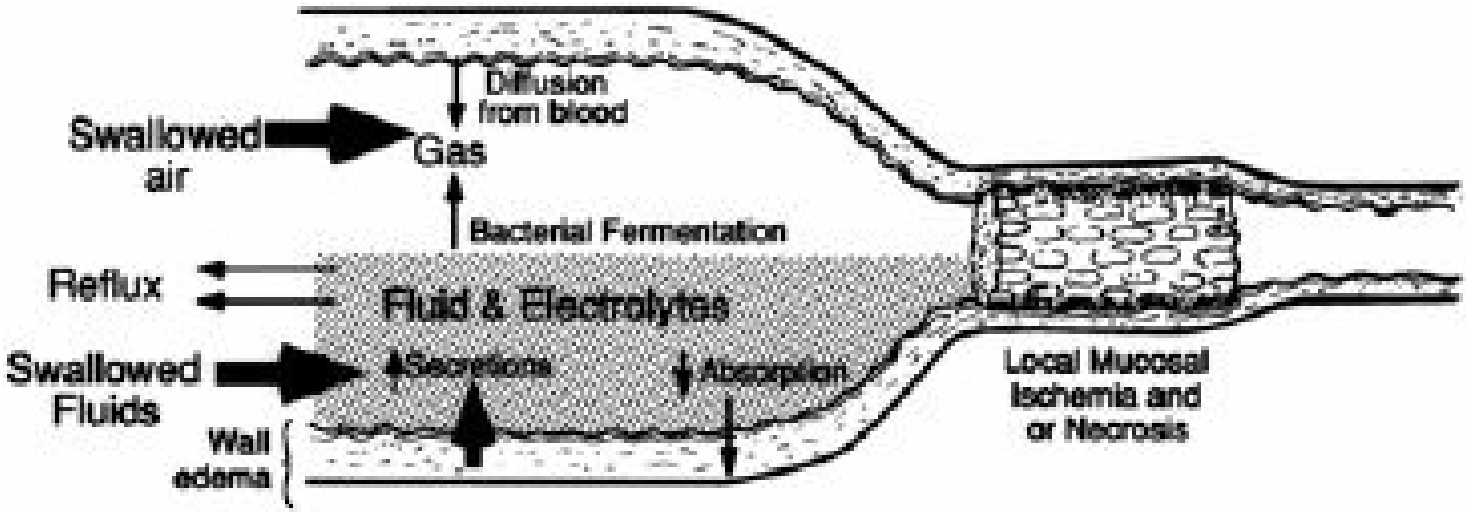

Figure 35-2. The pathophysiology of simple mechanical obstruction associated with an intraluminal foreign body. See text for details.

Fluid accumulation is a result not only of retention of ingested fluids but also of the significant production of secretions in the upper gastrointestinal tract. It is estimated that a 40 kg dog actually produces in excess of 2100 ml of secretions per day. Most of these secretions are reabsorbed in the lower jejunum and ileum; only an estimated 4% to 1% of the water volume reaches

the colon.[7] Water transport in the gut is normally passively regulated, principally by hydrostatic pressure gradients that are created mainly by solute transfer. The intracellular solute pathway that allows passive diffusion between the pores and tight junctions of epithelial cells is controlled by electrochemical, osmotic, and hydrostatic pressure gradients.

During mechanical obstruction, the absorption of water from the gut lumen is reduced by several mechanisms. Transport of solutes through the epithelial cells is impaired, which normally occurs by active transport via sodium ion membrane pumps or brush border membrane

carriers. Intraluminal osmolality is usually increased and additive factors such as lymphatic and venous congestion also reduce the absorption of solutes.[8] In addition, intestinal mucosal secretion is increased owing to the cyclic AMP mechanism. Factors believed to contribute to increased secretion and decreased absorption include increased concentration of intraluminal bacterial enterotoxins, increased levels of bile and fatty acids, or products of tissue ischemia.[9] The distended bowel may lose its ability to absorb fluids within 24 hours after onset of obstruction.

Normal intraluminal pressure in the canine small bowel is 2 to 4 mm Hg. It

is estimated that normal peristalsis may produce pressures in the range of 15 to 25 mm Hg. Three days after creation of a total obstruction, intraluminal pressure in the small bowel of dogs can be as high as 44 mm Hg.[10] During vomiting it can rise as high as 95 mm Hg. Rapid lymphatic and capillary stasis occurs when intraluminal pressure reaches 30 mm Hg, and total occlusion of venous drainage occurs at 50 mm Hg.[9] Because the arterial supply is not affected, capillary congestion can occur at the microcirculatory level. The increased hydrostatic pressure at the capillary bed level produces a net shift of fluid into the interstitium, resulting in bowel wall edema. Eventually, fluid can shift

not only from the bowel wall into the lumen but also through the serosal surface into the peritoneal cavity.

Increases in pressure also cause circulatory impairment of the submucosa and muscular layers of the bowel wall. Early impairment of the villous circulation within the mucosa is seen when the pressure reaches 20 mm Hg. Reductions in mesenteric and submucosal blood flow occur when the intraluminal pressures reach 30 mm Hg. Oxygenation of the intestinal mucosa decreases significantly when the intraluminal pressure exceeds 40 mm Hg. At 44 mm Hg arteriovenous shunting occurs at the mucosal villous base. Therefore, selective mucosal

ischemia can follow simple mechanical obstruction if intraluminal pressure rises above 40 mm Hg. Because in naturally occurring mechanical obstruction physiologic pressure probably does not exceed 50 mm Hg, full-thickness devitalization of the wall usually does not occur in the dilated proximal segment.[10]

Reduced Motility and Bacterial Overgrowth

The bowel responds to gaseous and fluid distention with periodic bursts of neuromuscular activity, resulting in peristaltic rushes. These wave-like movements begin in the proximal bowel and traverse the entire length of

intestine above the point of obstruction. Periods of hyperactivity are then followed by quiescent periods of varying duration. Experimental studies in dogs have shown increased myoelectric activity above the point of obstruction. The intestine distal to the obstruction simultaneously exhibits reduced peristaltic activity. With increased distention from prolonged obstruction, clusters of intense myoelectric activity are felt by the patient as intermittent cramps (colic). It is believed that this phenomenon is largely caused by stimulation of the proximal bowel through cholinergic pathways and by inhibition of the bowel distal to the obstruction through noncholinergic nonadrenergic

pathways.[11]

Small intestinal stasis may lead to luminal bacterial over-growth. In normal intestinal mucosa, bacteria and their enterotoxins are not able to cross the mucosal barrier. In the impaired mucosal barrier, a potential exists for increased permeability and migration of bacteria and their toxic products into the systemic circulation or the peritoneal cavity.[1] Decompression of the distention usually allows reversal of the circulatory changes and provides for rapid mucosal regeneration.[10] However, if necrosis of the bowel wall occurs owing to prolonged severe distention or direct pressure from the obstructing object, the mucosal barrier

may break down and transmural migration of bacteria and endotoxins beneath the obstructing foreign body may occur.

Level of Obstruction and Electrolyte Loss

The classic clinical signs associated with high (duodenal and proximal jejunal) obstruction are described as frequent vomiting that begins soon after the onset of obstruction. Yet experimental data support the observation that dogs and cats with high intestinal obstruction may not begin vomiting for 24 to 72 hours. Electrolyte loss is closely associated with the level of obstruction. With

obstructions at the pylorus, gastric fluids that are rich in potassium, sodium, hydrogen, and chloride ions are vomited. Hypochloremic, hypokalemic, moderately hyponatremic metabolic alkalosis with dehydration may result in early stages.[4] Animals that vomit profusely do not survive as long as those that do not vomit at all.[8]

Severe vomiting associated with duodenal and proximal jejunal obstruction causes loss of gastric hydrochloric acid and bicarbonate-rich alkaline pancreatic secretions. Dehydration with mild metabolic acidosis usually results. With continued fluid depletion, progressive

hypovolemic shock occurs. The major cause of mortality from upper small-intestinal obstruction is associated with this severe and rapid hypovolemia. Dogs with experimental complete upper intestinal occlusion usually died within 3 or 4 days without crystalloid fluid therapy.[8] Mortality was greatly reduced with parenteral infusion of physiologic saline or lactated Ringer's solution. Experimental reinfusion of vomitus into the dog's bowel below the obstruction was also life saving.[8]

With low small-intestinal obstruction, the onset of vomiting may not occur until 2 or 3 days after onset of obstruction and it is often intermittent. The distention usually is gaseous

during the initial 24 hours, but thereafter is accompanied by loss of varying quantities of fluid into the bowel lumen. Fluid sequestered in low intestinal obstructions is usually mildly hyperosmotic and similar in composition to plasma. Analysis of intraluminal fluid after experimental low obstruction in dogs reveals a mean level of sodium of 140 mEq/L; of potassium, 16.8 mEq/L; and of albumin, 3.6 mg/dl.[8] The sequestration of these fluids from the upper gastrointestinal tract and the increase in secretion of new fluid electrolytes and protein cause a net loss of these compounds. The intraluminal fluid volume increases as the obstruction persists, although some sequestered

fluid may move orally and eventually reach a nondistended loop of bowel, where normal reabsorption occurs. Lethargy and anorexia are often apparent in dogs with low intestinal obstruction. These animals exhibit steady weight loss and drink but do not eat. Dogs with experimentally created complete low intestinal obstructions may survive three weeks or longer if adequate water is provided.[9]

Evaluating Intestinal Viability

Intestinal viability is best evaluated after decompressing the dilated loops of bowel and removing the obstruction. In most cases of simple

nonstrangulated obstruction, bowel viability is maintained and the appearance of dark distended loops of bowel improves rapidly after enterotomy and removal of the obstruction. Questionable areas of bowel viability are assessed with standard clinical criteria, including bowel-wall color, presence of arterial pulsations, and presence of intestinal peristalsis. The continued presence of intestinal myoelectric activity is the most important parameter of viability.[4] The *pinch test* should be performed on questionable areas of intestine, to determine whether smooth muscle contraction and peristalsis can be initiated.

Experimentally, bowel-wall viability has been assessed using temperature probes, pH monitors, Doppler devices, intravenous vital dyes, and surface oximetry. Fluorescein dye given intravenously through a peripheral vein at a dose of 20 mg/kg has been shown to be beneficial in determining intestinal wall (but not gastric wall) viability, particularly if the ischemia is mainly arterial versus venous in origin.[10] The tissues are subjected to 365-nm ultraviolet light (Wood's lamp). Normal bowel wall viability is represented by a bright green glow with smooth, uniform fluorescence. Areas of the bowel are considered viable if they have a normal or fine granular fluorescent pattern. Areas of

bowel are considered nonviable if they have a patchy density where areas of nonfluorescence exceed 3 mm diameter or where only perivascular fluorescence is seen.[12] Pulse oximetry has also been utilized as a feasible technique to evaluate experimental intestinal ischemia in dogs. Dogs with bowel segment values exceeding PO_2 of 85% in general survived, whereas those with values lower than this had statistically higher incidence of ischemia and anastomotic breakdown. All anastomoses performed in segments with PO_2 values of 60 to 70% failed.[13]

Strangulation Obstruction

Causes and Classification

By definition, strangulation obstruction implies an obstructive process with loss of vascular integrity to the bowel wall. Common causes include intussusception, traumatic avulsion of the mesentery, mesenteric arteriothrombosis, mesenteric (intestinal) volvulus, and strangulated diaphragmatic, inguinal, or abdominal hernia. Foreign bodies can also create local small discrete areas of "pressure" strangulation necrosis. Strangulation obstruction may occur secondary to venous obstruction or thrombosis, arterial obstruction or thrombosis, or a combination of both. If the strangulating process incorporates the mesenteric vessels, devitalization of

large segments of the intestinal tract may occur. Strangulation obstruction should be considered a medical and surgical emergency. Death is often rapid, the result of hypovolemia and septic shock secondary to devitalization of the intestinal wall.

Pathophysiology

Pathophysiologic changes as described under simple mechanical obstruction occur proximal to the strangulation obstruction in addition to the direct changes attributable to the strangulated bowel segment. Partial venous occlusion, such as that caused by partially strangulated hernia or intussusception, is a common type of

intestinal strangulation in small animals. With venous occlusion alone, the arterial supply remains intact, allowing bowel-wall edema and sequestration of blood in the intestinal wall. Motility changes in the bowel wall are proportional to the duration of venous obstruction. Spike activity and motility of the affected bowel segment may be initially increased. As tissue hypoxia progresse, cyanosis becomes evident and motility gradually decreases until it ceases completely.

With complete venous occlusion or thrombosis, wall edema, hemorrhage, and mucosal epithelial sloughing can occur as early as 1 to 3 hours after the

insult. The strangulated loop then gradually becomes more turgid, and whole blood begins accumulating in the bowel lumen and extravasating into the peritoneal cavity (Figure 35-3). The bowel wall becomes visibly thickened and dark red to blue. Eight to 12 hours after complete venous occlusion the bowel segment turns black and distends maximally. When complete arterial occlusion occurs, as with mesenteric volvulus, full-thickness ischemia of the bowel wall occurs and bacteria and red cells invade all layers of the wall within 20 hours of strangulation.

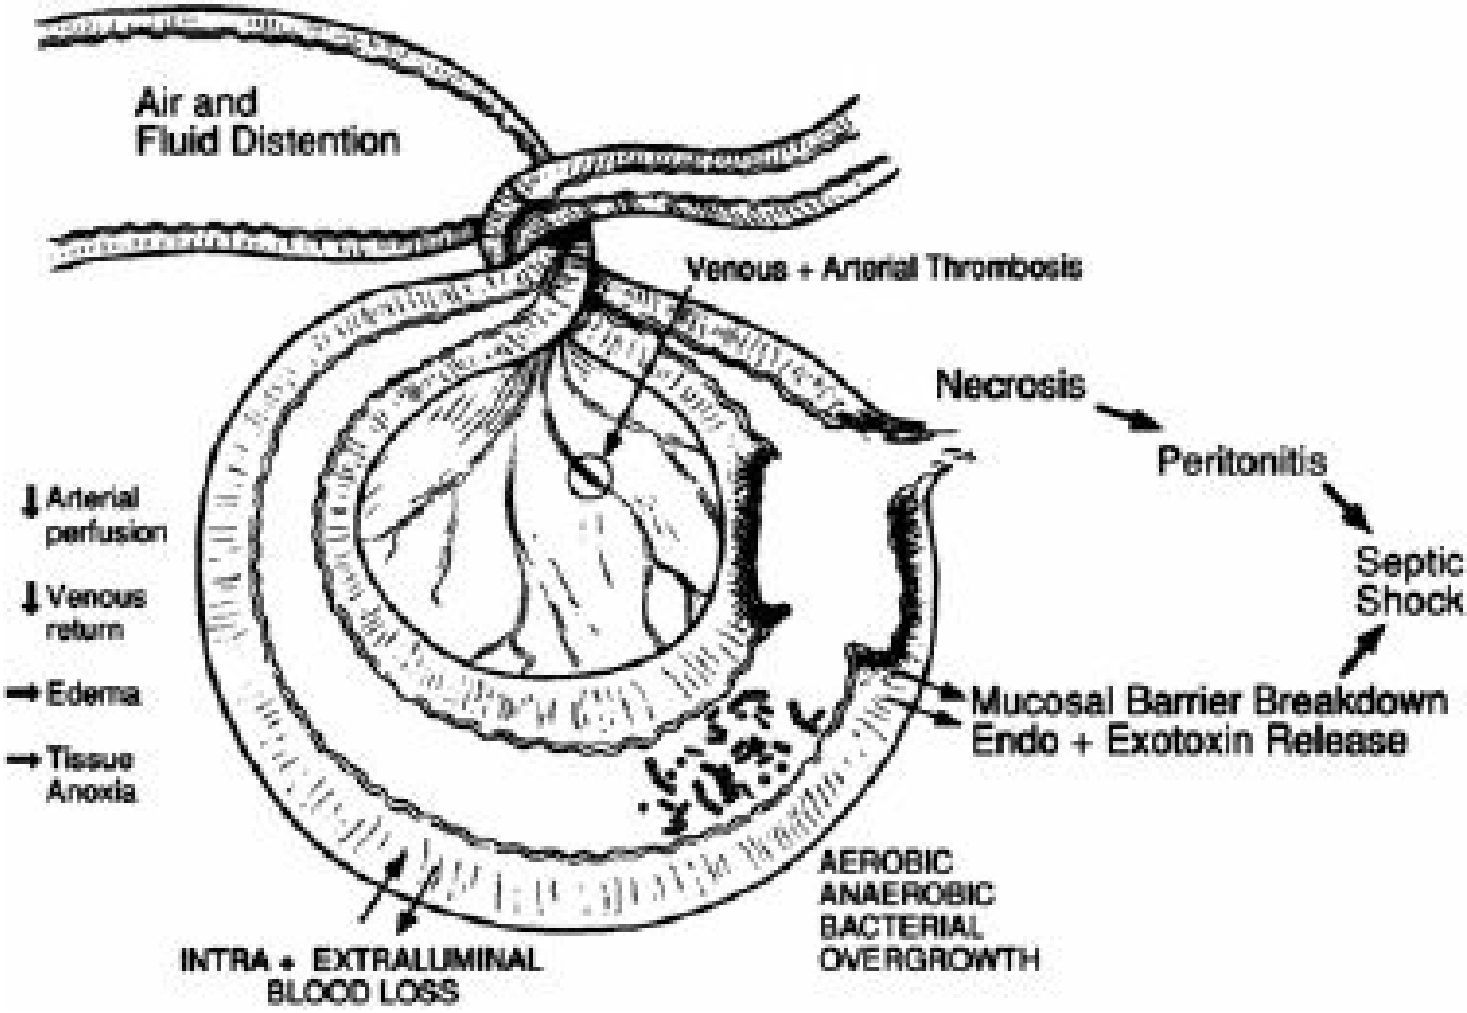

Figure 35-3. The pathophysiology of strangulation obstruction associated with intestinal volvulus. See text for details.

Translocation of Bacteria

The flora in the proximal small bowel consists primarily of gram-positive, facultative bacteria, whereas the distal

small intestine contains primarily aerobic coliforms and anaerobic species. Organisms that are normally found in the terminal intestinemove to upper levels of the small intestine. Marked increases in aerobic coliform bacteria and Streptococcus species occur, in addition to large increases in anaerobic Clostridia and Bacillus species. Small intestinal bacterial concentrations that normally range from 10^2 to 10^4 per milliliter liquid secretion may increase to 10^8 to 10^{11} per milliliter within just 6 hours after the onset of strangulation.[14] A massive proliferation of resident bacteria also occurs within the strangulated section of bowel. Bacteria, particularly *Clostridium perfringens,* play a key role

in the mortality of strangulation obstruction because germ-free animals live significantly longer than those with normal intestinal flora in experimental models.

Loss of mucosal function leads to passage of viable bacteria or endotoxins through the epithelial mucosa into the lamina propria and then to the intraabdominal cavity and systemic circulation. Bacterial translocation does occur in simple mechanical obstruction of the small bowel or colon. In strangulation obstruction, the loss of gut barrier function occurs more severely compared with simple obstruction because the ischemia promotes the

rapid destruction of the intestinal epithelium. Three mechanisms that promote bacterial translocation have been identified: 1) intestinal bacterial overgrowth; 2) increased permeability of the intestinal mucosal barrier; and 3) deficiencies in host immune defenses.[14]

Clinical Presentation

Clinically, free peritoneal fluid begins to accumulate shortly after the development of strangulation obstruction. Initially, the fluid is a transudate resulting from effusion from serosal vessels secondary to venous congestion or obstruction. The initial fluid is pink, clear, and odorless, and

relatively low in protein. As the length of time of strangulation obstruction increases, the appearance of the fluid changes: it becomes black and has a foul odor. This is thought to be caused by filtration of lumen contents through the devitalized bowel wall.[14] After prolonged strangulation obstruction, hypoxia in the intestinal wall results in complete breakdown of the mucosal barrier. With arterial thrombosis, full-thickness necrosis occurs, as does perforation and septic peritonitis, with resultant inflammatory cells, ingesta, and bacteria.

Many experimental and clinical studies have independantly proposed the hypothesis that the loss of gut barrier

function and the consequent translocation of bacteria and their products may play an important role in the development of multiple organ failure (MOF) in strangulation obstruction. Evidence is growing that loss of gut barrier function to bacteria and or “endotoxins” might induce a local intestinal inflammatory response and lead to the subsequent release of cytokines (TNF, IL-1, 1L-6, IL-8, etc.).[15] Strangulation obstruction has been shown to cause increased release of IL-6 to intestinal venous blood in pigs.[16]

Plasma lactate has been shown to be of value in the diagnosis of gastrointestinal ischemia. In dogs with GDV, serum lactate values of more

than 6 mm/L have been shown to be a positive predictor of gastric necrosis.[17] Likewise, peritoneal lactate levels in dogs with experimentally induced ischemia of the small intestine were found to be highly predictive for intestinal ischemia in these animals.[18]

Treatment

Treatment for strangulated intestinal obstruction involves not only fluid and electrolyte support but also aggressive antibiotic therapy, and possibly nonsteroidal anti-inflammatory drugs. If massive blood loss has taken place, blood transfusions may also be warranted. Early surgical removal of the devitalized section of bowel wall is

essential. In experimental models of strangulated obstruction in dogs, death is delayed by the administration of broad-spectrum systemic antibiotics, particularly the aminoglycoside derivatives in combination with penicillins and metronidazole or third-generation cephalosporins.

Intestinal Pseudo-obstruction

Chronic intestinal pseudo-obstruction is a syndrome, originally described in humans, characterized by chronic or recurrent symptoms of intestinal obstruction. The obstruction occurs in the absence of both organic luminal obstruction and a recognized

underlying disease. Although previously limited to the human literature, the disease syndrome has been described in two dogs and a cat.[19-21] Clinical manifestations result from delayed intestinal transit caused by disordered motility. Although all portions of the alimentary tract can be affected, the small bowel is most often involved. In some cases of pseudo-obstruction no pathologic abnormality can be found. In other cases, histologic examination has shown two distinct pathologic abnormalities. In humans, one pathologic subtype includes direct degeneration of intramural neurons, which are specifically associated with arrangement of the myenteric plexus, the celiac ganglion, the spinal cord,

and even the brain. This type of chronic pseudo-obstruction has been labeled “visceral neuropathy.” The second type of idiopathic intestinal pseudo-obstruction is caused by degeneration of intestinal smooth muscle cells -- so-called visceral myopathy. Histologic sections of bowel of this type have shown vacuolization of the smooth muscle and atrophy of muscle fibers in both the longitudinal and circular muscle layers of the bowel wall. All affected animals had chronic vomiting and weight loss with concurrent dilatation of the small intestine. In a mixed breed dog, atrophy of cecal smooth muscle fibers as well as infiltration of plasma cell lymphocytes and macrophages and

mild lymphoplasmacytic enteritis were present.[19] In an English bulldog, both atrophy and fibrosis with monocellular infiltrate were noted from the duodenum to the colon.[20] In a cat, a regional jejunal area also displayed marked atrophy of the outer longitudinal muscular layer along with fibroplasia and vacuolar degeneration consistent with visceral myopathy in humans.[21] Clinical signs of idiopathic intestinal pseudo-obstruction in man include abdominal pain, constipation, diarrhea, and vomiting. In the acute stages, abdominal distention may occur. Surgery is usually avoided if possible; it is rarely beneficial. Stimulation of the gastrointestinal smooth muscle by prokinetic agents

such as metoclopramide or cisapride might be helpful, as might nutritional support, in the form of enteral hyperalimentation. Results of surgery in animals have been similarly unsuccessful.

Chapter 36

Ileus

Gary W. Ellison

Ileus, also known as adynamic ileus, paralytic ileus, postoperative ileus, or intestinal dysmotility is a transient and usually reversible intestinal obstruction caused by delayed intestinal motility. Intestinal contents fail to progress aborally because of ineffective intestinal propulsion in the absence of mechanical occlusion of the lumen. Ileus is clinically manifested by abdominal distension, lack of bowel

sounds, delayed passage of ingesta, and accumulation of gas and fluid in the bowel that may lead to nausea and vomiting. The exact pathophysiologic basis of ileus is unknown but is likely multifactorial with three major interrelated mechanisms -- neurogenic, inflammatory, and pharmacologic -- leading to its development.[1] It is among the most significant side effects of abdominal surgery in humans and horses, accounting for increased morbidity and prolonged hospitalization. The condition is less well understood in small animals. Whether it is less prevalent or whether the clinical signs are less severe than in other species is unclear.

Etiology

Ileus may be caused by a wide variety of intraabdominal, extra-abdominal, and systemic conditions, in addition to a host of chemical and pharmacologic agents (Table 36-1). Peritoneal inflammation, caused by infection, bile leakage, pancreatic enzymes, or surgery, can induce ileus in small animals. Systemic derangements owing to sepsis and electrolyte imbalances are also associated with ileus. In addition, ileus can be pharmacologically initiated via the administration of opioids, anticholinergic drugs, and the phenothiazine tranquilizers. Reported extra-abdominal causes may include

systemic toxicity, uremia, spinal cord trauma, shock, and prolonged anesthesia.[2] Extra-abdominal thoracic lesions such as pneumonia, myocardial infarction, congestive heart failure, or rib fractures are reported causes of ileus in humans, but these remain undocumented in the dog and cat. Abrasion of the intestinal serosal surfaces with dry surgical sponges creates an ileus model in dogs that is used to study the human disease.[3] Postoperative ileus is inherent to any intraabdominal surgical procedure, but its severity and duration appear less with laparoscopic procedures.[1]

Neurohormonal Mechanisms

of Ileus

Parasympathetic (cholinergic) stimulation increases intestinal motility and secretion, whereas sympathetic (adrenergic) stimulation results in reduced motility and an increase in sphincter tone. Postoperative ileus may occur secondary to sympathetic hyperactivity and parasympathetic hypoactivity. Evidence of increased circulating levels of epinephrine and norepinephrine following abdominal surgery supports this theory. Stimulation of the sympathetic nervous system inhibits the interdigestive motor complexes that ordinarily propel the bowel contents aborally. Release of

norepinephrine also appears to inhibit release of excitatory neurotransmitters such as acetylcholine, thereby allowing the inhibitory neurons to dominate.[2] The protective effect of alpha and beta sympathetic nerve blockers, splanchnic nerve division, or spinal anesthesia against the development of postoperative ileus in dogs and cats further supports this concept.[3]

Arteritis

The dog normally undergoes a period of reduced myoelectric activity after exploratory laparotomy. Studies in dogs have shown that normal small intestinal myoelectric activity usually resumes by 12 hours postoperatively, whereas gastric paresis persists for approximately 24 hours. Colonic

motility is most affected; normal status does not return until approximately 48 hours after laparotomy.[4] Myoelectric slow waves still exist in the outer longitudinal muscles with ileus but do not initiate action potentials and associated contractile activity within the circular muscle layers. This electromechanical dissociation appears to result from a tonic discharge of inhibitory neurons and an absence of spike waves. Because the presence of ingesta may stimulate parasympathetic tone and resultant contractile activity, surgeons have noted that patients receiving enteral alimentation in the immediate postoperative period experience less postoperative ileus than do patients who are made to

fast.[1]

Humoral intestinal peptides may also contribute to the pathophysiology of postoperative ileus. The hormone vasopressin disrupts jejunal motility and occurs in high levels in plasma following laparotomy, whereas the prokinetic hormones motilin and neurotensin stimulate small-intestinal activity and are suppressed for 24 hours following laparotomy.[4] Return of motilin to normal levels corresponds with return of motility. Release of endogenous opiates has also been proposed as a cause of ileus. Although naloxone does not relieve postoperative ileus in dogs, fedoztozine, a k-opioid agonist does

restore intestinal motility in rats.[5]

Electrolyte imbalances have been associated with experimental ileus in dogs. A significant reduction in intestinal propulsion is associated with decreases in serum sodium and chloride values. Potassium deficits may play a more profound role than the sympathetic nervous system in the development of ileus. Hypokalemia may negatively effect the exchange of cellular potassium for plasma hydrogen ions when acidosis is present and greatly reduce smooth muscle contractility.[6]

Progression of Ileus

Ileus may affect the entire

gastrointestinal tract or may be localized to one area. Obstruction in any one segment of the intestine may secondarily affect the rest of the intestinal tract via an intestinointestinal reflex whereby distention of bowel in one area inhibits motility in other areas. Therefore, segmental ileus can ultimately become diffuse. With prolonged ileus, pathophysiologic changes are similar to those seen in simple mechanical obstruction. Although there is no physical barrier to the passage of ingesta, the bowel becomes functionally obstructed owing to lack of effective intestinal motility. The lumen of the adynamic segment fills with swallowed air, gas from bacterial

fermentation, ingested fluids, and secretions from the stomach, pancreas, intestine, and biliary tract. During ileus, these fluids are not resorbed and additional fluids are secreted from the distended gut wall. The net loss of circulating intravascular fluid results in dehydration and ensuing hypovolemic shock.[3]

Unresolved ileus perpetuates a vicious cycle, whereby distention promotes further ileus, which leads to greater distention. Prolonged ileus may also result in diffuse intestinal damage as a result of lymphatic and venous obstruction. Mucosal arteriovenous shunting, hypoxia, ischemia, and necrosis may all result. Early ischemia

of the bowel wall initially results in hypermotility and spasms; complete cessation of motility occurs as the bowel-wall ischemia progresses toward necrosis. Similar to simple mechanical obstruction, bacterial over-growth occurs, and endotoxins may be produced in larger quantities than normal. In severe cases of long-standing ileus, transmural migration of bacteria and endotoxins may result in signs consistent with septic shock.

Pain-Induced Ileus

Animals that have post-laparotomy ileus characteristically do not show severe abdominal pain, although those that develop ileus secondary to septic

peritonitis show abdominal splinting and clinical signs associated with abdominal pain. The mechanism of ileus secondary to peritonitis is a direct result of noxious stimuli of the abdominal viscera and parietal peritoneum. Visceral pain impulses stimulate sympathetic splanchnic nerves, which traverse the splenic ganglion and sympathetic chain to increase sympathetic tone. The inflammatory response must involve multiple nerve endings and be acute in order to create visceral abdominal pain (colic). This adrenergic stimulation of receptors in the gut wall is thought to inhibit intestinal motility.

Nerve endings of pain fibers are

located in the submucosa of the bowel wall. Therefore, any process that causes fluid or gaseous distention, intestinal obstruction, forceful contraction, hypersegmentation, or traction (adhesions) may produce pain. Inflammation, whether it be secondary to peritonitis or due to tissue ischemia produces abdominal pain by creating a local intestinal inflammatory response, which leads to the subsequent release of cytokines (TNF, IL-1, IL-6, IL-8).[7] Nerve endings are also plentiful in the parietal peritoneum, and these are sensitive to the massive inflammatory response. This is why the splenic rigid abdominal posture and resistance to palpation are seen in most cases of ileus secondary to generalized

peritonitis.[8]

Drug-Induced Ileus

Postoperative pain can cause bowel stasis, abdominal distention, discomfort, and vomiting. Analgesic intervention may alleviate these signs but may also have the potential to exacerbate ileus. Perioperative administration of drugs that inhibit intestinal motility may potentiate the severity of ileus in the postoperative period. In dogs, opioids such as morphine or hydromorphone act as gatrointestinal μ2 receptor agonists. They cause stasis by decreasing longitudinal muscle propulsive motility and increasing segmental contractions.

Other opiates such as loperamide decrease pancreatic and biliary secretions and have antisecretory effects on the bowel that contribute to their antidiarrheal properties.[1] The effect on motility of other opioids such as butorphanol or pentazocine at recommended analgesic doses appears less inhibitory in dogs.[9]

The use of analgesics is particularly important with regard to intestinal motility in cats. The combination of ketamine (5 mg/kg) and midazolam (0.1 mg/kg) decreases gastrointestinal motility. Intramuscular acepromazine at 0.1 mg/kg combined with buprenorphine 0.01 mg/kg or medetomidine (50 μg/kg) does not

affect orocecal transit time when used for short periods; however, oral buprenorphine used over several days may slow transit time.[10] Transdermal fentanyl patches do not seem to slow motility in dogs or cats. Anesthetic regime also will affect the incidence of postoperative ileus. In human medicine, the use of short-acting induction agents such as propofol, rapidly cleared inhalants such as sevoflurane, and minimally inhibitory opiates such as fentanyl is a preferred regime in the prevention of postoperative ileus.[9]

Clinical Signs

Clinical signs associated with ileus in

dogs and cats are often obscure. Small-animal clinicians rarely auscultate the abdomens of their patients so reduction in intestinal sounds and borborygmi may be inconsistent findings. Gross abdominal distention may be present, and evidence of fluid and gas distention of the small intestine may be noted on radiographs or ultrasonography. Distended loops of bowel also may be present on abdominal palpation. Loops of bowel distended by ileus are generally not as large, turgid, or painful as those distended by simple mechanical or strangulation obstruction. In long-standing cases of ileus, feces may be minimal or absent. In the absence of peritonitis, pain is not usually

associated with ileus unless intestinal distention becomes severe. Gastric reflux on intubation is a hallmark of intestinal ileus in horses and humans, but its significance in small animals appears minimal.[2]

Treatment

Ileus that is uncomplicated and not associated with organic obstruction often resolves spontaneously without aggressive treatment. Early postoperative feeding is recommended to stimulate gastrointestinal motility and speed intestinal wound healing in patients recovering from gastrointestinal surgery. Failure of ileus to resolve spontaneously indicates

that mechanical obstruction, strangulation obstruction, or septic peritonitis may be present. Abdominocentesis may be indicated to differentiate simple ileus from more severe strangulation obstruction.

Successful treatment of ileus involves the correction of concurrent electrolyte imbalances, elimination of underlying abdominal disease (including decompression of the distended bowel when possible), and possibly, promotilility drug therapy. Dehydration and serum electrolyte and acid-base status imbalances should be corrected. Serum potassium concentration is particularly important, because the concurrent

movement of potassium from the extracellular to the intracellular space may result in hyperkalemia or hypokalemia. In the case of hypokalemia, supplementation with intravenous potassium is indicated. Bicarbonate supplementation may also be indicated to correct metabolic acidosis.

Because most cases of paralytic ileus in dogs and cats resolve spontaneously, the presence of continued, unaccounted for intestinal distention should warn the clinician of a residual problem that warrants exploratory laparotomy. Any areas of devitalized bowel must be removed at surgery. Gas and fluids should be removed from

remaining distended loops of bowel, using a 22-gauge needle and continuous-suction apparatus. An indwelling nasogastric tube may also be placed, to decompress the stomach in the postoperative period. Continuous or intermittent suction can be applied to these tubes to facilitate continued gastric and intestinal decompression in the postoperative period.

Pharmacologic Therapy

Administration of drugs to stimulate intestinal motility and counteract the effects of ileus has not been consistently successful. Sympathetic blockade, parasympathetic stimulation,

or both have been advocated. The anticholinesterase drug neostigmine does increase propulsive motility of the colon, although it decreases propulsive motility of the jejunum and delays gastric emptying. Pain may also occur secondary to intestinal spasm. In addition, neostigmine may increase the risk of anastomotic dehiscence and, therefore, is not recommended.[3]

Sympathetic nervous system blockade with phenothiazine derivatives such as chlorpromazine has been used to treat postoperative ileus in humans. This drug is a sympathetic alpha-blocker, which can potentiate shock. Therefore, animals should be well hydrated and their cardiovascular status stable

before acetylpromazine or chlorpromazine is administered.[1] Sympathetic blockage with topical analgesics or opioids has been shown to counteract ileus in people, but is little used in dogs.

Metoclopramide is an anti-dopaminergic drug that appears to enhance coordination of gastroduodenal motor activity. Its gastrointestinal smooth muscle action is thought to result from antagonism of the inhibitory neurotransmitter dopamine; however, it now appears that metoclopramide acts to directly enhance gastrointestinal motility by augmenting release of acetylcholine, and perhaps by inhibiting serotonin

release. Metoclopramide was shown to reverse decreased gastrointestinal myoelectric and contractile activity in surgically created adynamic ileus in dogs but its efficacy in humans is questionable.[1,11] Metoclopramide may decrease nausea and vomiting owing to its gastric effects rather than by correcting postoperative ileus.

Cisapride is a benzamide drug that stimulates gastrointestinal motility, most likely by facilitating acetylcholine release from myoenteric nerves. Unlike metoclopramide, cisapride possesses no antidopaminergic properties. In addition, it has no effect on gastrointestinal secretion. Experimentally it has been shown to

increase lower esophageal sphincter tone, accelerate gastric emptying, and accelerate colonic transit. Experimental work in dogs indicates that cisapride increases the amplitude of intestinal peristaltic waves.[12] The drug was withdrawn from North American and Western European markets in 2000 owing to reported cardiac effects in people, but the drug is still available through compounding agencies in the United States. A new human prokinetic agent, tegaserod may prove useful in therapy of intestinal motility disorders of animals in the future. Tegaserod is a potent partial nonbenzamide agonist without the effect of prolonging cardiac QT intervals as does cisapride. Tegaserod

at doses of 3 to 6 mg/kg has been shown to normalize intestinal transit time in opioid-induced bowel dysfunction in dogs.[13]

Nonsteroidal anti-inflammatory drugs may reduce the incidence of ileus by reducing postoperative pain and inflammation. The Cox-2 inhibitors in particular are thought to reduce the risk and duration of postoperative ileus in people, in part owing to reduction in the need for opiates by as much as 30%.[1] This, of course, must be balanced with the increased tendency toward gastrointestinal bleeding and nephrotoxicity.

Opioid antagonists such as naloxone

and alvimopan have been used in human medicine in an attempt to reduce postoperative ileus. Naloxone has been unsuccessful but alvimopan was shown to reduce the incidence of postoperative ileus if given before surgery.[1]

Experimental work has demonstrated that electrical pacing can alter frequency and direction of propagation of the enteric myoelectric pacesetter in dogs. Potentially, antegrade pacing might be expected to enhance gastric or intestinal emptying or to play a positive role in disorders of intestinal atony or stasis. Although these studies are experimental, clinical use may be feasible in the future.[3]

Summary

Motility of the intestinal tract depends on a highly integrated and coordinated response of the smooth muscle of the bowel wall. Motility of the small and large intestineis controlled by three basic mechanisms: myogenic, neural, and humoral. Present understanding of the control mechanisms and the physiologic and pathologic states that initiate ileus is not complete; however, it can be said that motor disorders usually affect the entire gastrointestinal tract. The disorders can be intrinsic to the gut wall itself, can be caused by an inflammatory process or myogenic dysfunction, or can result from inflammation of the

bowel.

Surgical therapy is seldom indicated for the treatment of adynamic or postoperative ileus. Promotility agents, including metoclopramide, cisapride, and tegaserod may be useful in the supportive treatment of hypomotility disorders. Opiates prolong gastrointestinal transit time and may compound the problems seen with ileus. Opioid antagonists may show promise as potentiators of intestinal motility in the future. Laparoscopic procedures show promise of reducing the incidence and severity of postoperative ileus when compared with open laparotomy.

Chapter 37

Disorders of Visceral Healing

Gary W. Ellison

The small-animal surgeon routinely creates wounds in the gastrointestinal tract for biopsy, for foreign body or neoplasm removal, or for correction of strangulation obstruction. The urinary bladder wall is likewise wounded to remove calculi or to resect bladder wall tumors. The uterus is incised during cesarean section or removed in ovariohysterectomy, electively or when necessitated by infection. Although

dehiscence of a skin wound is often easily remedied with appropriate local wound treatment, dehiscence of a hollow viscus is usually life threatening. Wound dehiscence of the digestive system often leads to generalized bacterial peritonitis and subsequent death. Wound dehiscence of the uterus can have the same outcome if pre-existing intrauterine sepsis is present. Leakage of cystotomy closure may also lead to uroperitoneum, uremia, hyperkalemia, and ultimate death as well. Therefore, factors that negatively affect visceral healing are potentially of great clinical significance to the surgeon.

Normal Wound Healing of the Viscera

The gastrointestinal, urinary, and reproductive tracts follow the same basic healing curve as the skin but have accelerated healing properties. The *lag* or *inflammatory* phase of healing lasts 3 to 4 days.[1] Immediately after wounding, blood vessels contract, platelets aggregate, the coagulation mechanism is activated, and fibrin clots are deposited to control hemorrhage. The fibrin clot offers some minimal wound strength on the first postoperative day, but the main wound support during the lag phase of healing comes from the sutures.[2] Enterocyte and uroepithelial regeneration begins

almost immediately after wounding; however, the epithelium offers little biomechanical support.[2,3] The lag phase is the most critical period during visceral wound healing, because most dehiscences take place within 72 to 96 hours after the wound has been created.[2]

The *proliferative* or *logarithmic* phase of visceral wound healing lasts from day 3 or 4 through day 14.[1] Rapid proliferation of fibroblasts occurs logarithmically during this period. The fibroblasts produce large amounts of immature collagen, resulting in rapid gains in wound strength. The proliferative phase of wound healing is a dynamic process in which collagen

synthesis takes place in the presence of collagenolysis. In the stomach, small intestine, and urinary tract, collagenase activity at the wound edge is minimal and rapid gains in tensile and bursting strength occur. At the end of 14 days, gastric and small-intestinal wound bursting strength is approximately 75% that of normal tissue. The urinary bladder heals even faster, regaining 100% of normal tissue strength at 14 to 21 days.[3] Conversely, the colon heals much more slowly owing to marked collagenase activity at the wound edge and regains only about 50% of its normal tensile strength 14 days after wounding.[1] Factors such as traumatic suturing, fecal material, bacterial

contamination, and infection all increase the amount of local collagenase produced at the wound edge.[2]

The *maturation* phase of wound healing is characterized by reorganization and cross-linking of collagen fibers. This phase extends from day 14 through day 180 in the gastrointestinal tract of the dog,[1] and from day 14 through day 70 in the dog bladder.[3] As with skin wounds, the size and thickness of the scar decrease during this time without weakening the wound. The maturation phase is relatively unimportant clinically in visceral wound healing, because acceptable tensile and bursting strength have been established by the

end of the proliferative phase of wound healing and leakage is virtually nonexistent at this point.[2]

Factors that Negatively affect Visceral Wound Healing

Nutritional Depletion

Tissue trauma, sepsis, burns, and major surgery induce major metabolic changes in small-animal patients. With each of these stresses, the animal's basic metabolic rate is accelerated and protein metabolism occurs, leading to a potential state of negative nitrogen balance. Protein-calorie malnutrition (PCM) occurs because of starvation,

when a metabolic response to injury becomes prolonged, or when a hypermetabolic state occurs such as that caused by sepsis. It takes only 5 to 10 days of anorexia to compromise the immune system and deplete the body's muscular and hepatic glycogen stores.[4] When PCM is present, cell-mediated immunity is impaired, and there is a high risk of infection, anemia, and hypoproteinemia. Wound healing may also be impaired.

Caloric and protein depletion in experimental animals has been shown to inhibit dermal, muscular-fascial, and visceral healing, but only after a loss of 15% to 20% of body weight.[5] Decreases in wound breaking strength

are directly proportional to the carcass weight loss. It is estimated that 75% of animals with elective surgical wounds attain functional wound union during the period of negative nitrogen balance;[6] however, extended PCM from muscle, visceral, or plasma tissue losses increases the risk for visceral wound disruption. Impaired visceral wound healing is due both to a prolonged lag phase of healing and to diminished capacity for fibroplasia within the logarithmic phase.[7]

Effect of Early Postoperative Enteral Feeding on Visceral Healing

Malnutrition induces intestinal mucosal atrophy, reduced motility, increased incidence of ileus, and the potential for bacterial translocation through the bowel wall, with resultant sepsis. Impaired wound healing owing to nutritional causes may be ameliorated by feeding an enteral or parenteral diet that supplies energy needs in the form of fatty acids and sugars and provides essential amino acids.[4,7] Feedings of high-protein meals after injury can optimize conditions for normal visceral wound healing. Amino acids provided through enteral nutrition are utilized for the synthesis of hexosamines, proteoglycan polymers, nucleic acids, and structural proteins such as actin, myosin,

collagen, and elastin.[7]

Early, if not immediate, postoperative enteral feeding has been shown to have a positive influence on the healing rate of intestinal anastomosis in dogs. Bursting pressures and collagen levels of ileal and colorectal anastomosis were compared in Beagles fed elemental diets versus those fed only electrolyte and water for four days. The dogs fed elemental diets had nearly twice the bursting strengths of the control group and nearly double the amount of both immature and mature collagen at the wound site.[8] Total parenteral nutrition (TPN) does not appear to ameliorate the mucosal atrophy or increase collagen

deposition as does enteral nutrition. In human studies, the incidence of septic complications was significantly lower in people fed between 8 to 24 hours after surgery versus those maintained on TPN. Additionally, those patients fed early had a reduced incidence of postoperative ileus and reduced hospital stay.[9]

Anemia

Small-animal patients with polytrauma, major burns, or malignancies are frequently anemic. Studies of experimental anemia in rats induced by phlebotomy or iron-deficient diet have shown suppression in wound healing only if the animals'

blood volume remained deficient or significant malnutrition accompanied the iron-deficient diet.[5] With anemia resulting from phlebotomy, intravascular volume replacement results in normal wound healing.[10] Therefore, anemia in the absence of concurrent malnutrition or volume deficit does not appear to be a factor in suppressed visceral wound healing.

Leukopenia

Neutropenia caused by disease processes or induced by chemotherapy has been suspected of causing impaired wound healing. Contaminated wounds are more likely to become infected in the presence of neutropenia, but

minimal problems are encountered with clean wounds. Neutropenic animals have been shown to have a reduced number of neutrophils at the wound site during the inflammatory phase of wound healing. However, normal progression of wound debridement occurs, owing to the presence of macrophages. When neutropenic rats are compared with controls, fibroplasia is unaffected, collagen deposition is unchanged, and wound strength is normal.[10]

Lymphopenia also fails to affect wound healing in rats. A normal inflammatory response is seen during the first 24 to 48 hours of the lag phase of healing, and normal wound strength

and collagen content are found at 7 and 14 days.[10] Thus, leukopenia owing to either neutropenia or lymphopenia alone fails to suppress wound healing as assessed by histologic and biochemical techniques.

The macrophage plays a vital role in wound healing. Systemic hydrocortisone-induced monocytopenia can reduce tissue macrophage levels to approximately one third that of controls. Mild inhibition of wound debridement is observed, but collagen synthesis is unaffected. However, when antimacrophage serum and hydrocortisone are combined, clearance of wound debris is much decreased and fibroplasia and collagen

synthesis are reduced. Macrophages are also important in enhancing neovascularization at the wound edge.[11] Activated macrophages are associated with a higher frequency of neovascularization. Injection of activated peritoneal macrophages into dermis and subcutaneous tissues of rats immediately before wounding increases wound breaking strength at 8 days.[11]

Corticosteroids

The anti-inflammatory action of glucocorticoid hormones may prolong the inflammatory phase of wound healing. Specific mechanisms include the stabilization of lysosomal

membranes, mobilization of neutrophils, decreased local phagocytosis, and inhibition of deoxyribonucleic acid (DNA) synthesis.[10] Hydrocortisone and methylprednisolone have a greater anti-inflammatory affect than does dexamethasone. Corticosteroids are also associated with increased risk of wound infection. They interfere with the logarithmic phase of healing by delaying fibroblast proliferation and collagen synthesis and crosslinking.

The negative effect on wound healing is critically dependent on the dose and timing of steroid administration. If glucocorticoids are started 3 days or more after creation of the wound,

progression of cellular infiltration and resulting fibroplasia are histologically unchanged and produce no negative effect on wound tensile strength at 7 days.[10] Impairment of wound healing by corticosteroids is most obvious at 7 to 14 days, owing to their negative effect on fibroplasia during the logarithmic phase. However, by 3 to 4 weeks after injury the wound tensile strength in animals receiving corticosteroid treatment approaches that of control animals.

Dose is also an important factor. In rats, small doses (5 mg/kg) of hydrocortisone have no adverse effect on wound tensile strength, whereas larger doses significantly decrease it.

The nutritional state of the animal is another important variable. Hydrocortisone at a dose of 5 mg/kg had no effect on the tensile strength of incised wounds in rabbits fed a regular diet but produced a marked inhibitory effect in rabbits that were 25% underweight. Along with the healing effects on the gastrointestinal tract, corticosteroid-induced gastric and colonic perforations are well documented in dogs being treated for concurrent spinal cord disease.[10]

It is possible that anabolic steroids may counteract the negative effects of glucocorticoids on wound healing. In one study, rats given 10 mg hydrocortisone for eight days had

significantly weaker dermal wounds. However, rats supplemented with 5 mg testosterone propionate or nandrolone phenpropionate had similar wound strength to that in control animals.[12] In other studies, lower doses of testosterone did not reverse the detrimental effects of cortisone in rats five days after wounding.[12]

Nonsteroidal Anti-Inflammatory Drugs

Prostaglandins (PG) have been implicated as a major mediator in wound healing, particularly during the inflammatory phase. The PG-induced inflammatory response proceeds via lipid mediators metabolized from

arachidonic acid through the cyclooxygenase pathway. Corticosteroids are thought to inhibit phospholipase A2 activity in cell membranes, resulting in reduced release of prostaglandin precursors (arachidonic acid). Nonsteroidal anti-inflammatory drugs (NSAID), on the other hand, inhibit the action of cyclooxygenase in the prostaglandin-formation cascade. Excessive doses of older NSAIDs such as aspirin, indomethacin, and phenylbutazone have been shown to significantly delay increases in skin wound strength in animals during the inflammatory phase. Flunixin meglumine was evaluated for its effects on dermal, fascial, gastric, and colonic wound

healing in rats. Flunixin, 1.1 mg/kg b.i.d., significantly decreased the tensile strength of wounds in the skin and linea alba, but it did not affect visceral bursting strength at five days after surgery. At 14 days after surgery, no significant difference in wound strength was seen between the group given flunixin and control groups.[13] Other than liver toxicity, the newer Cox-2-inhibiting NSAIDs such as carprofen or deracoxib do not appear to negatively affect alimentary healing and may, in fact, reduce postoperative ileus by their analgesic and anti-inflammatory properties. The newer NSAIDs may work by reducing the release of cytokines (TNF, IL-1, IL-6, and IL-8) during the inflammatory

stage of wound repair.[14] They probably do not effect the proliferative phase of visceral healing when fibroplasia is the factor influencing gain in visceral wound strength.[13]

Radiation

Radiation has a negative effect on wound healing for several reasons. Injury to the chromatin of dividing fibroblasts may decrease their accumulation in the wound. Collagen production is reduced in most irradiated wounds. Progressive fibrosis of blood vessels results in decreased blood flow and lower oxygen tension after radiation therapy. This delayed or impaired perfusion delays wound

healing and also increases the risk of infection.[15]

Confusion exists about when to initiate radiation therapy in the perioperative period. Initiation of radiation therapy prior to or at the time of surgery may increase chances of dermal or visceral wound dehiscence. In one study of rats, a single dose of 2000 rad was given at seven days before, on the day of skin wounding, and at seven days thereafter. The wounds that were irradiated one week before surgery and at the time of surgery were significantly weaker than those irradiated one week after surgery. Because radiation interferes principally with the logarithmic proliferative

phase of wound healing, it would be ideal to initiate radiation a minimum of 7 to 14 days after visceral wounding has occurred.[10] When suturing previously irradiated viscera, a nonabsorbable suture material or slowly absorbable synthetic monofilament absorbable suture should be chosen. Irradiated bladder wounds sutured with polyglycolic acid were stronger than those sutured with chromic catgut, but no difference was noted in nonirradiated bladders.[15]

Effects of Cancer on Wound Healing

Cancer has been incriminated in delayed wound healing, but impaired

nutrition is probably the underlying cause. Except as a result of cancer cachexia, adverse wound healing owing to cancer is difficult to document. The presence of macroscopic tumor remote from the wound or microscopic tumor within the wound does not appear to impair healing.[10] Humans with esophageal cancer who have residual microscopic tumor at the surgical margins did not have a significantly higher rate of leakage at the anastomosis than did patients with no tumor present.[16] No evidence exists that the presence of tumor directly impedes healing; in selected cases, it may actually accelerate healing. In excisional biopsy for invasive cutaneous melanoma,

those portions of the incision that contained residual tumor were stronger than those that did not. Further evidence indicates that presence of a tumor may have a positive effect on the wound strength of distant surgical wounds. Wounds were stronger in rats with hepatomas than in control rats. Increased wound strength in the presence of tumor may be due to the presence of growth factors that act as fibroblast mitogens. Other tumors such as mast cell tumors, which release vasoactive substances such as histamine, may retard wound healing.[17]

Effects of Chemotherapy

Chemotherapeutic agents affect wound healing in several ways. Neutropenia, a common side effect of chemotherapy, increases the risk of infection but does not interfere directly with wound healing. Interference with the inflammatory stage of wound healing is often not seen unless therapy is begun preoperatively.[10] Many chemotherapeutic agents exert their antineoplastic effect by interfering with DNA replication, RNA production, protein synthesis, or cell division.[12] Inhibition of fibroblast proliferation, reduced formation of collagen, and impaired neovascularization have been documented subsequent to chemotherapy in animals. Therefore, the greatest potential for impairment

of wound healing would be during the proliferative or logarithmic phase, when fibroblasts are dividing and are metabolically active. In addition, anorexia and cachexia are common side effects of chemotherapy and may have an additive adverse effect with preexisting cancer cachexia. This can exacerbate negative nitrogen balance and PCM. Similar to corticosteroid therapy, the effects of chemotherapy are largely affected by time of administration and dose of the drug. The relative effects of various antineoplastic agents on wound healing are listed in Table 37-1.

Vincristine

Vincristine is commonly used to treat lymphosarcoma and other carcinomas in animals. The drug exerts its effect by binding with intracellular microtubular systems, causing mitotic arrest.[10,12] Impairment of dermal wound healing by this agent appears to be minimal. In mice treated with vincristine, mildly reduced dermal wound strength was seen 3 days after surgery, but not at 7 or 21 days thereafter.[18] Clinical trials in humans using preoperative vincristine do not indicate increased incidence of wound dehiscence or morbidity.

Vinblastine

Vinblastine is another plant alkyloid

used to treat mast cell tumors and in some lymphoma protocols. This compound acts by binding to microtubules in the mitotic spindle, thereby preventing cell division. There is no direct association with disruption of wound healing, but gastroenterocolitis and myelosuppression are common.[19]

Table 37-1. Antineoplastic Agents and Wound Healing

Agents clearly detrimental to wound healing Cisplatin

Levamisole

Agents with variable or no effect on wound healing

Vincristine

Vinblastine

Azathioprine

Agents inadequately studied for effect on wound healing

Lomustine

Mitoxantrone

Mechlorethamine HCl

Doxorubicin

Doxorubicin (Adriamycin), an antitumor antibiotic, acts by inhibiting DNA and RNA synthesis. Doxorubicin inhibits cell division during the proliferative phase of wound healing. Doxorubicin given to rats reduced wound breaking strength at 5, 10, 15, 20, and 30 days after wounding when compared with controls.[20] In addition, doxorubicin impaired wound healing when it was given up to 5 weeks prior to wounding or as much as 4 weeks after wounding. The effects of doxorubicin on wound healing are dose dependent. Animals given high levels of the drug show significantly impaired wound healing, whereas those given normal therapeutic doses show little if any effect on wound healing.[17]

Cyclophosphamide

Cyclophosphamide is an alkylating agent that acts by cross-linking DNA strands and, thereby, preventing cell division. Cyclophosphamide interferes with fibroblast production and collagen production and also decreases neovascularization.[10] Experimental studies in animals indicate that cyclophosphamide significantly impedes healing at therapeutic doses. Rats given cyclophosphamide at the time of wounding had decreased strength of skin wounds at 1, 3, and 5 weeks after wounding. Larger doses of cyclophosphamide have also been shown to delay scar maturation in rats. However, in clinical studies of human

patients, no adverse effect on visceral wound healing was observed, regardless of the time of administration of cyclophosphamide.[18]

Methotrexate

Methotrexate is an antimetabolite folic acid antagonist that prevents DNA maturation. High doses of methotrexate are associated with increased rates of wound infection in mice.[21] The effect is dose-dependent and is reversible with concurrent folic acid administration. Wound breaking strength is decreased and rate of wound healing was also retarded for as long as 21 days after wounding. However, these effects are not

observed if methotrexate is given in therapeutic doses at the time of surgery. Methotrexate given to humans at the time of surgery increases the rate of wound dehiscence. This complication is minimized by delaying chemotherapy 10 to 14 days or by concurrently administering folic acid. In mice, intraperitoneal methotrexate given in therapeutic doses causes decreased wound strength on day three but not on day 7 or 21.[10]

5-Fluorouracil

5-Fluorouracil (5-FU) has been used extensively in small animal patients with carcinomas and in humans with intestinal carcinomas. Because it is

commonly given systemically or intraperitoneally after resection of carcinomas, its effect on intestinal wound healing has been studied directly but results have been conflicting. No impairment of healing of colon anastomoses occurred in rats when chemotherapy was given at operation and at 4, 7, and 11 days postoperatively.[22] However, rats given 5-FU alone or 5-FU in combination with levamisole were noted to have bursting strengths of healing colon anastomoses only 65% of that seen in the control group. In vitro studies showed that both of these agents significantly inhibit fibroblast proliferation. These effects were more pronounced in animals with weight

loss or nutritional deficiencies;[23] however, the effect was dose related, and mice given therapeutic doses had minimal adverse effects. Although 5-FU is related to methotrexate in mode of action, the apparent risk for impaired visceral wound healing is much less with 5-FU than it is with methotrexate when given in therapeutic doses.[10]

Cisplatin and Carboplatin

Cisplatin, a heavy metal compound, has been used for various carcinomas including transitional cell carcinomas in dogs. Its effects on visceral wound healing have been evaluated in rats. Large- and small-bowel anastomoses were performed and compared at 4, 7,

14, and 28 days postoperatively.[24] Cisplatin was given in doses of 5 mg/kg 1 and 5 days preoperatively. At four days after surgery, wound breaking strength of both the large- and small-bowel anastomosis were too low to measure.[10,27] At all times during the study, wound breaking strength of treated animals was below that of controls. From these results and from studies in humans it appears that cisplatin is one of the most dangerous chemotherapeutic agents with regard to the potential for interfering with visceral wound healing. Carboplatin is a less toxic cousin to cisplatin that can be used in cats. Gastrointestinal irritation with this drug is reduced when compared with cisplatin, but the

mechanism of action is the same and so caution should be exercised when using this drug concurrently with visceral surgery.[25]

Newer Chemotherapeutic Agents Requiring Further Study

Lomustine

This alkylating agent is used primarily in the treatment of canine mast cell tumor. No mention has been made of adverse wound healing, but vomiting, diarrhea, and stomatitis are common side effects.[25]

Mechlorethamine HCL

This alkylating agent is used as a rescue drug for lymphoma as well as for intracavitary administration of some neoplasms. It has significant gastrointestinal effects, which can lead to severe vomiting and diarrhea and may halt therapy.[25]

Mitoxantrone

This synthetic antitumor antibiotic has been used with some success in the treatment of lymphoma and transitional cell carcinoma, and as a radiation sensitizer against squamous cell carcinoma. Its side effects include myelosuppression, vomiting, and diarrhea.[25]

Conclusion

Healing of visceral wounds is negatively affected by a variety of factors. Chronic weight loss of 15% to 20% owing to cancer cachexia or other reasons has a negative effect on visceral wound healing. Correction of cachexia as well as early postoperative enteral feeding appears to increase collagen deposition and bursting wound strength. Glucocorticoids have a negative effect on wound healing when given in large doses prior to the third day after wounding. NSAIDs appear to affect the early inflammatory phase of wound healing, but do not appear to interfere with the proliferative phase of wound healing

or have a significant negative effect on visceral healing strength. Radiation therapy interferes with fibroblast mobilization, replication, and collagen synthesis. It also causes sclerosis of the microvasculature, thereby reducing oxygenation at the wound site. Whenever possible, radiation therapy should be initiated after visceral wound healing is complete. The negative effects of cancer on wound healing appear to be secondary to nutritional deficiencies rather than direct tumor impairment of wound healing. Visceral wound healing may actually be mildly augmented owing to release of growth factors by the neoplasm. Effects of chemotherapeutic agents on visceral wound healing are

variable. Drugs such as vincristine, vinblastine, and azathioprine seem to be safe when used in therapeutic doses. Drugs such as cyclophospha¬mide, methotrexate, 5-FU, and doxorubicin have been shown to delay wound healing in both experimental and clinical studies. Cisplatin appears to significantly impair intestinal wound healing in rats and should be used with caution after intestinal surgery. Newer antineoplastic drugs require further evaluation.

Chapter 38

Short Bowel Syndrome

Michael Willard

Short bowel syndrome (SBS) has been described in people for over 30 years. Despite being a well recognized syndrome for decades, however, we do not yet have a universally accepted definition.[1] Occurring after major intestinal resection, the key features of SBS in people are generally acknowledged to include dehydration (caused by diarrhea), malabsorption, and subsequent malnutrition severe

enough to cause morbidity and put the patient at risk for death. The best definitions of SBS generally describe the constellation of signs caused by resection of excessive amounts of intestine (i.e., dehydration, malabsorption) or their consequences, rather than the amount of intestine resected. For example, one definition of human SBS is based on intestinal failure following resection being so severe that the patient needs parenteral nutrition for more than 1 to 3 months post-surgery.[1]

Trying to define SBS based on how much bowel has been resected creates problems. Even though most surgeons agree that having less than 25% of the

expected intestinal length left is almost always associated with SBS in people, one must also consider what portion of the bowel was resected (i.e., jejunum, ileum, colon), the functionality of the remaining bowel, and the body condition of the patient. For example, if one resects 65% of a person's intestines but leaves the ileum and colon intact, there is much less chance of SBS than if the ileum and colon were resected.[2] Furthermore, it has been stated that removal of the ileocolic valve is associated with a poorer prognosis; however, this seems to be based on a study in puppies[3] and may nor may not be true for people. In fact, although most papers describe how much intestine was removed, it would

probably be more important to know how many centimeters of intestine remain in the patient, and which segments of bowel were left.

SBS in Veterinary Medicine

Defining SBS in veterinary medicine has principally consisted of taking the criteria used in people and applying them to dogs and cats. Part of the reason for this is that, while SBS is generally well recognized in people, only a handful of cases are reported in the veterinary literature.[4,6] This paucity of reports is probably because veterinary patients with such a guarded-to-poor prognosis and requiring intense therapy (total

parenteral nutrition) for long periods of time are typically euthanatized instead of treated. Therefore, much of the discussion of SBS in dogs and cats must draw on experimental work done in dogs and rats, as well as on clinical reports in people. Obviously substantial species differences may exist, and one must be cautious about extrapolating from human beings to dogs and cats. For example, people are usually expected to develop SBS if more than 75% of the intestines are resected, but dogs have been reported to tolerate 80% to 85% resection and function well postoperatively.[3,5,7,8] Therefore, SBS in veterinary medicine should probably be defined by the inability of the patient to compensate

adequately after massive intestinal resection as seen by the need for protracted nutritional/pharmacologic therapy to keep the patient alive until intestinal adaptation occurs.

Intestinal Adaptation

Adaptation refers to the functional and structural changes that occur in the intestines as they attempt to increase fluid and nutrient absorption to pre-resection levels. The primary goal of therapy of the patient with SBS is generally to maintain the patient until sufficient intestinal adaptation can occur so that parenteral nutrition may cease.

Shortly after massive intestinal

resection, the remaining intestines begin to adapt by increasing in length and diameter. Hypertrophy and hyperplasia occur of all layers of the remaining intestines,[1] with epithelial hyperplasia in the intestinal crypts beginning within two to three days. Hyperplasia of the intestinal epithelium is one of the most important events.[2] The mechanisms for this adaptation are probably multifactorial and may include secretions from the remaining gastrointestinal tract (e.g., pancreatic) and various hormones, growth factors, and cytokines. However, the presence of enteral nutrition may in fact be the most important factor required for adaptation to occur. Studies in dogs[9]

showed that enteral nutrition is associated with intestinal adaptation, whereas dogs feed strictly parenterally showed no evidence of intestinal adaptation. The composition of the enteral nutrition may be similarly critical. It is believed that complex nutrients are more trophic to the intestinal mucosa than are simple nutrients, and long-chain unsaturated fats may be the most important nutrients in this regard.

As intestinal adaptation takes place, usually some degree of dilatation of the diameter of the bowel lumen occurs,[9] which in turn, results in some degree of stasis of luminal contents.[10] Changes can also occur in intestinal

myoelectrical activity that slow the velocity of duodenal and jejunal motor activity.[11] Whereas these changes are designed to aid in digestion and absorption of nutrients by prolonging the exposure of the intestinal mucosa to the nutrients, they also have some potential disadvantages. A dilated small intestine with slowed motility can promote bacterial overgrowth. Administering drugs designed to increase transit time (e.g., opioids such as loperamide) can make this situation even worse. In some patients, poor gut motility coupled with bacterial overgrowth can lead to bacterial translocation from the intestines to the blood, mesenteric lymph nodes, and spleen.[1]

Another problem that can be caused by an altered gut anatomy plus bacterial flora changes is d-lactic acidosis. When nutrients are malabsorbed in the small bowel, substantially increased amounts of carbohydrates may enter the colon. Colonic metabolism of these carbohydrates can result in acidification of the colon with subsequent overgrowth of bacteria that tolerate acidic environments, such as Lactobacilli. If overgrowth of Lactobacilli occurs, overproduction and subsequent absorption of d-lactate may follow as well.[12] The resulting acidosis can be so severe as to make patients weak and encephalopathic.

In people, intestinal adaptation may

require months to years of support (i.e., parenteral nutrition to maintain the patient plus enteral nutrition to stimulate adaptation) before the intestines regain sufficient function and can maintain the patient without parenteral support.[1] No obvious, recognized relationship exists between the residual intestine length and the time required for adaptation. In general, about 75% of people with SBS ultimately adapt and are able to stop parenteral nutrition. In general, children seem to have more potential than adults to have successful intestinal adaptation, but this depends on many factors.[1]

Treatment

The most important aspect of treating SBS is trying to avoid massive resection in the first place. For example, when faced with a condition that seems to require massive intestinal resection, it may be better to leave questionable tissue instead of resecting it, even though a second operation will be required 1 to 3 days later to assess the viability of tissue left the first time. The risks involved with performing a second surgery may be less than the risks occurring if SBS develops.

If SBS occurs or seems highly likely to develop, then aggressive medical management is the first step. The first phase of therapy consists of stabilizing

the patient; this generally requires up to 4 weeks in affected people.[13] Administration of intravenous fluids is generally required to maintain hydration as well as normal electrolyte and acid-base status. Oral rehydration solutions have been reported to be beneficial in some human patients,[14] but they have not replaced IV administration. Nutrition is best started sooner rather than later. If one anticipates SBS, then parenteral nutrition can begin two to three days after surgery. Partial parenteral nutrition is easier than total parenteral nutrition, but if long-term therapy is needed, and it usually is, then total parenteral nutrition may be preferable.[13]

The second phase of therapy consists of promoting intestinal adaptation by gradually increasing the amount of nutrients entering the intestines. Enteral nutrition should usually begin shortly after starting parenteral nutrition (during the first phase of therapy). Various studies have looked at the addition of glutamine and various other nutrients, hormones (e.g., growth hormone[15]), and/or enzymes (e.g., pancreatic enzymes[16]) to the enteral diet, but none has been shown to help unequivocally.[13,14] Use of hydrolyzed diets has not been shown to be beneficial in human infants with SBS.[17] People with SBS are generally expected to malabsorb 30% to 50% of ingested nutrients; therefore, these

patients are often fed 50% more than their calculated caloric requirement.[10] Owing to the intestines' reduced ability to absorb water and nutrients, it is important to start administering relatively small amounts of more dilute enteral diets and gradually increase the volume, lest severe diarrhea occur with subsequent dehydration.[18] Therefore, a constant-rate infusion of enteral diet as opposed to bolus feeding is usually preferred. In people with SBS, the presence or absence of a colon affects the choice of diet.[19] For example, patients with colons can obtain energy from bacterial fermentation of carbohydrates within the colon. Whether the same occurs in dogs is unknown.

Initiating enteral nutrition is typically associated with severe diarrhea. Therefore, antidiarrheals (e.g., loperamide) have typically been used.[13] In people, loperamide has seemed more effective than other opioids.[10] However, the decreased intestinal absorption that characterizes SBS often means that higher than normal doses may be required. In some cases, IV administration is necessary. Occasionally, a combination of loperamide and another opioid (e.g., codeine) is necessary.

Gastric hypersecretion is commonly seen after massive intestinal resection[10,20] and seems to contribute substantially to the diarrhea.

Therefore, inhibition of gastric secretion with H-2 receptor antagonists (e.g., famotidine) or proton pump inhibitors (e.g., omeprazole) is often necessary as well. Peptic ulcer disease and gastroesophageal reflux are recognized complications of SBS in people, ostensibly due, at least in part, to the gastric hypersecretion.[10] Rarely, somatostatin analogs (e.g., octreotide[10]) or other drugs (e.g., clonidine[21]) are required to control intestinal hypersecretion in people with SBS.

Bacterial overgrowth, for reasons stated earlier (intestinal dilatation, loss of ileocolic valve, altered motility), is a concern in human patients with SBS. In

addition, pharmacologic suppression of gastric acid secretion necessary to minimize problems caused by gastric hypersecretion may help enable such overgrowth. The term “small bowel bacterial overgrowth” is controversial in dogs and cats, and the criteria used to diagnose small bowel bacterial overgrowth in people are not clearly appropriate for dogs and cats.[22,23] Nonetheless, dogs can have antibiotic-responsive enteropathies apparently caused, at least in part, by excessive numbers of bacteria in the small intestines.[23,24]

Bacterial overgrowth is usually suspected either when there is failure to respond to apparently appropriate

therapy, or when unexpected weight loss occurs in a previously stable patient. Antibiotic therapy is often utilized in these patients. One cannot hope to eliminate all bacteria from the remaining small intestines; rather, one seeks to decrease the number of bacteria so that they no longer cause disease. Tetracycline, tylosin powder, metronidazole plus enrofloxacin, and cephalosporins are examples of therapy that have been used for this problem in veterinary medicine.[25] One must often experiment to see which antibiotic(s) will be most effective in a particular patient. Periodic rotation of antibiotics is sometimes practiced in people in an effort to prevent selection of resistant bacteria inhabiting the

dilated section of intestine. Restriction of carbohydrates, use of probiotics (with or without concurrent prebiotics[26]), periodic small bowel irrigation with balanced hypertonic electrolyte solution,[27] and surgery (to reduce the lumen of the bowel[1]) have also been used to try to reduce bacterial overgrowth in affected people.

In people, the goal of therapy is eventually to wean the patient from parenteral nutrition (i.e., adequate intestinal adaptation occurs) and be able to maintain the patient on enteral nutrition. When this happens, one must consider whether supplementation of micronutrients

(e.g., zinc, magnesium, cobalamin, fat-soluble vitamins) will be required. Some patients do not respond adequately to medical management alone.

Cases of SBS reported in Veterinary Medicine

To date, seven cases of canine SBS have been reported in the veterinary literature. The first case was a 12-month-old German shorthaired pointer that had an intussusception.[5] It was reported to have 1.5 meter of small bowel remaining and was euthanatized within eight weeks of surgery. The second case was an 8-year-old dog that had surgery 15 months prior to

admission. It was euthanatized approximately six weeks after admission and had 66 cm of small and large intestines remaining.[4] Next there was a series of four dogs.[6] Three of these dogs (i.e., a 4-year-old pointer, a 4-month-old German shepherd, and an 8-year-old German shepherd) died within three months of surgery. One of these three dogs (i.e., the 4-year-old pointer) did well initially and declined only after it refused to eat the prescribed diet. It had received total parenteral nutrition promptly after surgery. The dog that did well was lost to follow up after 27 months. The last report is of a 10-year-old Doberman pinscher that had approximately 80% of its intestines, including the ileocolic

valve resected. It did well and was primarily treated with enteral nutrition.[28]

Surgical Therapy of SBS

Surgery is considered in humans with SBS when it appears that medical/nutritional management will be inadequate. Intestinal transplantation seems to hold the most promise. It is unreported in clinical veterinary medicine but has been performed experimentally in dogs.[29] Surgical therapy of SBS has principally aimed at decreasing the diameter and/or increasing the length of the remaining intestines. Various techniques are reported in human SBS

patients (e.g., intestinal tapering and plication, antiperistaltic segments, creation of intestinal valves, longitudinal lengthening, serial transverse enteroplasty, colonic interposition), and specific indications exist for each surgery.[1] For example, patients with a short, dilated bowel are candidates for serial transverse enteroplasty, whereas those with a dilated bowel that is sufficiently long might be managed by simple tapering enteroplasty. Because we have minimal experience with these techniques in clinical veterinary medicine, it appears that such surgeries should be reserved for those patients in which aggressive medical/nutritional management has failed or appears

likely to fail.

Chapter 39

Megacolon

Amy Zalcman
Ronald M. Bright

Megacolon describes the condition of prolonged dilation of the large bowel. It may contribute to or result from chronic constipation. In the absence of defining criteria, it is a diagnosis of radiographic and functional assessment with systematic elimination of potential underlying causes.

Only a small population presents with

primary megacolon. The majority of patients who present with megacolon can be classified according to their primary disease: obstructive versus non-obstructive (colonic inertia). The various etiologies determine appropriate treatment (Table 39-1).

Anatomy

The large intestine is that portion of the intestinal tract that is aboral to the ileum, is separated by the muscular ileocolic sphincter, and concludes at

the rectum. At its proximal extent lies the cecum, a spiral diverticulum just wider in diameter than the ileum. From the ileocolic junction, the colon tracks cranially for a short distance and is relatively fixed in position by the mesocolon in the right caudal abdomen. The transverse colon travels the width of the abdomen to the descending colon; the large bowel joins the rectum at the pelvic inlet.[1] The junction between colon and rectum is ill defined and can be described as the abdomino-pelvic boundary, the 7th lumbar vertebra, or the point at which the cranial rectal artery dives below the seromuscular layer.[2]

The histologic anatomy of the colon

consists of four layers: serosa, muscularis (longitudinal and circular), submucosa, and muscosa.[3] The serosa maintains no externally distinct property, whereas the mucosa is lined by a single layer of tall columnar epithelial cells.[3] In this portion of the gastrointestinal tract, the crypts of Lieberkühn maintain mature epithelial cells at the tip, while the proliferative epithelial cells are neighbored by the glandular cells at the base.[1] Goblet cells are abundant in the colon; their increased concentration allows space for a minimal amount of lamina propria and provides the histologic boundary from the ileum.[3] The submucosa houses the vascular supply and lymphatic system in loose

connective tissue that also suspends the nervous supply.[1] As the rectum becomes a distinct structure, lymph nodules become more apparent.

The vascular supply to the large intestine is divided. The ileocolic junction to the midportion is supplied by branches of the cranial mesenteric artery as the ileocolic, midcolic, and right colic arteries. The caudal mesenteric artery, as the left colic artery, supplies the descending colon and cranial rectum. The venous system is established through the middle colic and ileocolic veins into the caudal mesenteric vein, leading to the portal vein.

All aspects of colonic innervation are maintained within the autonomic nervous system; this can be separated into intrinsic and extrinsic components. The intrinsic nervous supply coordinates global gastrointestinal movement. It is composed of the submucosal (Meissner's) and the myenteric (intramuscular, Auerbach's) plexuses that are linked in reflex circuits.[4] The intrinsic nervous system regulates secretion and absorption, vascular tone, and motility. Enteric primary afferent neurons transmit information about stretch or tension, although some communicate chemical or mechanical stimuli. These cells then stimulate others within their class to produce

coordinated responses.[5] The arc is completed by effector nerve endings controlling secretory and smooth motor units.[4] Excitatory and inhibitory motor neurons produce coordinated events resulting in defecation. The interstitial cells of Cajal have been credited with controlling the rate of peristaltic waves.[5] Extrinsic innervation is supplied by parasympathetic (cholinergic) fibers, which stimulate muscle activity, whereas sympathetic (adrenergic) fibers inhibit.

Physiology

Motility

Motility is influenced by integrating

cellular excitability, chemical control, and nervous input. The complex cellular events result in segmental and propulsive muscular contractions. In combination with interneuron stimulation of proximal contraction and distal relaxation, aboral movement ensues while mixing ingesta.[5] Evacuation of the colon by mass contractile movements originates in the distal segment of the colon. Colonic motility is also influenced by neurotransmitters, such as substance P, vasoactive intestinal polypeptide, somatostatin, and cholecystokinin.[6]

The ileocolonic junction permits a bolus of ingesta to enter the proximal segment of the colon; this ensures

regulated filling and prevention of reflux.[1] Emptying of the proximal colon is controlled through the perception of tone in the presence of fatty acids as well as the volume and consistency of ingesta: both trigger waves of contraction.[5] Propagating waves are triggered more frequently in the proximal colon than in the distal, and they begin to dampen about midcolon.[5] This explains infrequent daily defecations when compared with the extensive movement of stool in the colon. Conversely, more frequent segmental contractions occur in the distal colon.

Defecation, as studied in humans, is a process that begins nearly an hour

prior to the expulsion of feces.[5] Propagating waves increase in number in the distal colon, with a dramatic increase within 15 minutes, producing a conscious sensation. Sequentially, oral initiation of these waves results in a full distal colon and stimulation of the anorectal phase.[5] Stool and gas stretch the rectal wall and trigger the rectoanal inhibitory complex, allowing relaxation of the rectum and the involuntary internal anal sphincter. When the external anal sphincter is relaxed voluntarily, a coordinated muscle event assists the passage of feces.[5] Suppression of defecation results in storage of stool in the rectum (accommodation).

Chronic accommodation and retention of stool can result in megarectum and exacerbation of perineal hernia. Anal continence is the result of appropriate rectal capacity in the presence of sphincter coordination and reflexes. Normal reflexes and sphincter mechanism are insufficient, in the absence of an adequate reservoir, to maintain continence.

Absorption and Secretion

The majority of absorption occurs in the proximal half of the colon (absorbing colon); the distal portion serves to store feces prior to expulsion (storage colon). The majority of metabolite digestion and absorption

for the body occurs in the small intestine; colonic bacteria complete this locally in the large intestine. Products of this metabolism, such as short-chain fatty acids, are rapidly absorbed by epithelial cells.[1] Short-chain fatty acids, specifically butyrate, provide energy to mucosal cells; deprivation leads to compromised colonic mucosal health.[1] Bacteria also digest dietary fiber; the remainder is fermented. Both processes allow the colon to take up carbohydrates inaccessible to the small intestine.

Water absorption is a passive process with the exchange of sodium. By means of Na^+/K^+ ATPase, sodium is actively pumped into the colonic epithelium.

This action is preserved through the high sensitivity of tight junctions that prevent back-diffusion in this region of the bowel.[6] Because it has a higher electrical gradient than does the small intestine, the colonic epithelium permits diffusion across the apical membrane.[1] This activity is enhanced by glucocorticoids, mineralocorticoids, and catecholamines.

Bicarbonate is secreted in exchange for the absorption of chloride.[6] This assists in the neutralization of acidic bacterial byproducts. The gradient created by the exchange of sodium and chloride into the colonic epithelia allows water to follow passively.

Potassium exchange can occur in both directions.[6] Again, the potential difference generated is greater in the colon; a net secretion of potassium occurs, assisted by active conductance on the apical membrane.[1] Mucus is the predominant secretory product serving to lubricate formed feces, thereby facilitating defecation while protecting the mucosa.

Bacteria of the colon contribute to the production of nutrients in addition to aiding further digestion. Cellulose breakdown is of particular importance to herbivores. Vitamin K production by bacteria is essential to the support of the clotting cascade.[7]

Pathophysiology

Feces can be retained for several days in the normal dog and cat without permanent damage to the distal colon. Prolonged retention can derange the absorptive process such that the feces become more dehydrated and, therefore, firmer with time.[8] These concretions are painful to pass and can become impossible to eliminate (obstipation). When retention is severe and prolonged, irreversible changes in colonic motility can lead to colonic inertia. Significant distention in excess of three to four months is speculated to produce such effects.

Animals can demonstrate variable presenting signs. Central nervous

system depression, anorexia, and weakness have been attributed to toxins absorbed by the compromised mucosa.[8] Abdominal pain and distention can result from the excessive amount of feces within the abdominal colon. Vomiting occurs secondary to the obstructive nature of colonic impaction, the effect of toxins on the chemoreceptor trigger zone, or vagal stimulation of intestinal distention.[8] Diarrhea may be observed as fluid bowel contents can pass about the solidified feces. Mucosal irritation by the mechanical obstruction results in increased mucus secretion by goblet cells and often exudation of blood. This produces a watery, mucoid, and potentially, bloody diarrhea. Common

presenting complaints can include lethargy, anorexia, vomiting, tenesmus, weight loss, and diarrhea.[8]

Idiopathic Megacolon

Affecting middle-aged to older cats with few exceptions, idiopathic megacolon has an unknown etiology. Described as progressive intractable constipation, histologic evaluation does not identify abnormality in animals as it does in its human analog. Hirschprung's disease (HD), described as aganglionosis of the distal large intestine, is often identified early in children owing to associated clinical features.[9] Important features of HD, characterized as a process of slow-

transit constipation, are decreased ganglionic density and decreased concentration of Cajal cells.[10] These directly affect the motility of the distal large intestine and the production of a normal defecation reflex.

In the absence of histologic abnormalities, feline idiopathic megacolon (FIM) is attributed to inappropriate intrinsic or extrinsic innervation of the colon. Washabau and Stalis demonstrated the presence of myenteric neurons in colonic smooth muscle in cats with FIM as well as the neurons hyposensitivity to stimulation.[11] They postulated that the disorder is limited to the intrinsic nervous system in the absence of lower

urinary tract signs.[11]

Many owners are not intimately aware of their animal's defecation habits and, so do not identify unusual behavior early in the disease. Most cats present with prolonged and, therefore, severe disease. FIM is an exclusionary diagnosis made through the elimination of other predisposing causes of constipation (i.e., renal insufficiency) by blood work, urinalysis, and imaging studies. The results of blood work can be consistent with pre-renal azotemia and electrolyte abnormalities compatible with metabolic acidemia in cases of severe, prolonged constipation. Abdominal radiographs demonstrate

fecal distention in the colon with all causes of megacolon. Radiographs should be scrutinized for pelvic fracture malunions, distortions in the spine, and extramural compression. This can be supplemented by abdominal ultrasound and computed tomography for confirmation of soft tissue and bony obstructive etiologies, respectively. Rectal examination, colonoscopy, and contrast radiography can also assist in the systematic exclusion of causes.

Severity of dehydration and metabolic derangement must be addressed prior to intervention. Obstipation can then be the focus of treatment by the administration of stool softeners and

enemas. Manual evacuation of stool should be performed gently in the anesthetized patient to minimize further mechanical trauma to already compromised mucosa. As the translocation of bacteria and toxins is a concern, administration of prophylactic antibiotics is recommended. Medical management includes high-fiber diet, stool softeners, bulk laxatives, prokinetic agents, and intermittent enemas. When aggressive medical therapy is unsuccessful, surgery can be considered.

Surgical management by subtotal colectomy is the treatment of choice. The surgeon must identify the objectives of colectomy when assessing

the need to excise the ileocolic junction. Although removal of the ileocolic junction may produce looser stools, preservation may allow affected colonic tissue to remain. A survey of 22 cats undergoing subtotal or total colectomy demonstrated significantly looser stools in the group with total colectomy.[12] Recurrence of constipation occurred at comparable rates in the two populations, suggesting that the colonic tissue associated with the sphincter is insufficient to produce significant complications.[12] Removal of the ileocolic sphincter will likely allow some degree of recto-ileo reflux. Thus, preservation of the ileocolic junction has been recommended as surgical

management of FIM. Initially, diarrhea is observed, but completely resolves or progresses to semi-formed stool in a period of weeks to months. The ileum and rectum are credited with the absorptive and reservoir capabilities that allow function to normalize with time.[13] Gregory et al evaluated the enteric functions of cats that had undergone colectomy; they found minimal differences between surgically-treated and untreated cats.[13] Serum concentrations of electrolytes remained within the normal limits. Trends in fecal concentrations of sodium and potassium were higher and lower, respectively, but not statistically significant; this was directly attributed to the removal of the proximal colon.[13]

Megacolon Secondary to Neurologic or Medical Disease

Disruption of the nervous supply of the large intestine can contribute to decreased or complete absence of colonic motility. Interruption of the appropriate signals can interfere with the normal defecation reflex and lead to constipation and megacolon. Removal of the affected colon may provide a satisfactory result when reflex mechanisms remain intact.

Manx cats have demonstrated abnormalities in their sacral spinal cord, producing urinary and fecal incontinence.[14] These abnormalities

are manifested in bony structural deformities as well. Surgical intervention is not recommended owing to co-morbidities.

Megacolon secondary to autonomic ganglioneuritis was reported in a dog with a 6-week history of constipation and tenesmus.[15] Neurologic exam revealed only generalized muscle weakness. Histopathology demonstrated moderate lymphoplasmacytic infiltrates of the autonomic ganglia. The muscularis was normal, while the mucosa was edematous and mildly congested. The etiology of the neuritis was never identified.[15]

Constipation has been observed with poorly managed metabolic disease, potentiating the development of megacolon if the constipation is frequent and prolonged. Although not described in veterinary literature, toxic megacolon has been documented in humans.[16,17] Other neurologic and medical etiologies of megacolon have also been reported (Table 39-1).

Outlet Obstruction

Megacolon has been described secondary to a variety of processes physically obstructive to the outflow tract of the colon. Pelvic fracture malunion is one of the most common causes of secondary megacolon in the

cat and the dog. Neoplasia, primary to the colon (intramural) or of adjacent tissue (extramural), can cause obstruction at a critical size. Altered anatomy, such as perineal hernia and anal or rectal atresia can result in constipation and then megacolon. In rare cases, foreign body or inappropriate nutrition can lead to obstruction of outflow.

Any disease process resulting in a prolonged, severe distention can result in permanent changes to colonic smooth muscle function.[18] Reduced motility or inertia can be particularly difficult to treat.

Clinical signs of outflow obstruction

mimic those of idiopathic megacolon; therefore, diagnosis should place special importance on a thorough rectal examination. Following identification of the underlying obstruction, treatment is focused on surgical correction of the cause. Invasive procedures such as hemipelvectomy or pelvic reconstruction may be required to correct intrapelvic abnormalities. Schrader evaluated six animals with pelvic malunion and determined that surgical correction by pelvic osteotomy was successful in those animals whose clinical signs were less than six weeks in duration.[19] Clinical signs exceeding six weeks resulted in colonic inertia and, when obstipated, these animals

were not managed successfully by pelvic reconstruction or ostectomy.[19] Removal of the ileocolic sphincter, in the subset of cats with megacolon secondary to pelvic malunion, is offered as a means to produce loose stools and minimize the intensity of continued medical management.[20] This population remains at risk of recurrent constipation despite total colectomy and may warrant continued medical management.

Neurology

Chapter 40

Injury to the Brain

Rodney S. Bagley
Chadwick R. West

Injury to the brain can occur from both endogenous and exogenous causes. Exogenous injury most commonly results from automobile-related trauma, although external blows to the head and face, penetrating wounds, gunshot injury, and impact from falling are also possible. At initial impact, primary mechanical disruption of intracranial tissues may occur. The

force of impact can rupture axons, blood vessels, and other neural elements. Primary mechanical injury may then initiate numerous secondary pathophysiologic sequelae, such as metabolic alterations in neuronal or glial cells, impairment of vascular supply to normal tissue (ischemia), impairment of cerebrovascular autoregulation, hemorrhage (intraparenchymal, intraventricular, extradural, or subdural), irritation (seizure generation), obstruction of the ventricular system, edema formation, production of physiologically active products, and, most often, increased intracranial pressure (ICP). As ICP reaches life-threatening levels, shifts of brain parenchyma or brain herniation

can occur. Differing types of brain herniation include subfalcial, rostral and caudal transtentorial, and foramen magnum herniation. Although some forms of herniation are treatable, brain herniation through the foramen magnum is often deadly.

The intracranial nervous system resides in a unique physiologic environment. Protected by, but also confined within, the bony limits of the cranium, nervous tissue exists with cerebrospinal fluid (CSF) and blood. Disease of the brain parenchyma or other intracranial tissues alters this physiologic equilibrium. As primary injury can be prevented but not treated per se, treatment of brain injury is directed

toward treatment of secondary pathophysiologic events and basic life support. Important secondary pathophysiologic consequences of intracranial injury are discussed further so that a fundamental understanding of the intracranial environment following injury can be appreciated during the treatment process.

Cerebral Edema

Many intracranial diseases result in or are associated with brain edema. With acute injury, brain edema becomes maximal between 24 and 48 hours after injury, but may persist for a week or more.[1] Brain edema has been

categorized as vasogenic, cytotoxic, or interstitial based on cause and anatomic areas of involvement.[2] Any or all of these types of edema may be present in an animal with brain disease.

Cytotoxic edema (intracellular edema) results from failure of cellular energy, with resultant failure to extrude sodium from within the cell. Intracellular water increases and cells swell. This edema most often results from disease processes such as toxicity, ischemia, or hypoxia.

Interstitial edema is defined as increased water content of the periventricular white matter owing to

movement of CSF across the ventricular walls in instances of hydrocephalus. Periventricular white matter is reduced owing to the disappearance of myelin lipids secondary to increases in hydrostatic pressure or decreases in periventricular blood flow in the white matter.[3]

Vasogenic edema is the most common form of edema associated with CNS neoplasia. This type of edema results from vascular injury secondary to physical disruption of the vascular endothelium or functional alterations in endothelial tight junctions. Differences in transmural pressure gradients result in extravasation of fluid from cerebral vessels to the

extracellular fluid (ECF) spaces of the brain.[4] These abnormalities allow for fluid to move from the vascular to perivascular spaces. Areas of the brain where ECF is normally enlarged provide a natural conduit for fluid movement. Increases in intravascular pressure owing to loss of autoregulation, vascular obstruction, or hypertension (e.g., Cushing's response and cerebral ischemic response) may perpetuate edema formation.

Vasogenic edema migrates away from areas of vascular disruption via bulk flow.[4] Fluid movement depends on a balance between the opposing forces of capillary hydrostatic pressure and

tissue-resistance pressure. Vasogenic edema usually spreads readily through the white matter, possibly because of the orderly arrangement of nerve fibers found there. Also, the movement of this type of edema may be related to the low capillary density and blood flow in normal white matter. Deep white matter of the involved cerebral hemisphere is preferentially affected.

Hemorrhage

Hemorrhage, either within or around the brain may result in rapid cerebral dysfunction often by alterations in cerebral volume (mass effect). In comparison with humans, subdural hematomas are uncommon in dogs.[5]

Systemic coagulation abnormalities (e.g., thrombocytopenia) and hypertension may potentiate hemorrhagic potentials. Vascular damage from therapeutic intervention (e.g., radiation therapy) may also influence the incidence of tumor-related hemorrhage. Also, loss of cerebral vascular autoregulation may predispose to hemorrhage or infarction.

Ventricular Obstruction

Space-occupying intracranial disease may impinge on the ventricular system, resulting in obstruction of CSF flow. Common areas of obstruction, owing to the inherently small diameter

of the ventricular system, include the interventricular foramen (connection between the lateral and third ventricles) and the mesencephalic aqueduct. Knowledge of normal CSF flow allows for determination of the location of the obstruction. Sequestration of CSF in an obstructed component of the ventricular system may result in increases in intracranial pressure and interstitial brain edema.

Increases in Intracranial Pressure

Intracranial pressure is the pressure exerted between the skull and the intracranial tissues. As the skull is relatively inelastic compared with the

other intracranial tissues, ICP is determined primarily by changes in intracranial tissue volume and the compensatory ability of these tissues to accommodate for volume changes.[1,6-8]

The three major components of volume residing within the intracranial space are the brain tissue (intracranial cellular elements), the cerebrospinal fluid, and blood.[7] Intracranial disease often increases the volume of one of these components. For ICP to remain normal, an increase in volume of one of these three intracranial components must be compensated for by a decrease in volume of one or both of the other components (intracranial compliance). Although compliance can initially aid

in stabilizing ICP, it has finite limits. When compliance is exhausted, ICP will increase. This relationship may vary among individual patients and may be influenced by the extent and location of an intracranial mass as well as cerebral blood flow.[9] As ICP increases, the pressure within the intracranial space decreases cerebral blood flow. With decreased cerebral perfusion, neuronal ischemia, hypoxia, dysfunction, and death ultimately result.

Cerebral blood flow and CSF are in constant flux. ICP is dynamic and pulse-like, with a small pressure wave occurring almost simultaneously with each heart beat.[10,11] This wave form is

referred to as the intracranial pulse pressure wave (ICPPW). Periodic fluctuations may occur in response to normal body functions, such as coughing or abdominal straining, via increases in intrathoracic pressure and venous pressure impairing venous return from the intracranial space. With intracranial disease, ICP may be elevated persistently or episodically, resulting in persistent or episodic clinical abnormalities, respectively. As exemplified by Lundberg, periodic elevations in ICP (plateau waves) with ensuing return of ICP to normal levels can occur in humans with intracranial disease.[12] These periodic elevations are thought to originate from cerebral vasodilation secondary to decreased

cerebral perfusion in patients with intact cerebrovascular autoregulatory capacity.[13] In this situation, single-time measurements of ICP may not accurately reveal these episodic elevations, and critical periods of raised ICP will be overlooked.

Numerous physiologic and nonphysiologic variables influence ICP measurements. These include anesthetic agents[14-18] and body weight.[19] The effects of anesthetic agents on ICP are many and varied, and the need for anesthesia to measure ICP can potentially alter values obtained. Specific effects of anesthetic agents on ICP have been reviewed elsewhere.[14-18]

An absolute level wherein ICP is elevated has not been established. This may be the result of the inherent inaccuracies of the monitoring equipment and the normal variation in baseline ICPs. Most information from humans suggests that ICP higher than 15 to 20 mm Hg is elevated.[20] Cerebral blood flow may not be significantly decreased until ICP reaches about 30 mm Hg.[21] Experimentally, however, ICP was raised to very high levels (> 100 mm Hg) before brain death occurred.[22] We have seen ICPs as high as 30 to 40 mm Hg in dogs that subsequently have recovered from brain injury. Whereas some have suggested that the degree and persistence of ICP elevation is

associated with outcome after head injury,[20] others have suggested that ICP monitoring does not influence overall prognosis.[23]

Clinical Effects of Intracranial Pressure Alterations

The major intracranial effect of increasing ICP is alteration of cerebral perfusion pressure (CPP) (Figure 40-1).[9,21,24,25] Cerebral perfusion is dependent on systemic blood flow and intracranial pressure expressed via the formula CPP = MABP - ICP (MABP = mean arterial blood pressure).[19] For CPP to remain constant, the effects of increased ICP on blood flow to the

brain must be reciprocated by increases in systemic blood pressure. Cerebral perfusion pressure is a determinant of cerebral blood flow (CBF) but is not always equivalent; in many instances, however, as CPP decreases so does CBF. Intracranial pressure and CPP, however, have an inverse relationship (Figure 40-1). When CPP falls below 60 to 70 mm Hg, this creates physiologic abnormalities within the brain.

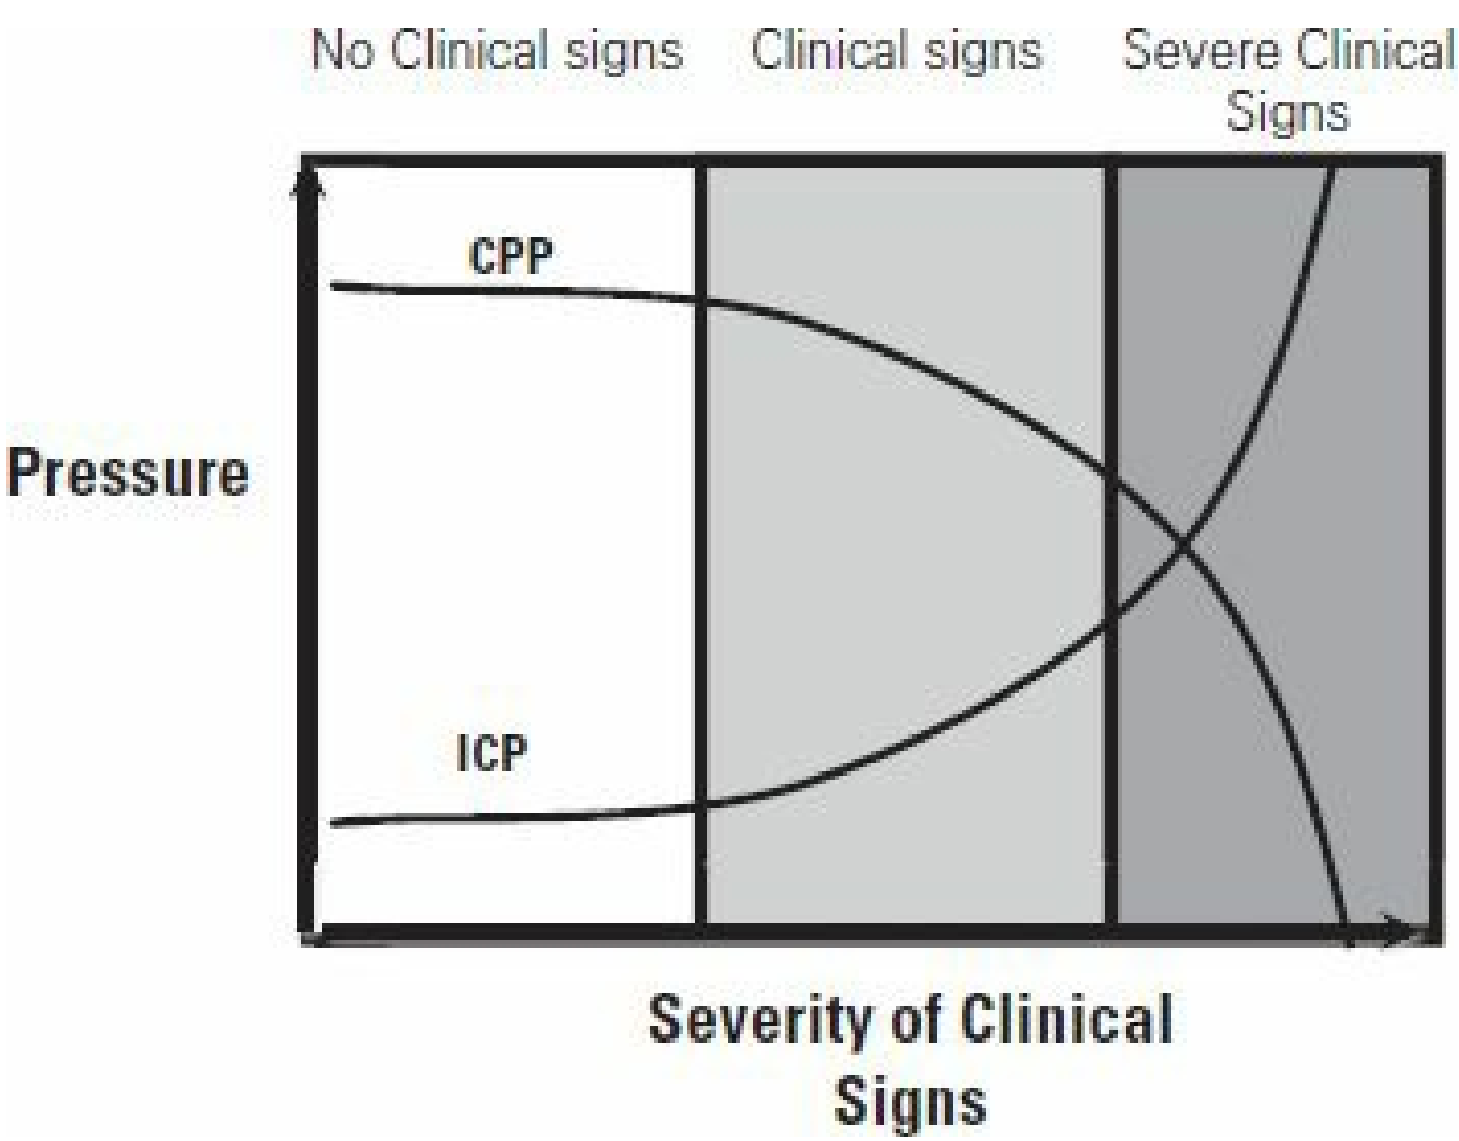

Figure 40-1. Schematic relationship between intracranial pressure (ICP) and cerebral perfusion pressure (CPP). As ICP increases, CPP ultimately decreases to result in clinical signs.

Blood flow to the brain is coupled to the cerebral metabolic rate. When CBF decreases, the brain recognizes the ischemia and evokes a spectrum of

physiologic alterations known as the cerebral ischemic response.[26] These physiologic alterations are thought to emanate from vasomotor centers in the lower brain stem. Failure of adequate blood flow to remove CO_2 from receptors in these centers increases local CO_2 concentrations, which in turn, stimulates the sympathetic nervous system to increase systemic blood pressure. Systemic hypertension results as an attempt to maintain cerebral blood flow. Baroreceptors within the systemic vascular system recognize this hypertensive situation, and send this information to vagal centers also found in the lower brain stem. The resultant increase in systemic vagal tone reflexively causes

bradycardia. The systemic hypertension and associated reflex bradycardia is commonly referred to as Cushing's reflex and may explain why many animals with intracranial disease have bradycardia.

As ICP increases and CPP subsequently decreases to a significantly low level, a large catecholamine release occurs.[22] This catecholamine release may result in myocardial ischemia known as brain-heart syndrome.[11,27] Clinically, arrhythmias are noted. Focal myocardial ischemia is the pathologic lesion, with focal white streaks seen grossly in the myocardium.[27] Histologically, myocardial degeneration is common. Brain-heart

syndrome has been described with numerous intracranial and spinal pathologic lesions and in different species including dogs, sheep, cattle, horses, pigs, goats, and humans.

Intracranial pressure alterations are often responsible for clinical decline in many animals with brain disease. As stated previously, owing to the confining nature of the skull, changes in intracranial volume increase ICP when compensation is exhausted. With structural brain disease, the brain component usually enlarges as a result of neoplastic cell infiltration, edema, or inflammation. As the brain compartment volume increases, the CSF and blood compartments must

decrease or ICP will increase. Compensation for increased brain tissue volume initially involves shifting of CSF out of the skull, decreased CSF production, and eventually decreased cerebral blood flow.

These compensatory mechanisms prevent increases in ICP for some undetermined period of time. In general, the more slowly the volume increase occurs, the more readily this volume increase is compensated. When compensatory mechanisms are exhausted, relatively small increases in intracranial volume result in dramatic elevations of ICP. At this time, clinical signs become apparent. Initial signs of increased ICP may be nonspecific and

limited to alterations in mental status (progression to stupor and coma), cranial nerve dysfunction, and paresis. Unfortunately, clinical signs of increased ICP often become most obvious too late in the disease to allow for effective therapy.

Alterations in Cerebral Blood Flow (Ischemia and Hypoxia)

Because normal function of neurons depends on an adequate supply of oxygen, physical disruption of blood flow can significantly impair normal brain function. Cerebral vessels are directly responsive to $PaCO_2$ concentrations, with cerebral blood

flow coupled to cerebral metabolic rate.[1] As $PaCO_2$ concentrations increase, cerebral vessels dilate to increase blood flow to the brain. The opposite effect is seen with decreased $PaCO_2$. This effect of $PaCO_2$ is a component of cerebral blood flow autoregulation. The cerebral vessels have the ability to change diameter in response to $PaCO_2$ (chemical autoregulation) as well as blood pressure (pressure autoregulation) in order to maintain a relatively constant cerebral blood flow. Cerebral vessels change diameter through perivascular changes in pH as a direct result of $PaCO_2$ concentrations similar to what occurs in the chemosensitive area of the medulla oblongata for stimulation

of respiration.

If autoregulation is intact, hyperventilation to decrease $PaCO_2$ will cause cerebral vasoconstriction, decreased cerebral blood volume, and subsequently, decreased ICP. Cerebrovascular autoregulatory capability is affected by a variety of intracranial processes. For example, local acidosis, common in many hypoxic and ischemic events, will disrupt local autoregulatory functions.[28] If chemical autoregulation is absent in the diseased brain, hyperventilation will not alter the vascular diameter in the affected area. In this instance, two situations are possible, both dependent on the

premise that cerebrovascular autoregulatory capacity is absent owing to local disease.

As $PaCO_2$ is decreased by hyperventilation, vessels in surrounding normal brain will constrict. Vessels in the damaged or abnormal area of the brain are already maximally dilated and, therefore, are unable to constrict. Because of the vasoconstriction in normal brain, vascular resistance increases in this area, shunting blood into the abnormal area (inverse steal or Robin Hood phenomenon).[28] This has the positive effect of increasing cerebral blood flow to the abnormal and potentially hypoxic areas of the brain. The

negative effect, however, is potentiation of hemorrhage and cerebral edema in the abnormal area owing to the increased flow.

The opposite may occur as $PaCO_2$ increases. Vessels in normal brain surrounding the diseased area will dilate. Again, vessels in the abnormal area are already maximally dilated owing to loss of autoregulation. Vascular resistance will be decreased in surrounding normal brain, blood will be shunted away from abnormal areas, potentially decreasing hemorrhage and edema but resulting in further hypoxia (steal phenomenon).[28]

Autoregulation of cerebral blood flow

can also occur in response to systemic changes in blood pressure in order to maintain relatively constant cerebral blood flow during times of both hypo- and hypertension.[1] This prevents underperfusion and resultant ischemia during times of hypotension and hemorrhage and edema at times of hypertension. In most instances, cerebral blood flow is maintained constant throughout shifts in systemic blood pressure of between 50 and 150 mm Hg.[1] Above and below these limits, cerebral blood flow depends directly on systemic blood pressure.

Whether autoregulation remains intact in brain disease is difficult to predict clinically. Global autoregulatory

function of pressure has been assessed in human patients with head injury and found to be intact in about 69%.[29] It has been suggested that a crude clinical estimate of intact autoregulatory function is level of consciousness, with conscious patients thought to have intact autoregulatory capacity more often than do unconscious patients.[1] Local loss of autoregulation, however, is almost impossible to predict in the clinical setting without sophisticated testing that is not practically available.

Additionally, at least in the instance of exogenous head trauma, discrepancies can occur between the intact function of pressure versus chemical ($PaCO_2$-

responsive) autoregulatory capacities.[29] With head trauma, pressure autoregulation is often abnormal; however, $PaCO_2$-responsive autoregulation remains intact. This is termed dissociative vasoparalysis and has important ramifications during treatment. As the cerebrovascular response to blood pressure changes are abnormal, a more intimate control of systemic blood pressure and central venous pressure is required to prevent large shifts of blood pressure and subsequent cerebral blood flow. While correction of hypotension is often necessary in the animal with concurrent head trauma and shock, hypervolemia should be avoided.[25] If pressure autoregulation is defective,

significant increases in mean arterial blood pressure will increase cerebral blood flow and, ultimately, ICP.[29] If pressure autoregulation is intact, decreased blood pressure will cause cerebrovascular vasodilation, increasing cerebral blood flow, and ultimately, increasing ICP.

Pressure autoregulation may also falsely appear intact (false autoregulation) even when vasomotor paralysis is present.[28] In this situation, cerebral blood flow is found not to increase when systemic blood pressure is increased, suggesting intact pressure autoregulation. Because of associated cerebral swelling, however, further dilation of cerebral vessels is

prevented. Therefore, no additional increase in cerebral blood flow is possible, regardless of blood pressure. All of these factors contribute to myriad intracranial blood flow alterations that can affect intracranial pressure.

Cerebral blood flow, therefore, is normally maintained through a combination of systemic blood flow (pressure) and cerebral vasculature autoregulation. Autoregulation is important to maintain a near constant cerebral blood flow over a range of systemic blood pressures. Brain injury may alter cerebral vascular autoregulatory mechanisms, thus making cerebral blood flow more

dependent on systemic blood pressure. This results in inadequate perfusion of neurons during times of hypotension and overperfusion (possibly perpetuating edema formation) during times of hypertension (also referred to as luxury perfusion). Subsequent re-establishment of blood flow may also have possible detrimental effects (reperfusion injury) on spared brain through such processes as free radical formation and lactic acid accumulation.

Terminal Effects of Compartmentalized ICP Increases Brain Herniation

As intracranial volume continues to

increase beyond the limits of compensation, ICP will increase so precipitously that shifts of brain parenchyma, termed brain herniation, will occur.[8] Coma and severe neurologic impairment are noted. Unfortunately, in many instances, brain herniation becomes a terminal event.

Five major types of brain herniation have been described; rostral or caudal transtentorial, subfalcial or cingulate gyrus, foramen magnum, and herniation through a craniotomy defect.[2,8] Of these, caudal transtentorial, subfalcial, and foramen magnum occur most commonly. Clinical signs of caudal transtentorial

herniation are frequently the result of pressure distributed ventrally through the midbrain with subsequent compression of the oculomotor nerve. With unilateral herniations, an ipsilateral dilated pupil, unresponsive to light stimulation, may be seen. Monitoring for clinical signs of this type of herniation, therefore, should include periodic pupillary evaluations. If unilateral mydriasis is noted in this setting, immediate and aggressive attempts to decrease ICP should be instituted.

Foramen magnum herniation may occur quickly and results in respiratory arrest owing to associated pressure on the respiratory centers in the caudal

brain stem. Foramen magnum herniation is invariably fatal, and surgical attempts at decompression after this type of herniation have not been helpful in affected dogs.

Treatment of Intracranial Pathophysiologic Sequelae

Effective treatment of the pathophysiologic sequelae of increased ICP depends on the determination and effective treatment of the primary disease. Unfortunately, in the situation of brain injury, the primary event has occurred prior to treatment. It is often necessary, therefore, to acutely treat the more immediately life-threatening secondary sequelae such as increased

intracranial pressure to allow time for treatment of the primary disease. Treatment of secondary pathophysiologic events subsequent to intracranial injury is a more important determinant of acute survival than is treatment of the primary disease process. The following section provides an overview of treatment possibilities for these secondary pathophysiologic events. In-depth discussion of pros and cons of individual treatments have been discussed elsewhere.[30-33]

One of the most important aspects of treatment of intracranial injury is to maintain appropriate cerebral perfusion, primarily by maintaining effective intravascular volume. This is

accomplished through the administration of intravenous crystalloids and/or colloids. Mannitol has been shown to decrease blood viscosity, which may contribute to increased cerebral perfusion and decreases in ICP.[34] Decreasing blood viscosity will increase cerebral perfusion at the same level of pressure. Vasoconstriction will result, lowering cerebral blood volume and concurrently lowering ICP. Other hypertonic solutions appear to be less effective at lowering ICP as compared with mannitol, however, hypertonic saline administration has shown some benefit.[35]

Treatment of intracranial hemorrhage

varies depending on whether the hemorrhage has formed a discrete lesion that is increasing intracranial volume at the expense of the surrounding normal nervous tissue. In such an instance, surgical drainage may be necessary to bring about resolution. Although it is uncommon, traumatic subdural hematoma can be used as an example. As the lesion matures it becomes relatively hyperosmolar, resulting in imbibition of water and expansion of the lesion. The patient with traumatic subdural hematoma should, therefore, benefit from surgical drainage of the lesion.[5] It is also important to identify and treat any predisposing factors to hemorrhage such as hypertension or a

bleeding disorder.

Craniotomy/Craniectomy

A major tenet of the Monro-Kellie doctrine is that intracranial contents are confined within the cranium. It would follow, therefore, that surgical removal of the skull would potentially decrease ICP. Unilateral or bilateral craniectomy has been used as a treatment for ICP elevations which cannot be decreased by the more conventional methods stated earlier.[36-40] Although skull removal alone may be beneficial, subsequent dural incision appears significantly more effective in lowering ICP. This has been shown clinically in humans and

experimentally in dogs and cats.[41,42] Ultimate functional recovery, however, remains dependent on the underlying primary brain damage caused by the initial disease process. Postoperatively, the extent and magnitude of the decrease of ICP subsequent to surgery remains uncertain.

Craniectomy and durotomy have been shown to lower ICP by 15% and 65%, respectively, in dogs and cats, and humans.[41,38] Intracranial pressures in normal dogs approached atmospheric pressure when a bilateral or unilateral rostrotentorial craniectomy and durotomy were performed. Adequate decompression in animals with structural disease would be suggested if

intraoperative ICP approached similar levels.

If large amounts of skull are removed, a cranioplasty may be necessary. Otherwise, postoperative scarring may result in brain compression similar to that which occurs because of the formation of laminectomy membrane after extensive laminectomy, resulting in spinal cord compression. Cranioplasty can be delayed until life-threatening elevations of ICP are stabilized. Some humans had improvement in persistent neurologic signs after delayed cranioplasty, suggesting that clinical signs after initial recovery may result from both the initial injury and surgical

scarring.[52]

Other Treatments with Questionable Benefits

Much debate remains regarding the most appropriate head position for patients with head injury. Many current recommendations from human traumatologists suggest a horizontal or neutral position to maintain cerebral perfusion. Head elevation to 30° above heart level, however, has been shown to decrease ICP primarily by facilitating venous drainage.[43,44] Opponents suggest that head elevation may decrease cerebral perfusion and, therefore, be detrimental to brain functions. Reduction of ICP with this

relatively simple treatment may be beneficial in combination with other ICP-decreasing measures.

If chemical autoregulation remains intact, hyperventilation can decrease ICP owing to the established effects of $PaCO_2$ concentrations on cerebral blood flow.[1,9] Hyperventilation is performed to maintain the $PaCO_2$ concentration between 25 and 35 mm Hg.

Cerebrospinal fluid aspiration may be used as the initial means to decrease ICP.[45] This is most helpful in humans if a ventriculostomy is present and if ICP elevations do not exceed 30 mm Hg.[9] The use of routine CSF collection alone

for this purpose is not recommended in animals with suspected increased ICP owing to the increased risk of precipitating brain herniation.[46] In one study in animals, however, no increased risk of brain herniation was found in dogs and cats with intracranial disease after CSF collection.[47]

Corticosteroids have received much use in the treatment of spinal trauma, and have been recommended as a treatment for elevated ICP.[48,49] Although corticosteroids have shown to be beneficial by reducing cerebral edema in brain tumor patients, caution should be exercised when using corticosteroids for brain injury. One

study in rats has suggested that corticosteroids may be advantageous in brain injury;[49] however, corticosteroids may not be efficacious in head trauma and are known to perpetuate neuronal damage if ischemia is operant.[50,51] Corticosteroid administration may increase blood glucose, a factor that may negatively influence outcome after head injury.[52] Also, the onset of beneficial effects of decreasing cerebral edema may be delayed too long to be helpful in acute elevations of ICP. Unfortunately, until further data are reported, the benefit of corticosteroid use in head injury and elevated ICP remains nebulous. Additionally, other treatments such as barbiturate-induced coma and hypothermia require further

investigation.[24,53-55]

Chapter 41

Surgical Diseases of the Brain

Rodney S. Bagley
Annie V. Chen

Intracranial surgery in animals is most commonly employed for removal of intracranial masses, biopsy of intracranial lesions, placement of ventricular cerebrospinal fluid (CSF) shunting devices, decompression and debridement of intracranial tissues, and short-term treatment of increased intracranial pressure (ICP). Surgery may include removal of sizable

portions of the skull (craniotomy or craniectomy) or be limited to smaller burr holes for decompression and evacuation of hematoma or stereotactic biopsy. Additional indications for intracranial surgery in humans that may be employed in animals include treatment for seizures, chronic pain, and movement disorders.

Intracranial surgery used as treatment for intracranial disease is most appropriately considered following an appropriate diagnosis (both physical and anatomic) and with an understanding of the pathophyisology associated with the disease in question. Surgical approaches to intracranial lesions are chosen based on lesion

location, extent, anticipated consistency, nature (inflammatory versus neoplastic versus hemorrhagic), and the goal of the surgery (tissue removal versus biopsy versus decompression).[1] Limited approaches are more often used for biopsy, hematoma decompression, and intraventricular shunt placement. The size and extent of bone removal are also limited by skull anatomy, surrounding soft tissues, and the associated vasculature. Surgical approaches to the brain have been reviewed elsewhere.[1-4] The more common disease processes in which intracranial surgery is currently utilized are discussed further.

Neoplasia

The most appropriate treatment for dogs with brain tumors has yet to be defined. Survival for dogs with brain tumors that are not treated, however, is reportedly dismal. In one study, median survival for dogs with varying tumor types that did not have treatment was 6 days.[5] Anecdotal reports exist, however, of dogs with brain tumors living for months to years without definitive treatment. The natural course and overall survival times of animals with brain tumors are not well established, making objective determination of treatment effects more difficult.

Surgical removal is most readily used

for superficially located, encapsulated, relatively small, benign tumors of which meningiomas are the most common (Figure 41-1). Surgery also affords the possibility of cure that is uncommon with other treatment modalities for brain tumor. Depending on the type and location of the tumor, a surgical approach is made to the skull. The overlying skull is removed by performing a craniotomy or craniectomy. The mass is identified and, ideally, its borders are determined. The tumor can then be biopsied, debulked, or ideally, removed in total via a combination of sharp, blunt, and aspiration resection. Surgical equipment and techniques have been described elsewhere.[1] Tumor

removal is performed with magnification or with the aid of an operating microscope to improve visualization of the microvascular anatomy and to provide a better view of the tissue. An ultrasonic aspirator unit may be useful in some instances to more safely remove softer tumor tissue or necrotic brain at the borders of the tumor.

Many brain tumors are removed in a piecemeal fashion to avoid compression of normal brain and further brain damage. The inner portions of the tumor are removed first to collapse the volume of the mass. Next, the capsule is identified and removed, if possible. The dura in

contact with the lesion is incised with as large a margin as possible. In instances of meningioma, a biopsy of normal-appearing dura at the edge of the lesion is collected for histologic evaluation of tumor margins.

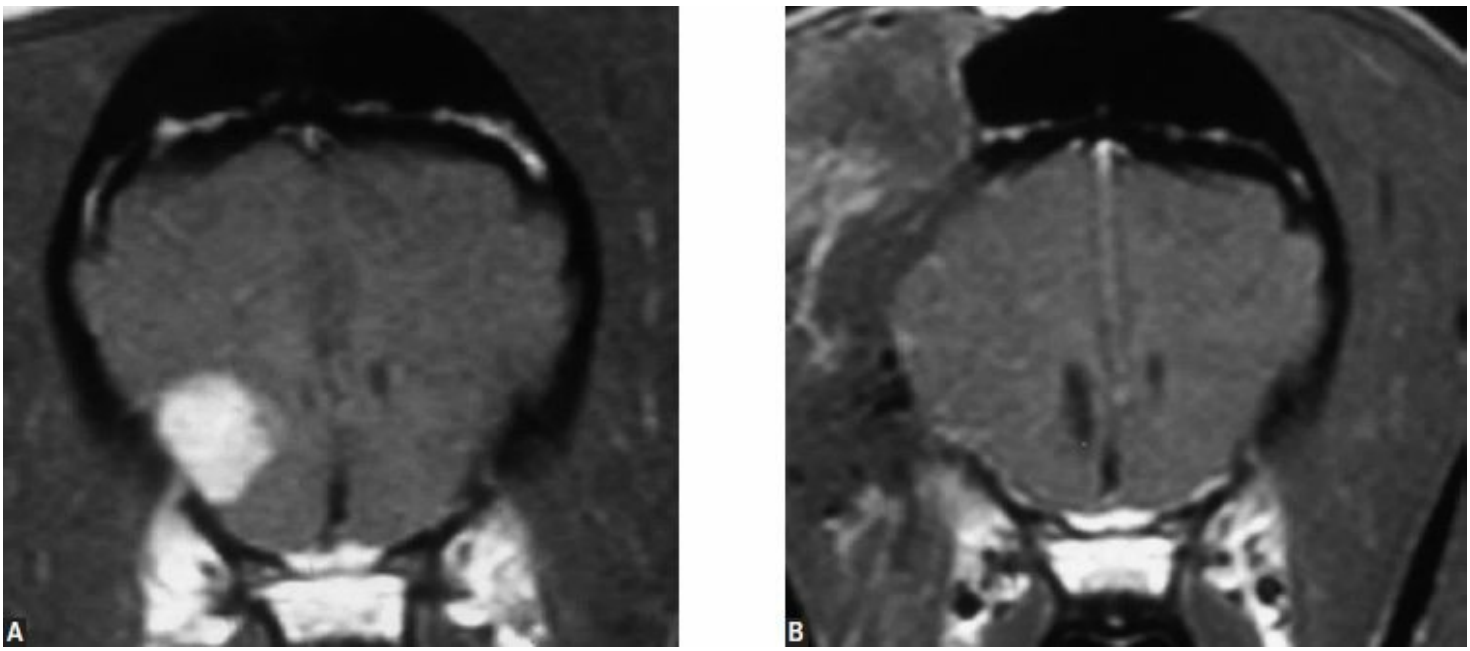

Figure 41-1 (A,B) Transverse, T1-weighted MR images following intravenous contrast administration of dogs with meningioma (left) before and (right) after surgical removal (From Bagley RS: Fundamentals of Veterinary Clinical Neurology, Ames, IA: Blackwell Publishing, 2005.)

In dogs, even when meningiomas are histologically benign, these tumors are often not well encapsulated and hence are difficult to differentiate from surrounding non-tumorous brain. Brain damage in areas adjacent to the tumor can make gross delineation of tumor borders difficult if not impossible. Tumor may be located in areas of the brain where access and exposure are limited, increasing the risk of surgical morbidity. Poor surgical access often leads to increased surgical mortality. If the tumor is within the parenchyma or within a ventricle, it is impossible to surgically access the lesion without damage to at least some surrounding or overlying brain. Many intracranial tumors have multiple vessels supplying

them, leading to the risk of hemorrhage during resection. These factors may limit successful removal of brain tumors; in some instances, however, surgery is successful in bringing about cure or long-term remission of brain tumors.[1,2,5-12]

Surgical treatments for brain-stem tumors are often hindered by inadequate exposure of the lesion and infiltration or compression of vital brain structures. Cranial nerves are often entwined within these masses, making complete resection difficult. Tumors of the cranial nerves may also require surgical removal similar to other tumors of peripheral nerves.[7] Median survival times reported in dogs

with all types of brain tumors after surgery vary but tend to cluster around 140 to 150 days.[1,2,5-12] For meningiomas, median survival times may be slightly longer (240 to 300+ days). Mortality is significant within the first 30 days of surgery for animals with infratentorial compared with supratentorial tumors.

Surgical excision is more readily accomplished in cats, as meningiomas in this species tend to be well encapsulated and easily delineated from normal brain. Studies have determined a median survival interval of cats after meningioma resection to be 22 and 27 months.[13,14]

Pituitary tumors may be treated surgically primarily through a transsphenoidal approach.[15-18] It can be difficult, however, to access larger tumors (> 1.0 cm) surgically, leading to incomplete removal and increased surgical morbidity.

Treatment of metastatic tumor to the brain is rarely performed in animals. With humans, however, surgical removal of metastases often improves survival. Tumors invading the skull, such as multilobular chondrosarcoma or osteosarcoma, may also be surgically removable depending primarily on size and anatomic location at the time of diagnosis.[19,20]

Many factors may affect survival following brain surgery, including neurologic and systemic abnormalities. In general, most dogs are probably diagnosed relatively late in the course of their disease and only when clinical signs become obvious. By this time, the tumors are relatively large, have caused significant associated brain injury, and are often infiltrative or tightly adherent to the nervous tissue. An overall deterioration of systemic health may have occurred prior to definitive treatment because of lack of adequate nutrition, chronic stress, pain, or deleterious effects of medications administered to control clinical signs, namely corticosteroids. Non-nervous system organ effects such

as brain-heart syndrome may adversely compromise systemic health. In addition, as intracranial surgery in small animals has a relatively short history, the learning curve is still steep in regard to intracranial surgical techniques. All of these factors affect historical morbidity and mortality statistics of animals with brain tumors.

Unfortunately, primarily because of relatively small numbers of dogs with brain tumors that have been definitively treated, all dogs with tumors tend to be grouped for analysis. This means that all dogs with brain tumors, regardless of tumor location or tumor growth characteristics, are regarded as being equal, when the

behavior and aggressiveness of the various tumor types and locations are ignored. Additionally, treatments given are variable even for animals with the same clinical characteristics. These factors introduce bias into the determination of overall survival. Finally, some lesions are diagnosed as brain tumors based primarily on imaging characteristics without a subsequent biopsy diagnosis. All of these potential influences make it difficult to communicate accurately with owners the prognosis of the many different types and locations of brain tumor. In an attempt to begin to determine whether certain characteristics influence overall survival, we have evaluated dogs with

biopsy-diagnosed tumors regarding the influence of tumor type and location on survival after initial surgical treatment. Preliminary conclusions indicate that dogs with supratentorial tumors are more likely to survive longer than 30 days following surgery compared with dogs with infratentorial tumors. The mortality associated with supratentorial surgery is also lower than for infratentorial surgery in dogs with brain tumor. Overall, dogs have a 30-day survival rate of approximately 60% following intracranial surgery for brain tumor. Conversely, there is a 30-day mortality rate of approximately 40% for dogs with brain tumors. Survival for longer than six months depends on tumor type and location.

Surgical treatment of brain tumor should ideally not only cure the dog of the tumor but also improve or resolve the clinical signs associated with the tumor. Surgical resection of tumors, for example, may increase the likelihood of seizure control or help in the control of effects of increased ICP.

Syringomyelia and hydromyelia are increasingly diagnosed as a cause of spinal cord dysfunction in dogs and, rarely, in cats. Because several possible pathogenic mechanisms can result in or perpetuate syringomyelia and hydromyelia, an appropriate pathophysiologic diagnosis of the actual cause of these diseases is imperative for appropriate treatment

planning. Commonly, syringomyelia and hydromyelia are associated with abnormal CSF dynamics at the level of the fourth ventricle/foramen magnum area. This may be the result of malformations of the foramen magnum or cranial cervical region, and may be associated with Chiari-like malformation of the infratentorial area.

If clinical signs are mild, non-surgical treatments with confinement, restricted activity, corticosteroids, or pain medication may provide symptomatic relief. Medical management of this condition may improve clinical signs in some dogs, and it is often attempted prior to, or

concurrent with, surgical treatments. Corticosteroids (prednisone) are most often used at anti-inflammatory dosages (0.5-1 mg/kg every 12 to 24 hours). If medical treatment is the sole treatment to be used (i.e., because an owner does not wish to pursue surgical treatment), corticosteroid dosages are adjusted (increased) if clinical signs are not improved, and the animal is monitored closely for side effects. If improvement or resolution of clinical signs occurs within the first one to two weeks following corticosteroid therapy, this medication can be used in decreasing doses to achieve the lowest dose necessary to achieve remission of clinical signs.

If the clinical signs are the result of a Chiari-like malformation or other foramen magnum or infratentorial abnormality, surgical removal of any stenosis and decompression of the brain stem, cerebellum, and cranial spinal cord may alleviate clinical signs. Decompressive surgery of the foramen magnum usually includes a suboccipital craniectomy and durotomy.[21,22] After portions of the occipital bone and associated fibrous tissues are removed, a dura graft, such as a temporalis fascia graft, is placed over the foramen magnum area in an attempt to prevent further scaring of tissues in this area. In other situations where syringomyelia is associated with hydrocephalus, ventriculoperitoneal

shunting may improve clinical signs (see further under hydrocephalus).

Primary cystic structures may also be present in the intracranial region, usually in or around the caudal and dorsal third ventricle. These cystic structures are often referred to as arachnoid or subarachnoid cysts. In some instances, surgical fenestration through a craniotomy or craniectomy can produce improvement in clinical signs. Similarly, epidermoid or dermoid cysts may be surgically resectable. Although there is no primary treatment for occipital dysplasia, the clinical consequences of Chiari-like malformation such as syringomyelia may be improved with a foramen

magnum decompression via a suboccipital craniectomy with subsequent surgical reconstruction of this region.

Hydrocephalus

Several medical and surgical treatment options may be beneficial for animals with hydrocephalus. The choice of treatments is generally dictated by the degree of physical impairment, age of the animal, and cause of the hydrocephalus, if known. Medical treatment may include general supportive care and medications to limit CSF production and reduce intracranial pressure. Surgical treatment is designed to provide

drainage of CSF from the brain to another site within the body for reabsorption.

Surgical treatment for hydrocephalus is generally required for those animals that do not improve within two weeks of the institution of medical therapy or for those animals whose clinical signs deteriorate during medical therapy. Surgical procedures are designed to provide controlled CSF flow from the ventricles of the brain to either the peritoneal cavity or the right atrium. Shunt systems designed for use in humans seem to be adaptable for animals. Ventriculoperitoneal (VP) shunts are technically easier to install and are most commonly used in human

neurosurgery. Emergency placement of shorter-term CSF-removal devices may be used in the management of secondary hydrocephalus. Vascular access ports or similar subcutaneously implanted devices have been used for this purpose.

Ventriculoperitoneal shunt systems are used in the long-term management of hydrocephalus in humans and dogs. These shunt systems have three required components: a ventricular catheter, a siphon control mechanism, and a distal catheter. The three components can be obtained separately and fitted together at surgery, or purchased as a unit with the three parts permanently connected.

The ventricular catheter is a fenestrated section of silicone tubing that is usually placed in a lateral ventricle via a small burr hole placed in the skull. This ventricular catheter is connected to a siphon control valve. The valve is designed to reduce the siphon effect of gravity-induced hydrostatic pressure in the distal catheter, thereby maintaining physiologic ventricular pressures. Hydrostatic pressure, which is greatest when the animal stands up, would cause overdrainage of CSF if not attenuated by the valve. There are low-, medium-, and high-pressure valves to maintain ventricular pressures within preset ranges. As normal ICP in dogs is thought to be between 8 and 12 mm

Hg, a shunt that works at or above these pressures is usually used. The distal catheter carries CSF from the valve to the peritoneal cavity. Surgical placement of these shunts has been described elsewhere.

Regardless of the type of shunt used, strict aseptic technique and thorough hemostasis must be used to avoid shunt failure. The two most common complications of shunt placement in humans are infection and undershunting. Overshunting and seizures are less commonly encountered, but possible. Placement of VP shunts is contraindicated if systemic infections are present. All infections should be resolved prior to

surgery.

Even if patients do not have a systemic infection at the time of surgery, they may develop an infection at a later time. Fever and deterioration of neurologic functions are the most common signs of shunt infection. If an infection is suspected, CSF can be collected from the subcutaneous shunt reservoir for culture and sensitivity examination. Prophylactic antibiotics are suggested for patients with VP shunts at times of potential for development of bacteremia or septicemia (e.g., dental procedures). Shunt nephritis has been reported in humans owing to chronic, low-level shunt infection causing immune

complex deposition in renal glomeruli.

Undershunting (not removing enough CSF from the ventricle through the shunt) results from blockage, disconnection, or kinking of the catheter system. Possible causes of blockage include obstruction by choroid plexus and buildup of proteinaceous accretions, blood, or cellular debris (inflammatory or neoplastic). The blockage may occur in the ventricular catheter, siphon control valve, or distal catheter. Several methods, including shunt tapping and radiographic examinations, have been developed to evaluate shunt patency and locate the site of blockage.

Complications associated with overshunting have not been well described in animals, but they most likely do occur. In humans, overshunting results in formation of subdural hematomas and/or very small ventricular size (slit ventricle syndrome). Overshunting of CSF can cause collapse of the brain with tearing of vessels, which produces subdural hematoma formation. Animals with large dilated lateral ventricles and only a thin rim of cerebral cortex remaining have the highest risk for brain collapse and hemorrhage. The risk of brain collapse can be minimized by not allowing large amounts of CSF to escape during shunt placement. Additionally, a siphon control valve

with the proper pressure range must be selected. Intracranial bleeding and brain collapse are most easily confirmed with advanced imaging studies such as MR or CT imaging following shunt placement.

Successful, long-term resolution of clinical signs of hydrocephalus has been achieved in dogs with these types of surgical shunting procedures. Experimental evidence suggests that reconstitution of the cerebral hemispheres after shunting occurs only in the white matter. Reconstituted white matter is characterized by myelin destruction, remyelination, and reactive astrocytosis. Because neuronal loss and cortical laminar destruction

are irreversible, hydrocephalus should be treated aggressively as early as possible.

Inflammatory Diseases

Treatment of encephalitis and meningitis is ideally directed at a specific causative organism. In some instances, intracranial inflammation or infection will coalesce to form a discrete mass or abscess. As an abscess and its associated inflammation can rapidly increase intracranial pressure, surgical drainage and decompression of a focal abscess should occur as soon as possible after detection. Similarly, penetrating intracranial wounds may require debridement to avoid infectious

complications.

Intracranial Hemorrhage and Vascular-Based Disease

Treatment for CNS bleeding includes treatment of any underlying bleeding disorder and stopping or resolving the local effects of any accumulated hemorrhage. Various treatments exist for individual coagulopathies and for thrombocytopenia. Current recommendations for treatment of these bleeding disorders should be reviewed.

Treatment for a localized hematoma within the CNS is focused on evacuation of the hematoma, usually

via a craniotomy or craniectomy. If the underlying bleeding disorder is still active, a difficult choice exists between the need for surgical drainage of the hematoma and the risk of causing increasing amounts of hemorrhage. Short-term hemostatic support with blood products or platelets may provide a window of patient stability for a surgical procedure to be performed. Ultimately, if the accumulation of bleeding in the central nervous system is becoming life-threatening, surgical drainage is a necessity, which is undertaken in full recognition of the increased risk of hemorrhagic complications. While it is impossible to reverse all of the effects of the hemorrhage, decreasing the size

of an expanding hematoma with the resultant decrease in nervous tissue pressure may improve clinical signs. Two caveats should be considered. One is that, by decreasing intraparenchymal pressure, blood flow to the area may be restored and a rebound hemorrhage may occur. Second, along the same lines, if the original cause of the bleeding was a ruptured vessel (aneurysm or arteriovenous malformation), hematoma removal may result in rebleeding. In both of these situations, however, hemostasis can be employed intraoperatively to decrease this possibility.

In chronic hematomas, especially if the

initial bleeding tendency has subsided, surgical drainage is reasonably straightforward if the extent of the hematoma can be localized. Usually, a black, sometimes greenish, soft lesion consistent with an established hematoma is found. This can be removed with suction aspiration. The edges of the hematoma tend to be more organized and require blunt dissection for removal.

Intracranial Traumatic Injury

Surgical treatments for intracranial trauma are indicated primarily for decompression and debridement of abnormal tissue or blood. A major

tenet of the Monro-Kellie doctrine is that intracranial contents are confined within the cranium. It would follow, therefore, that surgical removal of this structure would potentially relieve ICP elevations. Unilateral or bilateral craniectomy has been used as a treatment for ICP elevations that cannot be decreased by the more conventional methods stated earlier. Although skull removal alone may be beneficial, subsequent dural incision appears significantly more effective in lowering ICP.[23] This has been shown clinically in humans and experimentally in dogs as well as cats. Ultimate functional recovery remains dependent on the underlying primary brain damage inflicted by the disease

process. Because ICP may increase during wound closure and anesthetic recovery, the magnitude of ICP decrease subsequent to surgery remains uncertain.

Craniectomy and durotomy have been shown to lower ICP by 15% and 65%, respectively, in dogs and cats, and humans. Intracranial pressures in normal dogs approached atmospheric pressure when a lateral rostrotentorial craniectomy and durotomy were performed. Adequate decompression of the brain in animals with structural disease would be suggested if intraoperative ICP approached similar levels.

Surgical Treatment for Diseases of Cranial Nerves

Cranial nerves can occasionally be affected with disease independent of the intracranial nervous structures.[24] Tumors, for example, often arise within or around the trigeminal nerve. Trigeminal nerve abnormalities can occur with infiltrating neoplasia (lymphosarcomas) that involve a branch or the entire nerve. Myelomonocytic leukemias and other hematocellular neoplasia may affect this nerve. Tumors of the coverings of the nerve (nerve sheath tumors) may arise on or around the trigeminal nerve. These tumors can infiltrate or compress the nerve, resulting in

dysfunction. Unilateral muscle atrophy of the temporalis and masseter muscles is suggestive of an isolated disease of this cranial nerve. Surgical removal of these tumors has been performed, but can result in cosmetic consequences owing to complete trigeminal denervation of head muscles. Radiation therapy has been used in a limited number of cases with apparently encouraging results.

The vestibular nerve may be affected either peripherally (usually by disease of the middle or inner ear) or centrally at the brain stem level. Tumors of the ear more often occur in older animals. Squamous cell carcinoma and adenocarcinoma are most common.

Treatment may include surgical resection or radiation therapy. Inflammatory polyps occur in cats. Surgical removal of these polyps is often helpful. Otitis media/interna may require systemic antibiotics (clavulanic acid), or surgical debridement (bulla osteotomy) may be necessary.

Future Directions-Surgical Treatments of Seizures

Surgical treatments for seizure control are used for selected human patients with seizures that are not controlled adequately with medical therapies. Similar surgical treatments are rare in animals, but we hope will increase

with a better understanding of seizure generation and location.[25,26] This will occur through advances in intracranial imaging and electrophysiologic monitoring for animals.

Chapter 42

Spinal Cord Compression

Lisa Klopp

Causes of Spinal Cord Compression

Diseases can affect the spinal cord by parenchymal disruption (intramedullary disease) or by compression of the tissue. Collectively, diseases that cause compression are probably the most common causes of spinal cord dysfunction. Compression can occur from pathology outside the

dura (extradural compression) or within the dura (intradural-extramedullary compression). The mechanism of injury, rate of onset, force and kinetic energy of an injury, and the duration of compression all play a role in the severity and progression of clinical signs.[1-3] For example, an acute severe spinal cord compression is more likely to cause acute paraplegia in comparison with a spinal meningioma, which grows slowly and allows functional compensation to occur. However, once the limit of compensation is reached, deterioration of neurologic function can occur rapidly.[4] Clinical signs associated with spinal cord compression depend on the location of

the lesion. Clinical signs of spinal cord dysfunction can be found in Chapter 46: Intervertebral Disk Disease. A list of the most common diseases that cause spinal cord compression can be found in Table 42-1. Images of various disease processes that cause spinal cord compression are shown in Figures 42-1 to 42-7.

Pathophysiology of Spinal Cord Compression

Morphologic and Histologic Changes

Spinal cord compression can occur relatively slowly over the course of time, with such disorders as developing

neoplastic disease, arachnoid cyst, synovial cyst, or soft tissue hypertrophy/hyperplasia associated with caudal cervical vertebral malformation/malarticulation. In a chronic progressive process, the spinal cord tissue compensates for some period of time before clinical signs become evident.[5-7] Typically, this results in a large volume of pathology and severe compression prior to clinical dysfunction and diagnosis.

Acute spinal cord injuries occur as a result of rapid spinal cord compression, such as that seen with acute intervertebral disk extrusion and fracture/luxation. Acute spinal cord injuries involve both primary and

secondary pathologic processes.[2,8-21] The primary injury is the inciting mechanical event itself, which then induces a complex series of vascular, biochemical, and cellular events that result in progressive secondary injury to the spinal cord parenchyma. Vascular events include ischemia, hemorrhage, impaired autoregulation of blood flow, microcirculatory disruption, vasospasm and thrombosis.[11,13,17,22,23] Secondary biochemical events ultimately result in edema, lipid peroxidation, and cytotoxic injury.[22-27] These include cellular ion derangement (increased intracellular sodium and calcium and extracellular potassium).[8-10,13] Extracellular release and accumulation

of neurotransmitters (serotonin, catecholamines, and glutamate) occur and are injurious to the spinal cord cells in large quantities.[9,13,28] Induction of the arachidonic acid cascade, production of eicosanoids, and generation of free radicals result in progression of inflammation via cytokines and lipid peroxidation of cellular membranes of all spinal cord elements (endothelium, myelin, neurons, and glial cells).[15,29-32] Cellular energy failure via loss of adenosine-triphosphate pathways and cellular apoptosis also occurs.[13,30]

Table 42-1. Diseases that Cause Spinal Cord

Compression

Diseases that cause extradural spinal cord compression

Intervertebral Disk Disease

- Type I
- Type II

Articular facet joint synovial cysts

Cartilaginous exostosis

Vertebral canal stenosis

- Caudal cervical vertebral malformation/malarticulation ("Wobbler's disease")
- Congenital stenosis
- Cervical bony stenosis
- Stenosis associated with

- hemivertebra (usually thoracic in location)

Neoplasia

- Sarcomas arising from the vertebra
- Osteosarcoma
- Chondrosarcoma
- Fibrosarcoma
- Hemangiosarcoma
- Lymphosarcoma
- Multiple myeloma

Epidural abscess

Fracture/luxation

- Congenital
- Atlantoaxial luxation
- Traumatic

Hematoma (most commonly associated with intervertebral disk extrusion or trauma)

Diseases that cause intradural-extramedullary spinal cord compression
Arachnoid cyst
Arachnoid scarring/fibrosis
Hematoma
Neoplasia
Meningioma
Nerve root tumor
Metastatic neoplasia

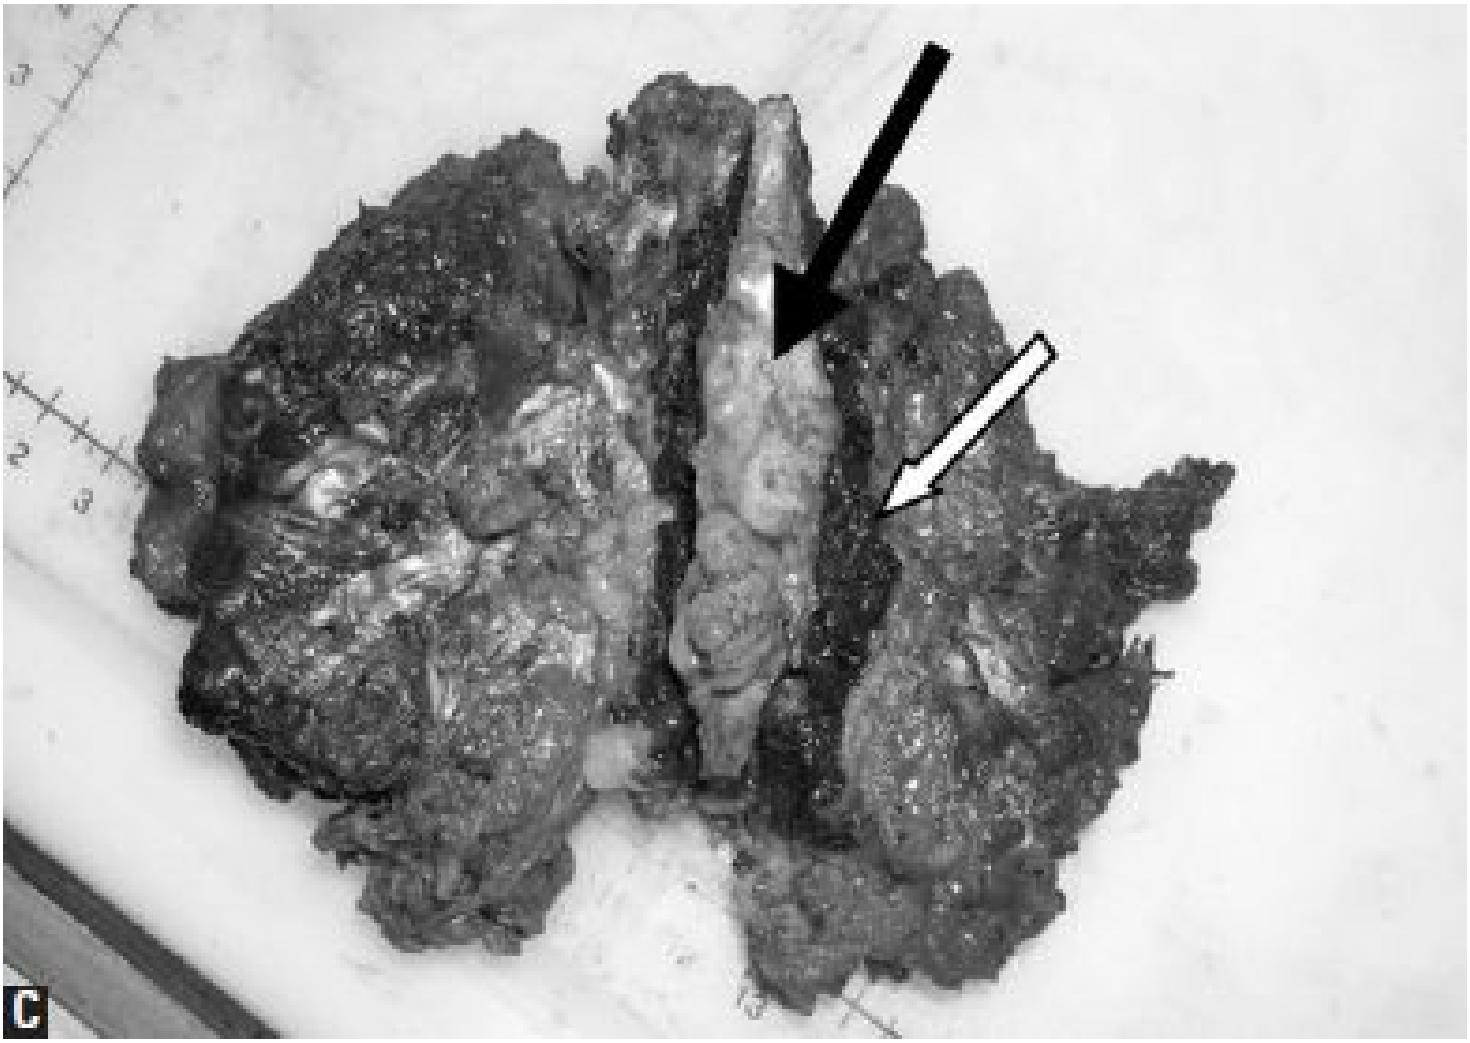

Figure 42-1. Extradural compression: T9 chondrosacroma in an 11-year-old MC bloodhound with acute deterioration of chronic paraparesis. The tumor was removed and the dog's neurologic function improved daily. A. T2-weighted, sagittal MRI. The tumor has severely and completely compressed the spinal cord. (arrow) B. T2-weighted, transverse MRI. The compressed spinal cord is indicated by the arrow. C. The tumor has been removed *en bloc* (ventral view of the dorsal lamina) and is surrounded by tumor capsule and normal muscle tissue. The dorsal lamina

has been replaced by chrondoscarcoma (black arrow). The tumor margin has been outlined with paint (white arrow).

Most of what is known about the pathophysiology of spinal cord compression comes from acute spinal cord injury, cervical myelopathy, or animal models of spinal cord compression. In a clinical setting, histologic findings of spinal cord compression have been best described in human patients with cervical spondylitic myelopathy, which is a synonymous disease with canine caudal cervical vertebral malformation/malarticulation ("Wobbler's disease")[14,33-35] When the spinal cord is compressed, the central grey matter and medial portions of the

white matter are usually the most severely affected with cystic cavitation (syrinx), gliosis, edema, and demyelination.[3,33,36-42] Wallerian degeneration is observed cranial to the compression site in the posterior and posteriolateral columns.[3,39,43] Lower motor neuron dropout occurs at the site of compression, and demyelination and axonal degeneration occur in the corticospinal tracts caudal to the compression site.[14,33,39,44] Studies have shown that clinical signs typically appear after the spinal cord has been compressed by 30%.[8,33,45,46] In addition, because of the relative tolerance of the cervical spinal cord to encroachment, the development of clinical myelopathy was found to be

highly correlated to pre-existing congenitally narrow spinal canal.[33,47]

Ogino et al.[48] followed nine patients with cervical myelopathy throughout their clinical course and postmortem. He found that the severity of compression was correlative to the pathologic changes. Minor compression was most associated with degeneration of the posteriolateral white matter (including the corticospinal tracts). Advancing severity of compression resulted in infarction and loss the α-motor neurons in the anterior horn grey matter. As compression became more severe, extensive grey matter infarction ensued. The dorsal horn

columns and lateral white matter tracts were also affected only in cases of severe compression. However, anterior white matter appeared remarkably resistant to degeneration, a finding supported by other studies.[49] The severity of histologic findings correlated well to the clinical neurologic findings in all patients.

In a study by Yamaura et al.,[35] twy/twy mice, which spontaneously develop dorsolateral calcified deposits at C1 and C2 vertebrae by four months of age, were used to study chronic spinal cord compression. At six months of age, the spinal cords in these mice were already significantly compressed. Grey matter degeneration was

observed as small, flattened neurons that were decreased in number, especially in the dorsal horns where the compression was most significant. Loss of axonal and glial elements and myelin destruction were observed in the white matter at the site of the compression as well as in descending tracts caudally and ascending tracts cranially.

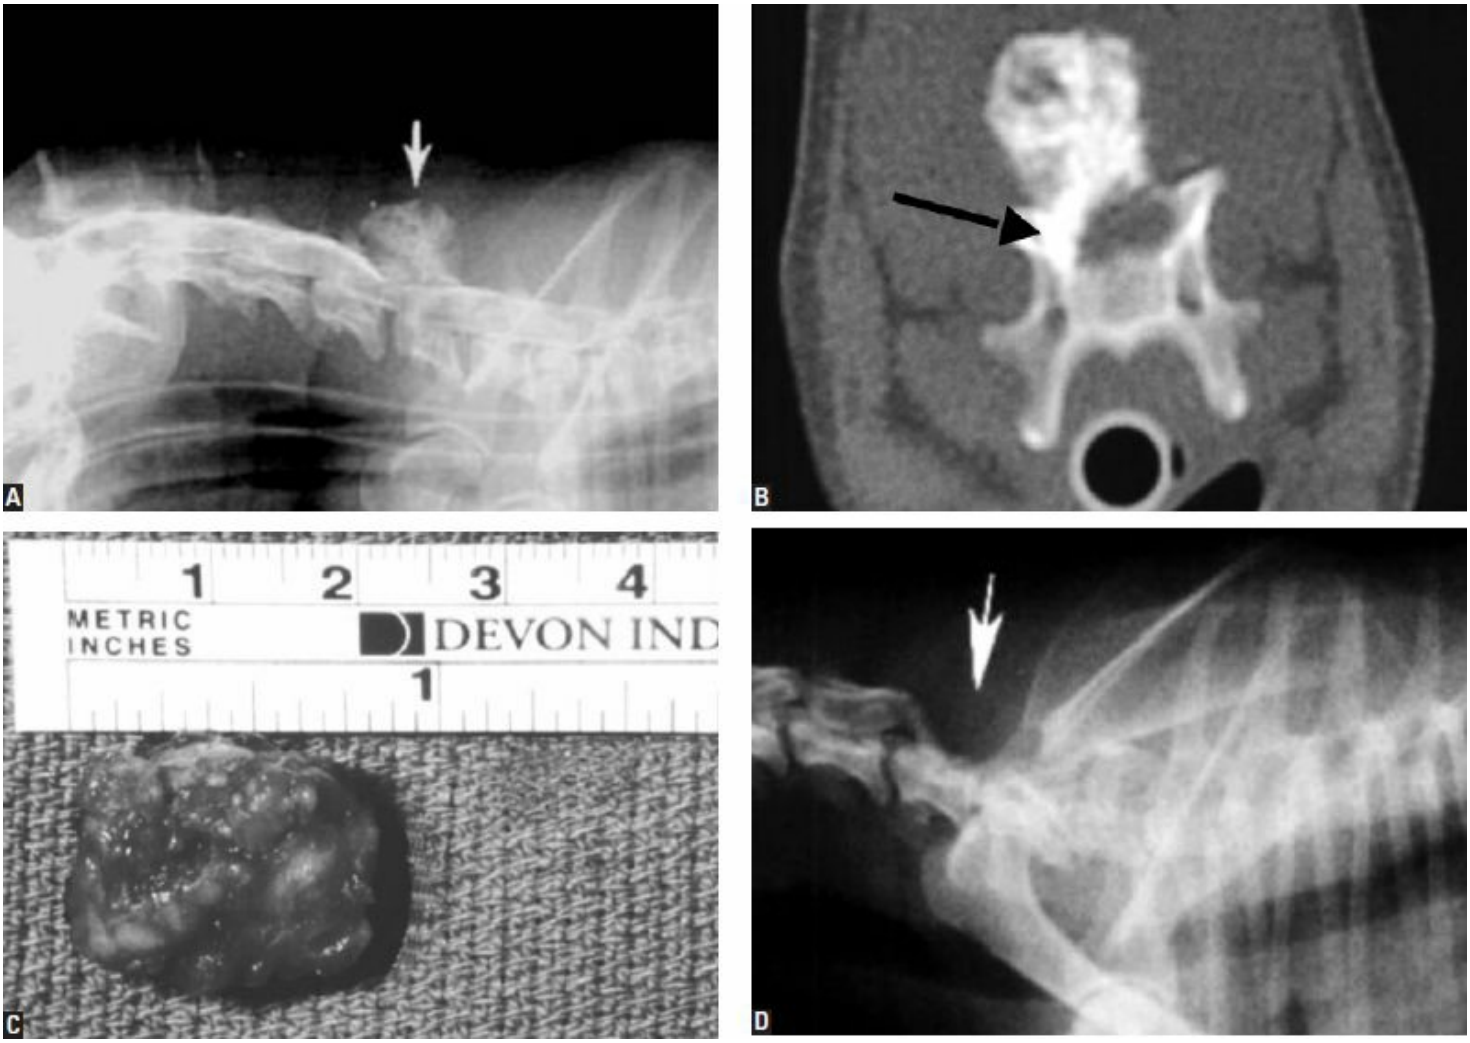

Figure 42-2. Extradural compression: Low-grade osteosarcoma of the lamina and pedicles of C6 in a 6-year-old, FS Yorkshire terrier. The tumor was removed *en bloc* and there was no recurrence until the animal was lost to follow-up 2 years later. A. Lateral image of a myelogram. Note the significant dorsal compression of the spinal cord (arrow). B. Computed tomographic scan following myelogram. The tumor has extended into the pedicle on one side (arrow). C. The tumor has been removed *en bloc*. D. A radiograph

taken 1 year postoperatively.

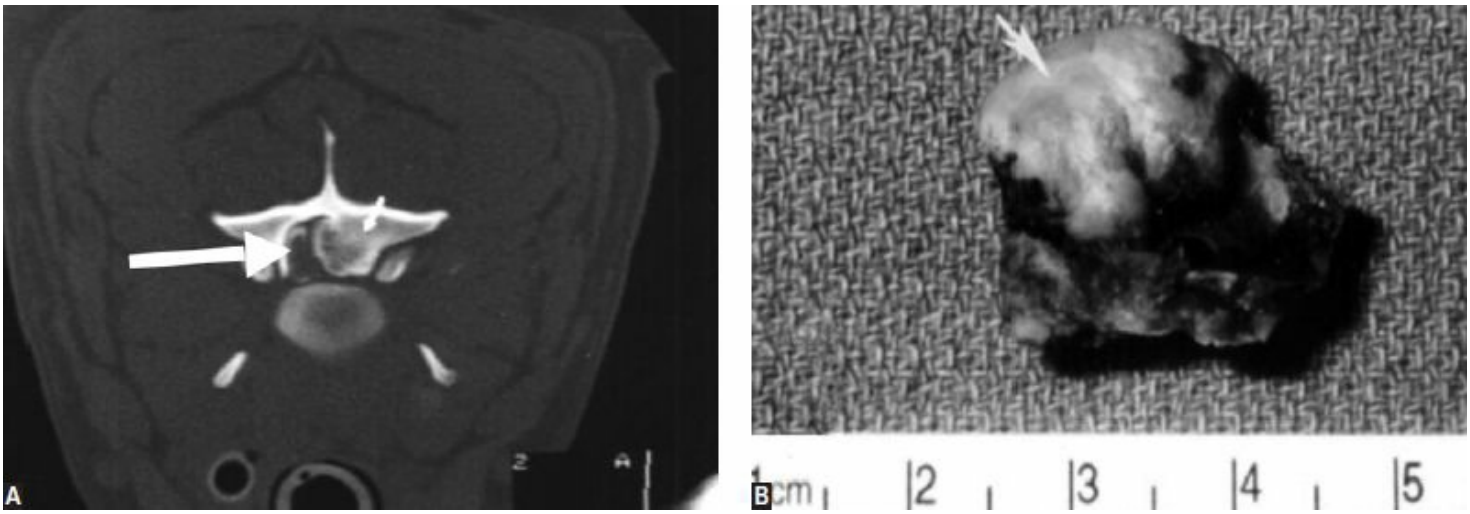

Figure 42-3. Extradural compression: Cartilaginous exostosis of the C4 caudal articular process in an 11-month-old, MC Airedale terrier mix with a 6-month history of progressive tetraparesis. A. Postmyelogram transverse computed tomographic scan. The spinal cord (large arrow) has been compressed to about 25% of its normal diameter by the mass (small arrow). B. The benign tumor was removed, the dog recovered to normal neurologic status and was still normal at 5 years postoperative.

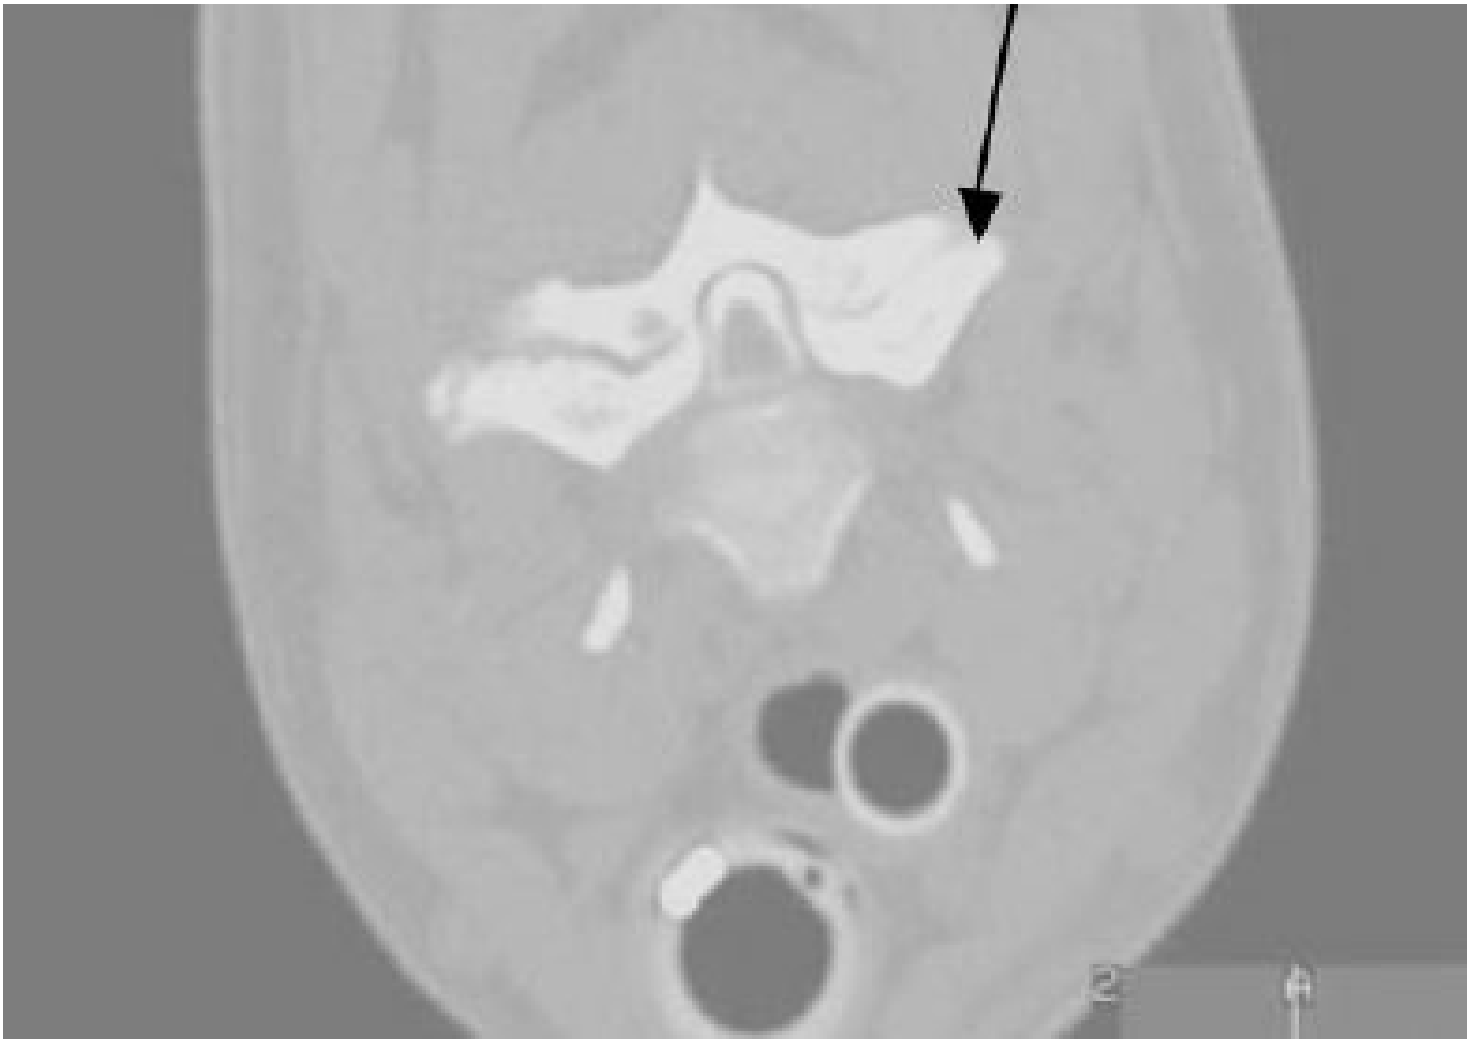

Figure 42-4. Extradural compression: severe stenosis at the level of the C4-5 facet joint in a 7-year-old, FS Basenji with unremitting cervical pain and mild neurologic dysfunction. A computed tomographic scan of the C4-5 spinal level. The spinal cord is triangular-shaped from the compression. A hyperplastic facet joint is indicated by the arrow. This dog had similar stenoses at 3 other levels in her cervical spine (C3-4, C5-6, and C6-7). She had modified medial facetectomies at all levels and recovered to normal function and her pain resolved.

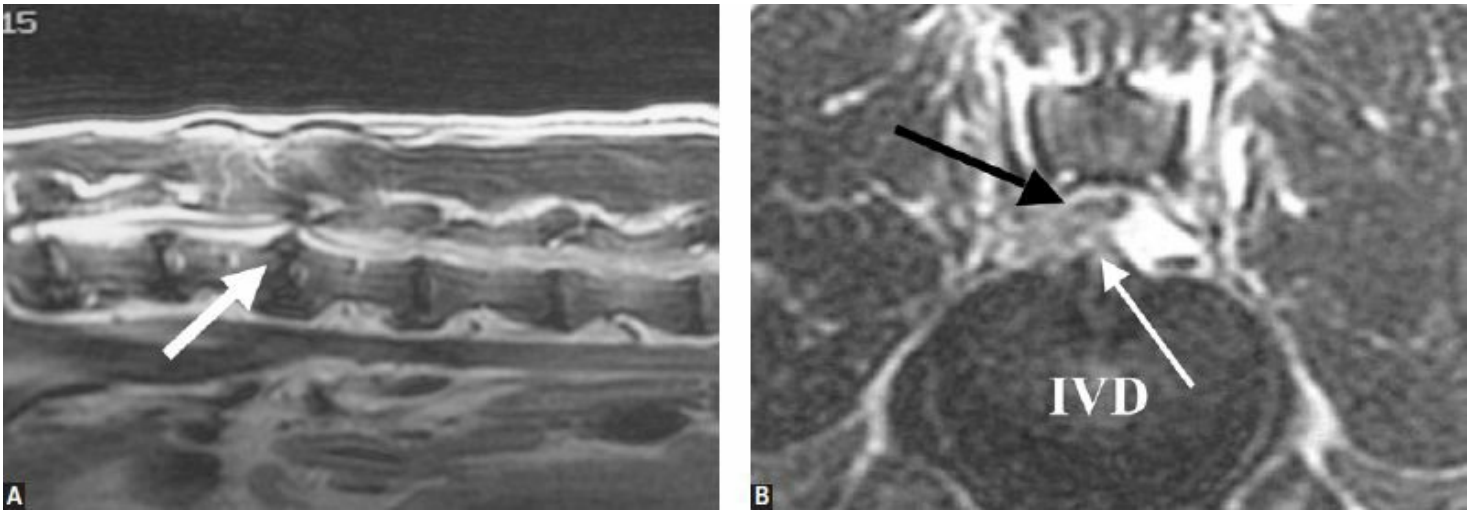

Figure 42-5. Extradural compression: L1-2, type II intervertebral disk extrusion in a 4-year-old, MC German shepherd dog that displayed mild paraparesis and significant thoracolumbar pain. A. T2-weighted, sagittal MRI. The spinal cord is severely compressed by the disk extrusion (arrow). B. T2-weighted, transverse MRI. The spinal cord is compressed to the right and dorsally (black arrow) by the protruding intervertebral disk (white arrow). (IVD = intervertebral disk)

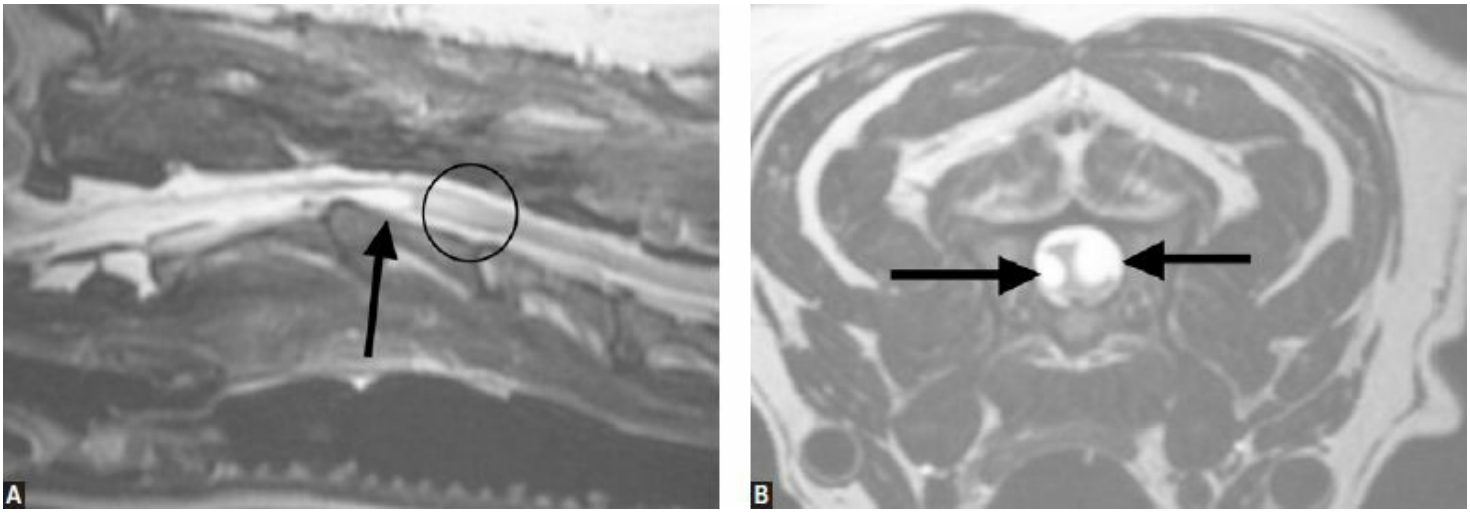

Figure 42-6. Intradural, extramedullary compression: Multiple arachnoid cysts in a 7-year-old, Springer spaniel that had a history of cervical pain and mild tetraparesis after being hit by a car 2 years earlier. At the time of the MRI the dog was poorly ambulatory. The arachnoid cysts were believed to have formed secondary to arachnoiditis from hemorrhage and inflammation. The arachnoid cysts were addressed surgically and she recovered to ambulatory tetraparesis but began to slowly deteriorate over time. Repeat MRI revealed that the cysts were resolved, but that there were progressive parenchymal changes in the spinal cord. A. Preoperative T2-weighted, sagittal MRI. The arrow indicates one arachnoid cyst. Signal hyperintensity within the parenchyma is seen within the circle. This was likely an area of malacia, edema, or early syrinx formation. B. T2-weighted, transverse MRI. The cysts are indicated by the arrows. The spinal cord has taken on an “apple-core” shape due to the intradural compression.

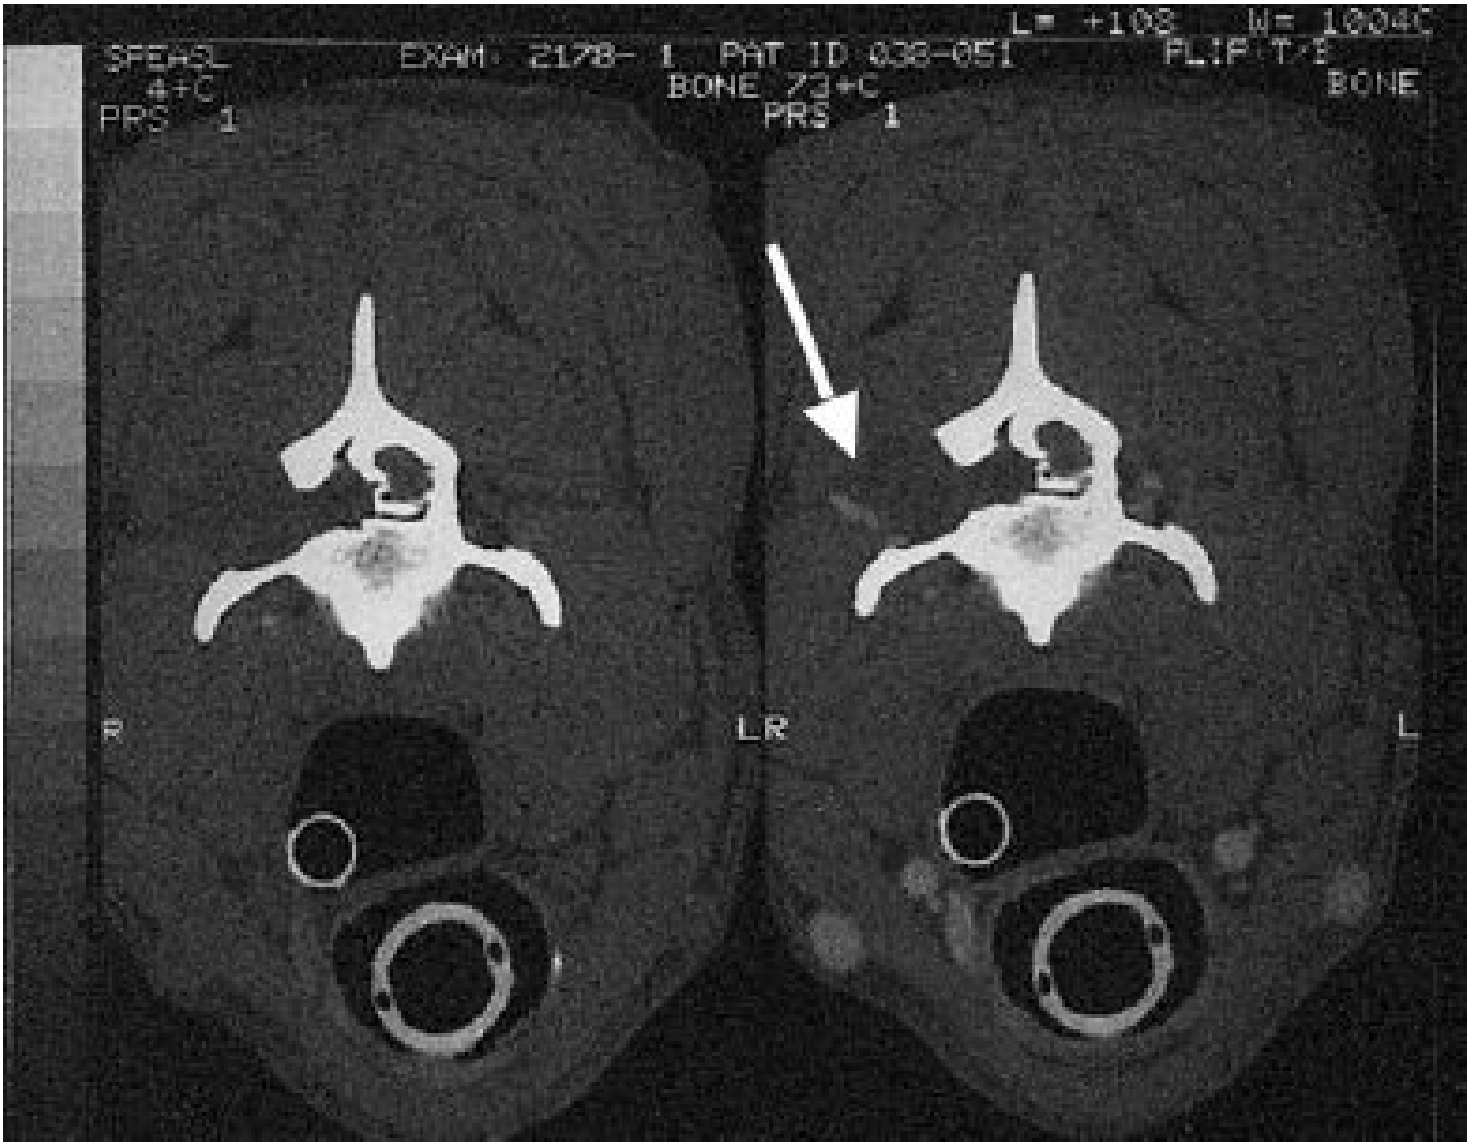

Figure 42-7. Intradural-extramedullary compression: C3 nerve root tumor in a 7-year-old, FS Doberman pinscher that presented with ataxia and cervical pain. Post-myelogram computed tomographic scan with the precontrast image on the left and the postcontrast image on the right. The tumor has caused pressure necrosis of the pedicle and the foramen is widened. (Note the presence of pedicle bone on the left side.) The tumor did not contrast-enhance with the exception of a small blush at the periphery (arrow).

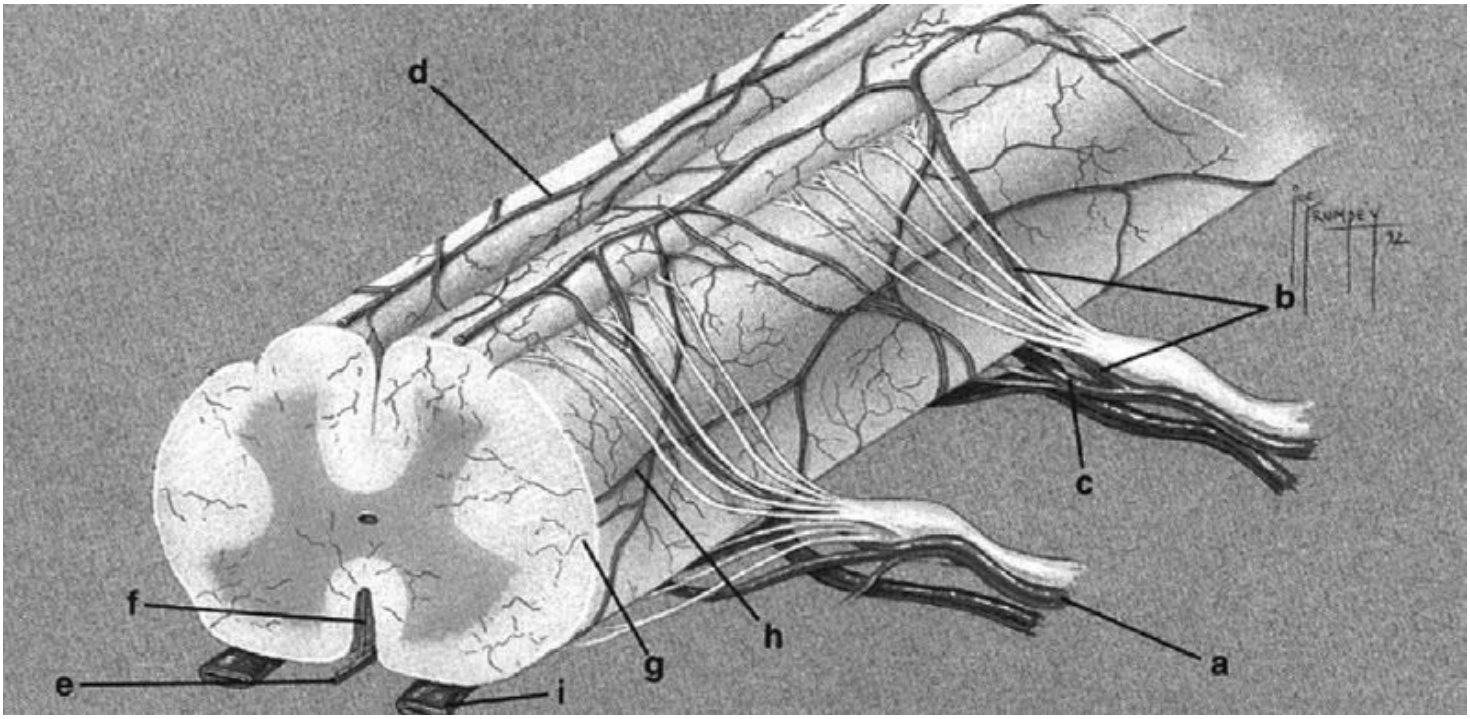

Figure 42-8. A Schematic of the lumbar spinal cord blood flow. Spinal arteries (a) traverse the intervertebral foramen with the spinal nerves. In most cases these arteries are bilateral and present at every level. The spinal artery branches into the dorsal radicular artery (b) and the ventral radicular artery (c). The dorsal spinal arteries (d) that arise from the dorsal radicular arteries are paired and take a more tortuous course than depicted in the drawing. The unpaired ventral spinal artery (e) arises from branches of the ventral radicular arteries and perforates the ventral fissure of the spinal cord, giving rise to the vertical arteries (f) that supply much of the spinal cord grey matter and ventral white matter. (g) Radial arteries arise from the superficial surface arteries to

supply much of the white matter and some peripheral grey matter. Venous blood from the capillaries goes to the surface veins (h) that drain into the venous sinuses (i) that are found on the floor of the spinal canal. (With permission from Wheeler SJ, Sharp NJH. Functional anatomy. In Small Animal Spinal Disorders: Diagnosis and Surgery. Wheeler SJ, Sharp NJH (eds). London: Mosby-Wolfe, 1994. Illustration by Joseph E. Trumpey, North Carolina State University.)

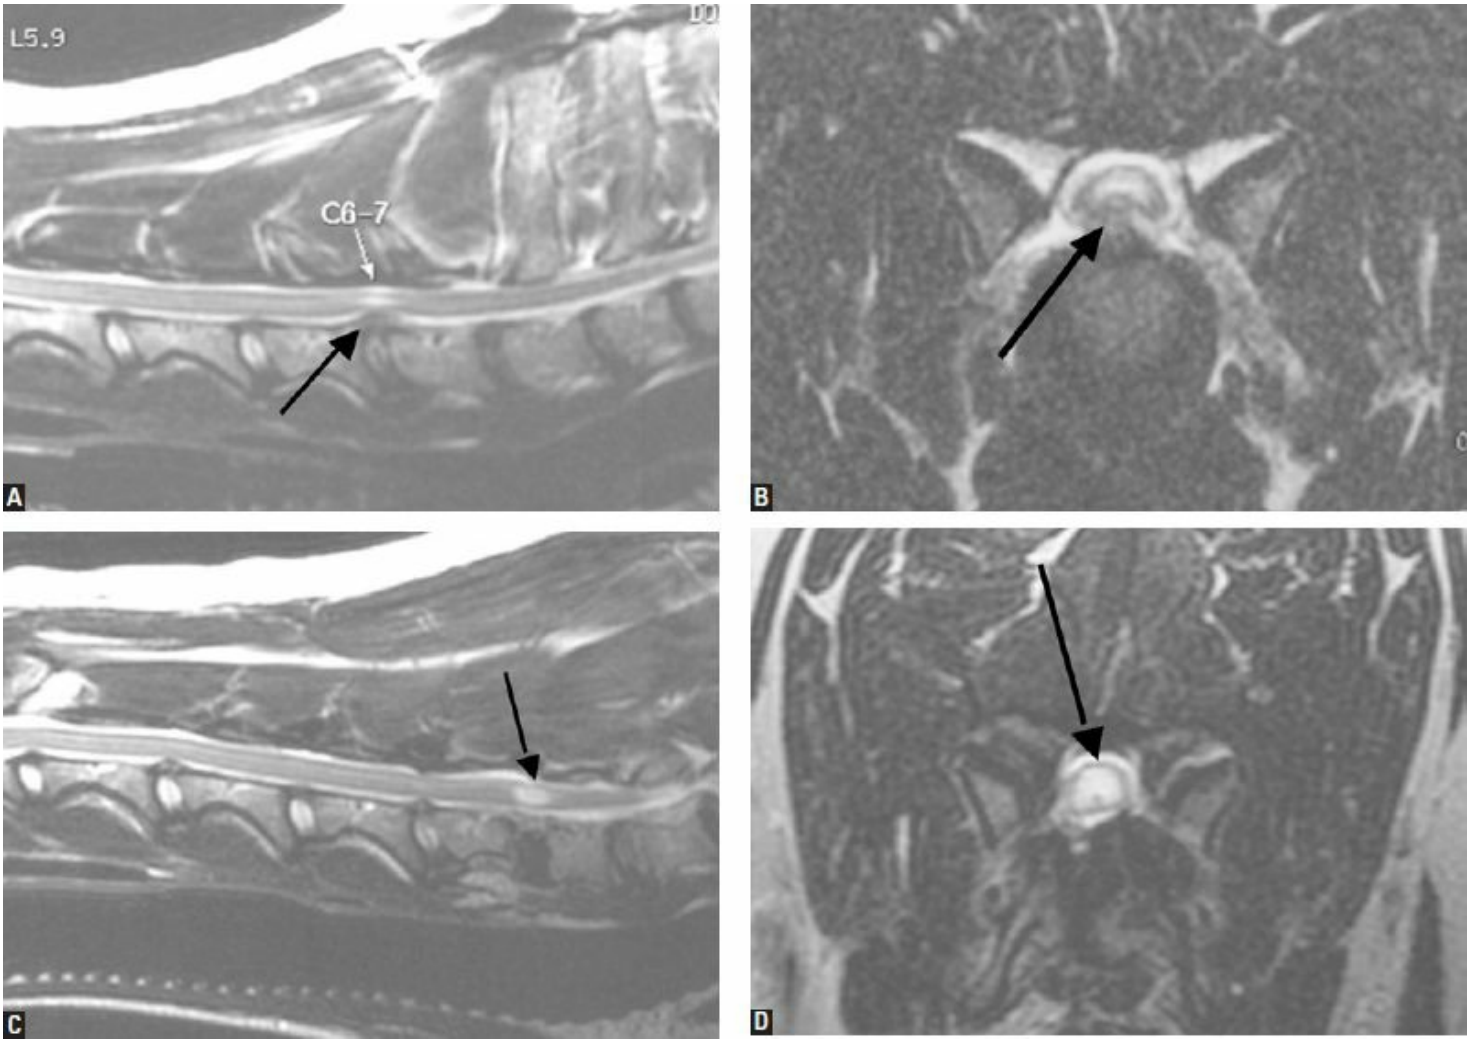

Figure 42-9. Syrinx progression in an 11-year-old, MC Dalmatian that was treated for an extradural compression from a C6-7 intervertebral disk extrusion. He initially presented with mild neurologic deficits and mild spinal discomfort. He recovered well from surgery but at 1 year postoperative, developed progressive tetraparesis and severe, unremitting pain. A. Preoperative T2-weighted, sagittal MRI. The C6-7 intervertebral disk (black arrow) has protruded and is compressing the spinal cord. There is signal hyperintensity in the spinal cord, which may have

indicated edema, malacia, or syrinx formation. B. T2-weighted, transverse MRI. Note the signal hyperintensity in the middle of the parenchyma. The disk extrusion is indicated by the arrow. C. T2-weighted, sagittal MRI taken 18 months postoperative. The spinal cord has been decompressed at C6-7 but the signal hyperintensity in the parenchyma has progressed. D. The severity of progression in the parenchyma is best observed on the T2-weighted, transverse MRI. This was believed to be a large syrinx at the time. Because the dog was in a great deal of pain and surgery was unlikely to result in resolution of pain, the dog was euthanized.

Cellular Apoptosis in Spinal Cord Compression

Apoptosis, or programmed cell death, is a natural process of self-destruction in certain cells that are genetically programmed to have a limited life span or are damaged. Apoptosis plays

an important role in development and homeostasis by controlling cellular density and deletion of abnormal cells.[33,50] Apoptosis is differentiated from necrosis by the lack of inflammation, karyorhhexis, and karyolysis. In apoptosis, the cells disintegrate into membrane-bound particles that are then eliminated by phagocytosis.[23,33,51,52] Apoptosis can be induced either by a stimulus, such as trauma, compression, irradiation, or toxic drugs or by the removal of a repressor agent. Necrosis can be induced by similar injuries to the spinal cord, and which cellular pathway is taken may depend on the severity of cellular damage.[23]

Apoptosis in the central nervous system has been shown to be controlled by several promoting and blocking genes.[33,53-55] Apoptosis of neuronal and glial cells has been reported with pathologic processes in the spinal cord, including injury, ischemia, and neurodegenerative conditions such as amyotrophic lateral sclerosis and spinal muscular atrophy.[33,40,56-66] Apoptosis in acute spinal injury has been proposed as a mechanism of degeneration of neuronal elements at the site of the injury and as a cause of chronic demyelination some distance away from the injury.[40,56,59-61,66] In the previously mentioned twy/twy mouse chronic compression model,[35]

apoptosis was identified in both the white and grey matter at the most severely compressed location. Oligodendrocytes displayed markers of apoptosis, suggesting that programmed loss of these cells may be a cause of demyelination and of poorly myelinated cells some distance from the lesion.

Derangements in Neuronal Conduction

Alterations in myelin (demyelination and remyelination) and axonal integrity and caliber occur soon after spinal cord injury and impact the conduction capabilities of axons at both the site of injury and for some

distance from the site of injury.[3,67-71] Changes in axonal conduction and spinal cord morphology following spinal cord injury have been studied in several different animal models[69,71-84] and in postmortem evaluation of human patients.[85,86] Morphologically, significant reduction in axonal numbers, axonal degeneration, and reactive astrocytosis has been reported. In addition, myelin sheaths are thinner, and remyelination of axons by invading Schwann cells (peripheral nervous system myelinating cells) as well as by oligodendrocytes (central nervous system myelinating cell) has been observed.[71,74,75,77-80,87-89] In a study by Wrathall et al.,[90] mRNA levels of important myelin structural proteins

(myelin basic protein and proteolipid protein) were decreased in the chronically injured spinal cord of rats, suggesting either aberrant metabolism of or a decrease in the number of functional oligodendrocytes. Changes in axonal diameter, observed as either reduced median diameter in a spinal tract or enlarged axonal swellings, are dependent on the white matter tract evaluated and possibly the species as well.[3,71,72,74,75,77-80,87,91-94] Swollen axons are likely terminal bulbs, which are the accumulation of organelles that occurs when axonal transport is disrupted.[71,85]

Electrophysiologic testing has revealed that the injured spinal cord axons

display decreased compound action potential (CAP) amplitude, reduced conduction velocity, prolonged refractory periods, and inability to respond to high-frequency stimulation. These axons were considerably less excitable and required a much higher stimulus intensity to elicit even half the maximal response of that seen in the spinal cords of the non-injured control group.[71,76] Reduction in the amplitude of the CAP is a function of many factors including axonal density, axonal diameter, and axonal input resistance and channel activation.[71] Reduction in the CAP in spinal cord injury can be explained by the altered spinal cord morphology (reduced axonal numbers, reduced axonal

diameter) as well as by the changes in conduction (increased stimulus intensity required to cause an action potential and prolonged refractory period) that would result in lower than normal number of axons conducting during testing.[71] Conduction velocity depends on the fastest conducting fibers, thus the large caliber, heavily myelinated fibers. Alterations in the axonal size, myelin loss, reduced myelin thickness, and disrupted axonal integrity observed in these studies would all result in reduced conduction velocity.[71] Myelin reduces capacitance and limits the exchange of ions to the nodes of Ranvier and, allows more rapid repolarization of the axonal membrane. The faster membrane

repolarization occurs, the faster action potentials can be propagated. Therefore, the alterations of myelin in injured spinal cord axons previously described would also explain the prolongation of the refractory period and inability to respond to high frequency stimulation.[71]

Derangements in Spinal Cord Blood Flow and Cerebrospinal Fluid Flow

Considerable evidence exists that interruption to the vascular supply of the spinal cord plays a role in the pathophysiology of spinal cord compression.[33,34,36,37,39,48,95-103] The

spinal cord is relatively protected from circulatory insufficiency owing to segmental blood flow and a rich vascular plexus. The arterial supply to the spinal cord arises from the usually paired segmental spinal arteries adjacent to the spinal nerve roots within the intervertebral foramen.[104] These arteries bifurcate into ventral and dorsal radicular arteries that supply rich anastamotic networks on the ventral and dorsal pial surfaces of the spinal cord.[104] The dorsal spinal arteries are paired and tortuous on the dorsal pial surface, whereas the ventral spinal artery is a distinct single artery located in the ventral spinal fissure.[104] These arteries are connected by several anastomotic connections. The ventral

spinal artery gives rise to the vertical arteries, which penetrate the ventral fissure of the spinal cord and supply most of the grey matter and some white matter of the spinal cord.[104] Radial arteries arise from the superficial surface arteries to supply much of the white matter and some peripheral grey matter (Figure 42-8).[104-111] The capillary network within the spinal cord and nerve roots are continuous and lined with vascular endothelial cells bound by tight cellular junctions that form the blood-spinal cord or blood-nerve barrier.[112] In one study, an intravenous injection of a protein tracer did not leak through the blood-nerve barrier; but when it was injected into the cerebrospinal fluid, it

was taken up by capillary pinocytotic vesicles and excreted in to the veins, suggesting that there is no blood/spinal fluid barrier.[113]

The venous drainage occurs via radial veins that drain into a network of surface veins that ultimately drain into the vertebral venous plexus located on the floor of the vertebral canal. The venous plexus also receives venous drainage from the vertebral bodies. The venous plexus drains via the intervertebral veins that are also associated with the spinal nerve root at the intervertebral foramen (Figure 42-8).[104,109-111]

In cervical spondylotic myelopathy in

people, the relative sparing of the anterior columns and subpial posterior columns is believed to be related to the architecture of the blood supply.[33,97] For example, the dorsal spinal arteries are paired and tortuous and are, thereby, resistant to tension when the cord elongates in flexion.[33,97] The anterior spinal artery travels in a longitudinal direction, and forces that compress the spinal cord tend not to disrupt the flow. In contrast, the transversely oriented perforating vessels that arise from the vertical artery in the ventral sulcus supply and the grey and medial white matter may be more susceptible to compression.[33,97]

Ligation of a single radicular artery in animal models was not shown to induce spinal cord dysfunction.[112,114-116] In one study in dogs, ligation of five pairs of thoracic spinal nerve roots and associated radicular arteries and veins resulted in only a 20% to 30% reduction in blood flow and oxygen tension and did not result in clinical loss of neurologic function.[112] The findings of this study suggest that collateral circulation from the pial vascular plexus and intact segmental arteries were adequate to maintain spinal cord metabolism. It was also hypothesized that the cerebrospinal fluid flow system plays a supplementary role in supplying nutrients to the spinal cord.[117]

Vascular derangements in spinal cord compression may actually be associated with impairment in venous blood flow rather than with impairment in arterial flow.[4,112,118-120] In one dog model, chronic compression as a result of chronic arachnoid scarring was induced by applying a circumferential silicone tube for three months. Histologic evaluation at termination revealed a patent superficial medullary artery, whereas the superficial medullary vein was compressed and thrombosed. In addition to these findings, syrinx formation was identified in the dorsal column.[121] A study using kaolin injection in the subarachnoid space in rabbits resulted in total circumferential

occlusion of the arachnoid space in 86% of the animals and partial occlusion in 14%. In the animals in which total occlusion occurred, intramedullary edema secondary to increased vascular permeability was also present. In addition, syringomyelia and/or hydromyelia were found histologically in this group.[122] The findings from both studies suggest that total circumferential ablation of the subarachnoid space results in loss of nutrient supply and lack of removal of cellular waste products via the cerebrospinal fluid as well as disturbing venous blood flow, resulting in spinal cord edema, necrosis, syrinx formation, and neurologic

dysfunction.[24,26,27,41,121,122] A comparison of the effects in the spinal cord from arterial obstruction (thoracic aorta) versus venous obstruction (caudal vena cava) was studied in a dog model. The blood-nerve (spinal cord) barrier remained intact when the thoracic aorta was obstructed. However, the blood-spinal cord barrier was disrupted as revealed by leakage of an Evans Blue albumin protein tracer and edema in the parenchyma of the spinal cord and nerve roots.[123] The results of these laboratory models may correlate with the findings of parenchymal edema and formation of syringomyelia and/or hydromyelia seen on T2-weighted magnetic resonance imaging and histologically

in chronic myelopathy (Figure 42-9).[3,24,26,27,41,124,125]

Role of Duration of Spinal Cord Compression

Much debate has occurred in human as well as veterinary medicine on the timing of decompression. Compression is considered to play a role in initiation and progression of secondary spinal cord injury.[126] Whereas several studies and clinical experience have shown the importance of decompression in mitigating secondary spinal cord injury, poor consensus exists on the appropriate timing for surgical intervention.[126-136] Several animal studies have been done on the

time-dependent pathologic effects of spinal cord compression. Many of these studies have established a relationship between increased duration of compression and neurologic recovery.[126,134-138] In a dog study by Carslon et al,[2] thoracic spinal cord compression was induced by a loading device precalibrated to indent the spinal cord at a constant of 0.17 mm/min and maintained for either 30 or 180 minutes. The loading pressure of the spinal cord was maintained at a constant once the somatosensory evoked potentials were decreased by 50% of baseline values. The peak loading spinal cord interface pressures were highest at the end of dynamic loading and actually decreased by

more than 50% once sustained compression was maintained for five minutes. After 30 minutes of sustained pressure, the interface pressures decreased to 25% of the peak pressure. Dogs were allowed to recover and were evaluated for 28 days by parameters that included spinal cord somatosensory evoked potentials (intraoperative and preterminally), functional neurologic assessment, magnetic resonance imaging, and histologic study. Amplitude of somatosensory evoked potentials (SSEP) decreased to about 90% of baseline values at the time of peak loading pressures. SSEP amplitudes improved to 63% of baseline within 90 minutes after decompression in the 30-

minute compression model. Recovery of SSEP did not occur in the 180-minute compression model. All dogs in the 30-minute compression model had functional recovery and were walking normally or with mild deficits within 21 days of the surgery. Only 50% of the dogs in the 180-minute compression model developed the ability to bear weight, but none were ever able to walk with, at best, minimal deficit. T2-weighted MRI imaging at 28 days postoperatively revealed increased signal intensity in the central area of the spinal cord; these lesions were significantly larger in volume in the 180-minute compression model. Both groups of dogs developed central cavitation in

the spinal cord (syrinx formation), but the 180-minute compression group had significantly larger lesions, correlating to the finding on magnetic resonance imaging. These findings agreed with an earlier model of compression by Delmarter et al,[137] using circumferential ligature and decompression at time zero, 1, 6, and 24 hours, and 6 weeks after compression.

One important difference between this and many other studies evaluating the effects of spinal cord compression was that, in most of the other studies, spinal cord compression was applied with an unremitting interface force utilizing weights, balloon, or dynamic

clips in which interface forces did not rapidly decline. It is hypothesized that the clinical causes of spinal cord compression were associated with interface pressures that were greatest at the time of impact with relaxation of interface pressures ensuing. This phenomenon is known as a visoelastic relaxation response to dynamic spinal cord loading.[1,139] There appears to be a range of maximum pressures that occur prior to declines in SSEP amplitudes; pressures above this limit may cause aberrations in regional blood flow.[1,140,141] This was determined in a previous dog study by Carlson et al.[1] The spinal cord was compressed until SSEP amplitudes were diminished to 50% of baseline. The

spinal cord was then either decompressed at 5 minutes or subjected to sustained compression for 3 hours without decompression. Regional spinal cord blood flow was evaluated using a fluorescent microsphere extraction technique. Spinal cord blood flow decreased by about 33% at the time of maximum interface pressures. Within 5 minutes of sustained compression, interface pressure dissipated by 51%; however, the SSEP amplitudes continued to decrease to 16% of baseline values. In the group that underwent decompression, regional blood flow and SSEP amplitudes recovered to baseline within 30 minutes. This initial hyperemic response was followed by a

mild decline in regional spinal cord blood flow. In the 3-hour sustained compression group, interface pressures relaxed to 13% of the maximum values within 90 minutes, but there was no recovery of SSEP values. Regional spinal cord blood flow remained significantly lower than baseline values at 30 minutes, but was similar to the decompression group at 180 minutes. Results of both of these studies imply that, in spite of visoelastic relaxation, sustained compression was associated with regional hypoperfusion and ischemia, poorer SSEP recovery, poorer functional outcome, and lesions visible on magnetic resonance imaging and histologic evaluation.[1,2]

Dynamic movement of the spine in addition to static spinal cord compression also plays a role in spinal cord injury.[142-144] This phenomenon is most commonly observed in the condition of cervical myelopathy associated with vertebral malformation/malarticulation. In a cat study by Wolfa et al,[144] a C3 corpectomy was performed and the vertebra was replaced with a hinged anterior compression device with and without C3 dorsal laminectomy to evaluate the impact of spinal movement on the pathologic processes of static compression. The results of this study revealed several findings. First, in the cats that did not undergo laminectomy, as the degree of

compromise of the spinal canal rose above 20%, the epidural pressure began to rise as well, suggesting that some compensatory mechanism exists in the spinal cord and dura until that point. At spinal canal compromise greater than 20%, the compensatory mechanisms are overwhelmed, and it is at this point that clinical dysfunction and electrophysiologic (somatosensory evoked potential) changes occur.[1,144] Epidural pressures were higher in cervical extension than in a neutral position, whereas pressures were not affected in flexion. This finding supports the hypothesis that the dorsal structures (ligamentum flavum and joint capsule) contribute to compression when the neck is in

extension.[144] Another important finding in this study was that the mean epidural pressure was significantly higher during passive neck movement than was the mean pressure in neutral positioning. It appears that during repeated flexion and extension visoelastic relaxation does not have time to occur, resulting in increases of both mean and maximum epidural pressures. In the laminectomized animals with spinal canal compromise of less than 75%, mean epidural pressure was remarkably lower in neutral positioning, in all degrees of spinal compromise associated with flexion and extension, and during spinal neck movement, supporting the benefit of dorsal decompression on

mitigating progressive spinal cord injury.

Spasticity and Spinal Cord Compression

Spasticity is an inevitable consequence of chronic spinal cord injury or disease[145,146] and contributes to clinical complications such as limb contractures and decubital ulcers.[145,146] Spasticity is defined as an abnormal increase in tone (hypertonicity), which is observed as a resistance to passive limb movement that is proportional to the velocity of the movement.[145,146] The velocity-dependent stiffness of the affected limbs is associated with increased stretch-evoked reflexes.[147-151]

However, decreased compliance of the surrounding soft tissue structures of the limb (muscles, tendons and ligaments) may also contribute to spacticity.[152,153]

Although spasticity has been studied in numerous experimental models, the exact mechanisms that induce spasticity are not completely understood. Spasticity is most often associated with chronic spinal cord disease in which spasticity develops in a time-dependent fashion with lasting neuroanatomic, neurophysiologic, and neuropharmocologic changes in the spinal cord.[145,146,154-156] Once established chronically it is unlikely to improve without pharmacologic and/or surgical intervention.[145,146,154-

156 It is proposed that the changes in the spinal cord are related to increased excitability of the monosynaptic reflexes that originate in the muscle-stretch receptor and synapse on the α-motoneuron that directly innervates the same muscle (e.g., the patellar reflex).[145,147,151,157-161] Studies in cats and rats (as well as observations from clinical cases) have demonstrated increased magnitude of the lumbar monosynaptic reflexes (hyper-reflexia) caudal to severe thoracic transverse myelopathy (i.e., hemisection of the spinal cord).[155,156,162-164] The changes in reflex responses have been shown to be associated with fundamental processes that control reflex excitability, namely reduction in rate

modulation of synaptic activity during repetitive stimulation.[145,146,156] In normal rat monosynaptic reflex neurons, the amplitude of recorded CAPs declines as the frequency of afferent stimulation is increased.[146] In animals with midthoracic spinal cord contusion injuries, the influence of rate-depression on the reflex CAP magnitude is attenuated and decreases in a time-dependent manner following injury.[146,165-167] Rate-depression of reflex magnitude is just one of three processes, including facilitation and potentiation, that compete to control the expression of the monosynaptic reflex.[146,168-172] The change in the magnitude of the reflex is not related to decreased action potential or to

excitability of the α-motoneuron directly, but rather is associated with long-acting presynaptic inhibition in the spinal cord afferent neurons mediated by γ-aminobutyric acid (GABA) and the $GABA_B$ receptor.[145,173-177] GABA is one of the most important inhibitory neurotransmitters in the central nervous system and the $GABA_B$ receptor modulates voltage-gated calcium channels.[145,173-177] Calcium entry into the terminal axon is necessary for neurotransmitter release; therefore, activation of voltage-gated calcium channels on the presynaptic afferent neuron in the reflex arc leads to decreased amplitude of the postsynaptic excitatory potentials without altering the conductive

properties of the α-motoneuron itself.[145,173]

In addition to altered $GABA_B$ receptor function, loss of spinal cord interneurons has also been implicated in alterations in rate depression.[145] Loss of interneurons at the site of injury does not explain changes in rate depression in segments caudal to the lesion. It is recognized that the interneurons that mediate presynaptic inhibition are influenced by descending input from other spinal cord regions, the brain stem, and the cerebral cortex.[178-186] It has been postulated that the time-dependent development of spasticity is associated with secondary pathology that occurs in the

descending pathways.[145,154-156] One descending pathway believed to be involved in modulation of sensory input and rate depression is the midbrain nucleus locus coeruleus which has been shown to send axons to all levels of the spinal cord.[146,187] Norepinephrine is the primary neurotransmitter in this pathway. The influence of this system on spinal cord spasticity has been studied by using an immunotoxin for dopamine β-hydroxylase, an enzyme in the cellular pathway that produces norepinerphine.[156,188-190] Results of these studies have suggested that loss of input from descending noradrenergic fibers that contribute to $GABA_B$-mediated rate depression in the

monosynaptic reflex contributes to the development of spasticity in the chronically injured spinal cord.[145,146] The development of spasticity and altered rate depression serving as an adaptive recovery process rather than a maladaptive process has been proposed an alternative theory.[191-194]

Pain and Spinal Cord Compression/Injury

Pain that originates from the spinal cord or nervous tissue (also referred to as central pain syndrome) is reported primarily in human patients following severe spinal cord injury.[170,195,196] Following initial injury, the patient usually manifests acute pain, which is

the result of injury to the spinal column and adjacent soft tissue. This nociceptive type of pain is most often described as dull, aching, and movement-related. It tends to resolve well with appropriate treatment such as rest, opioids, and anti-inflammatory medications, as well as time.[4] Pain associated with spinal cord injury tends to occur months to years after the initial injury and is difficult to manage and treat.[195-201] This type of pain should be considered a disease in and of itself, rather than a clinical manifestation of some other problem. The incidence is reported to be between 10% and 90% of all spinal cord injured patients and is often more of a concern to the patient than the

residual functional disabilities.[202-204] This is not a commonly recognized phenomenon in veterinary patients that are managed long-term following spinal cord injury, but is reported in rodent models of spinal cord injury.[195,200,205-209]

Pain associated with spinal cord injury may be spasticity related or may arise from the nervous system or both. The types of pain sensations reported are variable among patients.[145,196] In people, pain of spinal cord injury can be divided into transitional-zone pain and central dysesthesia syndrome. Transitional-zone pain occurs at the level of the spinal cord injury and is often associated with nerve root injury.

This type of pain seems to arise most commonly with injuries at the thoracic level. It is often present at a few contiguous spinal segments and is often asymmetrical. Transitional-zone pain often “mimics” pain sensations that have been felt in the past. The pain occurs early as allodynia or hyperalgesia and may improve spontaneously.[196] This type of pain is often addressed early in the course of the disease, therefore decreasing the chances of it’s becoming a long-standing illness. Severe, persistent cases are often treated with nerve blocks or dorsal root entry zone (DREZ) procedures.[196]

Central dysesthesia syndrome is

associated with a “burning” sensation below the level of the spinal cord injury.[196] In contrast to transitional-zone pain, it is often diffuse and symmetrical. The pathophysiology behind this syndrome has been studied but remains somewhat of an enigma. Multiple hypotheses have been generated, but it is not known if the same mechanisms underlie all central pain syndromes, because there appears to be no one lesion type or location that is associated with a higher relative risk. This type of pain has been attributed to abnormal associations of the spinothalamic and dorsal column pathways that transmit pain information.[145,210] The functional spinothalamic tracts, which normally

transmit protopathic sensations such as temperature and pain, are severely impaired. The dorsal column pathways, which normally transmit epicritic information about light touch, discrimination of touch, and vibratory sensations, are spared. In central pain, it is believed that the dorsal column pathways begin to transmit pain sensations normally transmitted by the spinothalamic pathways. Patients with central pain often have abnormal pain and temperature sensibilities. Of interest is that lesions within the spinothalamic pathways are not required to induce this phenomenon, but rather tend to influence the character of the abnormal sensations. It appears that the critical disinhibition

occurs in the ventroposterior, medial, and intralaminar thalamic nuclei that receive and integrate information from the spinothalamic pathways.[211-213] These thalamic regions in general tend to have an inhibitory influence on pain sensation. Abnormal functioning in this pathway results in abnormally high levels of pain and hypersensitivity. How these cells ultimately become disinhibited after spinal cord injury is not truly known;[145,214] however, on a cellular level excitatory amino acids, glutaminergic N-methyl-D-aspartate (NMDA), and serotonergic receptors have been implicated.[17,214-216] The excitatoxic amino acids may influence cytokine production, breakdown of

structural proteins, second messengers, and transcriptional proteins in ways that result in abnormal signaling in the pain processing pathways.[145,170,200,217,218] In experimental models of spinal cord injury, abnormal electrical activity has been identified in segments surrounding the injury site on electrophysiologic testing.[206,219,220] The abnormal activities reported include increased stimulus response, increased spontaneous background activity, and increased after-discharge responses. In a rat spinal cord clip-compression study by Bruce et al,[214] the influence of serotonin in development of central pain of spinal cord injury was investigated. Serotonin

immunoreactivity in the dorsal horn was found to be decreased caudal to the thoracic injury site (T9-11) and increased three-fold in regions rostral to it. The decrease caudal to the injury was believed to be consistent with loss of descending serotonergic antinociceptive pathways. The presence of increased serotonin activity in dorsal horns rostral to the injury was an unexpected finding. Because serotonin is also known to possess pronociceptive properties, it was postulated that this observation may be involved in the disruption of inhibition of pain pathways.

Central pain may remain stable, escalate in severity, or decrease over

time and it can be very difficult to treat.[145,210,221,222] Autonomic dysnergia, such as distended bladder or constipation, can result in increased pain transmission, raising baseline pain levels in these patients.[223]

Another complication of spinal cord injury is the development of syrinx within the parenchyma of the spinal cord (syringomyelia).[196,198] This injury most commonly occurs years after the injury and is associated with ascension of the sensory and motor level dysfunction owing to the expansion as well as to the development of new pain sensations. Typically, this pain is located in the region of the syrinx but may cause a burning-type pain above

the level of the injury or syrinx. The natural course of syringomyelia is continued escalation of the pain that is often not responsive to medications or surgical intervention with syringopleural shunting. Post-injury or post-compression syrinx formation appears to be a more common source of pain in dogs than is the enigmatic central pain syndrome (Figure 42-9).

Chapter 43

Peripheral Neuropathy

Joan R. Coates
G. Diane Shelton

Neuropathies comprise a group of disorders that affect the neuron of the motor unit. It is important for the veterinary surgeon to understand the pathophysiology of peripheral neuropathy in order to recognize clinical signs and make appropriate decisions for surgical intervention. Clinical presentation of orthopedic, spinal and muscle disorders often will

mimic peripheral neuropathy and pose a diagnostic dilemma for the clinician. Conversely, polyneuropathy can cause paraparesis or tetraparesis that must be differentiated from orthopedic or spinal cord disease or other components of the motor unit (neuromuscular junction or muscle). In this chapter we review basic anatomy and physiology of the peripheral nervous system and associated clinical features of peripheral neuropathy. Other excellent resources to consider for more in-depth knowledge relevant to specific neuromuscular diseases and their categorical descriptions are provided by Shelton[1,2] and Braund.[3]

Anatomy and Physiology

The peripheral nervous system (PNS) consists of those structures (including cranial nerves and spinal nerves) containing motor, sensory, and autonomic nerve fibers or axons that connect the central nervous system (CNS) with somatic and visceral end organs. Anatomic structures that comprise the peripheral nervous system are derived from the neural crest from which several cranial nerves also receive contributions from ectodermal placodes.[4] Nerve fibers that terminate either in striated muscles or viscera are termed somatic or visceral, respectively. There are 12 pairs of cranial nerves with afferent and

efferent fibers that traverse to and from the brainstem.[5] The spinal nerves usually number in 36 pairs for the dog and cat.[6] Of the spinal nerves, 8 are in the cervical (C1-8) region, 13 in the thoracic (T1-13) region, 7 in the lumbar (L1-L7) region, 3 in the sacral (S1-3) region, and 5 or more in the caudal region. Each pair of spinal nerves communicates with the spinal cord segment of the same number. The somatic peripheral nervous system (PNS) consists of ventral and dorsal rootlets, spinal nerve roots, spinal nerves, dorsal and ventral rami, plexuses, and individual peripheral nerves and their branches.[6] The C6-T2 spinal cord segments comprise the cervical intumescence from where the

nerve roots of the brachial plexus originate.[7,8] The L4-S3 spinal cord segments comprise the lumbosacral intumescence which contributes to the cauda equina and the lumbosacral plexus.[9,10] Nerve roots are minimally myelinated and traverse within the subarachnoid space containing cerebrospinal fluid (CSF). Thus, nerve roots are more susceptible to traction injury, and exposure to toxic and infectious agents. The nerve roots exit as spinal nerves through intervertebral foramina as myelinated fibers. Similarly, cranial nerves exit from foramina of the skull.

The visceral nervous system includes components of the central and

peripheral nervous system that are involved in the homeostatic control of body functions.[11] The autonomic nervous system is subdivided into parasympathetic and sympathetic and includes only the general visceral efferent or motor components.[12] The neural pathway consists of two neurons; the first neuron (preganglionic neuron) is located in the CNS and terminates in ganglia in the PNS. The second neuron (postganglionic neuron) is located outside the CNS in the ganglion and terminates on an effector organ. The parasympathetic division is known as the craniosacral division of the autonomic nervous system because preganglionic neurons are located in

the brainstem and the sacral spinal cord. Preganglionic neurons are located in the parasympathetic nuclei of cranial nerves III, VII, IX, X, and XI and in the intermedial lateral gray matter of the sacral spinal cord. The sympathetic division is known as the thoracolumbar division of the autonomic nervous system. The preganglion neurons are located in the intermedial lateral gray matter of the thoracic and first four to five lumbar spinal cord segments. Preganglionic neurotransmission in both systems is cholinergic, by which acetylcholine binds to the nicotinic receptors on the postganglionic neuron. In the parasympathetic system, postganglionic neurotransmission

occurs with the binding of acetylcholine to a muscarinic receptor of the effector organ; in the sympathetic system, the postganglionic neurons synapse on noradrenergic receptors via the neurotransmitter norepinephrine.[11]

An individual peripheral nerve contains a variable mix of nerve fibers, myelinated and unmyelinated.[6] Most peripheral nerves contain both motor and sensory axons. Motor axons of spinal nerves and cranial nerves originate from neurons that lie within the gray matter of the spinal cord (ventral horn) and brainstem, respectively. Cell bodies for sensory axons are contained within the dorsal

root ganglia or ganglia of cranial nerves. One nerve fiber consists of an axon surrounded by a myelin sheath which is composed of neurolemma (sheath of Schwann). Afferent fibers (sensory) can be myelinated or unmyelinated. Efferent fibers (motor) to striated muscle are always myelinated. Unmyelinated efferent fibers are postganglionic sympathetic fibers supplying smooth muscles.

The peripheral nerve in cross-section is composed of many nerve fibers arranged into fascicles (Figure 43-1). The nerves have three separate connective tissue sheaths: endoneurium, peineurium, and epineurium.[13] The loosely arranged

endoneurium immediately surrounds myelinated and unmyelinated fibers. Bundles of fibers are gathered into fascicles surrounded by a perineurium. The epineurial epineurium encases the nerve trunk, containing fascicles that are separated by mesoneurium (epifascicular epineurium). The epineurium contains connective tissue, small lymphatics, and blood vessels that supply the nerve. The number and size of fascicles within a nerve can vary from one nerve to another but also within the same nerve along its course.[14]

Neuron

A neuron consists of three parts: cell

body (perikaryon or soma), dendrite, and axon. The cell body contains the nucleus. Dendrites are extensions of the cell body and function to transmit excitatory or inhibitory impulses toward the cell body. Axons are usually single, straight structures that project further away from the cell body than dendrites and branch near their synaptic terminus. Axons often acquire a myelin sheath. Communication of an electrical signal (action potential) between an axon terminal and the dendrite or somatic membrane of another neuron is called electrical transmission. The electrical impulse occupying the axonal terminal (presynapse) leads to release of a transmitter (chemical transmission)

which interacts with receptor molecules in the postsynaptic membrane of the receiving cell.[15]

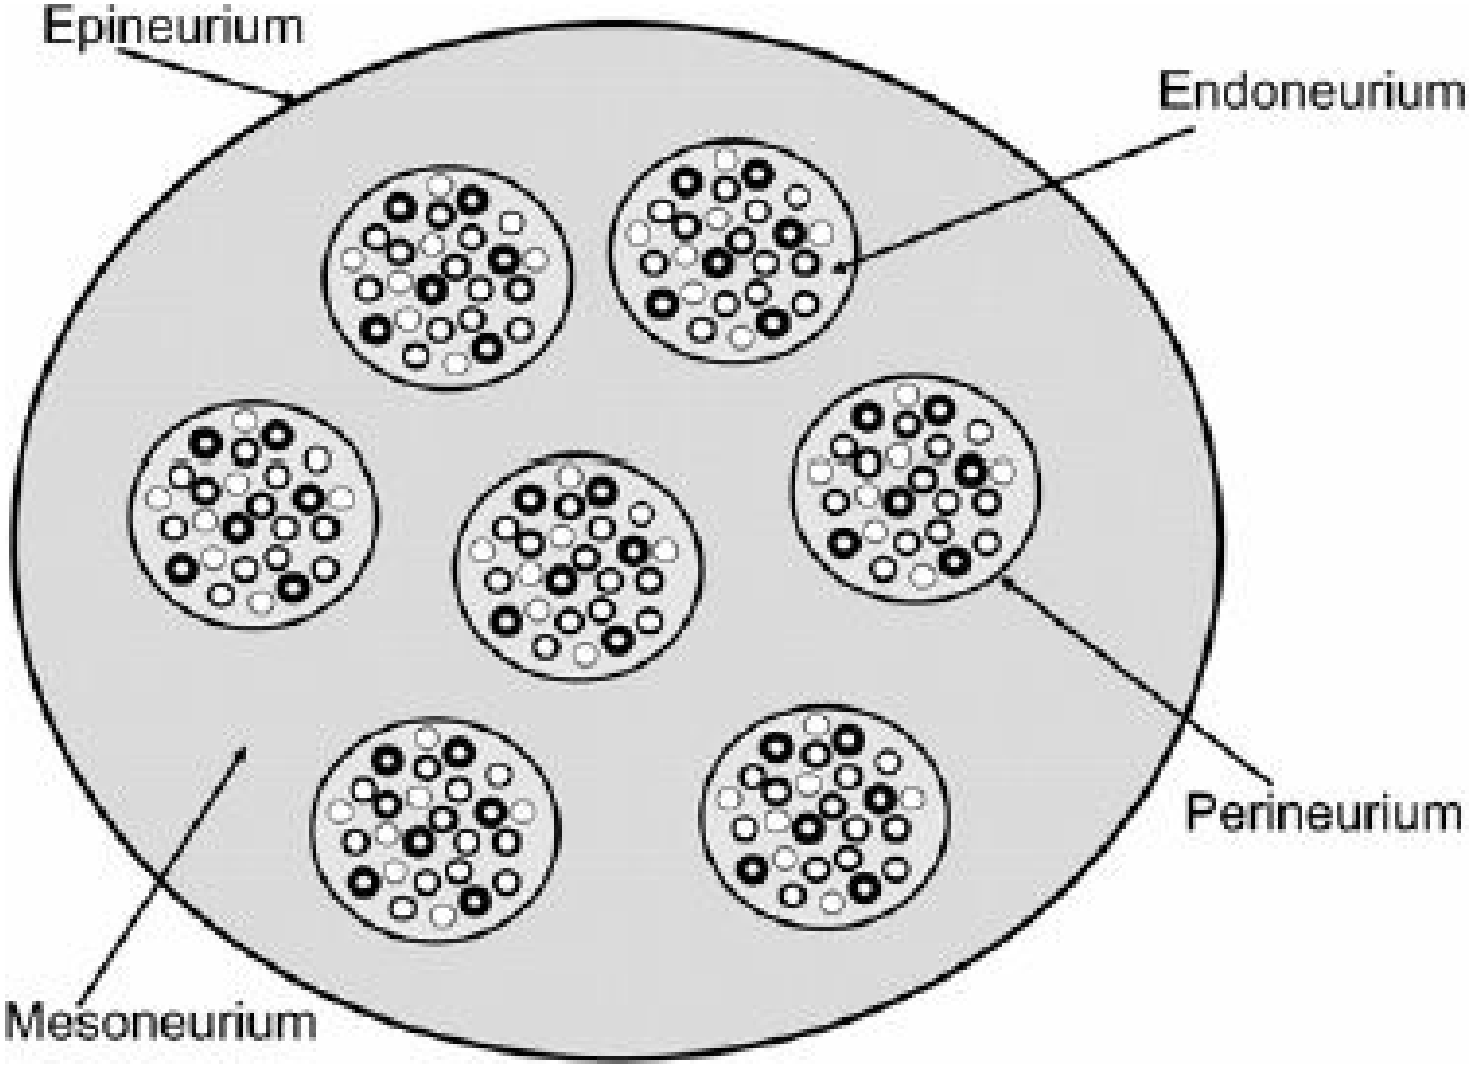

Figure 43-1. Peripheral nerve in cross section of 7 fascicles surrounded by perineurium that is ensheathed by epineurium and mesonerium. Nerve fibers of varying myelin thicknesses are separated by endoneurium.

Axon

The origin of the axon from the cell body is the axon hillock and initial segment, which are unmyelinated.[13] The axon hillock and initial segment are considered the trigger zone, which contains a high concentration of voltage-gated sodium channels.[15] This area is considered to have a low threshold and be the site for generation of an action potential. Conduction of an action potential is considered polarized relative to the cell body; it propagates in an orthodromic direction toward the terminus. An action potential that is artificially induced on the axon also can conduct toward the cell body (antidromic propagation).

The axoplasm contains neurofilaments, mitochondria, and agranular endoplasmic reticulum.[13] Axoplasmic flow is bidirectional along the axon. Longitudinally oriented neurofilaments and microtubules interconnected by cross-bridges transport substances away from the cell body to the axon terminal (anterograde transport) and from the distal axon to the cell body (retrograde transport). Anterograde and retrograde transport play an important pathophysiologic role in the transmission of neurotoxins (i.e., tetanus toxin) and neurotropic pathogens (i.e., rabies and pseudorabies viruses).[16] Flow rates differ as slow (1 mm/day) and fast (10 mm to 2 m/day).[13] Slow flow consists

of soluble proteins and of particulate matter for growth and maintenance of the neuron. Fast flow consists of organelles, mitochondria, and materials for enzymatic reactions to facilitate synaptic transmission. Microtubules are organelles that facilitate fast axonal flow.

Myelin

Myelin is formed by Schwann cells in the PNS and oligodendrocytes in the CNS. Processes from these cells wrap around an axon in a unique multilamellar structure analogized as a "Swiss roll" to fuse with the inner axonal membrane. Myelin provides a role in axonal support and

maintenance.[17] The correct thickness of the myelin sheath is regulated by a transmembrane protein expressed by the axon.[18] The myelin sheath is not continuous over the length of the axon but is interrupted at regular intervals (1 μm) at the ***nodes of Ranvier***, so that the axon membrane is in direct contact with the extracellular fluid.[13] The cylindrical sheath of myelin between the nodes is called the ***internode***. Internodes can be as long as one mm. The node of Ranvier is considered an electrotonic sink consisting of a high density of sodium channels for depolarization to occur.[19] Myelin acts as an insulator by having high resistance and low capacitance to the internode region. This allows an

electrical impulse to propagate rapidly down the axon, jumping from node to node, a process called ***saltatory conduction*** (Figure 43-2).

The conduction velocity in myelinated fibers is much faster than in nonmyelinated axons. Conduction velocity for motor and sensory nerve fibers varies from 50 to 120 m/sec. The larger the diameter of the axon, the thicker is the myelin sheath. The longer the internodal distance, the faster is the conduction of the action potential. Small myelinated fibers (fast, sharp pain) conduct at rates of 12 to 30 m/sec; unmyelinated C fibers (slow, dull pain) conduct at much slower rates of 0.5 to 2 m/sec.

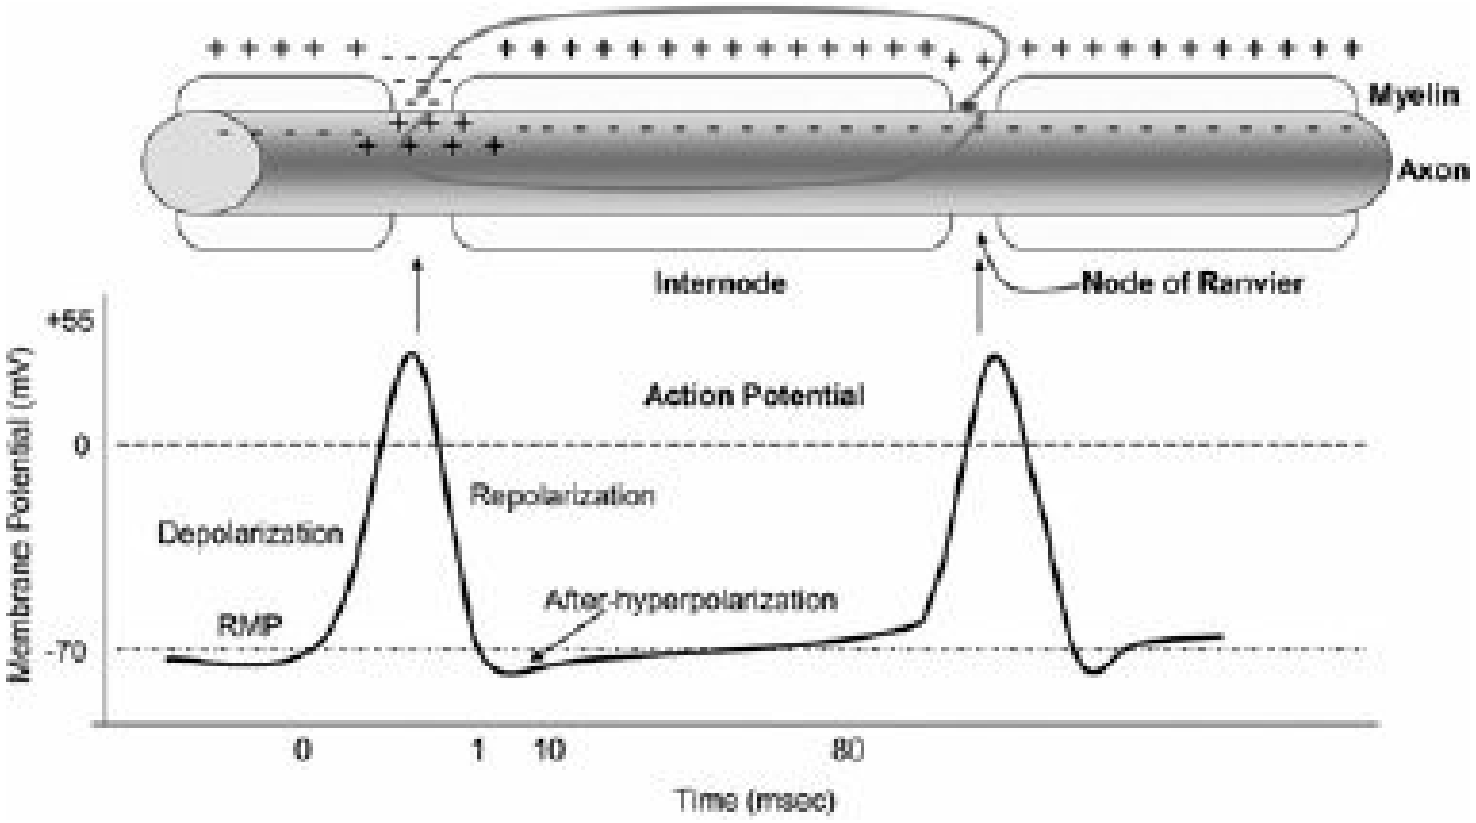

Figure 43-2. Saltatory conduction of an action potential along a myelinated axon. Transmembrane action potential currents (inward sodium movement and outward potassium movement) occur only at the nodes of Ranvier that contain a high density of voltage-gated sodium changes. The internodal region of the axon facilitates very rapid movement of currents down the axon. (Modified with permission from Blankenship JE: Neurophysiology. St. Louis, Mosby Inc. – Elsevier Science, 2003)19

Action Potential

The basis of electrical transmission within the nervous system is the action potential.[19] The action potential, "nerve impulse," is a brief electrical signal within nerve and muscle cells (Figure 43-2). The change in membrane potential represents a transient change from the resting state, in which the internal potential of the neuron moves from an equilibrium resting state (resting membrane potential -70 mV) to a positive value and then back to the resting state. At the resting potential (-60 mV), the electrical and concentration gradients act on sodium and potassium ions across the membrane. The gradients at rest are nearly equal for potassium, but for sodium both the concentration and

electrical gradients are directed inward. The action potential is caused by the membrane's becoming suddenly permeable to sodium ions (depolarization) until the membrane potential reaches the sodium equilibrium potential (+55 mV). As the electrical gradient of sodium and potassium become equal, the electrical gradient for potassium is directed outward. If the neuron is made highly permeable to potassium and impermeable to sodium, the potassium ions readily move out of the cell in response to the outwardly directed concentration and electrical gradients. The efflux of potassium ions causes the neuron to become increasingly negative (repolarization) until the

membrane reaches a potassium equilibrium potential (-75 mV; hyperpolarization).

Motor Unit

A motor unit is composed of a neuron cell body, its axon, the neuromuscular junction, and associated muscle fibers. A group of myofibers innervated by one neuron is considered a motor unit. An abnormality in any portion of the motor unit can result in clinical signs of neuromuscular disease – lower motor neuron. The functional component of the motor unit involves the ***reflex arc***. The arc consists of a sense organ, an afferent neuron (cell body in dorsal root ganglion), one or

more synapses centrally, an efferent neuron, and an effector organ. An all-or-none action potential is generated in the afferent nerve and modulated centrally to be generated again as an all-or-none potential in the efferent nerve. A reflex with a single central synapse is a monosynaptic reflex (i.e., patellar reflex); a reflex with more than one central synapse (interneurons) is a polysynaptic reflex (i.e., flexor withdrawal reflex).

The LMN system consists of three functional divisions: general somatic efferent, special visceral efferent, and general visceral efferent systems.[20] The general somatic efferent system consists of spinal motor neurons and

cranial nerves III, IV, VI, and XII, which innervate voluntary striated muscles. The special visceral efferent system consists of cranial nerves V, VII, IX, X, and XI, which innervate voluntary striated muscle associated with respiratory and gastrointestinal functions. The general visceral efferent system consists of the parasympathetic and sympathetic nervous systems that innervate involuntary smooth muscle.

Pathophysiology of Neuropathy

Peripheral neuropathies consist of disorders that affect the axon -- axonopathies; the Schwann cells or myelin directly -- myelinopathies

(demyelinating diseases); or both the axons and Schwann cells -- mixed axonal and demyelinating diseases. Underlying pathologic processes of the peripheral nerve include Wallerian degeneration, axonal degeneration, and segmental and diffuse myelin degeneration (Figure 43-3).[21] In most cases, these pathologic reactions are not disease-specific but occur in various combinations with peripheral nerve disease. Axonal degeneration and demyelination specify the underlying pathologic process and location to the peripheral nerve, but rarely occur as separate disease entities. Central neuropathies that affect the neuronal cell bodies are termed motor neuron disease.

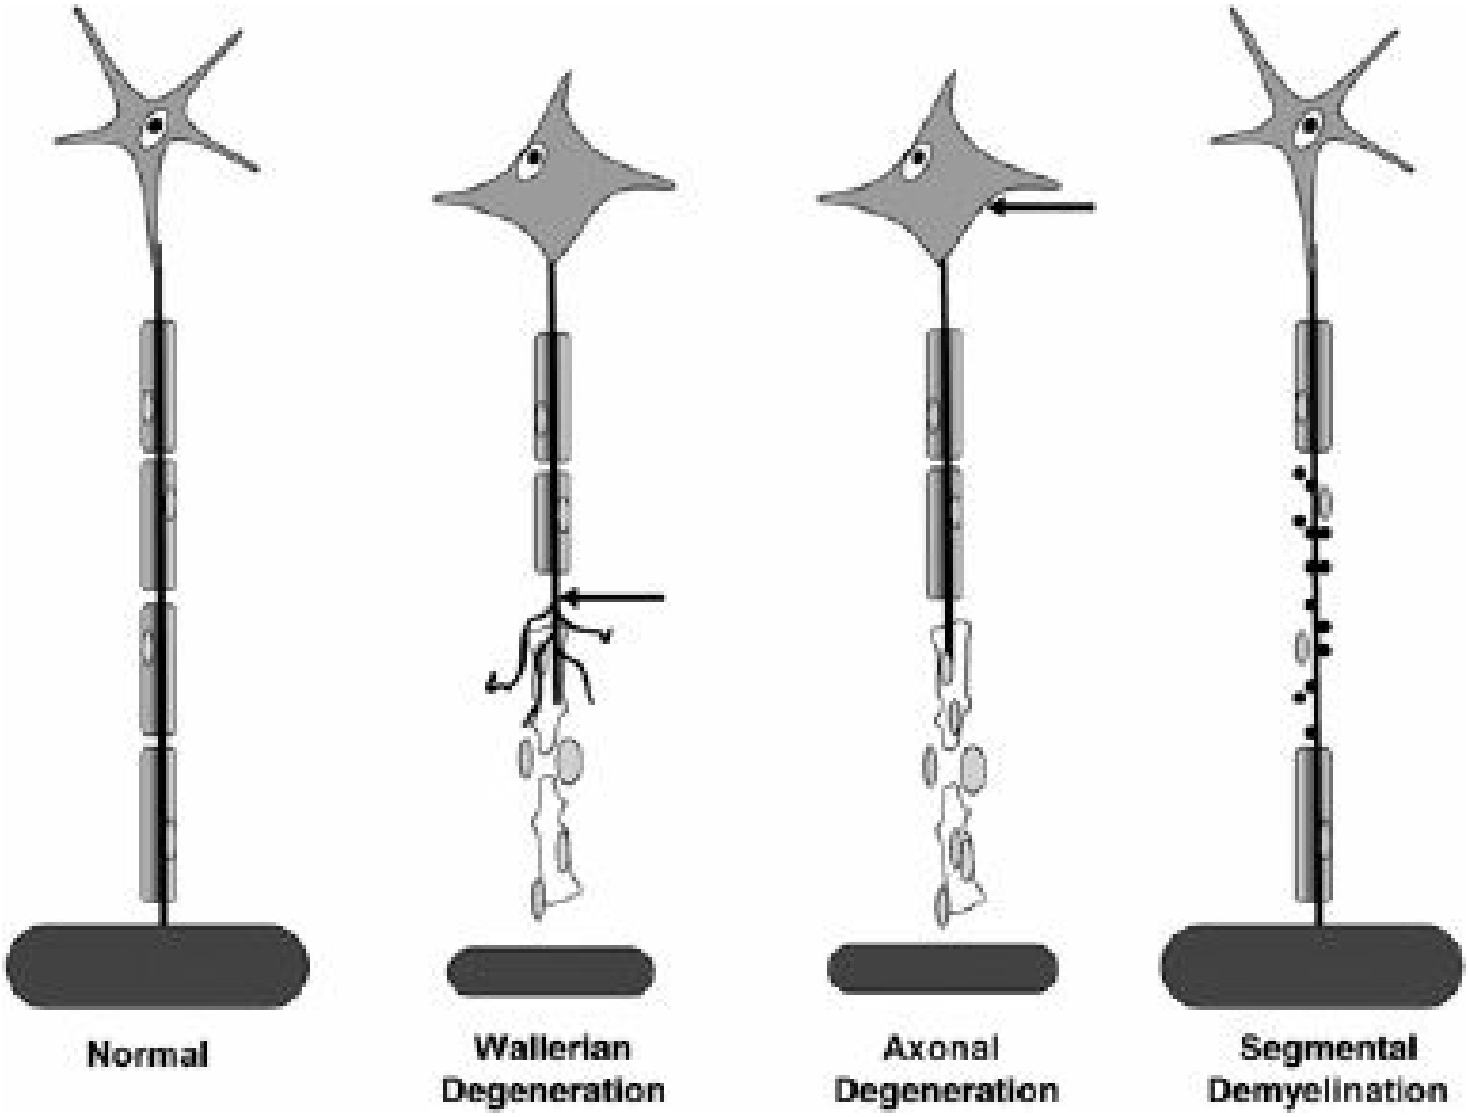

Figure 43-3. Basic pathologic processes affecting peripheral nerves. Wallerian degeneration shows degeneration of the axon and myelin distal to the site of axonal damage (arrow). In axonal degeneration, primary neuronal disease causes distal degeneration of the axon and myelin (arrow). Note the eccentric displacement of the nucleus and swelling of the neuron cell body with Wallerian degeneration and axonal degeneration. Both Wallerian and axonal degeneration cause neurogenic muscle atrophy. With

segmental demyelination the axon is spared, thus no muscle atrophy occurs.

Wallerian Degeneration

Original classifications of peripheral nerve disorders were based on anatomic and clinical observations following focal nerve damage. Waller demonstrated predictable degeneration of nerve fibers in the distal stump of a transected nerve, describing alterations of the axolemma with subsequent dissolution of axons and myelin.[22] Seddon followed with a clinical classification of nerve injury, using morphologic and electrophysiologic studies.[23] ***Neurapraxia*** is a transient interruption of the nerve function and conduction without associated axonal

degeneration. Pathology involves myelin injury or an ischemic process. Recovery can occur within hours to weeks. ***Axonotmesis*** describes focal destruction of axons and myelin sheaths from the neuronal cell body. The endoneurium and Schwann cell sheath remain intact. Axonal and myelin degeneration (***Wallerian degeneration***) occurs distal to the lesion site. Wallerian degeneration consists of degeneration of both the axon cylinder and myelin sheath distal to the site of axonal damage. Severance of the axon prevents transport of organelles to the distal axon for replenishing membrane reconstruction and neurotransmitter processes. The motor neuron undergoes

chromatolysis with rounding of the cell body, eccentrically displaced nucleus, and dispersion of chromatin. Recovery is prolonged (1 mm per day), occurring first in nerve segments closest to the site of damage. Completeness and length of recovery depend on the degree of nerve disruption and the distance to the end organ. ***Neurotmesis*** describes complete transection of the nerve from its cell body. Regenerating axons often take an aberrant course with fibroblastic formation to form a neuroma. Both axonotmesis and neurotmesis are followed by Wallerian degeneration.

Axonal Degeneration

Axonal degeneration results from disease within the neuronal cell body or of the axon itself. Often the degeneration of the axon and its myelin sheath begins distally and extends proximally. The neuron undergoes chromatolysis. This process has been termed as “dying-back” neuropathy, distal axonopathy, or distal sensorimotor neuropathy. These processes preferentially affect long, large-caliber, myelinated nerve fibers. Clinical signs usually are recognized first in the distal limbs as a consequence of the distance of the nerve from the cell body. Both axonal degeneration and Wallerian degeneration cause neurogenic muscle atrophy. The time of onset usually is

considered chronic, with a progressive time-course. These disorders often are inherited, idiopathic, or toxic in origin.

Demyelination

Demyelination is caused by disease of the Schwann cell or myelin sheath. Demyelination is loss of the myelin sheath along the length of the internode (segmental demyelination) or near the paranodal area (paranodal demyelination). Disease can occur continuously (diffuse demyelination) or randomly along the nerve path. Diffuse myelinopathies occur with inherited, metabolic, and toxic disorders. In immune-mediated neuropathies, nerves are damaged by

cellular or humoral mechanisms on various components of myelin. Repeated processes of demyelination and remyelination also occur with some disease processes, i.e., inflammatory demyelinating polyneuropathies. Remyelination restores function. Disruption of the myelin sheath causes the electrical current to dissipate through the internode as a result of increased capacitance and decreased resistance. This results in a longer time to charge the next internode, thus prolonging the conduction time. Conduction failure occurs with severe demyelination.

Diagnostic Approach

Establishing an accurate diagnosis is based on following a logical sequence of diagnostic tests. History provides the signalment, presenting clinical signs, background, and time of onset and temporal progression of clinical signs. Specifically, disorders of the motor unit with acute onset include polyradiculoneuritis, tick paralysis, botulism, and fulminant myasthenia gravis. Myopathic and neuromuscular junction (i.e., myasthenia gravis) diseases often are episodic in onset. Signalment is especially important in young animals with a predilection for breed-specific neuropathies. A physical examination is performed to localize the clinical signs and detect other systemic abnormalities. The neurologic

examination will establish the existence of peripheral nervous system disease and further assist with determining disease symmetry and distribution (focal, multifocal, or diffuse). The neurologic examination should include sensory testing. Proper neuroanatomic localization is crucial to the direction of the diagnostic approach. A complete blood count, serum chemistry (including creatine kinase concentration and electrolytes), and a urinalysis serve to establish a baseline health profile and further identify other systemic abnormalities. Thoracic radiography may show evidence of concurrent megaesophagus and aspiration pneumonia, which can be a sequela of peripheral neuropathy.

Additionally, thoracic radiography and abdominal ultrasonography are used to screen for underlying metastatic disease and evidence of paraneoplastic neuropathy. CSF analysis will show abnormalities in cellularity and protein concentration with some peripheral neuropathies. Serology is useful to evaluate for infectious and immune-mediated diseases. Endocrine function testing, especially thyroid hormone, will further delineate any underlying cause of the neuropathy.

Diagnostic Electrophysiology

Electrophysiology is useful for determining disease localization within the motor unit and the extent of the

disease process.[24] Temporal development of neuropathies has important implications for diagnostic yield of the electrophysiologic examination. Neuropathic disease must be present for 3 to 7 days before evidence can be detected by electrodiagnostic examination.[25] Diagnostic electrophysiology is thoroughly reviewed in Chapter: Electrodiagnosis

Briefly, ***electromyography*** (EMG) will assess electrical activity within a discrete region of an accessible muscle. The activity is recorded by inserting a needle electrode into the muscle. The pattern of electrical activity in muscle has been characterized and

abnormalities have been correlated with some disorders at different levels of the motor unit. Relaxed muscle normally shows no spontaneous electrical activity except in the end-plate region, but various types of abnormal activity occur spontaneously in diseased muscle. Typically, abnormalities caused by denervation occur on EMG with axonal disease but not with pure demyelinating disorders.

Nerve conduction studies provide a technique of confirming the presence and extent of peripheral nerve damage. Studies of several types of acquired and hereditary axonal and demyelinating neuropathies have shown different patterns of

distribution, which further assist with differential diagnosis. ***Motor nerve conduction studies*** are performed by recording the electrical response of a muscle to stimulation of its motor nerve at two or more points along its course. This permits the conduction velocity, amplitude, and duration of action potentials to be determined in the fastest-conducting motor fibers between the points of stimulation. Results may give an indication of altered function of axons and myelin. ***Sensory nerve conduction studies*** are performed by determining the conduction velocity and amplitude of action potentials in sensory fibers when these fibers are stimulated and responses recorded at another point

along the course of the nerve. Conduction studies do not provide information regarding smaller fiber function; thus autonomic nerve abnormalities go undetected. ***F wave-response studies*** evaluate the latter motor response; F waves may be abnormal when lesions of the proximal portions (nerve roots) of the peripheral nervous system are present.

Muscle and Nerve Biopsy

Histopathologic examination of a muscle biopsy specimen is a critical part of the evaluation of a motor unit disease and can indicate whether the underlying weakness is neurogenic or myopathic in origin.[26] With

neuropathic disease, myofibers can show angular atrophy, small and large grouped atrophy, fiber-type grouping if denervation has been followed by reinnervation, replacement of muscle fibers by fatty tissue, and pyknotic nuclear clumps in end-stage disease (Figure 43-4). In myopathic disease, pathologic changes can include variability in fiber size, necrosis and phagocytosis, cellular infiltrations, connective tissue expansion, cytoarchitectural abnormalities, and inclusions and vacuoles (Figure 43-5).

A properly processed peripheral nerve biopsy often provides insight into the pathologic process of peripheral nerve disease. Techniques for collection of

nerve biopsies have been described in detail, but often consist of a fascicular biopsy.[26,27] Evaluation of resin-embedded semi-thin sections provides the most information regarding axonal degeneration and regeneration, demyelination and remyelination, and abnormalities of supporting structures (Figure 43-6). In selected cases, electron microscopy, teased nerve fibers, and nerve fiber morphometry can provide additional information. Processing of peripheral nerve biopsies for only paraffin or frozen sectioning provides only limited information.

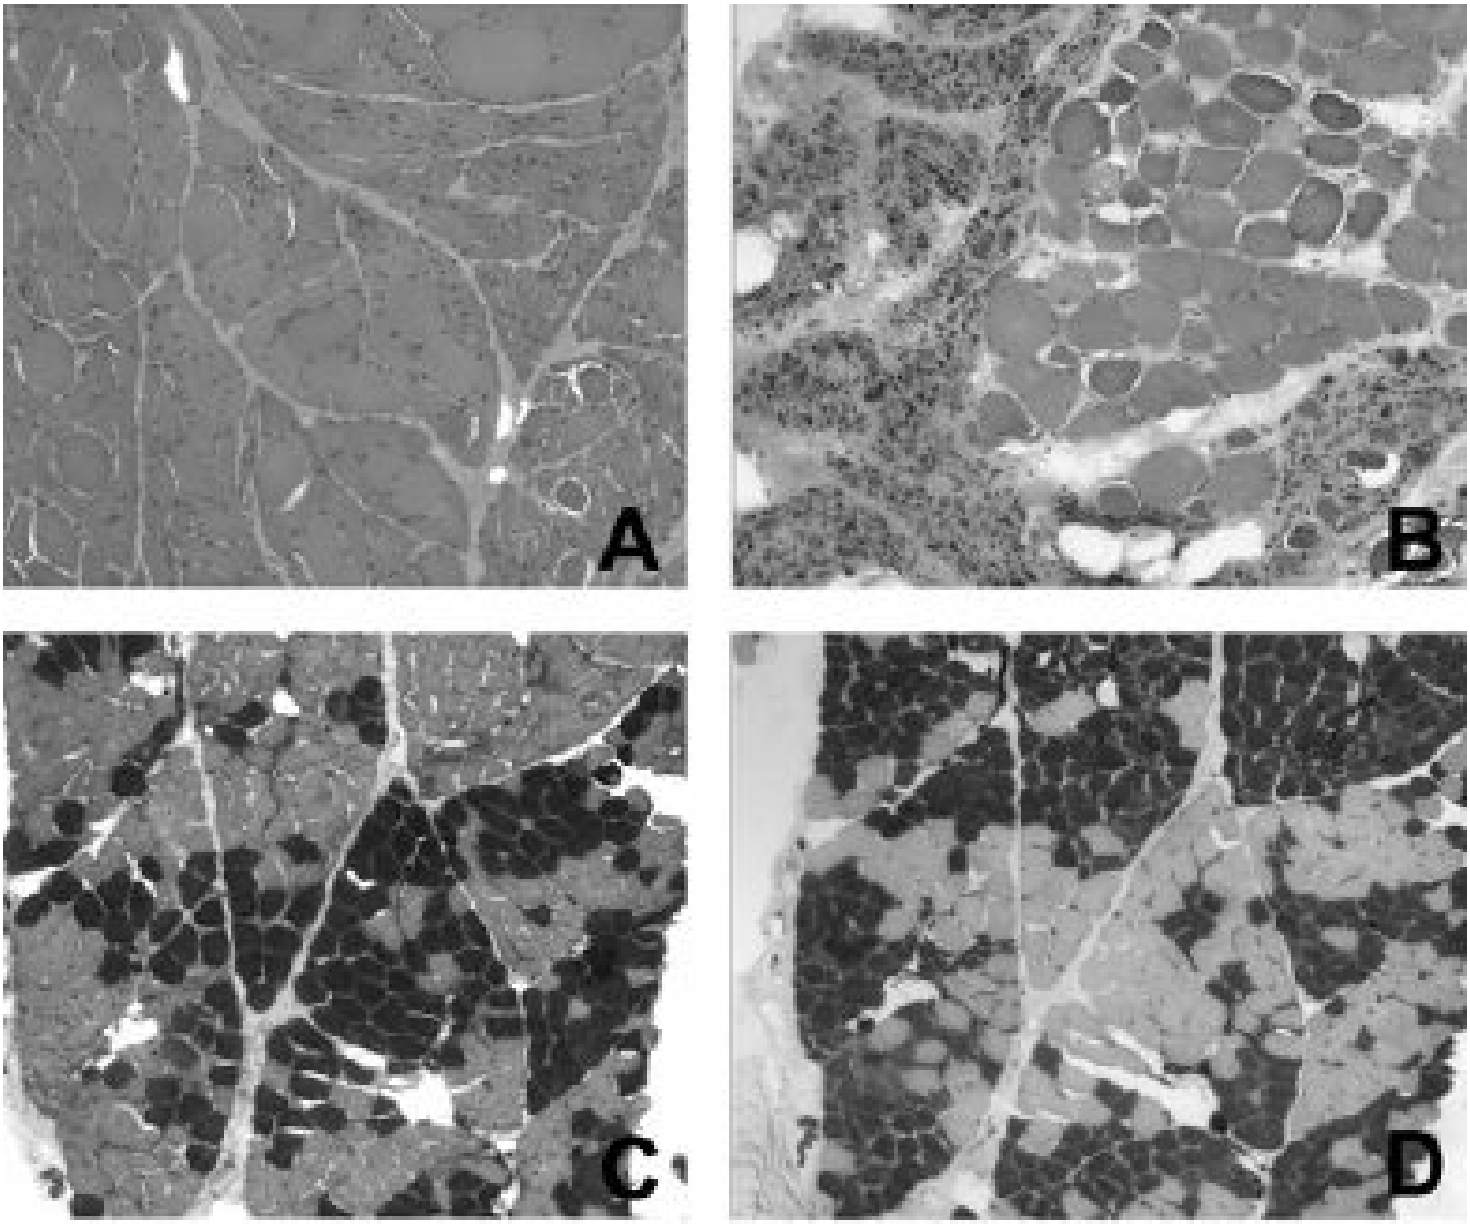

Figure 43-4. Specific patterns of muscle fiber atrophy are present in denervation. Angular atrophied fibers may be scattered among fibers of normal size or be present in small and large groups (A: H&E stain). With end-stage denervation, pynotic nuclear clumps are obvious (B: H&E stain), and muscle fibers are replaced with fatty or connective tissue. Fiber type grouping is an indicator of chronicity and reinnervation (C: ATPase reaction at pH 9.8; type 1 fibers are light and

type 2 fibers are dark; D: acid reversal of ATPase reaction at pH 4.3 with type 1 fibers dark and type 2 fibers light). Note loss of the normal mosaic pattern of muscle fiber types. Magnification X 100 for all images.

Clinical Features and Differentials

Pattern recognition of clinical signs assists with ascertaining an underlying cause and formulating a diagnostic plan and possibilities of treatment. Specifically, establishing a time course of the disease process is informative. Most acute polyneuropathies develop over 2 to 3 days and include inflammatory, immunologic, toxic, or vascular causes. Some toxic, nutritional, and systemic diseases of the nerve will develop over weeks.

Chronic neuropathies that develop over weeks to months include inherited and/or degenerative, metabolic, paraneoplastic, and idiopathic diseases. Chronic neuropathy also may have a time course with intermittent periods of improvement.

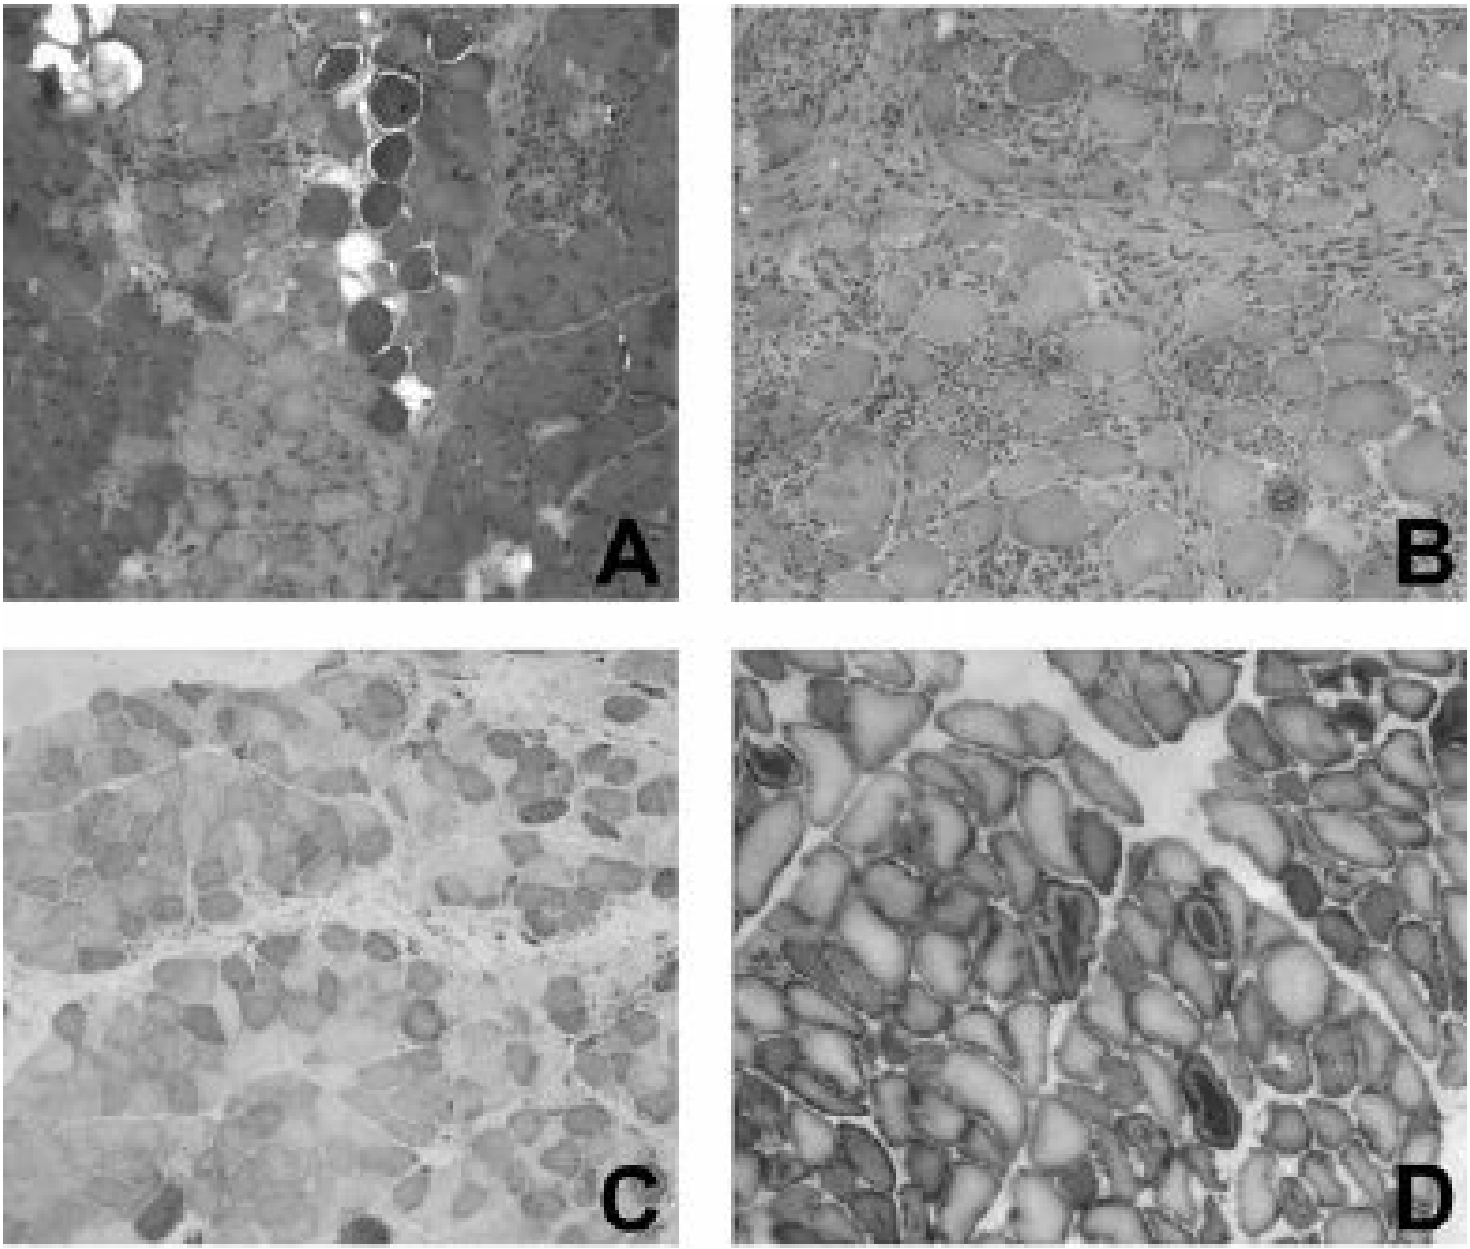

Figure 43-5. Pathologic changes typical of muscle disease include degeneration and regeneration as in muscular dystrophy (A: H&E), multifocal areas of mononuclear cell infiltration in inflammatory myopathy (B: H&E), excessive accumulation of storage products such as neutral triglycerides in lipid-storage myopathy (C: oil red O stain), and cytoarchitectural changes such as the central

accumulations of mitochondria in inherited myopathy of Great Danes, previously called central core myopathy (D: succinic dehydrogenase reaction). Magnification X 100 for all images.

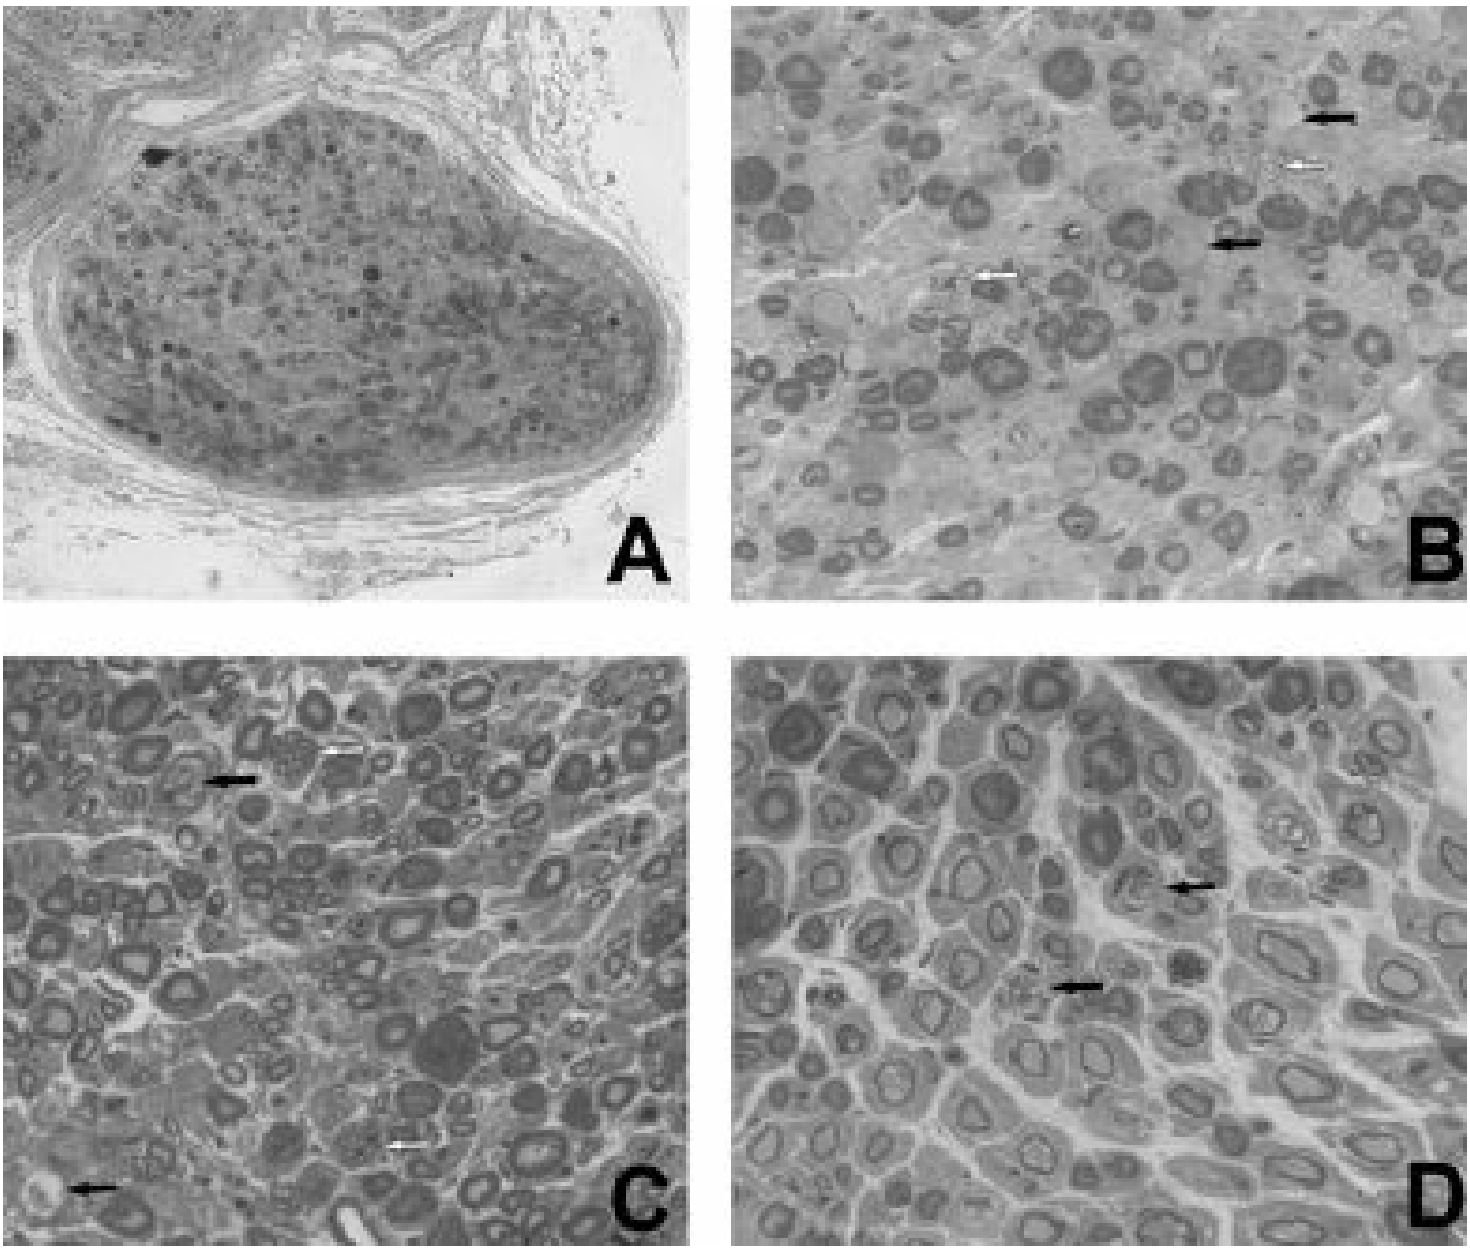

Figure 43-6. Pathologic changes in resin-embedded nerve-biopsy sections typical of peripheral nerve disease. Nerve fiber loss and endoneurial fibrosis (A)

are common findings in dogs with chronic peripheral neuropathy and may also be found in cats. Nerve fiber loss is usually a sequelae of chronic axonal degeneration (B). Myelin ovoids (black arrows) and foamy macrophages (white arrows) may be seen. Active axonal degeneration (C; black arrows) and regenerating clusters (white arrows) are commonly found. In chronic demyelinating disorders (D), onion bulbs (arrows) and inappropriately thinly myelinated fibers are typical of recurrent episodes of demyelination and remyelination. Toluidine blue-basic fucshin, magnification X 40 for A and X 100 for B-D.

Patterns of peripheral neuropathy are described based on distribution: neuronopathy, polyneuropathy, polyradiculopathy, mononeuropathy, and plexopathies. Neuronopathies are selective for loss of sensory or motor neurons. Polyneuropathies are diffuse lesions of the peripheral nerves that produce weakness, sensory

disturbance, and/or reflex abnormalities. In general, polyneuropathies involve several nerves and are bilateral and symmetrical. Differential diagnoses for symmetric neuropathies include degenerative, metabolic, idiopathic, and toxic diseases. Idiopathic polyneuropathy is the most common diagnosis. Polyradiculopathies imply nerve root involvement and present with asymmetric signs, weakness, and multifocal sensory disturbance. Asymmetric and multifocal neuropathies often are associated with inflammatory, immune–mediated, or ischemic disease.

Mononeuropathy is a disorder of a

single peripheral or cranial nerve, often owing to trauma or entrapment and, less commonly, from tumor infiltration, inflammation, and ischemic infarction. Mononeuropathies of cranial nerves also occur as idiopathic disease. Plexopathies involve multiple nerves within the brachial or lumbar plexus and usually affect one limb. Disorders of the brachial plexus and other mononeuropathies (Table 43-1) are covered in more detail in Chapter 44: Traumatic and Neoplastic Diseases of the Brachial Plexus.

Table 43-1. Differentials for Mononeuropathies in Dogs

and Cats

Disease Category	Specific Diseases
Neoplasia	Nerve sheath tumor, lymphosarcoma, metastasis
Inflammation	Brachial plexus neuritis
Trauma	Brachial plexus avulsion, injection injury, iatrogenic surgical trauma, lumbosacral injury, pelvic fractures, humeral and femoral fractures

Toxic	Tetanus
Vascular	Thromboembolic disease, fibrocartilagenous embolism

Peripheral Nerve Disease

Peripheral neuropathies are broadly classified as motor neuron disease, motor neuropathy/radiculopathy, sensory neuropathy, autonomic neuropathy, and mixed neuropathy. Most peripheral neuropathies or polyneuropathies involving spinal nerves are considered mixed neuropathies that affect motor, sensory, and autonomic nerves in

varying degrees. Pathologic studies of peripheral neuropathies show a combination of demyelination and axonal degeneration. The distal axon of the nerve is more sensitive to disease as a result of its distance from the cell body and interruption of axonal transport. Some peripheral nerve diseases affecting the axons and myelin involve both the CNS and PNS, but clinical signs manifest as disease of the PNS. Differential diagnoses for polyneuropathy consist of a wide spectrum of diseases (Table 43-2).

Motor Neuron Disease

Motor neuronopathies are disorders of the ventral horn cells that cause

generalized weakness. Loss of motor neurons results in progressive weakness with muscle atrophy. A characteristic feature of motor neuron disease that differs from peripheral neuropathy is muscular weakness and fasciculations with muscle atrophy, but preservation of reflexes until the disease is advanced.[28] Motor neuron diseases are rare, usually occur in young growing animals, and have an insidious and progressive clinical disease course. Inherited forms have been described in the Brittany spaniel,[29] English pointer,[30] Swedish Lapland dogs,[31] and the Maine coon cat,[32] and are suspected for other breeds.[28] An adult form has been reported in cats.[33]

Motor Neuropathy/Radiculopathy (Polyneuropathies and Mononeuropathies)

Peripheral neuropathies that involve the motor nerve and nerves roots often manifest as hallmark signs of lower motor neuron disease with impairment of motor function. Motor neuropathies are characterized by a flaccid paresis or paralysis, postural reaction deficits, neurogenic muscle atrophy, and reduced to absent spinal reflexes.[22] Muscle fasciculations, spasms, and cramps also can occur. Tremors can be a clinical feature with some pure demyelinating diseases.[34,35] Neurogenic muscle atrophy is rapid

and severe, occurring within 1 to 2 weeks from onset of clinical signs and progressing to joint contracture in chronic cases.[3] Muscle atrophy is a clinical feature for Wallerian degeneration and axonal degeneration, but not for pure myelinopathies (axons still remain intact).

Gait evaluation commonly reveals moderate to severe sensory ataxia with loss of proprioceptive fibers. Animals with lower motor neuron dysfunction often have a shortened stride and an inability to support weight associated with the appendicular and axial musculature. Limb tone is reduced, and flaccidity often becomes more apparent in the distal limbs.[36] Limb

posture will be crouched with tendency for joints to be flexed. Ventroflexion of the neck also signifies generalized weakness. Dogs with only distal polyneuropathy often show a high-steppage or pseudohypermetric pelvic limb gait.[37] This represents a compensatory response to allow the carpi or tarsi to flip forward for limb placement. It is not uncommon for polyneuropathy to manifest as paraparesis before tetraparesis because the longer (sciatic nerve) and more myelinated proprioceptive fibers usually are affected first.

Loss of tendon and flexor withdrawal reflexes is a sign of peripheral nerve disease. Early in acute

polyneuropathy, the reflexes may be diminished although not absent, but they become more reduced from day to day. In disease of small fibers, tendon reflexes still may be retained.[38] Conversely, reflexes can be diminished out of proportion to weakness because of involvement of the large afferent fibers of muscle spindles.

Disease of spinal nerves (mixed nerves) often causes sensory loss along with motor deficits distal to the lesion.[39] Hypesthesia or anesthesia may be evident with involvement of the sensory component of the nerve. Hypesthesia denotes decreased sensation or partial lesion; anesthesia refers to a complete lesion. Sensory

function may be normal or decreased with polyneuropathy. A hallmark feature of mononeuropathy associated with complete nerve transection is anesthesia of a specific dermatome. A dermatome refers to a cutaneous region innervated by afferent nerve fibers from a single spinal nerve.[6] Cutaneous sensory testing uses the ***two-step pinch technique*** to assess nociception (superficial and deep pain) with the autonomous zone of the dermatome being tested.[40] A conscious response or withdrawal reflex indicates function of the peripheral nerve being tested. Loss of deep nociception indicates a poor prognosis.

Sensory disturbance also may reflect

increased sensitivity to stimuli. Pain associated with disease of the peripheral nerve is termed *neuropathic* pain.[38] In humans, types of neuropathic pain manifest as symptoms (i.e., tingling, burning, prickling, etc.) that we are unable to recognize in animals. Sensory disturbances in animals may manifest as clinical signs of dysesthesia (paresthesia) and hyperesthesia.[39] Hyperesthesia is a general term for increased cutaneous sensitivity from a non-noxious stimulus. Dysesthesia denotes an abnormal sensation without application of an external stimulus. Animals with peripheral nerve regeneration are predisposed to mutilation of the anatomic area

undergoing reinnervation as a result of axonal sprouting and excessive excitation causing dysesthesia.[39] Dysesthesia also may result from irritation of the nerve sheath itself. Tactile stimuli may cause a perversion of sensation or allodynia, which refers to a type of stimulus that evokes another type of sensation (i.e., touch as pain). This may be related to the type of pain observed with polyradiculopathies and diabetes mellitus.

Sensory Neuropathy

An animal with a *pure* sensory neuropathy may show gait and postural reaction deficits (sensory

ataxia), decreased nociception, paresthesia, evidence of self-mutilation, and reduced to absent spinal reflexes *without* muscle atrophy.[36] Pure sensory neuropathies are rare and often have an inherited cause.[41] Some acquired diseases also may show sensory disturbances.[42] Unlike in humans, clinical signs of sensory loss (numbness, pain, temperature alterations) associated with polyneuropathy in animals often are impossible to recognize or go undetected.

Table 43-2. Differentials for Polyneuropathies in Dogs and Cats

Disease Categories		Specific Disorders in Dogs	Specific Disorders in Cats
Motor Neuronopathy			
Inherited		Brittany spaniels, English pointer, German shepherd, Rottweiler, Doberman pinscher, Griffon Briquet Vendeen dog, saluki, collie, giant breed dogs, Swedish Lapland dog	Maine coon cat, domestic short-haired
Idiopathic		Dysautonomia	Dysautonomia
Motor Neuropathy/Radiculopathy			
Inherited	Storage diseases	Fucosidosis, globoid cell leukodystrophy	Globoid cell leukodystrophy, glycogenosis type IV, mannosidosis, Niemann–Pick disease type A
	Distal sensorimotor polyneuropathies	Alaskan malamute, German shepherd, Great Dane, Leonberger dog, Rottweiler, Doberman pinscher (dancing Doberman disease), laryngeal paralysis polyneuropathy complex (Dalmatian, Rottweiler, Pyrenean mountain dog)	
	Myelin-associated polyneuropathies	Congenital hypomyelination (Golden retriever), hypertrophic neuropathy (Tibetan mastiff)	Laminin alpha2-deficient muscular dystrophy (domestic short-haired cat, Siamese cat), hypertrophic polyneuropathy (domestic long-and short-haired cats)
	Central-peripheral distal axonopathy	Progressive axonopathy in Boxers, giant axonal neuropathy in German shepherd	Birman cat distal polyneuropathy
Metabolic		Hypothyroidism, hypoglycemia, insulinoma, diabetes mellitus	Diabetes mellitus, hyperchylomicronemia in cats, hyperoxaluria in cats
Paraneoplastic		Multiple myeloma, bronchogenic carcinoma, leiomyosarcoma, hemangiosarcoma, anaplastic sarcoma, synovial sarcoma, adenocarcinomas, mammary gland neoplasms, lymphosarcoma	Rare in cats, lymphosarcoma
Nutritional			Phenylalanine and tyrosine deficiency
Idiopathic		Chronic relapsing demyelinating polyradiculoneuritis, canine chronic axonal degeneration, chronic polyneuritis, distal sensorimotor polyneuropathy	Acute idiopathic polyneuropathy, chronic inflammatory demyelinating polyneuropathy, chronic relapsing polyneuropathy, vaccine-induced polyneuropathy
Inflammatory/Immune		Protozoal polyradiculoneuritis, acute canine polyradiculoneuropathy (Coonhound paralysis)	Feline leukemia virus, feline immunodeficiency virus
Toxic		Drugs – vincristine, cisplatin, aminoglycosides; heavy metals (lead, mercury, thallium, zinc); insecticides – organophosphate compounds	Insecticides – organophosphate delayed neuropathy, pyrethrins; drugs – vincristine, salinomycin; heavy metals – thallium, mercury
Vascular		Vasculitis, multifocal thromboses	Vasculitis
Sensory Neuropathy			
Inherited		Long-haired Dachshund, English pointer, Short-haired pointer, Jack Russell terrier	
Metabolic		Diabetic neuropathy	Diabetic neuropathy
Idiopathic		Sensory ganglioneuritis	
Traumatic		Reinnervation	Reinnervation
Autonomic Neuropathy			
Idiopathic		Dysautonomia	Dysautonomia
Toxic		Strychnine, tetanus, botulism, organophosphate compounds	Strychnine, tetanus, organophosphate compounds

Autonomic Neuropathy

Autonomic nerve dysfunctions arise coincident with a variety of diseases. Autonomic neuropathy can occur as a single disease entity (dysautonomia) or in conjunction with other polyneuropathies. In veterinary medicine, the term ***dysautonomia*** refers to acute or subacute idiopathic panautonomic failure in animals.[43] Common clinical signs of autonomic nerve dysfunction include pupillary impairment, altered tear production and salivation, micturition dysfunction, gastrointestinal stasis, and decreased heart rate variability. These signs can be isolated to a single

nerve (i.e., Horner's syndrome) or be multiple as with panautonomic nerve dysfunction. Horner's syndrome (miosis, enophthalmos, ptosis, and third-eyelid protrusion) can occur with disease of the first, second, or third order neuron system. Differential diagnoses include trauma, inflammation, neoplasia, or idiopathic causes.[44] Lower motor neuron injuries (trauma, iatrogenic) are the most common cause of Horner's syndrome in animals.[45]

Cranial Nerve Disease

Peripheral neuropathy of cranial nerves can occur with focal, multifocal, or diffuse (polyneuropathy) disease.

Mentation, gait, postural reactions, and spinal reflexes are normal with focal neuropathy of a cranial nerve. Typically, only one cranial nerve is affected. If disease is in the brainstem, mentation, postural reactions, gait, and multiple cranial nerves will show abnormalities. Neurologic deficits are more severe on the ipsilateral side. Myopathic and neuromuscular junction diseases also can mimic neuropathy of cranial nerves, i.e,. myasthenia gravis will manifest clinical signs of megaesophagus (regurgitation). Some neuropathies are specific for a particular cranial nerve (Table 43-3, page 242).[46-48] These disorders usually are congenital or idiopathic in origin. Idiopathic neuropathies more

commonly affect cranial nerves V and VII.[47] Multifocal disease processes include some hematogenous neoplasms and inflammatory diseases that may cause asymmetric multiple cranial nerve deficits.[49] Neoplastic disease can affect multiple cranial nerves by mass effect or direct extension. Many cranial nerves are located within the superficial structures of the head and are more susceptible to trauma.[47]

Multiple cranial nerve deficits with generalized LMN signs should suggest polyneuropathy. Cranial nerves V, VII, VIII, IX, X, and XI usually are involved. Animals with polyneuropathy may also have clinical signs of dysphagia, dysphonia, and

dyspnea.[47] Dyspnea associated with upper respiratory tract signs suggests laryngeal paralysis.[50] The laryngeal abductor muscles are innervated by the recurrent laryngeal nerve, which is one of the longest peripheral nerves and thus susceptible to distal neuropathy. Polyneuropathy must be considered as an underlying cause of laryngeal paralysis.[51] Diffuse motor neuropathies also cause respiratory compromise if the intercostal and phrenic nerves are involved.

Table 43-3. Common Differentials for Cranial Neuropathies in Dogs and Cats

Cranial Nerve	Clinical Signs	Specific Focal Cranial Neuropathies	Acquired Neuropathies
Olfactory nerve (CN I)	Anosomia, behavior change, depressed appetite	Idiopathic	Neoplasia, inflammation (encephalitis)
Optic nerve (CN II)	Blindness, absent menace response, absent pupillary light reflex	Sudden acquired retinal degeneration, optic hypoplasia, optic disc atrophy	Neoplasia or space-occupying masses, inflammation (infectious, noninfectious), trauma, vascular
Oculomotor nerve (CN III)	Decreased to absent PLRs, external ophthalmoplegia, lateral strabismus, ptosis	Resting anisocoria (CNIII, sympathetic n.), dysautonomia	Spastic pupil syndrome (FeLV, inflammation, lymphosarcoma), neoplasia, inflammation (encephalitis), increased ICP
Trochlear nerve (CN IV)	Dorsal lateral rotation of pupil (cats); lateral deviation of dorsal retinal vessels	Rare as solely affected	Neoplasia, inflammation (encephalitis)
Trigeminal nerve (CN V)	Sensory and motor deficits, dropped jaw, masticatory muscle atrophy, loss of palpebral and corneal reflexes, loss of facial sensation, neurogenic keratopathy	Idiopathic trigeminal neuritis – dropped jaw	Neoplasia (nerve sheath tumor), inflammation (encephalitis)
Abducens nerve (CN VI)	Medial strabismus, absence of retractor bulbi reflex	Rare as solely affected	Neoplasia, inflammation (encephalitis)
Facial nerve (CN VII)	Lip/ear droop, loss of palpebral reflex, deviation of nasal philtrum, decreased tear production – exposure keratopathy, neurogenic KCS	Idiopathic facial nerve paralysis, hemifacial spasm	Neoplasia, inflammation (otitis media/interna, encephalitis), iatrogenic surgical trauma, hypothyroidism
Vestibular/cochlear nerve (CN VIII)	Deafness Vestibular signs – head tilt, spontaneous nystagmus, deficits of physiologic nystagmus, strabismus	Congenital deafness Idiopathic vestibular disease, congenital vestibular disease	Neoplasia, inflammation (encephalitis, nasopharyngeal polyp, otitis media/interna), toxicity, hypothyroidism
Glossopharyngeal nerve (CN IX), Vagus nerve (CN X), Accessory nerve (CN XI)	Dysphagia, regurgitation, megaesophagus, dysphonia, upper respiratory tract signs	Idiopathic/congenital megaesophagus, dysautonomia, idiopathic/congenital laryngeal paralysis, laryngeal paralysis polyneuropathy complex	Neoplasia, inflammation (encephalitis), iatrogenic surgical trauma, polyneuropathy, myasthenia gravis
Hypoglossal nerve (CN XII)	Ipsilateral paresis	None	Trauma, neoplasia, inflammation (encephalitis)
Sympathetic nerve	Miosis, enophthalmos, third eyelid protrusion, ptosis	Idiopathic Horner's syndrome	Iatrogenic surgical trauma, brachial plexus avulsion, neoplasia, inflammation (otitis media/interna)

Chapter 44

Traumatic and Neoplastic Diseases of the Brachial Plexus

Andy Shores
Laurie Pearce

The brachial plexus is the collective name for the lower motor neuron (LMN) components of the lower cervical and upper thoracic spinal cord segments (C6 toT2), which innervate the shoulders and forelimbs.[1] Injuries to the brachial plexus, either by trauma or neoplasia, result in dysfunction of

muscle groups innervated by the involved nerves. In this chapter we present an overview of the anatomy and function of the brachial plexus and a review of the incidence, mechanisms of injury, diagnostic methods, prognosis, and treatment options for traumatic and neoplastic diseases of the brachial plexus.

Anatomy and Function

Figure 44-1 depicts the location of the spinal cord segments, peripheral nerves, and forelimb muscles associated with the brachial plexus' general somatic efferent (GSE) function. Each LMN consists of a cell body located in the ventral gray matter

of the spinal cord, the ventral root, the spinal nerve, the peripheral nerve, and the myoneural junction.[2] Motor nerves of the forelimb are formed by ventral branches of spinal cord segments C6, C7, C8, and T2.[3] The fifth cervical segment occasionally contributes to the plexus, but when it does, the second thoracic segment usually contributes nothing. When both C5 and T2 contribute to the brachial plexus, the ventral branches of each are small. The ulnar, median, radial, axillary, musculocutaneous, subscapular, suprascapular, thoracodorsal, and lateral thoracic branches are the motor nerves formed by the brachial plexus, and they innervate intrinsic and extrinsic muscles of the shoulder,

brachium, and antebrachium.[1]

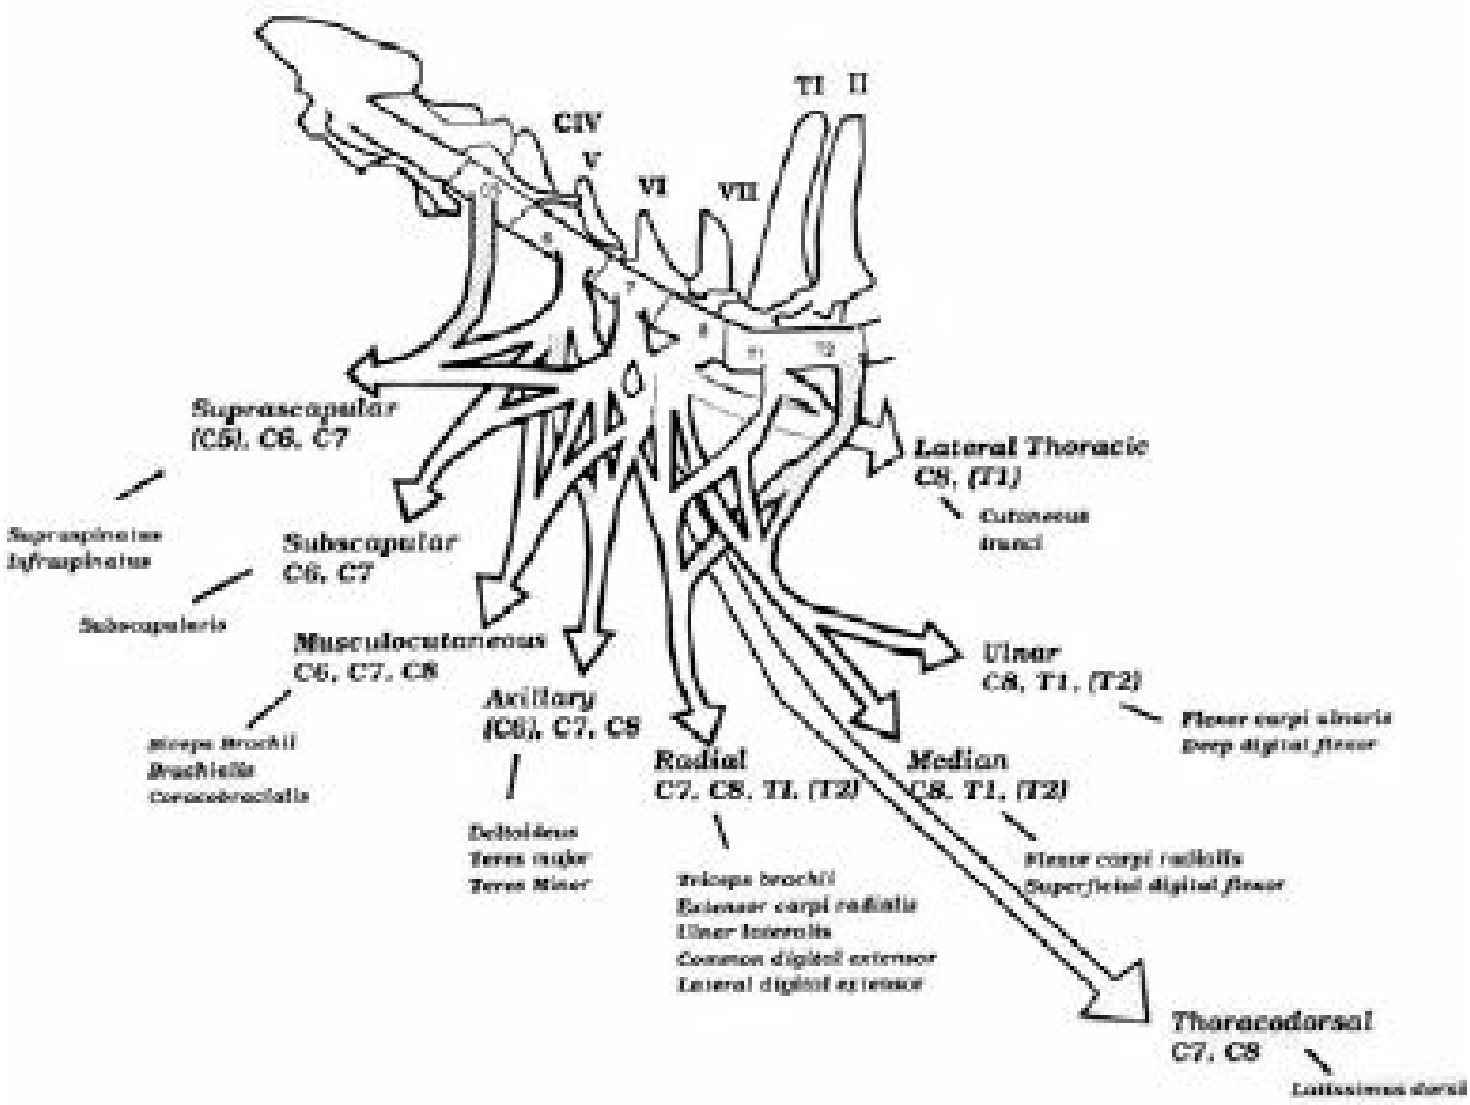

Figure 44-1. Anatomy of the brachial plexus: cervical vertebrae (Roman numerals), spinal cord segments, distribution of the spinal cord segments to the peripheral nerves of the brachial plexus, and muscles innervated by the peripheral nerves of the brachial plexus.

Injuries to the Brachial Plexus

Causes

Automobile accidents are the most frequent cause of injuries to the brachial plexus. Additional causes include projectiles, falling or jumping from moving vehicles, and foreign bodies that enter the axillary region.[4]

Mechanism

Avulsion of the brachial plexus follows extreme abduction of the shoulder or traction of the forelimb caudally, placing traction and longitudinal forces on the nerves.[3] Spinal nerve roots, the ventral nerve root branches,

and the brachial plexus are subject to injury. Spinal nerve root avulsion probably occurs more frequently because these structures contain less connective tissue and, so, are less elastic than the extravertebral components of the LMN. Peripheral nerve dysfunction resulting from an avulsion injury is usually severe and permanent, although one study showed a 28% (8/29) rate of return to acceptable limb function 4 months after injury. Loss of radial nerve function is most critical because adequate limb function cannot be achieved without at least partial triceps muscle function.[5]

Classification

Neuropraxia is a temporary loss of nerve function without structural damage. *Axonotmesis* is loss of function from separation of the axons when the endoneurium remains intact. Complete severance of the nerve trunk defines *neurotmesis* (Figure 44-2). Return of function following neuropraxia may take 1 to 3 weeks. With axonotmesis or neurotmesis, the nerve undergoes Wallerian (axonal and myelin) degeneration distal to the site of injury. Regeneration of the axon fibers can occur, albeit slowly, if unimpeded by organized blood clots in the neural sheath (which occurs with axonotmesis) or by separation of the neural sheath (neurotmesis).[6]

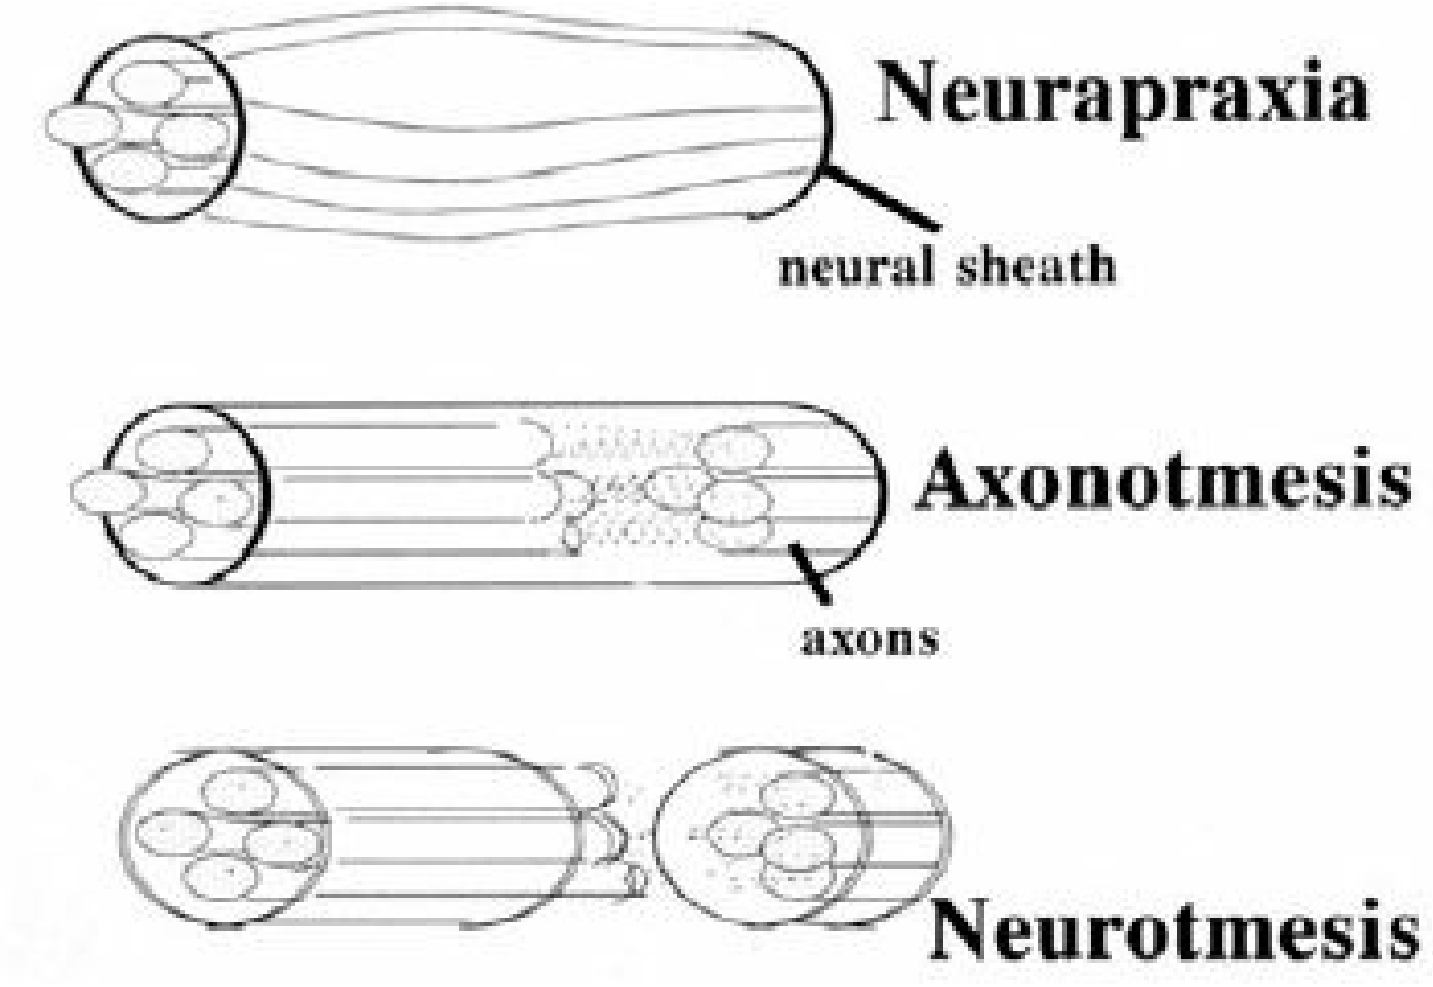

Figure 44-2. Classification of nerve injuries and associated structural changes.

Clinical Signs

Animals with brachial plexus injuries frequently have a history of loss of function in one forelimb noted immediately following trauma.

Bilateral brachial plexus injuries are rare. Readily apparent clinical signs may include inability to fully extend the elbow or bear weight on the limb, and knuckling of the forepaw. Ipsilateral miosis, protruding third eyelid, enophthalmos, and ptosis (Horner's syndrome, Figure 44-3) may be evident, and the cutaneous trunci (panniculus) reflex may be absent on the affected side. Animals presented 10 to 14 days after brachial plexus injury exhibit neurogenic atrophy of the affected muscles (Figure 44-4).[3]

Injury to any component of the LMN, whether temporary or permanent, results in dysfunction of the entire unit. The *neuropathic syndrome*

characterizes the clinical signs accompanying LMN dysfunction: decreased or absent muscle tone (hypotonia, atonia), reduced or absent segmental reflex responses (hyporeflexia, areflexia), and neurogenic muscle atrophy.[7]

Figure 44-3. Anisochoria/partial Horner's syndrome in a dog with a left brachial plexus avulsion. The

miotic left pupil results from a reduced or absent sympathetic nerve supply.

Figure 44-4. Right forelimb of a dog 2 weeks after a partial brachial plexus avulsion. Complete loss of ulnar, median, radial, and axillary nerves was noted; minimal musculotaneous and suprascapular nerve function was preserved. Notice the extreme neurogenic atrophy.

Complete avulsion of the brachial plexus spinal nerve roots (C6 toT2) results in a flaccid, fully extended limb that is incapable of bearing weight. Avulsion of only the caudal plexus roots (C8 to T2) causes the animal to carry the limb with the elbow and shoulder flexed as a function of the remaining musculocutaneous, axillary, and suprascapular nerves.[8] Injury to the T1 nerve root may also damage sympathetic innervation to the eye, causing ipsilateral Horner's syndrome. Avulsion of the C8 nerve root results in ipsilateral loss of the cutaneous trunci reflex.[3]

Radial, axillary, and thoracodorsal nerve dysfunction caused by direct

nerve damage or injury to the C7, C8, and T1 roots results in more ventral carriage of the elbow from loss of a majority of the shoulder flexors. The limb is unable to support weight. Cutaneous analgesia includes the caudal scapular region, a small area of the lateral brachium, the dorsum of the paw, and portions of the cranial and lateral antebrachium.[3,8]

Peripheral nerve injuries not caused by traumatic avulsions of the brachial plexus can involve specific nerves, and the level of injury dictates the type of dysfunction. Radial nerve injury distal to the triceps muscle branches causes knuckling of the forepaw and loss of carpal and digital extensor function.

Most animals compensate by learning to flip the carpus forward when walking or running. Distal radial nerve damage causes analgesia of the dorsal surface of the paw and of portions of the cranial and lateral antebrachium. More proximal radial nerve damage creates similar cutaneous sensory loss but more severe motor dysfunction. The elbow is carried more ventrally because the shoulder flexor function of the long head of the triceps muscle is lost. Intact elbow and shoulder extensor function causes the limb to be carried upward (flexed). Attempts to use the limb result in knuckling of the forepaw and collapse of the limb. An animal with radial nerve injuries that cause loss of triceps function is unable

to bear weight on the limb.[3]

Selective involvement of specific nerves of the brachial plexus other than the radial nerve does not produce substantial disability.[3] Sensory loss is evident in areas associated with the injured nerve (Figure 44-5). Loss of ulnar nerve function, which provides sensory innervation to the lateral aspect of the foot, predisposes animals to abnormal wear and abrasions of the lateral aspect of the footpads as the foot is allowed to slide laterally when bearing weight.[9]

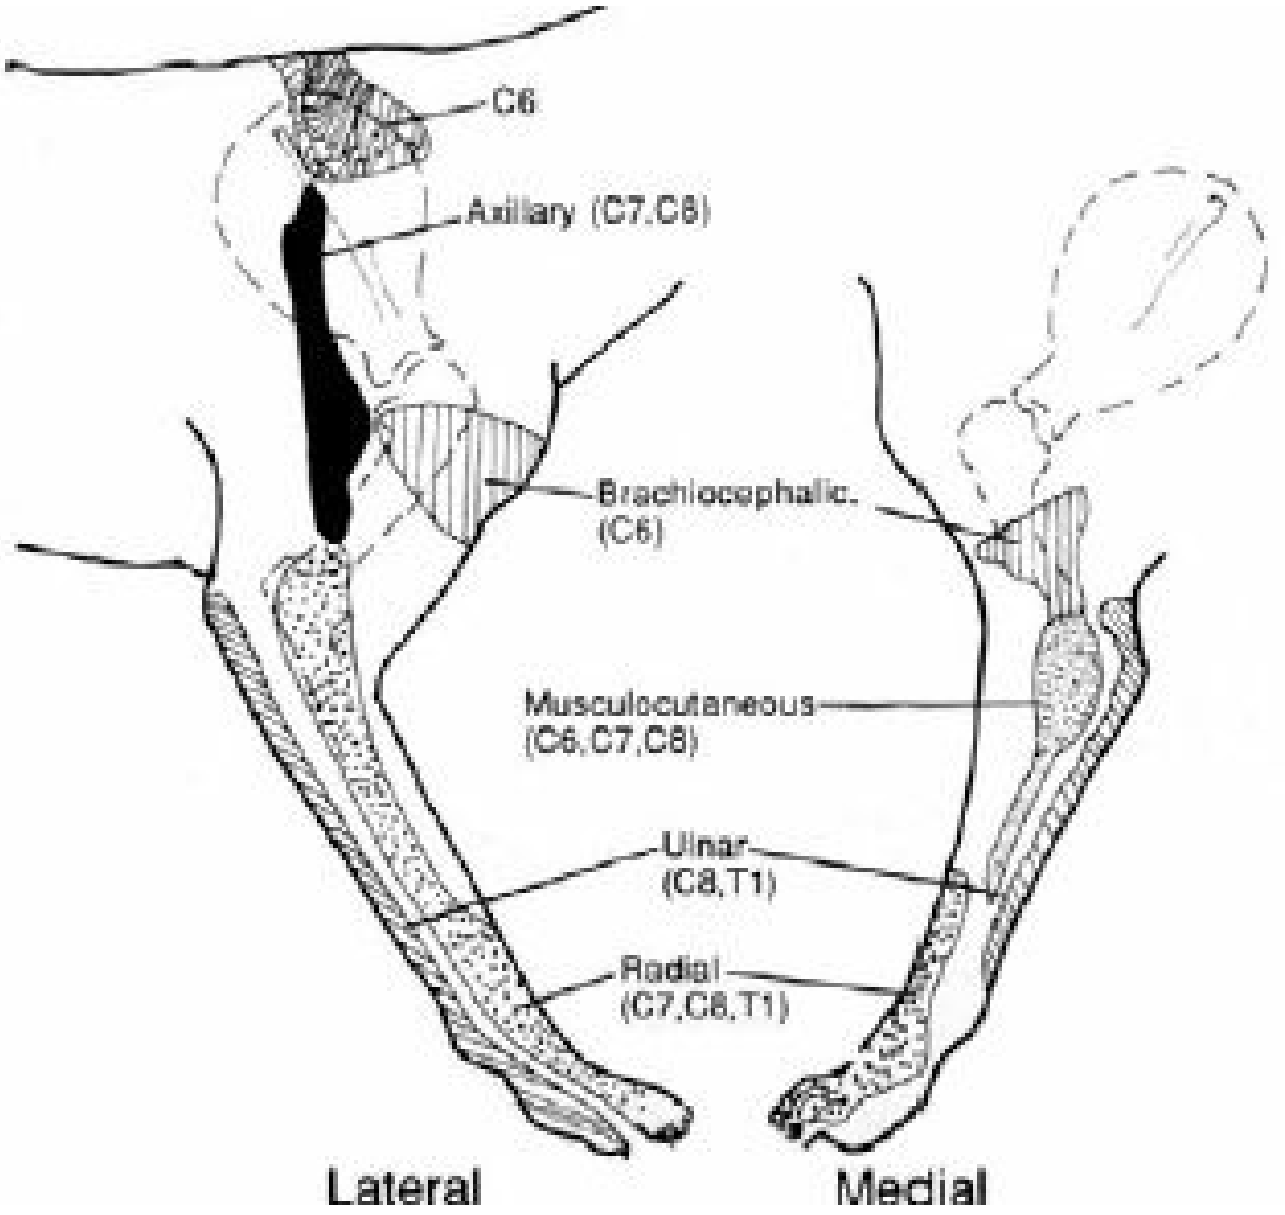

Figure 44-5. Autogenous zones on the lateral and medial aspects of the canine forelimb.

Tumors of the Brachial Plexus

Nerve sheath tumors are infrequent in

dogs, rare in cats, and most often involve peripheral nerves derived from the brachial plexus. A survey of all entries from 21 veterinary colleges to the Veterinary Medical Data Program records for a 10-year period revealed the incidence was less than 1 per 32,000 dogs (0.003%) and less than 1 per 160,000 cats (0.0006%). These neoplasms have been described as schwannomas, neurilemmomas, neurinomas, and neurofibrosarcomas. Collagen content, encapsulation characteristics, and structures from which the tumors arise have been used to differentiate the tumor types; however, even with special staining and electron microscopy, differentiation is frequently a difficult

and speculative process in veterinary pathology. Nerve sheath tumor is perhaps the best accepted term for these neoplasms in dogs and cats.[10]

Lymphosarcomas occasionally involve peripheral nerves or spinal nerve roots.[7,11] Other primary neoplasms such as meningiomas, which are extramedullary and intradural, can produce signs referable to the brachial plexus. Metastatic neoplasms, especially those involving the vertebrae, can also cause signs referable to the brachial plexus.[7]

Nerve sheath tumors of the brachial plexus are usually slow growing, rarely metastasize, and are classified as

extramedullary and intradural when growth of the mass extends into the spinal canal.[10] The most caudal cervical (C7, C8) and the first thoracic spinal roots were more frequently involved in two clinical reports, but any of brachial plexus spinal nerve roots, ventral branches, or peripheral nerves can be primary sites of origin.[10,12] Clinical signs are slowly progressive and usually manifest as pain followed by muscle atrophy, limb dysfunction, and finally, spinal cord compression with continued growth of the tumor. Occasionally, the first sign noted is the animal's licking or chewing of the foot or carpus of the affected limb. Involvement of the T1 spinal nerve root may result in

ipsilateral Homer's syndrome; with C8 spinal nerve root neoplasms, the cutaneous trunci reflex may be decreased or absent on the involved side.[3,10]

Diagnosis is based on typical history and clinical signs, palpation of a mass in the axillary region, electrodiagnostic tests, myelographic changes consistent with an extramedullary or intradural structure, and surgical biopsy findings. Early diagnosis is crucial to successful long-term management of animals with nerve sheath tumors, but it is frequently delayed by incomplete diagnostic evaluations and symptomatic treatment for suspected musculoskeletal or intervertebral disk

disease.[7,10] One study reported an interval of more than 6 months from onset of signs to diagnosis in a survey of 18 dogs with nerve sheath tumors.[10]

Diagnostic Methods

History and Signalment

Brachial plexus injuries are usually associated with a history of trauma, although injuries from foreign bodies that penetrate the axillary region may be the exception. Owners of animals with brachial plexus tumors often relate a history of obscure lameness, resistance to palpation of the limb, possibly licking and chewing of the foot or carpus, and finally a reluctance to bear weight on the limb. The course

of this history may be a few days to several weeks.[10,13]

A survey of brachial plexus nerve sheath tumors reported from 21 veterinary colleges to the Veterinary Medical Data Program during a 10-year period did not reveal a breed predisposition for brachial plexus nerve sheath tumors. Large-breed dogs (i.e., Labrador retrievers) appear to be over-represented in the literature, but this likely represents breed popularity rather than increased incidence rate.

Physical and Neurologic Examinations

Thorough examination is important

when brachial plexus injury or neoplasia is suspected. Animals presented following motor vehicle trauma should be assessed for thoracic and abdominal injuries as well as fractures or nervous system injuries remote to or associated with the brachial plexus. In addition to a thorough physical examination, animals with suspected brachial plexus tumors are carefully assessed for the presence of other tumors.

Neurologic deficits found with brachial plexus injuries or tumors reflect the location and extent of brachial plexus and spinal cord involvement. Early signs of a nerve sheath tumor may not include neurologic deficits, but

advanced signs may include hyporeflexia, muscle flaccidity, cervical spinal cord compression, and involvement of the contralateral limb. Brachial plexus trauma produces lower motor neuron dysfunction of the injured spinal nerve roots, ventral branches, or peripheral nerves. Complete brachial plexus involvement abolishes triceps, biceps, and forelimb flexor reflexes.[3]

Sensory innervation mapping is used to locate areas of cutaneous anesthesia on the limb. This examination requires a patient examiner, a cooperative patient, and a quiet, uninterrupted environment. Beginning on the dorsum of the paw, small, curved Halsted

forceps are used to pinch the skin in a two-step procedure (Figure 44-6). An assistant gently restrains the animal while distracting its attention from the examiner. First, a small amount of skin is grasped lightly and lifted slightly with the forceps. Next, the hemostats are used to pinch the skin. Intact sensation is determined by vocalization of the animal, looking at the site of stimulation, or attempts to discourage the examiner from pinching the skin. Only consistent and repeatable results are considered valid. The examination is continued, proceeding up the antebrachium on the medial, lateral, cranial, and caudal sides. A cutaneous zone is the total cutaneous area supplied by a peripheral nerve. Some

peripheral nerves have cutaneous zones that overlap. Autogenous zones are cutaneous regions that receive sensory innervation from only one peripheral nerve. Analgesia in an autogenous zone implies a loss of sensory function for the nerve represented by that zone.[3,4] Figure 44-5 illustrates the autogenous and cutaneous zones of the forelimb in the dog; the distribution is similar in cats. Certain dorsal spinal nerve branches in the brachial plexus region also have cutaneous and autogenous zones. The distribution of the cutaneous analgesia is used to determine which spinal and peripheral nerves are impaired.

Figure 44-6. A and B. Two-step method for cutaneous sensory evaluation of the forelimb, a modification of the technique described by Bailey.

Electrodiagnostic Tests

Several electrodiagnostic tests can be used to confirm and further characterize suspected nerve dysfunction. The electromyogram (EMG) is a graphic and auditory

analysis of muscle function. Certain waveforms and sounds recorded from muscles may reflect denervation, reinnervation, or normal function.

Spontaneous activity consisting of fibrillation potentials and positive sharp waves are patterns associated with denervation and can be recorded 5 to 14 days after denervation. Low-amplitude monophasic or polyphasic motor unit action potentials (MUAP) or giant MUAP may be demonstrated from muscle undergoing reinnervation. Early stages of reinnervation can result in small MUAP when the number of regenerated axons is few, and polyphasic waves indicate a disparity in the degree of remyelination among

the regenerating fibers. Giant MUAP occur when denervated muscles are reinnervated by adjacent functional nerves, resulting in a low muscle nerve branch to muscle fiber ratio.

Early evidence of reinnervation is not predictive of full recovery of function. Serial EMG evaluations that produce consistent physical and electrophysiologic evidence of active muscle reinnervation are more reliable indicators of a reinnervation process sufficient to produce some return of function. Serial microscopic examination of muscle biopsy specimens from the most proximal affected muscles (e.g., supraspinatus, deltoid) may be used to further confirm

the regenerative process. Normal muscle exhibits insertional activity as the EMG electrode is passed through it; in anesthetized animals, however, electrical silence is evident after the electrode is stationary. A thorough EMG examination 2 to 3 weeks after a brachial plexus injury documents the extent of muscle denervation and confirms the distribution of nerve root injury. The EMG may be helpful in early diagnosis of brachial plexus tumors, especially when limb dysfunction is minimal or absent and a pattern of scattered spontaneous activity indicative of denervation (fibrillation potentials, positive sharp waves) is found in the distribution of one nerve.

Nerve conduction studies are of limited value in the assessment of brachial plexus dysfunction. Soon after avulsion, before Wallerian degeneration has proceeded far distally, a motor nerve can conduct an evoked impulse at a velocity within the normal range. After Wallerian degeneration, impulses cannot be conducted. This information adds little to the findings of physical and electromyographic examination. Sensory nerve conduction studies may be useful in determining the location of the nerve injury. When sensory nerve fibers are avulsed proximal to the dorsal root ganglia, however, the sensory fibers of the peripheral nerve do not degenerate and are capable of

conducting an evoked impulse, even with complete analgesia in the autogenous zone.[14]

Spinal evoked potentials (cord dorsum potentials) may be more valuable for determining the integrity of the sensory nerve function. Stimulation of the nerve in the distal portion of the limb and recording an evoked response from an electrode over vertebra C6 or C7 indicate that a portion of the sensory tracts is functional for that nerve. The value of this test for predicting return of function is unknown.

Other motor evoked responses that might be useful but have not been

sufficiently evaluated in veterinary medicine are the H wave and F wave. The H wave is produced by a submaximal stimulation and is equivalent to a monosynaptic reflex. The H wave can be recorded only if the dorsal and ventral roots are intact. The F wave is produced by a supra¬maximal stimulus, represents antidromal and orthodromal transmission of the electrical impulse, and requires an intact peripheral nerve, ventral root, and ventral horn cell. Presence of an F wave indicates a functional motor nerve.[15]

Radiography and Advanced Imaging

Radiography and advanced imaging techniques (myelography, ultrasonography, computed tomography, magnetic resonance imaging) are used to evaluate the vertebrae and spinal cord of the caudal cervical region.[16-20] Brachial plexus nerve sheath tumors that invade the spinal canal often create bony lysis at the intervertebral foramen. The widened foramen may be demonstrated on lateral views of the spine. Myelography usually depicts spinal cord compression and an extramedullary intradural pattern.[19] With brachial plexus avulsions of the spinal roots, the contrast material may be seen outside the subarachnoid space, at the site of the avulsion. The

expanded availability of ultrasonography, computed tomography, and magnetic resonance imaging in veterinary medicine has proven useful in determining avulsion sites and the extent of nerve sheath tumors in the caudal cervical region (Figure 44-7).[16-18]

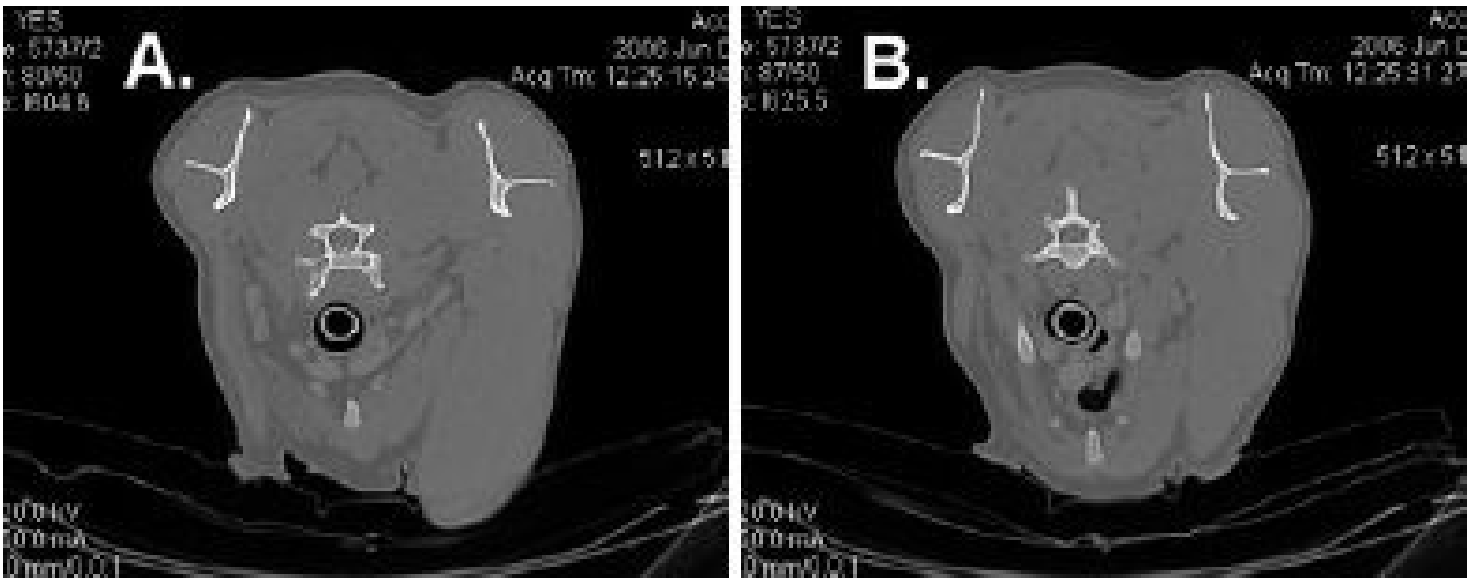

Figure 44-7. Computed tomographic images of a patient with brachial plexus avulsion. Note the extreme atrophy of the right appendicular muscles, but relatively mild atrophy of the scapular muscles. Electrodiagnostics in this patient indicated avulsion of

the caudal cervical nerve roots (C7 through T2) and, therefore, some sparing of the suprascapular and subscapular nerves. A. Level of the C6 vertebra; B. Level of the C7 vertebra.

Therapeutic Options and Guidelines

Injuries to the Brachial Plexus

Most brachial plexus injuries unfortunately result in permanent dysfunction of the affected nerves and associated muscles of the forelimb. Most plexus avulsions occur at or within the spinal cord, and surgical repair would require extraordinary effort, expertise, and expensive equipment (e.g., operating microscope,

microsurgical instruments).[9] More distal injuries, involving peripheral nerves, warrant surgical exploration and, when indicated, primary surgical repair. Caution and prudence should guide the decision for primary nerve root repair. Low-frequency laser technology for nerve anastomosis may warrant consideration in the future.

Definitive therapy for brachial plexus injury is delayed until the full extent of injury is known. Figure 44-8 is an algorithm that outlines a schedule for serial evaluation of brachial plexus injuries and the various treatment options available. The initial concern is protection of the limb from further injury and prevention of flexor tendon

contracture. If elbow flexion is not sufficient to prevent the carpus from dragging on the ground, the carpus is bandaged. Limb carriage and sensory mapping are documented in the medical record for future reference. In 7 to 14 days the limb is re evaluated: sensory mapping is repeated, muscle atrophy is noted, and EMG evaluation is performed if available. Evidence of self-mutilation, skin abrasions on the dorsal surface of the carpus, and flexor tendon contracture are addressed at this time. Amputation is considered if there is total analgesia distal to the elbow and evidence of self-mutilation and if improvement is not noted within three weeks. To prevent flexor tendon contracture, a coaptation splint can be

applied or the owners can perform hyperextension exercises on the limb for 10 minutes four times a day. The latter approach requires cooperation from the animal and strict compliance from the owner. Weekly reevaluations are scheduled for three weeks. If improvement is noted, conservative therapy is continued. Axon regeneration does not begin until 7 to 14 days after injury, and neuropraxia may take three to six weeks to fully resolve.[6] Muscle biopsy and EMG are needed to confirm evidence of reinnervation. If no improvement is noted during the three weekly visits, therapeutic options are these: conservative (no further treatment) and surgical (amputation, tendon

transposition, nerve-muscle transposition).

When no improvement is noted, if the limb is not constantly subjected to trauma (dorsal carpal skin abrasions, self-mutilation) and limb appearance is acceptable to the client, no additional care is needed or indicated.

Tendon transpositions have been reported by several authors as therapeutic options when musculocutaneous function is intact;[9,21-23] however, most reports are of experimental and not clinical data. In most spontaneous brachial plexus injuries, any musculocutaneous nerve function remaining is partial, and

neither the brachialis nor the biceps brachii muscles have sufficient functional muscle fibers to both flex and extend the elbow.[5] The transposition procedure is intended to supply function to the triceps muscle, allowing extension of the elbow. Even if sufficient triceps function can be supplied, sensory deficits remain and self-mutilation can begin any time after the injury. If the tendon transposition is successful, carpal arthrodesis should be considered as an adjunct to triceps function. Arthrodesis should align the carpus in slight hyperextension (8° to 12°) and 5° to 8° outward rotation.[9] With each step of the tendon transposition or carpal arthrodesis therapy, owners are again

counseled about the ever present threat of self-mutilation.

Nerve-muscle transpositions have shown limited success in experimental radial nerve transection. The efficacy of nerve allografts has varied, with failure usually related to immune-mediated reactions.[9] Intact neurovascular muscle pedicle grafts have been considered; this requires microvascular technique and may have future clinical applications.

Tumors of the Brachial Plexus

Early diagnosis is the single most important factor in successful

treatment of brachial plexus tumors. Any well founded suspicion of a brachial plexus tumor is an indication for surgical exploration, although the more common items in the differential diagnosis must first be ruled out. Brachial plexus neuritis, trauma, and vascular thrombus are all characterized by acute onset of substantial lower motor neuron dysfunction of one or both pelvic limbs.[5] Radicular and spinal cord compression may have a slower, more insidious onset, although clinical signs and radiographic studies should differentiate these conditions from brachial plexus tumors. Radicular compression from an intervertebral disk extrusion involves only one cervical segment, even when

progressive, and should be demonstrable on plain film radiography or myelography. Caudal cervical spinal cord compression from an intervertebral disk extrusion or spinal cord neoplasm usually produces clinical signs, which are more evident in the hind limbs than the forelimbs, although neck pain can be the only sign. Again, radiographic studies should demonstrate the lesion.

When brachial plexus tumors are diagnosed or when other more common causes of forelimb LMN dysfunction are ruled out, exploration of the brachial plexus to determine the extent and distribution of the suspected neoplasm is the best method of

definitively diagnosing the problem. All too often, the decision to explore is delayed unnecessarily.[5]

The surgeon tailors the surgical approach to the location of the suspected mass. Careful palpation, before and after induction of anesthesia, is helpful, as is a through knowledge of brachial plexus anatomy, EMG changes in the limb, and results of the neurologic examination. If the tumor is palpable and located distal to the mid-humerus, a linear incision is made from the proximal third of the humerus to the middle of the antebrachium. The tumor is identified and resected, along with a margin of normal-looking nerve proximal and

distal to the mass.[5]

Exploration of the region from the brachial plexus to the spinal canal is accomplished through an incision over the scapula followed by muscle dissection on the cranial, caudal, and dorsal aspects of the scapula and reflecting the scapula toward the surgeon (Figure 44-9). Neural structures from the spinal canal to the mid-humerus can be explored with this exposure. The axillary lymph node can be biopsied with this approach. Prior knowledge of the precise location of the mass, through palpation or advanced imaging techniques, allows some modification of this approach. If the mass is in the cranial-most brachial

plexus area, transection of the omotransversarius muscle and retraction plus blunt dissection allow exposure of this region. For the caudal brachial plexus, the rhomboideus muscle is transected and retraction plus blunt dissection are adequate for exposure of this area.[5]

An alternative surgical approach is the craniolateral approach. The reported advantage is improved exposure of the proximal brachial plexus; whereas the craniomedial approach described above offers a better exposure of the peripheral nerves.[24]

If the mass extends into the spinal canal, the tumor is resected to the point of the intervertebral foramen and the spinal canal is explored later

(preferably within a week). Nerve sheath tumors that invade the spinal canal may also extend to the opposite side, necessitating extensive exposure of the canal for resection.

Limb amputation is a practical consideration if the mass extensively involves the brachial plexus or if resection will cause permanent triceps muscle dysfunction. If the mass extends into the spinal canal and has extensive brachial plexus involvement,

euthanasia is a rational decision for the owners to make, since a cure is unlikely, long-term prognosis is poor, and the postoperative discomfort, physical rehabilitation, and dysfunction may be considerable. Palliative therapy is reserved for animals that cannot or should not undergo surgery for any reason (including recurrence of the tumor) and whose pain or discomfort can be controlled well enough to allow quality life in the time remaining.

Estimating Prognosis

Estimating prognosis is difficult early in the course of brachial plexus injuries and when proof exists of complete

removal of a nerve sheath tumor on microscopic examination of tissue margins. Most avulsions cause permanent damage. Most nerve sheath tumors recur. It is the responsibility of the veterinarian to give clients accurate information so that they may make an informed decision.

Postoperative Rehabilitation

Care of the animal with brachial plexus injury that has undergone surgery for tendon transposition or nerve repair includes immobilization of the limb for at least 2 weeks. When arthrodesis of the carpus is performed, 6 to 8 weeks' immobilization is needed to allow

fusion. Amputees seldom require major care after the immediate postoperative period. Animals recovering from surgery for brachial plexus neoplasms require physical therapy and much the same care as animals with traumatic brachial plexus injuries: protection of the carpus and hyperextension exercises to prevent flexor tendon contraction. Because the involved nerves are usually severed and return of function is not a consideration, the owners are made aware of the need for life-long commitment to this care. Any changes in the animal's ability to use the limb, signs of pain, or other factors that might herald recurrence of the mass should be reported immediately.

Chapter 45

Atlantoaxial Subluxation in the Dog

Daniel P. Beaver

Atlantoaxial subluxation is typically a congenital or developmental disease affecting immature toy breed dogs.[1,2] Atlantoaxial subluxation has also been reported in other mammals including cats, horses, and cattle. In people, both the ligamentous laxity associated with Down's syndrome and the bony destruction of erosive rheumatoid arthritis can cause atlantoaxial

subluxation.[2,3,4,5] In dogs with atlantoaxial subluxation, instability of the atlantoaxial joint results from a loss of ligamentous support of the axis, often with concurrent aplasia, hypoplasia or dysplasia of the dens. Acute or chronic spinal cord compression causing clinical signs consistent with an upper cervical myelopathy can result from this instability.[2]

Anatomy

The occipitus, atlas, and axis are the three bones that comprise the craniovertebral junction. Through their specialized shapes and interrelationships of movement, they

allow a wide range of motion of the head.[6] The atlanto-occipital joint is the cranial part of the overall occipito-atlanto-axial complex. It allows for dorsoventral motion of the head on the neck. The more caudal atlantoaxial joint allows for rotational movement of the head about the longitudinal axis of the vertebral column. At the center of this rotation is the dens, a bony protuberance that extends cranially from the axis and lies along the floor of the vertebral foramen of the atlas. The dens is the major point of attachment for ligaments that stabilize the atlantoaxial joint. The synovial joint cavities of the occipito-atlanto-axial complex are interconnected to form a single composite joint cavity.[7]

Interosseous ligaments provide stability to the occipito-atlas-axis complex (Figure 45-1).[8] The apical ligament attaches the cranial aspect of the dens to the ventral aspect of the foramen magnum. The paired alar ligaments attach the dens to each of the occipital condyles. The transverse ligament is a tough fibrous band that acts as a restraint, keeping the dens against the body of the atlas. The transverse ligament allows rotational movement, but prevents the dens from tipping up into the vertebral canal. The dorsal atlantoaxial ligament and membrane extending between the vertebral arches of the atlas and axis also contribute to atlantoaxial stability.[8]

Pathophysiology

Dogs with atlantoaxial subluxation usually have congenital abnormalities that predisposed them to injury. Although various congenital malformations of the entire occipito-atlanto-axial complex have been described in association with atlantoaxial subluxation, most commonly only aplasia or hypoplasia of the dens is present in dogs.[2,9] Dorsal deviation and so-called “nonunion” or separation of the dens have also been reported in the dog.[2,10,11,12]

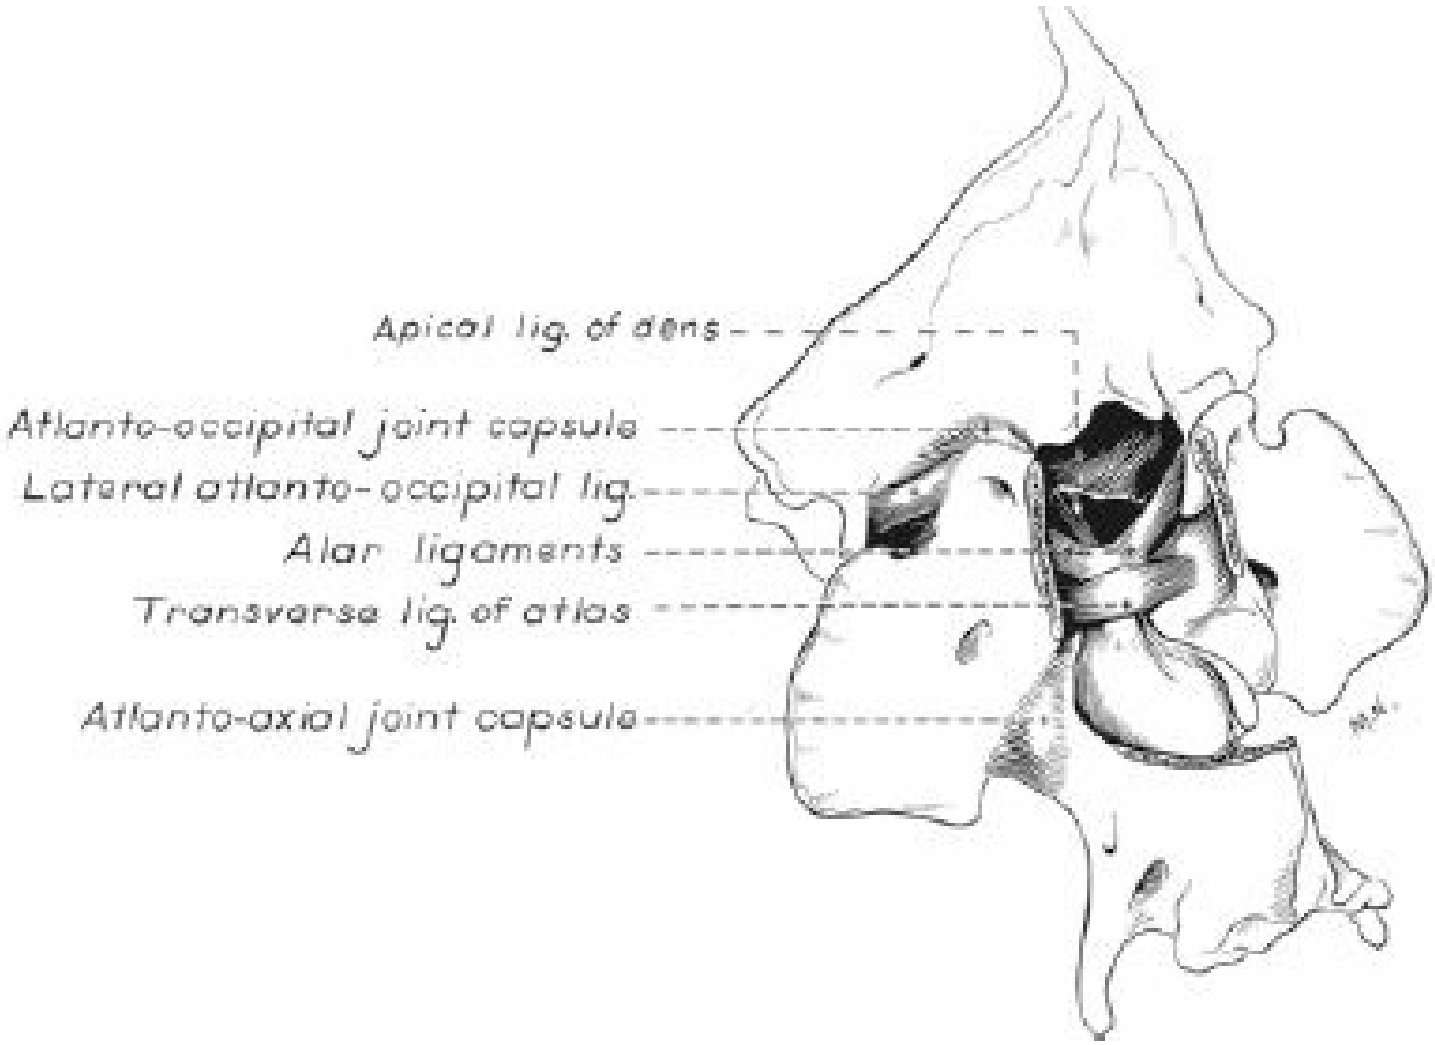

Figure 45-1. The ligaments of the occiput, atlas, and axis in a normal dog. (Reprinted with permission from: Evans HE, Christensen GC: Millers Anatomy of the Dog, 3rd ed. Philadelphia: WB Saunders, 1993, p. 227.

The cause of aplasia, hypoplasia, or dysplasia of the dens is unknown. At birth, the axis is composed of four separate ossification centers: the right

and left neural arches, centrum 1 and centrum 2. Three additional ossification centers develop in the axis in postnatal life: intercentrum 2, the epiphysis, and the centrum of the proatlas (Figure 45-2.) An early hypothesis was that an assumed single ossification center for the dens fails to develop prenatally.[11] Subsequent investigation of the postnatal ossification centers of the atlas and axis in Miniature Schnauzers and other breeds revealed that the dens originates from two ossification centers.[6,13] The cranial one quarter originates from the centrum of the proatlas, and the caudal three quarters of the dens as well as the cranial part of the axis body originate from

centrum 1 of the axis. The authors of this study thus contended that dens hypoplasia or aplasia is unlikely owing to congenital absence of an ossification center. They proposed that a vascular-related ischemia may lead to postnatal resorption of at least the middle part of the dens, resulting in dens dysplasia.[13]

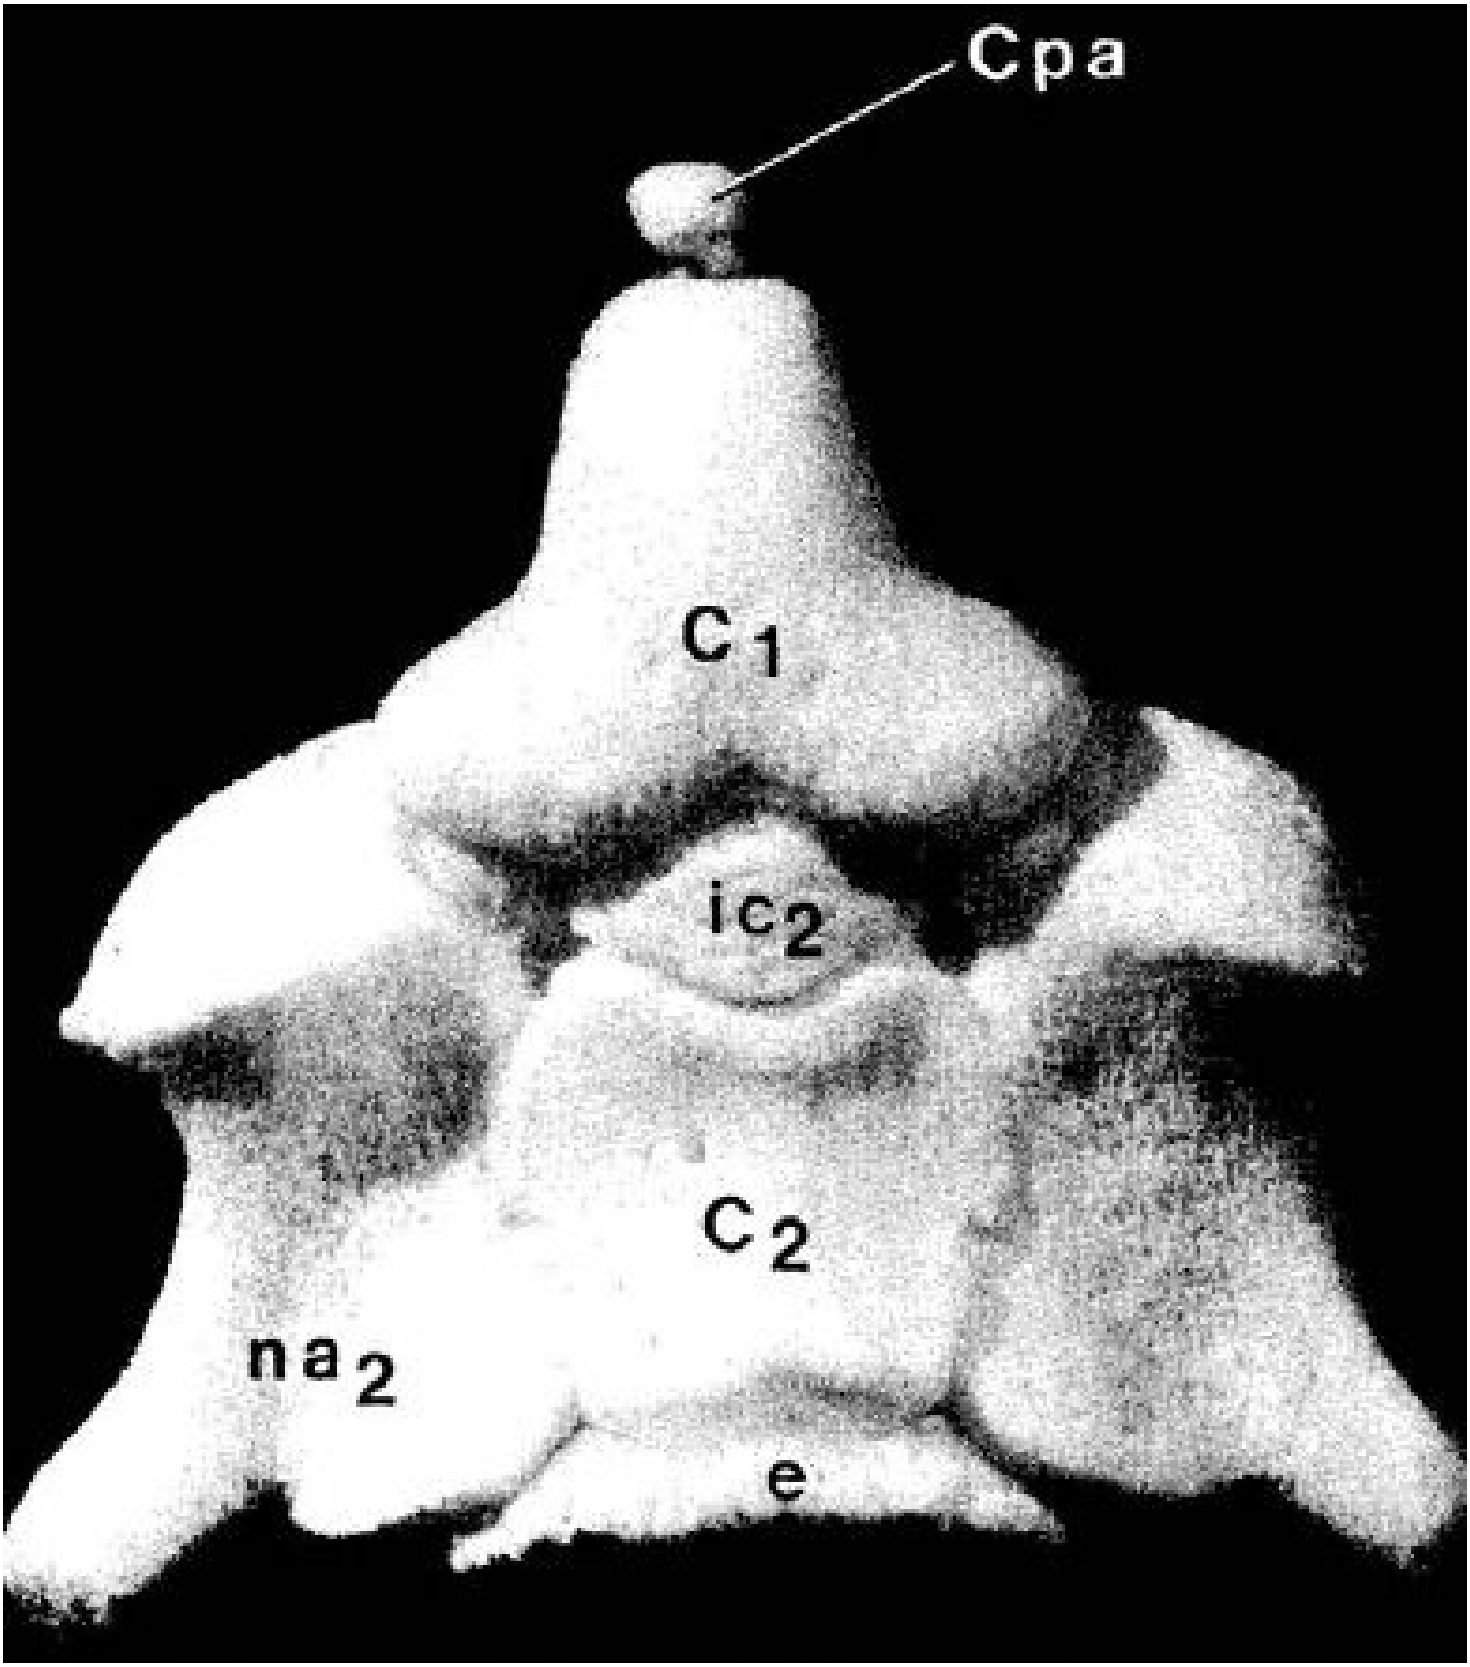

Figure 45-2. Ventral aspect of the axis from a 10-week-old Miniature Schnauzer, revealing 7 ossification centers: Cpa = centrum of the proatlas;

C_1, C_2 = centrum 1 and centrum 2, respectively; ic_2 = intercentrum 2; na_2 = right neural arch center of the axis; e = epiphysis; x 5. (Photo courtesy of Dr. Alastair Watson. As the dens is a major attachment point for ligaments that stabilize the atlantoaxial joint, dogs with absent or hypoplastic dens are susceptible to trauma causing subluxation of the joint. Tearing of the dorsal atlantoaxial ligament and membrane often occurs with subluxation of the joint. With flexion of the head on the neck, ventral compression of the spinal cord occurs. Trauma to the spinal cord can come in the form of an apparently single acute episode or from more

chronic progressive damage.

Atlantoaxial subluxation can occur in dogs with normal dens conformation as well. These cases usually result from traumatic rupture of the transverse ligament or fracture of the dens. A case of a dog with normal dens conformation with instability secondary to absence of the transverse ligament has been reported.[14] Such soft tissue abnormalities may be present in other cases of atlantoaxial subluxation in dogs with normal dens conformation. Dogs with atlantoaxial subluxation and a normal dens conformation may be at greater risk of severe spinal cord compression as the intact dens tilts dorsally into the

vertebral canal. In one study, however, the conformation of the dens, whether it was normal, hypoplastic, or aplastic, did not affect the odds of a successful surgical outcome.[9]

Clinical Findings

Atlantoaxial subluxation is a disease that most often affects immature, toy breed dogs of both sexes. Breeds most commonly affected include the Yorkshire terrier, toy and miniature poodle, Pomeranian, Pekingese, Chihuahua, and Maltese. However, atlantoaxial subluxation may occur in any size and breed of dog and at any age if significant trauma to the neck occurs.

Toy breed dogs with atlantoaxial subluxation often do present with a history of trauma, although this is often a mild incident such as jumping off a chair or being dropped by a child. Clinical signs of atlantoaxial subluxation may be mild to severe depending on the degree of compression and the chronicity of the disease. Most, but not all, dogs with atlantoaxial subluxation have neck pain, exhibited by rigid guarding of the neck, reluctance to move, or pain on cervical palpation. Mild cases of atlantoaxial subluxation may have ataxia or a spastic gait. Front and hind limb reflexes may be normal or increased, and postural reaction deficits may be present. More severe

cases exhibit tetraparesis or tetraplegia. True paralysis from atlantoaxial subluxation is also associated with respiratory arrest and death owing to injury to the respiratory centers in the cervical spinal cord.

Occasionally, dogs with atlantoaxial subluxation have neurologic signs that may be localized to the caudal brainstem.[9,15,16,17,18] These may be seen more often in more neurologically compromised patients or following surgical manipulation. The cause of these signs often goes undiagnosed. They may be a result of concurrent congenital brain abnormalities, iatrogenic cervical spinal cord and

brainstem trauma , or hypothetically, ischemia in the brainstem owing to compression of the basilar artery.[18]

Diagnosis

The diagnosis of atlantoaxial subluxation is usually confirmed with radiography. Lateral radiographic views will show dorsal displacement of the axis in relation to the atlas, with an abnormally increased distance between the dorsal arch of the atlas and the dorsal spine of the axis, and dorsal displacement of the body of the axis (Figure 45-3). On occasion, there may not appear to be enough distance between the dorsal aspects of the atlas and axis to be able to confirm

atlantoaxial subluxation. General anesthesia may aid in getting diagnostic radiographs. Stressed views may be made by slightly flexing the neck; however, this maneuver can be very dangerous especially in the anesthetized unguarding animal. Fluoroscopy can aid in visualization of instability during flexion and extension. Myelography may also demonstrate spinal cord compression. Ventrodorsal radiographs of the atlantoaxial joint that demonstrate an absent or hypoplastic dens support a diagnosis of atlantoaxial subluxation (Figure 45-4). An open-mouth radiographic view demonstrates the conformation of the dens; however, because flexion of the neck is required

for this view, it is usually not recommended. Computed tomography and magnetic resonance imaging modalities are also useful in diagnosing atlantoaxial subluxation.

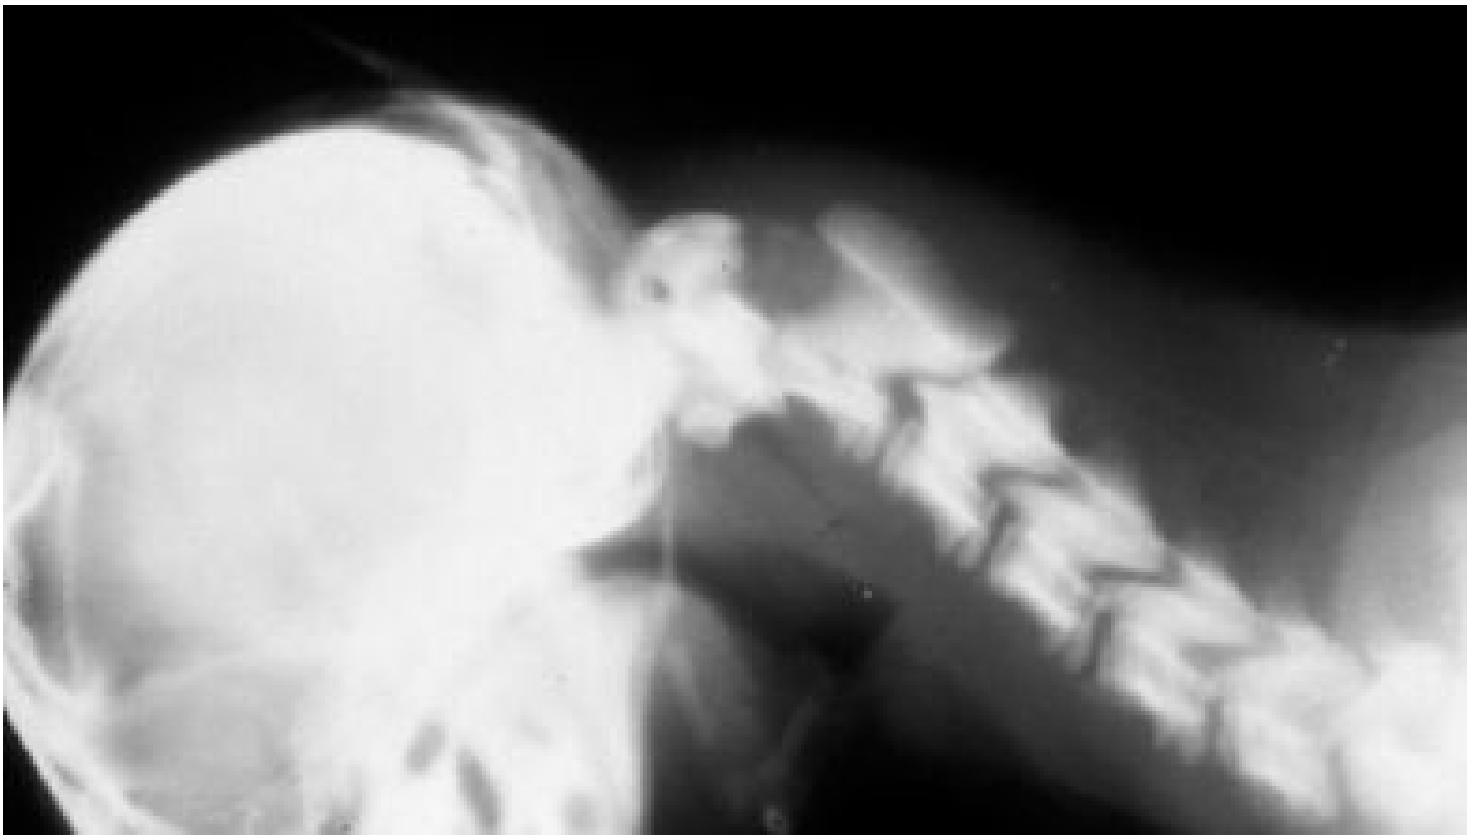

Figure 45-3. Lateral radiograph of caudal head and neck of an immature dog with atlantoaxial subluxation. Note the increased distance between arch of atlas and spine of axis.

Differential diagnosis for cranial cervical spinal cord lesions in toy breed dogs includes focal myelitis associated with canine distemper, toxoplasmosis, or granulomatous myelitis and meningitis (most often immune-mediated in the young dog). Cervical disc disease is common in the middle-aged to older small breed dog. Neoplasia is also a rare possibility.

Treatment

Treatment of atlantoaxial subluxation consists of relieving spinal cord compression by reduction and permanent stabilization of the atlantoaxial joint. This has been achieved through both surgical and

conservative methods.

Figure 45-4. Ventrodorsal radiograph of caudal head and the neck of an immature dog with atlantoaxial subluxation. Note the absence of the dens on the axis.

Surgical Management

Surgical stabilization of the atlantoaxial joint is technically demanding. The vertebrae in toy breeds are extremely small and little margin for error exists when placing implants. The bone in immature dogs is soft. Implants can break the bone, migrate out of position, or cause impingement on the spinal cord. Manipulation of the atlantoaxial joint during surgery can also cause significant spinal cord trauma with subsequent death. However, most authors have recommended surgical stabilization for atlantoaxial subluxation. In dogs, both dorsal and ventral approaches to the atlantoaxial joint have been successfully used, with the goal of permanent fixation.

Dorsal Techniques

The first surgical stabilizations of the atlantoaxial joint in dogs were performed dorsally.[1,15,16,19] They consisted of orthopedic wire or suture material (even the nuchal ligament[19]) placed through the epidural space, then over the arch of the atlas, and finally, attached to the dorsal spine of the axis. A dorsal technique using a metal retractor[20] and a dorsal technique using a combination of pins and polymethylmethacrylate[21] have subsequently been described. Surgical implants applied on the dorsal surfaces of the atlas and axis have a theoretical biomechanical advantage as they are placed on the tension side of the joint

subluxation; therefore, less implant strength is required to hold the joint reduced. Another advantage of the dorsal approach is the ease of surgical approach and the good exposure of the dorsal aspects of the atlas and axis. Complications of the dorsal techniques include resubluxation owing to suture or wire breakage or to these materials tearing through the soft immature bone. Also, life-threatening spinal cord damage may occur while attempting to pass material through the dorsal epidural space to the atlas. Dorsal surgical techniques do not allow access to the ventral articular surfaces of the atlantoaxial joint to attempt an arthrodesis. Long-term stability after dorsal procedures presumably is

attributable to fibrosis across the dorsal aspects of the atlas and axis.

Ventral Techniques

Ventral stabilization techniques are advocated by most authors. The first ventral stabilizations involved placement of two transarticular Kirschner wires from the ventral aspect of the axis bilaterally through the joint to just medial to the alar notches on the wings of the axis.[10,16] This technique allowed for curettage of the articular surfaces of the atlantoaxial joint and the placement of bone graft to promote a permanent bony fusion. The ventral technique also allowed access to the dens for odontoidectomy

procedures if necessary. More recently described ventral atlantoaxial stabilization techniques are modifications of the two-Kirschner-wire technique that often use additional Kirschner wires or bone screws in the atlas and axis.[17,22,23] The exposed ends of the Kirschner wires or bone screws are usually incorporated within a mass of polymethylmethacrylate bone cement. Other surgical methods that have been described to stabilize the atlantoaxial joint from a ventral approach include bone plating[16] and lag screw techniques.[15,16]

Postoperatively, dogs should be managed in a cervical splint (as described in the following section) to

protect the surgical fixation. Cage rest should be enforced for six to eight weeks. Radiographs may be made 8 weeks after surgery to confirm atlantoaxial alignment and progression of arthrodesis.

Conservative Management

Although most authors have recommended surgical stabilization, conservative management of atlantoaxial subluxation by use of a cervical splint has been reported,[24] and more recently advocated.[25] If a cervical splint is used, the neck must be positioned in extension to allow for healing with the atlantoaxial joint reduced. Cervical splints must be light

weight so that they are well tolerated by the pet. They may be circumferential or ventral only and should incorporate fiberglass, x-ray film, formable plastic splint material, or aluminum bars for stiffness. Cervical splints should be maintained for six to eight weeks. Radiographic evaluation should be performed prior to splint removal to confirm atlantoaxial alignment.

Restriction of activity is important to maintain atlantoaxial joint reduction and to keep the cervical splint from causing sores or loosening prematurely. Controlled, limited activity may have therapeutic value in the rehabilitation of dogs with

neurologic compromise.

The success of conservative management relies on scar tissue formation across the atlantoaxial joint. As these dogs may be at risk of resubluxation later in life, long-term exercise restriction (e.g., preventing them from jumping off furniture) should be considered.

Corticosteroids such as oral prednisone have often been used in conjunction with both conservative management and surgical management. No scientific information is currently available showing that they improve the prognosis of these patients.

Prognosis

Nonsurgical management of atlantoaxial subluxation with a cervical splint was evaluated in a retrospective study.[25] Of 16 dogs, 10 (62%) were considered to have a good outcome 12 months after removal of the cervical splint. The authors of this study suggested that dogs with an acute onset of clinical signs and no prior history of neurologic disease, young dogs with immature bone in which surgical fixation may not provide adequate stability, or dogs for which there are financial constraints, should be considered for nonsurgical management. The authors of this study did not find that severity of deficits at

admission was a reason to opt for a surgical approach.

Most authors consider surgical management the preferred treatment for atlantoaxial subluxation, especially in dogs with neurologic compromise. A 1995 review of the literature on surgical management of atlantoaxial subluxation revealed a 61% (32/52 dogs) success rate for dorsal procedures and a 62% (21/34 dogs) success rate for ventral procedures. Success was defined as improvement in clinical signs with no reported recurrence or necessity of reoperation.[2] These modest success rates have caused surgeons to strive to develop more reliable techniques to provide

permanent rigid immobilization of the atlantoaxial joint. Three more recent studies reported modified surgical techniques with a combined 87.5% (35/40) of dogs having a good or excellent outcome.

A retrospective review of 46 cases of atlantoaxial subluxation in dogs identified risk factors affecting the outcome of surgical treatmenet.[9] Age of onset of clinical abnormalities of less than 24 months was significantly associated with greater odds of a successful first surgery and outcome. Duration of clinical abnormalities of less than 10 months was significantly associated with greater odds of a successful first surgery. Preoperative

neurologic status was only marginally sensitive and specific in predicting a successful first surgery. Potential risk factors that did not affect the odds of a successful outcome include the type of surgery performed (the dorsal wire or suture technique vs. the ventral two-Kirschner-wire technique), grade of atlantoaxial joint reduction, conformation of the dens, and the need for a second surgical procedure. The long-term prognosis for dogs with atlantoaxial subluxation managed with surgery appears to be good provided the animal survives the perioperative period.[9]

Chapter 46

Intervertebral Disk Disease

Lisa S. Klopp

Anatomy of the Intervertebral Disk and Supporting Structures

Related Anatomic Structures of the Spine

The joining of two adjacent vertebrae is facilitated by several types of articulations (syndesmoses, arthroses, and amphiarthroses). The supporting

structures of the spine include the various ligamentous structures (syndesmoses), the articular facets (arthroses), and the intervertebral disks (amphiarthoses). The ligaments of the spinal column include the interspinous and supraspinous ligaments, the intertranversarious ligaments, ligamentum flava, transverse intercapital ligaments, and the longitudinal ligaments (ventral and dorsal) (Figure 46-1).[1] The intertranversarious ligaments unite the adjacent transverse processes of the lumbar spine. The supraspinous ligament is a thick ligament extending along the apices of the dorsal spinous processes from the first thoracic vertebra to the third sacral vertebra.[1]

This ligament plays an important role in preventing excessive separation of the dorsal spinous processes during spinal flexion. The interspinous ligaments blend with the interspinous muscles and connect adjacent dorsal spinous processes of the thoracic and lumbar vertebrae on midline. Some fibers from this ligament blend with the supraspinous ligament. These ligaments play a role in maintaining the relationship between the dorsal spinous processes when the spine is in flexion; however, they are not as strong as the supraspinous ligament.[1]

The transverse intercapital ligaments attach to the rib heads bilaterally by crossing the spinal canal

perpendicularly to its long axis at each intervertebral disk beneath the dorsal longitudinal ligament. These ligaments are associated with the second through the tenth thoracic vertebrae in the dog. Although present between the eleventh rib heads, the transverse intercapital ligament is much less developed there. These ligaments aid in maintaining tight opposing rib head attachments to the vertebrae at the costovertebral joints, resulting in minimal cranial to caudal movement of the rib head.[1] The presence of this additional stabilizing ligamentous structure, in addition to the rigidity of the rib cage, is believed to play a role in the small numbers of clinically significant intervertebral disk extrusions observed in the thoracic

region.

The dorsal longitudinal ligament courses along the entire length of the floor of the vertebral canal (dorsal to the vertebral body and dorsal annulus fibrosus). It is arranged as a parallel bundle of fibers that is approximately 2 millimeters or less in thickness when healthy. It is firmly attached to the dorsum of the vertebral body at its midline and fans out to blend fibers with the dorsal annulus fibrosus of the intervertebral disk.[2] Its anatomic location and relationship to the intervertebral disk allow it to help contain centrally extruded intervertebral disk material between it and the spinal cord.[2] The ventral

longitudinal ligament is a similar type of ligament that traverses the ventral aspect of the vertebral bodies. In the dog, it is thinner than the dorsal longitudinal ligament and is probably of limited significance in support of the spine.[1]

The articular facets are true arthrodial joints that posses a typical synovial joint capsule and articular cartilage on the opposing surfaces.[3] The cranial articular process of the caudal vertebra and caudal articular process of the cranial vertebra forms this joint between two adjacent vertebrae. In the cervical region, the joint is in a nearly horizontal plane and the caudal articular process lies dorsally over the

cranial articular process. In the cranial thoracic region, these joints become more perpendicular in their orientation to the longitudinal spinal axis, whereas in the lower thoracic and lumbar regions the cranial articular process is lateral to the medially situated caudal articular process. The facet joints play an important role in the stability of the spine in rotation and flexion. In extremes of spinal motion, it is not uncommon for these joints to fracture.

The Intervertebral Disk

The dog has 26 intervertebral disks excluding those found between coccygeal vertebrae. There are no intervertebral disks between the first

two cervical vertebrae or, in a normal situation, between the sacral segments. The intervertebral disk is an amphiarthrodial joint (an articulation between bony surfaces that provides limited movement and is connected by ligaments or elastic cartilage) that binds adjacent vertebral bodies.[2,3] The intervertebral disk is mechanically and structurally required to be extremely strong as it provides for protective alignment of the spinal column and withstands the various physiologic forces imparted to it. In spite of the minimal movement of this type of joint, the multiple vertebral segments impart an overall flexibility to the spine. The disks differ somewhat in size and detail between spinal regions

but are essentially identical in structural organization. The disks are widest in the cervical and lumbar area; the caudal cervical intervertebral disks are the widest disks in the dog. The intervertebral disk can be divided anatomically, histologically, and functionally into two sections: the nucleus pulposus (an internal semi-fluid mass) and the annulus fibrosus (an external layer of fibrous connective tissue) (Figure 46-2).

The nucleus pulposus develops from the embryonic notochord.[1] In neonates, it is large and contains a large number of cells of notochordal origin.[4] These cells tend to disappear with age, and chondrocyte-like cells

then predominate.[4-6] The nucleus pulposus is positioned eccentrically within the confines of the fibrous annulus pulposus. The ventral aspect of the annulus fibrosus is approximately two times the height of the dorsal annulus, thus leaving the nucleus pulposus closer in position to the spinal canal (Figure 46-2). The nucleus pulposus is composed of loose, delicate fibrous strands in a gelatinous matrix that suspends fibrocyte- and chondrocyte-like cells in an avascular environment.[7] Most of the fibers within the nucleus are not arranged in any fashion, but those closest to the vertebral endplate embed into it at an angle.

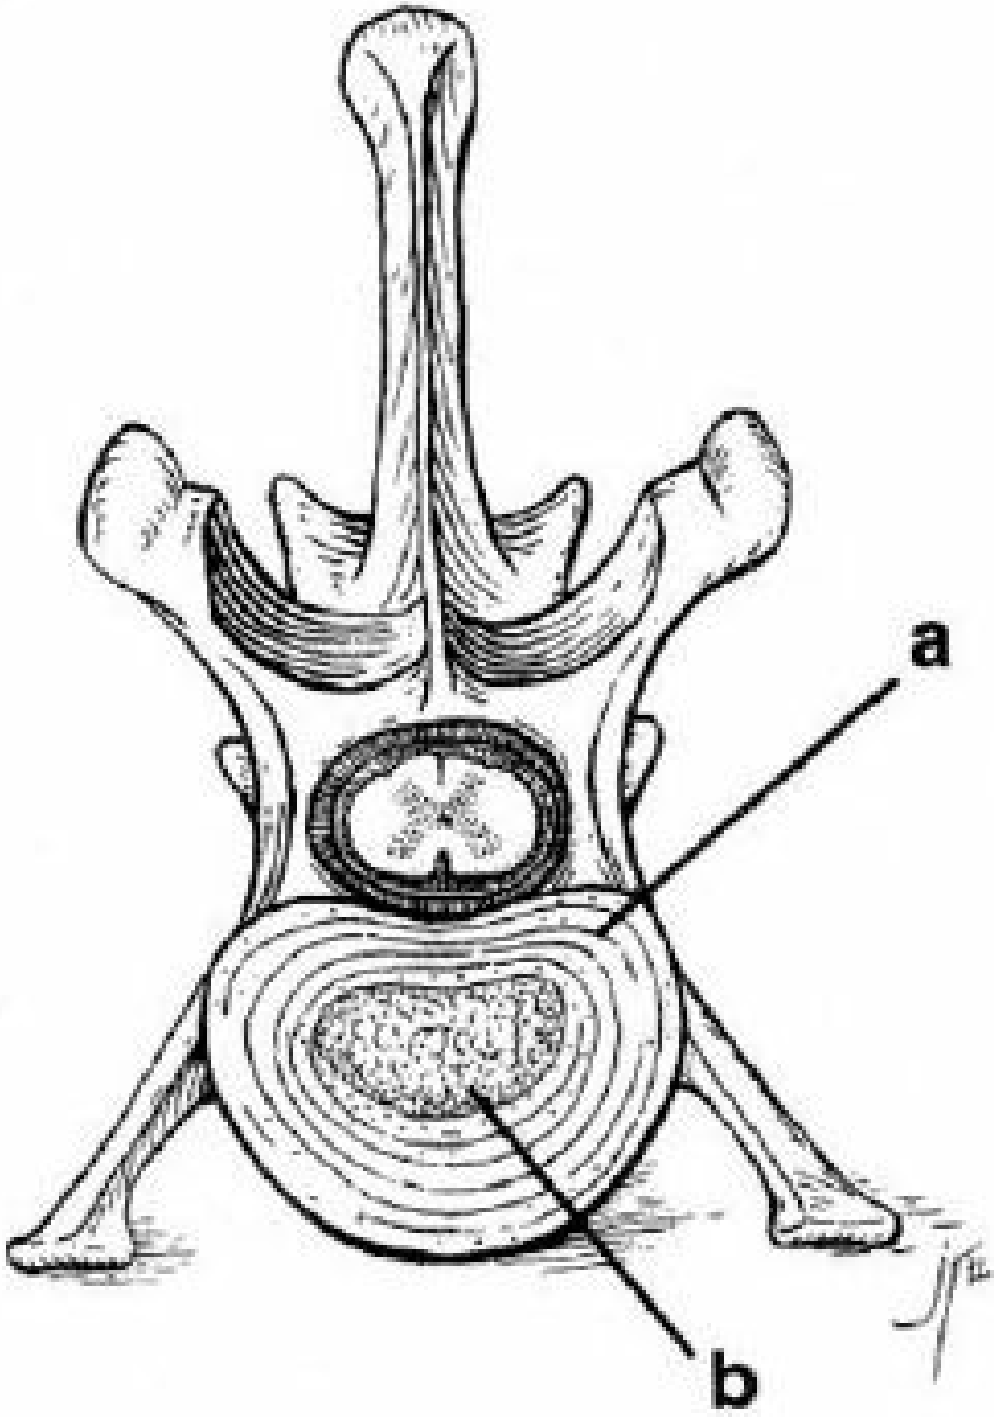

Figure 46-2. Schematic transverse drawing of a lumbar vertebra at the level of the intervertebral disk. a.annulus fibrosus; b.nucleus pulposus. (With permission from Wheeler SJ, Sharp NJH: Functional anatomy. In Small Animal Spinal Disorders: Diagnosis

and Surgery. Wheeler SJ, Sharp NJH (eds). London: Mosby-Wolfe, 1994. Illustration by Joseph E. Trumpey, North Carolina State University.)

The annulus fibrosus forms the confinement of the nucleus pulposus and strongly attaches to the adjacent intervertebral bodies. The primary cell type in this portion of the intervertebral disk has fibrocyte characteristics.[8] The cells are located between bundles of fibrocartilage that is arranged in parallel fiber bundles (lamellae) that course in oblique orientation, crossing at angles of 100 to 120 degrees to each other.[7,9,10] When cut transversely, these fibers have an appearance of concentric rings surrounding the nucleus pulposus.[7,9,10] The lamellae are thinner

and more densely packed in the dorsal aspect (closer to the spinal canal) of the annulus fibrosus. By comparison, the lamellar bands are thicker and more distinct in the ventral aspect of the annulus.[2] No definable structural interface exists between the nucleus pulposus and annulus fibrosus; their fibers blend imperceptibly in a transitional zone. In this region, the lamellae of fibrocartilage become less organized and the collagenous and cellular composition begins to change.[7] Cells in the outer annulus fibrosus are similar to fibroblasts but the cells in the transitional zone are more chondrocytic in nature.[2] This region is involved in the postnatal development of the intervertebral disk and has been

observed to be broader in immature disks from chondrodystrophic breeds of dogs.[11]

The articular surface of the vertebral body, or the vertebral endplate, is concave in its center and covered with cribriform cartilage that renders this region porous.[12] Unlike typical arthrodial joints, the surface of the endplate does not possess compact cartilage tissue between the medullary cavity of the vertebral body and the nucleus pulposus of the intervertebral disk. In this region, the bony trabelculae blend with the chondrous endplate and the fibers of the nucleus pulposus and inner lamellae of the annulus fibrosus.[13-17] Adjacent to the

central depression of the endplate, dense compact bone forms the edges of the vertebral body. This region of the endplate serves as an apophysis for attachment of the fibers of the annulus fibrosus and dorsal and ventral longitudinal ligaments.[18] The osseous outer ring provides the firmest attachment of the disk to the vertebral body where the outer lamellar bands of the annulus fibrosus (also referred to as Sharpey's fibers) penetrate it.[18-20] The outermost lamellar fibers of the annulus extend beyond the confines of the disk to blend with the vertebral periosteum and longitudinal ligaments.[1,2]

Physiology of the Intervertebral Disk

Macromolecular Composition

The major macromolecular components of the intervertebral disk are collagenous and noncollagenous proteins, proteoglycans, and glycoproteins.[7,17,21-24] Collagen forms the strong structural fibrocartilage network of the disk and anchors it to the vertebral endplates, allowing containment of the cells and extracellular matrix.[5,7,25] It is found in the highest concentration in the annulus fibrosus. The annulus fibrosus possesses mostly type I and some type II collagen; the nucleus pulposus only possesses type II collagen.[22,26,27] In

transition from the inner lamellae of the annulus fibrosus to the nucleus pulposus, the concentration of type II collagen increases and type I decreases.[27,28] The type of collagen present in each region is related to its mechanical function. Type II collagen is most suited to load-bearing functions, whereas type I collagen is better at withstanding tensile loads.[25,29-31] Other collagen types are found in much lesser concentrations within the disk.[5,28,32] Elastic fibers are also present within the disk and are oriented parallel to the collagen fibers.[5] They are found in dense concentration between the lamellae of collagen fibers and likely play a role in sliding and recoil of the lamellar fibers

during deformation.[5,33]

The proteoglycans found in the extracellular matrix are composed of glycosaminoglycans or GAGs (long chains of monosaccharides) covalently bound to a central protein core (Figure 46-3).[34-39] Aggrecan is the most abundant of these proteoglycans in the intervertebral disk.[4,27,40] The GAGs present in the intervertebral disk are primarily chondroitin sulfate and keratan sulfate.[12,24] The highest concentration of proteoglycans is found in the nucleus pulposus, which is associated with type II collagen,[41] but these proteins are also present in the intercellular matrix of the annulus fibrosus. Proteoglycans are negatively

charged macromolecular complexes. Those concentrated in the nucleus pulposus and transitional zones possess polar groups (carboxyl and sulfonyl) that convey a high degree of hydrophilicity. Binding of water to the hydrophilic groups, up to 9 times the volume of the proteins,[5,12,26,27,34,40,42,43] is responsible for the gelatinous consistency of the nucleus pulposus.[24,27] The normal intervertebral disk is highly hydrated; the water content of a young intervertebral disk is approximately 80 to 85% in the nucleus pulposus and 60 to 78% in the annulus fibrosus.[24,27] The nucleus pulposus of a young disk has seven to eight times more proteoglycan than the annulus fibrosus, and half as

much collagen.[44-46] Proteoglycan turnover varies with age, but in people, the average turnover rate is two to three years.[12,40] With age, the nucleus pulposus becomes more collagenous in structure.

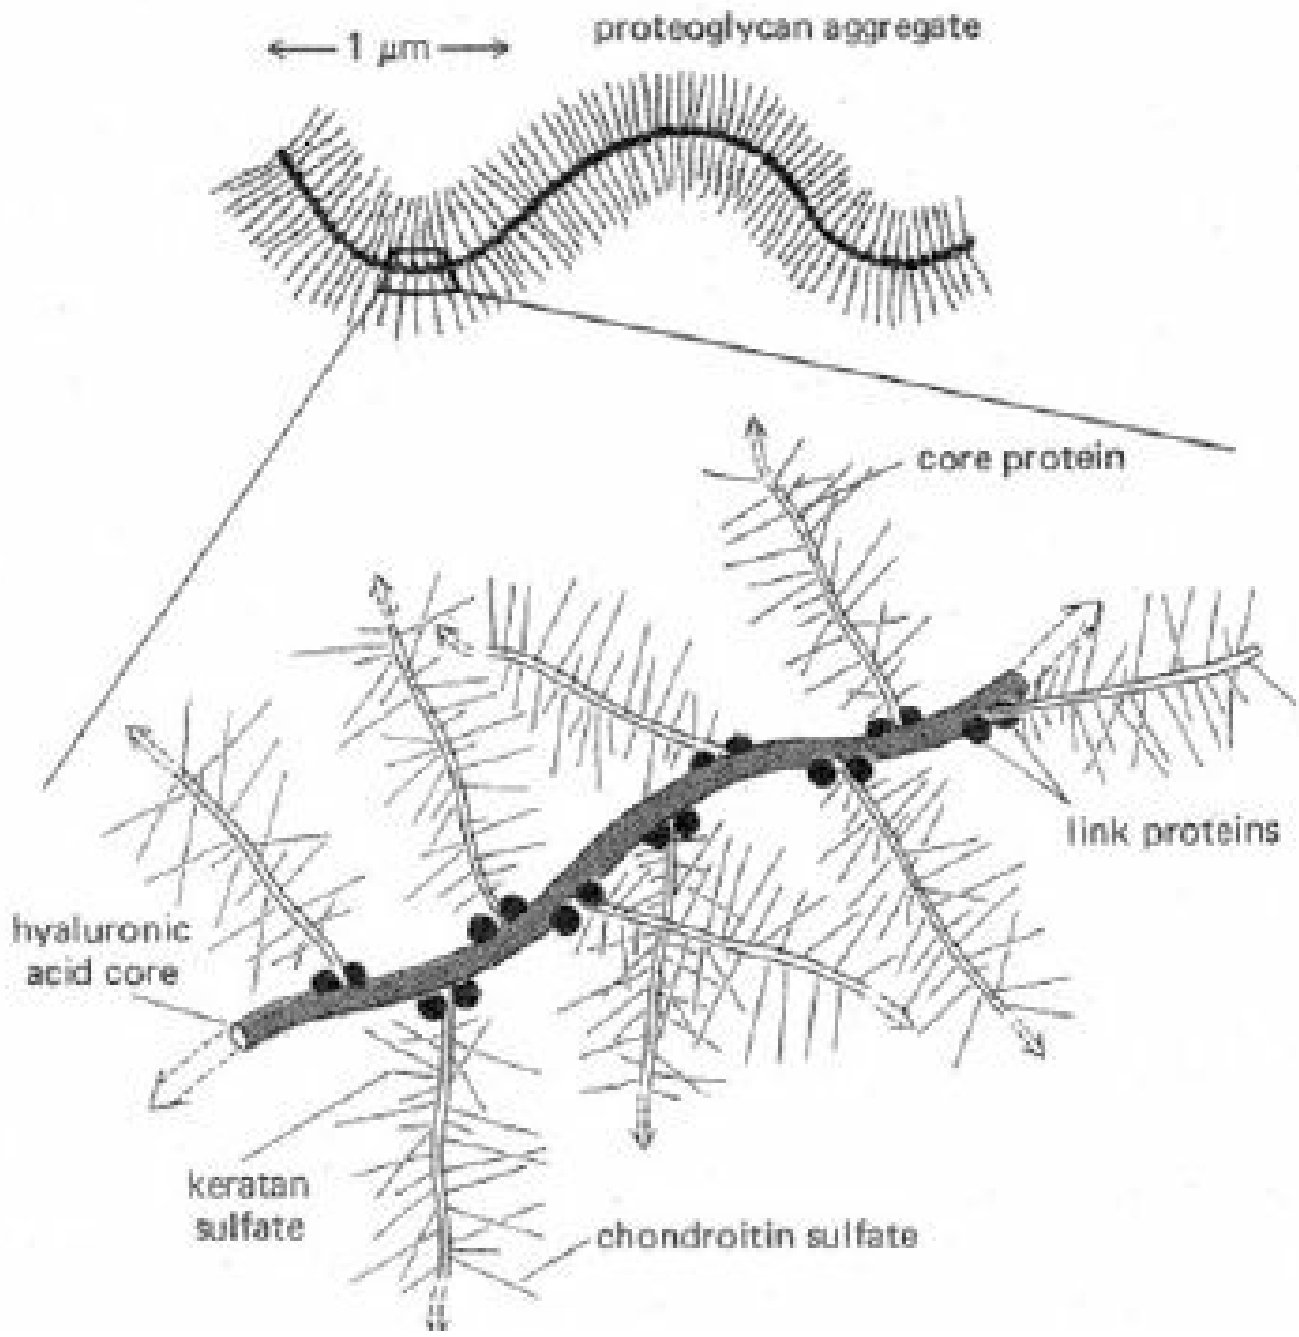

Figure 46-3. Schematic of the glycosaminoglycan aggregate and its associated molecular components. (With permission from Alberts B, Bray D, Lewis J, et al: Molecular Biology of the Cell, 2nd ed. New York: Garland Press, 1989.)

Blood Supply and Nutrition of the Intervertebral Disk

The intervertebral disk is the largest avascular structure in the body, but it is biochemically vital. It is characterized by a high rate of metabolic activity[4,47,48] and, unlike arthrodial joints that receive nutrition through synovial fluid, it receives its nutrition and disposes of metabolic waste via diffusion. Nutrition and metabolic waste product removal are brought to and from the disk, respectively, by diffusion from two sources: the bone-disk interface vasculature of the vertebral endplate, which supplies the majority of the disk, and an adjacent peripheral vascular

plexus, which supplies the outermost one to two mm of the annulus fibrosus and surrounding soft tissues.[5,16,48-52] In some instances the nutrients may need to diffuse several millimeters to parts of the disk farthest from the endplate capillary system.[5,50] The endplate arterial supply to the disk arises from the same supply as the vertebral body and drains into either a venous network or into bone marrow veins.[53] The endplate capillary system forms terminal loops that penetrate the subchondral endplate,[13,54-58] and diffusion of materials to and from the disk occur at this interface. The concentration of capillaries is highest at the center and decreases toward the periphery of the disk.[17] This

vasculature, like the systemic vasculature, is regulated by the autonomic nervous system (muscarinic receptors) and is responsive to external stimuli.[59]

Like most systems that are dependent on diffusion for equilibrium of solutes, two properties affect this diffusion: the partition coefficient and diffusion coefficient.[12] The partition coefficient defines the equilibrium of solutes between that found in the plasma and the intervertebral disk.[12] It depends on both the size and charge of the particle of interest.[12,17,60] Small uncharged solutes will be near equilibrium between the plasma and the intervertebral disk, whereas large

molecules such as albumin and lysozyme are excluded.[12,50,60,61] In regard to ionic solutes, the intervertebral disk matrix possesses a high content of proteoglycans, which behave as fixed, negatively charged aggregates.[26,34,42,43,45,60,62] The concentration of these molecules is much higher in the nucleus pulposus and inner annular lamellae compared with that in the outer annulus fibrosus.[17] Particles or solutes with positive charge diffuse easily into this region, allowing for a higher concentration of cationic particles in the disk compared with that in the plasma.[12,17,60] Negatively charged particles are repulsed by the existing overall negative charge of the disk and

tend to be in higher concentration in the plasma.[12,14,17] This differential in ionic permeability has been supported by studies on antibiotic concentrations in the intervertebral disk; negatively charged antibiotics (penicillin and cefuroxime) penetrate much less effectively than positively charged antibiotics (aminoglycosides).[61,63,64] Because of differential concentrations of proteoglycans, and thus, fixed negative charges throughout the disk, some difference may exist between the sources of diffused solutes based on the partition coefficient. Cationic solutes may diffuse more easily from the endplate interface vasculature and anions from the peripheral vasculature, whereas small uncharged

particles are equally distributed from both vascular capillary systems (Figure 46-4).[12,60]

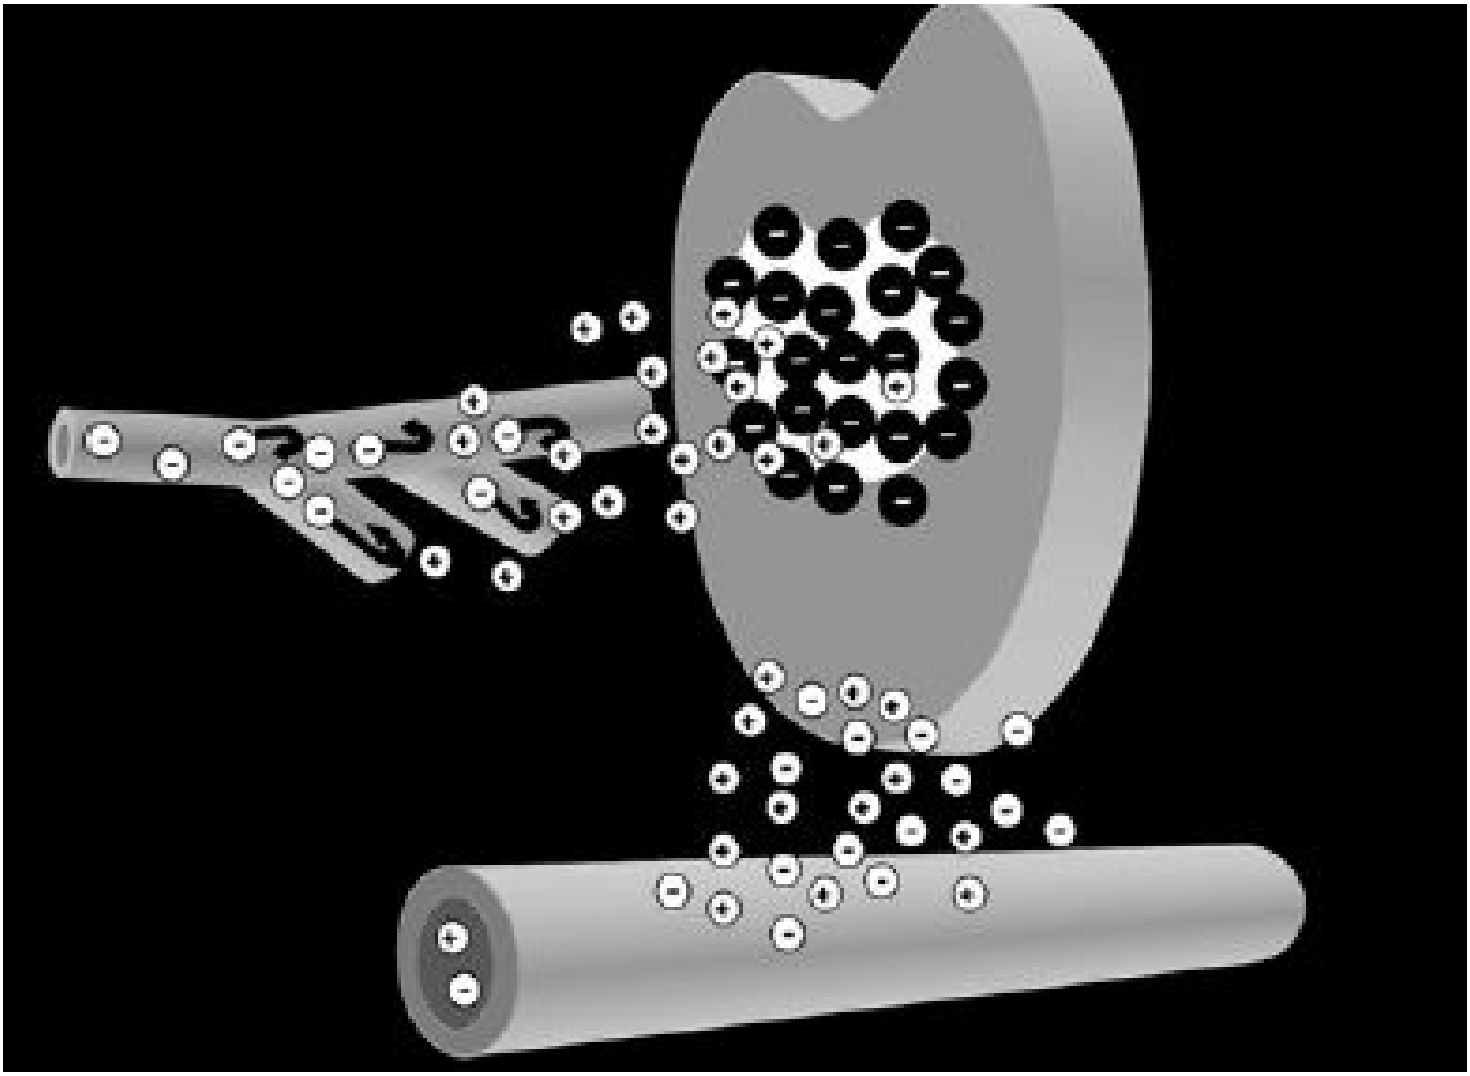

Figure 46-4. The central portion of the intervertebral disk (nucleus pulposus and inner lamellae of the annulus fibrosus) possesses a predominately negative charge owing to higher concentrations of proteoglycans. Because of the differential charge in the

inner and outer regions of the disk, the partition coefficient for charged particles differs between the peripheral vascular plexus and interface vasculature at the vertebral endplate. Cationic solutes more readily diffuse from the interface vasculature than do anionic solutes. Anionic solutes are more likely to diffuse from the peripheral vascular plexus.

The diffusion coefficient characterizes solute mobility.[12] Solute mobility is slower in the intervertebral disk compared with that in the plasma because of the presence of large compact molecules such as collagen and proteoglycans.[12] Without considering solute charge, the diffusion coefficient is 40 to 60% of that in water.[12,14] Mobility is greatest where the water content is higher, as seen in the nucleus pulposus and inner annular lamellae.[12]

Movement along the spine may provide a “pumping” action, and likely aids in diffusion of the larger molecules into the disk.[12] This “pumping action” may induce some degree of convective transport by which negatively charged and larger molecules with lower diffusion coefficients may move into the disk.[65-68] Convective transport may also aid in the movement of molecules synthesized by the disk cells.[17]

Like any organ, the intervertebral disk requires an adequate supply of nutrients and biochemical building blocks to maintain its integrity. Glucose is consumed at a high rate as the primary energy source of the intervertebral disk.[69] Because of low

oxygen concentration in the disk, anaerobic glycolysis with production of lactic acid is the primary metabolic pathway.[17,27] The intervertebral disk develops mechanisms by which to survive in an acidic environment.[27] When glucose demands are not met, disk cell vitality is adversely affected.[70-75] In addition, when lactic acid production is decreased, the increasing pH of the intervertebral disk results in reduced production of extracellular matrix components. The production and activation of proteases that breakdown the extracellular matrix is not likewise impaired.[76] Thus, the overall net effect of inadequate energy supply is impaired cellular viability and loss of extracellular

matrix components. The disk is not as dependent on oxygen supply as it is on glucose. Under hypoxic conditions, the cells become dormant and synthesis of extracellular matrix is impaired.[5,72,76,77] Long-term, however, this would result in a net loss of extracellular matrix as well.

The diffusion of molecules is regulated by the rate of metabolism leading to diffusional gradients. Gradients for oxygen and glucose exist throughout the disk, especially toward the center of the disk where concentrations are lowest.[71,72,77] For example, glucose consumption is up to 100 times greater than the rate of incorporation of sulfate during proteoglycan

synthesis.[16] The diffusional gradient for sulfate is low because it is consumed and replenished easily, whereas the diffusional gradient for glucose is steep because the concentration is low.[16] Accordingly, high cellular density in certain regions of the disk also results in steeper diffusional gradients simply by the nature of higher demand. Cell density tends to be highest where the diffusional distances are the shortest; thus, cell density is dictated by nutrient diffusional constraints.[78]

Function of the Intervertebral Disk

The primary function of the

intervertebral disk is both to contribute to protective structural alignment and to resist and redistribute stresses along the spine.[29] It must be strong enough to withstand normal physiologic loads (torsion, shear, bending, and compression)[7,10,56,79-85] and yet deformable enough to allow flexibility and mobility.[12,23,86-89] Whereas the spinous ligaments and articular facets tend to withstand torsional, bending, and shear forces, the intervertebral disk is biomechanically best constructed to withstand compressive forces.[12,23,86,88,89] The mechanical properties of the intervertebral disk are conferred upon it by its biochemical nature related to the quantity and quality of its matrix

glycosaminoglycans.[5,10,40] Altered biochemistry of the intervertebral disk alters its mechanical properties and ability to withstand axial stresses. The nucleus pulposus is anatomically situated within the intervertebral disk along the center of the axis of movement, which is the equilibrium between tension generated on the convex side and compression on the concave side when the spine is bent.[31,90-93] Because of its gelatinous make up, the nucleus pulposus behaves as a viscous fluid under applied pressure (compression) with considerable elastic rebound and return to its original position on release of the pressure. The nucleus pulposus essentially serves as a

“hydraulic shock absorber” allowing disk deformity and dissipation of forces equally over the annulus fibrosus and vertebral end plates.[23,29,31,94,95] Fluid is essentially incompressible; therefore, the internal pressure achieved during compression of the nucleus pulposus pushes the annulus out radially in a horizontal plane of distortion (Figure 46-5).[12,31,84,94-96] The annulus fibrosus itself is normally highly elastic and readily absorbs axial stresses, but it is constructed to best resist the high tensile forces generated during compression by sliding of the lamellar fibers across one another.[12,29,31,40,87,94,95] The lamellae of the annulus fibrosus are strongest when forces are generated along the

direction of its fibers and these forces, therefore, are best counterbalanced by the alternating, oblique arrangement of these lamellae.[31,84,97,98] The tensile forces are the highest in the outer lamellar layers and this is where the majority of injuries to the intervertebral disk occur.[31] Initially, the intervertebral disk is easily deformed, but as compressive force increases, it becomes "stiffer" to prevent structural collapse.[90,96,99,100] With increasing sustained compression, gradual efflux of interstitial fluid out of the disk will result in additional microscopic movement of the disk known as "creep."[96,101] This is particularly noted as a diurnal effect in people, in whom 25% of the fluid is

expressed during the day with loading and reimbibed when they sleep at night when the axial stresses are relieved.[5]

The spine is loaded both by external forces and internal forces generated by muscles (preload).[5,102] Regular movement and normal physiologic loads are necessary for extracellular matrix composition; metabolic activity of the disk cells is regulated in response to these loads.[103-109] Nucleus pulposus cells primarily respond to changes in hydrostatic and osmotic pressure, whereas the annulus fibrosus responds to tensile strains that originate from flexion or extension.[5] Dynamic compression of the spine has

been shown to result in alterations of gene expression and histochemisty within 2 hours to 1 week of loading.[110,111] Biomechanical stresses modulate the maintenance and remodeling of the connective tissue and extracellular matrix of the disk. In turn, the quality and quantity of these components are responsible for the effectiveness of these tissues to withstand these loads.[109]

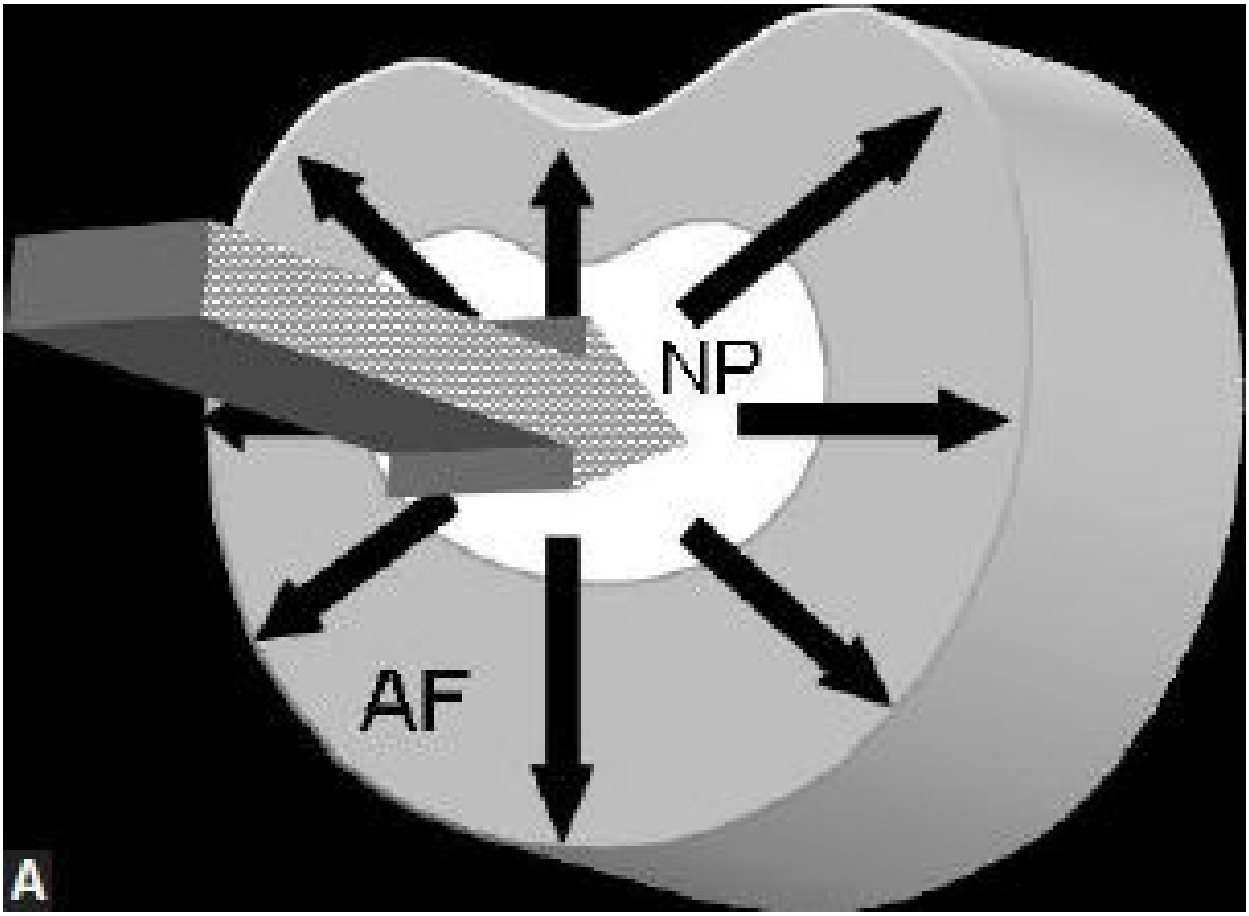

Figure 46-5A. The nucleus pulposus (NP) absorbs axial compressive forces along the spine. The nucleus is fluid by its nature and, thus, incompressible.

Aging and Pathology of the Intervertebral Disk

Degeneration is a deterioration of the physical properties of a tissue with changes in cellular function and tissue

content that result in destruction or inhibition of function. Degeneration is an ultimate consequence of aging. Although aging is the most common cause of tissue degeneration, genetics, nutrition, and external factors (i.e., lifestyle) also play a role.[50,59,112-123] Aging and degeneration of the intervertebral disk usually occur in parallel and may be a continuum of the same process.[17,27,124] Distinguishing aging from degeneration is difficult; separating these two processes may be the key to understanding degenerative changes that are not age-related.[17,25,27,124] With degeneration, alteration of the intrinsic structure, biochemical characteristics, and cellular function and apoptosis

ensues.[27] The biochemical and biomechanical alterations that occur lead to further progression of degeneration of the intervertebral disk.[38,125-130]

Although the cellular component is only about 1% of the disk composition,[5] these cells are responsible for the production and maintenance of all the macromolecules. Not only do they produce the extracellular matrix, but they also produce enzymes that break it down. In the healthy disk, the rates of synthesis and catabolism are in equilibrium.[5] Matrix degradation occurs when the rate of production decreases and/or rate of breakdown

increases.[5] With a limited cell density, it is not surprising that the cells cannot maintain the health of the disk indefinitely. Degeneration is associated with both an alteration in cellular activity and celluar density.[124,131] The chondrocytic cells change the characteristics and decrease the synthesis of new extracellular matrix components.[132,133] Initially, clusters of cells involved in a reparative process may be present within the disk, but cells undergo limited cell division.[17] As degeneration progresses, cells undergo both apoptosis and necrosis.[17,134,135]

Several cytokines have been implicated in intervertebral disk degeneration. The role of cytokines in health and in

the cause or effect of degeneration of intervertebral disks is not yet understood. Implicated cytokines include tumor necrosis factor (TNF), interleukin-1a and 1b (IL-1), vascular endothelial growth factor (VEGF), nerve growth factor (NGF), and matrix metalloproteinases (MMPs). Ingrowth and proliferation of nerve fibers,[136] endothelial cells,[137,138] and fibroblasts have been observed in relation to the degenerative disk, suggesting that biochemical events are occurring that have autocrine and paracrine effects.[25] Expression of VEGF has been demonstrated in the intervertebral disk.[139] Synthesis of NGF by vessels growing into the disk has been demonstrated,[25] suggesting that the

neovasculature is influencing the ingrowth of nerve fibers. IL-1 has been shown to be involved in cartilage homeostasis[140] and is associated with a switch from anabolic to catabolic metabolism in the chondrocyte.[141,142] IL-1 has been shown to regulate angiogenesis, potentially by activating VEGF.[143,144] It has also been implicated in both the initiation of extracellular matrix degeneration and pain associated with disk disease.[145] The release of prostaglandins involved with the mediation of pain, such as prostaglandin $E2_{\alpha}$($PgE2_{\alpha}$), and production of degradative enzymes, such as matrix metalloproteinases (MMPs), have been shown to be increased under the influence of IL-

1b.[145] Concentrations of interleukin-6 (IL-6) and $PgE2_{\alpha}$ were shown to be higher than normal in culture of herniated disks.[145] The stimulus for production of these cytokines has not been identified. In cartilage, these molecules may be intermediaries in the suppression of proteoglycan synthesis by interleukin-1 (IL-1),[146] promoting a net loss of proteoglycans. Conversely, IL6 is a tissue inhibitor of MMP (TIMMP) in articular cartilage and may actually serve a protective role by inhibiting matrix degeneration.[147]

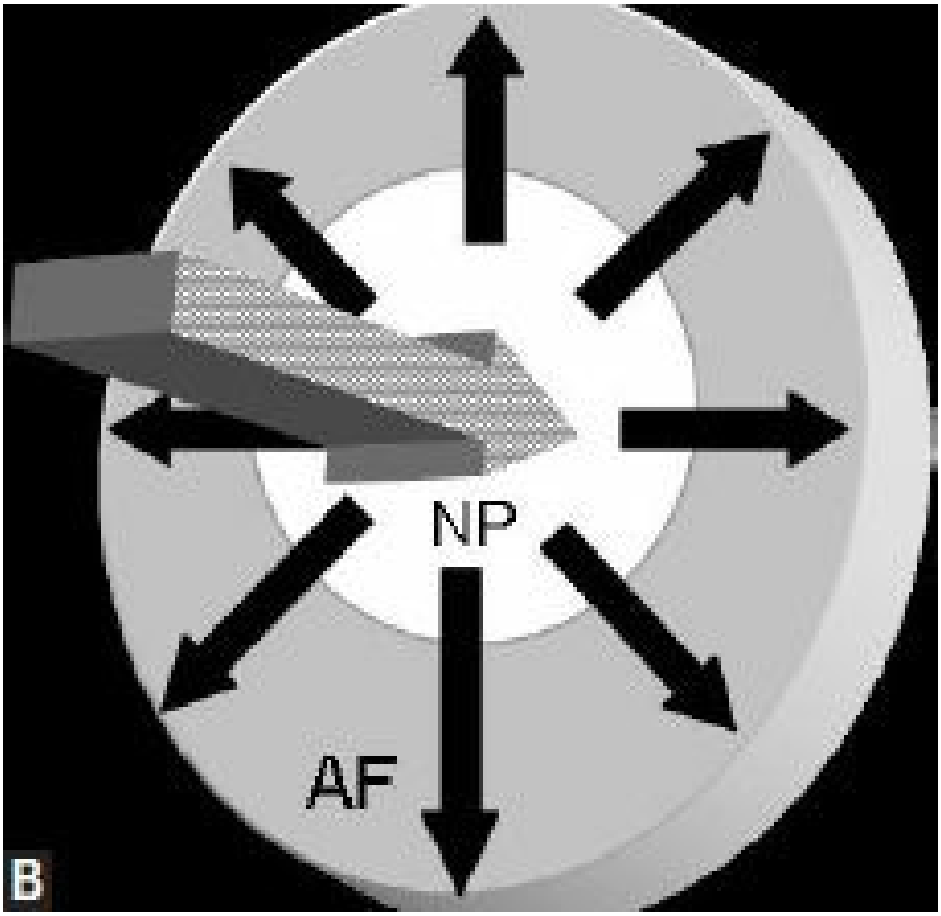

Figure 46-5B. The nucleus (NP) transmits the forces radially across the disk to the annulus fibrosus (AF) which is elastic and can expand to accommodate the tensile forces.

Interest has been intense over the last 10 years in the role of matrix metalloproteinases (MMPs) in degenerative joint disease. Less is known about their role in intervertebral disk metabolism and

degeneration; however, herniated disks cultured in vitro have been shown to produce relatively high levels of MMPs, primarily gelatinase and stromelysin (which degrade gelatin and the core proteins of proteoglycans, respectively).[145,148-153] Matrix metalloproteinase expression is highly regulated by cytokines and proinflammatory mediators such as TNF, IL1, IL8, and prostaglandins.[151,154-156] The exact role of MMPs is not known, but they have been shown to be involved in the inflammatory cascade and may play a role in radiculopathy and disk matrix degeneration. This is especially true of disk matrix proteoglycans.[151] Because the production of these enzymes in

normal intervertebral disks is low, MMPs may also play a role in disk maintenance by acting as a stimulus to remodel and by partially resorbing herniated disk.[151] One problem with previous studies evaluating MMPs is that healthy "control" disk material was not compared with degenerative herniated material.[149,157] Two possibilities exist for the production of MMPs during intervertebral disk degeneration: 1. degenerating disks make more matrix degenerative enzymes and cytokines, resulting in breakdown of the disk matrix; or 2. the herniated disk itself stimulates the production. However, it is possible that both events are concurrent. The degenerative cells may be

biochemically altered, which is followed by disk herniation, which further promotes the production of matrix degenerative enzymes and cytokines.[151]

Many macromolecular changes occur with normal aging and with degeneration of the intervertebral disk. Some of these changes are likely "preprogrammed" events during development such as loss of notochordal cells, mesenchymal apoptosis, and loss of the congenital vasculature.[27] With these events, the characteristics of homeostasis within the disk change dramatically.[27] The most significant of these in aging and degeneration of the disk are alterations

in the structure and function of the proteoglycans and collagens. Alterations in these macromolecules subsequently lead to loss of hydration and impairment of biomechanical function of the disk. As the disk ages, aggrecan is proteolyzed by matrix metalloproteinases and cleaved by free radicals,[23] and its concentration decreases within the disk.[23,158] This is particularly prominent in the nucleus pulposus.[159] In addition to proteolysis of aggrecan, the chain length of chondroitin sulfate is shortened on the proteoglycan, and a shift occurs from chondroitin sulfate to keratan sulfate as the predominant glycosaminoglycan.[127] The synthesis of chondroitin sulfate, but not keratan

sulfate, requires oxidation of glucuronic acid. The alteration in chain length and ratio of these GAGs may reflect decreased supply of oxygen as the disk grows in size and the nuclear cells move farther away from the vasculature.[160] With degeneration, loss of nutrient and oxygen supply to the disk results from altered diffusion through the endplate, further contributing to the altered GAG ratio. It is the aggregate negative charge of the proteoglycans and their GAGs that maintains adequate hydrostatic pressure within the disk. Proteolysis results in a high concentration of nonaggregating proteoglycans that are too large to diffuse from the disk.[7,27] These retained nonaggregating

proteoglycans may still contribute to the hydrostatic pressure of the disk, but are not as functional.[5,7,27] Therefore, the disk, losing as much as 20% of its water content, becomes dehydrated and the disk height decreases.[7] In addition, there is an increase in collagen type II production in the nucleus pulposus,[161,162] with more relative decreases in water and proteoglycan content.[132] The nucleus begins to become more fibrocartilaginous in structure and less distinct grossly from the annulus fibrosus. The fluid-like behavior of the nucleus pulposus transforms into more solid-like properties,[163] and the function of the nucleus pulposus in dissipating compressive forces fails.

Collagenous tissues change structure with age, wear, and time.[25] As the disk collagen ages, collagenase damages the fibrillar collagen.[132,164] Damage to the collagen increases with age and becomes more extensive. Accumulation of these damaged fibers reflects the slow metabolic rate and repair of collagen in the intervertebral disk.[27,132,164] Damaged collagen fibers fray and fibrillate,[114] resulting in loss of lamellar organization.[124] In addition to collagen damage, the fibril diameter tends to increase over time by cross-linking via glycation.[23] Thickening of the fibrils results in impaired sliding of the lamellae and adversely affects the biomechanical properties of the disk.[165] As these injuries accumulate

over time, the mechanical strength of the disk eventually weakens.[27] With the concurrent degenerative changes in the nucleus pulposus, the annulus bears higher percentage of the compressive forces than normal, further contributing to injury.[25,166] Both radial and concentric fissures begin to develop, and the disk may bulge. With progressive degeneration and injury, the annulus may eventually fail and collapse.[7,167] Microfractures in the vertebral endplate also occur and may actually precede the disk pathology as a consequence of increased intradiskal pressure and altered nutrition.[20,167-169]

Alterations in normal motion and mechanical loading of the

intervertebral disk may also play a role in accelerating degeneration.[40,102] The cells can exhibit both catabolic and anabolic responses depending on type, magnitude, duration, and localization of the forces exerted on the intervertebral disk. With low to moderate magnitude of static compression, anabolic activity increases in the inner AF and NP. For example, normal tensile forces have been shown to induce type I collagen synthesis,[10,162] promoting maintenance of disk function. Abnormal intradiskal pressures, either too high or low, have a catabolic effect, inhibiting prostaglandin synthesis and increasing synthesis nitrous oxide and matrix metalloproteinases.[10170] Most likely,

magnitudes and frequencies of forces exist that are physiologically healthy for each cell type within the intervertebral disk to promote maximal biosynthesis and repair.[102,171]

The effects of both overload and immobilization have been studied by Stokes et al.[102] In vitro motion segment testing revealed that annular tears can occur with both excessive static or repetitive loading.[172,173] The annulus fibrosus is damaged by both fiber disruption and separation of lamellar layers. Multiple fissures and microfailure occur before complete failure. Periods of static compression induced changes in the cell synthesis and gene expression for collagen, PGs,

and proteases as well as increased cellular apoptosis[161,174-181] Overload to the spine results in "wear and tear," with localized trauma to the intervertebral disk, which is difficult to heal because of slow metabolic turnover.[7] Accumulation of injury continues to weaken the disk until its ability to repair is overcome by recurrent injury.[182] Conversely, hypomobility may not necessarily be beneficial for the intervertebral disk. Most of what is known about hypomobility of joints has been studied in articular cartilage and is not yet proven for the spine.[102,183-188] Stokes et al[102] postulated that hypomobility will also lead to degeneration of the intervertebral disk. In a state of

hypomobility, the stimulus to cellular activity is altered as is transport of nutrient metabolites, which alters the viability of the disk.

Both hypermobility and hypomobility may occur in the early and late stages of disk degeneration, respectively. Degeneration initially results from increased movement and excessive loading, which ultimately leads to pain, resulting in tissue stiffening owing to limitation of motion. People with low back pain develop altered muscle activation patterns that change the physiologic loading of the spine, which ultimately results in even more axial compression and shear loading.[189] Altered muscle activation

patterns with resultant change in forces generated on the intervertebral disk likely occur in animals as well, as evidenced by abnormal postures (e.g., kyphosis).

Adequate blood supply is necessary for continued health of the intervertebral disk; derangements in nutrient supply are associated with disk degeneration.[17,50] The integrity of the vasculature is affected by both aging[115,190] and injury.[115,21190] Blood and nutrient supply to the disk may be affected in several ways. Diseases that may block blood flow through the vasculature, such as atherosclerosis[118,120] and thrombotic disorders,[113,117] have been associated

with degenerative disk disease. Other factors observed in people such as smoking[50] and chronic exposure to vibration[59] (such as long-haul trucking) may impair the vasculature by affecting muscarinic receptors[191] and are shown to have an association with higher incidence of disk degeneration. 0In addition, the thickness of the vertebral endplate diminishes with age and becomes calcified.[25,27,94,192,193] Sclerosis of the subchondral bone and vertebral endplate calcification alters the permeability of the endplate and has been associated with degenerative disk disease.[73,192] It is not known, however, if these endplate changes precede or are a part of the degenerative process.[17] As the

intervertebral disk becomes dessicated, the relative content of proteoglycan increases and the movement of solutes becomes even more restricted, setting up a vicious cycle of loss of nutrition.[17]

Degenerative Disk Disease of the Dog

In the dog, morphologic and physiologic changes in the intervertebral disk have been divided into two categories: Hansen's type I and type II. Hansen's type I disk degeneration is associated with chondroid metaplasia, which is characterized by extracellular matrix degeneration, peripheral and central mineralization of the nucleus pulposus,

and cellular death.[11] These changes are biochemically associated with a 40 to 50% decrease of proteoglycan and reversal of the chondroitin sulfate: keratan sulfate ratio. Decreased GAG content results in decreased water imbibition by the disk and loss of properties of "shock absorption" and deformability.[2,22,46,194,195] The annulus is then subject to increased loading by axial pressures. Failure of the mechanical properties of the nucleus pulposus results in dysfunction of the annulus fibrosus, causing fissures and displacement of the nucleus pulposus.[2] Alternatively, it is possible that the changes in the annulus pulposus are primary rather than secondary. It is theorized that an increased proteolysis

of type I collagen and elastin leads to the weakening of the annulus pulposus.[2] Hansen's type I disk degeneration is associated frequently with massive extrusion of nucleus pulposus material and dorsal annulus pulposus (Figure 46-6). Hansen's type I disk material consistency ranges from soft and cheesy to firm with a granular appearance (mineralization). Historically, the period of time over which the disk extrusion occurs in the clinical setting varies from acute to slowly progressive.

Hansen type I intervertebral disk disease is primarily seen in chondrodystrophic breeds of dogs.[2] The breed most commonly affected with

this form of disk degeneration by far is the dachshund, with a relative risk[12] six times greater than any other breed.[196] Other affected breeds include the Shih tzu, Lhasa apso, Pomeranian, beagle, poodle, Basset hound, Cocker spaniel, and the Welsh corgi. However, other less commonly considered breeds appear to have similar changes. For example, the author has seen many Dalmatians with this form of disk pathology, particularly in the cervical disks. In these breeds, the aging pattern of the interverteberal disk is different from that found in Hansen's type II disk degeneration. Degeneration of the disk may start as early as four months of age and is usually complete by 12 to18 months.[2]

Mechanical properties of the disk are usually decreased by two to three years of age, about the time when clinical signs first occur.[2] Although disk degeneration is seen in dachshunds as old as 13 to15 years of age, most animals are between two and eight years of age when clinical signs first occur. Although the older dog probably has disk degeneration, the change in the disk may reach a stage where the intradiskal pressure is so low that the annulus is no longer affected.[2] Genetics have been shown to play a role in the disease in the beagle and dachshund.[2] In dachshunds, intervertebral disk disease is thought to be governed by polygenetic, nondominant, factors that are not sex-

linked.[197] Environmental factors such as life-style and nutrition probably play a role.

Hansen's type II IVDDz is most commonly seen in nonchondrodystrophic dogs and is an aging change that results in fibroid metaplasia of the intervertebral disk, particularly the nucleus pulposus.[2] This type of degeneration is more similar to the aging and degenerative changes in the intervertebral disk commonly observed in people. The disease is usually seen in middle-aged-to-older large breed dogs but any nonchondrodystrophic breed is susceptible to type II disk disease.[2] Even chondrodystrophic breeds may

develop this type of disk degeneration with advancing age. As the intervertebral disk ages, the nucleus pulposus is gradually replaced by more mature fibrocartilage (fibroid metaplasia), and eventually the difference between the nucleus pulposus and the annulus fibrosus is difficult to determine grossly. The disk eventually changes in its biochemistry to possess lower GAG levels.[2,47,124] Mineralization of the disk is uncommon in this type of degeneration. Typically, type II disk disease is associated with a partial rupture (fissures) in the dorsal annulus. This is observed as a herniation (or bulging) of the dorsal annulus.[2] Although massive ejection of the

nucleus pulposus is not considered to be part of the disease process, acute rupture with concussive spinal cord injury is possible. Typically, when this occurs and surgery is performed, the material removed from the spinal canal is more ligamentous and similar to the annulus fibrosus in appearance.

The pathogenesis of spinal cord injury with intervertebral disk extrusion is associated with both concussive and compressive forces. Although compression secondary to extrusion is associated with some degree of concussion, concussive injury does not always result in compression of the spinal cord. In the author's experience, concussive disk extrusions without

significant compression are seen most commonly in poodles and Cocker spaniels. Paucity or complete absence of disk material has been observed by many surgeons during surgical intervention.

The velocity and force of the intervertebral disk extrusion is the single most important factor responsible for irreversible paraplegia. In experimental spinal cord injury, it is the magnitude of the force of the injury (=/> 400 g/cm) that produces irreversible changes.[198] The the sequelae of the concussive event are hemorrhage, ischemia, and vascular spasm.[198] This results in release of potent inflammatory mediators, as

well as iron and propagation of ischemia with a final common pathway to the production of oxygen free radicals.[198] These biochemical events induce an inherent, progressive autodestruction of the spinal cord.[198] These autodestructive processes may continue for 24 to 48 hours[198] and are probably responsible for those animals that are presented for surgery within a few hours of onset with good deep-pain response and wake from anesthesia without a deep-pain response. When these autodestructive processes are not limited to a focal area of injury, they may continue in both directions from the injury and result in ascending/descending myelomalacia. Impacts of lesser

magnitude and rate often produce more transient dysfunction and are associated with reversible changes.[198] Improvement in these cases is probably secondary to resolution of edema, hemorrhage, demyelination, and ischemia.

Compression of the spinal cord may result in a grossly swollen, indented, flattened, or atrophied spinal cord, depending on the duration of the compression. Adherence of disk material to the dura is sometimes observed with chronic lesions. Extensive epidural and/or subdural hemorrhage may be present with highly concussive disk extrusions. The disk material may migrate over one to

two vertebral bodies. Microscopic changes in the spinal cord depend on the force of disk extrusion and duration of compression. Severe concussion of the cord will result in edema, inflammation, and focal and multifocal hemorrhage and malacia in the gray and white matter.[199-221] Astrocytosis and skeletonized trabeculae of blood vessels are observed in old malacic lesions.[200,206-227] Chronic compression is associated with demyelination, remyelination, Wallerian degeneration, and focal areas of ischemia.[200,206-227] The pathomechanisms of spinal cord compression are discussed in depth in Chapter 42.

Clinical Signs of Intervertebral Disk Disease

Clinical signs associated with intervertebral disk disease depend on both the location (lesion localization) and the degree and severity of disk extrusion. One of the earliest clinical signs of intervertebral disk disease is pain. The origins of pain associated with disk disease are presented in the following section. Neurologic abnormalities occur either concurrently or may follow pain when intervertebral disk extrusion results in compression and concussion of the spinal cord. Determining the localization of a neurologic lesion is important for choosing the appropriate

clinical diagnostic tests, list of differential diagnoses, and occasionally, prognosis. Lesion localization can be divided into four anatomic spinal cord syndromes: C1-C5 (cervical), C6-T2 (cervicothoracic), T3-L3 (thoracolumbar), and L4-S3 (lumbosacral). Clinical signs of spinal cord disease can be divided into anatomic syndromes because, in general, the clinical signs are similar for lesions inclusive in these spinal cord segments. This is because of the location of the lower motor neurons supplying the thoracic (C6-T2) and pelvic limbs (L4-S3). Not all of the clinical signs (neurologic deficits) will be present in each case. The signs associated with each syndrome can be

found in Tables 46-1 through 46-4.

No evidence exists that trauma plays a role in the pathogenesis of intervertebral disk extrusion; however, clinical signs may be precipitated by a seemingly minor trauma or normal activity. Many dogs that become acutely paralyzed with Hansen's type I thoracolumbar intervertebral disk extrusions have a recent history of jumping off a piece of furniture. Trauma is not necessary, however, for clinical signs to occur. Significant trauma is usually required to cause extrusion (rupture) of a healthy disk. This has been most commonly observed by the author in animals that have been hit by motor vehicles or have run

head first into a solid immovable object (i.e., tree or wall).

Approximately 70% of intervertebral disk extrusions are between T11-12 and L2-3. C2-3 is reported to be the most common location of cervical intervertebral disk extrusions,[2] but extrusion is seen commonly in all cervical disks up to C6-7. C7-T1 extrusions do occur but are rare. Dogs are less likely to be neurologically affected with cervical disk extrusions compared with thoracolumbar intervertebral disk extrusions unless they are severe and/or acute. Advanced imaging, such as computed tomography or magnetic resonance imaging, has helped to identify severe

compression of the spinal cord (e.g., disk material filling 75% of the canal) when the only clinical sign the dog displays is unremitting cervical pain (Figure 46-6). Dogs with thoracolumbar disk extrusions are more likely to show neurologic deficits than are those with cervical disk extrusion, but dogs may have significant compression of the spinal cord and show only spinal pain clinically.[228] Cervical and lumbar disk extrusions in the intervertebral foramen can result in radiculopathy and nerve root signature as the only clinical sign.

Pathogenesis of Pain

Associated with Intervertebral Disk Disease

Animals with acute intervertebral disk extrusion are almost always in pain. This differentiates disk extrusion from fibrocartilagenous emboli, which are almost never associated with persistent pain. Pain associated with disk disease in the thoracolumbar region is usually manifested by a kyphotic posture. A dog with pain from cervical disk disease will often keep its neck flexed with the nose pointed to the ground and roll the eyes upward when spoken to or encouraged to move. Because of the low head carriage, these animals may also appear to have a kyphotic posture. Pain may be elicited by

palpation of the neck and cervical spine manipulation, such as lifting the head or turning the neck laterally. Pain often decreases in intensity over time and with the use of analgesics or anti-inflammatory medications. Animals with Hansen's type II disk extrusions are often not in overt pain or may not be experience pain on spinal palpation if the lesion is chronic.

Table 46-1. Clinical Signs of C1-C5 (Cervical) Syndrome

Signs	Comments
Mentation	Normal
Gait	May be ataxic in all 4

	limbs, or just in pelvic limbs if compressive lesion is very mild May be weak or paralyzed in all 4 limbs (tetraparesis/ tetraplegia) or in the ipsilateral limbs on one side (hemiparesis/plegia) if a lesion is affecting only one side of the spinal cord (uncommon)
Postural reactions	Hopping may be decreased to absent in all

	4 limbs or in the limbs on the side that is ipsilateral to the lesion (uncommon) Conscious proprioception may be decreased to absent in all 4 limbs or any of the limbs
Spinal reflexes	Limb tone is normal to exaggerated (spastic) Myotatic reflexes are normal to exaggerated (hyperreflexic) in all 4 limbs

	Crossed extensor reflexes may be elicited in all or any of the limbs
Pain	Painful diseases include: intervertebral disk disease, vertebral neoplasia, diskospondylitis, osteomyelitis, meningomyelitis, trauma/fracture, spinal cord neoplasia (+/-), and vertebral anomalies (+/-)

	Nonpainful diseases include: vascular injuries (i.e., FCE), spinal cord degenerative diseases, neoplasis, and vertebral anomalies
Urinary incontinence as seen in table 46-2	Spinal cord neoplasia, and vertebral anomalies
Horner's syndrome	If present, usually partial*

Respiratory difficulties	May occur with severe lesions (breathing maintained by diaphragmatic muscles; the chest wall muscles are weak or paralyzed from injury to descending motor axons from the respiratory center in the medulla)** Loss of diaphragm function may occur with lesions in the mid-cervical region (C4)

***Partial Horner's signs are usually anisocoria and occasionally mild enophthalmos. These signs are attributed to injury of the lateral tectotegmental spinal tracts that carry information from the posterior hypothalamus (which exerts excitatory activity on the sympathetic nervous system) through the brain and cervical cord to the preganglionic nerve cell bodies in the thoracic spinal cord. Usually these signs are observed in only severe cases of C1-5 syndrome (e.g., acute tetraparesis/plegia).**

**** Usually these signs are observed in only severe cases of C1-5 syndrome (e.g., acute tetraparesis/plegia).**

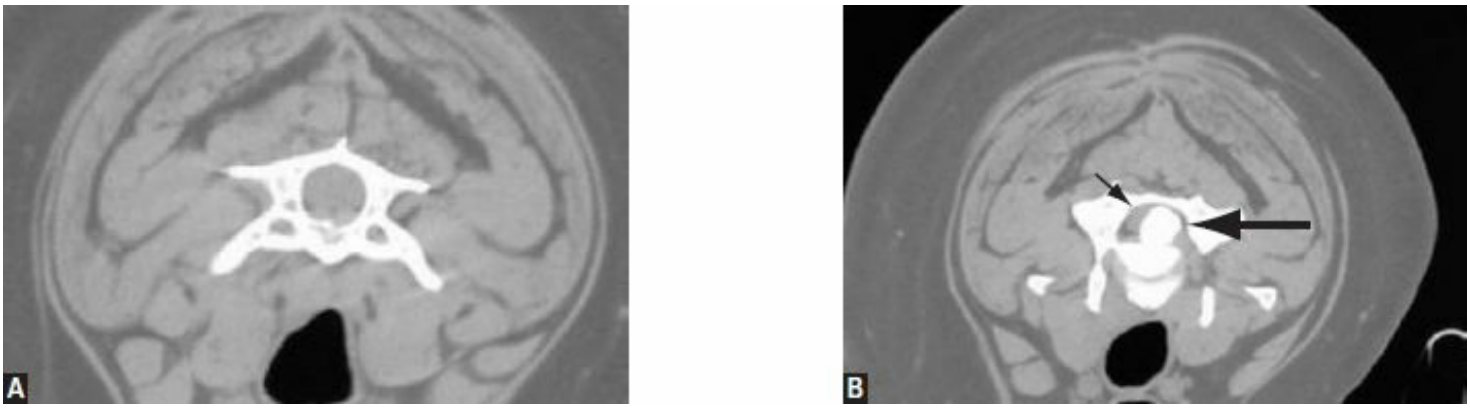

Figure 46-6. A. Computed tomographic image (uncontrasted) of a normal vertebral canal and spinal cord; B. massive Type I disk extrusion (large arrow)

has severely compressed the spinal cord to about 20% of its normal diameter to the left of the disk (small arrow).

Table 46-2. Clinical Signs of C6-T2 (Cervicothoracic) Syndrome

Signs	Comments
Mentation	Normal
Gait	May be ataxic in all 4 limbs, or only in pelvic limbs if compressive lesion is very mild May be weak or paralyzed in all 4 limbs

	(tetraparesis/ tetraplegia) or in the ipsilateral limbs on one side (hemiparesis/ plegia) if a lesion is affecting only one side of the spinal cord (uncommon)*
Postural reactions	Hopping may be decreased to absent in all 4 limbs or in the limbs on the side that is ipsilateral to the lesion (uncommon) Conscious proprioception may be decreased to

	absent in all 4 limbs or in any of the limbs	
Spinal reflexes	Thoracic limbs	
	Muscle tone is decreased (hypotonic) to absent (flaccidity)**	
	Myotatic reflexes are decreased (hyporeflexic) to absent (areflexic) in the thoracic limbs (some or all reflexes)	

May have neurogenic muscle atrophy (chronic)

Pelvic limbs

Muscle tone is normal to exaggerated (hyperreflexic)

Myotatic reflexes are normal to exaggerated (hyperreflexic)

Muscle atrophy is not present unless the animal is paralyzed and has disuse atrophy

Panniculus reflex may be decreased to absent on the ipsilateral side or on both sides from a lesion in the T1-2 area (the motor component of this reflex) with normal sensation along the back

Crossed extensor reflexes may be elicited in the pelvic but not thoracic limbs

May have decreased to

	absent deep pain response in all 4 limbs
Pain	Painful diseases include:
	intervertebral disk disease, vertebral neoplasia, diskospondylitis, osteomyelitis, meningitis, trauma/fracture, spinal cord neoplasia (+/-) and vertebral anomalies (+/-)

	Nonpainful diseases include: vascular injuries (i.e., FCE), spinal cord degenerative diseases (degenerative myelopathy), spinal cord neoplasia, and vertebral anomalies
Urinary incontinence	Upper motor neuron bladder (uncommon unless the signs are severe, i.e., tetraplegia)
Horner's	If present, usually partial

syndrome	if the lesion is cranial to T1***
	May have a complete ipsilateral Horner's syndrome if the lesion is in the T1-2 region
Respiratory difficulties	May occur with severe lesions (breathing maintained by diaphragmatic muscles; chest wall muscles are weak or paralyzed from injury to descending upper motor neuron

axons from the respiratory center in the medulla)

---

* **Occasionally an animal will display postural reaction deficits in just one thoracic limb and both pelvic limbs.**

Caudal cervical lesions such as vertebral malformation/malarticulation may have some signs similar to C1-C5 lesion (spasticity in the thoracic limbs), but when carefully examined significant weakness in myotatic biceps brachii and withdrawal reflexes with spasticity in triceps muscle tone are observed. Mild C6-T2 lesions (e.g., disk herniation) may appear similar to a C1-C5 lesion (normal reflexes). The ability to localize a lesion to the cervical region vs. other areas is probably more important; signalment may help with differential diagnoses.

**Partial Horner's signs are usually anisocoria and occasionally mild enophthalmos. These signs are

attributed to injury of the lateral tectotegmental spinal tracts that carry information from the posterior hypothalamus (which exerts excitatory activity on the sympathetic nervous system) through the brain and cervical spinal cord to the preganglionic sympathetic nerve cell bodies in the thoracic spinal cord. Usually these signs are observed in only severe cases of C1-5 syndrome (e.g., acute tetraparesis/plegia).

	Nerve root signature (less
	common than C6-T2 lesion
	May have tail
	weakness/paralysis/hypoe

***An increased patellar reflex may be observed when a lesion affects the nerve cell bodies and spinal roots that form the sciatic nerve (L6, L7, S1) but not those that form the femoral nerve (L4-6). This arises because there is a loss of function in the antagnostic muscles innervated by the sciatic nerve. This is not truly hyperreflexia and is, therefore, termed "pseudohyperreflexia."**

The spinal cord itself does not possess pain receptors. Pain associated with intervertebral disk degeneration has been shown to be secondary to both biochemical mediators and nervous

tissue impingement. The ligaments, joint capsule and bone of the spinal column are highly innervated.[7] The external periosteum, articular facet joint capsule, and longitudinal ligaments receive sensory innervation by way of the medial branches of the dorsal rami of the spinal nerves. These rami form the recurrent sinuvertebral nerve.[12] The dorsal longitudinal ligament and the ventral meningeal surface are highly innervated by complex encapsulated nerve endings as well as poorly myelinated free nerve endings.[12] These fibers also innervate the outer lamellae of the dorsal annulus fibrosus,[12,136,229] and direct stimulation of the intervertebral disk has been shown to induce pain.[7]

Although the innervation to these structures is diverse and includes postganglionic efferent fibers from the thoracolumbar autonomic ganglia (which mediate smooth muscle function of the vasculature of the spinal canal) and proprioceptive fibers (which modulate postural reactions), the majority of these fibers are nociceptive in function.[12,136] In fact, it has been shown experimentally that stimulation of tissues innervated by the sinuvertebral nerve elicits back pain.[12] In the clinical setting, mechanical impingement of the nerve roots (radiculopathy) and meninges by extruded disk material and hypertrophy of supporting structures play a role in generation of pain.[36,230]

For example, as the intervertebral disk space narrows, concomitant settling of the facet joint and narrowing of the cross-sectional area of the intervertebral foramen occur, which may result in nerve root compression.[231,232] The production of osteophytes may also play a role by contributing to pre-existing narrowing of the intervertebral foramen.[231] In addition, arthritic changes often occur in the facet joint synovium and joint capsule.

Disruption of the intervertebral disk and its ligaments and compression of nervous tissue lead to production of neuropeptides. Algesic molecules can activate nociceptors in the dorsal

longitudinal ligament and dorsal annulus.[40,230] The somata of the dorsal root ganglia make various algesic neuropeptides that are transported to central and peripheral terminals.[230] Implicated neurogenically derived cytokines include substance P and calcitonin gene-related protein (CRGP). Substance P has been shown be a part of the inflammatory cascade and of the generation of pain in radiculopathy. CGRP found in primary sensory neurons has been shown to mediate nociception and mechanoreception.[230] Non-neurogenic-derived chemicals released during tissue damage (e.g., bradykinin, serotonin, histamine, and Pgs) also sensitize pain fibers.[230] Extruded

intervertebral disk material itself has been implicated as a source of biochemical mediators in the pathophysiology of radicular pain.[157,233-235] In an in vitro study of human herniated disk material removed during decompressive surgery, nitric oxide, prostaglandin E2a, and interleukin 6 concentrations were elevated compared with nonherniated control disks from patients undergoing spinal surgery for other reasons (e.g., scoliosis correction).[151] Nitric oxide is a novel mediator of inflammation and immune regulation.[235] This biochemical has been shown to have both proinflammatory and anti-inflammatory functions. As a

proinflammatory agent, it exerts strong vasodilatory effects, promoting vascular leakiness resulting in edema. As an anti-inflammatory agent, it has been shown to inhibit production of IL-6, PgE_2, and thromboxane. The exact function of nitric oxide in the disk and disk degeneration is not known at this time, however.

Chapter 47

Discospondylitis: Diagnostic and Therapeutic Aspects

Laurent Cauzinille

Discospondylitis is a bacterial or fungal infection of the intervertebral disc space and contiguous vertebral endplates. When the lesion involves only the vertebral body, the terminology is spondylitis. Nestel provided the first description of discospondylitis in a dog secondary to tuberculosis in 1957.[1] Since then, this disease has been reviewed multiple

times.[2] The avascular nucleus pulposus is nourished by the dense capillary bed of the adjacent vertebral end plates. Commonly, the infectious agent migrates hematogenously toward the slowly flowing venous channels of the vertebral end plates, proliferates, and spreads to the disk by local diffusion. Remote infected sites, vegetal material migration, extension of paravertebral abscess, penetrating wounds, or vertebral surgeries are often implicated in bacterial or fungal discospondylitis. It is a painful condition that, later in the course of the disease, may induce neurologicl deficits because of extradural spinal cord or nerve root compression.

Diagnosis

The diagnosis of discospondylitis is based on clinical findings and complementary examination results.

Clinical Findings

Discospondylitis has been more often described in young adult to middle-aged dogs of large or giant breeds; males are twice more often affected than females.[3,4] Although rare, discospondylitis has also been described in cats.[5,6] The clinician should look for a history of interdigital wound or inhaled grass awn, recent use of immunomodulating drugs to treat immune-mediated diseases of young dogs (e.g., suppurative aseptic

meningomyelitis, polyarthritis), or recent viral infection with immunosuppressive capacity (e.g., parvovirus). Any chronic skin, ear, bladder, prostatic, uterine, or oral infection may also be a source of bacteria.

Hyperesthesia and lameness are the most common initial clinical signs that the owner describes. The pain may stay unlocalized, and the owner will report only decreased spontaneous physical activity. Pain and lameness often decrease with administration of anti-inflammatory drugs but recur as soon as the drugs are discontinued. Depending on the immune status of the patient and the nature of the infectious

agent, the disease evolves in a subacute or chronic manner. Later, pain may become so severe that the animal is reluctant to move and becomes aggressive if manipulated. Excruciating pain is usually associated with severe cord or nerve root compression, subluxation, or pathologic vertebral fracture. Systemic signs of infection are often not present initially; hyperthermia may be the only sign but it is not a constant finding. Later in the course of the disease, weight loss, anorexia, and localized pain become more obvious. Reactive inflammatory osseous or discal tissues protrude in the vertebral canal and induce spinal cord or nerve root compression, which explains signs of

ataxia and paresis. The localization of the affected vertebrae along the vertebral column determines the clinical presentation. With a C1-C5 or T3-L3 compressive lesion, the clinical findings are decreased conscious proprioception and upper motor neuron signs on the four limbs or rear limbs only, respectively. With a C6-T2 compressive lesion, decreased conscious proprioception in all four limbs, lower motor neuron signs in the front, and upper motor neuron signs in the rear limbs are present. The vertebral segment most commonly involved is L4-S1, especially the lumbosacral junction. With this lesion, the patient will manifest a more or less complete *"cauda equina syndrome"*: rear

end pain, short-strided pelvic limb gait, pelvic limb lameness or root signature, and later, lower motor neuron signs, i.e., rear limb weakness, tail paralysis, and urinary and fecal incontinence. In lesions of the cervical spine, which is rarely involved, pain precedes paresis or paralysis usually weeks before the lesion protrudes enough to cause spinal cord or spinal root compression. When the diagnosis is made late in the course of the disease, lesions may be multiple with adjacent or nonadjacent vertebrae involved.

Complementary Exam Findings

Early in the course of the disease, the

differential diagnosis may include many conditions. Systemic disease inducing hyperthermia and generalized weakness, orthopedic conditions such as polyarthritis or panosteitis, other neurologic diseases such as polymyositis or juvenile meningitis have the same clinical presentation as discospondylitis. When pain is localized to the vertebral column or when neurologic deficits are more obvious, plain radiographs under general anesthesia are the first diagnostic tools of choice. It is essential to radiograph the entire vertebral column because more than one space may be involved, pain may not be localized above the involved vertebrae, or the major radiographic changes may

not be localized at the most painful sites. Radiographic characteristics of discospondylitis are decreased size of the intervertebral space (Figure 47-1), lysis of the vertebral endplates, sclerosis of the adjacent vertebral bodies, and sometimes, spondylosis. The time interval between the onset of clinical signs and the first radiographic signs (i.e., irregularity or lysis of the middle endplates area) may be two to four weeks.[7] This is why radiographs must be repeated in a few weeks when initial radiographs are not diagnostic but the suspicion of discospondylitis is high. More advanced lesions may show shortening of the vertebral bodies or subluxation or collapse of the vertebral bodies. Once discospondylitis has been

diagnosed, a thorough physical examination is essential to look for a primary site of infection (urinary or genital tract, ear canals, teeth, etc.).

Myelographic findings indicate extradural compression because of a protruding infected disc, swollen and displaced ligaments, or periosteal reaction. However, a myelographic study is rarely necessary unless multiple affected sites are present and the clinician wants to evaluate which one is the most compressive for surgical decompression and culture.

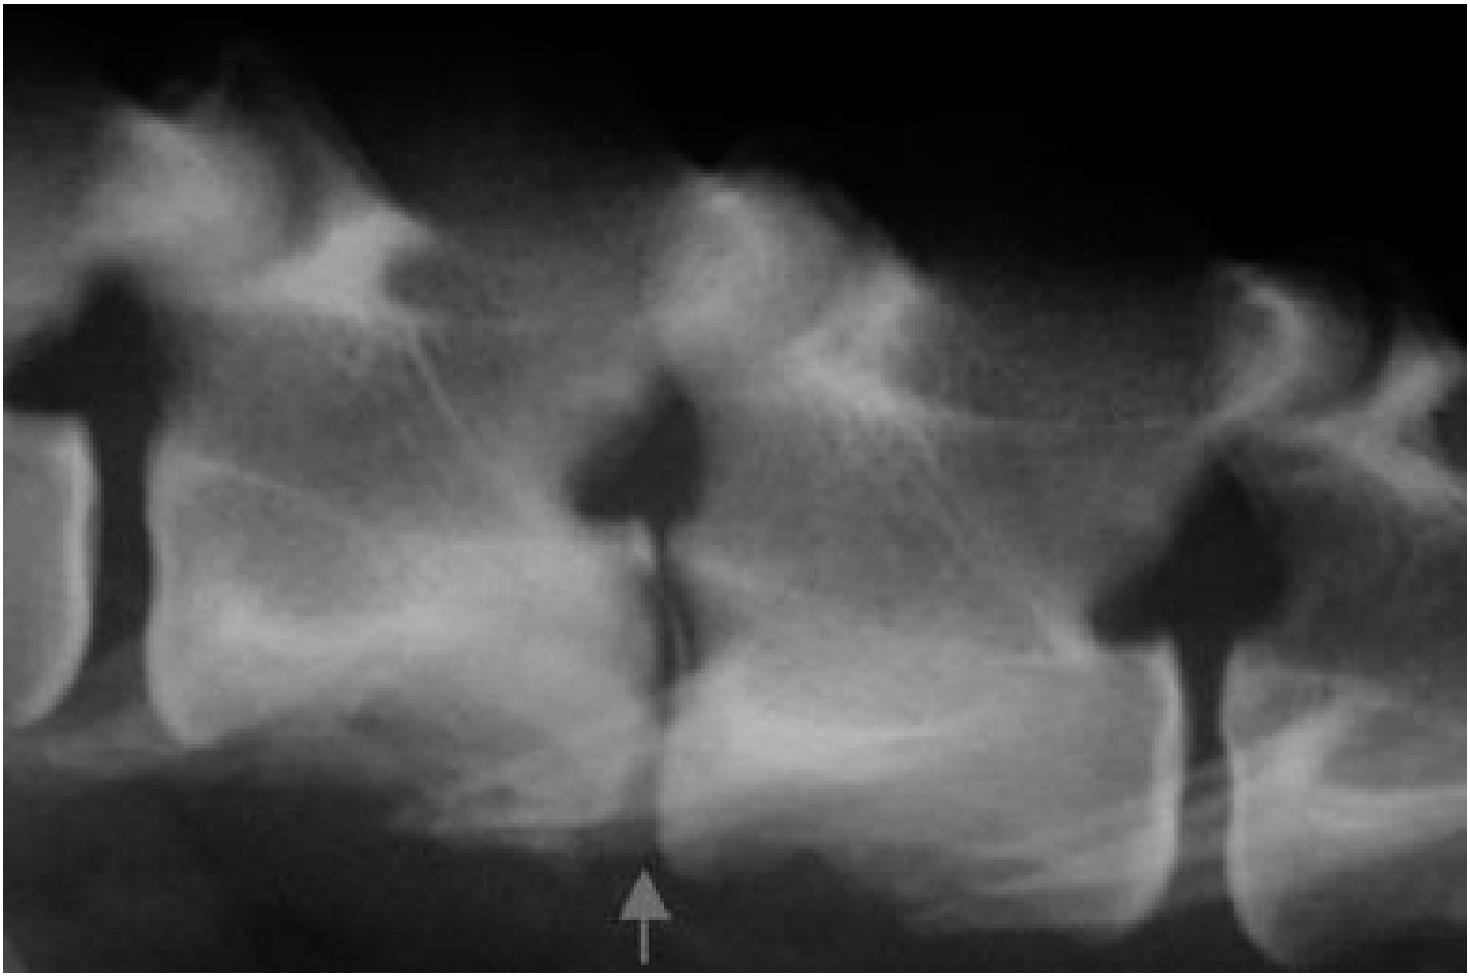

Figure 47-1. Lateral radiograph of a midlumbar discospondylitis; notice the early signs of end plate lysis and intervertebral space collapsus.

Computed tomography and magnetic resonance imaging are also useful tools for the diagnosis of discospondylitis (Figures. 47-2 and 47-3).[8] Magnetic resonance imaging, especially, may detect subtle nucleus and annulus

changes earlier than radiographic identification.9 Increased T2 and decreased T1 signal intensity of intervertebral discs, end plates, and subvertebral soft tissues, as well as interface contrast enhancement are classically described.[10,11] These advanced imaging techniques do not eliminate the need for culture of the causative organism for definitive diagnosis and treatment (see below).

Bone scintigraphy with gallium-67 or technetium-99m may also detect a disc inflammation sooner than radiographs, especially if spondylosis is misleading; a hot spot will be found in the first case, not in the second. However, the sensitivity of this test is poor; on an

aged dog, it does not rule out neoplasia. Discospondylitis and spondylitis may be difficult to distinguish initially from a primary vertebral neoplasm in adult dogs; except for osteoblastic sarcoma, a primary vertebral neoplasm should not cross the intervertebral space.

White blood cell count and urine analysis usually do not show a neutrophilic leukocytosis unless there is a concurrent systemic infection. Cerebrospinal fluid collection and culture are not necessary. A moderate proteinorachia and, more rarely, a mild pleocytosis may be found. Diffuse suppurative meningitis associated with an extension of an abscess to the

subarachnoid space is uncommon; when it does occur, prognosis is extremely poor and generalized sepsis is highly probable.

In order to isolate the causative organism, aerobic and anaerobic bacterial culture (and fungal culture depending on the geographic region the patient has visited) should be done prior to treatment. Urinary culture may help to detect the causative agent up to 50% of the time. Blood culture is positive in up to 75% of cases.[12] When a draining tract of the paravertebral region is present, it should be cultured during the surgical exploration for a foreign body. The infectious agent may also be cultured from a spinal needle-

aspiration guided by fluoroscopy. An ultrasound-guided aspirate is also technically possible on lumbar or lumbosacral sites. Finally, a surgical biopsy must be considered if the previous cultures are negative and treatment is ineffective. The most commonly encountered agents are *Staphylococcus sp* coagulase positive, *Streptococcus sp*, *Aspergillus sp*, and *Mycobacterium sp*. More recently, discospondylitis caused by *Pseudomonas earuginosa*, *Enterococcus faecalis*, *Staphylococcus epidermidis*, and *Bordetella sp* have been published.[9,13,14] Before breeding dogs, an agglutination test must always be performed to confirm the absence of *Brucella canis*; this test has an excellent predictive

value.[15,16] Infection with this organism is considered an important public health consideration in many countries, as the disease is transmissible to humans, especially those handling aborted puppy fetuses. Results of blood culture are less likely to be positive for *Brucella canis* than for discospondylitis caused by other organisms.[17] The fungal agents able to induce discospondylitis are *Aspergillus sp, Paecilomyces sp, Coccidioides immitis,* and *Actinomyces sp*.[18-20]

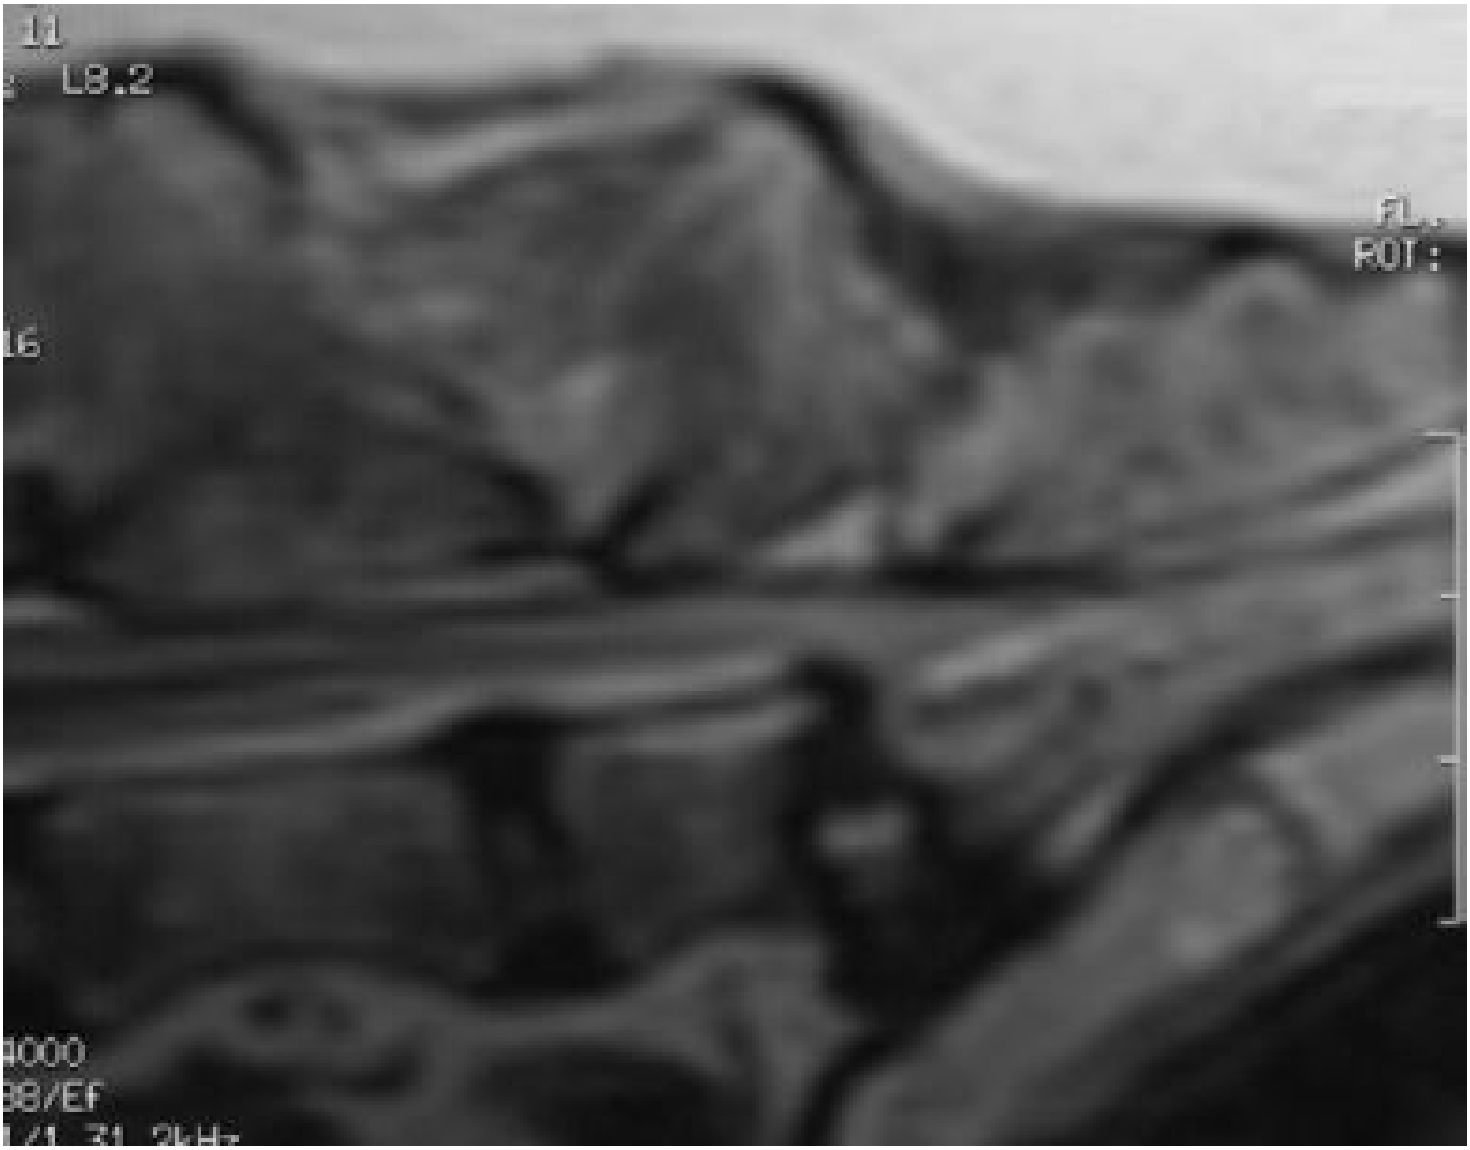

Figure 47-3. Sagittal T2-weighted magnetic resonance image of a lumbosacral discospondylitis in a dog; notice the contrast enhancement of the intervertebral space.

Therapeutic Aspects

Ideally, identification of the causative organism and sensitivity results help to

select the antimicrobial of choice. Bactericidal antibiotics are recommended for patients that may be immunocompromized. A treatment lasting a minimum of 6 weeks is necessary. Without identification of the organism or pending the results, assuming that *Staphylococcus* sp coagulase positive is the most common agent, the following are appropriate first choice antibiotics: cephalosporins (cephalexin: Rilexine, Virbac, 20-30 mg/kg b.i.d., IV, IM, or PO), beta lactamase-resistant penicillins (amoxicillin and clavulanic acid: Clavamox, Pfizer, 12.5 mg/kg b.i.d., PO), and clindamycin (Antirobe, Pharmacia, 11 mg/kg b.i.d., PO). Intravenous treatment is preferred

initially if the disease is long standing. Nonsteroidal anti-inflammatory drugs or narcotic agents may be necessary for pain control. The author regularly uses steroids at an anti-inflammatory dosage (prednisolone: Megasolone, Merial, 0.2-0.3 mg/kg b.i.d., PO) to alleviate the pain when nonsteroidal drugs are not effective. They must be tapered and discontinued within a week or two. Clinical improvement must be noticed within one week; by that time, steroids, when used, are tapered. When the lysis is extensive, because pathologic fractures are possible, the patient must have only minimal physical activity for the first weeks. If the patient is responsive to therapy, radiographs should be

repeated no more than every 4 weeks to assess the progression or regression of the lytic lesions. In adult dogs, the radiographic deterioration continued, despite a successful clinical response, for 3 to 9 weeks.[7] Radiographic evidence of healing may take 4 to 6 months.

In a patient that fails to improve, the clinician should consider reassessment and culture of the disc space by aspiration or open biopsy, especially if the neurologic deficit progresses. Fluoroscopy-guided percutaneous discectomy or surgical exploration must then be considered in order to fenestrate and decompress the infected site.[21] Biopsies for histopathologic

analysis and culture are submitted along with urine and blood. Internal stabilization (plates, pins, screws, and methylmetacrylate) may be necessary if stability is compromised, although the risk of implant superinfection is high. A surgical technique involving distraction and stabilization of the lumbosacral vertebral segment using external skeletal fixation associated with or without cancellous bone graft has been described.[22]

Dogs infected with Brucella canis should not be treated. In the countries where this disease is considered a zoonosis, the infected dogs are euthanized.

Fungal infection must be treated with ketoconazole (Nizoral, Janssen, 10 mg/kg, PO, q 24 h) or itraconazole (Sporanox, Janssen, 5 mg/kg, PO, q 24 h). Temporary remission is more common that definitive cure.[13,20,23]

Prognosis

Patients with severe neurologic deficit have a poorer prognosis than those with pain only. However, in a multicenter retrospective study, neither significant correlation between the degree of compression in the affected site and the clinical outcome, nor between ambulatory status and the final outcome was found.[24]

Chapter 48

Caudal Cervical Vertebral Malformation/Malarticulation

Lisa S. Klopp

Anatomy and Pathophysiology

Caudal cervical malarticulation/malformation (CCVMM), also known in lay terms as "Wobbler's syndrome," is referred to by many names in the literature including: cervical vertebral instability, cervical vertebral spondylopathy,

caudal cervical spondylomyelopathy and cervical spondylolithesis.[1-19] The plethora of terminology indicates the confusion and lack of understanding about the underlying pathogenesis of this disease. This is a fairly common spinal column disease of mature Doberman pinschers that appear to have instability-related pathology and young Great Danes and Mastiffs that appear to have congenital stenosis of the spinal canal.[2,5,6,9,11-14,16,17,19] The Boerboel, an African relative of the Mastiff, which is becoming a more popular breed in the United States, appears to have similar pathology to the Mastiff breed. These syndromes have been observed much less frequently in other large breed dogs

such as the Weimaraner, Dalmatian, German shepherd, Borzoi, and Samoyed. The Borzoi may have a recessive mode of inheritance for this disease.[20] A similar syndrome of vertebral malformation/malarticulation has been recorded in many breeds, but the changes are often recognized in the cranial part of the cervical spine.[1-3,5-7,8-12,14,16-22] The author has recognized similar severe changes in the caudal cervical vertebrae of middle-aged-to-older Yorkshire terriers as well. Whether this finding is related to a similar underlying pathogenesis is not known.

The cervical spinal column possesses

the greatest range of motion of all the vertebrae. In addition to the paracervical musculature, several soft tissue structures play a role in the anatomy and stability of the cervical spine.[13,21,23] A more complete description of this anatomy is found in the first section of Chapter 46: Intervertebral Disk Disease. The dorsal longitudinal ligament, the articular facet joint capsules, the intervertebral disk, and ligamentum flavum bind the vertebral elements together and help prevent excessive motion that could damage the spinal cord and nerve roots. Motion induced by physiologic loads should not cause spinal cord damage in an anatomically stable spine. Malformation and malalignment

of the cervical spine may result in spinal cord injury when the intervertebral movement is within normal or less than normal ranges.

The true underlying cause of CCVMM is not known; the pathogenesis is highly complex and may include genetic, nutritional and growth rate factors. The pathologic changes that account for clinical signs are well described.[2,3,5,8-12,14,16,17,19,20] For purposes of understanding the pathophysiology, the disease can be subdivided into instability and congenital/developmental stenosis. In the Doberman pinscher, the most likely basis for the degenerative changes is a malformation and malarticulation of

the caudal vertebrae, which result in abnormal stressors on the soft tissues (ligaments, intervertebral disks, joint capsule of the articular facet, and paraspinal musculature).[2,3,5,9,13,14,16,17,19] With this micro-instability, the ligamentous elements that confer stability, hypertrophy and osteophytes (spondylosis, articular facet osteophytes) form at joint spaces. These degenerative changes result in static and dynamic compression of the spinal cord (Figures 48-1 and 48-2). The early events that lead to these changes are not completely known but likely include genetic and nutritional factors as is suspected for most diseases of abnormal bone development;

evidence of these changes has been shown in very young Doberman pinscher puppies.[2] The three chronic degenerative changes of the spinal column that are associated with this type of CCVMM are chronic degenerative disk disease (Hansen's type II), osteoarthritic changes, and hypertrophy of the ligamentum flavum and dorsal longitudinal ligament. A dog with this disease may have one, multiple, or all of the changes described.[2,3,5,9,11,12,14,16,17,19]

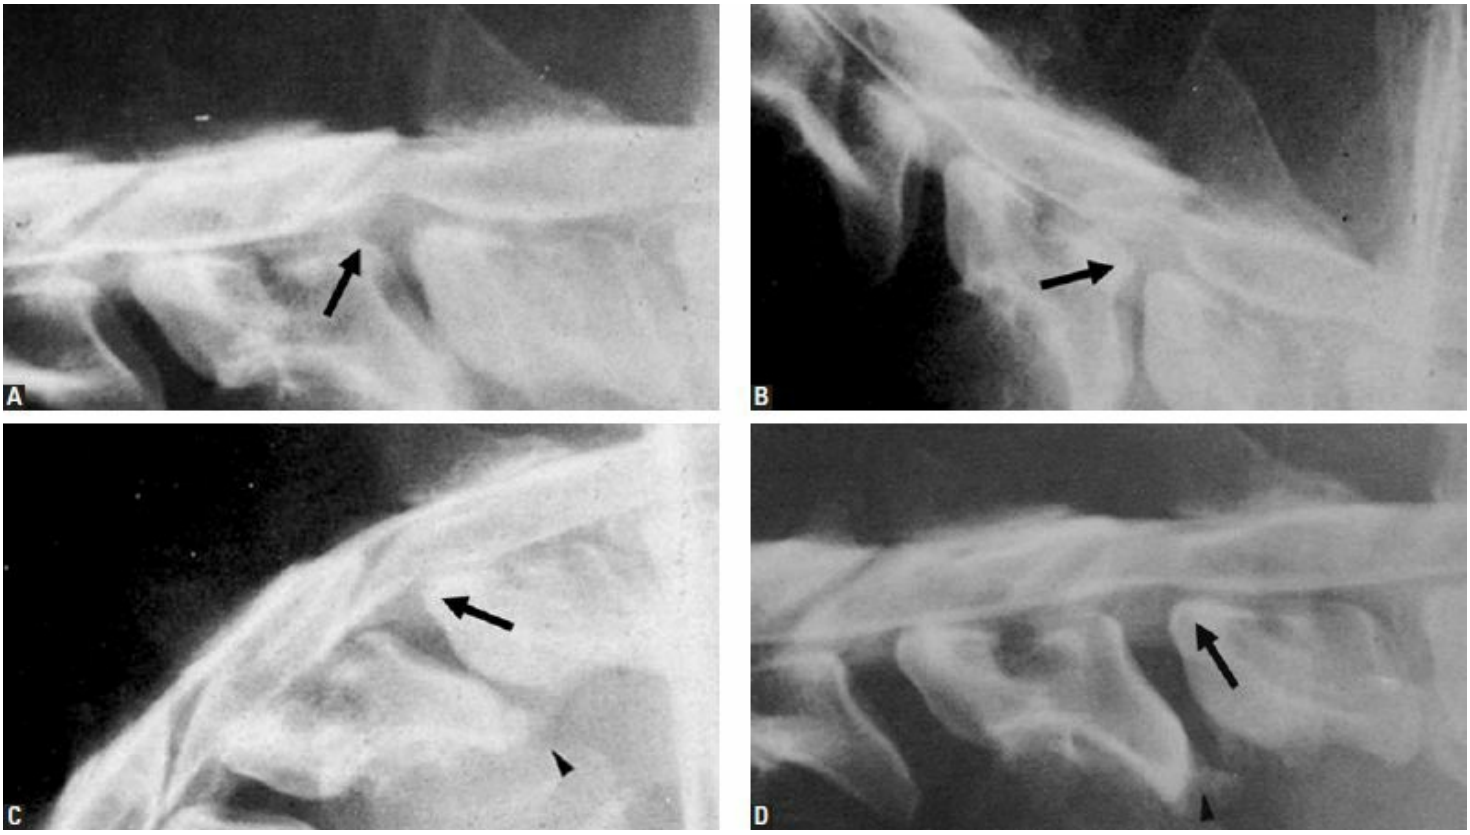

Figure 48-1. Lateral myelogram of caudal cervical malformation/malarticulation with instability at C6-7 in a Doberman pinscher. A. The neck has been placed in a neutral position. A considerable amount of extradural compression by the intervertebral disk and dorsal longitudinal ligament is observed (arrow). Ventral spondylosis is indicated by the arrowhead. The C7 vertebra is abnormally shaped. B. The neck has been positioned in extension. The compression on the spinal cord becomes more severe (arrow) and the interarcuate ligament may contribute dorsally to the compression. C. The neck is now positioned in flexion and the compression is significantly relieved (arrow). D The neck has been pulled into traction. Compression

on the spinal cord still exists but it has been relieved to some extent (arrow). (From Seim HB, Withrow SJ: Pathophysiology and diagnosis of caudal cervical spondylomyelopathy with emphasis on the Doberman pinscher. J Am Anim Hosp Assoc 18:241-251, 1982.)

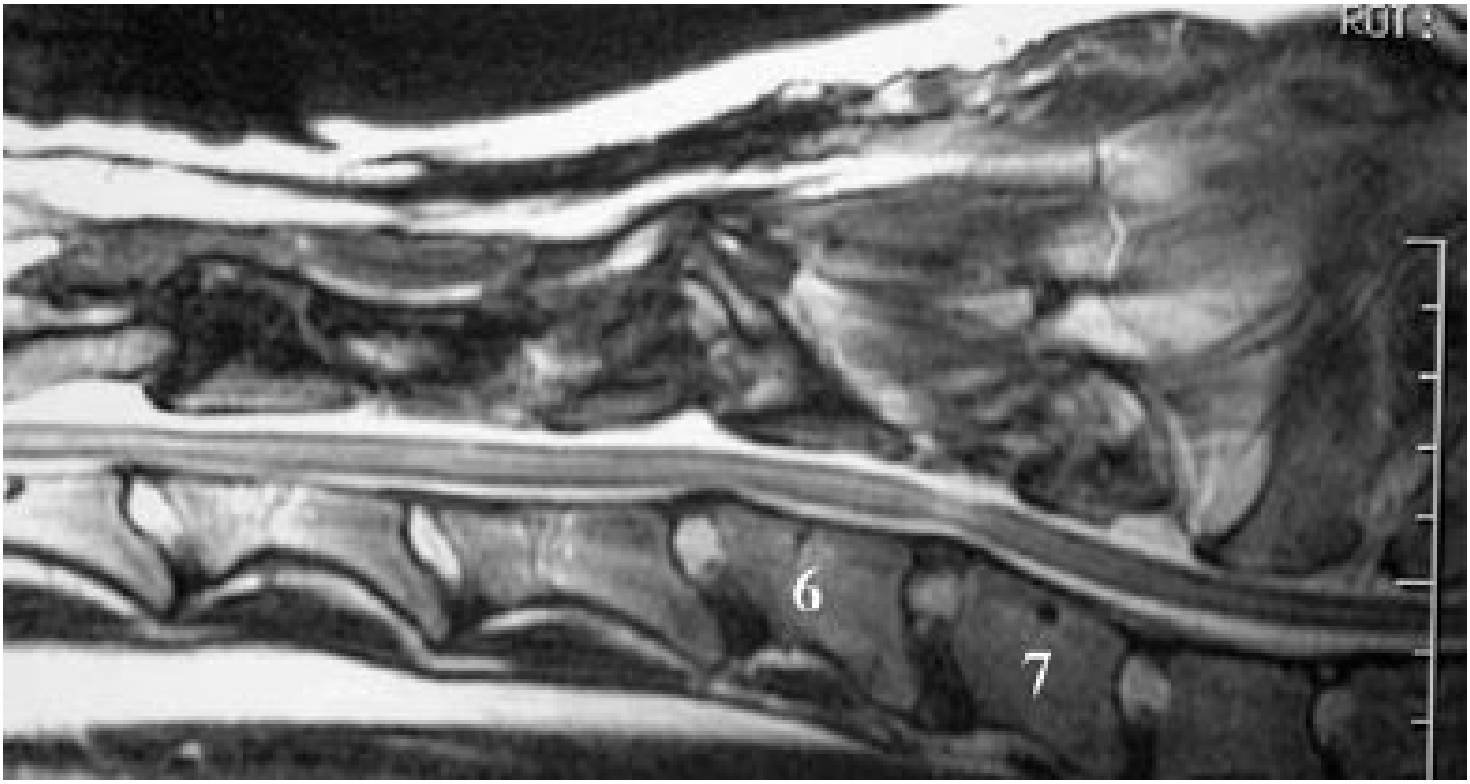

Figure 48-2. A T2-weighted lateral MRI of caudal cervical malformation/malarticulation. The C6 and C7 vertebrae are malformed. The C5-6, C6-7, and C7-T1 intervertebral disks are mildly degenerative as indicated by loss of signal intensity. Mild spinal cord compressions are at C5-6 and C6-7. Mild hydromyelia is observed in the spinal cord over the C6-7 disk space.

Chronic Degenerative Disk Disease (Hansen's type II)

This change is observed mostly as a proliferative (hypertrophied, hyperplastic, or both) dorsal aspect of the annulus fibrosus and hypertrophied dorsal longitudinal ligament causing compression of the spinal cord from the ventral aspect. Although fibrous metaplasia and degeneration of the IVD is seen, extrusion of the nucleus pulposus is uncommon. It is not known if the type II disk degeneration is a cause or effect of the pathology. One source claims it is the underlying disease; however, from the chronicity of the anatomic changes, it would appear that the disk degeneration is an

effect of chronic abnormal anatomy and instability.

Osteoarthritic Changes

Articular facet joint capsule hypertrophy, spondylosis, and rounding of the cranial ventral aspect of involved vertebrae may be observed. Articular facet osteophytes and capsule hypertrophy may contribute to spinal cord compression from a dorsal or dorsolateral direction. Osteochondrotic changes (cores of retained cartilage, subchondral cysts, and osteoporosis) have been observed in the articulations of dogs with CCVMM.

Hypertrophy of the Ligamentum Flavum and Dorsal Longitudinal Ligament

Hypertrophy of the ligamentum flavum is probably an attempt at stabilization and can be a source of significant dynamic compression on the spinal cord from the dorsal direction. The dorsal longitudinal ligament also hypertrophies (although some sources disagree). The dorsal longitudinal ligament and type II disk herniation cause compression of the spinal cord from the ventral direction.

Congenital or developmental osseous anomalies are the more common changes seen in young Great Dane,

Mastiff, Boerboel, and other large breed dogs.[1,3,5,9,11,14,16,19] A component of cervical stenosis often exists. The most common change seen is enlarged articular facets resulting in a dorsolateral stenosis at the level of the joint (Figure 48-3). Multilevel stenosis is a common finding. In other cases, the neural canal may be flattened in the dorsoventral direction, but lateral stenosis from the laminae/pedicle is also observed. Instability may also be involved in the development in some of these dogs, because spondylosis and articular facet osteoarthrosis are not unusual findings.

In both types of this disease, the primary pathophysiology is a reduction

in the diameter of the spinal canal, which results in spinal cord compression and traction injury, causing neurologic deficits.[1-3,5,7-10,14-16,19,20,22,24] An extensive description of the pathology of spinal cord compression is found in Chapter 42.

Clinical Presentation

The disease is usually chronic and progressive over many months to years. Clinical signs may be present from two days to two years. The average age of Doberman pinschers with clinical signs of disease is six to eight years (range 1-11 years), whereas the average age for Mastiffs and Great Danes is 11 to 24 months.[2-

[5,7-11,14-20,22,23,24] Animals may present with acute exacerbation with neurologic deterioration. The underlying malformation and instability occur during development. The chronic changes probably occur over many years.[2-5,7-10,14-20,22-24] By the time dogs show clinical signs with CCVMM, permanent damage to the spinal cord may be significant. Although some animals may present with an apparently acute onset of severe clinical signs, the pathology suggests chronicity. The degree of neurologic dysfunction is highly variable. Initial signs are wide-based stance and abnormal gait in the pelvic limbs. Clients may not recognize these signs early in the course of the disease.

Dogs usually begin with pelvic limb ataxia and conscious proprioceptive deficits followed by or concurrent with a short, stilted thoracic limb gait if the lesion occurs at C6-7. Signs usually progress over time to mild-to-moderate tetraparesis and dysmetria. Some dogs become nonambulatory. Signs progress at variable rates; some dogs deteriorate acutely from mild trauma or massive intervertebral disk extrusion.

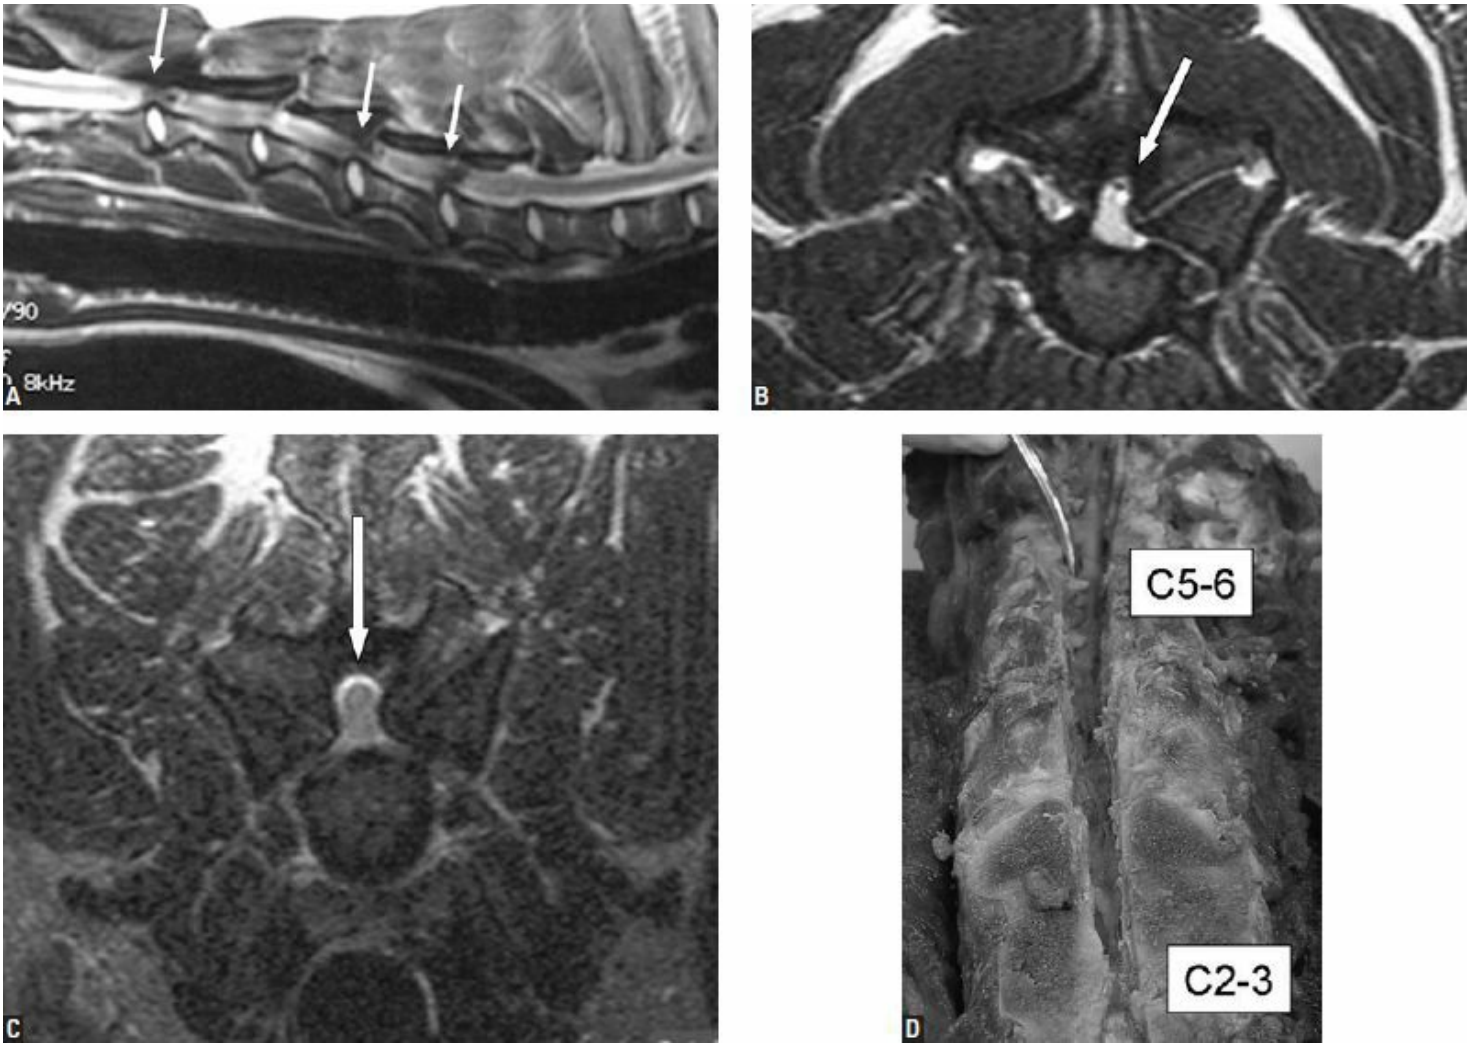

Figure 48-3. A. T2-weighted parasagittal MRI image from an 11-month-old Boerboel with severe ataxia and mild tetraparesis. The arrows indicate the location of the multiple enlarged facet joints that are compressing the cord laterally. B. T2-weighted axial MRI image at the level of C2-3. The stenotic change at the facets has resulted in severe spinal cord compression and changes in spinal cord signal intensity (increased signal) that may indicate edema or malacia. C. T2-weighted axial MRI image at the level of C5-6. Less severe stenosis has occurred with severe spinal cord

compression. D. Postmortem evaluation of the spinal canal reveals severe stenosis of the canal at C2-3 and a sharp indentation (hemostats) of the canal at C5-6.

The most common lesions are at C6-7, with the next most common changes at C5-6.[2-5,7,24,8-10,13,14,16-19,21-24] This is particularly true for the instability seen in the Doberman pinscher. The gray matter in this area contributes to brachial plexus nerves responsible for supplying innervation to the shoulder and flexors of the elbow (suprascapularis and musculocutaneus nerves). When closely examined, these dogs often have some degree of atrophy in the scapular and biceps brachii muscles. When severely affected, these dogs may not be able to flex their limbs to withdrawal of their

limbs or to lie in sternal recumbency. Thus, the lesion may result in lower motor neuron signs to the flexors and upper motor neuron signs to the extensor muscles. The extensor muscles are the most dominant muscle group in the thoracic limb of the dog. When opposing tone and function to flexor groups are lost, the extensor muscles display increased tone.

CCVMM is not typically considered a painful disease. Dogs may carry their head in ventroflexion. Although dogs may sometimes display discomfort when the head and neck are extended, they do not often display the degree of pain that is seen in type I disk extrusions, vertebral tumors, and

meningitis. Mild discomfort may be representative of meningeal compression, arthritis, or nerve root pain. Dogs that display significant pain may have a massive disk extrusion or radiculopathy from nerve root impingement. Discussions of the pathogenesis of pain associated with intervertebral disk disease and nerve root compression are found in Chapter 46: Intervertebral Disk Disease, and Chapter 50: Lumbosacral Disease, respectively.

Chapter 49

Degenerative Myelopathy

Laurent Cauzinille

Many, if not all, disease processes will eventually terminate in degenerative changes of the involved organ. In neurology, the terminology "degenerative myelopathy" may be used as a broad descriptive term, for example in association with any compressive spinal cord process (chronic disc disease, vertebral instability, spinal meningioma, etc.). Based on clinical signs and

neuropathologic features, the terminology “degenerative myelopathy,” used in its strictest sense, is a chronic, progressive leukomyelopathy that may represent an abiotrophic type of degenerative disease.[1] Several forms of degenerative myelopathy (DM), although clinically similar, may exist. One of these clinical and pathologic conditions is most often observed in 5- to 14-year-old German shepherd dogs.[2,3] However, a similar condition has been described in other breeds of different size, as well as in mongrels and even in a cat.[4,5,6] Corgi and Boxer breeds, for instance, have a high incidence of late onset, non-painful, non-compressive degenerative myelopathy. Research into these

conditions is being supported by breed clubs and other foundations. Until more information becomes available, the etiology of these degenerative conditions remains idiopathic.

History and Clinical Presentation

The time course of the disease prior to presentation is usually long (i.e., months) and is progressive in nature. The owner often describes an insidious gait abnormality of the hind limb with dysmetria and crossing of the feet of the pelvic limbs, especially when making a sudden turn. Knuckling of the toes is another common complaint. Deficits may initially be more

pronounced on one side. Later, paresis will appear along with difficulty rising, dragging of the toes, and wearing of the nails of digits III and IV.[7] Over the next 6 to 36 months, these signs progress slowly in the pelvic limbs to obvious truncal ataxia and severe paresis without apparent bladder dysfunction.[7] On neurologic examination, one finds proprioceptive deficits in the hind limbs, normal to exaggerated patellar reflexes, and crossed extensor reflexes. Nociception is unimpaired. This upper motor neuron presentation is reflective of a partial loss of spinal cord function between the brachial and lumbar medullary intumescences (T3-L3). The patellar reflexes may be depressed and

the withdrawal reflex may be increased, uni- or bilaterally.[3] This type of presentation is more consistent with an L4-L6 spinal cord or nerve root involvement, although neurologically normal dogs may have an age-dependent decline in patellar reflex.[8] However, sciatic, caudal, and sphincter functions remain normal, which reflects sparing of the caudal lumbosacral intumescence or nerve roots. Such lower motor neuron clinical findings may be more common in Boxer dogs with signs of progressive DM (unpublished data).

Diagnosis

Diagnosis is based on signalment,

clinical signs, and complementary tests, which rule out any of the other common causes of myelopathy. The T3-L3 clinical presentation associated with this degenerative syndrome is identical to numerous other chronic spinal cord or vertebral diseases. The differential diagnosis should include, at least initially when neurologic deficits are subtle, any orthopedic disease (hip dysplasia, cruciate ligament rupture, degenerative joint disease) or caudal abdominal disease (prostatic disease, perineal hernia). When neurologic deficits are more obvious, *cauda equina* signs, common in large breeds and especially in German shepherd dogs, should be ruled out by neurologic examination and diagnostic imaging.

Lumbosacral diseases that induce rear limb and tail weakness or paralysis, and fecal or urinary incontinence, do not belong on the list of differential diagnoses for DM, which has generally a T3-L3 clinical presentation. A misleading finding may be the weak patellar reflex when the degenerative lesion involves the cranial lumbar intumescence or its nerve roots. Overall, pain is a common clinical sign in lumbosacral compressive or infiltrative diseases; pain is not found in DM.

A slowly protruding disc herniation of the T3-L3 spinal segment is probably the most common disease that the clinician has to rule out. It cannot be

done solely based on clinical signs or plain vertebral radiographs and will require advanced imaging. Other diseases such as dorsal spinal cord compression by articular facet spondylosis, synovial cyst formation, slow growing vertebral or meningeal tumors, or a low-grade myelitis must also be ruled out. Results of hematologic studies, blood chemistries, and urinalysis are normal in dogs with DM.

It is not uncommon to find a mild to moderate increase in protein content (proteinorachia) of the lumbar cerebrospinal fluid without pleocytosis.[9] This albumino-cytologic dissociation is neither sensitive nor

specific for DM.

Spinal radiographs may show spondylosis; this finding, often multifocal in older large breed dogs, does not rule out DM. Compressive medullary consequences of spondylosis cannot be assessed without spinal cord imaging unless foraminal calcification of a protruding disc is visible above the degenerative site. A myelographic study, high-quality computerized tomography or magnetic resonance imaging are necessary to rule out any compressive or infiltrative vertebral or medullary disease. Myelography should not demonstrate the presence of a compromised subarachnoid space in cases of DM, ruling out compressive

lesions. High-quality magnetic resonance imaging is very sensitive; interpretation of the images requires a considerable expertise if the reader does not want to under- or over-appreciate the significance of any abnormality.

To the author's knowledge, high-field magnetic resonance imaging does not reveal intraparenchymal lesions throughout the spinal cord in DM cases.

Electrodiagnostic findings are unremarkable unless clinical presentation belongs to the rare lower motor neuron form. Spinal cord evoked potentials may confirm an

intramedullary conduction defect. Stimulation is applied at the level of the sciatic nerve and the compound evoked potentials are recorded at the cisterna magna. Diminished amplitude and prolonged or separated N1 wave changes are not sensitive at detecting a peculiar form of myelopathy; however, they tend to worsen as the signs of DM progress.[3]

Dogs with signs of progressive DM have a depressed response to mitogens associated with the presence of peripheral blood suppressor cells, especially if they are severely affected.[10] A mitogen response assay performed twice failed to confirm the diagnosis of DM, although

histopathology did, in one reported case.[11]

A change in the dog leucocyte antigen gene region has been found at the University of Florida in German shepherd dogs that have a high suspicion for DM based on standard diagnostic testing. Sensitivity and specificity of this DNA marker is being evaluated as a test for DM.

In a patient with chronic spinal cord disease, especially a German shepherd, the diagnosis of DM based on clinical signs alone is no more likely to be accurate than a diagnosis of chronic protruding disc. Vertebral and spinal cord imaging and cerebrospinal fluid

analysis can increase the degree of suspicion to “most probable.” Definitive diagnosis still requires histopathologic confirmation.

Histopathologic Findings

Several forms of degenerative myelopathies may be distinguished histopathologically, even if they are clinically similar. Ideally, no obvious macroscopic changes should be found once the spinal cord has been removed from the vertebral canal. However, any compressive lesion of discal, vertebral (chronic disc disease, major spondylosis, or vertebral degenerative changes) or meningeal origin (major dural ossification or masses) should be

evaluated. Once the meninges are removed, dorsal and ventral roots and rootlets should appear normal.

At a microscopic level, DM is a disease of white matter although in some cases the central gray matter may also be involved; this may account for signs related to specific peripheral nerve involvement.[2,7] All white matter funiculi, especially dorsolateral and ventromedial, appear affected throughout the length of the spinal cord in a diffuse manner. Both motor and sensory tracts are involved. On longitudinal sections, the lesions are not continuous.[12] The myelopathy is more obvious in the thoracic segments; this explains the classic T3-L3 clinical

presentation. Macrophages invade the degenerative areas; myelin sheaths appear swollen, and dystrophic axons tend to disappear. Astrocytosis and gliosis may be present. The cases presenting with lower motor neuron signs tend to have similar changes in the low lumbar spinal nerve roots. In early publications, lesions were not found extending into the brainstem.[2] More recently, chromatolysis, gliosis, and neuronal loss were observed in the red, lateral vestibular, and occasionally, in the dentate nuclei.[13] In some dogs, if ventral roots are unaffected, dorsal roots, dorsal root ganglions, and dorsal gray horns may show degenerative changes.[2,7]

Pathogenesis

The pathogenesis of DM is unknown. The theory of a “dying back” motor and sensory neuropathy is not supported by morphologic and morphometric data.[7,12,13]

As a similar disorder has been described in young German shepherds and Siberian huskies, it may be that this disease has a genetic origin.[5,12] Based on the theory that DM may be a late-onset neurodegenerative disease that has a heritable basis, a search for candidate genes is in progress.[7,13]

A depressed response to mitogens has been described in dogs affected with DM. This may be related to the release

of prostaglandins, reflecting an attempt by the host to control an immune event.[10] Immunoglobulin G and the third component of complement have been found in spinal nerve tracts of affected German shepherds.[14] Depression of cell-mediated immune responses, increased circulating immune complexes, plasma cell infiltrates in kidneys and intestinal tracts suggest that DM may be an immune-mediated neurodegenerative disease.[9]

An associated enteropathy, bacterial overgrowth, and decreased serum levels of cobalamin (vitamin B12) have also been described in dogs with DM.[15,16] However, parenteral

administration of cobalamin has not reversed the clinical evolution of developing DM in dogs.[13]

Indications exist that vitamin E transport may be involved, resulting from an impaired function of the hepatic alpha-tocopherol transfer protein.[17] The alpha tocopherol transfer protein gene could then be used for pre mortem diagnosis of DM in comparison with human patients with familial ataxia associated with vitamin E deficiency. Recent research to determine whether a deficiency or a defect of the canine alpha-tocopherol transfer protein could be a primary factor in DM suggests that this is unlikely.[18]

Treatment

Because dogs with various types of compressive myelopathy may also have concomitant DM, treatable diseases should be addressed first. However, in the case of a strong suspicion of DM in a dog that also has other mild chronic disease (hip dysplasia, chronic disc protrusion), it is essential to avoid any unnecessary surgical procedure that might be useless or that might accelerate clinical deterioration.

No treatment is known to be effective in either reversing or slowing of the progression of clinical signs of DM. Although no controlled experiments have been published, each

pathogenesis theory may support a therapy. Recommended treatments involve a combination of different protocols: exercise, massive corticosteroid therapy, multiple vitamin and mineral supplementation, dietary manipulation, acupuncture, and aminocaproic acid.

Nonsteroidal anti-inflammatory drugs are recommended to alleviate other inflammatory conditions (degenerative joint disease, spondylosis, nerve root signature, etc.) that may aggravate the clinical signs. Prednisolone, (Megasolone, Merial,) 1 mg/kg/day for a few days, then reduced to maintenance levels of 0.5 mg/kg every other day, is indicated if clinical

deterioration is acute.[19] However, long-term use of corticosteroids favors muscle atrophy and other side effects. No other immunosuppressive trials have been published.

Although not proven, tocopherol (vitamin E) supplementation at high dosage (2000 IU /day) along with B complex vitamins are recommended.

Aminocaproic acid (Amicar, Immunex), a blocker of the final common pathway of tissue inflammation, given at 500 mg PO t.i.d., has been reported to alter the course of the disease.[3,19] Improvement is usually seen within 2 months. No recent retrospective or prospective study has been published

for this drug protocol or for others addressing the same mechanism.

Exercise should be sustained or even increased when possible to maintain muscle mass and joint elasticity.

Prognosis is poor; the time course for progression may take from weeks to months for signs to reach the level of a complete disuse of the pelvic limbs. When the dog's neurologic deficits reach the point that it is no longer ambulatory, decubitus care, passive physiotherapy, bladder control, and the use of a cart may still preserve a reasonable quality of life.

Chapter 50

Lumbosacral Disease

Lisa Klopp

Anatomy of the Lumbosacral Spine

The structural anatomy of the lumbosacral spine includes the intervertebral disk, the articular facet joints, and spinal ligaments. Detailed descriptions of these structures are discussed in Chapter 46: Intervertebral Disk Disease. The last lumbar vertebra (L7) attaches to the fused three-

segment (S1-3) sacrum rather than to another individual vertebra (Figure 50-1). The range of motion of the sacrum is limited by its attachment to the pelvis. This anatomic difference leads to different biomechanical loading forces at this level in comparison with the other lumbar vertebra.[1,2] The characteristic that renders the lumbosacral joint unique clinically is that, in most instances in the dog and cat, the spinal cord itself does not extend into this region. At birth the spinal cord extends through the vertebral canal of the sacrum.[3] Differential growth rates between the vertebral column and spinal cord result in termination of the spinal cord around the L6 vertebra in medium-to-

large breed dogs and at L7 cats (Figure 50-2).[3] Small-breed dogs (< 7 kg) may have longer spinal cords in which case the spinal cord may terminate as far caudally as the lumbosacral junction.[3] Caudal to the lumbar intumescence, the spinal cord tapers to an elongated cone, or the conus medullaris, which contains the sacral and caudal spinal cord segments.[3] The spinal cord itself terminates as the filum terminale, which is a band composed of glial and ependymal cells.[3] The filum terminale unites with the dura and arachnoid layers to form the caudal ligament around the S1 vertebra. The caudal ligament anchors the spinal cord by fusing with the periosteum and dorsal longitudinal ligament in the caudal

vertebrae. The thecal sac and arachnoid space, which contain cerebrospinal fluid, extend beyond the filum terminale up to 2 cm and may extend as far as the S1 vertebra.[2] Because the spinal cord terminates before the lumbosacral junction, the caudal lumbar, sacral, and caudal nerve roots travel the remaining distance to exit the spinal canal at the appropriate intervertebral foramen. This collection of the nerve roots is referred to as the cauda equina.[3] The dorsal and ventral nerve roots fuse distal to the dorsal root ganglion near the intervertebral foramen to form the spinal nerves. The spinal nerves carry the axonal fibers that form the sciatic, pudendal, parasympathetic, and

caudal nerves (Figure 50-3).[3] Throughout the thoracic and lumbar spinal cord, spinal nerves exit caudally to the vertebra of the same number (e.g., L7 nerve root exits at the L7-S1 intervertebral foramen) just cranially to the intervertebral disk. Therefore, with lumbosacral disease, typically the last lumbar and sacral roots are most clinically affected. However, degenerative disease at L6-7 can occur independently or in conjunction with lumbosacral disease. The nerve roots, like the spinal cord, are covered by epidural fat which acts as a protective layer against injury. Paired venous sinuses, present the length of the spinal canal, diverge laterally over the disk spaces and converge toward the

midline as they reach the mid-body of the vertebrae.

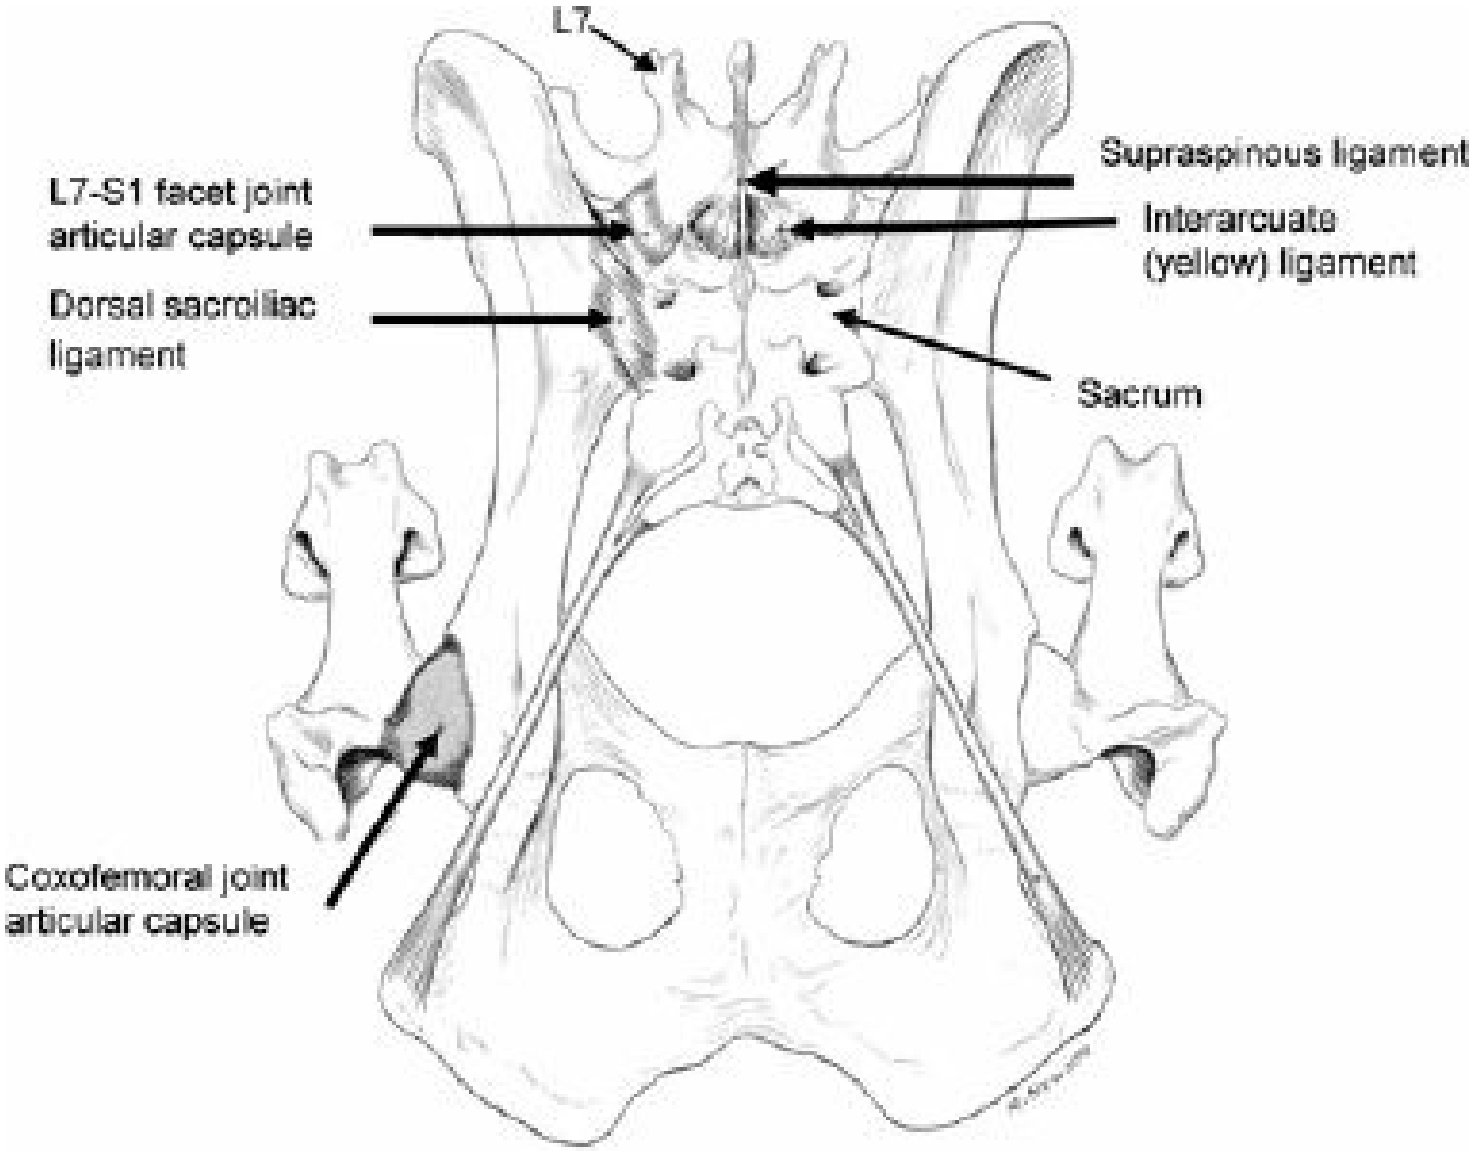

Figure 50-1. A schematic drawing of the anatomy of the lumbosacral junction. (From Miller ME, Christensen GC, and Evans HE: Anatomy of the Dog. Philadelphia: WB Saunders, 1964. Drawn by M. Newsom)

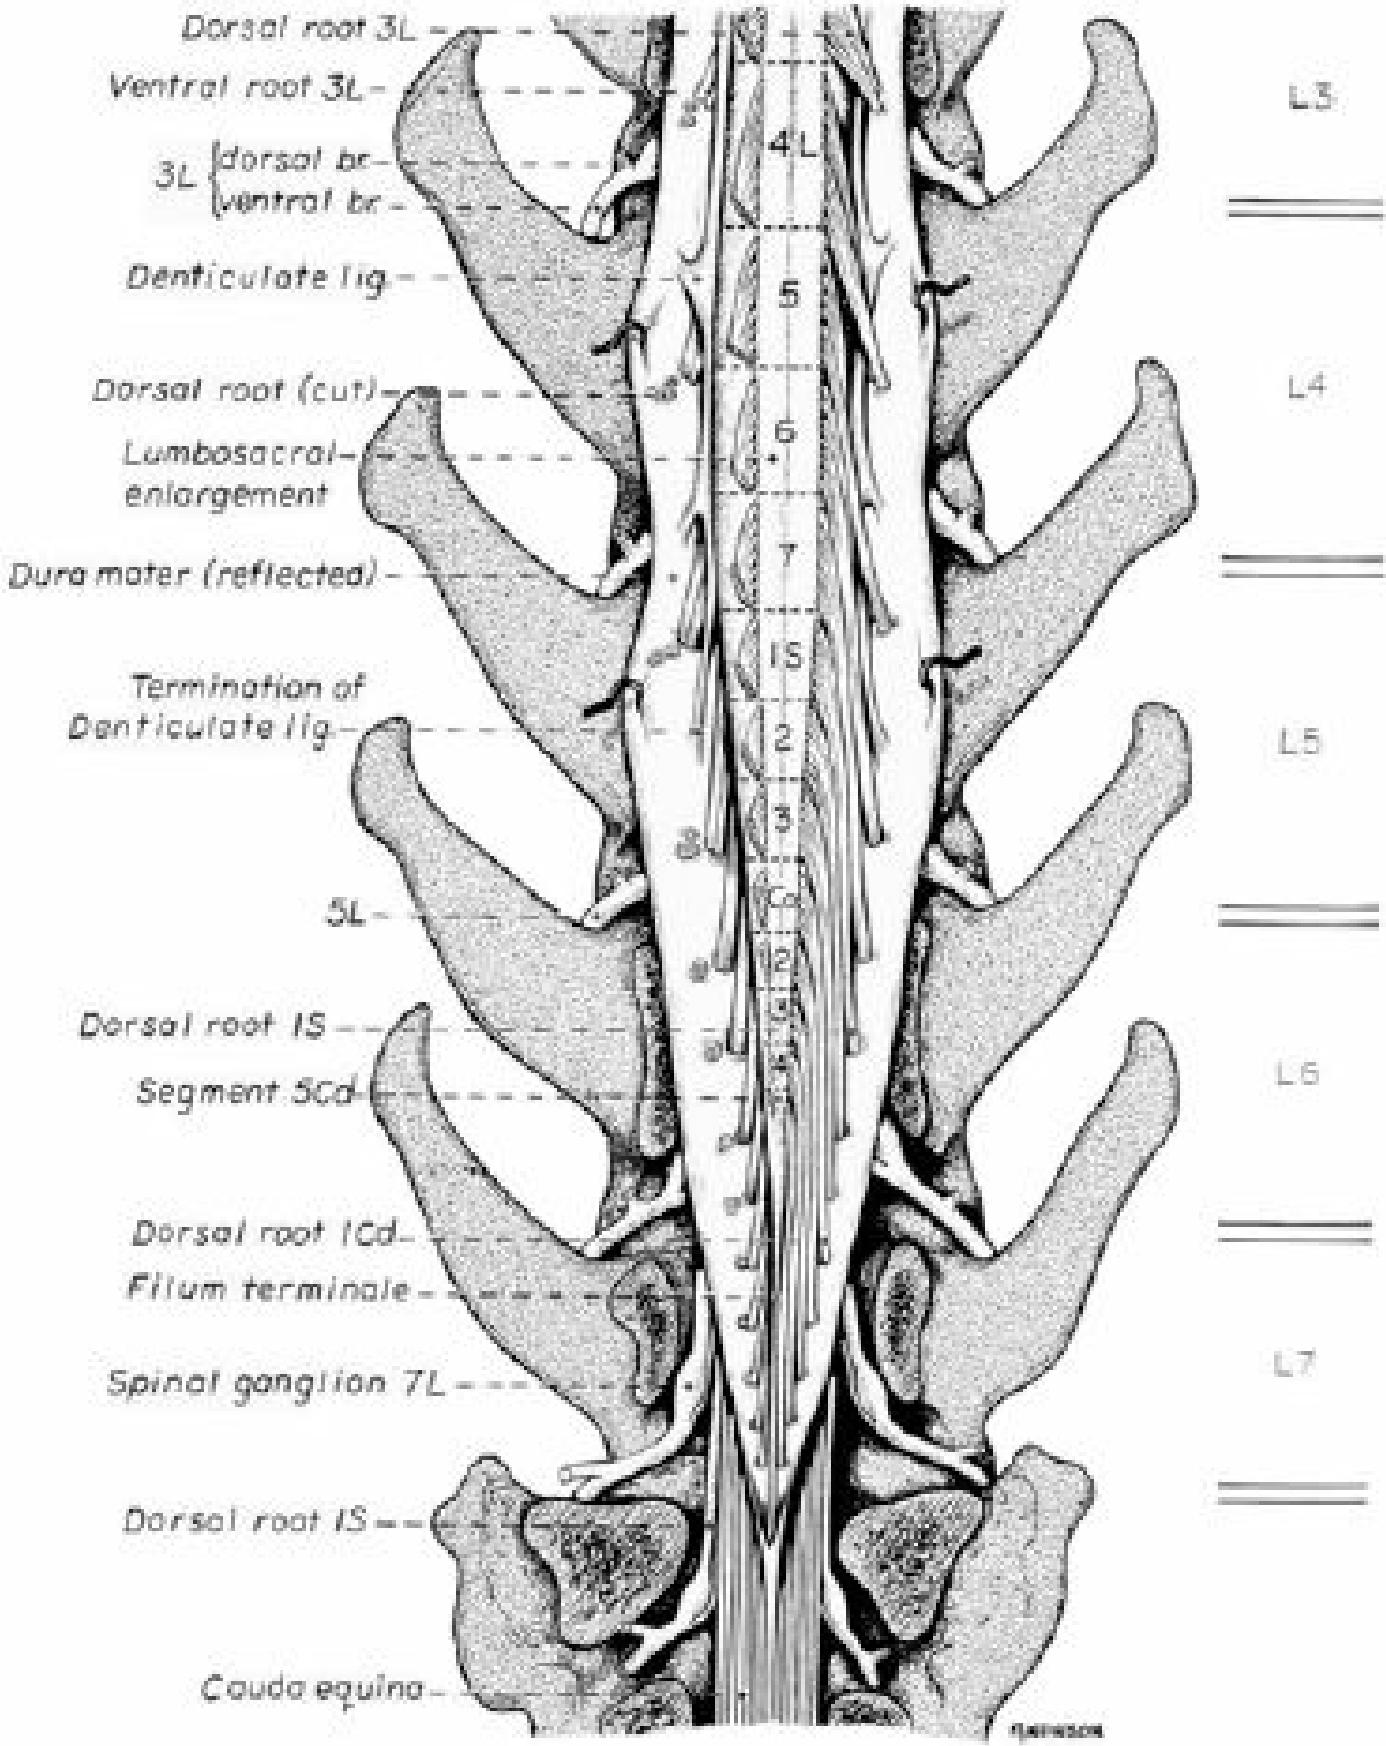

Figure 50-2. Spinal cord segmental relationship to the

vertebral bodies. From T11 through the caudal segments the spinal cord, roots, ganglia, and nerves have been exposed by removal of the vertebral arches. The dura mater has been removed except on the right side. The numbers on the right represent the levels of the vertebral bodies. (From Miller ME, Christensen GC, and Evans HE: Anatomy of the Dog. Philadelphia: WB Saunders, 1964. Drawn by M. Newsom)

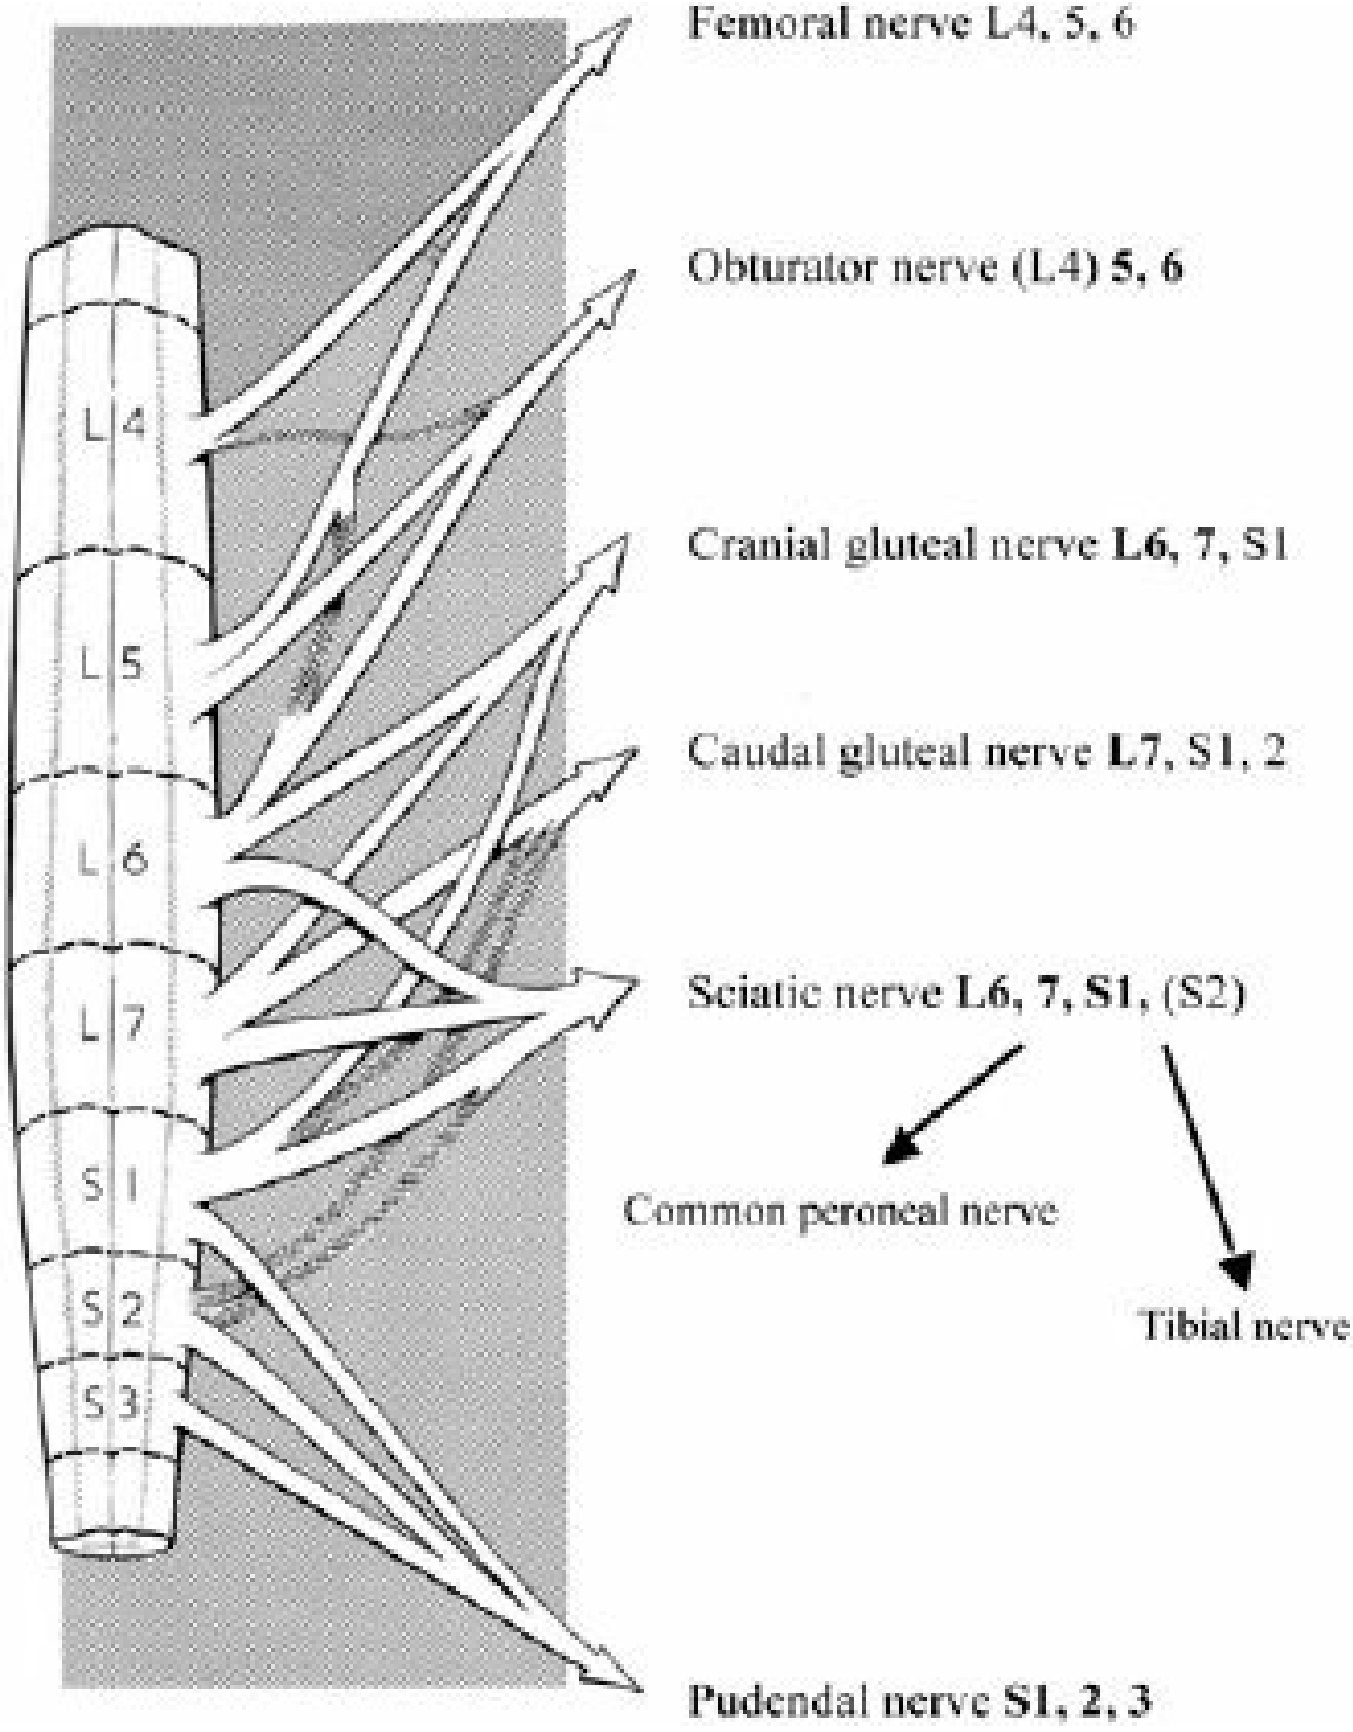

Figure 50-3. Peripheral nerve formation from the spinal cord segments of the lumbar intumescence in

the dog. (Modified from De Lahunta A: Veterinary Neuroanatomy and Clinical Neurology, 2nd ed. Philadelphia: WB Saunders, 1983.)

Two adjacent vertebral bodies and the intervening intervertebral disk constitute a motion segment. In the vertebral motion segment are three joints: two articular facets and the intervertebral disk. Motion is constrained by associated joint capsules and ligaments.[4] As these structures reach the limits of their elasticity and tensile forces are encountered, flexibility is reduced.[1] Movement in the joint is primarily flexion with more restricted degrees of rotation, lateral bending, and extension.[1,5] Flexion in the sagittal plane is limited by the supraspinous,

intraspinous, interarcuate, and dorsal longitudinal ligaments and the articular facet joint capsules.[1,5] Extension is restricted by the ventral longitudinal ligament and articular facet joint capsules.[1,5] Lateral bending is controlled by the articular facet joint capsules, the intertranverse ligaments, the annulus fibrosus of the intervertebral disk, and to some degree, by the pelvis.[1,5] Finally, axial rotation is controlled by the articular facets and annulus fibrosus of the intervertebral disk.[1,4]

Gross Pathology of Lumbosacral Disease

The most common cause of cauda

equina pathology is stenosis, or narrowing of the spinal canal, resulting in compression of the cauda equina (Figure 50-4).[2,4-8] Although stenosis can be congenital in nature, it is often secondary to degenerative lumbosacral disease, which encompasses multiple changes in the structural anatomy at this location. Most often, these changes affect the intervertebral disk, the articular facets, and the ligaments of the spine. Congenital abnormalities, such as instability, transitional vertebrae, and osteochondrosis of the sacral or L7 endplate,[8,9] as well as trauma are also associated with lumbosacral disease. These abnormalities usually result in acquired secondary degenerative

changes, which ultimately contribute to clinical signs at a later time.[2,4,5,7,8,10] True congenital lumbosacral spinal stenosis may present early with clinical signs prior to development of degenerative changes if the canal diameter is narrowed severely enough. However, congenital abnormalities and prior trauma are not required for degenerative changes to occur at this level and are certainly not as common as aging and degenerative changes. Other diseases that affect the lumbosacral spine and cauda equina are neoplasia, trauma (fracture), inflammation, infection, and vascular injuries. In this chapter, the focus is on degenerative lumbosacral disease. The anatomic pathology associated with

degenerative lumbosacral disease is found in Table 50-1.

Table 50-1. Anatomic Pathology Associated with Degenerative Lumbosacral Disease

Acquired disease

Degenerative disk disease

Type II *

Degenerative changes of other spinal structures

Ligamentum flavum (interarcuate ligament) hypertrophy/ inflammation

Dorsal longitudinal ligament

hypertrophy/inflammation

Articular facet joint capsule hypertrophy/inflammation

Articular facet osteophytes

Thickening and induration of epidural fat

Fibrous adhesions to nerve roots

Spondylosis

Congenital diseases that may cause lumbosacral disease and contribute to degenerative changes

Congenital stenosis

Malarticulation or malformation of the lumbosacral joint (e.g., instability)

Transitional vertebrae

Osteochondrosis of the L7 or S1 vertebral endplate

*** Type I disk extrusion can occur in this region but is relatively uncommon even in chondrodystrophic breeds.**

The lumbosacral joint is one that transitions between a more freely flexible region of the spine (lumbar segments) and one that is static in position (sacrum) because of the attachment to the pelvis. The range of motion is higher at this location than at any of the other lower lumbar motion segments.[11] It is not surprising that this joint can undergo excessive biomechanical stresses. It is postulated that the disease is most prevalent in large breed dogs owing to an

imbalance between body weight and dimension of the lumbosacral contact area not seen in smaller breeds and resulting in higher loading forces around the joint.[12] Spondylosis and osteophyte production around the articular facet joints commonly observed with degenerative lumbosacral disease may be one way of reducing the loading forces.[12,13] German shepherds, which have a high reported incidence of the disease, have been shown to have hypermobility and increased longitudinal extension.[8,12]

One of the earliest changes occurs in the intervertebral disk and is related to type II degeneration. An extensive review of type II intervertebral disk

disease can be found in Chapter 46. As the disk degenerates at the lumbosacral joint, derangements occur in the normal load-bearing functions. As the disk begins to herniate or collapse, the normal disk height is lost, the facet joints begin to share more than their normal biomechanical load,[8,14] and subluxate to some extent.[15] Although collapse of the disk results in foramen narrowing,[5,16] the significance of this is not known. The clinical significance of foraminal narrowing without spinal canal stenosis has been challenged in the human literature.[17] As in other diarthrodial joints, development of periarticular osteophytes occurs in response to excessive biomechanical stressors.[18] Osteophytes often form on

the ventromedial side of the facet and the dorsolateral endplate of L7.[18-20] They may severely restrict the foramen and L7 root, especially if the joint is extended.[14] In addition, changes in the function of the motion segment may cause interarcuate ligament hypertrophy and infolding into the spinal canal, which may contribute to stenosis and compression of the nerve roots dorsally.[4,5,21,22] Ventral spondylosis is a typical finding; however, it is most often an indicator of degenerative changes rather than a true cause of clinical signs.

Congenital anomalies tend to accentuate the effects of excessive biomechanical loads and contribute to

lumbosacral degenerative changes. Congenital instability is typically related to malformation and malarticulation of the facets and abnormal vertebral alignment. The response to instability at this joint can be likened to that seen with caudal cervical malformation/malarticulation ("Wobbler's disease"). Osteochondrosis is the most recently reported congenital anomaly that contributes to degenerative changes at the lumbosacral joint. The cartilaginous endplate defect is more commonly seen in the cranial sacral endplate than the caudal lumbar endplate.[9] Not surprisingly, this anomaly has been most commonly observed in German shepherd dogs, with a higher male:

female ratio.[9] It is often seen clinically in dogs younger (as early as 18 months) than the typical patient presenting with lumbosacral disease.[9] Degenerative changes at the lumbosacral joint may be attributable to an increase in abnormal stresses and possibly impairment of intervertebral disk nutrition at an age earlier than that of typical type II intervertebral disk degeneration.

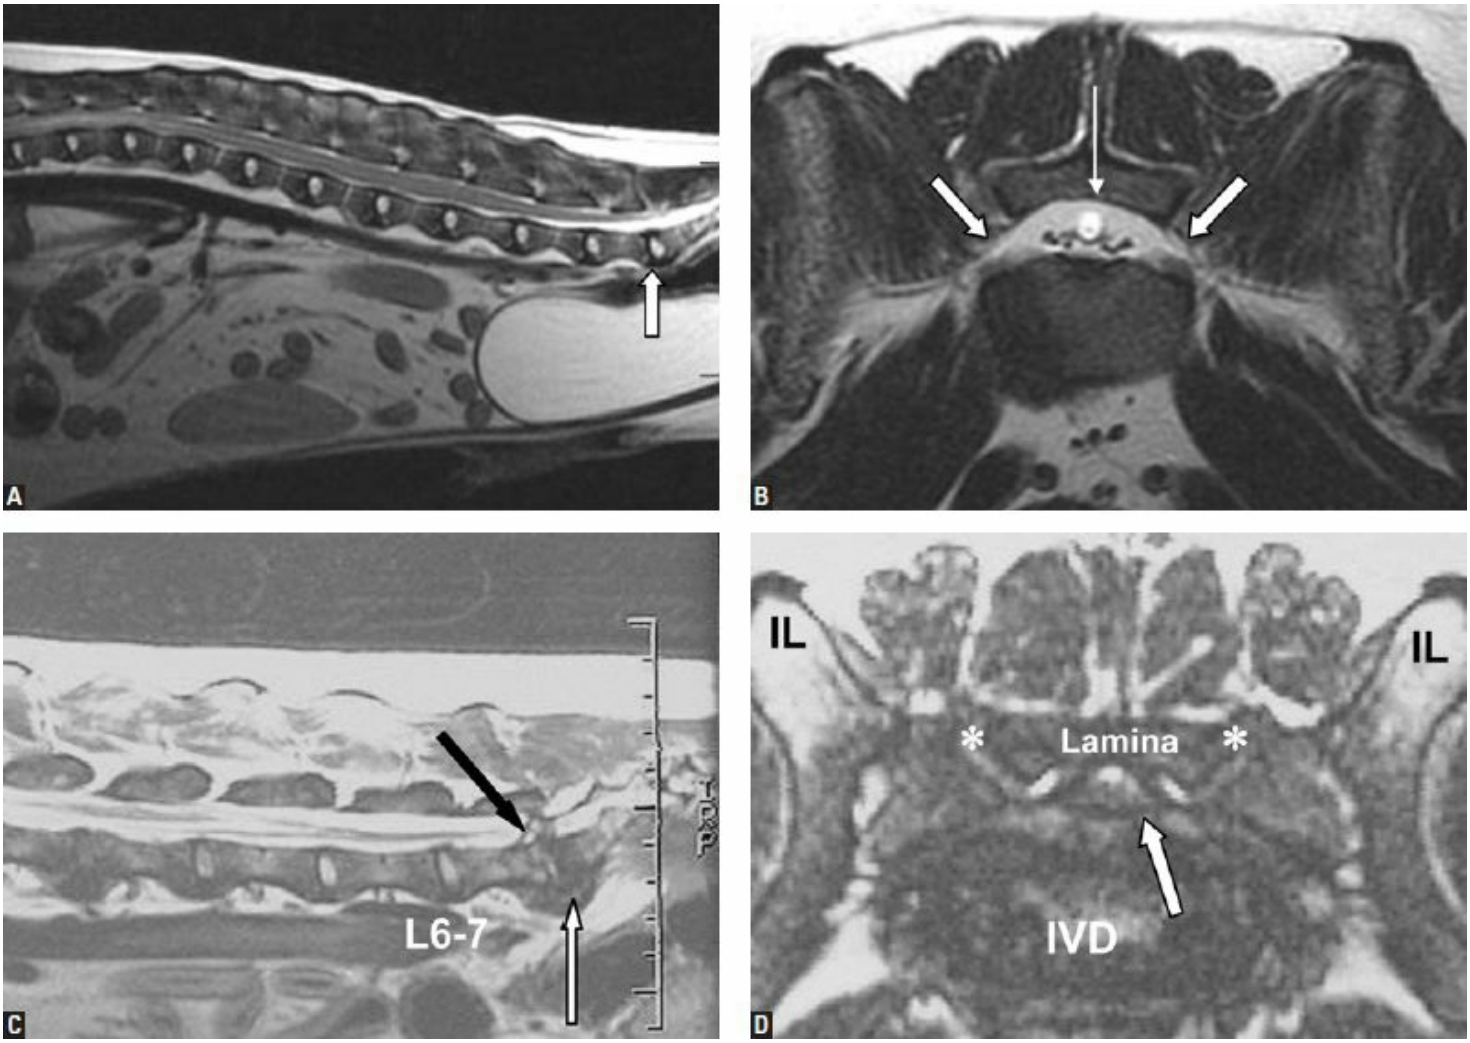

Figure 50-4. MRI images of a dog with a normal lumbosacral junction (A and B) and from a dog with degenerative lumbosacral disease (C and D). A. T2-weighted sagittal plane MRI. All of the intervertebral disks are well hydrated. The neural tissue and fat are easily identified in the lower lumbar and sacral spinal canal. White arrow = L7-S1 disk B. T2-weighted transverse plane MRI through the L7-S1 joint. Thin arrow = spinal canal containing the dural tube, nerve roots and epidural fat. Block arrows = L7 nerve roots exiting the L7-S1 intervertebral foramen. C. T2-

weighted, sagittal plane MRI. There is a large disk extrusion at the L7-S1 disk and the canal is severely stenotic. (black arrow) Multiple degenerative intervertebral disks (noted by loss of signal owing to dehydration) are at L3-4, L4-5, and L7-S1. Ventral spondylosis is noted at the lumbosacral joint (white arrow) and other disk spaces as well. D. T2-weighted, transverse plane MRI through the L7-S1 disk space. The spinal canal is obliterated with extruded disk material (white arrow), and the neural anatomy is difficult to appreciate. IL = wing of the ilium; IVD = intervertebral disk; * = L7-S1 facet joint.

The term transitional vertebrae encompasses a variety of congenital osseous abnormalities seen in vertebrae between the spinal segments. Most commonly, these changes have been seen in the lumbosacral motion segment.[23] This abnormality displays morphologic characteristics of both lumbar and

sacral vertebrae.[24-26] Normally, the development and alignment of the last lumbar vertebrae are such that the transverse processes are not in contact with the ilia.[23] Abnormal development arises through abnormal mechanisms during growth in the ossification centers of the sacrum and/or L7 vertebrae.[23] The most distinct abnormalities usually occur in the transverse processes, which may or may not be attached to the ilium or sacrum.[23,24,26] Variations in the morphology of the vertebral body are less common.[23,26] These abnormalities may result in abnormal sacroiliac attachments (usually shortening of the attachment on the affected side) and abnormal rotation of the pelvis.[23] The

abnormal anatomic alignment likely results in altered biomechanics and excessive loading on the intervertebral disk and facet joints. Transitional vertebrae may, therefore, be clinically relevant to degenerative lumbosacral disease, especially in German shepherd dogs, which have a high reported incidence of degenerative lumbosacral disease.[23,24,26-28]

Transitional vertebrae in people are more likely to be associated with degenerative disk disease and facet joint degeneration at the joint above the transitional vertebra, and this malformation is somewhat protective against degenerative changes to the disk below.[29] The joint between the

transverse process of the transitional vertebra and the sacrum may be restrictive to rotation and bending, thus protecting the lumbosacral disk (L5-S1 disk in people) from excessive biomechanical forces.[29,30] The disk height below the transitional vertebra is found to be shorter than disc heights of the upper levels in young men, but the disk height is similar in people with this condition in comparison with that in normal men in the middle-aged population.[29] The shortened disk height in the unaffected older population is presumably a result of degeneration.[29,31] The protective effect of the transitional vertebra on the disk below is stronger for the annulus fibrosus than the endplate and nucleus

pulposus but it is postulated that the degenerative changes seen in these structures may be induced by another mechanism, i.e., natural aging of the disk.[29]

Clinical Signs of Lumbosacral Disease

Clinical signs of lumbosacral spinal disease are differentiated from injury to the lumbosacral spinal cord segments. Because of the neurologic anatomy at the lumbosacral joint, the L7 and the sacral and caudal nerve roots are typically affected rather than the spinal cord by pathology at the lumbosacral junction. Compression of the cauda equina is most often

associated with pain, gait changes, and mild-to-moderate degrees of neurologic dysfunction compared with injury to the lumbosacral spinal cord segments that may be more complete or severe. Table 50-2 is a list of the possible findings during the neurologic examination in animals with cauda equina syndrome. It is important to note that not all of the deficits listed in the table are necessarily present in any one patient.

The most common disease entity affecting the cauda equina is stenosis, or narrowing of the spinal canal, which results in compression of the nerve roots.[2,4-7] Dogs often display signs of lumbosacral pain observed on

deep lumbosacral palpation with or without hip extension, dorsal elevation of the tail base, rectal palpation (pressing dorsally), and pelvic limb wheelbarrowing. Clients often comment on lower tail carriage or lack of tail wagging. Pain associated with lumbosacral disease may originate from the disk (diskogenic pain), nerve root and inflamed articular facet capsules, and spinal ligaments. Radicular, or nerve root, pain may be manifested as allodynia, dysesthesia, hyperesthesia, orparesthesia.[32] Definitions of these pain syndromes are shown in Table 50-3. The pathogenesis of pain associated with lumbosacral disease will be discussed further.

It is critical to rule out the presence of coxofemoral osteoarthritis as a source of lumbar area pain, which can also be present concurrently. Lumbosacral pain often leads to lameness, which is either intermittent or persistent, and a bunny hopping gait. These gait changes are also seen with coxofemoral disease. Difficulty rising, exercise intolerance, and inability to perform tasks that were once normal activities may be attributed to both pain and/or weakness.

Neurologic examination may be normal in an animal with only lumbosacral pain, or, if the results are abnormal, the examination may reveal pain and mild deficits in postural

reactions and spinal reflexes. Earlier recognition of signs, improved health care for pets, and finally, improvements in diagnostic modalities and therapies may contribute to the lower incidence of significant neurologic deficits seen by the author. However, the disease may result in variable degrees of dysfunction in the postural reactions and reflexes innervated by the sciatic, sacral, and caudal nerves. These include deficits in conscious proprioception, hopping reactions, decreased-to-absent spinal reflexes, urinary and/or fecal incontinence, and abnormal tail and perineal function or sensation.

The patellar reflex is spared because

the nerve roots that supply the femoral nerve (L4-L6) have exited the spine rostral to the lumbosacral joint. Paraplegia is rare because when femoral nerve function is intact, the pelvic limb can extend and bear weight. In cases of severe sciatic nerve dysfunction, the animal may be very weak, but not usually nonambulatory. When the sciatic nerve is extremely dysfunctional, the patellar reflex may appear to be exaggerated. This is called “pseudohyperreflexia” because it is not a true “upper motor neuron” sign, but occurs secondary to loss of antagonist muscle action in the biceps femoris, semitendinosus, semimembranosus, and gatrocnemius muscles. Typically, this “false” reflex is

observed as a brisk extension of the limb with a poor rebound of flexion of the hock. True hyperreflexia is associated with clonus of the limb.

Table 50-2. Neurological Examination Findings with Lumbosacral Disease

Signs	Comments
Mentation	Normal
Gait	Normal thoracic limbs
	May be ataxic in the pelvic limbs
	May be weak

(paraparesis or monoparesis) in the pelvic limbs, primarily in the muscles innervated by the sciatic nerve (weakness is usually mild and paralysis is rare)

Lameness (intermittent or persistent)

Bunny-hopping gait

Difficulty rising

Decreased exercise tolerance

Postural reactions	Normal in thoracic limbs Conscious proprioception may be normal or decreased-to-absent in the pelvic limbs, depending on the severity of the nerve root injury Hopping reactions may be normal-to-decreased; rarely absent unless injury to nerve roots is severe (spinal fracture with root avulsion)

Spinal reflexes	Normal in thoracic limbs
	Muscle tone in pelvic limbs and anal sphincter may be normal, or decreased (hypotonic)-to-absent (flaccid) depending on the severity of the nerve root injury
	Myotatic femoral (patellar) reflex is normal*

Myotatic reflexes are normal or decreased-to-absent (hypore-flexia to areflexia) in the distribution of reflexes innervated by the sciatic and sacral nerves, depending on severity of the nerve root injury

Deep pain response is often intact but may be decreased-to-absent in the lateral toes, tail, and perineal region,

	depending on severity of the nerve root injury
Pain	Most diseases in this region cause pain: intervertebral disk disease/degenerative acquired disease vertebral neoplasia diskospondylitis osteomyelitis trauma/fracture vertebral anomalies (+/-)

	Non-painful diseases
	Nerve root avulsion without spinal fracture
Urinary incontinence	May have lower motor neuron bladder dysfunction
	May dribble urine
Other	May have fecal incontinence and/or dilated anal sphincter
	Nerve root signature (less common than C6-T2 lesions)

	May have tail weakness/paralysis Paresthesia may lead to self-mutilation (tail, pelvic limbs) Dysesthesia

Table 50-3. Definitions of Pain Syndromes that May Occur with Nerve Root Injury[32]

Allodynia	Pain caused by a stimulus that does not normally induce pain

Dysesthesia	An unpleasant abnormal sensation, whether spontaneous or evoked
Hyperalgesia	Increased response to a stimulus that is normally considered painful
Paresthesia	An abnormal sensation, whether spontaneous or evoked

Occasionally, the single or most severe clinical sign of lumbosacral disease is loss of autonomic function, such as urinary and/or fecal incontinence. The function of the bladder is impaired by disruption of the S1-3 parasympathetic

nerve fibers that form the pelvic nerve and control function of the detrusor muscle of the urinary bladder. The somatic fibers that are present in the S1-3 spinal nerves control the external urinary sphincter, or urethralis muscle. In addition, the sensory afferent fibers are also affected. The sensory afferent fibers send information to the sacral spinal cord that facilitates local reflex activity. Ascending information from these fibers also converges on the sympathetic preganglionic nerve cell bodies in the thoracolumbar spinal cord (around L1-4) which form the hypogastric nerve that innervates the internal urinary sphincter. The varying degree of loss of ascending information to these cell bodies may result in

inefficient internal urinary sphincter tone as well. However, this sphincter may be somewhat more functional than the urethralis muscle and may contribute to any retention of urine present. Presence of significant autonomic dysfunction typically results in a guarded prognosis even with therapy.[5,33]

An animal sometimes displays nerve root signature with compression of the cauda equina. This is characterized by lifting the pelvic limb on ceasing movement. It is probably related to an attempt to improve comfort by decreasing stretch of the nerve root that has been compressed. Nerve root signature appears to be much more

common with cervical radiculopathy in which the animal will hold up a thoracic limb.

Pathophysiology of Pain in Lumbosacral Disease

Pain is one of the key clinical features of lumbosacral stenosis and degenerative disease. Although the causes of pain might seem some what obvious, the variable nature of the degree of pain and the lack of resolution of pain following decompressive surgery among individual human and animal patients remain an enigma.[34] Direct mechanical compression of the nerve roots plays a role in the pathogenesis of pain, but it

is not the sole cause. A tremendous amount of research has been conducted in both experimental and clinical settings to elucidate the underlying causes of low back pain with lumbosacral degenerative disease. Pain results from compression and inflammation of sensory nerve roots (radicular pain) and from degenerative and inflammatory changes in the articular facet joints, other supporting structures, and the intervertebral disk (diskogenic pain).[35]

Many of the neuropathic pain models that have been developed experimentally involve the manipulation of the sciatic nerve, the cauda equina, or an isolated nerve

root. Injury to the nerve, nerve root(s), or cauda equina has been induced by many mechanisms: manipulation, transaction, ligation, cryoneurolysis, crush, and chronic constriction.[36-39] Local pathophysiology at the site of nerve injury has implicated a plethora of potential mediators of pain. Compression of the nerve or nerve roots results in mechanical deformation with spontaneous (ectopic) depolarization of the nerve, vasogenic edema, infiltration of immune cells with subsequent up-regulation of immune mediators in both the nerve roots and spinal cord, and central sensitization of the spinal cord to up-regulate pain perception.[35,40] These factors are not

independent entities and are interrelated in a complex pathway (Figure 50-5).

Nociception in the Anatomic Structures of the Spine

On a basic nociceptive level, sensory innervation is present to all of the structures of the spine.[41] Innervation to these structures primarily arises from the primary dorsal nerve root distal to the dorsal root ganglion.[42,43] Recurrent articular nerves innervate the vertebral periosteum, articular facet joint capsules, and ligamentous tissues of the dorsal neural arch (e.g., interarcuate ligament).[42] Another branch forms the sinuvertebral nerve,

which enters back into the intervertebral foramen and gives rise to cranial and caudal branches that supply rich innervation to the dorsal longitudinal ligament and dorsal annulus fibrosus of the intervertebral disk.[42] These fibers were recently shown to possess sensory-specific sodium-gated pain channels (SNS/PN3 and NaN/SNS2), which may provide a new therapeutic mechanism for analgesia.[41] The extension of these fibers over one to two vertebral segments may limit precise localization of pain to a specific intervertebral joint.[41] These two sensory nerves also have an intimate association with the autonomic plexus.[41] Painful or pathologic conditions of these nerves

or of structures innervated by them may result in autonomic manifestations.

Because the articular facet is a true arthrodial joint, facet-associated pain can be attributed to mechanical stresses, osteoarthritis, and synovial inflammation.[44-47] Similar to other load bearing joints, degenerative changes in the articular facet include hyaline cartilage degradation, remodeling and osteosclerosis of subchondral bone, and osteophyte formation.[47] Although inflammatory processes in typical joints (i.e., knee and hip) have been well documented, studies evaluating the facet joint are few.[47] Pain secondary to osteoarthritis

and joint degeneration is associated with cytokines produced by the arachidonic acid cascade. In one study, multiple prostaglandins and leukotrienes, both products of the arachidonic acid cascade, were produced in the facet joint, disk tissues, and subchondral bone of human patients with degenerative lumbosacral spinal disorders. The cytokines produced were similar to those obtained from cartilage and subchondral bone tissues of other osteoarthritic joints.[48] In another human clinical study,[47] the synovium and joint cartilage of 40 patients undergoing lumbar spinal surgery were harvested for evaluation of cytokine production. Although the focus of the

study was to identify the presence of interleukin-Iβ (IL- Iβ) and tumor necrosis factor-α (TNF-α), the authors were surprised to find that these cytokines were not found in a high concentration in patients with either lumbar disk disease or spinal canal stenosis. However, interleukin 6 (IL-6) concentration was elevated in both groups of patients. IL-6 production has been found to be induced by both IL-Iβ and TNF-α. Both of these cytokines are believed to be present early in acute inflammation and subsequent production of IL-6, further contributing to the inflammatory cascade.[49-54] The presence of elevated IL-6 without increased IL-Iβ and TNF-α may be attributed to the chronic nature of

degenerative lumbar disease.

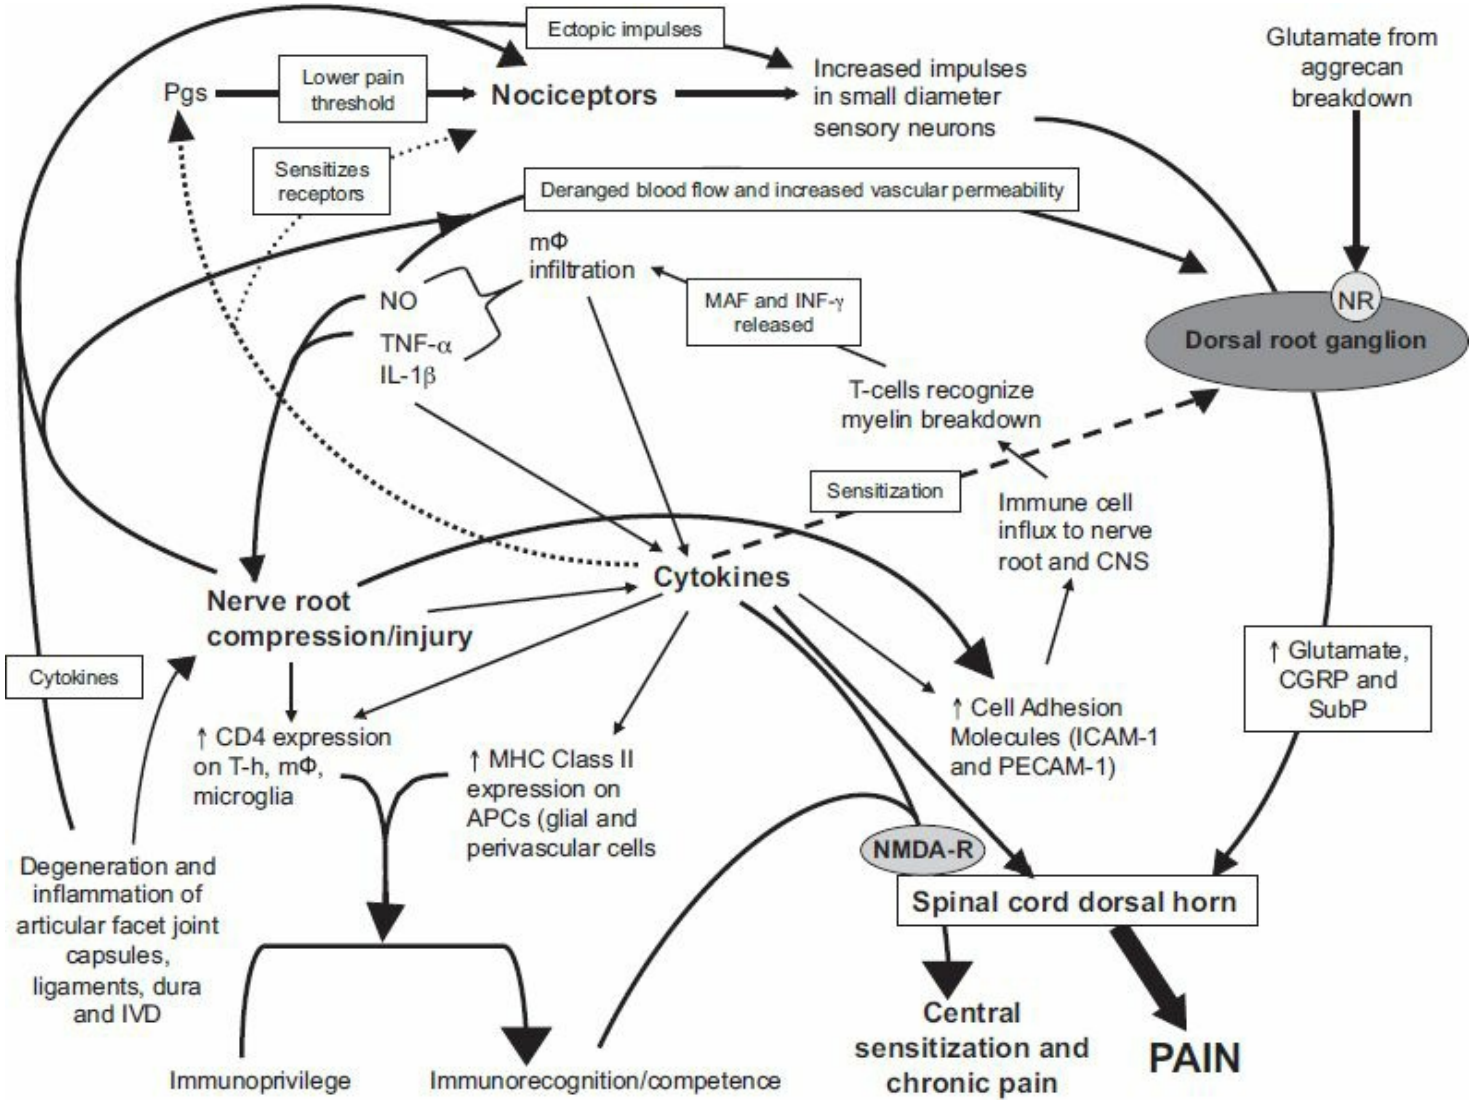

Figure 50-5. A schematic overview of the interplay of factors in acute and chronic radicular pain with nerve root compression. Abbreviations: Pgs = prostaglandins; NO = nitric oxide; mΦ = macrophages; TNF-α = Tumor Necrosis Factor-α; IL-1β = Interleukin-1β; MAF = Macrophage Activating Factor; INF-γ = Gamma-interferon; NR = nociceptive receptor; T-h = T-helper cells; APCs = antigen presenting cells; ICAM-1 = Intercellular Adhesion Molecule 1; PECAM = Platelet Endothelial Cell

Adhesion Molecule-1; CGRP = Calcitonin Gene Related Peptide; SubP = Substance P; NMDA-R = N-Methyl-D-Aspartate Receptor; IVD = intervertebral disk.

Less attention has been given to pain generated from compression and inflammation of the dura mater. Sensory innervation of the dura mater is provided by the sinuvertebral nerve which carries both sensory and sympathetic fibers.[55] Many peptidergic (pain-associated) nerve fibers are distributed throughout the dura mater[55] and likely play a role in generation of pain.

Mechanical Deformation of the Nerve Roots and Cauda

Equina

In the normal state, the nerves of the cauda equina are somewhat moveable within the spinal canal and intervertebral foramen to accommodate changes in spinal extension and flexion and movement of the pelvic limbs. When the nerve roots become compressed or entrapped by extruded intervertebral disk, hypertrophied tissues, or canal stenosis, the movement of the nerve root becomes limited and traction and compression of the nerve root induce pain mechanisms and morphologic changes in the nerve. Chronic compression can be thought of as repeated episodes or persistence of acute compression.[40] The basic

underlying pathophysiology of pain in degenerative lumbar spinal disease has been extensively studied. It begins with nerve root compression within the entire cauda equina or with compression of select nerve roots. Direct mechanical, chemical injury or mechanical injury to lumbar roots in the rat produces mechanical allodynia and thermal hyperalgesia.[56] Pain, allodynia, and numbness are subjective symptoms of lumbar radiculopathy that may be induced by ectopic or spontaneous firing of nociceptive sensory neurons.[43,57] Excitability and spontaneous firing in the dorsal root ganglion have been shown to be linked to sensory nerve sodium-gated channels (SNS/PN3 and NaN/SNS2)

recently implicated in neuropathic pain.[41] Mechanical compression has additionally been shown to lead to intraneurial tissue reaction, including edema, demyelination, and fibrosis.[40,58,59] Various morphologic and physiologic changes occur with separate phases (acute, subacute, and chronic) of nerve root compression.[37,40,59-62] A study by Kobayashi et al[40] evaluated the morphologic derangements induced by clip compression of the L7 nerve root in a dog model. The clip was retained postoperatively and the nerve roots were evaluated at 1 and 3 weeks postoperatively. Three characteristic processes were observed: Wallerian degeneration, influx of macrophages,

and radiculitis. Wallerian degeneration was observed in the nerve root proximal and ventral to the dorsal root ganglion. In the regions of Wallerian degeneration, macrophages were observed metabolizing necrotic debris. Macrophages are involved in the inflammatory cascade by enhancement of vascular permeability, production of chemotactic signals for other inflammatory cells, and modulation of these cells' activity the exact origin of the macrophages is unknown.[63,65] Nervous tissue does not possess a lymphatic system; however, the cerebrospinal fluid may play a role similar to the lymphatic system because the flow of the fluid can remove metabolites and waste

products from the spinal cord and nerve roots.[63-65]

Many studies have been performed elucidating the pathogenesis of radiculitis associated with nerve root compression. Chemically induced inflammation of the nerve root by the presence of ruptured disk tissue disseminated along the root sheath has been proposed.[35,63,66] Disk substances thought to play a role in inducing chemical radiculitis include glycoproteins, immunoglobulin G, phospholipase A_2, cytokines, and hydrogen ions.[35,63,64,66-69] Although these findings do not explain the production of inflammation with lumbar canal stenosis, compression of

a nerve root results in intraneurial edema and macrophage influx, which is associated with production of inflammatory cytokines, such as IL-1β, IL-6, and TNF-α, nitric oxide, and proteases.[49-54,67]

In a study paralleling the dog nerve-clipping model,[63] changes in the dorsal root ganglia were evaluated at 24 hours, 1 week, or 3 weeks after clipping. Compression of the dorsal roots proximal to the dorsal root ganglion resulted in an impairment to axonal flow in the root and morphologic changes including central chromatolysis in cell bodies of the dorsal root ganglion. Axonal transport plays a role in both the retrograde and

anterograde movement of neurotransmitters, nutrients, and neurotrophic factors that are synthesized by dorsal root ganglion cells. Disturbance of axonal flow would be expected, then, to cause neurologic dysfunction. Central chromatolysis and other morphologic changes seen in the ganglion were considered a reflection of decreased synthesis of neurotransmitters and other neuronal homeostatic factors in favor of structural proteins such as the cytoskeleton and neurotrophic factors required for repair.[63,70;71] Nerve growth factors and other neurotrophic factors are thought to be involved in the maintenance of sensory neurons and may actually inhibit cell death

after nerve transecton.[63,72-76] When compression results in mild central chromatolysis, the neuron can usually recover fully once the compression is relieved. However, sustained compression could result in irreversible damage to the dorsal root ganglion, which may, in part, explain those patients that do not recover neurologic function after decompressive surgery.

Intraneurial Blood Flow and Edema

Decreased blood flow within nerve roots or the cauda equina may play a role in the symptoms seen in patients with degenerative or stenotic lumbosacral disease.[77] Blood flow is

shown to be negatively affected by experimental nerve root constriction,[61,78-81] and hypoxic stress was shown to induce ectopic firing in the dorsal root ganglion and increased sensitivity to mechanical stimuli.[78,82] A large number of sensory roots pass through the dorsal root ganglion, which has an abundant vascular network and no blood-nerve barrier.[80,83] Compression likely occurs first in thin-walled venules, which results in impaired perfusion of the capillary system that feeds the nerve roots, producing ischemia and augmenting radicular edema.[58,62,82,84,85] Increased vascular permeability and subsequent edema in the remainder of the root are

attributable to a break down in the blood-nerve barrier.[40,63,84,86] Endoneurial edema, which has been shown experimentally to be temporally associated with the onset of nerve root pain and neurologic dysfunction, is observed in the dorsal root ganglion during compression.[57,80] Edema results in high pressures being exerted on the ganglion cells because the perineurium prevents leakage into the epineurium and the fluid is retained[87,88] (Figure 50-6). The edema may then increase the functional compression in addition to the mechanical stress and contribute to the impaired cell function.[80] In the aforementioned study of canine L7 clipping by Kobayashi et al,[40] increases in vascular permeability were most

marked at 1 week postoperatively and began to resolve by 3 weeks. The early marked edema was attributed to loss of vasomotor control induced by vasoactive amines and neuropeptides produced in response to injury at this site. The persistence of increased vascular permeability beyond the acute injury phase was attributed to a greater demand for blood flow to provide nutrients and metabolic building blocks during regeneration.[40,89] Support of the contribution of vascular compromise in nerve root compression was offered by Hida,[90] who showed that nerve-root blood flow measured intraoperatively during spinal lumbar decompressive surgery was increased in those patients

whose neurologic deficits or pain resolved shortly after operation compared with those patients whose neurologic deficits or pain did not resolve after surgery.

Neuroimmune Responses, Inflammatory Mediators, and Central Sensitization

The process of nociception involves the generation of nerve impulses in small-diameter sensory neurons and propagation of those impulses to the spinal cord. A complex interplay exists between the nociceptors and the inflammatory cascade. Inflammatory mediators cause sensitization or

enhanced responsiveness to stimuli, which are also accentuated by neuropeptides released in the inflammatory cascade.[34] Leukocyte trafficking into spinal cord has been observed in nerve root compression.[91]

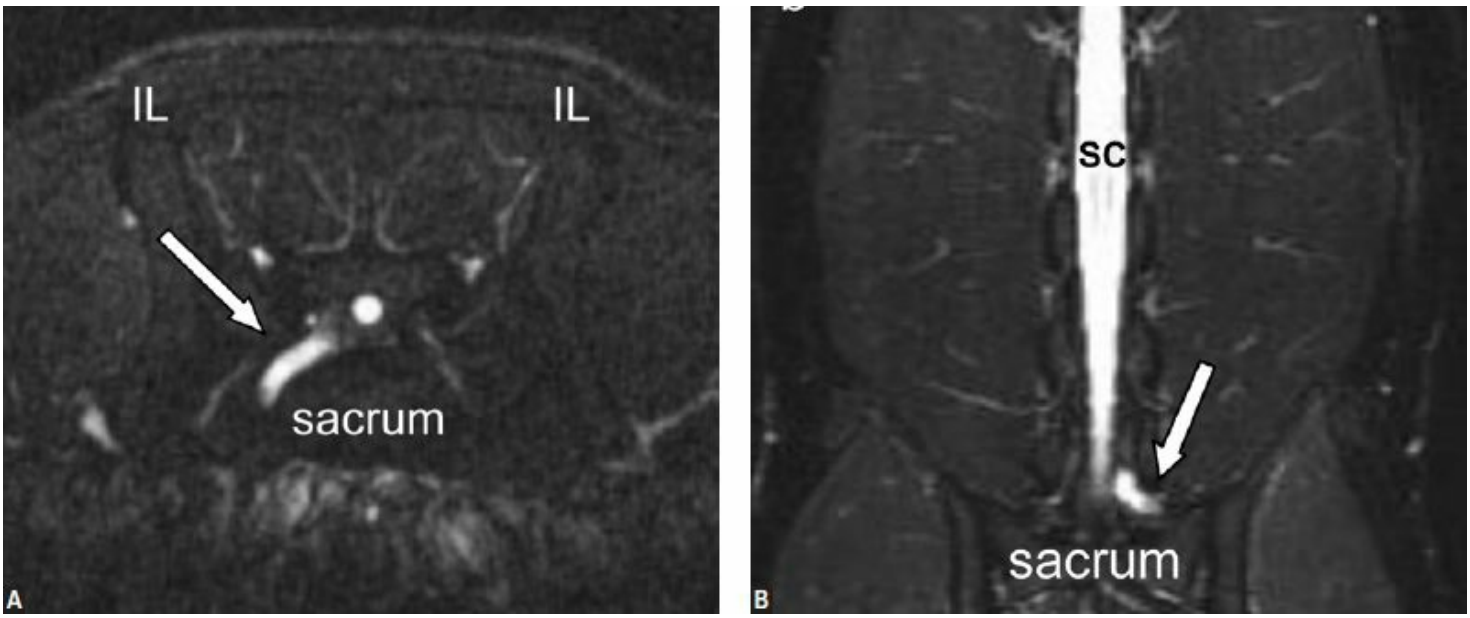

Figure 50-6. A. T2-weighted, transverse plane MRI image at the level of the lumbosacral joint of a dog with left pelvic limb muscle atrophy and lumbar and limb pain. The dog had mild conscious proprioceptive deficits and weakness in the left pelvic limb. Severe swelling of the nerve root was identified (white arrow) intraoperatively and confirmed by biopsy. A

foraminotomy was performed; the dog improved and was normal at 6 months postoperative. IL = wing of the ilium B. T2-weighted, coronal plane MRI image of the same dog. White arrow = edematous nerve root. SC = spinal cord.

The nervous system is considered immunologically privileged, meaning that it is not typically surveyed by circulating lymphocytes as are other organs. Immune-membrane glycoproteins (CD4 and major histocompatibility complex, or MHC class II) and cell adhesion molecules (intracellular adhesion molecule-1, or ICAM-1, and platelet endothelial cellular adhesion molecule-1, or PECAM-1), which are integral to immunologic activation, and influx of immune cells were found to increase in

response to nerve root injury.[91] MCH class II molecules are usually expressed on antigen-presenting cells (APCs) for interaction with T-cells in immune recognition. The antigen-presenting cells in the nervous system are perivascular cells and microglia.[92,93] Glial cells do not usually express MHC class II molecules, but expression can be induced by cytokines.[94] CD4 membrane glycoprotein, expressed on T-helper cells, macrophages, and microglia,[95] plays the role of antigen recognition by APCs in association with MHC class II molecules. Lumbar nerve root injury resulted in enhanced CD4 expression in the grey matter of the spinal cord compared with sham operated and normal rats.[91] The role of

the CD4 molecules is not completely known, but contribution to immunocompetence and response in the CNS after nerve root injury is likely. The nervous system constitutively expresses very low levels of these membrane proteins, which contribute to the nervous system's immunoprivileged status.[91]

Nerve root injury may produce a cascade of events that upregulates ICAM-1, which enables entry of the hematogenous cells into the CNS, contributing to neuroinflammation and the development of central sensitization.[91,91,96-98] The upregulation of these molecules has been temporally associated with the onset of

mechanical allodynia after nerve root injury.[91] Additionally, these changes are associated with the dorsal horn laminae in which nociceptive sensory fibers terminate.[91] Increased expression of cell adhesion molecules and membrane glycoproteins has been demonstrated with various disease processes of the CNS and PNS, including infection, autoimmune inflammation, and nerve root compression.

Experimental models have produced evidence for central neuroinflammation from nerve root compression, which includes astrocyte and glial activation and increased expression of proinflammatory

cytokines.[98-100] Local production of proinflammatory cytokines via immune-cell activation has been implicated in enhanced nociceptor activity.[101] The CNS becomes infiltrated by immune cells from the peripheral circulation.[91,02] Microglia and astroctyes also become activated in response to peripheral nerve or nerve root injury[37] and release pro- and anti-inflammatory molecules, chemokines, and cellular adhesion molecules.[96,97,102]

T cells recognize myelin sheath breakdown products and release macrophage-activating factors such as γ-interferon.[103] Activated macrophages begin to infiltrate locally to remove

cellular debris and release inflammatory cytokines such as IL1-β, nitric oxide, and TNF-α. When applied epineurially, TNF-α was shown to produce hypersensitivity that was blocked when antibodies against TNF-α were co-administered.[101] TNF-α and nitric oxide may potentiate demyelination by Schwann cell injury. Nitric oxide also contributes to increased vascular permeability[104,105] and pain.[106-108] Prostaglandins, which also play an important role in inflammation, have not been shown to have a direct nociceptive effect but may lower the pain threshold at sensory nerve endings.[109] In addition, algesic spinal neuropeptide expression (calcitonin gene-related peptide, or

CGRP and substance P, or SP) was shown in models of nerve root compression.[110] Mechanical compression of the dorsal root ganglion in rats resulted in an increase of substance P concentration in the ipsilateral dorsal root ganglion and spinal dorsal horn cells, which was linked to the onset of pain.[111] Accumulation of SP inside the axons of the central branches increased distal to the dorsal root ganglion as the strength and duration of compression increased, suggesting neurotransmitter dynamics are involved in the appearance of radicular pain.[112]

The amino acid glutamate is one of the most ubiquitous neurotransmitters and

has been shown to be associated with pain processing throughout the nervous system.[113-117] Glutamate antagonists that work at NMDA, AMPA, and kainite receptors have been shown to attenuate pain responses in rat models.[113-120] Although the actions of glutamate in the dorsal root ganglion are not completely known, the cell bodies have been shown to possess a high density of glutamate receptors[121-124] colocalized with nociceptive neurons,[114,125,126] and mechanisms for reuptake of glutamate from the neuromuscular junction have been identified.[122,123,127-129] Consequently, glutamate is also found in high concentrations in aggrecan, the most

prevalent proteoglycan in the extracellular matrix of the intervertebral disk.[117,130-133] Harrington et al[134] hypothesized that glutamate released by proteoglycan degradation during disk degeneration may be a potential source of biologically active neurotransmitter by diffusing across the extradural space to affect glutamate receptors in the dorsal root ganglion.[117,133,135,136] Human herniated and non-herniated intervertebral disks were evaluated using both high-performance liquid gas chromatography and immunohistochemistry to test for the presence of glutamate. Glutamate was found to be abundant in the extracellular matrix of the

intervertebral disk with concentrations significantly higher in the herniated disk material, suggesting release of glutamate from the proteoglycan structure. In addition to identification and semi-quantification of glutamate from the intervertebral disk, they evaluated the ability of tritiated-glutamate to diffuse across the epidural space and bind with glutamate receptors on dorsal root ganglion cells in a rat model. Tritiated glutamate was found to be bound to dorsal root ganglion receptors when infused into the epidural space at levels two magnitudes lower than that measured in the herniated disk material. These results suggested that the dorsal root ganglion cells were capable of

glutamate uptake from the epidural space and that the concentration of glutamate normally present in the epidural space was relatively low, resulting in a steep concentration gradient diffusing from the herniated intervertebral disk material into the dorsal root ganglion. Further studies are required to understand how free glutamate affects nociceptive pathways in the dorsal root ganglion.

Pain from lumbosacral disease is characteristically chronic in its nature. Nerve injury may lead to potentiation of central sensitization and the development of chronic lumbar radiculopathy.[34] It has been shown that long-term potentiation occurs in

the spinal cord in response to noxious stimulation or injury to peripheral nerves.[137] Repeated nerve root injury in a rat model produced significant increases in the magnitude and duration of mechanical allodynia in the paw of the rat.[34] Studies have shown the involvement of chemical factors (cytokines) around the nerve root associated with radicular pain.[138-141] Moreover, early on, pronounced spinal neuroimmune activation and inflammation induce central sensitization by directly or indirectly inhibiting interneuron inhibitory activity at the dorsal horn in the spinal cord.[37] Glial and neuronal proinflammatory cytokines can sensitize the peripheral nociceptive

fields and dorsal root ganglia.[142,143] Glial cells synthesize proinflammatory cytokines, proteases, inducible-NO, excess glutamate, oxygen free radicals, eicosanoids, and other toxins that act at the NMDA (N-methyl-D-aspartate) receptors that are implicated in central nervous system sensitization.[56,144-149] Finally, supporting the concept of central sensitization, nerve root compression exhibits the features of mirror pain.[34] Mirror pain is the presence of pain sensation in the opposite limb when only unilateral nerve root compression is present.

Part VI

Respiratory System

Chapter 51

Brachycephalic Upper Airways Syndrome

Gilles P. Dupré
Cyrill Poncet

Brachycephalic breeds are usually distinguished from mesocephalic and dolicocephalic breeds by their shortened skull, which is a result of early ankylosis of the skull cartilages. Brachycephalic breeds have been defined by different measurements:[1,2] A skull width to length ratio greater

than 0.81, a face to skull ratio of 1.6 to 3.44, or a craniofacial angle less than 14° (angle between the base of the skull and the facial skull). Breeds usually recognized as brachycephalic by these definitions include: Boston terrier, English and French bulldog, pug, Pekinese, Shi-tzu, and Cavalier King Charles. Some miniature breeds as Yorkshire terriers and miniature pinschers are also often included in this list.

Upper respiratory syndrome has been described in brachycephalic dogs (BD). Clinical signs usually include snoring, inspiratory dyspnea, exercise intolerance, stridor, cyanosis, or even syncopal episodes in more severe

cases. These problems are usually aggravated with stress, exercise, or heat. Labored breathing is accompanied by over dilatation of the chest, because a higher intrathoracic negative pressure tends to suck the abdomen into the thoracic cavity. The upper respiratory syndrome usually becomes more severe with increasing age. Vomiting or regurgitation of saliva is also frequently encountered in association with this syndrome.

Anatomy of the Upper Airways in Brachycephalic Dogs

Several anatomic abnormalities can be found in the brachycephalic dog.[1,2,3]

The cartilaginous skeleton of the external nares is usually shorter, thicker, and medially displaced compared with non-brachycephalic breeds, causing secondary obstruction of the nostrils. Owing to shortening of the skull, the size and shape of the conchae are modified, leading to potential intranasal stenosis. The transition from hard to soft palate is usually caudal to the last molar in dolichocephalic and mesocephalic breeds, whereas it is more caudally located in BD. The soft palate, which normally extends to the top of the epiglottis, can extend up to 1 to 2 cm beyond the epiglottis and can be readily aspirated into the rima glottidis during inspiration. On radiographic

examination (Figures 51-1 and 51-2) one can readily see that, in BD, the soft palate is not only overlong but also over-thick.[4] In many BD, especially French and English bulldogs, the base of the tongue is also hyperplastic; the term macroglossia has usually been used to define this abnormality. Besides these findings, other tissue redundancies can be found, especially in the oro- and nasopharynx region.

The rima glottidis, the narrowest airflow passage of the upper airways, is formed by the paired arytenoid cartilages and the vocal folds. The laryngeal saccules, or ventricles, are located cranial to the vocal folds and cannot be seen in a normal dog. In

many BD, the laryngeal ventricles can be seen protruding into the laryngeal lumen.[5] Owing to an abnormal embryogenesis, the trachea of some brachycephalic dogs (mainly English bulldogs) is hypoplastic, which further decreases the upper respiratory air flow.[6]

These anatomic anomalies are responsible for a multifocal obstruction of the upper-airways. The nostrils are narrowed by medially displaced nares, the nasopharynx and the oropharynx are “blocked” between a hyperplastic tongue and an overthick soft palate, and the rima glottidis is obstructed by the overlong soft palate. These anatomic abnormalities have

secondary adverse functional consequences on laryngeal function.

Figure 51-1. Lateral radiograph of pharyngeal region of a mesocephalic dog. The oro- and nasopharynx can be readily seen as two broad stripes of aeric density.

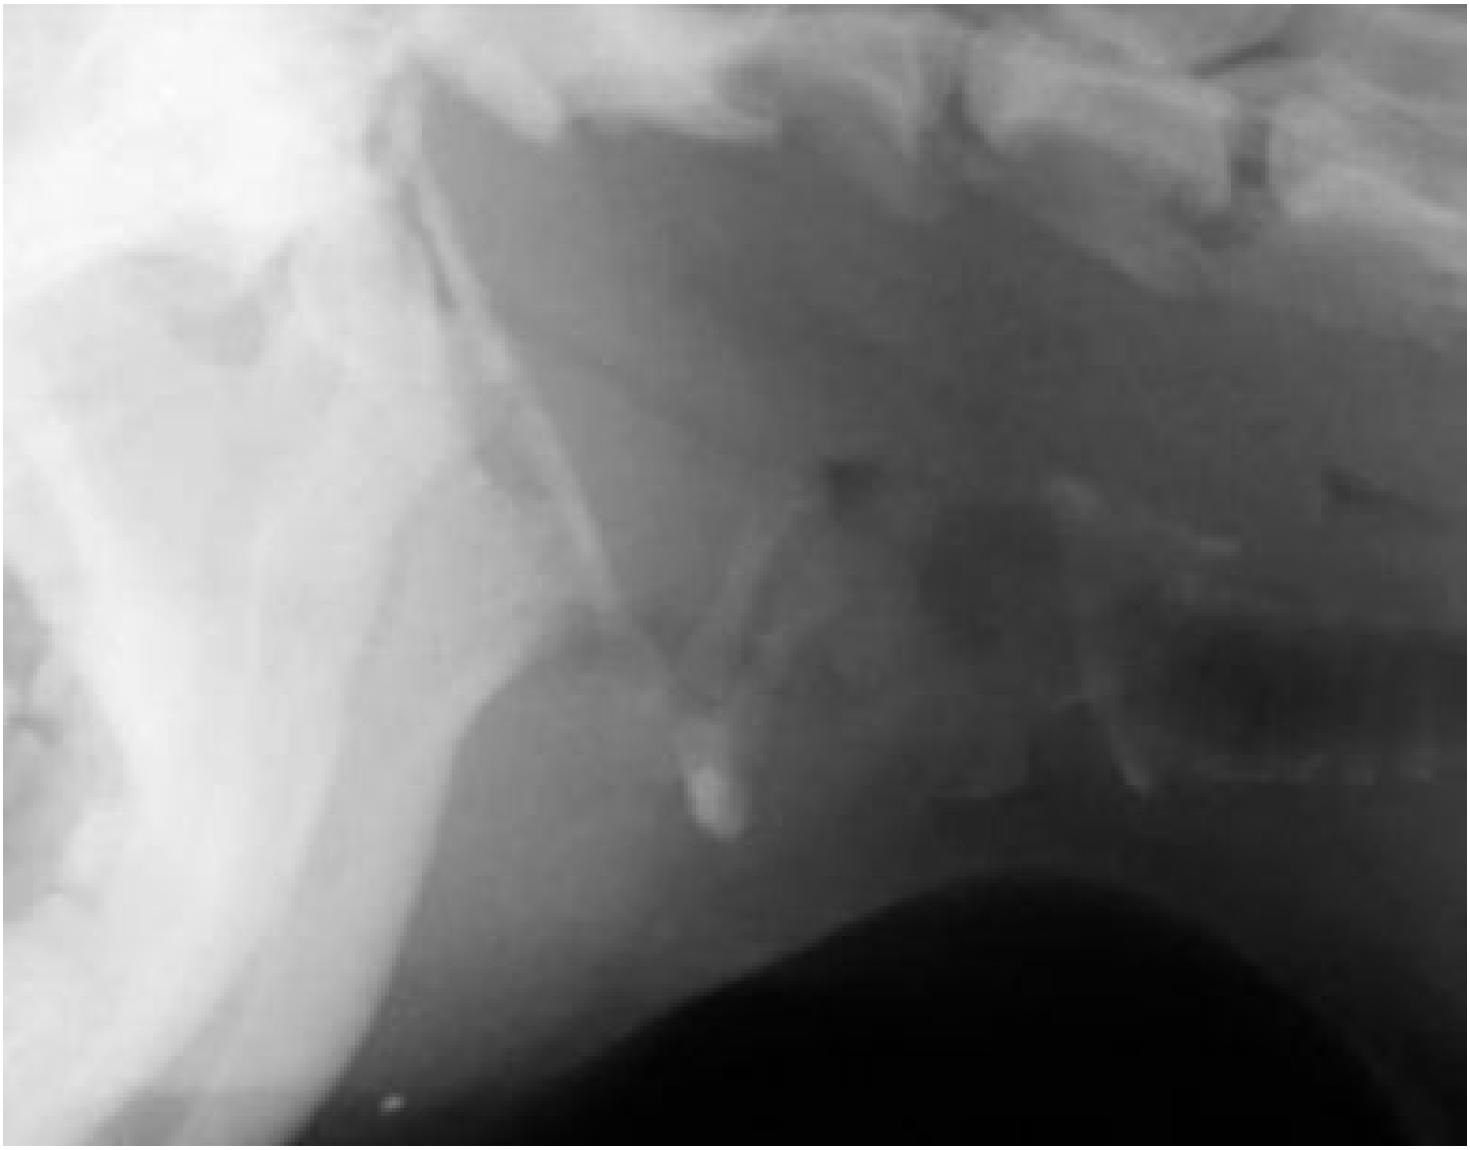

Figure 51-2. Lateral radiograph of pharyngeal region of a brachycephalic dog. The two broad stripes of aeric density have disappeared and the soft palate appears both elongated and thickened.

Pathophysiologic Consequences

Brachycephalic dogs must produce higher negative pressure to breathe properly given their narrowed nostrils and nasal passages. During inspiration, the soft palate flutters into the rima glottidis and can even obstruct it. In some instances when negative pressure is high enough, it may exceed the natural resistance of the tissues, causing their collapse. This can be observed clinically in the nostrils and also in the larynx. The cuneiform and corniculate cartilages are drawn into the glottal opening following increased inspiratory efforts, causing laryngeal collapse. In these cases, an inspiratory stridor and even suffocation can be observed. In such patients the laryngeal ventricles are

usually everted into the laryngeal lumen. Everted laryngeal ventricles and laryngeal collapse are secondary events that lead to even more severe respiratory compromise.[2,5,7]

Other Findings in Brachycephalic Dogs Suffering from Upper Airway Compromise

Many owners describe signs of regurgitation or vomiting when their BD becomes excited or suffers respiratory distress.[7,8,9] In these instances, signs of respiratory distress are usually relieved when the dog vomits or regurgitates large packs of

“foam.” In one study on 73 brachycephalic dogs suffering from upper airway syndrome,[9] respiratory and digestive signs were graded as minimal (grade 1), moderate (grade 2), or severe (grade 3), according to their frequency and severity. Respiratory signs were moderate in 20 dogs (27.4%) and severe in 51 (69.9%). Nineteen dogs (26%) were presented with grade 1 digestive disorders, 19 (26%) with grade 2, and 35 (48%) with grade 3. Among the 35 dogs with grade 3 digestive signs, 28 (80%) suffered from grade 3 respiratory disorders, 5 (14.3%) from grade 2, and 1 (5.7%) from grade 1. A correlation between the severity of gastric and respiratory signs was

demonstrated ($p = 0.059$).

Diagnosis

Several steps should be undertaken in order to make an accurate diagnosis of brachycephalic syndrome.

History And Clinical Signs

The history usually describes snoring and progressive exercise intolerance aggravated by warm temperature when the dog is 1 to 2 years old.[5,9,10] Therefore, most owners become aware of the problem during the second summer of the dog's life.[7,9,11] Unfortunately, because snoring is considered a normal respiratory feature of BD by most owners,

breeders, and even practitioners, no further diagnostic or therapeutic steps are usually undertaken. With time, the condition worsens until signs of laryngeal collapse occur (inspiratory stridor). In these cases, most owners spontaneously find a way to open their pets' upper airways by opening the mouth and pulling the tongue forward. Concomitantly, vomiting or regurgitating food or saliva usually happens and this is also considered to be a normal feature of BD in most owners' and breeders' minds.

Radiographic Examination

Radiographic examination of the head can be used to assess the length and

thickness of the soft palate. It can often be observed that both oropharynx and nasopharynx are equally compressed by mucosal hyperplasia (Figures 51-1 and 51-2). Thoracic radiographs are recommended in order to diagnose hypoplastic trachea, aspiration pneumonia, and/or secondary right-sided heart failure.[2,11]

Endoscopy

Given the common involvement of upper airways and the upper gastrointestinal tract, endoscopy should be conducted as part of a basic diagnostic work-up.

Length and thickness of the soft palate are assessed and, after removal of the endotracheal tube, the motion of the arytenoid cartilages and position of the ventricles are evaluated. In some cases, especially in very small brachycephalic dogs (e.g., pugs or Pekinese) the arytenoid cartilages are flaccid and have a tendency to rotate inward into the laryngeal lumen.[7] During the same procedure, upper gastrointestinal endoscopy is done. The esophagus, cardia, stomach, pylorus, and duodenum are evaluated. Gastric and duodenal biopsies are recommended.[7,8,9]

Macroscopic and Endoscopic

Findings

Stenotic nares and soft-palate hyperplasia are the two most common anomalies (present in 50 to 85% and 96 to 100% of cases, respectively.[5,8,10,11] Everted ventricles are usually found in 54 to 60% of cases,[10,11] and although more rarely mentioned in the past,[5,11] a moderate to severe laryngeal collapse was present in 64% (39/61) of the patients in a retrospective study.[9]

Although many anatomic malformations of the gastrointestinal tract have been described in BD,[12-15] some authors specifically studied digestive disorders in BD affected by upper airway compromise.[7,8,9] In one

such study,[9] 71 of 73 dogs (97.2%) were presented with esophageal, gastric, or duodenal anomalies. Forty-four dogs suffered esophageal anomalies; 12 presented with an esophageal deviation, 28 had cardial atony, 23 had gastro,esophageal reflux, 3 had axial hiatal hernia and 27 had distal esophagitis. Chronic vomiting, slow gastric emptying, and hiatal hernias have been classically described to explain gastroesophageal reflux.[16] In brachycephalic breeds, a possible explanation is the high positive abdominal pressure generated by recurrent vomiting as well as the negative intrathoracic pressures generated by increased inspiratory work.[17-21] In the same study,[9] among

the 71 dogs suffering gastric anomalies, 65 presented with diffuse inflammation of the body or antrum and a punctiform inflammation was seen in 28 dogs; 23 presented with gastric stasis, 63 with pyloric mucosal hyperplasia, 22 with pyloric stenosis, 4 with pyloric atony, and 6 with duodenogastric reflux. A chronic diffuse or follicular gastritis was found in 50 of 51 specimens (98%). Gastritis was histologically graded as minimal in 13 cases (26%), moderate in 25 cases (50%), and severe in 10 cases (24%).

Gastrointestinal and Respiratory Signs: A Common

Pathophysiologic Pathway

Gastroesophageal reflux associated with regurgitation and vomiting can contribute to upper esophageal, pharyngeal, and laryngeal inflammation. These phenomena have been documented experimentally in animals[22] and clinically in infants.[23] They can further contribute to upper respiratory problems. In turn, respiratory distress could stimulate the autonomous sympathetic nervous system, which would slow gastric motility and increase the gastric emptying time. Furthermore, the dilated antrum would stimulate gastrin-producing cells responsible for muscular hyperplasia.[13,24] In a study in exercising race horses, the pressure

over the lower esophageal sphincter was shown to be related to the obstruction of upper respiratory tract.[25] In humans, a high prevalence of hiatal hernia and gastroesophageal reflux has been demonstrated in asthma patients.[26] Finally, in the dog several cases of gastroesophageal diseases or hiatal hernia have been described associated with upper airway obstruction.[7-9,26,27] The correlation between respiratory and digestive disorders suggests the influence of upper respiratory tract diseases on gastroesophageal diseases, and vice versa. The gastroesophageal disorders, ptyalism, regurgitation, vomiting, and reflux, can aggravate the respiratory signs by encumbering the pharyngeal

region and stimulating persistent inflammation. Conversely, chronic respiratory depression promotes gastroesophageal reflux. The close relation between respiratory and digestive problems is sustained by the fact that most of these animals “vomit” large packs of saliva when excited or stressed or during respiratory distress.

Treatment

Early Relief of Respiratory Compromise

According to the pathophysiology of the syndrome, early relief of the proximally located obstruction should be attempted because it is postulated that early correction could prevent or

even reverse ventricular eversion or laryngeal collapse.[5] Therefore, as soon as snoring is observed, rhinoplasty and palatoplasty are recommended. This has been done as early as at six months of age but the value of an earlier rhinoplasty is still debated.

Medical Treatment of Gastroesophageal Disease

The influence of surgical treatment of the upper airway on improvement in gastrointestinal signs has also been studied.[28] In this study, when an inflammatory gastrointestinal disease was observed endoscopically, a medical treatment, based on inhibition of hydrogen ion secretion (omeprazole

0.7 mg/kg per os every 24 hours) and prokinetic medication (cisapride 0.2 mg/kg per os every 8 hours), was recommended immediately after surgery. If distal esophagitis was noted, an antacid was prescribed for 15 days (magnesium hydroxide, 1 ml/kg per os after meals). Following histologic results, medical treatment was adjusted for each case. For moderate to severe gastritis, a 2-month course of treatment was recommended, including an inhibitor of hydrogen ion secretion (omeprazole, 0.7 mg/kg per os every 24 hours), a prokinetic (cisapride, 0.2 mg/kg per os every 8 hours), a surface protector (sucralfate, 1g per os every 12 hours apart from the meals). For severe gastritis and/or

duodenitis with parietal fibrosis, the same treatment was advised for 3 months and corticosteroids were added (prednisolone starting at 0.5 mg/kg per os every 12 hours).

This study also suggested that, after surgical treatment of the upper airways and despite discontinuation of medical treatment in more than 80% of the cases, a clear improvement of upper gastrointestinal tract disease was observed. In the cases where a control gastroesophageal endoscopy could be obtained six months after upper airway surgery, it always showed a complete resolution of the gastroesophageal endoscopic and histopathologic signs. These findings

support the previous hypothesis of a common pathophysiologic pathway for upper respiratory and upper gatroesophageal disease in brachycephalic dogs.

Surgical Treatment

Nostrils

Several techniques of rhinoplasty have been developed.[2,5] They all aim at opening the lateral wings of the nostrils. Removing this part increases the diameter and contributes to improvement of the nasal air flow.

Elongated and Hyperplastic Soft Palate

Current techniques for treatment of elongated soft palate involve excision of the elongated part.[2,5] Although the level of excision has been recommended to be somewhere between the midpoint and the end of the tonsils, it is also considered wise to cut the soft palate at a level where it just comes into contact with the tip of the epiglottis. A new technique of palatoplasty, the so-called "Folded flap palatoplasty," has been developed to address both the pharyngeal and the laryngeal obstruction.[4] This technique achieves a marked reduction of the thickness of the soft palate, thereby relieving the nasopharynx and oropharynx from obstruction. As with the conventional techniques, the soft

palate is shortened and the laryngeal obstruction is also relieved.

Laryngeal Collapse

In one study,[9] 64% (39/61) of the patients were presented with moderate to severe laryngeal collapse and 54% (33/61) with everted ventricles. Because it is postulated that laryngeal collapse and ventricular eversion are secondary events most likely a result of increased respiratory depression, relief of proximal obstruction should alleviate signs of laryngeal collapse. This has been observed clinically. In this study, only 1 dog out of 61 had laryngeal surgery (arytenoid lateralization) and 1 had an oral

ventriculectomy. Although ventriculectomy has been recommended as a treatment for ventricular eversion, it increases local inflammation and can result in laryngeal webbing. Its benefit in improving clinical signs has not yet been proven. To the contrary, in a retrospective study looking at dogs with ventricular eversion, the overall prognosis was better in those that did not have a ventriculectomy.[10]

Treating laryngeal collapse remains challenging. In cases where clinical signs are not improved after rhinoplasty and palatoplasty, lateralization of one of the arytenoid cartilages can be attempted. This

usually provides an adequate laryngeal opening in cases where the cartilage is stiff enough. In some cases, the arytenoid cartilages are flaccid and have a tendency to invert into the laryngeal lumen. In our experience, these dogs do not respond favourably to lateralization and a permanent tracheostomy should be recommended.

Prognosis

Following this overall medicosurgical protocol, the prognosis 6 months after surgical treatment was graded as good in 22% and excellent in 67% of the cases.[29] Results with this protocol compare favorably with previous studies conducted at the same

institution not accounting for gastroesophageal treatment.[10]

Conclusion

In brachycephalic breeds, anatomic anomalies of the upper respiratory tract, (i.e., stenotic nares and over-long and over-thick soft palate) progressively lead to further impairment of breathing owing to progressive laryngeal compromise (i.e., laryngeal collapse and ventricular eversion). In addition, gastroesophageal disease can be found clinically, endoscopically, and histologically in many brachycephalic dogs suffering from upper airway impairment. To relieve the upper

airway obstruction, an early surgical treatment of the stenotic nares and of the over-long and over-thick soft palate is recommended. A concurrent medical treatment of gastroesophageal signs has also been shown to improve the overall prognosis.

Chapter 52

Laryngeal Paralysis

Catriona MacPhail

The function of the larynx is to regulate airflow, protect the lower airway from aspiration during swallowing, and control phonation. Laryngeal paralysis is the failure of the arytenoid cartilages to properly abduct secondary to muscle or nerve damage. This results in upper airway obstruction because of interference with airflow, particularly during inspiration. Although laryngeal

paralysis can occur in cats, this condition is far more common in dogs and should be considered as a possible differential diagnosis for animals presenting with respiratory distress and stridor.

Functional Anatomy

The larynx is a term used to describe the cartilages that surround the rima glottidis and that are responsible for control of airflow during respiration. The four cartilages that make up the larynx are the paired arytenoids, and the unpaired epiglottis, cricoid, and thyroid cartilages. The base of the epiglottis attaches to the cranial trough of the thyroid cartilage. Laterally the

epiglottis is connected to the cuneiform processes of the arytenoid by mucosa that makes up the aryepiglottic fold. The apex of the epiglottis extends into the oropharynx just beyond the caudal edge of the soft palate. The thyroid cartilage is a U-shaped structure with dorsal horn-shaped projections on each end known as the rostral and caudal cornu. The rostral cornu articulate with the thyrohyoid bones of the hyoid apparatus, whereas the caudal cornu connect with the cricoid cartilage. The cricoid cartilage is a ring-shaped structure that is wider dorsally than it is ventrally. The caudal aspect of the cricoid cartilage connects with the trachea. The paired arytenoid cartilages are irregular structures with

four sets of processes: the corniculate process dorsally, the cuneiform process rostrally, the muscular process caudally, and the vocal process ventrally. The rima glottidis is the elongated opening between the arytenoid cartilages, and it is the narrowest part of the larynx. The glottis consists of the rima glottidis dorsally and the vocal folds ventrally, which are created by vocal ligaments extending from the vocal processes of the arytenoid cartilage.

The cricoarytenoideus dorsalis muscle is solely responsible for enlarging the glottis. The muscle originates on the dorsolateral surface of the cricoid and inserts on the muscular process of the

arytenoids. Contraction of the muscle results in external rotation and abduction of the arytenoids that then pulls the vocal processes laterally. The recurrent laryngeal nerve innervates all of the intrinsic muscles of the larynx except the cricothyroid muscle, which is supplied by the cranial laryngeal nerve. The right side branches from the vagus nerve at the level of the middle cervical ganglion in the thoracic inlet, curves dorsocranially around the right subclavian artery, and then courses cranially along the dorsolateral surface of the trachea. The left side leaves the vagus nerve at about the level of the middle cervical ganglion, but travels caudally and then medially around the aortic arch before

coursing cranially along the ventrolateral aspect of the trachea.

Etiology

Laryngeal paralysis is a common unilateral or bilateral respiratory disorder that primarily affects older large breed dogs. However, a congenital form does occur in certain breeds. Laryngeal paralysis is caused by damage to the recurrent laryngeal nerve or cricoarytenoideus dorsalis muscle resulting in failure of arytenoid abduction during inspiration.

Congenital Laryngeal Paralysis

Congenital laryngeal paralysis has been reported in a variety of canine breeds. An autosomal dominant trait has been documented in the Bouvier des Flandres, resulting in Wallerian degeneration of the recurrent laryngeal nerves and abnormalities of the nucleus ambiguous.[1,2] Although a precise mode of inheritance has not been established, a hereditary predisposition has also been identified in Siberian husky dogs, Alaskan malamutes, and crosses of those two breeds.[3-5] Laryngeal paralysis-polyneuropathy complexes have been described in Dalmatians, Rottweilers, and Leonberger dogs.[6-8] Other reported breeds with congenital laryngeal paralysis include bull terriers and

white-coated German shepherd dogs.[9,10] Respiratory signs are often apparent within the first few months of life, but most dogs are diagnosed at less than a year of age. The prognosis for dogs with congenital laryngeal paralysis is poor, especially in those with concurrent polyneuropathy.

Acquired

Acquired laryngeal paralysis is a common condition of older large and giant breed dogs. The Labrador retriever is by far the most common breed reported, but Golden retrievers, Saint Bernards, Newfoundlands, and Irish setters are also over-represented.[11-16] Average age of onset

ranges from 9 to 11 years. In most studies, male dogs appear to be more commonly affected.[12,14,15] Laryngeal paralysis has also been described in cats.[17] Proposed causes of laryngeal paralysis include accidental trauma, intrathoracic masses, cervical masses, and neuromuscular disease (Table 52-1). There is an association between acquired laryngeal paralysis and hypothyroidism, but a direct link has not been determined.[18] For dogs that are diagnosed with concurrent hypothyroidism, thyroid supplementation should be instituted, but this typically does not improve the clinical signs of laryngeal paralysis. An underlying cause of laryngeal paralysis often cannot be determined, and these

cases are then deemed idiopathic.

Diagnosis

Suspicion of laryngeal paralysis arises from the history of the dog as well as from consistent clinical signs. A routine work-up for a dog suspected to have bilateral laryngeal paralysis includes physical examination, neurologic examination, complete blood count, biochemical profile, urinalysis, thoracic radiographs, thyroid function screening, and laryngeal examination. Definitive diagnosis of laryngeal paralysis requires visual examination of the larynx. However, laryngoscopy is a poorly specific diagnostic test, as false positives are common owing to

the influence of anesthetic agents on laryngeal function. By definition, laryngeal paralysis is the absence of arytenoid abduction on inspiration. In particular, the corniculate process of the arytenoid cartilages that frame the rima glottidis dorsally are observed for purposeful motion (Figure 52-1). However, an absolute diagnosis should not be made based solely on the lack of arytenoid movement. Laryngeal paralysis is a fixed upper airway obstruction that results in inflammation and swelling of the laryngeal cartilages. Diagnosis may also be confused by the presence of paradoxical movement of the arytenoids, which can lead to a false negative result. In this situation, the

arytenoid cartilages move inward during inspiration owing to negative intraglottic pressure that is created by breathing against an obstruction. The cartilages then return to their original position during the expiratory phase, giving the impression of abduction. An assistant can state the stage of respiration during laryngoscopy to help distinguish normal from abnormal motion.

- Abscess
- Granuloma

Neuromuscular Disease

- Immune-mediated disease
- Endocrinopathy

Treatment

Dogs often do not have severe clinical signs until they have bilateral laryngeal paresis or paralysis. For dogs with bilateral laryngeal paralysis, the decision to institute surgical treatment is based on the quality of life of the dog, the severity of clinical signs, and the time of the year. Surgical treatment of laryngeal paralysis is primarily directed at increasing the functional area of the rima glottidis. This is most commonly performed by unilateral arytenoid lateralization, but other methods include variations of partial laryngectomy and castellated

laryngofissure. Permanent tracheostomy is also described as a surgical treatment as a means of bypassing the upper airway obstruction entirely. Bilateral arytenoid lateralization is no longer considered a reasonable option for this disease because of the number of postoperative complications; also, it is not necessary to enlarge the area of the rima glottidis to that degree to alleviate clinical signs.[15,19] According to Poiseuille's law, air flow through the glottis is directly proportional to the radius of glottis to the fourth power (Figure 52-2). For example, if the radius of the rima glottidis is doubled, resistance to air flow through the glottis is reduced by a factor of 16.

However, this equation is used most appropriately to describe laminar low velocity flow through a straight tube, generally the small peripheral airways. Movement of air through the trachea, rima glottidis, nose, and mouth is high velocity turbulent flow with heavy resistance. Yet, different methods of unilateral arytenoid lateralization have resulted in varying degrees of increase in rima glottidis area without any difference in short-term clinical outcome or complication rate.[20] Cricoarytenoid laryngoplasty, in which the suture is passed from the muscular process of the arytenoid cartilage to the dorsocaudal aspect of the cricoid cartilage, results in a 207% increase in the area of the rima glottidis. This is

compared with a 140% increase in rima glottidis area for dogs with thyroarytenoid lateralization, in which the suture travels from the muscular process of the arytenoid cartilage to the caudodorsal aspect of the thyroid catilage.

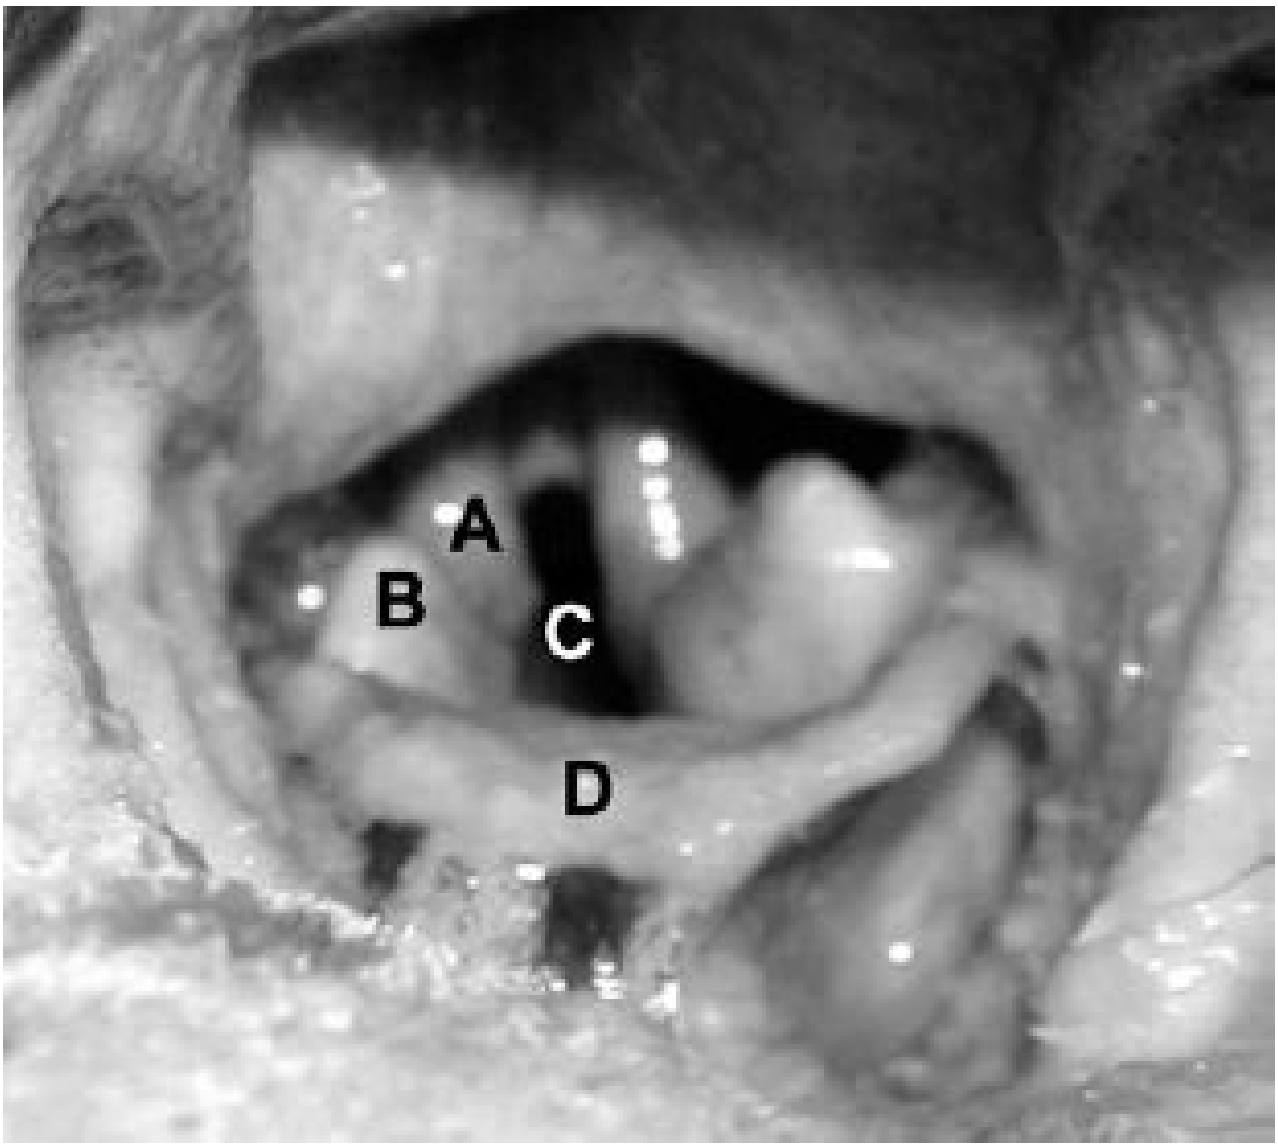

Figure 52-1. Laryngeal anatomy as visualized during laryngeal examination: A = Right corniculate process of the arytenoid cartilage; B = Right cuneiform process of the arytenoid cartilage; C = Rima glottidis; D = Epiglottis.

The effect of the degree of suture tension on the area of the rima glottidis has also been evaluated in canine cadavers.[21] It was found that a low-tension suture (the suture was tied until resistance was felt from the cranial part of the cricoarytenoid articulation joint capsule) increased the area of the rima glottidis when the epiglottis was open without an increase in the area of the rima glottidis not covered when the epiglottis is closed. A high-tension suture (the suture was tied as tight as

possible) resulted in a significant increase in the area not covered by the epiglottis in a closed position (467% larger than the low-tension suture). It was suggested that the use of a low-tension suture in clinical cases may reduce the potential risk of postoperative aspiration pneumonia.

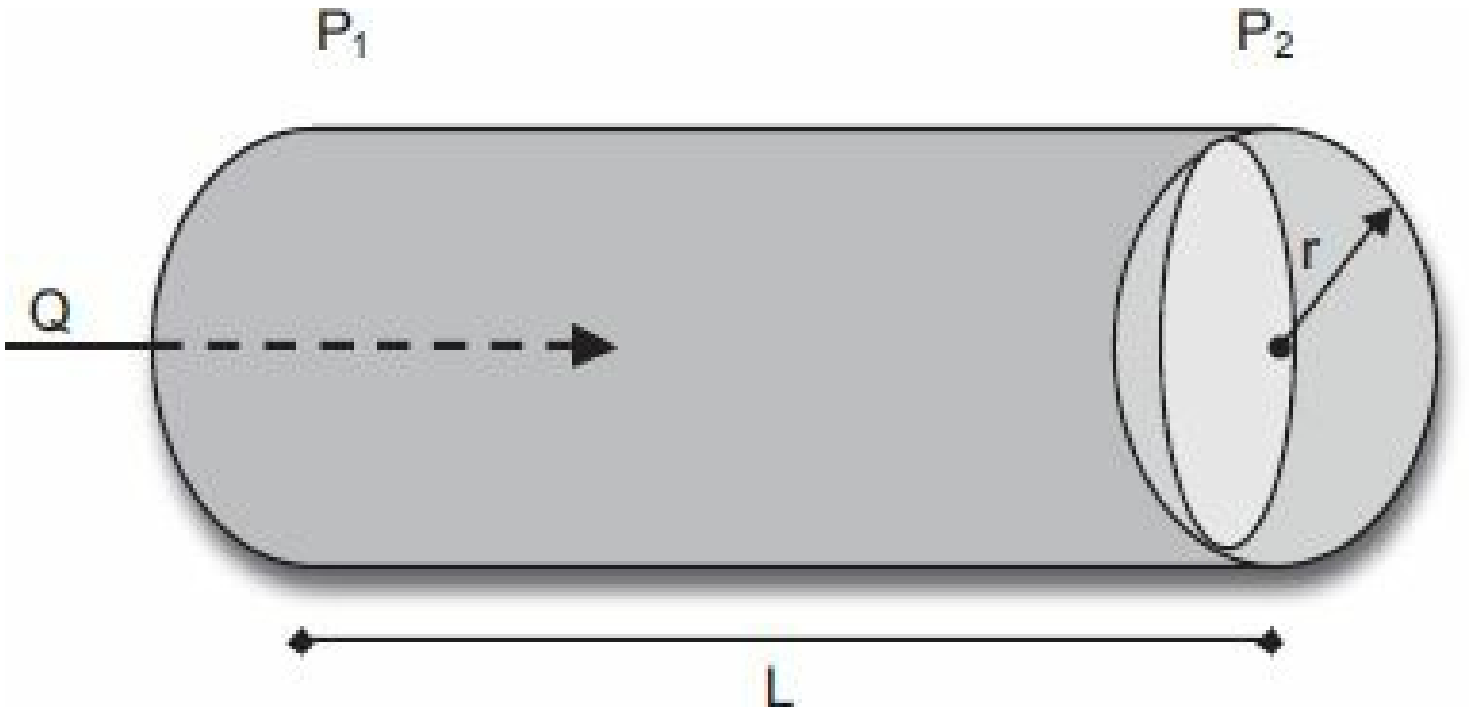

Figure 52-2. Schematic representation of Poiseuille's ($Q = \pi r^4 P/8\eta L$) law where Q = flow rate, r = radius of the tube, L = Length of the tube, P = pressure

within the tube, and η = viscosity.

Surgical Complications

Following surgical treatment of laryngeal paralysis, postoperative aspiration pneumonia has been reported to occur in 8 to 19% of dogs following unilateral arytenoid lateralization.[15,22] Although aspiration pneumonia is most likely to occur in the first few weeks following surgery, it has been recognized that these dogs are at risk for aspiration pneumonia for the rest of their lives.[15] Factors that have been significantly associated with a higher risk of developing complications include preoperative aspiration pneumonia, postoperative megaesophagus, temporary

tracheostomy placement, and concurrent neoplastic disease.[15]

The use of a temporary tracheostomy tube before surgery has been found to be a significant negative risk factor in dogs with laryngeal paralysis. Of dogs that had a temporary tracheostomy preoperatively, 50% developed complications postoperatively. The increased risk was not related to whether the dog was presented as an emergency. The presence of a tracheostomy tube results in loss of cilia, epithelial ulceration, submucosal inflammation, and retained secretions. The trachea becomes colonized with bacteria from oropharyngeal flora within 24 hours after tracheostomy

tube placement. It is theorized that tracheostomy tubes significantly interfere with the normal function of the mucociliary apparatus such that these dogs are then unable to effectively clear aspirated substances.[23]

Prognosis

Without surgical complications, unilateral arytenoid lateralization for treatment of canine laryngeal paralysis results in less respiratory distress and stridor and improved exercise tolerance. Owner satisfaction with this procedure has been reported as excellent, with the majority of owners believing the quality of their dog's life was dramatically

improved.[14,22,24]

Laryngeal Paralysis in Cats

Laryngeal paralysis is an uncommon condition in the cat. Clinical presentation is similar to that of the dog and both unilateral and bilateral laryngeal paralysis have been reported. Cats with unilateral laryngeal paralysis can present with significant clinical signs, unlike dogs, which are rarely symptomatic. There also appears to be a prevalence of left-sided unilateral laryngeal paralysis in cats, which is similar to what is reported in humans and horses. The specific etiology of laryngeal paralysis in cats is unknown, but several cases

have been associated with trauma, neoplastic invasion, and iatrogenic damage. Successful surgical treatment primarily utilizing unilateral arytenoid lateralization has been reported.[17]

Chapter 53

Tracheal Collapse

Catriona MacPhail

The primary function of the trachea is to serve as a conduit for air into and away from the bronchial tree. Tracheal collapse occurs when there is malacia of the tracheal cartilages leading to varying degrees of dorsoventral flattening, impeding airflow. Controversy exists over management of tracheal collapse as medical management is directed only at symptomatic therapy, and surgical

treatment is burdened by complications.

Functional Anatomy

The trachea of the dog or cat is composed of 35 to 45 incomplete C-shaped cartilage rings, although variations may exist between breeds and individual animals.[1,2] The ends of the cartilages are connected by the dorsal tracheal membrane, which is the thin, strap-like muscle on the dorsal surface of the trachea. The first tracheal ring is complete and partially covered by the cricoid cartilage. The remaining tracheal rings are linked together by elastic annular ligaments that result in the rigid, yet flexible

tube.

The blood supply to the trachea is from the cranial thyroid artery, caudal thyroid artery, and bronchoesophageal arteries. Branches of the thyroid arteries penetrate the tracheal rings on either side and then arborize in the submucosa to create a rich subepithelial plexus in the cervical and proximal thoracic trachea. Branches of the bronchoesophageal arteries supply the terminal trachea, carina, and mainstem bronchi. The trachea is innervated by the autonomic nervous system; stimulation results in muscle contraction and glandular secretion.

The trachea is composed of four

distinct layers: mucosa, submucosa, musculocartilaginous layer, and adventitia.[3] The mucosa is made up of pseudostratified, ciliated, columnar epithelium and goblet cells, and is oriented in longitudinal folds. Tracheal glands within the submucosa contribute mucus to respiratory secretions. The musculocartilaginous layer is composed of hyaline cartilage, fibroelastic tissue, and smooth muscle that blend with the connective tissue of the adventitia.

The main function of the trachea is to channel air through the phases of respiration. The lumen diameter of the trachea is capable of changing in size by contraction of the dorsal tracheal

membrane. Muscle contraction brings the ends of the incomplete cartilage rings closer together, narrowing the diameter, and thus reducing ventilatory dead space and increasing airflow velocity. The tracheal diameter can also enlarge to accommodate increases in airflow volume and reduce airway resistance. Insult to the tracheal wall can affect how the trachea adapts to changes in airflow and external pressures. Airflow velocity increases as diameter decreases and, according to the Bernoulli effect, internal pressure decreases. A normal trachea is rigid enough to withstand external pressure, but weakened tracheal cartilages are subject to collapse.

Another important role of the trachea is to trap aspirated debris and transport this material back up the tracheobronchial tree. The mucociliary apparatus is responsible for clearance of small particles (1 to 5 μm) that are able to pass through the nasopharynx.[4] These particles adhere to the mucus lining of the large airways; cilia of the epithelial cells beat in the mucus layer, pushing material back toward the pharynx. Normal cilia beat at a rate of 15 to 20 times per second, resulting in a clearance time in the normal dog of 5 to 26 mm per minute.[5] The mucociliary apparatus and clearance rate can be markedly affected by airway disease and mucosal trauma.

Pathophysiology

Tracheal collapse results from structural abnormalities of the cartilage rings and secondary changes in the dorsal tracheal membrane. Histopathology and ultrastructural analysis of tracheal cartilage in dogs with tracheal collapse found hypocellularity leading to decreased chondroitin sulfate and glycosaminoglycans and transformation of normal hyaline cartilage to fibrous cartilage.[6] This chondromalacia makes the trachea less rigid and less able to withstand external pressures, resulting in dorsoventral flattening. The specific etiology of tracheal collapse is

unknown but is thought to be multifactorial with a congenital or inheritable component.[7]

Tracheal collapse may be confined to an isolated segment or may involve the entire trachea and bronchial tree. The thoracic inlet is the most commonly involved area (Figure 53-1). Collapse typically occurs in a dorsoventral direction as the cartilages weaken and the dorsal tracheal membrane thins and lengthens; however, lateral collapse of the tracheal walls has been reported.[8]

Collapse in the cervical tracheal and thoracic inlet classically occurs on inspiration as pressure within the

lumen drops and the walls are susceptible to atmospheric pressure; intrathoracic trachea collapses on expiration. Although pressure within the trachea decreases on inspiration, luminal pressure still exceeds intrapleural pressure, which keeps airways open. On expiration, intrapleural pressure becomes less negative and exceeds intraluminal pressure. Dogs with weakened cartilages lack sufficient strength to withstand the increased intrapleural pressure. The thoracic inlet is most susceptible to tracheal collapse as this is the site of the equal-pressure point: where intrapleural pressure equals intraluminal airway pressure and where the transition from intrapleural

to atmospheric pressure occurs.[7] One study, however, found occasional evidence of dogs that had intrathoracic collapse on inspiration and extrathoracic collapse on expiration, although no explanation could be offered.[9]

Dogs with tracheal collapse have varying degrees of secondary injury owing to chronic coughing. Coughing causes further increase in intrapleural pressure and worse tracheal collapse. In cases of moderate to severe collapse, opposing epithelial linings come into contact causing mucosal lesions and irritation. This chronic irritation leads to inflammation, mucus gland hyperplasia, epithelial

desquamation, and disruption of the mucociliary clearance.[7]

Figure 53-1. Lateral thoracic radiograph showing severe tracheal collapse at the thoracic inlet.

Signalment/Presentation

Tracheal collapse is typically

associated with middle-aged toy and miniature breed dogs. Classic breeds include Yorkshire terriers, toy poodles, miniature poodles, Pomeranians, Chihuahuas, and pugs. This condition has also occasionally been described in young large breed dogs[10,11] and in cats.[12-14] In cats, tracheal collapse has been associated with intraluminal, extraluminal, or nasal masses.

Most dogs are diagnosed around 6 to 7 years of age; however, it has been reported that 25% of affected dogs are symptomatic by 6 months of age.[15] Dogs present with an easily solicited cough that is most often described as a "goose-honk." Severely affected dogs may have exercise intolerance,

respiratory distress, and syncope. Clinical signs are exacerbated by stress or excitement.

Dogs with tracheal collapse may suffer from a variety of concurrent problems. Almost 50% of dogs suffer from a degree of obesity that worsens clinical signs.[7] Laryngeal paresis or paralysis has been reported in 20 to 30% of dogs, while one third of dogs have concurrent systolic heart murmurs consistent with mitral valve insufficiency.[7,15,16] Upper respiratory signs may be aggravated by an enlarged left atrium, putting pressure on the carina and mainstem bronchi.

At least 40% of dogs are believed to

have a degree of dental or periodontal disease.[7] Aspiration of oral bacteria into diseased airways is hypothesized to contribute to exacerbation of clinical signs owing to increased airway inflammation or increased coughing. In a study of 37 dogs with tracheal collapse, 83% had a positive large-airway culture, with 59% growing greater than one species of bacteria.[17] This is of interest as oropharyngeal flora have been found in the trachea of normal dogs, but only 17% had multiple, mixed colonization.[18] Concurrent cytologic inflammation however, was not consistently found in a population of dogs with tracheal collapse; therefore, an association between bacterial colonization of large

airways and clinical signs has not yet been proven.[17]

Concurrent hepatomegaly and hepatopathy are also common in dogs with tracheal collapse. In a study of 26 dogs, 46% had increased serum activity of two or more liver enzymes, with 92% having elevated serum basal bile acid concentrations.[19] The reason for this association is still unclear, although speculative theories include passive hepatic congestion or centrilobular liver cell necrosis secondary to chronic hypoxia.

Diagnosis

The diagnosis of tracheal collapse is often suspected based on signalment,

history, and physical examination findings. Lateral survey thoracic radiographs of the neck and thorax can confirm this diagnosis. Views should be taken of the cervical and thoracic trachea on both inspiration and expiration. Cervical trachea narrows during inspiration owing to negative pressure within the trachea, whereas intrathoracic trachea collapse occurs during expiration owing to increased intrapleural pressure. Static radiographs may only detect collapse in 59 to 92% of cases,[9,15,16] yet radiographs should be closely evaluated for signs of concurrent airway pathology or cardiac disease.[7,20] Dynamic evaluation of the trachea can be performed using

fluoroscopy and is particularly helpful for identification of intrathoracic collapse. When comparing fluoroscopy and standard radiographic evaluation, radiography has been found to underestimate the frequency and degree of tracheal collapse.[9] Detection of tracheal collapse using ultrasonography has also been described.[21]

Bronchoscopy allows direct visualization and evaluation of the entire tracheobronchial tree (Figure 53-2A). In particular, bronchoscopy allows evaluation of the main stem bronchi (Figure 53-2B). Airway samples for cytology and bacterial culture can be obtained by tracheal

brushing or bronchoalveolar lavage, as tracheobronchitis or bronchopneumonia may play a role in the severity of clinical signs. The disadvantage of bronchoscopy is that general anesthesia is required. However, this provides an opportunity to assess laryngeal anatomy and function.

Tracheal collapse can been graded by its appearance on fluoroscopy or bronchoscopy (Table 53-1; Figure 53-3). This grading scheme allows for the determination of the severity of the collapse, establishes a baseline from which to assess disease progression, and identifies or eliminates the potential for surgical intervention.

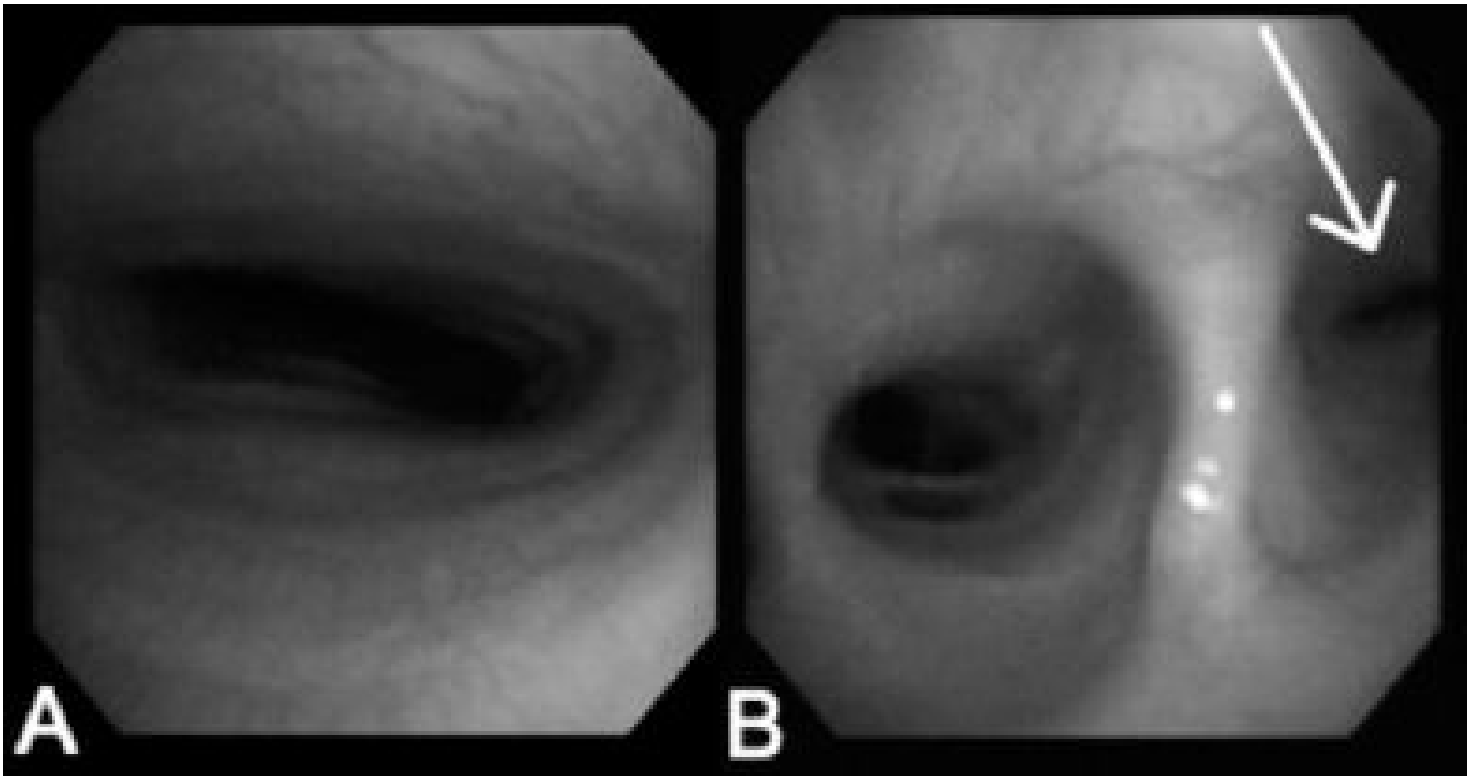

Figure 53-2A and 53-2B. Bronchoscopic view of cervical trachea collapse and left mainstem bronchi (arrow) of the same dog.

Table 53-1. Grades of Tracheal Collapse

Grade	Reduction in airway diameter (%)	Characteristics
1	25	Mild protrusion of dorsal tracheal membrane into lumen
2	50	Mild to moderate elongation and flattening of tracheal rings
3	75	Marked flattening of tracheal rings
4	> 90	Dorsal deviation of ventral tracheal surface

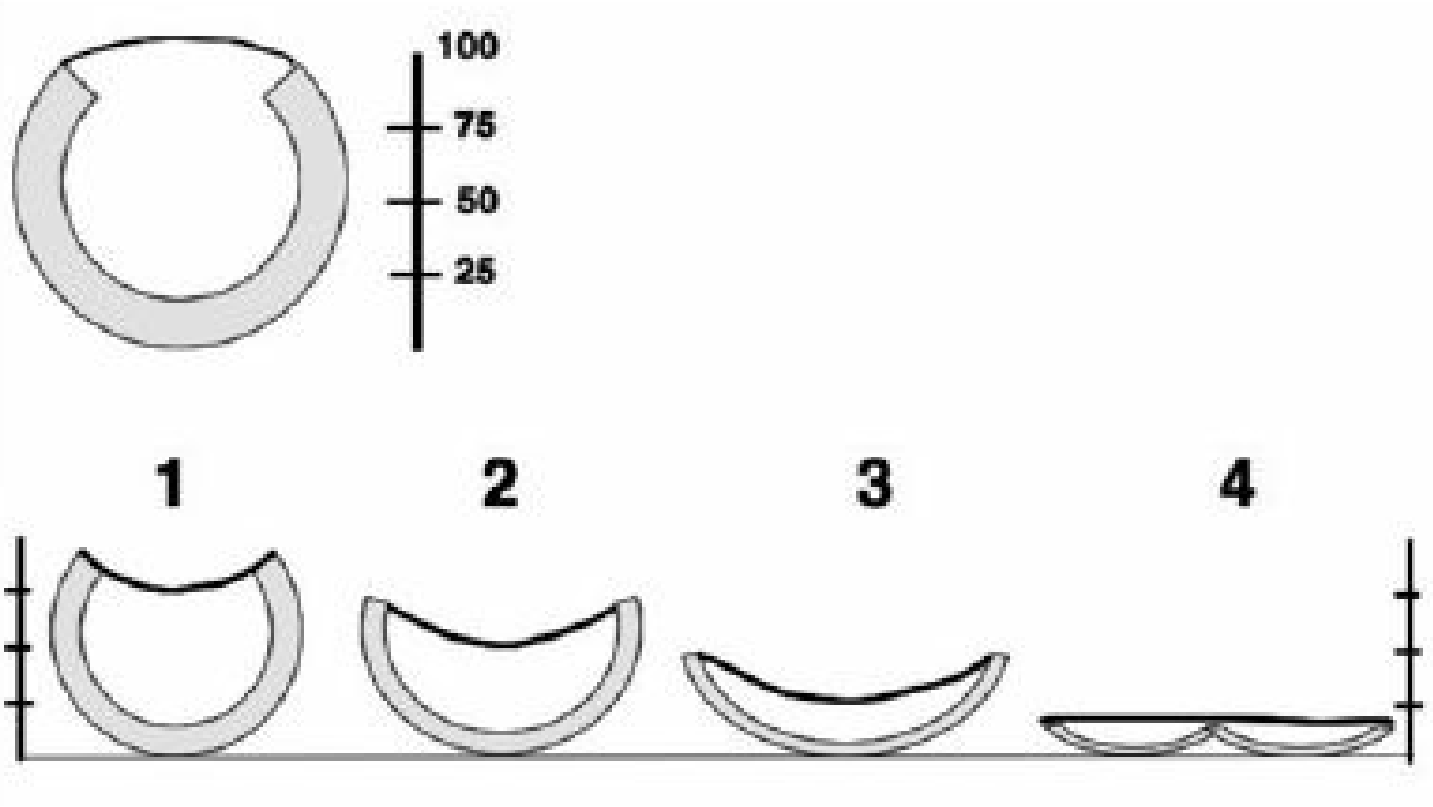

Figure 53-3. Graphic representation of tracheal collapse grading scheme.

Treatment

Medical management of tracheal collapse results in improvement in most dogs.[15] Weight loss is critical to the success of other medical therapies. Environmental modifications, such as the use of a harness instead of a collar

and creation of a nonsmoking environment, may help some dogs, as will management of concurrent underlying conditions. It has also been advocated to perform dental prophylaxis in affected dogs to decrease the bacterial load that can be aspirated into the trachea.[7] Frequently used medications include cough suppressants, bronchodilators, anti-inflammatories, and antibiotics.

Surgical intervention is suggested in patients with moderate to severe tracheal collapse that are refractory to medical management. Surgery is not recommended in patients with mainstem bronchi collapse, underlying laryngeal disease, and concurrent

cardiopulmonary disease. Although other techniques have been described, surgical treatment of tracheal collapse is currently achieved by either extraluminal ring prostheses or endoluminal stenting.

Extraluminal tracheal ring prostheses can be implanted in dogs with cervical tracheal collapse or proximal intrathoracic tracheal collapse. Good to excellent outcomes have been reported in 75 to 85% of patients, however, this technique is limited by candidate selection and surgical complications.[16,22] Following surgery, laryngeal paralysis, laryngeal necrosis, and postoperative distress requiring permanent tracheostomy have been

reported.[22] Dogs older than 6 years appear to have worse outcomes than younger dogs regardless of the degree of collapse.[22]

Endoluminal stenting has been reported in a variety of settings and using a large array of materials.[23-25] Endoluminal stenting can be used in dogs with intrathoracic tracheal collapse or diffuse tracheal collapse to provide rapid relief of clinical signs, and has been used in dogs with coexisting bronchial collapse. Complications reported with endoluminal stent implantation include stent migration, stent fracture, granuloma formation, pneumonia, and chronic coughing.[26,27]

Conclusion

Tracheal collapse is a challenging condition to diagnose and treat. Diagnosis is complicated by concurrent illnesses that exacerbate clinical signs, and treatment standards of care have not been established. Appropriate medical management may alleviate clinical signs in a large percentage of dogs affected, however dogs refractory to pharmacologic intervention may benefit from extraluminal or endoluminal support.

Chapter 54

Lung Lobe Torsion

Prudence J. Neath

Anatomy and Etiology

The lungs of the dog and cat are divided into specific lobes by deep fissures, which allow the lungs to alter position in response to movement of the diaphragm or spine.[1] The extent of movement of each lung lobe is usually limited by the presence of adjacent lobes, as well as the surrounding structures such as the heart,

mediastinum, diaphragm, and thoracic wall. Pulmonary ligaments are thin sheets of pleura that extend from the caudal lobe of each lung to the mediastinum and provide further stabilization of these lobes.[2] The accessory lobe is isolated between the mediastinum and the plica vena cavae, providing significant support for this lobe. The space between the parietal and visceral pleura contains only a thin film of pleural fluid, which eases a sliding movement of the lung lobes, but the normal negative pressure within this pleural space helps to minimize excessive movement of the lobes.[3]

Development of a lung lobe torsion

requires the lobe to overcome the stabilizing forces of these anatomic features in order to twist around its longitudinal axis. Various theories have been considered, and any condition that may increase the mobility of a lung lobe might predispose it to developing a torsion. Review of the human literature indicates lung lobe torsion to have occurred in association with pleural effusion, pneumothorax, and accidental or surgical trauma. The most common predisposing cause in humans appears to be surgical manipulation of the lung lobes. It is thought that the division of pulmonary ligaments during a thoracic procedure, in combination with deflated lung lobes, may predispose a consolidated

lobe to twist about its axis.[4] Similarly, reports of lung lobe torsion in the dog have proposed that suspension of a consolidated or atelectatic lung in fluid (pleural effusion) or air (pneumothorax) could predispose the lobe to rotational movement.[5,6] Lung atelectasis can result from a variety of causes such as trauma, pneumonia, pleural effusion, pneumothorax, or surgical manipulation, although surgical trauma is rarely the predisposing cause of lung lobe torsion in dogs or cats. There have also been reports of lung lobe torsion occurring without any history of predisposing factors; therefore,spontaneous torsion may occur.[7-9] Reports of lung lobe torsion in cats are rare, and have all

been associated with underlying disease such as chylothorax, pyothorax, or chronic asthma.[10,11]

As a lung lobe rotates about its axis, the pulmonary vessels and bronchus become occluded by the rotation at the hilus, leading initially to obstruction of the thin-walled pulmonary vein. Because some blood continues to flow through the pulmonary artery, the lobe becomes congested. Fluid leaks from the blood vessels into the interstitial tissues and airways, leading to consolidation of the lobe. The parietal pleura is eventually breached, leading to the accumulation of pleural effusion in the majority of cases.[6,9]

The thin, narrow right middle lobe of the lung is affected most commonly in dogs and cats, although the left cranial lobe is affected almost as often in the dog. Torsion of each lung lobe has been reported, as have occasional episodes of multiple lobe torsions. The right middle and left cranial lobes may be predisposed to torsion because they have less extensive attachments and, therefore, increased mobility compared with the other lobes.[5-11]

Clinical reports of lung lobe torsion are dominated by descriptions of large, deep-chested dogs, and it is thought that this thoracic shape might predispose to rotation of a lung lobe. The Afghan hound was found to be 133

times as likely to develop lung lobe torsion as other breeds in one study.[6] More recent reports have noted a trend for lung lobe torsion to occur in the pug, and the barrel-shape of the chest has been suggested as a predisposing factor in these dogs.[7-9]

Clinical Signs and Investigations

Clinical history commonly includes dyspnea or tachypnea, coughing, and lethargy, often accompanied by anorexia and vomiting. Physical examination usually reveals varying degrees of respiratory distress, often accompanied by dull cardiopulmonary sounds on thoracic auscultation.

Absence of breath sounds may be extensive if significant pleural effusion is present, or there may be a focal absence over the affected lung lobe. Other signs such as pyrexia, cardiovascular instability, vomiting, and depression have also been reported.[5-11]

Analysis of a complete blood count and serum biochemistry panel usually reveals mild non-specific results in these patients, but may be influenced by the presence of an underlying thoracic disease process.[6,9]

Imaging of the thorax will reveal pleural effusion in the majority of patients, and thoracocentesis may be

required before radiographic details of the lungs can be revealed.[5-11] Lung lobe consolidation is typically seen, and occasionally more than one lobe is consolidated.[6,9] One severely consolidated lung lobe with minimal abnormalities of the other lung lobes is highly suggestive of lung lobe torsion, especially if accompanied by abnormal bronchial positioning. Air bronchograms or air alveolograms may been seen if the lobe has twisted recently, but as fluid or blood moves into the airways, the lobe will become opacified.[5-11] The differential diagnosis for the opacified lung lobe includes atelectasis, neoplasia, pneumonia, edema, and pulmonary contusions.

Thoracic ultrasonography may confirm the presence of pleural effusion and can provide further details of the underlying reasons for opacification of the affected lung lobe, as well as revealing any fluid accumulation in the bronchi.[6,9] Ultrasound-guided biopsy may be performed to determine whether any underlying disease process is present.[7] Confirmation of bronchial occlusion using fiberoptic bronchoscopy has been reported.[9,12] Thoracoscopy would allow confirmation of lung lobe torsion, but has not been reported in any clinical case reports to date in the author's knowledge.

Pleural fluid collected from these

patients is usually serosanguinous or hemorrhagic, although chylous effusion has been reported in many cases.[5-11] Cytologic findings often indicate an inflammatory cell population with high levels of neutrophils, lymphocytes, and some erythrocytes.[6] Underlying disease processes may complicate interpretation of the pleural fluid. Reactive mesothelial cells may be seen as a result of pleural inflammation: these should not be over-interpreted because mediastinal mesothelioma is rare.[6] Bacterial culture may yield growth in some cases, although pyothorax is rarely reported to accompany lung lobe torsion.[5,6,9] Identified bacteria have included *Escherichia coli*, *Staphylococcus* spp.,

Proteus spp., and *Pseudomonas* spp.[6,9] Chylous effusion is suspected when a milky-white opaque fluid is obtained, and confirmed by demonstration of a triglyceride concentration greater than that of the serum.

Treatment

Medical stabilization is required before surgical intervention. Provision of oxygen via a mask, nasal catheter, or oxygen cage may be necessary. Removal of all pleural effusion by thoracocentesis will improve ventilation of the unaffected lung lobes, relieving signs of respiratory distress. Many patients require fluid resuscitation prior to induction of

general anaesthesia. Administration of intravenous antibiotics is recommended as intraoperative contamination from the respiratory tract is likely to occur.

Exploratory thoracotomy is performed via a lateral intercostal approach at the appropriate intercostal space. The affected lung lobe usually appears dark and consolidated and may be friable. Necrosis may have already begun, increasing the fragility of the lobe. Lung lobectomy without untwisting of the pedicle is recommended to minimize the risk of cytokine release into the circulation and potential reperfusion injury. The bronchus should be clamped prior to lobectomy,

and the pedicle can then be ligated by hand or with an appropriate stapling device. A portion of the lung lobe should be submitted for bacterial culture, and the rest of the lobe for histologic examination. Evaluation of the other lung lobes and the rest of the thoracic structures should be performed. Any abnormal tissue is biopsied to allow submission for histologic study and bacterial culture. If chylothorax is present, thoracic duct ligation and pericardectomy might be performed. This treatment decision may be influenced by the breed of the patient. Although chylothorax has been reported to resolve following lung lobectomy in many patients, Afghan hounds appear to be predisposed to

development of chylothorax and are likely to require further surgical treatment of the condition following the initial lung lobectomy.[5,6] Prior to closure of the thorax, a chest tube should be placed and adequate inflation and correct orientation of the other lung lobes should be confirmed.

Postoperative care involves analgesia, antibiotics, and intravenous fluid therapy as indicated by regular assessment of the patient. Oxygen supplementation is sometimes required. Drainage of the chest tube takes place at regular intervals until fluid production is less than 5 ml/kg/day and the chest tube can be safely removed.

Histopathologic examination of the excised lung lobe usually reveals bronchi filled with hemorrhagic fluid, thrombosis of blood vessels, plasma cell and lymphocyte infiltration of the tissues, and necrosis.[6,9] Occasionally, an underlying disease is revealed such as pneumonia or neoplasia that may have predisposed the lobe to twisting.[6,11]

Prognosis

The majority of patients treated for spontaneous lung lobe torsion without an underlying disease process will recover quickly without significant complications.[5-9] If neoplasia is responsible for the development of

pleural effusion and subsequent lung lobe torsion, the prognosis is likely to be poor.[6,9] Some patients will develop systemic inflammatory response syndrome pre- or postoperatively, leading to death or euthanasia. This is believed to result from cytokine release by necrotic lung tissue and may be complicated by cardiovascular compromise, disseminated intravascular coagulation, or acute respiratory distress syndrome.[6,9]

Persistent pleural effusion may occur in these patients, and persistent chylothorax is reported most often.[5,6,9] It is thought that disruption or impedance of the thoracic duct or thoracic lymphatic vessels leads to

lymphangiectasia, resulting in chylous effusion into the pleural cavity.[13] Although chylothorax has been detected at the time of diagnosis of lung lobe torsion, it is usually reported to develop following surgical correction of lung lobe torsion.[5,6,9,10] Resolution of the chylothorax will occur within 7 days in most patients, but persistent chylothorax has been reported in Afghan hounds and a cat.[5,6,9,10] It has been suggested that Afghan hounds may have a thoracic lymphatic system that has a lower tolerance for any degree of trauma, predisposing them to development of chylothorax.[6] The prognosis for Afghan hounds who developed chylothorax in association with lung lobe torsion has

been reported to be poor,[6,9] but reports of surgical treatment for chylothorax have revealed a more favorable outcome for dogs and cats than has been reported in the past.[13-15]

Chapter 55

Pneumothorax

David A. Puerto
Susan W. Volk

Pneumothorax is defined as the accumulation of free air or gas in the pleural space. This accumulation of air may come from three general sources but rupture of the visceral pleura with secondary leakage from the lung via a pleuropulmonary leak is the most common cause. Alternatively, atmospheric air may enter from disruptions to the esophageal, tracheal,

bronchial, or chest walls. Gas may also be formed within the pleural space from infection with gas-forming organisms, although this is a rare occurrence.

Pneumothorax may be categorized into four broad categories: traumatic, iatrogenic, spontaneous, and infectious. Traumatic pneumothorax is the most common form and develops when disruption of the integrity of the lung, esophagus, or thoracic wall allows air to leak into the pleural space. Traumatic pneumothorax can be further subdivided according to whether there has been loss of integrity to the chest wall (open pneumothorax) or no discernible disruption (closed

pneumothorax). Iatrogenic pneumothorax is a consequence of thoracotomy, but also can occur as a result of inadvertent trauma to the lungs during diagnostic or therapeutic procedures. Spontaneous pneumothorax is defined as a pneumothorax that occurs with no history of prior trauma and results from a pleuropulmonary leak, which is usually found at a site of pulmonary tissue damage secondary to a variety of underlying causes. Pneumothorax may also occur secondary to infection of the pleural space with a gas-producing organism.

Regardless of underlying etiology, the progression of the pneumothorax

depends on the defect size, ability to seal itself, and whether it acts as a one-way valve or allows air to enter and exit the pleural space. The patient's respiratory pattern may also influence progression of the pneumothorax.

Physiology and Pathophysiology

The visceral (pulmonary) pleura is the serous membrane tightly adhered to the lungs, following all irregularities of their surfaces.[1] The parietal pleura covers the walls of the thoracic cavity and diaphragm, as well as the inner surface of the mediastinum. The pleurae of dogs and cats are approximately 20 microns thick.[2] The

pleurae form two complete sacs on either side of the chest and are referred to as the pleural cavities. The right pleural cavity is larger than the left owing to the displacement of the mediastinum to the left caudal to the heart. Except for a thin film of capillary fluid moistening the flat mesothelial cells of the pleurae, the visceral pleura lies in contact with the parietal pleura. This fluid effectively couples the lungs to the thoracic wall while allowing the lungs to move within the thoracic cavity during the phases of respiration. Owing to the fluid coupling of the two pleural surfaces and negative intrathoracic pressure, changes in thoracic volume confer changes in lung volume.

Only during pathologic conditions in which fluid or air accumulate between these two layers does the pleural cavity exist as a true cavity. The opposing elastic recoil of the lung and thorax creates negative interpleural pressure relative to both atmospheric and alveolar pressure.[3] For optimal function, the pleural space must be devoid of both air and fluid. Fluid secreted into the pleural cavity normally is reabsorbed by lymphatics underlying the parietal pleura. The relative negative total gas pressure of the surrounding tissue favors absorption of gas from the pleural space.

With introduction of air into the

pleural space, as occurs with pneumothorax, the pressure of gas in the space approaches or eventually reaches atmospheric pressure. By comparison, the pressure within the surrounding tissues remains subatmospheric. This pressure difference favors reabsorbtion of the pneumothorax, with each gas being reabsorbed independently. Pleural oxygen diffuses down its concentration gradient (from approximately 149 mm Hg to 40 mm Hg), out of the pleural cavity and into the interstitial fluid. With the loss of oxygen from the pleural space, the volume of gas decreases and the relative concentration of nitrogen increases. The residual oxygen and nitrogen

within the pleural space, followed by carbon dioxide and water vapor, continue to be absorbed until all gases are evacuated from the cavity. The rate of resorption depends on several factors, including: the quality of the pleural surface (pathologic conditions leading to increased pleural thickness will decrease the resorptive rate), the total surface area of the thoracic cavity, and the initial volume of air to be resorbed. Oxygen therapy has been shown to hasten the resolution of pneumothorax by decreasing the alveolar nitrogen partial pressure and, therefore, venous nitrogen pressure.[4,5] The increased gradient between pleural and alveolar space nitrogen facilitates its diffusion from the pleural

to the alveolar space, thus speeding the absorption of the pleural air.

The cardiopulmonary effects of progressive pneumothorax have been investigated in both anesthetized and conscious dogs.[6-11] As the pleural surfaces separate, and elastic recoil is abolished, the thoracic cavity expands with simultaneous collapse of the lungs, although degree of lung collapse is disproportionately greater than that of thoracic cavity expansion.[10] In addition to a decrease in tidal volume, the collapse of the lung creates a ventilation/perfusion mismatch, leading to diminished arterial partial pressures of oxygen.[10,12] This fall in PaO_2 leads to a concomitant increase

in respiratory rate via a vagally mediated elimination of the abdominal expiratory muscle activity.[7] As pneumothorax progresses, hypoxemia induces resistance vessels of the lungs to undergo vasoconstriction (hypoxic vasoconstriction), in an effort to reduce ventilation-perfusion mismatch by diverting blood from hypoxic regions and to maintain PaO_2. Initially, early compensatory mechanisms are capable of maintaining alveolar ventilation despite reductions in tidal volume, but as the degree of pneumothorax increases, they are overcome and additional cardiopulmonary derangements become evident.[10,11] It is also of clinical significance that many

compensatory mechanisms are abolished during anesthesia, augmenting the cardiorespiratory depression in anesthetized patients with pneumothorax.[13] Respiratory rate, central venous pressure, and alveolar-to-arterial O_2 tension difference increase in a linear relationship proportional to the degree of pneumothorax, while tidal volume, and arterial and mixed-venous pH and PaO_2 decrease in a linear relationship and a manner inversely proportional to the degree of pneumothorax. Heart rate and mean arterial pressure are not significantly affected by mild to moderate pneumothorax.[10,11] As the pneumothorax progresses, cardiovascular effects become more

evident. Increased intrathoracic pressure may impair venous return directly by compression of the great vessels and indirectly by eliminating the thoracic pump. Additionally, pulmonary artery pressure elevation and myocardial ischemia may diminish cardiac output.

Tension pneumothorax occurs when the torn edge of lung or thoracic wall forms a flap and acts as a one-way valve allowing air to enter but not to exit the pleural space. Air accumulation may be rapid and initial pathophysiologic changes described above can rapidly progress to cardiopulmonary collapse if not promptly detected and treated. As

supra-atmospheric pressure develops in the pleural space, severe compression atelectasis of the lung, flattening of the diaphragm, and compression of the major vessels occur. These events lead to ventilatory impairment, profound hypoxemia, and dramatically reduced venous return, which are ultimately fatal if not aggressively treated.

Although it is clear that increasing volume of air within the pleural space correlates with the degree of cardiorespiratory dysfunction, underlying lung pathology has a substantial impact on clinical presentation. In normal experimental subjects, pneumothorax equivalent to 150% of the calculated lung volume

were well tolerated;[11] however, patients with concurrent pulmonary disease and ventilatory compromise may exhibit pathophysiologic derangements with much smaller volumes of pneumothorax. Furthermore, concurrent head trauma, fractures, large airway disruptions, diaphragmatic hernias, myocardial contusions, and intraabdominal disease seen in trauma patients with pneumothorax may further compromise these patients.

Syndromes and Pathogenesis

The categorical designation of a patient with regard to underlying

etiology is an important step in logical diagnostic and therapeutic decision-making.

Traumatic Pneumothorax

Pneumothorax attributable to a traumatic event has been estimated to occur in up to 87% (92/105) of pneumothorax cases and is most often the result of an automobile accident.[14] Less commonly, a bite or stab wound, gunshot or shearing injury may cause a penetrating injury and disruption of the integrity of the thoracic wall (open pneumothorax). In the absence of a pleurocutaneous defect (closed pneumothorax), air may gain access to the pleural space through a

pleuropulmonary leak or disruption of the conducting airways or esophagus. This may occur from barotrauma secondary to massive, sudden increase in intrathoracic pressure, which occurs with blunt-force chest compression against a closed glottis or from shearing or tensile forces generated from impact.

Rib fractures and penetrating foreign bodies may also directly lacerate pulmonary parenchyma. Concurrent pneumothorax has been shown to occur in 56% of cats with traumatic rib fractures and 58% of dogs and cats with flail segments.[15,16] In a study that included 92 cases of traumatic pneumothorax, the most common

nonrespiratory-associated injury was to the musculoskeletal system, with an incidence of approximately 50% of these cases.[14] Similarly, over one half (6/11) of dogs and cats treated for thoracic bite wounds in one study were diagnosed with pneumothorax.[17] Pneumothorax associated with high-rise syndrome has been reported to occur in 32% of dogs and in 63% of cats.[18,19] Owing to the chance of concurrent injuries, animals may be less likely to tolerate smaller volumes of pneumothorax. In addition, more aggressive treatment for the pneumothorax may be necessary in the event that the concurrent disease necessitates emergency surgical management, because anesthesia may

abolish compensatory cardiorespiratory mechanisms. Interestingly, in one study, survival rate was not significantly affected by the presence of concurrent injury in treated animals.[14]

Open pneumothorax results when the thoracic wall is disrupted and air is able to enter the pleural space via the wound: penetrating foreign bodies (i.e., gunshots, sticks, etc), and combined blunt/sharp trauma secondary to bite wounds or vehicular trauma. An open chest wound results in significant compromise of pulmonary function because it allows rapid equilibration of intrathoracic pressure with atmospheric pressure

with an inability to expand the lung.

Iatrogenic Pneumothorax

Iatrogenic traumas associated with diagnostic and therapeutic veterinary procedures are reported causes of pneumothorax in the dog and the cat. Pneumothorax is an accepted risk of thoracocentesis, thoracostomy tube placement, fine-needle lung aspiration biopsy, or biopsy of other intrathoracic structures.[20,21] Pneumothorax was reported to occur in 31% of dogs undergoing transthoracic needle biopsy.[21] Animals undergoing general anesthetic procedures are at risk for barotrauma to conducting airways and alveoli.[22,23] Of dogs and cats

undergoing prolonged periods of therapeutic mechanically-assisted ventilation, the incidence of pneumothorax was 29% and 28%, respectively.[24,25] The combination of pulmonary pathology and positive end-expiratory pressures makes these patients particularly susceptible to the development of pneumothorax. Furthermore, the use of positive pressure ventilation may convert a simple pneumothorax into a tension pneumothorax. Pneumothorax is a reported complication of thoracolumbar disk fenestration.[26] Physical restraint during venipuncture was theorized to be the cause of pneumothorax in a kitten.[27] Other procedures in which pneumothorax has

been induced include closed-chest cardiopulmonary resuscitation, central venous cannula placement, pacemaker implantation, and inadvertent diaphragmatic incision during celiotomy.

Spontaneous Pneumothorax

In the absence of a preceding traumatic event, a pneumothorax is categorized as spontaneous (with the rare exception of those caused by gas-forming bacteria). In comparison with cases of trauma-induced pneumothorax, spontaneous pneumothorax occurs much less frequently and has an estimated prevalence of 0.11%. Underlying

pulmonary parenchymal pathology may be the site of the leak. Alternatively, rupture of the air-containing space within or immediately beneath the visceral pleura may lead to the pleuropulmonary communication and are referred to as blebs or bullae, depending on location.

Blebs are contained entirely within the pleura between the two layers of the lamina elastica (interna and externa), but they communicate directly with adjacent alveolar spaces.[28,29] They are most frequently found at the apices and appear as small “bubbles” or “blisters” on the surface of the lung. Bullae are lined by a combination of

thickened pulmonary tissue and by emphysematous lung (Figure 55-1). In the largest study of canine spontaneous pneumothorax cases to date, 68% of cases in which a definitive diagnosis was reached were attributable to bullous emphysema,[30] supporting reports from smaller studies that blebs and bullae were the most frequent cause of spontaneous pneumothorax in the dog.[31-34] Interestingly, Siberian huskies were over-represented in the case population studied at the University of Pennsylvania.[30] In a study of 12 dogs with spontaneous pneumothorax attributable to bullae or blebs, all 12 had lesions in one or both cranial lung lobes, with 10 of the dogs having

multiple lesions. Bilateral lesions were seen in 36 to 58% of dogs and multiple lung lobes were affected by bullae in 37% of dogs.[3,30] By comparison, this condition appears to be much less prevalent in cats, with only seven cats reported in the literature.[35,36]

Figure 55-1. Intraoperative view of a pulmonary bleb/bulla in a dog with spontaneous pneumothorax.

(Courtesy of David Holt, University of Pennsylvania)

The pathogenesis of pulmonary blebs and bullae in dogs and humans is poorly defined. Exposure to cigarette smoke has been shown to be a significant risk factor for the development of these lesions in humans.[37] In addition, increased distensile forces associated with conformation, changes in atmospheric pressure, and certain inflammatory conditions have all been theorized to predispose to their development.[38-42] Although no studies have specifically examined pathogenesis of blebs and bullae in dogs, histologic similarities between these human and canine lesions suggest that similar

mechanisms in their development may exist.

Less commonly, spontaneous pneumothorax develops secondary to a specific pulmonary pathology, which has caused weakening of the alveolar walls and visceral pleura with subsequent formation of a pleuropulmonary leak. Bullae may be grossly visible in the pathologic tissue. In dogs, spontaneous pneumothorax has been associated with a variety of infectious and inflammatory conditions, including pulmonary abscesses, pneumonia, parasitic granulomas and associated pulmonary arterial thromboembolism, and heartworm disease, as well as

pleuritis.[30,43-47] Neoplasia, primary or metastatic, has also been implicated in the development of pneumothorax.[30,48,49]

Infectious Pneumothorax

Pneumothorax that occurs secondary to an infection with gas-producing organisms is a rare condition in dogs and cats.

Pneumomediastinum with Pneumothorax

Pneumomediastinum is defined as the presence of free air within the tissues of the mediastinum. Pneumomediastinum can be seen

radiographically in some animals with pneumothorax. Additionally, air may be seen dissecting in fascial planes of the neck, the pericardium, and the retroperitoneal space. This can occur with disruption of the lower airways, esophagus, and marginal aleveoli of the lung.[22,50-56] Mediastinal pleura may commonly rupture with over-distention and lead to pneumothorax, but pneumothorax cannot cause a pneumomediastinum.[55,56] When pneumomediastinum occurs, it is rarely of clinical significance, but clinicians should be aware that it may lead to pneumothorax.

Treatment for patients with minimal respiratory compromise is

conservative. Placing the patient in lateral recumbency with the affected side down may be of benefit, even in patients that are mechanically ventilated. Thoracocentesis or placement of thoracostomy tubes with intermittent or continuous suction may be needed. If the leakage is secondary to positive pressure ventilation, positive end-expiratory pressure (PEEP) should be discontinued if possible. Surgery is rarely necessary and is reserved for patients that do not respond to conservative treatment. The recommended treatment of spontaneous pneumothorax involves stabilization of the patient by thoracocentesis or tube thoracostomy followed by early surgical exploration

with median sternotomy for patients that do not have identifiable non-surgical disease or diffuse pulmonary disease. Cases of spontaneous pneumothorax treated surgically had a lower recurrence, 3%, and mortality, 12%, versus 50% recurrence and 53% mortality for non-surgically managed cases.[30]

Chapter 56

Pyothorax

Trent Gall
Matthew Rooney

"In cases of empyema treated by the cautery or incision, when the matter is pure, white, and not fetid, the patient recovers; but if of a bloody and dirty character, he dies."..

Hippocrates (470-410 BC) in his original works on empyema.[1]

Pyothorax or thoracic empyema is a disease that affects dogs and cats. This

disease has been recognized in humans for over 2000 years, with Hippocrates being one of the first people to document it.[1] Pyothorax is characterized by a septic thoracic effusion and infection of the pleural space. This rare but life-threatening disease has many proposed etiologies and often the cause is not found antemortem.

Etiology

The many proposed mechanisms for pyothorax include: inhaled or ingested plant material (plant awns), migrating foreign bodies, esophageal perforation, parasitic migration, penetrating thoracic wounds, hematogenous or

direct extension of infection (systemic sepsis), secondary to bronchopneumonia, parapnuemonic spread, mediastinitis, iatrogenic causes, and subphrenic infection.[2-4] The majority of the time the inciting cause of pyothorax is never determined antemortem.

In cats, one of the widely believed mechanisms for pyothorax is penetrating thoracic bite wounds. Although bite wounds account for a small percentage of documented cases of pyothorax, this cause is rarely identified antemortem.[2,3,5] The mechanism of development of pyothorax from a bite wound is contamination from normal oral

flora.[3,6,7] This has been popularized because there is an overrepresentation of cats from multi-cat households, but interestingly enough, intact male outdoor cats are not overrepresented in some studies.[3,5] Also no statistical difference exists in the number of indoor cats versus outdoor cats in these studies.[3,5] The most commonly held description for the overrepresentation of cats from multi-cat households is that these bite wounds are small and go unnoticed, and the wounds go on to abscess and rupture intrathoracically.[3,5] The authors of one paper contest this belief and subscribe to the thought that parapneumonic spread of infection after colonization and invasion of lung tissue by

oropharyngeal anaerobes is the most frequent cause of feline pyothorax.[3] The overrepresentation of cats from multi-cat households can be attributed to the fact that cats from this population are more predisposed to upper airway infections, thus leading to pneumonia and then parapneumonic spread of bacteria, leading to pyothorax.[3] Because of the controversy surrounding the cause of pyothorax in cats a complete physical exam (including dermatologic examination for bite wounds) and a thorough history (inquiring about recent upper airway infections) should be performed on all cats.

In dogs, the most commonly accepted

etiology is the migration of plant awn material via inhalation, ingestion, or trandsdermal migration from the awn penetrating elsewhere in the body. Common species of plants that have been identified have been grasses of the *Poaceae* family, *Hordeum jubatum* (in the majority of the United States), *Stipa* and *Setaria* (in the southern United States), and *Hordeum murinum* in France and Australia.[8] This etiology has gained support because of the predominace of sporting breeds in the reported literature.[2,8-13] The inhaled or ingested plant material is thought to carry oral flora into the lungs with the awn as well as environmental contaminants such as *Actinomyces* spp. and *Nocardia* spp. The plant awns that

migrate through the skin are thought to carry environmental bacterial species as well as skin contaminants. This idea is supported by the fact that in most cases the pyothorax is composed of polymicrobial populations that contain these oral and environmental microorganisms.[2,3,9,10,12,14,15] Adding further confusion to the problem, some dogs that have pyothorax have not had exposure to plant awn material. With any case of pyothorax, a complete physical and thorough history should be performed, although it is uncommon to find the inciting cause in many cases of pyothorax.[2,10,11,14]

Microbes

Pleural fluid that is suspicious for pyothorax (exudative fluid) should be submitted to a labratory for cultures and antimicrobial sensitivity analysis for aerobic, Mycoplasma, and anaerobic microbes. Pyothorax has a high prevalence of polymicrobic infections.[2,3,9,10,12,14,15] Both *Actinomyces* spp. and *Nocardia* spp. are common environmental microorganisms that are thought to be introduced into the animal through plant material foreign bodies. *Actinomyces* spp. can also be found as part of the normal oropharynx flora in both dogs and cats.[4] *Actinomyces* spp. are opportunistic pathogens that rely on mechanical disruption of normal mucosal barriers, such as what

happens with plant awn migration.[4] Infections with *Nocardia* spp. are thought to be similar in nature because Nocardia spp. are ubiquitous soil saprophytes that degrade organic matter and are found in soil, water, and on plants.[4] The most common isolated microorganisms from dogs and cats are *Bacteroides, Clostridium, Peptostretococcus,* and *Pasteurella multocida.*[7,15] These bacteria are considered normal flora of the oropharynx and upper respiratory system of dogs and cats. (Table 56-1).[16]

History, Signalment, and Physical Examination

Findings

Pyothorax has been recognized in dogs with a mean age of 3 to 4 years (range: 1-11 years) with one case report of a neonate boxer puppy.[2,9,11-14,17] Cats range in age from 1 to 11 years with a mean of 3.83 to 5.8 years with one report of a 4-month-old lion cub and a report of 1-month-old kitten.[3,5,11,18-22] Sex predilection for pyothorax is still somewhat disputed. Several studies report that canine males are more predisposed than females: 2:1 in one study and 1.25:1 in another;[2,9,11,14] but other studies suggest that no sex predilection exists.[12,13,15] Some discrepancy in sex predilection seems to exist in cats as

well. One study suggested a male to female ratio of 2 to 2.5:1,[5,11] and other studies showed no difference between the sexes.[3,15,21] The majority of affected dogs are medium- to large-breed dogs, with hunting/working dogs being overrepresented in certain geographies.[12] No specific breed predilection is apparent, with most cases occurring during fall and winter months, which corresponds with typical hunting seasons.[10]

Table 56-1. Reported Microbes Associated with Canine and Feline Pyothorax[2,7,10,11,15,17]

Anaerobic bacteria	Aerobic bacteria	Fungus
Bacteroides species	*Actinomyces* species	*Candida albicans*
Clostridium species	*Escherichia coli*	
Eubacterium species	*Enterobacter* species	
Fusobacterium species	*Klebsiella* species	
Peptostreptococcus species	*Mycoplasma* species	
Porphyromonas species	*Nocardia* species	
Prevotella species	*Pasteurella* species	
Propionibacterium species	*Proteus* species	
	Pseudomonas species	
	Staphylococcus species	
	Streptococcus species	

Dogs and cats often present with clinical signs consistent with pleural effusion but this can vary depending on the severity of the effusion. The signs include: exercise intolerance, poor athletic performance, shortness of breath, tachypnea, lethargy, and weight loss. Other signs are open-mouth breathing with dyspnea on the inspiratory phase, abducted elbows, extended head and neck, labored breathing, muffled heart sounds, decreased lung sounds, dull percussive

sounds of the ventral thorax, thoracic and/or abdominal wall swellings, penetrating wounds or other trauma.[2,3,9-11,13,14,17,23] The majority of cats present with a history of partial or complete anorexia as the most common historical finding,[3] with other signs similar to that of dogs. Owners often miss the subtle signs in cats with pleural effusion. Less common signs such as lethargy, reluctance to lie down, and anorexia can be initial complaints for dogs.[2,3,9-11,13,14,17] Less common presenting complaints include cough, diarrhea, polyuria, and polydipsia. The most severe cases present with acute respiratory distress, shock, dehydration, pale mucous membranes, and hypothermia.[10,19]

Complete Blood Count and Biochemical Analysis

Biochemical analysis is not specific for pyothorax; the most common abnormality is hypoalbuminemia. Other abnormalities include hyponatremia, hypochloremia, hyperglobulinemia, elevations in alanine aminotransferase or alkaline phosphatase, hyperglycemia, hypoglycemia, increase in blood urea, increase in creatinine, and increased bile acids.[2,3,5,11,14,19]

It is recommended that all cats with pleural effusion be tested for feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), and

heartworm disease.[24]

Results of hematology studies vary and are typically indicative of bacterial infections. These abnormalities include neutrophilic leukocytosis with or without a left shift, monocytosis, and eosinophilia. Anemia may or may not be present.[2,3,5,11,14,19]

Diagnostic Imaging

Right and/or left lateral and either ventrodorsal or dorsoventral views can be taken in patients that are stable. Findings include blurring of the cardiac silhouette, presence of interlobar fissure lines, rounding of the lung margins at the costrophrenic angles, separation of the lung borders away

from the thoracic wall, scalloping of the lung margins dorsal to the sternum, lung lobe collapse or suspected pulmonary mass, elevation of the trachea, widened mediastinum, thickening of visceral pleura, enlarged sternal lymph nodes, diffuse and focal alveolar infiltrates, air bronchograms within consolidated lung lobes, bronchointerstitial disease, and diffuse interstitial disease.[2,3,10,11,25] Atelectasis can be documented in some cases. It is not always possible to distinguish among recoil atelectasis, lobar consolidation, and encapsulated pleural fluid.[3] It is advantageous to remove as much of the pleural effusion as possible before attempting radiographs. This will improve

visualization of thoracic anatomy and often makes the patient more comfortable while positioning for the radiographs. If the patient is in respiratory distress, horizontal-beam radiographs can be taken.[21] These views are often useful because they help the clinician to differentiate pyopneumothorax from gas-producing bacteria. Radiographs can detect as little as 50 to 100 ml of fluid; the recumbent ventrodorsal position appears to be the most sensitive for detecting the smaller amounts of fluid.[26] It has been reported that animals with radiodense lesions in the mediastinum or pulmonary fields have a poorer prognosis if they are treated medically rather than surgically.[2]

The majority of affected dogs and cats present with bilateral effusion.[2,3,5,11,21] One study reported 82% (of total animals) presenting with bilateral effusion; 29% of cats had unilateral effusion, and 14% of dogs had unilateral effusion.[11] Another study in cats reported a similar finding of 76% bilateral and 24% unilateral effusion.[3] In this study, 40% of cats had radiographic evidence of concurrent pneumonia.

Thoracic ultrasonography can be helpful in the diagnosis of pyothorax and may be used to find small volumes of pleural fluid not detected radiographically, to quantitate or further characterize an effusion, or to

guide thoracocentesis.[27] Abnormal findings include free pleural fluid, consolidated or collapsed lung lobes, and/or fibrinous or fibrous tags that can extend between the parietal and visceral pleura.[5,11] Occasionally, effusions have been accompanied by septations and parietal pleural thickening.[27] Cranial mediastinal masses, pulmonary abscesses, pericardial effusion, and restrictive pleuritis can be detected using ultrasonography.[11,27] It is also feasible to conclude that foreign bodies could be detected with ultrasound; however, to our knowledge, this has not been documented in published reports. It is advantageous to have pleural effusion present when performing ultrasound in

the thorax as the fluid provides an "acoustic window" that allows the ultrasonographer to visualize more of the thoracic anatomy.[27]

Computed tomography (CT) and MRI are commonly used in human medicine to diagnose thoracic disease and with these modalities becoming more and more common in veterinary medicine, it is a resource that can be used depending on whether the patient is stable enough for general anesthesia or heavy sedation. These modalities are especially helpful for diagnosing certain disease processes such as neoplasia[28] and pulmonary abscesses.

Pleural Fluid Analysis

Thoracocentesis is a procedure that is simple, diagnostic, and therapeutic. The complications of thoracocentesis are minimal if proper technique is used. These complications can include laceration of underlying lung tissue, causing pneumothorax, hemothorax, or pulmonary hemorrhage.[10] If the pleural effusion is "pocketed," radiographs or ultrasound can help guide the clinician to draw from these "pockets." Approximately 5 to 10 ml of aspirated fluid should be saved for bacterial culture and antimicrobial sensitivity testing as well as analysis. Ideally these samples would be taken at the time of therapeutic thoracocentesis and before antibiotic therapy is initiated. A portion of the

fluid should be placed in an EDTA tube for total nucleated cell count, total protein count, specific gravity, and cytologic examination.[10,25,29] The remainder of the sample fluid should be placed in a glass serum tube (red top without clot activator) for biochemical analysis as well as into culture-transport media for aerobic, *Mycoplasma*, and anaerobic cultures, and antimicrobial sensitivity analysis.[10,29] Samples that are going to be submitted for culture and sensitivity must be handled properly to maximize identification. Refrigeration of the samples must be avoided, and they must be submitted to the laboratory within 24 hours.[10,30] At the time of fluid collection for analysis 4 to 6

direct smears of fluid onto a microscope slide should be made, especially if the samples are to be sent out to a laboratory.[25,31] If these slides are to be sent to an outside laboratory, several should be unstained. If the clinician is going to examine the slides, they should be Gram stained and/or Diff Quick stained for examination.[3,25]

Pleural effusion samples should be analyzed for physical, chemical, and cytologic characteristics. Physical parameters include volume, color, turbidity, viscosity, presence of sulfur granules, and odor.[10,25,29,31,32] Increased turbidity, high viscosity, bad odor, and varying color (e.g., sanguineous, brown, tan,

white/greenish, or “creamy” red) are characteristics of septic effusions.[10,25] Degenerating leukocytes and bacteria can compose flocculent debris in the form of yellow flecks or sulfur granules.[10,25] If possible, this debris should be included in the direct smears and in the samples that are submitted for culture and sensitivity.[10]

Normal pleural fluid contains less than 1.5 g/dl of protein and less than 500 cells/μl. Exudative fluids typically contain more than 3 g/dl of protein and more than 7,000 cells/μl with variable cell types and have a specific gravity greater than 1.025.[10,29] Some chemical properties have been shown to be useful in evaluating pleural fluid

in humans and cats. To the authors' knowledge these have not been determined to be accurate in canine fluid analysis.[10,32] These parameters include lactate dehydrogenase (LDH), pH, and glucose levels. LDH levels greater than 200 IU/L, acidic fluid, and glucose measurements less than 30 mg/dl have been shown to be consistent with exudative fluids in cats.[10,33] In humans, increased levels of LDH are consistent with cell damage or inflammation.[10,32,34]

When evaluating pleural effusion, the lack of microorganisms and/or degenerative neutrophils seen on cytologic analysis does not rule out an infectious cause.[10,29] Some bacteria

may not produce enough toxins to cause toxic changes to neutrophils, and the absence of microorganisms may be a result of antibiotic administration prior to sampling or owing to the presence of microorganisms without cell walls (e.g., *Mycoplasma*).[10]

Prognosis

Pyothorax carries a fair to good prognosis in both dogs and cats treated with aggressive medical or surgical management. Reports of survival rates range from approximately 60% to 90%, depending on early diagnosis, underlying etiology, and aggressiveness of treatment.[2,10] In one retrospective study, dogs that had

confirmed infection with *Actinomyces* spp. had a significant difference in disease-free intervals between those that were treated medically versus those treated surgically (1.56 to 15.78).[2] In dogs that had evidence of mediastinal or pulmonary lesions, the difference in disease-free intervals was also significant between medically versus surgically treated animals (2.16 to 22.46).[2] This evidence suggests that animals with confirmed *Actinomyces* spp. and/or mediastinal or pulmonary lesions have a better prognosis when they are treated surgically versus medically.[2] Cats with pyothorax were more likely to come from multi-cat households than single-cat households.[5] Hypersalivation and bradycardia were

more common in non-surviving cats with pyothorax than in survivors.[5]

Conclusion

Pyothorax carries a fair to good prognosis with the appropriate management. Often the inciting cause cannot be identified during antemortem examinations. Successful resolution of pyothorax depends on early detection, appropriate antimicrobial selection, and aggressive management. Aggressive management includes early surgical intervention when surgery is warranted.

Chapter 57

Pleural Effusion

MaryAnn G. Radlinsky

Pleural effusion results in ventilatory compromise by preventing pulmonary expansion in response to diaphragmatic and thoracic movements. With large amounts of effusion, diaphragmatic and thoracic movement may be severely limited. The etiology of the effusion, volume, and rate of accumulation determine clinical signs and severity of the ventilatory compromise. The

impairment of pulmonary expansion results in decreased vital capacity and maximum tidal volume, inspiratory reserve volume, and functional residual capacity, or pulmonary volume at the end of exhalation.[1] Atelectasis results, which may further exacerbate ventilation and perfusion abnormalities. Supportive treatment for cases of pleural effusion often includes thoracocentesis, fluid therapy, nutritional support, and other treatments depending on the type and etiology of the effusion. Repeated drainage of pleural fluid may result in significant loss of fluid, protein, electrolytes, and perhaps lipid, vitamins, and white blood cells, which underscores the need for supportive

and specific therapeutic measures.

An understanding of the etiologies and pathophysiologies of pleural effusion is therefore vital to the management of clinical cases. In this chapter we provide insight into the diagnosis and pathophysiology of the different types and causes of pleural effusion.

Normal Anatomy

The normal pleural space is lined by a single layer of mesothelial cells with an adjacent layer of elastic connective tissue containing vascular and lymphatic channels. The parietal pleura lines the thoracic wall, diaphragm, and mediastinum, and the visceral pleura lines the pulmonary

surfaces including the interlobar fissures. The normal pleural space is occupied by a small amount (2-3 ml) of fluid that is low in both cell numbers (< 500 cells/ml) and protein (< 1.5 g/dl).[2] The pleural fluid lubricates the surfaces of the lungs and surrounding structures as they move throughout the ventilatory cycle. The parietal pleura is supplied by the systemic circulation (intercostal, diaphragmatic, and pericardial arteries), and venous drainage is via the azygous and internal mammary veins. The visceral pleura is supplied by the lower pressure pulmonary circulation (pulmonary and bronchial arteries) and drains via the bronchial veins. Stomas between mesothelial cells of

the parietal pleura increase in numbers ventrally along the thoracic wall and diaphragm, increasing the drainage of lymph from the parietal pleura.[3] The parietal pleural lymphatic drainage proceeds into the intercostal lymphatics and eventually into the thoracic duct.[4]

The visceral pleural lymphatic drainage enters the peribronchial and interlobar lymphatics and into the thoracic and right lymphatic duct, which receives lymph from the lungs, heart, abdomen, mediastinum, and diaphragm. The diaphragmatic lymphatics allow some communication between the peritoneal and pleural cavities. The thoracic duct is the

continuation of the cisterna chyli, located ventral to the first through fourth lumbar vertebrae, and carries lymph from the abdominal viscera and caudal half of the body. The duct travels dorsolaterally to the aorta on the right in the dog and on the left in the cat. The duct crosses to the left in the dog at the fifth or sixth thoracic vertebra and terminates in the left external jugular or jugulosubclavian angle in most members of both species.

Normal Physiology

Fluid production in the pleural space is based on Starling's law, primarily on hydrostatic and colloid osmotic pressure differences between the

capillary and lymphatic beds of the parietal and visceral pleura. The following equation provides the determinants of pleural fluid dynamics, including vascular permeability:[1]

Movement of fluid =

K x ([HPc parietal – HPc visceral) – HPif] – [COPc – COPif]) Adjust the equation – there are an unequal number of open- and closed-paretheses

K = filtration coefficient (ml/sec/cm^2/cm H_20)

HP = hydrostatic pressure (cm H_20)

c = capillary

if = interstitial fluid

COP = colloid osmotic

pressure (cm H_20)

General pressure gradients for fluid production and absorption are shown in Figure 57-1. Because the systemic and pulmonary capillary hydrostatic pressures are greater than that of the pleural space, hydrostatic pressure favors fluid production. The gradient between the systemic circulation, or parietal pleura, and the pleural space is greater than that formed on the pulmonary side, or from the visceral pleura. Osmotic pressure of both the systemic and pulmonary vascular beds is greater than that of the fluid in the pleural space, favoring absorption of fluid across the parietal and visceral pleura. When the net hydrostatic and

osmotic pressure gradients are added together, fluid tends to enter the pleural space from the parietal pleura and be absorbed by the visceral pleural lymphatics and capillaries. However, the parietal pleura contains many stomas, and parietal lymphatics may absorb fluid.[5] Absorption via parietal lymphatics is encouraged by the movement of the intercostal and diaphragmatic musculature and the lungs. Parietal lymphatics may play an important role in cases of pleural effusion in which pulmonary capillary absorption decreases or cannot maintain absorption in the face of high-volume effusion.

Pathophysiology

Abnormal fluid accumulation occurs upon alterations in hydrostatic pressure, osmotic pressure, vascular permeability, or with lymphatic dysfunction. Increased systemic hydrostatic pressure, as with right-sided congestive heart failure, may lead to increased fluid production. Decreased osmotic pressure, as in hypoalbuminemia, will affect fluid reabsorption in that the osmotic pressure of the vascular system is decreased, which decreases the gradient favoring fluid resorption by the parietal and visceral pleura. Inflammatory conditions of the pleural space lead to increased vascular

permeability, increasing pleural fluid production. Concurrent vascular or lymphatic obstruction may alter hydrostatic pressures and lymphatic reabsorption of fluid. Lymphatic obstruction owing to reduction of flow or obstruction at the lymphaticovenous junction also decreases pleural fluid resorption and may lead to the leakage of fluid from the thoracic duct(s).

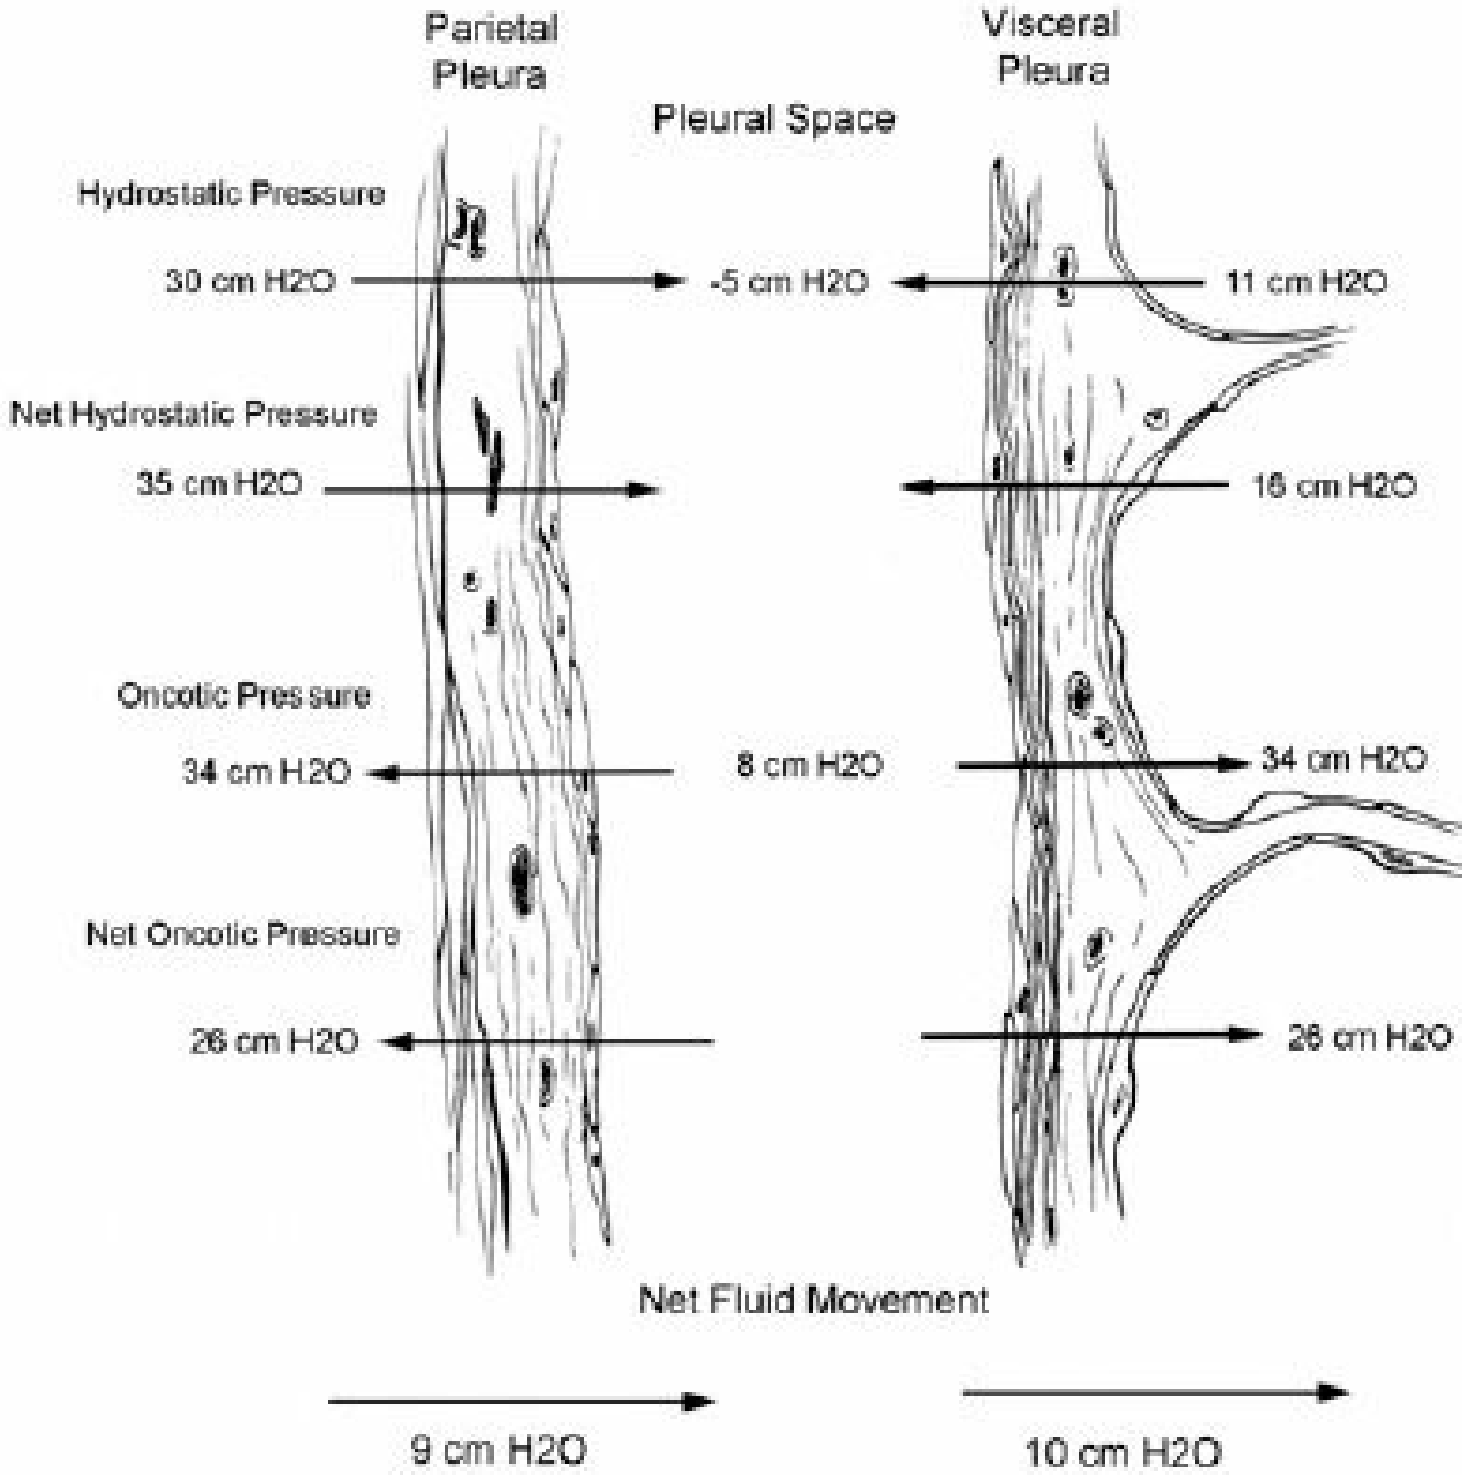

Figure 57-1. Forces and resultant gradients responsible for pleural fluid production and absorption. (Adapted from Pathophysiology in Small Animal Surgery, MJ Bojrab (ed). Philadelphia: Lea & Febiger, 1981.)

Other factors, such as trauma, neoplasia, or focal conditions may cause fluid accumulation by different forces. Generalized increases in hydrostatic pressure are not present, for example, in cases of lung lobe torsion, but a localized severe increase in hydrostatic pressure will cause fluid accumulation. Trauma to blood vessels or hemorrhage from abnormal blood vessels (e.g., neoplasia) leads to the accumulation of blood within the pleural space. Alterations in coagulation may also result in hemothorax from minimal trauma.

Types of Pleural Effusion

Pleural fluid is generally classified into

three categories based on the protein concentration, cell count, and potentially the types of cells present and specific gravity of the fluid. Classification of the fluid is usually the first step in developing the definitive diagnosis of the condition. When the signalment, history, physical findings, and fluid type are combined with the laboratory classification of the fluid, the differential list is narrowed dramatically, and the etiology becomes apparent.

Laboratory classification of fluid includes transudate, modified transudate, and exudate. The protein content and cell count increase along the classification scheme. Some

variation exists in the literature, but general divisions in protein content and cell numbers are listed in Table 57-1. The etiology of fluid accumulation is not included in this classification scheme. Further diagnostic testing may elucidate the cause of effusion and ultimately its diagnosis. Clinically useful classification of pleural fluid includes pure transudate, serosanguineous, sanguineous (or hemorrhagic), inflammatory, chylous, and neoplastic. Differentials for each type of effusion are listed in Table 57-2.

Pure Transudate

Pure transudates most often develop

secondary to hypoproteinemia. Lack of serum protein, mainly albumin, results in decreased oncotic pressure of the vascular system. Lack of oncotic pressure results in increased fluid leakage (increased production) and decreased reabsorption, which causes fluid accumulation in the pleural space. Decreased protein production may be due to hepatic dysfunction, starvation, or severe nutritional deficiency. Significant protein loss may occur with conditions such as protein-losing enteropathy or nephropathy. Congestive heart failure may also result in production of a pure pleural transudate via increased hydrostatic pressure, but more often heart failure is associated with a modified

transudate. Any chronic pure transudate may become modified over time; therefore, transudative etiologies must be considered in the diagnostic plan for a modified transudate.

Table 57-1. Laboratory Classification of types of Pleural Fluid

Type	Protein (g/dl)	Specific Gravity	Cell Ct. ($x10^9$/L)	Cytology
Transudate	< 3	< 1.018	< 3	Mesothelial, macrophages, lymphocytes
Modified Transudate	3-5		< 5	RBCs, lymphocytes, mesothelial cells
Exudate	> 3	> 1.018	> 7 Septic 30-200 Non-septic 5-15	Neutrophils (degenerate if septic)

Table 57-2. Clinical Classification and Etiologies of Pleural Effusion

Type	Etiology	Type	Etiology
Transudate	Congestive heart failure	Inflammatory	Idiopathic
	Hypoproteinemia		Foreign body
	Ascites associated effusion		Trauma
	Hyperthyroidism		Esophageal or tracheal disruption
Serosanguineous	Lung lobe torsion		Surgery
	Diaphragmatic hernia		Thoracocentesis
	Pericardial effusion		Systemic infection
	Neoplasia		Mediastinitis
	Thromboembolism		Extension of cervical infection
Sanguineous	Trauma		Pulmonary abscess
	Surgery		Pancreatitis
	Neoplasia		Feline infectious peritonitis
	Coagulopathy	Neoplastic	Mesothelioma
Chylous	Idiopathic		Primary or secondary pulmonary tumor
	Congestive heart failure		Heart-base tumor
	Neoplasia		Carcinomatosis
	Trauma		Lymphosarcoma
	Cranial vena caval compression or obstruction		Other neoplasia
	Fungal infection		
	Dirofilariasis		
	Congenital anomaly		

Serosanguineous Effusion

Serosanguineous effusion most often is concurrently categorized as a modified transudate. Red blood cell numbers, and thus the hematocrit, of the fluid are far below that of the peripheral blood. Many conditions can result in serosanguineous effusion via different

pathologic routes. Lung lobe torsion causes venous and lymphatic occlusion in the presence of intact arterial blood flow. This results in significant increased hydrostatic pressure and increased production of pleural fluid. Lymphatic absorption is concurrently decreased. The initial effusion associated with lung lobe torsion may be sanguineous; however, lung lobe torsion may be primary or secondary.[5] Suspension of pulmonary parenchyma in a pre-existing pleural effusion may predispose more mobile lung lobes, such as the right middle lobe or caudal lung lobes, to twist around their long axis.[5] Primary effusion, such as chylothorax, must be ruled out, as pneumolobectomy will not result in

resolution of the effusion. Diaphragmatic hernia with hepatic entrapment may similarly cause venous and lymphatic obstruction. Fluid leaks from the congested hepatic parenchyma. Pericardial effusion resulting in cardiac tamponade and right-sided heart failure cause increased fluid production owing to increased vascular hydrostatic pressure. Neoplasia can result in a variety of effusions via lymphatic or vascular obstruction, decreasing serum protein concentrations, or by inciting inflammation. Diffuse neoplasia such as mesothelioma or carcinomatosis commonly results in serosanguineous effusion. Lastly, idiopathic pleuritis and pleural effusion has been

diagnosed in both dogs and cats. It is most often associated with a modified transudate.[6]

Sanguineous Effusion

Hemorrhage into the pleural space is commonly associated with trauma, which may be blunt, penetrating, or surgical. The packed cell volume of the blood in the effusion is similar to that of the periphery, but owing to rapid defibrination, it may not clot. The source of iatrogenic hemorrhage depends on the approach taken and the procedures performed. Intercostal, internal thoracic, pulmonary, pericardial, mediastinal, and cardiac vasculature are all possible sources.

Intercostal vessels are at risk during lateral thoracotomy, which may also traumatize the internal thoracic vessels if extended ventrally on the thorax. The other vessels may be traumatized depending on the procedure done and the condition of the structures. Mediastinal vessels may be increased in size and number with inflammatory conditions of the thorax. Tumors within the chest can erode into vessels or adjacent tissue, leading to significant hemorrhage. Common tumors include chemodectoma, which may invade adjacent great vessels, and hemangiosarcoma of the right atrial appendage. Certain tumors (e.g., hemangiosarcoma) or diffuse neoplasia can be associated with disseminated

intravascular coagulopathy and hemothorax.

Life-threatening hemorrhage of any etiology requires aggressive stabilization and potentially surgical intervention. Blood loss and atelectasis must both be considered prior to surgical intervention. Supportive care and stabilization are appropriate and may preclude surgery, allowing for reabsorption of blood from the pleural space. Autotransfusion may be considered as well, as contamination of the effusion with bacteria is rare. Neoplastic cells may be present in the transfusate, and the long-term prognosis should be considered in light of the need for autotransfusion. It is

unlikely that the neoplastic cells in the transfusate will significantly decrease prognosis in a case of neoplasia-induced hemothrax.[3]

Chylous Effusion

Chylothorax is usually grossly apparent, as the fluid is milky white or white with a pink hue. Chyle is classified as a modified transudate with protein values usually less than 4 g/dl, cell counts less than 7000/ml, and specific gravity less than 1.032.[2] The cells may be predominantly lymphocytes, but with time nondegenerate neutrophils may be more numerous. A definitive diagnosis is made by comparing serum

triglyceride and cholesterol levels with those of the effusion. Triglyceride is higher and cholesterol lower in the fluid compared with serum levels. Pseudochylous effusion in which the cholesterol level is elevated compared with serum, triglyceride content is low, and chylomicrons are not present has been described in people but not in dogs or cats. Other diagnostic tests include staining chylomicrons in the fluid with Sudan black or performing an ether clearance test. Pleural fluid is placed into two tubes and both are alkalinized with potassium hydroxide. Ether is added to one tube and tap water to the other. The ether will cause clearance of the opacity, water will not.

Chylous effusion can result from any condition that increases hydrostatic pressure in the cranial vena cava; obstruction or relative obstruction of the lymphaticovenous junction leads to dilation and leakage from the thoracic lymphatics. Pulmonary lymphatics may also be a source of chylous effusion.[7] Blunt or penetrating trauma can cause chylothorax, but the thoracic duct is expected to heal spontaneously.[8] Other conditions associated with chylothorax are listed in Table 57-1. Specific conditions include cardiomyopathy, mediastinal masses (e.g., lymphosarcoma and thymoma), dirofilariasis, blastomycosis, jugular venous thrombosis, diaphragmatic hernia,

pericardial effusion, congenital anomalies (e.g., tetrology of Fallot, tricuspid dysplasia, cor triatriatum dexter, or a thoracic duct anomaly), and heart-based tumors. Despite the numerous conditions associated with chylothorax, the most common cause is idiopathic and is associated with thoracic lymphangiectasia. Afghan hounds and Siamese cats may be affected more often than other breeds, and lung lobe torsion may be associated with long-standing chylous effusion.

The etiology of the effusion is determined by performing thoracic radiographs after removal of the effusion to rule out mass lesions.

Failure of the lungs to expand after therapeutic thoracocentesis suggests fibrosing pleuritis. Fibrin deposition on the visceral pleura occurs secondary to chronic inflammation, which causes mesothelial cell changes. Cellular changes include altered permeability, increased desquamation, and coagulation cascade activation.[9] Increased collagen production and subsequent fibrosis with decreased fibrinolysis leads to constriction of the pulmonary parenchyma.[9] Decreased fibrinolysis may be a dilutional effect of the pleural fluid on plasminogen activator or may be due to alterations in mesothelial cell function.[9]

Ultrasound of the chest requires some

fluid to obtain an acoustic window to evaluate structures in the mediastinum; the heart and its function should also be examined. Routine blood work may show lymphopenia and hypoproteinemia secondary to loss into the effusion. Diagnostic testing should be complete before backing into the most frequently diagnosed etiology – idiopathic chylothorax. Cases of idiopathic chylothorax usually also undergo further imaging with lymphangiography, which is traditionally performed by catheterizing an intestinal lymphatic vessel. Water-soluble contrast is injected at a dose of 1 ml/kg diluted 1:1 in sterile saline. Thoracic radiographs are taken to identify the

number and location of thoracic duct branches to be ligated. Post-ligation lymphangiography is used to confirm complete occlusion of all duct branches.[10]

Inflammatory Effusion

Inflammation of the pleural space may or may not be associated with infection. Nonseptic effusions are usually associated with a much lower nucleated cell count than is septic inflammation (Table 57-1). Lymphocytes, macrophages, and neutrophils may be present; degenerative changes of the neutrophils occur with septic inflammation. Septic exudate filling

the pleural space is referred to as “pyothorax” or “thoracic empyema.” Fluid accumulation secondary to inflammation is a result of increased production owing to vasodilation and increased vascular permeability. Decreased fluid reabsorption may also occur owing to increased oncotic pressure of the pleural space and thickening of the pleura as the condition becomes more chronic.

Nonseptic inflammation may be caused by infectious diseases (e.g., feline infectious peritonitis), chronic chylous effusion, diaphragmatic herniation of abdominal organs, neoplasia, or abdominal conditions such as pancreatitis. The inflammatory

effusion associated with pancreatitis may be a result of the localized inflammation associated with the diaphragm and release of pancreatic enzymes known to cause localized fat necrosis and inflammation.[3] The exudate associated with feline infectious peritonitis is high in protein (5-12 g/dl) and specific gravity (> 1.017); the nucleated cells are usually nondegenerate neutrophils, but with chronicity, macrophages, plasma cells, and lymphocytes appear.[1] Chronic diaphragmatic hernia, chronic chylothorax, and chronic lung lobe torsion may also cause nonseptic inflammation. Fungal and bacterial cultures should be pursued in any case of pleural exudation to rule out the

possibility of an infectious process, even if organisms are not apparent on cytologic examination. Idiopathic pleural effusion has also been associated with exudative effusion.[6]

Septic inflammation is primarily traumatic in origin. The route of bacterial access to the pleural space may be extension from any of the following: penetrating thoracic wall trauma, esophageal trauma or foreign body, tracheal trauma, foreign body inhalation and migration through the small airways or lung, caudal cervical trauma or infection leading to mediastinitis, repeated thoracocentesis, or cervical or thoracic surgery. Extension from a systemic infection,

pneumonia, or rupture of a pulmonary abscess less commonly results in a septic pleural exudate. Both aerobic and anaerobic cultures should be performed on any pleural exudate. Exudates are most often polymicrobial, and anaerobes are common in polymicrobial pleural infection.[11] Special care should be taken to evaluate and culture for *Actinomyces* and *Nocardia*, which are frequently present in chronic septic exudates.[12]

Neoplastic Effusion

Obstruction of vessels and lymphatics, inflammation, decreased serum albumin, and increased oncotic pressure within the pleural space may

all contribute to fluid accumulation associated with a neoplastic condition within the pleural space. Specific tumor types erode vessels (e.g., hemangiosarcoma) to cause hemorrhagic effusion or may obstruct or erode into the thoracic duct (e.g., mediastinal neoplasia) to cause chylous effusion. Diffuse neoplasia may be primary, as with mesothelioma, or secondary, as in cases of carcinomatosis. Diffuse neoplasia usually results in the accumulation of a modified transudate; however, neoplastic cells are rarely identified within the fluid. Cytologic evaluation rarely provides the diagnosis of neoplasia, because reactive mesothelial cells display many

characteristics of neoplasia, making the two cell types difficult to differentiate. The diagnosis may require more invasive techniques with tissue sampling for histopathologic examination.

Clinical Signs

Pleural fluid accumulation usually results in tachypnea owing to the lack of pulmonary expansion. The ventilatory pattern is referred to as “restrictive,” and is characterized by rapid and shallow ventilation in an effort to maintain minute ventilation. The duration and rapidity of fluid accumulation will determine the severity of clinical signs. Animals with

a small amount of effusion may be asymptomatic. Likewise, a slow accumulation of fluid allows the animal to compensate and adapt to the change in residual capacity until stressed by activity, increased ambient temperature, or anxiety. The rapid accumulation of a large volume of pleural fluid results in more severe signs such as an acute onset of tachypnea, dyspnea, and/or collapse. Cyanosis, orthopnea, and a distended thoracic cage may also occur with large volumes of pleural fluid. Other clinical signs accompanying pleural effusion include exercise intolerance, cough, lethargy, inappetance, reluctance to lie down, and weight loss. Additional clinical signs may

depend on the etiology of the effusion.

Physical examination findings consistent with pleural effusion include a restrictive ventilatory pattern and diminished heart and lung sounds, especially ventrally. Bronchovesicular sounds may be increased dorsally. The chest may sound dull on percussion, or percussion may demonstrate a fluid line. Cats may exhibit apparent “breath holding” in which inspiration seems forced and exhalation is somewhat delayed. Fever may accompany exudative effusions, a heart murmur, jugular venous distention, hepatomegaly, ascites, or lymphadenopathy may be present depending on the primary disease

process.

Conclusion

Noncardiogenic pleural effusions should be approached based on their type (transudate, modified transudate, etc.) and etiology. The forces resulting in the accumulation of fluid include decreased oncotic pressure, increased hydrostatic pressure, increased vascular permeability, abnormal lymphatic function or permeability, and relative lymphatic volume overload. These forces should be understood, as they are vital in the diagnosis of pleural effusion. Sampling of the pleural fluid provides the type of effusion, prompts further specific

testing, and narrows the list of possible causes. Definitive diagnosis then allows for the development of therapeutic options and provides a prognosis for the patient.

Chapter 58

Thoracic Wall and Sternum

Dennis Olsen

The thoracic wall and sternum play an integral role in various normal physiologic processes that are essential in maintaining homeostasis. The physiologic roles of the thoracic wall and sternum include housing and protecting the thoracic viscera as well as providing the semirigid framework that supports respiratory effort and function. When the functions of the wall and sternum are altered through

malformation (congenital or acquired) or trauma, homeostasis can be disrupted with results ranging from inconsequential to catastrophic. Therefore, it is incumbent on the veterinarian to understand the normal functions of the thoracic wall and sternum as well as to recognize potential consequences when these functions are disrupted. Unfortunately, clinical signs that indicate the presence of thoracic wall pathology may be either overshadowed by concurrent, more obvious, clinical signs from separate problems or be insidious in presentation and relatively difficult to detect.

Thoracic wall trauma is considered to

be more common than congenital and acquired deformities,[1] and traumatic injuries to the thoracic wall can be categorized as blunt or penetrating.[1-4] Blunt injuries to the thoracic wall result from vehicle accidents, adverse interactions with other animals or humans, falling from heights, and crushing injuries. The pliant nature of the thoracic wall in small animals has been suggested as a primary reason that blunt trauma may not always be manifest by visible pathology to the thoracic wall.[5-10] However, owing to the enclosure of vital thoracic organs, absence of visibly obvious pathology does not preclude the possibility of damage to these organs. Many reports have indicated that injury to

pulmonary and cardiac tissues are common sequelae to blunt injury despite the lack of visible damage to the thoracic wall.[2,11-13] When injuries to the thoracic wall are apparent, it should be assumed that damage to the underlying organs has also occurred, and therapy addressing this damage may take priority over other less threatening injuries. Pulmonary damage, alterations of the pleural space, disruption of tracheobronchial structures, damage to the heart and great vessels, and diaphragm rupture are common potential sequelae to blunt thoracic trauma.

Penetrating injuries to the thoracic wall are not as common as blunt injury

and result from high- and low-velocity projectiles, animal bites, and impalement (accidental or purpose driven). The integrity of the pleural space and underlying organs becomes a primary concern in that loss of the integrity and function can be rapidly fatal. Penetrating wounds must also be considered contaminated and the potential for infection realized.[3] The degree of trauma resulting from penetration is dependent on several factors. Among these are the type of tissue, the mass, shape, size, and velocity of the penetrating object, and the behavior of the object on penetration.[14,15] Generally speaking, the more kinetic energy transmitted to the tissues, the greater the tissue

damage will be. This generalization, however, does not take into account that vital functions may be completely disrupted by even relatively little tissue damage, depending on the organ involved. Penetrating wounds to the thoracic wall alone would rarely be a cause of major concern if not for the role the thoracic wall plays in respiration and in protecting vital organs.

Deformities of the thoracic wall and sternum, as previously mentioned, are much less common than is traumatic injury.[1] The pathologic results of deformities can alter normal physiologic function of the chest wall and major organ systems housed

within the thoracic cavity.[1,3,6,16] However, such disruption of function is not common and is relative to the severity of the deformity. Congenital deformities include pectus excavatum, pectus carinatum, and various rib and spinal deformities. Finding a significant congenital deformity of the thoracic wall and/or sternum is not an automatic indication for surgical or medical intervention because in many cases those affected are asymptomatic.[16,17] Acquired deformities of the thoracic wall may be a result of neoplasia or infection. Neoplastic disorders may arise from soft tissue or skeletal structures of the thorax or be a metastatic extension from a distant site.[17] Infections can

result from bacterial or fungal invasion secondary to chest wall trauma or migrating foreign bodies. These infections can present as mass lesions or can disrupt the integrity of the thoracic wall, leading to pleural space and possibly pulmonary disease.

In this chapter, I focus on the basics of anatomy and physiology to provide sufficient information for the reader to recognize pathophysiology of selected disorders of the thoracic wall and sternum.

Anatomy

The thoracic cage provides the dorsal, lateral, and ventral peripheral boundaries of the thoracic cavity,

which contains all or part of the heart and great vessels, lungs, pleurae and pleural space, trachea, esophagus, thymus, lymph nodes, and nerves of the somatic and autonomic systems. Also protected by the thoracic cage are the diaphragm, liver, gall bladder, stomach, and all or part of the spleen, right kidney and adrenal gland, intestines, and abdominal extensions of the great vessels and autonomic nerves.[18] The morphology of the thoracic wall can generally be described as a laterally compressed cone with the base as the caudal extent and the apex cranial. The lateral compression results in a greater dimension in the dorsoventral direction.[16,18] The skeletal components

include the sternum, thoracic vertebral bodies, and ribs. The sternum is composed of 8 individual bones called sternebrae, which make up the floor of the thoracic cage. The cranial- and caudal-most sternebrae are specifically designated as the manubrium and xiphoid process, respectively. Interposed between the sternebrae are cartilaginous plates, and extending caudally from the xiphoid process is the flattened xiphoid cartilage. The dorsal aspect of the thoracic cage is formed by the 13 thoracic vertebral bodies and the vertebral extremities of the ribs. Thirteen pairs of ribs constitute the lateral walls of the thoracic cage, each with osseous dorsal and cartilaginous ventral components.

Each rib has synovial articulations dorsally with the vertebrae in two locations, the head with the vertebral bodies (or body) at or near the intervertebral disc and the tubercle with the transverse process. Ventrally the first 9 pairs of ribs have synovial articulations with the sternum. The first pair with the manubrium, pairs 2 to 7 with the corresponding intersternebral cartilage plates, and pairs 8 and 9 share an articulation site at the last intersternebral cartilage. Pairs 10 to 12 attach to the preceding rib through the ventral costal cartilages and form the costal arch. The 13th pair are commonly known as floating ribs because they do not articulate with the sternum and the ventral cartilaginous

portions are enclosed in the surrounding abdominal muscles.[6,16,18] The diverging nature of the sternum and vertebral bodies and the increasing arch of the ribs from cranial to caudal account for the aforementioned cone shape.[18]

The soft tissue components of the thoracic wall include the costal parietal pleura, the endothoracic and external thoracic fasciae, and various muscles that are important structurally as well as functionally for respiration. The parietal pleura is a serous membrane that has a layer of mesothelial cells supported by a layer of delicate elastic fibers. The parietal pleura also lines the surface of the diaphragm.[18,19] The

parietal pleura is supported by the endothoracic fascia which is deep to the thoracic musculature. The external thoracic fascia covers the external surfaces of the muscles and the chest wall.[18]

The intercostal muscles are confined within the space between each rib. Closest to the parietal pleura are the internal intercostals. These muscles extend from the cranial borders of ribs 2 to 13 and course in a cranioventral direction to insert on the caudal border of the preceding rib.[16,18] In the interosseous area of the thoracic cage, this arrangement results in the ribs being pulled in a caudal direction. Other muscles of the thoracic wall also

function to pull the ribs caudally. These include the external intercostals of the caudal-most interspaces, rectus abdominus muscles on the ventral aspect, the costal portions of the external abdominal oblique muscle at the ventrolateral aspect of the chest wall, the caudal portion of the serratus dorsalis located caudodorsally, and the transverses thoracis on the internal surface of the ventral thorax.[16,18,20,21] The external intercostals, as the name implies, lie lateral or external to the internal intercostals. These muscles arise from the caudal border of ribs 1 to 12 and course caudoventrally to insert on the cranial border of the succeeding rib.[16,18] The fibers run at a right angle to the fibers of the internal

intercostals and in the craniodorsal interspaces have essentially the opposite action, that of pulling the ribs cranially. The other muscles of the thoracic wall that pull ribs cranially include the interchondral portion of the internal intercostals, rectus thoracis located cranioventrally, the scalenus on the ventrolateral aspect, and the cranial portion of the serratus dorsalis on the dorsolateral aspect of the chest wall.[16,18,20,21] The other muscles that cover the thoracic wall and function in mobility of the spine and thoracic limb include the epaxial muscles over the dorsal thoracic region, the serratus ventralis on the craniolateral surface, the rhomboideus and trapezius muscles over the craniodorsal walls, the

pectoral muscles on the ventral surface, and the latissimus dorsi along the lateral wall.[16,18] Finally, loose subcutaneous tissues, the cutaneous trunci muscle and the skin form the outer layers and covering of the thoracic wall.

Vascular supply to the thoracic wall is generally through the intercostal arteries and veins. The arteries originate either from the costocervical trunk or the dorsal intercostals from the thoracic aorta and course along the caudal border of the ribs to anastomose with the ventral intercostal arteries arising from the internal thoracic arteries that lie on the internal surface of the ventral thoracic wall. Branches

of the ventral intercostals can be found on the cranial and caudal aspect of the ribs. The intercostal veins course with the arteries along the caudal border of the ribs and drain into the azygous vein between the vertebral bodies and thoracic aorta.[18]

Innervation to the thoracic wall is primarily from branches of the thoracic spinal nerves. The intercostals nerves arise from the ventral branches and course with the arteries and veins along the caudal border of the ribs.[18]

Physiology

Respiration can be divided into four major functions: pulmonary ventilation, diffusion of O_2 and CO_2

between alveoli and the blood, transport of O_2 and CO_2 within the blood to the cells of the body, and regulation of ventilation.[22] The anatomic morphology of the thoracic wall contributes primarily to pulmonary ventilation. The cone-like shape of the thoracic cage and the muscle attachments allow for expansion and contraction of the thoracic cavity. Because the diaphragm is located near the base of the "cone," as it contracts the craniocaudal dimension of the thoracic cavity is increased. The combination of rib morphology, rib articulation with the spine and sternum, and thoracic wall musculature lead to a "bucket-handle" type of motion to the ribs.[6,23] As the

ribs are pulled in a cranial direction by thoracic wall muscles, the sternum moves further away from the spine and the arches of the ribs become more abaxially positioned. This results in an increase in both the dorsoventral and lateral dimensions of the thoracic cavity. Those muscles that function to pull the ribs cranially are called muscles of inspiration while those that pull the ribs caudally are muscles of expiration.

By convention it has been thought that the external and internal intercostal muscles have distinctly inspiratory and expiratory functions, respectively. This convention has changed and the individual effects of these muscles on

respiration are determined more by topography and nervous input.[20,21] It is now thought that the external intercostals in the craniodorsal interspaces and the interchondral portion of the internal intercostals (a.k.a. parasternal intercostals) are inspiratory and pull the ribs in a cranial direction.[20,21]

The parasternal intercostal contribution to the cranial movement of the ribs is estimated at approximately 80%.[24] The interosseous portion of the internal intercostals and the external intercostals of the caudal-most interspaces are expiratory and pull the ribs caudally.[20,21]

The pleural space contained within the thoracic cavity is, in actuality, only a potential space. This is because the subatmospheric or negative pressure within the space keeps the pulmonary pleura held in contact with the parietal pleura of the thoracic wall. This negative pressure is created by fluid movement into and out of the pleural space.[22] Starling's forces and pleural membranes that are porous allow protein-containing interstitial fluid to transude into and out of the pleural space. The net effect of capillary hydrostatic pressures and colloid osmotic pressures between systemic capillaries and pulmonary capillaries favors flow from the systemic capillaries through the pleural space

and absorption into the pulmonary capillaries. As the volume of fluid increases above that which is necessary for lubrication of the pleural surfaces, the lymphatic vessels pump excess fluid away. The pumping action of the lymphatic system helps to produce the negative intrapleural pressure. Fluid flow dynamics and the lymphatic actions produce a “liquid coupling” between the pulmonary and parietal pleural surfaces. This coupling allows complete transmission of changes in the thoracic cavity volume to the lungs.[19] So, as thoracic cavity dimensions are increased in response to respiratory muscle action, the lungs are able to expand.

The thoracic wall and lungs have an elastic nature that is independent of each other. Without fluid coupling, the thoracic wall would expand to a point where, when relaxed, a specific thoracic volume (V_o) would exist.[6] When muscles of inspiration increase the thoracic volume above V_o, the thoracic wall has a tendency to recoil inward until V_o is reached. If thoracic volume is less than V_o, the thoracic wall has a tendency to spring outward, again until Vo is reached.[6] The elastic nature of the lungs, without fluid coupling, would result in an inward collapse to a point where only a residual volume of air remained. The opposing elastic recoil of the thoracic wall and lungs, with fluid coupling,

has a point where balance is achieved. That is, the inherent tendency of the lungs to collapse is prevented by the inherent tendency of the thoracic wall to spring outward and vice versa. At this point of balance, the thoracic volume is less than V_o and the volume within the lungs is the functional residual capacity (FRC).[6,23] When the muscles of inspiration cause expansion of the thoracic volume, the lungs also expand owing to fluid coupling. This results in an increase in the negative pleural pressure, which generates negative pressure within the airways and alveoli relative to the atmosphere (transpulmonary pressure) and allows air to flow into the lungs. Because the thoracic volume is held to less than V_o,

the inherent tendency of the thoracic wall to spring outward actually assists in the inspiratory effort until V_o is reached or exceeded. Then, when inspiratory muscle contraction ceases, the thorax passively returns to the point of balance.

The change in volume of the lungs and thoracic cavity in response to changes in pressure is called compliance.[6,22,23] The compliance of the lungs and the thoracic wall together make up the total compliance of the pulmonary system. When the ability of either the thoracic wall or the lungs to change volume in response to change in pressure occurs, the total compliance will change. The effort required to

generate sufficient negative transpulmonary pressure to overcome the compliance of the pulmonary system and the resistance to airflow within the airways for inspiratory flow or to overcome resistance to expiratory flow is the work of respiration. The work of respiration will be altered if compliance is altered.[1,6] If thoracic wall compliance is decreased because of trauma or disease, the work of respiration will increase.

Trauma

Blunt Trauma

Blunt trauma to the thorax induces tissue injury by transference of the kinetic energy of the impacting object

to the chest wall without creating an opening between the pleural space and thoracic organs and the external environment. The greater the kinetic energy transmitted the greater potential for damage to the thorax. Additionally, the energy is also transferred to the thoracic organs with potential damage to those organs. Direct trauma produces crush and shear injury to the soft tissues and skeletal structures. Low-speed trauma produces a localized crushing injury to the tissues.[1] With this type of trauma the skin may appear relatively undamaged owing to the resilience of the cutaneous epithelium. Underlying tissues such as muscle and bone however, may exhibit a greater degree

of damage. Muscle tissue is extremely sensitive to pressure.[25] This sensitivity can result in muscle damage with localized rhabdomyolysis, and myoglobin, potassium, phosphorus, and creatinine phosphokinase are released into the surrounding tissues. When more than 200 grams of muscle are injured, the serum myoglobin levels can be increased and myoglobin may be detected in the urine.[26] Despite the fact that myoglobinemia is rapidly cleared, it must be remembered that the products of myoglobin breakdown are nephrotoxic.[27,28] Skeletal muscle contains more potassium than any other body structure.[29] Extensive damage to muscle tissue with muscle necrosis can lead to hyperkalemia.[30]

Phosphorus can leak from damaged muscle tissue and contribute to hyperphosphatemia.[31] Creatinine phosphokinase is an enzyme released from damaged muscle; an increase in levels of creatinine phosphokinase is a sensitive indicator of muscle injury from any cause, and the increase will parallel the degree of damage. Muscle that has been injured in this manner becomes edematous and swollen and looses its elasticity and ability to contract efficiently. This decreases the compliance of the thoracic wall and, therefore, increases the work of respiration. However, the resulting pain may contribute to a decreased respiratory effort, which may contribute to hypoventilation.

Higher speed trauma produces shearing injury in addition to crushing.[1] Shearing injury results when two adjacent tissues with different specific gravities are suddenly accelerated or decelerated.[1,32] Because of the specific gravity variation, the momentum of the tissues during the abrupt change is also different. This generates shear forces at the junction of the two tissues. If the shear forces exceed the inherent elasticity of the tissue junction, the result will be a separation between the tissues. Although soft tissue damage of the thoracic wall is rarely a major cause of morbidity or mortality,[1] it is critical to remember that the kinetic energy of the impact is also transmitted to the

thoracic organs, and crush and shear injuries may occur to these structures.

The resistance of skeletal structures of the thoracic cage to injury through blunt trauma is attributed to inherent resilience.[2,4,6,9] Despite this resilience, the lack of obvious skeletal damage does not preclude the possibility of severe, even life-threatening soft tissue or thoracic organ damage because considerable force is required to induce fracture and that force is also transmitted to the thoracic organs. Blunt trauma that results in fractures of the thoracic cage most commonly is from a direct force applied to the lateral body wall resulting in rib fractures.[4] Ventral-dorsal compression

of the thorax from bite wounds or falls from heights can result in sternal and rib fractures, but these are considered rare.[4,33] Research has shown that local bending and shear are some of the primary loading modes during impact trauma.[34] When the force or load applied to skeletal components exceeds the ultimate strength, the failure point is reached and a fracture is produced. Interestingly, the rate at which a force is applied to the cortical bone of ribs will affect the material characteristics of the bone. The ultimate strength of the bone is lower if the load is applied slowly. Conversely, high-speed application results in a higher ultimate strength. This property is known as viscoelasticity.[35] This property can

affect the amount of kinetic energy absorbed by the bone when a force is applied. Slow application of load to failure results in less kinetic energy absorbed and the resulting fracture will likely be a simple two-piece fracture with minimal energy released and subsequently minimal damage to the surrounding tissues. High-speed load to failure will result in an increase in absorbed kinetic energy and a more complex fracture with more surrounding tissue damage.[35] The proximity of the pleural space and lungs to the thoracic cage puts them at risk when a fracture occurs; the more complex the fracture, the higher the risk to these vital structures. Rib and sternal fractures alter the function of

the thoracic cage by decreasing compliance. However, in simple nondisplaced fractures and displaced fractures that will not damage the underlying pleural space and lung, therapy should be directed at the underlying pulmonary damage and pain rather than at the fractures. If the fracture fragments endanger these vital organs, then therapy is directed at stabilization of the fragments.

Flail Chest

When the trauma to the thoracic wall is severe enough to fracture adjacent ribs (at least two) in two locations, the result is flail chest. This complex fracture eliminates the costal arch

support of the section of thoracic wall between the fractures. The section "flails" asynchronously with normal thoracic motion and is characterized by inward displacement during inspiration and outward displacement during expiration. The degree of paradoxical motion is determined by the pleural pressure becoming more negative during inspiration and the action of the parasternal intercostal (interchondral internal intercostal) muscles which pulls the flail segment inward.[36,37] This paradoxical motion can be a dramatic clinical finding, which may overshadow the less apparent but clinically more significant damage to the thoracic organs. It has been shown in a

nontraumatic model of flail chest in the canine that arterial blood gases and the respiratory pattern did not change while the flail segment existed. This suggests that the severe effects of traumatic flail chest are a result of pulmonary damage, pleural space disruption, and the accompanying pain from the trauma rather than the paradoxic motion of the flail segment.[5,38] Disruption of the thoracic wall from fractured ribs will decrease the compliance of the thoracic cage and the work of respiration will increase; however, the accompanying pain causes a restriction in the ventilatory efforts. Understanding the pathophysiology of flail chest has refocused primary therapy from flail

segment stabilization to improving respiratory function and pain control.[1,5] If the trauma or fracture fragments have resulted in pleural space disruption or if they endanger the pulmonary parenchyma, it is important that therapy also include restoration of the pleural integrity and stabilization of the fractures.

Penetrating Trauma

Penetrating injury usually results when a mechanical force is abruptly applied to a focal area and the integrity of the thoracic wall and pleural space is breached. The resulting damage is from severe stretching and crushing of tissues in the direct path of

penetration. Penetration of the thoracic wall itself would not be a primary cause of concern except that the pleural space and thoracic organs may be damaged. The severity of penetration injury depends on the resulting degree of dysfunction and the degree of damage to vital organs.

Low-velocity penetration injury is essentially limited to the confined area because relatively little energy is transferred from the penetrating object to the tissues. Simple bite wounds, stabs, arrows, and some pneumatically propelled projectiles are examples of low-velocity penetration. Cutaneous and subcutaneous tissue, muscle, fascia, and possibly bone are damaged

in the path of penetration. When the parietal pleural layer is penetrated and direct communication with the external atmosphere occurs, the negative pressure within the pleural space is lost and air now fills the pleural space. Fluid coupling of the thoracic wall and parietal pleura with the visceral pleura and lung is disrupted and the inherent elasticity of the lung causes an inward collapse while the thoracic wall expands. The individual compliance of the lungs and thoracic wall decreases and the work of respiration necessarily increases. Without the assistance of the thoracic wall, the lungs are unable to expand adequately and the degree of negative transpulmonary pressure needed to allow efficient airflow into

the airways is not generated. The result is an expanded thoracic cage and a compensatory rapid shallow respiratory pattern.[6]

Impalement injury is another type of low-velocity penetration in which a foreign object traverses and remains transfixed within the thoracic wall. This uncommon injury is generally the result of collision or impact between the body and an immovable object.[39] Even though this injury is classified as penetrating, it can be argued that there are characteristics of blunt trauma as well.[40,41] The distance and trajectory of the penetration dictate which (if any) thoracic organs or other body areas may also be involved. In

impalement injury, the foreign object may fill the wound sufficiently such that the pleural space is effectively closed and also provide a tamponade effect to the surrounding organs or vessels.[4,42,43] It is recommended for this reason that the impaling object not be blindly removed from the body but left in place and stabilized for transport to a hospital for removal under direct visualization and controlled surgical conditions.[40-43] It may be necessary to cut and shorten the object for patient extrication and this should be done with extreme care so as not to cause further disruption or accidental dislodgement. Impaled wounds may be contaminated with unusual pathogens from the environment as well as with

resident microorganisms from cutaneous tissues and potential hollow viscus disruption.[43]

Bites are a relatively common source of low-velocity penetrating thoracic wounds. Bite wounds, like impalement, also have characteristics of blunt trauma but they also introduce the potential of severe tearing injury away from the point of penetration owing to the scissor action of teeth and the shaking that may accompany a bite wound. The blunt trauma aspect of bite wounds to the thoracic wall is a relatively common source of fractures.[4,5,8] Tearing of the intercostal muscles and potential fracture can severely disrupt the thoracic wall and

pleural space such that pulmonary herniation may occur.[6] Occasionally, the cutaneous epithelium may remain intact despite complete disruption of muscular and skeletal structures. When this occurs, the skin may move in a paradoxic manner and mimic flail chest.[6] As with other penetrating thoracic wounds, microorganism contamination is inevitable, with the possibility of subsequent infection. The spectrum of contaminating organisms includes normal cutaneous flora and numerous intraoral microorganisms.

Penetrating injury through high-velocity projectiles most commonly results from either accident or malicious intent. As mentioned

previously, the amount of kinetic energy a penetrating object transfers to the tissues dictates the amount of damage. Several formulas calculate the amount of kinetic energy. The simplest of these is:

$$KE = 1/2\, mv^2$$

Where KE is the kinetic energy, m is the mass of the projectile and V is velocity.[44] As is readily seen from the equation, velocity is the most important factor when it comes to kinetic energy transfer and therefore tissue damage. The transfer of energy to the tissues produces injury in various ways. Lower velocity projectiles, such as those from air guns,

damage tissues primarily through crushing and laceration. Higher velocity projectiles also have crushing and laceration components in the path of penetration, but they also produce a temporary cavity that is formed by forward acceleration of the tissues in the wake of the projectile, which causes radial stretch of the wound cavity. Cavitation can lacerate tissues, create contusions, damage vascular lining, and rupture large vessels. The greater the energy transferred to the tissue, the further from the bullet track these injuries will extend. Another method of injury is through shock waves that travel ahead of and to the sides of the projectile. At lower velocities these shock waves produce

little damage, but at high velocity the pressure created can be significant.[14]

Another factor includes the type of tissue penetrated. The major characteristics of body tissues that influence the degree of damage are specific gravity (density) and elasticity.[14] These characteristics have differing influences on the degree of tissue damage when penetrated by a high-velocity projectile. Tissues that have a high specific gravity will incur greater damage whereas tissues that are highly elastic will have less damage. Muscle has a relatively high density and some elasticity and, therefore, is severely damaged. The variable density of bone may divert the

trajectory of the projectile. If the bone is fractured by the projectile, the created fragments can in turn become projectiles.[45]

Structural Deformities

Pectus Excavatum

Pectus excavatum (PE) is a morphologic deformity of the thoracic wall characterized by sternal and costal cartilage abnormalities that can result in dorsoventral flattening of the thorax to concave deformation of the ventral thoracic wall.[1,3,6,16] Although the condition is generally considered congenital in small animals, the etiology is largely unknown. Various theories exist as to the cause, including

defective development of cartilage and bone such that the sternum and costal cartilages are readily deformed by respiratory pressure gradients; anatomic variations in soft tissue attachments to the sternum; excessive costal cartilage growth; and abnormal intrauterine pressures.[1,3,46] Because PE is seen most commonly in brachycephalic dogs and Burmese cats and has been reported in cases of mucopolysaccharidosis, it is feasible that a genetic basis for the condition exists.[1,6,46-48] It is also possible that there is an acquired aspect of PE as can be seen in humans with upper airway obstruction.[1,46,49,50] In brachycephalic dogs the upper airway obstruction that results from

brachycephalic airway syndrome may lead to an increase in the negative pleural pressure, which deforms the immature cartilage and bone of the thorax. Generally, the condition is localized in the caudal sternal area but cranial sternal deformities have also been reported.[51]

Patients with PE may show an increased work of respiration, and this suggests a decrease in the compliance of the pulmonary system. Abnormal anatomy of the sternum and costal cartilage will decrease compliance of the thoracic wall, and pulmonary compression will decrease pulmonary compliance. Clinically, this can be seen as varying degrees of tachypnea,

exercise intolerance, dyspnea, and cyanosis. Other signs may include recurrent respiratory infection, cardiac murmurs, vomiting, weight loss, and decreased growth.[1,46] Deviation of the heart owing to PE can lead to heart murmurs, conduction abnormalities, and apparent enlargement.[1,6,16,46,52] It is important to differentiate potential congenital cardiac defects from the secondary effects of cardiac compression and malposition. Many of the clinical abnormalities associated with PE can be alleviated or eliminated by repair of the defect.

Diagnosis of PE is usually made by thoracic palpation. However, in some, the flattening of the chest is not as

apparent as evidenced by diagnosis later in life when clinical signs indicate a potential cardiovascular or respiratory problem. Radiographs of the thorax can provide a means of objective measurement of the relative degree of PE. The frontosagital index is a ratio between the width of the chest at the 10th vertebral body and the dorsoventral measurement from the ventral surface of the 10th vertebra to the sternum. The range of normal ratios for nonbrachycephalic dogs is 0.8 to 1.4, for brachycephalic dogs is 1.0 to 1.5, and for cats is 0.7 to 1.3. The vertebral index has also been used and is calculated as the dorsoventral measurement from the dorsal surface of the vertebral body selected to the

sternum and the dorsoventral measurement of the vertebral body itself. Nonbrachycephalic dogs have a vertebral index range of 11.8 to 19.6, brachycephalic dogs from 12.5 to 16.5, and cats from 12.6 to 18.8.[52] Although these measurements and ratios can help classify the degree of PE and help to determine anatomic improvement after repair procedures, they do not necessarily correlate to the severity of clinical presentation or physiologic abnormalities.[1]

Other Congenital Deformities

Pectus carinatum is essentially the reverse of pectus excavatum and is described as a protrusion deformity of

the sternum.[16,53] Because the thoracic cage of small animals is laterally compressed, this condition would be inherently difficult to detect. In fact, to the author's knowledge, no cases have been reported in small animals. Other chest-wall deformities include missing ribs, extra ribs, and rib malformations. Toxin exposure in utero may lead to these types of abnormal skeletal formations.[54] Although there are scattered reports of such anomalies in the veterinary literature, they are often incidental findings. Severe spinal malformations such as scoliosis and kyphosis may lead to thoracic cage malformation and decreased compliance.[46] The abnormality may also lead to pulmonary restriction with

decreased compliance and abnormal respiratory function.[55] These abnormalities are also rare, and reports in the veterinary literature are uncommon.

Acquired Deformities

Acquired deformities of the thoracic wall that lead to dysfunction are uncommon. Such deformities can present as mass lesions readily visible externally or as a mild chest-wall thickening with significant intrathoracic extension that leads to respiratory or cardiovascular dysfunction.[3,6,17] These deformities include primary chest-wall tumors, metastatic tumors, and

pyogranulomatous or purulent infection.

Infection

The contaminating nature of penetrating wounds raises the potential of clinical infection at or near the site of the wound. The infectious process may produce cellulitis, abscesses, or granulomas. Various aerobic and anaerobic bacteria and fungal organisms have been isolated from thoracic-wall lesions. Migrating foreign bodies such as grass awns (“fox tails”) may be the source of the infection, and the degree of tissue involvement can be extensive. Lesions from infectious microorganisms can

adversely affect the function of localized areas of the thoracic wall through alteration of muscle action and destruction of musculoskeletal tissues. However, extension of the infection into the pleural space and organs of the thoracic cavity can produce more serious conditions such as pyothorax, lymphadenopathy, and pulmonary infiltration.[17] Therapy for infectious conditions may be simple drainage and appropriate antimicrobial medications, but it may require extensive debridement or excision of diseased tissue to facilitate resolution. In this case, therapy may also contribute to altered thoracic function.

Neoplasia

Tumors of the thoracic wall can originate from skeletal structures or soft tissues; the type of tumor will determine the biologic behavior. Although tumors of the thoracic wall are considered uncommon, it is important to differentiate between benign and malignant tumors in order to plan the appropriate therapy. Benign tumors can often be removed without wide or radical types of excision, and a cure can be expected. Malignant tumors should be removed with a variable margin of normal tissue, depending on the tumor type and the tissues involved. Those that have a high probability of recurrence

should have large borders of normal tissue removed three dimensionally around the tumor.[56] The extent of the surgical excision may not only affect the function of the thoracic wall but will dictate the type of closure or thoracic wall reconstruction required.

Primary tumors affecting the supporting skeletal structures of the thoracic wall are malignant more often than they are benign.[1,3,6,16,46,57] Most authors report that osteosarcoma is the most common type of malignant rib tumor, with chondrosarcoma being second;[1,3,6,16,46,57] however, some authors have this order reversed.[17] The common site of occurrence in dogs for both types of tumor is the

costochondral junction; rarely the sternum is the site.[1,3,16,57] These tumors are often firmly attached to other tissues of the thorax, making them relatively immobile. This characteristic may be an indication of malignancy.[46] Younger to middle-aged dogs seem to be affected more often with these tumors.[1,16,57,58] The occurrence of these tumors in this location in the cat is rare.[57]

The most common bone tumor in dogs is osteosarcoma; approximately 25% occur in the axial skeleton, with 10% of those occurring in the ribs.[59] Clinically, dogs with osteosarcoma of the thorax present with a palpable mass of the ribs or sternum that may

be painful,[59] although many authors describe them as nonpainful.[16,17,57] Dyspnea has been reported as a clinical sign by various authors with suggestions that pulmonary impingement owing to intrathoracic extension, pleural effusion, and pulmonary metastasis may be the cause.[1,16,57,58] Others state that respiratory signs owing to these conditions are not commonly seen.[59] One characteristic that is generally agreed on is that the biologic behavior of osteosarcoma in the rib is similar to that in other locations. Locally, osteosarcoma is aggressive, with lysis and production of bone and replacement with neoplastic tissue.[59] Early metastasis is a hallmark of

osteosarcoma with the lungs as the primary location for tumor spread.[6,57,58] This predilection for metastasis is responsible for the poor prognosis for osteosarcoma. The median survival times for patients treated by en bloc excision and excision plus adjunctive chemotherapy are 3 and 8 months, respectively.[59,60,61] The poor prognosis emphasizes the need for accurate diagnosis.

Chondrosarcoma seems to have a predilection for flat bones; it occurs in these 61% of the time.[59] In dogs, the range of occurrence on the ribs is from 6% to as high as 33%, according to various sources.[17,57] In cats, common locations near the thorax are the

scapula and vertebrae; rarely, if ever, the ribs or sternum. Ostensibly not as aggressive as osteosarcoma, this tumor may attain large dimensions before diagnosis. It is locally invasive, invades the pleural space, and may cause pleural effusion.17 Metastasis is reported to be slower than with osteosarcoma and the prognosis is somewhat better.[17,59] A wide variation exists in reported median survival times for dogs with chondrosarcoma of the ribs, but they are considerably longer than with osteosarcoma, with sources reporting survival up to 1080 days.[59,61] As with osteosarcoma, therapy for chondrosarcoma is en bloc resection of the tumor with reconstruction of the thoracic wall if

needed.

Metastatic neoplasms of the thoracic wall have been described and the ribs are considered a common site, whereas the sternum is rarely reported.[1,59] When metastasis to the ribs (and other bones) occurs, it seems to be localized near the diaphyseal area near the nutrient foramen rather than the costochondral junction.[17,59] The incidence of metastasis of osteosarcoma to other bones such as the ribs may be increased following chemotherapy regimens.[59]

Primary tumors of thoracic soft tissues include various sarcomas (e.g., fibrosarcoma, hemangiosarcoma,

hemangiopericytoma, and malignant fibrous histiocytoma) and occasional discrete cell tumors (i.e., mast cell tumor).[3,46,62] Wide three-dimensional surgical excision is recommended for these tumors. If removal requires en bloc excision of the thoracic wall, reconstruction may be required.

Part VII

Special Senses

Chapter 59

Ear

Jamie R. Bellah

Surgical procedures of the ear fit into two basic categories. They are adjunctive to medical therapy of ear disease, or they attempt to provide complete resolution of local neoplastic or inflammatory disease. Occasionally, traumatic injuries to the ear are resolved surgically. Ear disease is most commonly inflammatory and complicated by secondary infection with bacteria and/or yeast. The ear

canal, as an extension of the skin is affected by generalized skin disorders such as atopy, food allergy, and generalized seborrhea. The warmer, more humid microclimate is a predisposing factor to secondary infection. Neoplastic processes, whether benign or malignant, obstruct ear canal drainage, alter defense mechanisms, and often result in secondary local infection. Congenital stenosis, stenosis from wound healing processes, and vascular disorders also may affect the ear canal and pinna. Whereas the middle ear is most commonly affected because it is the near neighbor of the external ear canal, disease that begins within the middle ear can secondarily affect the

external ear canal and nasopharyngeal passages. The proximity of the temporomandibular joint and facial and sympathetic nerve branches may result in clinical signs being referred to more distant structures. The ear may also be affected by vascular disorders that in some instances require surgery. My mission in this chapter is to focus on pathophysiologic processes that affect the ear and how surgery may be used to support treatment efforts or to resolve the disease process.

External Ear Canal

The pinna of the external ear is a breed characteristic, but more importantly, it has specific functions.

As a funnel, its cartilaginous plate and shape receive vibrations and transmit or direct them down the ear canal to the tympanic membrane. The ear canal provides protection for the tympanic membrane from direct injury, and provides or maintains an open conduit for conduction of sound to the eardrum.[1] The shape of the pinna is altered by 19 auricular muscles attached to each ear that control movement independently.[2] The convex surface of the pinna is the medial and caudal surface of the ear, whereas the concave surface is the rostral and lateral surface and directs sound down the ear canal. The blood supply to the pinna is provided by the medial, intermediate, and lateral branches of

the caudal auricular arteries, which arise at the base of the ear in subcutaneous tissue at the base of the convex side of the ear.[2]

Auricular Cartilage

The auricular cartilage includes the helix, anthelix, tragus, and antitragus. The helix is the free edge of the auricular cartilage, which has medial and lateral parts that meet at the apex. The anthelix is located on the medial wall of the ear canal, forms a low horizontal ridge, and has a prominent tubercle that is seen near the entrance. The tragus is the lateral wall of the entrance to the ear canal. The intertragic notch separates the thicker

dense tragus from the more caudal and thinner antitragus. The aforementioned structures and the medial and lateral crura of the helix encircle the ear canal (Figure 59-1). The auricular cartilage of the ear canal attaches to the skull at the dorsolateral-facing external acoustic meatus. The vertical ear canal extends to the transversely oriented horizontal canal, which terminates at the end (most medial aspect) of the ear canal, formed by the tympanic membrane. The tympanic membrane is also the lateral wall of the middle ear (Figure 59-2). The annular cartilage is located medial to, and in part telescopes into, the rolled portion of the auricular cartilage and then has ligamentous

attachment to the temporal bone.

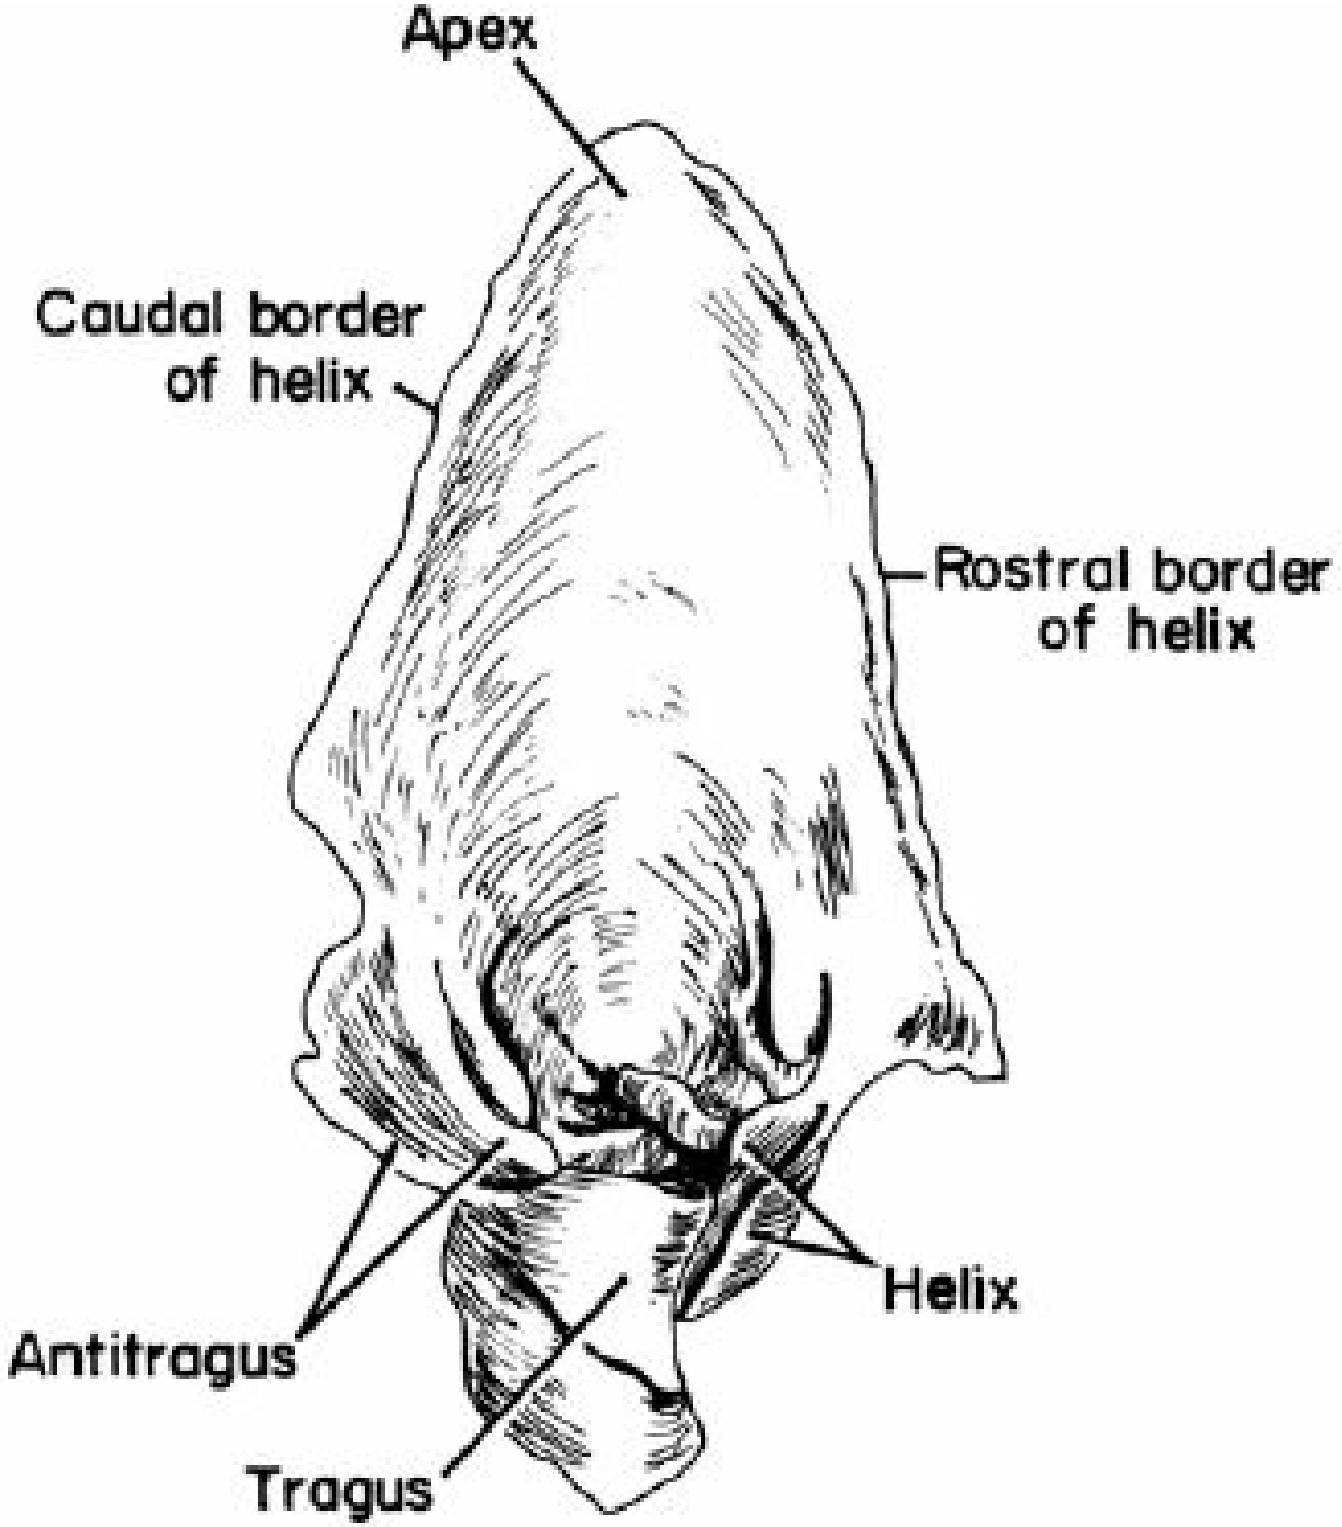

Figure 59-1. Diagram of pinna and auricular cartilages. (Redrawn from Miller's Anatomy of the

Dog, 2nd ed. Evans HE, Christensen GD, (eds). Philadelphia: WB Saunders, 1979.)

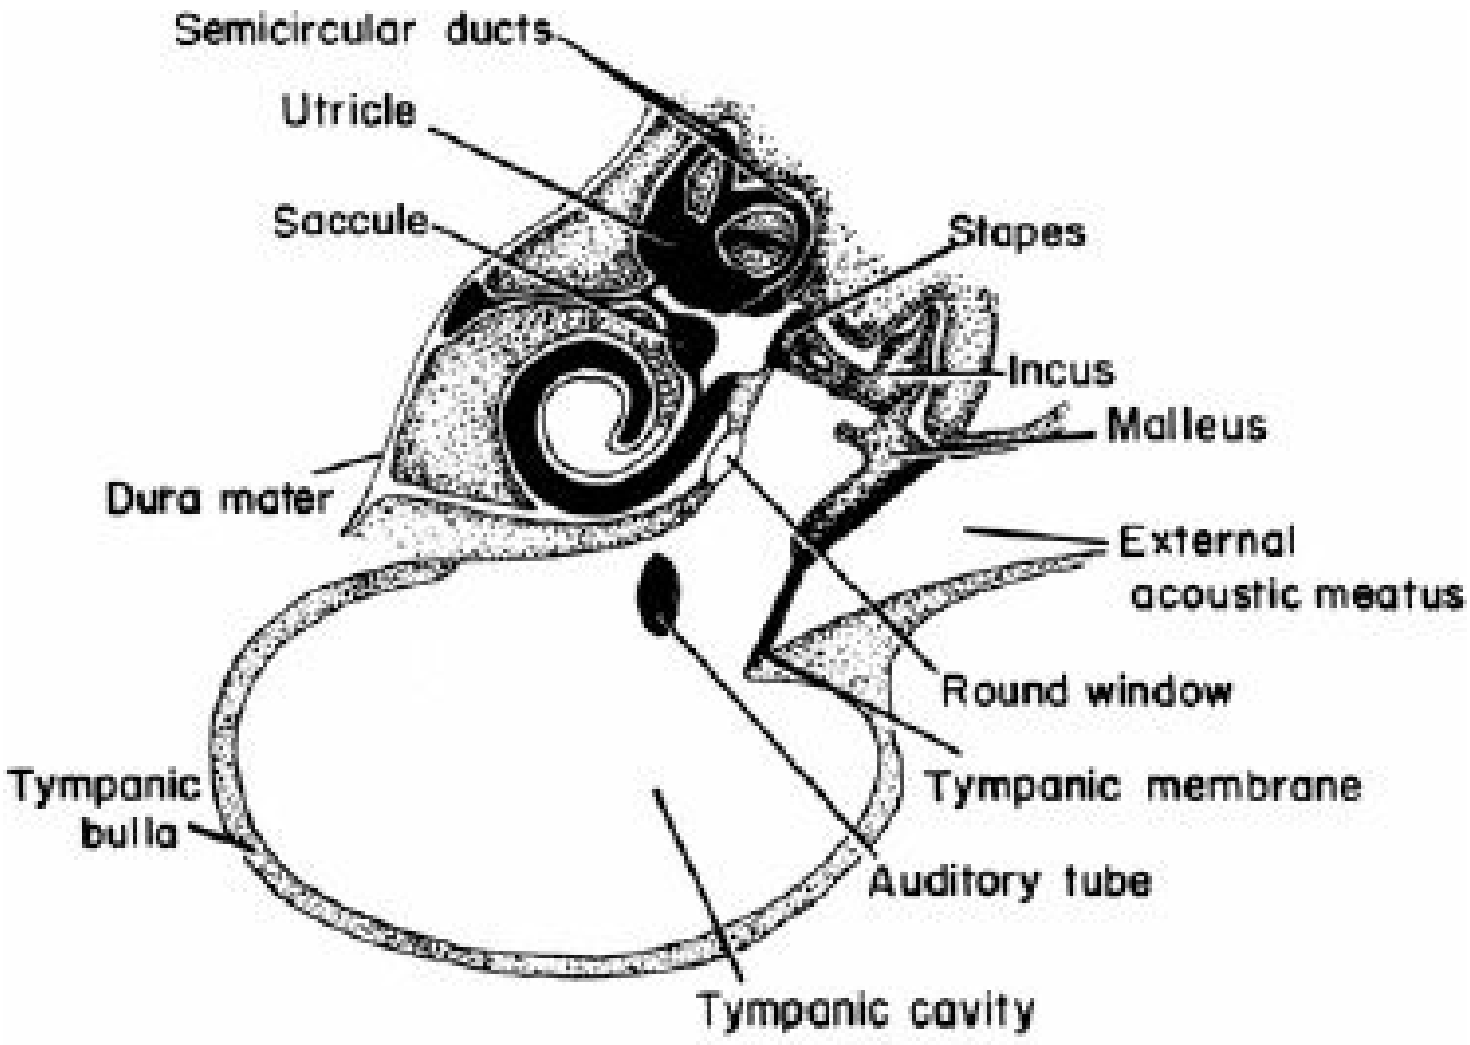

Figure 59-2. Diagram of the middle ear and inner ear. (Redrawn from Miller's Anatomy of the Dog, 2nd ed. Evans HE, Christensen GD, (eds). Philadelphia: WB Saunders, 1979.)

External Acoustic Meatus

The external acoustic meatus is lined by a continuation of stratified squamous epithelium from the ear canal and the adnexa, which include the more superficial sebaceous glands, tubular apocrine (ceruminous) glands located in the deeper connective tissue layer, and hair follicles. Both apocrine and sebaceous glands are responsible for the production of the cerumen. Although there is breed variation, hair follicles are located on the pinna and within the ear canal. The density of follicles, sebaceous glands, and tubular glands decreases in the depth of the canal and is least within the osseous meatus. Dogs with heavy hair coats have more compound hair follicles and have a consistent follicle density

throughout the horizontal canal. Short-coated breeds tend to have fewer follicles and simple follicles near the eardrum.[1,3] Cats have little hair in the ear canal, and have more adnexa in the proximal third of the horizontal canal. Hair tends to point outward and, therefore, facilitates cerumen and debris moving out of the ear canal and resists movement toward the eardrum.

The skin of the entire ear canal is supported by a dense layer of connective tissue and gradually becomes thinner as it extends into the external acoustic meatus (Figure 59-3). Coiled apocrine glands are noted in the deeper dermal layers of the peripheral ear canal. Normal canine ear canals

contain actively secreting sebaceous follicles, which produce a holocrine substance that is secreted through ducts near the surface of the skin and occasionally directly to the skin surface.[2] Cerumen is a combination of desquamated corneocytes, apocrine secretions and sebaceous secretions, which contain protein, lipids, amino acids, and mineral ions. Cerumen tends to be sticky, and this adhesive character is considered a local protective mechanism, helping to prevent debris from moving toward the tympanum. Small coiled tubular apocrine glands are not common in healthy ears and are located below the sebaceous glands. In long-standing otitis externa, secretions from both

sebaceous and apocrine glands become copious and accumulate within the external auditory meatus. The increased activity of the cerumen glands results in excessive cerumen accumulation, which is a good growth medium for bacteria, especially for pathologic microorganisms.[2,3]

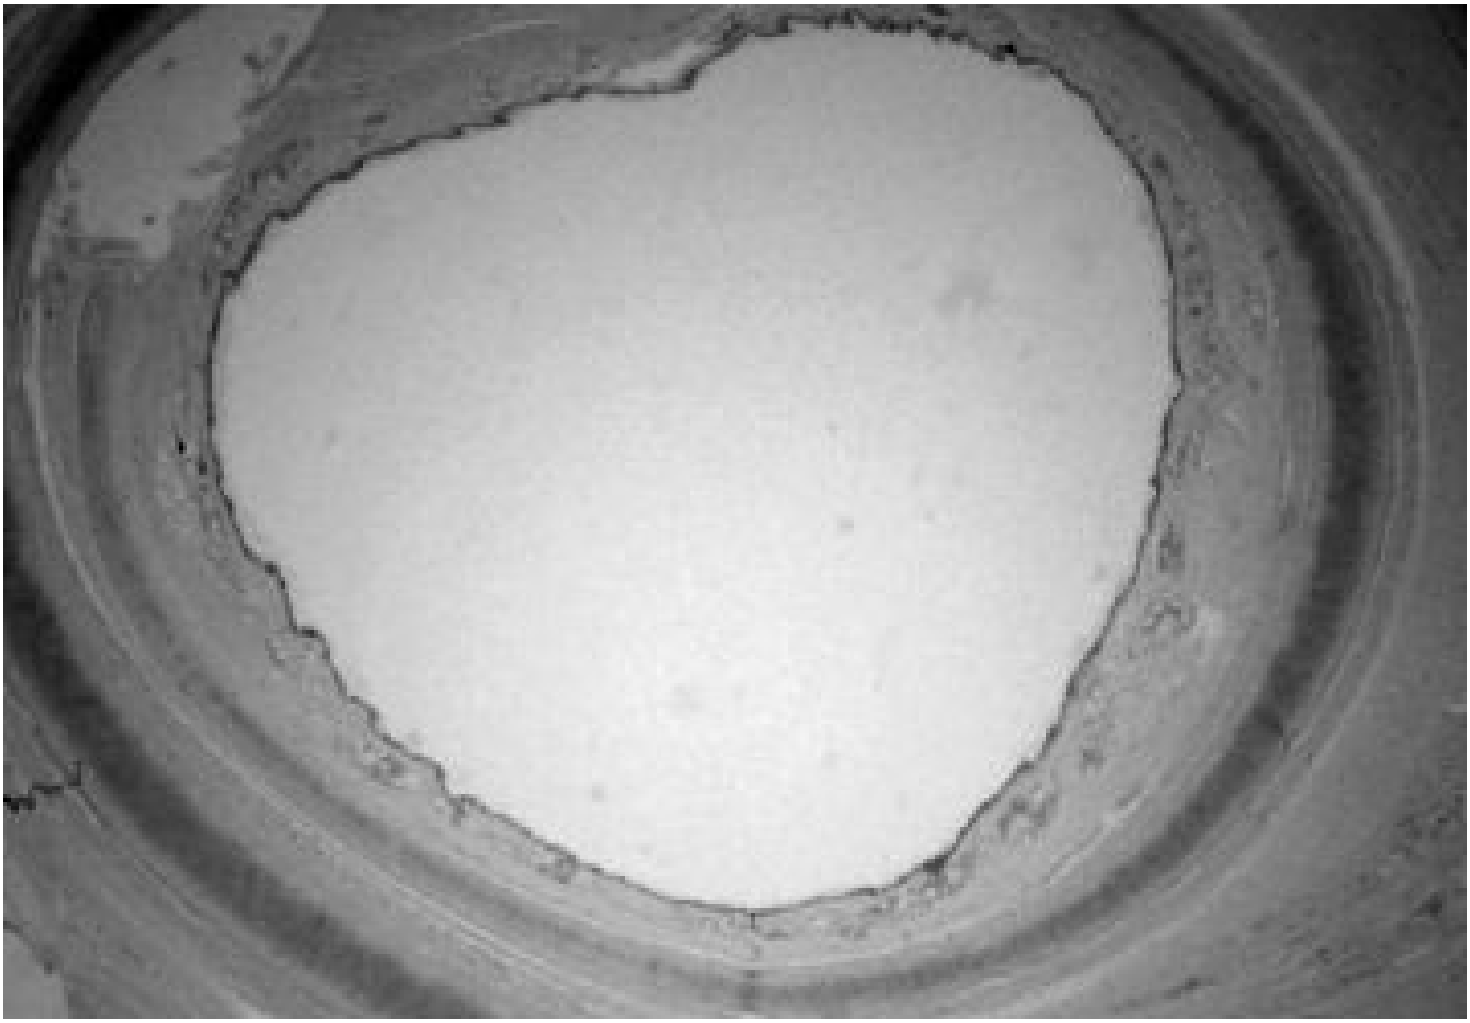

Figure 59-3. Histopathologic photomicrograph of a transverse section of a normal canine ear canal (H & E). Photomicrograph courtesy of Dr. Pam Ginn, University of Florida. (Reprinted with permission from Bellah JR: When should you recommend total ear canal ablation and lateral bulla osteotomy? Vet Med June:544-550, 1997.)

Peripheral Nerves

Peripheral nerves that supply the ear canal are the vagus nerve, which provides sensory innervation to the external auditory meatus, and the facial nerve, which is responsible for motor innervation but also provides two branches that enter the caudal and caudolateral aspect of the vertical canal. These branches provide sensory innervation to a portion of the pinna.[4] These small sensory branches of the

facial nerve are transected during ear canal ablation.[4]

Epithelial Migration

The ear is hypothesized to have a self-cleaning function that is thought to be a mechanism that keeps the external auditory meatus clean.[5] Investigative work has suggested that epithelial migration occurs from the tympanic membrane outward toward the opening of the ear canal. The tympanic membrane has a generation center (a region where epithelial cell mitosis is increased) that is thought to replace cells that migrate actively off the tympanum and outwardly or distally along the ear canal wall. Cells

in the stratum basale and stratum spinosum are implicated as being important in this process because of their asymmetrical shape and their long-axis orientation in the direction of epithelial movement. These cells also have a high concentration of contractile proteins when compared with other cells.[2] In this way, the debris is passively transported toward the canal opening. The hypothesized lateral epithelial migration may explain, in part, the rapid wound healing potential within the ear canal and the general lack of debris within the canal.

Tympanic Membrane

The eardrum or tympanum is a thin, transparent barrier between the external ear canal and the middle ear. It is made up of the pars flaccida, the small triangular region that is located between the lateral process of the malleus and the margins of the tympanic incisure, and the pars tensa, the larger region of the membrane. The umbo membranae tympani is a depressed point opposite to the distal end of the manubrium. Otoscopically, the stria malleolaris is seen running dorsocaudally from the umbo membranae tympani toward the pars flaccida. The pars tensa is attached firmly to the surrounding bone by a fibrocartilaginous ring, known as the annulus fibrocartilaginous, and the

latter is attached by fibrous tissue to the external acoustic meatus.[1]

The Middle Ear

The middle ear is located just medial to the ear drum in the tympanic cavity, which is an oval-shaped cavity in the petrous temporal bone. The middle ear includes the auditory (Eustachian) tube, the larger bulbous or pear-shaped cavity known also as the osseous bulla, and the epitympanic recess, which houses the three auditory ossicles. In the cat, the tympanic cavity is bisected into a dorsolateral compartment and a ventromedial compartment by a boney septum. Structures of importance in the middle ear are the auditory ossicles

(malleus, incus, and stapes), the vestibular (oval) window, the cochlear (round) window, and the auditory tube (Eustachian tube). The vestibular window is occupied by the base of the stapes (Figure 59-4). The auditory tube ostia is located rostrodorsally near the cochlear window. The chorda tympani nerve, a branch of the facial nerve, passes through the dorsal aspect of the tympanic bulla, crossing the manubrium of the malleus, and eventually joins the lingual nerve. The vital structures within the tympanic bulla are located dorsomedial in the cranial-most region. The tympanic bulla is bordered externally by the digastricus muscle laterally and by the styloglossus and hyoglossus muscles

medially. The hypoglossal nerve is located medial to the bulla. The tympanohyoid cartilage of the hyoid apparatus attaches to the mastoid process of the skull, which is caudal to the external acoustic meatus and caudolateral to the tympanic bulla. The air-filled tympanic cavity is lined by columnar ciliated epithelium, which forms an essentially translucent membrane lining which continues into the Eustachian tube. Simple squamous epithelium lines the ventral aspect of the tympanic cavity and also invests the auditory ossicles, the inner surface of the tympanic membrane, and the membranes over the vestibular (oval) and cochlear (round) foramina.

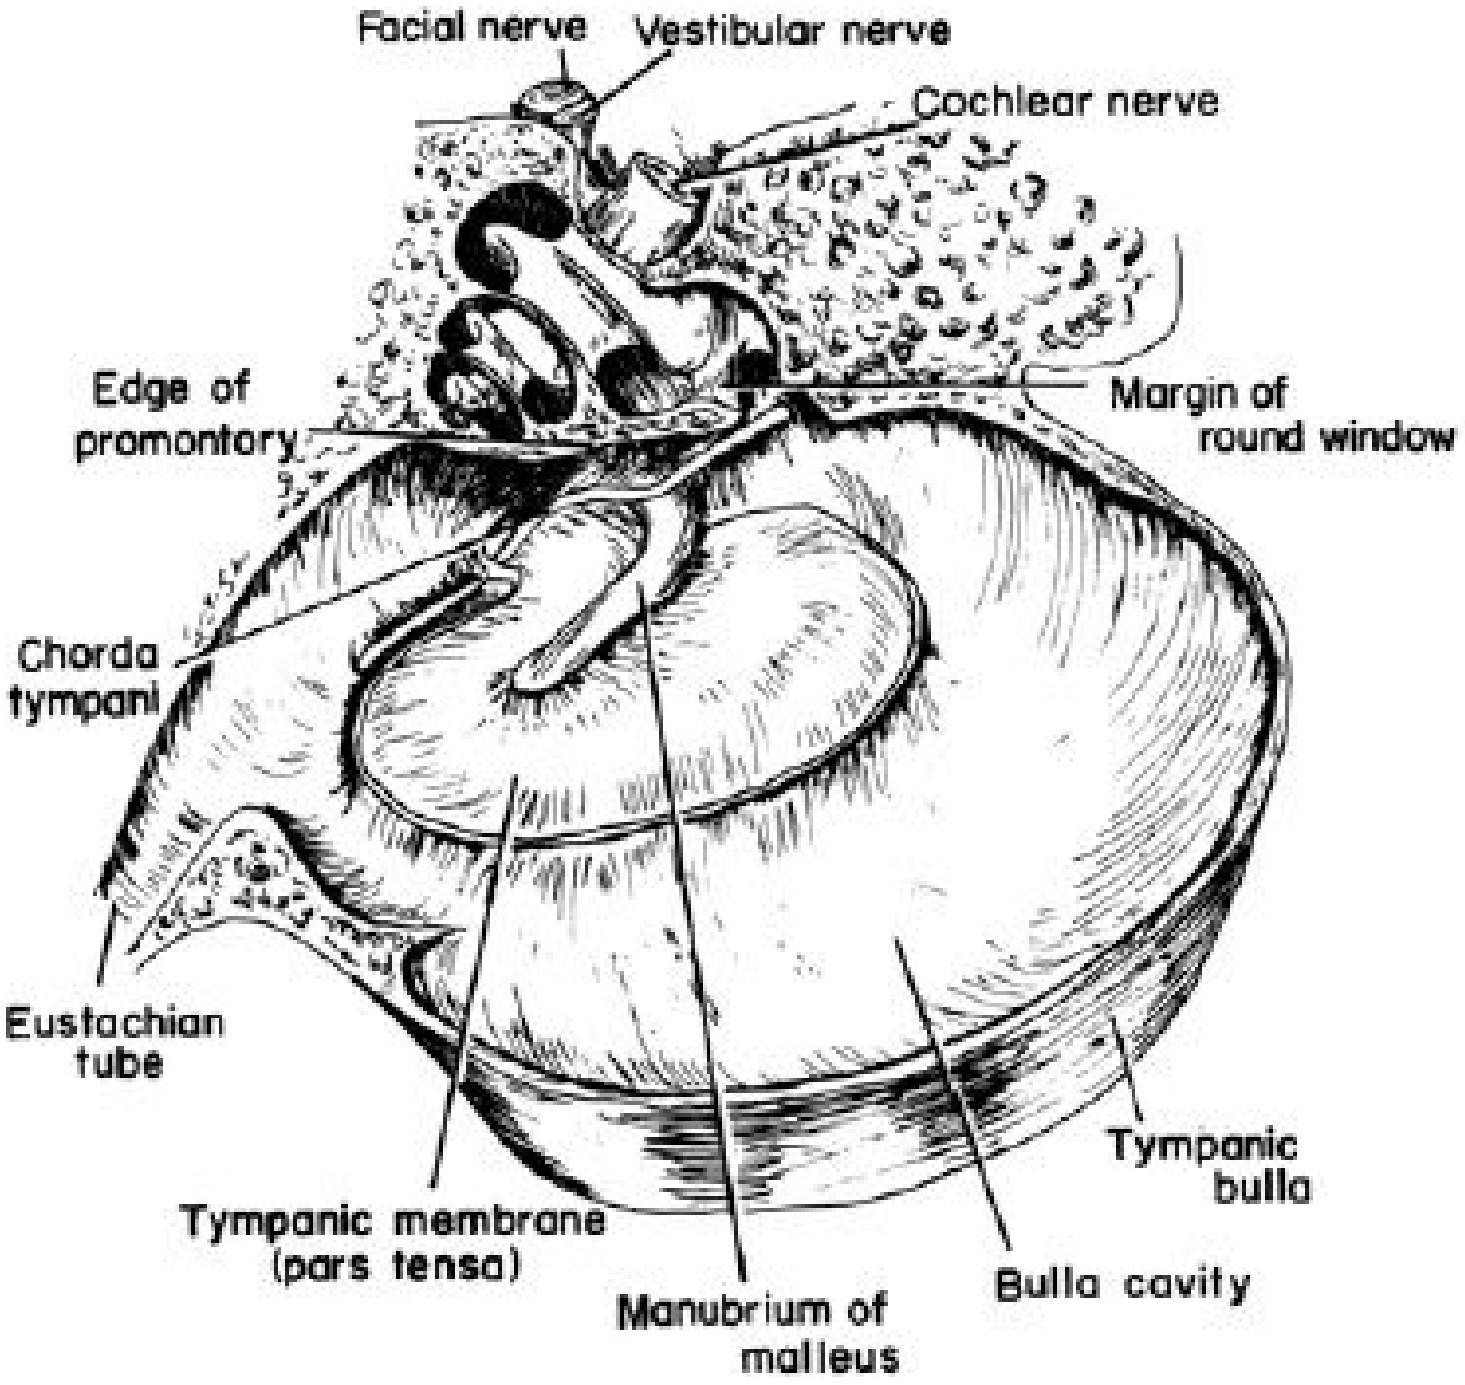

Figure 59-4. Sculptured medial view of the right middle ear and cochlea. (Redrawn from Miller's Anatomy of the Dog, 2nd ed. Evans HE, Christensen GD, (eds). Philadelphia: WB Saunders, 1979.)

The Inner Ear

The osseous labyrinth within the petrous temporal bone contains the cochlea, vestibule, and the semicircular canals. Within the osseous labyrinth are membranes that form a closed system that contains endolymph and is termed the membranous labyrinth. The membranous labyrinth is made up of three parts -- the vestibule (saccule and utricle), the cochlea, and three semicircular canals -- and is the sensory end organ for the vestibulo-cochlear nerve and the vestibular mechanism. Changes in the position of the head are detected by this proprioceptive apparatus, which then directs tenseness of postural muscles. It

is this mechanism of the ear that when damaged results in vestibular signs, including a head tilt toward the affected side and horizontal nystagmus. The fast phase of horizontal nystagmus is away from the affected side when the injury or disease is peripheral. Small animals that are severely affected often cannot walk and will roll toward the affected side. The median longitudinal fasciculusand accompanying cranial nerves III, IV, and VI allow communication from the vestibular nuclei to the ocular muscles and, therefore, are the neurologic pathway that results in nystagmus.

Developmental Anomalies

Congenital problems within the ear canal are rare in dogs and cats. Anotia, the absence of an ear canal, usually occurs in conjunction with anophthalmia and other deformities, and affected animals often die or are euthanized prior to weaning. In puppies the external ear canal membrane occludes the ear canal until 14 to 17 days of age, when the canal opens. Complete failure of this membrane to disintegrate usually results in deafness, whereas a partially retained ear canal membrane will predispose to otitis externa secondary to poor aeration and drainage. Suspected atresia of the distal acoustic meatus has been reported in a Bouvier des Flandres, and associated otalgia

was resolved by total ear canal ablation and lateral bulla osteotomy.[6]

Dentigerous cysts and temporal odontomas may occur from ectopic tooth development. The incompletely developed tooth is usually found near the mastoid process of the petrous temporal bone and causes a sinus tract to form and drain near the base of the ear canal. Surgical removal of the sinus tract and the cyst resolves the condition.

Congenital deafness occurs as a result of a defect of the inner ear or because of a lesion of the auditory center and is either perceptive or central, respectively. These defects are

associated with a lack of cilia in the organ of Corti, improper development of the cochlear nerve, or agenesis of the cochlea.

Acquired Disease of the Ear Canal

Otitis Externa

Inflammation of the ear canal may be caused by predisposing, primary, and perpetuating factors, and the degree of involvement may include one or more regions of the ear. Factors that alter the microenvironment of the ear canal predispose the canal to pathogenic and opportunistic microorganisms. Examples of such factors include pendulous ears, congenital stenosis of

the ear canal, and mechanical obstruction of the canal by ear canal tumors or foreign bodies. It is known that ear anatomy plays a role in the development of otitis externa, and otic humidity seems to play a more important role than temperature.[3,7] Dogs with pendulous ears have significantly more otitis externa than dogs with erect ears, and some breeds (Labrador retrievers, American cocker spaniels, and English Springer spaniels) have greater numbers of apocrine (ceruminous) glands and, therefore, increased wax production.[3] The aforementioned breeds also had a higher density of hair follicles throughout the horizontal canal when compared with greyhounds and

mongrel dogs.[3] Poodle and Lhasa apso breeds have a higher density of compound hair follicles, which promotes accumulation of ear wax and debris and interferes with migration of material out of the canal. Beagles and setters are breeds that are the exception to the above and are less frequently affected by otitis than are other pendulous-eared breeds. Alternatively, German shepherd dogs, as an erect-eared breed, are over-represented. The Chinese Sharpei breed tends to have a narrow, long vertical ear canal, which is essentially a stenosis in comparison with other breeds. Ear canal stenosis can be coincidental in other breeds; Chow-chows and their crosses also tend to

have narrow canals. Acquired canal stenosis occurs from periaural masses such as neoplasia. Microflora that normally occur in the ear may be more apt to cause otitis externa when the microenvironment of the ear canal better supports organism growth. The stratum corneum can be broken down by increased moisture content in the ears, as maceration of the epidermis occurs, allowing microorganisms to colonize the ear canal resulting in otitis. Excessive moisture in the ear from swimming, excessive bathing, and environmental humidity and temperature (characteristic of the southeast region of the United States) can cause maceration of the surface of the ear canal and can influence the

incidence of otitis externa. An investigation of first-time otitis externa cases over five geographic regions in North America found that monthly variations in ambient temperature, rainfall, and relative humidity correlated positively with the incidence of initial ear infection. The investigation found a 2-month delay between a climatic change and an increased incidence of otitis externa.[3]

Mechanical trauma to the ear canal from excessive cleaning or from the excessive use of cleaning agents or drying agents may damage the ear canal. Systemic diseases may predispose to otitis externa as they may impair cell-mediated immunity.

Ulcerative otitis externa has been reported to respond to immunosuppressive therapy in dogs.[8] Examples of diseases that may result in such immune impairment include feline leukemia virus, feline immunodeficiency virus, canine distemper, and canine parvovirus. Endocrine disease such as hyperadrenocorticism, hypoadrenocorticism, hypothyroidism, and diabetes mellitus may also be associated with otitis externa.[3]

Parasites such as Otodectes cyanotis and Demodex canis are commonly responsible for otitis externa in young animals,[9] especially in cats in which approximately 50% of cases are

secondary to mite infestation. Ear mites cause mechanical irritation but the dog or cat can also become sensitive to antigens in mite saliva. When hypersensitization is present, it takes very few mites to cause severe inflammation. Demodex mite infestation generally causes a severe ceruminous otitis in dogs and in cats, and the presence of otitis may be the only sign of infestation. Other mites and Otobius megnini, the spinous ear tick may also be found in the canal, but these are less common than those previously mentioned. Grass awns, foxtails, and other foreign material including impacted wax may initiate otitis. The most common cause for bilateral otitis externa in the dog is

hypersensitivity. Allergic conditions that commonly produce secondary otitis externa include atopy, food allergy, and contact allergy. Atopy, for example, affects as many as 50% of dogs at a given time, and is commonly associated with secondary infection. When atopy and other hypersensitivities that affect the ear are uncomplicated, the pinna and the vertical ear canal are reddened and pruritic, and the horizontal canal can be normal.[2] Otitis externa is present in 88% of dogs with food allergy.[10] Contact allergies are most commonly due to topical therapy; the indication of this is a worsening of the otitis and lack of improvement with the initiation of therapy.[3,5]

Seborrhea is a disorder of keratinization that can result in ceruminous otitis. Other endocrine disorders that may be associated with otitis externa include hypothyroidism, male feminizing syndrome (Sertoli or interstitial cell tumors), and ovarian imbalance.[3]

Tumors within the ear canal cause mechanical interference with normal movement of the cerumen from the ear canal and with drainage of exudates once otitis externa has occurred. Ceruminous gland adenoma and adenocarcinoma, sebaceous adenocarcinoma, mast cell tumor, squamous cell carcinoma, and benign conditions such as polyps can obstruct

the ear canal.

Perpetuating factors that prevent resolution of otitis externa or that worsen preexisting otitis are usually microorganisms. The normal ear canal has microflora in low numbers that include both commensal and pathogenic bacteria. *Staphylococcus intermedius* is a common bacterium involved in otitis externa, and other species frequently encountered include Pseudomonas spp, Proteus spp, *Escherichia coli*, enterococcus spp, and Corynebacterium spp. Pseudomonas is cultured from 12 to 35% of ears with otitis externa.[11] Multiple organisms can occur in otitis externa. In 20% of cultures another organism may be

missed, and this is one criteria that should be considered in treatment failure.[12] These organisms benefit by alteration of the microenvironment within the ear canal and impaired drainage from the canal, which results in their proliferation and potentiation of the inflammatory response. Malassezia spp is the most common fungal organism found in the ear canal, and it can be present in both normal and inflamed ears, but is highly opportunistic in macerated and inflamed ears, and is common as a secondary complication in atopic skin disease or food allergy. Other fungi, such as Candida, Aspergillus, and Microsporum may cause otitis externa.[3]

Otitis externa results in progressive injury to the ear canal if medical therapy is not able to control the cause and the inflammatory response. Initially, when otitis is acute, canal erythema and swelling occur as many inflammatory cells infiltrate the dermis and epidermis. Apocrine glands hypertrophy and dilate, with an accompanying increase in the production of cerumen. The cerumen that is produced differs in composition as well. Normally, epidermal migration occurs toward the opening of the ear canal, but if the inflammatory response is progressive the epidermis begins to fold (Figure 59-5) and epidermal migration is inhibited. Eventually, the increased glandular

activity, epidermal thickness, and decreased epidermal migration lead to excessive wax production with a buildup of keratinaceous debris, and proliferation and overgrowth of bacteria occurs. Persisting inflammation results in dermal fibrosis within the horizontal canal and calcification of annular and auricular cartilages, usually from deeper regions to the exterior, and ossification can occur late. The end-stage result is permanent stenosis of the ear canal lumen.[3,5] Complete obstruction of the ear canal lumen can result, and the inflammatory process can “break-out” of the ear canal and result in development of periaural fistulae (Figures 59-6 and 59-7)

Clinical signs of ear canal disease do not necessarily differentiate the varying causes of otitis. Pruritus, pain, erythema, swelling, and drainage are common. Depending on the severity and amount of drainage from the ear and whether the middle ear is involved, a head tilt may be noted to the affected side. Excessive head shaking may lead to aural hematoma. A discharge or foul order is often present. Periauricular excoriations and alopecia may be noted. In uncomplicated allergic otitis externa, erythema of the pinna and the vertical canal may occur and the horizontal canal may be relatively unaffected. Proliferative disease may be limited to the vertical canal. Ulcerations and

erosions of the ear canal may occur with contact dermatitis or gram-negative bacterial infections. As the otitis externa becomes more chronic, the compliance of the cartilage support of the ear canal is lost as it becomes mineralized. Acute otitis externa is painful to dogs and cats; but as the condition becomes more chronic, less dramatic pain responses are elicited during examination. However, calcified ear canals are associated with intense pain. Hearing loss is often detected by the owners as otitis becomes end-stage.

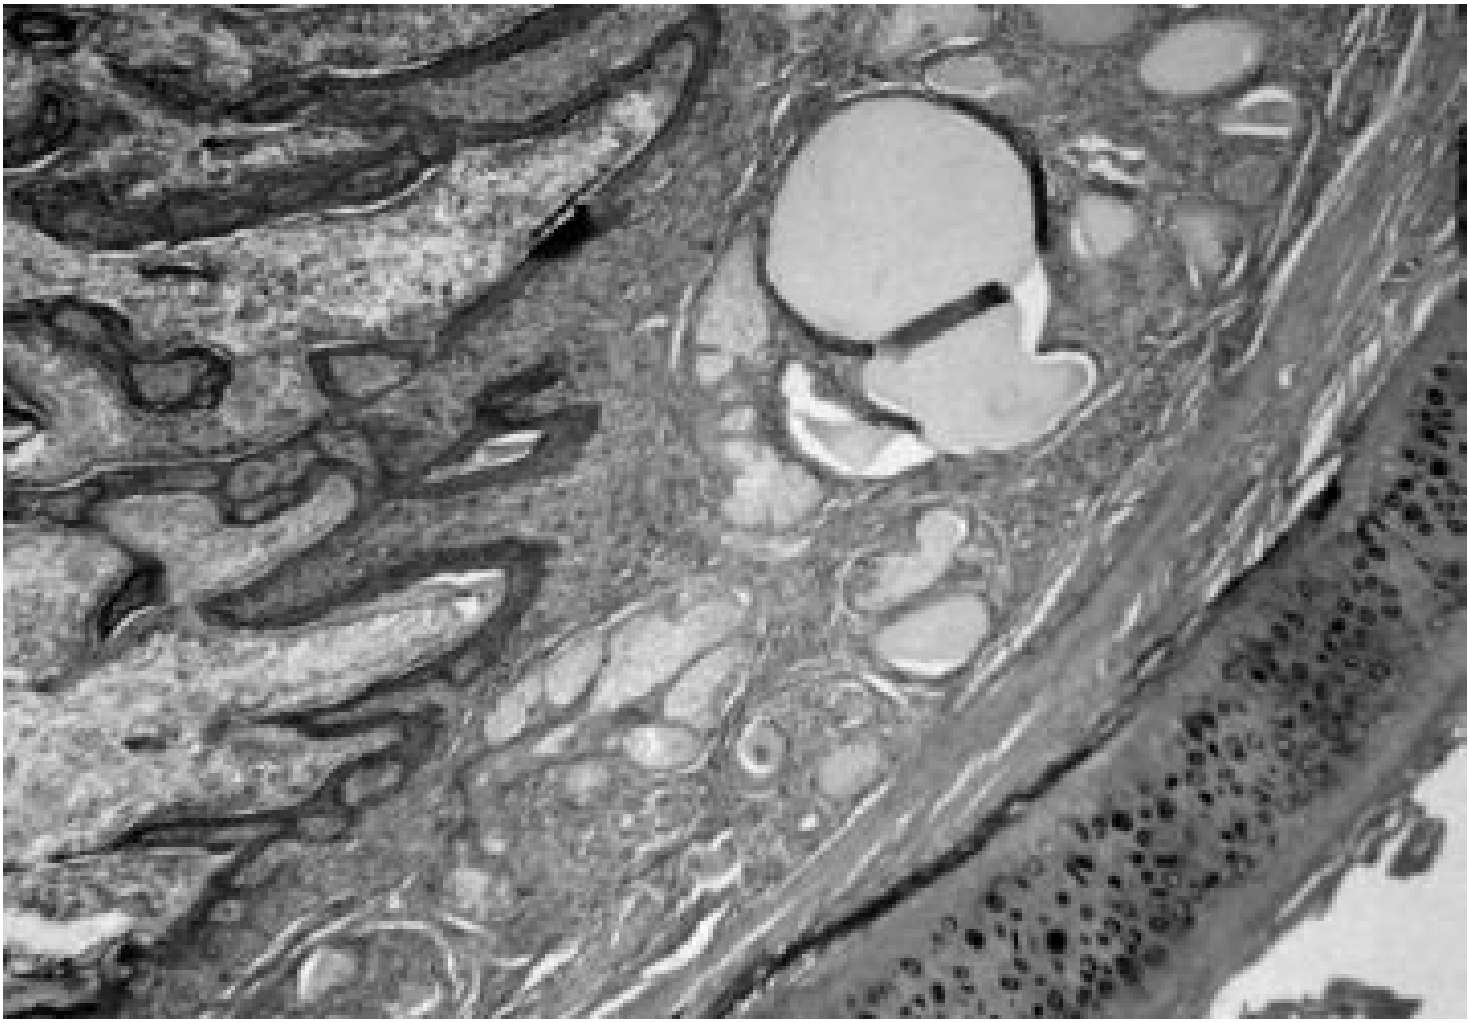

Figure 59-5. Histopathologic photomicrograph of a transverse section of an ear canal in a dog with otitis externa (H & E). Note hyperplasia of apocrine tubular glands, thickening of the epidermis, and a buildup of keratinaceous debris. (Photomicrograph courtesy of Dr. Pam Ginn, University of Florida.)

Tympanic Injury

Tympanic injury is most commonly

secondary to otitis externa in small animals.[13] Proteolytic enzymes that accumulate from bacterial release and from the degradation of inflammatory cells have destructive effects on the epithelial surface of the tympanic membrane. Once a perforation occurs, the bacteria, enzymes, and debris have access to the respiratory epithelium of the middle ear.[13] Traumatic perforations occur from direct trauma (i.e., cotton-tipped applicator or excessive fluid pressures against a weakened membrane) during ear canal cleansing. Masses, such as nasopharyngeal polyps in cats, may cause pressure necrosis as they push against the tympanic membrane, and secondary infection and its by-products

cause additional injury.

Figure 59-6. Labrador retriever with end-stage otitis externa and break-out abscessation with the draining fistulae. The ear canal was ablated (see Figure 59-7). Vet Med June:544-550, 1997.)

The tympanum is capable of healing, and will attempt to do so if remnants of the eardrum remain. Two factors are required to accomplish tympanic membrane healing: a satisfactory blood supply and an intact germinal epithelium. The blood supply to the germinal epithelium arises from vessels within the pars flaccida; therefore, this region of the eardrum must be intact for healing to occur. The germinal epithelium that produces the epidermal layer of the tympanum is located near the manubrium of the malleus. From that location, the tympanic epithelium grows radially toward the annulus of the tympanic membrane, and healing can be complete in a period of 3 weeks to 4 months.[13]

Tympanic membrane wound healing has been investigated. Keratinocytes proliferate on the external surface of the eardrum simultaneously with proliferation of fibrous connective tissue cells in the middle layer. The inner layer of epithelium differentiates into ciliated and secretory cells at the border of the perforation. Early healing and closure of the tympanic wound is by the migration of the superficial epithelial layers of the eardrum, and permanent apposition and closure of the defect is by the slower-migrating basal epithelium.[13] In naturally occurring eardrum perforations, pathologic changes tend to be progressive, such that inflammation, fibrosis,

tympanosclerosis, and hyperkeratosis are found to impair wound healing progress. Keratinized epithelial proliferation may localize to the medial side of the tympanum and protrude into the middle ear cavity. Otitis media, because of the production of mucous and purulent exudates, including proteolytic enzymes, impairs eardrum healing. If lysis of the malleus occurs and the germinal epithelium is destroyed, or if fibrous scar devitalizes the pars flaccida, perforation will be permanent.[13] A ring of hyperkeratotic epithelium in the region of the perforated tympanum is an indication of chronic permanent perforation. Persistent drainage with relapsing otitis media occurs in this condition.

Surgery of the External Ear Canal

Surgical treatment of the external ear canal is done to treat relapsing or persisting otitis externa, stenosis of the vertical or horizontal ear canal, neoplasia, vascular disease of the pinna, and traumatic injuries to the ear canal. Specific techniques for specific conditions of the ear are not the objective of this chapter, but commentary on specific areas of the ear and the surgery appropriate for those areas follows.

Pinna

The pinna of dogs and cats is

important functionally to pets but also cosmetically to pet owners. Traumatic lacerations and injuries to the pinna are common and result from skirmishes between cats, between dogs, between cats and dogs, and from gunshot and other missiles. Many partial-thickness lacerations do not require suturing, but apposition using fine sutures (3-0 to 5-0) often improves the cosmetic result. Full-thickness lacerations benefit by including the cartilage of the ear canal in the suture loop (i.e., vertical mattress), so careful apposition of the cartilage edges is done, followed by suturing the skin on the opposite side. Lacerations on the haired (convex) side of the ear canal may be more easily apposed and sutured because

subcutaneous tissue separates the dermis and cartilage on that side of the pinna.[2,14]

When it is necessary to remove a mass, from the pinna,the haired surface of the convex surface of the ear canal has sufficient skin that may be undermined and closed after tumor excision. Depending on the location of the mass, it is possible to remove masses up to 2 cm in size 14 with the expectation of achieving primary closure without creating a flap from the head or neck. Moveable skin is more readily available near the base of the pinna. On the concave surface, the skin and cartilage are in close contact, so undermining is difficult. Small non-

malignant masses may be excised with narrow margins, and the small minor wound may heal by second intention. Small malignant masses may be excised by removing skin, mass, and underlying perichondrium and cartilage, whereas larger masses with known malignant character are best aggressively removed by excision of the entire pinna. This results in cosmetic asymmetry but is preferable to leaving microscopic tumor at the excision site.

Large defects of the lateral non-haired skin of the pinna are difficult to correct because of the inability to undermine skin extensively and because the auricular cartilage is inelastic. Various

reconstructive techniques are available including the creation of local skin flaps from the skin of the cheek or neck. Flaps of varying shapes may be designed to repair the ear cosmetically using staged techniques. The different hair color or direction and the thickness of the skin are disadvantages to consider. Defects of the central portion of the pinna may also be resolved with similar techniques.

Amputation of a portion of the pinna is simplest when neoplastic involvement or traumatic devitalization of a portion of the pinna is located at the periphery of the ear. Full-thickness incisions, using a scalpel blade, can be done by obtaining a

margin of normal pinna to be removed with the tumor. A scalpel is the instrument of choice as it is the least traumatic instrument for incision versus traumatically crushing the auricular tissues with scissors. Occasionally, curvilinear incisions at the edge of the pinna may be made with very sharp scissors as it is sometimes easier to make a more cosmetic (rounded) incision. The concave and convex skin margins are sutured over the cartilage, using fine suture. Excisions of masses along the anterior or posterior margins of the ear canal may done by removing a triangular portion of the edge of the canal (a wedge), and apposing the full-thickness margins in two layers.

Sometimes this will narrow the pinna of pendulous ears or make the pinna slightly more convex in erect ears, but once the hair grows back, a good cosmetic result is often attained.

Lateral Ear Resection (LER)

Lateral ear resection, the Zepp procedure, has been done to aid management of otitis externa in dogs since 1949.[15] Over the years, veterinary surgeons have altered their approach to otitis externa, from recommending lateral ear resection frequently in dogs that have relapsing otitis externa, to rarely recommending this surgery. The advent of better ear care in general and the knowledge that

the results of lateral ear resection surgery are not the panacea for resolution of otitis that might have been anticipated. The potential for adjunctive surgical therapy to be efficacious was a sincere goal, as approximately 4% of veterinary hospital admissions involve some form of otitis externa.[16] Lateral ear resection does result in a significant change in the microclimate of the ear, and in one study relative humidity was reduced by 10% in operated external ear canals.[17] In a study of 281 dogs with otitis externa, Tufvesson found LER to resolve approximately 50% of otitis externa in dogs, with another 15% of the dogs showing improvement, and the remaining 35% showing minimal

or lack of improvement.[18] In this study, age or breed did not affect the outcome; however spaniels, poodles, and Airedale terriers were predisposed.[18] A similar outcome was reported by Gregory and Vasseur in a small number of dogs (N = 26), where 41% had good outcomes, 12% improved, and 47% had a poor outcome.[19] They concluded that a technically correct LER does not ensure a successful outcome, but also noted that clinical signs improved in some instances where the surgery was a technical failure.[19] A post-surgical investigation by Lane and Little, of 135 dogs with persistent aural drainage after ear surgery found concurrent otitis media, irreversible

disease of the medial vertical ear canal, and unsatisfactory drainage from the horizontal canal to be the most common factors recognized with surgical failure.[20] Surgical outcome in another study showed LER to achieve acceptable results in 45% of the dogs treated and 55% to be unacceptable. Acceptable outcomes were rated excellent (the ears no longer required regular cleaning and the dog had no more than 2 bouts of otitis externa since the surgery) or good (the ears had occasional flare-ups of otitis externa, no more that 2 per year that readily responded to topical medical management. Unacceptable outcomes were rated fair (the ears required regular cleaning in order to prevent a

relapse of the otitis and the dog experienced an average of 3 or more bouts of otitis annually) or poor (the ears progressed to an end-stage with an occluded canal as determined by follow-up physical examination). The Cocker spaniel breed had poorer results than other breeds, showing a failure rate of 86.5%. Non-Cocker spaniel breeds had an LER acceptable result percentage of 63%. The Shar pei breed was found to have narrower vertical ear canals.[21] Other studies have shown varied acceptable results from LER surgery.[19] Johnston found disappointing results when LER was performed in 41 dogs, after otitis media was present and severe changes developed in the ear canal with

ruptured tympanums. Aggressive middle ear flushing and appropriate antimicrobial use based on culture and susceptibility testing in addition to LER found in these dogs clinical improvement, but head shaking and drainage from the horizontal canal persisted.[22] A lesser affected group in this study, 70 dogs with a history of 1 to 2 years of otitis externa and minimal canal changes were treated by LER. In this group, 50 had severe eardrum perforations and the other 20 had diseased and likely ruptured eardrums; LER resulted in slight to moderate discharge with reduced discomfort and head shaking.[22] The third group of 33 dogs in this study were dogs that had been affected by

lifelong otitis externa at 12 to 18 months of age (based on breed, a minimum of 3 episodes of otitis externa after treatment and evidence of atopy or other allergic skin disease). Dogs in this group did not have tympanic rupture. In this latter group of 33 dogs, all dogs had resolution of ear discharge and discomfort at 6 months after surgery, and no dogs had eardrum perforation.[22] The conclusion was made that LER (Zepp) was definitively indicated once a predisposition to otitis externa was diagnosed and before irreversible changes are present within the ear canal, tympanum, and the middle ear.[22] If surgical intervention is considered a last resort after

proliferative disease and canal obstruction is in progress, the procedure is doomed to fail.

Indications for recommending surgical resection of the lateral wall of the vertical ear canal or creating a lateral ear canal flap that is positioned ventrally (Zepp) may be when masses involve the lateral aspect of the vertical ear canal or when opening the vertical canal to change the microclimate of the ear canalis judged beneficial to the individual dog with otitis externa.[23] The latter indication presents a more difficult decision as lateral ear resection is an adjunctive measure and not considered a curative procedure for otitis externa. The

procedure does change the microclimate of the ear canal and can have a positive impact on aiding treatment of otitis externa. In addition to altering the microclimate of the ear canal, LER improves drainage of fluid and exudates from the horizontal canal by eliminating the vertical canal "reservoir" that must be overcome by head shaking. The region aerates better and is more easily cleaned, and in some dogs at the least this is palliative. A horizontal ear canal with minimal chronic proliferative changes is necessary for this surgery to be considered.[24]

Lateral ear resection does not require special equipment and it is not a

difficult procedure to complete. The most common error made is an inaccurate incision of the vertical canal. This can happen if the lateral canal flap is made too thin on the lateral aspect, making the base of the flap too narrow, or on the medial side, resulting in a narrow strip of vertical ear canal remaining and a lateral canal flap that is difficult to bend to a ventral location. The goal is to incise the flap so the ventral aspect of the horizontal canal is wide open and the lateral flap makes a smooth cranioventral bend. The flap created is trimmed to a length of approximately 2 cm and sutured such that it remains ventral. The method of suturing is up to the individual surgeon's preference.

The most difficult area to suture is the deep corner of the lateral ear canal flap where it bends away from the vertical ear canal. A figure-of-eight mucocutaneous suture pattern (similar to that used for mucocutaneous apposition) may be used to make the sutures more accessible at suture removal.[23,25]

Vertical Ear Resection (VER)

A slightly more aggressive ear canal excision is the vertical canal resection. It is less commonly used for otitis externa.[26] Complete resection of the vertical ear canal is more commonly done when trauma has lacerated and injured the vertical canal badly or

when neoplasia involves the vertical segment of the ear canal. Atopic dogs and dogs with food allergy, in which inflammation and swelling are more focally located within the vertical canal, benefit by having the proliferative changes in the vertical ear canal removed.[27] The horizontal canal is commonly spared severe inflammatory effects in these two allergic conditions; the most pruritic region seems to be the vertical canal and extending upward toward the pinna.[3] When vertical ear canal excision is considered for aural tumor excision, the most important factor is determining the presence of sufficient horizontal canal for wound closure after resection. Imaging the ear canal

and skull by computed tomography (CT) prior to surgery aids preoperative decisions. In the absence of CT, local inspection to explore the canal during surgery by means of a lateral ear resection approach may be necessary. If the horizontal canal is insufficient, a total ear canal ablation is done to achieve the best surgical margin possible beyond the tumor. The surgical approach for vertical canal resection requires conservation of periaural skin for wound closure and, therefor, differs from lateral ear canal resection. A T-shaped incision is commonly used, and the incision correlating to the top of the “T” can meander along the margin of the tragus cartilage if the skin is normal.

to preserve all available skin for closure under the pinna. Conserving skin facilitates apposition of wound edges between the horizontal ear canal stoma and the pinna.

The vertical canal is isolated around its entire circumference by dissection next to the cartilage of the ear canal and pushing or making a minor incision in the parotid salivary gland to aid exposure. Remaining directly adjacent to the ear canal is especially important on the concave surface of the canal so the auricular vessels that supply the pinna of the ear are not damaged. The level of the incision at the dorsal aspect of the ear canal is dependent on the position of the tumor being excised

or the level of proliferative disease if done for atopy. Once the resection is completed and hemostasis obtained, the horizontal canal remaining may be divided into dorsal and ventral baffle plates if enough canal is present. If not, the skin is sutured directly to the circular remnant of the horizontal canal. The figure-of-eight mucocutaneous suture pattern is useful when little horizontal canal remains. The apposition of skin around the horizontal canal is done first, followed by apposing the skin to the pinna from the anterior and posterior edges.

Total Ear Canal Ablation and Lateral Bulla Osteotomy

(TECA-LBO)

End-stage otitis externa results in obstruction of the ear canal to the extent that normal lateral epidermal migration of debris and keratinized epithelium does not occur, and in most canals the eardrum is ruptured, and otitis media is present as well. Removing the entire ear canal is a common procedure in dogs, and less common in cats.[28-30] In cats, the most common indication for TECA-LBO in one investigation was neoplasia,[29] with 86% of the neoplasms being ceruminous gland adenocarcinoma.[29] Total ear canal ablation is indicated to resolve the discomfort and chronic infection and drainage from end-stage otitis externa and calcified canals,

from neoplastic disease located deep within the ear canal with or without secondary infection, and to resolve para-aural abscessation that results from traumatic avulsion and secondary stricture of the ear canal.[31,32] Traumatic avulsion of the annular cartilage from the external auditory meatus in a cat has also been reported and was treated by ablation of the ear canal.[33] Traumatic ear canal separations may be managed by isolating the distal end of the horizontal ear canal (annular cartilage) and suturing the open end to the skin to allow cleaning and maintenance of patency.[34]

Many references and texts contain

reviews of the surgical technique for ablation of the ear, and each surgeon has specific methods to facilitate exposure and completion.[28-30,35,36] Many surgeons use a "T-shaped" incision similar to that used for vertical canal resection; however, the author's preference is to make an incision from the cranial aspect of the opening of the ear canal in a caudoventral direction but following the edge of the ear canal to the caudal aspect of the ear canal opening, and then extending ventrally parallel to the vertical ear canal to a level below the horizontal canal. The purpose of this incision is to conserve as much skin as possible to aid closure after resection of the ear canal, essentially in the manner of a single

pedicle advancement toward the concave surface of the pinna. Once the incision is made, dissection is carried to the level of the cartilage and soft tissues are removed by sharp and blunt dissection around the entire circumference of the vertical ear canal. The level of the incision made to release the dorsal aspect of the vertical canal depends on where the proliferative disease extends. All proliferative disease should be removed, but the higher the level of the vertical canal resected the more important it is to carefully remain intimate with the cartilage of the ear canal so auricular vessels supplying the pinna are protected. Dissection down to the horizontal ear canal and

continuing down to the external acoustic meatus is carefully continued. Note that branches of the facial nerve, the caudal internal auricular nerve and the lateral internal auricular nerve penetrate the caudal and lateral aspects of the horizontal canal, respectively.[4] Each is associated with an artery that is ligated. The facial nerve is located just caudal and ventral to a boey protuberance about 5 o'clock or 7 o'clock, depending on whether the left or right ear canal is being ablated. The facial nerve need not be identified at surgery as its trunk is located just caudal to the external acoustic meatus and just ventral to the mastoid process, a protuberance that can be palpated during surgery. These landmarks allow

the location of the facial nerve to be kept in mind so careful retraction of neighboring soft tissues may be done and care is taken not to compress this region as the nerves movement is restricted by the close proximity to the stylomastoid foramen where the nerve exits the skull. Rarely, facial nerve is incorporated in an inflammatory response that extends from the ear canal, but more often is simply pushed away by the expansion of the canal tissues.

The dorsal-most aspect of the circumference of the horizontal canal is the location that allows the most convenient entry into the tympanic cavity. The ear canal can usually be

pushed away from the meatus using a Freer elevator. The remainder of the circumference is then released by gradually extending the separation around the entire circumference. The caudo-ventral aspects of the canal attachment are the most difficult and this is also where bony proliferation is the most extensive. The retroarticular foramen should be avoided so hemorrhage from the retroglenoid vein does not occur. Tissues or debris are collected for culture and histopathologic examination once the canal is released. Bacteria cultured from TECA-LBO sites commonly include *Streptococcus canis* and *E. coli*.[37] One investigation showed bacteria to remain after debridement and lavage

of the tympanic cavity, and in this study, only 26% of isolates showed susceptibility to cefazolin.[38]

Access to the tympanic bulla is accomplished by lateral bulla osteotomy and is done to allow thorough removal of debris and tissue extending into the middle ear. An air drill is the most efficacious method for removing the thick cortical bone of the external acoustic meatus. Ronguers can be used effectively. Care must be taken to avoid wrapping up soft tissues around the canal if a drill is used and also to carefully inspect the tissues just ventral to the external meatus so no secretory epithelium remains. Branches of the carotid artery are located deep

to the tympanic bulla and severe hemorrhage may result if these vessels are torn during dissection. Thorough lavage is done and closure of the surgical wound is performed.

Drains are not necessary to maintain drainage after TECA-LBO.[35] Primary closure is most commonly done after TECA-LBO but passive drains may be used at the discretion of the surgeon. Drains may be used in some instances where “breakout” abscessation has occurred and fistulae are apparent prior to ablation, as the extent of wound infection can be well beyond the region of the ear canal. Soft tissues are apposed, being careful to avoid deep suture bites that may penetrate

vessels. Subcutaneous tissues are apposed and cartilage may be included in the suture pattern if necessary for wound strength. The apposition of the wound margin of the pinna (remainder of the auricular cartilage) to the skin flap is done from a cranial to caudal direction, as “dog-ear” correction is simple to do at the caudoventral aspect of the incision.

Facial paralysis is the most common complication and likely results from ischemia caused by compression or traction of the facial nerve near the mastoid process. Incidences vary from 5% to 58%.[30] Ischemia, if sustained long enough, will cause fiber degeneration within the nerve and

result in loss of function. As long as the facial nerve is intact, function should return, as the fibers regenerate at a rate of approximately 1mm per day. Although the incidence of facial nerve paralysis is high, careful technique in the region of the mastoid process and ventral to the external acoustic meatus will protect nerve function. In cats, facial nerve paralysis occurred in 56% of cats that underwent TECA-LBO, and 42% had Horner's syndrome.[29] Nerve fragility was suggested to be greater in cats in comparison with dogs.[29]

Persistent otitis media and development of periaural sinus have been reported to be as high as 30% in dogs undergoing total ear canal

ablation;[30,39] however, most veterinary surgeons would estimate that less than 10% are affected.[40,41] The source of the fistulae may be tissue or material within or outside the tympanic cavity.[40] Plain radiographs and sinography may be used to demonstrate the source of drainage.[42] It is uncommon for persisting otitis media with sinus tract development to be successfully treated with drainage and antimicrobial therapy; only 1 of 17 and 1 of 8 dogs in 2 reports were successfully treated in that way.[41,43] In the author's opinion, lateral bulla osteotomy is the procedure of choice to attempt resolution of draining sinuses and persisting otitis media. Although a ventral bulla osteotomy may be used

and will accomplish good exposure of the tympanic cavity, it is difficult with this procedure to access the region of the acoustic meatus, especially laterally where remnants of secretory epithelium may be found. Retraction of the external carotid artery and at least partial transaction of the digastricus muscle is required to obtain exposure to the lateral aspect of the external acoustic meatus if a ventral approach is used.[40] Facial nerve location is difficult with the lateral approach after TECA-LBO as the canal landmark is not present. The mastoid process is still palpable, however, and careful dissection along the deeper portions of the sinus will help protect the facial nerve. A lateral approach allows the

sinus tract to be followed (inserting a red rubber catheter into the tract is an effective method for following the tract during surgery) to the remnant of the external acoustic meatus and for the tympanic cavity to be reopened to a wide enough dimension and be debrided of debris and any adnexal structure that may be causative.

Vestibular signs, including nystagmus, head tilt, and postural abnormalities may occur when trauma to the promontory and the oval and round windows occurs during curettage of the tympanic cavity.[30] This is a rare complication but is probably the most disconcerting to an owner because the dog shows such anxiety as it tries to

walk. Usually, vestibular signs abate over a period of weeks, but residual signs such as a persisting head tilt may remain.[40]

Necrosis of the pinna from careless dissection, hemorrhage, and airway obstruction have been reported to occur after ear canal ablation. The latter complication has been noted when severe hemorrhage occurs, and when bilateral ear canal ablations are done during one anesthetic episode. Airway structures are in close proximity to the tympanic bullae such that severe hemorrhage or edema may result in airflow resistance when dogs are extubated. Cervical bandages that are too tight may also restrict good air

flow.

Multiple regimens exist to provide analgesia for aural surgery. Opioids and combinations of systemic administration and local nerve blocks are used commonly.[44] Bupivicane splash blocks and bupivicane administration by analgesia catheter placement have also been used.[45] A comparison of systemic opioids with systemic opioids and preoperative nerve blocks found no advantage to the latter protocol.[44] The great auricular and auriculotemporal nerves may be blocked.[36] Extended release morphine tablets and transdermal patches may be used as well.[36] Tranquilization may be necessary, not

for analgesia, but to provide restraint from head shaking and pawing at the incision in some animals. Physical restraint with E-collars to prevent the dog or cat from traumatizing the surgical site is also used.

Perioperative antimicrobial use is recommended for ear canal surgery, especially for TECA-LBO, and therapeutic use beyond the post-operative period should be based on the results of culture and susceptibility testing.[38]

Auditory Function after Ear Canal Ablation

Pet owners are commonly worried

about the effect of ear canal ablation on their pet's hearing. Dogs with bilateral end-stage otitis externa have been evaluated before and after surgery by auditory evoked response.[46] Prior to surgery, all dogs could hear a loud voice or noise, 3 dogs could hear a voice at a normal volume level, and 13 of 14 ears of the 7 dogs had a positive brainstem auditory-evoked response (air-conducted or bone conducted). After surgery, 2 dogs responded to a normal voice and all 7 dogs responded to a loud voice or noise. There were 3 of 13 ears that did not respond to an air-conducted stimulus that did prior to surgery, but all 13 ears in the dogs responded to a bone-conducted stimulus.[46] Experimentally, normal

dogs that underwent ventral bulla osteotomy had reduced auditory evoked potentials after wound healing.[47] Proliferation of scar and bone in a subperiosteal location in some dogs impaired function of the auditory ossicles and tympanum. Although most dogs in the study reformed a tympanic cavity without hearing impairment, the internal surfaces were found to easily produce new bone, which if extensive, can affect hearing function in dogs.[47]

Conductive hearing loss was evaluated in dogs experimentally using brain stem auditory evoked response threshold and latency-intensity. Dogs had their ears canals obstructed by an

ear plug rated at 26 decibels, had mechanical irritation to induce transient stenosis of the external ear canal, a needle puncture of the tympanum, and extensive destruction of the tympanum with electrocautery.[48] The investigators found that only the mechanical plug and the destruction of a major portion of the eardrum produced pronounced hearing loss.[48] The size and location of the perforation and especially the loss of integrity of the auditory ossicles were factors that affected the severity of auditory-evoked response.[48]

Otoacoustic emission (termed tinnitus in humans), an audible ringing from the ear canal, has been reported in a

dog. Otoacoustic emission is the term used in animals because it cannot be determined if the animal consciously perceives the sound.[49] The dog was reported to have a normal brain-stem auditory evoked-response test, indicating the intitial phases of sound processing in the affected ear were normal.[49]

Otitis Media

Otitis media is defined as inflammation of the middle ear, and is usually caused by bacterial infection that has extended directly from the external ear canal.[50,51] In most situations the tympanum has ruptured, but the tympanum may appear intact at

examination, as small defects may have healed.[52] Positive cultures of the middle ear cavity may often be obtained by myringotomy in the presence of an intact eardrum. In one investigation of 46 ears in dogs with otitis media, 71% of the ears had intact eardrums.[52] Bacteria are the most common cause of otitis media but yeast may be the causative agent as well.[52] Hematogenous route and the Eustachian tube are also sources of infection for otitis media.[53] Bacterial infection of the middle ear is usually secondary, from extension of otitis externa or cholesteatoma. Primary otitis media may occur owing to neoplasia, inflammatory polyps, and rarely, primary infections. Middle ear

disease has been associated with congenital palatine defects in both dogs and a cat, without evidence of external ear disease.[54]

The initial clinical sign of primary otitis media is pain, causing the dog to hold the affected ear down.[2] Clinical signs of disease involving the middle ear can be similar to those in other types of ear disease, but the routine head shaking, pawing at the ear, and drainage from the ear canal are more common in otitis media. Drainage may occur if the eardrum should perforate. Otoscopic or videoscopic examination of the eardrum, which often requires anesthesia, may reveal it to be discolored or possibly bulging into the

external ear canal, and to have congested blood vessels.[2] A bulging discolored tympanum (dull, and grey to yellow) in the presence of a normal external ear canal suggests an origin of disease to be hematogenous or via the Eustachian tube. A myringotomy is done to obtain specimens for cytologic examination and for culture and susceptibility testing.

Disease of the middle ear can be expansile and result in an enlargement of the volume of the tympanic cavity ventrally, or the disease process can break through the boundaries of the tympanum. This can result in a mass that is sometimes palpable ventral to the bulla. Because of the proximity of

the osseous bulla to the nasopharynx, if the expansile mass becomes large enough that it extends down toward the soft palate and compresses against these structures, oral examination may reveal the region of the dorsal tonsillar pillar and soft palate to bulge into the oropharynx. Noisy respiration may be noted if the nasopharynx is compromised. In addition, the osseous bulla is in close proximity to the temporomandibular joint so disease processes that cause inflammation and pain in this region may cause irritation when the mandible moves, resulting in dysphagia.

Diagnostic evaluation includes basic otoscopic examination, radiographs of

the tympanic bulla, and cytologic evaluation of drainage from the ear. Computerized tomography is an ideal imaging technique for the middle ear, and use of contrast can provide valuable diagnostic information.[22,55] One report showed that CT was more accurate than skull radiographs for diagnosing middle ear disease when the degree of disease was moderate to high; however, when the severity of involvement of the middle ear was low, skull radiographs and CT were more variable in their ability to detect abnormalities.[56] Findings of proliferation of bone, lysis of bone, and in particular, extension of invasive processes toward or into the calvarium allow judgments to be made to avoid

surgery as well as to help plan exploratory surgery. Once the diagnostic imaging is done, specimens from the middle ear can be obtained if the ear canal is not obstructed. Soft catheters may be placed by myringotomy if the tympanum is intact, or through a perforated tympanum, to obtain specimens for cytologic examination and for culture and susceptibility testing.

In dogs, aural cholesteatoma can be a sequela to ear canal occlusion and chronic otitis externa.[3] A cholesteatoma is an epidermal cyst that is found within the middle ear cavity and originates from a pocket of tympanic membrane that bulges into

the tympanic cavity. This prolapse of epidermis adheres to the inflamed mucosa of the middle ear cavity and fills with keratin lamellae (Figure 59-8) which is produced by the tympanic membrane epidermis.[3,57] This process can result in expansion of the osseous tympani bulla with remodeling of the bone that normally borders the dimensions of the normal tympanic cavity (Figure 59-9). Cholesteatomas are most commonly secondary to otitis externa in dogs, but can be congenital or acquired.[57] Cholesteatomas that expand within the middle ear can cause oropharyngeal compression and partial obstruction of the nasopharyngeal tube.[57,58] Cholesteatomas that are secondary to

chronic otitis externa can be managed successfully by total ear canal ablation and lateral bulla osteotomy. The large epidermal-lined cystic structure can be gently removed from the middle ear cavity. A ventral bulla osteotomy can be done and the epidermal cyst removed; however, if the cholesteatoma is secondary to chronic otitis externa, the tympanum and residual epidermis may remain.

Surgical Approaches to the Middle Ear

The three methods of access to the middle ear include myringotomy, ventral bulla osteotomy, and lateral bulla osteotomy. The most

conservative approach is myringotomy, which is most commonly done to obtain specimens for culture and susceptibility testing and cytology when otitis media is suspected. Lateral bulla osteotomy is the more common surgical approach but is done in conjunction with total ear canal ablation for the purpose of debriding tissue and debris from the tympanic bulla. Ventral bulla osteotomy is done to explore the tympanic bulla,to remove tissue, tumors, and debris for histopathology and for culture and susceptibility testing. It is also done for removal of cholesteatomas and to promote ventral drainage. The ventral approach to the tympanic bulla is usually done when diagnostic

evaluation reveals focal disease within the bulla, or if otitis media is not responsive to myringotomy and medical therapy, and if all efforts done to salvage hearing function are desired by the owner.

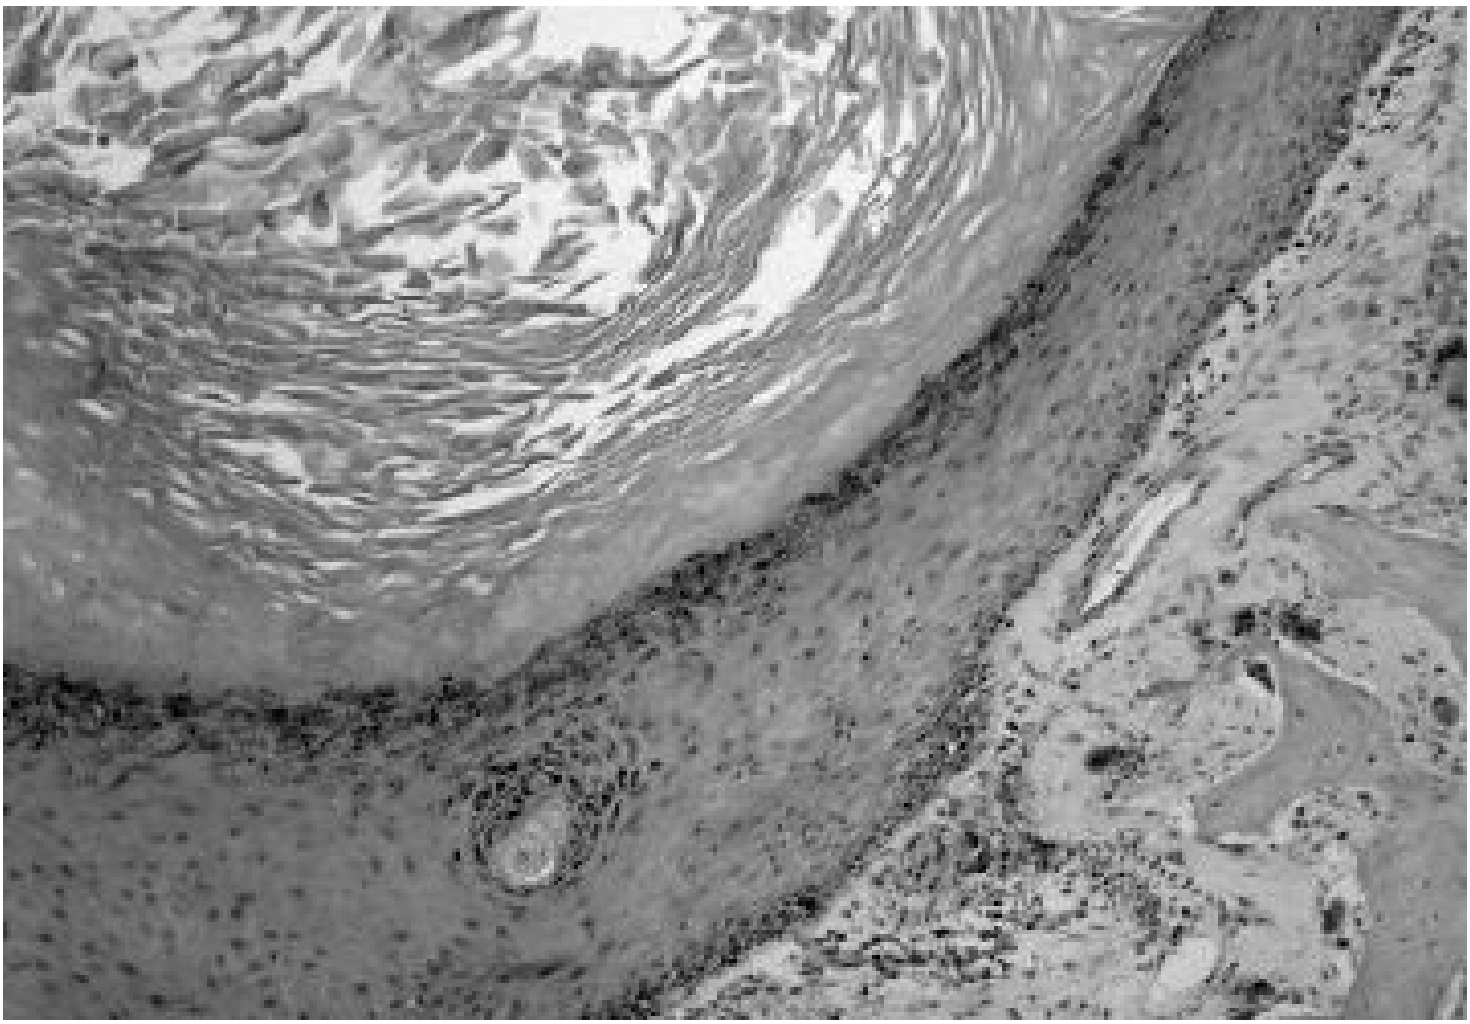

Figure 59-8. Histopathologic photomicrograph of a section of the tympanic bulla in a dog with

cholesteatoma. Note the epithelium and keratin flakes. (Photomicrograph courtesy of Dr. Pam Ginn, University of Florida.)

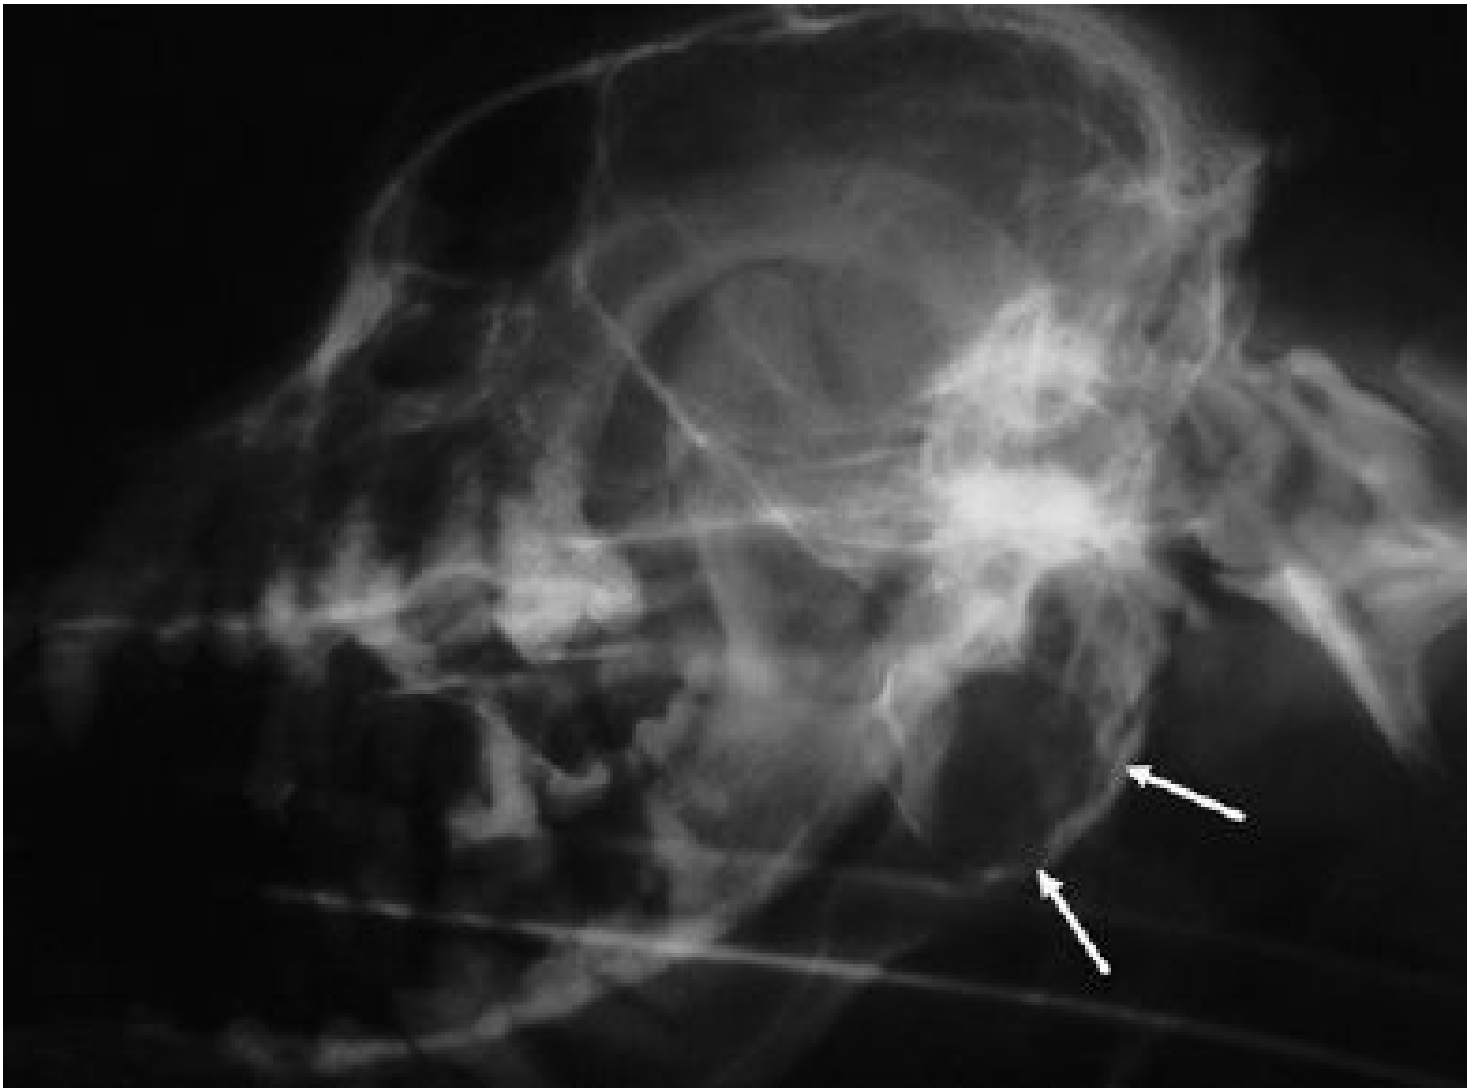

Figure 59-9. Lateral radiograph of the affected tympanic bulla (Figure 59-8) in a dog with cholesteatoma. Note the lacy expanded margin of the tympanic bulla (open arrows).

Surgical judgment is required when

deciding which approach to perform for middle ear disease. Lateral bulla osteotomy is most appropriate for treatment of otitis media secondary to end-stage otitis externa. A ventral approach can be done but provides poor access to the lateral aspects of the external acoustic meatus. Ventral bulla osteotomy provides the most complete exposure to the tympanic cavity and is used when primary otitis media and other middle ear diseases are present. In dogs, breed differences cause ventral bulla osteotomy to vary in difficulty. For example, dissection is deep in stocky breeds such as the English bulldog and Boxer, whereas in dolicocephalic breeds the dissection seems easier. In cats, the osseous

bullae are palpable prior to incision; however the tympanic bulla is partitioned into dorsolateral and ventromedial compartments. The surgical anatomy is basically the same, but the degree of difficulty of getting to the bulla may vary greatly. Vital structures encountered during the approach include the hypoglossal nerve, the external carotid artery, the lingual artery, and the sublingual salivary gland. Remember, the vital structures within the tympanic bulla are located dorsally and cranially; thus, the initial osteotomy approach must be made ventrally and caudally. The bulla is located between the angle of the mandible and the jugular process of the skull, but a convenient

landmark that aids in finding the bulla is the hyoid apparatus. The tympanohyoid cartilage (attached at the stylohyoid bone) attaches caudal to the external auditory meatus, which is caudolateral to the tympanic bulla. It is also important to remember that, in addition to the vital structures in the periphery of the approach to the ventral aspect of the tympanic bulla, the oropharynx is just a few millimeters away and cavalier medial dissection can result in exposure of the oral cavity.

Inflammatory Polyps in Cats and Dogs

Inflammatory polyps are common in

young cats and have been rarely reported in dogs.[59-61] These polyps are non-neoplastic and the exact etiology is not known, as neither a congenital origin or a secondary result of middle ear infection has been confirmed.[62] Polyps in cats do not appear to be associated with feline leukemia virus or feline immunodeficiency virus infections.[62] Attempts to find viral evidence by polymerase chain reaction (PCR) have been unsuccessful.[63] Chronic irritation to the mucosal surface of the middle ear may lead to the production of the inflammatory polyp, which is typically composed of well vascularized fibrous tissue stroma covered with respiratory epithelium. The ulcerated epithelium has an

underlying stroma that contains both acute and inflammatory cells. Although the polyps can occur in cats of any age, the average age at diagnosis is 1.5 years.[62] Inflammatory polyps in cats are thought to originate most commonly in the middle ear near the junction of the auditory tube and the tympanic bulla, and from this location migrate into the horizontal ear canal by protrusion through the tympanum or into the nasopharynx via the auditory tube. Because the respiratory epithelium is continuous within the tympanic cavity, the Eustachian tube, and the nasopharynx, it is difficult to know the exact location of origin.[62] In the pharynx, polyps may attain a large enough size to cause stertorus

respiration. Rarely, dysphagia may result. Surgical removal is accomplished by avulsing the polyp from the horizontal ear canal, or by ventral bulla osteotomy, or by an oral approach that may or may not require incision of the soft palate. Ventral bulla osteotomy to allow removal of the septum of the middle ear and curretage of the polyp base decreases recurrence of the polyps.[64,65] The polyp usually originates from the dorsolateral compartment. Curettage of both areas must be complete or recurrence of the polyp is likely. Horner's syndrome is usually transient after bulla curettage in cats (as many as 48% can have this complication).[62]

Traction or avulsion of the inflammatory polyp can be done from either canal or nasopharyngeal locations. A lateral ear resection can improve exposure.[62] Regrowth of the polyp may occur if the polyp stalk remains. In 22 cats that had inflammatory polyps treated by traction alone, 41% had recurrence.[66] Prednisolone was also used in cats reported in this investigation and was believed to aid suppression of recurrence, as 8 cats that received the corticosteroid did not have recurrence and 9 of 14 cats that did not receive the drug had recurrence of the polyps.[66] It has also been reported that nasopharygeal polyps are 4 times more likely to be successfully treated

by traction alone than those that occur in the ear canal.[62,66] Perendoscopic trans-tympanic excision (PTTE) has been described and utilizes endoscopic view and endoscopic forceps to pinch away the polyp. In one report, 8 of 10 cats had complete resolution for 24 months, 2 cats required repeating PTTE, and 2 cats had temporary Horner's syndrome.[67]

Laser ablation of inflammatory polyps can be done using videoscopic exposure and a CO_2 laser.[62] Small polyps may be vaporized and gradually removed until the polyp stalk can no longer be seen. Larger polyps are removed by initially vaporizing a portion of the polyp

stalk, avulsing the polyp, and then going back to finish vaporization of the polyp stalk.[62] Corticosteroid and azithromycin therapy are also recommended.[62] Antimicrobial therapy should be based ultimately on antimicrobial culture and susceptibility testing.

The tympanum is commonly destroyed when inflammatory polyps extend out into the horizontal canal. Although remnants of the tympanum and proliferation of scar tissue may result in reformation of the tympanum and partitioning of the middle ear from the external ear, persistence of this communication may result in relapse of otitis externa and media with

persisting drainage from otitis media. In some cats, TECA-LBO may be necessary to resolve chronic otitis externa and media that may result.

In dogs, nasopharyngeal polyps and aural polyps rarely develop.[62] Polyps can enter the nasopharyngeal tube and affect the airway. In one dog, a polyp was removed by a staphylotomy approach, which allowed the polyp to be grasped and removed.[59] Polypoid masses are often large ceruminous-gland adenomas, rather than inflammatory polyps.[62]

Complications of bulla osteotomy include injury to vital structures such as the hypoglossal or glossopharyngeal

nerves, creation or exacerbation of otitis interna (vestibular signs), Horner's syndrome when sympathetic fibers are damaged, facial nerve paralysis, and hemorrhage. Head tilts present prior to surgery, especially if chronic, may persist despite resolution of disease.

Aural Hematomas

Aural hematomas are most commonly diagnosed in dogs but are occasionally seen in cats. They occur within the cartilaginous plate (intrachondral) of the auricle (pinna) of the ear. The hematoma, which consists of blood, serum, or both, has classically been thought to result from self-inflicted

trauma to the ear. Pruritus, owing to allergy or ectoparasites or secondary to otitis externa, results in head shaking or scratching. The trauma is believed to cause a shearing force that causes separation of the cartilage of the pinna. The hematoma is painful and irritating to the dog or cat and causes more head shaking and pawing at the ear with subsequent extension of the region of involvement. In cats, aural hematomas are most commonly diagnosed when ear mite infestation and otitis externa are concurrent.[2] Aural hematomas show trauma to be a precipitating rather than an underlying factor. They are uncommonly associated with chronic skin diseases, and commonly occur

when there is no other evidence of ear disease in the affected dog.[68]

The aforementioned pathogenesis of aural hematomas in dogs was challenged in the late 1980s. Most veterinary surgeons have made the diagnosis of aural hematoma in the presence of a pristine ear canal; therefore, understanding the association of otitis externa and trauma is sometimes in question. An immune-mediated pathogenesis had been hypothesized on the basis of one study where 30% of affected dogs were LE cell positive, 100% of affected dogs were Coomb's test positive, and 52% of affected dogs had positive antinuclear antibody titers.[69] It was suggested that

the inflammatory disease in the ears might serve as a triggering mechanism for an autoimmune reaction that could be responsible for cartilage degeneration, cartilage clefts, and subsequent development of the aural hematoma. Local treatment of aural hematoma remains unchanged, but judgment as to whether systemic therapy is appropriate is warranted. Dexamethasone has been recommended, based on these papers, to control the immune-mediated component thought to be responsible. This treatment remains controversial, and what works for some veterinarians may not work for others. Reported causes (or associations) include fungi, bacteria, parasites, atopy, aural

foreign bodies, and aural neoplasia. An autoimmune pathogenesis posited in the literature in the past, has not been substantiated by more recent investigation.[68] The latter investigation did find cartilage degeneration associated with fibrovascular granulation tissue that may have been the end result of a macrophage-mediated process.[62,68]

It is important to treat aural hematomas, because if left untreated, the result is usally a thickened fibrous scar that causes the ear to fold. The auricular cartilage perichondrium is highly chondrogenic, and chondroblast invasion into an organizing aural hematoma results in a firm hard

cartilaginous mass of scar, and distortion of the pinna occurs. The end result of a conservatively treated aural hematoma is an abnormal shape that is most noticeable in breeds with erect ears. Various methods of treatment exist but all must be combined with careful otoscopic examination to discern whether self-inflicted trauma or head shaking is evident, as medical management of a concurrent problem is important for complete treatment.

Conservative techniques to drain aural hematomas are effective, and because a large incision is not made, minimal scarring of the pinna occurs. Active drainage technique or pressure can be an aid to evaluation of fluid from the

aural cavity.[70] Each type of drain is placed into the cavity encompassing the hematoma after a small stab incision is made. The teat cannula is placed in the dependent portion of the hematoma. The drain must be cleansed daily to assure patency, and it may be necessary to leave it in place 14 to-21 days. If the drain becomes clogged by exudate, or if it is removed prematurely, recurrence of the hematoma is likely. Bandaging protects the ear from further trauma related to head shaking and also prevents soiling of areas in the home when drainage occurs.

More invasive techniques usually involve making incisions parallel to

the pinna, evacuating the fluid, and suturing to appose the tissue layers with the hope of resolving and preventing recurrence of the aural hematoma. Various incision and suture patterns can be used to accomplish this; the choice depends on the individual surgeon. Too much tension on sutures may cause secondary contracture and deformation of the ear so care should be taken when placing sutures. Some surgeons feel a large curvilinear incision does not allow contraction to deform the pinna of the ear. A narrow gap is desired to aid maintenance of drainage from the concave surface of the ear. Nonadherent contact dressings are used. Bandaging techniques also vary

but are used to protect the ear from head shaking and to absorb drainage. Sutures are often left in place for 14 or more days.

More chronic aural hematomas may be firm and organized, as after 7 to 10 days fibroblastic infiltration of the hematoma occurs, and eventually cartilage forms. It is helpful to remove this material surgically and obliterate the space using sutures. In this state, drainage by the aforementioned techniques is not feasible. Organized hematomas must be removed by incision on the concave surface of the ear. The hematoma is removed and bleeding vessels are cauterized or ligated. The incisional margins are

excised such that the edges do not meet and drainage is promoted. The dead space in the cavity is obliterated with through-and-through mattress sutures placed parallel to and on each side of the incision, with the knots on the external surface of the ear. An alternative technique is to place the mattress sutures from inside the ear through the cartilage without penetrating the opposing skin surface. A better cosmetic result is obtained as the development of stitch abscesses on the haired side of the pinna is prevented. Noncapillary suture material should be used (i.e., monofilament nylon or polypropylene), and mattress sutures should be placed parallel to the long

axis of the pinna to preserve blood vessels that are oriented in that direction. The carbon dioxide laser can also be used to treat aural hematomas.[71] Regardless of technique, a protective bandage and head wrap are applied and changed every 2 to 3 days, and sutures are removed in 10 to 14 days.

Antibiotic therapy is not indicated unless infection is suspected or confirmed by culture and sensitivity testing, but corticosteroids are used by those who feel an immune-mediated component contributes to the development of aural hematomas. Corticosteroids are also important to lessen head shaking and for patient

comfort. Use of corticosteroids may also be therapeutic if the inflammatory response is in part responsible for cartilage separation and development of the aural hematoma.

Marginal Auricular Dermatosis and Ear Margin Fissures

Short-haired dogs with pendulous ears occasionally develop thickened areas at the apical edges of the pinna. These areas eventually become scab-like, which when removed reveal a raw bleeding surface. As these wounds heal, exposed cartilage disappears but the edge of the flap remains eroded and thickened.[2] Pinnal necrosis, often

idiopathic, can affect toy breeds and requires surgical excision of the edge or apex of the pinna. (Figures 59-10A and 59-10B) Biopsy of lesions of the pinna, especially on the concave surface, may be done using a 3 mm skin punch. Hemorrhage can be controlled by digital pressure, needle-tip cautery, or a cauterizing agent. It is important to obtain dermal tissue in the specimen. A small hypodermic needle can be used to tease the fibrous tissue off the cartilage base.

Ear margin fissures occur as a result of scratching or flapping the ears. This lesion appears as small wounds at the margin of the distal aspect of the pinna, and with continued trauma may

become several centimeters long.[2] Treatment of the primary reason for the discomfort and head shaking (flapping) is important to break the cycle that results in recurrent injury. Treatment of long fissures requires debridement and suturing. Multiple small fissures are usually treated by excision of the most superficial edge of the pinna. A scalpel or sharp scissors (depending on the thickness of the edge of the pinna) can be used to excise the affected edge just proximal to the fissure. Sutures are not always required, but the ear must be bandaged across the head to prevent trauma to the wound margin from head shaking. Alternatively, the medial and lateral edges of the skin can be apposed

gently over the cartilage edge with fine interrupted sutures of non-absorbable material, taking care to avoid penetrating the cartilage where possible. While the ear margin is healing primarily or by secondary wound healing, the primary cause for the irritation and trauma must be treated, so that once the ears are left unbandaged, ear flapping is minimized.

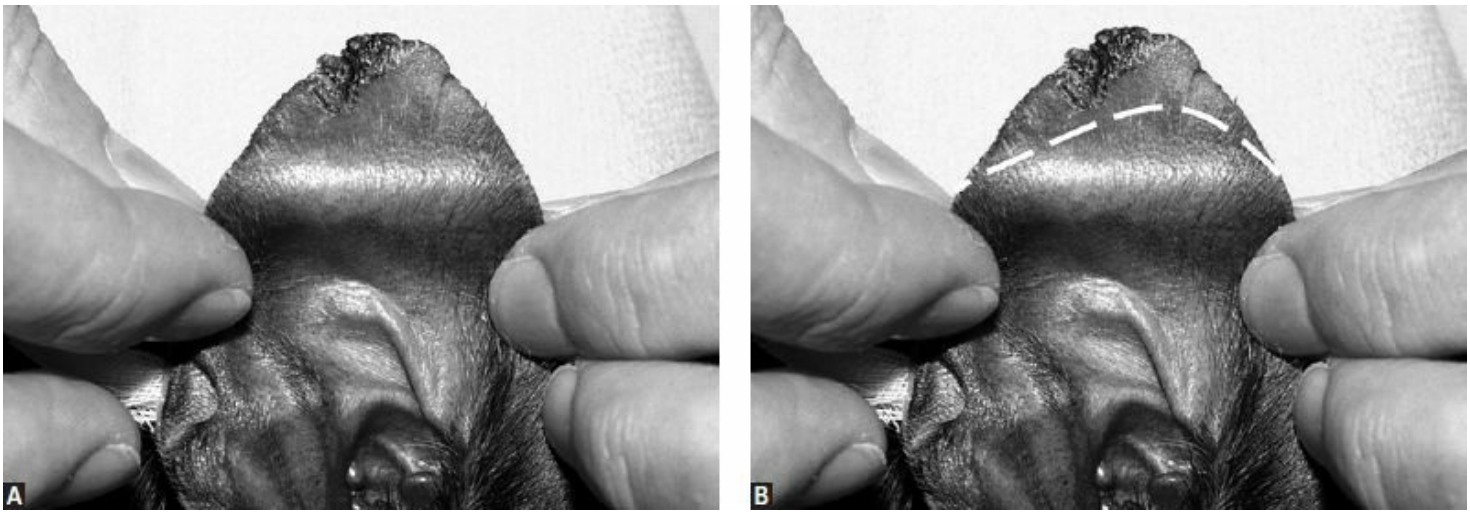

Figure 59-10A. Photograph of the ear of a Chihuahua with idiopathic pinnal necrosis. Surgical biopsy of

this lesion is indicated and (B) cosmetic distal pinna excision, depicted by the dashed line, may be curative. (Photograph courtesy of Dr. Robert Kennis, Auburn University.)

Auricular chondritis, resulting in bilateral thickening of the pinnae was reported in a cat. Slight curling of the pinna, intense erythema, and pain were evident. The cat responded to treatment with prednisolone.[72]

Otolithiasis

Rarely, mineralized opacities may occur in the tympanic bullae. Mineralized necrotic material from previous otitis media may be the source of otolithiasis. Otolithiasis has been reported in three dogs and was detected by skull radiographs and

CT.[73] Otoliths may be identified in active cases of otitis media, or in some dogs, maybe an incidental finding.

Aural Neoplasia

In dogs and cats, tumors of the ear canal are relatively rare, comprising between 2% and 6% of dog ear surgery admissions and 1% to 2% of cat ear surgery admissions, respectively.[74] Malignant aural tumors in dogs and cats include ceruminous gland adenocarcinoma, squamous cell carcinoma, and carcinoma of undetermined origin.[74] It has been stated that malignant tumors in dogs are less aggressive than those in cats.[75] It is expected that dogs generally live

longer than 2 years after surgical excision of an aural tumor, whereas cats' median survival is about 1 year.[75] The median survival rates for dogs and cats with malignant tumors in a 1996 study were longer than 58 months and 11.7 months, respectively.[74] A more recent study in cats showed a median survival time of 50.3 months for those with ceruminous gland adenocarcinoma.[29] Negative prognostic factors were extensive tumor involvement, neurologic signs at the time of diagnosis, diagnosis of squamous cell carcinoma or of carcinoma of undetermined origin, and lymphatic or blood vessel invasion.[74] Squamous cell carcinoma is known to arise from the middle ear in cats, and

may cause Horner's syndrome, vestibular dysfunction, and facial paraylsis.[29,76] In the more recent study in cats, a mitotic index of greater or equal than 3 found cats living significantly less than cats with a mitotic index of less than or equal to 2.29 Approximately 25% of malignant aural tumors will have tympanic bulla involvement; therefore, imaging studies such as CT are helpful to plan surgical removal.[75] Metastasis to the thorax or to regional lymph nodes is present in about 10% of dogs and cats at the time of diagnosis.[75] For both dogs and cats, aggressive surgical resection of malignant tumors (i.e., total ear canal ablation with lateral bulla osteotomy), results in the longest

survival times. Benign ear canal tumors can be managed with more conservative surgical resection, depending on the location of the tumor and the condition of the ear canal. Radiation may be used adjunctively where resection is incomplete, but little is known about the efficacy of chemotherapy.[75]

Chapter 60

Feline Aural and Nasopharyngeal Polyps

Rod A.W. Rosychuk

Feline aural-nasopharyngeal polyps are non-neoplastic growths that originate from the middle ear and/or the adjacent entrance to the auditory canal. Aural polyps are those that extend from the middle ear, through the tympanum into the horizontal canal of the ear. Nasopharyngeal polyps are those that extend through the auditory canal into the posterior

pharynx. Aural-nasopharyngeal polyps are the most common nasopharyngeal disease of young cats and the most common non-neoplastic mass of the feline ear.[1,2]

Polyps are seen in young to middle-aged cats, with the mean age at presentation variably reported as 18 months 3-5 or 6.0 years.[6,7] The range is 3 months to 18 years.[3-7] There does not appear to be any breed or sex predisposition.[3-7]

Etiopathogenesis

Polyps appear to be inflammatory or post inflammatory lesions. Histologically, the growths are characterized by loosely arranged

fibrous tissue throughout which are scattered plasma cells, lymphocytes, neutrophils, lymphoid aggregates or follicles, and variable numbers of mucus-secreting glands.[4,8,9] Often, just beneath the epithelium, are focal areas of increased vascularity and, at times, heavy infiltrations of both acute and chronic inflammatory cells.[8,9] Polyps are covered by a stratified squamous to ciliated columnar epithelium that may be ulcerated.[3,8,9] The ciliated columnar epithelium cannot be differentiated from that covering the nasopharynx, auditory canal, or lining of the middle ear.[10] Grossly, polyps may be smooth or lobulated and pale pink or grey.[9] Nasopharyngeal polyps and many aural polyps are usually firm or

rubbery on cut section.[9] This firmness facilitates grasping with forceps for purposes of removal by traction or avulsion. Some aural polyps tend to be more myxomatous, and friable, suggesting a shorter duration of growth.[8]

The etiology of polyps remains unclear. Because the lesions have an inflammatory component, the most likely initiating cause would be irritant in nature.[10] Both viral[2,7,11] and bacterial infections[9] have been hypothesized. Support for an infectious etiology is suggested by the occasional observation of multiple, unrelated cats all developing polyps at about the same time.[11]

Although reports exist of calicivirus isolation from polyp material,[11,12] the incidence is low and is likely an incidental finding. In a study of 41 polyps, feline *herpesvirus*-1 and feline *calicivirus* were not found by RT-PCR and PCR.[7] The fact that the samples in this study were formalized may have contributed to some false negative results. Although this data suggests that viral persistence is not a likely cause of the problem, it does not rule out the possibility that viruses may initiate the syndrome, but are eventually cleared.

It is also possible that bacterial infection that has ascended the auditory tube may be responsible for initiating and perpetuating polyp

growth.[9] Cats are prone to viral upper respiratory infections that may be complicated by secondary bacterial infection. However, most cats do not have a history of upper respiratory infections antedating polyp development,[7] and the middle ear of cats with nasopharyngeal polyps are usually sterile.[4] This again does not preclude the possibility that bacterial infection may have initiated the problem.

A role for other infectious organisms such as *Bartonella*, *Mycoplasma*, and/or *Chlamydia* has not been evaluated to date.

Because polyps have been noted in

very young individuals, it has also been hypothesized that they may be congenital defects arising from remnants of brachial arches.[13] However, no data exist to support this conjecture.

The initiating cause of polyp growth is likely no longer present at the time of clinical presentation. This is supported by the fact that relatively complete removal utilizing ventral bulla osteotomy (VBO) results in a lack of regrowth in the vast majority of cases of both aural and nasopharyngeal polyps.[3,4,6,7]

Site of Origin

The middle ear of the cat is divided into a smaller dorsolateral and a larger ventromedial chamber by a thin bony plate. The dorsolateral chamber is bordered medially by the bony cochlear promontory and petrous temporal bone and laterally by the tympanum. It contains the auditory ossicles and a postganglionic sympathetic nerve plexus that fan out over its medial wall.[14,15] The communication between these chambers is limited to a narrow fissure between the bony plate and cochlear promontory on the caudomedial aspect of the compartment. Toward its caudal extremity, the fissure enlarges into a triangular foramen.[14,15] The round window of the cochlea makes up part

of the medial wall of this opening. The auditory canal, which is 5 to 8 mm long,[15] arises from the anterior-most aspect of the dorsolateral chamber and extends into the posterior pharynx.

Only rare reports exist of post-mortem dissection to document the site of origin of polyps. In one young cat with nasopharyngeal and middle ear polyps, the only site of attachment for both was in the region of the opening of the middle ear into the auditory canal.[16] Site of origin correlations are otherwise presumptive and based on radiographs and observations made during surgical therapy.

A middle ear site of origin for both

aural and nasopharyngeal polyps is supported in the vast majority of cases by the observation that a middle ear mass is seen radiographically and by surgical exploration via ventral bulla osteotomy.[4,5] A dorsomedial chamber site of origin is supported by the observation that, during ventral bulla osteotomy in affected cats, polyps are attached to the walls of the dorsolateral compartment but not to the walls of the ventromedial chamber. Polyp growth likely extends from the dorsolateral chamber through the communicating fissure and foramen to fill the ventromedial chamber. Its growth may produce pressure necrosis of the thin bony plate that separates the chambers. This would explain the

observed absence of the bony plate at the time of ventral bulla osteotomy in many patients. Nasopharyngeal polyps are occasionally seen without radiographic middle ear involvement. In these individuals, polyp growth appears to occur from around the opening to the auditory canal.[4] After traction for removal of nasophyaryngeal polyps, a stalk is seen attached to the polyp that corresponds to the approximate length of the feline auditory canal.[4]

The attachment of the polyp to submucosal tissues overlying the medial bony wall of the dorsolateral chamber is further supported by the common occurrence of a transient

Horner's syndrome following avulsion/traction of both aural or nasopharyngeal polyps.[4,6]

Complicating Factors

Mucoid secretions are commonly noted in the middle ears of cats with middle ear polyps.[14] The epithelial lining of the middle ear contains mucus-containing goblet cells.[17,18] With chronic irritation, mucus-secreting glands are also noted to develop.[17,18] The presence of polyp material within the middle ear likely stimulates increased mucus production through irritation. It is also noted that occlusion of the auditory canal in normal cats results in the accumulation

of a viscous, mucoid material which is of goblet cell and mucus gland origin.[17,18] These secretions normally exit the middle ear through the auditory canal. Polyp material partially obstructing the auditory canal likely results in mucoid-material retention in affected cats.

Secondary bacterial infections are also commonly noted in the middle ears of cats with aural polyps (17 of 22 reported cases).[5,6,19-21] Bacteria noted (in decreasing order of frequency) include *Pasturella multocida, Beta Hemolytic Streptococcus, Staphylococcus hominis, Bacteroides sp, Pseudomonas sp, and Sreptococcus zooepidemicus*.[6] The incidence of secondary infections

warrants the routine practice of cytologic examination and culture and the use of postoperative antibiotics in the management of aural polyps.[6] This tendency toward the development of secondary infections is likely related to perforation of the tympanum and bacterial access from the ear canals.

It is uncommon to have secondary middle ear infections in cats with nasopharyngeal polyps (3 of 23 cases in one study[4]). In these cases, the bacteria isolated included *Bordetella sp, Pasturella sp,* and *Achromobacter sp.* Obstruction of the auditory canal is noted to predispose to secondary bacterial infection of the middle ear in the cat.[17] The middle ear of the cat has

a normal, transient bacterial flora. Retained secretions associated with obstruction likely produce a microenvironment that is conducive to infection. Partial obstruction owing to nasopharyngeal growth may predispose to infection through a similar mechanism.

History and Clinical Signs

Initial clinical signs may be noted from days to years prior to presentation.[3,4,7] Polyps are most commonly unilateral at presentation. In one study of cats with only nasopharyngeal polyps, 21 were unilateral, 4 were bilateral.[4] In a group with only auricular polyps, 10 were unilateral, 2 were bilateral.[6]

Growth of the polyp from the middle ear is usually into the auditory canal or through the tympanum into the horizontal canal, or both. In one study of 28 cats, 50% were otic alone, 21% nasopharyngeal alone, and 29% a combination of both.[7] In another study of 37 cats, 51% had growth into the nasopharynx, 38% into the ear, and 11% of cats had both.[3]

At the time of presentation, polyps have almost always extended into the horizontal ear canal or the nasopharynx. It is difficult to say what clinical signs, if any, are associated with early polyp growth confined to the middle ear. It is likely that clinical signs at this point are minimal as

supported by the lack of clinical signs of otitis media (head shaking, pain on opening mouth, neurologic signs) seen in a group of individuals with only nasopharyngeal polyps and radiographic and exploratory evidence of bulla involvement.[4]

The clinical signs associated with auricular polyps include debris accumulation within the ear canals, head shaking, scratching, and intermittent or consistent head tilting.[6] Intermittent head tilting is usually because of discomfort rather than neurologic dysfunction. These signs are likely products of perforation of the tympanum, irritation within the horizontal canal, and secondary

bacterial and/or *Malassezia* colonization/infection within the canals. Debris accumulation in the canals is common and may be waxy to purulent.[5] These accumulations are a product of disruption of the normal "flushing" mechanism of the ear (lateral epithelial growth from the region of the tympanum), polyp irritation, and bacterial and/or *Malassezia* colonization/infection. Any source of irritation or inflammation within the ear canal results in increased ceruminous secretions. The actual incidence of bacterial and/or *Malassezia* colonization/infection has not been reported in affected cats; however, in the author's experience, they are common.

Neurologic signs of otitis media (Horner's syndrome, facial paresis, and paralysis) and otitis interna (head tilt, nystagmus, ataxia) are only uncommonly noted in patients with aural polyps.[5,8,19] These signs are most likely complications of secondary infections of the middle ear that could gain access to the inner ear through the membrane-covered oval or round window.[19] When infection is not present, it has been suggested that inner ear signs may be a product of increased pressure within the inner ear, mediated by pressure on the round and/or oval windows.[21]

The clinical signs associated with nasopharyngeal polyps are related to

progressive growth down the auditory canal, occlusion of the auditory canal, or gradual growth and expansion into the posterior pharyngeal region. Most masses are visible within the posterior pharynx at the time of clinical presentation, both clinically and radiologically (30/31 cases in one study[4]). Visualization is facilitated by forward traction on the soft palate. Clinical signs of the expanding mass in the posterior pharynx include inspiratory stridor and snoring,[5] nasal discharge, gagging, and sneezing.[4,5] Nasal breathing may be compromised,[22] and sleep may be interrupted because of a need to mouth breath. Severe obstruction may result in dyspnea, cyanosis, and syncopal

collapse.[15] Breathing difficulties and/or decreased ability to smell may result in significant inappetance. Large masses may impinge on the larynx and cause voice changes and may produce dysphagia. Affected cats may want to eat, but may have difficulty in swallowing. Halitosis may be significant.[3] These various problems may produce significant weight loss and loss of general bodily condition. Affected patients are prone to the development of secondary bacterial rhinitis or sinusitis. These signs may contribute to the symptoms and may be difficult to differentiate from the signs associated with polyps. Lower respiratory tract disease (pneumonia) can develop in chronic or severe cases,

likely owing to compromise of large-airway clearance mechanisms. Neurologic signs associated with nasopharyngeal polyps are uncommon (noted in 3 of 31 cases in one study 4). These are most likely related to the development of secondary infection within the middle ear as suggested for aural polyps.

Factors Affecting Prognosis

Once polyps are clinically visible, the nature of the inflammatory process seems to make the masses relatively resistant to the effects of both anti-inflammatory and immunosuppressive dosages of oral glucocorticoids and topical glucocorticoids (for aural

polyps).[8]

In those cases in which significant tissue is left within the bulla, regrowth is common.[4,6,7] In one study, mean time to regrowth was 3.5 months; range of 1 to 9 months.[3] This is most commonly noted with aural polyps treated with traction/avulsion[3,7] and is most likely related to the fact that, with this technique, significant polyp material remains within bulla. For this reason, many authors recommend VBO as the management of choice for both aural and nasopharyngeal polyps.[4,7] More recently, it has been noted that the use of a decreasing dosage regimen of oral glucocorticoids results in the lack of regrowth following partial

removal via traction/avulsion of both aural and nasopharyngeal polyps.[3] Significant polyp remained within the bulla of affected patients and regrowth would have been expected in several. No regrowth was noted in 8 of 83 and 6/6 cases.[23] These observations would suggest that, even with significant polyp material left in the bulla, the creation of an acute inflammatory microenvironment through traction/avulsion allows the anti-inflammatory effects of glucocorticoids to be effective in causing residual polyp tissue to regress.

Part VIII

Skin/Integument

Chapter 61

Skin Wound Healing

Tannaz Amalsadvala
Steven F. Swaim

A wound is defined as any interruption in the continuity of the body's tissue.[1,2] After injury, a wound immediately begins a complex process of healing, which involves sophisticated synchronization of molecular and biochemical events at the cellular level, to bring about tissue repair and regeneration. Wound healing is this fine-tuned process that restores

anatomic and physiologic integrity to the tissue and culminates in the formation of a scar.[3]

Wound healing may be compartmentalized into four stages, i.e., inflammation, debridement, repair/proliferation, and maturation/remodeling.[3-6] These stages exhibit a significant degree of overlap and occur as a continuum from start to finish. Thus, more than one stage of healing can occur at one time and, regardless of wound size, all normally healing wounds undergo all stages of healing.

Etiologic factors for wounds are numerous and varied, ranging from

mechanical trauma to physical agents such as extreme temperatures, chemicals, neoplastic processes, microbial infection, and surgery.[3]

Inflammation and Debridement Stages

The inflammatory stage of healing is the body's vascular and cellular defensive response.[7,8] It is separated into early and late phases.[4,5] The early phase consists of immediate responses including vascular tone dynamics and hemostasis, whereas the late phase is characterized by vascular responses as well as recruitment and activation of inflammatory cell populations.[7,8]

Tissue Reactions

The first response to any injury is hemorrhage, with the magnitude varying in accordance with the insult. Vasoconstriction occurs in an attempt to control hemorrhage. This is accompanied by an immediate enlargement of the defect, owing to inherent cutaneous elasticity and external muscle tension that retracts wound edges, causing wound gaping.[4] As a result, a wound may appear large; however, manipulation of the tissues may reveal that much of the enlargement is a result of tissue retraction.

Hemostasis, Lymphatic

Reaction, and Scab

Torn blood vessels have exposed basement membranes containing subendothelial collagen, which when in contact with platelets bring about platelet activation and aggregation and initiate the intrinsic path of the coagulation cascade,[3,4,7,9] culminating in thrombus formation and hemorrhage control, i.e., a fibrin clot in the wound. The clot not only attenuates hemorrhage, but also occludes ruptured lymphatics, thereby preventing drainage, promoting edema, and localizing inflammation.[4] Later in the healing process, fibrinolysis dissolves fibrin plugs in the lymphatics, and lymphatic drainage resumes. When exposed to the external

environment, the clot desiccates to form a scab.[3,4] A tightly adhered scab acts as a biologic bandage, beneath which wound contraction and epithelialization can progress undisturbed.[4,5]

Vascular and Humoral Events and Cellular Movement

The initial vasoconstriction is closely followed by reflex vasodilation and increased vascular permeability, resulting in plasma exudation[4,5] and the escape of inflammatory mediators and cellular components from blood vessels. Initiation of the arachidonic

acid cascade results in production of prostaglandins, thromboxanes, and leukotrienes.[3,4,7,8] These humoral factors, along with histamine, serotonin, bradykinin, and complement activation, help perpetuate inflammation.[8] Mast cell-derived serotonin and histamine cause rounding of vascular endothelium, thereby causing loss of tight cellular junctions and promoting extravasation of plasma and other inflammatory mediators into the surrounding tissues.[8]

Surface receptors for leukocytes on endothelial cells become activated, with resultant leukocyte margination and eventual migration into interstitial

tissues.[5,8]

Endothelial cells within blood vessels adjacent to the wounded tissue exhibit cellular adhesion molecules (CAMs), which bind inflammatory cells and assist in their passage between endothelial cells to the wound.[7] Further cellular migration is brought about with the help of proteinases (serine, metallo-, cysteine, and aspartic) which, by catabolizing ground substance and extracellular matrix, create a path for the cells.[7] Fibrin polymers are cross-linked to form a scaffold over which neutrophils and macrophages migrate toward the wound after diapedesis from the blood vessels.[3]

Polymorphonuclear leukocytes are the first responders to various chemotactic signals and appear at the site within hours of trauma.[4,8,9] They are followed closely by macrophages, and finally, T-lymphocytes.[8] Neutrophils are generally short-lived whereas macrophages persist for a significantly longer period.[5]

Cellular Functions

Besides playing a major role in coagulation, platelets also produce several cytokines and growth factors important to the progression of healing. Platelet activation results in release of platelet-derived growth factor (PDGF), transforming growth

factor-α and -β (TGF-α and -β), and tumor necrosis factor-α (TNF-α)[2-4,7] from platelet alpha granules.[2,8] These signaling molecules are chemotactic for neutrophils, macrophages, and T-lymphocytes, which migrate toward the wound.[3,7] Platelet alpha granules contain four adhesive glycoproteins: fibrinogen, fibronectin, von Willebrand factor, and thrombospondin.[8] These glycoproteins participate in coagulation as well as temporary matrix synthesis.

Neutrophils and macrophages debride the wound of necrotic, devitalized tissue. Later, macrophages coordinate tissue proliferation.

Neutrophils are not essential to wound healing, despite being the first to arrive in the wound.[3,9] Neutrophils phagocytose bacteria and kill them by generating toxic reactive oxygen species or free radicals.[2,7] Their granules contain various proteinases, among which cathepsin G, urokinase-type plasminogen activator, collagenase, and elastase are predominant.[2,7] These proteinases can digest extracellular matrix components including elastin, fibrin, fibronectin, vitronectin, laminin, collagen, and proteoglycans. Proteinase inhibitors protect normal healthy tissues from the action of proteinases. Once spent, neutrophils are removed from the wound by macrophages or via wound

exudate.[4]

Monocytes are transformed into macrophages once they are out of circulation and sequestered within tissue. Macrophage numbers reach their peak within 24 hours.[8,9] Macrophages are capable of phagocytosis as well as of discharging proteinases, specifically matrix metalloproteinases (MMPs), both of which are crucial during wound debridement and subsequent healing. Debridement and tissue proliferation are decelerated in wounds devoid of macrophages.[7] Tissue inhibitors of metalloproteinases (TIMPs) protect healthy tissue from the indiscriminate action of MMPs. Macrophages are

activated to synthesize signaling molecules, including colony-stimulating factor, TNF-α, PDGF, interleukin-1, TGF-α and -β, fibroblast growth factor (FGF), and insulin-like growth factor-1, which induce cell proliferation, especially of keratinocytes, fibroblasts, and endothelial cells.[2,7] Therefore, macrophages are the bridge between the inflammatory and repair phases of wound healing.[7]

T-lymphocytes play a regulatory role in wound healing. They are not vital; however, their absence retards the healing process. Lymphocytes produce growth and regulatory factors that govern functions of other cells. The

role of lymphocytes in healing is generally associated with a foreign antigen or secondary infection. They arrive in the wound at the same time as macrophages and interact with them in producing an immune response. Macrophages process foreign antigens, and these modified antigens are presented to the lymphocytes. The lymphocytes produce cytokines such as interferon-gamma (IFN-γ) and interleukins 2 to[2,4] Lymphocytes also produce TGF-β.[4]

The role of eosinophils in wound healing has not yet been elucidated. They are present in healing wounds and peak around 1 week post injury.[8] A rabbit cutaneous wound healing

model demonstrated that eosinophils appeared to be responsible for secreting TGF-α after day 7,[8] however, eosinophils may delay wound re-epithelialization.[7]

Repair/Proliferation Stage

The repair/proliferation phase is composed of fibroblast proliferation and migration with production of wound extracellular matrix, neovascularization, and epithelial proliferation and migration.[2-6,8] Fibroblast activity and neovascularization result in granulation tissue formation.

Macrophages play a significant role in this stage of healing. They become

activated in response to growth and chemotactic factors released from platelets during the latter part of the inflammatory and debridement phases. Digestion of fibronectin and collagen further potentiates macrophage activation and release of additional mediators of fibroplasia and angiogenesis, such as nitric oxide, which is essential for granulation tissue synthesis.[3,4] Macrophages recruit lymphocytes, which release lymphokines (interleukins and interferons) responsible for further reactivating macrophages, to ensure adequate levels of molecular mediators and vasoactive peptides throughout the proliferative phase.

Granulation Tissue – Production and Functions

Granulation tissue is composed primarily of fibroblasts, capillaries, macrophages, and collagen.[3,4,10] and appears in the wound between three and six days after commencement of healing.[5] Granulation tissue provides a mechanical barrier against microbial infection of the wound and a biologic barrier owing to the presence of granulocytes and macrophages on its surface.[3] It is also a source of collagen, which is required for wound repair and remodeling. Granulation tissue brings about wound contraction and serves as a foundation across which epithelial migration takes place.[4]

Fibroblasts are a predominant component of this stage of healing and a major constituent of granulation tissue. Sources of wound fibroblasts include pericytes and undifferentiated perivascular mesenchymal cells found in connective tissue.[4,6,8,9,11] Under the influence of factors such as PDGF, epidermal growth factor (EGF), FGF, IGF-1, and TGF-β, this quiescent cell population becomes activated, proliferates, and develops cytoplasmic extensions called ruffled membranes.[9] Fibroblasts secrete IGF-1, β-FGF, TGF-β, PDGF and keratinocyte growth factor (KGF).[4] Contact guidance, haptotaxis,[8,10] chemotaxis, and the use of ruffled membranes assist fibroblast movement along the fibrin meshwork

within the wound.[4,8] As fibroblasts repopulate the wound bed, they continue synthesizing intercellular matrix constituents, including fibronectin, proteoglycans, collagen, and elastin.[4,8]

Neovascularization

The second component of the repair stage is neovascularization. Endothelial cell proliferation and subsequent migration occur in the presence of interstitial matrix or the absence of an intact basement membrane, resulting in capillary buds sprouting from pre-existing venules.[3,4,6,10] and capillary loop formation.[8,10] Once canalized, blood

flow begins and circulation is established. New blood vessels grow at an approximate rate of 0.4 to 1.0 mm per day. In vitro studies have demonstrated that endothelial cells cultured on collagen types IV and V, the components of basement membranes,[8,12] form tubular structures instead of confluent monolayers, which are observed when cells are cultured on collagen types I and II.[8] Capillary buds that do not form lumens regress.[3,4,6] Lymphatics, although much slower to re-establish, follow a pattern similar to that of the capillaries and, therefore, lymphatic drainage during the early phases of wound healing is inadequate, contributing to edema formation.[3,4,8]

Wound pH and oxygen are important factors for fibroblast function and neovascularization. Optimal collagen synthesis is achieved when the microenvironment of the wound maintains a mildly acidic pH.[8] Oxygen tension at the wound periphery is almost 90 mm Hg, whereas in the center of the wound bed it falls to almost zero.[2,11] Under these hypoxic conditions, glycolysis–derived energy is sufficient to initiate fibroplasia. However, to sustain collagen production, molecular oxygen is vital for post-translational hydroxylation of proline and lysine moieties and cross-linkage of collagen fibrils.[11] Twenty mm Hg appears to be the critical oxygen tension for fibroplasia and

collagen synthesis;[8,9] however, another report suggests that oxygen tension below 40 mm Hg impairs fibroplasia.[11]

Despite its deleterious effects on wound healing, a hypoxic environment and the oxygen tension gradient act as a stimulus for fibroblast mitosis, angiogenesis, and sustained secretion of growth factors from macrophages.[3,4,11] An oxygen tension gradient is a prerequisite for neovascularization.[8]

Angiogenic growth factors include PDGF, vascular endothelial growth factor (VEGF), tumor necrosis factor (TNF), and endothelin-1.[2,11] Upregulation of these angiogenic

factors in endothelial cells increases cellular mitotic activity and thereby promotes neovascularization. Endothelial cells demonstrate a phenomenon called dynamic reciprocity, whereby they respond to environmental influences, such as cellular and chemical signals, and are capable of transforming their environment to induce changes beneficial to wound healing.[11]

As healing progresses, early components of the process regress as repair components increase. Fibrinolysis by plasmin disrupts the clot in the wound bed.[4] Gradually, neutrophils and lymphocytes are cleared from the wound by apoptosis

or phagocytosis by macrophages. Fibrin, proteoglycans, tropocollagen, and protocollagen are substituted by collagen fibrils synthesized by the wound fibroblasts.

Collagen is a major component of granulation tissue.[10] Fibroblasts, under the influence of TGF-α and -β, EGF, PDGF, β-FGF, IL-1, and TNF, synthesize collagen fibrils and the viscoelastic extracellular matrix.[9,12] Collagen biosynthesis is a complicated process that involves gene transcription and translation, intracellular, intercellular, and extracellular transformation, and fibril assembly and cross-linkage.[12] Collagen includes two specific amino acids, hydroxylysine and 4-

hydroxyproline.[12,13] These amino acids, along with glycine, form alpha peptide chains. These alpha peptide chains are intertwined to form a triple helix.[2,6,12,13] which is further convoluted to form a supercoiled helix.[13] Galactose is added to the superhelix before being extruded from the fibroblast as procollagen, which is further cleaved to produce tropocollagen.

Increase in wound strength is due to collagen deposition and collagen maturation. Tropocollagen is aggregated and cross-linked to produce collagen filaments. Collagen filaments are cross-linked to form collagen fibrils, which, when cross-linked

together, form collagen fibers. On maturation, collagen type III becomes collagen type I[3,4,6,10] which as it matures and reorients within the wound increases the tensile strength of the wound.[4] In the first 2 weeks of wound healing, fibroblasts, fibrin, and collagen are vertically arranged between the wound edges, and the increase in tensile strength of the wound is due to an increase in collagen deposition.[9] In the late repair stage, the fibers are aligned horizontally.[3,4,8] Early strength of the wound is attributed to its collagen content, whereas late wound strength is associated with collagen type, maturation, and three-dimensional remodeling. As the collagen content of

a wound increases, collagen synthesis balances collagen lysis. Extracellular proteoglycan matrix decreases proportionately as collagen increasingly occupies space.[4] This signals the beginning of the maturation phase.

Wound Contraction

Granulation tissue also contributes to wound contraction. Wound contraction is the centripetal force by which a wound achieves a reduction in size,[3,4,6,10] which may or may not culminate in complete wound closure. This phenomenon is especially important in open wound healing. Wound contraction does not involve

synthesis of new skin, but rather centripetal movement of skin around the wound.[4,10]

One theory on wound contraction states that a sub-population of fibroblasts from the granulation tissue develop a higher percentage of actin-rich fibers, thereby transforming them into myofibroblasts.[2] These fibers are called stress fibers and contain myosin and tropomyosin.[8] TGF-β is thought to play a role in differentiation.[3,4,10] This response is an attempt to counteract by the inherent elastic nature of skin the retractive forces exerted by the wound edges.[4,10] Fibronexus is the interconnection between myofibroblasts and extracellular

matrix. It plays a role in mediating wound contraction by reorienting the ground substance.[8] Additionally, fibronexus links myofibroblast stress fibers with collagen via fibronectin.[8]

A second theory on wound contraction suggests that regular fibroblasts use cell membrane tractional forces to reorganize and rearrange collagen fibrils.[4,6,10] As the fibroblast traverses the collagen, the cell membrane pulls collagen fibrils toward the center of the wound. This is best explained by the "toy tank moving over loose carpet" comparison.[4,10] This process is enhanced by PDGF, which stimulates extracellular matrix contraction, whereas FGF and IFN-γ inhibit the

process.

Wound contraction is terminated by contact inhibition, that is, when one edge of the wound meets the other or when tensions exerted by skin elasticity at the wound edges and fibroblasts and myofibroblasts within the wound are equal.[4,10] The number of myofibroblasts present in any wound is proportional to the size of the wound and the tension on the wound edges; large, open wounds demonstrate higher numbers, whereas wounds that have undergone primary closure have significantly fewer myofibroblasts.[9]

Epithelialization

Epithelialization protects against external infection and fluid loss.[3] For epithelialization to occur, the wound must be free of infection and must maintain a moist, oxygen-rich microenvironment.[8] Epithelialization occurs independently of wound contraction and, in open wounds, occurs after granulation tissue has been laid down, i.e., after a lag phase of four to five days;[4] whereas in closed-wound healing, it begins almost immediately and is complete within two days.

Epithelial cells are influenced by β-FGF, EGF, IL-1, PDGF, and TGF-α and β. When up-regulated, these factors induce accelerated mitotic activity of

epithelial cells. Mitotic activity and migration are not interdependent factors.[8] Epithelial cells develop microvilli within cell membranes. They then extend pseudopodia that facilitate migration.[3] Two theories elucidate epithelial migration. One theory proposes that desmosomal and hemidesmosomal attachments of basal epithelium to the basement membrane and adjacent epithelial cells at the wound edge are lost, thereby promoting migration of cells across the wound bed in monolayers.[2,3] This is known as the sliding theory.[4,8] The second hypothesis is called the leapfrog theory. This states that basal epithelial cells at the wound edge migrate on to the granulation tissue and implant.

The epidermal cells just behind them migrate over the newly implanted epithelial cells and attach once they contact granulation tissue.[4,8] Epithelial migration is terminated by contact inhibition and desmosomal attachments are re-formed.[3,4,8] Epithelial cells also possess phagocytic activity, which is potentiated by fibronectin. This facilitates epithelialization over the wound bed under the scab or through wound exudate.[8]

Maturation/Remodeling Stage

Early wound strength increases as quickly as within the first 24 hours of

wounding. The fibrin clot is the first contributor toward wound strength; however, strength does not reach a significant degree until 6 days.[4] Between days 5 and 15, continued deposition of collagen fibrils is reflected in a gain in wound tensile strength.[9] As healing progresses, extracellular matrix, collagen fibrils, capillary growth, and adhesive forces of epithelial cells add to building early wound strength.

Late wound strength starts only after wound healing has continued undisturbed for at least 21 days.[4] Once the rate of collagen synthesis is on par with that of collagen lysis, collagenases and matrix

metalloproteinases digest extraneous material and preserve appropriately oriented collagen fibers. Collagen type III is replaced by collagen type I, which increases the tensile strength of the wound. As maturation progresses, the newly formed collagen bundles and the preexisting dermal collagen coalesce such that differentiation between the two is extremely difficult. No matter how complete the wound healing or how minimal the scar formation, it is always about 20% weaker than the adjacent uninjured tissue.[3,4,11]

As practitioners and their clients observe wound healing progress, certain visible processes will appear

that have significance as to what is occurring. These can be helpful to the practitioner in explaining wound healing to the client and in management of the wound (Table 61-1).

Table 61-1. Clinical Relevances of the Visible Wound Healing Process

Process	Relevance
Wound hemorrhage	May help cleanse the wound of foreign material and toxins.
Wound edge retraction	A wound may appear larger than it actually is. Manipulate the edges to ascertain if tissue is absent, and to get an idea of what will be required for reconstruction.
Blood clot/scab	Provides a scaffold base for granulation tissue formation. Scab is a surface beneath which healing occurs.
Exudate, hyperemia, heat, edema, pain	Necessary parts of the inflammatory- debridement stage. Often wounds will appear (look and smell) worse before they start to improve (repair). Often at its peak at 3-5 days after wounding.
Granulation tissue	The first visible sign that the wound is progressing into the repair stage.
Wound contraction	A "friendly" process on the trunk of a dog and cat. Some large wounds may heal completely by this process. Weekly tracing on clear acetate can monitor its progress.
Epithelialization	Provides a temporary wound cover while contraction occurs. Indicates a granulation tissue bed is healthy enough to graft (if grafting is indicated). Provides poor durability if it is the final cover for a wound (reconstructive surgery is indicated).

Conclusion

The physiology of wound healing is an intricately woven, delicately balanced process involving fine-tuned communication between cellular players and various cytokines, vasoactive peptides, and chemical signals. The process of wound healing can be compared to the performance of a symphony orchestra. When each instrument plays its part in conjunction with other instruments at the appropriate time, beautiful music is the result. The same is true of wound healing. When each component performs its function in conjunction with other components at the proper time, uncomplicated wound healing

takes place. The slightest upset of this fine-tuned equilibrium is capable of impairing it. Although we have come to learn so much about wound healing, more discoveries await around the corner.

Chapter 62

Burns

Mark W. Bohling
Steven F. Swaim

Small animal burn injuries can be some of the most challenging cases that the veterinarian will be called upon to manage, and a thorough understanding of the pathophysiology of burn injury is crucial to maximizing the chance of successful treatment. Fortunately, our knowledge of burn pathophysiology has greatly increased in the past decade, and much of this

knowledge has already been put into practice in the clinical management of burn cases. As with many other areas of veterinary medicine, much of the clinical and basic science literature comes from human medicine, and this chapter draws heavily from those resources. For purposes of clinical application, it is fortunate that many advances in the treatment of human burns are based largely on data derived from animal experimentation, in which the dog is a common model. This fact gives relevance for veterinary application of the human literature; however, care must still be exercised in the interpretation and application of the human literature to animals owing to the important anatomic and

physiologic differences between humans and animals. This chapter reviews historical and recent advances in the understanding of burn pathophysiology and identifies areas for application of this information to the clinical management of burns in small animal practice.

Classification of Burn Injuries

Burns are classified into one of four types based on etiology:[1,2] *Thermal burns* are caused by exposure to temperature extremes (either high or low) sufficient to cause cellular damage. *Chemical burns* are caused by exposure to chemicals that cause tissue

necrosis via chemical reactivity or thermal effects. *Electrical burns* are suffered when electrical current of sufficient amperage and voltage to cause cell death passes through the patient. *Radiation burns* are caused by exposure to ionizing radiation at levels that cause acute cell death; this injury is most commonly seen either from exposure to solar radiation, or as a side effect of radiation therapy for neoplastic disease, and will not be specifically discussed in this chapter. Knowledge of the source of the burn and the mechanism by which it inflicts injury is vital to the proper initial care of the burn patient; e.g., copious lavage for many chemical burns, rapid cooling of tissues exposed to high heat,

gentle rapid rewarming of frozen tissues, etc.

With few exceptions, the primary organ system involved is the integument. Some types of burn injuries, notably chemical, electrical, and radiation, may have gastrointestinal or other primary sites of injury, and thermal burns that primarily involve the integument often have systemic effects, but the skin is normally the first and most important site of injury because it is usually the location where the initial damage occurs that leads to systemic sequelae and, therefore, is the focus of most of the investigation in burn pathophysiology and therapeutics.

Thermal Burns

Technically, thermal burns include injuries caused by exposure to either excessive heat (hyperthermic burns) or excessive cold (hypothermic burns). In this chapter, the use of the term "thermal burns" will deal with the former, whereas the term "frostbite" will be used for the latter. Thermal burns are subclassified according to the heat source, i.e., a flame or fire, scalds from hot liquids or gases, and burns from direct contact with a hot object.[3] Thermal burns occur when heat is transferred to the tissues in one of three ways: via conduction, convection, or radiation. Conduction is the most common source of thermal

injury and occurs when the body is in direct contact with a hot object such as a heating pad or boiling water. Convection is the transfer of heat via airborne currents, such as the superheated air that comes from a fire. In radiation burns, energy in the form of electromagnetic radiation travels through the air until it strikes the body and is converted into heat; heat lamps can produce burns via this process.[1] Burn severity has historically been classified according to the depth of tissue destruction; this classification system has proven useful for treatment planning and prognostication. *Partial-thickness* burn injuries can be divided into two categories. *First-degree* burns are superficial injuries involving only

the epidermis, with erythema as the only observable change. Because the dermis is not involved, skin integrity is maintained, with no blistering or open wounds, and rapid, scar-free healing occurs without medical intervention. First-degree burns are painful, because nociceptors in the epidermis are stimulated at the time of the injury. *Second-degree* burns are partial-thickness injuries of the skin that involve the dermis. In addition to pain and erythema, these injuries are characterized by blister formation and exudation of fluid (note: blisters are common in humans, but rare in dogs and cats owing to differences in dermal histologic structure). Partial-thickness burns can vary from

superficial to deep, but at least some of the dermis and adnexa survive the injury so that scarring is usually absent. Complete healing usually requires 2 to 3 weeks in uncomplicated cases. Full-thickness burns can be further divided into three categories. *Third-degree* burns extend through the skin to the level of the subcutaneous tissues; some classification schemes recognize two further categories; *fourth-degree* burns, extending to the underlying muscle, and *fifth-degree* burns involving bone.[2] Depth of tissue destruction is directly proportional to factors that concentrate heat in the area of the injury; i.e., temperature to which the tissue is heated, and duration of exposure or contact.[4]

Failure of cellular function and tissue necrosis follow a predictable progression as the temperature of the skin increases. Between 40 and 44°C cellular enzymatic activity is affected, resulting in sodium pump failure. Epidermal sloughing (partial-thickness burn) results if skin is heated to 60°C for more than 1 second, and skin temperatures above 70°C produce full-thickness burns.[5]

Local Response to Thermal Burn Injury

The local burn injury has been divided into three functional and anatomic areas; moving outward from the center of the burned area, the innermost area

is the *zone of coagulation* (also known as the zone of necrosis or destruction). Complete loss of tissue viability occurs within this zone; the therapeutic goal in this area is debridement. The next area is the *zone of stasis*; in this area, heat-induced changes in erythrocytes reduce their deformability and reduce their ability to flow through microscopic vessels. This is compounded by reduction in microvessel luminal area owing to increased extraluminal pressure from tissue edema brought about by inflammation and subsequent increase in capillary permeability. The increase in local capillary permeability in response to burn injury is not an all-or-none phenomenon, but rather is a

graded response based on the severity of the injury. In a scalded canine hindlimb model, the capillary permeability, as measured by local lymph flow and protein content, increased with increasing scald temperature.[6] Taken together, these changes cause sluggish blood flow and tissue hypoxia; in this intermediate zone, tissue either proceeds to necrosis or healing depending on further insults sustained and/or the effectiveness of treatment, making this area the principle focus of burn therapy. Finally, the outer *zone of hyperemia* is the area of the local inflammatory response to the burn. Tissue in the zone of hyperemia remains viable and will proceed to healing if no further

insult is sustained.[7]

The local response to burn injury is similar to that of other inflammatory lesions, and is characterized by local vasodilation, an increase in vascular permeability, edema, and migration of inflammatory cells into the injured area.[8] The burned tissue and resident inflammatory cells at the time of injury are the primary source of chemokines that initiate the inflammatory response, including endotoxin,[9] prostaglandin E_2,[10] histamine, and activated complement.

Immediately after thermal injury, an upregulation of blood flow to the burned area occurs. Administration of

the autonomic blocker hexamethonium ablates this response, indicating that this regional arteriolar vasodilation appears to be at least partly under postganglionic autonomic control.[12] Local upregulation of nitric oxide (NO) production also plays an important role in the regional vasodilatory response to burn. Several studies have demonstrated an increase in NO production in thermally injured tissue,[13] and in the surrounding nonburned skin as well.[14] NO is well known as a potent vasodilator that increases blood flow in local tissue beds in response to a variety of inflammatory stimuli including burns. NO has been demonstrated to act directly and also indirectly, by

potentiating the release of other vasodilatory molecules such as substance P.[15]

Vascular permeability also increases in the periwound tissues after burn injury. The increase in permeability is mediated by the activation of the inflammatory cascade and is a graded phenomenon, i.e., transvascular flux of fluid and protein is directly proportional to the severity of the burn.[6] Increased vascular permeability, coupled with increased blood flow, leads to burn wound edema. Extravascular migration of neutrophils is partly a consequence of increased vascular permeability and partly mediated via direct effects on

neutrophil diapedesis. Expression of the adhesion molecules CD11b/CD18 and adhesion to vascular endothelium are enhanced in neutrophils that are incubated in the presence of burn serum; this effect is blocked by the administration of monoclonal antibodies to the adhesion molecules.[16]

Interestingly, burn wounds seem to lack the ability of normal surgical wounds to stimulate their own healing. When angiogenic activity of wound fluid from surgical wounds, skin graft (donor) wounds, and burn wounds was compared, burn wound fluid was found to be completely lacking in ability to stimulate endothelial cell migration or proliferation, and contained less than

5% of the levels of fibroblast growth factor-2 (FGF-2) of surgical wound fluid.[17]

Most of the interest in the local burn response concerns the acute post-burn period, because so many life-threatening side effects begin with the acute burn wound. For those patients that survive, the burn wound enters a chronic stage that may result in wound healing problems as the skin attempts repair. In first- and second-degree burns the epidermis may be damaged but the basement membrane remains intact, and skin healing is generally rapid and uncomplicated. Third- and higher-degree burns present a problem, because necrosis of the dermis means

that the overlying basement membrane is gone. The basement membrane is a necessary surface to direct the migration of stem cells onto the wound from the stratum basale of the surrounding unburned skin. As with any injury involving loss of the basement membrane, healing is by scar formation as fibroblasts enter the wound and lay down a collagenous matrix. Two chronic pathophysiologic processes that may affect burn wounds in small animals are scar contracture and post-burn blistering.

Wound contraction is the process by which motility of fibroblasts and myofibroblasts within the matrix exerts force that reduces the open wound

area. This is a generally beneficial process, especially in dogs and cats that have more abundant skin on the body. It reduces the amount of tissue exposed to dehydration and contamination, and it stops when the burn is completely covered with new epithelium.[18] In contrast, *scar contracture*, although involving the same underlying mechanisms, is considered a pathologic process because it continues after the wound has been epithelialized.[18] Scar contracture results in pain and loss of mobility, and can be particularly debilitating when it is extensive or occurs over a joint or in an area with minimal skin mobility.[19] The degree of contracture appears to be proportional

to the amount of scar tissue; therefore, prevention of contracture is directed toward prevention of excessive scar formation. Treatment of contracture is accomplished by surgical excision of the existing scar and application of a graft or flap to the resultant defect.[20]

Post-burn blistering is a relatively common complication in human burn patients.[21] Although uncommon in animals, we have also observed this phenomenon in a dog. After a large burn wound has healed by second intention, blisters may spontaneously appear, rupture, and heal in a continuous cycle. Immunohistochemical and ultrastructural analysis of the blisters

reveals that the basement membrane displays areas of discontinuity and detachment from the dermis.[22] One hypothesis is that defective reorganization of the basement membrane may be associated with observed ultrastructural aberrations of dermal fibroblasts.[23]

Systemic Response to Thermal Burn Injury

Pulmonary System

The most important and far-reaching effect of thermal burn injury on the pulmonary system is from smoke inhalation.

Smoke inhalation occurs commonly as

an intercurrent injury with thermal burn. Besides the often serious and even fatal local (pulmonary) effects, smoke inhalation also profoundly exacerbates the systemic sequelae of burn injury. The pathophysiologic response of the lung to smoke inhalation can be divided into several components: pulmonary edema, atelectasis, increased alveolar pressure, and deactivation of pulmonary surfactant.[24] These highly interdependent events combine to lead to the development of the acute respiratory distress syndrome (ARDS) that is one of the major complications of burn injury.[25]

The etiologic agents of smoke

inhalation injury are numerous and interrelated, and include cytokines, eicosanoids, activated neutrophils, nitric oxide (NO), free radicals, and neurotransmitters such as substance P.[26,27] Three major sources of cytokines appear to be involved in the cytokine-mediated pulmonary injury and dysfunction following a burn. The first source is cytokines released from the burned tissue; the second source is the lung, which has been damaged by smoke inhalation; the third is the intestinal tract, which conveys cytokines to the lungs via the mesenteric lymphatics. These cytokines appear to act synergistically with bacteria and endotoxin to maximize increases in pulmonary vascular

permeability and apoptosis of alveolar cells.[28]

Pulmonary edema begins to develop soon after smoke inhalation, as fluid, mucus, and neutrophils accumulate within alveoli and airways.[29,30] The eicosanoid thromboxane A2, synthesized and released from pulmonary tissue in response to smoke inhalation, plays a major role in the pathophysiology of smoke inhalation. Increased pulmonary lymph concentration of thromboxane A2 post-smoke exposure is associated with a parallel increase in pulmonary transvascular flux and vascular resistance, both systemic and pulmonary. The increased pulmonary

vascular resistance appears to be primarily caused by an intense but transient venoconstriction.[24] Inhibition of thromboxane A2 with a thromboxane A2 synthase inhibitor significantly attenuates these changes.[29]

Nitric oxide (NO) is another systemic mediator of inflammation that is involved in pulmonary edema after burn injury.[31,32,26] Significant increases in NO in plasma and pulmonary lymph are seen within 24 hours post-burn owing to upregulation of inducible NO synthase and are associated with increases in pulmonary microvascular permeability, cardiac depression, and hemoconcentration.[32] NO appears to

affect vascular permeability differently between species: in an ovine model, leakage of fluid increased while protein flux remained at normal levels,[33] while in the rat, transvascular albumin flux increased by 100%. Pulmonary compliance also decreases after a burn; this effect is caused partially by pulmonary edema and partly by reduction in production of pulmonary surfactant.[34]

Part of the complexity of smoke inhalation injury stems from the complex chemical composition of the inhaled smoke. Most burned small animals with smoke inhalation are exposed in an indoor environment such as a house fire. The smoke from house

fires contains over 200 toxic substances.[35] Principal among these are carbon monoxide (from incomplete combustion of wood), hydrogen cyanide (from combustion of nitrogen-containing products, i.e., nylon, formica, melamine, wool), and inorganic acids HCl, HF, and HBr (from polyvinyl chloride, teflon, neoprene, and various plastics). Carbon monoxide toxicity occurs via three mechanisms: 1) binding to hemoglobin and reducing its oxygen carrying capacity; 2) carboxyhemoglobin formation, which results in a leftward shift of the oxyhemoglobin dissociation curve, reducing oxygen delivery to the tissues; and 3) binding with myoglobin to

reduce oxygen availability to muscle, especially cardiac and skeletal. Hydrogen cyanide binds with mitochondrial cytochrome oxidase, thereby preventing oxygen utilization by cells. Hydrogen chloride and the other diatomic halide acids are all intensely irritating to respiratory mucous membranes, producing laryngospasm and bronchospasm at concentrations found in smoke.[36] Smoke inhalation also causes a dose-dependent injury to tracheobronchial epithelium and lung parenchyma via free hydroxyl and carbon radicals contained in the smoke and also via the accompanying neutrophilic infiltration.[35]

Cardiovascular System

Hypovolemia and Vascular Dysfunction

Loss of fluid volume from the vascular space is one of the early pathophysiologic changes seen with severe burns. Within 10 minutes after a burn, systemic vascular permeability to fluid and albumin increases, via myosin-mediated contraction of vascular endothelial cells, which increases the intercellular gap size in the endothelium.[37] Direct damage to endothelial cells, mediated by complement activation, histamine, and oxygen free radicals from the burn site,[11] exacerbates the process and causes further interstitial edema and

loss of vascular fluid volume.[38]

The burn wound is another source of fluid loss via evaporative losses that are 4 to 20 times greater than for normal intact skin.[39] These losses can constitute a significant source of the fluid loss that leads to hypovolemia in large burns. The cumulative effect of hyperpermeability and fluid loss is to create profound hypovolemia within the first few hours after a large burn. Hypovolemia and reduced RBC deformability combine to cause hyperviscosity of the blood. This problem is compounded by systemic vasoconstriction, which is mediated by the sympathetic response to baroreceptor and nociceptor

afferents[40,41] and is proportional to the severity of the burn.[42,43] The combined effects of hypovolemia, hyperviscosity, and vasoconstriction in turn lead to hypoperfusion and metabolic acidosis.[44,45]

Myocardial Effects

Direct myocardial effects also constitute a portion of the pathophysiology of burn shock. Left ventricular contractility was significantly decreased during the 6-hour post-burn observation period in dogs after a 50% total body surface area burn.[46] This impaired contractility is paralleled by a significant increase in intracellular Ca++ of cardiac

myocytes.[47] At least a portion of this post-burn myocardial Ca++ influx and contractile dysfunction is mediated via the increased translocation of gut bacteria, endotoxin, and cytokines, and the ensuing systemic inflammatory response syndrome.[48] In one experiment, depopulation of the gut with oral antibiotics reduced post-burn myocardial levels of TNF-α and other cytokines and improved myocardial contractility.[49] Increased sympathetic input is another stimulus that causes cardiomyocytes to synthesize and release increased levels of TNF-α and other cytokines, resulting in defects in cardiac contraction and relaxation.[50]

Smoke inhalation also causes decreased

cardiac output[51,29] and myocardial damage via the toxic effects of carbon monoxide, which decreases myocardial oxygen delivery and utilization. In a canine model, smoke inhalation caused an increase in carboxyhemoglobin, decreased ATP production by cardiomyocytes, and zymographic and histopathologic evidence of myocardial necrosis.[52]

Gastrointestinal System

The GI system can be profoundly affected by large burns, and in turn, is a major effector organ for the syndrome of shock, sepsis, and multiple organ failure that follows severe burns. Studies have

demonstrated that, after a severe burn, loss of GI barrier function occurs, with translocation of gut bacteria, endotoxin, and cytokines, leading to septic shock.[53-56] Burn injury has been demonstrated to increase the rate of apoptosis of gut mucosal cells, with no effect on mucosal proliferation; this may be an important aspect of the loss of GI mucosal integrity seen after burns.[57] Post-burn GI motility is also impaired via a nitric oxide-dependent mechanism; inducible NOS expression by neurons of the myenteric plexus appears to play a significant role.[58]

The liver is also affected by burn injury. Burns cause increased oxidative stress in hepatocytes, marked by a

decrease in liver glutathione level and increases in malondialdehyde (MDA) and myeloperoxidase (MPO) activity at 24 hours post-burn.[59] Hepatocyte turnover is also increased post-burn, as demonstrated by increases in both apoptosis and proliferation.[60] Liver synthetic function is also affected. Upregulation of certain products such as acute-phase proteins and downregulation of others has been noted by 3 days post-burn.[61]

Renal System

The incidence of acute renal failure in seriously burned human patients ranges from 1.3% to 38% and is associated with a high mortality rate,

between 73% and 100%.[62] Burn severity (as percentage of total body surface area) is an independent predictor of the likelihood of acute renal failure and associated mortality.[63] A number of contributory factors including hypotension,[63] hypoalbuminemia,[63] hemoglobinemia, myoglobinemia,[63] sepsis,[63,64] reduced cardiac output, and systemic vasoconstriction have been identified, with elevated levels of stress hormones (catecholamines, vasopressin, angiotensin, and aldosterone) implicated in the mechanism.[65] Atrial natriuretic peptide (ANP), which is also elevated in post-burn patients, may play a protective role by increasing renal blood flow and urine output.

Dogs receiving a constant norepinephrine infusion responded to exogenous ANP administration with improvement in renal and hemodynamic parameters.[65]

Acute renal failure may also develop as a late consequence of burn injury. The etiology is thought to be multifactorial, including late effects of renal ischemia, sepsis, nephrotoxic effects of antibiotics or other drugs, and renal glomerular deposition of proteins such as hemoglobin and myoglobin and other cellular debris from necrotic cells.[1,64]

Hematologic Responses

Burn injury produces an immediate and long-lasting reduction in circulating erythrocyte numbers. This so-called “burn anemia” results from increase in red cell loss coupled with decreased erythropoiesis. Up to 10% of the circulating red cell mass may be trapped and destroyed in a large burn,[66] but this only accounts for a portion of the total red cell losses – human burn patients average 12% loss of red cell mass within 6 hours of a large (15 to 40% TBSA) burn and may lose up to 18% of their red cell mass within 24 hours.[67] Within 1 hour of a burn injury, plasma free hemoglobin levels increase. Increased hemolysis occurs owing to a combination of factors. First, increased osmotic

fragility appears to be caused by damage to the RBC membrane from activated complement, neutrophils, and oxygen free radicals.[68] Second, a decrease in erythrocyte deformability is caused by oxidative stress and subsequent lipid peroxidation of the red cell membrane.[69,70] In spite of the loss of RBC mass, which stimulates an appropriate elevation in erythropoietin release from the kidneys, erythropoiesis is nonetheless depressed.[71,72] Reduced erythropoiesis appears to be caused by an erythroid inhibitory protein[73] and as a secondary effect of decreased iron availability.[72] Administration of supplemental exogenous erythropoietin helps restore red cell mass after a burn.[74]

Burn injury also produces significant negative effects on leukocyte production and function. For example, lymphoid apoptosis is upregulated after burn injury, and may be linked to a parallel upregulation of TNF-α.[75] Burn injury also caused a downregulation of chemotactic cytokine production by mouse T cells, resulting in increased susceptibility to sepsis. This effect appears to be mediated via the sympathetic nervous system. Chemically sympathectomized mice had normalized cytokine production and improved resistance to sepsis. In vitro, T cells from burned mice or from normal mice treated with norepinephrine also demonstrated reduced cytokine production.[76]

Neurologic System

Effect of Pain on Burn Wound Response

Burns cause intense pain; even full-thickness burns, in which cutaneous nociceptors are destroyed, can still be painful because the full-thickness burn is surrounded by tissue that is damaged but not completely destroyed.[77] In this area of damaged tissue, peripheral nociceptors are activated by the burn injury, sending afferent input along A delta and C fibers.[78] Cellular damage and the ensuing inflammatory response also cause the release of chemical mediators of pain (kinins, prostaglandins), which further sensitize local nociceptors, causing a

hyperalgesic state.[77] The intense pain stimulates a massive sympathetic discharge, which in turn drives many of the cardiovascular changes of burn shock. Even after the initial burn shock has been treated, chronic pain in burn patients continues to stimulate a chronic, albeit lower level of catecholamine release that mediates a number of the metabolic and organic derangements seen in burn patients.[78]

Other Neuromodulators of the Burn Wound Response

Besides the modulation of burn pain and its secondary effects, the peripheral nociceptor system is also involved in the initiation of the local

inflammatory response to burn injury through its effect on vasomotor tone and chemotaxis of inflammatory cells. Scald injury of the rat hindpaw induced release of substance P and calcitonin gene-related peptide (CGRP) from peripheral sensory neurons. Both of these substances induced vasodilation in the injured tissue. In addition, neuropeptides have been demonstrated to induce chemotaxis and activation of neutrophils, eosinophils, mast cells, and monocytes following tissue injury,[79] and have been demonstrated to play a role in the development of ARDS following smoke inhalation.[27]

Metabolic and Endocrine Changes

Burn injury induces profound changes in energy and protein metabolism. These changes are initiated by two primary events: local effects, i.e., release of pro-inflammatory cytokines (TNF-α, IL-6, IL-8) and oxidant stress from cell lysis, and systemic effects from increased release of catabolic hormones (primarily cortisol and catecholamines).

Post-burn metabolism follows a biphasic course. There is a period of hypometabolism immediately after injury (the “ebb phase,” which occurs during the shock), followed by a

hypermetabolic state (the "flow phase"), during which basal energy expenditure increases by over 100% compared with pre-burn.[80,81] This change is caused by several conditions at the local and systemic levels. Loss of the barrier function of skin means that large amounts of body water are lost to evaporation; along with the water loss, significant heat is lost as the heat of evaporation. The hypothalamic "set point" is also elevated post-burn by 1 to 2°C in response to the release of cytokines and eicosanoids as part of the inflammatory process. The energy "cost" of this increased thermogenesis is paid via increases in non-productive metabolic work that consumes energy and produces heat. For instance, there

is a 450% increase in triglyceride-fatty acid cycling and a 250% increase in glycolytic-gluconeogenic cycling in post-burn patients.[82]

Protein and carbohydrate metabolism are also altered in the post-burn state. Amino acid utilization for energy production is increased, producing a decline in lean body mass as body protein is catabolized. This negative energy and nitrogen balance differs significantly from that of simple starvation. In simple starvation, body adipose stores supply 90% of the basal energy requirement, and lean body mass accounts for only 5% to 8% of the body's energy needs. In the postburn state, relative insulin

resistance caused by increased catabolic hormones (glucagon, cortisol, and catecholamines) results in a completely different energy consumption profile, in which only 50% of the body's energy needs are supplied by adipose tissue and lean body mass accounts for 30%.[83] Upregulation of hepatic gluconeogenesis and relative insulin resistance results in a persistent hyperglycemic/catabolic state marked by glucose intolerance and hyperinsulinemia, with reduced rate of glucose extraction by peripheral tissues (muscle, fat, etc.). Increased glucose uptake is limited to the burn wound, which has a high energy requirement for anaerobic glycolysis by

inflammatory and endothelial cells and fibroblasts.[82] This so-called "burn diabetes" is a serious complication of burns in both the acute and chronic stages, as prognosis deteriorates with increasing loss of lean body mass.[83]

Application of Burn Pathophysiology to Treatment

The treatment of human patients with burns over a large percentage of the body surface area has gone through an interesting progression. Initially, the entire focus was on the burn site, and various bandaging, enzymatic, and other local treatments were developed for non-surgical debridement. The

problem with the local therapy focus was that a high percentage of patients died of systemic complications of their burns, so attention was turned to developing treatments for burn shock and the other systemic complications of burn injuries.

More recently, the focus of treatment for patients with large full-thickness burns has once again turned to the local site, as the connection between the burned area and systemic pathophysiology has become clear. Today, large full-thickness burns are treated by complete surgical excision of the burn eschar as soon as the patient can be made stable enough for surgery. The benefit of this strategy is

obvious: the burn eschar is the stimulus that drives the inflammatory reaction, leading to the entire cascade of local and systemic events described above. Early complete escharectomy removes this stimulus and effectively converts the burn - a major physiologic threat - into a comparatively benign, large, clean, open wound. Systemic post-burn levels of endotoxin and E-selectin (but not TNF-α or interleukin-10) were significantly reduced at 1 and 3 days after escharotomy in human burn patients.[9]

In one clinical study of severely burned children, administration of the anabolic agent oxandrolone improved net nitrogen balance, lean body mass,

and expression of genes for muscle protein synthesis when compared with controls.[84]
