Early enteral feeding has been demonstrated to ameliorate some of the GI effects of burns. By reversing the increased rate of apoptosis seen in mucosal epithelium after burn injury, early enteral feeding helps to maintain mucosal integrity.[57] This may be particularly important owing to the connection between loss of mucosal integrity and post-burn septic shock.

Frostbite

Frostbite may be seen when animals suffer lengthy exposure to cold, especially those that are injured or

debilitated. Under these conditions, the extremities are most often affected, particularly the pinnae[85] and digits. The flank folds are also predisposed to frostbite owing to the extreme thinness of the skin in this region. Frostbite may also be encountered as an iatrogenic condition when cryotherapy is delivered improperly.[86] Three pathophysiologic mechanisms cause the tissue damage seen in frostbite: tissue freezing, hypoxia, and release of inflammatory mediators. These events occur simultaneously and work synergistically, as the pathologic changes caused by one exacerbates the others.[87,88]

Tissue freezing causes cell damage in

two ways. Freezing causes formation of ice crystals, both intracellularly and extracellularly. Initially, extracellular ice crystals damage the cell membrane, leading to disruption of the osmotic gradient and intracellular dehydration. As tissue temperature continues to fall, intracellular ice crystals form and expand, causing direct physical disruption of the cell membrane and cell death. Freezing also causes direct cell damage via denaturation of cell membrane lipid-protein complexes.[87,88]

Local hypoxia is induced by cold-induced vasoconstriction. Initially, as tissues cool, local vascular beds respond with alternating cycles of vasoconstriction and vasodilation, the

"hunting reaction."[87] Vasoconstriction causes decreased blood flow via decreasing vessel diameter; also blood viscosity increases. The vasodilatory phase brings partial thawing of frozen tissue and the reestablishment of blood flow. This is the freeze-thaw cycle that causes the greatest amount of tissue damage. After repeated cycles, vessel thrombosis occurs, leading to a continuous hypoxic state. The combined effects of direct cellular damage and tissue hypoxia stimulate the release of inflammatory cytokines (prostaglandins, thromboxanes, bradykinin, histamine) and activation of the inflammatory cascade, much the same as that seen in thermal burn injury. Activation of the inflammatory

cascade leads in turn to clotting activation and intravascular thrombosis, completing the "vicious cycle."[87,88]

Current concepts in frostbite treatment focus on taking advantage of knowledge of the mechanisms of injury. Treatment includes 1) rapid rewarming of the frozen tissues, but not under "field conditions" where re-freezing may occur and exacerbate injury; 2) fluid therapy to improve local circulation; and 3) NSAIDs to combat activation of the inflammatory and clotting cascades.[87]

Chemical Burns

Chemical burns occur either through

chemical reaction with cellular components, or via thermal effects when the chemical(s) in question produces an intense exothermic or endothermic reaction. The degree of tissue damage is proportional to the toxicity of the chemical, its quantity and concentration, and the duration of exposure.[1] Chemical burns tend to continue until the chemical in question is neutralized by reaction with tissue components (or by another externally applied chemical), or is washed off or sufficiently diluted during first aid treatment. Different classes of chemicals have different modes of tissue toxicity. Acids act as powerful oxidizing agents that disrupt protein structure and function by insertion of

oxygen atoms into peptide bonds. Alkalis are reducing agents that denature protein through reduction of amide bonds that crosslink polypeptide chains; these reactions can be intensely exothermic, causing simultaneous thermal burns. Hydrocarbons act as lipid solvents that disrupt the cytoplasmic membrane.[1] Vesicants are chemical agents that cause blistering; therefore, the definition for this group of compounds is a functional rather than chemical one.[89] One agent in this group, the chemotherapeutic agent doxorubicin, is of special interest and concern because of its common use in veterinary medicine and high level of tissue toxicity when extravasated during administration. The exact

mechanism of doxorubicin tissue toxicity is not known. One theory is that it may be a result of intercalation of doxorubicin with cellular DNA. Another theory is that enzymatic reduction of doxorubicin results in the formation of free radicals, which are the actual toxic constituents.[89] Doxorubicin is particularly toxic to tissues because, unlike many other chemical agents, it is not neutralized during the course of reaction with cellular constituents. Therefore, after doxorubicin causes cellular necrosis, it is released with the lysis of the cell and is able to continue its local tissue toxicity.[89] Current recommendations for doxorubicin extravasation include surgical excision, local injection with

hyaluronidase to promote vascular uptake of the drug, thereby diluting it, and infiltration of the site with DMSO or other free radical scavengers such as dexrazoxane. The latter, a metal ion chelator, was developed as a cardioprotectant to reduce doxorubicin-induced cardiomyopathy. It has also shown promise as a treatment for doxorubicin extravasation in humans and has also been used in veterinary patients.[90] The proposed mechanism of action is that dexrazoxane protects tissues against free radical damage by iron-doxorubicin complexes by binding iron and thus making it unavailable.

Electrical Burns

Electrical burns in small animal patients are not common; most occur as oral burns, owing to chewing of electrical cords, or as a result of improper grounding of the patient when electrocautery is used. Heat, generated from the resistance of the tissues to current flow, is the major component of electrical injury. Joule's law ($J = I^2RT$) describes these relationships and indicates that heat production is directly proportional to tissue resistance and time of exposure, and proportional to the square of the amperage.[1,91] Tissue resistance is particularly important in determining the distribution and severity of the wound, with more resistant tissues suffering greater damage than less

resistant ones. In particular, bone has a much higher electrical resistance than the surrounding muscle and fascia and also dissipates heat more slowly owing to its higher density. The net effect is that the superficial skin injury in electrical burns can appear to be relatively minor, while muscle, fascia, and neurovascular structures adjacent to bone have sustained severe damage.[91] This is an important consideration in prognostication and treatment of injuries where bone lies close beneath the area of visible burn, such as with electrical burns of the oral cavity.

Conclusions

Burns, particularly large ones, are among the most physically devastating and clinically challenging wounds that the veterinarian will treat. Virtually all body systems are impacted to one degree or another, with many complex interactions between systems. Although many of the critical pathophysiologic events begin at the local level, systemic sequelae often are the ultimate determinants of patient morbidity and mortality, and the application of the knowledge of these processes can have a major impact on burn mortality rates. Reported mortality rates from human burn centers have declined dramatically in the past 30 years. For example, a recent review of 1818 patient records

at the Boston Shriners Burns Hospital compared mortality from two time periods, 1974 to 1980 and 1991 to 1997. The study showed an overall 88% reduction in mortality and a 57% reduction in mortality for the most severely burned (60 to 100% TBSA) patients.[92] These gains have been attributed to the adoption of aggressive fluid resuscitation, early escharectomy, improvements in sepsis prevention and pain control, and nutritional support.[92-94] Similar application of burn pathophysiologic principles may well yield comparable results for veterinary medicine.

Chapter 63

Congenital Skin Diseases

Mark W. Bohling
Steven F. Swaim

Congenital cutaneous disease accounts for only a small percentage of veterinary surgical cases; nonetheless, a few congenital skin disorders are noteworthy in that they may benefit from surgical intervention or may drastically affect an animal's response to surgical treatment. The congenital dermatopathies of greatest importance to the veterinary surgeon are

cutaneous asthenia, dermoid sinus, nasal dermoid sinus cyst, and aplasia cutis. Other congenital skin diseases of minor surgical importance that are briefly discussed in this chapter include Chediak-Higashi syndrome, cutaneous mucinosis, acral mutilation syndrome, and inherited disorders of keratinization. Congenital dermatoses are skin conditions present at birth. Although the exact cause of all congenital dermatoses is not known, most are thought to be the result of genetic defects. True congenital dermatoses are uncommon; more common are hereditary defects that manifest later in life.

Cutaneous Asthenia

Definitions and Mechanisms

Cutaneous asthenia has also been called Ehlers-Danlos syndrome, “rubber puppy” disease, dermal fragility syndrome, dominant collagen dysplasia, and dermatosparaxis.[1,2] Cutaneous asthenia is a group of inherited congenital connective tissue diseases that affect man and a number of animal species including dogs, cats, horses, cattle, sheep, rabbits, and mink.[1-5] The disease complex resembles Ehlers-Danlos syndrome in humans, which has at least eleven different variations that may be distinguished clinically, genetically, and biochemically.[1,3] In general, the

condition is inherited as a simple autosomal dominant trait in dogs and cats,[1,2,4-7] although it has been reported to be a recessive trait in Himalayan cats.[1,2,8-10]

The condition is characterized by skin fragility, hyperextensibility (Figure 63-1), and laxity, with fragility being the primary feature of the condition.[1-5,11-13] The lack of tensile strength and decreased stiffness of the skin may be related to the organization or cross-linking of collagen molecules in the dermis.[3,13] The tensile strength of affected skin has been reported to be anywhere from one third to one fortieth that of normal skin.[1,11,12,14] In cats, a nine-fold reduction in tensile

strength has been reported.[1,12] The collagen abnormality in Himalayan cats is due to a deficiency of procollagen peptidase.[8,10]

Histopathologically, the dermis of affected dogs has been reported to be normal in thickness,[15] or thinner than that of normal dogs (1.21 vs. 1.71 mm, respectively).[12] No significant difference in dermal thickness was noted between affected and normal cats in one study (1.41 and 1.44 mm, respectively);[12] another study reported significantly thinner dermis between affected and normal cats (0.25 vs. 1.71mm, respectively).[15] Epidermal thicknesses of both affected and unaffected dogs and cats ranged

between 0.02 and 0.03 mm.[1,3,12]

Histopathologic abnormalities in the dermis are related to collagen, which gives tensile strength to the skin. In general, in affected animals, dermal collagen bundles are irregular in size and fibrillar in nature, and they lack the normal characteristic interweaving pattern of collagen bundles.[3,12] In addition, collagen bundles appear to be fine, often fragmented, with a lack of orientation and have a whorled appearance.[3,5,12,14] Mature collagen bundles are also lacking, and in some areas collagen fibers are surrounded by mucinous degeneration.[3,14]

The dermis of affected cats has fine,

fibrillar collagen with collagen bundles of varying sizes, some of which appear to be unraveled. Large, short, whorled collagen bundles appear in the deep dermis.[12] The wrapping of collagen fibers around blood vessels and a coiled arrangement of fibers around sweat glands has also been reported in cats.[16] Electron microscopy reveals disorganization of collagen fibrils, with variation in fibril size and shape and irregular orientation resulting in a "moth-eaten" appearance.[1,5]

Figure 63-1. This cat with cutaneous asthenia has typical hyperextensibility of the skin.

Surgical Significance

The fragility of skin presents clinically significant factors for the veterinary surgeon. The incidence of lacerations is increased in affected animals, owing to the ease with which skin tears.

Lacerations should be sutured promptly.[1] When manipulating skin for wound closure, excessive forceps tension on the wound edges should be avoided to prevent tearing the tissue, and careful undermining of the skin may be necessary to allow closure without tension.[8,12,17]

Mattress sutures, specifically a horizontal mattress pattern with or without stents of rubber tubing, has been recommended to help prevent the sutures from tearing through the skin.[1,8] However, cruciate sutures placed 5 mm from the wound edge have been found to be less likely to tear through the skin than simple interrupted, vertical, or horizontal

mattress sutures.[12,13] Small tapered-point needles with swaged-on suture material have been advocated to help prevent skin tearing.[12,17] Because of the thin dermis, the skin tends to evert when it is sutured.[17]

Wound Healing

Delayed wound healing has been reported as a complication in Ehlers-Danlos syndrome in humans,[13,17] but using clinical and histologic criteria, wound healing in dogs and cats with cutaneous asthenia appears to be similar to that in unaffected animals.[17] In dogs with cutaneous asthenia, healed scar tissue has greater tensile strength than adjacent skin; in affected

cats, however, the tensile strength of scar tissue is no different from adjacent skin.[13] The increased tensile strength reported in dogs was speculated to be caused by (1) a greater degree of intra- and intermolecular cross-linking of collagen fibrils in the scar, (2) amplified production of type I collagen in the scar, or (3) reduced collagenolysis, or a greater degree of collagen ground substance interaction in the scar.[13]

Dermoid Sinus and Nasal Dermoid Sinus Cyst

Definition and Mechanism

A dermoid sinus (pilonidal sinus) is a neural tube defect that results from

incomplete separation of the skin and neural tube during embryonic development.[1,2,18-24] The sinus is a tubular skin indentation that extends as a blind sac from the dorsal midline to varying depths in the underlying tissues.[1] Dermoid sinuses have been classified by their depth of penetration (Figure 63-2).[20,21] Classes I through IV have an opening to the skin surface; in addition, a fifth type (Class V) has been reported and is a true cyst with no skin opening.[21,23,24] The sinuses occur in the cervical, craniothoracic, and sacrococcygeal regions (i.e., craniad and caudad to the area of the ridge of hair on Rhodesian ridgebacks). The sinuses occur most frequently in the cervical area and less often in the

sacrococcygeal area.[20] One or more sinuses may be present on the same animal.[18-20,23] In the cervical area, the sinus is generally attached in the area of the dorsal spinous process of the second cervical vertebra and seldom extends any deeper. Class IV sinuses, which communicate with the dura mater, are seen mainly in the sacrococcygeal region, extending cranioventrad to the last sacral vertebra.[20] Dermoid sinuses occur by far most commonly in the Rhodesian ridgeback (Figure 63-3).[18-21,24] Cases have also been reported in the golden retriever,[25] shih tzu, boxer,[26] Yorkshire terrier,[22] springer spaniel,[27] chow-chow,[23] and Siberian husky.[28] In Rhodesian ridgebacks the condition

may be caused by a gene complex.[1,21] Most historical data on inheritance of dermoid sinus suggests that the condition may be inherited as a simple recessive trait;[18-20] a more recent study suggested a more complex dihybrid mode of inheritance with differential penetrance.[21]

Nasal dermoid sinus cyst is unique from dermoid sinus and has been reported in the Golden retriever,[29] English bull terrier,[30] and Brittany, springer, and cocker spaniels.[29,31] In this condition, a sinus tract of invaginated keratinized epithelium with adnexal structures (hair follicles and glands) extends from a dorsal midline opening just caudal to the

nasal planum (the so-called “nasal pit”), caudally into the nasal septum.[29] The condition is congenital and in man is caused by a neuroectodermal remnant in the prenasal space located between the nasal and frontal bones and the cartilaginous nasal capsule in the embryo.[29]

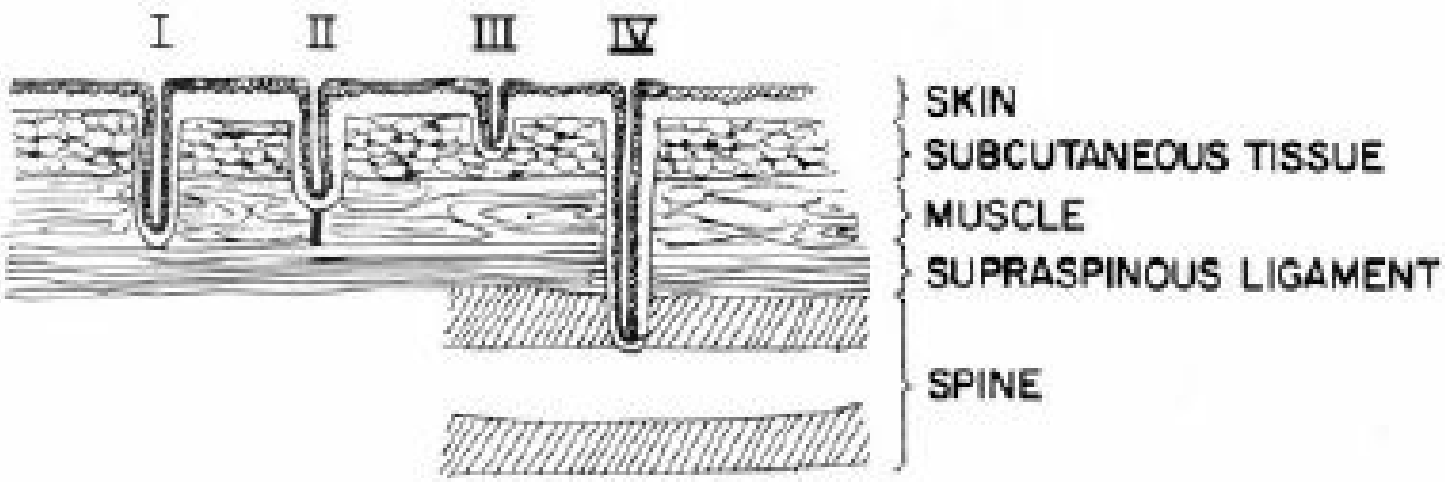

Figure 63-2. Classes of dermoid sinus. Class I, sinus extends to the supraspinous ligament where it is attached. Class II, sinus extends into muscular or subcutaneous tissue and is connected to the supraspinous ligament by a fibrous band. Class III, sinus extends into muscular or subcutaneous tissue

but is not connected to the supraspinous ligament. Class IV, sinus extends to the spinal canal and is attached to the dura mater. Class V, (not illustrated) is a true cyst with no connection to the skin. (Adapted from Mann GE, Stratton J: Dermoid sinus in the Rhodesian ridgeback. J Small Anim Pract 7:631, 1966.)

Surgical Significance

Surgical excision is the treatment of choice for dermoid sinus and nasal dermoid sinus cyst;[1,18,20,29] however, observation without treatment has been described if the lesion is quiescent. When drainage or neurologic signs are present, surgery should be performed.[1] Careful dissection of all sinus structures is important; introduction of a small (3.5 Fr) urinary catheter into the sinus may

help with identification of the sinus as dissection progresses. In dermoid sinus, deep fibrous attachments, possibly to the dura mater, may make complete excision impossible.[1,18] Incomplete sinus removal may result in recurrence of clinical signs.[18] Meningitis often complicates cases in which the dermoid sinus is attached to the dura mater;[1] therefore, extreme care and aseptic technique are indicated.[1,19] When dermoid sinuses communicate with the dura mater, hemilaminectomy or craniotomy with removal of part of the dura mater and associated abnormal tissue may be necessary to ensure complete removal of all sinus tissue.[20,26]

Aplasia Cutis

Definition and Mechanism

Aplasia cutis is a rare congenital disorder characterized by focal discontinuity of the epidermis. The condition has also been referred to as epitheliogenesis imperfecta. Most of the reports of this disease in the veterinary literature have been in cattle, horses, sheep, and pigs. In these species aplasia cutis is thought to be an autosomal recessive disorder.[32] There have been only isolated case reports in puppies and kittens.[33-35] The cause of the disease in these species is unknown.

Surgical Significance

Small lesions may be corrected by surgical repair or may heal by contraction and epithelialization. It has been suggested that in cattle the disease is not only an inherited defect in epidermal development but a more complex disorder of fibroblast metabolism.[36] Cultured fibroblasts from affected cattle have several metabolic disturbances, including a decrease in biosynthesis of both collagen and lipids. If the same is true in other species, the probability of normal wound healing following surgical repair is decreased.

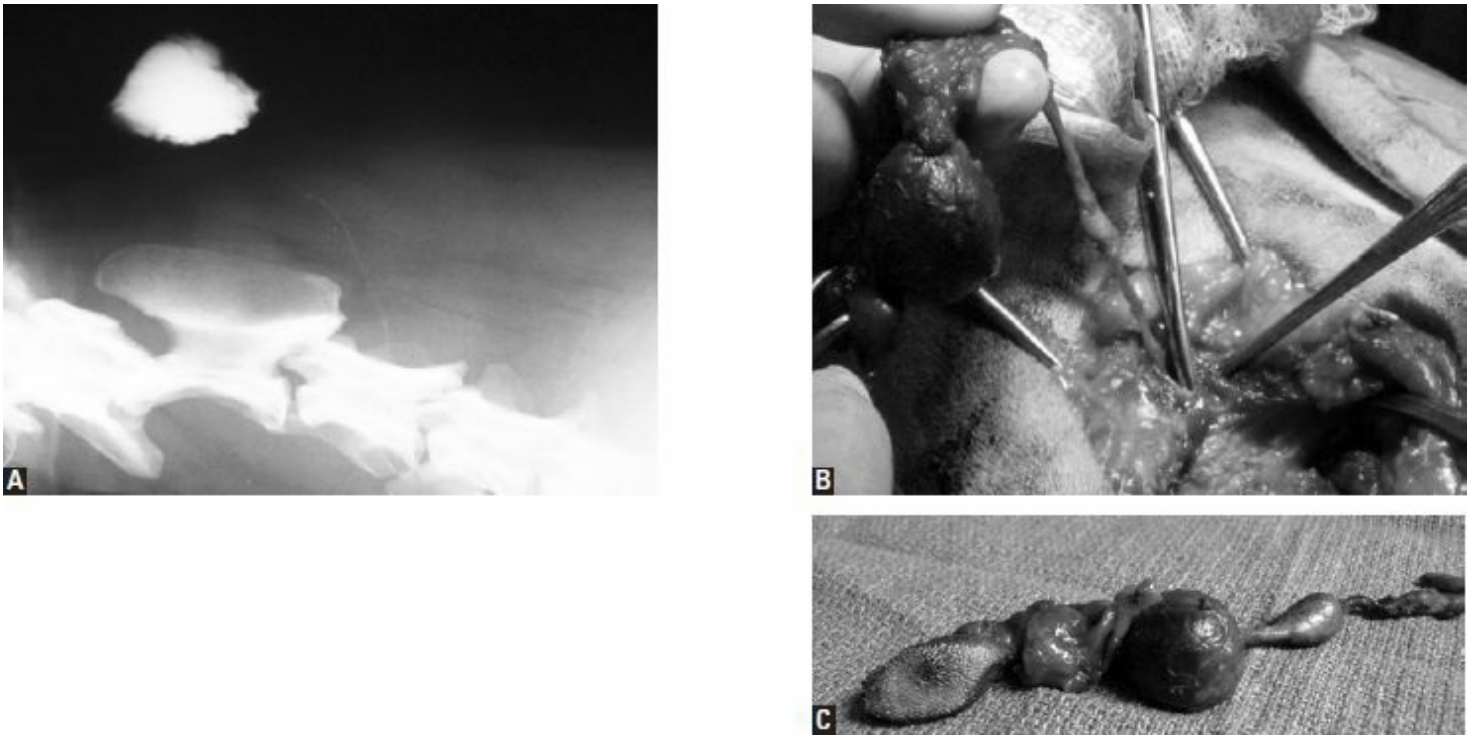

Figure 63-3. A. fistulogram of a cervical dermoid sinus in a Rhodesian ridgeback. Note the superficial cyst-like structure and extension of the contrast (delineating the sinus) to the spinous process of the third cervical vertebra. B. Surgical resection of the sinus. C. The excised sinus tract. Note the slightly darker area in the center of the ellipse of excised skin; this was the location of the sinus communication with the skin surface.

Chediak-Higashi Syndrome

Definition and Mechanism

The Chediak-Higashi syndrome is a rare autosomal recessive genetic defect that has been seen in several species, including humans and Persian cats.[37,38] Affected individuals have a structural defect that results in abnormally large granules in neutrophils, monocytes, and eosinophils. Melanin granules are likewise enlarged. The cellular abnormalities of affected animals include increased fragility of leukocyte granules, defective granular fusion, and enzyme deficiencies. These abnormalities may result in cellular rupture and tissue damage, defective chemotactic responsiveness, and reduced intracellular killing.[38,39] Affected animals may succumb to recurrent infections or lymphoid

neoplasia.[38]

Surgical Significance

The distinct coat and eye color of affected Persian cats should alert the veterinary surgeon to the possibility of Chediak-Higashi syndrome. Knowledge of this syndrome may prevent unnecessary surgery, which could be complicated by excessive postoperative bleeding and infections. Recombinant canine granulocyte colony-stimulating factor has been shown to enhance neutrophil function in affected cats and may be a useful adjunct to reduce risk of infection when surgery is required.[39]

Cutaneous Mucinosis

Definition and Mechanism

In dogs both discoid lupus erythematosus[40] and hypothyroidism[41,42] have been shown to increase dermal mucin deposition. The Chinese Shar pei appears to be unique in its propensity to have cutaneous mucinosis, and this dermal abnormality appears to be inherited, and "normal" to some degree, in all Shar peis. In extreme cases, a Shar pei may develop severe myxedema and mucoid vesicles.[43,44] Cutaneous mucinosis is manifested histologically by wide separation of dermal collagen bundles by mucin. Even the "normal" Shar pei has more mucin deposition

between collagen bundles than other breeds.

The cause of this increase in dermal mucin is unclear, but the source is thought to be the dermal fibroblast.[40] Myxedema may be the result of an increase in the synthesis or a decrease in the degranulation of mucopolysaccharides.[45] The mucopolysaccharides that accumulate in the dermis are chondroitin sulfate and hyaluronic acid.

Surgical Significance

Incision into the skin of the Shar pei will reveal a gelati¬nous material that tends to form beads or threads. It has

been suggested that in severely affected Shar peis maturation of dermal fibroblasts may be delayed,[43] which could result in poor wound healing.

Acral Mutilation Syndrome

Definition and Mechanism

The acral mutilation syndrome is not a congenital anomaly but rather an inherited disease. This disease of self-mutilation has been reported in English pointers and French spaniels in North America, German short-haired pointers in Europe, and English springer spaniels in Australia.[46-48] Pedigree examination in each affected breed indicates that the condition is

probably inherited as an autosomal recessive sensory neuropathy. Biochemical studies of affected pointers have demonstrated a reduction in substance P-like immunoreactivity,[49] while histologic examination has shown a reduction in the size of spinal ganglia as well as a deficiency of ganglionic neurons.[47]

Surgical Significance

Affected animals are difficult to maintain because of their persistent determination to chew their paws. Chronic wound management with topical medications and bandages, and constant use of muzzles or other forms of restraint are required. Even after

healing, many dogs relapse as soon as restraints are removed; faced with this discouraging situation, many owners elect euthanasia.[46-48]

Inherited Defects of Keratinization

Definition and Mechanism

This category of rare diseases is grouped together because all share the feature of abnormal keratinization. Footpad hyperkeratosis has been described as a familial condition in the Irish terrier[50] and Dogue de Bordeaux;[51] related individuals of several other breeds (Labrador and

golden retrievers, Kerry blue terriers, and mixed breed dogs) have also been reported.[1] A heritable defect of keratin filament formation causing increased epidermolysis was reported in 7 related Norfolk terriers; autosomal recessive inheritance is suspected.[52] Epidermolytic hyperkeratosis, a congenital condition in man characterized by collapse of the keratin filament cytoskeleton, has been reported in a single canine patient, a 6 month-old Labrador-retriever mix.[53]

Surgical Significance

The aforementioned keratinization defects appear to be rare in dogs, and although specific information

regarding surgical complications is lacking, several reasonable inferences can be made. In each of these conditions, the cytologic and biochemical abnormalities appear to be limited to the superficial layers of the epidermis (superficial to the stratum basale);[50,52,53] therefore, primary healing should not be impacted to any great extent. However, the greatly thickened and cracked skin predisposes to bacterial and mycotic infections,[52] so superficial wound infection may be expected to be a problem. Appropriate therapy should be instituted prior to elective procedures to improve the condition of the epidermis and, thereby, minimize infection risk. In addition, while not

confirmed, second intention healing might be impacted owing to possible effects of abnormal keratinization on wound epithelialization. A moist wound environment and judicious use of mild desquamating agents may prove beneficial.

Conclusion

Although the exact mechanism for the development of all of the congenital skin diseases is unknown, most have been found to have a genetic basis. In many instances, the condition is inherited as an autosomal recessive trait. With this in mind, it must be recommended that not only should affected animals be withdrawn from

the breeding pool, but in most instances, the parents, and perhaps siblings, should not be used for breeding purposes. In some cases, test mating to affected animals may provide evidence that a particular animal does not carry the abnormal gene.[1,2,54]

Part IX

Urinary System

Chapter 64

Renal Failure: Surgical Considerations

Don R. Waldron

The kidneys receive approximately 20 to 25% of cardiac output and regulate the composition of extracellular fluid by filtration, reabsorption, secretion, and hormone production.[1] Many important systemic parameters are influenced by the kidneys, including acid-base status, electrolyte balance, the concentration of waste products of bodily metabolism, and red blood cell

mass.[1-3] The diagnosis of renal failure implies sufficient loss of renal function to cause elevated levels of metabolic waste products, possible abnormalities in fluid and electrolyte balance, and loss of renal biosynthetic function.

The loss of function is reflected in laboratory tests as an increase in nonprotein nitrogenous waste products (blood urea nitrogen (BUN) and creatinine), a condition called azotemia. The inability to excrete nonprotein nitrogenous waste products may be caused by prerenal, primary (intrinsic renal), or postrenal mechanisms. Prerenal azotemia is caused by renal hypoperfusion states such as dehydration or hypotension.

Postrenal azotemia is associated with obstruction of urine flow or disruption of urinary tract structure, resulting in leakage of urine into tissues or body cavities. Azotemia caused by prerenal or postrenal mechanisms may progress to cause renal damage and thus primary renal failure. Azotemia that is caused by primary renal disease has been classified based on duration as acute or chronic; in either case, the biochemical abnormalities associated with renal failure may cause profound changes in the animal's ability to maintain a normal homeostatic state.

In surgical patients, it is important to recognize prerenal or postrenal azotemia early in the course of disease,

as early correction may prevent progression to primary renal failure. Patient factors such as age, cardiac status, and the concurrent administration of nephrotoxic drugs may compound other prerenal factors and influence the progression to primary renal disease. Postrenal azotemia is readily diagnosed by a good history plus physical examination with particular attention to palpation of the bladder and urethra. Some cases however, may require urethral catheterization, abdominocentesis, or imaging techniques such as radiographic contrast studies or ultrasound to confirm azotemia as postrenal and to identify the specific anatomic defect.

Acute renal failure (ARF) is an abrupt deterioration of renal function that occurs over hours to days, resulting in azotemia and decreased ability of the kidneys to regulate water and solute balance.[4] Differentiating ARF from chronic renal failure (CRF) can be difficult; however, correct diagnosis is important as ARF is potentially reversible whereas CRF is not.[5] ARF affecting surgical patients is most likely to occur in a hospital setting. The incidence of hospital-acquired ARF in animals appears to be relatively low. However, a previous study has documented a survival rate of only 40% in such cases; thus prevention of ARF is critical.[6] ARF in small animal species usually is caused by

nephrotoxins; in humans, the cause is usually hypoperfusion.[6,7] Either nephrotoxins or hypoperfusion states may cause tubulointerstitial nephritis, glomerular or vascular disease, or renal tubular necrosis. Because prerenal azotemia may progress to ARF, early recognition is imperative, so that it can be corrected and primary renal damage prevented. Primary or intrinsic renal failure has been subdivided into phases and may or may not be reversible. During the induction phase of ARF, if causative factors are removed when tubule cell dysfunction may predominate over cell necrosis, recovery of cell function is possible and more likely than when the maintenance phase of ARF is reached.

Evidence of early renal damage includes low specific gravity (less than 1.030 in dogs, less than 1.035 in cats), renal tubular cells and granular casts in urine sediment, failure of BUN and creatinine to return to normal after correction of hypoperfusion, and glucosuria in the normoglycemic patient.

The maintenance phase of ARF is characterized by irreversible renal tubular cell injury, with cellular necrosis. Correction of hypoperfusion during this phase has little effect if any on BUN and creatinine concentrations, and oliguria is often present after correction of hypovolemia or hypoperfusion. Oliguria in the dog is

defined as urine production of less than 0.27 ml/kg/hour.[8] Patients with ARF that are nonoliguric may have a quicker recovery. This is not always the case, however, because ARF associated with aminoglycoside toxicity may or may not be reversible but is often nonoliguric. In a recent study, 39% of animals with ARF were nonoliguric.[9] If loss of nephrons with interstitial inflammation and fibrosis occurs, recovery of adequate renal function may be impossible. Adequate healing of renal tissue, however, may occur, initiating the recovery phase of ARF. This may not occur for two to three weeks after the onset of the maintenance phase. The recovery phase is characterized by an increase

in urine production, and often polyuria. If oliguria was not present, the recovery phase is characterized by resolution of azotemia.[7]

Clinical consequences of ARF include disorders of fluid balance, inadequate urine production, and electrolyte and acid-base imbalance.[4] Other body tissues such as gastrointestinal, pulmonary, and cardiac systems may also be affected by renal failure.

Multiple factors often contribute to the decreased glomerular filtration rate (GFR) seen in cases of ARF. Hemodynamic factors are probably most important during the induction phase, involving a reduction in renal

perfusion pressure or vasoconstriction of afferent arterioles. Possible mechanisms include response to adrenergic stimulation, failure of intrarenal autoregulation from lack of prostaglandin production, endothelial cell swelling, activation of the renin-angiotensin system, and a decrease in glomerular permeability. Tubular factors that cause decreased GFR may be more important during the maintenance phase of ARF. Obstruction of tubules with cells, cellular debris, and precipitated protein, leads to increased back pressure, thereby reducing GFR. Damage to tubular cells may also allow leakage of glomerular filtrate into interstitial tissues, reducing urine flow

and allowing reabsorption of fluid and solute.[4,10]

Chronic renal failure or dysfunction is a more common clinical entity than ARF. The prevalence of CRF has been estimated to range between 0.5% and 7% in dogs and 1.6% and 20% in cats.[11,12] Causes of CRF are multifactorial and include familial, congenital, or acquired diseases. Renal lesions are most often tubulointerstitial or glomerular. In most cases, a specific initiating cause is not identified.[13] Recognition of CRF in a patient prior to anesthesia and surgery is necessary to avoid the potential for postoperative complications, prolonged hospitalization, or onset of

acute renal failure. Ultimately, recognition of potential causes or risk factors for ARF in the perioperative period is important so that it may be prevented or treated early, when renal damage is least severe and potentially reversible, and metabolic complications can be avoided or minimized. Similarly, identification of patients with chronic renal disease already present is important for prognostic reasons and to prevent decompensation to a clinical diseased state or ARF after an anesthetic and/or surgical procedure. In this chapter, potential causes and risk factors for ARF in surgical patients are discussed with the goal of prevention or early treatment. The effects of uremia on the

surgical patient are also discussed so that potential surgical complications may be prevented or minimized.

Etiology and Risk Factors for ARF in the Perioperative Patient

Hospital-acquired renal insufficiency is not uncommon in humans. In one study, iatrogenic factors were implicated in the majority of such episodes.[14] The most common inciting causes in 29 dogs with hospital-acquired acute renal failure were exposure to nephrotoxins and advanced age.[6] Chronic heart disease, preexisting renal disease, and anesthesia were identified as apparent

contributors to ARF in these dogs. Those patients that do recover from ARF require lengthy and expensive treatment.[2] A number of risk factors and diseases have been described for the development of ARF in both the human and veterinary literature but it is unclear how many of the factors have been documented in animals (Table 64-1). Many factors have been identified in gentamicin-induced ARF in dogs, and it has been stated that those same predisposing factors likely affect the development of ARF in other cases as well.[2] Some of these factors are potentially correctable prior to an anesthetic and/or surgical treatment; thus, attention should be focused on identification and treatment of those

factors. In a retrospective review of acute renal failure in dogs, pancreatitis, shock, sepsis and disseminated intravascular coagulation (DIC) were classified as ischemic disease states associated with ARF.[9]

Hypoperfusion States

Renal hypoperfusion may be caused by dehydration, hemorrhage, or shock. Dehydration has been sited as the most common and most important risk factor for ARF.[2] In humans, renal hypoperfusion associated with hemorrhage, surgery, or dehydration is a common cause of ARF.[15] In normal dogs, however, renal hypoperfusion by itself may not lead to persistent renal

damage and ARF.[16] The canine kidney appears to be more resistant to ARF occurring secondary to shock or other hypotensive states. In contrast to animals with normal renal function, it has been shown experimentally that, after a hypotension episode, dogs with reduced renal mass had decreased GFR and mild histologic lesions compatible with ARF.[17] Similarly, it is thought that hypotension as a result of third-space disease (ascites or pleural effusion), decreased oncotic pressure (hypoalbuminemia), decreased cardiac output (cardiac failure), or an anesthetic episode may predispose the small animal surgical patient to ARF, particularly if clinical or subclinical renal disease already exists.

Pancreatitis has been reported as a cause of ARF in animals, however, the pathophysiology is unclear. Possible causes include hypovolemic or septic shock, DIC, or the direct effects of trypsin or vasopressors released by the pancreas on glomerular capillaries.[18,19]

Table 64-1. Disease or Risk Factors for Acute Renal Failure in Dogs and Cats

Preexisting renal disease	Sepsis
Advanced age	Decreased cardiac output
Hypotension/Shock	Dehydration

Hypertension	Sodium, Potassium, Calcium deficiency or excess
DIC	Acidosis
Pancreatitis	Hyperviscosity syndromes
Nephrotoxic Drugs	

Modified from Grauer G: Prevention of acute renal failure. Vet Clin North Am 1996, and Grauer GF: Prevention of acute renal failure. *In* Textbook of Small Animal Surgery, 3rd ed. Slatter DH (ed). Philadelphia: Saunders, 2003.

Hypoperfusion may also potentiate the effects of nephrotoxic agents such as nonsteroidal anti-inflammatory drugs (NSAID), aminoglycoside antibiotics, anesthetic agents, and myoglobin

(Table 64-2).[20] It appears that risk factors are additive in nature, and although a specific agent may not cause clinical problems in the normal animal, dehydration will potentially initiate nephrotoxicity of an otherwise safe drug such as Cox-2 selective NSAID. In surgical patients, hypoperfusion associated with an anesthetic episode may cause renal decompensation, especially if the animal has borderline or sublcinical renal disease.

Sepsis

Sepsis is a clinically important complication in perioperative patients that may lead to acute renal failure.

Sepsis leads to ARF through a variety of mechanisms, including renal hypoperfusion owing to redistribution of renal blood flow, deposition of microthrombi in renal vasculature, or from direct toxic damage to tubular cells by bacteria or endotoxin.[21] Appropriate volume expansion and antibiotic therapy in septic patients may prevent ARF.

Canine pyometra has been associated with a variety of renal lesions. Renal defects include antigen-antibody-mediated-membranoproliferative glomerulonephritis, tubulointerstitial nephritis, and nephrogenic diabetes insipidus.[22,23] Many patients, however, have decreased GFR not associated

with renal lesions or hypovolemia. Decreased GFR may occur in animals with or without azotemia, suggesting that some factor associated with pyometra causes a decrease in renal perfusion. Acute renal failure in dogs with pyrometra has been associated with *Escherichia coli* endotoxin although not all dogs with pyometra and renal failure have *Escherichia coli* infection.[2] Many animals with pyometra also have urinary tract infections including pyelonephritis.[24] Because of polyuria and lack of water consumption owing to malaise, prerenal azotemia may also be present. Renal hypoperfusion, glomerulonephritis, tubular damage, and pyelonephritis may all contribute to the development of ARF in patients

with pyometra as may disseminated intravascular coagulation (DIC), sepsis, or septic shock. In geriatric patients with pyometra, azotemia may be present from prerenal and/or a combination of acute and chronic renal failure. The chronicity of renal disease may be difficult to determine until the pyometra is corrected.[24] Renal biopsy may assist in diagnosing the extent of renal dysfunction in such cases.

Table 64-2. Therapeutic/Diagnostic Agents with Nephrotoxic Potential

Antibacterial Agents

- Aminoglycosides
- Nafcillin
- Cephalosporins
- Sulfonamides

Toxins

Myoglobin is an uncommon but potential nephrotoxic cause of ARF, especially in the face of dehydration. Myoglobinuria can occur in the perioperative patient from malignant hyperthermia, exertional rhabdomyolyis, or prolonged grand mal seizures.[25-28] Early recognition and treatment will minimize potential renal damage from these diseases. Malignant hyperthermia is an acquired metabolic myopathy and has been related to exercise or general anesthesia (particularly halothane anesthesia). Greyhounds seem predisposed to the disease.[26,29]

Hemoglobin is not nephrotoxic in well

hydrated patients, however hemolysis of whole blood is known to be toxic in humans. Conditions that could lead to hemolysis and possibly acute renal failure in small animal patients include burns, rapid intravenous infusion of large volumes of hypotonic solutions, transfusion reactions or hemolysis of whole blood during improper administration, immune-mediated hemolytic disease, infection by red blood cell parasites such as Babesia or Hemobartonella, or administration of acetaminophen, particularly in cats. In addition, methylene blue, which has been used in animals during surgery to aid in identification of neoplasia of the pancreas, may cause hemolysis in dogs and cats. Acute renal failure following

burns is likely multifactor and caused by both hemolytic and red blood cell membrane fragmentation as well as hemo-concentration and catecholamine response leading to redistribution of blood flow.[30] Avoidance of these conditions or early recognition of hemolysis followed by appropriate fluid therapy to maintain renal blood flow and urine output may prevent renal damage from hemoglobinuria.

Electrolyte imbalances can increase the risk of acute renal failure. Hypercalcemia in the adult dog is often associated with neoplasms, most commonly lymphosarcoma but also anal sac apocrine gland adenocarcinoma, adenocarcinoma of

the mammary gland or nasal cavity, thyroid carcinoma, and parathyroid gland tumors.[31] In a review of 29 dogs with primary hyperparathyroidism, 13 dogs had high blood urea nitrogen levels at initial presentation. Postoperatively, 7 dogs suffered from renal failure, 4 of which had elevated BUN preoperatively. Dogs that developed renal failure had significantly higher preoperative total calcium levels compared with animals that had normal renal function.[32] Hypercalcemia can contribute to prerenal azotemia because of decreased water consumption and polyuria from the direct effects of calcium on tubular concentrating ability. Chronic hypercalcemia causes

tubular and interstitial damage that can lead to renal failure.[33] Acute hypercalcemia can cause defects in urine concentrating ability but does not lead to a decrease in GFR until the calcium concentration exceeds 16 mg/dl.[34] Damage caused by acute hypercalcemia may include direct tubular cell toxicity as well as ischemic injury from vasoconstriction. Early recognition of hypercalcemia in surgical patients (so that appropriate saline volume diuresis can reduce the serum calcium value) may help prevent renal damage, particularly in the face of possible renal hypoperfusion associated with anesthesia and surgery. For patients refractory to saline diuresis alone,

corticosteroid and diuretic therapy may be needed to reduce serum calcium concentration to an acceptable level.

Other electrolyte abnormalities may contribute to acute renal failure concurrent with other risk factors. Hyponatremia is reported to potentiate contrast-media-induced acute renal failure in dogs.[35] Hypocalcemia, hypomagnesemia, and hypokalemia may potentiate the nephrotoxic effects of aminoglycoside antibiotics.[2]

Drug-Induced ARF

Many therapeutic agents have the potential to be nephrotoxic and thus may be predisposing factors to ARF in the surgical patient (Table 64-2).

Nonsteroidal anti-inflammatory drug (NSAID) use in dogs has grown markedly in the past 10 years. This class of drugs is now commonly used in dogs for treatment of pain related to osteoarthritis and in the perioperative period to decrease pain associated with both orthopedic and soft tissue surgical procedures. Renal toxicity is the second most important NSAID toxicity, after gastrointestinal effects.[36] The primary action of NSAID is to block expression of cyclooxygenase (COX) in cell membranes. Cyclooxygenase exists as both COX 1 and COX 2 isoforms; these have roles in normal homeostasis and are induced by proinflammatory stimuli. During periods of hypotension and reduced renal perfusion,

prostaglandins are important for autoregulation to maintain renal blood flow and glomerular filtration, and thus are protective in nature. NSAIDs have the potential to cause prerenal renal impairment by depleting the kidney of vasodilatory prostaglandins.[37] The introduction of selective COX-2 inhibiting NSAIDs has decreased the prevalence of gastrointestinal toxicity, but because the kidney has both COX-1 and COX-2 isoforms, there may be little difference in the incidence of renal toxicity associated with the various NSAIDs. Any NSAID may cause renal toxicity especially if in the presence of preexisting renal disease. The exact mechanisms of renal impairment are

unknown, but primary effects on the renal parenchyma may include acute interstitial nephritis, which may progress to papillary necrosis.[37] It appears that the overall occurrence of ARF owing to use of the newer NSAID (carprofen, deracoxib, and meloxicam) in dogs is low. Most dogs that develop ARF as a result of these NSAIDs either ingest excessive quantities of the drug or have a concurrent disease predisposing them to ARF.[38]

Specific antibiotics, particularly gentamicin, have known nephrotoxic potential. Gentamicin may cause an idiosyncratic acute renal tubular cell necrosis in humans and animals.[39,40] Several factors are known to

predispose to gentamicin toxicity including dehydration, concurrent administration of furosamide, and hypokalemia.[41] It is known that measurements of BUN and creatinine levels are not good early indicators of renal damage from aminoglycoside toxicity. Glycosuria, proteinuria, hematuria, cylindruria, or decreased specific gravity are better indicators of renal damage.[42] Measurement of gamma glutamyl transpeptidase (GGT) activity in the urine or use of the urine GGT-to-creatinine ratio are more sensitive indicators of early nephrotoxicity from gentamicin therapy.[40,43] Nafcillin used as prophylactic antibiotic therapy in surgical patients was suspected of

causing ARF in seven dogs at one institution. None of the dogs had preexisting renal disease and none had suffered a hypotensive episode. Six dogs recovered following intensive therapy for ARF.[44]

Radiographic contrast agents are often used parenterally for diagnostic purposes in surgical patients. Contrast agents used for excretory urography are hyperosmolar and cause an osmotic diuresis after administration. Possible pathogenic mechanisms for ARF caused by contrast agents include direct tubule injury, tubule precipitation of urinary proteins with contrast media causing obstruction, vasoconstriction of renal vessels

leading to ischemic injury, or idiosyncratic reaction.[45] The prevalence of contrast-agent-induced renal failure in small animals appears to be very low but has been described in two case reports.[46,47] In one of the reported cases, preexisting renal disease was present prior to contrast administration. Correction of sodium or potassium imbalances is recommended prior to administration of intravenous contrast agents and the presence of preexisting renal disease should dictate caution in their administration.[35] Correction of dehydration and administration of fluids during and after the contrast study should be considered.

Vascular Disorders

Disseminated intravascular coagulation (DIC) is a clinicopathologic condition that can cause both a hemorrhagic diathesis and thrombosis of vasculature. DIC is always a secondary disease and has been associated with or caused by infectious, inflammatory, neoplastic, and toxic conditions. DIC may be seen in up to 50% of dogs with hemangiosarcoma.[48] Laboratory evidence of DIC includes thrombocytopenia, prolonged coagulation times, and decreased concentration of antithrombin III in plasma. A more recent test for the detection of elevated D-dimer protein in serum is a sensitive marker of clot

lysis and strongly suggests DIC when elevated; a negative test all but excludes DIC as a diagnosis.[48] Acute renal failure from renal ischemia associated with renal vasculature thrombosis occurs in some cases of DIC. Because sluggish vascular flow, metabolic or respiratory acidosis, and shock can enhance DIC,[49] it is important to recognize and correct these predisposing conditions early in perioperative patients.

Anesthesia/Surgery

Anesthesia, surgery, and renal function may interact by several mechanisms. Renal disease may cause changes in fluid homeostasis, electrolyte levels, or

acid-base status. These changes along with renal disease may affect the pharmacokinetics of drugs used in anesthesia. Ketamine is eliminated almost unchanged by the kidneys in the cat; thus renal disease in cats may result in prolonged duration of effect of ketamine in that species. Azotemia causes an increased sensitivity to thiobarbiturates; a decreased dose is advised for animals with renal disease.[50]

Anesthetic agents may affect renal function either by direct toxic effects or by changes produced in physiologic function. Anesthetic agents depress renal arterial pressure and the resultant hypotension causes release of

renin by the juxtaglomerular apparatus. Renin, in turn, activates the angiotensin cascade, which stimulates the adrenal gland to increase aldosterone production. Aldosterone causes increased reabsorption of sodium, thereby promoting water retention, which helps maintain blood volume. Anesthetic agents such as halothane and isoflurane stimulate the renin-angiotensin system.[51] The stress of anesthesia and surgery also stimulates the renin-angiotensin system via sympathetic pathways. Hypovolemia as a result of intraoperative hemorrhage is also a potent stimulus for renin release. Glomerular afferent arteriolar vasoconstriction caused by the effects

of angiotensin II and ADH in response to increased renin release is a proposed mechanism of decreased GFR in acute renal failure. Anesthesia, therefore, may contribute to the development of ARF through this mechanism.

Anesthesia and surgery may adversely affect normal renal function by causing increased release of ADH from the posterior pituitary. ADH causes vasoconstriction in the splanchnic and renal circulation while increasing the tubular reabsorption of water. Restricting the oral intake of water prior to anesthesia and/or administration of halothane or thiopental causes a mild elevation in

ADH concentration. ADH secretion is a protective mechanism in most instances, but it may compound ischemia caused by hypovolemic shock.

The only anesthetic agent with direct nephrotoxicity that is commonly used in veterinary practice is the inhalant methoxyflurane.[50] This agent is now essentially obsolete because of lack of availability and because agents exist with safer and more desirable characteristics. The liver metabolizes methoxyflurane to free fluoride and oxalate. The fluoride ion is a potent nephrotoxic agent but by itself uncommonly caused renal disease in dogs.[52,53] A combination of methoxyflurane anesthesia, preexisting

renal disease, and/or concurrent use of another nephrotoxic drug such as an NSAID makes methoxyflurane potentially dangerous.[54] Sevoflurane metabolism also produces fluoride ion; however, it has been determined that the potential for nephrotoxicity in dogs is low.[55] Sevoflurane also decomposes to the nephrotoxic agent Compound A in the carbon dioxide absorbent of a circle system. Low oxygen flow rates may raise the concentration of Compound A; thus it is recommended to avoid oxygen flow rates of less than 20 ml/kg/minute with this agent, especially in animals with renal disease.[50]

Chronic Renal Failure

Chronic renal disease/dysfunction (CKD) is the most common kidney disease in dogs and cats.[13] CKD is characterized by renal damage that has existed for 3 months or more or by a decrease in GFR of more than 50% from normal persisting for 3 months.[13] Many disease processes including neoplastic, infectious, and immune-related have been identified as causes of chronic renal failure in dogs and cats. When considering dogs with primary renal azotemia, tubulointerstitial nephritis, glomerulonephropathy, and amyloidosis are the most common lesions. The clinical magnitude of renal

disease in animals with CKD varies considerably as the disease may or may not affect renal function. In early chronic renal disease, the animal is not azotemic and may have few clinical or laboratory abnormalities associated with disease. As the condition progresses, animals with chronic renal failure may have anemia, systemic hypertension and electrolyte and mineral imbalances. Hyperphosphatemia, hypercalcemia, or hypocalcemia are also seen in animals, depending on the stage of renal failure. Azotemia causes metabolic acidosis and may progress to uremia and anorexia and vomiting.

Identification of patients with chronic

renal disease is important during the preoperative workup. The animal may be presented for a surgical problem unrelated to the urinary tract; however, the outcome of treatment for the primary surgical problem may depend on accurate assessment and awareness of problems related to renal disease.

Effects of Renal Failure on Surgical Patients

Wound Healing

Uremia has a detrimental effect on wound healing. Experimentally, azotemic and uremic rats show delayed gain of tensile strength in healing wounds.[56] The decreased wound

strength may be a result of synthesis of poor quality collagen or increased collagen degradation.[57,58] Depressed formation of granulation tissue and division of epithelial cells have also been reported in uremic mice.[59]

The effects of uremia on wound healing may be theoretically clinical as wounds in azotemic and uremic patients proceed to heal normally, although more slowly. Selection of appropriate suture materials in view of potential slower wound healing is advised.

Hemostasis

Platelet function may be abnormal in

animals with renal failure.[3,13] It is thought that uremia and one or more uremic toxins cause impairment of platelet adhesiveness and aggregation.[13,61] Diminished thromboxane–A2 production, abnormal intracellular calcium mobilization, and increased intracellular cAMP have been described in uremic platelets.[61] Coagulation factors are normal, so the most practical test of hemostasis in the uremic patient is a buccal mucosal bleeding time.

Administration of desmopressin acetate (DDAVP) has been reported to shorten bleeding times in uremic humans. Hemorrhagic diathesis of chronic renal failure is likely clinically insignificant

in animals unless other coagulation disorders are present.[3]

Anemia

Patients with chronic renal failure frequently have mild to severe nonregenerative anemia. The anemia is characterized by normochromic, normocytic red blood cells. Although the anemia of chronic renal failure is often multifactorial, the most important cause of the anemia is a relative erythropoietin deficiency.[63] The lack of sufficient erythropoietin results in hypoplasia of erythroid precursors in the bone marrow; leukocyte and platelet production are not affected.

Other factors suggested to contribute to anemia in animals with renal failure are shortened red blood cell survival, platelet dysfunction, nutritional abnormalities, and gastrointestinal hemorrhage from mucosal ulceration.[13,62] Serum iron concentrations are also frequently below normal.

Cardiopulmonary Function

Pulmonary function can be impaired in animals with renal failure, thus potentially compromising their ability to tolerate anesthesia and surgery. Interstitial pneumonitis has been reported in a group of 10 dogs with chronic renal failure.[63] Of these dogs, 4

had respiratory signs and 3 had alveolar infiltrates within the lungs. Pulmonary arterial thromboembolism leading to dyspnea has occurred in canine patients with the nephrotic syndrome associated with glomerular disease.[66] This appears to be caused by a hypercoagulable state associated with excessive urinary loss of antithrombin III or with abnormal platelet function associated with hypoalbuminemia.[64,65] The clinical significance of pulmonary disease secondary to uremia for the anesthetized veterinary patient is unknown and seems questionable.

Cardiovascular abnormalities may occur as co-morbidities in animals with

renal failure. Clinically, the most important potential abnormality is systemic hypertension. Systemic hypertension may be a cause or a consequence of chronic kidney disease.[13] The incidence of hypertension in dogs with chronic disease is reported to be from 30% to 90%.[66,67] Apparently, the condition is much more common in the cat, occurring in up to 66% of animals affected with renal disease.[68] The presence of a high initial systolic blood pressure (164 to 217 mm Hg) in dogs with renal disease increases the risk of having a uremic crisis and also seems to be a predictor of a faster decline in renal function in affected animals.[66] Hypertension also impairs the ability

of the kidney to autoregulate renal perfusion, thus potentially complicating an anesthetic episode.[69] Pericardial effusion has been described in two clinically affected dogs secondary to renal disease.[70,71] In a further review of necropsy records from another 150 dogs with renal disease, 11 dogs had varying amounts of clear or hemorrhagic pericardial fluid.[70] The clinical significance of pericardial effusion as a result of renal failure in dogs is unknown but its occurrence seems uncommon.

Nutrition or Malnutrition

Anorexia and weight loss are nonspecific but common clinical signs

associated with advanced kidney disease. Nausea and vomiting leading to malnutrition are also common, especially as uremia becomes advanced. Uremic gastropathy and gastrointestinal mucosal ulceration associated with gastric hyperacidity and histamine release from mast cells within mucosa contribute to nausea and vomiting. Oral lesions such as ulcers or stomatitis may be associated with anorexia especially in cats.

The importance of proper nutrition for prevention or treatment of disease in animals is well recognized. Protein-energy malnutrition can further intensify the catabolic state associated with general anesthesia and surgery.

Deleterious effects of protein-energy malnutrition that are of particular importance to the surgical patient include impaired immune function, increased susceptibility to infection, and delayed wound healing.[72] Inadequate energy intake leads to use of body protein for energy, which worsens azotemia (and perhaps uremia) in animals with renal failure and reduces the protein available for renal repair in ARF.[73] Animals that have remained anorectic for more than 3 days or that have lost more than 10% of their body weight should receive nutritional supportive therapy.[73]

Chapter 65

Bacterial Urinary Tract Infections

Carl A. Osborne
Jody P. Lulich

In context of surgery, conceptual understanding of alterations in interactions between host defenses and pathogenic microbes that result in bacterial urinary tract infections (UTI) are important for at least two reasons. First, many surgical procedures designed to correct noninfectious

disorders of the urinary tract may partially or totally interfere with local host defenses that normally prevent or impair development of UTI. Second, surgical correction of abnormalities that affect host defense mechanisms may be a prerequisite to preventing recurrent or persistent bacterial UTI.

Why is it Important to Recognize that Bacterial Urinary Tract Infection is not a Primary Diagnostic Entity?

Although the urinary tract communicates with an external environment loaded with bacteria and

other potentially pathogenic agents, most of it is normally sterile and all of it is normally resistant to infection. As with all systems of the body, resistance to urinary tract infection is dependent on the interaction of several host defense mechanisms.[1] The pathogenesis of UTIs is related to the relationship between the virulence of uropathogenic infectious agents (analogous to seeds) and the functional status of host defense mechanisms (analogous to soil; Table 65-1). Growth of bacteria (seeds) usually will not occur unless abnormalities of host defenses (suitable soil) are present. Therefore, in context of diagnosis, prognosis, and therapy, a bacterial urinary tract infection (UTI) may be

viewed as a secondary (or complicating) rather than a primary (or definitive) diagnostic entity.

CAVEAT--In addition to focusing on antimicrobial treatment of bacterial pathogens (which are usually secondary causes of urinary tract disease), it is also important to consider detection and treatment of abnormalities in host defenses that allow bacteria to colonize and invade tissues of the urinary tract (Tables 65-1 and 65-2). If UTIs are managed inappropriately, one or more sequelae may occur (Table 65-3). Early detection followed by proper treatment and follow-up evaluation will minimize the occurrence and severity of these

sequelae.

What Diagnostic Classification will Facilitate Treatment of Bacterial Utis?

Bacterial UTI encompass a wide variety of clinical entities whose common denominator is microbial invasion of any of its components. Urinary tract infections may be classified on the basis of 1) anatomic location (i.e., kidney, ureter, bladder, and/or urethra), 2) etiology (*Escherichia coli, Staphylococcus intermedius,* etc.), 3) complexity (uncomplicated or complicated), and/or 4) response to therapy (persistent, relapse, reinfection, or

superinfection).[1-3]

Anatomic localization of infections within the urinary tract should be considered because it may influence the prognosis; type, dosage, and dose interval of antimicrobial agent selected; and duration of therapy. Classification of UTIs based on complexity is also of prognostic and therapeutic significance because it allows differentiation of uncomplicated (or simple) urinary tract infections from complicated urinary tract infections (Tables 65-1 and 65-2).

Table 65-1. Natural and Acquired Urinary Tract

Defenses against Bacterial Infection

I. Normal Micturition

- A. Adequate urine volume
- B. Frequent voiding
- C. Complete voiding

II. Anatomic Structures

- A. Urethral high pressure zones
- B. Surface characteristics of urethral urothelium
- C. Urethral peristalsis
- D. Prostatic secretions (antibacterial fraction and immunoglobulins)
- E. Normal length of urethra
- F. Ureterovesical flap valves

G. Ureteral peristalsis

H. Glomerular mesangial cells?

I. Extensive renal blood supply and flow

III. Mucosal Defense Barriers

A. Local antibody production

B. Surface layer (hydrophilic glycosaminoglycans)

C. Intrinsic mucosal cell antimicrobial properties

D. Exfoliation of cells

E. Commensal microbes (normal flora) of distal urethra and distal genital tract that interfere with infection by uropathogens

IV. Antimicrobial Properties of

Urine

A. Extremes (high or low) of urine pH

B. Hyperosmolality (highly concentrated urine)

C. High concentration of urea

D. Organic acids

E. Small molecular weight carbohydrates

F. Tamm-Horsfall mucoprotein

G. Leukocyte esterase-like substances (cats)?

V. Systemic Immunocompetence

A. Cell-mediated immunity

B. Humoral-mediated immunity

Table 65-2. Some Predisposing Causes of Complicated UTI

I. Interference with Normal Micturition

- A. Mechanical obstruction to outflow
  - 1. Uroliths, neoplasms and strictures (especially of urethra)
  - 2. Herniated urinary bladder
  - 3. Prostatic cysts, abscesses, or neoplasms
- B. Incomplete emptying of excretory pathway
  - 1. Damaged innervation
    - a. Vertebral fractures, luxations, subluxations, anomalies

b. Neoplasia

c. Reflex dyssynergia

2. Anatomic defects

a. Diverticula of urethra, bladder, ureters, and renal pelves.

b. Vesicoureteral reflux

II. Anatomic Defects

A. Congenital or inherited

1. Urethral anomalies

2. Ectopic ureters

3. Persistent urachal diverticula

4. Vulvar abnormalities predisposing to perivulvar dermatitis

B. Acquired

1. Diseases of the urinary tract, especially lower portions

2. Urethrostomy and other surgical diversion procedures

III. Alteration of Urothelium

A. Trauma

1. Catheterization and other instrumentation

2. Urolithiasis

B. Metaplasia

1. Administration of estrogens

2. Estrogen-producing sertoli cell neoplasms

C. Neoplasia

D. Urinary excretion of cytotoxic drugs such as cyclophosphamide

E. Alteration of normal flora of distal urethra, prepuce, and vagina

IV. Alterations in the Volume, Frequency, or Composition of Urine

A. Decreased urine volume

1. Negative water balance

2. Primary oliguric renal failure

B. Voluntary or involuntary retention

C. Glucosuria

D. Formation of dilute urine

V. Impaired Immunocompetence

A. Diseases

1. Congenital immunodeficiency?

2. Acquired

a. Hyperadrenocorticism?

b. Uremia

B. Corticosteroids; immunosuppressant drugs

Uncomplicated UTI

An uncomplicated UTI is defined as an infection in which an underlying structural, neurologic, immunologic, or functional abnormality cannot be identified. Although useful, this classification may be misleading in that it implies that bacterial infection is the primary rather than a secondary abnormality. However, most bacteria survive and multiply only when host defenses are compromised. Many simple UTIs encompass transient and

potentially reversible defects in the patient's innate defense mechanisms, even though the underlying cause may escape detection. Others occur when normal host defenses are overwhelmed by virulent uropathogens. For example, nosocomial UTI could occur as a result of improper transurethral catheterization in a hospital intensive care unit harboring resistant uropathogens. Uncomplicated UTIs might also be caused by replacement of the normal microbial flora (so-called good bacteria) of the distal urethra and genital tract with uropathogenic microbes that have emerged as a consequence of prior treatment of the patient with antibiotics. Uncomplicated UTIs are usually

associated with a better prognosis for recovery.

Complicated UTI

Complicated UTIs occur as a result of bacterial invasion of the urinary system secondary to an identifiable disease that interferes with one or more defense mechanisms (Table 65-2).[1,2,4] A relationship exists between the severity of host defense abnormality and the frequency and severity of UTI. In general, the abnormality in host defenses must be corrected or removed if secondary bacterial infection is to be completely eradicated and prevented from recurring. Failure or inability to do so

is a common cause of persistent or recurrent UTI (relapse or reinfection).

CAVEAT--Differentiation of uncomplicated from complicated UTIs and anatomic localization of UTI require appropriate diagnostic evaluation, which may include transrectal palpation of the genitourinary tract, ultrasonography, survey and contrast radiography, cystoscopy, and aspiration, punch, or surgical biopsy.

Why is it Important to Differentiate UTIs According to whether they are Persistent, Relapses,

Reinfections, or Superinfections?

Relapses

Recurrent bacterial UTIs that occur following withdrawal of therapy may be classified as relapses or reinfections (Table 65-4). Relapses (i.e., relapse of a persistent pathogen) are defined as recurrences of clinical signs caused by the same species (and serologic strain) of microbe. In this situation, remission of clinical signs and eradication of bacteria from the urine are not associated with eradication of pathogenic bacteria from tissues of the urinary tract. Although viable bacteria remain sequestered in sites inaccessible to bacteriocidal concentrations of

antimicrobics, results of the culture of urine samples obtained by cystocentesis during antimicrobic therapy are likely to be negative if the drug is eliminated in high concentration in urine. Relapses of clinical signs usually occur within several days to a few weeks after interruption of antimicrobic therapy. The bacteria may become more resistant to antimicrobial agents than prior to therapy. The pathogenesis of relapsing UTI likely involves failure to completely eliminate pathogenic bacteria before antimicrobic therapy is withdrawn. Relapses represent antimicrobial treatment failures associated with one or more causes, and affect both male and female dogs

throughout their lifespan (Table 65-5). Relapses have the potential to cause significant morbidity if mismanaged (Table 65-3).

Table 65-3. Potential Sequela to Untreated or Improperly Treated Bacterial Urinary Tract Infections

1. Lower urinary tract dysfunction (acute or chronic)
    a. Dysuria, pollakiuria
    b. “Urge” incontinence
    c. Damage to the detrusor muscle
    d. Damage to the urethra

2. Prostatitis (acute or chronic)
3. Struvite urolithiasis and its sequelae
4. Infertility
5. Renal dysfunction (acute or chronic)
    a. Pyelonephritis
    b. Renal failure
    c. Septicemia (especially in patients with concomitant obstruction to urine outflow)
6. Anemia of chronic inflammation
7. Lumbosacral discospondylitis

Reinfections

Reinfections are defined as recurrent UTI caused by one or more different

pathogens (Table 65-4). In this situation, bacteria have been eradicated from urine and surrounding tissue, but persistent dysfunction of one or more host defense mechanisms predisposes to reinfection with different uropathogens (Tables 65-2 and 65-6). If superficial damage to tissues of the urinary tract induced by bacteria by the initial infection have time to heal, recurrence of clinical manifestations of reinfections often occur at a longer interval following cessation of therapy than relapses. Reinfections appear to be more common in female dogs and young to middle-aged cats with lower urinary tract disease.

Superinfections

Superinfections are defined as infections with one or more additional pathogens during the course of antimicrobial therapy.[1] They are most likely to occur in association with in-dwelling transurethral catheters; as a sequela to urinary diversion techniques (i.e., antepubic urethrostomy, tube cystostomy, percutaneous nephropyelostomy); and because of anatomic abnormalities that promote ascending migration of bacteria into the urinary tract.

CAVEAT--The therapeutic plan for relapses often differs from the therapeutic plan for reinfections. Therefore, it is important to compare

results of bacterial culture of urine obtained prior to initiation of therapy to bacterial cultures of urine obtained during and/or after withdrawal of therapy.

Why is Diagnostic Urine Culture the Gold Standard of Diagnosis of Bacterial UTI?

Because UTI encompasses a spectrum of underlying abnormalities in host defense mechanisms in addition to bacterial pathogens, diagnostic and therapeutic requirements vary from case to case. No pathognomonic history, physical examination, radiographic, or ultrasonographic

findings are associated with bacterial UTI.

Table 65-4. Examples of Patterns of Bacteriuria Detected by Sequential Urine Cultures Performed to Monitor Response to Antimicrobial Treatment of UTI

Time and Status of Culture of Urine for Bacteria					
Prior to Treatment	3 to 5 Days After Initiating Treatment	3 to 5 Days Before Finishing Treatment	7 to 14 Days After Treatment Discontinued	More Than 2 Weeks After Treatment Discontinued	Interpretations
Positive	Positive	Does not apply	Does not apply	Does not apply	Persistent UTI; Treatment failure
Positive	Negative	Negative	Positive for same microbe	Does not apply	Relapse (Table 65-5)
Positive	Negative	Negative	Negative	Negative	Cure
Positive	Negative	Negative	Negative	Positive for different microbe	Reinfection (Table 65-6)

Table 65-5. Checklist of

Potential Causes of Recurrent UTIs Owing to Relapses

Use of Ineffective Drugs

1. Mixed infections with more than one type of pathogen in which all pathogens were not eradicated by antimicrobial therapy
2. Bacteria are resistant to drug selected
3. Antimicrobic does not attain therapeutic concentration in urine
4. Antimicrobic does not achieve therapeutic concentrations at infection sites (especially kidneys, prostate gland, and infection-induced uroliths)

5. Patient does not absorb a portion or all of an orally administered drug because of ingesta, gastrointestinal dysfunction, or interaction with other drugs

6. Initiation of therapy at an advanced state in the course of the disease

7. Acquired drug-resistant bacteria, including L-forms

8. Host factors detrimental to drug efficacy

Ineffective Use of Drugs

1. Use of improper antimicrobial susceptibility tests and/or misinterpretation of results

2. Prescription of antimicrobics for an insufficient period to eradicate

uropathogens

3. Failure to prescribe a proper dosage and/or maintenance interval for an antimicrobic that would otherwise be effective

4. Lack of compliance characterized by failure or inability of owners to give the prescribed dosage of antimicrobic at the proper maintenance intervals and for sufficient a duration

5. Inappropriate use of combination of drugs that interfere with their ability to eradicate uropathogens

6. Premature assessment of therapeutic response

In addition to bacterial infection,

many diverse noninfectious disease processes, including neoplasia and urolithiasis, result in inflammatory lesions of the urinary tract characterized by exudation of RBC, WBC, and protein into urine. The resultant hematuria, pyuria, and proteinuria suggest inflammatory urinary tract disease, but do not indicate its cause or location within the urinary tract. Diagnosis of bacterial UTI solely on the basis of urinalysis and detection of inflammatory cells in urine sediment will result in over-diagnosis. Therefore, it is essential to distinguish between inflammation and infection related to urinary tract disease. Although detection of bacteria in fresh urine sediment should prompt

consideration of UTI, it should be verified by urine culture. Non-bacterial "look-alikes" in urine sediment are often confused with bacteria.[4]

Quantitative urine culture is considered to be the gold standard for diagnosis of bacterial UTI.[18] In addition to facilitating differentiation of bacterial contaminants from bacterial pathogens, accurate identification of specific bacterial species aids in selection of antimicrobial drugs. Also recall that recurrent UTIs owing to relapses cannot be distinguished from recurrent UTIs owing to reinfections without comparison of pretreatment bacterial culture results to follow-up culture results.

CAVEAT--Failure to perform bacterial urine cultures or failure to correctly interpret the results of urine cultures may lead not only to diagnostic errors but therapeutic failures as well. Although detection of bacteria in properly collected urine samples is highly indicative of bacterial UTI, further information is required to confirm and localize the site(s) of infection.

Table 65-6. Checklist of Potential causes of Recurrent UTIs owing to Reinfections

1. Invalid culture results caused by:

a. Contamination of specimen during collection, transport, storage, or handling

b. Improper technique of bacterial culture of urine

2. Continued dysfunction of host defense mechanisms (Tables 65-1 and 65-2)

3. Failure or inability to recognize and eliminate predisposing causes

4. Iatrogenic infection, especially associated with transurethral catheterization

5. Sequelae to surgical techniques that have impaired host defense function, especially urethrostomies and urine

diversion procedures

6. Spontaneous reinfection

How should Urine Samples be Collected for Diagnostic Culture?

We prefer to collect urine samples for bacterial culture by cystocentesis to eliminate problems of differentiating contaminants from pathogens.[3] Detection of bacteria, even in low numbers, in urine aseptically collected by cystocentesis is indicative of UTI. However, false positive results may occur if the needle penetrates a loop of intestine during cystocentesis, or if the sample is contaminated during transfer

to culture media. For this reason, quantitative urine culture is routinely recommended, even for samples collected by cystocentesis. Urine culture results should be interpreted in context of other clinical findings (Table 65-7).[5]

CAVEAT--Catheter-induced UTIs (nosocomial infections) are common in patients with urinary tract diseases, and could even result in iatrogenic pyelonephritis, renal failure, and septicemia. Therefore, transurethral catheterization of patients at increased risk for UTI should be evaluated in context of risks and benefits.

Table 65-7. Checklist of

Factors Influencing Interpretation of Qualitative Bacterial Cultures of Urine

- Method of urine collection?
- Time lapse between urine collection and bacterial culture?
- Method of preservation if urine is not cultured within 30 minutes?
- Pure or mixed culture of bacteria?

  1 isolate in about 75% of UTI

  2 isolates in only 20% of UTI

  3 isolates in only 5% of UTI

- Magnitude of inflammatory response (if any) detected by urinalysis?
- Light microscopic detection of

bacteria in uncontaminated fresh unspun urine?

How should Urine Samples be Preserved Prior to Culture?

If diagnostic bacterial cultures are to be performed, urine should be collected for culture before antibacterial therapy is initiated. If the patient is currently being treated with an antimicrobic, it should be discontinued for approximately 3 to 5 days prior to diagnostic urine culture in order to minimize inhibition of in vivo and in vitro bacterial growth.

Because urine may be a good culture

medium at room temperature (bacterial counts may double every 20 to 45 minutes), it should be cultured within 15 to 30 minutes from the time of collection.[6] Another indication for culture of fresh urine samples is that destruction of some fastidious bacteria may be detectable within an hour of collection. If for any reason culture of freshly collected urine samples is not possible, the samples should be kept in a sealed sterile container and immediately refrigerated following collection. Refrigerated samples may be stored for 6 to 12 hours without significant additional growth of bacteria.[6] However, it is emphasized that fastidious organisms may be killed in the urine environment if

refrigeration storage time is prolonged.

Alternatively, commercially manufactured collection tubes combined with refrigeration may be used to preserve samples for up to 72 hours. Commercially manufactured urine culture and susceptibility test kits are also available (IndicatoRx, Idexx Laboratories, Westbrook , Maine).

CAVEAT--Transport of urine specimens to a commercial microbiology laboratory results in increased time between urine collection and aerobic culture and, therefore, adds a potential source of error, especially if the samples are not properly preserved. Freezing urine samples may also

destroy bacteria.

Why are Quantitative Bacterial Urine Cultures a Standard of Practice in the Management of Utis?

The gold standard for diagnosis of UTI is isolation of bacteria in a properly collected urine sample. However, the presence of bacteria in urine per se is not synonymous with UTI because urine may be contaminated with bacteria as it flows through the urethra, and after it is removed from the patient, but before it is cultured. Quantitative urine culture includes determination of the number of bacteria (colony-forming units) per

milliliter of urine in addition to isolation and identification of bacteria. Because it facilitates differentiation of bacteria that have contaminated the urine sample from bacteria that are likely to be causing UTI, quantitative culture is the preferred method of diagnostic culture for urine samples obtained by any collection method.

The concept of significant bacteriuria was introduced to aid differentiation between harmless bacterial contaminants of urine and pathogenic bacteria causing infectious disease of the urinary system.[1,2,7] A high bacterial count in a properly collected and cultured urine sample indicates the high probability of UTI (Table 65-8).

Small numbers of bacteria obtained from untreated patients usually indicate contamination.

The lower limit of numbers of bacteria isolated from feline urine that indicate infection (so-called cutoff values) has not been precisely determined. However, it is usually less than that in dogs because feline urine appears to be less conducive to bacterial growth than urine of dogs (Table 65-8).[8]

CAVEAT--When interpreting bacterial cultures, several variables should be considered (Table 65-7). In up to 20% of canine patients, bacterial UTI may be present with less than 10,000 colony-forming units per milliliter of

urine.[2,3] In this circumstance, samples collected by catheterization or during voiding might erroneously be interpreted as contaminants (Table 65-8). This observation emphasizes the importance of cystocentesis as the preferred method of collection for diagnostic urine culture.

How can Routine Quantitative Aerobic Cultures of Urine be Adapted to a Primary Care Veterinary Practice?

Many veterinarians do not routinely perform urine cultures because of the time and expertise required to

specifically identify bacteria. However, all individuals can recognize lack of growth of bacteria on culture plates. Therefore, we recommend that veterinarians quantitatively culture urine on microbiology plates (such as blood agar and MacConkey agar) utilizing calibrated microbiologic loops.[9] If no growth occurs after incubation of the culture plates at 37° for approximately 24 hours, or if only small numbers of bacteria grow (contaminants), further efforts to identify bacterial species is unnecessary, and treatment with an antimicrobial drug is usually not warranted (Table 65-8). If significant numbers of bacteria (colony-forming units) are isolated, the microbiologic

plates, or swab cultures from the plates, can then be sent to commercial laboratories for species identification and antimicrobial susceptibility tests. Therapy with an appropriate antimicrobial drug (refer to next section on empirical choices of antimicrobics) may be initiated pending results from the commercial laboratory.

We routinely use calibrated bacteriologic inoculating loops (available from Veterinary Lab Supply, 120 S. 1st Ave., Winterset Iowa 50237) or microliter mechanical pipettes that deliver exactly 0.01 or 0.001 milliliters of urine to culture plates. To facilitate culture, urine is streaked over the

surface of agar plates with the inoculating loops by conventional methods. The plates are placed in an incubator upside down at 37°C for 18 to 24 hours, and then examined for bacterial growth. Blood agar will support growth of most aerobic organisms encountered in patients with UTI. MacConkey agar provides information that aids in tentative identification of bacteria and prevents “swarming” of microbes.

This strategy of in-hospital bacterial culture of urine not only fosters appropriate diagnosis and therapy, it is also financially sound. The fee normally paid to the diagnostic laboratory for a sterile urine culture

can be rightfully earned by the veterinary hospital. This strategy also enhances use of urine cultures to monitor the effectiveness of therapy (so-called “test of effectiveness”).

Table 65-8. Interpretation-Quantitative Urine Cultures in Dogs and Cats*

Collection Method	Significant		Suspicious		Contaminant	
	Dog	Cat	Dog	Cat	Dog	Cat
Cystocentesis	≥ 1000†	≥ 1000	100 to 1000	100 to 1000	≤ 100	≤ 100
Catheterization	≥ 10,000	≥ 1000	1000 to 10,000	100 to 1,000	≤ 1000	≤ 100
Voided midstream	≥ 100,000‡	≥ 10,000	10,000 to 90,000	1000 to 10,000	≤ 10,000	≤ 1000

***The data represent generalities. On occasion, bacterial UTI may be detected in dogs and cats with the fewer numbers of organisms (i.e., false negative results).**

† Numbers represent colony-forming units of bacteria per milliliter of urine.

‡Caution: Contamination of midstream samples may result in colony counts of 10,000/ml or higher in some cats, and especially female dogs

(i.e., false positive results). Therefore, they should not be used for routine diagnostic culture of urine.

CAVEAT--Before culture, urine should not be kept at room temperature or frozen. Also, urine should not be placed in enrichment broth immediately following collection to enhance bacterial growth, as this will invalidate the results of quantitative culture.

Canine and Feline Urolithiasis: Pathophysiology, Epidemiology and Management

Jodi L. Westropp
Annette L. Ruby
Scott J. Campbell
Gerald V. Ling

Overview of Urolithiasis

Uroliths are organized concretions found in the urinary tract that contain

primarily organic or inorganic crystalloid (ionic component of crystals) and a much smaller amount of organic matrix. When urine becomes supersaturated with minerals, and other parameters are conducive to crystallization, minerals can precipitate and individual crystals can be observed in the urine. Crystalluria does ***not*** mean that the patient is at risk for urolithiasis. Crystalluria is not a disease and no particular treatment is necessary unless a urolith is currently present or a urolith or urethral plug has formed in the past.

Supersaturation of urine with crystalloids depends on the interaction of dozens of crystalloid species formed

by common mineral elements in the urine derived from the amount of each solute ingested and excreted in the volume of urine produced.[1] Organic molecule contributions, such as protein inhibitors or promoters of crystallization, may also influence crystal and stone formation.[2] Urine samples should be analyzed within 1 hour of collection to minimize temperature- and time-dependent in vitro crystallization.[3]

Urine pH also affects crystal formation: Struvite, calcium carbonate, and calcium phosphate are less soluble in alkaline urine; cystine, uric acid, and silica are less soluble in acid urine. Depending on which salt of uric acid is

present, the solubility of the urate stone may be pH dependent. For example, ammonium urate is more soluble in an alkaline pH, but other salts of uric acid may not be influenced by urine pH to the same extent. Further research is required to properly identify the exact salts present in these calculi. Urine pH does not appear to have a major effect on the solubility of calcium oxalate (CaOx), and CaOx calculi can be observed over a wide spectrum of urine pH. In addition to urinary pH, factors that predispose to urinary stasis play an important role in urolithiasis, because crystals that remain in the urinary tract for a sufficient time to allow aggregation may allow urolith formation.

Relative Supersaturation

The most frequently reported method for evaluating the crystallization potential in canine and/or feline urine is the calculation of relative supersaturation (RSS),[4-6] although many other methods of assessment have been reported in humans.[7-9] Concentrations of lithogenic substances and urine pH are used to calculate the urinary RSS values for particular crystal types. A validated computer program is used to calculate the concentrations of numerous soluble ion complexes and the activity products of the stone-forming ion complexes.[6] The RSS for a particular crystal type is then calculated from the ratios of the

activity products to the thermodynamic solubility products for each complex. A RSS less than 1 indicates that the urine is undersaturated with the ion complex evaluated, whereas a RSS greater than 1 indicates that the urine is supersaturated with the ion complex evaluated.

Imaging the Animal with Urolithiasis

Radiographs should be taken prior to stone removal and should include the entire urinary tract. CaOx, apatite, struvite, and silica stones are generally radioopaque. Most urate and cystine stones cannot be identified on plain radiography. Immediately after stone

removal, additional radiographs should be assessed to be certain that no stones were inadvertently missed. CaOx stones oftentimes occur as multiple, small calculi and can be difficult to flush from the urethra. Contrast studies or ultrasound should be used to determine the presence or absence of residual urate or cystine stones after surgery. Periodic imaging (every 3 to 4 months) is essential to monitor for recurrent urolithiasis. This will enable the clinician to institute non-invasive therapy while stones are small and surgical interventions may be prevented.

Removal of Calculi

Removal of cystic calculi can be performed by various methods. Oftentimes, a cystotomy is performed. If clinically warranted, at the time of stone removal, a bladder biopsy can be obtained for histologic evaluation and culture. Alternatively, for larger cystic calculi in dogs and cats, laser lithotripsy is available at some referral institutions. Holmium:YAG laser lithotripsy can fragment stones by means of a photothermal process and the laser energy is absorbed in less than 0.5 mm of fluid, making it safe for urologic procedures.[10] The Ho:YAG laser has been reported to fragment all types of canine uroliths in vitro,[11] but more studies are needed to evaluate the time required to fragment canine

and feline stones in vivo. Once the stones are fragmented, a basket can be inserted through the cystoscope and the largest fragment can be grasped to ensure that it will pass easily through the urethra. The larger pieces should be included for stone analysis to properly identify all the layers of the stone. This is important to subsequently initiate proper management strategies. All other fragments can be removed by voiding urohydropropulsion. Urohydropropulsion is also useful when the animal presents with small cystic calculi. If “sand and debris” or even small stones (3 to 5 mm) are seen in the urinary bladder, surgery is often not necessary and voiding urohydropropulsion may be a less

invasive procedure for stone removal. For a complete review of this technique, the reader is referred to the literature.[12]

When to perform surgery in cats with ureteroliths is often a topic of debate among surgeons and internists. Results from a larger retrospective study of ureteral calculi in cats suggests that medical and surgical management are associated with high morbidity and mortality rates.[13] Medical management with aggressive fluid diuresis, parenteral diuretic therapy, analgesia, and even hemodialysis is recommended prior to any surgical intervention. When the ureteral calculus remains lodged in the ureter, despite medical

therapy, and is causing renal compromise or significant discomfort to the cat, surgery should be performed to remove the obstruction. Ureterotomy or ureteroneocystostomy can be done to remove the ureterolith, with the latter procedure performed most often when the ureterolith is in the distal third of the ureter. Recurrent ureterolithiasis is reported to be as high as 40% in cats that were evaluated with serial abdominal imaging. Most of the ureteroliths we analyze at our laboratory are CaOx,[14] but we have noted an increased incidence of dried solidified blood calculi in the ureters of cats.[15]

Struvite Urolithiasis in Dogs

Struvite-containing calculi comprise about 45% of all canine uroliths analyzed at the UC-Davis Urinary Stone Analysis Laboratory. Almost three quarters of all struvite calculi occurred in female dogs. A strong statistical association between the female sex and increased risk of struvite-containing calculi in dogs has been documented.[16] An increased risk for struvite-containing calculi has been reported in Cocker spaniels, springer spaniels, and Labrador retrievers. A lower risk for struvite-containing calculi in dogs that were subject to stone formation was noted in both sexes of Dalmatians, Pomeranians, and

Maltese.[17] We have reported a trend change in the proportion of canine urinary calculi composed of struvite from 1981 to 2001.[18] For both sexes, a 20-year statistically significant decrease was observed in the proportion of calculus specimens that contained struvite. This decrease in proportion was greater in males than in females. The change in trend may depend on breed, age, gender, and on the interaction among these three factors.

Struvite uroliths are most commonly found in the lower urinary tract, but occasionally are found in the renal pelves and ureters. Struvite uroliths come in a variety of shapes and sizes

and other minerals such as calcium and phosphate can be incorporated into the stone because of secondary urine pH changes.

In dogs, virtually all struvite calculi are infection-induced, and the causative organism is usually *Staphylococcus intermedius* or, less commonly, *Proteus mirabilis*. These bacteria have the ability to hydrolyze urea into ammonia, bicarbonate, and carbonate. The resulting increase in the urine pH results in urinary supersaturation of the ions. The elevated pH is also thought to be a contributory factor in causing damage to the underlying uroepithelial glycosaminoglycan layer. It has been reported in humans, that

non-urease-producing bacteria, may also influence the formation of urinary stones,[19] but this has not been evaluated in dogs. Occasionally, in the absence of infection, the urine can become supersaturated with the minerals that compose struvite uroliths, and stone formation can occur in the absence of infection. The solubility of struvite increases when the urine pH is less than 6.8.

Struvite Urolithiasis in Cats

Based on previously published epidemiology studies, struvite was the most common stone reported in cats until approximately 1993, when the incidence of CaOx began to increase.[20]

Between 1998 and 2003, struvite was the second most common stone type at another laboratory.[21] We have also noted that struvite is the second most common mineral type found in calculi submitted to the UC-Davis Urinary Stone Analysis Laboratory, and the number of struvite stones has significantly decreased when evaluating the past 15 years.[22] However, the proportion of struvite stones analyzed in the past few years appears to be increasing, whereas the proportion of CaOx-containing uroliths is declining (Figure 66-1). We have noted a change in feline urolithiasis trends beginning in 1993, when 53% of the stones *contained* CaOx, while only 47% contained struvite. The

proportion of CaOx-containing uroliths continued to increase over the next 8 years, while the proportion of struvite-containing uroliths decreased during that same period. Stones not containing CaOx or struvite appeared to be static during that same period. One hypothesis for this apparent change in trend could be that less highly acidifying diets are being prescribed by veterinarians, but diet histories were not available from these records to confirm or deny this hypothesis.

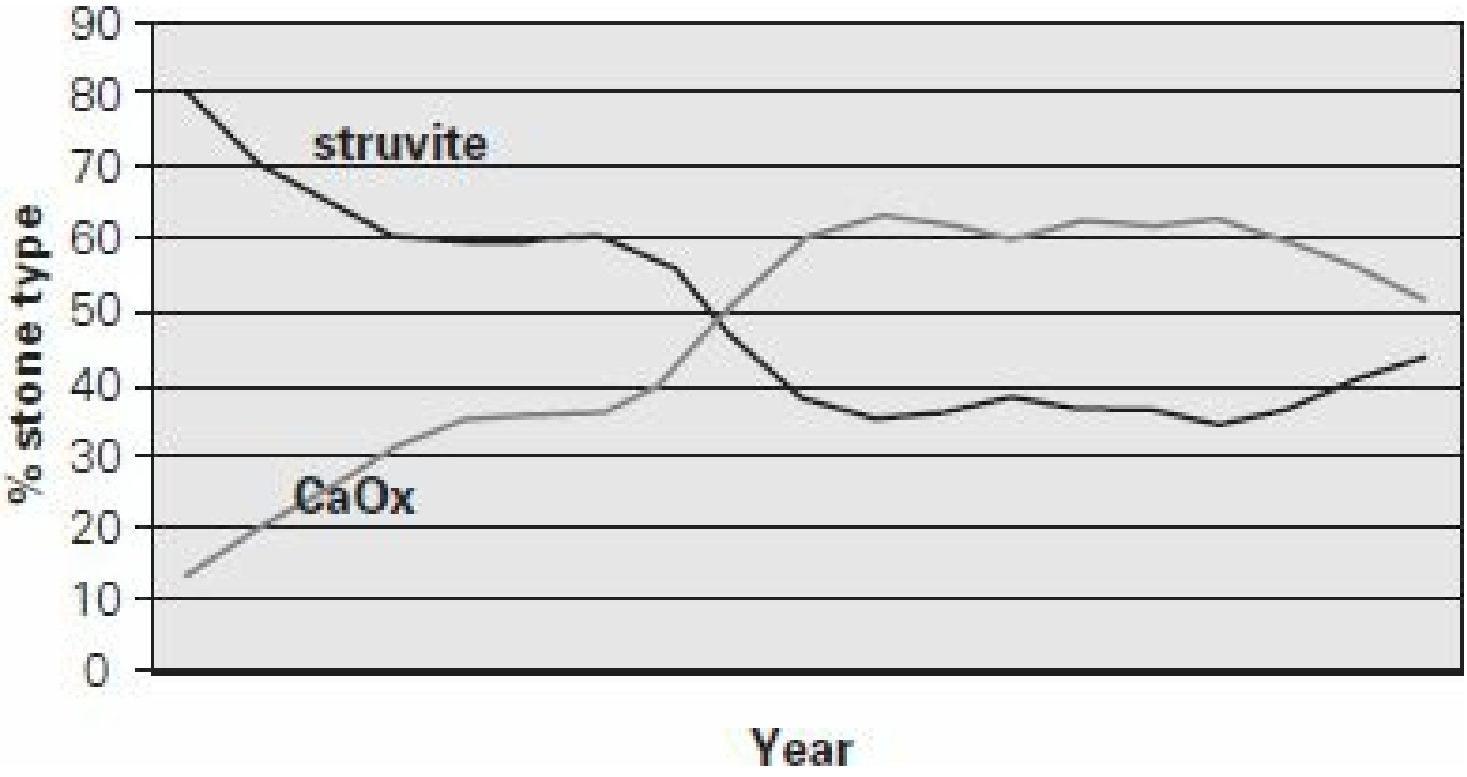

Figure 66-1. Average of struvite and calcium oxalate stones in cats over 3 years.

In 2000, the University of Minnesota Urolith Center reported that the foreign shorthair, ragdoll, Chartreux, Oriental shorthair, domestic shorthair, and Himalayan were breeds at risk for the formation of struvite calculi.[20] The Rex, Burmese, Abyssinian, Russian blue, Birman, Siamese, and mixed breed cats had a significantly lower

risk of developing struvite uroliths. Table 66-1 provides a table of relative breed risks for struvite and CaOx formation that we have seen at The UC-Davis Urinary Stone Analysis Laboratory.[22] The bladder is the most common site for struvite urolith retrieval, and approximately 90% of the struvite uroliths submitted to our laboratory are removed from this site. Struvite stones were also submitted after being removed from the urethra (7%) and the upper urinary tract (0.34%) or after the stones were voided (2.5%). Ureteral stone submittals have significantly increased over the past 15 years.[22]

In cats, struvite stone formation

usually occurs in sterile urine. This is in contrast to dogs in which struvite stones are usually associated with a urease-producing bacterial infection. Epidemiologic studies on diet and struvite formation in cats have been published,[23] but the pathophysiology of struvite urolith formation in cats is not yet completely understood. Struvite urolith formation likely results from a combination of breed, sex, and dietary factors. Struvite is more soluble in slightly acidic urine (pH < 6.8). Therefore, factors that may be associated with the formation of alkaline urine (e.g., family history of struvite stones, a diet low in animal protein, or distal renal tubular acidosis) should also be considered in

cats with struvite urolithiasis.

Table 66-1. Relative Breed Risks for Struvite and CaOx

Breed	Calcium oxalate (n)	Risk ratio	95% confidence interval	Struvite (n)	Risk ratio	95% confidence interval

Calcium Oxalate Urolithiasis in Dogs and Cats

The exact mechanism of CaOx stone formation is unknown and likely

involves interrelationships among gender, genetics, breed, diet, and environmental factors. In either species with proven or suspected CaOx urolithiasis, serum should be evaluated to assess the calcium concentrations. Elevated calcium from various causes (neoplastic, primary, or secondary hyperparathyroidism, or idiopathic hypercalcemia in cats) can predispose the animal to CaOx stone formation. In humans, approximately 75% of kidney stones are composed predominantly of CaOx, and oxalate metabolism is thought to play a crucial role in stone development. Hyperoxaluria can occur from increased dietary intake as well as a loss or diminished activity of oxalate-degrading bacteria in the colon

(*Oxalobacter formigenes*).[24] Primary hyperoxaluria type I is an inborn error of glyoxylate metabolism and can lead to marked increases in hepatic oxalate production in humans.[25] Human beings are also much more prone to developing nephrolithiasis, particularly in industrialized nations, whereas bladder stones are found most frequently in developing countries[26] (as well as in dogs and cats). Although urinary supersaturation with crystals is implicated in stone formation in humans, several studies have investigated the possibility that the urine is not the initial site of stone development. A vascular etiology for nephrolithiasis in humans has been proposed,[26] suggesting that vascular

abnormalities (e.g., hypertensive vascular injury, atherosclerosis) can lead to Randall's plaques (papillary lesions that are usually associated with calcium and phosphate or CaOx).[27] Stoller et al, hypothesized that the primary event in CaOx nephrolithiasis in humans may begin in the vascular bed at the tip of the renal papilla. Still other studies have investigated a role for elevated lipids in CaOx urolith formation in rats and humans.[28] Therefore, the primary site of urolithiasis may be unrelated to urinary stasis, infection, or other secondary causes for urinary stones, and novel treatment regimens may need to be investigated. No studies investigating these disorders or

hypotheses have been published for cats and dogs and what, if any, relationships can be made between these species remains to be seen.

CaOx is one of the most common mineral types present in specimens of calculi that are obtained from dogs. The incidence of CaOx stones appears to be increasing over the past 20 years (with a reciprocal decrease in the proportion of struvite uroliths).[18] CaOx calculi appear to be more common in older, castrated male dogs.[16,29] Other risk factors for CaOx uroliths in dogs include obesity[29] and breed. Several small-breed dogs, including the miniature schnauzer, a breed that is recognized to also be at risk for

hypertriglyceridemia, have a higher risk of CaOx urolith formation. Elevated cholesterol[26] and triglycerides have been evaluated in other species with CaOx uroliths, and research in rats suggests that elevated lipids may play a role in CaOx urolith formation.[26,28] However, the pathogenesis of stone formation in dogs and cats may differ from that in rats and humans.

CaOx stones are the most common urolith type found in people, and during the past 15 years the incidence of CaOx urolith formation has been increasing in cats.[20] CaOx stones are composed of calcium oxalate monohydrate (whewellite) or calcium

oxalate dihydrate (weddellite). The exact cause of CaOx stone formation in the cat is unknown. The concern regarding struvite stone disease in cats seems to have led pet food manufacturers to restrict the magnesium content of feline diets and has also has resulted in the formulation of diets with greater urinary acidifying potential. Unfortunately, an increase in the frequency of CaOx urolithiasis appears to have occurred since these dietary modifications began. Between 1984 and 1995 the percentage of stones submitted to the University of Minnesota Urolith Center that were found to be composed of CaOx increased from 2% to 40%.30 We reported a similar trend from our

laboratory.[14] Although dietary acidification can enhance the solubility of struvite crystals in the urine of cats, it also promotes the release of calcium carbonate from bone as a metabolic buffer, and hypercalciuria results.[31] Results have shown that differences in age, sex, breed, and reproductive status did not contribute to the apparent reciprocal relationship between occurrences of CaOx and struvite uroliths in cats.[20] However, as mentioned earlier in the struvite section, we, and others[21] have also noted a decrease in the proportion of CaOx stones submitted over the past few years. CaOx uroliths can occur anywhere in the urinary tract, and when ureteroliths are present in cats,

the mineral composition is likely to be CaOx. Approximately 73% of CaOx stones we analyzed from cats were removed from the bladder, 7.3% were removed from the ureter(s), 4.3% were removed from the kidney(s), 13% were removed from the urethra and 2% were voided. Most of the time, if CaOx stones were removed from the urethra or voided, stones were also located elsewhere in the urinary tract.

Cat breeds reported to be at higher risk for CaOx urolithiasis include the ragdoll, British shorthair, foreign shorthair, Himalayan, Havana brown, Scottish fold, Persian, and exotic shorthair. The Birman, Abyssinian, Siamese, and mixed breed cats were at

significantly lower risk for developing CaOx uroliths.[20] As mentioned, cats with CaOx urolithiasis are generally older than cats with struvite urolithiasis. Cats between 7 and 10 years of age are reported to be 67 times more likely to develop CaOx uroliths than are cats between one and two years of age.[20] Male cats were reported to be 1.5 times more likely to develop CaOx uroliths than were female cats, while neutered cats were seven times more likely to develop CaOx uroliths as compared with sexually intact cats.

Urate Urolithiasis in Dalmatian Dogs

Unlike most other breeds of dogs, Dalmatian dogs have well described alterations in purine metabolism that lead to the excretion of urate (salts of uric acid) or, much less commonly, uric acid in the urine rather than the more soluble metabolite, allantoin.[32] In Dalmatians, the liver does not completely oxidize available uric acid, even though it contains a sufficient concentration of uricase, the enzyme necessary to convert uric acid to allantoin. It is hypothesized that the hepatic cellular membranes are partially impermeable to uric acid.[33] In addition, Dalmatians are reported to excrete excessive amounts of uric acid from the kidneys, which is the result of a combination of reduced tubular

reabsorptive capacity and increased tubular secretion.[34] Increased uric acid excretion appears to be a risk factor for urate stones, but not the only cause. All Dalmatians excrete relatively high amounts of uric acid (400 to 600 mg of uric acid per day as compared with 10 to 60 mg per day in non-Dalmatian dogs); however, not all Dalmatians form urate stones. It is likely that a combination of breed and other factors, such as a lack of urinary inhibitors,[35] may play a role in the pathogenesis of urate stone formation. It has been reported that most Dalmatians that form calculi are males.[17] Reasons for this sex difference could be that there is a contributing X-linked genetic trait, or that stones

become lodged in the smaller diameter urethra of male dogs. Genetic studies have reported that the mode of inheritance is not X-linked and the prevalence of the clinical disease in male Dalmatians ranges form 26% to 34%.[32]

Depending on which salt of uric acid is present, the solubility of the urate stone may be pH dependent. For example, ammonium urate is more soluble in an alkaline pH, but other salts of uric acid may not be influenced by urine pH to the same extent. Further research is required to properly identify the exact salts present in these calculi.

Urate Urolithiasis in Non-Dalmatian Dogs

A high incidence of ammonium urate stones have been reported in dogs with portal vascular anomalies. Portal vascular shunts provide communication between systemic vasculature and the systemic circulation, bypassing the liver and resulting in decreased hepatic function. As a result, uric acid accumulates and may predispose the animals to urate stone formation. It is hypothesized that surgically correcting the underlying problem and eliminating the hyperuricosuria can prevent urate stone prevention for dogs with portovascular anomalies. Allopurinol is

generally not recommended in dogs with portovascular anomalies, because of alterations in metabolism of this drug.

Other canine breeds (without hepatic dysfunction) have been reported to have an increased incidence for urate urolithiasis, particularly the English bulldog. The pathogenesis of the urate stone formation in this breed has not been determined and evaluation of eight male English bulldogs with stones revealed mild elevation in serum uric acid concentrations. Hepatic function was normal when assessed.[33] The miniature schnauzer, Shih tzu, and Yorkshire terriers,[33] and perhaps the Russian black terrier,[36] are also over

represented.

Feline Urate Urolithiasis

We have evaluated the mineral composition of 4933 feline uroliths submitted to the UC-Davis Urinary Stone Analysis Laboratory from 1986 to 2003. Of these, 10.4% contained urate. Approximately half of these stones were composed of 100% urate. Others were mixed with struvite or CaOx, and of these, 49% were from female cats and 51% were from males. When evaluating data from our laboratory, the incidence of urate calculi in cats does not appear to have changed over the past 20 years; therefore, the occurrence of these

calculi does not appear to be influenced by the dietary changes that occurred to minimize struvite stone formation. CaOx may be a secondary component of some urate stones, and urate stones found in cats with portosystemic shunts often also contain struvite.[30] Often, the pathophysiology of urate urolith formation in cats is unknown.

Cystine and Silica Urolithiasis in Dogs and Cats

Cystine uroliths account for a small percentage of uroliths we analyze at the UC-Davis Urinary Stone Analysis Laboratory. Other laboratories in the

United States also report this stone type infrequently.[37] Cystinuria can occur in some dogs and cats and appears to be a heterogeneous disease. Cystinuria is an inherited renal transport disorder characterized by excessive urinary excretion of cystine as well as the other dibasic amino acids ornithine, arginine, and lysine. Dibasic aminoaciduria has also been reported with cystinuria. Concurrent excess carnitine has also been reported in the urine of five dogs with cystinuria that were studied.[38] The molecular basis of cystinuria has been investigated in Newfoundland dogs, and the cloning and sequencing of the canine SLC3A1 gene (the amino acid transport gene) and the identification of a nonsense

mutation in exon 2 of this gene have been reported.[39] Cystine is insoluble in urine and the solubility of this amino acid decreases further in acidic urine. Generally cystine uroliths are not visible on plain radiography, unless they are exceptionally large. Cystine uroliths are rare in cats; they accounted for only 0.2% of uroliths from cats at the Minnesota Urolith Center[40] and 0.15% of the feline uroliths analyzed at our laboratory.

A diet that is high in moisture and reduced in dietary protein has the potential for minimizing the recurrence of stone formation in dogs with cystine uroliths. If protein is restricted in a dog excreting excessive sulfur amino acids,

taurine supplementation is recommended. The effects of sodium on cystine excretion have not been evaluated in dogs, however, sodium has been reported to enhance cystinuria in humans.[41] The thiol–containing drugs (e.g., n-(2-mercaptopropionyl)-glycine (2-MPG)) can decrease the concentration of cystine in the urine by participating in a thiol-disulfide exchange reaction. In one retrospective study of 88 dogs,[42] the most common breeds with cystine urolithiasis were dachshunds, Tibetan spaniels, and basset hounds. Cystine excretion appeared to decrease as the animal aged. According to this study in dogs with recurrent cystine urolithiasis, dissolution was induced by increasing

the tiopronin dosage to 40 mg/kg body weight per day. Adverse effects were found using the thiol-containing drugs and included aggressiveness and myopathy. All signs disappeared when treatment was stopped. In addition to the use of the thiol-containing drugs, increasing water intake should also be initiated.

Silica urolithiasis is uncommon in dogs and rare in cats. These uroliths account for approximately 0.1 to 2.0% of the uroliths seen each year from the Minnesota Urolith Center[43] as well as from the UC-Davis Urinary Stone Analysis Laboratory. Most dogs with silica uroliths are older, and male dogs appear to be predisposed. The most

common breeds associated with silica urolithiasis at our laboratory include the German shepherd, Labrador retriever, and Australian shepherd. The hypothesized pathophysiology of silica stones is reviewed nicely elsewhere and the reader is referred to the literature for information pertaining to management.[43]

Chapter 67

Feline Lower Urinary Tract Diseases

Carl A. Osborne
Jon M. Kruger
Jody P. Lulich

Terminology

Feline Urologic Syndrome (FUS)

In 1970, the term ”feline urologic syndrome” and the acronym “FUS” were first used and soon became

widely adopted as a diagnostic umbrella to refer to naturally occurring and experimentally induced feline lower urinary tract disease (FLUTD) with different sites of involvement, different combinations of clinical signs, and fundamentally different underlying causes.[1] The common denominator of all of these disorders was varying combinations of recurrent dysuria, pollakiuria, stranguria, hematuria, periuria (urinating in inappropriate locations), and/or urinary outflow obstruction. The similarity of clinical signs of FLUTD caused by diverse causes is understandable since the urinary tract can respond to various diseases in only a limited and predictable fashion.

Unfortunately, use of the acronym FUS to lump all FLUTDs together, rather than separating them on the basis of specific underlying causes, fostered fundamental errors in the design of experimental, epidemiologic, and clinical studies designed to investigate the biologic behavior and diagnosis of this problem.[2] In addition a diagnosis of FUS based solely on history and physical examination findings resulted in a stereotyped approach to medical and surgical treatment and prevention of obstructive and nonobstructive LUTD, regardless of underlying cause.

Feline Lower Urinary Tract Disease (FLUTD)

In the early 1980's we advanced the concept that FUS was a poor synonym for a heterogeneous group of FLUTD that resulted from fundamentally different causes.[3,2] The causes may be single, multiple, and interacting or unrelated. This change in perspective with which we consider the naturally occurring forms of feline lower urinary tract disorders is of fundamental clinical significance because it helps to eliminate the stereotyped approach to treatment and prevention fostered by use of FUS as a diagnostic endpoint. We continue to urge our colleagues to substitute a clinical diagnosis of FUS with refined diagnostic terms pertaining to sites (e.g., urethra, bladder), causes (e.g., anomalies,

urolithiasis, bacteria, fungi, parasites, neoplasms, metabolic disturbances, idiopathic forms), morphologic changes (e.g., inflammation, neoplasia), and pathophysiologic mechanisms (e.g., obstructive uropathy, reflex dyssynergia) whenever possible. If the cause of FLUTD cannot be identified after appropriate evaluation, we suggest that it be called idiopathic FLUTD with the understanding that not all cases of idiopathic FLUTD have the same underlying cause. Idiopathic FLUTD is an exclusion diagnosis.

Feline Idiopathic Cystitis and Feline Interstitial Cystitis

In the early and mid 1990's, investigators hypothesized that cats with idiopathic forms of LUTD had interstitial cystitis because they observed that some cats had abnormalities similar to those reported in humans with interstitial cystitis.[4,5] Human interstitial cystitis is a nonmalignant neuro-inflammatory disorder of humans of unknown etiology.[6] The disease is characterized by dysuria, pain above the pubic region which is relieved by voiding; dysuria; pyuria, hematuria, and/or proteinuria detected by urinalysis; distinctive petechial hemorrhages in the submucosa (called glomerulations) detected by cystoscopy; and decreased urine concentrations of

glycosaminoglycans. In subsequent pilot studies of cats, decreased urine concentrations of glycosaminoglycans and increased urinary bladder permeability were also reported.[7] Therefore, they recommended that idiopathic LUTD be renamed feline interstitial cystitis (FIC). Since that time they have stated that use of the term feline interstitial cystitis as an umbrella term for all cats with idiopathic FLUTD is inappropriate . They reserve use of the term feline interstitial cystitis for cats that have persistent or frequent recurrence of clinical signs of lower urinary tract disease. Idiopathic FLUTD can be acute or chronic, but interstitial cystitis by definition is an idiopathic chronic

inflammatory process. Currently the terms idiopathic FLUTD and feline idiopathic cystitis are often used as synonyms.

Incidence and Proportional Morbidity of LUTD

Incidence

The incidence of disease is defined as the annual rate of appearance of new cases of disease among the entire population of individuals at risk for the disease. The overall incidence of feline FLUTD in the United States and Great Britain has been estimated to be 1.5% per year.[8,9] Although idiopathic disease currently accounts for the majority of

these cases,[5,10] the actual incidence of idiopathic disease, its rate of recurrence, and frequency of sequelae are unknown. There have been no contemporary controlled epidemiologic studies designed to evaluate subsets of cats with LUTDs defined on the basis of specific diagnostic criteria.

Proportional Morbidity Rates

The incidence of naturally occurring hematuria, dysuria, and/or urethral obstruction in domestic cats should not be confused with the frequency that such cats are seen in veterinary hospitals (so-called proportional morbidity rates). As apparent in the following discussion, proportional

morbidity rates for FLUTD are not a reliable index of FLUTD incidence, since they may be affected by factors such as local population economics, geography, season, type of veterinary practice, and the interest and training of veterinarians.

Results of a recent retrospective study indicate that the proportional morbidity of FLUTD at Veterinary Teaching Hospitals from 1980 to 1997 was 8%, with significant variation between hospitals (3%-13%)[11]. The wide variance reported by veterinary teaching hospitals emphasizes the need for caution in formulating generalities about proportional morbidity rates of LUTD on the basis of reports from one

center. Lower urinary tract disease is more commonly encountered and/or recognized in Veterinary Teaching Hospitals with special interests in FLUTD. Although proportional morbidity rates reported by these centers are unlikely to be representative of veterinary hospitals without a special interest in urology , the frequency with which specific causes of LUTD are recognized by contemporary diagnostic evaluation suggests that specific causes of LUTD are “under-diagnosed”.

Results of prospective studies performed at two Veterinary Teaching Hospitals indicate that the most commonly encountered forms of

FLUTD are idiopathic LUTD (~65 %) and urolithiasis (~25%).[5,10] Diseases encountered less frequently include bacterial urinary tract infections, congenital defects, neurogenic disorders, neoplasia, and trauma.[9,11]

Priority of Diagnostic and Therapeutic Plans for Lower Urinary Tract Diseases

Logically, in order to localize and define different causes of diseases of FLUTD, the need for contemporary diagnostic evaluation of each patient becomes indisputable. In addition to an appropriate history and physical examination, complete urinalysis performed on samples that have not

been altered by reverse flushing solutions, and evaluation of the urinary tract by survey abdominal radiography or ultrasonography should be performed. Screening quantitative urine cultures are indicated if pyuria is identified by urinalysis. Contrast radiography and/or endouroscopy may be required to aid in localization of problems in addition to identifying the underlying cause(s) of persistent or recurrent clinical signs. Localizing the site(s) and cause(s) of urethral obstruction is especially important if urethral surgery is being considered. A neurologic examination may also be helpful. Patients with renal dysfunction caused by urethral obstruction should be evaluated with

the aid of complete blood cell counts, and serum chemistry profiles (especially potassium and bicarbonate concentrations), and perhaps electrocardiograms (for evaluation of the toxic effect of elevated serum potassium concentration on the heart). Quantitative mineral analysis of uroliths and urethral plugs should be routine. Tissue removed surgically should be evaluated routinely by light microscopy.

If the cause of feline lower urinary tract disease cannot be identified after appropriate evaluation, the terminology idiopathic FLUTD or feline idiopathic cystitis (FIC) is recommended.

Developmental Abnormalities

As with other species, congenital abnormalities of the lower urinary tract may be associated with hematuria, dysuria, urinary incontinence, and/or urethral obstruction[9]. However, these causes of FLUTD are uncommonly recognized. Vesicourachal diverticula are an exception to this generality as they have been diagnosed in as many as 1 of 4 cats with lower urinary tract disease. They are worthy of further discussion.

Vesicourachal Diverticula

Function and Dysfunction of the Urachus

The urachus is a fetal conduit that allows urine to pass from the developing urinary bladder to the placenta. It becomes nonfunctional at birth. Microscopic remnants of the fetal urachus characterized by microscopic lumens lined by transitional epithelium have been detected at the bladder vertex in adult healthy cats. In a study of 80 feline urinary bladders, more than 40% had microscopic urachal diverticula.

Microscopic remnants persisting in the urinary bladder vertex after birth usually are clinically silent, but

represent a risk factor for development of development of macroscopic diverticula of the urinary bladder in adult cats.[12] Abnormal and/or sustained increase of bladder intraluminal pressure associated with feline lower urinary tract disorders may cause enlargement and/or tearing of microscopic diverticula leading to development of self-limiting macroscopic diverticula of varying size.

Congenital and Acquired Vesicourachal Diverticula

In our experience, radiographically detectable diverticula affecting the vertex of the urinary bladder wall

occur in almost 1 of 4 adult cats with hematuria, dysuria, and/or urethral obstruction.[12,13] They occur twice as often in male (27%) as female (14%) cats. We have not observed a breed predisposition. The mean age of affected cats at the time of diagnosis in our series was 3.7 years (range = 1 to 11 years); clinical signs of LUTD were not observed when the cats were younger than one year of age. The higher frequency of occurrence of vesicourachal diverticula in males compared to females is likely related to the higher prevalence of urethral outflow obstruction in males.

There are two etiologically distinct forms of macroscopic vesicourachal

diverticula. In cats with the most common form, microscopic remnants of the urachus located at the bladder vertex remain clinically silent until lower urinary tract disease develops. Radiographically detectable diverticula may develop at the bladder vertex as a result of enlargement of these microscopic vesicourachal remnants following onset of increased intraluminal pressure caused by acquired urethral obstruction and/or detrusor hyperactivity induced by inflammation. This hypothesis is supported by the observation that many macroscopic diverticula in cats resolve within 2 to 3 weeks after amelioration of clinical signs of lower tract disease.[13]

The second uncommon form consists of congenital macroscopic vesicourachal diverticula.[12] Although the exact sequence of events resulting in their formation has not been defined, they appear to be caused by disorders that cause abnormally high or sustained pressure in the bladder lumen. Congenital macroscopic vesicourachal diverticula typically are associated with signs of LUTD in immature cats. In our experience, they do not spontaneously resolve. Persistent congenital macroscopic diverticula predispose to bacterial urinary tract infections. If infections are caused by urease producing calculogenic microbes (especially staphylococci), infection induced struvite uroliths often

develop.

Urachal diverticula are an uncommon primary factor in development of feline lower urinary tract disease. Most macroscopic diverticula of the bladder vertex are a sequela of lower urinary tract dysfunction. Furthermore, most macroscopic diverticula may be self limiting if the urinary bladder and urethra return to a normal state of function.[12,13] Acquired diverticula usually heal within 2 to 3 weeks following elimination of the underlying cause of increased intraluminal pressure.[13]

Uroliths and Urethral Plugs

The urinary system is designed to

dispose of waste products in soluble form. However, some waste products are sparingly soluble and occasionally precipitate out of solution to form crystals. Growth or aggregation of microscopic crystals may lead to formation of macroscopic uroliths. Urolithiasis may be conceptually defined as the formation of uroliths from less soluble crystalloids of urine as a result of multiple genetic and/or acquired physiologic and pathologic processes. If such crystalloids become trapped ion the urinary system, they may grow to sufficient size to cause clinical signs.

Urolithiasis should not be thought of as a specific disease, but as a sequelae to

one or more underlying abnormalities. Epidemiologic studies indicate numerous pathophysiologic, demographic, and environmental risk factors may be associated with the clinical expression of urolithiasis. Therefore, detection of uroliths is only the beginning of the diagnostic process. Determination of their mineral composition narrows etiologic possibilities. Knowledge of the patient's age, gender, diet, environment, and urine concentrations of calculogenic minerals, crystallization promoters, crystallization inhibitors, and their interactions provide additional insight into the diagnosis and management of uroliths.

Terminology

There are physical and probable etiopathogenic differences between feline uroliths and urethral plugs. Therefore, these terms should not be used as synonyms.

Uroliths are polycrystalline concretions composed primarily ($\geq$ ~95%) of minerals (organic and inorganic crystalloids) and smaller quantities ($\leq$ ~5%) of matrix. Unlike urethral plugs, uroliths are not disorganized precipitates of crystalline material, but are comprised of crystal aggregates with a complex internal structure.

Feline urethral plugs commonly are composed of large quantities ($\geq$

~50%) of matrix mixed with minerals.[15] However, some urethral plugs are composed primarily of matrix, some consist of sloughed tissue, blood, and/or inflammatory reactants, and a few are composed primarily of aggregates of crystalline minerals. They may form a cast of the urethral lumen, implying a rapid rate of formation.

The mineral composition of uroliths and urethral plugs should be used to describe them since most therapeutic regimes have been based on their mineral composition. A variety of different minerals have been identified in uroliths and urethral plugs of cats.

Epidemiology of Uroliths and Urethral Plugs

Uroliths

In 2004, 8711 feline uroliths were submitted by veterinarians to the Minnesota Urolith Center for mineral analysis. Struvite was the primary component in 45 percent of the uroliths, calcium oxalate was the primary component in 44%, and salts of uric acid were the primary component in 5%. Less than 1% of the uroliths were composed of calcium phosphate and cystine.

Urethral Plugs

In 2004, 524 feline urethral plugs were

submitted by veterinarians to the Minnesota Urolith Center for mineral analysis. Struvite was the primary component in 87 percent of the uroliths, while 10% of the plugs contained noncrystalline matrix. Less than 1% of the uroliths were composed of calcium oxalate and calcium phosphate.

Uroliths

Biologic Behavior of Uroliths

Overview: Detection of a urolith is not always justification for surgical management. In cats, small uroliths may remain asymptomatic within the

urinary tract (especially the renal pelvis and urinary bladder) for months or years. However, the underlying cause(s) of uroliths and the sequela of uroliths (partial or total obstruction, urinary tract infection) remain potential hazards. In those situations in which uroliths are fortuitously detected in asymptomatic patients without significant bacteriuria, minimizing risk factors by medical management and monitoring urolith activity by appropriate procedures is an accepted alternative to surgery. If the urolith(s) remain inactive, therapy designed to dissolve or remove them is not mandatory. If the urolith(s) become active, appropriate medical and/or surgical therapy are

recommended.

Rate of Formation: The rate of formation of uroliths varies from days to months, being influenced by mineral composition, and a variety of risk factors. Once crystals of one mineral type form in urine, they may reduce the amount of lithogenic substances required for other mineral types of crystals to form. The principle involved is called heterogeneous nucleation (or “seeding“) and operates in the same way as when foreign substances like suture material or catheters predispose to formation of uroliths. Viewed in this context, a crystal of one mineral type serves as a risk factor for formation of crystals of other types, and provides

one explanation of why macroscopic uroliths may contain more than mineral.

Movement of Uroliths: Small uroliths that form in the urinary bladder may pass into the urethra of male or female cats. Because of the tendency of uroliths to change in size and position, radiographic evaluation of the urinary system should be repeated if there has been a significant time lapse between diagnosis and surgery scheduled to remove them.

Recurrence: Cats that have formed uroliths are at increased risk for recurrent stone formation. In our experience, sterile struvite uroliths

have recurred within weeks to several months after elimination. Cystine uroliths also may recur within a few weeks to several months following removal. Calcium oxalate, calcium phosphate and ammonium urate uroliths also have an unpredictable tendency to recur, typically within months or years (rather than weeks) following removal.

Pseudorecurrence: Because many feline uroliths are small, complete surgical removal of all uroliths may be difficult. In a retrospective clinical study performed at the University of Minnesota, uroliths were detected by radiographs taken within 14 days following cystotomies in 20 percent of

the patients.[16] We call this phenomenon pseudorecurrence. Results of this study emphasize the importance of postsurgical radiography, ultrasonography, or uroendoscopy to assess urolith status prior to evaluating recurrence and/or therapeutic efficacy.

Ammonium Urate Uroliths

In the series of feline uroliths from the Minnesota Urolith Center, ammonium urate and uric acid collectively called purines comprised approximately 6 percent of the total. The urinary bladder and urethra were the most common sites of purine uroliths (99%), while kidneys and ureters (< 1%) were less common sites. In our series,

males were affected as often as females. The mean age of affected cats was 6.1 ± 3.1 years (range = 5 months to 15 years).

Although portovascular anomalies associated with hyperammonemia and hyperuricemia have been confirmed as the underlying cause in a few cases of urate uroliths in cats, the cause(s) of formation of most urate uroliths has not been established. However, formation of ammonium urate uroliths is likely to be associated with several risk factors (Table 67-1).

Calcium Oxalate Uroliths

The underlying cause(s) of calcium

oxalate urolith formation has not been defined. Risk factors incriminated include age, gender, breed, hypercalciuria, hyperoxaluria, decreased urine concentration of crystallization inhibitors, hypocitrituria, hypomagnesuria, acidosis, increased urine concentration, decreased urine volume, and urine retention (Table 67-2). Several nutritional risk factors have also been incriminated.

The frequency of detection of calcium oxalate urolithiasis in cats has increased in recent years. In 2004, calcium oxalate uroliths comprised approximately 44% percent of the feline uroliths submitted to the

Minnesota Urolith Center. Although calcium oxalate uroliths were located primarily in the urinary bladder (72%), they were also found in various combinations in the kidneys, ureters, and urethra.

Table 67-1. Potential Risk Factors Associated with Ammonium Urate Urolithiasis

Risk Factor	Etiopathologic Disorder	Pathophysiologic Mechanism
Hyperuricosuria	Hepatic portal vascular anomaly and other forms of hepatic failure	Reduces availability and/or function of hepatic urate oxidase and thereby minimizes conversion of uric acid to allantoin, which is more water soluble
Hyperuricosuria	Excess dietary purine	Promotes hyperuricemia and hyperuricosuria
Hyperuricosuria	Increased nucleic acid breakdown (e.g., lymphoma, leukemia, diffuse tissue destruction)	Results in accelerated metabolism of purines, which are further metabolized to uric acid
Hyperammonuria	Excess dietary protein	Provides additional urea for metabolism to NH_3, and glutamine for conversion to NH_4
Hyperammonuria	Metabolic acidosis	Promotes metabolism of glutamine to NH_4
Hyperammonuria	Aciduria	Ionizes NH_3 that has diffused into renal tubule lumens; trapped NH_4^{+1} is subsequently excreted
Hyperammonuria	Hypokalemia	Produces intracellular acidosis and subsequent NH_4 excretion
Hyperammonuria	Urinary tract infection by microorganisms that produce urease	Promotes conversion of urea in urine to NH_3 and NH_4
Aciduria	Aciduria	Decreases solubility of urine uric acid
Decreased urine volume	Intravascular volume depletion	Conservation of water promotes increased urine concentration and urine supersaturation of uric acid. Urine retention provides additional time for crystal nucleation and growth.

Calcium oxalate uroliths may occur at any age. However, they are recognized more frequently in older cats. In one study, cats older than 7 years, but less than 10 years were 67 times more likely to develop calcium oxalate uroliths than cats 1-2 years of age.[17] In

our series, male cats (57%) were affected more than females (43%). Neutered cats were 7 times more likely to form uroliths than sexually intact cats. Case control epidemiologic studies indicate increased risk of calcium oxalate uroliths in Burmese, Himalayan, and Persian, British and exotic shorthair, Havana brown, ragdoll, and Scottish fold breeds suggesting that genetic factors may enhance risk in some cats.[9,17,18,19]

In most cats with calcium oxalate uroliths, serum concentrations of minerals, including calcium, have been normal. The sequence or sequences of events that promote initiation and growth of calcium oxalate uroliths in

normocalcemic cats have not been defined. However, epidemiologic studies have identified several probable risk factors (Table 67-2).[20,21] Mild hypercalcemia (11.1 to 13.5 mg/dl) has been observed with sufficient frequency (35%) to warrant routine evaluation of serum total calcium concentration in affected patients.[21] The mechanism(s) of hypercalcemia has not been identified in most cats. Hypercalcemia promotes urinary calcium excretion, and may result in precipitation of calcium oxalate crystals. If hypercalcemia is confirmed in serially obtained serum samples, serum ionized calcium, parathormone, and vitamin D concentrations should be evaluated.

Cats with calcium oxalate urolithiasis typically have acid (urine pH of 6.3 to 6.7) urine. Pretreatment blood pH and total carbon dioxide concentration are often reduced (pH = 7.3). However, the solubility of calcium oxalate crystals is apparently not directly influenced by urine pH within the physiologic range. The indirect association between aciduria, acidemia, and calcium oxalate urolithiasis may be that acidemia promotes mobilization of carbonate and phosphorus from bones to buffer hydrogen ions. Concomitant mobilization of bone calcium may result in hypercalciuria. Hypercalciuria in turn is a risk factor for calcium oxalate crystals. In addition, low urine

pH decreases urinary citrate concentration by promoting renal tubular reabsorption of citrate. Results of epidemiologic studies support this association inasmuch that cats with calcium oxalate uroliths were 3 times more likely as hospitalized cats to have been fed diets that promote urine pH values less than 6.3.[18,22]

Table 67-2. Potential Risk Factors Associated with Calcium Oxalate Urolith Formation

Risk Factor	Possible Cause(s)	Proposed Pathophysiologic Mechanisms
Hypercalciuria	Excess dietary calcium	May result in hypercalciuria
Hypercalciuria	Hypercalcemia	Results in increased renal clearance of calcium and hypercalciuria
Hypercalciuria	Excess vitamin D	Augments intestinal calcium absorption. By suppressing parathyroid hormone, promotes hypercalciuria.
Hypercalciuria	Acidosis; consumption of urine acidifying diets	Promotes skeletal mobilization of calcium, and reduces renal tubular reabsorption of calcium
Hypercalciuria	Hypophosphatemia (e.g., reduced dietary consumption or hyperparathroidism)	Stimulates calcitriol production, which augments intestinal calcium absorption
Hyperoxaluria	Reduced dietary calcium	May enhance intestinal absorption and renal excretion of oxalic acid
Hyperoxaluria	Excess dietary oxalate	Results in hyperoxaluria
Hyperoxaluria	Excess vitamin C	May be a precurser of oxalic acid
Hyperoxaluria	Pyridoxine deficiency	Promotes increased endogenous production of oxalic acid
Hyperoxaluria	Primary hyperoxaluria	Results in increased endogenous production of oxalic acid
Hypocitraturia	Idiopathic	Increases urine concentration of calcium ions available to bind with oxalate
Hypocitraturia	Acidemia (e.g., renal tubular acidosis)	Promotes renal tubular utilization of citrate and reduced excretion of citrate
Decreased macromolecular inhibitors?	Inherited disorder?	Minimizes production of glycoproteins capable of inhibiting calcium oxalate crystal growth and aggregation
Decreased volume of concentrated urine	Decreased water consumption; consumption of dry foods	Conservation of water promotes increased urine concentration and urine supersaturation of calcium oxalate. Urine retention provides additional time for crystal nucleation and growth.

Several diet related risk factors may be associated with calcium oxalate uroliths. Urine acidifying potential and the effect of water consumption on

urine volume and concentration are especially important.

Although reduction of urine calcium and oxalic acid concentrations by reduction of **dietary calcium** and oxalic acid appears to be logical goals, they are not necessarily a harmless maneuvers. Reducing consumption of only one of these constituents (such as calcium) may increase the availability of the other (such as oxalic acid) for intestinal absorption and subsequent urinary excretion.[9,20,22] Based on recent epidemiologic information suggesting that marked dietary calcium restriction is associated with increased risk for calcium oxalate urolith formation, the general consensus of

opinion is that restricting dietary calcium is inadvisable. Moderate levels of dietary calcium are recommended in normocalcemic cats.

In one study, consumption of higher levels of **sodium** augmented renal excretion of calcium in healthy cats, but reduced supersaturation of urine with calcium oxalate.[20] The explanation of this paradox may be that the effects of oral sodium on water intake and its diluting effect on urine calcium concentration were greater than the effect of sodium on promoting urine calcium excretion. However, studies of cats with naturally occurring calcium oxalate uroliths revealed that consumption of a low sodium diet

designed to minimize recurrence of calcium oxalate uroliths was associated with reduced urine calcium concentration and reduced supersaturation of urine with calcium oxalate.[23] Based on this evidence, moderate dietary restriction of sodium would be a logical recommendation for active calcium oxalate urolith formers.

Dietary phosphorus should not be restricted in patients with calcium oxalate urolithiasis because reduction in dietary phosphorus may be associated with activation of vitamin D, which in turn promotes intestinal calcium absorption and subsequent urinary calcium excretion. In addition, pyrophosphate is an inhibitor of

calcium oxalate urolith formation.[22]

Increased urine **magnesium** concentration reduces formation of calcium oxalate crystals in vitro.[9] For this reason, supplemental magnesium has been used to minimize recurrence of calcium oxalate uroliths in man. However, supplemental dietary magnesium may contribute to formation of magnesium ammonium phosphate uroliths and hypercalciuria in cats. On the other hand, epidemiologic studies suggest that cats fed foods with reduced magnesium and urine acidifying capabilities are at risk for developing calcium oxalate uroliths. Pending further studies, we do not recommend dietary magnesium

restriction or supplementation for cats with calcium oxalate uroliths.[20,24]

Ingestion of foods that contain high quantities of animal **protein** may contribute to calcium oxalate urolithiasis by increasing urinary calcium and oxalic acid excretion, and by decreasing urinary citric acid excretion. Some of these consequences result from obligatory acid excretion associated with protein metabolism. However, because cats are obligatory carnivores, dietary protein restriction is not recommended.

Epidemiologic studies performed at the University of Minnesota revealed that cats consuming canned diets had one

third the risk for calcium oxalate urolith formation compared to other dietary formulations.[22] Increased urine volume could minimize formation of uroliths by reducing the concentration of calculogenic substances in urine, and also by promoting voiding before crystals have an opportunity to grow of sufficient size to cause clinical disease. Total **water** consumption is often less in cats fed dry diets resulting in formation of a lower volume of highly concentrated urine.

In summary, based on contemporary knowledge, diets that minimize calcium oxalate urolithiasis should be formulated to minimize acidosis, and should not contain excessive oxalic

acid precursors. Likewise, excessive levels of vitamin D (which promote intestinal absorption of calcium), ascorbic acid (a precursor of oxalate), and sodium should be avoided. They should contain adequate, but not excessive, quantities of calcium, phosphorus, magnesium, potassium, and citrate. The diet should be adequately fortified with vitamin B_6 since vitamin B_6 deficiency promotes endogenous production and subsequent urinary excretion of oxalic acid. Canned diets are preferred over dry formulations to enhance formation of less concentrated urine and to promote increased micturition.

Struvite Uroliths

Results of our clinical and experimental studies indicate that two distinct etiologic mechanisms may be responsible for development of uroliths containing large quantities of struvite.[9] Formation of sterile struvite uroliths (perhaps in association with dietary risk factors) is the most common type. Formation of “infected” or “urease” struvite uroliths as a sequela to urinary tract infection with urease producing bacteria is a second type.

In 2004, approximately 45 percent of the naturally occurring feline uroliths submitted to the Minnesota Urolith Center were primarily struvite. Although the exact percentage of

sterile versus infection-induced struvite uroliths in this series could not be precisely determined, we estimate that at least 90 percent to 95 percent were composed of sterile struvite. The remainder of this discussion pertains to sterile struvite uroliths. Information about infection induced struvite is described elsewhere.[2]

Compared to cats that develop calcium oxalate uroliths, cats with struvite uroliths tend to be younger. Cats $\geq$ 4 years of age but $\leq$ 7 years of age had the highest risk for developing struvite uroliths.[17] Struvite uroliths occur more commonly in females (55%) than males (45%). A case control comparison performed at the

University of Minnesota revealed increased risk in domestic shorthair, foreign shorthair, oriental shorthair, ragdoll, Chartreux, and Himalayan breeds.[17] Neutered cats were 3.5 times more likely to develop struvite uroliths as sexually intact cats. The urinary bladder was the most common site of detection of struvite uroliths, while the kidneys, ureters, and urethra were less common sites.

Data derived from cats with induced sterile struvite uroliths indicate that several dietary factors play a role in the etiopathogenesis of naturally occurring sterile struvite uroliths. Of these, factors affecting urine magnesium concentration, urine pH,

and urine concentration are of major therapeutic importance.[9,20] A decrease is urine volume and increase in urine specific gravity secondary to decreased water consumption would be a logical risk factor for urolith formation (Table 67-3). Likewise, excessive consumption of food (perhaps associated with ad libitum feeding) would be expected to result in obesity and excretion of excess minerals (some of which could be calculogenic) in urine. Cats maintain magnesium homeostasis by excreting excessive dietary magnesium in their urine.

Urethral Plugs

Urethral plugs contain varying

quantities of minerals in proportion to large quantities of matrix. Although a variety of different minerals have been identified in urethral plugs of cats, struvite is the most common. Of 524 feline urethral plugs submitted to the Minnesota Urolith Center in 2004, the primary mineral composition of approximately 87% was struvite. Less than 1% were composed of calcium oxalate or calcium phosphate.

Risk factors associated with the formation of calcium oxalate, calcium phosphate, and magnesium ammonium phosphate crystals found in urethral plugs are probably similar to those associated with mineral formation in classic uroliths. The mineral

composition of urethral plugs should be used to describe them, at least in part, since therapeutic regimes are often influenced by knowledge of their mineral composition.

Compared to uroliths, urethral plugs contain large quantities of matrix. Some urethral plugs do not contain crystalline components; 10% of the plugs evaluated in 2004 contained only noncrystalline matrix. The question about specific composition of urethral plug matrix has not yet been answered. However, it appears as though the amorphous matrix traps crystals and non- crystalline structures (including red blood cells, white cells, epithelial cells, spermatozoa, virus-like

particles, and bacteria) in a manner analogous to the formation of fruit jello.[25]

Bacterial Urinary Tract infections

Initial episodes of LUTD in young adult cats usually occur in absence of significant numbers of detectable aerobic bacteria.[26,27] In prospective diagnostic studies of male and female obstructed and nonobstructed cats, aerobic bacterial urinary tract infections were identified in less than 3% of patients.[5,10] The infrequency with which aerobic bacteria have been isolated from urine of young adult and middle age cats during the initial

phases of LUTD is related to highly effective local host defense mechanisms in this species.[26]

Table 67-3. Potential Risk Factors Associated with Sterile Struvite Urolith Formation

Risk Factor	Possible Cause(s)	Pathophysiologic Mechanism
Hypermagnesuria	Excess dietary magnesium	Results in increased renal clearance of magnesium and hypermagnesuria
Hyperammonuria	Excess dietary protein	Provides additional urea for metabolism to NH_3 and glutamine for conversion to NH_4
Hyperammonuria	Metabolic acidosis	Promotes metabolism of glutamine to NH_4
Hyperammonuria	Aciduria	Ionizes NH_3 that has diffused into renal tubule lumens; trapped NH_4 is subsequently excreted
Hyperammonuria	Hypokalemia	Produces intracellular acidosis and subsequent NH_4 excretion
Hyperphosphaturia	Excess dietary phosphorus	Results in increased renal clearance of phosphorus and hyperphosphaturia
Alkaline urine	Diet related factors	Increases urine concentration and saturation of PO_3^{-3} by removing hydrogen ions from $H_2PO_4^{-1}$ and HPO_4^{-2}
Decreased volume of concentrated urine	Decreased water consumption; consumption of dry foods	Conservation of water promotes increased urine concentration and urine supersaturation of calcium oxalate. Urine retention provides additional time for crystal nucleation and growth.

Although bacterial UTI is encountered in only 1 to 3% of young adult cats, the prevalence of UTI increases to 10% or greater in cats 10 years of age or older.[11,28] The frequency with which bacterial UTI has been recognized in geriatric cats with LUTD should prompt appropriate diagnostic evaluation in this population of clinical patients.

When bacterial UTI has been detected in cats, it usually is a secondary or complicating factor rather than as a primary etiologic factor. Local urinary tract defenses against bacterial infection are frequently compromised in cats with various forms of naturally occurring nonbacterial LUTD,

especially if the episode is associated with urethral obstruction.

Use of indwelling transurethral catheters is associated with a high prevalence of secondary or complicating bacterial urinary tract infection. In studies of normal cats, and cats with induced LUTD, catheter-induced bacteriuria was detected in 33% of cats after 1 day of catheterization, and in 50% to 83% of cats after 5 days of indwelling catheterization.[29] Bacterial UTI is also a common sequelae in cats following perineal urethrostomies. Consult the chapter entitled, “Bacterial urinary tract infections: Diagnostic and therapeutic caveats for further

information.

Idiopathic Feline lower Urinary Tract Disease

Etiopathogenesis

In approximately 65% of naturally occurring cases of LUTDs, the exact cause(s) of hematuria, pollakiuria, stranguria, periuria, and/or urethral obstruction are still unknown. After appropriate diagnostic evaluation, these cats are classified as having idiopathic FLUTD, feline idiopathic cystitis (FIC), or feline interstitial cystitis. Because there is no pathognomonic test or diagnostic procedure diagnosis of idiopathic LUTD is dependent on exclusion of

other known causes.

Clinical observations suggest that stress may play a role in precipitating or exacerbating signs associated with idiopathic cystitis.[30,31,32] Neuroendocrine abnormalities identified in cats with chronic idiopathic cystitis are indicative of increased activity of the sympathetic nervous system and diminished adrenocortical responsiveness.[33,34] Based on these observations, strategies designed to normalize reactivity of the stress response system have been advocated to minimize recurrence of feline idiopathic cystitis.

Clinical Manifestations

Nonobstructive idiopathic FLUTD occurs in males and females of all ages, but more commonly in young to middle aged cats (mean 3.5 years, range 0.5-17.5 years).[5,10]

It is uncommon in cats less than one year and less common in cats older than 10 years. There are no apparent breed predilections.

Periuria, pollakiuria, stranguria, and gross hematuria are the most common clinical signs observed in cats with nonobstructive idiopathic FLUTDs and often precede the obstructive form of the disorder.

Unless complicated by concurrent illness, results of CBCs and biochemistry profiles of cats with nonobstructive idiopathic FLUTDs are usually normal. Urine obtained from cats with idiopathic FLUTDs is usually concentrated and acid. Hematuria and proteinuria in the absence of pyuria or bacteriuria are typical urinalysis findings.[9,35] Although microscopic hematuria may be a consequence of cystocentesis-induced trauma, the observation of gross hematuria in 81% and microscopic hematuria in 95% of nonobstructed cats with idiopathic FLUTDs suggests that hematuria is a prevalent feature of idiopathic FLUTDs.

The prevalence, magnitude, and type of crystalluria are variable in cats with idiopathic FLUTDs and do not appear to differ from unaffected control cats.[10] Struvite crystals have been the most common crystal type identified in urine of cats with idiopathic FLUTDs. Undoubtedly, some instances of struvite crystalluria in these patients represent in vitro rather than in vivo formation.

Results of urine culture from cats with idiopathic FLUTDs have been negative for aerobic bacteria, mycoplasma, ureaplasma, and viruses. Most cats with idiopathic FLUTDs are seronegative for FIV antibodies and FeLV antigen.[10,35]

Survey abdominal radiographs of cats with nonobstructive idiopathic FLUTD are usually normal. Contrast cystourethrography may be normal or may reveal thickening of the bladder wall, mucosal irregularities, urachal diverticula, and/or urethral narrowing. Ultrasonographic findings of idiopathic FLUTDs have not been characterized; however, blood clots and mural irregularities or thickening may be detected.

Cystoscopic examination of cats with nonobstructive idiopathic LUTDs may reveal increased mucosal vascularity, superficial urothelial desquamation, and petechial hemorrhages in the submucosa (so called

"glomerulations").[7] Glomerulations are nonspecific and may be associated with other urinary bladder disorders.[6] In addition, cystoscopy induced urothelial trauma may be confused with primary pathologic lesions. Pending results of additional studies, detection of glomerulations by cystoscopy should be interpreted in the context of the results of other diagnostic evaluations.

Exploratory cystotomy has been commonly used for diagnostic evaluation of idiopathic FLUTDs. With the advent of less invasive means of evaluating the lower urinary tract, the need for cystotomy and surgical biopsy of the urinary bladder for the sole

purpose of establishing a diagnosis has largely been eliminated. Even when performed most biopsy samples reveal mucosal erosions and ulcerations, and varying degrees of submucosal hemorrhage, edema, and fibrosis. These light microscopic findings are nonspecific, and rarely lead to improved therapy. Therefore, we cannot recommend cystotomy over less invasive diagnostic procedures for establishing a diagnosis of idiopathic FLUTDs.

Biologic behavior of Idiopathic LUTD

Clinical signs of hematuria, dysuria, and pollakiuria in many untreated

nonobstructed males and females with acute idiopathic FLUTDs frequently subside within 5-7 days. These signs may recur after variable periods of time and again subside without therapy. Our impression is that recurrent episodes of acute idiopathic LUTDs tend to decrease in frequency as the cats become older.[37,38]

Though recurrent clinical signs in patients with idiopathic FLUTDs are often assumed to be recurrence of the original disease, recurrent signs may also be the result of a delayed manifestation of the original disease (for example, spontaneous or iatrogenic urethral stricture). In addition, onset of a different disease

associated with clinical manifestations similar to those of the original disorder (such as urolithiasis) may occur.

Occasionally we have encountered cats with hematuria and dysuria that have persisted for weeks to months and for which a specific cause was not identified. Whether chronic idiopathic FLUTDs represent one extreme in the spectrum of clinical manifestations associated with similar etiologic factors, or whether it represents an entirely different mechanism of disease than that associated with acute self-limiting idiopathic disease is unknown.

Since clinical signs associated with this form of the disease are frequently self-

limiting and of short duration, any form of therapy might appear to be beneficial, as long as it is not harmful. The self-limiting nature of clinical signs in many cats with idiopathic FLUTDs underscores the need for controlled prospective double-blind clinical studies in order to prove the efficacy of various forms of therapy.

Chapter 68

Ureteral Ectopia

Mary A. McLoughlin

Anatomy of the Ureter

Ureters are fibromuscular tubes that transport urine through the retroperitoneal space from the renal pelvis to the urinary bladder.[1,2] Vascular supply to the ureter is derived from the cranial and caudal ureteral arteries that travel longitudinally and anastomose alongside the ureter. In males, the ureter passes dorsal to the

ductus deferens, whereas in females, the ureter travels through the base of the broad ligament. Ureters exit the retroperitoneal space between the two-layer folds of peritoneum forming the lateral ligaments of the urinary bladder. Urine moves progressively through the ureters owing to organized peristaltic motion. Size of the ureter varies with species and patient size Ureters are considered to be larger than normal in dogs if the diameter is greater than 0.09 times the length of the second lumbar vertebrae. Enlarged ureters are usually greater than 3.0 mm.[3] Ureters attach to the dorsolateral surface of the bladder in the region of the bladder neck and pass through the bladder wall at an oblique angle

creating a functional valve-like effect. The vesicoureteral junction can take on a “j”-shaped appearance.[3]

Embryologic Development

Understanding the complex embryologic development of the urogenital system forms a foundation for the understanding of some of the congenital abnormalities encountered in clinical medicine. Developmental abnormalities of the ureteral bud do not typically occur as an isolated event, but instead impact the development of the kidneys, bladder wall, trigone, vesicourethral junction, proximal urethra, internal sphincter mechanism, and some of the

reproductive structures.

Development of the “normal” kidney and drainage system is classically described as proceeding through three successive yet integrated renal systems, pronephros, mesonephros, and metanephros, that share developmental components with the reproductive systems.[2,4-8] The most primitive form of the excretory system recognized in vertebrate animals is the pronephros. It is nonfunctional and quickly replaced by the mesonephros. However, a major portion of the pronephric duct is retained and later referred to as the mesonephric or Wolfian duct. The mesonephric duct system represents the second stage of

excretory system development.[2,4,5] This will become the mature excretory system in amphibians, but only parts of this system are retained in the development of the excretory system of vertebrate animals. The mesonephric ducts are paired structures that fuse with the ventrolateral aspect of the cloaca.[5] As the cloaca divides to form the rectum and the urogenital sinus, the site of attachment of the mesonephric ducts differentiates, forming the posterior or dorsal wall of the urinary bladder. In males, parts of the mesonephric duct give rise to the ductus deferens. Close to their openings into the urethra, the seminal vesicles form.[2,4,5,8] In females, the reproductive structures actually arise

and differentiate from the paramesonephric or Müllerian ducts. The Müllerian ducts arise separately in the mesoderm in close apposition to the mesonephric ducts (during the period of migration of the ureteric bud to the metanephros). It has been demonstrated that the Müllerian ducts arise inside the basal membrane of the mesonephric duct and may be derived from the same cells.[5] As, the Müllerian ducts migrate toward the urogenital sinus, they fuse together forming the uterus and vagina. The site of fusion between the Müllerian ducts and urogenital sinus forms the vestibulovaginal junction. A small layer of paramesonephric tissue referred to as the hymen is positioned

between the membranes of the urogenital sinus and parametanephric duct.[8] This hymenal membrane usually ruptures at birth. Ultimately, the developing mesonephric ducts are resorbed leaving only scattered Gartner's glands as the only remnant in mature females.[2,4,5,8]

On the dorsal surface of the mesonephric duct, close to its attachment to the cloaca, the metanephric diverticulum or ureteral bud first arises.[2,4-8] Development of the metanephric system represents the third phase in the developmental progression. The ureteric bud extends dorsally to contact the developing metanephric blastemal ridge in the

intermediate mesoderm and ultimately becomes the ureter. This contact or interaction between the ureteric bud and metanephric blastema is essential for the normal development of both the kidney and ureter, referred to as induction.[2,4,5-10] Within the metanephric blastema differentiation of the glomeruli, proximal and distal convoluted tubules, and the loops of Henle are initiated and maintained, forming the renal cortical structures. The proximal portion of the developing ureteral bud undergoes sequential division to form three major calyces, which, in turn, divide to form the minor calyces, papillary ducts, and collecting tubules, composing the medullary portion of the mature

kidney. Synchronous migration of the kidney and ureter is occurring during this process of differentiation (Figure 68-1). Cranial migration of the kidney occurs to assume its final sublumbar position. Concurrently, the distal end of the ureteral bud is drawn toward the urogenital sinus.[4,5-9] The region of the mesonephric duct located between the urogenital sinus and the proximal region of the ureteral bud is referred to as the common excretory duct.[8] Migration or absorption of the common excretory duct into the wall of the urogenital sinus results in caudal migration of the ureteral bud. The future bladder neck and internal urethral meatus forms at the site of contact between the ureteral bud and

urogenital sinus. The ureteral bud is positioned medial to the common excretory duct at the site of contact with the urogenital sinus. Cranial lateral migration of the ureter and caudal medial migration of the opening of the mesonephric duct occurs. Following migration, the ureteral orifice and the mesonephric duct opening (future deferent duct opening in males) are located equidistant from the neck of the bladder.[5,6,8] The common excretory duct extending between these openings develops into the trigonal base plate and ultimately the deep and superficial muscle layers of the trigone and proximal urethra in females and pelvic urethra in males, forming the internal

urethra sphincter mechanism.[5-9]

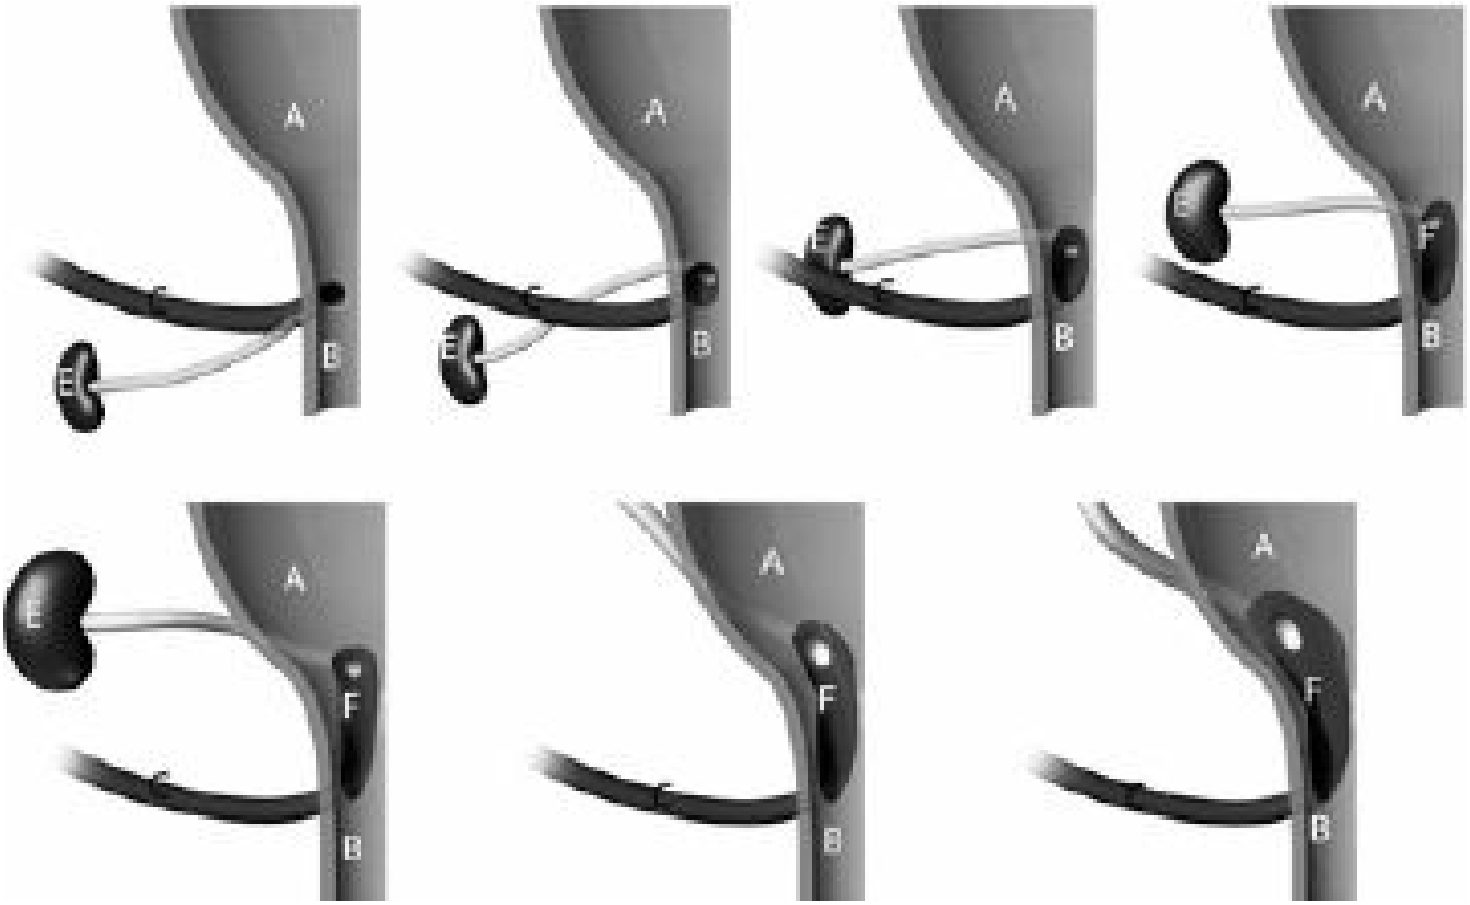

Figure 68-1. Migration of the ureteral bud and mesonephric opening through extrophy of the common excretory duct. A and B. Urogenital sinus (A to become the urinary bladder, B to become the urethra). C. Mesonephric duct. D. Ureteric bud. E. Metanephric mass to become the kidney. F. Region of common excretory duct (to form the trigone). (Adapted from: Cannizzo, K.L.: Uroendoscopic evaluation of ureteral ectopia in female dogs. Master's of Science Thesis, The Ohio State University 2001).

Dysembryogenesis of the ureteral bud is the underlying cause of many congenital malformations of both the upper and lower urinary system.[6,7,10] Failure of the ureteral bud to arise from the mesonephric duct or failure of the bud to contact the metanephric blastema results in renal agenesis and may also result in failure of reproductive structures to develop. Abnormal positioning or lateral displacement of the ureteral bud on the mesonephric duct results in an altered migration pathway as the common excretory duct migrates or is absorbed into the wall of the urogenital sinus.[6-8] This subsequently results in distal displacement of the ureteral orifice, resulting in ectopic ureters and

malformation of the structural integrity of the trigone (Figure 68-2). Bifurcation of the ureteral bud or formation of multiple ureteral buds will result in the formation of the duplex collecting system as the bud contacts and induces the metanephric blastemia.[6,7,9]

Urethral ureteral ectopia. E. Vestibular ureteral ectopia. (Adapted from: Cannizzo, K.L.: Uroendoscopic evaluation of ureteral ectopia in female dogs. Master's of Science Thesis, The Ohio State University 2001)

Ureteral Ectopia

Ureteral ectopia is a well-recognized congenital anomaly that may encompass a variety of malformations of both the urinary and reproductive systems. Ureteral ectopia is hallmarked by distal displacement of one or both ureteral orifice(s) to sites distal to the expected anatomic position at the tip of the trigone, frequently resulting in urinary incontinence.[11-16] Ureteral ectopia has been reported in dogs, cats, rats, horses, cattle, camilids, poultry, and humans.[2,4,8-23] The majority of the scientific literature pertaining to this developmental anomaly is focused on dogs and children. Distinct differences in the

anatomy, morphology, and clinical presentation of ureteral ectopia exit between dogs and people. In humans, approximately 80% of all ectopic ureters are associated with a duplex collecting system, defined as a single kidney with complete duplication of the pyeloureteral system.[24,25] The ectopically displaced ureter is virtually always associated with the drainage of the upper moiety of the duplex system. Reports of duplex kidneys in veterinary patients are rare.[22,26]

The exact incidence of ureteral ectopia is unclear. Documentation of this anomaly is usually based on clinical signs of urinary incontinence in juvenile patients evident since birth or

in adult female patients after ovariohysterectomy. Two previous studies have attempted to characterize the incidence of ureteral ectopia in a clinical population of dogs. One study reviewed a total of 67,721 small animal patients over a 7-year period, identifying 11 dogs with a confirmed diagnosis of ureteral ectopia. A second study reviewed 106,790 small animal patients, identifying a total of 18 affected dogs. An identical percentage incidence of occurrence was calculated at 0.016% for both studies.[4,27]

The specific locations of the displaced ureteral orifices have been well documented in both female and male dogs. Common sites of ectopically

displaced ureteral orifices in females include sites within the trigone or bladder neck, vesicourethral junction, along the entire length of the urethra, or within the vagina or vestibule. However, in males the majority of displaced ureteral orifices are identified at the vesicourethral junction or pre-prostatic urethra in dogs.[4,12,13,15-18] Ureteral ectopia is frequently associated with intermittent, continuous or positional urinary incontinence and is considered to be the most common cause of urinary incontinence in young female dogs.[18] Affected females are identified approximately 4 to 20 times more frequently than affected male dogs.[4,13,15,16,18] This disparity likely

reflects both a true sexual predisposition and under-diagnosis in continent male dogs. Urinary incontinence in male dogs with ectopic ureters may occur less frequently owing to the relative length of the urethra and increased pressure in the prostatic urethra and external sphincter mechanism that together oppose the passage of urine distally, resulting in retrograde bladder filling.[13,23]

Ureteral ectopia is reported in both purebred and mixed-breed dogs. It has been documented with greater frequency in specific breeds including Labrador retriever, Golden retriever, Siberian husky, Newfoundland, Skye

terrier, West Highland white terrier, wire-haired fox terrier, and soft-coated Wheaten terrier, as well as standard and miniature poodles.[3,4,8,11-18] The specific etiology of this developmental anomaly remains unclear. A heritable basis for ureteral ectopia has been repeatedly suggested based on an increased incidence in predisposed breeds and potentially within family lines, identification of multiple affected littermates, and a single report of parent to offspring transmission.[5-8,16, 28-31] However, a genetic basis determined by a controlled breeding study, pedigree analysis, DNA analysis, or evaluation for gene mutations has not been performed. Hypervitaminosis A,

deficiency in vitamin A and folic acid, and irradiation have been shown to result in urinary tract anomalies, including ureteral ectopia in rats but not in dogs.[32] Supplementation with vitamin A during gestation was also shown to eliminate these developmental defects.[4,5,7,8,32] At this point, no evidence suggests that diet or other specific environmental factors play a role in the development of ureteral ectopia.

Ectopic ureters are characterized as extramural or intramural based on their anatomic pathway. Extramural ectopic ureters bypass the urinary bladder and open directly into the vesicourethral junction, urethra,

uterus, vagina, or vestibule.[4,8,11-13,15-18] Once considered to be a common finding, with improved diagnostic modalities it is now recognize that the incidence of extramural ectopic ureters in dogs is rare.[33,34] Intramural ectopic ureters attach to the serosal surface of the bladder in the expected dorsolateral position in the region of the bladder neck, but fail to open into the bladder lumen at the tip of the trigone. Intramural ureters tunnel distally below the submucosal layer to open at sites within the trigone, vesicourethral junction, urethra, vagina, or vestibule.[3,4,12,15,18,33-35] A number of anatomic variations of the terminal ureteral segment have been reported, including variations in the

size and shape of the orifice, ureteral troughs, two ureteral openings on one or both ureters, multiple fenestrated openings along the submucosal tunnel, two submucosal tunnels opening through a single orifice, and presence of an ectopic ureterocele.[4,13,15,18,28,33-35] Ureteral ectopia is commonly associated with additional anomalies of the urinary system, including absent, small, or irregularly shaped kidneys, renal dysplasia, hydronephrosis, dilated ureter, tortuous ureter, pelvic bladder, shortened urethra, indistinct vesicoureteral junction, urachal remnants, and abnormal shape of the ureterovesical junction.[3,5,7,10]

Hydroureter is the most frequently reported abnormality associated with ureteral ectopia. It results from intermittent or partial urinary outflow obstruction. Ureteral dilation is most commonly associated with intramural ureters that are displaced to the distal aspect of the urethra or vestibule.[3,4,13,28,33,34] Intraluminal pressure within the urethra is increased between periods of micturition to maintain urinary continence. As urethral pressure increases and the lumen collapses, the ureteral remnant tunneling below the urethral mucosa also collapses, obstructing urine outflow. It is important to note that not all intramural ureters are dilated. Ureters that are minimally displaced,

located within the trigone or vesicourethral junction, submucosal tunnels with multiple fenestrated openings, and ureters associated with a "trough-like" orifice are dilated less frequently.[4,12,13,33]

Clinical Presentation

Ureteral ectopia is the most common cause of urinary incontinence in young female dogs.[18] Ureteral ectopia should also be considered as a primary rule-out for patients with history of urinary incontinence developing after ovariohysterectomy, especially in breeds with a known predisposition for this anomaly. Normal voiding patterns and behavior can also be observed in

affected patients. The cause of urinary incontinence associated with ureteral ectopia is considered multifactorial. Incontinence results from ureteral discharge of urine distal to the bladder neck and urethral sphincter mechanism or from functional and structural abnormalities of the vesicourethral junction and urethra, which result in primary sphincter mechanism incompetence.[4,12,13] The degree of urinary incontinence and patterns of urination cannot be used to confirm the diagnosis of ureteral ectopia nor determine if unilateral or bilateral disease exists.[4,12,13,16] Physical examination findings are often normal with the exception of moist or urine stained hair in the perivulvar or

prepucial region. Secondary dermatitis or urine scalding may be observed. Abdominal palpation may detect marked abnormalities in kidney size or structure that can result from hydronephrosis or dysplasia. Hematologic and serum biochemical evaluations are normal unless associated abnormalities that diminish renal function exist. Urinary tract infections resulting from ascending bacterial pathogens are frequently identified.[2,36]

Methods of Diagnosis

The specific diagnosis of ureteral ectopia is based on identification of the ureteral orifice(s) distal to the expected

position at the tip of the trigone. Historically, the diagnosis of ureteral ectopia has focused on the use of contrast radiographic procedures.

Plain and contrast radiography are frequently used to evaluate the upper and lower urinary tract of patients with suspected congenital anomalies and/or urinary incontinence. Excretory urography (IVU) and retrograde urethrography have long been considered the primary methods of diagnosis for ureteral ectopia in small animal patients.[4,11-13,16,33] These methods have been shown to provide a positive and anatomically accurate diagnosis in 62% to 77% of the confirmed cases of ureteral ectopia.[33]

However, a variety of factors has been shown to compromise the diagnostic utility of these contrast procedures, including patient positioning and preparation, caudal displacement of the bladder (pelvic bladder syndrome), obscured visualization of the trigone and proximal urethra by overlying pelvic structures, degree of ureteral dilation or retrograde contrast accumulation.[33]

Intravenous urography provides valuable information regarding the upper urinary tract including renal structure and function, location, size and morphology of the ureters, and has the potential to determine location of the ureteral orifices. Lateral,

ventrodorsal, and oblique radiographic views are necessary to assist in delineating the distal ureteral segment in the pelvic region. However, the diagnosis of ureteral ectopia often remains elusive following appropriate radiographic evaluation.[12,13,33]

Retrograde urethrography or vaginourethrography may provide additional information regarding length of the urethra, structure of the vesicourethral junction, identification of the ureteral orifices, and distal ureteral morphology.[33,37,38] One study demonstrated that retrograde ureteral filling with iodinated contrast was not observed in patients diagnosed with ectopic ureters unless the ureters were

abnormally dilated. Dilation of the displaced ureters is reported in only 59% of the affected patients.[33]

Contrast-enhanced computed tomography (CT) is now considered the method of choice for evaluating ureteral ectopia in humans.[33] Improved spatial and temporal resolution characteristics of helical or axially acquired transverse imaging allows a more detailed evaluation of the anatomy because it is not obscured by overlying structures. A study to determine the diagnostic utility of helical CT for the diagnosis of ureteral ectopia was performed in 24 incontinent dogs with suspected ureteral ectopia. CT imaging reliably

and accurately diagnosed ureteral ectopia and the specific location of the displaced ureteral orifices compared with traditional methods in 17 affected dogs.[33] Although CT imaging may be more costly, the superior diagnostic information obtained with CT as compared with other established techniques warrants its use. CT image interpretation does require experience and can be made more difficult by the need for systematic review of multiple image frames.[33]

Direct visualization of the lumenal surface of the lower urinary and reproductive tracts using a rigid or flexible endoscope can be performed in patients larger than 3 kg.

Uroendoscopy has dramatically improved our ability to accurately diagnose ureteral ectopia and associated malformations of the ureteral orifices, vesicourethral junction, trigone, urethra, vestibule and vagina. This procedure also provides additional information regarding the anatomic pathway and morphology of the terminal ureteral segment.[12,13,16,28] Endoscopic evaluation of the distal segment of a dilated ureter can also be performed by gently passing an appropriately sized endoscope through the ureteral orifice into a dilated ureter. Radiographic evaluation of the upper urinary system should also be performed when the diagnosis of ureteral ectopia has been

made by means of uroendoscopy. Contrast radiography, ultrasonography, or CT can be performed to assess the kidneys and ureters. Ultrasonographic examination is noninvasive and has been shown to be a reliable method of diagnosing ureteral ectopia when performed by a skilled operator. The confirmation of ureteral ectopia is made by identifying the location of the ureteral jet in addition to evaluating the size and structure of the ureter.[39,40]

Urodynamic evaluation, including cystometrogram and urethral pressure profile (UPP), has been shown to be a useful tool in the evaluation of the function of the bladder and urethra in

patients with urinary incontinence and other voiding disorders. Results of urodynamic measurements have been reported in nine incontinent female dogs diagnosed with ureteral ectopia prior to surgical correction. Reduced bladder capacity and abnormalities in the urethral pressure profile consistent with urethral incompetence were noted in 89% of the dogs. Urodynamic assessment of dogs with ureteral ectopia may be valuable in identifying concurrent functional abnormalities of the lower urinary tract, but it may have limited use in predicting postoperative continence.[41]

Treatment

The goal of medical or surgical treatment of ureteral ectopia is resolution of urinary incontinence, re-establishment of anatomic integrity of the lower urinary system, and preservation of renal function. The treatment of ureteral ectopia is based on location and morphology of the ectopic ureter(s), and associated abnormalities of the urogenital systems.[4,12,13,16,35] Evaluation of renal function is necessary prior to instituting any type of therapy. Ultrasonographic evaluation of the kidneys and ureters combined with either IVU or renal nuclear scintigraphy is used to characterize renal function. Nephroureterectomy is performed when a kidney is

determined to be nonfunctional and contralateral renal function is normal. A renal biopsy and culture are obtained if structural abnormalities of a functional kidney are noted or pyleonephritis is suspected.

Medical Treatment

Urinary incontinence associated with ureteral ectopia often is unresponsive or minimally responsive to accepted medical therapies, including the alpha-adrenergic agonists ephedrine sulfate or phenylpropanolamine, anticholinergic therapy such as oxybutinin, or hormonal therapy such as diethylstilbesterol (DES) in females or testosterone cypionate in males.[42,43]

Minimally Invasive Treatments

The treatment of primary sphincter mechanism incompetence using submucosal urethral bulking with bovine gluteraldehyde cross-linked collagen has been shown to be successful in female dogs with clinical signs of urinary incontinence.[44] The use of collagen injected both periurethrally and submucosally to treat urinary incontinence in women has been reported.[44] Urologic collagen is composed of highly purified bovine dermal collagen that is cross-linked with gluteraldehye in phosphate buffered saline. This product is composed of approximately 95% Type

I collagen with 5% or less Type III collagen. A 14 or 19 French rigid endoscope with a 30-degree angle and a 4 French biopsy channel is used for uroendoscopy and placement of submucosal urethral bulking agents.

Complete evaluation of the lower urinary tract is performed prior to the injection of collagen. The tip of the endoscope is positioned to visualize the bladder neck and proximal urethra. The injection instrument is passed through the biopsy channel of the endoscope. The sites for injection are located approximately 1.5 cm. distal to the vesicourethral junction. Positioning of the endoscope facilitates inserting the beveled tip of the injection device

below the urethral mucosa. Collagen is injected slowly while visualizing the distention of the urethral mucosa into the urethral lumen. Three to four sites are usually injected in a circular manner.[44] The procedure is considered complete when the injection sites appose one another. Complete urethral obstruction has not been reported in dogs.

Submucosal collagen implants have also been used to successfully treat selected dogs with proximally displaced ureteral ectopia without surgical intervention. The submucosal injection sites are positioned 1 to 1.5 cm distal to the displaced ureteral orifices, resulting in reflux of urine into

the bladder lumen as well as creating obstruction to urine outflow. Ectopic ureter patients with moderate or severe ureteral dilatation or diminished renal function would not be consider a candidate for this noninvasive procedure.

Surgery

Evaluation of the upper and lower urinary tract is performed following a ventral midline celiotomy extending to the pubis. A stay suture placed in the apex of the bladder provides manipulation and retraction during the surgical exploratory and corrective procedures. The intrapelvic aspect of the female urethra can be exposed into

the abdominal cavity by gentle traction on the apex of the bladder. A ventral midline cystotomy and urethrotomy are performed for direct visualization of the lumenal surface of the trigone, bladder neck, and urethra permitting identification of intramural ureters, submucosal tunnels, ureteral troughs, and most of the ectopically displaced ureteral orifices. Ureteral orifices located at the extreme terminal aspect of the urethra or vestibule may not be visualized from this approach without performing an osteotomy of the pubis to extend the urethral incision.

Ureteral Reimplantation/

Transposition

Transposition of a displaced ureter and ureteral orifice is indicated if the site of ureteral attachment is distal to the bladder neck. Surgical conformation of extramural ureters is infrequently reported.[12,13,28,33] Persistent urinary incontinence may result because the ureteral orifice is positioned distal to the bladder neck and urethral sphincter mechanism. Repositioning the distal segment of the ureter and ureteral orifice directly into the bladder may restore urinary continence if additional structural and/or functional abnormalities of the primary sphincter mechanism do not exist.

A ventral midline celiotomy is

performed, and the extramural ureter is isolated distally where it attaches to the dorsal or dorsolateral surface of the bladder neck, vesicourethral junction, urethra, vagina, or uterus. The ureter is ligated at its most distal point of attachment with an absorbable suture and transected cranial to the ligature. The distal ureteral segment is isolated from the retroperitoneal space, respecting the ureteral blood supply that is positioned longitudinally within the fascial attachment. A ventral midline cystotomy is performed and the site of ureteral transposition is identified. This site can be located at any point between the apex of the bladder and the trigone. A mosquito hemostat is passed through a mucosal

defect at an oblique angle and gently passed through the bladder wall. A small stay suture placed through the incised edge of the ureter is grasped to manipulate the ureter through the bladder wall. Once positioned within the bladder lumen, the terminal aspect (3-4 mm) of the ureter is excised and discarded. Intravesicular ureteral anastomosis is performed by suturing the ureteral mucosa to the bladder mucosa with a 5-0 absorbable monofilament suture material in an interrupted pattern. Surgical magnification may be necessary to accurately position these sutures. The bladder is closed in a routine manner.[2,4,12,13,35,45,46]

Neoureterostomy and Urethral/Trigonal Reconstruction

Intramural ectopic ureters pass through the bladder wall but fail to terminate and open into the bladder lumen at the tip of the trigone. This type of ectopic ureter continues to tunnel submucosally through the trigone to open at a site within or distal to the bladder neck. Urinary incontinence results owing to the ectopic location of the ureteral orifice and/or disruption of the smooth muscle layer of the urethral sphincter mechanism by the submucosal pathway of the ureteral remnant. Historically, surgical repair of intramural ectopic ureters has

focused on the creation of a new ureteral opening within the bladder lumen and ligation of the distal submucosal ureteral segment, redirecting urine flow into the bladder lumen.[2,4,12,13,35,45-47] Persistent or recurrent urinary incontinence has been frequently reported after surgery.[2,12,13,35] To restore the functional anatomy of the internal urethral sphincter mechanism to improve continence after surgery, the terminal segment of the intramural ureter is resected from the surrounding tissues of the bladder neck and urethra. Surgical apposition of the mucosa and smooth muscle layers of the remaining defect are performed to realign the smooth muscle layer of the internal

urethral sphincter mechanism.[12,13]

A ventral midline cystotomy and urethrotomy are performed, identifying the displaced ureteral orifices within the bladder neck and urethra. However, if a displaced ureteral orifice is located distally beyond the extent of this approach, in the terminal aspect of the urethra, a small incision is made through the distal urethral mucosa directly into the lumen of the submucosal ureter creating an orifice and avoiding the surgical morbidity of pelvic osteotomy. An appropriately sized urethral catheter (5, 8, or 10 French) is passed retrograde through each displaced ureteral orifice or distal ureterotomy

incision. The catheter is passed retrograde to the site where the ureter passes through the bladder wall. It is essential to determine that this site is appropriately positioned near the tip of the trigone; if not, ureteral transposition should be performed. With the catheter in place, the submucosal ureter is sharply dissected from the surrounding urethral tissues including the mucosa, submucosa, and muscularis. Primary closure of the remaining defect in the bladder neck and urethra is performed using a 5-0 synthetic absorbable, monofilament suture material in a continuous or interrupted pattern. Closure of the urethral mucosa including a deep bite of the underlying smooth muscle layer

is performed. Local hemorrhage is controlled by placement of the suture pattern to close the urethral defect. It may be necessary to dissect a portion of the submucosal ureter, immediately followed by closure of the defect to control hemorrhage before continuing with the complete dissection. The ureteral remnant is completely dissected from its submucosal position distally to the site where the ureter passes through the bladder wall. The ureter is transected approximately 0.5 cm from this site and sutured to create a new permanent ureteral opening within the bladder. Ureteral mucosa is sutured to the bladder mucosa using a 5-0 absorbable monofilament suture in an interrupted pattern. A balloon-

tipped urethral catheter is passed into the bladder lumen, and a closed urine collection system is maintained for 24 to 36 hours after surgery. The cystotomy and urethrotomy are closed using 4-0 absorbable monofilament suture in a single or double layer continuous or interrupted pattern. Following removal of the urinary catheter, stranguria is frequently noted for several weeks after surgery.[12,13]

Nephroureterectomy

Removal of a nonfunctional kidney and associated ureter is indicated as a salvage procedure provided renal function in the contralateral kidney is normal. Aerobic bacteriologic cultures

from the renal pelvis are obtained if a urinary tract infection has been documented or pyelonephritis is suspected. The ureter is sharply dissected from the ureteral fascia and retroperitoneal space to its termination. The ureter is ligated at its most distal point of attachment and transected cranial to the ligature. Removal of a nonfunctional kidney without the removal of an associated intramural ureter remnant will likely result in persistent urinary incontinence after surgery. The submucosal portion of the ectopic ureter is excised as previously described.

Post-Surgical Considerations

Persistent urinary incontinence is the most common complication after surgical repair of unilateral or bilateral ectopic ureters. Urinary incontinence has been reported to occur in 44% to 67% of patients after surgery.[2-4,15,18,27,35,36,41] Incontinence has been reported after ureteral reimplantation of extramural ectopic ureters as well as with neoureterostomy of intramural ectopic ureters and nephroureterectomy of a nonfunctional kidney associated with an ectopic ureter.[36] Associated primary sphincter mechanism incompetence is hypothesized to be an underlying cause of persistent urinary incontinence.

Identification and treatment of urinary tract infection are the first steps in the management of any patient with persistent or recurrent urinary incontinence. Standard medical treatments with alpha-adrenergic agonist or anticholinergic drugs may have improved success in some patients with mild incontinence after surgery. Endoscopic injection of glutaraldehyde cross-linked collagen submucosally within the urethra has also been used successfully to treat persistent urinary incontinence.[1,2,44]

Chapter 69

Canine Urethral Sphincter Mechanism Incompetence

Peter E Holt

During urine storage, urethral resistance is maintained by a complex mechanism of factors. These include tone in the urethral smooth muscle (the “internal” sphincter), tone in the urethral striated muscle (the “external” sphincter), the natural elasticity of the urethral wall tissues (not only musculature), the physical properties of the urethra (length and diameter),

and the degree of engorgement of suburothelial venous plexuses. Because no true bladder neck sphincter exists in the bitch and continence is maintained by a complex mechanism of interacting factors, the term “urethral sphincter mechanism incompetence” was suggested to describe a weakness of the urinary sphincter.[1] This term has been widely adopted.

The neuromuscular function of the lower urinary tract in the dog is complex and not completely understood. A summary is provided in Figure 69-1.

Urethral sphincter mechanism incompetence occurs in dogs and cats,

although it is rare in the latter. In dogs referred for the investigation of urinary incontinence, urethral sphincter mechanism incompetence is the most common diagnosis made in adults and is second only to ureteral ectopia in juveniles, particularly in females.[2-4]

It can present as a congenital or acquired condition. The acquired form is rare in the cat; in that species, most cases of urethral sphincter mechanism incompetence are congenital.[5] Although urethral pressure profilometry can be used to demonstrate incompetence of the urethral sphincter mechanism,[6] this technique is not readily available in

general practice and is predisposed to a number of artefacts that can make interpretation difficult.[7,8] In general practice, therefore, the diagnosis is usually made on the basis of the breed and the history, and by the elimination of other possible diagnoses using imaging and laboratory techniques.

Congenital Urethral Sphincter Mechanism Incompetence in Bitches

This tends to be a problem of large breeds of dog, predominantly bitches. Leakage of urine is more copious compared with animals with ureteral ectopia and occurs predominantly when the dogs are recumbent. The

urethra may be abnormally short or even absent, especially in cats, and urethral diverticula and dilations may be present in juvenile male dogs.[9] In many bitches, no gross abnormalities are detected on contrast radiographic investigations, apart from a caudally positioned bladder. The diagnosis frequently relies on the history and elimination of other possible causes of incontinence. Approximately half of affected bitches become continent following their first estrus. Those that do not may be candidates for medical or surgical management. Estrogens are contraindicated in juvenile bitches with this condition because of possible adverse “feed-back” effects on the pituitary, but alpha-adrenergics such as

phenylpropanolamine could be used, pending estrus.

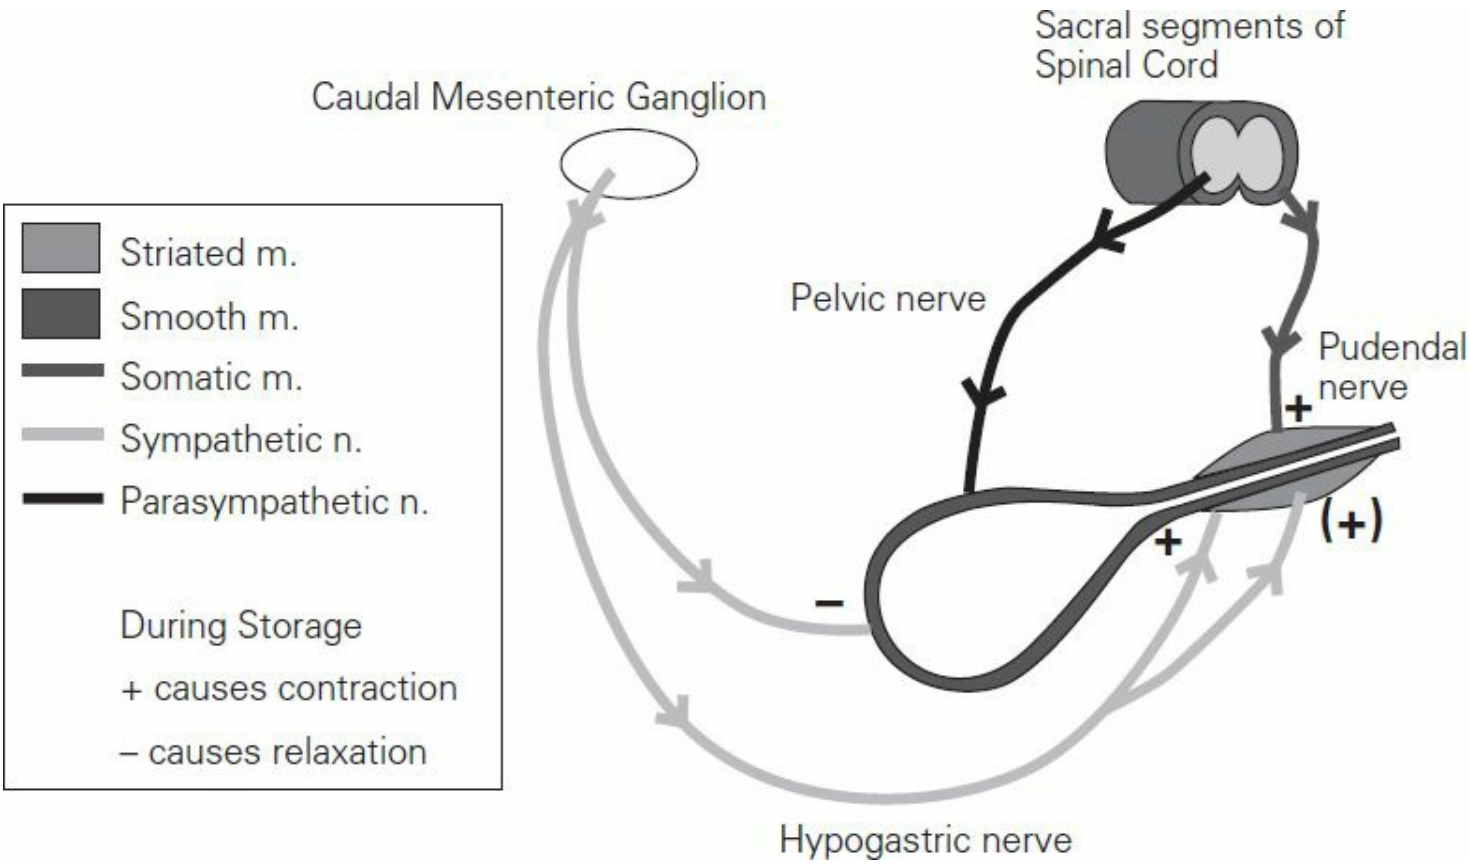

Figure 69-1. The neuromuscular control of urinary continence. During storage, the sympathetic innervation exerts a β (relaxation) effect on the bladder and an α-adrenergic (contractile) effect on urethral smooth muscle. In some species such as humans and cats, the sympathetic innervation also acts on the urethral striated muscle, but this has not yet been shown to occur in the dog. Urethral striated muscle provides additional tone during times of stress

and is under voluntary control via the pudendal nerve.

Acquired Urethral Sphincter Mechanism Incompetence in Bitches

Acquired urethral sphincter mechanism incompetence usually (but not always) follows spaying in the bitch.[10,11] and castration in male dogs.[12] Before treatment can be contemplated, an understanding of the pathophysiology of urethral sphincter mechanism incompetence is required. The exact abnormality leading to urethral sphincter mechanism incompetence and the region of the urethra in which it occurs are unknown. It is a multifactorial problem and various

factors are known or suspected to contribute to its clinical manifestation of urinary incontinence. These factors include urethral tone, urethral length, bladder neck position, body size and breed,
ovariohysterectomy/ovariectomy, hormones, and obesity.

Urethral Tone

The introduction of urethral pressure profilometry as an investigative aid in the bitch has allowed confirmation of the belief that poor urethral tone is implicated in urinary incontinence owing to urethral sphincter mechanism incompetence.[6] Urethral tone is maintained by a complex interaction

of neuromuscular, vascular, and passive elastic components, and it is unclear which of these is deficient in sphincter mechanism incompetence.

Urethral Length

Considerable variation exists in urethral length among bitches of different sizes. However, taking body size into consideration, bitches with urethral sphincter mechanism incompetence tend to have shorter urethras than do continent animals.[13]

Bladder Neck Position

Several authors recorded the radiographic finding of a “pelvic

bladder" during the investigation of incontinent animals. The significance of this finding was disputed in the past but good evidence exists that an intrapelvic bladder neck contributes significantly to urinary incontinence owing to urethral sphincter mechanism incompetence.[13] The caudal bladder position in affected dogs is associated with the shorter urethral length and also the fact that the bladder moves caudally when a bitch moves from a standing to a relaxed recumbent position. This movement is more pronounced in bitches with urethral sphincter mechanism incompetence than in normal animals, suggesting a deficiency in supporting mechanisms in the lower urinary tract of affected

animals.[14] The role of bladder neck position in bitches with urethral sphincter mechanism incompetence is thought to be due to changes in transference of abdominal pressures to the urethra (Figure 69-2).[13,15,16]

Body Size and Breed

Body size appears to be a factor because large and giant breeds are particularly at risk. Urethral sphincter mechanism incompetence is most common in the United Kingdom in Dobermans and Old English sheepdogs, and evidence exists that these breeds as well as Rottweilers, Weimaraners, springer spaniels, and Irish setters are particularly at risk.[10]

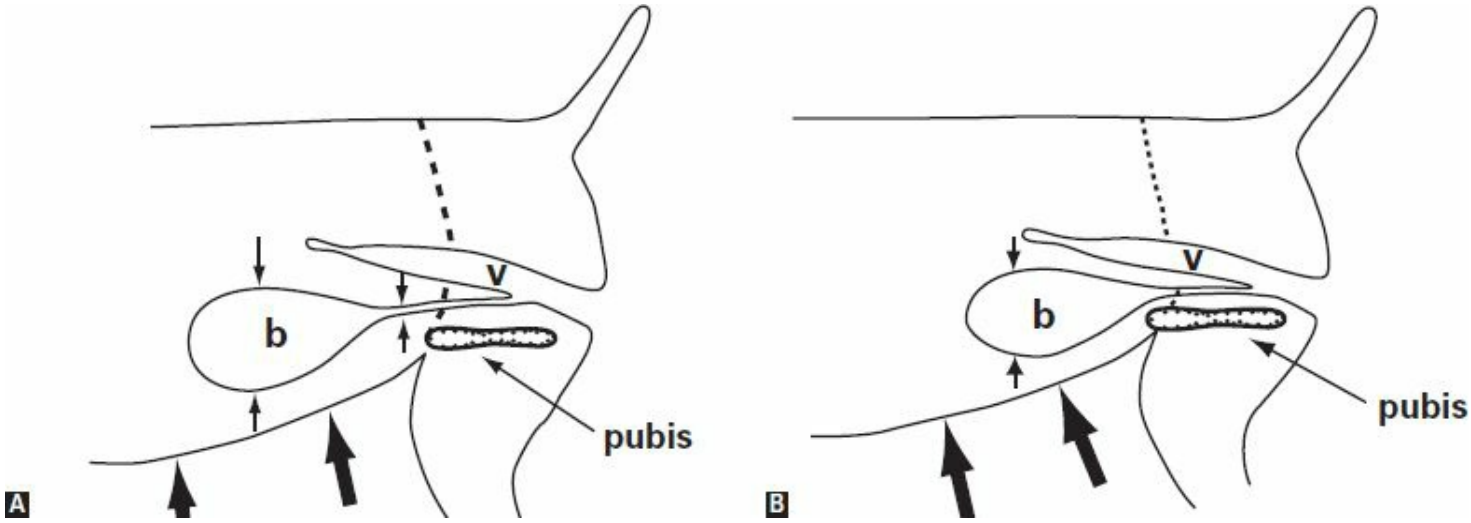

Figure 69-2. The effect of bladder neck position on continence control. In an animal with an intraabdominal bladder neck (A), increases in abdominal pressure are transmitted not only to the bladder but simultaneously to the bladder neck and proximal urethra. Thus any increase in intravesical pressure may be counteracted by an increase in urethral resistance. If the bladder neck is intrapelvic (B), however, abdominal pressure increases act predominantly on the bladder and less efficiently on the bladder neck and proximal urethra. If urethral tone is adequate, bladder neck position is of little relevance but, if urethral sphincter mechanism incompetence exists, the bitch with the anatomy illustrated in Figure 69-2B is more likely to leak urine at times of intraabdominal pressure increases (e.g., recumbency). Unfortunately for affected bitches and male dogs, the intrapelvic bladder neck is a common

finding in animals with urethral sphincter mechanism incompetence. Retroperitoneal accumulations of fat in obese animals are likely to worsen this situation by displacing the caudal extent of the abdominal cavity cranially.
v – vagina; b – bladder; the dotted line represents the caudal extent of the abdominal (peritoneal) cavity.

Ovariohysterectomy/Ovariect and Hormones

Aan association exists between spaying and urinary incontinence.[11] This is probably caused by a lack of circulating estrogens,[17] although one study suggests that an excess of gonadotrophins may also be a factor.[18] In general terms, spayed animals are nearly 8 times as likely to develop this form of urinary incontinence as are

intact bitches.[11] However this should be considered in terms of dog years. In simple terms, if 100 bitches were not spayed, 10 years later, two of them would be incontinent. If 100 bitches were spayed, about 16 of them would be incontinent after 10 years. Spaying before the first season may increase the risk, although this could not be proved conclusively in a prospective study,[11] probably because of the low number of animals examined. One study suggested that, if early gonadectomy of female dogs is practiced, it should be delayed until the animal is at least three months of age.[19] The function and morphometry of the lower urinary tract are affected by the changes in hormone balance

that occur during the estrus cycle.[20]

Obesity

Although not a cause of the condition, obesity may worsen the degree of incontinence, and weight loss may improve the situation.

Vestibulovaginal Stenosis in Relation to Urethral Sphincter Mechanism Incompetence in Bitches

Vestibulovaginal stenosis (owing to a true stricture or persistent perforate hymen) has been linked to urinary incontinence by some authors.[21-23] Holt and Sayle suggested that the

incontinence might be associated with urine accumulating cranial to the stenosis during micturition and subsequently dribbling out.[21] However, Holt later demonstrated no difference in the prevalence of vestibulovaginal stenosis between normal and incontinent bitches.[13] The author now believes that vestibulovaginal stenosis per se is not a cause of incontinence, although if a bitch is already incontinent and leaking urine into the vagina, some may accumulate cranial to the stenosis, exacerbating the signs and predisposing to vaginitis. Experience suggests that the incontinence is a result of other causes such as urethral sphincter mechanism incompetence and that, if the

incontinence owing to these other causes can be cured, the vestibulovaginal stenosis is irrelevant.

Urethral Sphincter Mechanism Incompetence in Male Dogs

Urethral sphincter mechanism incompetence in male dogs is uncommon.[9] As in the bitch, the condition can occur as either a congenital or acquired condition. The congenital condition is often associated with gross prostatic/pelvic urethral deformities (urethral dilatations and prostatic urethral diverticulae) and is unlikely to be successfully treated. As in the bitch, the acquired form is

associated with neutering,[12] and larger breeds appear to be at risk. Incontinence is likely to occur when intraabdominal pressure increases (e.g., during recumbency). Affected animals tend to have intrapelvic bladder necks, although a short urethra does not appear to be a factor in males.[12] Conservative management is frequently disappointing. In comparison with the bitch, the condition is less likely to respond to medical therapy. The pathophysiology of male urethral sphincter mechanism incompetence is poorly understood, making rational treatment difficult. Drugs used in its management include androgens, estrogens, and alpha-adrenergics. Of these, alpha-

adrenergics gave the best results but, even then, more than half of the dogs failed to respond to therapy.[9] Attempts have been made to relocate the intrapelvic bladder neck to an intraabdominal position. These have mainly involved pexy of the deferent ducts to the abdominal wall.[24,25] although the author has used prostatopexy (in castrated males) to the prepubic tendon.[26] As with medical treatment, the impression in a limited number of cases is that surgical treatment alone of urethral sphincter mechanism incompetence is less successful in males than in bitches.

Practical Applications

The treatment of sphincter mechanism incompetence may be difficult and most therapies correct only one of the factors discussed. It is unlikely, therefore, that any one form of treatment alone will cure 100% of cases in the long term.

In theory, sympathomimetic or parasympatholytic agents should improve continence control by increasing urethral tone or reducing intravesical pressure, respectively (Figure 69-1), but the results of clinical trials are variable and possible long-term adverse systemic effects have not been evaluated. Currently, the most popular medical treatment is the alpha-adrenergic,

phenylpropanolamine.[27-30] Affected spayed bitches may also respond to therapy with estrogens such as estriol.[31] In some animals that respond initially to alpha-adrenergics or estrogens, the response ceases eventually. In the case of estrogens, this is possibly a result of desensitization of estrogen receptors. Estrogens sensitize the urethral smooth muscle to alpha-adrenergic stimulation and so a combination of estrogen and alpha-adrenergic therapy may be useful and reduce the dose of each individual drug, lessening the chances of side effects. Androgens have been employed in castrated male dogs but, in the author's experience, the results are disappointing.

The main options for surgical treatment are to attempt to:

- **increase urethral resistance** - e.g., peri-urethral surgical slings[32,33] or artificial sphincters;[34] intra-urethral injection of bulking agents;[35-37]
- **increase urethral length**, using bladder neck reconstruction techniques;[38]
- **re-locate the bladder neck to an intraabdominal position** by means of colposuspension,[39-43] vas deferentopexy,[24,25] urethropexy,[44,45] or prostatopexy.[26]

The potential problem with techniques intended to increase urethral resistance is that they may increase the morbidity

by making an incontinent animal dysuric. Urethral bulking agents have been used most commonly to increase urethral resistance. Similarly, increasing urethral length carries potentially serious surgical risks and, in the author's view, should be reserved for animals with severe congenital urethral hypoplasia. In the author's opinion, the technique least likely to lead to serious complications is relocation of the bladder neck to an intraabdominal position by means of colposuspension. The greater experiences of medical urologists treating incontinent women suggests that colposuspension provides firmer anchorage of the lower urogenital tract than urethropexy and avoids urethral

trauma. It may also prevent the caudal movement of the bladder that occurs during recumbency and is more pronounced in bitches with urethral sphincter mechanism incompetence.[14] However, a review of urethropexy as a treatment for urethral sphincter mechanism incompetence in 100 bitches revealed similar results to colposuspension,[45] although the prevalence and severity of urethral complications was higher. The reviewer believes that cystopexy is contraindicated in these cases because it may result in detrusor instability, a further cause of urinary incontinence.

Colposuspension is intended to move the intrapelvic bladder neck of bitches

with urethral sphincter mechanism incompetence to an intraabdominal position so that increases in intraabdominal pressure can act simultaneously on the bladder and urethra. Thus, any increase in intravesical pressure is counteracted by an increase in urethral resistance (Figure 69-2).

Although great progress has been made over the past three decades in our understanding of the pathophysiology and, thus, the treatment of canine urethral sphincter mechanism incompetence, a recent editorial by one of the world's most respected urologists suggests we still have a great deal to learn.[46] Despite over 200

procedures being described for the treatment of human stress incontinence, the author was left asking, when it comes to his own patients, what should he do?

Chapter 70

Urethral Disease and Obstructive Uropathy

Cheryl S. Hedlund
Giselle Hosgood

Urethral disease usually induces urinary incontinence or obstruction and produces characteristic clinical signs, including dysuria, stranguria, hematuria, pollakiuria, and urethral discharge. Urethral disease may be congenital or acquired and cause a functional or mechanical lesion (Table

70-1).

Table 70-1. Urethral Abnormalities Identified According to Predominant Clinical Characteristic

Urethral Abnormalities

Urethral Incompetence	Urethral Obstruction
Neurogenic	Functional
Non-neurogenic	Mechanical
Congential	Calculi, plug
Hypospadia	Neoplasm
Epispadia	Polyp
Fistula	Granuloma
Stricture	Stricture
Ectopic ureter	Malpositioning
Ureterocele	Penile fractures
Acquired	Clots
Paradoxical incontinence	
Urethritis	
Sphincter mechanism incompetence	

Other Abnormalities

Prolapse

Disruption

Normal Urethra

Anatomy

The urethra is the tube that conveys urine from the urinary bladder to the exterior of the body.[1] The male urethra is divided into prostatic, membranous, and spongiose or penile portions.[1,2] The prostatic portion extends from the urinary bladder to the caudal edge of the prostate, where the membranous portion begins. The membranous portion ends at the point of the bulb of the penis, where the spongiose portion continues to the external urethral orifice.[1,2] The vascular erectile tissue of the spongiose portion is continuous with the corpus spongiosum of the penis.[1] The female urethra corresponds

to that portion of the male urethra cranial to the prostate.[1] The urethral mucosa is thrown into folds (rugae) that disappear with urethral distention. A prominent dorsomedian fold remains, known as the dorsal urethral crest.[1,2] In the male, the colliculus seminalis, an oval enlargement located in the middle of the urethral crest that projects into the urethral lumen, contains the minute openings of the uterus masculinus and is closely associated with the deferent ducts, which open on either side.[1,2]

The wall consists of four layers, mucosa, submucosa, muscularis, and adventia. The mucosa of both male and female urethras is predominantly

transitional epithelium; it gradually changes to stratified squamous epithelium near the external urethral orifice. Stratified cuboidal, stratified columnar, or simple columnar epithelium is interspersed between these two sites.[2,3]

The propria submucosa consists of loose connective tissue with many elastic fibers and smooth muscle cells. The urethra in bitches is 68% to 78% connective tissue by volume.[4] Diffuse lymphatic tissue and nodules are also present in dogs.[2,3] Male cats also have simple tubular urethral glands.[2] Cavernous spaces in the submucosa and lamina propria along the entire length of the male and female urethra

give the appearance of erectile tissue.[1-3] The quantity and size of cavernous spaces increase in the penile urethra where it becomes the corpus spongiosum.[2]

The urethral muscle is composed of three inner layers of smooth muscle and an outer layer of striated muscle and is continuous proximally with the detrusor muscle of the urinary bladder wall.[1] The amount of smooth versus striated muscle varies at sites along the urethra. In females, the proximal urethra is predominantly smooth muscle with a thick inner circular layer interspersed with thin, oblique fibers[5] and covered by a thin outer longitudinal layer.[3] Proximal smooth

muscle has sphincter-like properties but is not a true anatomic sphincter and not under conscious control. Distally, the smooth muscle fibers become intermixed with striated muscle fibers and are replaced principally by circular striated bundles and a few longitudinal fibers. Terminally, a thin layer of circular smooth muscle lies on the inner side of predominant striated muscle bundles.[3] In males, smooth muscle predominates in the proximal urethra and striated muscle becomes dominant in the post-prostatic urethra.[6] In bitches, skeletal muscles is located in the distal half of the urethra.[7] Unlike dogs, cats have well organized circular and longitudinal smooth muscle fibers in

the proximal urethra which shorten and widen the urethra during voiding.[7] Female cats have skeletal muscle in the distal third of the urethra.[7] The distal striated urethral muscle is functionally more efficient in males than in females and is under voluntary control.[8] Smooth muscles in the lower urinary tract are electrically coupled, exhibit spontaneous action potentials, contract when stretched, and are under autonomic control. Urethral muscle is surrounded by an adventitia of loose or dense irregular connective tissue.[2]

The blood supply to the urethra is by branches of the internal pudendal artery and vein.[1] Nerves leaving the pelvic and sacral plexuses (pelvic,

pudendal, and hypogastric nerves) control functions involving the urethra.[1] Lymphatic drainage occurs through the medial iliac (formerly external iliac), hypogastric (formerly internal iliac), and sacral lymph nodes.[1]

Physiology

The primary functions of the urethra are (1) to maintain continence by providing resistance to urine flow in the nonvoiding state,[9] (2) to allow unhindered passage of urine during urinations,[9] and (3) to contribute to the normal host defenses against urinary tract infection.[10,11]

Micturition and Continence

Urinary continence is maintained by smooth and striated muscle tone, urethral wall elastic tension, and intraabdominal pressure and is influenced by urethral length. During voiding, simultaneous contraction of the urinary bladder and relaxation of the urethra allow urination.[12] It is triggered either by reflex or voluntarily. In reflex micturition, bladder afferent fibers excite neurons that project to the brainstem and activate the micturition center in the rostral pons and inhibit sympathetic preganglionic fibers that prevent voiding. Commands from the micturition center reach the sacral spinal cord through a reticulospinal

pathway.[13] In voluntary micturition, the external sphincter is voluntarily relaxed by cortical inhibition of the pudendal nerve, which allows urine to flow through the meatus. With either mechanism, contraction of the destrusor muscle causes a vigorous discharge of the mechanoreceptors in the urinary bladder wall, which further activate the supraspinal loop and cause complete emptying of the urinary bladder.[14] During these phases, the urethra and the urinary bladder function interdependently and rely on the cerebral cortex for voluntary control.[9,12,14]

Micturition involves coordination of autonomic and somatic afferent and

efferent activities. Postganglionic sympathetic innervation is via the hypogastric nerve, with preganglionic branches from the first and second lumbar spinal cord segments (L1, L2) in dogs or the second and third segments (L2, L3) in cats.[12,14] Parasympathetic innervation via the pelvic nerve originates from the first, second, and third sacral spinal cord segments (S1, S2, S3).[12,14] Somatic innervation of the striated urethral muscle is via the pudendal nerve originating from sacral cord segments S1 to S3.[12,14] Autonomic sympathetic impulses are mediated by acetylcholine at preganglionic synapses and norepinephrine at postganglionic synapses. Norepinephrine excites both

alpha receptors (for contraction of smooth muscle; excites trigone and internal urethral sphincter) and beta receptors (for relaxation of smooth muscle; inhibits detrusor muscle).[12,14] Autonomic parasympathetic impulses activate cholinergic receptors of the urinary bladder and induce contraction of the detrusor smooth muscle.[12,14] The somatic innervation of the striated urethral muscle involves a single synapse between the motor nerve and the muscle, mediated by acetylcholine.[12,14]

Sympathetic autonomic activity dominates the storage phase: β-adrenergic stimulation facilitates relaxation of the detrusor muscle and

α-adrenergic stimulation produces contraction of the trigone and proximal urethral smooth muscle to maintain continence. There is also α-adrenergic-mediated inhibition of parasympathetic transmission, decreasing cholinergic stimulation of the detrusor muscle and allowing relaxation.[8,12]

The primary adrenergic receptor within the prostatic urethra is the α_{1A} subtype (which is responsive to phenylephrine in a dose-dependent manner).[13] The striated urethral muscle plays a minimal role in maintaining continence, but somatic stimulation can cause temporary rapid contraction should increased resistance

to urine flow be required.[8,12] The fibroelastic tissue of the urethra is also responsible for a significant component of resting urethral tone.[8,12]

The voiding phase is dominated by parasympathetic autonomic activity. Distention of the urinary bladder stimulates preganglionic parasympathetic sensory receptors through the pelvic nerve and initiates the micturition reflex.[12] Transmission through the parasympathetic ganglia in the pelvic plexus to postganglionic fibers stimulates the detrusor muscle and produces a wave of depolarization and subsequent strong, complete contraction of the urinary bladder. Simultaneously, sympathetic inhibition

of the trigone and proximal urethra via the hypogastric nerve allows the smooth muscle to relax.[12] Pelvic nerve sensory neurons also send collaterals to inhibit interneurons in the sacral spinal cord. These in turn inhibit cell bodies of the pudendal nerve innervating the striated external urethral muscle.[12] When the urinary bladder is empty, discharges from the pelvic nerve cease, allowing for loss of inhibition of the hypogastric nerve (sympathetic) and the pudendal nerves (somatic) and closure of the urethra.[12]

Central control of micturition resides in the brain stem, at the level of the pons, and receives sensory stimulus from stretch and pain receptors in the

urinary bladder. Voluntary control of the brain stem micturition center includes the cerbral cortex, basal gangia, thalamus, and cerebellum, and these components exert mostly an inhibitory influence over micturition.[12]

The Role of the Urethra in Host Defense

Some of the natural defense mechanisms of the urinary tract to prevent infection include the length of the urethra, the high pressure zones within the urethra, urethral and ureteral peristalsis, the vesicoureteral flaps that prevent urine reflux from the urinary bladder into the ureters, and the extensive renal blood supply and

flow.[10,15] Other host defenses include the antimicrobial properties of urine, renal defenses, and systemic defenses. Most of the urinary tract is sterile; however, bacteria normally reside in the lower genitourinary tract. In dogs, these bacteria include species of *Staphylococcus, Streptococcus, Corynebacterium, Pasteurella, Proteus, Klebsiella, Mycoplasma, Escherichia coli* and others.[10] This resident population of bacteria may decrease establishment of a uropathogen or may emerge as a uropathogen if normal host defenses are altered. The uropathogenicity of each organism varies. The majority of urinary tract infections (UTI) result from ascending migration of pathogens.[10] The most common canine

uropathogens are *Escherichia coli* (44.1%), *Staphylococcus spp* (11.6%), *Proteus* (9.3%), *Klebsiella spp* (9.1%), *Enterococcus spp* (8.0%) and *Streptococcus spp* (5.4%).[16] The identification of bacteria in the urine is not indicative of a urinary tract infection. An infection exists if a high number of bacteria exist in a properly collected and cultured sample.[10] The urethra contributes to the local host defenses involving normal micturition, anatomic barriers, and mucosal defense barriers.

Normal Micturition

Mechanical washout induced by unimpeded frequent and complete

voiding of an adequate urine volume inhibits bacterial colonization of the urinary tract by rapidly eliminating organisms that reach the proximal urethra and urinary bladder.[10] Urination also reduces the microbial population of urethral mucosa by flushing the urethra with sterile urine. Washout is aided by distention of the urethra, which obliterates mucosal folds that could harbor bacteria.[10] The effectiveness of voiding depends on the rate of urine production, the frequency and completeness of voiding, and the rate of bacterial proliferation.[10] Urine composition also helps to prevent infections. Urine contains substances that inhibit bacterial colonization, including a high urea concentration,

organic acids, low molecular weight carbohydrates and Tamm-Horsfall mucoprotein.[10,15] Cell-mediated and humoral immunity within the urine or urinary tract also give protection.[10,15] Antimicrobial properties of urine include extreme high or low urine pH, hyperosmolality, high urea concentration, organic acids, low molecular weight carbohydrates, Tamm-Horsfall mucoproteins, and perhaps others.[10,15]

Anatomic Barriers

A functional high-pressure zone in the mid-urethra of female dogs, corresponding to an area of smooth and striated muscle, has been

hypothesized to inhibit the migration of bacteria along the urethra.[10] Surface characteristics of the urethral epithelium differ in the proximal and distal urethra and correlate, respectively, with absence or presence of bacteria. The normally sterile proximal urethra contains longitudinal folds called microplicae, which flatten when the lumen expands. The distal urethra contains microplicae, but it also has randomly arranged fingerlike projections called microvilli.[10] Urethral peristalsis, beginning in the proximal urethra and moving distally, may be important in maintaining unidirectional urine flow and inhibiting ascension of bacteria.[10] The incidence of cystitis is lower in males

than in females, perhaps because of the gram-positive and gram-negative bactericidal fraction of prostatic fluid.[10] Nevertheless, in some dogs the prostate may act as a reservoir for bacteria.[17] In addition, the longer male urethra may provide greater resistance to bacterial access to the proximal urethra and urinary bladder.[10]

Mucosal Defense Barriers

Urinary tract mucosal defense barriers prevent bacterial migration and colonization. These barriers include a glycosaminoglycan layer, antibodies, intrinsic mucosal antimicrobial properties, cell exfoliation, and bacterial interference by commensal

microbes of the distal urethra and distal genital tract.[15] Bacterial adherence to urethral epithelial surface is essential to subsequent tissue invasion and colonization.[11] The normal negative electric charge of both the bacterial cell wall and the urethral epithelium tends to repel the bacteria and prevent contact. Bacterial adherence is achieved by molecular bonding between molecular structures known as adhesins and specific receptor sites on the urethral epithelial surface.[11] Adhesins are present on bacterial cell wall fimbriae of gram-negative bacteria or on fibrillae of gram-positive bacteria. Although the mucosa has few direct antibacterial properties, a surface

mucopolysaccharide glycosaminoglycan layer provides a barrier to bacterial adherence.[10] The urethral mucosa may also produce secretory immunoglobulin A (IgA).[10] Most of the IgA in the urine orginates from this source and inhibits bacterial ascent from the urethra to the urinary bladder.[10] Disruption of the surface glycosaminoglycan layer by acid or povidone-iodine, allows bacterial adherence to the urethral epithelium.[11] Exfoliation of urethral epithelial cells is a natural phenomenon that may be accelerated by abnormal conditions. This may expedite the removal of bacteria from the urethra during voiding.[10]

Urethral Dysfunction

Loss of normal urethral function usually results in urinary incontinence or obstruction. Urinary incontinence occurs when the intravesicular pressure exceeds the intraurethral pressure, resulting in uncontrolled loss of urine from the body. Incontinence may also occur owing to anatomic abnormalities that bypass the normal continence mechanisms (ectopic ureters). Such urinary incontinence is primarily caused by incompetence, and may be non-neurogenic or neurogenic. Urethral dysfunction causing urinary tract obstruction may be functional (neurogenic) or mechanical (intraluminal or extraluminal

obstruction or loss of integrity). Urethral disease may also affect the ability of the urethra to contribute to host defenses against UTI. UTI is often a concurrent finding with urethral dysfunction, causing either incontinence or obstruction.

Urethral Incompetence

Non-Neurogenic Urethral Dysfunction as a Cause of Incontinence

Congenital or acquired urethral abnormalities may result in incontinence, including urethral malformations and conditions that cause urethral incompetence. In

addition, urethral obstruction that leads to urinary bladder over-distention may cause detrusor damage and atony leading to overflow incontinence.

Congenital urethral disorders are infrequent. Urethral agenesis, urethral duplication, hypospadias, epispadias, diverticula, stricture, fistula, urethral ectopia, hermaphroditism, and pseudohermaphroditism have been reported. These conditions sometimes result in incontinence or abnormal flow of urine from the urethra.

Ectopic ureters may be associated with anatomic and functional abnormalities of the bladder and urethra.[18,19]

Anatomic abnormalities of the urethra and vaginal vestibule are common in dogs with ectopic ureters and may result in continued incontinence after surgical repair if they are not treated concurrently. Urethral troughs, fenestrations, tenting, striping, and the intramural ureter in the dorsal urethral wall may affect the ability of the urethra to generate adequate closure pressure.[18,19] Congenital urethral incompetence that does not resolve after surgical treatment for ectopic ureters may also be a result of persistent ureteral malpositioning, vestibulovaginal malformation, or a congenital neuromuscular deficit on the proximal urethra.

For a discussion of acquired urethral incompetence see Chapter 69: Canine Urethral Sphincter Mechanism Incompetence

Paradoxical Urinary Incontinence

Paradoxical urinary incontinence mimics urethral obstruction without a physical obstruction.[20] Affected animals have a large urinary bladder and attempt to urinate without success. They may develop postrenal azotemia and uremia. Obstruction is believed to be caused by spastic contraction and inflammation secondary to chronic urethritis.[20] It is difficult to catheterize awake animals but anesthetized

animals are catheterized without impedence. As the urinary bladder fills, intravesicular pressure eventually exceeds the resistance caused by the urethral lesion, resulting in urinary incontinence.

Urethritis

Chronic inflammation of the lower urinary tract may produce a syndrome of incontinence characterized by frequent, uncontrolled, involuntary detrusor contractions. It is a disorder of the storage phase of urination and is often referred to as urge incontinence. Inflammation of the urethra may be infectious or noninfectious. Urethritis is not a common clinical entity and is

often associated with other urogenital inflammatory diseases, including prostatitis, cystitis, and vaginitis.[20] Noninfectious causes of urethritis, including trauma, chemicals, neoplasms, and urolithiasis, may predispose to bacterial urethritis. The normal urethra is not sterile, and resident bacteria normally populate the distal urethra.[10] Infectious urethritis may also occur secondary to infection elsewhere in the urogential tract (e.g., cystitis, prostatitis, or vaginitis).[20] Catheterization may induce urethritis through trauma, bacterial contamination, and reaction to the material of an indwelling catheter.[21]

Acute urethritis may induce stranguria or pollakiuria.[20] Gross hematuria may be present at the beginning of micturition. Urethral discharge must be differentiated from preputial or vaginal discharge.[20] Chronic urethritis may lead to urethral incompetence owing to fibrotic changes in the tissue. Similarly, infiltrative diseases such as neoplasms or granulomatous urethritis may also cause urethral incompetence.[22,23] As the intravesicular pressure increases, the damaged or diseased urethra is unable to prevent the flow of urine, and urinary incontinence results. Chronic urethritis with stricture or infiltrative disease can progress to cause urethral obstruction (see discussion of

mechanical urethral obstruction later in this chapter).[22,23]

Neurogenic Urethral Dysfunction as a Cause of Incontinence

Lesions of the sacral spinal cord, sacral roots, or pudendal nerve decrease urethral pressure. Urethral muscle hypotonicity is commonly associated with lower motor neuron lesions at or caudal to the level of the L5 vertebrae (L6 in the cat). These lesions damage the sacral spinal cord segments or nerve roots (pudendal nerve and pelvic nerve).[24] Detrusor areflexia, with or without complete loss of urethral tone,

usually results. With complete lesions, the striated urethral muscle is denervated but the hypogastric nerve innervating the proximal urethral smooth muscle remains intact, because it originates from lumbar spinal cord segments.[25] The sacral lesion abolishes normal sensory input from the stretch receptors in the detrusor muscle. As a result, the proximal urethral smooth muscle does not relax in response to the increased pressure of urinary bladder filling and remains fixed.[25] Manual expression of the urinary bladder may be easy or may meet resistance. Once the urinary bladder fills, the intravesicular pressure overcomes the proximal urethral smooth muscle resistance and overflow

incontinence results. Some pain receptors in the hypogastric nerve may remain intact, and the animal may show discomfort and make unsuccessful attempts to urinate.[25]

Consequences of Urethral Incompetence

Urinary incontinence owing to urethral dysfunction results in urine soiling of the environment and pet, particularly causing skin irritation and scalding of the hind limbs, perineum, and ventral abdomen.[10,15] Overdistention of the urinary bladder may damage the muscle cells and also cause separation of the tight junctions between the detrusor muscle fibers, preventing

excitation-contraction coupling (see discussion of consequences of chronic urethral obstruction later in this chapter). Increased capacity and incomplete emptying of the urinary bladder can result in large amounts of residual urine and predispose to recurrent urinary tract infection. Bacterial elimination from the urinary bladder is impaired after overdistention of the urinary bladder. Possible consequences of UTI include septicemia, discospondylitis, urolithiasis, incontinence, prostatitis, pyelonephritis, renal failure, and urinary bladder neoplasms. Long-standing urinary bladder distention and chronic UTI cause hypertrophy, hyperplasia, and connective tissue

infiltration of the urinary bladder wall or urethra. This results in poor contractile function of these structures, and it reduces the capacity of the urinary bladder, thereby exacerbating the problem of urinary incontinence.

Urethral Obstruction

Urethral obstruction may be mechanical or functional. Diseases of the urethra frequently result in partial or complete obstruction of urine outflow. Calculi, neoplasia, granuloma, stricture, or urethral malpositioning can cause urethral obstruction. Occasionally, neurologic disease, prostatic disease, or blood clots may cause obstruction. The

condition may be life-threatening and animals should be evaluated for hyperkalemia and metabolic acidosis. Total obstruction is an emergency as it quickly leads to uremia (two to three days) and death (three to six days) if untreated. Additionally, urethral obstruction can result in prolonged bladder distention, which causes temporary or permanent detrusor contractile dysfunction.

Functional Urethral Obstruction

Functional obstruction results from failure of coordination of urethral relaxation with detrusor contraction. Upper motor lesions of the urinary

bladder with spinal lesions above L5 affect the suprasacral spinal cord segments.[12] The micturition reflex is lost, and detrusor areflexia with hypertonus of the urethra is the result of lack of inhibition of the hypogastric and pudendal nerves.[12] The urethral hypertonus causes increased resistance to urine flow, and manual urinary bladder expression is difficult. The animal does not perceive vesicle fullness, owing to loss of conscious sensation and cerebral motor control.[12] Micturition can be initiated by spinal reflexes, and a reflex bladder may develop over several days to weeks after the injury.[12] Once a threshold bladder capacity is reached, a "myotactic-like" reflex is initiated via

stretch receptors in the bladder wall. These receptors send afferent impulses via the pelvic nerve to the sacral spinal cord. Depolarization of the pelvic nerve efferents contracts the detrusor muscle, but voiding is interrupted, involuntary, and incomplete, owing to failure of urethral relaxation.[12]

Partial suprasacral lesions may result in inappropriate contraction or relaxation failure of the urethral muscle, coincident with detrusor contraction. This condition is termed detrusor-urethral or reflex dyssynergia. The animal makes voluntary attempts to urinate but micturition is incomplete, giving the appearance of mechanical urethral obstruction.[12] The

major resistance to urine flow is where the distal striated urethral muscle overlaps the proximal smooth muscle--approximately in the mid-urethra of females and the postprostatic membranous urethra of males. The primary cause of obstruction is thought to be over-discharge of the sympathetic nerve impulses to both the smooth and striated urethral muscle, causing increased intraurethral pressure during attempts at voiding.[12] Abnormalities of the somatic innervation to the urethral striated muscle may also contribute to the dyssynergia. Accompanying problems might include urinary tract infection, bladder atony, prostatic enlargement, urolithiasis, and priapism.[26,27]

Mechanical Urethral Obstruction

Intraluminal urethral obstruction may result from congenital or acquired urethral strictures, urethroliths, neoplasms, polyps, proliferative urethritis,[22] foreign bodies, blood clots, malpositioning, or penile fractures.[20,28-31] Urethral strictures may form secondary to previous urethral injury such as surgery, urethroliths, external trauma, or urethral catheterization. Urethral uroliths originate in the urinary bladder and cause urethral obstruction more frequently in male dogs, although this is reported in females. The most frequent site of urethral obstruction is

the caudal end of the os penis, but uroliths can lodge elsewhere in the urethra. Clinical signs include stranguria and complete inability to urinate.

Primary urethral tumors are reported more frequently in older female dogs. Transitional cell carcinoma and squamous cell carcinoma are most common.[32-34] Other reported tumors include leiomyoma, leiomyosarcoma, prostatic adenocarcinoma, hemangiosarcoma, rhabdomyosarcoma, myxosarcoma, and lymphoma.[32-35] Metastases localize in regional lymph nodes and lungs.[32,33,35] Clinical signs vary and include stranguria associated with

partial to complete obstruction. Hematuria and urinary incontinence are also reported.[34]

Proliferative urethritis (granulomatous infiltrative urethritis) is poorly defined in dogs. It is clinically indistinguishable from urethral neoplasms; typical clinical signs are stranguria, hematuria, and urinary obstruction.[22,23] Proliferations are often bands of tissue that are attached to the mucosa on both ends rather than being pedunculated or papillary. The mucosal proliferations can cause a one-way valve effect that causes outflow obstruction but often permits retrograde passage of urethral catheters. The urethra can be palpated

as thickened and firm. Older female dogs appear predisposed to proliferative urethritis. The cause is unknown but the tissue reaction may represent a specific, cell-mediated reaction to antigens, organisms, or foreign bodies. Histologic findings include lymphoplasmacytic and neurotophic inflammation of the urethra.[22,23] The urethral epithelium becomes mildly to moderately hyperplastic. Multifocal, nodular, and coalescing aggregates of lymphocytes, plasma cells, macrophages, and neutrophils are observed in the mucosal and submucosal layers.[22,23]

Urethral obstruction in cats with idiopathic lower urinary tract disease

may occur. Reasons for obstruction may include urethral inflammatory swelling, muscular spasms, reflex dyssynergia, luminal accumulation of sloughed tissue, inflammatory cells or erythrocytes, and formation of matrix-crystalline plugs.[36]

Extraluminal urethral obstruction can occur secondary to adjacent compressive masses or swelling. Fractures and tumors of the os penis have been reported to cause urethral obstruction.[37,38] Traumatic loss of urethral integrity from poor catheterization technique, pelvic fracture, and gunshot or bite wounds can lead to failure of urine outflow and signs consistent with outflow

obstruction.

Consequences of Urethral Obstruction[8,39]

The consequences of urethral obstruction depend on whether the obstruction is acute or chronic and partial or complete. Partial or early outflow obstruction may not impair renal function sufficiently to cause uremia; however, complete obstruction causes signs of uremia within 24 hours. As functional renal mass decreases or as intravesical, ureteral, and renal pressure increases, urine concentrating ability is lost. Additionally, urethral obstruction may lead to detrusor atony, mucosal damage, urinary tract

infection, and urethral or urinary bladder rupture. Acute complete or severe partial obstruction produces postrenal azotemia and uremia that, if not corrected, is fatal in 3 to 6 days. In contrast, chronic partial obstruction causes excessive pressure in the excretory pathway as the urinary bladder's capacity is exceeded. This increase in pressure causes progressive dilatation of the urinary tract, and damage to renal parenchyma may be sufficient to cause chronic renal failure.

Acute Complete Urethral Obstruction

Acute complete urethral obstruction

manifests as anuria and results in overdistention of the urinary bladder. Local pressure at the obstruction site damages the muscosa, causing swelling, hemorrhage, and epithelial denudation. Overdistention of the urinary bladder causes similar changes. Outflow obstruction results in increased pressure in the urinary bladder and urethra proximal to the site of obstruction. As intravesicular pressure increases, damage occurs to the urothelium and detrusor muscle. Nerves in the urinary bladder wall are damaged and inflammatory cells infiltrate. The kidneys and ureters are affected if back pressure persists. As the urinary bladder's capacity is exceeded, intraureteral and renal

intratubular pressures increase.[40] Normal pressure in the renal pelvis and ureters of the dog ranges from zero to 10 mm Hg.[41] With complete ureteral obstruction during saline diuresis, ureteral pressure in dogs reach 50 to 150 mm Hg within 5 to 15 minutes.[42,43] After 4 hours of obstruction, intratubular pressure declines but can still be as much as 3 times normal.[44-46] The decline in intratubular pressure is thought to result from a reduction in fluid volume in the tubular system because of decreased glomerular filtration rate (GFR), increased tubular reabsorption, or increased capacity of a compliant renal pelvis.[40]

Reduced Glomerular Filtration Rate

The GFR is determined by (1) the net ultrafiltration pressure across the glomerular capillaries (the difference between the hydrostatic pressure in the glomerular capillaries and the sum of the plasma oncotic pressure in the glomerular capillaries plus the hydrostatic pressure in Bowman's space); (2) the permeability of the glomerular capillary wall to water and small solutes; and (3) the surface area of the capillaries.[40] Urinary tract obstruction can affect one or more of these factors, significantly decreasing GFR.

As intratubular pressure increases, a decrease occurs in the effective filtration pressure (the difference between intraglomerular capillary pressure and the pressure in Bowman's space or intratubular pressure). This decrease is mainly due to a reduction in hydrostatic pressure in the glomerular capillaries and is accompanied by a marked decrease in renal blood flow after 24 hours' obstruction.[47-49] Progressive preglomerular constriction occurs with obstruction for longer than 5 hours, with a decrease in GFR of approximately 80% after 24 hours' obstruction.[50-52] Obstruction results in heterogeneous nephron function. Some nephrons cease to function and others

show decreased GFR; they are, respectively, known as nonfiltering and filtering nephrons.[40] The GFR of outer, cortical nephrons is less affected than that of the inner, juxamedullary nephrons: after 24 hours' obstruction, decreases are 60% to 70% and 50% of normal, respectively.[52] After 24 hours, GFR decreases further owing to the major vasoconstricting agents thromboxane A_2, angiotensin II, and maybe the endothelial-derived relaxing factor.[39] The obstructed kidney may prevent further decrements in GFR by the production of vasodilatory prostaglandins such as prostaglandin E_2 and prostacyclin which antagonize the vasoconstrictive effects of thromboxane A_2 and angiotensin II.[39]

Recovery of GFR following relief of obstruction decreases as the duration of obstruction increases.

Renal Hemodynamics

During obstructive uropathy, changes in renal blood flow can be divided into 3 phases.[40] During the first phase, 1 to 2 hours after obstruction, renal cortical blood flow actually increases above normal, in association with a decrease in intrarenal resistance and gradually increasing intraureteral pressure.[53-57] However, inner medullary blood flow decreases from the onset of obstruction, reaching less than 30% of normal within 6 hours.[85] The initial increase in blood flow may be the

result of augmented production of vasodilatory prostaglandins (prostaglandin E_2 [PG E_2] and prostacylin) by the obstructed kidney.[59-60] Increased renal prostaglandin production by the interstitial medullary cells is thought to be the result of a decline in the inner medullary blood flow secondary to the increase in ureteral pressure. The prostaglandin synthesis causes abrupt changes in vascular resistance with an overshoot in renal blood flow, seen in the fist phase.[40] During the second phase, 2 to 5 hours after obstruction, the renal blood flow decreases to normal and intraureteral pressure continues to increase. The second phase may be the result of an increase

in renal resistance, a direct effect of increasing ureteral pressure on the interstitium. Finally, in the third phase, ureteral pressure begins to decrease but renal blood flow continues to decline progressively with time. The final, chronic phase is the result of an increase in resistance at the preglomerular level.[40] The progressive decrease in blood flow may be a result of increased production of thromboxane A_2, a metabolite of arachidonic acid and a powerful vasoconstrictor.[40] Persistent renin secretion and angiotensin production may also play a role in vasoconstriction, although the evidence is conflicting.[61-62] Renin initiates the production of angiotensin, a potent

vasoconstrictor. Cells of the outer cortical nephrons have a higher concentration of renin than those of the juxtamedullary nephrons.[41] Increased renal nerve activity or high levels of catecholamines at critical sites in the kidney might also contribute to vasoconstriction and decreased renal blood flow.[63-65]

Soon after the onset of acute ureteral obstruction, an influx into the kidney occurs of leukocytes, primarily macrophages and T lymphocytes.[39] This influx is associated with a relative depletion of macrophages from the glomeruli. After relief of obstruction, the macrophage and T-lymphocyte infiltrate decreases over days.

Tubular Effects

The degree and duration of obstruction determine the degree and nature of tubular effects and their recovery.[39] Tubular abnormalities include a concentrating defect, altered reabsorption of solutes and water, and impaired excretion of hydrogen and potassium. Sodium, potassium, phosphate, magnesium, and proton retention may occur during obstruction. Tubular dysfunction may continue after relief of the obstruction owing to tubular damage.

Electrolytes

Complete urinary obstruction can lead to death from uremia in 3 to 6 days.

Death is a result of combined abnormalities in fluid, electrolyte, and acid-base balances that result in accumulation of metabolic waste products.[39] Characteristically, hyperkalemic metabolic acidosis occurs, and serum phosphorous and calcium values may be elevated. Fractional excretion of potassium increases after relief of obstruction and hypokalemia may occur postobstruction.[39] This may be caused by increased delivery of sodium to the distal tubule where sodium-potassium exchange occurs.

Acidifying Defect

Metabolic acidemia associated with

urethral obstruction results from retention of metabolic acids, consumption of bicarbonate to stabilize plasma and compartmental pH, generation of lactate associated with hypovolemia and hypoxia, and decreased conservation of bicarbonate in the obstructive and postobstructive periods.[39]

Direct effects of acidemia include decreased myocardial contractility, stroke volume, and cardiac output; excitable membrane alterations leading to dysrhythmias; central nervous system depression; and dysfunction of metabolic pathways.[39] Indirect effects of acidemia include alterations in transcellular potassium

distribution, plasma protein binding, ionization of pharmacologic agents, oxygen transport, tissue catabolism, and increased parasympathetic activity. Whereas animals with urinary tract obstruction have hyperkalemic metabolic acidosis, a urine acidifying defect is apparent and may persist after relief of the obstruction.[40] Two defects have been isolated, a selective aldosterone deficiency and distal renal tubular acidosis, or the two may be combined. Two mechanisms are proposed. First, bicarbonate excretion increases markedly, owing to altered proximal tubule reabsorption.[40] Second, the kidney's ability to acidify urine at distal sites is impaired. The ability of outer cortical nephrons to

secrete hydrogen ions appears intact, and the defect is most likely in the collecting duct or juxtamedullary nephrons.[66]

Sequela after Release of Obstruction

The decrease of GFR associated with 24 to 36 hours of obstruction is completely reversible.[67] Most early alterations in the kidney are functional and do not result in permanent loss of nephrons.[68] Complete obstruction for more than 6 days does result in permanent loss of nephrons.[68] Dogs with unilateral ureteral obstruction showed 39% recovery of renal function after 2 weeks of obstruction, 10% after 4

weeks, and 2% after 6 weeks.[40] Urinary tract obstruction, even after release, alters the kidney's ability to modulate water and electrolyte excretion. One of the first abnormalities in kidney function following obstruction is a decrease in the urinary concentrating ability. Following release of urinary tract obstruction a dramatic loss of water and solute occurs, a phenomenon referred to a postobstructive diuresis.[40,41] The factors presumed to be involved in the concentrating defect of obstructive uropathy include decreased removal of solute from the thick ascending limb of the loop of Henle, decreased total number of juxtamedullary nephrons, washout of

solutes from the medulla owing to increased medullary blood flow, and decreased hydro-osmotic response of the cortical collecting duct to antidiuretic hormone.[69]

Factors contributing to this phenomenon include the volume status of the animal before release of the obstruction. Animals often receive intravenous fluids and undergo volume expansion. In part, the increased urine flow and sodium excretion after release of obstruction is a physiologic response to volume expansion.[70] Accumulation of urea and other relatively nonabsorbable solutes during obstruction can promote solute diuresis and result in loss of much sodium and

water after release.[40]

The inappropriate increase in urine output after urinary obstruction release may also result from an intrinsic defect in renal tubular function. Studies have demonstrated a defect along the proximal and distal tubules of outer cortical nephrons and to the level of the loop of Henle in the juxtamedullary nephrons.[51,67] Other studies suggest the medullary collecting duct may be the site of altered water and sodium reabsorption.[41]

The medullary interstitial cells, responsible for prostaglandin synthesis, show proliferative changes by 5 days after obstruction.[39] Increased

medullary prostaglandin synthesis decreases the reabsorption of sodium chloride by the medullary ascending limb of the loop of Henle and the medullary solute content.[40] Increased prostaglandin secretion may also increase blood flow in the vasa recta and cause persistent increase in blood flow in the vasa recta and cause persitent washout of the medulla. A decrease in medullary solute content has the end result of decreasing the diffusion of water out of the collecting duct.[40]

An increase in medullary prostaglandin production may antagonize the effect of vasopressin, reducing the permeability of the

collecting tubules to water and contributing to the decrease of urine osmolality.[40] After obstruction, vasopressin-dependent cAMP production may also be impaired.[71,72]

Chronic Urethral Obstruction

Chronic partial obstruction is not immediately life threatening but results in pathologic changes in the urinary bladder, ureters, and kidneys. Chronic overdistention of the urinary bladder owing to resistance to urinary outflow may cause varying degrees of hydroureter and hydronephrosis.

During the early phases of obstruction, functional and morphologic changes in

the ureter and renal pelvis include muscular hypertrophy and hyperplasia. Later, collagen and elastic connective tissue are produced by the smooth muscle cells, which impairs myogenic impulse transmission and distrupts normal peristalsis.[39]

Structural renal changes during hydronephrosis can result in chronic renal failure. Experimental urethral obstruction in the rat, rabbit, and dog cause initial changes in the proximal tubules, which show a transient dilatation over several days, and then undergo atrophy.[8] By 14 days postobstruction, there is progressive dilatation of the distal and collecting tubules with atrophy of the proximal

tubular cells.[8] By 28 days, medullary thickness is reduced by 50%, anddilatation and atrophy of the distal and collecting tubules continues.[8] The cortex becomes thinner and the proximal tubules are markedly atrophic. Glomerular changes are noted after 28 days. By 8 weeks, only a thin parenchymal strip of connective tissue and small glomeruli remains.[8]

During chronic hydronephrosis with high intratubular pressures, 80% to 90% of the urine is reabsorbed into the tubules and exits via the renal veins.[8] A small portion of urine is reabsorbed into the hilar lymphatic vessels, and some fluid is extravasated into the perirenal spaces.[8]

Chronic Urinary Bladder Distention

Urinary bladder outlet obstruction with distention produces significant alterations in detrusor structure and function.[73] Chronic urinary bladder outlet obstruction causes increased thickness of the urinary bladder wall owing to muscle hypertrophy, hyperplasia, and collagen deposition by the smooth muscle cells.[74] Hypertrophy is the predominant response to moderate obstruction, whereas hyperplasia with more collagen deposition is the predominate response to severe obstruction.[74]

Although the urinary bladder enlarges,

its compliance and capacity decrease.[73] This is demonstrated by a sharp incline in the filling limb of the cystometrogram.[73] Chronic obstruction results in reduced detrusor contractility and evidence of partial denervation is reported.[75-77] Postjunctional supersensitivity secondary to partial denervationcontributes to detrusor instability,[75,76] characterized by frequent, inappropriate detrusor contractions. Obstruction can cause rapid changes, and muscarinic receptor density is reduced by 50% after 24 hours' distention.[73] The defect in contractile mechanism is not solely due to low muscarinic receptor density.[78] Other factors in reduced contractility include a decrease in the myofilaments

of hypertrophic smooth muscle cells; weak contractions of hyperplastic, immature muscle cells; weak contractions of hyperplastic, immature muscle cells;[74] increased noncontractile elements in the urinary bladder wall;[73] and decreased propagation of action potentials through the detrusor muscle secondary to intercellular disruption.[79] Electron microscopy studies of rabbit detrusor muscle after urinary bladder distention have shown acute disruption of intercellular junctions with secondary intercellular fibrosis.[80] Two months after urinary bladder distention, intracellular separation of the cytoplasm from the plasma membrane of the detrusor muscle fibers was demonstrated.[79] Results of another

study question whether these changes are significant and really represent "disruption" of junctions. Gosling and coworkers reported similar findings in distended bladders and those of normal control subjects.[81] They proposed that these junctions represent normal "intermediate" junctions, as opposed to "close" or tight junctions. In their study, neither junction type was affected by distention.[81]

Urinary bladder outlet obstruction also alters the metabolic function of the urinary bladder, which may contribute to altered contractility.[82] After 2 weeks of obstruction, urinary bladder tissue showed a decrease in aerobic metabolism and an increase in

anaerobic metabolism.[82] The ability of the urinary bladder to maintain a contraction and empty may be directly related to aerobic metabolism. Subsequently, the decrease in aerobic metabolism, even in the presence of increased anaerobic metabolism, may contribute to the decreased ability of the obstructed urinary bladder to empty.[82] Another study found that urinary bladder tissue shows a marked decrease in ATP concentration after obstruction, which may be attributed to the ischemic conditions created by distention.[81] Distention of the dog's urinary bladder for 2 hours reduced blood flow in the mucosa, muscularis, and total bladder tissue by 25% to 30% in each component.[81] In addition, the

increase in connective tissue in the urinary bladder wall lowers the overall intracellular concentration of ATP in the smooth muscle.[81]

Sequelae after Release of Chronic Obstruction

Outflow obstruction predisposes to bacterial infections. Contributing factors include catheterization, urine stasis, vesicoureteral reflux and pre-existing infections. Detrusor atony and urethral swelling or spasm may contribute to urine stasis.[39]

After release of chronic urinary obstruction, postobstruction diuresis and concentrating defects are

observed. The amount of function recovered depends on the duration of obstruction.[8] Release of obstruction within 6 days may allow full return of function. Release after 14 days may restore 50% to 65% function. Release after 30 days of obstruction may restore up to 30% of function. Obstruction for more than 4 weeks may result in permanent damage.[41]

Postobstruction renal failure may occur as a result of renal parenchymal loss owing to sustained increased intrarenal pressure, cytokine production by infiltrating leukocytes, electrolyte imbalances, fibrosis of damaged renal parenchyma, and renal ischemia owing to dehydration.[69]

Death may be associated with fluid and electrolyte imbalances as a result of cardiopulmonary failure.

Other Abnormalities

Urethral prolapse

Urethral prolapse is an eversion or prolapse of mucosa from the tip of the penis. Dogs present for signs of preputial or penile bleeding. It is seen most often in young male brachycephalic dogs and can be associated with sexual excitement or stranguria associated with urethral infection or urolithiasis.[83,84] The exact cause is unknown but theories speculate a genetic predisposition or an increased abdominal pressure

secondary to chronic upper airway obstruction.[84] In people, poor attachment between the muscle layers of the urethra associated with episodic increases in abdominal pressure is proposed as a cause.[84]

Urethral Trauma

Urethral injury may be associated with catheterization, obstruction or external trauma, especially abdominal, pelvic, or perineal trauma. Types of trauma include urethral contusions, tears, avulsion, or os penis fracture. Contusions may be asymptomatic or may cause hematuria, dysuria, and pollakiuria. Those with tears or avulsion may be unable to urinate or

may have hematuria. Trauma resulting in disruption of urethral integrity results in urine leaking into the surrounding tissues or abdomen, causing a chemical-type irritation. Leakage into the subcutaneous tissues results in severe swelling, discoloration, and sometimes tissue necrosis. Urine contact with tissues for more than 12 to 24 hours results in inflammation, edema, and cellulitis, which delays healing and promotes fibrosis.[85] Uroabdomen results in profound dehydration, life-threatening hyperkalemia, severe postrenal azotemia, chemical peritonitis, and metabolic acidosis.[85] Manifestations of uroabdomen include lethargy, anorexia, vomiting, dehydration,

abdominal distention, and pain. Additional complications of urtheral injury include stricture formation and urinary incontinence.

Urine is hyperosmolar and an accumulation in the abdominal cavity creates a concentration gradient across the peritoneum from the extracellualr fluid compartment to the abdominal cavity. Large molecules such as creatinine pull water into the abdomen whereas smaller solutes such as urea and electrolytes (potassium) diffuse into the extracellular fluid compartment. Sodium and chloride diffuse into the abdomen. Dehydration results from a combination of fluid shifts, fluid losses from vomiting, and a

decrease in fluid intake. Dehydration leads to a decrease in glomerular filtration and a subsequent decrease in excretion of urea and creatinine. Retention of urine in the abdomen with accumulation of excretory products also results in increased serum urea and creatinine. The body's normal buffer system is depleted as hydrogen retained in abdominal urine is reabsorbed through peritoneal capillaries, leading to metablolic acidosis. The production of lactic acid secondary to poor tissue perfusion resulting from dehydration and hypovolemic shock also contribute to metabolic acidosis.

Urine accumulation in the abdomen

causes a chemical peritonitis that results in functional ileus and pain. Septic peritionitis may occur if a urinary tract infection existed or a penetrating injury had occurred. Peritionitis contributes to a shift of fluid from the extracellular space into the abdomen with a concurrent loss of albumin into the abdominal effusion.[85]

Clinical Renal Transplantation in Cats

Criteria for the Renal Recipient

Renal transplantation is one method of treatment for renal insufficiency.[1-5] It cannot be regarded as an emergency treatment or “last-ditch” effort to save the life of a critically ill, malnourished patient. Surgical intervention has to take place before all medical means of therapy have been exhausted. The authors consider body weight to be an important indication of the status of the renal transplant candidate. If a cat has been in compensated renal failure and starts to lose body weight, or presents in renal failure with a history of chronic weight loss, transplantation should be considered as an option before further weight loss occurs. In the critically ill human surgical patient, maximum physical

performance deteriorates after a 10% loss in normal body weight. Greater than a 40% weight loss is usually lethal. Previous attempts by the authors to alter the course of physical deterioration resulting from decompensated renal failure via enteral or parenteral alimentation prior to transplantation have failed. Hemodialysis, however, is highly effective in managing severely uremic patients several days prior to surgery. The authors use hemodialysis to correct electrolyte and acid/base imbalances and lower the blood urea nitrogen concentration to 100 mg/dl or less. Blood urea nitrogen concentrations greater than 100 mg/dl predispose cats to postoperative cerebral edema and

seizures owing to rapid clearance of the blood urea nitrogen by a normally functioning renal graft. Age, plasma creatinine, blood urea nitrogen, and other clinical pathologic assessments of renal function cannot in themselves indicate a suitable patient for transplantation. All physical and biochemical parameters must be assessed to determine the overall suitability of a candidate.

Feline candidates for renal transplantation should be free of feline leukemia virus infection and active acquired immunodeficiency syndrome and free of other complicating diseases. It appears that renal insufficiency can produce systemic

hypertension in the feline patient, leading to congestive heart failure. Cats in renal failure often have systolic murmurs secondary to anemia that may not represent significant cardiac disease. Cardiac enlargement determined by ultrasonographic examination, gallop rhythms, and/or electrocardiographic abnormalities are possible indications to decline a candidate for transplantation. An abdominal ultrasonographic examination and intestinal biopsies should be performed if neoplasia or inflammatory bowel disease is suspected. Immunosuppression often enhances tumor growth, and inflammatory bowel disease appears to promote acute allograft rejection.

The feline renal donor/recipient pair do not have to be related or tissue matched, but they must be blood cross-matched. The antigens present on red blood cells are also present on the endothelium of the graft blood vessels. Preformed antibodies to these antigens will cause clotting of the graft vessels and infarcts of the organ at the time of surgery. The feline renal recipient must also be blood cross-matched to 2 to 3 blood donor cats. The primary reason for this is the anemia that accompanies chronic renal failure. Following rehydration of a patient prior to surgery, packed red blood cell volumes may fall as low as 12% to 15%. To attain a packed red blood cell volume of 30% in the renal recipient prior to

surgery may require 180 to 250 milliliters of whole blood. Also, in our experience, some cats in chronic renal failure are unable to accept blood transfusions, i.e., all cross-match assays show agglutination of donor red cells. In two instances, the renal disease was secondary to Lupus erythematosus. In one other, however, no cause for the coagulopathy could be found. All cats were of the same blood type (A). This is an important consideration if the transplant patient is traveling a great distance to the transplant clinic. Cross matching should be done locally to ensure transfusions can be given prior to surgery. Erythropoietin can be helpful in controlling the anemia associated

with renal failure. Administration of erythropoietin starting one to two months prior to surgery can greatly reduce the need for blood products.

Renal diseases successfully treated by renal transplantation in the cat include membranous glomerulonephropathy, chronic tubulointerstitial nephritis, polycystic renal disease, and ethylene glycol toxicosis. Cats with a suspected history of bacterial urinary tract infection should have a renal biopsy performed and be subject to a 2-week cyclosporine challenge prior to surgery. Cyclosporine is administered orally at 4 mg/kg twice daily, and urine cultures are performed 7 and 14 days following the initiation of

cyclosporine treatment. Latent infections will often become active once cyclosporine is administered. We currently recommend renal transplantation for cats whose renal failure was secondary to obstruction by calcium oxalate uroliths; however, clients must be warned that some of these cats may form additional uroliths following transplantation that may obstruct and injure or destroy the transplanted kidney. Cats with renal failure whose kidneys are of normal or increased size should have a biopsy performed to rule out lymphosarcoma.

In the past, cats that had positive serum titers for toxoplasmosis, either IgG or IgM, were not considered

candidates for immunosuppression and transplantation. Both cats and dogs have developed fatal toxoplasmosis infections following renal transplantation and immunosuppression.[6] Currently, animals with positive serum titers that undergo transplantation are administered clindamycin or trimethoprim/sulfadiazine prior to surgery and for the life of the patient. (LR Aronson, University of Pennsylvania, personal communication). Trimethoprim/sulfadiazine must be used with care because this drug can enhance cyclosporine nephrotoxicity.

Criteria for the Renal Donor

The renal donor should be in excellent health and have no evidence of renal insufficiency based on clinical pathologic testing: complete blood count, serum chemistry panel, urinalysis, and urine bacterial culture. An intravenous pyelograph is performed to assure that the donor has two normally shaped and well vascularized kidneys. The feline donor should be free of feline leukemia virus infection and be blood cross-match compatible and of similar weight and body size of the recipient. The renal donor should have a normal life expectancy following unilateral nephrectomy.[7] Elevation in serum creatinine levels and proteinuria have

been reported in human kidney donors, and long-term monitoring of renal function has been recommended.

Preoperative Preparation of the Recipient

Prior to surgery, the renal recipient is given balanced electrolyte solutions subcutaneously or intravenously at 1.5 to 2 times daily maintenance requirements. Whole blood or packed red blood cell transfusions are administered until a packed red cell volume of 25% to 30% is achieved. Hemodialysis is employed for cats that maintain a blood urea nitrogen concentration equal to or greater than 120 mg/dl despite aggressive fluid

diuresis. Cyclosporine oral solution (Neoral) is administered 48 hours prior to surgery at a dose of 3 to 5 mg/kg every 12 hours. The cyclosporine oral solution should be placed in gelatin capsules prior to administration. Capsule sizes #0 or #1 work well for most cats. Cyclosporine oral solution has an unpleasant taste that causes some cats to salivate profusely, resulting in partial loss of the dose. Clindamycin is administered to animals with positive serum titers for toxoplasmosis.

The morning of surgery, a blood sample is taken from the recipient 12 hours following the last oral dose of cyclosporine. This will give a 12-hour

trough blood concentration. The authors follow whole-blood concentrations of cyclosporine assayed by high pressure liquid chromatography. In cats, a concentration of 500 ng/ml is maintained for the first 30 postoperative days, reducing to 250 ng/ml by 3 months after transplantation. Prednisolone, 1 mg/kg/12 hours, orally, is also started the evening following surgery and is reduced to 0.5 to 1 mg/kg/24 hours by 1 month postoperatively if renal function is normal. If renal function starts to deteriorate in the first weeks to months following transplantation, i.e., serum creatinine concentrations begin to rise above 2 mg/dl,

azathioprine (0.3 mg/kg/72hours) is added to the immunosuppressive protocol. Cats receiving azathioprine should have blood cell counts and serum chemistry profiles performed weekly until a safe and effective dose is found. White blood cells counts should be maintained at higher than 3000/µl and serum chemistry profiles should be evaluated for evidence of hepatitis or pancreatitis.

Surgery

Two teams perform renal transplantation: One team harvests the donor kidney and closes the abdominal wound, and one team prepares the recipient vessels and receives the

kidney.[2,3,5,8] The two-team approach minimizes the warm ischemia time of the donor kidney, which should be kept to less than 60 minutes, unless preservation protocols are employed.[9] The authors have not used perfusion solutions to maintain the kidney prior to vascularization, but iced heparinized saline solution is used to flush blood from the kidney following harvest. It is important to thoroughly cool the kidney immediately following excision from the donor. Cold sponges should be placed on the kidney during the implantation procedure to keep it from prematurely warming.

Anesthesia protocols vary with each patient. In general, the recipient

receives atropine (0.03 mg/kg) and oxymorphone (0.05 mg/kg) subcutaneously prior to induction. The cat is mask- or boxed–induced, and anesthesia is maintained using isoflurane or sevoflurane inhalant anesthesia and oxygen. During the procedure, balanced electrolyte solutions and/or whole blood or packed red blood cells are administered intravenously. Systemic arterial pressure is monitored by direct arterial catheterization or by indirect measurement using Doppler ultrasonography. Hypotension can be managed using dopamine (5 μg/kg/minute intravenously) and fluid boluses as necessary. Both cats receive broad-spectrum antibiotics

administered intravenously just prior to surgery. As the abdominal incision is made, the donor cat should receive mannitol (0.5 g/kg as a bolus followed by a constant infusion of 1 mg/kg/minute) to protect the kidney to be transplanted during harvest. Mannitol significantly reduces the incidence and duration of acute tubular necrosis associated with warm ischemia.

The donor nephrectomy is performed via a ventral midline celiotomy. Magnifying loupes providing 3.3x to 4.5x magnification are recommended for the vascular dissection. The vascular pedicle of the donor kidney can contain only one artery. Renal

arteries may bifurcate close to the aorta. A length of 0.5 cm or more is required for arterial anastomosis. If two or more veins are present, the largest is saved for venous anastomosis. The vascular pedicle should contain the longest vein possible, so the left kidney is explored first.

Once the kidney to be harvested is selected, the recipient team should be informed so they can prepare the recipient vessels. It is extremely important to clean the donor renal artery and vein of as much fat and adventitia as possible. The large fat pad in the renal pelvis should be removed, being careful not to damage

the ureter. Removal of the fat and adventitia from the vessels prior to nephrectomy reduces warm ischemia time. The diameter of the renal vein is measured and a sterile paper template is made to guide the size of the venotomy in the recipient's caudal vena cava. The ureter is isolated to the the level of the bladder. Donor nephrectomy is performed when the recipient team is prepared to receive the kidney. Anastomosis of the renal vessels and the ureter in the small dog and cat requires 3x to 10x magnification. The higher magnification is necessary to suture the ureter to the bladder. The authors use an operating microscope.

The recipient's post renal aorta and vena cava are isolated via a ventral midline celiotomy. The kidney is implanted between the left renal artery and the caudal mesenteric artery. First, the aorta is occluded using vascular occlusion clamps. Using an arterotomy clamp, a 1.5 to 2 mm defect is created in the aortic wall. The lumen of the aorta is flushed with heparinized saline solution. The caudal vena cava is then occluded adjacent to the arterotomy site in the aorta. Using the template created by measuring the donor renal vein, an oval defect is created in the caudal vena cava. The vena cava is flushed with heparinized saline solution.

Once the recipient vessels have been prepared for implantation of the graft, the donor kidney is harvested. The kidney is flushed with iced heparinized saline. The renal artery is gently dilated and adventitia is excised from the distal end. The artery is anastomosed to the aorta, end-to-side, using 8-0 nylon in a simple continuous pattern. The renal vein is then anastomosed to the vena cava using 7-0 silk or 8-0 nylon, depending on the size of the vein, in a simple continuous pattern. Owing to a lack of visibility of the wall adjacent to the aorta, the first side of the vein closest to the aorta is sutured inside the lumen of the vessels (back-wall technique). Once the first side is sutured, the side away from the

artery is sutured in a conventional manner.

As soon as both the renal artery and vein are sutured, the venous occlusion clamp is removed, followed by the arterial occlusion clamp. Hemorrhage is controlled by pressure, or by the addition of simple interrupted sutures if needed.

The ureter is sutured to the bladder in the following manner.[1,10,11] A 1-centimeter incision is made in the seromuscular layer of the bladder on the ventral surface. The mucosa will bulge through the incision. A 3- to 4-mm incision is made in the mucosa at the caudal aspect of the seromuscular

incision. The periureteral fat is excised from the distal 5 mm of the ureter, and the end of the ureter is spatulated. Using 8-0 vicryl in a simple interrupted pattern, the mucosa of the ureter is sutured to the mucosa of the bladder. The proximal and distal sutures are placed first. A 5-0 polypropylene stent is used to check patency of the stoma. Once the mucosal layers are opposed, the seromuscular layer is closed over the ureter using 4-0 absorbable suture in a simple interrupted pattern.

The kidney capsule is fixed to the abdominal wall by creating a peritoneal/transversus abdominus muscle flap based on a ventral pedicle. The flap is sutured to the renal capsule

using simple interrupted sutures of 5-0 polypropylene. Fixing the kidney to the abdominal wall prevents torsion of the kidney on its pedicle with resulting ischemia and loss of the graft. To provide nutritional support during the postoperative period, a gastrostomy or esophagostomy tube is placed prior to recovery from anesthesia.

In dogs, the transplanted kidney can be placed in the iliac fossa of the recipient. The renal vein is anastomosed end-to-side to the external iliac vein, using 4-0 or 5-0 silk in a continuous pattern. The renal artery is anastomosed end-to-end with the external iliac artery, using 4-0 or 5-0 polypropylene suture in a simple

interrupted pattern. As in the cat, a peritoneal/muscle flap is used to secure the kidney to the abdominal wall. The iliac vessels are no longer used as recipient vessels for feline transplant patients. While not a problem in dogs, loss of the iliac blood supply in cats can result in ipsilateral hind limb weakness, paralysis, and ischemia.[8]

Unless evidence exists of bacterial nephritis or severely enlarged polycystic kidneys, the authors do not remove the recipient's native kidneys at the time of transplantation. These kidneys are available to provide some support if the transplanted organ should fail, and can be removed at a

later date if indicated.

Postoperative Care of the Renal Recipient

During and following surgery, it is imperative to keep the transplant patient warm and the hematocrit and systolic blood pressure within normal limits. Avoid unnecessary stress and handling. Postoperative pain is controlled by the administration of oxymorphone (0.05 mg/kg subcutaneously) as needed. The recipient receives balanced electrolyte solutions supplemented to correct electrolyte or acid/base abnormalities.[1,11] Urine specific gravity is followed twice daily via free

catch of the urine. Urine specific gravity is usually greater than 1.020 by the third postoperative day. Packed blood cell volume, total plasma protein level, serum electrolyte levels, and the plasma creatinine concentration are assessed 3 to 4 times daily until renal function is stable. During the early postoperative period needless venapuncture, blood sampling, and patient handling should be avoided. If the surgery is a technical success, the urine specific gravity will be increased, and the plasma creatinine will be decreased by the third postoperative day. The recipient will look clinically improved. Normal appetite usually returns by postoperative day 3 to 5. If the graft has failed or has delayed

function, the recipient will be depressed and anorectic. The urine will remain isosthenuric. Approximately three days following surgery, an ultrasonographic examination of the transplanted kidney and ureter can be performed if renal function is not returning to normal. If perfusion of the graft is good without evidence of hydronephrosis or hydroureter secondary to obstruction, the graft may have suffered acute tubular necrosis consistent with delayed graft function. As long as the kidney remains perfused, function can start as late as 3 weeks following surgery.

Hypertension is a common complication that can occur within the

first 72 hours after surgery.[13,14] Cats can develop hypertension (systolic blood pressure $\geq$ 170 mm/Hg) and are at higher risk for neurologic disorders such as ataxia, blindness, seizures, and stupor. Occasionally, uncontrollable seizures and death can result. Controlling hypertension has significantly reduced the frequency of these complications. Indirect, systolic blood pressure is measured by ultrasonic Doppler every hour for at least 24 hours after surgery, and then at decreasing intervals over the next 48 hours. When the systolic blood pressure is equal to or higher than 170 mm/Hg, hydralazine (2.5 mg total dose/subcutaneously) is given. If the systolic blood pressure has not

decreased to normal within 15 to 20 minutes, a second dose is given. In the rare case that the hypertension is refractory to hydralazine therapy, acetylpromazine (0.01 mg/kg, intravenously, subcutaneously) is administered. Rarely, transplant patients can develop a lethal sensitivity to cyclosporine; this is termed hemolytic uremic syndrome.[15] Cats become uremic with a coexisting hemolytic anemia and thrombocytopenia. The transplanted kidney is lost to ischemia produced by diffuse vascular thrombosis. No treatment currently exists for this syndrome in cats.

If the transplant recipient is not eating

well by 24 hours following surgery, feedings are begun using the gastrostomy or esophagostomy tube. Normal caloric intake is attained over 24 to 48 hours. Cyclosporine is administered at levels necessary to achieve trough whole blood concentrations of 500 ng/ml. Prednisolone is administered at 1 mg/kg/12 hours, orally, and is tapered to 0.5 to 1 mg/kg/24 hours by 4 weeks postoperatively. Erythropoietin can be administered if the hematocrit remains below 25%.

Transplant recipients are discharged from the hospital when they have achieved an adequate nutritional intake and the cyclosporine blood level

has stabilized. The feeding tube is left in place until the cat has completely acclimated at home.

Long-Term Management of the Renal Recipient

Management of the transplant patient must be coordinated with the client, the local veterinarian(s), and the transplant center. Examinations are initially performed weekly by the local veterinarian. Measurements of packed blood cell volume, total serum protein concentration, plasma creatinine concentration, and whole blood cyclosporine concentration, and a urinalysis are performed. Periods between examinations are gradually

extended to 3 or 4 weeks. The authors recommend that a complete blood count should be performed monthly, and a serum chemistry panel, urinalysis with urine culture, and cardiac consult be performed 3 times a year.

During the first year after transplantation, the most common complications that occur are acute rejection, infections, and the development of cancers.[6,16-20] Acute rejection can often be attributed to poor owner compliance in giving medications and having cyclosporine blood concentration assays performed on a regular basis. Acute rejection is an emergency situation that must be

treated quickly and aggressively with injectable cyclosporine (Sandimmune [Norvartis AG, Basel, Switzerland], 6.6 mg/kg once daily over 4 to 6 hours), corticosteroids, and the intravenous administration of balance electrolyte solutions. Cats do not show illness associated with acute rejection, so rising creatinine concentrations are considered grounds for treatment unless obstructive uropathy can be proven by ultrasonographic evaluation of the kidney and ureter.[21,22] In cats, slow, chronic elevations of serum creatinine, in the presence of adequate blood levels of cyclosporine, are treated with the addition of azathioprine (0.3 mg/kg/72 hours) to the immunosuppressive protocol. The

white blood cell count and hepatic enzyme concentrations must be monitored and the dose adjusted as necessary to prevent severe leukopenia (< 3000 cells/μl) or hepatitis.

Transplant patients are susceptible to infections. Viral, bacterial, parasitic, coccidian, protozoal, and fungal infections can all develop. When treating bacterial infections, aminoglycoside and trimethoprim/sulfa antibiotics must be avoided as they are nephrotoxic when combined with cyclosporine. When adding any medication to the immunosuppressive protocol, check the drug insert that is provided with cyclosporine for possible interactions.

Many agents can raise or lower cyclosporine whole blood concentrations by interfering or promoting cytochrome P-450 enzyme activity.

Immunosuppressed patients are also at an increased risk for the development of cancer. The most common types are lymphoma and squamous cell carcinoma. Transplant recipients also develop diabetes mellitus with an increased frequency. Diabetes can be a temporary or a chronic problem. Insulin therapy can provide long-term control.

Clinical Renal

Transplantation in the Dog

There are only few differences in the technical aspects of renal transplantation between the dog and the cat. Most dogs, owing to their size, do not require magnification for anastomosis of the vessels, although 2x to 3x magnifying loops are helpful. In addition to implanting the graft on the terminal aorta and vena cava, the external iliac artery and vein can be used as recipient vessels for the transplanted kidney. The iliac vessels should not be used for the recipient vessels in cats because loss of the iliac blood supply in cats can result in rear limb weakness, paralysis, or ischemia.[8]

For ease of anastomosis, a left donor

kidney is placed in the right iliac fossa of the recipient, and a right donor kidney should be placed in the left iliac fossa. If necessary, a donor kidney can be placed in the ipsilateral iliac fossa of the recipient; however, the arterial anastomosis will be more difficult to perform. The chosen iliac fossa is prepared for end-to-end anastomosis of the renal artery to the iliac artery and end-to-side anastomosis of the renal vein to the iliac vein. The iliac artery is isolated, and a bulldog or other vascular clamp is used to occlude it near the aortic bifurcation. The iliac artery is then ligated distally, near the femoral ring, and is severed. The free length of the artery is flushed clean of blood using heparinized saline

solution. The end of the artery is gently dilated and the adventitia is excised from the proximal 3 to 5 mm. The iliac vein lies deep to the artery in fat and adventitia. It is isolated over the same area as the artery, gaining as much free length as possible. The iliac vein has multiple tributary veins in this region that must be ligated. Careful inspection dorsal and caudal to the vein will reveal these branches. Once the tributary veins have been ligated, two vascular clamps are placed on the iliac vein as far apart as possible. The first is placed distally, and the second is placed proximately. A section of the wall is excised from the iliac vein that is slightly larger than the diameter of the donor renal vein. It is important to

create a defect in the vein wall and not just a slit. The vein is flushed clean of blood using heparinized saline solution.

Two 4-0 to 6-0 sutures of silk are placed at each end of the defect in the vein wall. Each suture is subsequently placed at the cranial or caudal aspect of the renal vein and tied. The renal vein is then anastomosed to the iliac vein using a simple continuous pattern on both the medial and lateral sides of the vessels.

Following completion of the venous anastomosis, the renal artery and iliac artery are isolated near the midline of the recipient. The arteries are

anastomosed using 5-0 to 8-0 nylon or polypropylene in a simple interrupted pattern. Once arterial anastomosis is complete, the vascular clamps are removed from the vein and then the artery. Some hemorrhage is expected, can be controlled with light pressure, and should stop within a few minutes. Large defects in the arterial anastomosis have to be controlled by placement of additional sutures. Ureteroneocystostomy is performed using the same method as described for the cat. The kidney capsule is attached to the adjacent abdominal wall using simple interrupted sutures of 3-0 polypropylene or a peritoneal/transversus abdominis muscle flap.

Following renal transplantation, dogs are highly likely to develop intestinal intussusceptions. Two treatments have resulted in the prevention of this condition that develops postoperatively. First, morphine, 0.5 mg/ml, is administered subcutaneously as a premedication and postsurgically at 0.5 mg/kg subcutaneously every 3 to 4 hours to control pain.[23] Second, enteroplication is performed after the renal transplant procedure is completed. The seromuscular layers of the bowel are joined using simple interrupted sutures of 3-0 polydioxanone.[24]

Owing to the difficulty of immunosuppressing the dog's rejection

response, few renal transplants have been performed clinically for canine patients with renal failure. The primary difference in transplantation between the dog and cat is selection of the donor. Using cyclosporine and prednisolone to achieve immunosuppression, the authors will only use mixed-lymphocyte-response matched, related donors. The new formulation of cyclosporine, with conventional or newly developed agents, has proven to successfully control the canine rejection response.[25,26] With the use of MHC-nonmatched donors, the authors employ one of two immunosuppressive protocols: 1) cyclosporine and leflunomide (4-6 mg/kg/24 hours) or

2) cyclosporine (Neoral), azathioprine (1-5 mg/kg every 48 hours), and prednisolone (1 mg/kg/24 hours). Cyclosporine is administered at a dose that will achieve a trough whole-blood level of 500 ng/nl. Leflunomide is administered at a dose necessary to maintain a trough plasma blood concentration of 20 µg/ ml. Azathioprine dosage is adjusted to avoid leukopenia and hepatitis. The dose of prednisolone is reduced over 1 to 3 months, depending on the serum creatinine concentration and degree of side effects suggestive of Cushing's syndrome. In a long on-going study, Mathews et al[27] employed antithymocyte serum, cyclosporine, azathioprine, and prednisolone for

immunosuppression of unrelated dog donor-recipient pairs. A median survival time of eight months was achieved with two dogs surviving more than two years.[27] In a completed clinical study, the authors found that the combination of cyclosporine, azathioprine, and prednisolone prevented renal allograft rejection in 15 dogs. Of these, three dogs are alive 24 to 50 months following surgery, five of the dogs died in the perioperative period owing to the development of systemic thromboembolism, and four of the dogs died owing to the development of lethal bacterial infections. Renal allograft rejection can be controlled in the dog; however, a balance must be

maintained between the control of rejection and the development of lethal infections. Owing to the hypercoagulable state present in the canine renal failure patient, perioperative anticoagulation therapy must be employed (Gregory CR, et al. Unpublished paper in review).

Canine renal transplantation is still in the development phase. The work of Mathews et al[27] and our own studies have been invaluable in highlighting the techniques and the difficulties, both clinically and financially. Over the next several years, case selection, immunosuppressive management, and anticoagulation strategies will be further refined, and outcomes will

improve.

Client Education

Before performing renal transplantation for the dog or cat, clients must be fully informed of the risks, responsibilities, and costs associated with the procedure. Clients must be able to administer medications orally 2 times a day for the life of their pet. Fractious cats and dogs are not good candidates because of the extensive nursing required in the perioperative period and the need for regular examinations by the local veterinarian. Clients must have access to a 24-hour emergency facility. Finally, clients must understand that

no matter how carefully selected and managed, their cat or dog may die owing to the stress of the procedure or failure of the graft to function.

Feline and canine renal transplantation is becoming more widely available in the United States and is also performed in Australia, Japan, and Europe. Survival rates have improved with careful patient selection, better perioperative care and monitoring, and the introduction of the microemulsified form of cyclosporine (Neoral). Renal transplantation can offer long-term survival with a normal quality of life for cats and dogs with renal failure.

Genital System

Chapter 72

Prostate

Richard Wheeler

Prostate diseases, with few exceptions other than neoplasia, are diseases of intact male dogs. Most of these diseases evolve from endocrine-induced changes to the structure and integrity of the prostate. Resolution can often be achieved by medical management, hormone manipulation, or surgical intervention–including castration.

Anatomy

The canine prostate is a bilobed encapsulated organ composed of stromal cells, smooth muscle cells, and epithelial cells. It is closely associated with the neck of the urinary bladder, and encircles a portion of the urethra (prostatic urethra). Vasculature is supplied by the prostatic artery–a branch of the internal pudendal artery–and the prostatic vein.[1] Parasympathetic innervation, which stimulates glandular secretions, is supplied by the pelvic nerve.[1] Sympathetic innervation, which stimulates smooth muscle contraction during ejaculation, derives from the hypogastric nerve.[1] The blood vessels

and nerves approach the prostate from the craniodorsal aspect.

The prostate is located at the cranioventral edge of the pelvic inlet. Post-pubertal maturation and advanced disease result in enlargement of the prostate and advancement cranioventrally into the abdomen where it is accessible to surgery. The prostate is a pharmacologically privileged organ protected by a blood-prostate barrier imposed by gap junctions between epithelial cells.

Physiology

The prostate is the only accessory sex gland in the dog. It produces ejaculatory fluid to increase seminal

volume. The prostatic fluid may have some antibiotic effects and may play a role in activating spermatozoa for fertilization. Ironically, prolonged exposure to prostatic fluid is detrimental to sperm viability.

The canine ejaculate can be collected in three distinct fractions. The first fraction is of prostatic origin and is often an insignificant volume. The second fraction is concentrated sperm, derived from the epididymus. The third fraction is again prostatic and constitutes the most voluminous portion of the ejaculate. The total volume of the third fraction varies depending on the individual, breed, and duration of coitus (or collection);

it can range from 1 milliliter to more than 20 milliliters. Normal prostatic fluid is clear, serous, and has a neutral to slightly acidic pH.

Clinical Presentation

The presentation of prostatic disease is primarily attributable to prostatic enlargement. The magnitude of space-occupying effects determines the type and severity of clinical signs. Dramatic enlargement of the prostate by hypertrophy or mass lesions may cause dorsal displacement of the colon, resulting in tenesmus or “ribbon-like” feces. Cranioventral displacement of the bladder may cause dysuria, increased urgency, and compromise of

urinary tract defense mechanisms, predisposing to ascending cystitis and its associated clinical signs.

Other clinical signs are attributable to hyperplasia of the parenchyma and stroma. Increased vascularity and decreased stromal integrity predispose to microvascular hemorrhage, evidenced as hematospermia, hematuria, or hemorrhagic urethral discharge.[1] Occlusion of efferent ducts obstructs glandular secretions, forming cystic glands. These dilated acini may rupture, contributing to urethral discharge,[1] or they may coalesce into large cavitations that contribute to the mass effect. Hyperplasia compromises natural defense mechanisms and

immunity, predisposing to bacterial infection.[1]

Finally, duration of onset of disease plays a major role in clinical presentation. Acute prostatic inflammation is often associated with severe rectal or abdominal pain as the prostatic capsule is unable to accommodate rapid swelling. Chronic disease is often asymptomatic as the body accommodates to the insidious course of disease; however, once a critical mass is attained (i.e., obstructive enlargement), space-occupying effects become evident.

Diagnosis

Thorough history and physical

examination of the dog will provide important information for the interpretation of further diagnostic procedures. The presence of pain or pyrexia implicates an acute or septic disease process. Castrated dogs are at decreased risk of infectious disease and this may direct differential diagnosis toward neoplasia.

Rectal palpation is a highly subjective and nonspecific determinant of prostatic enlargement as only the caudal pole can be palpated. As the prostate enlarges and moves cranially and ventrally into the abdomen, abdominal palpation in conjunction with rectal palpation may be necessary in order to feel the prostate.[1]

Symmetry of the bilobed prostate should be evaluated.

Cytologic evaluation of prostatic fluid can identify erythrocytes, neutrophils, bacteria, and normal or neoplastic epithelial cells (Figure 72-1). Prostatic fluid is most easily obtained by manual ejaculation, isolating the third fraction. If the dog is not amenable to collection, prostatic massage and urethral flushing or the urethral brush method can be performed.[1] Blood or smegma from the prepuce or penis may contaminate the sample, complicating interpretation.

Culture of prostatic fluid must be interpreted carefully. Prostatic fluid is

collected as described above for cytologic evaluation. It must be noted that these techniques do not provide an aseptic means of fluid collection;[1] normal bacterial flora of the urethra or prepuce may contaminate the sample.

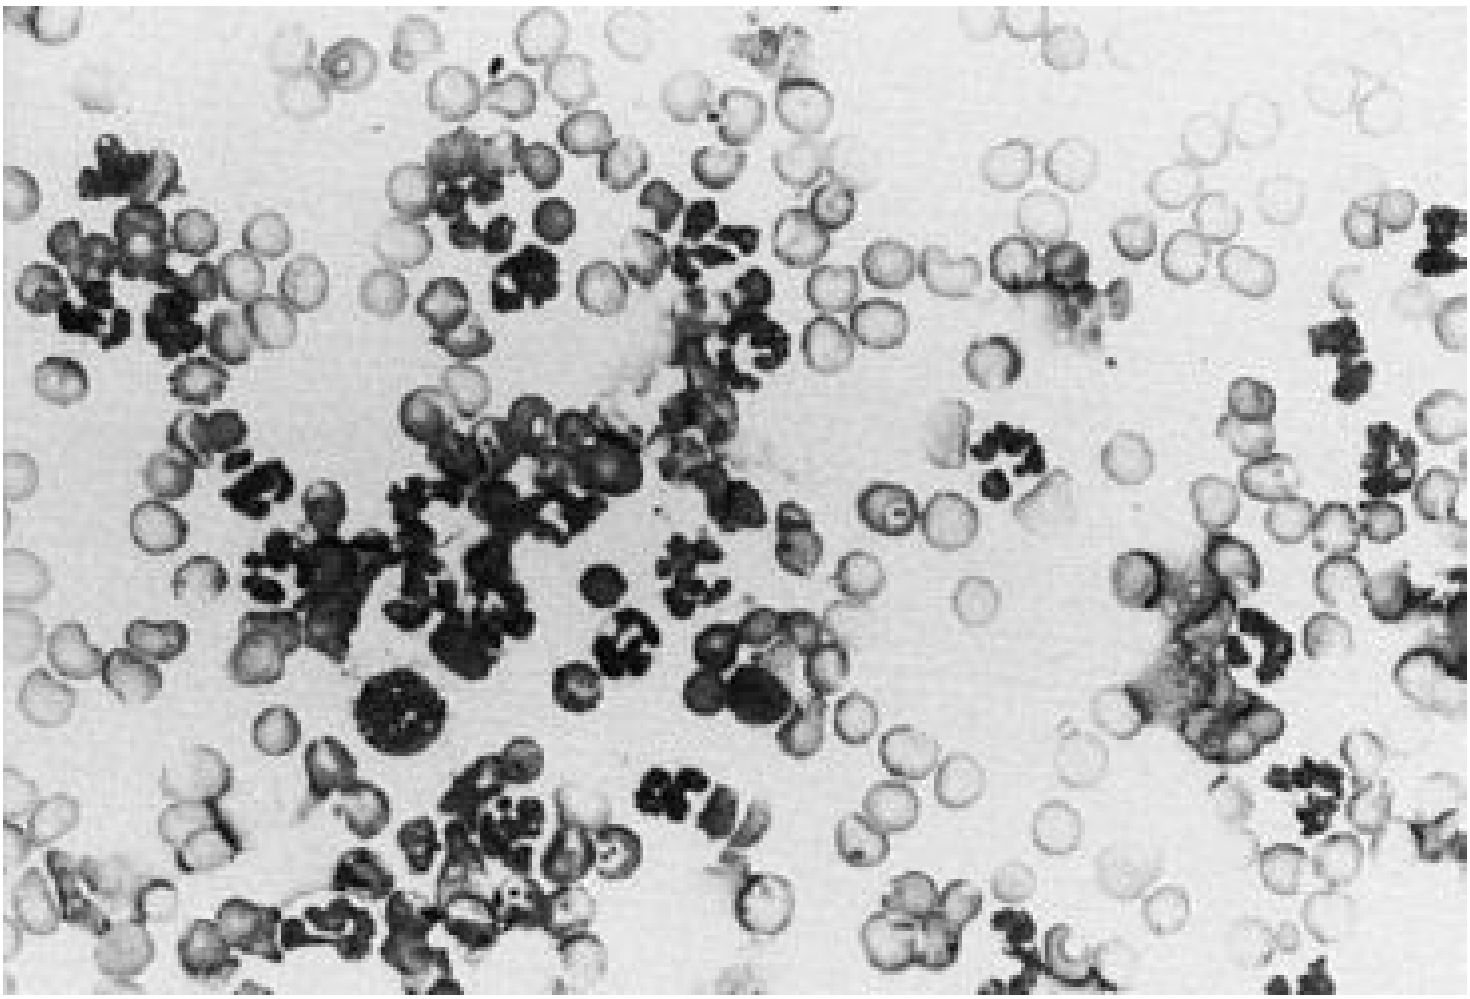

Figure 72-1. Prostatic fluid

Survey radiographs are often nondiagnostic for mild to moderate prostatic disease.[1] With advanced prostatic disease and significant enlargement, radiographs may demonstrate a soft-tissue density in the caudal abdomen, space-occupying lesion of the urinary bladder, or dorsal displacement of the colon.[1] However, they do not localize the lesion to the prostate or differentiate prostatic pathologies.

Retrograde cystourethrograms may more readily demarcate the borders of the prostate and its association to the bladder. Infiltration of contrast media into the prostate via the prostatic urethra may implicate specific

prostatic diseases.[1]

Ultrasonography is the most effective, noninvasive technique to differentiate prostatic diseases. Evaluation of prostatic size, symmetry, and echogenicity implicates specific disease processes; however, definitive diagnosis cannot be made by ultrasonography alone.

Ultrasound-guided fine-needle aspiration (US-FNA) of prostatic lesions may provide the most definitive diagnosis of prostatic disease. One study demonstrated 80% agreement in diagnosis comparing US-FNA to histopathologic findings at necropsy.[2] Potential complications include

seeding bacteria along the needle tract and leakage of suppurative material into the abdomen.[2]

Prostatic biopsy can be performed via laparotomy, transabdominally by ultrasound guidance, or by perirectal biopsy.[1] Again concerns arise for seeding bacteria along the needle tract and abdominal contamination.

Serology and hematology have limited application in diagnosing prostatic disease other than to rule out systemic infection. Mild elevations in alkaline phosphatase (ALP) are commonly seen, but are nonspecific for prostate disease.[3]

Prostate-specific markers have been used extensively in human medicine for early diagnosis of prostate cancer. To date, no such substance has been shown to reliably diagnose or differentiate prostatic diseases in the dog. The most promising marker, canine prostate-specific arginine esterase (CPSE), is produced by epithelial cells in response to androgens and is secreted in prostatic fluid.[3] CPSE serum levels are increased in dogs with benign prostatic hypertrophy compared with those in normal dogs; however this does not differentiate prostatic neoplasia.[3]

Pathophysiology

Benign Prostatic Hypertrophy (Hyperplasia)

Benign prostatic hyperplasia/hypertrophy (BPH) is a normal, senile, usually asymptomatic condition of aging, intact dogs. Fifty percent of intact dogs over the age of 5 years, and 95% of intact dogs older than 9 years have gross or histologic signs of BPH.[1]

Enlargement of the prostate is hormonally driven, as evidenced by prostatic atrophy after castration. The hypothalamic-pituitary-testicular axis is predominantly responsible for the production of male sex hormones. The hypothalamus produces gonadotropin

releasing hormone (GnRH), which induces pituitary secretion of the gonadotropins–luteinizing hormone (LH) and follicle stimulating hormone (FSH). LH stimulates testicular Leydig cell production of testosterone. Dihydrotestosterone (DHT) is the primary mediator of prostate growth.[1,4] It is synthesized in the prostate by the metabolism of testosterone under the influence of the enzyme 5a-reductase.[1,4] Both testosterone and DHT induce growth factors in stromal and epithelial (glandular) cells, which increase cell size (hypertrophy) and cell numbers (hyperplasia), and decrease normal rates of apoptosis (programmed cell death).[1,4,5] However, DHT binds to the

cells with 10 times greater affinity and dissociates much slower, exerting exponentially greater effects on prostatic growth than does testosterone.[1,4] Estrogen (E2) plays a significant, yet uncertain role in the development of BPH.[1,4] It may increase receptors or receptor affinity to DHT.[4]

BPH is generally eccentric (away from the center), so the prostatic urethra is not occluded, and stranguria is rarely seen as a presenting complaint in dogs.[1] BPH induces symmetrical enlargement that, if extreme enough, will produce symptoms of space occupying effects. Hematospermia is often an incidental finding during routine semen evaluation.

On ultrasound evaluation, BPH is diagnosed when the prostate exceeds normal parameters. In some cases of BPH, prostate size can be within normal parameters; however, changes in the appearance of the stroma and parenchyma indicate pathologic changes consistent with BPH.[1] These changes include diffuse echogenicity ("moth eaten appearance") or the presence of parenchymal cysts.[1]

Castration is the definitive treatment for BPH.[1] Elimination of testosterone induces complete regression of prostatic growth to near pre-pubertal size.[1,4] In valuable breeding animals, or when castration is not an option, life-long hormonal regulation aimed at

decreasing concentrations of testosterone or DHT can dramatically reduce BPH. Finasteride ("Proscar", Merck; 5 mg PO daily) blocks the enzyme 5a-reductase, preventing conversion of testosterone to DHT.[1,5] It has demonstrated good efficacy in reducing prostatic size.[1,5] It has a high margin of safety, maintains fertility, and has no reported side effects.[1,5] Megestrol acetate (MGA, "Ovaban," Schering 0.5 mg/kg PO daily), a synthetic progestin, inhibits gonadotropin release (LH) by negative feedback inhibition to the pituitary, resulting in decreased levels of testosterone and E2 production.[1] Lower levels of testosterone correlate to lower levels of DHT and reduction

of BPH. No detrimental effects on fertility or side effects have been reported. A gonadotropin releasing hormone (GnRH) vaccine ("Canine Gonadotropin Releasing Factor (GnRF) Immunotherapeutic," Pfizer Animal Health; 1 ml SQ, repeat in 4 to 6 weeks, booster every 6 months) has recently received conditional licensing for the treatment of BPH in dogs. Preliminary studies show an increase in anti-GnRH antibodies, a decrease in serum testosterone concentration, and a decrease in prostate and testicular size.[6] Effects on fertility have not been evaluated, but the decrease in testicular size is suggestive of decreased sperm production.

Prostatitis

BPH is the inciting cause of prostatitis.[1,4] BPH disrupts the integrity of the prostate and affects natural immunity and resistance to infection, lymphatic drainage, and the normal vascularity of the gland.[1,4] Two distinct forms of prostatitis are recognized: aseptic prostatitis and septic prostatitis.[4] Aseptic prostatitis is a noninfectious inflammatory reaction characterized by prostatic infiltration with neutrophils. Septic prostatitis develops as bacteria from the normal flora of the urogenital tract opportunistically invade the prostate.[1,4] *Escherichia coli* is the most common isolate; *Pseudomonas, Staphylococcus, Streptococcus,* and

Proteus are other common pathogens.[1,4] Septic prostatitis can further be categorized as acute or chronic. The fundamental difference is duration of onset and presenting clinical signs. Chronic prostatitis is often subclinical or symptomatic of low-grade infection.[1] Acute prostatitis presents as a sudden onset of severe abdominal pain and pyrexia.[1]

Diagnosis of prostatitis is made by demonstration of inflammatory cells in prostatic fluid. In the case of septic prostatitis, presence of intracellular bacteria or a positive bacterial culture should be confirmed. Culture and histology of a prostatic biopsy or fine-needle aspirate may provide definitive

diagnosis.

Successful treatment of prostatitis requires resolution of any infectious component and removal of the inciting cause, BPH. First, treatment of the bacterial infection requires use of antibiotics that are able to penetrate the prostatic barrier. Appropriate antibiotics must be lipophilic to penetrate the lipid bilayer, slightly basic as the normal and infected pH of the prostate is usually neutral to slightly acidic, and should have low protein-binding affinity to dissociate from the circulation.[1] Current antibiotic options (enrofloxacin, trimethoprim-sulfa, erythromycin, and chloramphenicol)[1] should be selected

based on safety and antibiotic sensitivity. Secondly, effective treatment of chronic prostatitis requires treatment of BPH (see above).

Prostatic Abscess

Septic prostatitis may progress to purulent vacuolization of the prostate or infection of parenchymal cysts.[1,4,7] The vacuoles or cysts may coalesce and form large intracapsular abscesses, causing asymmetric enlargement of the prostate.[1] Clinical signs vary from chronic, nondescript symptoms to acute onset with abdominal pain and pyrexia. If an abscess ruptures, presentation may be an acute abdomen and septic shock.[1] A

presumptive diagnosis is made by sonogram. History, clinical signs, and hematology help differentiate prostatic abscesses from intraprostatic cysts. Conclusive diagnosis is made by demonstration of suppurative fluid obtained by biopsy, fine-needle aspiration, or exploratory surgery.[1]

Treatment requires abscess drainage and long-term antimicrobial therapy and resolution of BPH. Surgical drainage and omentalization is the preferred surgical technique.[1] Other surgical options include complete or partial prostatectomy, marsupialization, or placement of Penrose drains. Successful, nonsurgical drainage by ultrasound-guided

aspiration has been reported.[8] Regardless of the treatment method, concurrent castration is highly recommended.

Cystic Lesions of the Prostate

Prostatic abcesses must be differentiated from prostatic cysts. Parenchymal (retention) cysts are diffuse hypoechoic structures within the parenchyma of the prostate that develop subsequent to BPH and are the most common cystic condition seen in the canine prostate.[1,7] "Squamous metaplasia," epithelial hyperplasia in response to estrogen exposure, is responsible for formation of some parenchymal cysts.[1,7] Epithelial

hyperplasia and stromal fibrosis block the efferent ductules of the glands, resulting in the accumulation of serosanguinous fluid and subsequent dilatation and destruction of the acini.[1,4,7,8] Cysts are lined by a single layer of epithelial cells.[1,4,7] Chronic prostatitis may lead to fibrosis and dissolution of the cystic lining, forming giant cavities (cavitary prostatitis) (Figure 72-2).[7]

Extremely large parenchymal cavities may extend beyond the margins of the prostate. Cavities or cysts may be asymptomatic or they may contribute to symptoms of hematuria or hematospermia if they rupture. They may cause space-occupying symptoms

or predispose to prostatic abcessation from ascending or hematogenous spread of bacteria.

Treatment of parenchymal cysts requires treatment of BPH pharmacologically or by castration. In squamous metaplasia, elimination of the estrogen source (e.g., exogenous estrogen therapy or endogenous estrogen production by Sertoli cell or adrenal tumors) is necessary.[1,7] Small cysts may regress, but large cysts and cavities may require surgical drainage if they are clinically significant. Drainage by US-FNA has been described.[8] Surgical excision and omentalization is the procedure of choice when surgery is warranted.[1]

Paraprostatic cysts (müllerian duct cysts) lie outside the prostatic capsule, distinguishing them from parenchymal cysts. They are not hormonally controlled, are not associated with BPH, and do not regress post-castration. They develop late in life from the remnants of the müllerian (paramesonephric) duct.[1,7] During embryogenesis, male sexual differentiation induces regression of the müllerian duct by secretion of müllerian inhibiting substance (MIS).[1] In females, the müllerian duct gives rise to the oviducts, uterus, and cranial vagina.[1] Incomplete regression of the müllerian duct can result in fluid-filled cysts located adjacent to the prostate, with variable degrees of prostatic

involvement. The cysts generally do not communicate with the prostate or the urethra. Paraprostatic cysts require drainage or surgical resection only if they are symptomatic.

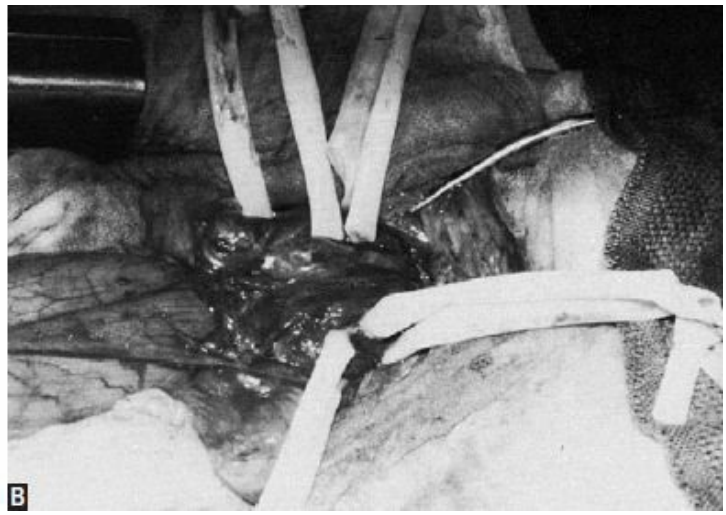

Figure 72-2A & B. Prostatic cyst in ultrasound (A) and in surgery (B).

Prostatic Neoplasia

The highest incidence of prostatic neoplasia occurs in castrated dogs.[9,10] There does not appear to be any

association with age at time of castration.[10] Adenocarcinoma is the most commonly diagnosed neoplasia.[9,10] Transitional cell carcinoma is also common, presumably from the close association of the prostate to the bladder.[9]

Presenting complaints may include stranguria, which is more common with prostatic neoplasia than with other prostatic conditions because of the invasive nature of the tumor into the lumen of the urethra.[1] Rectal palpation or ultrasonography commonly demonstrates asymmetry of the prostate. Ultrasonography may also identify echogenic mass lesions within the parenchyma.Definitive

diagnosis is made by biopsy or fine-needle aspiration.

Prostatic cancers are highly malignant and metastasis has usually occurred by the time of diagnosis.[1,9,10] Prognosis is grave to guarded at diagnosis and treatment is generally palliative, focusing on maintaining a patent urethra.[11] Therapeutic options that have been described include complete prostatectomy, chemotherapeutic and radiation therapy,[12] and transurethral resection (TUR).[11] All treatment modalities have been associated with significant side effects including incontinence and death; and none have prolonged or maintained the patients' quality of life.

Chapter 73

Disorders of the Testes

Cheri A. Johnson

In the absence of genetic and hormonal influences to the contrary, normal mammalian sexual differentiation will be female. In the embryo, cells from the genital ridge become bipotential, or indifferent, gonads. The single most important factor that determines the development of a testis from the indifferent gonad is located on the short arm of the Y chromosome. This has been termed the

sex-determining region Y, the Sry gene. Other genes on the autosomes and the sex chromosomes are also involved in determination of testis or ovary.[1] The hormones produced by the fetal testis in turn are responsible for the differentiation into the male phenotype. Fetal Sertoli cells produce müllerian-inhibiting substance (MIS), which, with its receptor, causes regression of the müllerian ducts that would otherwise have developed into the oviduct, uterus, and cranial vagina. Fetal Leydig cells produce testosterone, which, with androgen receptor, causes the Wolffian ducts to stabilize and develop into the ductuli deferentes and epididymes.[2,3] Dihydrotestosterone causes the urogenital sinus, the genital

tubercle, and the genital swelling to differentiate into the urethra and prostate, penis, and scrotum, respectively.[3] Testicular differentiation is observed in the canine fetus at day 36 of gestation. Müllerian duct regression is complete by day 46.[4]

Factors produced by the fetal testis also cause testicular descent from its fetal position near the caudal pole of the kidney, through the inguinal canal, into the scrotum. The transabdominal testicular descent is mediated by insulin-like 3 ligand (Insl3) and its receptor. Insl3 is produced by pre- and postnatal Leydig cells and induces growth and differentiation of the gubernaculum from the caudal

suspensory ligament. The transabdominal migration is androgen-independent, whereas, the inguinoscrotal descent is mediated by testosterone. Testosterone causes regression of the cranial suspensory ligament.[2,5] During the inguinoscrotal phase of migration, shortening of the gubernaculum and eversion of the cremaster muscle occurs. Normal testicular descent is a prenatal event in cats, and is normally complete by 10 to 42 days of age in dogs.[6]

Cryptochidism

Failure of normal testicular descent is referred to as cryptorchidism, which means hidden or covered testes. The

condition can be bilateral or unilateral. The undescended, or “retained” testes may be in an intraabdominal location anywhere along the line from the caudal pole of the kidney to the inguinal canal. Undescended testes can also be located in the inguinal canal or the subcutaneous tissue between the external inguinal ring and the scrotum. On rare occasions, a unilateral cryptorchid testis is found in the perineal subcutis just caudal or lateral to the scrotum.

The neonatal testes in puppies and kittens are mobile and easily move out of the scrotum back toward the inguinal area. For this reason, it is sometimes difficult to confidently

diagnose cryptorchidism in young animals. By 6 to 8 weeks of age, a typical age for puppies and kittens to be acquired and presented for their first vaccinations, both testes should be palpable in the scrotum. Anecdotal reports exist in dogs of testicular descent occurring as late as 6 months of age, but this is not normal. Some authors have recommended that a diagnosis of cryptorchidism not be made until a dog is 6 months old.[6] Whether these reports represent exceptionally mobile scrotal testes rather than truly delayed descent is not known.

Cryptorchid testicles continue to produce testosterone. Therefore,

secondary sexual characteristics, and typical male libido and behavior are seen. Spermatogenesis is impaired by the higher temperature to which non-scrotal testes are exposed, and also by other factors such as hormone receptor defects in the cryptorchid testis. Bilaterally cryptorchid animals are expected to be sterile. Monorchidism, the condition of unilateral testicular aplasia, is rare in dogs and cats.

The prevalence of cryptorchidism in the general population is not known. Of 1345 cats presented to a veterinary teaching hospital for castration, 23 (1.7%) were cryptorchid.[7] Of these, 18 were unilateral cryptorchids, with no difference in left- verses right-sided

involvement. All five cases with bilaterally cryptorchid testes were intraabdominal. Of 3038 male feral cats trapped for neutering, 35 (1.2%) were cryptorchid, and 46 (1.5%) were thought to have previously been neutered based on physical examination.[8] The prevalence of cryptorchidism in canine hospital populations is reported from 1.2 to 5 %.[6] Although the mode of inheritance is not known in either species, it is well accepted that cryptorchidism is associated with familial lineage. Therefore, the prevalence is likely to vary according to breed. For example, the incidence of cryptorchidism in a study of 2929 boxer dogs was 10.7%.[9] The heritability estimates in that study

indicated that the mode of inheritance was complex, but that genetic selection would be successful in changing the prevalence of cryptorchidism in the boxer breed.

Careful palpation of the scrotum is usually sufficient to establish the diagnosis of cryptorchidism in dogs and cats older than 6 to 8 weeks, keeping in mind the mobility of the testes. If doubt exists in such young animals, they should be re-examined at a later date. Occasionally, adult animals with no scrotal testes are adopted without knowledge of previous surgeries. In such cases, a question may exist as to whether the animal is cryptorchid or has been

castrated. Behavior typical of intact males, or the typical odor of tom cat urine, might raise the index of suspicion of cryptorchidism. The physical examination findings of penile spines in a cat, or a well developed prostate gland in a dog provide indirect evidence of the presence of a testis because both structures are androgen-dependent. Both involute or regress promptly after castration.

Other diagnostic tests for cryptorchidism include determination of serum concentrations of luteinizing hormone (LH) or testosterone, and ultrasonography. Following castration, serum concentrations of LH increase

because negative feedback from testosterone no longer occurs. Therefore, the finding of high serum LH in a male with no scrotal testes is indicative of previous castration, whereas low serum LH indicates the presence of androgen. The nidar of the episodic secretion of testosterone in intact male dogs and cats may be below the detection threshold of some testosterone assays. Therefore, serum concentrations of testosterone should be measured before and after the administration of gonadotropin-releasing hormone (GnRH) or human chorionic gonadotropin (hCG). Castrated animals have low resting testosterone and no response to GnRH or hCG. A single, random

determination of testosterone in an intact male dog or cat may also be low or undetectable, depending on the assay. High resting testosterone or an increase in serum concentrations in response to GnRH or hCG confirms the presence of a testis. Ultrasound may identify the presence and location of a cryptorchid testicle. This might be helpful in planning the surgical approach. Negative ultrasound findings do not necessarily exclude the possibility of cryptorchidism because the undescended testis can be small.

Castration is the recommended treatment because in dogs the risk of testicular neoplasia in the cryptorchid testis is significantly greater than in

scrotal testes. Although testicular neoplasia is uncommon in cats, it has been reported in cryptorchid testes.[10] If, at the time of surgery, the ductus deferens, testicular vessels, and/or the epididymis are found, it is highly likely that a testis also exists on the ipsilateral side. Monorchidism (testicular aplasia) is rare. When testicular aplasia is suspected, it is important to confirm the true absence of testicular tissue with appropriate hormonal testing as described above. Medical management to cause descent of intraabdominal testes has been unsuccessful. To date, results of treatment for testes in the inguinal subcutis have been largely anecdotal in veterinary medicine and highly

variable in human and veterinary medicine. Some have argued that the reported successful cases could have descended spontaneously or that they represented highly mobile, otherwise normal testes.[11]

Testicular Neoplasia

Testicular tumors are common in dogs but rare in cats. They may be incidental findings during physical examination, castration, or necropsy, or they may cause clinical signs. The most common testicular tumors are Sertoli cell tumors, Leydig (interstitial) cell tumors, and seminomas. They occur with about equal frequency except in intraabdominal testes in

which the tumor is most often of Sertoli cell origin. Sertoli and Leydig cell tumors can produce hormones and cause paraneoplastic syndromes.[12]

The most common clinical sign of testicular neoplasia is enlargement of the testis. Paraneoplastic syndromes commonly occur with testicular tumors that produce hormones. These syndromes include atrophy of the contralateral testis, alopecia, and hyperpigmentation, gynecomastia, pendulous prepuce, squamous metaplasia of the prostate, and bone marrow suppression. The bone marrow toxicity caused by estrogen can result in anemia, thrombocytopenia, and/or leukopenia. Therefore, the clinical

signs may be referable to anemia or bleeding. Intraabdominal testicular tumors may cause mechanical interference with other abdominal organs. Infertility is also a possible result of testicular neoplasia, but most affected dogs are past their breeding years.

Several risk factors for testicular neoplasia have been identified in dogs. Age is probably the most important. Testicular tumors are unlikely in dogs younger than 6 years of age but are fairly common in dogs 10 or more years old. In dogs older than 6, the incidence of testicular cancer has been calculated to be 68.1/1000 dog-years at risk.[13] Cryptorchidism is also a

significant risk factor. In a study of 1266 dogs, testicular cancer was diagnosed 10.9 times more commonly in cryptorchid testes than in scrotal testes.[14] Environmental carcinogens[15] and certain gene expressions[16] are also risk factors.

Neoplasia should be suspected for any testicular mass in an old dog. Gynecomastia and pendulous prepuce have been referred to as feminization. Feminization is caused by estrogen alone, or by an imbalance of estrogen and androgens.[17] These findings in an intact male, especially if alopecia is also present, should make one highly suspicious of an estrogen-producing testicular tumor. In a dog with an

enlarged prostate, squamous metaplasia is suspected on the basis of finding excessive numbers of squamous cells in the ejaculate or in fine-needle aspirate samples from the gland. Estrogen is the cause of prostatic squamous metaplasia. The presence of excess estrogen can be confirmed by exfoliative cytology of the prepucial mucosa, which cornifies under the influence of estrogen just as does the vaginal epithelium. A testicular tumor is the most likely source of excess estrogen in a male dog.

The diagnosis of testicular neoplasia is often made on the basis of palpation of a testicular mass. Tumors are usually more firm than the surrounding

testicular tissue. If a testicular tumor is not palpable in a dog with feminization or prostatic squamous metaplasia, or other situations where testicular neoplasia is a likely diagnostic consideration, testicular ultrasound should be performed. Ultrasound is useful in identifying small tumors, especially when they are deeper in the parenchyma and difficult to feel. Although fine-needle aspiration or biopsy could be used to confirm the diagnosis of neoplasia and to differentiate testicular tumors from one another, this is rarely indicated because the treatment for all is surgical removal of the affected testis. Because of possible bone marrow toxicity from estrogen production by the tumor,

preoperative evaluation should include a complete blood count. Because most affected dogs are geriatric, a preoperative biochemical panel and urinalysis are also appropriate.

If the dog still has value as a stud, unilateral castration should be performed. If not, both testes could be removed. The affected testis is then submitted for histopathologic evaluation. In contrast to the situation in men, most canine testicular tumors are benign. Therefore, complete staging of the disease could reasonably be delayed until histopathologic confirmation of malignancy. Intraabdominal metastasis is more likely than pulmonary. Treatment

options for malignant and metastatic tumors should be considered in consultation with a veterinary oncologist.

Relative to cryptorchidism and neoplasia, other testicular disorders are much less commonly seen in general small animal practice. Testicular masses other than neoplasia include spermatocele, granuloma, and cysts. Although abscesses can form in the testis, with testicular infection it is more common to have diffuse involvement than a focal mass. Owners may assume that an enlarged scrotum must be due to testicular enlargement. Other causes of scrotal enlargement include epididymal or spermatic cord enlargement (including

scirrhous cord), scrotal herniation of omentum or small bowel, hydrocele, or edema of the scrotal skin. Hydrocele is the accumulation of fluid between the visceral and parietal vaginal tunics in the scrotum. The fluid may be a transudate in the case of lymphatic obstruction of the spermatic cord, or it may be blood or exudate in the case of trauma or infection. In addition to careful palpation, ultrasound of the scrotal contents is extremely helpful in differentiating among the causes of scrotal enlargement.

Spermatocele/Sperm Granuloma

Spermatocele is a cystic dilation of the

ductal system that is caused by stasis and accumulation of sperm.[18] It is much more likely to occur in the ductus deferens or epididymis than in the testis. Spermatoceles may cause a local inflammatory reaction with infiltration of monocytes and macrophages and the development of a sperm granuloma. Conversely, preexisting testicular inflammation, orchitis, may cause the obstruction and formation of a spermatocele. Spermatoceles also occur as a result of trauma, including that induced by fine-needle aspiration or biopsy. Some spermatoceles are congenital in origin. Spermatocele may be an incidental finding causing no clinical signs, or it may cause swelling and/or a palpable mass. If it is

associated with an inflammatory condition, the animal may also experience discomfort.

Cysts occasionally arise from the seminiferous tubules or rete testis. These may be incidental findings during testicular ultrasonography, or the cysts may be large enough to alter the size or shape of the testis. Cysts involving the rete testis may completely obstruct the movement of sperm into the epididymis.

Whenever a lesion is found in one testis, both should be thoroughly evaluated to determine if the disorder is unilateral or bilateral. Differentiation of focal testicular

lesions such as tumors, granulomas, or cysts can be accomplished by ultrasound and fine-needle aspiration. Samples should be submitted for cytologic evaluation and culture, if appropriate. When cysts or spermatoceles are incidental findings causing no clinical signs, further evaluation is not necessary. Biopsies could also be obtained but fine-needle aspiration is usually sufficient for focal lesions. Surgical removal of the affected testis is often a more cost-effective approach than biopsy because it is potentially therapeutic as well as obtaining samples for histopathologic and microbiologic evaluation.

Orchitis

Infectious or inflammatory conditions of the testes are relatively uncommon in dogs, and rare in cats. When they occur, the epididymis is often also affected. Infections may be of hematogenous origin or from penetrating wounds. Of the infectious agents, *Brucella canis* is of particular concern in dogs because of its insidious nature and devastating effect on reproduction.[19] *Brucella canis* infection usually does not cause signs of systemic illness in dogs. The transient fever and testicular swelling following infection often go unnoticed. Although *B. canis* can cause epididymal and testicular enlargement, it is often not

of a magnitude to be found by casual observation. Scrotal dermatitis associated with the epididymitis has been reported, but this is certainly not a consistent finding. Only after dogs have become infertile do owners become aware of a problem. Occasionally *B. canis* infects nonreproductive organs including the eyes and intervertebral discs. When it does, there are associated clinical signs. With chronic infection the testes atrophy. Other bacteria and mycotic agents such as *Blastocymes* can also cause orchitis. Lymphocytic orchitis has been reported and is suspected to have an immune-mediated basis.[20] Testicular trauma can cause hemorrhage, edema, and inflammation.

Orchitis is suspected when swelling, heat, and pain are found during examination of the testis. If other signs of illness are present, these should be pursued as well. *Brucella canis* serology should be performed in every dog with orchitis or epididymitis. The rapid slide agglutination test (RSAT) is an excellent screening test. It is highly sensitive; therefore, a negative result is good evidence against the diagnosis, assuming that the infection has been present for at least 8 to 12 weeks and the animal has not been receiving antibiotic therapy. The RSAT is not specific. False-positive results are common. If the RAST for *B. canis* result is positive, antibiotic therapy must be withheld until confirmatory tests are

complete. If the RSAT for *B. canis* is negative, additional diagnostic tests for orchitis can be pursued. These could include ultrasound, seminal fluid cytology and culture, and/or fine-needle aspiration to obtain samples for cytologic evaluation and culture. Empiric treatment with antibiotics may be initiated pending the results. If trauma is the suspected cause, cold compresses may be considered to reduce swelling because pressure will have a negative effect on spermatogenesis. In the case of unilateral orchitis in a valuable stud, the fate of the contralateral testis must be considered. Spermatogenesis can be adversely affected by the heat, pressure, and/or direct extension of

infection. To save the unaffected side, hemicastration might be consider if response to treatment is not prompt.

Torsion of the Spermatic Cord

Other causes of testicular enlargement include spermatic cord torsion and spermatic cord occlusion. Torsion of the spermatic cord has often been referred to as testicular torsion, but torsion of the spermatic cord is more accurate. Torsion of the spermatic cord occurs more often in intraabdominal testes than in scrotal testes.[21] Often the intraabdominal testis also has a tumor. The most prominent clinical sign of spermatic cord torsion is the acute

onset of severe pain. The clinical signs may be typical of an acute abdomen when an intraabdominal testis is involved. The pain with intrascrotal spermatic cord torsion may be manifest by reluctance to walk.[22] Torsion of the spermatic cord causes swelling and firmness of the cord, the epididymis, and the testis. The spiral nature and dilation of the testicular vessels within the torsed spermatic cord may be recognized by ultrasound.

Treatment is castration of the affected intraabdominal testis. Castration is also usually recommended for intrascrotal spermatic cord torsion because irreparable damage to spermatogenesis may occur within

hours. A scrotal hernia can also cause occlusion of the spermatic cord,[23] in which case, the clinical signs are identical to torsion of the cord. More commonly, however, scrotal hernias do not occlude the spermatic cord or affect the testes. The usual signs of scrotal hernia are unilateral scrotal enlargement with minimal pain.

Testicular Hypoplasia

A variety of congenital disorders results in testicular hypoplasia or hypogonadism. Often abnormal genitalia are an associated finding. Hypoplasia and hypogonadism are recognized in young animals as they reach puberty. As discussed earlier,

genetic and hormonal factors are necessary for normal determination of the indifferent gonad into a testis and subsequent sexual differentiation into a phenotypic male. Therefore, abnormalities in expression of genes that determine the differentiation of the testis, in the testicular production of hormones, and/or in hormone receptors may be involved.[24-26] Determining the specific cause of testicular hypoplasia in an individual animal usually requires extensive evaluation, particularly if the external genitalia are a normal male phenotype. An exception is the calico or tortoiseshell tom cat.

Because both the orange and the black

coat color require an X chromosome to be expressed, male cats, having only one X, should not be able to show both colors. The calico or tortoiseshell coat color is therefore a marker for XXY or a chimeric state. At least 7 different chromosomal compliments have been described for male calico/tortoiseshell cats.[6] Some of these cats are fertile, phenotypically normal males with normal spermatogenesis found on testicular histopathology. Presumably these are chimeras with the normal feline 38, XY karyotype in the gonadal tissue. Some calico/tortoiseshell toms have testicular hypoplasia. Testicular histopathology may be normal in some areas; some or all seminiferous tubules without spermatogonia; or, some or all

tubules with Sertoli cells only.

In other animals with testicular hypoplasia, abnormalities anywhere along the hypothalamic-pituitary-gonadal axis, as well as disorders of sexual differentiation, must also be considered. The finding of concomitant abnormalities in the external or internal genitalia, such as ambiguous or female external genitalia, hypospadia, or persistent müllerian ducts, helps define the factors that might be involved.[27,28] Sometimes, straightforward karyotyping provides the answer.

Because animals with testicular hypoplasia are unlikely to have normal

semen quality and usually are otherwise not desirable for breeding, extensive workup may not be warranted for the benefit of the individual. However, if more than one animal in the lineage is similarly affected, workup may be worthwhile for the breed. Physical examination will confirm the abnormally small testes. If need be, the functional ability of hypoplastic testes could be evaluated by measuring testosterone before and after the administration of GnRH or hCG, and by evaluating semen. The results are unlikely to be normal, but if they were, some owners might elect not to have the animal castrated.

Testicular Atrophy

In contrast to hypoplasia, testicular degeneration and atrophy are acquired conditions. Testicular atrophy is common in geriatric dogs, especially those over 10 years of age. The American Kennel Club will not register puppies sired by dogs older than 12 years without documentation of normal semen. The testis is easily damaged and atrophy often results. The spermatogonia are usually more sensitive to damage than are Sertoli and interstitial cells. Therefore, testosterone production may continue even when spermatogenesis is lost. Heat, pressure, infection, certain toxins and drugs (including glucocorticoids),

radiation, nutritional deficiencies, and trauma (including biopsy) are a few of the many causes. By the time a male is presented with atrophic or degenerate testes, it may be difficult to determine the initiating cause. If a dog still has value as a stud, testicular function should be evaluated over longer than a 2-month period because the canine spermatogenic cycle is 62 days.[6] The prognosis for atrophic or degenerate testes to recover fertility is guarded, even if the cause can be found and corrected. If the condition is unilateral, submitting the affected side for culture and histopathologic evaluation would be reasonable.

Azoospermia

Male animals may be presented for evaluation of functional, rather than physical, abnormalities of the testes. A thorough history and physical examination should be performed. *Brucella canis* serology should be done in any dog presented for infertility. The first step in evaluating the endocrine function of the gonad is to determine serum concentrations of testosterone before and after GnRH or hCG. The first step in evaluating spermatogenesis is to perform a semen evaluation. Readers are referred to the textbook Canine and Feline Theriogenology[6] for a complete discussion of the diagnostic approach

to infertility in the stud. Our discussion will be limited to the absence of sperm, azoospermia, in the ejaculate because this is a situation that often warrants testicular biopsy. In animals that still have sperm in the ejaculate, biopsy is often recommended as the last diagnostic test because damage to the testicular parenchyma will be done in the process. Although in the absence of complications, testicular biopsy of normal testes apparently does not have an adverse effect on semen quality in dogs,[29] the same may not be true for testes wherein spermatogenesis is already marginal.

The absence of sperm in the ejaculate may reflect retrograde ejaculation,

incomplete ejaculation, obstruction to sperm outflow, or lack of spermatogenesis. Retrograde ejaculation of a few spermatozoa into the urinary bladder is normal in dogs and cats. The magnitude is greater when electroejaculation is the technique used for semen collection.[30] Although it has been considered by some to be a potential cause of azoospermia, the author has not observed retrograde ejaculation of such magnitude to explain a complete lack of sperm in the seminal fluid. To evaluate the possibility, the number of spermatozoa in the seminal fluid collected is compared with the number obtained from the urinary bladder after ejaculation.

The canine epididymis produces alkaline phosphatase. Therefore, the concentration of alkaline phosphatase in seminal fluid can be used as a marker for the presence of epididymal fluid in the ejaculate. Fluid originating from the epididymis should also contain motile spermatozoa. When it does not, but alkaline phosphatase concentrations are high, either bilateral obstruction to outflow of sperm from the testes to the epididymes exists, or the testes are not producing sperm. If an azoospermic sample has low concentrations of alkaline phosphatase, two possibilities exist. One is that only the first fraction (pre-sperm) of the ejaculate, which originates from the prostate, was

collected. The other possibility is bilateral obstruction to outflow of sperm from the epididymes.

In dogs and cats, samples obtained by fine-needle aspiration of the testis may be used to assess the presence or absence of spermatozoa. However, biopsy specimens will be necessary to fully assess the spermatogenic cycle.[31] Meticulous surgical technique and the postoperative application of cold compresses to the scrotum will help minimize post-biopsy swelling.[32]

Chapter 74

Pathophysiology of the Penis

Michelle Anne Kutzler

Development

Normal reproductive development in male dogs and cats is dependent on exposure of the embryologic urogenital sinus and mesonephric (Wolffian) ducts to androgens during the middle third of gestation (between 20 and 40 days before birth). At this stage of development, the urogenital sinus consists of a pelvic portion that

extends from the bladder to the ischial arch and from which the urethra is derived and also a phallic portion that is associated with the genital tubercle. The epithelial lining of the phallic portion expands along the genital tubercle as a solid cord called the urethral plate and hollows to form a canal. Mesenchymal proliferation on both sides of the urethral plate enlarges the urogenital folds, leading to the establishment of a median urethral groove on the ventral surface of the genital tubercle. The elongating genital tubercle develops into the penis and the urogenital folds fuse ventrally along the entire length of the genital tubercle, establishing the penile urethra. The erectile tissue of the

corpus spongiosum is formed by differentiation of mesodermal tissues within the urethral folds, and it advances along the urethra as fusion of the urethral folds progresses. The scrotal swelling that arises lateral to the urogenital folds gradually moves caudomedially and the caudal parts enlarge and fuse in the midline to form the scrotum and the scrotal raphe. The prepuce develops from a separation of two layers of ectodermal cells that originate on the distal tip of the penis. In prepubertal dogs, the separation of ectodermal layers forms an incomplete ring with a ventral connection between the under surface of the glans of the penis and prepuce, known as the frenulum. In contrast to dogs, the

prepuce of prepubertal cats is circumferentially adhered to the glans. In both species, this penile-preputial attachment prevents extension of the glans from the prepuce during erection. The normal preputial mucosa is composed of stratified squamous epithelium. When substitutes for preputial mucosa are needed during a surgical repair, buccal or intestinal mucosa has been successfully used as a substitute.[1]

During embryonic development, the urethra is reported to arise from the fusion of paired free edges of the urethral folds, resulting in a closure of the urethral fossa after rupture of the urethral membrane.[2] However,

subsequent research was unable to detect either fusion of the urethral folds or rupture of the urogenital membrane so the precise embryologic development of the urethra remains unclear.[3] What is not in dispute is that, in the absence of androgens (testosterone or dihydrotestosterone) or androgen receptors, the mesonephric ducts, penis, and penile urethra do not develop.[4] In addition, prenatal androgen exposure in female fetal dogs and cats masculinizes the urogenital sinus and allows persistence of the mesonephric ducts.[5]

Anatomy and Physiology

The prepuce is a fold of skin that

covers the glans penis when the penis is not erect. The prepuce consists of an external lamina and an internal lamina, which are continuous at the preputial opening. The internal lamina terminates at the fornix, where it becomes continuous with the skin of the glans, while the external lamina is the haired skin of the outer surface. The prepuce is suspended from the ventral abdomen by preputial ligaments and muscles. These modified cutaneous muscles keep the prepuce over the glans of the penis in the retracted state. The penis is attached to the ischial arch by the crura and ischiocavernosus muscles. The penis consists of the root, body, and glans. The root is not externally visible. The

body of the penis is made up of cavernous tissue. The distal corpus cavernosum is ossified (os penis) and extends distally from just behind the bulb to the tip of the glans.[6] A ventral groove within the os penis accommodates the urethra, the proximal end of which is a common site of urethral obstruction with urinary calculi.[4] The glans penis of the dog is divided into two principal parts: the pars longa glandis and the bulbus glandis. Applying pressure behind the bulbus glandis results in contraction of the ischiourethralis muscle, which inserts onto a fibrous ring that encircles the common trunk of the left and right dorsal veins of the penis. Contraction of the ischiourethralis

muscle occludes the dorsal vein, resulting in engorgement of the cavernous tissues within the penis. Additionally, the caudal twisting of the penis during tail-to-tail position taken during the genital lock in dogs occludes the emissary veins.[7] Transection of the ischiourethralis muscle prevents canine erection, including partial penile erection of the bulbus glandis.[8] Detumescence requires relaxation of these muscle fibers, which allows drainage through the pudendal veins.

On the glans of the adult intact cat penis is a band about 4 mm wide, consisting of 120 to 150 backward-pointing keratinized spines encircling the glans and forming 6 to 8 circular

rows.[9] These spines are androgen-sensitive and an indirect indicator of the presence of male hormones in cats.[9] The spines completely regress 13 to 24 weeks after castration.[9] The spines are an adaptation to provide additional stimulation during breeding to induce ovulation.[9] However, the smooth penis of the castrated male will still cause ovulation.[9] The urethral epithelium is also androgen-sensitive in male cats and is significantly higher with a lower fibrocyte density than in castrates.[4] The presence of penile spines can be used to identify incompletely castrated males.[10] Additional endocrine stimulation testing can be used to confirm a diagnosis of incomplete castration

beginning with a venous blood sample collected for baseline testosterone concentration. Post-stimulation blood samples are collected 30 and 120 minutes after intravenous (500 IU/cat) administration of human chorionic gonadotropin (HCG).[10] Testosterone concentrations increase by 5- and 10-fold in 30 and 120 minutes, respectively.[10] HCG administration by intravenous injection produces a more consistent stimulation than intramuscular or subcutaneous administration.

The vascular supply of the prepuce is through the dorsal artery and vein of the penis and a branch of the external pudendal vessels. The lymphatic

drainage is to the preputial and superficial inguinal lymph nodes. The blood supply to the corpus cavernosum penis is by the deep and dorsal penile arteries. Erection occurs when an increase in cavernosal arterial blood flow is coupled with a decrease in venous outflow from the corpora via the dorsal penile vein, resulting in sinusoidal relaxation and filling of the corpora cavernosum.

The corpus cavernosum is a conglomeration of venous sinusoids that functions as erectile tissue. The caudal epigastric artery can serve as a donor vessel to increase blood flow to the corpus cavernosa when flow has been reduced to the dorsal penile

artery.[11] In the dog, the rapid engorgement of the bulb also depends on dilation of helicine arteries in the erectile tissue along with venous blood from the pars longa glandis. An elaborate venous drainage system connects the corpora to the iliac veins, and leakage in this system is an important cause of impotence in man. The circumflex vein drains into the deep dorsal vein and provides additional drainage to the distal two thirds of the cavernous bodies. Minor cavernous vein leakage in the presence of normal arterial flow has minimal effect on the development of erection.[12] However, penile rigidity can be prevented by excessive cavernous vein outflow resulting from

pathologic changes in the cavernous smooth muscles, abnormal local venous drainage, insufficient neurotransmitter release, and alteration of the cavernous endothelium.[13] The corporal bodies are easily accessible to percutaneous needle punctures and can be used as an emergency vascular access in dogs with severe hypovolemia.[14]

The spinal nuclei for control of erection are located in the intermediolateral gray matter at the S1-S3 and T12-L3 in dogs.[15] The sacral nuclei axons fuse to form the pelvic nerve (nervus erigens), whose visceral parasympathetic efferent fibers (cavernous nerves) are located on the

lateral aspect of the urethra.[15] The cavernous nerves penetrate the tunica albuginea of the corpora cavernosa alone and enter with the deep penile artery and cavernous vein.[15] These nerves can be damaged easily during urogenital surgery. Desensitization of the glans penis results in genital disorientation during mating and also intromission failure in cats16 but not in dogs.[17] In the dog, thoracolumbar sympathectomy results in reduced mating frequency, but when copulation does occur, the genital lock, which is highly dependent on vasomotor changes in the penis, remains unaltered.[18] Erection can be induced via electrostimulation of the cavernous nerves along the posterolateral aspect

of the prostate.[11] Erection can also be induced in castrated males, but a higher threshold level of energy is needed. The minimum voltage required to induce erection in intact dogs (0.2 – 4.0 V) was half of that of castrates (0.6 – 12 V).[19]

The hypogastric nerve is a peripheral sympathetic nerve that plays a crucial role in the transport of sperm through the vas deferens, secretion of accessory gland fluid, and bladder neck closure. Pressure receptors for ejaculation are located in the body of the penis beneath the surface of the epithelium. Ejaculation failure occurs when sympathetic pathways from the lumbar splanchic nerve are injured bilaterally

in the retroperitoneum or within the pelvis, resulting in impaired bladder neck closure but unimpaired seminal emission.[20] Bilateral transection of the hypogastric nerves in dogs results in retrograde ejaculation, as the hypogastric nerves are the sole pathway of efferent signals for active bladder neck contraction at ejaculation.[20] The function of the hypogastric nerve can be returned after hypogastric nerve-hypogastric nerve reattachment.[20]

The male dog has two ejaculatory reflexes that are mainly controlled by somatic signals via the pudendal nerve from which the dorsal nerve of the penis arises. The first ejaculatory reflex

occurs following intromission, lasts for 15 to 30 seconds, and is characterized by intense pelvic movement, alternate stepping of the back legs, rapid engorgement of the glans penis, contraction of the bulbospongiosus muscle, and expulsion of the sperm-rich fraction of the ejaculate. The second ejaculatory reflex occurs during the genital lock, lasts for 10 to 30 minutes, and is characterized by rhythmic contraction of the urethral muscles, bulbospongiosus muscle, and ischiocavernosus muscle, and expulsion of prostatic fluid.

Congenital Penile and Preputial Abnormalities

Hypospadias

Hypospadias is an uncommon congenital abnormality of male external genitalia in dogs and cats.[21] The exact frequency is unknown because severe cases result in neonatal death and mild cases may go undiagnosed.[21] Few reports have been published of this condition in cats and a review of 2.2 million canine medical records from 17 veterinary teaching hospitals yielded only 66 cases.[21] Hypospadias occurs when development of the urethra is incomplete. Hypospadias is defined by the location of the urethral orifice: glandular, penile, penoscrotal, scrotal, and perineal.[1] Hypospadias may result from fetal androgen deficiency, 5-α-

reductase deficiency, or tissue resistance to androgens.[22] Hypospadia also occurs frequently with intersex conditions. Affected individuals are genetically male (XY) with abnormally formed external genitalia and bilateral cryptorchidism. In addition, a familial genetic component to hypospadias in dogs may exist as the Boston terrier breed is overrepresented with this condition.[21] Developmental preputial defects, such as those occurring with hypospadias, can be surgically corrected by manipulation of the preputial muscles to provide cranial advancement of the prepuce over the penis. A caudal superficial epigastric arterial pedicle flap has been suggested as a source of skin for preputial

reconstruction.[23] Blood supply to the flap site, skin availability, type and size of defect, and restoration of function following reconstruction all must be considered before surgery.

Persistent Frenulum

Persistence of the penile frenulum occurs infrequently in dogs and cats. Common clinical signs of a persistent frenulum include pain during erection, intromission failure, balanoposthitis, and dysuria.[24] In non-breeding animals, no clinical signs may be associated with the condition. Surgical ligation and sectioning of the frenulum are curative and the prognosis is excellent.[24]

Phimosis

Phimosis, a rare disorder in dogs and cats, is the inability to extend the glans penis beyond the preputial orifice and is characterized by a narrow preputial opening.[25] Few published reports exist on abnormally small preputial openings in dogs. Clinical signs of phimosis vary from an asymptomatic narrowing of the preputial orifice, to preputial urine retention with posthitis, to complete occlusion of the preputial orifice with signs of urinary obstruction. Surgical repair of phimosis includes resection of a small wedge of the dorsal preputial margin followed by apposition of the ipsilateral preputial skin and mucosal edges.[26] Care must be taken that the new

preputial opening is not made too large so as to allow continual protrusion of the penis.

Acquired Penile and Preputial Abnormalities

Paraphimosis

Paraphimosis is an inability to completely withdraw the penis into the prepuce.[27] It is most commonly seen in young intact males and may occur secondary to trauma, masturbation, sexual hyperactivity or the presence of a female in estrus, constriction of preputial hair around the penis, inability of the preputial muscles to pull the prepuce back over glans penis after erection, pseudohermaphroditism,

neurologic deficits in dogs with posterior paresis, or as an idiopathic event. Prolonged exposure of the glans penis causes vascular engorgement, epithelial drying, edema, and inflammation, thus exacerbating the paraphimosis.[27] The condition becomes worse with time and may progress to corporal thrombosis.

The conservative treatment is to replace the penis in the prepuce as soon as possible with the aid of regional anesthesia. Penile edema can be relieved by massage. A preputiotomy may be necessary to accommodate replacement of the penis. If a preputiotomy is performed, the tissues should be carefully closed to

the original state. In cases where nonsurgical management has failed, preputial lengthening (preputioplasty), preputial muscle myorrhaphy (shortening of the preputial muscles), and penile amputation with concurrent urethrostomy have been reported to correct the paraphimosis.[28] To amputate the penis, the prepuce is reflected caudally following excision of the suspensory structures and ligation of the preputial blood supply. The dorsal and deep arteries of the penis, both branches of the perineal artery, are ligated when the penis is amputated from the ischial attachments.[29] A segment of the urethra should be retained for urethrostomy.

Phallopexy is another method for treatment of paraphimosis that results from the creation of a permanent adhesion between the dorsal surface of the penis and the preputial mucosa.[27] Phallopexy should be performed on the dorsal surface of the penile shaft to avoid the urethra and the looser preputial tissues present on the ventral side.[27] During this procedure, care must be taken to avoid incising into the underlying cavernous tissue.[27] Urine pooling and balanoposthitis may result if this procedure is performed too far caudally in the prepuce.[27] The penile tip should be retained inside the preputial orifice 5 to 10 mm when the penis is in the nonerect state.[25]

Priapism

Priapism, an uncommon disorder in cats and dogs, is a persistent penile erection in the absence of sexual excitation that results in pain and dysuria. Priapism is most likely to develop secondary to trauma during mating or during castration, genitourinary infection or inflammation, or constipation resulting in persistent pelvic nerve stimulation, neurologic dysfunction (e.g., distemper-associated inflammatory lesions within the spinal cord), or from decreased venous outflow resulting from an occlusive thromboembolism or mass.[30] This form of priapism (low-flow priapism) is associated with a poorer prognosis as the damage from

the ischemia is more severe.[31] In low-flow priapism, the danger is not in the priapism itself, but in the reduction of oxygen and an elevation of carbon dioxide partial pressure resulting from the hemostasis within the cavernous tissues.[32] High-flow priapism results from a persistent increase in blood flow from a neuro-arterial disturbance or the development of arteriovenous fistulae.[31]

Arteriovenous fistulae are reported infrequently dogs and cats. Occasionally, arteriovenous fistulae develop on the prepuce.[33] Clinically, a preputial arteriovenous fistula manifests as a network of large tortuous pulsating blood vessels that

enlarge gradually over several months.[33] Diagnosis can be made using angiography. Angiography is the optimal technique for planning treatment of arteriovenous communications. Characteristic angiographic findings of arteriovenous fistulae include premature venous filling, absence of the normal capillary phase, and reduced distal arterial flow.[34] Conservative surgical treatment for arteriovenous fistulae involves ligating the proximal supplying vessels to reduce blood flow through the fistula.[33] The prognosis for dogs with arteriovenous fistulae depends on the size and site of the fistula and the degree of cardiovascular failure at the time of diagnosis.[34]

A penile cavernogram can be used to identify thromboemboli or masses resulting in decreased venous outflow as well as the extent of venous outflow impairment.[35] Dynamic cavernosography consists of infusing heparinized saline at increasing rates (3-25 ml/minute) until the intracavernous pressure plateaus at 80 mm Hg (full erection pressure) followed by infusion of 60% Hypaque meglumine contrast medium to opacify abnormally draining veins.[13] Butterfly needles (21-gauge) can be inserted into the corpora cavernosa and connected to a pressure transducer. Dynamic cavernosometry should be performed following erection induction with administration of intracavernous

papaverine (2-10 mg).[11,36] Papaverine decreases arterial resistance and increases venous resistance. Intracavernosal injection of epinephrine, norepinephrine, or phenylephrine prevents penile erection.[37]

Regardless of the primary cause, stagnation of blood containing a decreased concentration of oxygen and an increased concentration of carbon dioxide in the cavernous tissues results in edema formation with further venous occlusion and eventual irreversible fibrosis in the main venous outflow tracts of the penis. Histologically, severe cavernosal congestion with large hemoglobin

crystals and organizing fibrin thrombi develop.[30] Conservative treatment consists of various combinations of cold water compresses, penile lubrication, corticosteroids, antibiotics and diuretics. Because the penis cannot be manually reduced into the prepuce, it becomes congested, dry, and eventually necrotic. Medical treatment with intravenous benzotropine mesylate (0.015 mg/kg), an anticholinergic and antihistaminergic drug, has been used successfully in horses but must be administered within 6 hours after the onset of priapism.[38] Increasing venous outflow via drainage and flushing of the cavernous tissues with heparinized saline (0.9% NaCl) solution in combination with

infusion of phenylephrine[39] or epinephrine[40] has also been reported for the treatment of low-flow priapism. However, the penis may be irreparably damaged at the time of initial presentation, necessitating amputation and urethrostomy.

Trauma

Traumatic lesions of the penis and prepuce may result from bite wounds or automobile accidents, in association with a pelvic injury or during sexual activity while the penis is erect. Treatment of traumatic lesions of the penis varies depending on the damage. Emergency therapy should be directed at controlling hemorrhage and

maintaining patency of the urethra. If the tip of the penis is lacerated, it can be debrided and sutured. A tourniquet around the proximal penis will decrease the amount of blood in the field and improve the precision with which sutures are placed. If damage is extensive, it may be necessary to amputate larger parts of the traumatized penis. A wedge-shaped incision should be made through the corpora tissues, and the os penis distal to the lesion is removed with a rongeur.[29] The cavernous body of the penis is sutured and the urethral orifice is re-established on the ventral body of the penis. Following preputial reconstruction, daily penile extrusion should be carried out to prevent

adhesions between the penis and the prepuce.

The os penis can be fractured as a result of trauma; however, this injury is rare.[41] Fracture of the os penis may result in occlusion or disruption of the penile urethra. Presenting clinical signs include dysuria, stranguria, pollakiuria, and hematuria. In acute cases, pain can be elicited over the fracture site. Urethral catheterization may also indicate an obstruction at the level of the os penis. If a urinary catheter can be passed and the os penis fragments are well aligned, the fracture may heal satisfactorily with placement of an indwelling catheter for 5 to 21 days after the injury.[42]

Distraction of the fracture fragments or swelling-associated trauma can result in urethral occlusion, which necessitates a urethrostomy to re-establish urine flow. A prescrotal urethrotomy will allow catheterization of the bladder if a urethral catheter will not pass through the penile urethra and will preserve the male's reproductive function.[29] The retractor penis muscle should be reflected to one side because splitting the retractor penis muscle will result in muscle contraction and premature closure of the urethrostomy site.[29]

Radiography is necessary for definitive diagnosis of an os penis fracture.[43] Surgical repair of the fracture is

indicated if urethral obstruction is occurring. A rubber tourniquet is placed caudal to the os penis to minimize bleeding during surgery and a longitudinal incision is made through the epithelium on the lateral aspect of the penis.[43] A small periosteal elevator should be passed along the urethral groove in order to separate the corporal bodies from the os penis. Ventral ridges of the os penis can be debrided using bone-cutting forceps to allow expansion of the urethra within the urethral groove during healing of the fracture to prevent urethral narrowing. A finger plate[41] and Kirschner wires[44] have been used in the surgical repair of os penis fractures. Dorsal positioning of the screws

through the os penis will prevent occlusion of the urethra.[43] In chronic cases of os penis fractures, palpation of the penis may reveal slight thickening over the fracture site.[41] Chronic dysuria or complete urethral obstruction following bone callus formation along the fracture site impinging the urethra may occur within 2 years of the trauma.[41,43,45] A retrograde urethrogram using a contrast agent will confirm location of urethral narrowing.[43] Surgical repair is accomplished by removing excess bone and fibrous tissue.[43] The effect of a fracture of the os penis on breeding ability has not been reported.

Neoplasia

Neoplasms of the glans penis and penis are not common.[28] Neoplasia common to skin will occur on the penis and prepuce; this includes papilloma, hemangioma, melanoma, and histiocytoma.[28] The transmissible venereal tumor can be found on the glans penis and prepuce. It is a contagious, neoplastic disease, transmitted by transplantation of viable tumor cells during mating.[46] Malignant neoplasms include mast cell sarcoma, reticulum cell sarcoma, melanoma, hemangiosarcoma, squamous cell carcinoma, and venereal sarcoma. Squamous carcinoma may be seen on the epithelium of the glans; a hemangiosarcoma of the cavernous

tissues may occur.[28] Clinical signs include persistent or intermittent preputial discharge with the presence of solitary or multiple cauliflower-like, papillary, multilobulated or pedunculated masses. Any of these lesions should be widely excised and identified, and chemotherapy and/or radiation therapy should be instituted if indicated based on tumor identification.

Chapter 75

Dystocia in the Bitch

Catharina Linde Forsberg

Some of the more challenging but also most rewarding cases in the busy general practice are the bitches presenting with suspected, or confirmed dystocia, or where the owners ask for an elective Cesarean section. Often both the welfare of the mother and the chances for survival of the pups are dependent on the accurate assessments and informed decisions made by the veterinarians

and the staff at the clinic. To diagnose dystocia, a thorough appreciation of the various stages of the normal parturition – eutocia - in the bitch is vital.

Physiologic Changes During Pregnancy Start

Metabolic demands are increased during pregnancy. Blood volume increases by 40%, primarily composed of plasma, resulting in a hemodilution and a hematocrit of around 30% at term. This is thought to facilitate placental perfusion. Cardiac output is increased owing to enhanced heart rate and stroke volume. Oxygen consumption during pregnancy

increases by 20%, while the functional residual capacity of the lungs is decreased owing to anterior displacement of the diaphragm by the enlarged uterus. Pregnant animals also may have delayed gastric emptying owing to decreased gastric motility and displacement of the stomach.

Gestation Length

Gestation length in the bitch averages 63 days, but can vary from 56 to 72 days if calculated from the first mating.[1] This large variation is mainly owing to the long and variable period of behavioral estrus of the bitch. Gestation length is highly predictable when calculated either from the pre-

ovulatory surge of luteinizing hormone (LH), when it is 65 ± 1 days; from the day of ovulation, when it is 63 ± 1 days;[2] or from the time of fertilization of the oocytes, when it is 60 ± 1 days.[1,3]

The ability to determine gestational age and to predict the day of parturition in the bitch is of considerable clinical importance especially in case of suspected prolonged gestation, as well as in a bitch that is scheduled for elective Caesarean section. Some of the methods discussed here are applicable only in the bitch that has been examined in advance in anticipation of dystocia, whereas others are useful also

in acute cases of dystocia.

B-mode Ultrasonography

B-mode ultrasound can be used throughout pregnancy to assess the diameter of pregnancy structures and to estimate fetal size.[4-6] Inner chorionic cavity diameter on days 18 to 37 from ovulation and fetal head diameter on day 38 to parturition show the best correlation to gestational age and to predicting parturition day. Other fetal structures used to time pregnancies are fetal limb buds, first detectable at days 33 to 35; eyes, kidney, and liver at days 39 to 47; and intestines at days 57 to 63.

Radiography

Using radiography, the fetal skeleton is visible rarely before day 42; the skull on days 45 to 49; pelvic bones on days 53 to 57; and teeth on days 58 to 63.

Serum Progesterone

Serum progesterone concentration can be a useful predictor of the day of parturition. It is becoming increasingly more common that breeders determine the optimal day of mating of the bitch by checking the serum progesterone during proestrus and estrus. Progesterone rises sharply from near basal levels to $\geq$ 4.5 nmol/l ($\geq$ 1.5 ng/ml) at the time of the LH peak, and parturition can be expected to occur 65

± 1 days later. The accuracy of prediction of parturition day within a ± 1, ± 2, and ± 3 day interval using pre-breeding serum progesterone concentrations was 67%, 90%, and 100%,[7] and was not seen to be influenced by either body weight or litter size. The serum progesterone level is also useful in predicting the parturition day in the bitch at term, as it decreases sharply from 12 to 15 nmol/l (4-5 ng/ml) to below 6 nmol/l (2 ng/ml) starting 24 hours before the onset of whelping.

Other Clinical Signs

Relaxation of the pelvic and abdominal musculature is a

consistent but subtle indicator of impending parturition. It is, therefore, usually best observed by the owner of the bitch.

The drop in rectal temperature in most bitches is a good predictor of the day of parturition. During the final week of pregnancy the rectal temperature of the bitch fluctuates, as a consequence of the fluctuations in the (thermoregulatory) progesterone level, but it then drops sharply 8 to 24 hours before parturition, which is 10 to 14 hours after the concentration of progesterone in peripheral plasma has declined to less than 6 nmol/l (2 ng/ml). To properly assess the prepartum drop in body temperature,

however, measurements should be made every 1 to 2 hours as long as the temperature decreases, but can be done less frequently when the temperature is seen to increase again. The degree of the drop in rectal temperature varies between 1° C (33.8° F) and 3.5° C (38.3° F), probably as an effect of surface area/body volume ratio. Thus, in short-haired miniature breed bitches it can fall to 35° C (95° F), in medium-sized bitches to around 36°C (96.8° F), whereas it seldom falls below 37°C (98.6° F) in bitches of the giant breeds or bitches with a thick hair coat. In bitches with uterine inertia, a distinct drop in body temperature may not be seen to occur.

Behavioral changes may be manifested. Several days before parturition the bitch may become restless, seek seclusion, or be excessively attentive, and may refuse food. She may exhibit nesting behavior 12 to 24 hours before parturition concomitant with increasing frequency and force of uterine contractions. Shivering is a response to the drop in body temperature.

In primiparous bitches, **lactation** may be established less than 24 hours before parturition, whereas, after several pregnancies, colostrum can be detected as early as 1 week pre-partum.

Normal Parturition

Stress produced by the reduction of the nutritional supply by the placenta to the fetus stimulates the fetal hypothalamic-pituitary-adrenal axis, resulting in release of adrenocorticosteroid hormone, and is thought to be the trigger for parturition. An increase in fetal and maternal cortisol is believed to stimulate the release of prostaglandin F_{2a}, which is luteolytic, from the fetoplacental tissue, resulting in a decline in plasma progesterone concentration. Withdrawal of the progesterone blockade of pregnancy is a prerequisite for the normal course of canine parturition; bitches given long-

acting progesterone during pregnancy fail to deliver.[2] Concurrent with the gradual decrease in plasma progesterone concentration during the last 7 days before whelping is a progressive qualitative change in uterine electrical activity. A significant increase in uterine activity occurs during the last 24 hours before parturition, with the final fall in plasma progesterone concentration to below 6 nmol/l (2 ng/ml).[2,8,9] In the dog, estrogens have not been unambiguously shown to increase before parturition as they do in many other species. Sensory receptors within the cervix and vagina are stimulated by the distention created by the fetus and the fluid-filled fetal membranes.

This afferent stimulation is conveyed to the hypothalamus and results in release of oxytocin during second stage labor. Afferents also participate in a spinal reflex arch with efferent stimulation of the abdominal musculature to produce abdominal straining. Relaxin causes the pelvic soft tissues and genital tract to relax, which facilitates fetal passage. In the pregnant bitch, this hormone is produced by the ovary and possibly also by the placenta and uterus and rises gradually over the last two thirds of pregnancy.[10]

First Stage

The duration of the first stage usually

is between 6 and 12 hours. It may last 36 hours, especially in a nervous primiparous animal, but for this to be considered normal the rectal temperature must remain low. Vaginal relaxation and dilation of the cervix occur during this stage. Intermittent uterine contractions, with no signs of abdominal straining, are present. The bitch may appear uncomfortable, and the restless behavior may become more intense. Panting, tearing up and rearranging of bedding, shivering, and occasional vomiting may be seen. Some bitches show no behavioral evidence of first-stage labor. The inapparent uterine contractions increase both in frequency, duration, and intensity toward the end of the

first stage. Inexperienced breeders may not fully understand the function of this preparatory stage of parturition during which the recurrence of uterine tones, the softening of the birth canal, and the opening of the cervix take place.

During pregnancy, the orientation of the fetuses within the uterus is 50% heading caudally and 50% cranially, but this changes during first-stage labor as the fetus may rotate on its long axis and extend its head, neck, and limbs. This results in 60% to 70% of pups being born in anterior and 30% to 40% in posterior presentation.[11,12] The fluid-filled fetal membranes are pushed ahead of the

fetus by the uterine propulsive efforts and dilate the cervix.

Second Stage

It is crucial that the veterinarian is able to determine whether the bitch is in the second stage or still in the first stage of labor. If one or more of the following signs have been observed the bitch is in second-stage labor:

- The rectal temperature has been down and is returning to normal level
- Visible abdominal straining is observed
- Fetal fluids are passed

The duration of the second stage is

usually between 3 and 12 hours; in rare cases, it has lasted 24 hours. At the onset of second-stage labor the rectal temperature rises to normal or slightly above normal. The first fetus engages in the pelvic inlet, and the subsequent intense, expulsive uterine contractions are accompanied by abdominal straining. On entering the birth canal the allantochorionic membrane may rupture and a discharge of some clear fluid may be noted. Covered by the amniotic membrane, the first fetus is usually delivered within 4 hours after onset of second-stage labor.[13] Normally, the bitch will break the membrane, lick the neonate intensively, and sever the umbilical cord. At times, the bitch will

need some assistance to open the fetal membranes to allow the newborn to breathe, and sometimes the airways will have to be emptied of fetal fluids. The umbilicus can be clamped with a pair of hemostats and cut with a blunt scissors to minimize hemorrhage from the fetal vessels, leaving about 1 cm of the umbilicus. In case of continuing hemorrhage, the umbilicus should be ligated.

In normal labor the bitch may show infrequent and/or weak straining for up to 2, and at the most, 4 hours before giving birth to the first fetus. If the bitch is having strong, frequent but nonproductive straining, this indicates the presence of some obstruction.

Veterinary advice should be sought after no more than 20 to 30 minutes.

Expulsion of the first fetus usually takes the longest. The interval between births in normal uncomplicated parturition is from 5 to 120 minutes.[11,12] As long as pups remain in both uterine horns the fetuses are mostly delivered alternately from each side. When giving birth to a large litter a bitch may accumulate lactic acid in the myometrium and stop straining. Such a rest between the deliveries of two consecutive fetuses may last for more than 2 hours. The second-stage straining will then resume, until all the fetuses are born. A normal parturition stimulates fetal circulation, empties

airways of fetal fluids, and thereby, facilitates breathing.

Parturition is usually completed within 6 hours after the onset of secondstage labor, but it may last up to 12 hours. It should not be allowed to last for more than 24 hours considering the risks involved both for the bitch and the fetuses.

Third Stage

Expulsion of the placenta and shortening of the uterine horns usually follows within 15 minutes of the delivery of each fetus. Two or three fetuses may, however, be born before the passage of their placentas occurs.

Should the bitch ingest more than one or two of the placentas, she may develop diarrhea. The greenish postpartum discharge of fetal fluids and placental remains (lochia) will be seen for up to 3 weeks or more. They are most profuse during the first week. Uterine involution is normally completed after 12 to 15 weeks.

Dystocia

Dystocia, defined as difficult birth or the inability to expel all fetuses through the birth canal without assistance, is a frequent problem in the dog. The over all incidence is probably below 5%, but in some breeds may amount to almost 100%, especially

those of the achondroplastic type and those selected for large heads.[11,14,15] Dystocia in the bitch in around 75% of cases is of maternal origin, and in 25% of fetal origin (Table 75-1).[14]

Table 75-1. Causes of Dystocia in Bitches (182 cases) (Darvelid and Linde-Forsberg, 1994)

	Frequency (percent)
Maternal causes	75.3
Primary	48.9

complete inertia	
Primary partial inertia	23.1
Narrow birth canal	1.1
Uterine torsion	1.1
Uterine prolapse	–
Uterine strangulation	–
Hydrallantois	0.5
Vaginal septum formation	0.5
Fetal causes	24.7

Malpresentations	15.4
Malformations	1.6
Fetal oversize	6.6
Fetal death	1.1

Clinical Assessment

When a bitch with dystocia is presented, taking an accurate history and performing a thorough physical examination are important prerequisites for proper management. In the absence of an obvious cause for the dystocia, such as an obstructed fetus visible in the vagina, the three criteria for being in second-stage labor,

namely body temperature returned to normal, visible abdominal straining, and passage of fetal fluids, should be assessed. An evaluation of the bitch's general health status should be made and signs of any adverse effects of parturition noted. Observation should be made of the bitch's behavior and the character and frequency of straining. The vulva and perineum should be examined, noting color and amount of vaginal discharge. Mammary gland development including congestion, distention, size, and presence of milk should be evaluated. Palpation of the abdomen and estimating the degree of distention and the uterine tone should be carried out. Digital examination of the vagina using aseptic technique

should be undertaken to detect obstructions and determine the presence and presentation of any fetus in the pelvic canal. In most bitches, it is not possible to reach the cervix during first stage, but an assessment of the degree of dilation and tone of the vagina may give some indication of the status of the cervix and the tone of the uterus. Pronounced tone of the anterior vagina may indicate satisfactory muscular activity in the uterus, whereas flaccidity may indicate uterine inertia.[16] The character of the vaginal fluids also indicate whether the cervix is closed, with the production of a fluid that is scant and sticky, creating a certain resistance to the introduction of a finger, or open, when fetal fluids

lubricate the vagina, making exploration easy. When the cervix is closed, the vaginal walls also fit tightly around the exploring finger, whereas with an open cervix the cranial vagina appears more open.

Radiographic examination is valuable to assess gross abnormalities of the maternal pelvis and the number and location of fetuses, to estimate fetal size, and to detect signs of fetal death. Intrafetal gas will appear 6 hours after fetal death and can be detected radiographically, whereas overlapping of cranial bones and collapse of the spinal column will be seen after 48 hours. Ultrasound examination will determine fetal viability or distress,

with normal heart rate being 180 to 240 beats per minute, decelerating in the compromised fetus.

Diagnosis

The range of normal variations observed in dogs at parturition makes recognition of dystocia difficult. Although strict time limits are not applicable in all cases, and the intensity, duration, and frequency of the uterine contractions are also crucial factors, the following criteria may serve as rules of thumb, both in the discussions with the dog owners and to assist in the diagnosis:

- The rectal temperature has been down by 1 to 3° C and has returned

to normal with no signs of labor.

- Fetal fluids were observed 2 to 3 hours ago but there are no signs of labor.
- Labor is absent for more than 2 hours or has been weak and infrequent for more than 2 to 4 hours.
- Labor has been normal but is becoming increasingly more infrequent and weak.
- Strong and persistent non-productive labor has been occurring for more than 20 to 30 minutes.
- A green vulvar discharge is present but no fetuses have been delivered. (This discharge emanates

from the marginal hematoma of the placentas and indicates that at least one placenta is becoming separated from the maternal blood supply. It is normal once birth is underway).

- An obvious cause of dystocia is evident such as pelvic fracture or a fetus stuck in the birth canal and partially visible.
- The bitch has been in second-stage labor for more han 12 hours.

Signs of toxemia (disturbed general condition, edema, shock) are noted when parturition should be occurring.

Causes of Maternal Dystocia

Uterine Inertia

Uterine inertia is by far the most common cause of dystocia in dogs. In primary inertia, a normal uterus may fail to respond to the fetal signals because there are only one or two pups and, thus, insufficient stimulation to initiate labor (the single pup syndrome) or because of overstretching of the myometrium by a large litter, excessive fetal fluids, or oversized fetuses. Other causes of primary inertia may be an inherited predisposition, dehydration, or a nutritional imbalance, fatty infiltration of the myometrium, age-related changes, deficiency in neuro-endocrine regulation, or systemic disease in the bitch. Primary complete uterine inertia

is the failure of the uterus to begin labor at full term. Primary partial uterine inertia is said to occur when uterine activity is enough to initiate parturition but is insufficient to complete a normal birth of all fetuses in the absence of an obstruction. Secondary uterine inertia implies exhaustion of the normal uterine myometrium caused by obstruction of the birth canal. The pathogenesis of secondary inertia is thus different and medical treatment is seldom effective. Therefore, secondary intertia should be clearly distinguished from primary inertia.

Management of Uterine

Inertia

It is not unusual that pups are born in the car on the way to the veterinarian. Most of these pups would probably have been delivered in the calm and quiet of home had the owners tried to induce straining in the bitch themselves, thereby giving the pup a better start in life and possibly also resulting in the whole litter being born without further intervention. In cases of primary uterine inertia with a bright and alert bitch, therefore, the owners should initially be instructed to try to induce straining by actively exercising the bitch for 10 to 15 minutes, for instance by running around the house or up and down the stairs. Another

means to induce straining in the bitch with insufficient labor is by inserting two fingers into the vagina and pushing or “walking“ with them against the dorsal vaginal wall, thus inducing an episode of straining (the Ferguson reflex). This method can also be effective in initiating labor after successful correction of the position or posture of an obstructed fetus. Gentle massaging of the mammary glands will induce oxytocin release and may enhance labor progress. Owners should also be advised to provide the bitch with sufficient fluids and energy, e.g., glucose, to avoid dehydration and hypoglycemia during labor.

Psychological stress may lead to

nervous voluntary inhibition of labor, mainly in a nervous primiparous animal. Reassurance by the owner or administration of a low dose tranquilizer may remove the inhibition.[17] Once the first fetus is born, parturition will usually proceed normally.

The bitch with complete primary uterine inertia is usually bright and alert, has a normal rectal temperature, and has no evidence of labor. The cervix is often dilated, and vaginal exploration is easy to perform owing to the presence of fetal fluids, but the fetus may be out of reach because of the flaccid uterus. Before initiation of medical treatment of uterine inertia,

obstruction of the birth canal must be excluded. Per oral or intravenous fluids and glucose should be administered.

Calcium solutions and oxytocin are the drugs of choice in cases of primary uterine inertia. Oxytocin has a direct action on the rate of calcium influx into the myometrial cell, which is essential for myometrial contraction. Some 10 minutes before the administration of oxytocin, 10% calcium borogluconate, 0.5 to 1.5 ml/kg bodyweight, should be given by slow intravenous infusion (1 ml/min) with careful monitoring of the heart rate. The calcium can also be administered subcutaneously, which eliminates the risk for arrhythmia but

presents a small risk for granuloma formation at the injection site. Hypoglycemia may occur, particularly after prolonged straining. In such cases, a dilute (10 to 20%) glucose solution can be added to the infusion or given intravenously in doses of 5 to 20 ml. The recommended dose of oxytocin for the bitch is 1 to 5 IU given IV or 2.5 to 10 IU IM, and it can be repeated at 30-minute intervals. The response to treatment will, however, be reduced with each repeated administration. Higher doses than recommended or too frequent administration may result in prolonged contracture of the myometrium, preventing fetal expulsion and impeding uteroplacental blood flow,

causing hypoxia in the fetuses. The disadvantages of oxytocin administration also include a tendency to cause premature induction of placental separation and cervical closure. If there is no response to treatment after a second administration of oxytocin, the pups should be delivered without further delay, either with the aid of obstetrical forceps, if only one or two pups remain and are within easy reach in the uterine corpus, or by cesarean section. The long-acting ergotamines should never be used in connection with parturition.

The treatment regimen includes:

- A 10% solution of calcium

gluconate is given slowly intravenously while carefully checking the bitch's heart rate.

• The bitch is given 30 minutes to respond to treatment. If straining begins, the treatment can be repeated if necessary or continued with oxytocin.

• If the calcium infusion has no effect within 30 minutes, oxytocin is given intravenously or intramuscularly.

• The bitch is again given 30 minutes to respond to treatment. If straining begins, the treatment can be repeated if necessary, although each additional administration will

elicit a weaker response.

• If no response occurs within 30 minutes, further treatment is not likely to be successful. The fetuses should be delivered, either by forceps, if only one or two fetuses remain and are within easy reach, or by cesarean section.

Obstruction of the Birth Canal

Some maternal causes for obstruction are listed below:

Uterine Torsion and Uterine Rupture

These are acute, life-threatening conditions occurring either during late pregnancy or at the time of parturition. The condition of the bitch may quickly deteriorate. Surgery is always required and a quick diagnosis is essential for survival of the bitch.

Uterine Inguinal Herniation

Uterine inguinal herniation is often detected during the fourth week of pregnancy when the fetal uterine enlargements are 2 to 2.5 cm in size. The early stages may be mistaken for mastitis of the rear mammary glands. The condition is corrected by surgery, repositioning the uterine horns, and suturing the herniation. In case of

circulatory disturbance and substantial tissue damage, the uterus may have to be removed.

Soft Tissue Abnormalities

Soft tissue abnormalities such as vaginal septa and neoplasms or fibrosis of the birth canal may cause obstructive dystocia. Vaginal septa usually are remnants of the fetal müllerian duct system, but may also occur secondary to vaginal trauma or infection. If extensive, both septa and neoplasms may prevent the passage of the fetuses. Often, however, prepartum the vagina is relaxed enough to allow the fetuses to pass. Cervical or vaginal fibrosis is seen in rare cases and is

usually secondary to trauma or inflammatory processes and may in severe cases cause dystocia. Tumors and septa formations may be surgically removed, preferably during anestrus and before mating; but in cases of fibrosis, surgery is seldom successful because of new scar tissue formation during the healing process.

Narrow Pelvic Canal

Narrow pelvic canal causing obstructive dystocia may result from immaturity, congenital malformation of the pelvis, or pelvic fractures. The normal canine pelvis usually has a vertical diameter greater than the horizontal. Congenitally narrow birth

canals exist in some terrier and brachycephalic breeds, e.g., Boston terriers and Scottish terriers. In addition, fetuses of those breeds have comparatively large heads and wide shoulders. In the achondroplastic Scottish terrier, dorsoventral flattening of the pelvis modifies the normal pelvic inlet, and creates an obstruction to the engagement of the fetuses. Significant differences were found in Scottish terrier bitches whelping normally compared with those with dystocia owing to a too-narrow birth canal caused by a dorsoflattening and a shortening of the pelvis.[15] In Boston terrier bitches a significantly greater inner pelvic height was found in normally whelping bitches. In this

breed also, the size of the pups, and especially of their heads, was important because the weight of the pup was related to the size of its head. The English bulldog has a large, deep chest and pronounced waist. The fetuses, therefore, are presented at a relatively acute angle to the pelvic inlet. Bulldogs also may have slack abdominal musculature, leading to insufficient uterine contractions and abdominal straining to lift the fetus up into the pelvic cavity. In cases of pelvic obstructions, usually a cesarean section is necessary. Genetic counseling to breeders is also important in these cases.[15]

Causes of Fetal Dystocia

Fetal causes of dystocia include malpresentations/malorientations and oversized fetuses or monstrosities, e.g., those with hydrocephalus, edema, or duplications. Fetal death may result in dystocia owing to malpositioning or inadequate stimulation for parturition to begin. A healthy fetus is active during expulsion, extending its head and limbs, twisting, and rotating to get through. In most breeds, the greatest bulk of the fetus lies in its abdominal cavity, whereas the bony parts, the head and the hips, are comparatively small. The limbs are short and flexible and rarely cause serious obstruction to delivery in the normally sized fetus.

Posterior Presentation

Posterior presentation is considered normal in dogs, occurring in 30% to 40% of fetal deliveries.[11,12] Posterior presentations have, however, been related both to higher pup mortality[11] and to a predisposition for dystocia, particularly where this involves the first fetus to be delivered, because mechanical dilation of the cervix may be inadequate. In addition, expulsion is rendered more difficult because the fetal chest instead of being compressed becomes distended by the pressure from the abdominal organs through the diaphragm and because the fetus is being delivered against the direction of its hair coat. Occasionally, the fetus may have the elbows hooked around

the pelvic brim, preventing further expulsion. When a fetus becomes lodged in the pelvic canal, pressure on the umbilical vessels trapped between the fetal chest and the maternal pelvic floor may cause hypoxia and reflex inhalation of fetal fluids.

Breech Presentation

Breech presentation (i.e., posterior presentation with hindlegs flexed forward) can be a serious complication, especially in medium- and small-sized breeds. Vaginal exploration will reveal a tail tip and maybe the anus and the bony structure of the pelvis of the fetus.

Lateral or Downward Deviation of the Head

These are two of the most common malpositionings in the dog. Downward deviation is seen in brachycephalic breeds and long-headed breeds such as Sealyham and Scottish terriers whereas lateral deviation is most common with long-necked breeds such as rough collies. In downward deviation of the head, either both front legs and sometimes the nape of the neck of the fetus can be palpated, or both front legs may be flexed backwards and only the skull of the fetus be reached. In lateral deviation, vaginal exploration will demonstrate just one front leg, the one contralateral to the direction of

the deviation of the head (i.e., when the head is deviated to the left, the right front paw will be found and vice versa).

Backward Flexion of Front Legs

This condition is especially common when the fetus is weak or dead and is sometimes seen in combination with deviation of the head, especially downward. For bitches of the larger or even medium-sized breeds, it may be possible to deliver a puppy with one or both front legs flexed.

Bicornual or Transverse

Presentation

A fetus, instead of progressing from the uterine horn through the cervix to the vagina, may sometimes proceed into the contralateral uterine horn. This may be owing to some obstruction, or the fetus may have been implanted close to the body of the uterus. These cases always require surgery, because no room exists for manual correction.

Two Fetuses Presented Simultaneously

Sometimes one fetus from each horn is presented at the same time, jamming the birth canal. If one is coming backwards this one should when

possible be removed first, because it occupies more space.

Oversized Fetuses

A pup weight of 4% to 5% of the weight of the bitch is considered the upper limit for an uncomplicated birth. Oversized fetuses are often associated with small litter size. In brachycephalic breeds such as the Boston terrier and the Scottish terrier, dystocia occurs from the combination of a flattened pelvic inlet and puppies having a large or a long head. Obstructive dystocia was found to occur at pup weights of 2.5% to 3.1% of the adult weight in these breeds.[15]

Management of Fetal Malpresentations

If a fetus is present in the birth canal, manipulation by hand or by obstetrical forceps may be attempted before a decision is made to proceed with a cesarean section. This is relevant in cases where it is assumed that, by removing the obstructed pup, the birth of the remaining pups may proceed without problems.

Fetal position must be assessed. If the fetus has advanced partly through the pelvic canal, it will create a characteristic bulge of the perineal region. Easing the vulvar lips upward may reveal the amniotic sac and the

position of the fetus. Vaginal exploration and radiographic examination will aid in making a diagnosis in the cases when the fetus has not advanced as far. Having an assistant holding the bitch so that it is standing upright on the hind legs or with the bitch sitting on his lap facing forward takes advantage of the force of gravity to get the fetus within reach for palpation. In bitches of the giant breeds it may even be possible to insert one hand through the vagina into the uterus to extract the pup.

During natural birth the pup will almost make a full somersault, emerging from the loop of the uterine horn, progressing upward to pass

through the pelvic canal, and then down through the long vagina and vestibulum of the bitch, to reach the vulva placed some 5 to 15 cm below the level of the pelvic floor. Thus, after the fetus is seized, a traction should be gently applied in posteroventral direction.

If external manipulation is to be attempted, generous application of obstetrical lubricant (liquid paraffin, petroleum jelly, or a sterile water-soluble lubricant) is helpful, especially if the bitch has been in second-stage labor for some time. The narrowest part of the birth canal is within the rigid pelvic girdle. The fetus that cannot be easily pulled out may have

to be pushed cranially in front of the pelvic girdle, where corrections of its position or posture are easier to perform. This should be done between periods of straining of the bitch, never working against the uterine contractions. The widest part of the pelvic girdle usually is on the diagonal; thus, rotating the fetus 45 degrees may create sufficient room for passage.

Depending on the position and posture of the fetus, its head and neck should be grasped, from above or below whichever is most convenient, or its pelvis, or legs. Care should be taken because the neck and limbs of the fetus are easily torn when pulled. Correction of posture may be more easily

accomplished by manipulation of the fetus through the abdominal wall with one hand and concurrent transvaginal manipulation with the other. A finger may be introduced into the mouth of the fetus to help in correcting a downward deviation of the head. Should it be necessary to change the postures of the limbs, a finger should be inserted past the elbow or knee and the limb moved medially under the fetus and corrected.

A gently applied alternating right-to-left traction of the puppy, gently rocking it back and forth or from side to side and possibly twisting it to a diagonal position within the pelvis, will help free the shoulders or the hips

one at a time. By applying a slight pressure over the perineal bulge the fetus may be prevented from sliding back in again between strainings.

Obstetrical forceps should only be used for assisted traction of a relatively oversized fetus when the rest of the pups in the litter are likely smaller or when just one or two fetuses remain. The forceps is guided with a finger and never introduced further than to the uterine body because of the risk of getting part of the uterine wall within the grip, and thus causing serious damage. If the head of the fetus can be reached, the grip should be applied around the neck (Pålssons forceps) or across the cheeks. In posterior

presentation the grip should be around the fetal pelvis. If the legs can be reached, the grip should be around those, not around the feet.

Outcome of Obstetrical Treatment

Digital manipulation including forceps delivery and/or medical treatment for dystocia is successful in only 27.6% of the cases.[14] Around 65% of bitches with dystocia, thus, end up having a cesarean section. Early diagnosis and prompt treatment are crucial to reduce pup death rate in cases of dystocia.

Criteria for Cesarean Section

The indications for Cesarean section

include the following:

- Abnormalities of the maternal pelvis or soft tissues of the birth canal
- Primary, complete or partial, uterine inertia that does not respond to medical treatment
- Secondary uterine inertia with inadequate resumption of labor after removal of the obstruction
- Fetal absolute or relative oversize, or fetal monstrosity
- Excess or deficiency of fetal fluids
- Fetal malposition unamendable to manipulation
- Fetal death with putrefaction
- Pregnancy toxemia
- Neglected dystocia

- Prophylactic/elective (history of previous dystocia).

Once a decision has been made to deliver the litter by cesarean section, surgery should be carried out without delay. The bitch has often endured hours of more or less intensive labor and may be suffering from physical exhaustion, dehydration, acid-base disorders, hypotension, hypocalcaemia, and often, hypoglycemia. The prognosis for both bitch and offspring is good if surgery is performed within 12 hours after the onset of second-stage labor; it continues to be fairly good for the bitch after 12 hours but guarded for the fetuses. If more than 24 hours have passed after the onset of

second-stage labor the entire litter is usually dead and further delay compromises the life of the bitch.

The decision to perform an elective Cesarean section should be made by the veterinarian based on a well founded presumption that if surgical intervention was not provided the bitch would experience dystocia. The veterinarian may, however, also have to take into consideration that it may be better for practical purposes and for the safety of the bitch to do an elective cesarean section on a Friday afternoon rather than during the week-end when the clinic may not be fully staffed. Performing elective cesarean sections in a line of dogs that cannot reproduce

successfully without intervention, or for the convenience of the breeder, may be questioned on ethical grounds.

The bitch submitted for an elective cesarean section should be at term, and preferably have entered first stage of parturition, so that the fetuses are mature and have enough surfactant for normal lung function. Pre-surgery treatment with methylprednisolone 0.5, 1 or 2 mg/kg bw or dexamethasone preferably 24 to 48 hours and at least 1 hour pre-surgery to advance fetal lung maturation (especially of the brachycephalic breeds) and for maternal preparation is advocated by some, although not scientifically documented in the dog.

If peripheral plasma progesterone was determined at the time of mating, this is a good help in making the decision when to perform the elective cesarean section. C-section on a bitch before day 62 past the LH surge (defined as the initial raise in serum progesterone concentrations two times that of basal, i.e., in the range of 4.5 to 7.5 nmol/l [1.5 – 2.5 ng/ml]) is likely to result in a high percentage of neonatal losses owing to fetal immaturity. Elective cesarean sections, therefore, should be made at the earliest 62 to 64 days after the LH-surge (i.e., 58-60 days post fertilization). Progesterone at this time is usually less than or about 6 nmol/l (2 ng/ml).

Postpartum

The postpartum bitch should be examined if:

- Severe genital hemorrhage is continuous.
- All placentas have not been expelled within 4 to 6 hours after the birth of the last pup.
- The lochia are putrid and/or foul smelling.
- The rectal temperature is higher than 39.5°C (103 °F).
- The general condition of the bitch is affected.
- The general condition of the pups is affected.

Postpartum Hemorrhage

True hemorrhage should be distinguished from normal vaginal post-parturient discharge and from cases of subinvolution of the placental sites (SIPS). SIPS occurs predominantly in the young, primiparous bitch and is observed as a scant vaginal hemorrhage over many weeks or even months. This is no cause for alarm, as long as the bitch does not become anemic or develop a uterine infection. No effective treatment exists and the condition in the vast majority of cases heals spontaneously, and it usually does not recur at subsequent parturtitions.

Excessive hemorrhage after parturition

may, in contrast, indicate uterine or vaginal tearing or vessel rupture or may be evidence of a coagulation defect. The hematocrit should be checked, remembering that 30% is normal for the bitch at term. Inspection of the vulva and vagina should be performed in an attempt to locate the source of the bleeding. Oxytocin can be administered to promote uterine involution and contraction of the uterine wall. In more severe cases of uterine hemorrhage, an exploratory laparotomy may be necessary. The bitch should be monitored closely for signs of impending shock, and blood transfusion may be required while attempting to determine the cause of

hemorrhage.

Retained Placentas/Fetuses

Retained placentas in the bitch may cause severe problems, especially when accompanied by retained fetuses or infection. Clinical signs of retained placenta include a thick dark vaginal discharge. Retained fetuses can be identified by palpation or ultrasonographic or radiographic examination. The examination should also encompass the corpus uteri and the vagina for the presence of partly expelled fetuses or fetal membranes. A retained placenta is often palpable in the uterus, depending on the size of the bitch and the degree of uterine

involution. Extraction of retained tissue, by careful “milking“ of the uterine horn or by using forceps, is sometimes possible. Treatment with 1 to 5 IU oxytocin per dog SC or IM 2 to 4 times daily for up to 3 days can help expulsion of retained placentas. The long-acting ergot alkaloids should not be used because they may cause closure of the cervix. Antibiotic treatment is advisable if the bitch is showing signs of illness.

Chapter 76

Diseases of the Uterus

Bronwyn Crane
Michelle Kutzler

Uterine Prolapse

Prolapse of the uterus is rare in the bitch but can occur just prior to or following parturition when the cervix is open. The prolapsed tissue may include one or both uterine horns. If both horns have prolapsed, the diagnosis is relatively simple. If only one horn has prolapsed, vaginoscopy

may be required to differentiate the prolapsed tissue. In cases where only one horn has prolapsed, the bitch may present with abdominal discomfort and straining. The broad ligament may tear, resulting in hemorrhage from the uterine vessels. If hemorrhage occurs, the patient may present with hemoperitoneum or die quickly from exsanguination. In some cases of vaginal prolapse, the uterus can be included, along with other structures, in the prolapsed tissue.[1] Once the diagnosis of uterine prolapse is made, treatment aims are to replace it and to prevent infection. If the tissue has been severely traumatized and devitalized, the best treatment is ovariohysterectomy. Laparotomy is

often required to replace the prolapsed uterus. Another option is amputation without laparotomy, taking care to avoid the bladder and urethra.

Subinvolution of Placental Sites

Subinvolution of placental sites (SIPS) is characterized by prolonged hemorrhagic vaginal discharge that persists beyond the expected emission of lochia following parturition. Serosangineous vaginal discharge is normal for the first 4 to 6 weeks postpartum during the period of endometrial reconstruction. In cases of SIPS, trophoblast cells invade deep areas of the endometrium and

myometrium following placental separation during third-stage labor, resulting in frank intrauterine hemorrhage. The condition is considered to be self-limiting and there is no proven treatment. Administration of broad-spectrum systemic antibiotics does not shorten the disease course, but it is often used prophylactically to reduce the risk of concurrent endometritis. Bitches are clinically normal, afebrile, and have normal postpartum hematologic parameters. In rare cases, bitches can experience severe hemorrhage, necessitating a blood transfusion and/or ovariohysterectomy.

Uterine Infection

Endometritis is an infection and inflammatory reaction within the endometrium, whereas metritis is an infection with inflammatory changes in both the endometrium and myometrium. These conditions occur as a result of the introduction of bacteria following parturition and less commonly, following breeding. During the postpartum period, bacteria are able to ascend from the vagina to the uterus through an open cervix. Subsequently, the bitch may develop septicemia or endotoxemia. Metritis can occur in a bitch of any age and is not influenced by hormones as in the case of cystic endometrial hyperplasia

(CEH)-pyometra. A bitch is more likely to develop metritis postpartum following a retained fetus, retained placenta, obstetrical manipulations, or infectious abortion, but metritis may also occur following a normal parturition. The clinical signs of metritis are those of general systemic illness, such as vomiting, anorexia, lethargy, agalactia, and hyperthermia. A malodorous vaginal discharge is usually present that is distinct from and persists longer than normal lochia. Ultrasonographic evaluation of the uterus would reveal an increase in uterine wall thickness and in luminal diameter. Fluid may or may not be present in the uterus. In the case of a retained fetus, organized areas of

hyperechogenicity would be present.[2] A complete blood count would show a leukocytosis with a left shift. Radiography can also be used to detect retained fetuses and double-contrast hysterography can be used to identify a retained placenta. Histologic evaluation of the uterus following hysterectomy would show inflammatory cell infiltration into the endometrium and myometrium and an overall increase in thickness. If the bitch is not intended for breeding, or the condition is severe and a retained fetus is present, the best treatment is ovariohysterectomy. Otherwise, medical management includes the use of broad-spectrum systemic antibiotics and ecbolics to stimulate uterine

evacuation. Administration of PGF2α 0.01 to 0.1 mg/kg SQ every 2 to 4 hours is continued until uterine clearance is achieved.

Cystic Endometrial Hyperplasia-Pyometra

Cystic endometrial hyperplasia (CEH)-pyometra is the most common uterine disease in older and middle-aged intact bitches and queens, with an average age of 9.36 years.[3] CEH is infrequently diagnosed in dogs younger than 4 years old and occurs slightly more often in maiden bitches. In colony-raised beagle bitches, the incidence of CEH was 15.2%.[3] However, this incidence may be an over-estimation of

the occurrence in the general population as colony raised queens had a significantly higher incidence of CEH compared with feral queens.[4]

CEH is a subclinical disease characterized by the proliferation and hypersecretion of endometrial glands resulting in the formation of fluid-filled cysts. Alone, CEH is not associated with any clinical signs other than infertility. CEH is generally considered to be the initiating stage that progresses into pyometra after uterine bacterial colonization occurs. Pyometra is a life-threatening illness involving the accumulation of intraluminal purulent exudate within the uterus and inflammatory cell infiltration into the

layers of the endometrium and myometrium. Although CEH generally precedes pyometra, pyometra can occur without CEH.

CEH-pyometra is an endocrine disease. The condition occurs during diestrus when corpora lutea are present and progesterone concentrations are high. The average interval from the onset of proestrus to diagnosis of CEH-pyometra is 35 days (range 20-70 days).

Progesterone stimulates endometrial growth and glandular secretory activity. Progesterone also reduces myometrial contractility and maintains cervical closure. In addition,

progesterone diminishes immune function by decreasing neutrophil chemotaxis and phagocytosis and increases endometrial bacterial adherence. Despite this, peripheral serum progesterone concentrations in bitches with pyometra are not higher than in normal diestrus bitches. Estrogens also have a role in the pathogenesis of CEH through the up-regulation of endometrial progesterone and estrogen receptors. However, in studies in which CEH has been experimentally induced, estrogens alone were ineffective at inducing disease. Administration of estrogens followed by progesterone or progesterone alone will induce CEH. In cases of spontaneously occurring CEH,

estrogen receptor (ER) and progesterone receptor (PR) expression are increased within the surface epithelium, endometrial glands, stromal fibroblasts, and myometrium.[5] Clinically, CEH-pyometra are reported sequelae following the use of exogenous estrogens for pregnancy termination, exogenous progestins for contraception, anovulatory (cystic) follicles, and ovarian neoplasia. The use of medroxyprogesterone acetate for population control increases the prevalence of pyometra in treated bitches to 45% over a prevalence of only 5% in untreated bitches.[6]

Bacteria gain access to the uterus via ascension during cervical dilation that

occurs with estrus. Bacteria found in healthy uteri and the uteri of bitches with pyometra are representative of the normal microflora of the vagina and cervix. The most common bacteria isolated in cases of pyometra is *Escherichia coli*. Infusion of *E. coli* isolates obtained from bitches with pyometra into the uteri of healthy bitches resulted in the development of pyometra.[7] Certain serotypes of *E. coli* are more commonly associated with pyometra, indicating that these strains may possess increased virulence or arise from a concurrent urinary tract infection. The presence of the K antigen is common feature of *E. coli* isolates from cases of pyometra.[8] In addition, approximately 50% of *E. coli*

isolates from cases of pyometra contain cytotoxic necrotizing factor (CNF), which reduces the integrity of the endometrial epithelium. Other less common bacteria isolated from cases of pyometra include *Streptococcus sp., Enterobacter sp., Proteus sp., Klebsiella sp.,* and *Pseudomonas sp.* The mechanical irritation of bacteria within the endometrium provides a stimulus for CEH. In fact, any stimuli, from an embryo to a piece of silk thread, will stimulate local proliferation of endometrial glands and hyperplastic changes within the endometrium. In cases of mechanically induced CEH and pyometra, ER and PR expression are reduced in the surface epithelium and endometrial glands, whereas PR

expression is slightly increased in the stromal fibroblasts and myometrium.[5] This may be partly due to a loss of cellular integrity caused by damage to the endometrium or due to an increased response to progesterone, which naturally causes down-regulation of the two receptor types.

Histologic criteria and gross pathologic lesions for CEH have been categorized into five groups in an effort to classify the disease based on severity.[9] Bitches in group 1 have a slightly enlarged and rounded uterus and a histologic diagnosis of endometrial hyperplasia without endometritis. Bitches in group 2 have enlargement of the uterus less than or equal to 3 cm in diameter and

a histologic diagnosis of hyperplastic endometrium with irregular cysts. Bitches in group 3 have enlargement of the uterus and uterine horns greater than or equal to 7 cm and histologic lesions consisting of a roughened endometrial surface, cysts, and endometrial ulceration. Group 4 animals are subdivided depending on the patency of the cervix. Bitches in group 4 with an open cervix (group 4A) have enlargement of the uterus and uterine horns less than or equal to 3 cm with histologic evidence of endometrial fibrous, hypertrophic myometrium and cysts. Bitches in group 4 with a closed cervix (group 4B) have enlargement of the uterus with thinning of the uterine wall and a

histologic diagnosis of atrophic cysts within the endometrium and myometrium.

De Bosschere and colleagues developed a histomorphometric classification for CEH-pyometra.[10] CEH can be categorized as mild or severe based on the number of cysts and the percentage of the uterus affected. CEH is recognized by an increased endometrium-to-myometrium ratio. Pyometra is distinguished from CEH by the presence of inflammatory exudate. Pyometra can be categorized as hyperplastic or atrophic. In hyperplastic pyometra, a severe inflammatory reaction exists, and more than 25% of the endometrium is

occupied by luminal endometrial glands. Many large cysts are present, with an increase in endometrium-to-myometrium ratio and moderate fibroblast proliferation. With atrophic pyometra, a severe inflammatory reaction also exists, but no cysts are present, the endometrium-to-myometrium ratio is decreased, and no fibroblast proliferation occurs.

The clinical signs of pyometra include vaginal discharge (80%), fever (47%), polydipsia, polyuria, and vomiting.[11] Other symptoms include lethargy and anorexia. Uterine exudate in the form of vaginal discharge may be purulent, mucoid, or hemorrhagic. Many clinical signs of pyometra result from the

effects of bacterial toxins. Neutrophilia is a common hematologic finding, ranging from 15,000 to 60,000 cells/ml. Hyperproteinemia and hyperglobulinemia may occur secondary to dehydration and antigenic stimulation. Impaired renal function (hyposthenuria and proteinuria) results from *E. coli* lipopolysaccharide endotoxin on distal convoluted tubules and collecting ducts causing insensitivity to antidiuretic hormone. Cytotoxic necrotizing factor positive *E. coli* will also cause hepatocellular damage and/or hypoxia owing to dehydration and decreased circulation resulting in increased aspartate transaminase (AST) and alanine transaminase (ALT).

Diagnosis of CEH-pyometra is made by clinical signs, abdominal palpation of an enlarged uterus, hematologic and biochemical results, and radiographs or ultrasonography revealing uteromegaly. Ultrasonography is particularly useful as it can be used to evaluate endometrial integrity, uterine wall thickness, uterine distention (Figure 76-1) and the presence of cystic endometrial glands. In CEH without pyometra, endometrial glands are increased in size and number, appearing as 1- to 2-mm anechoic areas within the endometrium.[11] Subclinical CEH has also been identified in queens using fluoroscopy and scintigraphy, with hysterograms showing a corkscrew appearance to

the uterus with irregular filling defects in the lumen.[12] It is important to note that the corkscrew appearance is normal for diestrus in both queens and bitches (Figure 76-2). When fluid in the uterus is detected, pyometra may be differentiated from CEH with mucometra by measuring circulating prostaglandin-F metabolites (PGFM). Concentrations of PGFM $\geq$ 3054 pmol/l, $\geq$ 2388 pmol/l, or $\geq$ 1666 pmol/l indicate a 95%, 90%, or 80% probability of pyometra, respectively.[13] Combining PGFM results with percentage of band neutrophils present on hematologic evaluation increases the sensitivity of differentiating pyometra from mucometra to 100%. However, PGFM

determination is not clinically available.

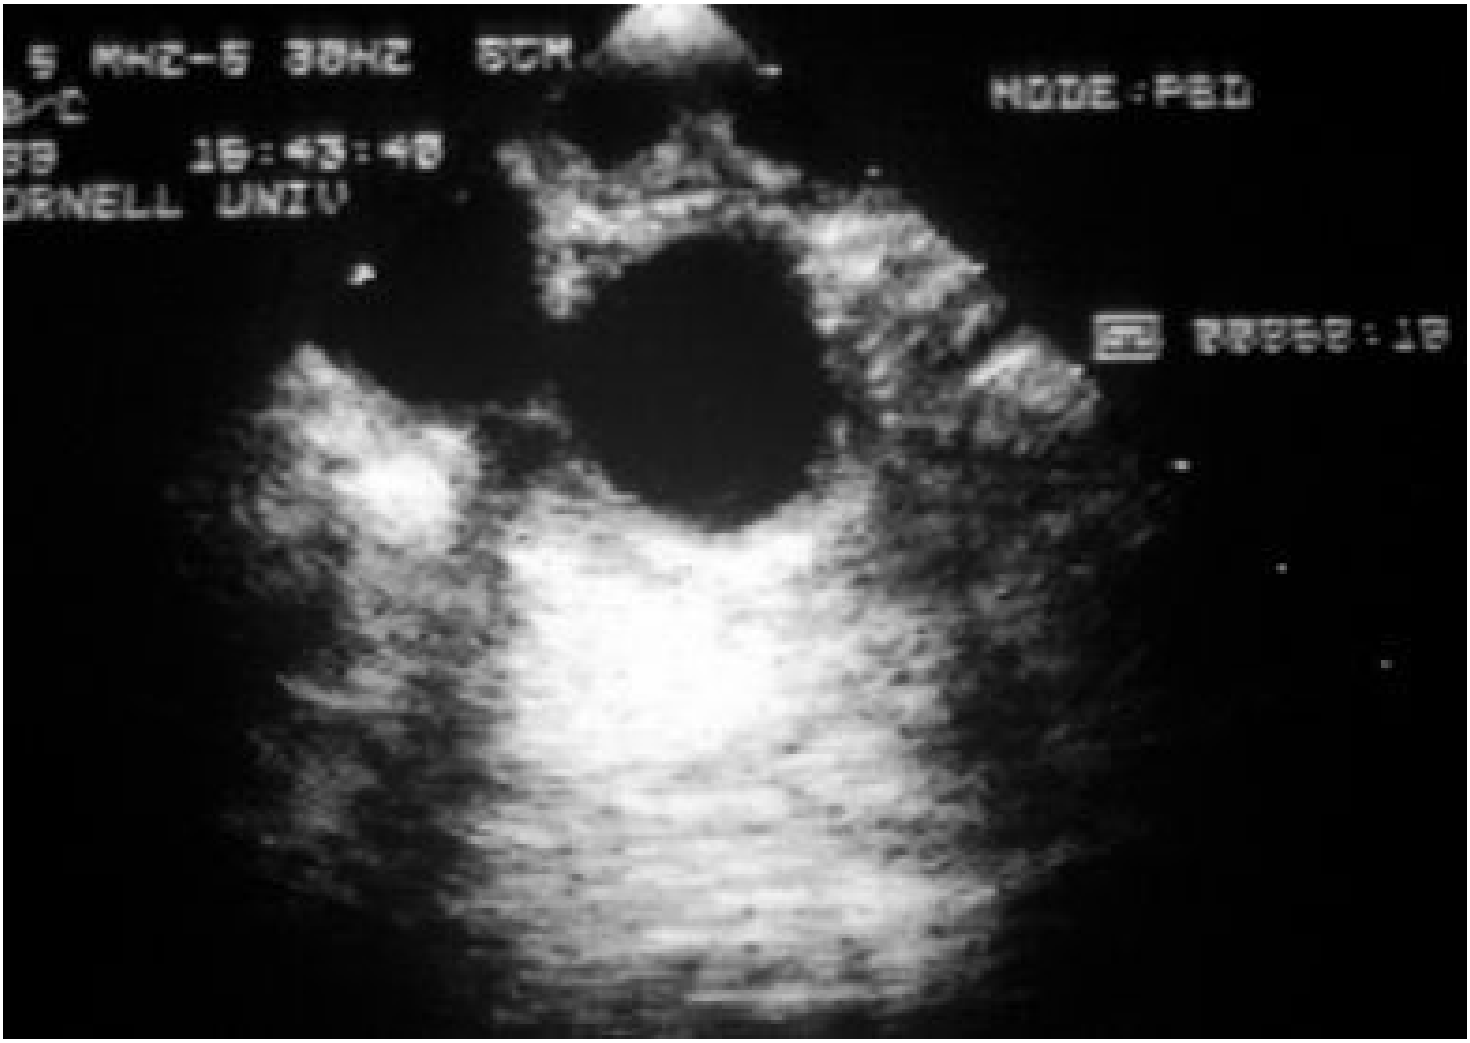

Figure 76-1. Anechoic intraluminal fluid distension of several loops of uterine horn in a bitch with a pyometra.

The recommended treatment for pyometra in most bitches and queens is

ovariohysterectomy. Prior to surgery, the patient should be stabilized, especially if endotoxemia is present. For less severe cases of pyometra in animals intended for breeding, patients can be treated medically with $PGF_{2\alpha}$ and systemic antibiotics. Prostaglandin $F_{2\alpha}$ causes myometrial contractility, which expels the luminal contents. It also causes luteolysis, which decreases progesterone concentrations. Side effects of $PGF_{2\alpha}$ are associated with the dose administered and include panting, salivation, anxiety, vomiting, diarrhea, urination, abdominal contractions, and ataxia within 15 minutes of administration. Side effects may last for up to 120 minutes. Therapeutic

regimens using high dosages of $PGF_{2\alpha}$ with infrequent treatment schedules are associated with the most severe side effects and least effective treatments. It is important to remember that the therapeutic index for $PGF_{2\alpha}$ in dogs is narrow, with a lethal dose of 5.13 mg/kg for dinoprost (natural $PGF_{2\alpha}$). Low doses (0.01-0.10 mg/kg) of $PGF_{2\alpha}$ administered subcutaneously every 2 to 4 hours until complete uterine evacuation and luteolysis have occurred is a highly effective treatment. Tolerance, in the form of fewer side effects, develops after repeated treatments. In addition, most side effects of $PGF_{2\alpha}$ can be avoided if it is administered

intravaginally. $PGF_{2\alpha}$ administered at a dose of 0.15 mg/kg in an intravaginal infusion every 12 hours for up to 12 days effectively alleviated the disease in 9 of 11 bitches treated.[14] Meyers-Wallen and coworkers reported that 40% of bitches treated for pyometra produced a litter within 1 year after treatment.[15] However, case selection for medical treatment is critical as bitches categorized in Dow's group 3 or 4 had a 40% recurrence rate of pyometra during the first post-treatment diestrus. Of treated bitches, 77% will redevelop pyometra within 27 months post-treatment.

Figure 76-2. Corkscrew appearance of the diestrus uterine horns in a queen during a routine ovariohysterectomy surgery.

Mucometra

Mucometra can occur as a sequela of CEH and as a precursor to pyometra. Glandular hyperplasia causes accumulation of mucoid or serous fluid in the uterine lumen. Mucometras typically are incidental findings at ovariohysterectomy in clinically

normal bitches. Diagnosis is made using ultrasonography and hematologic evaluation. Treatment for bitches not intended for breeding is ovariohysterectomy. Medical treatment for bitches intended for breeding and with mild forms of CEH is similar to that for pyometra.

Uterine Stump Pyometra

Uterine stump pyometra has a similar pathogenesis as pyometra with the exception that the patient was previously believed to have had the uterus and ovaries completely removed. In patients with a uterine stump pyometra, remnants of ovarian tissue with a variable amount of

uterine tissue have been left behind following ovariohysterectomy (OHE).[16] The clinical signs are similar to CEH-pyometra and include vulvar discharge, depression, and anorexia. Diagnosis is made by retrograde vaginography and ultrasonography that reveal single or multiple fluid-filled areas adjacent to the bladder. Treatment involves surgical resection of all remaining uterine and ovarian tissue. Simultaneous vaginopexy should be performed as a higher incidence of post-surgical urinary incontinence resulting from pelvic adhesions has been reported following this condition.

Uterine Neoplasia

Uterine neoplasia is uncommon in the bitch. Reported incidences for reproductive tract tumors range from 1% to 19%.[16] Uterine neoplasia occurs most commonly in bitches older than 10 years with no established breed predisposition. The most common benign uterine neoplasia is a leiomyoma. Uterine leiomyoma often exists without clinical signs and is an incidental finding during routine OHE. Other benign uterine tumors reported include fibroma, fibroleiomyoma, fibromyoma, fibroadenoma, adenoma, lipoma, angiolipoleiomyoma, and endometrial polyps. Malignant uterine tumors reported in the dog include adenocarcinoma, endometrial carcinoma, lymphosarcoma,

hemangiosarcoma, metastatic transmissible venereal tumor, and metastatic dysgerminoma. The clinical signs of malignant uterine adenocarcinoma include a bloody or purulent vaginal discharge, dysuria, hematuria, lethargy, anorexia, and abdominal distention. Presumptive diagnosis is based on clinical signs and radiographic and ultrasonographic findings. A definitive diagnosis requires excisional biopsy with histopathologic evaluation. The treatment for all uterine neoplasms is ovariohysterectomy. The prognosis depends on the degree of local invasion and the presence of metastasis.

Uterine neoplasia is also rare in the queen. One survey of 4402 neoplasms in cats found that only 13, or 0.29%, involved the uterus.[17] In this study, the age at diagnosis ranged from 3 to 16 years (median age nine years). Among cats with uterine neoplasia, more than half are purebred. However, the over-representation of purebred cats is likely owing to an increased proportion of intact purebred queens. The most common uterine neoplasias reported in queens are leiomyomas, leiomyosarcomas, and adenocarcinomas. Concurrent mammary adenocarcinomas have been reported with cases of uterine leiomyoma and adenocarcinoma. The presenting clinical signs of queens with

uterine neoplasia are variable and ranged from asymptomatic with incidental discovery at ovariohysterectomy, to infertility, weight loss, palpable abdominal mass, stranguria, hematuria, constipation, pyometra, lethargy, anorexia, and malodorous vaginal discharge. By the time of diagnosis, half of the queens with uterine adenocarcinoma had metastases and few lived longer than five months following ovariohysterectomy.

Surgical Disease of the Vulva and Vagina

Beverly J. Purswell
Kara A. Kolster

Anatomy

The vulva is the external portion of the reproductive tract. The vertical opening of the vulva is formed by the labia or lips, which meet at the dorsal and ventral commissures. The clitoris, a homolog of the male penis, lies within the clitoral fossa just inside the

ventral commisure of the vulva.

The vestibule lies dorsal and cranial to the clitoral fossa, and opens to the exterior at the vulva. The vestibule is oriented dorsally and turns 90° to horizontal as it clears the ishial arch. The urethral tubercle containing the external urethral orifice lies on the ventral floor of the vestibule, near the vaginovestibular junction. The portion of the tubular tract caudal to this point is shared by the reproductive and urinary systems. Lymph nodules are present in the subepithelial tissue of the vestibule, particularly in the area opposite the urethral tubercle.

The vagina extends from the vestibule

to the external cervical os. It is highly distensible except for the portion immediately surrounding the cervix. There is extensive longitudinal folding of the vaginal mucosa. A dorsal longitudinal fold is present leading toward the cervix. The external cervical os projects ventrally into the vaginal lumen and is undercut by a ventral fornix.

Vaginal Examination

Inspection of the vaginal tract is made through the vulva. It should begin with visual inspection of vulvar conformation, perivulvar skin, and labia. The size and turgidity of the vulva should be related to the stage of

estrous cycle. The presence and character of any discharge should be noted. The clitoris and vaginal mucosa are examined by parting the labia. The normal clitoris is relatively small and has a mucosal surface. The mucosa should appear smooth and pink along the entire length of the tract.

The cranial vestibule and caudal vagina can be examined visually and digitally. Visual inspection is aided by use of an otoscope or vaginal speculum. Digital examination with a lubricated, gloved finger is necessary to evaluate the texture of the mucosa and identify physical abnormalities such as vaginal bands or strictures. Irritation of the vestibular mucosa

leads to hyperplasia of the subepithelial lymph nodules, which is identified as a “sandpaper” texture to the mucosa.

Vaginoscopy is necessary for visual evaluation of the cranial vagina. The vaginal mucosa is edematous during proestrus. Edema decreases and the folds become angulated as estrogen levels fall and progesterone levels increase during estrus. Mucosal pallor increases during estrus. The cervix protrudes into the vagina and is directed ventrally. It is differentiated from the surrounding vaginal folds by its characteristic cobblestone appearance. The external os is located in the midst of the cobblestones. If

vaginoscopy is performed during estrus, serosanguinous discharge can be seen discharging from the external os. At the onset of diestrus and throughout diestrus and anestrus, the vaginal folds are flattened. A longitudinal striped appearance is apparent in early diestrus.

Exfoliative vaginal cytology is a useful technique to examine the vagina and determine the nature of vaginal conditions and discharges. Vaginal cytology can determine the presence or absence of estrogen influence and inflammation. Estrogen influence is evidenced by a large percentage of cornified squamous epithelial cells, usually more than 50%. Inflammation

is indicated by the presence of large numbers of degenerate and nondegenerate neutrophils. The only exception to this is early diestrus when large numbers of nondegenerate neutrophils are considered normal. This technique is useful in identifying the stage of the estrous cycle and as a diagnostic tool for vaginal discharges.

Episiotomy

Episiotomy is indicated to provide better exposure of the vestibule and distal vagina in conjunction with other surgical procedures. A vertical incision is made from the dorsal commissure directly on the midline to extend the vulvar opening and provide increased

exposure to pelvic tissues that are not accessible via laparotomy.

Episioplasty

Episioplasty is a reconstructive procedure that is indicated when the vulva is concealed by redundant perivulvar skin.[1-3] Turbulent urine flow and moisture retention lead to recurrent perivulvar pyoderma, vaginitis, vestibulitis, and urinary tract infections. The condition is commonly seen in bitches spayed prepubertally that have a juvenile vulva that is recessed within skin folds. In episioplasty, excess skin is removed dorsally and laterally to expose the vulva (Figure 77-1). If vaginal

discharge is present and not completely resolved by surgery, estrogen therapy may be considered. Treatment with estrogen thickens the vaginal epithelium, thus helping to resolve the chronic inflammation. Fatal bone marrow suppression is a risk of chronic estrogen use; therefore, low-dose therapy is used and tapered off over time, thus identifying the lowest effective dose. Weight loss is recommended prior to surgery in obese patients. Weight gain following surgery may cause the redundant skin fold to recur.

Vaginal Fold Prolapse (Vaginal Hyperplasia)

Vaginal fold prolapse results from an individual's exaggerated response to estrogen stimulation during estrus.[2,4,5,6] Historically, this condition has been referred to as vaginal hyperplasia, which is a misnomer. Occurring only during proestrus and estrus, the vaginal epithelium thickens normally owing to the effect of estrogen, a protective mechanism for the vagina during copulation. In cases of vaginal fold prolapse, the protruding mass has pronounced edema in the underlying tissues overlaid by multiple layers of cornified squamous epithelial mucosa, thus leading to the description of hyperplasia. With vaginal fold prolapse, a mass can be observed when

the vulvar lips are parted or it can be seen protruding from the lips of the vulva. The tissue involved usually originates from the vaginal floor cranial to the urethral papilla. The vaginal lumen is dorsal to the mass, which differentiates vaginal fold prolapse from vaginal prolapse, which usually presents as a circular doughnut-shaped mass. Biopsy shows hyperplastic, cornified epithelium characteristic of estrus. The mass usually regresses spontaneously following estrus but recurrence rates during subsequent estrous cycles is high. In some cases the mass is present throughout diestrus or pregnancy. Permanent resolution is achieved by ovariohysterectomy. Surgical removal

of the protruding mass is indicated if it is large or if extensive mucosal damage is present.[4,6] The external urethral orifice should be identified on the ventral aspect of the mass and catheterized to prevent damage during surgery. Approximately 25% of surgical cases recur in animals that have not had ovariohysterectomy. Potential complications include dysuria if the weight of the mass impinges on the urethra or if urethral damage occurs during surgery. Vaginal fold prolapse is most commonly seen in young, brachycephalic, and large breed dogs. Breeding of affected dogs is not recommended as the condition may be hereditary.

Figure 77-1. Postsurgical appearance of the vulva after episioplasty as treatment for chronic urinary tract infections and perivulvar inflammation. (From Textbook of Veterinary Internal Medicine, 6th ed. Ettinger SJ, Feldman EC (eds). Philadelphia: Elsevier, 2005, p.1689, with permission from the publisher.)

Vaginal Prolapse

Vaginal prolapse is less common than

vaginal fold prolapse. It is identified as a doughnut-shaped eversion of the entire vaginal circumference, with the vaginal lumen in the center. Prolapse typically occurs during estrus or parturition, when excessive straining occurs in the presence of relaxed perivulvar tissue. It may occur as a result of forced separation of a copulatory tie, protracted labor, or constipation. It is heritable and is most common in brachycephalic breeds. Surgical correction consists of reducing the prolapse. Resection may be necessary if significant tissue damage is present. Episiotomy, manual compression to reduce edema, and traction on the uterus through a ventral midline incision may aid

reduction. Reduction is maintained in the immediate postoperative period by placing nonabsorbable sutures across the labia. Cervipexy may decrease the incidence of recurrence. This is accomplished by tacking the cervix to the prepubic tendon. Care must be taken not to involve the urethra.

Vaginal Tumors

Vaginal tumors in the bitch are typically benign.[7] The common signalment is an older, intact female with a history of straining to urinate and defecate, vulvar discharge, or a mass protruding from the vulva. The most common tumor types are leiomyomas, fibromas, lipomas, and

transmissible venereal tumors (TVT). TVT can metastasize via lymphatics or be spread to the mouth by licking. Malignant leiomyosarcomas are seen rarely. Intraluminal tumors are usually pedunculated and may protrude from the vulva. These can typically be excised. Extraluminal tumors may cause bulging of the perineum. Extensive dissection may be required to remove extraluminal masses. TVT is most common in free-roaming dogs. Some TVTs can regress spontaneously after several months. Multiple masses are common and complete excision is difficult. Recurrence is common unless the tumors are also treated with radiation and chemotherapy. Chemotherapy with vincristine (0.025

mg/kg, IV, weekly, for 2-8 treatments) is considered the treatment of choice. Debulking of the tumor(s) may assist in therapy.

Clitoral Enlargement

Clitoral enlargement occurs owing to abnormalities of sexual differentiation (male pseudohermaphrodism), exposure to exogenous androgens, or excess sex hormone production secondary to hyperadrenocorticism (Figure 77-2). The bitch may present for excessive licking of the vulvar area, reluctance to sit, vulvar discharge, or appearance of a mass protruding from the vulva. An os clitoris may be present in cases of abnormal sexual

differentiation. Friction between the enlarged clitoris and vulva may cause inflammation and vaginitis. The tissue may also be traumatized from exposure if it protrudes from the vulva. Surgery is indicated if the enlarged clitoris is causing clinical signs or if an os clitoris is present. The clitoris will not regress with removal of androgen influence if an os clitoris is present. Accurate location of the urethra is critical prior to surgery.

Trauma

Trauma to the vulva and vagina may occur as a result of dogfights, breeding injuries, attempts to disrupt a coital tie, dystocia, malicious acts, or be

iatrogenic. Lacerations are usually longitudinal. Contusions or puncture wounds may also occur. Treatment is usually not necessary for minor injuries. Surgical correction is indicated for large lacerations or puncture wounds. Estrual bitches should be confined to prevent mating and reinjury.

Figure 77-2. Clitoris of a male pseudohermaphrodite, showing penis-like anatomy. (From Textbook of Veterinary Internal Medicine, 6th ed. Ettinger SJ, Feldman EC (eds). Philadelphia: Elsevier, 2005, p.1689, with permission from the publisher.)

Developmental

Abnormalities

A variety of congenital developmental abnormalities may occur that partially obstruct the vagina or vestibule and require surgical correction, especially in breeding animals. The paired müllerian (paramesonephric) ducts fuse embryologically to form the tubular reproductive tract in the female. The urogenital sinus fuses with the ducts and develops into the vestibule. The hymen forms at the vaginovestibular junction. Congenital abnormalities arise from incomplete fusion of these embryologic structures or from incomplete perforation of the hymen. Abnormalities manifest as vertical bands or circumferential

strictures and most commonly occur in the area of the vaginovestibular junction. The true incidence of congenital vaginal abnormalities is unknown because many cases are asymptomatic until breeding is attempted. Vaginal bands and strictures cause partial obstructions that can prevent natural mating and/or whelping. Other possible signs include chronic vaginitis and vulvar discharge. Digital examination, vaginoscopy, and contrast vaginography are useful diagnostic tools. Vertical bands can be small enough to break down digitally or may be thicker and require surgical resection (Figure 77-3). Strictures can be dilated or surgically resected but

scarring and recurrence are common. Partial vaginectomy has been reported as the most successful procedure for resolving clinical signs.

Figure 77-3. An instrument is used to demonstrate a large dorsoventral vaginal septum. The urethra is catheterized and an episiotomy increases surgical exposure.

Chapter 78

Mammary Gland Disorders of the Dog and Cat

Mitch Robbins

Mammary Gland Anatomy

The mammary glands are highly modified and enlarged sweat glands. The gland itself consists of epithelial glandular tissue, and the supporting connective tissue.

Although the number and location of mammary glands is variable, most

dogs will have 5 bilaterally symmetric pairs. The glands are named based on their location as: cranial thoracic, caudal thoracic, cranial abdominal, caudal abdominal, and inguinal. Most cats will have 4 bilaterally symmetric pairs of glands (cranial and caudal thoracic, abdominal, and inguinal).[1,2]

Blood supply to the individual mammary glands is based on location. The thoracic glands receive their primary arterial supply from the perforating sternal branches of the internal thoracic artery. Abdominal and inguinal glands are supplied by mammary branches of the epigastric arteries. The cranial superficial epigastric artery is located at the level

of the costal arch. It supplies the cranial abdominal gland and joins the caudal superficial epigastric artery. The caudal superficial epigastric artery is a branch of the pudendal artery. It runs cranially under the inguinal mammary gland to supply the inguinal gland and the caudal abdominal gland. Cranial to this, it joins the terminal branches of the cranial superficial epigastric artery.[1]

Lymphatic drainage of the mammary glands is bilaterally symmetric and is variable. The cranial thoracic glands drain directly to the axillary node. The inguinal gland drains directly into the inguinal lymph node. Drainage of the caudal thoracic and abdominal

mammary glands can be to either or both the inguinal or axillary lymph nodes. Communication between left and right sides has also been documented.[3]

Disorders of the Mammary Gland

Pseudopregnancy

Pseudopregnancy is a normal physiologic syndrome seen during diestrus in nonpregnant bitches; usually occurring 6 to 8 weeks after estrus. Clinical signs associated with pseudopregnancy include behavioral changes (nesting and maternal behavior) as well as physical changes (weight gain, mammary enlargement,

lactation, and contractions). The cause of pseudopregnancy is thought to be the rapid decrease in serum progesterone that stimulates synthesis and secretion of prolactin. Some nonpregnant bitches may be more sensitive to prolactin, causing an exaggerated response and leading to marked mammary gland enlargement and lactation.[4]

Bitches that present with exaggerated pseudopregnancy may be treated conservatively if the signs are mild. Pseudopregnancy is self-limiting and signs will usually subside within 3 weeks. An Elizabethan collar can be used to decrease mammary gland stimulation.

If a more aggressive therapy is necessary, treatment with prolactin inhibitors has been reported.[5,6] Cabergoline was used at a dose of 5 μg/kg orally once daily for 5 to 7 days or as a subcutaneous injection at a dose of 1.5 to 5 μg/kg every 48 hours for 2 to 3 treatments. The outcome of treatment was successful, with 95% to 100% of cases having resolution of mammary swelling and lactation within 5 to 7 days of the start of administration.[5,6] The most common side effects were vomiting, lethargy, and anorexia. Other prolactin inhibitors that have been used to treat pseudopregnancy include bromcriptine 10 to 100 mg/kg/day for 10 to 14 days and metergoline 0.2 mg/kg/day for 8

to 10 days.[4]

While ovariohysterectomy is the treatment of choice for the long-term prevention of pseudopregnancy in bitches that are not intended for breeding, its use as a primary treatment for pseudopregnancy is not advocated.[4] Ovariohysterectomy will lead to a sudden and severe decrease in progesterone levels and can exacerbate the rapid increase in serum prolactin concentration. For this reason, many surgeons will delay ovariohysterectomy for several months after estrus.

Mastitis

Mastitis is uncommon in lactating bitches. Patients will present to the veterinarian with systemic clinical signs such as lethargy, anorexia, and mammary gland pain of variable intensity. Diagnosis is based on history and physical examination findings of a large, swollen, hot, and painful mammary gland. Culture and sensitivity tests are helpful in identification of specific pathogens. *Escherchia coli*, beta-hemalytic streptococci, and staphylococci are most common.[4] Although antibiotic therapy (ampicillin or oxacillin[4]) are usually effective treatments, occasionally, severely infected glands may become necrotic and require surgical debridement.

In some cases, swollen, enlarged, and painful mammary glands can arise from nonseptic inflammation and milk stasis. Often, this will follow acute weaning of puppies from an actively lactating bitch. Treatment may be either to reintroduce the puppies to nursing or to try to stop lactation.[4] Surgery is not necessary for these patients because there is no progression to abscessation and necrosis of the glands.

Mammary Gland Neoplasia

Canine Mammary Gland Tumors

Mammary gland tumors are among the most common tumors in female dogs.

The average age for the development of mammary gland neoplasia is 8 to 10 years, with young dogs having a higher incidence of benign tumors.[7] Several factors have been shown to increase the risk of mammary gland tumor formation. These factors include obesity at 1 year of age, obesity 1 year prior to the diagnosis of the mammary gland tumors, intake of home-made versus commercial diets,8 and ovariohysterectomy.[9]

The influence of female hormones has been well established. Ovariohysterectomy at a young age reduces the risk of development of mammary gland tumors. Compared with an intact female dog, the risk of

developing mammary gland tumors in a dog that has an ovariohysterectomy before the first heat cycle is 0.05%. That risk increases to 8% if the ovariohysterectomy is performed after the first heat cycle and 26% if the ovariohysterectomy is performed after the second heat cycle. There is no protective benefit if ovariohysterectomy is performed after the third heat cycle.[9]

The presence of estrogen and progesterone receptors in canine mammary tumors has been established. Almost 100% of normal canine mammary tissue contains receptors for progesterone and estrogen. These receptors are found on 70% of benign

mammary tumors and 50% of malignant mammary tumors.[10]

Tumor Types and Behavior

Approximately 50% of mammary tumors in dogs are benign. Benign tumor types include fibroadenomas, benign mixed tumors, simple adenomas, and benign mesenchymal tumors.[11]

The most common malignancies (the other 50% of tumors) are carcinomas (solid carcinoma, tubular adenocarcinoma, papillary adenocarcinoma, and anaplastic carcinoma).

Sarcomas comprise approximately 10%

of malignancies. Reported sarcomas include osteosarcoma, fibrosarcoma, and osteochondrosarcoma. Extraskeletal osteosarcoma commonly occurs in the mammary gland. These osteosarcoma are typically seen in older female dogs. The reported metastatic rate for mammary gland osteosarcoma is 63% with a median survival of 90 days.[12]

Mixed malignant mammary gland tumors have histologic characteristics of mesenchymal and epithelial cell origin. They comprise approximately 8% of malignancies and behave similarly to carcinomas.

Inflammatory mammary gland tumors

are rare in dogs. Inflammatory mammary gland tumors are characterized by rapid growth, edema, erythema, and firmness and warmth of the tissue. Inflammatory mammary gland tumors must be differentiated from inflammatory and infectious diseases of the mammary gland. Fine-needle aspirate of inflammatory mammary gland tumors is usually suggestive of carcinoma. Prognosis for patients with inflammatory mammary gland tumors is poor. Distant metastasis is often present at the time of diagnosis and hemostatic abnormalities consistent with disseminated intravascular coagulation are present in 30% of patients.[13]

Diagnosis and Clinical Staging

Patients with mammary tumors may present to the veterinarian with clinical signs referable to the mass(es) in the mammary chain or signs related to lymphatic obstruction or metastasis.

Biopsy with histopathologic evaluation is the most accurate method of diagnosis of canine mammary tumors. Fine-needle aspiration is discouraged owing to the insensitivity of cytology to differentiate malignant from benign tumors.[14]

Staging of patients with mammary tumors should always include thoracic

radiographs and a minimum data base of information including complete blood count, serum chemistry profile, and urinalysis. Nuclear bone scans may be helpful in the identification of dogs with osseous metastasis. Pulmonary metastasis may be present in up to 50% of patients with malignant mammary tumors. When present, pulmonary metastasis may appear as well define nodules (64%), as poorly differentiated interstitial nodules (18%), or as pleural effusion with no evidence of pulmonary lesions (18%).[15,16]

Treatment

Treatment can ensue once a histologic

diagnosis has been obtained and staging has been performed. Surgery is the first line of treatment for mammary tumors. Effective surgical planning requires knowledge of anatomy, vascular and lymphatic supply, and the behavior of the tumor being treated.

In canine patients, surgical dose has not been associated with improved survival,[17] but has theoretical implications based on lymphatic drainage for invasive tumors. Options for surgical treatment include simple lumpectomy, mammectomy, regional mastectomy and radical mastectomy.

Performing ovariohysterectomy

concurrent with the removal of mammary gland tumors in intact females is controversial. In two studies, concurrent ovariohysterectomy improved survival 45%;[11,18] however, other studies indicate no difference in survival.[17,19]

Prognosis

Several prognostic indicators have been identified in canine mammary gland malignancy (Table 77-1). Among these are tumor size, tumor fixation to underlying tissue, skin ulceration, tumor type, tumor grade, evidence of vascular or lymphatic invasion, lymphoid infiltration into the tumor, lymph node involvement, and the

presence of estrogen or progesterone receptors.[20]

Feline Mammary Gland Tumors

Mammary gland tumors are the third most common cancer in cats.[21] Of mammary gland tumors in cats, 80% are malignant (adenocarcinoma), 25% of cats have ulcerated masses, and more than 50% have more than one gland involved. More than 80% of cats with mammary cancer will develop metastasis; 49% of cats have lymph node metastasis.[22]

Prognosis for cats with mammary gland carcinoma is dependent on

tumor size. Overall median survival is approximately 12 months. Cats with tumors less than 2 centimeters in diameter have a median survival of 2 years. Cats with tumors between 2 and 3 centimeters have a median survival of 2 years. Cats with tumors larger than 3 centimeters have a median survival of 6 months. Cats with histologically well differentiated tumors with no evidence of lymphatic invasion have a better prognosis than those with higher grade tumors.[22]

Table 78-1. Prognostic Factors in Canine Mammary Gland Cancer

Tumor Size		
	> 3cm diameter	30% recurrence
	> 3cm diameter	85% recurrence
Fixation to underlying skin or skin ulceration		Poorer prognosis
Grade/differentiation		
	Low grade	20% recurrence
	High grade	80% recurrence
Lymphoid infiltration into tumor		Better prognosis
Histologic type		
		Sarcomas worse than carcinomas
		Mixed same as carcinomas
Lymph node status	No histologic metastasis	20% recurrence
	Histologic metastasis	80% recurrence
Histologic evidence of lymphatic or vascular invasion		Poorer prognosis
Progesterone/estrogen receptors		Better prognosis

Surgery is the most effective means of treatment of feline mammary tumors. Radical mastectomy is recommended to decrease the chances of local recurrence. Local recurrence with conservative surgery is 66%.[22]

Feline Mammary Fibroadenomatous Hyperplasia

Fibroadenomatous hyperplasia is an

important differential diagnosis for mammary gland neoplasia in cats. Fibroadenomatous hyperplasia is a progestogen-dependent ductal hyperplasia. While the most common occurrence is in intact young female cats within 2 weeks of estrus, it has been reported in male and spayed female cats after treatment with megesterol acetate.[23] Clinically, cats present with large, red, and swollen mammary glands. Although most cases will respond to ovariohysterectomy or resolve spontaneously within 4 to 6 weeks, there have been reports of the use of the prosterone antagonist aglepristone for the treatment of cats with fibroadenomatous hyperplasia that does not respond to

ovariohysterectomy. Aglepristone was used at a dose of 10 to 20 mk/kg in variable frequency (1 to 2 times weekly). With this treatment, tumor regression was rapid in all cats within 1 to 2 weeks. Pregnant cats had a high tendency to abort and develop endometritis.[24,25]

Part XI

Endocrine System

Chapter 79

Diseases of the Thyroid Gland

Janet R Kovak

Anatomy

The thyroid glands are paired lobular glands lying adjacent to the tracheal rings, connected by an isthmus in the dog but independent in the cat. The normal size of each thyroid gland in the dog is approximately 2 cm x 1 cm x 0.5 cm and approximately 2 cm x 0.5 cm x 0.3 cm in the cat.[1,2] The blood supply varies slightly between the two

species. The blood supply in the dog is derived from the cranial and caudal thyroid artery; the cat thyroid lobes are supplied solely from the cranial thyroid artery. Venous drainage is via the cranial and caudal thyroid veins. Efferent lymphatic drainage in the dog is into the cervical lymphatic trunk or internal jugular vein.[2] Ectopic thyroid tissue can be present anywhere along the cervical region to the base of the heart.[1]

Thyroid Hormone Metabolism

The thyroid gland regulates basal metabolism. Two molecules, tyrosine and iodine, are important for thyroid

hormone synthesis. Tyrosine is a part of a large molecule (MW 660,000) called thyroglobulin, which is formed within the follicle cell and secreted into the lumen of the follicle. Iodine is converted to iodide in the intestinal tract and transported to the thyroid where the follicle cells trap the iodide through an active transport process. The tyrosyl ring can accommodate two iodide molecules: if one iodide attaches, it is called monoiodotyrosine (MIT), if two iodide molecules attach to the tyrosyl ring, it is called diiodotyrosine (DIT). The coupling of two iodinated tyrosines results in the formation of the main thyroid hormones. Two DIT molecules form tetraiodothyronine (T_4), whereas one

MIT coupled with one DIT molecule forms triiodothyronine (T_3). Thyrotropin, or thyroid stimulating hormone (TSH), is the most important regulator of thyroid activity. TSH secretion is regulated by thyroid hormones by way of negative feedback inhibition of the synthesis of thyrotropin releasing hormone (TRH) at the level of the hypothalamus and by inhibition of the activity of TSH at the level of the pituitary.

Thyroxine (T_4) is the major storage form of thyroid hormone, whereas T_3 is the active form of the hormone. The majority of T_3 formation occurs outside of the thyroid gland by the deiodination of T_4. Another type of T_3

is formed when an iodide molecule is removed from the inner phenolic ring of T_4. This compound is called reverse T_3 and has few of the biologic effects of thyroid hormones. Reverse T_3 increases in non-thyroidal illness and is responsible for the decrease in total serum T_4 (T T_4) seen in "euthyroid sick" syndrome. As for all lipid soluble hormones that are transported in plasma, T_3 and T_4 are bound to plasma proteins. The amount of thyroid hormone that is free in plasma is remarkably low, e.g., in dogs, the amount of free hormone is a little less than 1.0% for T_4 and slightly greater than 1.0% for T_3.[2-4]

Canine and Feline Hypothyroidism

Primary canine hypothyroidism is the most common cause of naturally occurring hypothyroidism, accounting for more than 95% of all cases.[3] The two histologic forms are lymphocytic thyroiditis or idiopathic thyroid atrophy. Congenital hypothyroidism may be caused by thyroid dysgenesis, dyshormonogenesis, T_4 transport defects, and goitrogens, or rarely, by iodine deficiency. Secondary hypothyroidism may be acquired, as in German shepherd dogs with cystic Rathke's pouch, or secondary to pituitary tumors, radiation therapy, or endogenous or exogenous

glucocorticoids.[2,5] Congenital causes of secondary hypothyroidism include hereditary TSH deficiency as observed in the giant schnauzer breed. Tertiary hypothyroidism can be acquired, for example, with hypothalamic tumors, or can be congenital as a result of defective TRH or TRH receptor defects.[5]

Feline hypothyroidism is generally iatrogenic, occurring after surgical or radioactive iodine treatment. This condition is usually transient, resolving when ectopic thyroid tissue resumes production of normal thyroid hormone concentrations.[6]

The signalment of hypothyroid dogs

carries a distinct breed predisposition, with high-risk breeds presenting as early as 2 to 3 years of age and low-risk breeds presenting at a slightly older age (4 to 6 years). Breeds predisposed to hypothyroidism include golden retrievers, Doberman pinschers, and dachshunds.[7]

Clinical Signs

Clinical signs of hypothyroidism are gradual and subtle in onset, with lethargy and obesity being most common. Owners are often not aware of the onset of signs and think that their dog is just becoming "older." Dermatologic evidence of hypothyroidism is the most common

clinical finding after lethargy and obesity. Symmetric truncal or tail head alopecia is a classic finding in hypothyroid dogs. The skin is often thickened because of myxedematous accumulations in the dermis.[5,7]

Cardiovascular signs of hypothyroidism, including bradycardia, decreased cardiac contractility, and electrocardiographic abnormalities, are rare presenting complaints.[3] Neuromuscular signs such as myopathies and megaesophagus are also uncommon manifestations of canine hypothyroidism. Neuropathies including bilateral or unilateral facial nerve paralysis, vestibular disease, and lower motor neuron disorders are

occasionally seen in hypothyroid dogs. Myxedema coma is an unusual finding in hypothyroid dogs and manifests as stupor and coma secondary to myxedematous fluid accumulations in the brain and severe hyponatremia.[4,5,7]

Diagnosis

The clinicopathologic finding of a normocytic normochromic anemia resulting from erythropoeitin deficiency, decreased bone marrow activity, and decreased serum iron and iron binding capacity may be seen in many hypothyroid dogs. Even more commonly seen is hypercholesterolemia, seen in approximately 75% of hypothyroid

dogs, owing to altered lipid metabolism, decreased fecal excretion of cholesterol and decreased conversion of lipids to bile acids.[3] Other findings include hyperlipidemia, presence of target cells, and rare mild hypercalcemia in cases of congenital hypothyroidism.[3]

Diagnosis is based on measurement of serum basal total thyroxine (T_4) and triiodothyronine (T_3) concentrations, serum free T_4 and T_3 concentrations, endogenous canine serum TSH levels, and/or dynamic thyroid function tests including the TRH and TSH stimulation tests. Variables that affect T_4 are many and include age, breed, environmental and body temperature, diurnal rhythm,

obesity, and malnutrition. Euthyroid-sick syndrome is characterized by a decrease in serum T T_4 and increase in reverse T_3 (see above). Concurrent illnesses such as diabetes mellitus, chronic renal failure (CRF), hepatic insufficiency, and infections can cause euthyroid-sick syndrome, resulting in decreases in serum T T_4 concentrations. Drugs such as anesthetics, phenobarbital, primidone, diazepam, trimethoprim-sulfas, quinidine, phenylbutazone, salicylates, and glucocorticoids can also decrease serum basal T T_4 concentrations.[3,5,7]

Free thyroid (FT) hormone concentrations, or unbound thyroxine and triiodothyronine, are used in

human medicine to differentiate between euthyroid sick syndrome and true hypothyroidism. In humans, the diagnostic accuracy of a single FT_4 measurement is approximately 90%.[8] Measurement of FT_4 concentrations is achieved by equilibrium dialysis (gold standard) or analogue immunoassays. Theoretically, FT_4 is not subject to spontaneous or drug-induced changes that occur with T T_4. Early studies, classifying dogs as hypothyroid based on TSH-stimulation tests, indicated that FT_4 by equilibrium dialysis was 90% accurate whereas other FT_4 assays (analogue assays) were no better than T T_4.[8]

With the advent of the endogenous canine TSH assay, veterinarians now have a method of assessing the thyroid-pituitary axis in dogs without dynamic testing. With thyroid gland failure, decreases in serum FT_4 and T T_4 are sensed by the pituitary gland, resulting in an increase in serum endogenous TSH concentration. As FT_4 concentration falls, a logarithmic increase occurs in serum endogenous TSH concentration making it the most sensitive test for the detection of early hypothyroidism. However, nonthyroidal disease can affect endogenous TSH concentrations as well as FT_4 and T T_4 concentrations; therefore, the use of endogenous TSH alone is not recommended as a method

of assessing thyroid function.[8,9]

Feline Hyperthyroidism

Hyperthyroidism is the most common endocrinopathy of cats. Middle-aged to older cats are typically affected, and no breed or sex predilection exists. Hyperthyroidism is characterized by hypermetabolism; therefore, polyphagia, weight loss, polydipsia, and polyuria are the most prominent features of the disease.[6] Activation of the sympathetic nervous system is also seen with hyperactivity, tachycardia, pupillary dilatation, and behavioral changes. Long-standing hyperthyroidism leads to hypertrophic cardiomyopathy, high-output heart

failure, and cachexia, which may lead to death.[2,6]

Diagnosis

Clinicopathologic features of hyperthyroidism include erythrocytosis and an excitement leukogram (neutrophilia, lymphocytosis) caused by increased circulating catecholamine concentrations. Increased catabolism of muscle tissue in hyperthyroid cats may result in increased BUN, but not creatinine.[10] Increased metabolic rate results in liver hypermetabolism; therefore, serum activities of liver enzymes increase (ALT, AST) in 80% to 90% of hyperthyroid cats. Serum cholesterol decreases, not as a result of

decreased synthesis, but rather as a result of increased hepatic clearance mediated by thyroid hormone excess.[6,10,11]

Diagnosis of feline hyperthyroidism is achieved by measurement of total serum concentrations of thyroxine (T T_4); total serum triiodothyronine (T T_3) is generally noncontributory to a diagnosis.[10,11] Because the disease has become more common and recognized in its early stages, serum free-thyroxine concentrations (FT_4) have recently been shown to be more diagnostic of early or "occult" hyperthyroidism.[8] Diagnosis may be challenging in cats with occult hyperthyroidism that demonstrate clinical signs suggestive of

hyperthyroidism (polyphagia, polyuria, polydipsia, weight loss, goiter) but who have normal (usually high-normal) T T_4 concentrations. In cases of suspected occult hyperthyroidism, dynamic endocrine testing using the T3-suppression test or the TRH-stimulation test may be beneficial.[10,12,13,14]

Treatment Options

Options for treatment of feline hyperthyroidism include oral supplementation, radioactive iodine treatment, or surgical thyroidectomy. Radioactive iodine (^{131}I) is the optimal therapy for feline hyperthyroidism. It is safe and effective with minimal side

effects or complications. Approximately 80% of cats become euthyroid within 3 months after a single treatment. Radiation safety procedures must be strictly followed.[15-17] Oral methimazole is given by supplementation daily and may be associated with side effects including anorexia, vomiting, pruritis, and uncommonly, more serious effects such as thrombocytopenia and agranulocytosis.[18] Surgical excision is a potentially definitive treatment. Patients may be high-risk candidates for anesthesia; when possible, euthyroid status is achieved prior to treatment with oral methimazole.

Surgical Techniques

Surgery is performed via a ventral midline cervical approach, and the thyroid glands are excised via an intracapsular, modified intracapsular, extracapsular, or modified extracapsular technique. A modified extracapsular approach has been associated with the lowest number of hypocalcemia-related complications. The patient should be monitored carefully after surgery for complications including hypocalcemia, hypothyroidism, and laryngeal paralysis.[2,19] Hyperthyroidism can reoccur if inadequate excision was performed or if hypertrophy of ectopic thyroid tissue exists. Recurrent disease may be treated with re-exploratory

surgery, medication, or ideally,[131] I therapy.[15]

Thyroid Neoplasia

Whereas benign adenomatous changes of the thyroid gland are most common in cats, a larger percentage of dogs have malignant disease. Although carcinoma in cats is often associated with clinical signs of hyperthyroidism, dogs have typically nonfunctional tumors.[2,4] In feline patients, treatment of thyroid carcinoma involves a combination of surgical and radioiodine therapy. Although complete excision may be curative for nonmetastatic disease, the rate of metastasis may be as high as 71%.[20]

Canine thyroid carcinoma is typically more aggressive than feline thyroid carcinoma. Of canine tumors, 90% are malignant; they are only rarely functional and associated with clinical signs associated with hyperthyroidism.[4,21] Dogs may present asymptomatically or with a palpable mass in the cervical region. Definitive diagnosis is based on histologic evaluation. Owing to the highly vascular nature of the tumor, coagulation parameters should be assessed prior to biopsy and open, rather than needle, biopsy is recommended. Ultrasound, nuclear scintigraphy, and CT scan have all been evaluated to better delineate the extent of tumor invasion.[22-24] Surgical

resection of the tumors has been associated with the best response if the mass is freely moveable, small in size, nonmetastatic, and completely resected.[25] Radiation or chemotherapy may be elected to treat masses that are incompletely resected or not amenable to resection.[26] Surgical complications include hemorrhage, damage to regional structures including the recurrent laryngeal nerve, as well as postoperative hypocalcemia or, rarely, hypothyroidism.[2,4,21,25] Long-term survival may be achieved in dogs depending on the histologic features of the tumor and whether early diagnosis is made before local invasion or metastatic spread of the disease.[21]

Chapter 80

Diseases of the Parathyroid Glands

Janet R. Kovak

The control of calcium and phosphate metabolism is vital as these ions play an important role in many physiologic processes. Calcium is necessary for intracellular reactions, including muscle contraction, nerve cell activity, the release of hormones through the process of exocytosis, and activation of numerous enzymes.[1] Inorganic phosphate also functions as an

important hydrogen ion buffering system in blood. Organic phosphate is an important part of the cell, including the plasma membrane and intracellular components including nucleic acids, ATP, and AMP. The regulation of calcium involves control of the movement of calcium between the extracellular fluid and three body organs: bone, gastrointestinal tract, and kidneys.[2]

Parathyroid Hormone

The main endocrine organ involved in the control of calcium and phosphate metabolism is the parathyroid gland. Four parathyroid glands are present in the cat and the dog. The external

parathyroid lies at the cranial-lateral pole of the thyroid gland, and the internal parathyroid gland rests medially within the thyroid parenchyma. Vascular supply to the parathyroid glands is provided via branches of the thyroid artery and vein.[3] During embryologic development, fragments of parathyroid tissue may migrate and be present ectopically in peritracheal fascia to the thoracic inlet or cranial mediastinum.[4] Parathyroid hormone (PTH), primarily an 84-amino acid, single-chain polypeptide, is synthesized, stored, and secreted by the chief cells of the parathyroid glands.[1]

The effect of PTH is to increase calcium

and decrease phosphate concentrations in extracellular fluids. PTH has direct effects on bone and kidney metabolism of calcium and indirect effects on gastrointestinal metabolism of calcium.[5] The initial effect of PTH on bone is to promote the transfer of calcium across the osteoblast osteocyte membrane. PTH acts on the distal convoluted tubules of the kidneys to increase absorption of calcium and decrease renal phosphate reabsorption through an effect on the proximal tubules. PTH is involved also in the activation of vitamin D at the kidney level. PTH mediates the absorption of calcium from the gut indirectly through its effect on vitamin D. PTH secretion is controlled by free (ionized) calcium

concentrations in blood; decreases in calcium stimulate PTH secretion, and increases in calcium turn off secretion.[1]

Hyperparathyroidism

Hypercalcemia can be caused by a variety of etiologies including hypercalcemia of malignancy, hyperparathyroidism, granulomatous disease, osteoporosis, hypoadrenocorticism, chronic renal disease, and hypervitaminosis D.[5] The initial signs of hypercalcemia are polydipsia and polyuria resulting from impaired response of distal renal tubules to antidiuretic hormone (ADH). Listlessness, depression, and muscle weakness result from depressed

excitability of neuromuscular tissue. Mild gastrointestinal signs of hypercalcemia include inappetence, vomiting, and constipation.[6] In cats, neoplasia, renal failure, and urolithiasis are the most common conditions associated with hypercalcemia.[7]

The diagnostic approach to hypercalcemia consists of ruling out the most common cause, which is hypercalcemia of malignancy. Lymphosarcoma and adenocarcinoma of the anal sac, tumors that are commonly associated with hypercalcemia, secrete a PTH-like hormone that increases bone resorption and inhibits renal tubular

reabsorption of phosphorus.[1,8] A thorough history and physical examination including lymph node and rectal examination, CBC, serum chemistry profile, urinalysis, and chest/abdominal radiographs are necessary to search for underlying neoplastic processes. Once a diagnosis of neoplasia has been excluded, the next differential for hypercalcemia is chronic renal failure. This is the most difficult to exclude because other causes of hypercalcemia may result in renal damage owing to soft tissue mineralization of the kidneys. Therefore, an animal with hypercalcemia, azotemia, and hyperphosphatemia could suffer from primary hyperparathyroidism or

primary renal failure with secondary renal hyperparathyroidism. Furthermore, patients with hypercalcemia secondary to renal disease may also exhibit elevations in intact PTH. Diagnosis of primary hyperparathyroidism is based on the findings of hypercalcemia (preferably ionized), hypophosphatemia, high-normal to elevated serum parathormone concentrations, and a mass in the cervical region. Intact PTH, using a sandwich assay validated for use in the dog and cat, should be measured.[9] It should be emphasized that a normal PTH concentration in the presence of elevated total and/or ionized calcium is "inappropriate" for the calcium level and would be

considered diagnostic for primary hyperparathyroidism. For suspected cases of hypercalcemia of malignancy in which the diagnostic approach has failed to identify a neoplastic process, PTH-related protein (PTH-rp) concentrations may be measured.[6,9]

Primary Hyperparathyroidism

Dogs with primary hyperparathyroidism may present asymptomatically or with polydipsia, polyuria, and weakness as well as with urinary tract signs attributable to urolithiasis and infection.[10-12] The most common clinical signs observed in cats with hypercalcemia are anorexia and

lethargy.[13] The majority of dogs have parathyroid adenomas or parathyroid hyperplasia with rare carcinomas reported.[14] If primary hyperparathyroidism is suspected, several imaging modalities, including ultrasonography, CT scan and scintigraphy may be utilized if a palpable neck mass is not present. Parathyroid scintigraphy has been shown to have poor sensitivity and specificity.[15] Ultrasonography may better delineate the side and size of parathyroid mass present.[16] Additionally, percutaneous ultrasound-guided techniques may be used to ablate masses. Radiofrequency as well as chemical ablation have been reported. Although these techniques

have proven to be safe and effective, the potential risk factors include hypocalcemia and laryngeal paralysis. Additionally, repeat injections may be required for successful treatment.[17,18]

Prior to surgical intervention, diuresis with normal saline may be instituted to lower serum calcium levels. For severe hypercalcemia, furosemide (in a well hydrated animal), glucocorticoid, or calcitonin therapy may be indicated.[5] Administration of glucocorticoids should be delayed until a definitive diagnosis has been made as administration may interfere with the ability to confirm lymphosarcoma histologically.[1] Bisphosphonates have been used to slow hypercalcemia in

humans; they function by inhibiting osteoclast function and viability.[19]

Surgery requires a full ventral neck exploration to evaluate both external and internal parathyroid glands bilaterally. Additionally, the whole cervical region to the thoracic inlet should be evaluated for ectopic parathyroid tissue. If all four glands are enlarged owing to parathyroid hyperplasia, excision of one to three of the glands may reduce the associated hypercalcemia.[3] Visualization of the abnormal parathyroid tissue may be aided with intravenous new methylene blue infusion, although Heinz body anemia is a risk factor of administration.[20] Patients should be

monitored postoperatively for renal failure and signs of hypocalcemia, which include panting, twitching, or tremors. Development of postoperative renal failure in dogs has been found, in one study, to be more likely to develop in dogs with a higher initial calcium level.[12] Hypocalcemia occurs in up to 58% of dogs after surgery owing to negative feedback and suppression of the remaining glands from elevated PTH levels.[14] Dogs with higher initial calcium levels ($>$ 14 mg/dl) are more likely to become clinically hypocalcemic after surgery.[1] Calcium, in the form of vitamin D (dihydrotachysterol) or calcitriol ($1,25(OH)_2D_3$), supplementation should be instituted pre- or

postoperatively and continued until calcium levels normalize over 2 to 8 weeks. Long-term prognosis after parathyroidectomy, if renal damage has not occurred, is favorable.[11-14]

Hypoparathyroidism

The classic biochemical findings in animals with hypoparathyroidism are hypocalcemia (both total and ionized) and hyperphosphatemia with an inappropriately low PTH level. Other causes of hypocalcemia include iatrogenic (post-thyroidectomy) hypoparathyroidism, chronic and acute renal failure, acute pancreatitis, hypoalbuminemia, puerperal tetany (eclampsia), ethylene glycol

intoxication, intestinal malabsorption, and nutritional secondary hyperparathyroidism.[21] The absence of PTH results in urinary calcium loss, decreased calcium mobilization from bone, and decreased intestinal absorption of calcium.[22] The majority of clinical signs are attributable to low circulating ionized calcium, leading to neuromuscular excitability.[21] Early signs of hypocalcemia are nonspecific and include anorexia, facial rubbing, nervousness, and a stiff gait. Later signs progress to cardiac arrhythmias, hyperventilation, and finally, generalized tetany and/or seizures.[21]

Diagnosis of primary hypoparathyroidism is achieved by

obtaining a complete blood count, chemistry profile, urinalysis, ionized calcium and magnesium levels, as well PTH level. Serum or plasma PTH concentrations should be measured on a freshly drawn sample in a fasted animal. Handling of the sample is crucial to appropriate diagnosis, as PTH is prone to degradation if subjected to warm temperatures.[9]

Treatment of hypoparathyroidism is directed at the underlying cause. In animals that undergo bilateral thyroidectomy, it is possible to autotransplant parathyroid tissue by sectioning the glands and implanting them within adjacent neck musculature.[3] Glands maybe functional

within 2 weeks of transplantation.[23] Medical therapy for hypoparathyroidism may require intravenous calcium administration for an acute crisis or permanent vitamin D supplementation in chronic cases.[24]

Chapter 81

Surgical Diseases of the Endocrine Pancreas

Emily Soiderer
S. Kathleen Salisbury

Anatomy

The pancreas is a lobulated structure adjacent to the duodenum that consists of a body and two lobes or limbs. The body lies adjacent to the pylorus, whereas the right limb is closely associated with the descending duodenum on its dorsomedial aspect,

enclosed by the mesoduodenum. The left limb of the pancreas lies between the peritoneal layers of the deep leaf of the greater omentum. It is caudal to the stomach and found dorsally in the abdomen adjacent to the left kidney and transverse colon.

The blood supply to the majority of the pancreas originates from the celiac artery via the hepatic and splenic arteries. The gastroduodenal branch of the hepatic artery gives off the cranial pancreaticoduodenal artery, which supplies the body of the pancreas and the cranial half of the right limb. The splenic artery supplies branches that enter the distal end of the left limb. The caudal pancreaticoduodenal artery

originates from the cranial mesenteric artery and supplies the remainder of the pancreas. Innervation of the pancreas is derived either from the vagus and splanchnic nerves or is intrinsic to the gland.[1]

Physiology of the Endocrine Pancreas

The endocrine function of the pancreas stems from specialized cells of the islets of Langerhans. These islets are ovoid collections of cells scattered throughout the parenchyma of the pancreas, making up a small portion of the pancreatic volume compared with the exocrine portion.[2,3] The origin of islet cells is believed by some to be

neuroectodermal, however this theory is controversial.[4-6] Islet cells are functionally grouped as amine precursor uptake and decarboxylation (APUD) cells.[2] These cells concentrate the amino acid precursors of certain amines and decarboxylate them to form the amines, which function as regulators and neurotransmitters. Functional tumors arising from these cells are termed APUDomas.

The cells of the islets are further categorized based on their hormonal production. Four distinct cell types have been described, each secreting a single hormone: A cells (alpha), B cells (beta), D cells (delta), and F (or P) cells.[2,7] A cells surround the centralized

B cells and produce glucagon.[2,8] B cells secrete insulin and account for 60% to 75% of the islet cell population.[2,9] They are located within the center of the islet.[2] D cells produce somatostatin and occupy an intermediate position within the islet between the A and B cells. F cells secrete pancreatic polypeptide and are found in low numbers.[9]

Disorders of the endocrine pancreas are usually a result of either an excess or deficiency in production of one of these hormones. Knowledge of the normal actions of each of these hormones, and the clinical signs and significance of their inappropriate production, is vital to understanding

diseases of the endocrine pancreas. Diseases related to excessive or deficient production of insulin are the most common disorders of the endocrine pancreas.

Insulin

The main metabolic function of insulin is to regulate serum glucose concentration and promote the conversion of glucose, fatty acids, and amino acids to their storage forms (glycogen, triglycerides, and protein). The stimulus for insulin release from B cells is high serum glucose concentration. Insulin is made in the rough endoplasmic reticulum of the B cells and is then packaged in the Golgi

apparatus into membrane-bound granules. The granules move to the plasma membrane via a process involving microtubules, and their contents are then expelled through exocytosis.[2] Other stimuli for insulin release include other sugars (fructose, mannose, ribose), amino acids, hormones (glucagon, secretin, gastric inhibitory peptide, cholecystokinin, growth hormone, adrenocorticotropin (ACTH), progesterone, and estrogen), drugs, fatty acids, potassium, acetylcholine, and ketones.[2] Glucose enters cells via facilitated diffusion or by secondary active transport with sodium (Na+) (intestine and kidneys).[2] Insulin facilitates glucose entry into cells by increasing the

number of glucose transporters in the cell membrane, particularly in muscle, fat, and some other tissues.[2] Glucose penetrates only a few tissues readily, such as the brain, liver, and red and white blood cells.

Insulin facilitates glucose utilization via glycolysis and promotes glycogen production in the liver, adipose tissue, and skeletal muscle by increasing glycogen synthase activity. Insulin also decreases gluconeogenesis because of the promotion of protein synthesis in peripheral tissues, thereby decreasing the amount of amino acids available for gluconeogenesis.[2]

In adipose tissue, insulin functions to

increase glucose entry, fatty acid synthesis, glycerol phosphate synthesis, triglyceride deposition, and potassium uptake.[2] It also activates lipoprotein lipase and inhibits hormone-sensitive lipase. In muscle, insulin increases glucose entry, glycogen synthesis, amino acid uptake, protein synthesis in ribosomes, ketone uptake, and potassium uptake. It decreases protein catabolism, and release of gluconeogenic amino acids. In the liver, insulin increases protein and lipid synthesis, decreases ketogenesis, and decreases glucose output owing to decreased gluconeogenesis, increased glycogen synthesis, and increased glycolysis.[2]

Glucagon

Glucagon is primarily a counter-regulatory mechanism hormone that restores plasma glucose levels in states of hypoglycemia by increasing gluconeogenesis, glycogenolysis, and protein-lipid flux in the liver.[10] It has an additional function in gastrointestinal smooth muscle relaxation.[10]

Somatostatin

Somatostatin inhibits the secretion of islet hormones, including insulin, glucagon, and pancreatic polypeptide. It also inhibits the secretion of gut peptides, including gastrin and secretin. Finally, it inhibits pancreatic

exocrine secretion and gastric acid secretion, and reduces splanchnic blood flow, intestinal motility, and carbohydrate absorption, while increasing water and electrolyte absorption.[10]

Pancreatic Polypeptide

Pancreatic polypeptide reduces cholecystokinin-induced gastric acid secretion, increases intestinal transit times by reducing gastric emptying and upper intestinal motility, and inhibits postprandial exocrine pancreas secretion via a vagal-dependent pathway.[10]

Specific Disorders of the

Endocrine Pancreas

Diabetes Mellitus

Diabetes mellitus (DM) is the most common disorder of the endocrine pancreas in the dog and cat. Therefore, it is important for the surgeon to understand the anesthetic and perioperative management of the diabetic patient.

DM may be caused by failure of insulin production, failure of insulin release, excessive degradation of circulating insulin, or resistance to insulin effects by target tissues.[11] In people, DM is classified as type 1, type 2, gestational diabetes, and other specific types of diabetes.[12] Presently, no classification

system exists for veterinary patients; however, the most common cause of DM in dogs and cats is failure of insulin production and secretion by the B cells of the pancreas. Type 1 diabetes in humans is characterized by B cell destruction leading to an absolute insulin deficiency.[12] The cause of this destruction is usually a cellular-mediated autoimmune response.[13] Humans have multiple genetic predispositions to autoimmune destruction of B cells. B cell destruction in humans is also related to environmental factors that are still poorly defined.[13] The cause of B cell destruction in dogs and cats is unknown, however, evidence supports a role for immune-mediated processes.

Inflammatory cell infiltration of pancreatic islets occurs in 46% of dogs with DM.[14] Anti-beta cell antibodies have been found in approximately 50% of dogs with insulin-dependent diabetes mellitus.[15] Islet cell destruction secondary to pancreatitis has also been proposed as a cause of diabetes mellitus. The pancreas has a large functional reserve, however, and progressive destruction of pancreatic tissue by recurrent or chronic pancreatitis is a rare cause of exocrine pancreatic insufficiency and diabetes in dogs.[16]

When surgery is considered in a diabetic patient, the status of the patient's diabetes must be determined

and the goals of the surgery should be considered.[11] Ideally, surgery should be delayed until the diabetes is well regulated. This is not always possible, however,as occasions may arise in which an urgent condition necessitates surgical intervention before diabetes can be regulated, or a patient's previously well-regulated state may become disrupted owing to the onset of a new condition. The benefit of surgery must be weighed against the risk of pursuing it with the patient in an unregulated state. Surgery may be elective and independent of the diabetes itself, it may be part of long-term management of the diabetic state, or it may be emergent.[11]

Pathophysiology

In diabetes mellitus, the deficiency of or resistance to insulin results in an inability to maintain a euglycemic state. Glucose transport into cells fails and despite high levels of glucose in the bloodstream, an intracellular glucose deficiency results: “starvation in the midst of plenty.”[2] This state of starvation leads to inappropriate signaling by cells to increase hepatic gluconeogenesis and glycogenolysis, and decrease glycogenesis. Glycogen stores are quickly depleted and the liver signals for alternate substrates for glycolysis. Energy requirements can only be satisfied by using protein and fat reserves. Lipolysis of fat stores

begins and fatty acids are metabolized, leading to the production of ketone bodies. The fatty acids are catabolized to acetyl-coA. The supply of acetyl-coA exceeds the capacity of the tissues to catabolize the acetyl-coA and the excess is converted to ketone bodies.[2] Muscle proteins are catabolized to amino acids for gluconeogenesis. The net effect of accelerated protein catabolism is a negative nitrogen balance, protein depletion, and wasting.

Diabetic patients may be complicated surgical patients owing to the various effects of their persistently hypoinsulinemic state. These patients may suffer from hepatic lipidosis

because of excessive fatty deposition in their livers from mobilization of fat stores as a substitute glucose source.[2,17] Fatty acids are transported to the liver and the triglyceride depot is expanded. At the same time, insulin deficiency decreases the release of triglycerides from the liver, leading to hepatic lipidosis and hepatomegaly. This is often a problem in poorly regulated patients, but even well regulated diabetic patients may still have compromised hepatic function. This will have bearing upon anesthetic protocols, and dosages for anesthetic agents metabolized by the liver may need to be reduced.[18]

Pancreatitis is another potential and

serious consequence of diabetes.[19-21] Many diabetic animals are prone to pancreatitis and may have a history of it. Anesthesia and manipulation of the pancreas can cause hypotension and subsequently result in decreased perfusion of the pancreas, leading to an acute bout of pancreatitis upon the patient's recovery.[18,21] This will complicate the management of the patient postoperatively and the need to withhold food from that patient will complicate the clinician's ability to regulate the diabetes.

Although rare, diabetic nephropathy is an additional complication that may occur.[22] Histologic findings include membranous glomerulonephropathy,

glomerular and tubular basement membrane thickening, glomerular fibrosis, and glomerularsclerosis. Severe proteinuria develops followed by azotemia, and eventually, uremia. Oliguric and anuric renal failure may ensue. The histopathologic findings are dependent on duration of the disease and control of hyperglycemia.[22] Other concurrent endocrinopathies may complicate management. Hyperadrenocorticism and acromegaly contribute to insulin resistance and may be causes for poor regulation of patients with diabetes mellitus.

Increased susceptibility to bacterial infections is a concern for the diabetic surgical patient.[23] Prolonged

hyperglycemia predisposes to infection, and risk of infection may increase with increasing glucose concentrations.[23,24] Defective function of polymorphonuclear leukocytes has been demonstrated in diabetes mellitus.[23,25] Chemotaxis, phagocytosis, serum opsonic activity, and bactericidal function of neutrophils of diabetic patients are all diminished. Abnormalities in antibody formation, complement system, and cell-mediated immunity also have been found in poorly controlled diabetic patients.[25] Perioperative antibiotic therapy is advisable in diabetic patients.

Preoperative Evaluation of

the Diabetic Patient

A thorough diagnostic evaluation should be completed prior to any surgical procedure in a diabetic patient. A thorough history and physical examination are essential. A minimum data base, including a complete blood count, serum chemistries, urinalysis and urine culture, is essential to identify concurrent problems. Urine culture should be performed owing to the susceptibility of diabetic patients to urinary tract infections. Evaluating the skin for evidence of dermatitis is important for identifying potential sources of infection that should be resolved prior to surgery. Radiographs,

electrocardiogram, ultrasound examination, etc., should be completed prior to surgery if indicated based on history, physical examination findings and laboratory analysis. If the determination is made that the patient is poorly regulated, elective surgical procedures should be postponed until appropriate control of the diabetic state is attained.

Perioperative Management of the Diabetic Patient

Management during surgery requires special attention. If the animal's disease is well regulated, food is withheld after midnight the night before the surgical procedure, and

blood glucose concentration is measured on the morning of surgery. If the blood glucose concentration is greater than 150 mg/dl, one half of the regular dose of intermediate- or long-acting insulin is administered.[26] If the blood glucose concentration is less than 150 mg/dl, insulin is not given and the blood glucose concentration is re-evaluated postoperatively. Transient hyperglycemia is much less dangerous than hypoglycemia. Intravenous fluids containing 2.5% or 5% dextrose are started at induction and administered throughout anesthesia at 10 ml/kg/hour, unless there are indications to adjust this rate. For procedures of less than 1 hour, blood glucose can be measured

postoperatively. Patients that have longer procedures and patients that are less well controlled should have their blood glucose concentration measured every 30 minutes. The dextrose drip should be adjusted as needed to prevent hypoglycemia. If the blood glucose concentration drops below 100 mg/dl, the rate of the dextrose drip (or its concentration for patients at risk of fluid overload) should be increased. If the blood glucose concentration is greater than 300 mg/dl, then 0.25 units/kg of regular insulin is administered subcutaneously.

Postoperative management is aimed at returning the patient to a normal

routine and eating habits. Blood glucose concentration is measured every 4 to 6 hours with the goal of maintaining it between 150 and 250 mg/dl. If it increases above 250 mg/dl, regular insulin may be administered subcutaneously. A small meal should be offered the evening of surgery. Fluid therapy is continued overnight and if the patient eats the following morning, fluids are discontinued and the normal intermediate-acting insulin regimen is re-instituted. Transient hyperglycemia and glucosuria may occur for a few days after discharge from the hospital. The owner should be notified of this and advised not to change the insulin dose.

Unregulated or ketoacidotic diabetic patients requiring emergency procedures should be assessed via immediate evaluation of blood glucose concentration with reagent strips, hematologic and biochemical analysis, and urinalysis. Blood gas analysis is ideal if available. Appropriate stabilization with fluid therapy and correction of ketoacidosis is vital to restore acid-base and electrolyte balance and to counteract dehydration. Regular insulin is administered following guidelines of an established protocol for diabetic ketoacidotic patients. The goal is to lower the blood glucose concentration to less than 300 mg/dl and resolve ketonuria. The animal may exhibit Kussmal breathing

as it attempts to blow off carbon dioxide and compensate for its metabolic acidosis. This should be recognized, particularly when the animal is under anesthesia, and not be mistaken for too light a plane of anesthesia. Falsely interpreting this breathing pattern and increasing the depth of anesthesia can have adverse consequences. Timing of surgery is determined by the patient's response to therapy and the nature of the emergency. Gradual restoration of imbalances is best tolerated rather than attempting to normalize them all at once.

Ovariohysterectomy in the

Diabetic Patient

Intact female dogs are especially prone to becoming unregulated as estrogen concentrations rise during proestrus and estrus and directly antagonize the effects of insulin. During the long luteal phase of diestrus, progesterone predominates and stimulates growth hormone secretion.[27] Growth hormone causes a decrease in the number of insulin receptors on target cell membranes and may also lower the affinity of the remaining receptors for insulin.[11] This leads to prolonged and possibly severe insulin resistance. The animal is at higher risk for developing ketoacidosis as well as a uterine infection. Intact diabetic females are at

risk for pyometra owing to the elevated progesterone concentrations and increased susceptibility to infection. The diabetic patient should undergo ovariohysterectomy before beginning her next estrus. If the patient presents in a ketoacidotic state, ovariohysterectomy may prove to be urgent in order to successfully control the diabetes. Postoperatively, insulin resistance will improve and the patient's insulin requirements may markedly decrease. Careful serial monitoring of blood glucose concentration should be done.

Pregnancy also can disrupt the diabetic patient's regulated state. Again, high concentrations of progesterone and

growth hormone lead to insulin resistance. The placenta and fetus increase the demands for energy and hyperglycemia persists, possibly leading to ketoacidosis. Increased fetal growth hormone may lead to large feti which can cause dystocia and necessitate emergency cesarean section in an unregulated diabetic patient. The feti may also develop fetal beta-cell hyperplasia owing to high circulating levels of glucose, plasma amino acids, and fats from the poorly regulated mother.[11] If they are carried to term, puppies and kittens may be prone to hypoglycemic seizures. It should also be recognized that the mother's insulin requirement will decrease by 50% when the placenta separates from the

uterus if a cesarean section is performed. Owing to the difficulties with blood glucose regulation associated with the estrous cycle and pregnancy, the increased susceptibility to developing pyometra, and the possibility of passing on diabetes mellitus to offspring, all intact females with diabetes should be spayed.

Pancreatic Transplantation for Treatment of Diabetes Mellitus

Pancreatic transplantation as a means of treating diabetes mellitus has been investigated for 4 decades. Whole pancreas transplantation has been successfully performed in dogs

exclusively for research purposes. The first pancreatic transplantation in a human was performed in 1966. The major goal of transplantation is prevention or reduction of long-term complications of diabetes (such as heart disease, renal failure, blindness, and stroke). Successful transplantation appears to stop the progression of diabetic nephropathy and diabetic neuropathy; however, it requires major surgery and potentially lifelong immunosuppression to prevent rejection of the transplant.[28] The value of pancreatic transplantation in diabetic pets is problematic because diabetic dogs and cats do not live long enough (even with normal life expectancy) to develop the long-term

complications seen in people. Ethical considerations are also a factor because one donor dog would have to be euthanized to provide a healthy pancreas for one recipient. Owners may find the side effects of immunosuppression more difficult to deal with than daily insulin administration. However, as technology improves, pancreatic transplantation may become a more viable option for pets.

Transplantation of pancreatic islets is a promising alternative to whole pancreas transplantation. Donor tissue can be altered to reduce immunogenicity, cost is moderated, and a larger number of patients can be

treated. However, many islets must be transplanted because the duration of graft survival can be correlated with the number of islets transplanted.[28,29] This often requires utilization of several donors, which may lead to a need for levels of immunosuppression that can be harmful to the recipient.[28] This has led to the development of immunoprotected islet transplantation through microencapsulation. This process completely encloses each islet within a semipermeable membrane made of a nontoxic polysaccharide that is permeable to small molecules such as insulin and glucose, but is completely impermeable to large molecules such as immunoglobulins. This makes them "invisible" to the recipient's immune

system. Microencapsulated pancreatic islets have been transplanted free into the peritoneal cavity of 12 pet dogs with naturally occurring diabetes mellitus. Blood glucose concentration decreased to normal or below normal within 8 to 12 hours. Euglycemia was present for 1 to 6 months, with a mean of 3 months.[28]

Insulinoma

The most common tumor of the endocrine pancreas in the dog is insulinoma, a functional tumor of the pancreatic beta cell. Insulinoma is diagnosed in middle-aged to older dogs (average age 9 years, range 3-15 years).[30] It occurs primarily in large

breed dogs including Irish setters, Labrador retrievers, German shepherds, and golden retrievers. No gender predilection is associated with insulinomas in dogs.[31] Insulinoma is considered rare in cats as few cases have been reported.[32-34] Of these reports, all cats were of older age (range 12-17 years) and 3 of 5 were Siamese.

Pathophysiology

Insulinomas secrete insulin independently of the normal suppressive effects of hypoglycemia. Although insulin is the most abundant hormone produced by these tumors, evidence exists of multihormonal

production, including pancreatic polypeptide, glucagon, somatostatin, serotonin, and gastrin.[35,36] Clinical signs associated with insulinomas result from the hypoglycemic effects of hyperinsulinemia, leading to neuroglycopenia, and stimulation of the sympathetic nervous system, leading to an increase in circulating catecholamines.[30,37,38] Clinical signs caused by neuroglycopenia include lethargy, weakness, ataxia, collapse, seizures, posterior paresis, and depression.[13,34] Clinical signs resulting from stimulation of the sympathoadrenal system include muscle tremors, nervousness, restlessness, and hunger.[37,38] Clinical signs are usually episodic because of

the counter-regulatory mechanisms that enable recovery from hypoglycemic episodes.[38] Clinical signs can be present for days to months, with most dogs being symptomatic for 1 to 6 months prior to presentation.[30,38] The onset of clinical signs is related to the degree of hypoglycemia and the rate at which it occurs.[30,38] Gradual blood glucose changes are less likely to cause clinical signs of hypoglycemia than an acute drop. Dogs that have a slowly decreasing glucose concentration over a prolonged period of time (i.e., weeks) may be able to adjust without showing clinical signs until the blood glucose concentration reaches a point at which the animal can no longer

adapt to the hypoglycemia and signs of neuroglycopenia result.[38] These dogs can typically adjust to blood glucose concentrations as low as 20 to 30 mg/dl. However, if the hypoglycemia develops acutely, perhaps over a few hours, clinical signs will develop quickly. Because of the failure of insulin secretion to drop during periods of hypoglycemia, dogs with insulinoma are predisposed to developing clinical signs during fasting and exercise.[38] In addition, insulin-secreting tumors remain responsive to many of the stimuli that promote insulin secretion in healthy dogs, such as eating, but the secretory response may be exaggerated, so severe hypoglycemia can occur.[38]

Normally, B cells of the pancreatic islets maintain the primary control of blood glucose concentrations. When blood glucose concentration rises above 110 mg/dl, insulin is secreted and the glucose concentration decreases into the normal physiologic range. When the blood glucose concentration falls below 60 mg/dl, insulin synthesis and secretion are inhibited and blood glucose returns to normal as tissue utilization slows and blood glucose concentration increases.[38] With insulinoma, insulin secretion is not inhibited and hypoglycemia results. Hypoglycemia triggers the production of counter-regulatory hormones including glucagon, epinephrine, growth

hormone, and cortisol. Glucagon, epinephrine, and norepinephrine concentrations increase at the onset of the counter-regulatory response; growth hormone and cortisol increase later.[38] Glucagon is the main counter-regulatory hormone in acute hypoglycemia. Glucagon secretion is stimulated by hypoglycemia and by beta-adrenergic nervous system stimulation and adrenomedullary catecholamines.[38] Glucagon is secreted into the portal circulation and activates glycogenolysis and gluconeogenesis in the liver. Hypoglycemia stimulates growth hormone secretion, which decreases glucose uptake into some tissues, increases hepatic production of

glucose, and possibly decreases tissue binding of insulin.[2] Adrenocorticotropic hormone and cortisol are increased by direct stimulation of the pituitary gland and stimulation of the pituitary-adrenocortical axis by the sympathetic nervous system. Long-term elevation of cortisol aids lipolysis, promotes protein catabolism and the conversion of amino acids to glucose by the liver and kidney, and limits utilization of glucose by tissues. The effects of increased cortisol and growth hormone do not occur for hours and are more effective in countering chronic hypoglycemia than acute hypoglycemia.

The autonomic nervous system

response to hypoglycemia has alpha- and beta-adrenergic effects. Hypoglycemia stimulates catecholamine secretion by the adrenal medulla. Alpha-adrenergic effects result in inhibition of endogenous insulin secretion and stimulation of peripheral vasoconstriction, causing an increase in cerebral blood flow in the healthy dog. Epinephrine stimulates hepatic glycogenolysis and gluconeogenesis, mobilizes muscle glycogen and gluconeogenic precursors, stimulates lipolysis, and inhibits glucose utilization by insulin-sensitive tissues. Beta-adrenergic effects include stimulation of hepatic and muscle glycogenolysis, increased plasma glucagon secretion, stimulation

of lipolysis, inhibition of glucose uptake by muscle, and increased cerebral blood flow secondary to an increase in cardiac output. Cholinergic effects lead to stimulation of pancreatic polypeptide secretion, increased gastric motility, and hunger stimulation.[38]

The counter-regulatory response to hypoglycemia can be effective in controlling hypoglycemia; however the continued production and secretion of insulin from an insulinoma will eventually overwhelm the ability of these mechanisms to counteract the hypoglycemia. Without surgical or medical intervention, the patient will succumb to the effects of

hypoglycemia.

Hypoglycemia can affect most cells, but the cells of the central nervous system (CNS) are the most vulnerable. The carbohydrate storage ability of these cells is minimal and glucose is their primary energy source. A continuous supply of glucose from the blood is essential. Glucose enters the cell via diffusion, independent of insulin. When the blood glucose concentrations are inadequate for intracellular oxidative processes, a decline in energy-rich phosphorylated compounds (adenosine triphosphate [ATP]) occurs in neurons.[38] The lack of energy results in cellular dysfunction and cellular changes similar to

hypoxia: increased vascular permeability, vasospasm, vascular dilation, and edema. This is followed by neuronal death.[11,38] Owing to varying metabolic rates in the CNS, the most active sites are affected first. In mammals this is the cerebral cortex. The least metabolically active area is the brain stem and, therefore, it is more resistant to hypoglycemia.[11,38] The majority of damage occurs in the brain, but peripheral nerve degeneration and demyelination can occur.[38] Other major organ systems are dependent on glucose for energy, but the CNS will show signs of an acute drop in blood glucose long before organ failure develops.[38]

Differential and Definitive Diagnosis

A thorough diagnostic workup must be performed to make a diagnosis of insulinoma. This begins simply with an accurate and thorough history from the owner as well as a thorough physical exam. A patient-side glucose test strip should be run at presentation, but results of serum chemistries will help most in identifying hypoglycemia as the primary or sole cause of the clinical signs. Hypoglycemia is defined as a blood glucose concentration below 60 mg/dl. The presence of hypoglycemia narrows the differential list, but does not establish insulinoma as the cause. Whipple's triad has classically been

used as a criterion for diagnosis: (1) presence of neurologic signs associated with hypoglycemia, (2) fasting blood glucose concentration below 60 mg/dl, (3) resolution of clinical signs with feeding or administration of glucose.[38-40] Whipple's triad however only confirms hypoglycemia as the cause of the neurologic signs. It does not yield a diagnosis of insulinoma, because any cause of hypoglycemia could fulfill Whipple's triad.[38-39,41]

Hypoglycemia results from excessive glucose utilization, impaired hepatic gluconeogenesis and glycogenolysis, deficiency of counter-regulatory hormones, inadequate dietary intake of glucose and/or its substrates, and

iatrogenic hypoglycemia.[38] Hepatic-induced hypoglycemia can be a result of congenital causes such as portosystemic shunts or acquired causes such as cirrhosis and acquired portosystemic shunting. Insufficient hepatic glycogen stores and inadequate hepatocellular function to support gluconeogenesis are responsible for the hypoglycemia associated with liver disease.[38] Any severe insult to the liver that results in decreased hepatocellular function, such as infection, toxic insult, or necrosis, can lead to hypoglycemia. Hypoglycemia can be caused by starvation or sepsis, or may be idiopathic in neonates, toy breed dogs, and hunting dogs.[42] Endocrinopathies such as adrenocortical insufficiency,

hypopituitarism, ACTH deficiency, glucagon deficiency and non-beta cell-derived hyperinsulinism can cause hypoglycemia. Glycogen-storage disease, renal failure, cardiac disease, and polycythemia are also associated with hypoglycemia. Artifactual hypoglycemia can occur from prolonged blood storage prior to separation of the red cells from the serum or plasma. Continuing metabolism of glucose by the red blood cells will decrease the glucose concentration in a whole-blood sample. Iatrogenic hypoglycemia can occur owing to insulin or oral sulfonylurea drug overdosage. Finally, extrapancreatic neoplasia, such as leiomyosarcoma and hepatic

adenocarcinoma, has been associated with hypoglycemia. Hepatic tumors may grow large enough that they utilize a large amount of glucose as well as interfere with gluconeogenesis. These tumors can also secrete insulin and insulin-like peptides that contribute to hypoglycemia. Often, patients with hypoglycemia not associated with hyperinsulinism will have other clinical pathologic abnormalities that will help to narrow the differential diagnosis list and guide further diagnostics.

The diagnosis of insulinoma is supported by finding an inappropriately elevated serum insulin concentration in the presence of

hypoglycemia. The insulin concentration must be compared with the concurrent blood glucose concentration. The serum insulin concentration in a healthy fasted dog is usually between 5 and 20 μU/ml. Blood glucose concentration is normally between 70 and 110 mg/dl. A serum insulin concentration that exceeds 20 μU/ml in a dog with a blood glucose concentration less than 60 mg/dl, along with clinical signs, strongly supports the diagnosis of an insulin-secreting tumor.[38] However, an insulin-secreting tumor is also possible with a serum insulin concentration in the high normal range (10–20 μU/ml). Animals with other causes of hypoglycemia as well as those with

insulin-secreting tumors may have a serum insulin concentration between 5 and10 μU/ml. In 85 dogs with blood glucose concentrations less than 60 mg/dl, 73% had a serum insulin concentration greater than 20 μU/ml, 21% had a serum insulin concentration between 10 and 20 μU/ml, and 6% had a concentration between 5 and10 μU/ml.[38] Several different insulin:glucose ratios have been used to further assess the likelihood of an insulin-secreting tumor. Although these ratios are controversial, the amended insulin:glucose ratio is considered to be the most reliable.[38] The amended insulin:glucose ratio consists of the following formula:

$$\frac{\text{plasma insulin (}\mu\text{U/ml) x 100}}{\text{plasma glucose (mg/dl)} - 30}$$

Based on the human literature, an amended insulin:glucose ratio greater than 30 is diagnostic for an insulin-secreting tumor. However, in dogs this test is not specific for insulinoma. Other causes of hypoglycemia, such as hepatic tumors and sepsis, may result in abnormal amended insulin-glucose ratios.[38] Because of this, the absolute serum insulin concentration during hypoglycemia should be evaluated in concert with the history, physical examination findings, and clinical pathologic test results.[38,39]

Provocative tests, including the

glucagon tolerance test, l-leucine test, tolbutamide and ethanol response test, oral glucose tolerance test, epinephrine stimulation test, calcium infusion test, C-peptide suppression test, and diazoxide infusion test, have been reported.[11,38,39] These tests are not considered more sensitive than the insulin-glucose pair, can be expensive and inefficient, and can potentiate significant hypoglycemia dangerous to the animal, so they are not recommended.

The disease process is further characterized with diagnostic imaging. Abdominal radiographs are usually unremarkable owing to the small size of insulinomas and their location

within the pancreas; a visible mass or visceral displacement is extremely rare.[38] Although metastasis can occur to the liver, lymph nodes, and peripancreatic omentum, these lesions are not likely to be detectable on radiographs. Pulmonary metastasis is rare, and thoracic radiographs are usually unremarkable until late in the disease. Abdominal ultrasonography is likely to be more useful than radiography, but can still be unrewarding. Detection of a mass in the pancreas is helpful in supporting a diagnosis of insulinoma in animals that have the appropriate clinical picture. It is common to be unable to identify a lesion in the pancreas and, therefore, the lack of an identifiable mass via

ultrasonography does not rule out its presence. Ultrasonography may also detect metastatic lesions in the liver and peripancreatic tissue.

The use of computed tomography (CT) for identifying insulinomas has recently been investigated. In one study of 14 confirmed insulinomas, ultrasonography, CT, and single-photon emission CT (SPECT) were evaluated for detecting and localizing canine insulinoma.[43] Five primary insulinomas were correctly identified with ultrasonography, 10 with CT, and 6 with SPECT.[43] CT identified 2 out of 5 lymph node metastases, but also showed 28 false-positive lesions.[43] The authors concluded that

ultrasonography could be used for initial evaluation of dogs with hypoglycemia, and although CT identified most primary tumors, intraoperative inspection and palpation were still superior. SPECT appeared as effective as ultrasonography and CT.[43] Scintigraphy has also been used as an additional imaging modality. In one study, 5 dogs with insulinomas were imaged using ^{111}In-pentetrotide scintigraphy to identify somatostatin receptors. All insulinomas expressed high-affinity somatostatin receptors.[44] However, scintigraphy was able to accurately predict the anatomic location of the primary tumor in only 1 out of 4 dogs, and was unable to

differentiate a right- from left-pancreatic lobe tumor.[44,111] In-pentetrotide scintigraphy was concluded to be a useful diagnostic adjunct but was unable to localize the tumor in some cases.[44]

Treatment

Surgical exploration of the abdomen offers the best results in terms of diagnosis, therapy, and prognosis. Most dogs with insulin-secreting tumors have visible nodules present upon inspection of the pancreas.[38] Definitive diagnosis is based on histopathologic evaluation of lesions resected or biopsied at the time of surgery. A solitary nodule within the

pancreas is likely to be resectable and will afford long-term control of hypoglycemia, however, cure is unlikely. The goal of surgery is to remove as much neoplastic tissue as possible; debulking of gross metastatic disease may afford a significant therapeutic effect. The blood glucose concentration should be stabilized as well as possible prior to anesthesia and surgery. Manipulation of an insulinoma may result in release of insulin and a further drop in blood glucose concentration.

Localization of a pancreatic mass is based on careful inspection and gentle palpation of the entire pancreas. Primary lesions are distributed equally

between the two limbs of the pancreas, and an identifiable mass was located approximately 92% of the time in one source.[38] Another source reported inability to identify a mass in 20% of cases.[45] If a mass is not identified, special methods, such as intravenous administration of methylene blue and intraoperative ultrasonography, can be used to assist in identification of the lesion.[46-48] Methylene blue is an azo dye that concentrates in the parathyroid glands and endocrine pancreas. Intravenous infusion of this dye has been recommended for identification of primary nodules and differentiation of metastatic versus nonmetastatic lesions.[46-48] Methylene blue stains normal pancreatic

endocrine tissue a dusky slate blue, whereas hyperfunctioning tissue is stained a reddish-violet.[34] Side effects include Heinz body hemolytic anemia, acute renal failure, pseudocyanosis, green-tinged urine, and possibly pancreatitis.[46-49] Intraoperative ultrasonography in humans has a success rate of greater than 95% for finding insulinomas; this modality may prove useful in dogs.[50]

Thorough exploration of the abdomen is vital to identifying the extent of metastatic disease. Gross metastasis is identifiable at the time of surgery in approximately 36% of cases.[51] Metastasis most commonly occurs to the liver, regional lymph nodes, and

peripancreatic tissue. Lesions should be biopsied or resected if possible. Ideally, all of the abnormal tissue should be removed and submitted for histopathologic evaluation.

Palpation may reveal a thickened pancreas, or the pancreas may feel completely normal.

Successful surgery depends on the location of the tumor. A tumor in the left or right limb at the distal aspect is the most amenable to resection. Tumors at the body or in the region of the common bile duct are the most difficult to remove and increase the risk of postoperative pancreatitis owing to the potential for disrupting

pancreatic blood supply. The extensive manipulation necessary to remove tumors in this area and the likelihood of incomplete resection may warrant a decision to leave the mass. If nonresectable disease is present, biopsy of the mass is the minimum the surgeon should accomplish. Closing the abdomen and pursuing medical therapy is advisable.

Intravenous fluids should be administered for 12 to 24 hours prior to, during, and after surgery to ensure adequate perfusion of the pancreas. Manipulation and dissection of the pancreas during surgery results in inflammation and predisposes the animal to postoperative pancreatitis.

Hypotension will result in poor perfusion of the pancreas and may potentiate pancreatitis. Aggressive fluid support may help avoid hypotension and minimize the severity of the pancreatitis. Dextrose therapy is often needed to counteract clinical signs of hypoglycemia. Administration of a 2.5% or 5% dextrose solution is usually adequate. Maintenance of normal blood glucose concentration intraoperatively is extremely important. It should be measured every 30 to 60 minutes during surgery with a goal of maintaining it above 40 mg/dl, but not to necessarily reach a normal blood glucose concentration. It is rare to need more than a 5% dextrose solution, and if needed, a constant rate

infusion of glucagon can help raise the blood glucose concentration when dextrose alone is inadequate.

Postoperative care is aimed at controlling pancreatitis, hypoglycemia, and if it occurs, hyperglycemia. Serum electrolytes and blood glucose concentration should be measured twice daily. If pancreatitis is recognized, intravenous fluid therapy is continued (routinely 120 ml/kg/day) and food and water are withheld for 24 to 48 hours. Plasma administration is advisable and parenteral nutrition is started.

If persistent hypoglycemia occurs postoperatively, functional metastatic

disease is present. Medical therapy to prevent clinical signs should be instituted as well as frequent feeding (every 4 to 6 hours) with a diet appropriate for pancreatitis. Feeding frequency is increased to at least 3 to 6 times per day. A variety of medical therapies can help to control hypoglycemia. Glucocorticoid therapy (prednisone or prednisolone 0.25 mg/kg PO every 12 hours) is often the first medication used when frequent feedings are not adequate. The glucocorticoid dose can be increased as needed to control clinical signs, keeping in mind the adverse side effects of this drug. Increasing doses of glucocorticoids will result in signs of hyperadrenocorticism and possibly

gastric ulceration. When these side effects become unacceptable, the glucocorticoid dose should be decreased and another therapy added to control the clinical signs of hypoglycemia.

Diazoxide (5 mg/kg PO every 12 hours) is a benzothiadiazide that is used alone or in combination with glucocorticoids. Diazoxide inhibits insulin secretion, promotes hepatic gluconeogenesis and glycogenolysis, and inhibits tissue use of glucose. Diazoxide can be difficult to obtain and is expensive. It is reported to be 70% effective in controlling hypoglycemia but does not have any antineoplastic effects.[52] The dose can be increased to 30 to 40 mg/kg PO every 12 hours if

necessary. Side effects include hyperglycemia, bone marrow suppression, cardiac arrhythmias, hypernatremia, cataracts, and gastrointestinal disturbances.[52,53]

Octreotide is a somatostatin analog that inhibits insulin secretion and has been used with varying success in humans.[54,55] Doses up to 40 μg every 8 to 12 hours are reported to be effective without causing adverse side effects.[56] In one study, the endocrine effects of a single subcutaneous dose of 50 μg of octreotide were studied in healthy dogs in the fasting state and in dogs with insulinoma. After octreotide administration to dogs with insulinomas, baseline plasma insulin

concentrations decreased significantly and plasma glucose concentrations increased.[57] However, evaluation of octreotide in a study of 3 dogs with insulinoma showed that octreotide had no benefit over placebo and little effect on circulating glucose and insulin concentrations.[58]

Streptozocin is a nitrosurea alkylating agent that is directly cytotoxic to pancreatic beta cells. It had previously not been advisable to use in dogs owing to its association with acute renal failure from renal tubular necrosis.[59-61] Other side effects are vomiting, which can be severe, and increases in hepatic enzyme activities. These toxicities are dose-dependent,

with vomiting and hepatic enzyme increases occurring at lower dosages. Acute renal tubular necrosis occurs at higher doses. A diuresis protocol has met with some success.[62] Normal saline was administered at 18.3 ml/kg/hour intravenously for 3 hours prior to streptozocin administration. The dose (500 mg/m^2) was diluted to the appropriate volume and administered over the next 2 hours at the same rate. Normal saline was then administered for another 2 hours after the streptozocin infusion was complete. Butorphanol (0.4 mg/kg IM) was given as an antiemetic immediately after streptozocin administration. Treatments were repeated every 3 weeks until there was no evidence of

tumor progression (> 50% increase in tumor dimensions), recurrence of hypoglycemia, or development of a streptozocin-induced toxicosis. Mean duration of euglycemia was 163 days compared with 90 days for the control group, although this was not statistically significant. Two dogs had measurable reductions in size of metastases, and the clinical signs of 2 of 3 dogs with polyneuropathy resolved. Side effects of the drug were minimal with the diuresis protocol.[62]

Prognosis

Long-term prognosis for insulinoma in dogs is guarded to poor owing to the malignant behavior of these tumors.

They are malignant in terms of their metastatic potential; microscopic or gross metastasis at the time of diagnosis is almost certain. Mean survival time from the onset of clinical signs has been reported to be 12 months for dogs treated medically.[63] However, Tobin reported a median survival time of 74 days for dogs treated medically and a median of 381 days for those that underwent surgery.[64] It should be noted that the medically treated dogs had advanced disease and may have had shorter survival times because of this and the owners' possible feelings of hopelessness leading to euthanasia. Prognosis also depends on age at the time of onset of clinical signs, with

younger dogs having significantly shorter survival times than older dogs. Dogs that have a solitary pancreatic nodule (stage I) have significantly longer disease-free intervals (mean 14 months) after surgery than those with metastatic spread to the liver, regional lymph nodes (stage II), or distant sites (stage III).[65] High preoperative serum insulin concentrations are also associated with shorter survival times.[65] Approximately one third of dogs undergoing surgery die or are euthanized within 1 month as a result of severe metastatic disease, uncontrollable hypoglycemia, or postoperative pancreatitis. Another one third die or are euthanized within 6 months of surgery owing to severe

metastatic disease and recurrence of clinical hypoglycemia. The final one third live beyond 6 months without recurrence of hypoglycemia and many of these survive well beyond 1 year.[63]

Gastrinoma (Zollinger-Ellison Syndrome)

Gastrinomas are pancreatic islet cell tumors that secrete excessive amounts of gastrin. They were first identified in humans in 1955 by Zollinger and Ellison.[66] The Zollinger-Ellison syndrome consists of hypergastrinemia, a neuroendocrine tumor, and gastrointestinal ulceration. These tumors are rare in veterinary patients with only a few reports in the

literature.[67-70] They occur in middle-aged dogs (range: 3-12 years, mean 7.5 years) and older cats (mean 11 years).[38] No breed predilection has been identified. Female dogs and cats may be overrepresented.[71]

The most common clinical signs of gastrinoma are vomiting, anorexia, and weight loss owing to gastroduodenal ulceration.[9,23,67-69] Other signs that may occur include lethargy, depression, hematemesis, hematochezia, diarrhea, melena, and abdominal pain. These animals are at risk for gastrointestinal perforation and peritonitis from the ulcerative disease, and may experience collapse and shock secondarily. Physical

examination may be unremarkable or may reveal an extremely sick animal if perforation has occurred.[9,30,67-69] Physical examination findings depend on the severity and duration of disease. Animals may be lethargic, thin to emaciated, febrile, dehydrated, and in shock.[38]

Pathophysiology

Gastrin is a polypeptide hormone produced by G cells in the lateral walls of the glands of the antral portion of the gastric mucosa.[2] It is also found in the pancreatic islets in fetal life. Gastrinomas are found in the pancreas, but it is uncertain if gastrin is found in the pancreas in normal adults.[2] The

main actions of gastrin are stimulation of gastric acid secretion and pepsin secretion, as well as stimulation of the growth of gastric mucosa and small and large intestinal mucosa.[2]

The stimulus for gastrin secretion is related to the contents of the stomach, with secretion increased by the presence of the products of protein digestion (amino acids) that act directly on G cells. Luminal distention is also a stimulus for gastrin secretion. Gastrin inhibition occurs via the direct effect of acid in the antrum on G cells and by release of somatostatin, a gastrin-secretion inhibitor.[2] In patients with gastrinoma, hypergastrinemia induces excessive gastric secretion of

hydrochloric acid, which is responsible for the development of esophageal, gastric, and duodenal ulcers, the disruption of intestinal digestive and absorptive functions, and the development of clinical signs.[38] With excessive gastrin secretion, hydrochloric acid secretion is increased and this hyperacidity leads to ulceration. Reflux esophagitis may occur, and as the excessive acid moves through the GI tract, it can cause direct ulceration of the duodenum and jejunum. Intestinal hyperacidity may also lead to intestinal inflammation, mucosal edema, villous atrophy, and inactivation of pancreatic lipase and bile salts.[38,72] Gastrinomas may also secrete other hormones including

insulin, ACTH, and pancreatic polypeptide.

Diagnosis

Diagnostic workup includes a minimum database consisting of a complete blood count, serum chemistries, and urinalysis. CBC abnormalities seen with gastrinoma include neutrophilia, hypoproteinemia, and regenerative anemia, likely resulting from inflammation and blood loss. Serum chemistry abnormalities may include hypoalbuminemia, hypocalcemia, and increases in alanine aminotransferase and alkaline phosphatase. Hypochloremia, hypokalemia, and metabolic alkalosis

may occur from frequent vomiting. Tumor secretion of other hormones such as ACTH and insulin may occur and possibly lead to hyper- or hypoglycemia. Sudan staining of fecal material may reveal steatorrhea; melena is usually present. Urinalysis is unremarkable.

Abdominal radiographs are usually unremarkable. However, if an ulcer has perforated, loss of abdominal contrast consistent with peritonitis may be present. Contrast radiography can identify gastric and duodenal ulcers and thickening of the gastric rugal folds, pyloric antrum, and/or intestine.[38] Increased gastrointestinal transit time as well as esophagitis and

secondary megaesophagus may be present. Abdominal ultrasonography may find thickened gastric and intestinal walls, gastric ulcers, a pancreatic mass, and/or metastatic lesions.[38] Gastrinomas can be difficult to identify because of their potentially small size; failure to identify a mass by ultrasonography does not rule it out. Scintigraphy with radiolabeled somatostatin analogues may be useful owing to a high concentration of somatostatin receptors in gastrinomas in people.[70] A positive scan can also help identify patients that may benefit from medical therapy with somatostatin analogues like octreotide, which decrease gastrin release.[67-70]

Gastroduodenoscopy may reveal ulcerative lesions in the stomach and duodenum as well as esophagitis. Gastric rugal folds may be thickened. Histologic evaluation of the gastric mucosa may reveal mild to severe inflammation with lymphocytic, neutrophilic, eosinophilic, or plasma cell infiltrates as well as mucosal hypertrophy.

Definitive diagnosis of gastrinoma is based on histopathologic and immunocytochemical evaluation of the mass excised at surgery. Baseline serum gastrin concentrations are useful prior to surgical exploration, particularly if a pancreatic mass is not visualized by ultrasonography.

Demonstration of persistent hypergastrinemia with appropriate clinical signs is supportive of a diagnosis of gastrinoma. Fasting serum gastrin concentration is measured with multiple blood samples drawn after an overnight fast. The reference range for gastrin concentration will vary among laboratories, but the upper limit is usually less than 100 pg/ml in dogs and cats.[70,73] The majority of reported cases of histologically confirmed gastrinoma in dogs and cats have gastrin concentrations greater than three times higher than the upper normal value. Normal gastrin concentrations have been documented in humans with gastrinoma, and so it is likely that dogs and cats with normal

gastrin concentrations may still have a gastrinoma. It is also important to note that an elevated fasting serum gastrin concentration is not pathognomonic for gastrinoma. Other syndromes associated with hypergastrinemia include chronic renal failure, chronic gastritis, gastric outflow obstruction, liver disease, achlorhydria, and administration of H_2-receptor antagonists.[38] Once hypergastrinemia is documented and other causes are ruled out, a presumptive diagnosis of gastrinoma can be made.

Treatment

Treatment is aimed at surgical excision of the tumor and control of gastric acid

hypersecretion. The decision as to when exploratory surgery is performed depends on the clinical status of the animal. Prior to undertaking anesthesia, the animal must be stabilized. Medical therapy with gastric acid blockers should be instituted first with the goal of reducing gastric hyperacidity and controlling its secondary effects. Surgical goals include identification of a pancreatic mass and definitive diagnosis, as well as successful resection of the tumor. Because approximately 80% of animals with gastrinomas have gastrointestinal ulcers, the stomach and bowel should be evaluated for evidence of deep or perforated ulcers, and resection of these areas should be performed when

necessary.[7] Surgery also offers an opportunity to stage the disease by identifying and biopsying gross metastatic lesions. Approximately 70% of animals have metastasis at the time of initial diagnosis.[38]

Medical therapy for gastrinomas involves blocking gastric acid hypersecretion with H_2-receptor antagonists and the H^+-K^+ ATPase inhibitor, omeprazole. For maximal hydrochloric acid secretion from parietal cells to occur, three receptor sites must be activated. These receptor sites bind gastrin, histamine, and acetylcholine. H_2-receptor antagonists bind to the H_2-receptor and block gastrin's stimulatory effect on

hydrochloric acid secretion because all three receptor sites are not occupied by their respective peptides.[38] H_2-receptor antagonists include famotidine (0.5 – 1.0 mg/kg PO every 12-24 hours), ranitidine (2.2 mg/kg PO every 12 hours) and cimetidine (10 mg/kg every 6-8 hours). Dosages may need to be increased as the disease progresses to control hyperacidity.

Omeprazole is the preferred drug for gastrinoma in humans.[38] It acts as a proton pump inhibitor (inhibits parietal cell H^+-K^+ ATPase), which is the last common step in gastric acid secretion. Omeprazole is considered to be more effective than H_2-receptor antagonists because it inhibits gastric

acid secretion stimulated by any of the secretagogues, while the H_2-receptor antagonists inhibit only the actions of histamine. Omeprazole has a long duration of action and is effective at controlling the clinical signs of gastrinoma in dogs.[73] Dosage is 0.7 to 1.0 mg/kg PO every 24 hours.

Octreotide, a long-acting somatostatin analogue, is occasionally used in humans with gastrinoma refractory to H_2-receptor antagonists and omeprazole. It has been used in dogs.[70] Dosing ranges between 5 to 20 µg subcutaneously every 8 hours.

Prognosis

The long-term prognosis for gastrinoma is poor owing to its highly malignant nature with 76% of cases having gross metastasis at the time of diagnosis.[74] In previous studies, surgical and/or medical treatment resulted in survival times of 1 week to 18 months.[75] With the availability of drugs to reduce gastric hypersecretion and to promote healing of ulcers, the short-term prognosis is improving.

Glucagonoma

Glucagonoma is a tumor of the A cells of the pancreatic islets in which excessive amounts of glucagon are inappropriately secreted. Glucagon-secreting tumors are rare in both

humans and animals, with only a few reported cases in dogs.[76-82] Dogs typically present with a characteristic dermatitis involving the foot pads that is consistent with superficial necrolytic dermatitis (SND). High levels of glucagon are thought to be involved in the development of these skin lesions, although the mechanism is poorly understood. Patients may also develop diabetes mellitus caused by stimulation of gluconeogenesis and glycogenolysis from excessive secretion of glucagon.[76] DM usually occurs when insulin production cannot match the increased glucagon secretion.[77] Other clinical signs include cheilosis, normocytic-normochromic anemia, venous thrombosis, weight loss, polyuria,

polydipsia, glossitis, stomatitis, and diarrhea. Three dogs with glucagonoma ranged in age from 8 to 11 years and had a chief complaint of chronic dermatitis. Skin lesions occur particularly in areas of trauma and involve hyperkeratosis of the foot pads; erythematous, erosive, and crusting lesions on the muzzle, external genitalia, perineum, and periocular region. Other common historical complaints included weight loss, polydipsia, and polyuria. Weight loss is likely a result of the catabolic effects of glucagon on fat and protein metabolism.[83]

Diagnosis

A baseline complete blood count, serum biochemistries, and urinalysis should be obtained. Clinical pathologic abnormalities can include a mild nonregenerative anemia, hypoalbuminemia, hepatic enzyme elevations, low blood urea nitrogen, and possibly persistent hyperglycemia. Elevated serum glucagon concentration in the absence of hypoglycemia is suggestive of the presence of a glucagonoma.[38,80] Other syndromes associated with mildly elevated glucagon concentrations include diabetic ketoacidosis, renal failure, hepatic failure, sepsis, and starvation.[30] Hypoaminoacidemia may also be a feature of this disease, and supplementation of amino acids may

improve dermatologic conditions.[30] Skin biopsies are necessary to diagnose superficial necrolytic dermatitis, which is characterized by diffuse parakeratotic hyperkeratosis, acanthosis, vacuolar changes of keratinocytes, and epidermal edema.[76-79] Submission of multiple biopsy samples from the edges of early skin lesions is most useful.[80] Diagnostic imaging of the thorax and abdomen may show evidence of local or metastatic disease. Abdominal ultrasonography may reveal hepatic lesions or a pancreatic mass, however, of 9 dogs with glucagonomas that had ultrasonography performed, a pancreatic mass was visualized in only one dog.[76-82] Abdominal computerized

tomography has been used in one dog to identify a pancreatic mass and was also successful in identifying multiple liver masses.[77]

Treatment and Prognosis

Surgical resection is the treatment of choice. Histologic evaluation of pancreatic masses in dogs has demonstrated pancreatic carcinomas with glucagon immunoreactivity.[77-79] Metastasis is common, and if present, tumor debulking may be helpful in palliating clinical signs. Chemotherapy has been attempted in humans with some success.[84-85] Dietary supplementation with essential fatty acids, zinc, and amino acids may

improve skin lesions, and has shown success as an infusion in one case report in a man.[86] Long-term prognosis is poor. Most canine patients are diagnosed late in the course of the disease, preventing the possibility of a cure. Short-term palliation of signs can be successful with early surgical and medical treatment.

Pancreatic Polypeptidoma

Pancreatic polypeptide (PP) is a common component of pancreatic islet cell tumors. It is well documented that the majority of endocrine tumors contain multiple hormones, and pancreatic polypeptide is the second most common hormone identified by

immunocytochemistry in canine pancreatic endocrine tumors.[87] This rare pancreatic islet cell tumor has been documented to produce clinical signs in only one dog. This 7-year-old spayed female cocker spaniel presented with a history of chronic vomiting, anorexia, and weight loss.[87] Elevated serum PP concentration was documented. Serum gastrin concentrations were also elevated but provocative testing was normal. Necropsy revealed a pancreatic adenocarcinoma with metastasis to the liver, gastric hypertrophy, and multiple duodenal ulcers. Immunocytochemical staining of the tumor for gastrin was negative. Serum PP concentrations were extremely

elevated and both the tumor and its metastases stained strongly positive for PP. The authors proposed that the high serum concentrations of PP contributed to the dog's gastrointestinal ulceration and vomiting.[87]

VIPoma and Somatostatinoma

VIPomas are pancreatic islet cell tumors that have been identified in humans, but have not been documented in dogs and cats.[38] Intestinal secretion of fluid and electrolytes secondary to high circulating concentrations of vasoactive intestinal polypeptide (VIP) causes clinical signs of profuse watery

diarrhea, fecal loss of potassium and bicarbonate, and low or absent gastric acid secretion. This may lead to a severe metabolic acidosis secondary to bicarbonate loss in the diarrhea. VIPomas are diagnosed based on measurement of serum fasting VIP concentrations by radioimmunoassay and histologic confirmation of a non-beta-cell pancreatic tumor with a high content of VIP.[88] Surgical excision is the treatment of choice, with 50% achieving remission when metastasis is not present.[89] Medical therapy with streptozocin plus fluorouracil has been used in humans with nonresectable or metastatic carcinoma. Octreotide has been used to lower plasma concentrations of VIP in patients

refractory to other treatment modalities.

Somatostatinomas have also been recognized in humans, but not in dogs and cats. Somatostatin has been found to be present in canine islet cell tumors.[32,35,36] In humans, excess secretion of somatostatin from D cells of the pancreas causes glucose intolerance, cholelithiasis, diarrhea, steathorrhea, hypochlorhydria, and weight loss.[90] Diagnosis is based on clinical features, documentation of increased serum concentrations of somatostatin, and histologic examination of the tumor. Metastasis occurs to the liver and adjacent lymph nodes and is usually present at the

time of diagnosis of these slow-growing tumors. Surgical excision is the treatment of choice, but chemotherapy with streptozocin has been attempted.[38]

Conclusion

The endocrine pancreas is a complex organ that presents multiple challenges for the veterinary surgeon. Its production of various hormones and their effects on the body require an understanding of the normal physiology of the endocrine pancreas as well as the pathophysiology of its disorders. These disorders can be challenging to diagnose and a thorough understanding of endocrine

function is necessary to correlate the clinical picture with its etiology. Diagnosis and appropriate management of affected cases relies on knowledge of the mechanism of disease, the potential for perioperative complications, and the long-term outcome with medical or surgical management.

Chapter 82

Adrenal Glands

Andrew E. Kyles

Anatomy

The adrenal glands are paired, retroperitoneal structures located cranial and medial to the cranial pole of each kidney. The right adrenal gland lies dorsolateral to, and is intimately associated with, the caudal vena cava. The left adrenal gland is more caudal in location. The phrenicoabdominal vein courses over

the ventral surface of each adrenal gland, while the phrenicoabdominal artery lies on the dorsal surface of the gland. The adrenal arterial blood supply is derived from branches of the aorta and phrenic, renal, accessory renal, phrenicoabdominal, and lumbar arteries. Venous drainage is into the caudal vena cava and renal and phrenicoabdominal veins. Malignant adrenal tumors sometimes invade these venous structures.

The adrenal gland consists of two separate endocrine components with distinct embryonic origins. The cortex is derived from the celomic epithelium and is of mesodermal origin. Histologically, the cortex is divided

into an outer zona glomerulosa, the chief site of aldosterone production, and the zona fasciculata and the inner zona reticularis, which together are responsible for the production of glucocorticoids and sex hormones. The medulla is derived from the sympathetic ganglia and is ectodermal in origin. The adrenal medulla produces catecholamines, epinephrine, and norepinephrine.

Glucocorticoids

Physiology

The production of glucocorticoids is regulated via the hypothalamic-pituitary-adrenal axis. Corticotrophin-releasing hormone (CRH) is a 41

amino acid peptide hormone. CRH is secreted by neurons in the anterior portion of the paraventricular nuclei of the hypothalamus. CRH is delivered to the pituitary gland via a portal circulation and acts to stimulate the secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland (adenohypothesis). ACTH is a 39 amino acid peptide hormone derived from a large precursor molecule, proopiomelanocortin. The primary function of ACTH is to stimulate the secretion of glucocorticoids from the adrenal cortex. Cortisol is the major glucocorticoid produced. Circulating cortisol and synthetic glucocorticoids produce a negative feedback inhibition

of the hypothalamus and pituitary, thus inhibiting ACTH secretion. During severe stress, such as pain, trauma, acute hypoglycemia, and surgery, the suppressive effects of glucocorticoids are overridden, resulting in increased secretion of CRH, ACTH, and glucocorticoids.

Hyperadrenocorticism

Hyperadrenocorticism (Cushing's syndrome) is caused by chronic exposure to excessive concentrations of glucocorticoids. Of dogs with naturally occurring hyperadrenocorticism, 80% to 85% have pituitary-dependent hyperadrenocorticism (PDH). PDH causes excessive production of ACTH

resulting in bilateral adrenocortical hyperplasia and excessive secretion of glucocorticoids. The majority of dogs with PDH have a small pituitary adenoma (microadenoma); 10% to 20% of dogs with PDH have large pituitary adenomas (macroadenoma). These tumors can compress and invade the overlying hypothalamus, resulting in clinical signs such as dullness, listlessness, inappetance, and disorientation, which can progress to neurologic signs such as aimless wandering, ataxia, head pressing, circling, and seizures. Pituitary carcinomas are rare in dogs.

Functional primary adrenocortical tumors secrete excessive amounts of

cortisol independent of pituitary control. The excess gluocorticoid production suppresses hypothalamic CRH and plasma ACTH concentrations, resulting in cortical atrophy of the contralateral adrenal gland. Functional adrenocortical tumors commonly retain ACTH receptors and respond to exogenous ACTH administration by secreting cortisol. Histologic differentiation of adrenocortical adenomas and carcinomas is challenging; it would appear that the two tumor types occur with approximately equal frequency in dogs. Cases of simultaneous occurrence of PTH and an adrenocortical tumor or pheochromocytoma have been reported, as have bilateral

adrenocortical tumors and simultaneous occurrence of an adrenocortical tumor and a pheochromocytoma. Naturally occurring hyperadrenocorticism should be differentiated from the iatrogenic form caused by chronic glucocorticoid therapy.

Signalment

The median age of dogs with naturally occurring hyperadrenocorticism is 11.4 years;[1] the disease is uncommon in dogs younger than 6 years of age. Hyperadrenocorticism is seen in a variety of breeds, with poodles, daschunds, various terrier breeds and German shepherd dogs being

commonly represented. Approximately 75% of dogs with PDH weigh less than 20 kg, whereas 45% 50% of dogs with a functional adrenocortical tumor weigh more than 20 kg.[1] Females account for 55% to 60% of dogs with PDH and 60% to 65% of dogs with a functional adrenocortical tumor.[1] Hyperadrenocorticism is rarely diagnosed in cats. There are reports of cats with clinical signs of hyperadrenocorticism caused by a progesterone-secreting adrenal tumor.

History and Physical Examination Findings

Hyperadrenocorticism is one of the most common endocrinopathies in

dogs. The clinical signs are largely attributable to chronic glucocorticoid excess, resulting in gluconeogenic, immune-suppressive, anti-inflammatory, protein catabolic, and lipolytic effects. Clinical signs include polydipsia and polyuria, polyphagia, bilateral symmetric alopecia and other skin abnormalities (hyperpigmentation, comedone formation, thin skin, thin hair coat, and calcinosis cutis), pendulous abdomen (owing to hepatomegaly, muscle wasting, and intraabdominal fat accumulation), muscle weakness, muscle atrophy, panting, heat intolerance, and anestrous or testicular atrophy. The number and severity of clinical signs vary markedly. PDH and

a functional adrenocortical tumor cannot be differentiated based on clinical signs.

Medical Complications Associated with Hyperadrenocorticism

1. Hypertension
2. Pyelonephritis
3. Diabetes mellitus
4. Pulmonary thromboembolism

Clinicopathologic Findings

CBC: Excess glucocorticoids produce a stress leukogram in most dogs, consisting of a mature neutrophilia, lymphopenia, eosinopenia, and

monocytosis.

Biochemistry profile: The most common abnormality is increased serum alkaline phosphatase (ALP) activity (a result in part of the induction of a glucocorticoid isoenzyme unique to dogs). Alanine aminotransferase (ALT) activity may also be increased associated with a steroid hepatopathy. Mild to moderate increases in cholesterol and triglyceride concentrations are common, and serum bile acid concentrations may be elevated. Serum bilirubin and albumin concentrations are usually within the reference ranges. Glucose concentration varies, with approximately 10% of dogs developing

overt diabetes mellitus (interestingly, up to 80% of cats with hyperadrenocorticism are diabetic). Blood urea nitrogen and serum creatinine concentrations may be low as a result of diuresis.

Urinalysis: Urine specific gravity is often low, although most dogs retain an ability to concentrate urine with water deprivation. Urinary tract infections occur in 40% to 50%.[2] Proteinuria is common, associated with urinary tract infection or glomerular leakage. Glucosuria may occur if the renal glucose threshold is exceeded.

Thyroid function tests: Decreased basal serum T_4 and/or T_3 concentrations are

common.

Diagnostic Imaging

Thoracic radiography: Mineralization of the tracheobronchial tree and pulmonary parenchyma is a nonspecific finding that is more common in dogs with hyperadrenocorticism. Radiographs should be evaluated for signs of pulmonary metastases and pulmonary thromboembolism.

Abdominal radiography: Findings include hepatomegaly, obesity, and mineralization of soft tissue structures. Adrenal gland mineralization occurs in approximately 50% of adrenocortical tumors.

Abdominal ultrasonography: Dogs with PDH usually have relatively equal sized adrenal glands with normal or enlarged dimensions. In dogs with a functional adrenocortical tumor, the affected adrenal gland is usually enlarged and irregular with mixed echogenicity, and a normal or atrophied adrenal gland is usually observed on the contralateral side. Compression or invasion of the phrenicoabdominal vein and/or caudal vena cava may have occurred, and intraabdominal metastases may be present. The liver is generally enlarged with increased echogenicity, and urinary calculi and dilated renal pelvises (caused by pyelonephritis) may be present.

CT or MRI: Used to rule out a pituitary macroadenoma. Abdominal imaging may provide additional information on adrenal anatomy, intraabdominal metastases, and vascular invasion.

Adrenal Function Tests

Screening tests are used to confirm the diagnosis of hyperadrenocorticism.

Basal plasma cortisol concentration: As cortisol is released episodically, this test has virtually no diagnostic value.

Urine cortisol:creatinine ratio: This test adjusts for fluctuating plasma concentrations of cortisol. Has high sensitivity but low specificity; may thus be a good test for ruling out

hyperadrenocorticism.

ACTH stimulation test: This measures the response of the adrenal glands to maximal ACTH stimulation. It has a sensitivity of 60 to 85% and a specificity of 85 to 90%.[3] It cannot differentiate PDH from a functional adrenocortical tumor. This is the only test that can identify dogs with iatrogenic hyperadrenocorticism and is the only test in veterinary medicine for monitoring response to therapy.

Low-dose dexamethasone suppression (LDDS) test: Dexamethasone is a synthetic glucocorticoid that does not cross react in the cortisol assay. In normal dogs, the cortisol concentration

decreases 2 to 3 hours after dexamethasone administration, whereas dogs with hyperadrenocorticism do not experience suppressed cortisol concentrations. For the LDDS test, dexamethasone is administered (0.01 mg/kg IV) and blood samples collected 4 and 8 hours later. The sensitivity of the test at 8 hours after administration is 85 to 95% and the specificity is 70 to 75%.[3]

Differentiating tests are used to differentiate PDH from a functional adrenocortical tumor.

High-dose dexamethasone suppression (HDDS) test: After administration of a

high dose of dexamethasone (0.1 mg/kg IV), approximately 75% of dogs with PDH have suppressed cortisol concentrations, whereas in dogs with a functional adrenocortical tumor, even large doses of dexamethasone should not suppress plasma cortisol concentrations.[3]

Endogenous plasma ACTH concentration: In dogs with a functional adrenocortical tumor, the hypothalamic-pituitary axis is suppressed and the ACTH concentration is low or undetectable, whereas dogs with PDH usually have an ACTH concentration above the reference range.

Surgery

Adrenalectomy: Surgical removal is the treatment of choice for adrenal tumors. During surgery, hemostasis is a definite challenge. Adrenal tumors can cause a tumor thrombus in the caudal vena cava. In most dogs with a caval thrombus, the tumor invades the phrenicoabdominal vein and extends into the caudal vena cava.[4] This results in a pedunculated caval thrombus based around the insertion of the phrenicoabdominal vein that can be removed by temporary caval occlusion and a venotomy centered around the insertion of the phrenicoabdominal vein. After unilateral adrenalectomy, cortisol secretion from the

contralateral, atrophied adrenal gland is suppressed and glucocorticoid supplementation is needed during and following surgery. Aldosterone secretion from the contralateral adrenal gland is usually adequate, although electrolyte concentrations should be closely monitored and mineralocorticoid therapy instituted if hyperkalemia and/or hyponatremia are observed. Bilateral adrenalectomy necessitates lifelong glucocorticoid and mineralocorticoid supplementation.

Dogs with hyperadrenocorticism are hypercoagulable and at increased risk of experiencing pulmonary thromboembolism after surgery; therefore, these patients should be

maintained on anticoagulant regimens following surgery. Other surgical considerations include impaired wound healing, a greater propensity for wound infection, impaired respiratory function, and hypertension. Postoperative mortality rates are relatively high (21-28%).[4,5] Other serious postoperative complications include pancreatitis, pneumonia, sepsis, and acute renal failure.

Hypophysectomy: Transsphenoidal hypophysectomy is the treatment of choice for humans with PDH and has been shown to be an effective treatment in dogs with PDH.[6,7] Potential intraoperative complications include hemorrhage from the arterial

circle during exploration of the fossa. Following hypophysectomy, dogs require lifelong therapy with glucocorticoids and thyroxine. Diabetes insipidus is normally transient, requiring short-term treatment with vasopressin. Reduced tear production is frequently reversible. Estimated survival rates at 2 and 4 years were 76% and 68%, and 2- and 4-year estimated relapse-free fractions were 75% and 58%.[7]

Medical Therapy

Mitotane (o,p'-DDD, Lysodren): Mitotane is a potent adrenolytic drug that causes selective destruction of the zona fasciculata and zona reticularis (site of

glucocorticoid production) while sparing the zona glomerulosa (site of mineralocorticoid production). The drug is most commonly used to induce and maintain a state of partial adrenocortical destruction, with the goal of restricting glucocorticoid production to amounts needed for daily life. The ACTH stimulation test is used to monitor therapy. It can also be used to induce complete adrenocortical destruction, a state that requires lifelong glucocorticoid and mineralocorticoid therapy. The results of using mitotane in cats with hyperadrenocorticism have been disappointing.

Trilostane: Trilostane is an orally

administered competitive inhibitor of the enzyme 3β-hydroxysteroid dehydrogenase. This enzyme converts pregnenolone to progesterone and 17-hydroxypregnenolone to 17-hydroxyprogesterone in the adrenal cortex. Trilostane thus inhibits the production of cortisol, aldosterone, and androstenedione. Similar to the use of mitotane, the aim is to restrict cortisol production and the dose of drug is altered based on the results of ACTH stimulation testing. Trilostane has been used successfully to manage PDH and functional adrenocortical tumors in dogs. Trilostane is reported to ameliorate the signs of feline hyperadrenocorticism.

Ketoconazole: Ketoconazole is a fungistatic drug that blocks several P-450 enzyme systems. It produces reversible inhibition of the synthesis of glucocorticoids and androgens, while sparing mineralocorticoid production. Trilostane has largely replaced ketoconazole for the management of hyperadrenocorticism. The use of ketoconazole in cats with hyperadrenocorticism has produced mixed results.

Mineralocorticoids

Physiology

The production of mineralocorticoids is primarily regulated by the renin-angiotensin system. Renin is produced

by the juxtraglomerular cells, which surround the afferent arterioles of the renal glomeruli. The juxtaglomerular cells monitor renal perfusion. Volume depletion and hypotension stimulate renin production. Renin acts on a plasma α2-globulin produced by the liver, releasing angiotensin I. Converting enzyme in the lung converts angiotensin I to angiotensin II, a potent vasoconstrictor and the primary stimulant for aldosterone production. The primary site of action of aldosterone is the renal tubule, where it promotes the resorption of sodium and water and the excretion of potassium. This results in expansion of the extracellular fluid volume, and removes the stimulus for renin

production.

Hyperaldosteronism

Primary hyperaldosteronism (Conn's syndrome) is caused by autonomous secretion of aldosterone by a tumor of the zona glomerulosa layer of the adrenal cortex. Hyperaldosteronism results in sodium retention, expansion of the extracellular fluid volume, and hypertension. The production of renin is suppressed. Increased potassium excretion leads to progressive depletion of body potassium and the development of hypokalemia and hypokalemic metabolic alkalosis.

The condition is rare in cats and dogs.

Clinical signs include weakness, which may be episodic, cervical ventroflexion (cats), lethargy, polyuria, and/or polydipsia. The most common clinicopathologic abnormality is moderate-to-severe hypokalemia. The sodium concentration may be normal or slightly elevated. Definitive diagnosis requires demonstrating an inappropriately elevated aldosterone concentration with a low renin concentration. Adrenalectomy is the treatment of choice in animals with no detectable metastases. Medical therapy consists of potassium supplementation and spironolactone (an aldosterone antagonist) administration.

Adrenocortical Insufficiency

Hypoadrenocorticism is a syndrome that results from deficient secretion of glucocorticoids and/or mineralocorticoids by the adrenal cortices. Primary hypoadrenocorticism (Addison's disease) is caused by the destruction of more than 90% of adrenocortical tissue. Primary hypoadrenocorticism is rare in the dog and cat. The most common cause is idiopathic adrenocortical insufficiency, which is most likely a result of immune-mediated destruction of the adrenal cortices. Iatrogenic hypoadrenocorticism is a possible complication of mitotane therapy in dogs with hyperadrenocorticism. Although mitotane usually spares the

zona glomerulosa and thus mineralocorticoid production, some dogs experience a permanent, complete adrenocortical failure. Other causes of primary hypoadrenocorticism include bilateral adrenalectomy, hemorrhage or infarction of the adrenal glands, granulomatous or neoplastic destruction of the adrenal glands, amyloidosis, and trauma. Secondary hypoadrenocorticism is caused by deficient production of ACTH, resulting in impaired secretion of glucocorticoids by the adrenal cortices; the production of mineralocorticoids is spared.

Deficiency of glucocorticoids causes a decreased tolerance to stress, including

a reduced ability to mount a stress response to surgery. Other signs include inappetance, vomiting, diarrhea, abdominal pain, and lethargy. Aldosterone deficiency impairs the patient's ability to conserve sodium and water and causes a failure to excrete potassium, resulting in hyponatremia and hyperkalemia. Hyponatremia induces lethargy, depression, and nausea, whereas hyperkalemia results in muscle weakness and impaired cardiac conduction. These patients experience hypovolemia, hypotension, reduced cardiac output, and impaired renal perfusion.

Signalment

Female dogs account for approximately 70% of cases.[8] Hypoadrenocorticism can be diagnosed in dogs of any age, but is most common in young and middle-aged dogs. No breed predilection has been identified.

History and Physical Examination Findings

Acute hypoadrenocorticism (Addisonian crisis) causes hypovolemic shock. Dogs present in a state of collapse or they collapse when stressed, with a weak pulse, profound bradycardia, vomiting, diarrhea, dehydration, and hypothermia. The

chronic form of hypoadrenocorticism causes vague, non-specific, and often episodic clinical signs. Signs include lethargy, anorexia, weight loss, vomiting, diarrhea, obtundation, shaking or shivering, muscle fasiculations, muscle weakness, and polyuria/polydipsia.

Clinicopathologic Findings

CBC: Changes can include lymphocytosis, eosinophilia, and a mild nonregenerative anemia.

Biochemistry profile: The most common abnormalities noted include hyponatremia, hyperkalemia, pre-renal azotemia, and metabolic acidosis. The normal sodium:potassium ratio is

27:1 to 40:1; most patients with hypoadrencorticism have a ratio below 25:1. In approximately 10% of dogs with primary hypoadrenocorticism, the serum electrolyte concentrations are within the reference ranges at initial examination.

Electrocardiographic Findings

Hyperkalemia impairs electrical conduction in the heart. An ECG can be used to evaluate patients with hypoadrencorticism. As a rough guide:

Modest hyperkalemia	Peaking of T waves

(5.5-6.5 mEq/L)	Shortening of Q-T interval
Moderate hyperkalemia (6.5-7.5 mEq/L)	Increased QRS duration P-wave amplitude decreases P-R interval prolonged
Severe hyperkalemia	P wave disappears

(> 7.5 mEq/L) Severe bradycardia

Adrenal Function Tests

ACTH stimulation test: The gold standard for diagnosing hypoadrenocorticism. The resting cortisol concentration is low or nondetectable with a subnormal or negligible cortisol response to ACTH.

Endogenous plasma ACTH concentration: Used to differentiate primary from secondary hypoadrenocorticism. Dogs with primary hypoadrenocorticism have a markedly elevated ACTH concentration (owing to a lack of negative feedback of cortisol), whereas

those with secondary hypoadrenocorticism have low or undetectable concentrations of ACTH.

Medical Therapy

Acute primary hypoadrenocorticism: Initial therapy consists of aggressive intravenous fluid therapy using normal saline (0.9% sodium chloride) at an initial rate of 60 to 80 ml/kg/hour for 1 to 2 hours. Urine output and, if possible, central venous pressure should be monitored. This therapy will correct the hypovolemia and hyponatremia. The serum potassium concentration decreases owing to dilution and improved renal perfusion, and specific therapy for hypokalemia

is usually not required. Other therapies for hyperkalemia include intravenous glucose administration (addition of 5% dextrose to intravenous fluids), which can be combined with insulin therapy and intravenous calcium administration.

Intravenous glucocorticoid therapy (hydrocortisone sodium succinate, prednisolone sodium succinate, or dexamethasone sodium phosphate) is initiated early during treatment of acute hypoadrenocorticism. Mineralocorticoid therapy is not essential for the management of an Addisonian crisis, but administration of a mineralocorticoid is usually initiated.

Chronic primary hypoadrenocorticism: During maintenance therapy, a mineralocorticoid is administered. Fludrocortisone acetate (15 mg/kg PO once daily, adjusting the dose to keep the serum sodium and potassium concentrations within the reference ranges) has mainly mineralocorticoid effects, although it retains some glucocorticoid activity. Desoxycorticosterone pivalate (DOCP; 2.2 mg/kg IM or SQ every 25 days) has no glucocorticoid activity and should be combined with a low dose of prednisone or prednisolone (0.1-0.2 mg/kg/day).

Prognosis

The long-term prognosis for the management of hypoadrencorticism is excellent with appropriate maintenance therapy. Animals should receive supplemental doses of glucocorticoids during periods of stress, such as when undergoing anesthesia and surgery.

Adrenal Medulla

Physiology

The adrenal medulla is essentially a large sympathetic ganglion that lacks postganglionic fibers. Catecholamines are the primary secretory product of chromaffin cells. Catecholamines are synthesized from the amino acid tyrosine. The first step in

catecholamine synthesis, the conversion of L-tyrosine to L-DOPA, involves the enzyme tyrosine hydroxylase, and is the rate-limiting step. Secretory products are stored in cytoplasmic vesicles in the chromaffin cells. Stimulation of the chromaffin cell results in exocytosis of the vesicles and expulsion of their contents. The end product of catecholamine synthesis is predominately epinephrine in humans and dogs, and norepinephrine in cats. The half-life of catecholamines in the circulation is short (minutes). Catecholamine catabolism is mediated by two enzymes, catecholamine-O-methyltransferase (COMT) and monoamine oxidase (MAO). The predominant metabolite is

vanillylmandelic acid (VMA), which, along with the catecholamines, is excreted in the urine.

Pheochromocytoma

Pheochromocytoma is a catecholamine-producing tumor derived from the chromaffin cells of the adrenal medulla. Neoplastic transformation of the chromaffin cells results in loss of regulatory control of catecholamine release. In the fetus, chromaffin cells are widely distributed and form paraganglia. Most extra-adrenal chromaffin cells involute after birth, although remnants remain, and tumors of the extra-adrenal chromaffin cells, paraganglionomas, are reported. A

substantial portion of dogs with a pheochromocytoma also have another malignancy. Pheochromocytomas can occur in human patients with multiple endocrine neoplasia type 2 (MEN2) syndrome, and a similar syndrome has been reported in dogs.

History and Physical Examination Findings

Clinical signs are often vague and episodic. Clinical signs may relate to either excessive circulating catecholamine concentrations or the presence of an abdominal mass. The most common signs in dogs are weakness and collapse. Signs related to catecholamine excess include

tachycardia and arrhythmias, panting, anxiety, pacing, seizures, blindness (from retinal hemorrhage), polyuria and polydipsia, vomiting, diarrhea, and anorexia. Signs related to the adrenal mass include hemoabdomen (associated with tumor rupture) and Budd-Chiari syndrome (owing to obstruction of the caudal vena cava producing ascites and hind limb edema and weakness). In some dogs, the pheochromocytoma is diagnosed as an incidental finding, for instance during performance of abdominal ultrasonography for an unrelated reason.

Clinicopathologic Findings

CBC and biochemistry panel: Findings are nonspecific.

Urinalysis: Proteinuria owing to hypertensive glomerulopathy may be present, as well as hyposethenuria or isothenuria.

Catecholamine concentrations: The measurement of basal plasma catecholamine concentrations and the urine concentrations of catecholamines and catecholamine metabolites is not routinely performed in veterinary medicine.

Arterial Blood Pressure Determination

Catecholamine secretion and systemic hypertension tend to be episodic in patients with a pheochromocytoma.

Diagnostic Imaging

Abdominal ultrasonography: Pheochromocytomas appear as adrenal gland mass lesions with variable echogenicity. The patient should also be assessed for the presence of intraabdominal metastases and vascular invasion.

CT or MRI: Abdominal imaging may provide additional information on adrenal anatomy, intraabdominal metastases, and vascular invasion.

Treatment

Adrenalectomy is the treatment of choice. Patients with a pheochromocytoma are a challenge to anesthetize. Dogs in which a pheochromocytoma is suspected are placed on phenoxybenzamine at least 2 weeks prior to surgery. Phenoxybenzamine is an α-adrenergic blocking drug with a long duration of action. It is considered the drug of choice for preoperative management of hypertension as it binds noncompetitively with the receptor, and thus, surges of catecholamine release cannot override the inhibition. A relatively high dose of phenoxybenzamine is recommended

(up to 2.5 mg/kg b.i.d. PO). Management of hypertension prior to surgery allows reexpansion of the intravascular plasma volume by removing the vasoconstrictive effects of high catecholamine concentrations. Intraoperative hypertension is managed by intravenous administration of phentolamine, a short-acting, competitive α-adrenergic blocking drug (loading dose 0.1 mg/kg; CRI 1-2 μg/kg/min). Intraoperative hypotension is managed by decreasing the dose of or discontinuing phentolamine; administration of phenylephrine; or rapid expansion of the vascular volume by administration of crystalloid fluid, plasma volume expanders, or blood

products. Phenylephrine is a short-acting α_1-adrenergic agonist that can displace phentolamine from the receptor. Esmolol, a short-acting β_1-adrenergic blocking drug, is administered intravenously (loading dose 0.1 mg/kg; CRI 50-70 μg/kg/min) in those cases with persistent tachycardia despite adequate α-adrenergic blockade and vascular volume expansion. Medications that stimulate catecholamine release should be avoided, including ketamine, morphine, and halothane. Moderate surface-induced hypothermia (esophageal temperature of 32° C) is recommended in case temporary caval occlusion is required.

Part XII

Hematopoietic System

Chapter 83

Spleen

Brigitte A. Brisson

Anatomy and Function

The spleen lies along the left body wall within the superficial leaf of the greater omentum and is attached to the greater curvature of the stomach by the omentum, more specifically, the gastrosplenic ligament.[1] Although its shape, size, and position vary with species and breed as well as other factors such as drugs or pathologic

conditions, the spleen is typically oblong and red-blue. Blood enters the spleen from the splenic artery, a branch of the celiac artery, and leaves through the splenic vein, which empties into the gastrosplenic vein and eventually into the portal vein.[1] Splenosis or accessory splenic nodules are commonly found within the omentum of small animals and likely represent small revascularized fragments of spleen that occur secondary to trauma.[1-4] Single nodules of ectopic splenic tissue embedded along the surface of the pancreas are described in cats but are not attributed to trauma.[4] Siderotic or siderofibrotic plaques are slightly raised, yellow to grey, irregularly sized deposits of

calcium and iron that are commonly found along the margin of the splenic capsule of older dogs.[5] These plaques are thought to develop secondary to splenic trauma.[6,7] The spleen of dogs and cats is often visible radiographically. On the ventrodorsal view, the head of the spleen sits laterally on the left side and is often visualized as a triangular soft-tissue density just caudal to the gastric fundus and cranial to the left kidney. On a lateral radiographic projection, the tail of the spleen can be identified along the ventral body wall just caudal to the liver.

The spleen is composed of a capsule rich in elastic and smooth muscle

fibers, a network of fibromuscular trabeculae, and the parenchyma, which is located between the capsule and trabeculae and consists of red and white splenic pulp.[1] The white pulp contains diffuse and nodular lymphoreticular tissue and the red pulp is primarily made of venous sinuses and cords of reticular cells.[1] Whereas the canine spleen is considered sinusoidal, the feline spleen has a poorly developed sinusoid system and is often referred to as nonsinusoidal. As whole blood filters through the trabecular meshwork of the spleen, plasma is skimmed off into the white pulp while red blood cells move toward the red pulp.[8] In dogs, a small portion of the blood that enters the spleen is

delivered directly into the venous sinuses of the red pulp, bypassing the splenic cords and travelling rapidly through the spleen; this is known as a closed circulation. A larger portion of the blood that enters the spleen empties into the red pulp and circulates slowly through the fine trabecular meshwork of the splenic cords; this is known as the open circulation. Within the cords, red blood cells distort themselves to squeeze through small pores between the reticuloendothelial cells lining the sinus walls to be released into the venous circulation. This process slows the flow of red blood cells through the spleen and results in increased blood viscosity, low blood pH, and decreased

blood concentrations of glucose and oxygen. These conditions cause increased mechanical and metabolic stress to older or damaged red blood cells. During their slow passage through the red pulp of the spleen, abnormal red blood cells, therefore, are culled or pitted as required and bacteria or unwanted debris are phagocytosed by the macrophages that line the trabeculae and venous sinuses.

Physiology – Normal Splenic Functions

Red Blood Cell Storage

The slow passage of red blood cells from the splenic cords to the splenic sinuses essentially traps red blood cells

within the trabeculae and makes the red pulp of the spleen a reservoir for red cells. It has been shown that 10 to 20% of a dog's red blood cells may be sequestered in the spleen at any one time.[9] Smooth muscle fibers of the spleen contract in response to endogenous or exogenous catecholamines in order to rapidly release the stored red blood cells into the general circulation.[9] In fact, blood loss equal to 40% of the circulatory volume is fatal in splenectomized dogs.[10] In addition, approximately 30% of circulating platelets can be found within the normal spleen at any given time.[9,11]

Hematopoiesis

Although the spleen actively participates in red blood cell production during fetal development, hematopoeisis within the spleen stops at birth when the bone marrow takes over this task almost exclusively. In times of high demand, when the bone marrow is unable to produce enough red blood cells, foci of extramedullary hematopoiesis can develop within the spleen.[11,12] These foci are thought to be derived from pluripotent hematopoeitic stem cells present within the spleen. Extramedullary hematopoeisis is a comon cytologic and histologic diagnosis in dogs and cats.[3,13]

Red Blood Cell Maturation

Reticulocytes released into circulation by the bone marrow become trapped within the spleen where they spend a few days in order to complete their maturation. While in the spleen, remaining intracellular material and excessive cell membrane are removed. By this process, immature cells entering the spleen leave as mature, biconcave cells.[8]

Removal of Abnormal or Senescent Red Blood Cells

Red blood cells live approximatly 4 months, after which time they are no longer pliable enough to squeeze

through the pores of the splenic sinuses. Older red blood cells either rupture as they attempt to pass through sinus pores or they simply become trapped within the spleen and are removed by the reticuloendothelial system; this is also known as culling.[8] During phagocytosis, the iron present in the red cells is recycled and released into circulation as plasma transferrin to be used by the bone marrow to produce new erythrocytes, or it is retained in the spleen and stored by the phagocyte as ferritin and hemosiderin.[14] Whereas normal red blood cells deform to pass through the fenestrations in the splenic sinuses, the passage of more rigid cells containing inclusion bodies is delayed. The

increased contact time with the perisinusoidal phagocytic cells allows removal of inclusion bodies such as Heinz bodies and Howell-Jolly bodies; this process is known as pitting.[8]

Immune Function

Because of its architecture and sluggish blood flow, the spleen provides an excellent environment for phagocytosis and immune function. For this reason, the spleen is more effective at removing poorly oopsonized bacteria than is the liver.[11] The pulp of the spleen contains large reticuloendothelial cells that phagocytose circulating debris, microorganisms (bacteria and

parasites), and antibody-coated cells. Removal of antibodies that coat the red blood cell surface (pitting) results in the formation of a smaller cell, a spherocyte. Because spherocytes are less pliable, they tend to get trapped within the spleen and are destroyed by phagocytosis.[8] The spleen is also thought to play a role in the complement pathways and in the the production of B and T lymphocytes, plasma cells, and antibodies (especially IgM).[8]

Other Functions

Other reported functions include the production of the tetrapeptide tuftsin, a potent stimulator of neutrophil and

macrophage phagocytic activity in man; storage and activation of Factor VIII; regulation of the formation and degradation of angiotensin-converting enzyme; and modulation of plasma norepinephrine levels and/or prostaglandin E_2 activity.[8]

Diseases of the Spleen

Dogs and cats with splenic diseases have clinical signs and hematobiochemical changes that vary considerably depending on the underlying pathology.[15,16] Ventricular tachyarrhythmias are prevalent in dogs with splenic masses, particularly if the mass has ruptured.[17,18] Arrhythmias have also been described in dogs with

splenic torsion[19,20] and have been commonly reported during and after splenectomy.[16,20] The mechanism of arrhythmias secondary to splenic disease is not well understood but may result from transient ischemic coronary episodes, shock, reduced cardiac output, acidosis, or toxemia.[20]

A study evaluating hematologic parameters in dogs with malignant and benign splenic lesions revealed that dogs with sarcomas have significantly higher total white blood cell counts compared with dogs with benign disease, and significantly higher neutrophil counts than do dogs with round cell tumors or benign disease.[21] Dogs with round cell tumors

have significantly lower platelet counts than do dogs with benign disease and lower monocyte counts than do dogs with sarcomas or benign disease.[21] Although the degree of anemia and presence of schistocytes was not shown to vary with the disease process in one study,[21] another reported that anemia, nucleated red blood cells and abnormal cell morphology were asociated with splenic neoplasia.[22]

Treatment for most splenic disorders (splenic abscess, torsion, neoplasia, and trauma) involves splenectomy. Splenectomy is also indicated when medical management of immune-mediated diseases (immune-mediated hemolytic anemia [IMHA] and

immune-mediated thrombocytopenia) has failed and for the detection of occult carriers of Ehrlichia, Babesia, or Hemobartonella in blood donors.[23] The effects of splenectomy are not completely understood but it is generally accepted that the spleen is not essential to life in dogs and cats. Following splenectomy, the functions of the spleen are carried out by the liver, lymph nodes, and bone marrow. However, since the spleen takes over hematopoeisis when the bone marrow is unable to do so, splenectomy is contraindicated in cases of bone marrow hypoplasia.

A study evaluating hematologic and biochemical changes at 3 and 10 days

post splenectomy in dogs with splenic disease revealed no consistent changes in RBC, WBC, and platelet counts, or bone marrow samples or biochemical profiles.[16] Although not signicant, thrombocytosis (platelet count greater than 500,000/μl) was reported in 50% of patients 10 days after surgery.[16] Serum iron, transferrin, and IgM concentrations also remained normal after splenectomy.[16] These findings differ slightly from those previously reported for normal dogs, which included significant increases in platelet counts, minimal elevation in WBC count, and reduction in hematocrit, red cell volume, plasma volume, and iron turnover.[24] The exact cause for postsplenectomy

thrombocytosis is unknown but it has been reported to resolve after 40 days in normal dogs.[25] Although postsplenectomy sepsis is commonly reported in people,[8,26] and a few cases have been reported in small animals,[9,27] this does not appear to be a common complication. A study reports that approximately 20% of patients undergoing splenectomy developed pyrexia in the postoperative period, but no correlation was found between pyrexia and positive bacterial culture of the splenic tissue.[16]

Because the spleen is no longer present to filter the blood, red blood cell inclusions such as Howell-Jolly bodies are more commonly seen and small

animal patients are at higher risk for developing parasitic blood infections.[28,29] Other reported consequences of splenectomy include decreased exercise tolerance and response to shock or hemorrhage.[30,31] Retrospective evaluations of patients undergoing splenectomy for various conditions have identified no complications related to the procedure itself or to asplenism.[15]

Prevalence of Splenic Diseases

Significant discrepancy exists with regard to the incidence of neoplastic versus nonneoplastic splenic lesions in dogs and cats. Some studies report that

benign splenic masses such as hematoma and nodular hyperplasia are most commonly diagnosed in dogs undergoing splenectomy,[3,9,15,32] whereas others describe neoplastic lesions, especially hemangiosarcoma as being most common.[22,33,34] Neoplastic splenic pathology, especially mastocytosis, is reported most commonly in cats.[4]

Splenomegaly

Splenomegaly is the term used to describe a uniformly enlarged spleen regardless of the cause. Splenic mass is the terminology used when an asymmetric enlargement of the spleen is noted. Dogs appear to develop

splenic masses more commonly than diffuse splenic enlargement, whereas cats most commonly develop diffuse splenomegaly.[3,4,22]

Drug-induced splenomegaly is reported with the administration of phenothiazine barbituates such as acepromazine and ultra-short-acting barbituates such as thiopental.[35] These drugs result in significant pooling of blood within the spleen secondary to smooth muscle relaxation of the splenic capsule.[9] In fact, as much as 5 to 40% of a dog's red blood cells may become sequested in the spleen during anesthesia.[36,37] One study revealed that induction protocols containing thiopental and a combination of

ketamine-diazepam caused significant splenic enlargement compared with induction protocols that used propofol.[38] Drug-induced splenomegaly has been shown to last more than 2 hours.[35,38] Other causes of congestive splenomegaly include portal hypertension, right-sided heart failure, and splenic torsion.[30]

Splenic Torsion

Splenic torsion is a rare condition that affects large, deep chested dogs and may occur as a primary entity or secondary to gastric dilation volvulus (GDV).[19,20] Great Danes and German shepherd dogs have been identified as breeds that are predisposed to splenic

torsion; males are affected more frequently than females.[19] Although the etiology of spontaneous splenic torsion is uncertain, it has been suggested that the spleen retains a rotated position after spontaneous resolution of a GDV or that repeated gastric dilation stretches the gastrosplenic ligament, making the spleen more prone to torsion.[39,40] Torsion of the splenic vascular pedicle and obstruction of the venous outflow causes blood to accumulate in the sinusoids, eventually leading to thrombosis of splenic vessels. Clinical signs vary, depending on whether the torsion is acute or chronic, and include shock and abdominal pain in acute cases and anorexia, lethargy, vomiting,

discolored urine, and polyuria/polydypsia in chronic cases.[19,20] A diagnosis of splenic enlargement is usually made by palpation and radiography.[19,41] Specific radiographic (C-shaped spleen) and ultrasonographic (generalized splenomegaly, hypoechoic pattern consistent with congestion and abnormal flow through the hilar splenic vessels) abnormalities have also been reported.[19,40-42] Splenectomy is the treatment of choice. Most surgeons recommend removal of the spleen without derotating the pedicle to prevent the release of thrombi, endotoxins, and free radicals,[19,20,43] although one report describes an acute case in which the pedicle was

derotated in order to salvage the spleen of a racing greyhound.[44] A previous case report described a 180-degree splenic torsion that was initially untwisted but required complete splenectomy four days later owing to complete torsion of the splenic pedicle.[20] Montgomery suggested that splenopexy should be performed if the surgeon elects to preserve the spleen but a technique was not described.[45] Gastropexy is recommended following splenectomy for splenic torsion, to decrease the risk of gastric torsion in the future.[19,46] Although the prognosis is not always good, one study reported 100% survival in 19 cases of splenic torsion.[19]

Splenic Hyperplasia

Splenic hyperplasia represents a more physiologic form of diffuse splenic enlargement that typically remains asymptomatic. Hyperplasia can occur owing to immune stimulation, secondary to infection or septicemia (splenitis), or with splenic hyperactivity related to the active removal of abnormal red blood cells in patients with IMHA or blood parasites. Passive congestion secondary to portal hypertension caused by hepatic disease or right-sided heart failure are other potential causes. Nodular hyperplasia is common in older dogs and is characterized by single or multiple subcapsular nodules of various size.

Nodular hyperplasia is of no clinical significance but must be differentiated from other less benign splenic masses.

Splenic Hematoma

Splenic hematoma can develop secondary to an underlying splenic pathology such as neoplasia, secondary to trauma, or as a spontaneous lesion.[5,34,47] An association has been made between splenic hematomas and nodular hyperplasia in the dog. Nodular hyperplasia results in distortion of the marginal splenic blood flow, causing an accumulation of blood within and around the hyperplastic nodules leading to the formation of a hematoma.[3] Splenic

hematomas can present as multiple smaller masses or as a single mass that might be as large as 20 cm in diameter.[33] Splenic hematomas cannot be grossly differentiated from hemangiosarcomas but are often larger, firmer, and more organized than hemangiosarcoma lesions.[3] Splenic hematoma is treated by splenectomy and appears to have a good prognosis, with one study reporting that all dogs died of unrelated disease at a median of 14 months postsplenectomy.[47] A more recent study reported 83% and 64% survival rates at 2 and 12 months, respectively.[32]

Splenic Neoplasia

Infiltrative neoplastic diseases such as lymphoma, histiocytosis, and mastocytosis are common causes of splenomegaly.[48,49] Malignant histiocytosis is most commonly reported in Bernese Mountain dogs.[49] Mast cell neoplasia is most frequent in cats and represents the number one splenic condition diagnosed in this species.[4] Hemangioma and its malignant counterpart hemangiosarcoma (HSA) are tumours of endothelial origin that occur commonly in dogs and less commonly in cats.[3,4] Hemangiosarcoma has been reported by some as the most common splenic mass diagnosed in dogs,[22,33,34]

but others have reported higher rates for benign lesions such as hemangioma, hematoma, and nodular hyperplasia.[3,9,15,32] Other neoplastic disorders such as leiomyoma, leiomyosarcoma, fibrosarcoma, lipoma, and liposarcoma as well as other sarcomas are associated with asymmetric splenic enlargement, resulting in a mass effect but these occur less frequently.[33,34,50,51]

Hemangiosarcoma has been described as the most common splenic tumor in dogs.[3,15,33,34] The heart, skin, and liver are other common sites of primary HSA.[52,53] Male, large breed dogs, particularly German shepherd dogs, Labrador and golden retrievers are

predisposed to HSA.[3,15,22,34,52] Splenic HSA can present as single or multiple masses of variable diameter; these masses can rupture and develop omental attachments.[33] Gross distinction between HSA and splenic hematoma is not possible, although splenic HSA tends to be multifocal with nodules that are individually smaller and more cavitated than those seen in cases of hematoma.[3] Metastasis to the liver is most common, followed by the omentum and mesentery;[33,52,53] more than 50% of patients have metastatic lesions at the time of diagnosis.[52] Other commonly reported sites of metastasis include the kidney, regional lymph nodes, heart, and lungs.[33,52,53] When metastasis is not present,

splenectomy is the treatment of choice. Lesions of nodular hyperplasia within the liver can easily be confused with metastasis; as such, hepatic nodules should be biopsied to confirm the diagnosis.[54] Partial splenectomy is not recommended even in cases where a localized mass is present.

Histologic differentiation between hematoma, hemangioma, and HSA can be difficult; multiple tissue sections should be examined to reduce the risk of misdiagnosis.[3,55] The interval between diagnosis and death is generally short (3 to 4 months) and does not appear to be affected by the stage of disease (presence or not of visible metastasis).[22,33,52,54] A large

retrospective study reported 31% and 7% survival rates at 2 and 12 months, respectively.[32] In this last study, the presence of a single mass was associated with an increased survival rate (16%) at 12 months.[32] Newer chemotherapeutic protocols may hold promise in improving survival.[56]

Splenic Trauma

Splenic trauma is most commonly related to blunt abdominal trauma. Trauma commonly results in rupture of the splenic capsule and parenchyma, leading to abdominal hemorrhage. Iatrogenic trauma to the spleen is also possible during abdominal procedures and laparoscopy. Owing to its highly

vascular nature, trauma to the spleen can lead to significant abdominal hemorrhage and possibly death. Surgical intevention may be required in cases where conservative treatment (abdominal pressure bandage, intravenous fluids, and blood transfusions) is not successful at controlling hemorrhage. Surgical treatment should aim to control hemorrhage and, if possible, to save the spleen. Hemostasis may be achieved by suturing the ruptured splenic parenchyma and capsule with mattress sutures and applying an omental patch or a hemostatic sponge such as Surgicel or Gelfoam to control residual oozing.[57-59] As in humans, if splenectomy is required, partial

splenectomy is preferred in order to retain some splenic function.[59-60] Autotransplantation of resected splenic tissue in an attempt to maintain some splenic function has been studied in dogs as a model for human trauma patients.[60-62] Techniques described include the implantation of avascular "splenic chips" or slices within a pouch of the greater omentum; conflicting results regarding the success of this technique have been reported.[60-62] Although autogenous splenic transplants have been shown to grow and hypertrophy in dogs, the amount of splenic tissue required for normal function is unknown.

Splenic Abscess

Splenic abscessation is rarely reported but can occur as a single abscess[15,33] or as diffuse microabscesses spread throughout the entire organ.[4,33,34] Abscesses have been described secondary to sepsis (bacteremia) and penetrating foreign bodies.[4,33,63] Single splenic abscesses can be removed by partial[15] or complete splenectomy.[33] Diffuse abscessation is best treated by complete splenectomy.[33,34]

Splenic Thrombosis and Infarction

Splenic infarction is a condition that is most commonly associated with a coagulopathy and splenomegaly as

well as other systemic disorders such as cardiac, liver, or renal disease, neoplasia, hyperadrenocorticism, sepsis, and DIC.[3,4,33,42] Splenic infarcts can have a nodular appearance that make them difficult to differentiate from nodular hyperplasia, hematoma, or HSA.[42] Treatment is generally aimed at correcting the primary condition. Splenectomy is reserved for patients with serious splenic complications such as hemoabdomen.[42] Splenic infarction secondary to splenic torsion (with or without GDV) is discussed elsewhere.

Chapter 84

Thymus

David Biller
Meredith Esterline

Anatomy

The thymus is a gray to pink bilobed organ found in the precardiac mediastinum.[1] It extends from just cranial to the first rib to the fifth rib in dogs or sixth rib in cats, although the size and shape are highly variable.[2] It is divided into right and left lobes. The left lobe extends more caudally than

the right to between the left thoracic wall and left ventricle, but composes only 40% of the weight of the thymus.[1] The larger right lobe is more laterally expanded and extends to the pericardial sac. Dorsally, the thymus is associated with the phrenic nerves, the trachea, and the cranial vena cava. The thymus is derived from the endoderm and ectoderm of the third pharyngeal pouch and the third branchial cleft.[3]

Nine arterial vessels have been identified that comprise the blood supply to the thymus.[4] The left lobe is supplied by several branches. Two branches of the brachiocephalic trunk supply the cranial and caudal poles of

the left thymus. The left internal thoracic artery sends a large branch to the caudal pole, has three thymic arterial branches with two going to the cranial pole and one going to the caudal pole, and feeds the pericardiophrenic artery, which sends a thin branch to the cranial pole. The right lobe is supplied by a branch of the right internal thoracic artery, the pericardiophrenic artery, which forms one branch to each pole of the right lobe. Veins of the thymus are associated with the arteries. Four to six lymphatic vessels empty into the cranial mediastinal and sternal lymph nodes.[1] Parasympathetic and sympathetic nerve fibers supply the thymus.[1,2]

The thymus has a capsule of fibrous intralobular septae separating the two lobes. These are difficult to separate cranially, but caudally allow separation into the two distinct lobes. These septae allow passage for vessels, nerves, and lymphatics.[3] The septae end near the corticomedullary junction in a compartment called the perivascular space, where nutrient and waste exchange occurs between the lobules and the blood and lymphatic circulation.[3] B-cells, plasma cells, myeloid cells, eosinophils, and mast cells also accumulate within the perivascular space. The cortex, located peripherally, is made up of a large population of small, immature thymocytes, specialized cortical

epithelial cells, and scattered macrophages. The centrally located medulla contains nearly mature and mature T-cells that are closely associated with medullary epithelial cells, dendritic cells, macrophages, and Hassall's corpuscles. Hassall's corpuscles appear onion like, with concentrically organized, highly keratinized epithelial cells. The medulla has a lower cell density than does the cortex. The cortex to medulla ratio is 1:1.[2] The most peripheral part of the thymus is the thin subcapsular zone, which is lined with a thin perivascular epithelium extending along the internal capsule and along the intralobular septae.[3]

Physiology

The thymus is responsible for seeding T-cells against foreign antigens while recognizing the tissues of the body as normal. T-cells begin formation in the bone marrow as common lymphoid precursor (CLP) cells, which may develop into T-cells, B- cells, or natural killer (NK) cells.[5] Some of the CLP cells enter the thymus and become immature thymocytes. These cells go through stages to become immature T-cells, making them positive for T-cell markers like CD4 and CD8.[3] Nurse cells in the cortex are thought to form protective environments for thymocyte differentiation. Each nurse cell is responsible for up to 200 thymoctyes.

Positive selection occurs in the cortex, exposing the thymocytes to foreign antigens, resulting in recognition.[5] In the medulla, negative selection occurs, with dendritic cells designed to stimulate apoptosis of the cells with excessive self reactivity.[6] A large number of macrophages are present to help remove the unwanted T-cells. Hassall's corpuscles also contribute to removal of unwanted T cells.[3] Only 5% to 10% of T-cells survive positive and negative selection.[3,5] T-cells remain in the thymus for 4 to 5 days during this process.[6]

The thymus enlarges until the animal is 4 to 5 months of age, and then begins a rapid but never complete involution

process.[2] It has been thought that increased adrenal corticosteroids coupled with a decrease in growth hormone may influence the involution process.[7] The thymic tissue is replaced by fat.

Neonatal thymectomy results in a loss of the cell-mediated immune response.[6] The number of circulating lymphocytes decreases dramatically, as do the lymphocytes in T-dependent areas. The number of plasma cells in lymphoid tissues, the amount of serum immunoglobulin, and antibody formation also decrease. Adult thymectomy results in a gradual decrease in the numbers of lymphocytes, suggesting that a

reservoir of thymus-derived cells exists and must be exhausted.[6]

Pathophysiology

Although rare, some thymic-related diseases have been reported. In a review of thymic disease processes, 54 of the 66 cases reported in dogs and cats were thymoma or thymic lymphoma.[8]

Thymomas

Thymomas are tumors that originate from the thymic epithelium.[9] In dogs, large breeds and females are overrepresented.[10] In cats, purebreds (especially Siamese) and domestic

shorthairs are commonly affected.[11,12] They usually occupy the cranial mediastium but may extend from the neck to the posterior mediastinum.[13] Thymomas are often nodular and encapsulated, causing compression of nearby structures. Cystic thymomas, more common in cats than in dogs, occur with distention and fusion of the perivasulcar space.[14] Variable degrees of lymphocyte infiltration may be present; small or heterogenous lymphocytes are usually found, although large lymphocytes predominate in one third of thymomas.[13] The epithelial cells of a thymoma are usually elongated, but occasionally may be round to oval. Epithelial cells are arranged in solid,

trabecular, cribriform, whorled, rosette, or angiocentric patterns.[13] Other cells found within thymomas include mast cells, eosinophils, macrophages, melanocytes, plasma cells, and neutrophils. The results of fine-needle aspiration of thymomas may contain any of these cells, along with large numbers of lymphocytes; the epithelial cells may be present in smaller numbers. Cystic thymomas often yield a nondiagnostic sample.[9] Staining for cytokeratin positively identifies the epithelial cells of a thymoma.[13] The majority of thymomas are benign, with few metastasizing; however, thymomas are better categorized as invasive or noninvasive. Noninvasive thymomas are typically

easy to resect. Invasive thymomas are nonresectable, and palliative partial resection can result in high morbidity. Approximately 70% of thymomas are resectable, and no diagnostic test has been proven to be predictive of resection preoperatively.[9] Most presenting clinical signs of thymoma involve the respiratory tract, with the most common presentation in the dog and cat being coughing and dyspnea, respectively.[11,15,16] Other clinical signs are often associated with general ill health and paraneoplastic syndromes.

Paraneoplastic processes are common in conjunction with thymomas. Acquired myasthenia gravis is the most common thymoma-associated

paraneoplastic condition, caused by the production of autoantibodies against acetylcholine receptors in muscular tissue, leading to generalized weakness and megaesophagus.[2] The presence of megaesophagus is an important prognostic indicator, because patients with megaesophagus prior to surgery are at a high risk for aspiration pneumonia postoperatively. Isolated reports of resolution of megaesophagus and decline in acetylcholine antibodies after thymectomy exist.[10,17] Polymyositis may be linked to myasthenia gravis as well, with 29% of dogs with myasthenia gravis having polymyositis.[10] The cardiac muscle may also be affected. Autoantibodies to

acetylcholine have been proposed to cause myocarditis or to attack the conducting tissue directly, resulting in third-degree atrioventricular heart block.[15,18] Hypercalcemia has been reported, and in one case parathyroid-related protein (PTHrP) was increased. Resection of thymoma caused calcium and PTHrP to return to normal levels.

Cats may present with exfoliative dermatitis characterized by auricular and periauricular reddening progressing to marked exfoliation over the head, neck, trunk, and limbs, with skin ulceration in the axillae and inguinal regions.[19,20] Brown waxy exudate is found in the interdigital region and in the claw beds.[21] Skin

histopathology shows an interface dermatitis with CD3+ lymphocytes, mast cells, and plasma cells, and folliculitis.[22] The presence of CD3+ lymphocytes may be related to abnormal immune regulation that could occur with thymic disease. One cat with a thymectomy made a full recovery; other cats included in the study were euthanized. Other non-thymic tumors commonly occur in approximately 10% of human patients, and this is seen in dogs and cats as well.[23]

Prognosis with thymoma is varied, and few retrospective large-scale studies exist. If megaesophagus is not present, an 83% 1 year survival has been

reported.[15] In 11 dogs that were treated with chemotherapy and/or radiation therapy, a wide range of survival times has been found, ranging from 61 days to over 1657 days, with a median of 180 days.[12] In a study of 12 cats, half of them survived after surgical excision for a median of 21 months.[11]

Thymic Lymphoma

Thymic lymphoma is the most common thymic disease in the cat. Siamese and feline leukemia-positive cats are overrepresented.[8] It is frequently accompanied by other findings associated with lymphoma, such as enlarged lymph nodes or

paraneoplastic hypercalcemia.[9] Chemotherapy for lymphoma is the definitive treatment, and a rapid and complete response is common.[9] If the response is partial or if no response to chemotherapy is seen, thymoma is suspected. Radiation therapy can be used along with induction chemotherapy to improve the likelihood of rapid remission; it can be used if there is a delay in beginning chemotherapy; or if the patient is resistant to chemotherapy.[24]

Thymic Hemorrhage

Fatal thymic hemorrhage usually occurs within 2 years of birth during the involution process.[2] The etiology is

uncertain, but several theories have been proposed. The vessels of the thymus are not well supported during involution, and relatively minor trauma to the neck may cause the fragile vessels to rupture.[25] Ingestion of anticoagulant medication may be linked; in a case series of 10 dogs, half of them had consumed rodenticide.[26] Sudden increases in blood pressure owing to excitement have been hypothesized to result in hemorrhage.[27] Epileptiform seizure activity has been linked to thymic hemorrhage and death.[28] There is some debate over whether thymic hemorrhage is considered to be a true pathogenic entity or if it is always secondary to another cause.[25] German shepherds

and cocker spaniels may be overrepresented, and two Shetland sheepdog littermates were affected.[27,29] The mediastinum does not contain sufficient tissue for a hematoma to form, so bleeding can go unchecked and spill into the thoracic cavity. The mortality rate with thymic hemorrhage is high, but aggressive medical treatment with fluid support, blood transfusion, and vitamin K therapy if rodenticide toxicity is suspected, or rapid thoracotomy for control of bleeding and thymectomy if medical treatment is unrewarding.[27,30]

Thymic remnants in aberrant locations have also been implicated in thymic hemorrhage. Fatal hemopericardium

has been reported secondary to bleeding from a heart base thymic remnant.[28]

Other Thymic Disorders

Premature thymic atrophy can be seen with viral disease (canine distemper, parvovirus, feline leukemia, feline immunodeficieny virus, and panleukopenia), zinc deficiency, and growth hormone deficiency in Weimerainers.[7] The absence of a thymus may be associated with fading puppy syndrome.[31] Thymic hypoplasia is associated with lethal acrodermatitis in bull terriers with zinc deficiency, with a severe reduction of lymphocytes in T-lymphocyte rich areas of lymphoid

tissue.[32] Thymic hyperplasia has been reported in cats with laryngeal lymphoma and skin disease.[8] Other neoplastic conditions of the thymus may include carcinoma in conjunction with thymoma, germ cell tumor, and thymolipoma.[2]

Orthopedic

Chapter 85

Primary Bone Healing

D.J. Griffon

General Aspects

Bone has a breaking strength similar to that of medium steel. Yet it is elastic and relatively light, representing only 10% of body weight.[1] A fracture occurs when a bone is subjected to forces greater than its ultimate failure load, resulting in a loss of continuity. In these instances, the main goal of orthopedic surgeons is to palliate the

biomechanical functions of bone until its structural integrity has been regained. Bone assumes other vital functions such as storage of phosphorus and of approximately 99% of the body's calcium.[1] Its medullary cavity is a site of hematopoiesis and, in adults, a storage area for fat. However, the consequences of fractures on these functions are typically negligible compared with their impact on the biomechanical functions of bones. Indeed, structural integrity of the skeleton is essential to maintain locomotion and protection of vital organs. Bone serves as a frame for the origin and insertion of surrounding muscles and allows transmission of loads across the weight-bearing axis.

Osteosynthesis was developed to restore these roles and promote early return to function of the patient.

The lack of callus formation between two bone fragments apposed under a rigid plate was first noted by Lane in 1914.[2] Krompecher later reported that a neutral biomechanical environment was required to allow primary angiogenic bone formation in embryonic intact bone. The lack of callus formation as seen on postoperative radiographs of fractures repaired with compression plates was documented by Danis in 1949.[3] He termed this mode of repair “internal welding,” referring to direct filling of the fracture site with bone, without

formation of mechanically relevant periosteal or endosteal callus. Schenk and Willenegger later confirmed that healing under these conditions occurred by direct osteonal proliferation.[4] Stable interdigitation of bone fragments is clinically achieved by application of rigid, nongliding implants, such as compression bone plates or lag screws. Precise reduction and rigid fixation appear to eliminate the biological signals that are known to attract osteoprogenitor cells from surrounding soft tissues and contribute to callus formation in secondary healing.[5] Even under these conditions, the microenvironment differs within the fracture site and influences the process by which bone is laid. Indeed,

full congruency between the fragment ends is never achieved, even after meticulous reposition. Instead, contact and compression are obtained in circumscribed zones (contact points), separated by areas where fragment ends are separated by small gaps.[6]

Primary Healing of a Diaphyseal Fracture or Osteotomy

In the presence of normal blood supply and cell functions, accurate apposition and compression between bone fragments are prerequisites for primary healing. This may be achieved in clinical cases after anatomic reduction of a simple fracture and

fixation with a compression plate. However, the application of a bone plate tends to create different biomechanical microenvironments within the fracture site. A compression plate applied across a transverse osteotomy generates high pressure and, therefore, improves contact in the cortex located directly under the plate (Figure 85-1). On the other hand, the far cortex becomes a tension side and is predisposed to gap healing.[7,8] Both gap and contact healing differ from secondary healing by their lack of resorption of the fracture ends, even if a high magnitude of compression is applied across the fracture site.

Contact Healing

Contact healing occurs between apposed cortical surfaces, when the defect between bone ends measures less than 0.01 mm and interfragmentary strain is less than 2%.[9,10] These conditions allow the defect to be filled by primary osteonal reconstruction. Lamellar bone is directly deposited in the normal axial direction of the bone.[8,10] The process is initiated by the formation of cutting cones at the ends of osteons located closest to the fracture site.[11]

Osteoclasts line the spearhead of the cutting cone, while osteoblasts form the rear of the cutting cones, so that bony union and Haversian remodeling

occur simultaneously.[7,11] Osteoclasts advance across the fracture site, forming longitudinally oriented resorption cavities.[7] Perivascular osteoblastic precursors accompanying the capillary loops within these cavities differentiate into osteoblasts and produce osteoid.[10] Crossing osteons appeared at osteotomy sites 3 weeks after canine radii had been experimentally transected and stabilized with a plate.[6,7] Based on tetracycline labeling, the daily progress of these cutting cones across the fracture site has been calculated to vary between 70 and100 μm, which is about 3 times the size of each individual osteoclast.[12] Crossing osteons mature by filling with osteonal

lamellar bone and become the “spot welds” that unite the two fragments, without formation of periosteal callus. The lamellar bone formed is immediately aligned parallel to the long axis of the bone, with Haversian canals deviating from this axis by less than 10°.[13] However, the newly formed bone is less dense than the intact cortex during the first few months; therefore, the fracture area remains visible on radiographs until complete remodeling, which takes a few months up to a few years, depending on the species.[8]

Gap Healing

A different process of primary bone

healing has been observed in experimental defects, and later confirmed to occur across small gaps of rigidly fixed fractures. If interfragmentary deformation remains less than 2%, bone directly forms in gaps measuring less than 800 μm to 1 mm. This “gap healing” differs from the healing in contact areas as bony union and Haversian remodeling become separate sequential steps.[7] The fracture site fills directly by intramembranous bone formation, but the newly formed lamellar bone is oriented perpendicular to the long axis and later undergoes secondary osteonal reconstruction. A vascular loop from the medullary vasculature grows into the gap, and loose connective tissue

fills the site.[9] Osteoprogenitor cells accompany the vascular loop and differentiate into osteoblasts. After two weeks, the blood supply is well established and osteoblasts deposit layer upon layer of lamellar bone on each surface of the gap, until the two fragment ends are united.[11] Woven bone may form initially in larger gaps, to subdivide the area into smaller compartments, subsequently filled with lamellar bone.[7] Although the fragment ends are united by lamellar bone, this area remains mechanically weak, as the bone is oriented perpendicular to the long axis and poorly connected to adjacent intact cortex. Haversian remodeling starts between three and eight weeks, when osteoclasts form

longitudinally oriented resorption cavities (Figure 85-1).[11] These cutting cones are formed by new osteons within the fracture gap and by osteons originating from the surrounding intact bone. They advance across the fracture plane to unite the new lamellar bone deposited in the gap to each fragment end. The resorption cavities mature into longitudinally oriented lamellar bone, so that with time, the anatomical and mechanical integrity of the cortex is reestablished.

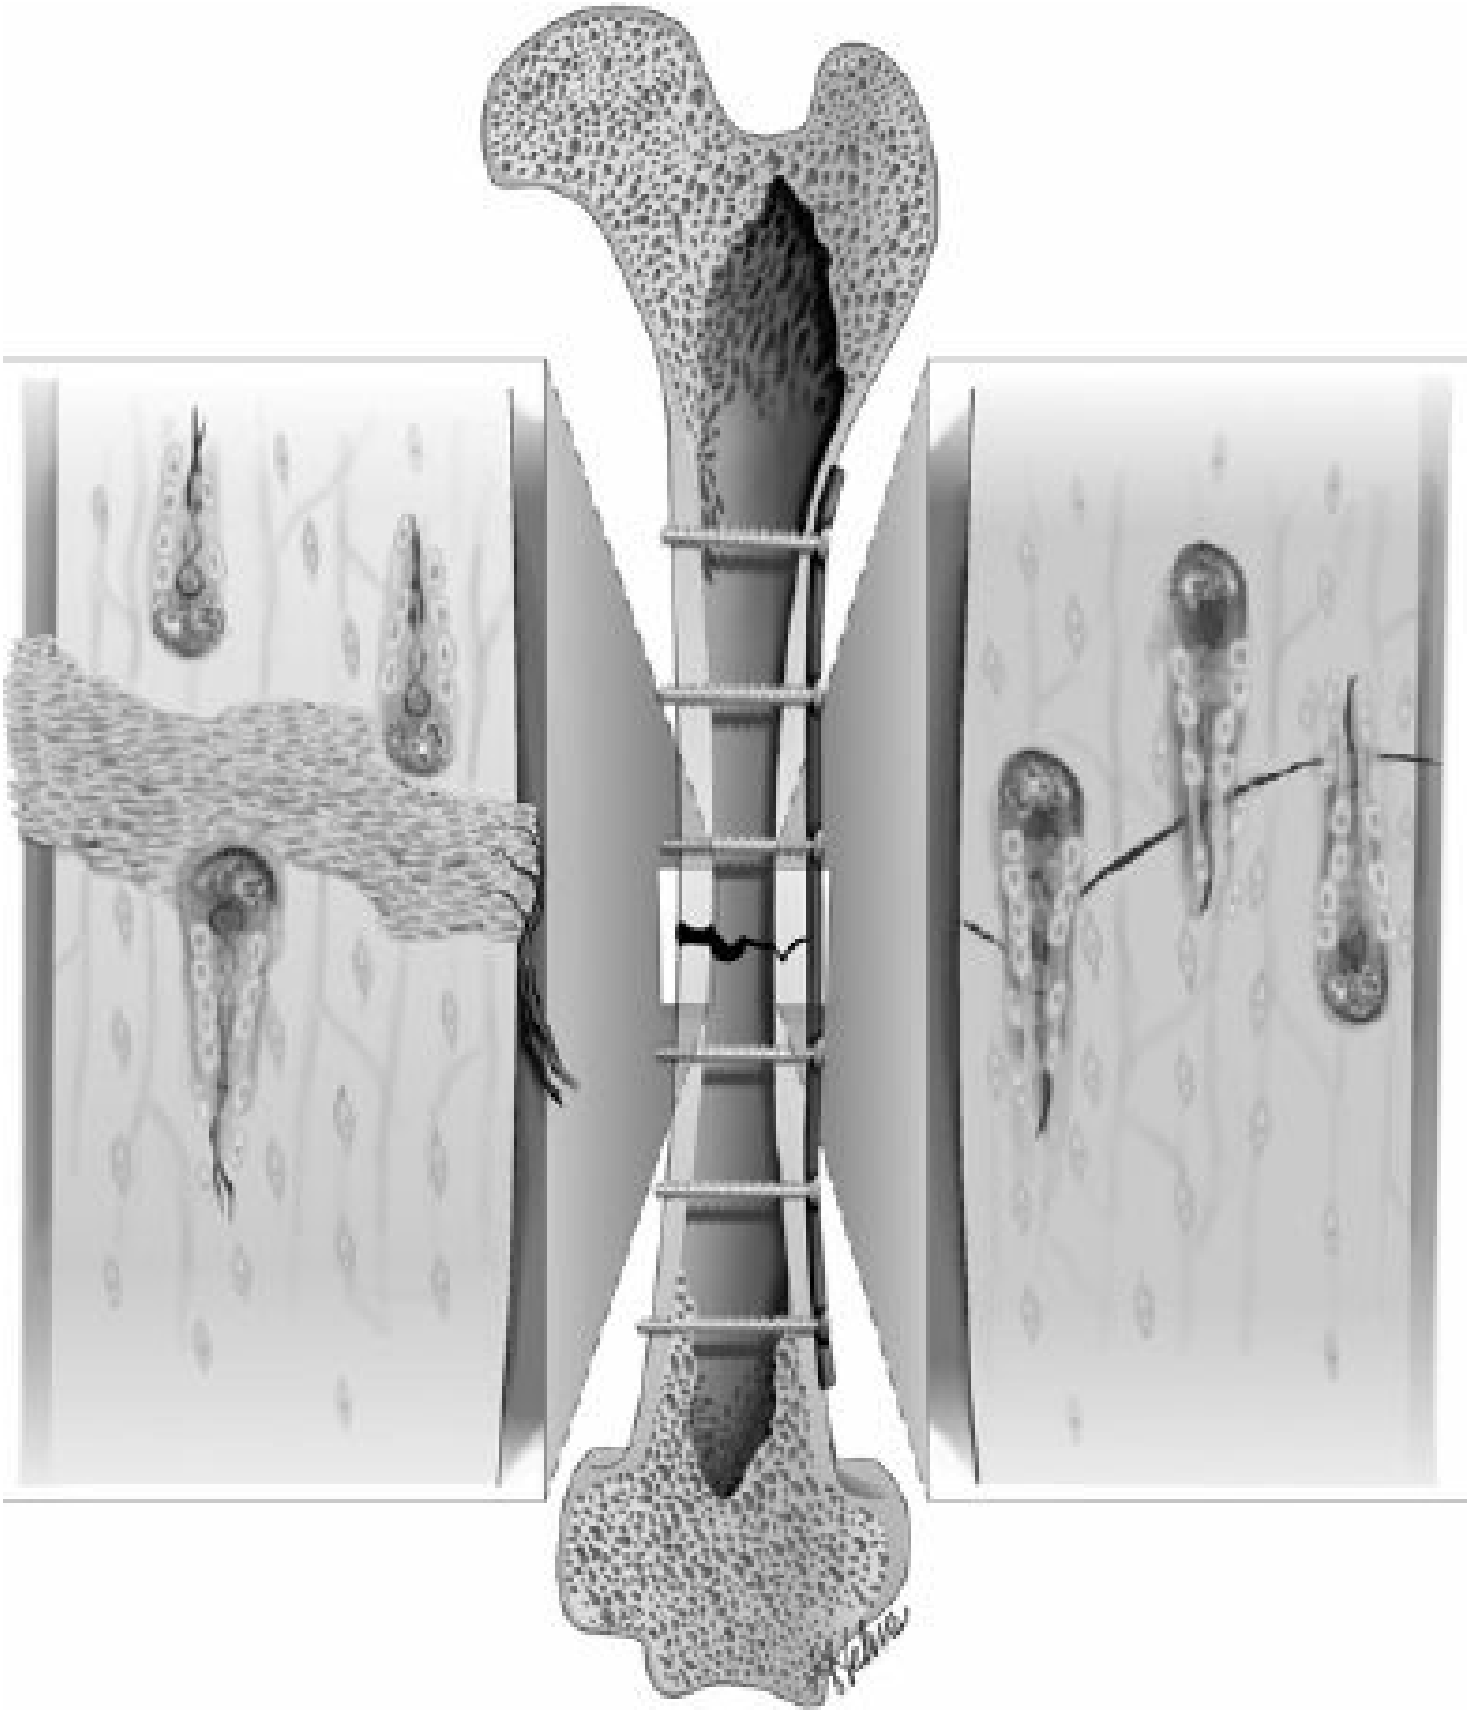

Figure 85-1. Primary healing after anatomic reduction of a transverse diaphyseal fracture and

application of a compression plate. The cis-cortex undergoes contact healing, whereas gap healing occurs in the trans-cortex.

Primary Healing of Cancellous Bone

Cancellous bone has a lower volume-to-surface ratio, which makes it 25 to 100 times weaker than cortical bone.[14] In a long bone, this relative weakness is palliated by the greater cross-sectional area of metaphyseal or epiphyseal bone, compared with the diaphysis. This characteristic improves the stability of metaphyseal bone in bending and torsion and increases its tolerance to strain, compared with diaphyseal bone. Indeed, any deformation applied to the bone will

be distributed over a larger area in the metaphysis than in the diaphysis. In addition, metaphyseal fractures often result in impaction of cancellous bone, thereby creating a mechanical environment minimizing interfragmentary motion.[15] Cancellous bone may consequently undergo primary healing, with new bone being deposited along the surfaces of the trabeculae.

Healing of cancellous bone has also been described in the context of bone grafting techniques. In dogs, the largest amounts of autogenous bone can be collected from the iliac crest, followed by the proximal humerus and medial proximal tibia.[16] Ribs and

proximal femur have been used less commonly as donor sites.[17,18] Metaphyseal cancellous bone is typically harvested via a round hole created through the cortex with a pin or a trephine. The healing of these circular defects has been studied in the proximal tibia of dogs.[19] By two weeks, a hematoma and fibrovascular tissue fill the bone defect. An endosteal callus forms by four weeks, with foci of cartilage and woven bone later replaced with lamellar bone. The normal structural arrangement of lamellar bone and hematopoietic marrow was reestablished in the marrow cavity at 12 weeks. Healing of donor sites was later found to vary somewhat with location, but a second

collection can be obtained from the same metaphyseal site 12 weeks after the first harvest.[16,17] Defects in the proximal tibia heal slower than do those located in the humerus and fill with more fibrous tissue.[17]

Primary Healing of Circular Bone Defects

The healing of circular bone defects occurs in a stable environment because the surrounding cortex remains continuous. However, the healing process varies with the diameter of the defect.

The healing of unicortical transverse burr holes has been described as

similar to fracture gap healing by Schenk.[6] In this experiment, unicortical 200 μm diameter holes created in the tibia of rabbits initially contained well vascularized granulation tissue. Osteogenic cells in the periosteum and endosteum rapidly proliferated and differentiated, initiating a healing process along the walls of the defect. Osteoblasts subsequently formed a continuous layer and deposited lamellar bone in a concentric manner. This bone was gradually replaced by longitudinally oriented osteons over the next months. Larger holes, up to 1 mm in diameter, are initially filled with a primary scaffold of woven bone. This scaffold consists of randomly oriented trabeculae, creating

200 μm diameter compartments filled with granulation tissue. Osteoblasts form a film over these trabeculae and begin to fill intertrabecular spaces with lamellar bone. Within a month, these compartments have narrowed down to the size of cortical bone vascular channels. Remodeling then proceeds to restore the original microscopic appearance of the cortex within a couple of months. Schenk drew four important conclusions from these observations; 1) small bone defects heal by primary intention, under stable conditions; 2) bone is always deposited on a solid surface, consisting of the wall of the defect or the surfaces of trabeculae within the defect; 3) osteoclasts do not appear within the

defect until 3 to 4 weeks, once remodeling is initiated; 4) the absence of osteoclasts within the first week after creation of small circular defects would imply that all signaling factors involved at this stage must influence osteprogenitor cells.

Filling of larger holes, such as screw holes, takes longer and may not be complete. Fibrous tissue is first formed along the surface of the walls (Figure 85-2).[20] Lamellar bone is then deposited into the fibrous network, proceeding from the periphery toward the center of the defect. Although remodeling gradually restores the orientation of the bone, the thickness of the cortex may not be regained. The

prolonged radiographic visibility of these defects reflects both their decreased cortical thickness and the presence of less mineralized new bone. Increasing the diameter of the defect eventually reaches a critical point, beyond which the regenerative capacities of the bone are exceeded and the defect persists permanently. The dimension of these critical-size defects vary with the location, species, and other environmental conditions. These defects are especially relevant in the skull and mandible, where they provide nonunion models for evaluation of new agents stimulating bone healing. In the diaphysis of long bones, the size of a bicortical circular defect, such as a screw hole, is

essentially limited by its stress-rising effect and potential for iatrogenic fractures. For example, defects measuring 20% of the diameter of the femur decreased the torsional strength of the bone by 34% in sheep.[21]

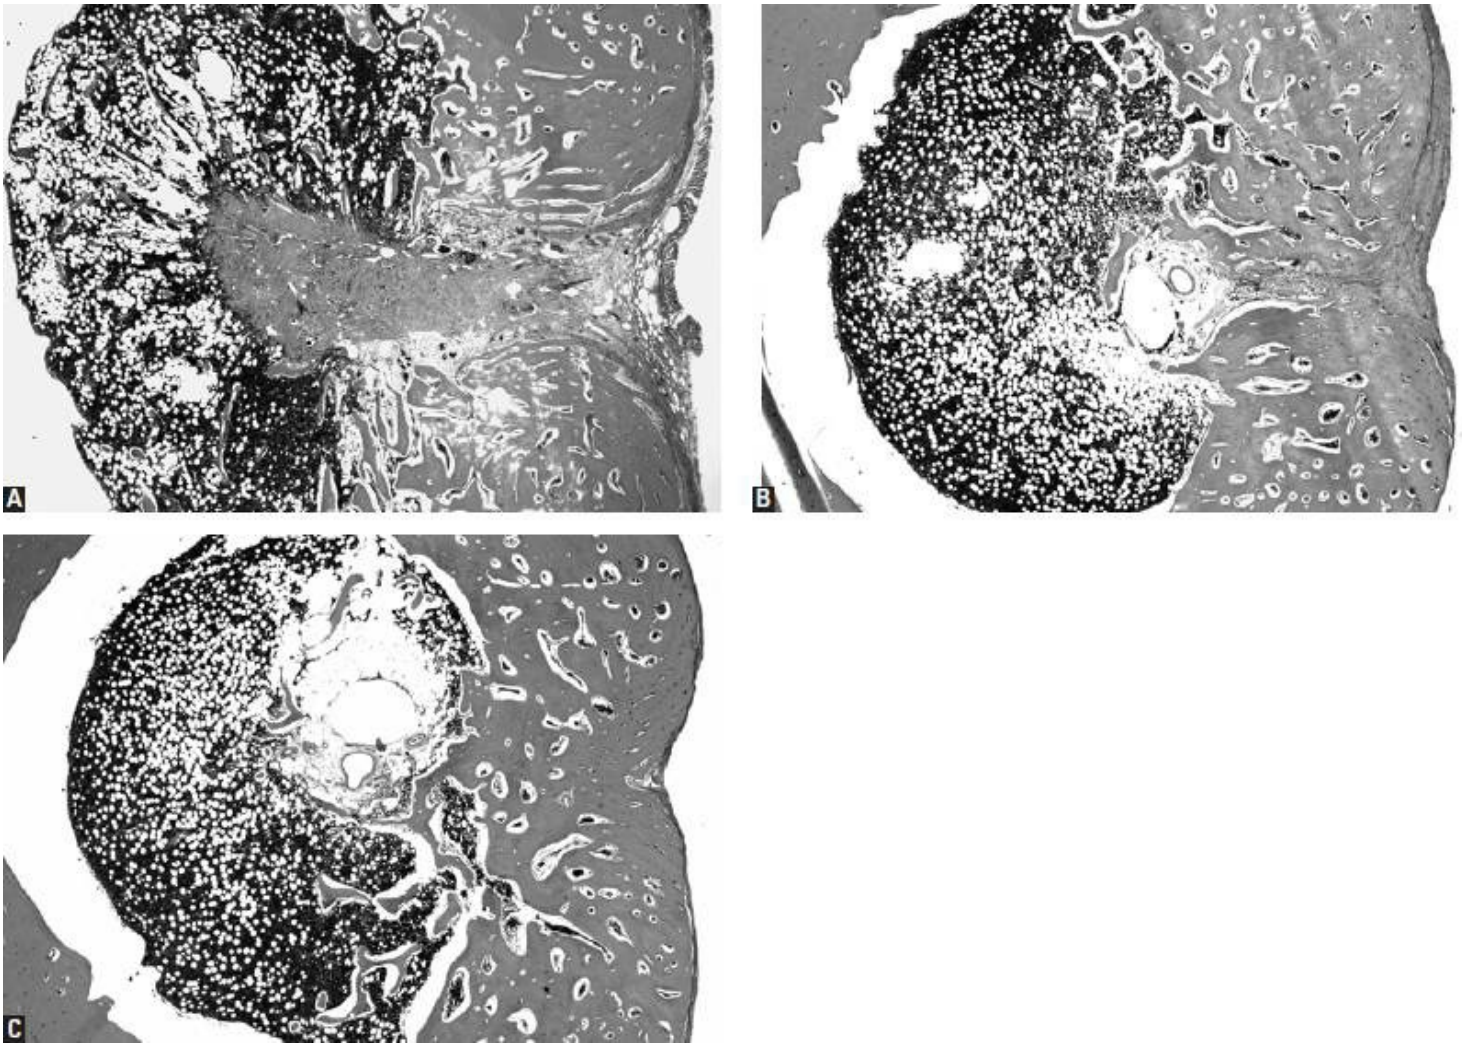

Figure 85-2. Healing of a 5-mm diameter unicortical circular defect in the femoral diaphysis of a dog (x1.2, H&E). The defect initially fills with connective tissue (A). Bone forms along the edges of the defect and progresses toward the center (B). Woven bone fills the entire defect and remodeling starts along the periphery (C).

Evaluation of Bone Healing

Clinical assessment of fracture healing has traditionally been based on physical examination and radiographs. Current research focuses on improving existing imaging techniques and developing new tools for early detection of complications (such as infection and delayed healing) and objective guidance of postoperative fracture management (return to function and implant removal).[22-24] For example, the ultrasonographic appearance of healing has recently been described after biologic fracture fixation of long bones (e.g., external coaptation, external fixators, or interlocking nails) in dogs and cats. Ultrasonographic signs of bony union included a hyperechoic continuous line

in three views and disappearance of intramedullary implants. In this clinical study, secondary fracture healing was diagnosed 20 days earlier via ultrasonography than it was radiographically.[25] Correlating these findings with a biomechanical evaluation of the callus would strengthen recommendations for implant destabilization or removal based on early ultrasonographic signs of healing. Indeed, fracture healing should intuitively be evaluated by the return of prefracture stiffness and ultimate strength, because the main goal of fracture management is to restore the structural functions of bone. Ultimate strength and stiffness of the bone defect are commonly measured to

quantify healing in experimental fracture models used to study bone repair or evaluate fracture treatment modalities. For example, no refracture nor angulation were diagnosed in an experiment where an external fixator was removed once the fracture gap had regained a stiffness equal to 10 Nm/degree.[26] Although measurement of fracture stiffness recently allowed early detection of human patients at risk for tibial nonunions, biomechanical testing of clinical cases remains impractical.[27] Instead, clinical assessments of fracture healing are based primarily on radiographic criteria. Experimental evaluation of fracture healing strives for added precision and objectivity, and often

includes densitometry and/or histologic techniques.

Radiographic Evaluation

Danis was the first to characterize primary fracture healing based on its radiographic appearance.[3] The gradual disappearance of a fracture line without formation of an external callus defines direct healing on serial radiographs (Figure 85-3). Although no resorption of the fragment ends occurs with contact healing, the progression of cutting cones across the gap decreases the radioopacity of the zone around the fracture.[8,28]

Complete remodeling of the fracture

varies with the location and species from a few months up to a few years, during which the fracture site remains radiolucent compared with intact cortex.[8] Primary healing displays few radiographic signs compared with secondary bone formation, and the monitoring of fracture healing under these circumstances is indirectly based on the absence of adverse clinical and radiologic signs.[29] Radiographic evidence of callus formation and bone resorption after “rigid” fixation of a fracture is consistent with secondary bone healing. These signs are interpreted as evidence that the stability and/or reduction achieved did not match those intended.

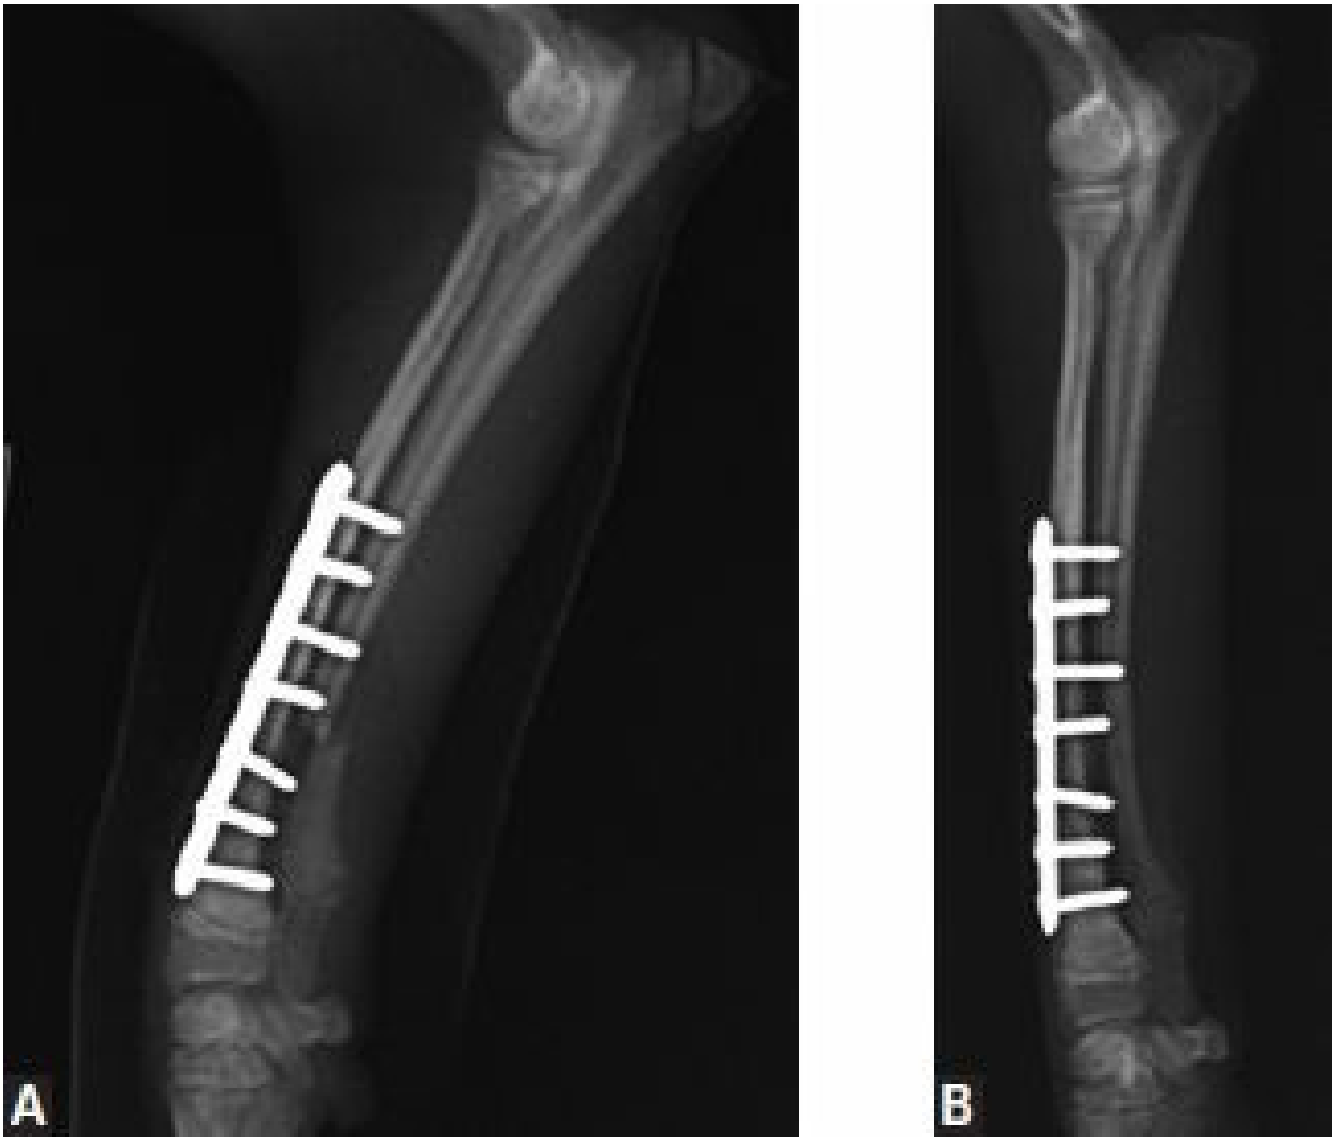

Figure 85-3. Radiographic appearance of primary healing. A. Postoperative lateral radiograph of transverse fractures of the distal diaphysis of the radius and ulna in a 6-month-old dog. The radial fracture has been managed with direct reduction and plate fixation. B. Similar projection obtained 8 weeks later. Cortical apposition and rigid fixation lead to bony union without formation of callus.

Dual Energy X-Ray Absorptiometry

Dual energy X-ray absorptiometry (DEXA) quantifies the bone mineral content and density of the entire skeleton (whole body analysis) or of a specific region of interest within a bone. The first mode of analysis is most commonly used to diagnose and monitor human osteoporosis. The second mode of analysis has been used experimentally in animals to objectively evaluate healing of bone defects.[30-33] Based on the area of interest selected, the computer software allows analysis of another region of similar dimensions, to act as a control. This control may consist of

an area of intact bone or the same region evaluated serially. Because the software measures areas rather than volumes, the thickness of samples should be standardized for meaningful comparison. DEXA can be repeated several times in small animals with no morbidity other than that of routine sedation. This lack of invasiveness makes DEXA especially relevant in longitudinal studies of unicortical bone defects and experimental osteotomies. DEXA measurements have been found to correlate with the torsional properties of healing canine tibial osteotomies.[30] These findings would support the use of DEXA as an objective guide for timing fracture fixation removal, recommendations

related to exercise regimen, and prediction of abnormal fracture healing patterns. However, metal implants create artifacts preventing the evaluation of regions in contact with plates. Therefore, osteotomies and fractures suitable for DEXA include those that do not require fixation (single ulnar osteotomy for example) or can be managed by external fixation. In the future, DEXA may also be indicated in veterinary patients for early detection of bone pathology, such as sclerosis (as a marker for elbow dysplasia), neoplasia, and infection. Clinical trials may also support its use, to monitor local bone metabolism and response to therapy in patients with osteomyelitis or neoplasia. In the

meantime, clinical applications of DEXA in veterinary medicine remain limited by the lack of indications and equipment cost.

Histology

Histologic evaluation of fracture sites has improved our understanding of the cellular mechanisms involved in primary healing. For example, gap and contact healing are essentially differentiated based on their microscopic appearance. Histology remains especially relevant when testing new therapies, where precise evaluation of the fracture site is required. Studies may focus on potential adjuncts to current fracture

treatments, in which case, the agent must be found to accelerate the normal healing process of an uncomplicated fracture or osteotomy model. Experiments focusing on the treatment of fracture complications, such as nonunions, test whether novel agents promote healing of critical defects that would otherwise not fill with new bone. In both instances, histologic evaluation provides valuable information regarding the type and extent of healing occurring within the defect. Biocompatibility of new grafting materials may be determined by the degree of inflammation shortly after implantation in bone defects. However, serial histologic studies are required to evaluate the

osteoconductive properties of an agent, its degree of incorporation, its rate of degradation, and cellular mechanisms involved in these processes.[34] Histologic evaluation of bone defect healing may be subjectively scored on 5-µm thick decalcified sections, stained with hematoxylin and eosin.[20,3] However the microscopic appearance of primary bone healing is best evaluated on thin sections of undecalcified bone.[14] These 50- to 80-µm thick sections may be obtained on fresh bone or bone defatted in xylene and embedded in methylmethacrylate.[20,35]

Histomorphometric analysis of these sections generates quantitative data that can serve as a basis for objective

evaluation of bone healing. Digital images of sections are captured with a digital camera and analyzed with image analysis software to quantify each type of tissue present within the defect. Nomenclature and calculations for bone histomorphometry have previously been standardized by the American Society of Bone and Mineral Research.[13] Four types of histomorphometric data may be directly measured on these images: area, length (such as a perimeter), distance (between points or lines), and number (of cells, for example). These measurements are indices of the amount of tissue examined and can only be compared between subjects when related to a common referent,

such as a clearly defined area or perimeter within a section. For example, we have used the total area of standardized cortical defects as a referent to measure the percentage of this area filled with implant, fibrous tissue, and new bone.[20,36] These measurements were then used to compare the degradation rate and osteoproductive properties of bone graft substitutes. Two-dimensional histologic sections actually display profiles of three-dimensional bone defects. Histomorphometric criteria, therefore, may also be reported as three-dimensional terms, as long as consistency is maintained throughout the study. Three-dimensional data commonly derived from measurements

of areas on histologic sections include bone volume, osteoid volume, and fibrosis volume. Bone and osteoid surfaces are calculated based on two-dimensional bone and osteoid perimeters, respectively. The fourth type of histomorphometric data, number measurements, can only be reported in two-dimensional analyses, thereby requiring a referent.

The origin of dynamic bone histomorphometry dates back to 1958, when Milch discovered the localization of tetracycline in bone.[37] A few years later, Frost developed the methodology to study the tetracycline-based histology of bone remodeling.[38] Since then, other fluorescent labels such as

xylenol orange, calcein blue, and calcein green have been used instead of, or in addition to, tetracycline (Figure 85-4). Combining labels of different fluorescence within the same study facilitates the identification of individual lines and corresponding time of administration. The mineral apposition rate (MAR) is then calculated as the distance between the midpoints, or between corresponding edges of two consecutive labels, divided by the time between the midpoints of the labeling periods.[13] The MARs for resting lamellar bone in mammals range from 0.83 to 2.7 μm/day.[6,39] Histologic techniques based on fluorescent bone labeling have played a key role in improving

our understanding of bone biology. These techniques provide crucial insights into the dynamic processes of activation, resorption, and formation (ARF) of the basic multicellular unit (BMU) responsible for the remodeling of cancellous and cortical bone.[40] Dynamic bone histomorphometry has contributed to numerous studies exploring the relationship between bone and various biomechanical or biologic factors. The findings of these studies supported mechanistic theories about the regulation of bone formation and maintenance, eventually leading to the Utah paradigm of bone physiology.[41] Dynamic histomorphometry is now commonly used to evaluate new therapies

stimulating bone formation.[36,39] For example, the MAR of woven and lamellar bone nearly doubled during distraction osteogenesis of an experimental osteotomy in goats.[39] We have previously measured MARs in an ovine metaphyseal defect model designed to evaluate the biologic properties of impacted bone graft substitutes.[20] In this study, the MARs measured within circular defects were 50% greater than remodeling rates 4 weeks after surgery, and returned to resting levels by 12 weeks. The values obtained at the center of the defects at 4 weeks were also greater than those obtained at the periphery of the defects at the same time period. Measurements obtained along the edges of these

defects appear to reflect a more mature phase of healing, with bone formation proceeding from the periphery toward the center of the defects. While these findings reflect the progression of healing in unicortical bone defects, they also stress the importance of standardizing techniques for histomorphometry. Measurements should be obtained on a representative number of sections and at standardized locations within bone defects to allow meaningful comparison of bone healing between treatment groups.

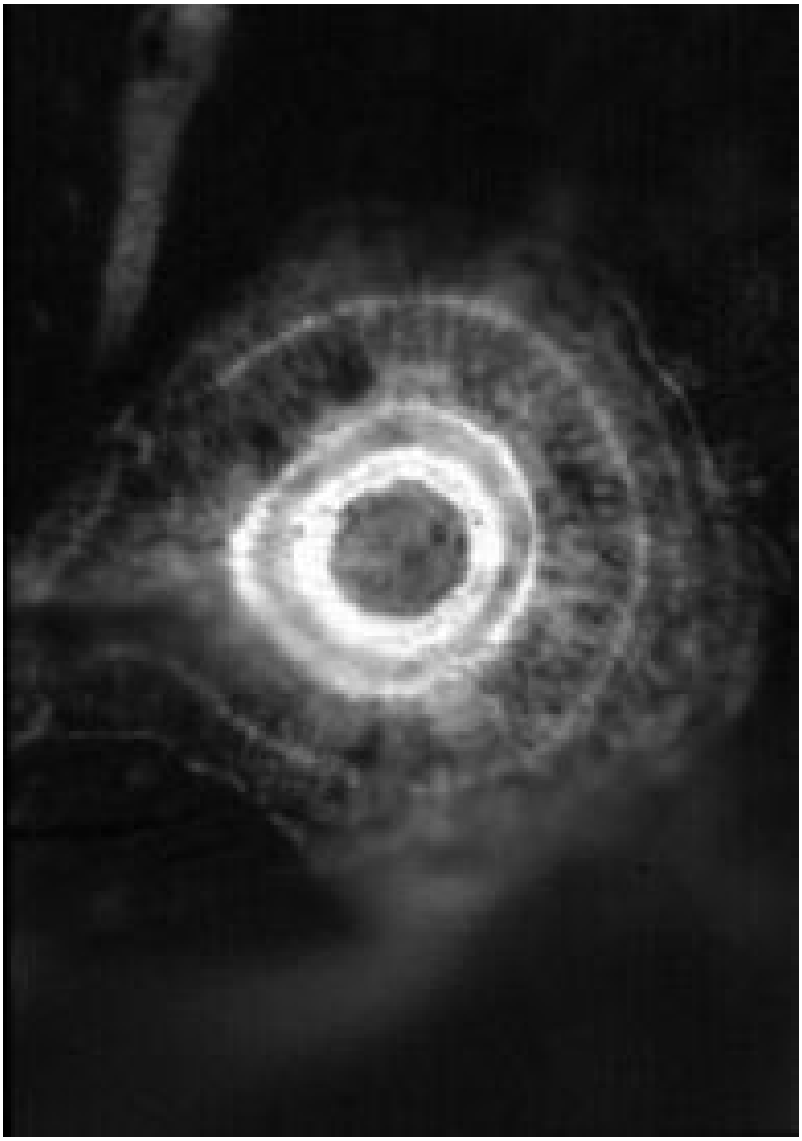

Figure 85-4. Fluorescence labeling for evaluation of bone healing in sheep. Bone labeling consisted of oxytetracycline (30 mg/kg) on days 23 and 35, and alizarin complexone (30 mg/kg) 84 days after creation of a metaphyseal bone defect.[36]

Advantages and Disadvantages of Rigid

Internal Fixation

Primary fracture healing skips the intermediate steps of tissue differentiation and resorption of the fragment ends, leading directly, although not necessarily faster, to the final remodeling of Haversian canals. Direct healing is rarely a goal in itself but rather a product of maintained absolute stability.[29] Rigid fixation is one of the concepts laid out by the association for the study of internal fixation or AO (Arbeitsgemeinschaft fur Osteosynthesefragen), in order to promote early return to mobility and function of the fracture patient. In 1958, the AO recognized the advantages of anatomic fracture

reduction, stable internal fixation, and preservation of the blood supply. At that time, the treatment of fractures involved mostly immobilization in plaster or by traction, often leading to prolonged healing and loss of function. In comparison, the pursuit of absolute stability, originally proposed for most fractures, immediately restored limb length and joint alignment. Rigid implants palliated the biomechanical function of bones and allowed early mobilization of joints adjacent to the fracture. Although AO principles still stand as fundamentals, their interpretation and clinical application have been adjusted in response to the knowledge emerging from experimental and clinical studies.

Anatomic reduction, compression of articular fragments, and rigid immobilization remain golden standards in the management of joint fractures (Table 85-1). Eliminating gaps or steps in the articular surface and preventing callus formation facilitate cartilage healing and minimize postoperative joint disease. However, the emphasis in extraarticular fracture fixation has evolved in recent decades from mechanical to biologic priorities. This change has mainly been prompted by a better understanding of the effects of plating on the underlying bone and the influence of micromotion on closely apposed bone fragments.

Table 85-1. Advantages and Disadvantages of Rigid Internal Fixation

Advantages	Disadvantages
Early return to function	Increased surgical time
Lack of complications associated with callus formation, such as nerve entrapment or obstipation	Trauma to adjacent soft tissues
Simple postoperative care (compared with external fixators)	Contamination of the fracture site
Anatomic reduction of articular fractures minimizes post-operative degenerative joint disease	Slower gain in biomechanical strength compared with callus formation
	Disruption of the blood supply

Traditional plating techniques affect the blood supply of a fractured bone not only by the design and nature of fixation, but also by the soft tissue trauma associated with their placement. The surgical approach, elevation of soft tissues, and manipulation of bone fragments required to achieve anatomic reduction and plate fixation add to the traumatic event initially responsible for the fracture. Rigid immobilization of the plate and bone construct then relies on frictional hold. The extent of this interface and the rigidity of the plate correlate with the degree of osteoporosis of the underlying cortex.[42] This ischemic osteoporosis has been attributed to a blockade of the

centrifugal flow of blood.[43] The vascular impairment is believed to be short-lived, with revascularization occurring four weeks after application of a plate and markedly increasing by eight weeks. Other studies failed to correlate bone necrosis of vascular origin with cortical porosis 8 and 24 weeks following plate application to intact canine femurs.[44] In fact, porosis was greater in the inner endosteal layer, away from the bone-plate interface, and in the absence of necrosis. If rigid fixation allows direct formation of bone, stress shielding develops when two components of different elastic moduli form one mechanical system. Adaptational osteopenia has therefore been

suggested as another mechanism to explain the osteoporosis of the bone in contact with a plate. Although the structural changes of bone after plate fixation have been well characterized, the relative contribution of decreased cortical perfusion and stress redistribution to these changes remains controversial. The biphasic appearance of these changes is currently attributed to an initial osteonecrosis 8 to 12 weeks after plate fixation, resulting from cortical vascular disturbances, followed by osteopenia at 24 to 36 weeks, secondary to the mechanical environment.[45] These studies support the design of new implants minimizing contact with the fractured bone and/or providing a "less-than-rigid" fixation.

The concept of “biologic fracture fixation” or “indirect fracture repair” has consequently gained acceptance among surgeons, affecting primarily the reduction techniques, method of fixation, and postoperative management of extraarticular comminuted fractures of long bones.[46]

Chapter 86

Secondary (Indirect) Bone Healing

D.J. Griffon

Whereas primary bone healing proceeds with direct formation of bone across the fracture site, secondary bone healing is characterized by a succession of stages and formation of an intermediate callus prior to bone formation. This process shares similarities with the healing of soft tissues and has arbitrarily been divided into three overlapping phases:

inflammation, repair, and remodeling (Figure 86-1).[1] Each of these healing phases has unique histologic features, and each can occur in isolation or in concert with the other to achieve bone union. This passage through intermediate tissues of increasing stiffness and strength gradually restores the mechanical stability required for bone formation. Ultimately, any tissue other than bone persisting within a fracture gap represents incomplete healing.[2]

Secondary healing is the most common type of healing encountered in clinical orthopedics, especially since the principles of biologic fracture fixation have gained popularity in man and

small animals. The concept of “biologic osteosynthesis” emphasizes the role of soft tissue integrity in bone healing and “less than rigid” fixation of the fracture.[3] This concept contrasts with the “biomechanical approach” to fracture management, aiming for anatomic reduction and rigid fixation, potentially leading to primary bone healing. Instead, the goals of biologic fracture fixation are to restore the overall length and alignment of the bone while limiting surgical approach and manipulation of fragments. Applied to highly comminuted fractures of long bones, biologic fracture management accelerates healing and return of biomechanical strength, thereby lowering

complication rates in man and small animals.[4,5] Once considered a sign of failure, callus formation has become a goal in the management of extraarticular fractures of long bones.

Staged Tissue Repair in Secondary Bone Healing

Inflammatory Phase

An inflammatory phase begins immediately after traumatic disruption of bone and surrounding soft tissues and persists until formation of cartilage or bone is initiated. This stage is essentially characterized by ischemic bone necrosis, hematoma formation, and formation of a fibrin mesh at the fracture line.

Fractures inevitably disrupt medullary vessels leading to hemorrhage. Although contraction and thrombosis of disrupted vessels minimize blood loss, interruption of blood flow leads to hypoxia and necrosis of bone, characterized histologically by the presence of empty lacunae. Radiographically, this resorption of fragment ends may be recognized as a local loss of radioopacity and widening of the fracture gap 5 to 7 days after injury.[6] Bone resorption is primarily mediated via prostaglandins E1 and E2, inflammatory mediators that may also stimulate angiogenesis and proliferation of osteoprogenitor cells.[7] Mononuclear phagocytes delivered by newly formed vessels assist in removal

of necrotic bone and aid in construction of the callus. Macrophages are also believed to orchestrate the orderly sequence of wound healing and play a similar role in fracture repair. They contain several growth factors, including fibroblast growth factor (FGF), initiating fibroplasia in soft tissue as well as bone repair.[8-10] Resorption of fragment ends is particularly obvious in spontaneous fracture healing: the fracture gap widens, thereby lowering interfragmentary strain and minimizing the deformation of local tissues.[11]

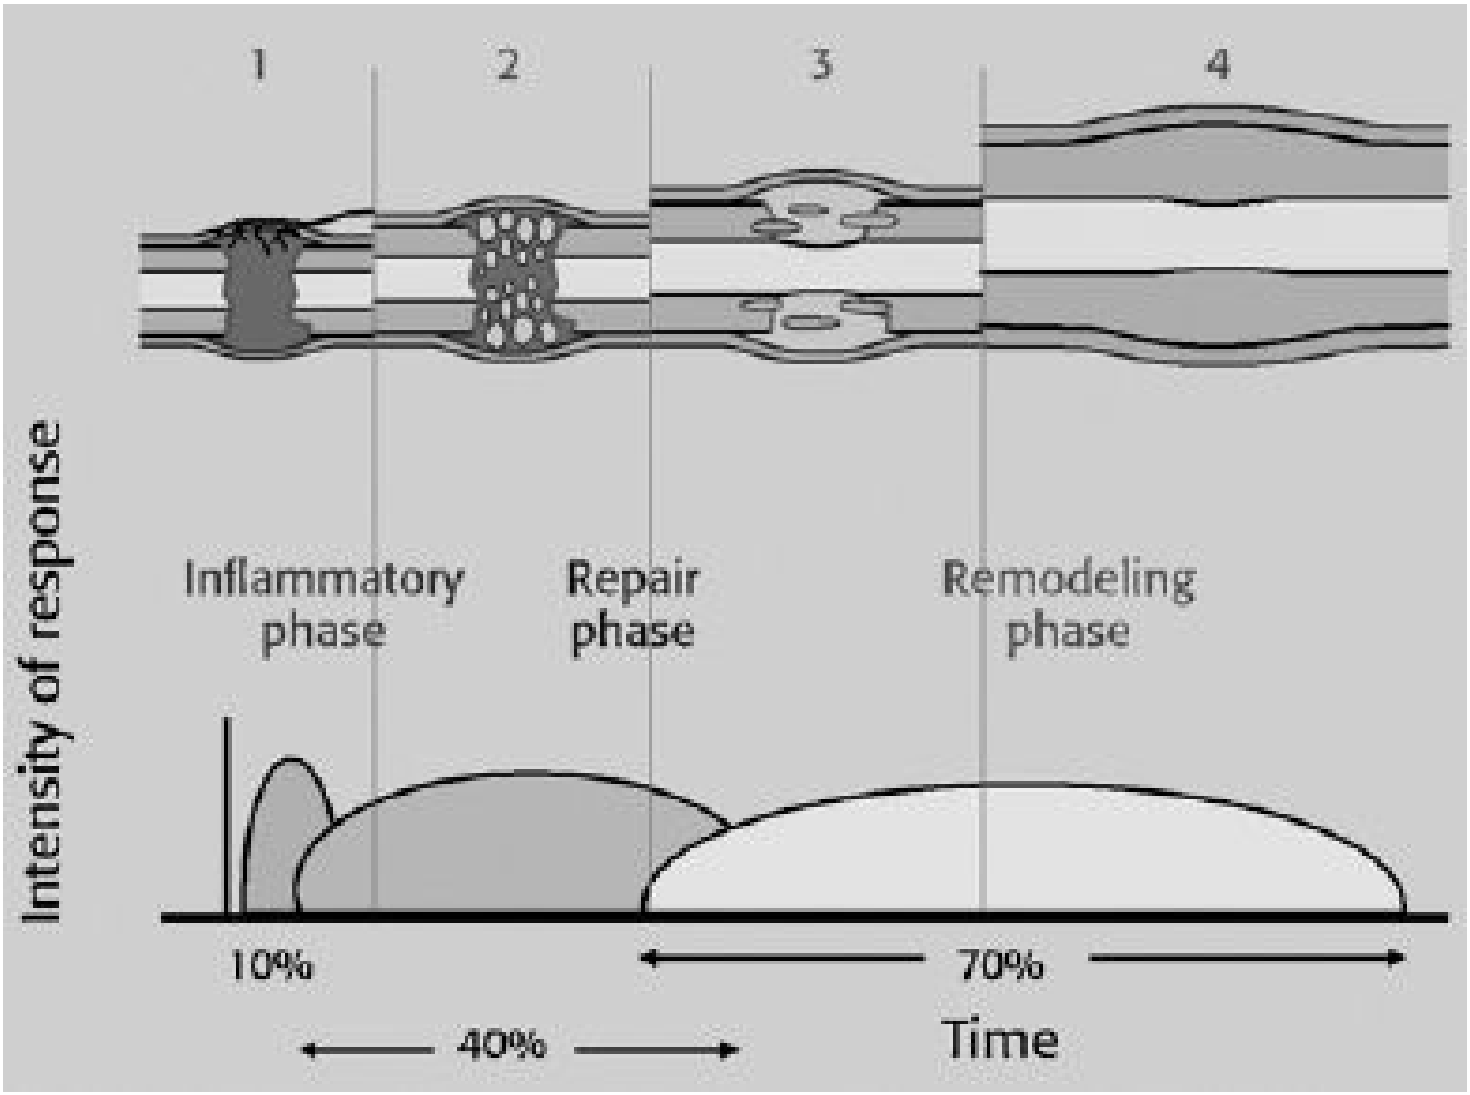

Figure 86-1. Phases of secondary bone healing. Inflammation (1) is the most intense and shortest phase of secondary bone healing. The fracture gap then fills with tissues of increasing stiffness and strength, eventually allowing bone formation. Granulation tissue (2) is replaced by a fibrocartilaginous callus (3) that mineralizes into a hard callus (4). Remodeling is the longest phase of secondary healing, resulting in gradual disappearance of the callus (Reproduced with permission from:

Griffon DJ: Fracture healing. In Johnson AL, Houlton JEF, Vannini R (eds). AO Principles of Fracture Management in Small Animals. Davos: AO Publishing, 2005, pp. 72-98).

The lack of mechanical support provided by the fracture hematoma is well established. Its biologic contribution to fracture healing, initially questioned, has gained general acceptance among surgeons. In fact, preservation of the fracture hematoma has become one of the goals of indirect reduction techniques and biologic fracture fixation. The main contribution of the hematoma is the release of growth factors, thereby setting the stage for the repair phase. Transplantation of fracture hematoma has been found to induce endochondral

bone formation in ectopic sites, which is consistent with osteoinduction.[12] The hematoma also acts as an osteconductive spacer, providing a scaffold for cells, thereby guiding the size and shape of the callus.[11,13] Local acidity and vascular endothelial growth factor (VEGF) contained in the hematoma encourage vascular ingrowth.[14] The formation of new vessels is also stimulated by mast cells, which are abundant during this phase and release vasoactive substances.[8,15] Within hours, a transient extraosseous blood supply emerges from surrounding soft tissues, revascularizing the hypoxic fracture site.[16] The proliferative vascular response was enhanced by a muscle

flap, thereby improving the healing of experimental tibial osteotomies in dogs.[17] This study illustrates the importance of preserving soft tissues around the fracture. Unless infection, excessive motion, or extensive necrosis of the surrounding soft tissues persists at the fracture site, the hematoma is resorbed by the end of the first week.[2] Clinically, the end of the inflammatory stage coincides with a decrease in pain and swelling.

Repair Phase

Granulation Tissue

Within a few days, capillary ingrowth, mononuclear cells, and fibroblasts

contribute to the transformation of the hematoma into granulation tissue. This initial stage of the repair phase coincides with a slight gain in mechanical strength because granulation tissue can withstand a tension force up to 0.1 Nm/mm^2.[18] Yet, its tolerance to elongation (up to twice the original length) explains its formation at a stage where interfragmentary deformation remains high.

Connective Tissue

As granulation tissue matures into connective tissue, collagen fibers become more abundant; ultimate tension strength (to 1-60 Nm/mm^2)

and resistance to elongation (17% maximum) increase. Types I, II, and III collagen are initially deposited, but as the maturation process continues, type I collagen predominates.[19] This interfragmentary fibrous tissue is organized in a diagonal pattern, optimizing its ablity to elongate.[11]

"Soft Callus"

Mesenchymal cells within the cambium layer of the periosteum, the endosteum, the bone marrow, and adjacent soft tissues start proliferating during the inflammatory phase and differentiate into chondrocytes during the repair phase (Figure 86-1). This proliferation and differentiation are

triggered by several growth factors, among which bone morphogenetic proteins (BMPS) and transforming growth factor-β (TGF-β) play major roles. Periosteal stripping in immature animals results in production of a callus away from the bone as osteoprogenitor cells are pulled with the periosteum.[1] In mature patients, the periosteum has a tendency to tear rather than strip; osteoprogenitor cells remain attached to the bone and produce a callus in contact with the fracture site. Interfragmentary strain, local blood supply, and tissue oxygenation also affect the elaboration and size of the cartilaginous callus. Local hypoxia encourages mesenchymal cells to differentiate into

chondrocytes rather than osteoblasts.[20-22] Whereas the external callus relies entirely on an extraosseous vascularization , the internal or medullary callus developing from the endosteal cell layer receives its blood supply from medullary arterioles.[22,23] The presence of a fibrocartilage layer within the medullary canal temporarily interrupts the medullary blood flow across the fracture gap. The external callus and the internal callus both constitute the "bridging callus."[24] The full extent of the bridging callus is underestimated on radiographs, because the cartilaginous portion is not visible (Figure 86-2).[6] This partly explains the discrepancy between palpation of a large callus and

radiographic visualization of a relatively smaller ossified bridge.

This early “soft callus” formed during the first 3 weeks after injury resists compression but its ultimate tensile strength (4-19 Nm/mm^2) and elongation at rupture (10-12.8%) are similar to those of fibrous tissue.[25] Production of a prominent external callus is a common finding in well vascularized unstable fractures. The resulting enlargement of the cross-sectional diameter in the injured area greatly increases the resistance to bending: the strength efficiency increases by the third power of the distance to the neutral axis of the bone, and the rigidity increases by the

fourth power.[26] Increasing proteoglycan concentrations within the fibrocartilage also contribute to the stiffening of the interfragmentary gap.[20]

"Hard Callus"

Callus formation does not become apparent on radiographs until mineralization proceeds. The periosteal component of the callus grows first and appears as a collar around the fracture site. The smaller internal callus forming within the medullary cavity is harder to visualize radiographically owing to superimposition with the external callus.[6] Mineralization of the soft

callus proceeds from the fragment ends toward the center of the fracture site and forms a “hard callus,” following a process similar to endochondral ossification of growth plates.[11] Mitochondria within chondrocytes first appear to accumulate calcium-containing granules.[27] Under hypoxia and anaerobic metabolism, these intramitochondrial deposits of calcium phosphate are released into the extracellular matrix and become the seeds for growth of apatite microcrystallites. Vascular invasion of fibrocartilage is then coupled with the degradation of nonmineralized matrix compartments by macrophages. Following this resorbing front, blood vessels and osteoprogenitor cells form

new trabeculae. Although the mechanical properties of this calcified fibrocartilaginous tissue have not been reported, these structures contribute greatly to the restoration of strength and stiffness within the fracture gap, thus allowing formation of compact bone. The ultimate tensile strength of compact bone is around 130 Nm/mm^2, but its modulus of elasticity (resistance to deformation) is high (10,000 Nm/mm^2) and ability to elongate is limited to 2%.[11] At the end of the repair phase, bone union is achieved but the structure of the fracture site differs from that of the original bone. Yet, the injured bone has regained enough strength and rigidity to allow low-impact exercise.[28] Maturation of

the fibrocartilaginous callus results in radiographic disappearance of the fracture line as the fracture gap gains a radioopacity similar to that of adjacent bone (Figure 86-2).

Remodeling Phase

This final phase of fracture repair is characterized by a morphologic adaptation of bone to regain optimal function and strength. This slow process may last for 6 to 9 years after initial trauma in man, representing 70% of the total healing time of a fracture (Figure 86-1).[29] The balanced action of osteoclastic resorption and osteoblastic deposition is governed by Wolff's law and modulated by

piezoelectricity, a phenomenon by which electrical polarity is created by pressure exerted in a crystalline environment.[22,30,31] Axial loading of long bones creates an electropositive convex surface, onto which osteoclastic activity predominates. On the opposite, concave, surface electronegativity is associated with increased osteoblastic activity. The external callus becomes more fusiform and gradually disappears (Figure 86-2). Remodeling of the internal callus allows reestablishment of a continuous medullary cavity in the diaphysis of the bone. As medullary blood flow resumes, this extraosseous blood supply subsides.

Influence of the Biomechanical Environment on Bone Healing

If adequate vascularity is a prerequisite for bone healing, the biomechanical environment determines the pattern of repair.[1] Bone formation requires restoration of mechanical stability, which may be achieved by a natural process of healing or by osteosynthesis, with partial or complete stabilization of the fracture fragments. Whereas primary bone formation occurs under extreme conditions of reduction and immobilization, spontaneous healing represents the opposite end of the spectrum and best illustrates the mechanisms involved in secondary

bone healing.

Figure 86-2. Radiographic appearance of secondary bone healing. Open lateral radiograph of the femur of a 10-month-old dog with a comminuted diaphyseal fracture (A). Radiograph obtained immediately after closed placement of an interlocking nail (B). A bridging callus is noted on radiographs obtained 6 weeks later (C). Remodeling of the callus can be appreciated 12 weeks after surgery, as the callus becomes more fusiform (D).

Spontaneous healing of complete fractures typically occurs in the presence of highly unstable fragment

ends. Bone repair must develop in spite of high interfragmentary strain, defined as the deformation occurring at the fracture site relative to the size of the gap. However, bone formation can occur only in a stable biomechanical environment with an interfragmentary strain lower than 2%.[32,33] Nature's ways to deal with this unfavorable situation become especially obvious: initial contraction of muscles surrounding the fracture, resorption of fragment ends, orderly repair with tissues suitable for the mechanical environment, and formation of a prominent external callus. Progression from soft to hard callus depends on adequate blood supply and gradual increase in

stability at the fracture site. If the fracture gap is well vascularized, uncontrolled interfragmentary motion will stimulate callus formation and the fracture will progress to a cartilaginous callus. However, if this callus is unable to stabilize the fragments, a hypertrophic nonunion and pseudoarthrosis will develop. A stable fracture with an adequate blood supply will allow formation of a mineralized callus; however, initial displacement of bone fragments owing to trauma and muscle contraction frequently results in malunions.

The pattern of healing after external coaptation or semi-rigid internal fixation of fractures is intermediate

between the biologic stabilization by a callus formed in spontaneous healing and the callus-free repair obtained after absolute stabilization. Fracture healing after external coaptation resembles spontaneous bone repair except that misalignment of fragments is minimized by closed reduction. Gliding implants such as intramedullary pins and nails typically allow some motion, including axial micromotion during weight bearing and rotational shear between fracture fragments that do not interdigitate. The amount of callus produced after application of external fixators is highly variable, depending on the fracture configuration and the rigidity of the applied frame. Callus formation

after plate fixation may occur when the implant is not placed on the tension side of the bone, fracture reduction is not perfect, or when the plate lacks rigidity.[34] These observations led to the concept of biologic fixation, which is especially relevant for comminuted fractures. In these cases, perfect apposition of fragments is unlikely and the surgeon privileges biologic factors over anatomic reduction and mechanical stability.[3,35] The general alignment of the joints is restored but manipulation of fragments and adjacent soft tissues is minimized. A buttress plate or a plate-rod combination is applied across the fracture gap, bridging the entire length of the bone. This “less-than-

rigid" surgical fixation is less invasive than traditional plate fixation and results in increased callus production. In one study, the bone density and osteogenesis in comminuted fractures were increased 12 weeks after application of a bridging plate, an intramedullary nail, or an external fixator compared with application of lag screws and compression plate.[5] Similar results have been reported in clinical studies where biologic fixation of comminuted fractures increased callus production and accelerated radiographic union and gain of biomechanical strength, allowing earlier return to function in man and small animals.[36,37] More recently, the concept of "elastic plate osteosynthesis"

has been applied to unilateral femoral shaft fractures in 24 immature dogs.[38] Each fracture was treated with a veterinary cuttable plate maintained to the bone with two screws placed as far as possible from the fracture site. Although care should be taken to restore the physiologic degree of femoral torsion, fractures were often bridged with callus by 4 weeks (Figure 86-3).

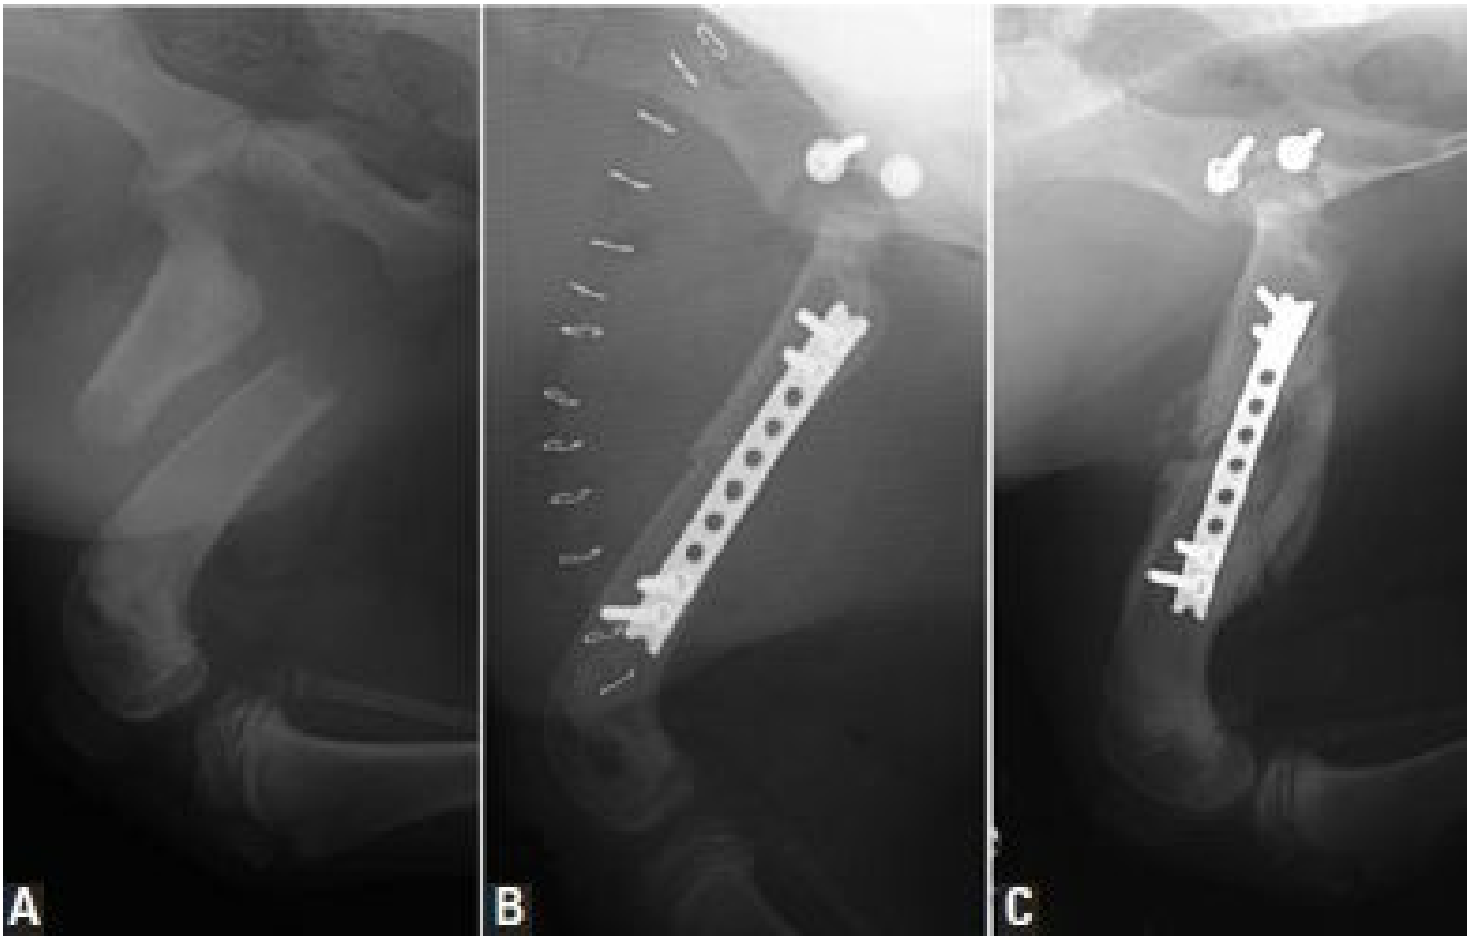

Figure 86-3. A femoral fracture in a 4-month-old dog. Elastic plating (A). A veterinary cuttable plate is maintained to the bone with two screws placed as far as possible from the fracture site (B). Note the amount of callus bridging the fracture 3 weeks after repair (C).

Role of Growth Factors and Inflammatory Mediators

Fracture healing is orchestrated by complex interactions between a

cascade of growth factors, local cells, and their environment. Although our understanding of the sequence of growth factors involved in fracture healing has drastically improved over the last 50 years, the list of agents affecting bone formation is still growing. Research efforts currently focus on signals triggering the release of growth factors and defining the role of each factor within the sequential tissue differentiation characterizing secondary bone healing. Conflicting results regarding the roles of osteoinductive agents reflect the influence of numerous factors on their effects, including target cells, dose tested, species, and characteristics of the local environment. For example,

the efficacy of osteoinductive preparations was initially questioned in primates, until further studies identified the dose-dependent effect of osteoinduction and the lower sensitivity of higher vertebrates compared with rodents.[39,40] In spite of these challenges, a general knowledge of growth factors is required to understand their impact on fracture management and their clinical applications as promoters of bone formation (Figure 86-4).[9,41]

The body of evidence supporting the role of growth factors in bone metabolism has led to the recognition of the inflammatory phase as an essential step in staging the subsequent

phases of bone healing. The fracture hematoma, once considered a potential hindrance to fracture healing, is now preserved as an endogenous source of prostaglandins (PGs), kinins, and other noncollagenous proteins.[42] Platelets are the first source of mitogenic factors at the traumatized site.[43] In addition to coagulation factors, they release platelet-derived growth factor (PDGF) and transforming growth factor-β1 (TGF-β1).[9] Although PDGF appears to stimulate osteoblastic proliferation in vitro, its exact role in fracture repair has not been clearly defined.[9] The fibrin seal forming between bone fragments provides a support for migration of inflammatory cells and their byproducts. Macrophages,

neutrophils, and mast cells release growth factors (FGF, PDGF, TGFβ, and FGF), promoting angiogenesis and stimulating fibroblasts. The fibroblast growth factors (FGF) are part of a family of nine structurally related polypeptides, among which acidic FGF (FGF-1 or α-FGF) and basic FGF (FGF-2 or β-FGF) are the most abundant. Both factors encourage growth and differentiation of a variety of cells, including epithelial cells, osteoblasts, and chondrocytes. The mitogenic effects of FGF-1 have been associated with proliferation of chondrocytes, while osteoblasts express FGF-2 receptors.[44,45] Inflammatory cells also produce cytokines (interleukins such as IL-1, IL-6, and tumor necrosis factor or

TNF), attracting mesenchymal cells to the fracture site (Figure 86-4). Pro-inflammatory stimuli and cytokines promote the formation of prostaglandins (PGs) by osteoblasts and osteoclasts. Among these, PG-E2 is the most abundant PG produced by osteoblasts and the most potent PG stimulating both bone formation and resorption.[42] These effects are mediated via interaction with four receptor subtypes (EP_1R, EP_2R, EP_3R, and EP_4R), especially EP_2R and EP_4R.[42] PGs increase the number and activity of osteoclasts.[46] These cells release proteases that dissolve bone mineral matrix and collagen and remove damaged bone, thereby contributing to bone resorption and

release of growth factors contained in the matrix. Other studies have documented increased bone formation and turnover after subcutaneous injection of PGE2 in dogs.[47,48] This activity would result from mitogenic properties on osteoblasts and stimulation of undifferentiated cells to engage in osteogenic differentiation.[42,46] In humans, impact loading has been associated with an increased production of PG.[49] These findings support the theory according to which PGs mediate the physiologic response to mechanical loading.[42] Based on their range of activities, PGs are likely to contribute to all phases of fracture healing, including the remodeling phase of secondary bone

healing.

In the repair phase, chemotaxis, proliferation, coordination, and differentiation of stem cells into chondrocytes or osteoblasts are orchestrated by numerous growth factors, among which TGF-β and bone morphogenetic proteins (BMPs) play a major role (Figure 86-4). Both are members of the TGF-β superfamily, a

group of dimeric proteins, acting as growth and differentiation factors during embryogenesis and tissue repair in postnatal life. TGF-β1 is released by platelets immediately after a fracture, but the most intense staining occurs during cartilage cell proliferation and endochondral ossification.[50] Although the response to TGF-β varies with dose, species, and biologic environment, this agent stimulates the proliferation of undifferentiated mesenchymal stem cells and induces the expression of BMPs.[9,41] Since Urist discovered the phenomenon of osteoinduction and attributed it to a single protein in 1965, the structure of 16 BMPs has been identified.[51,52] All belong to the TGF-β superfamily, except BMP-1.

Among these, BMP-2 through 7 and BMP-9 have been found osteoinductive, meaning that these proteins can provide the primordial signal for mesenchymal stem cells to engage into osteoblastic differentiation.[52] Each BMP exerts its effects by binding to a specific combination of membrane receptors (Type I and II serine threonine sulfate), and activating the intracellular Smad signaling pathway that eventually determines the outcome of the signal.[52] Numerous studies have described the typical sequence of endochondral ossification occurring after ectopic implantation (sites normally devoid of osteoprogenitor cells, such as the subcutaneous tissue) of these agents:

recruitment and proliferation of monocytes and mesenchymal stem cells, differentiation into chondrocytes, hypertrophy of chondrocytes, and calcification of the matrix, followed by vascular invasion, osteoblastic differentiation, and bone formation. This sequence ends with remodeling of the new bone, leading to bone marrow formation.[53] This staged differentiation of tissues illustrates the roles of BMPs in natural fracture healing and eventually led to clinical trials of two recombinant proteins, rhBMP-2 and rhBMP-7, in open and nonunion fractures of the tibia in man.[54]

Effects of Nonsteroidal Anti-

Inflammatory Drugs on Bone Healing

Much interest has been focused on the management of pain in small animals and its impact on bone healing. Nonsteroidal anti-inflammatory drugs (NSAIDs) are now routinely prescribed as part of the perioperative management of fracture patients for their antipyretic, analgesic, and antiphlogistic properties. Preoperative administration of NSAIDs can minimize peripheral and central sensitization to painful stimuli, thereby improving postoperative analgesia and preventing the development of chronic pain syndromes.[55] They do not cause sedation and appear to decrease the

doses of opioids required in the multimodal analgesic approach most commonly used to manage trauma cases in the immediate perioperative phase. Combined, these benefits accelerate postoperative return to function, shorten hospitalization, and reduce associated costs for owners.[56] NSAIDs act essentially at the peripheral and regional levels, but are potent enough to justify their use as sole analgesics for patients discharged from the hospital. Their action relies on the inhibition of cyclooxygenase (COX), a catalyzer for the enzymatic conversion of arachidonic acid liberated from cell membranes into prostaglandins, prostacyclin, and thromboxane (Figure 86-4). This

mechanism of action is responsible for the side effects of NSAIDs, including impaired platelet function, renal vasoconstriction, and gastrointestinal ulceration. These limitations have prompted the development of anti-inflammatory agents that inhibit preferentially the cyclooxygenase induced during inflammation (COX-2), while sparing the endogenous isoenzyme (COX-1). COX-2 preferential NSAIDS (coxibs) have a 2- to 100-fold difference in the concentration of drug necessary to inhibit COX-2 versus COX-1 in vitro.[57] These agents have essentially replaced nonselective cyclooxygenase inhibitors in small animal practice. Among these, carprofen has recently been evaluated

in dogs undergoing fracture repair.[58] In this prospective study of 26 traumatized dogs, perioperative administration of carprofen did not cause clinically relevant adverse effects on hemostasis or renal function. Nonetheless, the perioperative use of NSAIDs in fracture patients has been tempered by concerns of potential deleterious effects on bone healing. Indeed, NSAIDs may theoretically inhibit bone formation because they interfere with the release of inflammatory mediators, including PGs. COX-2 has been found to be the rate-limiting enzyme in the synthetic pathway of PGs.[46] Any inhibition of COX-2 would be expected to affect the release of PGs and suppress their

contribution to bone healing (outlined in the section on growth factors and bone healing). COX-2 expression naturally increases after fracture and suppression of this enzyme results in a relative reduction in osteoblastogenesis.[46] The effects of nonselective NSAIDs, such as indomethacin and aspirin, have been studied extensively, and the majority of experimental in vivo studies report a negative effect on bone healing.[59] Fewer studies have evaluated the effect of COX-1-sparing agents and several report conflicting results. Table 86-1 summarizes the results of selected experimental and all clinical studies published over the last 5 years regarding the effects of COX-2 selective

NSAIDs on bone healing.[60-68] Among these, the effects of short-term (10 days) administration of celecoxib (3 and 6 mg/ kg) were compared with a negative control in rats with induced femoral fractures.[64] Celecoxib impaired fracture healing and increased the rate of nonunions (26%, 9/34) compared witih the negative control (0/41). The fracture callus at 8 weeks contained more cartilage in the treated group, decreasing its biomechanical properties. Using the same fracture model, other investigators tested the effects of another COX-2 preferential agent, valdecoxib (5 mg/kg/day) administered for 7 or 21 days after fracture.[63] They found no difference in physical, biomechanical, and histologic

evaluations of healing after the shorter course of administration. In contrast, 21 days of treatment impaired healing at 21 days compared with the placebo group, but the difference disappeared by 35 days. The temporal effect of COX-2 selective NSAIDs on bone ingrowth was further evaluated using a bone chamber model in rabbits.[66] In this study, rofecoxib decreased bone production if administered continuously for 6 weeks, but had no adverse effect if administered for 2 weeks, whether early or late after implantation of the chamber in the tibia. The overall evidence derived from animal studies is that a short course of COX-1-sparing NSAIDS may alter the callus forming early in the

repair phase but has no long-term effect on fracture healing. However, extrapolation to small animal practice warrants caution because these results were obtained on rodents with drug regimens differing from those applied clinically. Few clinical studies have attempted to address the effect of COX-1-sparing NSAIDs in fracture patients (Table 86-1), with a validity limited by their retrospective nature. Better evidence was recently provided in a prospective, randomized, double-blind study of human patients undergoing spinal arthrodesis.[68] In this study, patients receiving celecoxib 1 hour before induction and every 12 hours for 5 days after surgery had lower pain scores and a similar rate of nonunions

at 1 year than did patients in the placebo group. Based on the current literature, no firm evidence-based recommendation can be made regarding the use of NSAIDs in fracture treatment. NSAIDs may theoretically delay bone healing, especially if long courses and/or high doses are prescribed in patients with compromised fracture healing. Even in these patients, the potential delay in bone repair must be weighed against the benefits of NSAIDs outlined earlier. In the future, large, randomized clinical trials of agents commercialized for small animals should be developed to assess their effects on objective signs of healing (bone mineral density, size of callus) as well as patient-oriented

measures of outcome (removal of implant, return to unrestricted exercise).

Table 86-1. Clinical Studies

(2000-2005) and Selected Experimental Studies Evaluating the Effects of COX-2 Preferential NSAIDs on Bone Healing.[59]

Authors	Year	Experimental Animals	Fracture	Drugs	Outcome
Gerstenfeld et al[63]	2004	Rats	Femoral diaphyseal Fx	Valdecoxib, 5 mg/kg/d for 7 or 21 d post fracture, compared to placebo	No effect if Tx limited to 7 d. Tx for 10d affected healing at 21 days but not at 35 d.
Brown et al[62]	2004	Rats	Femoral diaphyseal Fx	Celecoxib 3mg/kg/d starting on d1 and administered for 4,8, or 12 weeks	Increased amount of fibrous tissue in the Fx gap notes at week 4, no effect on mechanical properties and radiographic evaluation at weeks 4,8,12.
Bergenstock et al[64]	2005	Rats	Femoral diaphyseal Fx	Celecoxib, 3 or 6 mg/kg/d for 10d post fracture, compared to placebo	Impaired healing at 18 wks, based on radiographs, mechanical testing and histology. NU in 26% fractures
Goodman et al[66]	2005	Rabbits	Bone chamber, longitudinal study	Control (6 weeks without tx) then Rofecoxib, 12.5 mg/d for first 2 of 6 weeks, wash out, Rofecoxib, 12.5 mg/d for last 2 of 6 weeks, wash out, Rofecoxib, 12.5 mg/d for 6 weeks	Bone ingrowth was affected only if NSAIDs were administered for 6 weeks.
Authors	**Year**	**Clinical Study Design**	**Procedure**	**Drugs**	**Outcome**
Giannoudis et al[61]	2000	Retrospective	ORIF femur	NSAIDs (patient recall)*	OR of NU with NSAID use: 10.74
Bhandari et al[60]	2003	Observational	ORIF tibia	NSAIDs (patient recall)*	No effect of NSAID on healing
Bhattacharyya et al[65]	2005	Retrospective	Humeral shaft	NSAIDs (prescription records)*	Relative risk of nonunion with NSAID use 61-90 days after fracture: 3.9.
Reuben and Ekman[58]	2005	Prospective randomized	Spinal arthrodesis	Celecoxib, 400 mg, 1 dose before surgery, then 200 mg every 12 h for 5 d	No difference between groups
Reuben et al[67]	2005	Retrospective	Spinal arthrodesis	Given for 5 consecutive postoperative days: Celecoxib, 50 mg/d, Ketorolac, 20-110 mg/d, or Ketorolac, 120-240 mg/d	OR of NU with high-dose ketorolac: 8.8 OR of NU with low-dose ketorolac: 3.0 No difference between placebo, celecoxib, rofecoxib

NU: nonunion; OR: odds ratio; Tx: treatment; Fx: fracture; NSAID: nonsteroidal anti-inflammatory drug.

*** Study did not distinguish types of NSAIDs administered, dose, timing, or duration**

Chapter 87

Enhancement of Fracture Healing

Erick Egger
Elizabeth Pluhar

Physical Stimulation of Bone Healing

It has long been known that the mechanical environment of a long-bone fracture can influence the biologic process of healing.[1] Classically this has been demonstrated by the development of a large periosteal

callous through the pathway of endochondral ossification in fractures stabilized with relatively flexible fixation that allows some motion at the fracture site. This is opposed by healing with minimal periosteal callous formation by direct intramembranous ossification when fractures are rigidly fixed, allowing virtually no motion between fracture ends. Which of these two pathways is preferable has been debated extensively as reviewed in chapters 85 and 86 on “bone healing” in this text. More recently, researchers and clinicians have been manipulating these responses to mechanical environment to optimize or stimulate fracture healing. This section summarizes the current techniques

being investigated and used clinically, and the proposed mechanisms of action of these techniques.

Induced Micromotion (IMM)

This concept has been extensively studied by Goodship and Kenwright in the sheep tibia model[2-3] and in at least one human clinical trial.[4] This scheme uses an external fixator with pneumatic driven activator that provides axial tension and compressive forces that can be controlled in displacement, speed, and duration. A positive effect was seen in an ovine 3-mm transverse osteotomy gap model in callous formation and increasing stiffness of healing if stimulated by 1

mm of induced displacement when compared with nonstimulated controls.[2] More recent work suggests that the positive effects of IMM are greatest at relatively moderate or higher rates of induced motion (40 and 400 mm/sec versus 2 mm/sec).[3] This positive effect was greatest when IMM was initiated 1 week postoperatively when compared with delayed initiation (after 6 weeks) and when studied at 12 weeks. Consequently, these authors feel IMM has the optimal positive effect on the early phases of the repair process, which in their model appears to be endochondral ossification. A subsequent clinical trial on 39 human tibial fractures treated with IMM did show a significant decrease in healing

time compared with nonstimulated controls.[4] Another study[5] on externally induced motion was performed on 2-mm femoral osteotomies in rats. A specialized external fixator was used to provide cranial-caudal bending of the osteotomy from day 7 to day 18, 3 times a week. Finite element analysis found the cranial aspect of the healing osteotomy experienced approximately 7% tensile strain, while the caudal aspect of the osteotomy experienced 3.5% compressive strain. Overall, the tensile strains tended to promote endochondral ossification. They hypothesized by increasing the pool of mesenchymal progenitor cells and demonstrated increased bony bridging, whereas the compressive strains

suppressed chondrogenesis and encouraged intramembranous ossification.

Dynamization

Dynamization is a concept that was initially described by De Bastiani and incorporated in the design of a human external fixator system (Orthofix™).[6] De Bastiani proposed providing initially rigid fixation to allow revascularization and initial fracture healing followed by releasing the axial stabilization while continuing bending and torsional stabilization. Whereas many human clinical cases have been treated using this technique, most experimental studies have failed to

show an overall significant positive effect on osteotomy healing in dogs.[7] In one study that did report a positive overall affect with dynamization performed 7 days postoperatively, the effect may have reflected increased rigidity resulting from total osteotomy gap collapse.[8] Another study using a veterinary external fixator design suggested dynamization after two weeks tended to cause larger callous size and callous density, but may impede remodeling at the fracture gap.[9] Statistically significant differences were not found with densitometry, absorptiometry, or CT throughout the period of the study, and a lack of torsional stiffness or maximal strength difference was found at the

end, 13 weeks postoperatively.

Destabilization

The basis of this concept is to provide stabilized fixation initially and decrease that fixation rigidity as the fracture heals and develops strength. It developed as an attempt to combine the early advantages of stable fixation, such as rapid reduction in postoperative pain and increasing speed to limb use while avoiding the potential long-term disadvantages of rigid fixation such as stress protection of the fracture. Destabilization, also known as “staged disassembly,” developed as more rigid fixation was obtainable with external fixators

through the use of more complex frames,[10] new components,[11] and threaded fixation pins.[12] Clinical observation of periodic atrophic delayed and nonunions occurring with these rigid devices stimulated attempts to optimize fracture healing by manipulating the fracture fixation mechanical environment. Early experiments with both transverse[13] and oblique[14] canine tibial osteotomies suggested that destabilization from rigid configurations of external fixator to much less rigid type I configurations (twofold in torsion, threefold in bending, and sevenfold in axial compression)[15] resulted in more callous production but a decreased healing strength when performed at 0, 2, and 4

weeks after osteotomy. Minimal callous production and more appearance of remodeling with greater fracture strength were seen when destabilized six weeks after osteotomy. No effect was seen when the osteotomies were destabilized 12 weeks after osteotomy and compared with contralateral rigidly stabilized controls. These results suggested that too great or early reduction in fixation rigidity can cause the fracture healing pathway to convert from primary intramembranous ossification to secondary endochondral ossification. Destabilization could result in greater fracture strength when performed at six weeks, probably by stimulating the hypertrophy and remodeling phase of

primary bone healing. Late destabilization of that model provided no beneficial effect, either because the responsiveness of the healing tissue was inadequate at that time or the study did not go long enough (12 to 15 weeks). It was also noted that problems with fixation, pin loosening, and secondary lameness with infection developed as the fixation pin numbers decreased after destabilization. However, a similar, more recent and well controlled study performed by Dupuis' laboratory found no significant differences in healing of a 2-mm wide oblique osteotomy when destabilizing from a type II to a type I frame.[16] These authors concluded that the previous positive study results may

have reflected excessively rigidly control osteotomies, essentially causing stress protection, and that destabilization from a type III may, in fact, be a return to normal bone healing rather than enhanced bone healing.[17-19] However, they also recognize that different clinical situations may require different approaches, and slow-healing fractures may still benefit from a gradual increase in loading by progressive removal of fixation.[16]

Increasing Stabilization

A final scenario of fracture fixation manipulation that has been discussed is that of allowing early motion at the

fracture site to induce a large periosteal callous through the chondral precursor pathway, and then increasing rigidity to encourage the later stages of ossification. We performed a pilot study of this approach starting with a type I configuration for 4 weeks, followed by conversion to a rigid type III configuration after significant callous production. Overwhelming problems with fixation failure and pin loosening resulting in loss of reduction and poor limb use owing to pain caused the abandonment of this approach; however, with today's improvement in device design and threaded pin use, the concept deserves further study.

Direct Current Stimulation (DC)

DC uses a constant 20 μA to stimulate the fracture. The cathode is placed at the stimulation site and the anode/battery pack is buried in subcutaneous tissues. Brighton[15,20] showed that at the cathode, PO_2 is lower, which appears to favor bone formation; proteoglycan and collagen synthesis are increased. Currently, DC is approved for use in human established nonunions and spinal fusions,[21] with up to 83% success reported for tibial nonunions.[22] The implantable battery eliminates the problem of patient compliance, but usually requires removal after six

months.

Pulsed Electromagnetic Fields (PEMF)

The PEMF signal was developed to induce electrical fields in bones similar in magnitude and time to the endogenous electrical fields produced in response to strain.[21] They may reflect the ability of bone to respond to change in mechanical environment known as Wolff's Law. The signal consists of bursts of EM pulses repeated at 15 Hz. Various in vivo studies have shown upregulation of TGF-B and a several fold increase in BMP mRNAs, which increased chondroneogenesis by enhancing

differentiation of osteochondral precursor cells,[22] suggesting that PEMF will have optimal effect on endochondral bone production. That is consistent with the clinical observation that PEMF is more effective in treating hypertrophic nonunions than atrophic nonunions.[22] Currently PEMF is used in humans as an adjunct to standard fracture and delayed union therapy.

Capicitative Coupling (CC)

This approach uses 2 surface electrodes placed on alternate sides of the fracture; the induced field is driven by an oscillating electrical current.[21] Field strength is calculated to be 0.1 to 20 mV/cm continuously applied.

Stimulation of bone cell proliferation has been observed but the physiology of how electrical signals stimulate has been difficult to demonstrate in the laboratory.[23] CC is typically used with casting in treatment of nonunions with a 60% to 77% success rate and improvement from 65% to 85% success rates in obtaining spinal fusion.[23]

Combined Magnetic Fields (CMF)

CMF appears to affect calcium ion transport across cell membranes and activate secretion of growth factors (insulin-like-growth factor-II), increasing cell proliferation.[23,24] However, more study is needed to fully

explain its stimulation effect. Currently CMF is applied for 30 minutes a day in cases of nonunion and to stimulate spinal fusion.[21] Treatment of osteoarthritis and neuroarthropathy has been suggested but awaits more understanding of its mechanism of action.[21]

Low-Intensity Ultrasound (LIUS)

Low-intensity ultrasound with high-frequency short bursts has been shown to accelerate fracture healing, but no specific stage of healing appears to be more sensitive.[25] A minimal heating effect (less than 1 degree C) may increase some enzymatic activity.

Ultrasound does affect the exchange rate of potassium ions and increases the release of intracellular calcium and appears to stimulate proteoglycan synthesis in rat chondrocytes.[26] Also a greater degree of blood flow has been shown in canine ulnar fracture models with a generalized stimulatory effect.[27] In humans it is applied for 20 minutes daily. Current clinical indications are aimed at reducing the healing time of fresh fractures to avoid delayed unions and subsequent loss of fracture reduction.[28] It has also been used in treatment of nonunions and increasing strength of the new bone produced by distraction osteogenesis.[21]

Shock-Wave Therapy

Shock wave uses a high-energy variable-frequency mechanical impulse applied with a transducer that can focus the impulses to concentrate on deeper structures. A rapid positive pressure wave is followed by a variable negative pressure that may cause cavitation of soft tissues or disruption of large structures. It was originally used as lithotripsy for the noninvasive fragmentation of kidney stones.[29] Several studies have shown positive and variable effects on the healing of nonunions,[28] and one clinical study found a positive effect on late healing of acute tibial osteotomies in dogs.[30] Although the mechanism of action has not been clarified, it is

proposed that shock-wave application produces microtrauma with hematoma creation. Subsequently, the induced neovascularization stimulates connective tissue proliferation and activity.[31] Generally, 6000 to 12,000 shock impulses are applied at a treatment that may be repeated periodically. Currently, shock-wave therapy is recommended only as an adjunctive to traditional treatments for chronic nonunions, particularly those with compromised local circulation. A temporary weakening of the osseous structures may result from the trabecular microfractures produced. There also appears to be a significant analgesic effect so caution in post-treatment activity must be used to

avoid catastrophic fracture until the treated bone has an opportunity to respond and strengthen.

Biologic Stimulation of Bone Healing

Most fractures in companion animals heal in an acceptable time period with adequate stabilization of the fracture fragments. Factors that contribute to delay or prohibition of fracture healing exist. Major categories of these factors are deficiencies of vascular supply, deficiencies in the vigor of the osteochondral response, and deficiencies in stability or physical continuity. Use of cells, bioactive factors, and/or supportive matrices

can enhance fracture healing by providing or stimulating the deficient factor. Bioactive materials can be grouped based on their properties that enhance healing: osteogenesis, new bone formation; osteoinduction, recruitment and differentiation of bone-forming cells; and osteoconduction, mechanical support or scaffold for bone-forming cells. These therapeutic options can be used alone or in synergistic combinations. Some of the bioactive factors discussed here are available for clinical use; however others are not, and have only been used in experimental fracture or defect models.

Materials that are Primarily Osteogenic and Osteoconductive

Autogenous cancellous or corticocancellous grafts are frequently used by veterinary surgeons. These grafts are the gold standard for enhancing fracture healing against which bone substitutes are compared. Autograft is readily available from the metaphysis of several long bones or the ilium. The volume of graft is limited and donor site morbidity occurs. When handled properly, autograft provides mesenchymal stem cells and differentiated osteoblasts and osteocytes that can form new bone. The mineralized bone in the autograft

provides osteoconductive surfaces on which bone-forming cells can lay down new matrix. Bone grafts are addressed more extensively in Chapter 88.

Mesenchymal stem cells (MSC) or multipotent adult progenitor cells (MAPC) are pluripotent cells that have a high replicative capacity and the potential to differentiate into many tissues including the osteogenic lineage.[30] Approximately 1 in 25,000 nucleated cells from an adult canine bone marrow aspirate is a MSC.[32] These cells can be directed to develop into an osteogenic lineage during culture expansion by exposing the cells to a number of substances, such as transforming growth factor-β (TGF-β),

insulin-like growth factor (IGF), vascular endothelial growth factor (VEGF), dexamethasone, β-glycerophosphate, or ascorbic acid phosphate.[33,34] The MSCs in the marrow of an autogenous graft are exposed to these factors during the inflammatory response from the fracture and surgical intervention. Bone morphogenetic proteins or osteogenic proteins, BMP-2 or BMP-7/OP-1, are potent factors that induce MSC to differentiate into osteoblastic cells.[35-37] Local concentrations of bone morphogenetic protein (BMP) at a fracture site may increase as osteoclasts resorb bone matrix.[38] The multipotent cells that appear early in the fracture hematoma also appear to

synthesize BMPs, which creates a cascade of events that results in greater numbers of multipotent cells and increased levels of BMPs.[39]

Two services currently purify and expand MSC from either bone marrow (VetCell Bioscience) or lipoaspirates (Vet-Stem). These concentrates have been used to enhance healing of equine tendons and ligaments. MSCs expanded in culture and exposed to an osteoinductive factor have been loaded onto an osteoconductive carrier. Although these osteogenic and osteoconductive combinations have been shown to enhance fracture and bone defect healing in many experimental animal models, they are

not currently used in human or veterinary clinical fractures. The problems associated with clinical use of this treatment modality are that 1) 2 to 3 weeks are required to purify and expand the cells following the initial collection, causing a delay before sufficient amounts of patient-derived MSCs are available for re-introduction; 2) patient-derived MSCs may not be suitable for regeneration of damaged tissues if the patient is aged or if has bone marrow neoplasia; and 3) the cost of isolation, expansion, and safety and quality control must be covered for each patient and is cost-prohibitive.

Many surgeons are mixing unconcentrated bone marrow aspirates

with osteoconductive material, such as bone allograft or hydroxyapatite to enhance bone healing. The osteogenic potential of concentrated MSCs has been shown to be significantly greater than fresh bone-marrow aspirate. Systems that concentrate MSCs from fresh bone-marrow aspirates instantly in the operating room are commercially available. CELLECT® (Johnson & Johnson) filters fresh marrow through a central chamber that holds osteoconductive material (i.e., cancellous bone or demineralized bone matrix) and concentrates the MSC three- to fourfold.

Periosteum is tissue that covers the external surface of most bones. It is

composed of two microscopically distinct layers. An outer, fibrous layer is composed of fibroblasts, collagen, and elastin fibers with a neural and microvascular network.[40-42] The inner, cambium layer in contact with the cortical surface is highly cellular. It contains MAPC, osteogenic progenitor cells and osteoblasts, fibroblasts, tiny blood vessels, and sympathetic nerves.[41-43] Trauma activates the progenitor cells of the periosteum, although most studies have explored the use of periosteum to generate cartilage. Experimental models have shown that the osteogenic potential of this tissue can be stimulated by basic fibroblastic growth factor (bFGF), transforming growth factor-beta (TGF-

β) and BMPs.[44-46] One study showed the powerful ability of periosteum to heal 5-cm tibial cortical defects in sheep with new bone production.[47]

Activated platelets in the fracture hematoma release several growth factors including platelet-derived growth factor (PDGF) and bFGF. These factors stimulate the proliferation of periosteum-derived cells and contribute to the mitogenic response of the periosteum during callus formation.[48-50] After proliferation these cells differentiate into osteoblasts or chondroblasts to form bone or cartilage to allow bridging of the fracture gap.

Materials that are Primarily Osteoconductive

Processed allogenic bone graft has no osteogenetic capacity and little osteoinductive activity. Its primary purpose is to provide structural integrity and act as a scaffold for new bone formation.[51] In order to minimize its immunogenicity, the graft must be processed in some way, which in turn compromises its mechanical properties. The advantages of allograft are that it is readily available in virtually unlimited amounts and engenders no donor site morbidity. Large cortical allografts are pieces of dead bone, and subsequently, are not completely replaced by new host bone and are

more prone to infection. Veterinary Transplant Services Incorporated is a bone bank for canine and feline allograft bone in a variety of structures.

Synthetic bone graft substitutes consist of calcium sulfate or plaster of Paris; hydroxyapatite, tricalcium phosphate, and combinations of these minerals, known as ceramics; and synthetic glasses composed of SiO_2, Na_2O, CaO, and P_2O_5. The materials vary in fabrication technique, crystallinity, pore dimensions, mechanical properties, and resorption rate. All synthetic porous substitutes share numerous advantages over autograft and allograft including their unlimited

supply, easy sterilization, and storage. However, the degree to which the substitute provides an osteoconductive structural framework for new bone ingrowth differs depending on material composition. Calcium sulfate as cement and pellets is commercially available and its affordability, resorbability, and biocompatibility make it an option for veterinary surgeons. Cerasorb Vet (New Generation Devices) is a veterinary product of pure tricalcium phosphate that is available in granular and block forms.

Hydroxyapatite (HA) porous implants are produced when coral carbonate in the exoskeleton of a marine invertebrate of the genus Porite is

converted by a hydrothermal exchange. The new material is mechanically superior while maintaining the internal structure of the coral. It has parallel channels 230 μm in diameter with interconnecting fenestrations of 190 μm diameter that are similar to the structure of cortical bone. Fibrovascular tissue that initially invades HA implants is later replaced by mature lamellar bone.[52] Although some surface resorption of the bulk implant does occur by osteoclast-like cells, major remodeling is minimal owing to the inert, insoluble structure of the HA.

Many ceramic preparations are commercially available and are widely

used in human orthopedic surgery. Disadvantages of ceramic implants include brittle handling properties, variable rates of resorption, poor performance in diaphyseal defects, and potentially adverse affects on normal bone remodeling. These shortcomings have restricted their primary use to bone graft extenders and carriers for pharmaceuticals. A particulate bioglass preparation marketed for veterinary use (Consil, Nutramax Laboratories Inc.) is indicated for use in infrabony pockets associated with dental and periodontal disease and defects. Bioactive glass may induce more osteoproduction than other ceramics, but it is slowly resorbed.

Materials that are Osteoconductive and Osteoinductive

Demineralized bone matrix (DBM) is allograft bone that has undergone acid extraction of the mineralized portion of the matrix that increases the availability of inductive proteins. Several osteoinductive proteins, including bone morphogenetic protein, may be present in physiologic and biologic concentrations and proportions. One of the advantages of DBM is that, with time and continued remodeling, it will be completely resorbed and replaced by new host bone. Veterinary Transplant Services Inc. markets canine and feline DBM

powder alone or combined with cancellous allograft chips to provide an osteoconductive matrix.

As mentioned earlier, fresh bone marrow, that may be centrifuged or filtered to concentrate MSCs, can be mixed with DBM/cancellous chips to provide a graft material that has osteogenic as well as osteoinductive and osteoconductive properties. Another strategy that provides a synergistic effect among bioactive materials is to mix DBM or DBM and bone marrow aspirate with platelet concentrate. A platelet concentrating system, Symphony PCS (DePuy), uses an automated device to rapidly concentrate platelets from a relatively

small volume of a patient's blood. The concentrate has three to six times the levels of PDGF, IGF, TGF-β, and VEGF. These factors are chemotactic for stem cells, osteoblasts, and chondrocytes and are mitogenic for MSCs and osteoblasts. There is also a graft delivery system, Symphony GDS (DePuy) or GPS (Biomet) that has a specially designed graft chamber and manifold for the delivery of graft materials to an orthopedic surgical site. The system facilitates premixing of graft materials with platelet concentrate, bone marrow, or blood that can then be placed into a fracture site or bone defect.

Materials that are Primarily Osteoinductive

Osteoinductive molecules promote bone formation mediated by cell signaling that prompts multipotent cells to differentiate into osteoblasts. The most widely studied of these cytokines are the BMPs. This family of proteins has several members, but BMPs 2, 4, 6, and 7 (also known as osteogenic protein-1, OP-1) have the most potent osteoinductive efficacy.[53] Experimental preclinical studies in a variety of species including dogs have demonstrated healing of bone defects, fractures, and spinal fusions with the application of different BMP-carrier systems. Early studies used DBM or

highly purified BMP, and more recent studies use recombinant BMP, usually human recombinant BMP (rhBMP). These water-soluble proteins must be combined with a carrier to maintain sustained delivery of adequate protein concentrations in the desired site.

Much of the current research effort is to find the optimal carrier and optimal dose for different species and specific sites in every species. Bone morphogenetic protein 2 (Medtronic Sofamor Danek) on an absorbable collagen sponge, and the OP-1 implant (Stryker Biotech), OP-1 in a purified bovine type 1 collagen particulate matrix, are the most heavily studied osteoinductive biomaterials. These two

products are available for limited applications in human orthopedic surgery, including periodontal lesions, spinal fusions, and tibial nonunion fractures. Although these implants are not approved for veterinary use and their cost would most likely be prohibitive, they have had extra label use in a limited number of clinical cases of delayed or nonunion fractures in dogs. The latest method of delivery of BMPs and other bioactive cytokines to desired sites is by gene therapy. Delivery of the relevant DNA to host cells can be accomplished using nonviral, e.g, plasmid, or viral, e.g., adenovirus, vectors. The vectors can be delivered directly into the host tissues by in vivo transfer, or indirectly by in

vitro transfer into harvested host cells that are then returned to the desired site. Bone morphogenetic proteins are addressed more extensively in Chapter 86.

The exact roles in bone formation of other growth factors that have been identified are less clear. Conflicting results in experimental studies using these cytokines for fracture healing and clinical applications of these bioactive factors have been reported. Unlike the BMPs, these growth factors are incapable of de novo bone formation in an ectopic site. Transforming growth factor-beta is a protein found in platelets, bone, and cartilage that may act synergistically

with other cytokines to promote differentiation, proliferation, and matrix synthesis by osteoblasts. Osteoclasts degrade bone during fracture repair by acid hydrolysis of the matrix, creating an acidic environment that can activate latent TGF-β.[54] The TGF-β released from the bone matrix can activate osteoblasts to produce new bone matrix.

Basic fibroblast growth factor (bFGF) acts primarily as a mitogen, stimulating increased DNA synthesis and cell division. When injected into a fracture site on a fibrin or hyaluronan carrier, it increased callus size, mineral content, and mechanical strength of the healing bone.[55,56] Insulin-like

growth factors I and II stimulate bone formation by promoting proliferation of osteoblastic precursors and matrix production by osteoblasts. Platelet-derived growth factor is released by platelets during fracture healing and is chemotactic for fibroblasts, monocytes, and osteoblasts and stimulates proliferation of mesenchymal cells. Growth and differentiation factor-5 (GDF-5) is a divergent member of the TGF-β superfamily required for normal skeletal development. When loaded on a collagen matrix, GDF-5 induced ectopic cartilage and bone formation, new bone formation in long-bone defects in non-human primates, and fusion of vertebral transverse processes in rabbits.[57,58]

Chapter 88

Bone Grafting

André Autefage
Loïc M. Dejardin

Bone grafting is used extensively in human and veterinary medicine. It is commonly utilized for treatment of delayed unions or nonunions, filling of bone defects, or joint arthrodesis. It is estimated that 500,000 to 600,000 bone grafting procedures are performed in humans annually in the United States alone.[1] No accurate estimates exist for the number of bone

grafts performed in veterinary medicine.

Types of Bone Grafts – Terminology

Bone grafts are described based on the relationship between donor and recipient, on the type of bone harvested, and on the site of the application. **Autografts** are tissues that are transplanted from one site to another in the same individual. Because the genetic composition of the donor and recipient sites are identical, no immune response occurs. Cancellous bone autografts are the most commonly used bone grafts in veterinary medicine. **Allografts** are

transplanted from one individual to another of the same species. Genetic differences between the donor and recipient may induce an immune reaction based on the recognition of foreign antigens from the graft by the host immune system. Most bone allografts require some form of processing or preservation prior to use. **Xenografts** are tissues transplanted from one individual to another of a different species. Xenografts often induce a more severe immune response.

Bone grafts are also defined according to the type of bone transplanted. **Cancellous bone** grafts are composed of the porous, highly cellular

trabecular bone found in the long bone epiphyses and metaphyses as well as in the iliac wings and the sternebrae. The trabeculae are covered with a highly reactive endosteal membrane that includes osteoclasts, osteoblasts, and bone lining cells. The cavities between the trabeculae are filled with highly cellular bone marrow. **Cortical bone** grafts are composed of the dense, compact bone from the diaphyses of long bones. They are mechanically strong, but have a relatively low cellularity. **Corticocancellous bone** grafts are combinations of the two types of bone, which allow surgeons to take advantage of the benefits of both types of grafts. Ribs and the craniodorsal part of the iliac wings are

the main sources of corticocancellous bone grafts in dogs. An allograft used with fresh cancellous bone or bone marrow is termed a **composite graft. Vascularized bone autografts or allografts** are harvested with their blood supply and microvascular anastomoses are necessary at the time of implantation. **Osteochondral** grafts include bone and articular cartilage.

A bone graft placed in its normal position (i.e., within bone tissue) is said to have been **orthotopically** transplanted. If the graft is transplanted to an abnormal anatomic site, it is said to have been **heterotopically** transplanted.

Function Of Bone Grafts

An ideal bone graft would perform four functions: osteogenesis, osteoinduction, osteoconduction, and mechanical support.[2,3] However, depending on the type, the most common bone grafts are able to provide only one or more of these functions (Table 88-1).

Osteogenesis

Osteogenesis is defined as the creation of new bone by bone-forming cells regardless of their origin. This function may be performed by donor cells (osteoblast precursors, osteoblasts, or chondroblasts) that survived the transplantation (fresh autogenous

grafts only[2]) or by host cells stimulated by the graft or the grafting process. Cancellous bone has a much greater osteogenic potential than does cortical bone, in part because its copious porosity allows for fast and intense revascularization that contributes to cell survival.[4] Furthermore, cancellous bone is filled with bone marrow, which contains mesenchymal stem cells able to differentiate into osteoprogenitor cell lines. Finally, the trabeculae provide a large surface covered by lining cells and active osteoblasts. The survival of osteogenic cells in a graft depends on the nourishment they receive directly after transfer.[5] Although the percentage of cells surviving transfer of a fresh cancellous

autograft is unknown, it has been shown that, in vitro, approximately 65% of the cells may survive up to 3 hours when the graft is maintained at room temperature in a saline solution.[6] However, it has been estimated that the survival rate of osteogenic cells in vivo does not exceed 5% following transplantation.[7] With cancellous bone autografts, early osteogenesis is characterized by active new bone formation in direct contact with the transplanted graft within 1 week following transplantation.[4] Similarly, with vascularized cortical grafts, more than 90% of the osteocytes may survive transplantation,[8] with new bone formation beginning as early as 24 hours after surgery.[9] In contrast,

with nonvascularized cortical grafts, osteogenesis begins with vascular ingrowth, which does not occur until the sixth day after transplantation.[10]

Table 88-1. Functions of Types of Autologous Bone Grafts (Adapted from Finkemeier [12])

Function	Cancellous	Nonvascularized cortical	Vascularized cortical
Osteogenesis	+++	–	++
Osteoinduction	++	+/–	+/–
Osteoconduction	++++	+	+
Immediate mechanical support	–	+++	+++
Mechanical support at 1 year	+++	+++	+++

Osteoinduction

Osteoinduction refers to the recruitment of mesenchymal and pluripotent osteoprogenitor cells which

later differentiate into bone- or cartilage-forming cells at the implantation site. Differentiation of mesenchymal cells is regulated via growth factors such as bone morphogenetic proteins, transforming growth factor-beta, insulin-like growth factors, fibroblast growth factors, platelet-derived growth factors, tumor necrosis factor, prostaglandin E2, and other cytokines.[11] Although these factors are produced by live cells and are present in the bone matrix, living graft cells are considered more osteoinductive than bone matrix. Because of the trabecular structure, cancellous bone matrix proteins are more readily accessible than are those of cortical bone. Osteoinductive factors

may also be released during graft resorption, which in turn contributes to graft incorporation.[12] Despite the lack of evidence that inductive proteins and cytokines are active in autologous cancellous bone grafts, cancellous bone is widely believed to be osteoinductive.[12]

Osteoconduction

Osteoconduction refers to the three-dimensional process of tissue ingrowth within the graft, which acts as a scaffold. This process involves the invasion of the graft framework by capillaries as well as the migration of host osteoblasts, osteoclasts, and mesenchymal cells.[2,13] In porous

cancellous bone grafts, initial fibrovascular invasion occurs quickly and is followed by bone ingrowth, characterized by direct apposition of new bone on the graft trabeculae. During subsequent graft remodeling, necrotic trabeculae are progressively resorbed and replaced by new bone. Although growth factors, collagens, and noncollagenous proteins participate in the regulation of this process, the three-dimensional trabecular structure of cancellous bone is the primary determinant of the speed and completeness of graft incorporation.[13] Histologic differences observed during cancellous versus cortical graft incorporation illustrate this phenomenon. Indeed, dense

cortical grafts must undergo a resorptive phase, with removal of necrotic Haversian systems, before fibrovascular ingrowth into resorptive pores or channels can occur.[14] The process of initial bone resorption followed by fibrovascular invasion and appositional new bone formation as seen with cortical bone graft incorporation has been termed "creeping substitution." The differences between the incorporation of cancellous and cortical bone grafts suggest that the porosity and surface area of the pores directly influence the speed and rate of incorporation.

Mechanical Support

Mechanical or structural support describes the ability of a bone graft to act as a load-sharing space filler in the treatment of large bone defects, and its effectiveness depends on the nature of the graft. Although cancellous bone is an efficient space filler, it does not provide substantial structural support. In contrast, a cortical graft provides excellent early mechanical support. Importantly, the strength of a graft changes over time in response to the biomechanical environment. Local bone resorption and revascularization substantially increase porosity, causing nonvascularized cortical autografts to become weaker at the host-graft interface six weeks after grafting.[14-16] Conversely, vascularized cortical

autografts do not undergo resorption and revascularization and, therefore, show superior strength six weeks postoperatively.[15] However, six months following transplantation, the strength of nonvascularized and vascularized cortical grafts is similar.[15] Regardless of the type, cortical grafts are unable to withstand substantial loads, and must be supported by adequate internal fixation during the incorporation process to prevent catastrophic failure.

Biology of Bone Graft Incorporation

The term *incorporation* is used to describe the biologic interactions

between a bone graft and host tissue at the recipient site that result in bone formation with subsequent improvement in mechanical properties.[17] This process includes the host inflammatory reaction to the surgical trauma, the host inflammatory and/or immune reaction to the graft material, and the processes of cell proliferation, migration, differentiation, and revascularization, resulting in new bone formation and union between graft and host bone. The sequence of events leading to graft incorporation is relatively consistent, although some differences exist between incorporation of cancellous and cortical bone as well as vascularized and nonvascularized bone

grafts.[15,18-20] The biologic events occurring at the graft site include: (i) hematoma formation; (ii) inflammation, migration, and proliferation of mesenchymal cells, and development of fibrovascular tissue in and around the graft; (iii) vascular invasion of the graft; (iv) resorption of graft surfaces; and (v) bone formation on the graft surface. The incorporation of nonvascularized bone grafts (cancellous or cortical) begins with the formation of a local hematoma. This hematoma is rich in growth factors and other cytokines and allows for the survival of transplanted cells near the trabecular or cortical surfaces up to one week after transplantation.[21] The associated

inflammatory response leads to the formation of granulation tissue, which invades the grafted site and contributes to the revascularization of the graft. Revascularization and cell differentiation vary with the type of graft, surgical technique, mechanical environment, and quality of the recipient bed. Cancellous grafts are revascularized faster than are cortical bone grafts. Histocompatibility and immunogenicity of the graft also play an important role in the rate of vascularization. Incompatible bone grafts induce an immune reaction that delays or inhibits vascularization of the graft;[4] a major mismatch may induce resorption of a cancellous bone allograft and replacement by

fibrocartilage.[22] Aseptic and atraumatic surgical techniques improve the success rate of graft incorporation. Fluid exudation, infection, or devascularization of the recipient bed will delay or prevent revascularization of the graft. The mechanical environment of the graft site also has a profound effect on revascularization and cell differentiation. Although instability at the host-graft interface induces local shear strains that may impede vascular invasion of the graft, the effect of the mechanical environment on graft incorporation varies between cancellous and cortical grafts. Cancellous grafts are less susceptible to shear strains owing to their porosity and use as loosely

packed fragments. In contrast, the host-graft interface of dense, monolithic cortical bone grafts is highly vulnerable to instability because the proximity of the host and graft fragments induces large local shear strains that prevent vascular penetration of the narrow Haversian canals.[17] Accordingly, cancellous grafts do not require absolute stability, but cortical grafts must be rigidly stabilized. The quality of the tissues at the host site is also a primary factor in the incorporation process. Of particular importance is the vascularity in the graft bed and the abundance and competence of endothelial cell progenitors and connective tissue.[17] Excessive surgical trauma, the presence

of necrotic tissue, systemic steroids, infection, and radiation therapy may compromise vascularization of the recipient bed and the pool of local progenitor cells.[17,23]

Incorporation of Autografts

Cancellous Autografts

Although the rate of cell survival remains unknown, the majority of transplanted cells probably die as a result of local ischemia or induction of apoptosis. However, bone marrow mesenchymal cells and endothelial cell progenitors are relatively resistant to ischemia and may survive transplantation and may even proliferate in response to changes in

oxygen tension, pH, and cytokines.[17] Survival of these cells along with recruitment of host mesenchymal stem cells is the key to successful incorporation of cancellous bone autografts. Following cancellous bone autograft transplantation, vascular invasion of intertrabecular spaces and formation of abundant granulation tissue proceed from the host-graft interface. This process is usually complete within two weeks.[4] With vascular ingrowth, differentiation of osteoprogenitor cells into osteogenic cells (osteoblasts) occurs. Osteoblasts start laying down poorly mineralized new bone (osteoid) on the surface of the necrotic trabeculae,[24] while hematopoietic marrow elements

accumulate within the graft.[10] By 12 weeks, cancellous bone chip grafts have the radiographic and histologic appearance of mature cancellous bone.[4] Eventually, the necrotic trabecular framework will be resorbed and remodeled via osteoclastic and osteoblastic activity. New bone may be remodeled in response to local stresses. Indeed, when cancellous bone grafts are used for filling of diaphyseal gaps, the remodeling process transforms cancellous bone into cortical bone. Osteogenic activity peaks around 6 to 8 weeks following transplantation, while "corticalization" of the graft in response to mechanical stresses requires up to 24 weeks.[24]

Nonvascularized Cortical Autografts

Two major differences exist between cancellous and cortical graft incorporation: (i) the rate of revascularization and (ii) the process of new bone formation. Whereas fresh cancellous autografts are revascularized as early as 1 week after surgery, vascular invasion of cortical autograft is postponed until 7 to 8 weeks.[25] This delay is due to the structure of cortical bone, with vascular penetration of the graft requiring peripheral osteoclastic resorption and vascular infiltration of Volkmann and Haversian canals.[14] In experimental studies, the resorptive

activity was confined almost exclusively to the osteons, whereas resorption of interstitial lamellae was uncommon. As the Haversian canals reached a critical size, the resorptive process ceased in favor of new bone apposition.[10] By 8 weeks, only a third of the graft had been replaced with new bone, whereas the incorporation front showed increased porosity and the remaining core of the graft appeared as a necrotic mineralized matrix.[14,25] At 1 year, 40% of the original necrotic bone remained in cortical autografts.[14,19] It is not known whether the failure to repair nonosteonic lamellar bone persists indefinitely. It seems likely that the mixture of necrotic and viable bone in

the cortical graft remains unaltered once the anabolic and catabolic stages of repair have been completed. Thus, cancellous grafts tend to be completely replaced by new bone, whereas cortical grafts remain as mixtures of necrotic and viable bone.[10] While consolidation of the host-graft interfaces with woven bone stabilizes the graft and allows vascular penetration into the cortex,[26] the delay between initial bone resorption and later bone deposition increases bone porosity at the incorporation front, locally reducing the strength of the graft by half between 6 and 24 weeks.[14,25] As a result, protection of the graft segment via rigid fixation is necessary for at least 6 to 12 months.

Furthermore, in order to prevent graft site fractures, implant removal is not recommended.

Cortical bone autograft stabilization using rigid fixation favors its incorporation and influences the biologic events leading to its remodeling.[27] Lack of absolute stability at the host-graft interfaces delays graft incorporation. In a study using a canine ulnar diaphyseal segment model without stable internal fixation, only 22% percent were united at 12 weeks, 54% at 6 months and 66% at 1 year.[28] These results clearly contrast with another experimental study in which a cortical autograft was stabilized using internal fixation. By 3

months, both host-graft interfaces had healed.[26] Similarly another canine study showed that healing of a 4-centimeter femoral cortical autograft stabilized using rigid internal fixation was similar to bone healing under stable conditions.[27] New bone was deposited directly onto the surface of nonviable bone, and revascularization occurred from the recipient site medullary artery or a neonutrient artery traversing the cortical bone and reestablishing a medullary circulation. The graft was incorporated directly into the recipient site without local bone resorption and was used as a scaffold for new bone.[27] Incorporation, not resorption, was the prominent feature of the graft healing. Thus,

resorption and replacement are not the fate of all devascularized cortical autografts.

Vascularized Cortical Autografts

A vascularized cortical graft involves bone that has been harvested with its nutrient artery and vein; the transplantation is obtained by transfer to another site with microvascular anastomosis of the two vessels. Incorporation of vascularized cortical autografts is achieved more predictably. Because the blood supply of the grafts is maintained, their incorporation may differ markedly from that of nonvascularized grafts. In

particular, when the anastomosis is successful and the graft does not suffer intraoperative ischemia, up to 94% of osteocytes survive the transplantation procedure.[8] Such vascularized cortical grafts heal rapidly at the host-graft interface and their remodeling is similar to that of normal bone. Three months after surgery, vascularized grafts may be indistinguishable from normal bone.[25] Vascularized cortical grafts are stronger than nonvascularized grafts during the initial 6 weeks after transplantation because of the lack of resorption.[15] However, at 6 months, little difference exists in strength between vascularized and nonvascularized cortical autografts in the dog.[15] Although the vascularized

cortical graft is not significantly weakened during the initial incorporation phase, appropriate internal fixation must be used until the graft can undergo hypertrophy in response to changes in local mechanical loading, according to Wolff's law. Although vascularized grafts are not commonly used in veterinary medicine owing to the financial challenges associated with the acquisition and maintenance of operating microscopes and microvascular instrumentation, vascularized grafts are better than nonvascularized grafts for large segmental bone defects.[12]

Incorporation of Cortical Allografts

Bone allografts have been used in human and veterinary surgery for decades and the histologic events in allograft incorporation have been well described.[9,10,16,18,20,26,29-35] The main differences between cortical autografts and cortical allografts are the slowness of incorporation, the process of revascularization, and the biologic events resulting from the immunogenicity of the graft.

Incorporation of cortical allografts occurs via healing at the host-graft interface, which involves the gradual formation of a callus extending from

the host bone to the surface of the allograft without local resorption.[20,36] Union of the host-graft interface is generally obtained within 3 months,[26,31,37] although healing times may vary from 10 weeks to 37 weeks.[36] The principal determinants of host-graft union are stability of the construct and contact between host bone and the graft.[38] The process of revascularization and repair of the cortical allografts is controversial. In some studies, incorporation of cortical allografts followed a pattern similar to that seen with cortical autografts, albeit with slower and less extensive vascular penetration and slower new bone formation.[5,29,32] Revascularization and subsequent

resorption were almost complete one year postoperatively, although a large amount of necrotic bone remained within the graft.[32] Other studies,[20,26,27,33] however, suggest that the pattern of revascularization and repair differs from that observed for cortical autografts involving the deposition of a thin layer of new bone (1 to 2 mm thick) over the necrotic cortex of the graft that remained intact. Whereas the outer bone was supplied by extraosseous vessels, the medullary cavity was avascular.[33] The repair process was slow, with less than 10% of the graft being incorporated at one year and only 20% at 5 1/2 years.[20] Although anecdotal reports have shown that a femoral cortical

allograft can remain structurally intact for eight years and that it can assume the mechanical support of limb function for five years after plate removal,[33] from a mechanical standpoint, persistence of a large amount of necrotic bone in the allograft is likely to decrease strength in vivo over time. A 50% loss in allograft strength was noted after 10 years and was correlated with an increase in microfractures, probably related to mechanical stresses induced by weight bearing.[39] Because necrotic bone cannot repair itself, these microfractures may ultimately induce catastrophic allograft failure. In human medicine, the risk of these fractures (up to 19%) is significant in

the third year after implantation.[40-42]

Immunogenicity of bone allografts has been demonstrated in experimental studies. The immunologic response of the host is predominantly a cell-mediated response to cell surface antigens carried by cells in the allograft, i.e., major histocompatability complex (MHC) class I and class II antigens. MHC class I antigens are found on all nucleated cells of the body and MHC class II antigens are expressed on the surface of macrophage-myeloid lineage cells, as well as osteoblasts.[43,44] Accordingly, because bone marrow cells represent a significant source of MHC I and MHC II antigens, removal of bone marrow

in allografts is likely to decrease their immunogenicity.[45] Although both collagen and matrix can induce immune responses, they are considered relatively weak when compared with cell-mediated immunogenicity.[44] Evidence also exists that all types of allografts induce the production of graft-specific antibodies that can be detected as early as three weeks after transplantation.[46,47] Whereas the immune response depends on the MHC class I and class II disparities,[47] its duration and intensity also depend on graft treatment and size, with frozen mismatched allografts inducing a weaker response than fresh allografts.[46]

When the allografts are relatively small, the antidonor antibodies are detectable for a shorter period of time than when massive allografts are used.[47] Several studies on experimental animals have shown that the process of incorporation of bone allografts is negatively influenced by the degree of mismatch between major histocompatibility complex antigens.[29,30,35] However, even if antibodies are formed against bone allografts, no clear evidence exists that they are directly involved in the rejection process.[10] Despite the experimental evidence that allografts can induce a host immune reaction, the clinical significance of this reaction is unclear. In biopsy specimens obtained

9 to 78 months after transplantation of large frozen cortical allografts in humans, no clear relationship was demonstrated between the extent of graft incorporation and the degree of histocompatibility between graft and host.[48]

Although most cortical allografts heal via intramembranous bone formation, clinical and experimental studies have shown that incorporation and remodeling may vary extensively. Incorporation may involve complete revascularization, resorption, and repair,[29,32] or leave a large amount of necrotic bone, with biologic attachment of soft tissues to the allograft surface and good functional

results for several years.[20,33] Similarly, remodeling may occur in response to mechanical stresses, according to Wolff's law.[9,49]

Incorporation of Processed Cortical Allografts

Allografts are often treated to decrease their immunogenicity and for long-term preservation. Such processing methods influence the degree of biologic reaction and/or mechanical properties. Freezing reduces the effects of histocompatibility mismatch and the biologic activity of the graft, most likely because of cellular destruction.[35] Likewise, freeze-drying reduces the graft immunogenicity,[16] but also

substantially alters its material properties, making it more brittle[50] and susceptible to fractures.[37] Ethylene oxide (EO) sterilization allows storage of allografts for long periods of time and reduces the risk of infection from graft contamination. However, EO-sterilized bone develops structural alterations during storage at room temperature that decrease its compressive strength and screw pullout load.[51] Conversely, storage at -20°C for one year does not significantly modify a graft's resistance to compressive, bending, and torsional loads.[52] Although EO is an effective sterilization agent, it may have a deleterious effect on graft incorporation.[53-55]

Gamma irradiation is the most widely used method in human medicine. However, because irradiation alters collagen crosslinks[56] and destroys the bone matrix fibrillar network,[5] this process affects the material properties of the graft in a dose-dependent fashion.[50] Specifically, irradiation reduces graft strength and energy-absorbing capacity prior to failure.[57,58] However, experimental studies in rats have shown that low-dose irradiation followed by soaking in 70% ethanol and deep freezing does not compromise the natural course of graft incorporation.[59] Autoclaving induces protein denaturation, which significantly decreases the graft osteoinductive and osteoconductive

properties.[11] Although experimental studies in dogs showed that autoclaved cortical autografts can be incorporated,[60] the process markedly delays incorporation.[5] In addition, a 43% complication rate has been associated with the use of autoclaved allografts in human medicine.[61] In an attempt to increase cortical graft revascularization, microperforations of the graft have been performed. Although a perforation pattern involving an array of 300 μm laser-made holes placed 3 mm apart did not significantly affect compression strength and flexural deformity,[62] perforation of cortical bone has been shown to substantially improve the amount of newly formed bone and

enhance allograft incorporation.[63]

Incorporation of Osteochondral Grafts

Osteochondral grafts include shell grafts and massive grafts. Shell grafts include articular cartilage and 2 to eight mm of subchondral bone, and are generally used for joint resurfacing. Shell autografts are incorporated quickly and completely when fixation is adequate.[11] Bone healing is obtained within 3 months.[64-66] In fresh osteochondral autografts, articular cartilage remains viable. In an experimental study of mosaicplasty (multiple autologous osteochondral plugs implanted in articular cartilage

defects) in dogs, host-graft cartilage interfaces healed with fibrocartilage; a continuity between graft and host cartilage was obtained as early as 16 weeks and maintained until 1 year.[67] Massive allogeneic osteochondral grafts are used to reconstruct joints in limb-sparing procedures after tumor resection. These grafts are composed of cortical bone, epiphyseal and metaphyseal cancellous bone, and articular cartilage. The pattern of bone incorporation is similar to that of bone allografts.[29] Although the cartilage of frozen osteochondral allografts undergoes significant cellular and structural alteration including chondrocyte death, thinning, and fibrillation,[68] it may provide adequate

function for up to six years[55] before osteoarthritis becomes a problem.[42] Soft tissue including ligaments, tendons, and fascia may be firmly reattached to the surface of the allograft by a seam of appositional bone laid onto the graft.[55]

Use of Bone Grafts

The three principal indications for bone grafts are enhancement of bone healing, replacement of bone lost through trauma or surgical resection, and in joint surgery.

Cancellous Grafts

Cancellous bone autografts are the most commonly used bone grafts in

veterinary orthopedics, particularly to enhance healing in the treatment of comminuted fractures of long bones. Biologic fracture stabilization can be achieved using: (i) an "open-but-do-not-touch" approach that permits viewing of the fracture fragments, realignment of the bone, and cancellous bone grafting.[69,70] or (ii) a closed reduction that involves alignment without surgically exposing the fracture site. Although any nonreconstructible fracture that requires open reduction and internal fixation may benefit from a cancellous autograft, use of minimally invasive techniques of fracture treatment, i.e., closed reduction without cancellous bone grafting, is more successful than

open approaches.[71] In our experience, comminuted fresh fractures of long bones of dogs and cats treated with a minimally invasive approach and the use of a plate-rod construct without any cancellous graft heal successfully. Therefore, systematic use of cancellous bone autografts to enhance bone healing in comminuted fractures of long bones is questionable.

Treatment of delayed union or nonunion fractures includes the use of rigid fixation often associated with cancellous bone grafting. Although most nonunions are biologically viable and are adequately treated by rigid internal fixation with compression of bone fragments, fresh autologous

cancellous bone packed into the nonunion site and around bone ends should be considered as part of the procedure. In biologically inactive nonunions, cancellous bone grafting is essential.[72] Another major indication for cancellous bone autografts is filling of bone defects after surgical excision of benign bone tumors or bone cysts, after debridement of open fractures, and following sequestrectomy in osteomyelitis. Regardless of the condition, the bone ends and the surrounding soft tissues must provide revascularization of the cancellous graft, and adequate stabilization must be achieved. If the soft tissue bed is poorly vascularized, delayed grafting is preferable to immediate grafting after

debridement and wound lavage.[11]

Treatment of osteomyelitis requires excision of infected soft tissue and bone, which may result in significant bone loss, requiring filling of the defect with a bone graft or bone graft substitute. Because cortical grafts are likely to become infected and bone substitutes may act as foreign bodies, only fresh autologous cancellous bone should be used to fill such defects. However, because autologous cancellous bone undergoes significant resorption at the center of the graft,[73] cancellous bone autografts are usually not recommended for the treatment of large segmental bone defects.[73,74]

Masquelet et al [73] described a new procedure for the treatment of segmental defects using cancellous autografts. The first stage consisted of inserting a cement spacer into the defect. This spacer has a mechanical role, preventing invasion of the recipient site with fibrous tissue, which may preclude further bone healing. It also has a biologic role, inducing formation of a richly vascularized pseudosynovial membrane around the cement plug. In the second stage, 1 month later, the membrane is incised and the cement spacer replaced with cancellous bone autograft, after which the membrane is sutured over the graft. This technique has been successfully used experimentally to

treat large (3 cm) femoral diaphyseal and periosteal defects in sheep. In the group in which a cancellous graft was placed inside the induced membrane, the defects healed with restoration of the normal bone diameter. In contrast, graft resorption occurred in all animals when the autologous cancellous bone was placed after removal of the membrane.[73] This membrane, therefore, actively contributes to the revascularization of the bone graft, acting as an in situ delivery system for growth factors (VEGF, TGF-β) and osteoinductive factors (BMP-2).[73,75] In people, this technique allowed reconstruction of bone defects up to 25 cm in length.[75]

Joint arthrodesis requires stable fixation and use of cancellous bone graft (Figure 88-1). Several clinical reports and experimental studies have demonstrated the usefulness of autogenous cancellous graft in arthrodesis. Indeed, the use of autogenous cancellous graft has been shown to enhance the rate of new bone formation and joint fusion when compared with nongrafted joints, which allowed earlier removal of external coaptation devices.[76]

Figure 88-1. Partial carpal arthrodesis with a cancellous bone autograft. A: Day 0; B: follow up at 2 months showing graft incorporation and remodeling with complete bone fusion.

To optimize the incorporation and

survival rate of graft osteogenic cells, fresh cancellous bone graft should be placed in the recipient site as soon as possible after being harvested. For example, storage of cancellous bone for three hours, using methods similar to those used for organ preservation, resulted in a 20% decrease in the number of viable cells.[6] Cancellous bone may be applied to the surgical site with or without compression. Compression of cancellous bone autograft does not enhance osteogenic capability[77] and may reduce the osteoconductive potential of the graft.[78] Although a larger quantity of autologous cancellous bone is often considered beneficial, overfilling does not enhance early osteogenesis and

must be avoided if it necessitates the use of multiple harvest sites.[79] Small graft fragments (approximately 3 mm by 1 mm) have been shown to have the best rate of revascularization and the greatest rate of survival of osteogenic cells.[80]

Corticocancellous Grafts

Corticocancellous grafts obtained from the iliac crest or a rib may be used as either blocks or small chips. A block of corticocancellous graft may be used as a cortical graft in relatively small segmental defects (Figure 88-2). Whereas cortical bone provides mechanical support and volume expansion, cancellous bone enhances

graft incorporation. Accordingly, corticocancellous grafts are often useful in neurosurgery to induce spinal fusion (e.g., in Wobbler syndrome) or when relatively large amounts of bone graft are required.[81] Incorporation of corticocancellous grafts is similar to that for cancellous bone grafts.

Cortical Grafts

Although cortical allografts have been widely used in the treatment of long-bone comminuted fractures in dogs and cats,[2,11,24,26,27,31-33,36,37,51,82,83] the recent increased reliance on biologic fracture-repair techniques have made the use of cortical grafts nearly obsolete. Cortical autografts may be

used in opening wedge osteotomies to limit limb segment shortening in the treatment of angular deformities. A small piece of cortical bone is packed within the bone defect to provide mechanical support. With rigid fixation, incorporation of such a cortical autograft is obtained within 2 to 3 months. Cortical allografts, associated with autogenous fresh cancellous bone packed around the host-graft interfaces, are mainly used in limb-sparing surgeries for the treatment of bone tumors. Here, too, the use of distraction osteogenesis via bone transport or use of metal prostheses may contribute to the reduction of clinical use of cortical allografts.

Osteochondral Grafts

Neither massive osteochondral allografts nor mosaicplasty are routinely used in small animal surgery. Although massive osteochondral allografts could potentially be used in limb-salvage procedures, logistical difficulties in obtaining anatomically appropriate grafts to achieve good joint function makes the use of cortical allografts with arthrodesis a more effective option. Recession sulcoplasty (block or wedge) in the treatment of patellar luxation is the osteochondral autograft most commonly used in small animal surgery. With such an osteochondral autograft, healing between the grafted sulcus and the

femoral condyle is generally complete by 10 weeks. The subchondral trabecular bone is slightly thickened and the articular cartilage of the graft is viable and appears histologically normal.[64]

Chapter 89

Bone Substitutes

André Autefage
Loïc M. Dejardin

Rationale for Bone Substitutes

The ability of the skeletal system to heal is remarkable. When bone healing is impaired, however, the use of various types of bone grafts including cancellous autografts, vascularized cortical autografts, and cortical allografts, or bone transport

techniques has been recommended. Owing to limitations inherent in each technique, the search for bone substitutes remains a medical necessity and has been the subject of extensive research.

Cancellous bone autografts, while considered the gold standard for bone repair, are fraught with limitations, including donor site morbidity (infection, pain, hematoma), limited availability, and high cost owing to increased surgical time. The impact of such limitations is exacerbated if several harvesting sites are required to obtain a sufficient graft volume. Furthermore, cancellous bone autografts are poorly suited for the

treatment of segmental defects because of their tendency to undergo central resorption in cortical defects larger than 4 to 5 cm in people and ~3 cm in dogs.[1,2] Vascularized bone transplant, routinely used in specialized human surgical units, requires a major microsurgical operative procedure and a sophisticated infrastructure. Therefore, this technique is rarely used in veterinary medicine. Conversely, cortical allografts are widely used with many successes reported in both the human and veterinary orthopedic literature.[3-11] However, limited supply, high cost of bone banking, risk of rejection, and compromised mechanical properties make the continued reliance on cortical

allografts a serious concern.[12,13] The early attraction of distraction osteogenesis techniques has been somewhat mitigated by their shortcomings including local morbidity, limited response of soft tissues to distraction, and cumbersome follow-ups.

Therefore, a critical need exists to develop artificial bone substitutes to act as replacements for biologic bone grafts. The ideal bone substitute should be biocompatible, osteoconductive, osteoinductive, osteogenic, structurally similar to the bone to be replaced, easy to use, and affordable.[14] Further, it is advantageous if the bone substitute is also bioresorbable; however, this is not

a limiting factor.

Properties of a Bone Substitute

An **osteoconductive** material promotes bone apposition on its surface and functions as a three-dimensional scaffold supporting vascular and cellular ingrowth, leading to new bone formation. An **osteoinductive** scaffold material provides a biologic stimulus that induces the recruitment and differentiation of host and transplanted cells into osteoprogenitor cells and then into osteoblasts. An **osteogenic** material contains living cells directly capable of new bone

formation. Bioactivity is defined as the ability of a material to develop a strong, direct bond with the neighboring bone tissue, without the formation of the fibrous interface typically induced by an implanted foreign body.[13]

Approaches to Bone Substitutes

The use of bone substitutes, or more generally, bone tissue engineering, is based on three strategies: (i) matrix-based approaches, (ii) cell-based approaches, and (iii) factor-based approaches.

Matrix-Based Approaches

Matrix-based approaches utilize structural scaffolds to replace the missing bone. Consequently, repair of osseous tissue depends on the recruitment of endogenous osteoprogenitor cells. Optimally, these tissue-engineered scaffolds have a porous structure that facilitates bony ingrowth; however, their lack of biologic activity can limit their use.

Biomaterials

Calcium Phosphate Ceramics

Calcium phosphate (CaP) ceramics are inorganic synthetic materials with no inherent osteoinductive or osteogenic

properties. Because of their osteoconductive behavior in vivo, they have been shown to induce a biologic response similar to that of bone and are therefore deemed bioactive materials. For example, when implanted into healthy bone, osteoid and, subsequently, new bone are produced directly onto the surface of the CaP ceramic without any soft tissue interface. Calcium phosphate ceramics are extremely strong in compression but are also brittle and possess poor tensile strengths. Calcium phosphate scaffolds should be tightly packed in rigidly stabilized bone in order to protect them from shear and tensile stresses as well as to optimize bone incorporation.[15]

Hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$, HA) is structurally similar to the apatite found in normal human bone and, along with beta tricalcium phosphate ($Ca_3(PO_4)_2$, β-TCP), is the most highly biocompatible and widely used calcium phosphate bioceramic. However, the behavior of HA and β-TCP after implantation is slightly different. The rate of biodegradation of β-TCP is much greater than that of HA. As β-TCP is resorbed, new bone formation fills the area once occupied by the β-TCP scaffold.[16] In contrast, biodegradation of HA is slow and although it may be osteointegrated, fragments may still be present in the bone several years after implantation. When β-TCP was implanted in a

canine metaphysis, no inflammatory response occurred and direct bone apposition was noted at 4 to 6 weeks.[17] Because of its biocompatibility and bioresorbability, β-TCP is used as a filling material in defects where autografts are indicated or as a bone expander supplementing autologous cancellous bone grafts. The biocompatibility of HA has also been demonstrated in vivo, where incorporation occurs without inducing an inflammatory or foreign body response.[18] By three weeks, the HA surface is lined with fibroblasts and osteoblasts with an interposition layer of mineralized osteoid laid down directly by osteoblasts.[16] The precise chemical composition of macroporous

CaP ceramics influences their osteointegration capability. Significant differences in the amount of new bone were observed depending on the ratio of HA to β-TCP in biphasic CaP (BCP) mixtures, where BCPs containing a higher volume of β-TCP induced better osteointegration when compared with pure HA ceramics.[19]

Calcium phosphate materials are osteoconductive but usually not osteoinductive. Under some conditions, however, CaP scaffolds may acquire osteoinductive properties owing to the binding of an optimum amount of endogenous bone morphogenetic protein (BMP) to the material.[13,20] This indirect osteoinductive property

depends on both the type of CaP ceramic with different phasic composition and porous structure and the species of animal in which it is implanted.[20] When a BCP scaffold was implanted intramuscularly and subcutaneously, obvious bone formation was detected in dogs and pigs, but no bone formation was observed in rabbits, goats, and rats.[20]

CaP Cement

Calcium phosphate materials may also be used as bone cement. In an injectable bone cement, including particles of a BCP (60/40 HA/β-TCP) incorporated in a methyl cellulose carrier gel, bone ingrowth proceeded

at a greater rate than in BCP blocks alone.[21] However, the major drawback of this system is the lack of significant initial mechanical properties, which imposes the requirement of an additional method of bone stabilization and leads to difficulty in maintaining the composite within the defect during surgery. To address these concerns, ceramic pastes may be used. This type of injectable CaP solidifies in situ after several minutes via a nonexothermic reaction to form a high compressive strength material. In the metaphysis of long bone in dogs, a cement composed of a monocalcium phosphate monohydrate, β-TCP and $CaCO_3$, was both osteoconductive and biocompatible. At 2 weeks, extensive

apposition of woven bone and unmineralized osteoid had occurred on the cement, without interposition of fibrous tissue between bone and cement.[22] However, only a small proportion of the volume of this cement was resorbed and replaced by bone during the first 16 weeks. At 78 weeks, cement was not totally resorbed.[22]

The strength of macroporous CaP ceramics having interconnected porosity may be improved by filling the pores with a CaP cement. Using a highly soluble, self-setting calcium phosphate cement made of β-TCP and dicalcium phosphate dihydrate, it has been demonstrated that all the cement

is replaced by bone after 4 months. Filling the macroporous ceramic pores with the CaP cement significantly improved the mechanical strength of these ceramics without modifying their integration in the healing bone or its biocompatibility.[23]

Coralline Hydroxyapatite

Coralline hydroxyapatite is a natural material derived from sea coral. Certain sea coral species produce a CaP porous structure that is close to normal human bone structure. Coralline substitutes may be natural, e.g., directly harvested from the sea or manufactured by conversion from natural coral. It is processed by a

hydrothermal chemical exchange method that converts the coral calcium carbonate to a crystalline material. Goniopora and Porites species of sea coral may be used as biomaterials. Coralline HA-Goniopora has larger macropores, measuring 600 μm in diameter as well as 260-μm intercommunicating pores, a structure close to typical cancellous bone. In contrast, with smaller 230-μm macropores and 190-μm intercommunicating pores, the structure of coralline HA-Porites is similar to that of cortical bone.[24]

Coralline HA has a completely continuous three-dimensional pore structure with a high degree of

uniformity in both macro- and micropore size. Coralline HA exhibits many of the criteria for a functional bone graft substitute: it is readily available, is easily contoured, has an adequate compressive strength, and allows ingrowth of new bone. However, no evidence exists of rapid degradation.[16]

Bioactive Glasses

Bioactive glasses are materials consisting of calcium, phosphorus, and silicone dioxide. They possess osteointegrative and osteoconductive properties. Their mechanical strengths are significantly greater than porous CaP ceramics. However, when drilling

or shaping, they are susceptible to fracture and consequently are difficult to fix to the bone. Therefore, they are primarily used for filling bone cavities instead of as segmental bone replacements. Bioglasses have also found use as bone-graft expanders.[25]

Demineralized Bone Matrix

Demineralized bone matrix (DBM) is produced by acid extraction of the bone mineral phase. The preservation of the organic phase of the bone matrix confers DBM with some osteoconductive and osteoinductive properties. The osteoinductive capacity of DBM has been demonstrated by Urist.[26] Demineralized bone matrix has

poor biomechanical strength and can have variable osteoinductive capability depending on the processing steps, the sterilization method, and the final formulation.[27] To date, the true osteoinductive potential of DBM, in humans, has been challenged because ectopically implanted DBM is not capable of reliably inducing bone formation.

Bone formation that takes place directly on DBM may start during the inflammatory phase of healing, indicating early differentiation and osteoblast activity. During this early phase of healing, osteoprogenitor cells are recruited from the bone marrow, the endosteum, the periosteum, and/or

the vasculature.[28] This osteoinductive ability of DBM may be attributed to the presence of BMP 2 and BMP 7.[29] Growth factors such as insulin-like growth factors-1 (IGF-1) and transforming growth factor-beta 1 (TGF-β 1) have also been found in DBM.[30] Early new bone formation is also related to the osteoconductive capacity of DBM that allows osteoblast precursors to adhere to a collagen matrix similar to endogenous cortical bone matrix. Indeed, the surface of DBM looks like the surface of the injured bone, which is the site of bone deposition during healing.[28] A final advantage of DBM is its rapid resorption rate.

Polymer Composites

Polymer composites with CaP ceramics (HA and β-TCP), particularly polylactic (PLA) and/or polyglycolic acid (PGA), have been investigated. Generally, these composites are used as delivery vehicles or carriers for growth factors.

Porosity

Scaffolds for osteogenesis should mimic bone morphology, structure, and function in order to optimize integration into surrounding tissue. Pores are necessary for bone tissue formation because they allow migration and proliferation of osteoblasts and other mesenchymal cells, as well as vascularization via

micropore channels. Some controversy exists in the literature over the optimum pore size for bone tissue engineering scaffolds. For coralline HA, scaffolds containing larger pores (~500 μm) have been associated with greater bone ingrowth than implants with smaller pore size (200 μm).[24] Similarly, when using macroporous biphasic CaP ceramics, it was shown that implants having larger, 565-μm sized pores, provided more abundant newly formed bone than those with smaller, 300-μm sized, pores.[30] Although pore sizes of approximately 100 μm are sufficient to allow cell migration into the implant, capillary invasion of the scaffold, which is essential to enhance new bone

formation, requires pore sizes of 300 μm or greater. Indeed, while smaller pores (90-120 μm) may induce hypoxic conditions leading to osteochondral formation before osteogenesis, larger pores (~350 μm) will promote a more effective neoangiogenesis, leading to direct osteogenesis.[31,32] Interestingly, in some studies, the morphology of bone-formation porous HA blocks with 300 to 400 μm pores resembled that of the Haversian system in bone remodeling. This pore size coincides with the average diameter in the Haversian system (approximately 300 μm), indicating that the optimal pore size for bioceramic scaffolds should closely mimic the pore size of normal bone.[31]

Implant-Host Interactions

Biointegration of a bioceramic scaffold implant depends on its mechanical stabilization. Micromotion favors the formation of fibrous tissue and precludes biointegration even if the implant is bioactive, like CaP ceramics.[33] For CaP bioceramics, a strong chemical similarity exists between HA and the bone mineral crystals. These materials have the capability to initiate nucleation and crystal growth of CaP at their surface from biologic fluids by a dissolution/precipitation process. Thus, a layer of nanocrystalline carbonated apatite associated with specific bone proteins is deposited onto the CaP ceramic and enables osteoblast

adhesion and activity.[33] This process is similar to bone remodeling. The neoformed layer would present a composition analogous to the cement line at the edge of an osteon.[33] Thus, the bond between implant and bone is strong and mechanical tests demonstrate that 4 weeks after implantation, fractures occurred within HA ceramic and not at the implant-bone interface.[34]

When a bioactive material is implanted, inside the connective tissue that has replaced the initial hematoma osteoblasts differentiate in close proximity to the biomaterial. Such osteoblasts are immobilized at the material surface as they would be at

the surface of bone trabeculae. Owing to the polar activity of these cells, the extracellular matrix is synthesized by the cell pole in contact with the material, leading to the deposition of an osteoid matrix at the material surface. Both the immature bone formed in contact with the material and the scaffold itself are subject to remodeling and are subsequently degraded by osteoclasts and giant cells. New bone gradually replaces the de novo bone material, leading to osteointegration.

Incorporation

At 24 weeks following implantation of small cylinders of several types of

ceramics into rabbit cortical bone, there was no degradation of coralline HA-Goniopora, 27% degradation of coralline HA-Porites, and 46% degradation of β-TCP. New bone occupied 56% of the coralline HA-Goniopora implant, 53% of coralline HA-Porites, and 45% of the β-TCP implant.[24] In large segmental diaphyseal defects, HA and β-TCP alone are not suitable as bone substitutes. In a 2.5-cm long segmental canine radial defect, use of these ceramics resulted in nonunions in many of the limbs 24 weeks postoperatively. In contrast, all the defects filled with autologous cancellous bone grafts achieved union.[35] This study clearly showed the

limits of the inherent osteoconductive or osteoinductive capability of CaP ceramics. Osteointegration leading to healing of the bone defect requires active participation of host cells and a favorable recipient site environment that provides osteoprogenitor cells and neovascularization of the implant. In epiphyseal or metaphyseal cavities of relative small volume, CaP ceramics alone may be integrated because (i) packing of the ceramic may induce mechanical stabilization of the material, and (ii) the neighboring cancellous bone is well vascularized and contains mesenchymal stem cells capable of osteoblastic differentiation. In large segmental diaphyseal defects, the behavior may be different because

(i) mechanical stabilization is difficult to obtain, and (ii) the recipient site is not capable of providing osteoprogenitor cells in a sufficient quantity to completely colonize the implant. With porous scaffold materials, osteogenic cells do not differentiate homogeneously within the biomaterial. The thickness of the scaffold may be critical as it may impair revascularization at the center of the biomaterial and, therefore, limit cell survival. Moreover, the number of cells supplied by the granulation tissue may be inadequate in the central area of extensive defects because of the remoteness of source tissues.[36]

Cell-Based Approaches

Cell-based therapies entail transferring cells that have osteogenic potential directly to the repair site to facilitate synthesis of new bone, thereby reducing the reliance on local osteoprogenitors. These cell-based strategies rely on the implantation of (i) fresh autologous bone marrow, (ii) purified, culture-expanded mesenchymal stem cells (MSCs), or (iii) differentiated osteoblasts. Mesenchymal stem cells and progenitor cells are present in almost all normal tissues. Stem cells are resting cells that can be activated by biochemical signals to divide and differentiate. This cell division

provides two daughter cells that are not identical: one daughter cell returns to the original resting state of the mother cell while the second daughter cell proliferates, producing an abundance of progenitor cells. These progenitors are subsequently triggered to differentiate to form a mature tissue.[37] A heterogeneous population of cells, including actual stem cells and progenitors derived from these cells, is present in bone marrow, periosteum, bone trabeculae (within Haversian canals of cortical bone), adipose tissue, and muscle.

Of all potential sources of progenitor cells, the most readily available is the bone marrow, which can be harvested

via percutaneous aspiration or as a small core of cancellous bone. Pluripotent progenitor cells may evolve according to several pathways such as cells from liver tissue, central nervous system tissue, or osteoblasts. The differentiation of these cells down one pathway depends on their biologic environment and is influenced by factors such as oxygen tension, nutrient concentration, neighboring cells, mechanical stimuli, and the chemical composition of the surrounding extracellular matrix.[37] In addition, the osteoblastic differentiation pathway is modulated by a broad range of inducible factors, such as IGF and members of the TGF-β superfamily, including BMP-2 and

BMP-7.[37]

When a cell-matrix composite graft is used, it is essential to ensure that the environment created by the matrix, i.e., surface texture, pore size and geometry, three-dimensional architecture, and degradation properties, is compatible with the survival of the cells.[37] It is also important to consider the biologic environment of the implanted bone substitute. The survival of implanted cells depends on the capacity for oxygen and other nutrients to diffuse into and out of the site through the implant. Bone marrow harvested by aspiration contains on average from 350 to 1000 progenitors cells per

milliliter.[38,39] Mesenchymal stem cells appear to be present at a frequency of approximately 1 in 10^5 to 10^6 nucleated marrow cells.[39,40] An increase in the volume of bone marrow aspirate from 1 to 4 ml decreases the concentration of progenitor cells by 50%. Thus, it has been suggested that, in humans, the maximum number of progenitor cells may be obtained in four 1-ml aliquots rather than in one 4-ml aliquot.[38] Aspirates of bone marrow may be mixed with carriers, such as CaP ceramics or DBM, and this composite graft packed into bone defects. Use of the composite bone marrow-DBM in canine nonunions has been shown to induce healing at a rate at least equal, if not superior, to that

obtained using standard autologous bone grafting techniques.[41] The addition of bone marrow aspirate to HA or β-TCP dramatically improved the outcome of these scaffold implants in the treatment of experimentally induced segmental radial defect in dogs.[35] The biomechanical and radiographic parameters of β-TCP with bone marrow were roughly comparable to those of cancellous bone autografts at 12 and 24 weeks. At 12 weeks, 94% of defects filled with CaP augmented with bone marrow achieved union, whereas nonunion was observed in 90% of defects filled with CaP alone.[35] It has been estimated that the number of osteoprogenitors provided by bone marrow aspirates is

only 20% of what would be needed to permit colonization of the entire implant by new bone;[37] however, it is possible to improve the efficacy of aspirated bone marrow by concentrating the marrow-derived cells.

Centrifugal density separation yields an approximately 4-fold concentration of marrow-derived cells, which has been shown to significantly increase bone formation.[42] Mesenchymal cells can be isolated from bone marrow and expanded ex vivo without any apparent modification in phenotype or loss of function.[43] Using culture systems, ex vivo expansion produces a significant increase in the number of

MSCs that can be delivered back to the surgical site.[43] With a ceramic carrier, cultured MSCs promote faster and more extensive new bone formation than fresh bone marrow because of the 300-fold increase in the number of MSCs yielded by the culture expansion process.[44] In a critical-sized canine ulnar defect stabilized by internal fixation, porous HA beads loaded with cultured cells from cancellous bone cores were implanted. Invasion by bone tissue was found in the stromal cell-bearing implants but not in control implants containing only HA granules.[36,45] Similarly, when BCP cylinders augmented with cultured mesenchymal stem cells from bone marrow aspirates were implanted in a

critical-sized (21 mm) canine femoral defect stabilized by internal fixation, bone healing was achieved in 12 to 16 weeks. In contrast, no substantial bone regeneration occurred over the 16 week period when ceramic cylinders alone were implanted.[44] Under appropriate culture conditions, these MSCs may differentiate into osteoprogenitor cells and grow as a monolayer culture. Next, the matrix may be loaded with these cells and implanted, constituting a hybrid bone substitute. Marrow cells grown in primary culture for 10 days and transferred to porous coralline HA for a 2-week culture have shown an enhanced rate and extent of bone formation when compared with

samples implanted with undifferentiated marrow cells.[46]

Factor-Based Approaches

Factor-based therapies represent an attempt to overcome the limitation of ceramic scaffold implants used alone by directly providing osteoinductive stimuli. Growth and differentiation factors are carried by the implant that is inserted into the bone defect.

Growth factors and Bone Morphogenetic Proteins (BMPs)

Fibroblast growth factors (FGFs) play a role in angiogenesis and mesenchymal

cell mitogenesis. Activity of both FGF-1 and FGF-2 has been identified during the early stages of fracture healing. Using basic FGF in tibia osteotomies in dogs accelerated all the stages of bone repair and stimulation of callus remodeling.[47] It is unclear what the therapeutic role of other growth factors such as insulin-like growth factor and platelet-derived growth factor play in fracture healing.[48] Among the growth factors that have been investigated, BMPs, which are members of the TGF-β superfamily, appear to have the most osteoinductive potential. Bone morphogenetic proteins initiate the bone healing cascade through the recruitment of mesenchymal cells from local bone and soft tissues and also

guide the differentiation of mesenchymal cells into osteoblasts. To date, more than 15 BMPs have been described, but only a few seem active in the bone healing process[49] (Figure 89-1). Two BMPs are produced by recombinant gene technology and are commercially available: BMP-2 and BMP-7 (also known as OP-1). In veterinary medicine, experimental studies in dogs and clinical trials in dogs and cats have been performed to assess the efficacy of BMPs in the treatment of bone defects,[50,51] fracture nonunions, and arthrodesis.[52]

The efficacy of BMPs was evaluated in the healing of a critical-sized radial defect (2.5 cm) in dogs. In one study,

the defect was filled with a cylinder of natural coral (calcium carbonate) alone or enhanced with bovine-derived bone protein and compared to autologous cancellous bone graft.[50] Coral alone did not allow bone union whereas coral implants enhanced with bone protein achieved rates of union, bone formation, and biomechanical strength that were superior during the first 12 weeks, and comparable at 24 weeks with those of autogenous cancellous bone graft. In subsequent study, the effectiveness of recombinant human BMP-2 (rhBMP-2), delivered in a collagen sponge, was evaluated in the same segmental defect model in dogs.[51] None of the defects that were treated with a collagen carrier alone

healed. From the day of surgery to 12 weeks postoperatively, the rhBMP-2 implants produced bone at a rate equivalent to cancellous bone autograft and were biomechanically comparable. However, defects treated with rhBMP-2 showed evidence of cyst-like bone voids, whose incidence appeared to be dose-related. The specific mechanism by which these voids developed was not determined, but it clearly appears that further research for the optimal dose of rhBMP-2 protein is needed prior to clinical applications. A nonglycosylated rhBM2/fibrin composite was applied in 41 sites in 38 dogs and cats requiring an arthrodesis or revision surgery for fracture

nonunions.[52] Bone healing was obtained in 90% of the treated cases with rhBMP-2. Although cancellous bone autografts are the gold standard for the treatment of these clinical conditions, the number of animals showing radiographic bridging in pancarpal arthrodesis was higher in the group treated with rhBMP-2 than in the group treated with autografts at 17 weeks (100% vs. 59%).[53,54] Similar results have been obtained in the experimental treatment of segmental defects in animal models.

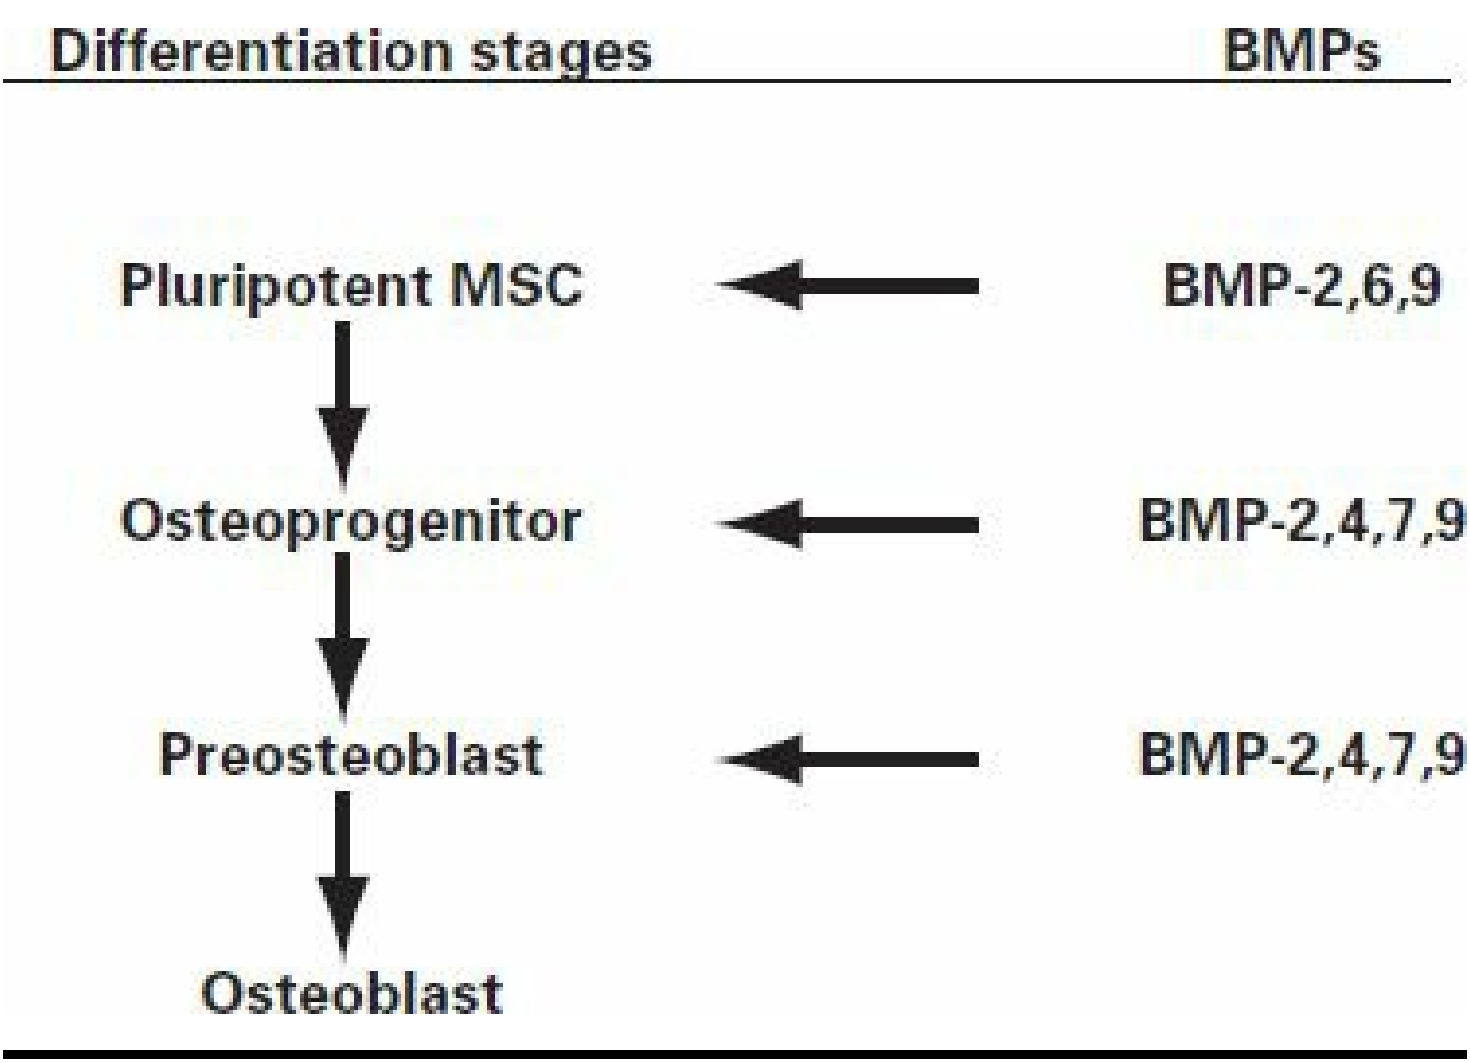

Figure 89-1. Main BMPs involved in the process of differentiation of Mesenchymal Stem Cells (MSC).

Gene Therapy

Gene therapy involves the transfer of genetic information to cells. When a gene is properly transferred to a target cell, the cell synthesizes the protein

encoded by the gene. In general, the duration of protein synthesis depends on the technique used to transfer the gene to the cell. Gene therapy can be applied either systemically or regionally. For bone healing, in normal patients, gene therapy can be used regionally. The gene can be introduced directly to an anatomic site with use of an in vivo technique, or it can be introduced via an ex vivo approach. In ex vivo gene delivery, cells are harvested from the patient, the cDNA is transferred to the cells in tissue culture and the genetically modified cells are then administered back to the patient.

Appropriate vectors must be used to

enhance the entry and expression of DNA into target cells. These vectors may be of viral or nonviral origin. Viruses are efficient vectors because DNA delivery is a critical aspect of their life cycle. However, several major concerns are related to the use of viral vectors. First, the possibility exists of recombination with other viruses in the host cell as well as replication and multiplication in the patient. Second, the duration of transgene product (protein) expression by the transduced cells may be limited owing to immune response to viral proteins.[48] Finally, the risk of malignant transformation following viral integration into the host genome is a serious concern.[55]

Gene therapy is considered as a tool in the treatment of bone defects because of the possibility of upregulating more biologic expression of individual proteins in specific tissues and cells. Although proteins used in bone tissue engineering can be manufactured, their life span is relatively short after being injected or surgically placed at the target site. Gene therapy provides the gene for the desired protein and then the transfected cells produce a biologically active protein in situ. This technique results in a higher and more constant level of protein production when compared with manufactured proteins. This is particularly important for proteins such as the BMPs.[56] One review reports the results of

experimental and clinical studies evaluating use of growth factors using gene therapy for enhancing fracture healing.[57] Although the production of the protein has a relatively short duration (e.g., up to 6 weeks) because of associated immunologic response to the vector used for transduction, this duration is satisfactory and useful to boost healing in the treatment of fractures or bone defects. In small animal models, growth factors delivered by gene therapy resulted in better healing than those delivered as recombinant proteins.[57] Experimental studies in large animals have yet to demonstrate the benefits, without any deleterious side effects, of gene therapy for fracture healing and filling

of bone defects.

Carriers for Delivering Growth Factors

Growth factors tend to rapidly diffuse away from the target site when administered alone. To limit this phenomenon and, therefore, to optimize their local osteoinductive potential, various carriers have been evaluated. The choice of the carrier or delivery system is essential to the success of growth-factor therapy. The ideal carrier should have several characteristics, including (i) the ability to deliver the growth factor at the appropriate time and at the proper dose, (ii) the ability to enhance cell

recruitment and attachment, (iii) the presence of structural voids to allow for cell migration and angiogenesis, and (iv) be biodegradable without inducing an immune or inflammatory response and without producing toxic byproducts.[48] Matrix requirements for BMP carriers vary from simple delivery systems, such as minipellets, beads, or microspheres, to complex three-dimensional structures with a macro- and microporosity that attempt to mimic the matrix of the repair tissue. Optimally, carriers should be resorbable. The four major categories of BMP carriers are natural polymers, inorganic materials, synthetic polymers, and composite materials.[58] Table 89-1 illustrates their main

properties.

The typical pharmacokinetic profile of BMP-2 release differs according to the delivery system. The initial burst delivery of BMP has a half-life of less than 10 minutes and appears to be carrier-independent. The secondary release of BMP is characterized by a half-life of 3 to 5 days with collagen carriers, whereas mineral-based delivery systems have a longer half-life, with BMP detected for up to 5 weeks.[58,59] In vitro and in vivo studies have shown the temporal sequence of BMP expression during membranous bone formation. Bone morphogenetic protein-6 appears first, followed by BMP-4 and later by BMP-2.

Considerable overlap exists in the time of expression, suggesting codependency of these factors. This sequential expression shows that the BMPs are not necessarily interchangeable and that it is possible that different BMPs can influence the expression of other BMPs as part of a cascade.[60] Moreover, co-administration of BMP-2/BMP-7 or BMP-2/BMP-6 have been shown to be 5 to 10 times more potent in inducing bone formation than BMP-2 alone.[27]

To date, the best strategy for bone repair using growth factors has not been determined. The optimal dose of proteins required to achieve bone repair in clinical studies is not clearly

established. The large variability in doses and experimental protocols among studies makes the determination of an optimal dose difficult. Moreover, the ideal delivery matrix for the appropriate factor has yet to be identified. There are three major obstacles to routinely using growth factors for bone repair: (i) the high costs of these growth factors, particularly BMPs, (ii) the selection of the optimal doses, and (iii) the optimization of the carrier matrix or delivery vehicle in order to allow vascular ingrowth, osteoprogenitor cell population, and invasion within the scaffold.

Table 89-1. Main Carrier Materials used for BMP Delivery

Categories	Carrier materials	Formulations	Advantages/*Disadvantages*
Natural polymers	Collagen	Gelatin	Biocompatible
		Demineralized bone matrix	Bioresorbable
		Fibrillar collagen	Sourcing
	Hyaluronan	Gels, sponges, pads	*Processing*
	Fibrin	Adhesive glue	*Disease transmission*
	Chitosan	Hydrogels, sponges, pads	*Immunogenicity*
Inorganic materials	CaP cement	Injectable, implantable, solid	Biocompatible
			Bioresorbable
			Osteoconductive
			Phase separation during injection
			Lack of macroporosity
			Lack of mechanical strength
	Sintered CaP ceramics	Granules, blocks	Biocompatible
			Osteoconductive
			Prolonged residence time
			Lack of mechanical strength
			Slowness of bioresorption
Synthetic polymers	Polylactide	Highly porous tridimensional scaffold	Design flexibility
	Polyglycolide Polylactide-co-glycolide	Linear oriented scaffold Fibers	Elimination of disease transmission
		Sheets	*Potential decrease of pH*
		Microspheres	*Bulk degradation*
			Excessive inflammation
Composites	CaP ceramics/natural polymers		Improvement of mechanical strength
	Natural/synthetic polymers		Improvement of release property
	Ceramic/natural polymers/synthetic polymers		Improvement of handling, porosity and providing injectability

Chapter 90

Salter Fractures

Dirsko von Pfeil
Charles E. DeCamp

In 1963 Salter and Harris described a system of categorizing fractures involving the growth plate in relationship to the epiphyseal plate, the epiphysis, and the metaphysis (Figure 90-1).[1] Today, these specific fractures involving the growth plate are commonly called “Salter Fractures.” Fractures of the growth plate may cause partial or complete arrest of

growth, which may result in the loss of bone length and/or subsequent development of angular limb deformities and gait abnormalities. It is imperative to understand the physiology of the growth plate and the possible consequences of trauma in order to properly assess the severity of damage, give an appropriate prognosis, and provide the correct treatment.

This chapter describes the basic anatomy of the growth plate, the relative contributions of the different growth plates to overall growth, the etiology and biomechanics of Salter fractures, and some diagnostic and prognostic guidelines.

Microscopic Anatomy

The growth plate consists of fibrous, cartilaginous, and bony components (Figure 90-1). The fibrous component surrounds the growth plate and is divided into an ossification groove, called the groove of Ranvier, and a perichondrial ring known as the ring of LaCroix. The groove of Ranvier contributes chondrocytes for growth in both the diameter and length of the growth plate.[2] The ring of LaCroix is located between the ossification groove and the periosteum of the metaphysis and provides mechanical support for the growth plate. A biomechanical study in rabbits suggested that this structure protects growth cartilage

from shear forces.[3]

The cartilaginous component of the growth plate is divided into reserve (or germinal), proliferative, and hypertrophic zones. The hypertrophic zone is further divided into the zones of maturation, degeneration, and provisional calcification (Figure 90-1). It is important to remember that damage to the reserve zone is associated with destruction of the germinal cells and, therefore, carries a high risk of resulting growth abnormalities. The hypertrophic zone is the weakest part of the growth plate and is most commonly involved in Salter fractures.[1]

Immediately adjacent to the cartilaginous component is the bony component of the growth plate. This is the portion of the metaphysis in which cartilage cells are transformed into bone. The major cell type of the growth plate is the chondrocyte. Cell matrix, consisting of 70% water and 30% collagen fibrils, proteoglycans, and other noncollagenous proteins, is found as well.[4] Collagen fibers provide tension and shear resistance to the cartilage. Proteoglycans and water give resistance to pressure.[5]

Vascular Supply

An intact vascular supply is necessary for cell proliferation and cartilage

resorption and calcification, which are all necessary for growth, and for healing of fractures. Injury that results in disruption of or changes in the vascular networks may cause abnormal growth or cessation of growth.[5] The arterial blood supply to the growth plate consists of branches of the vascular supply to the epiphysis and metaphysis (Figure 90-2). The multiple branches of the epiphyseal arteries arborize into the growth plate, providing vascularization to the first 4 to 10 cell columns of the proliferative zone. No vessels penetrate beyond the proliferative zone and, therefore, the hypertrophic zone is relatively avascular. Chondrocytes in the hypertrophic zone must use anaerobic

glycolysis to furnish energy. Perichondrial arteries supply the fibrous structures of the growth plate. The nutrient artery provides four fifths of the metaphyseal blood supply. Branches of the metaphyseal arteries supply the remainder. Terminal branches of these vessels end in small vascular loops or capillary tufts below the last intact row of chondrocytes of the growth plate.[6] Venous drainage of the metaphysis occurs via the large central vein of the diaphysis.[7]

In general, the blood supply to the growth plate does not enter through associated ligaments to the joint. However, it has been shown that in 28% of people, the femoral capital growth plate is supplied via branches of the artery of the ligament of the femoral head (epiphysis).[8] In contrast, no such blood supply is evident in the dog.[9]

Growth Plate Closure and Contribution of Different Growth Plates to Overall Growth

It is important to be aware of the closure times and the relative contribution of the different growth

plates to overall growth in order to better assess the risk for possible secondary problems after a Salter fracture. It is generally agreed that the rapid growth period of the dog is between 3 to 6 or 7 months of age.[10,11] Most dogs achieve 90 to 95% of their adult size by the end of 7 to 9 months.[11] Growth plates of giant breed dogs may not close until 15 to 18 months of age. Studies on bone growth have shown significant individual and breed variations in the time of growth plate closure. These studies also report that longitudinal growth may stop prior to radiographic evidence of growth plate closure.[10-12] Radiographic evidence of growth plate closure occurs between 4 months and 12 months of

age, depending on the specific anatomic site and breed of dog.[10-12] Table 90-1 shows a summary of the reported time frames of growth plate closure in the front and hind limbs of the average dog.[12,13] Growth plates that contribute a large percentage of the total axial growth of the long bones, such as the radius, ulna, and tibia, remain open longer compared with those of smaller bones, such as the carpal or tarsal bones. Cats have similar patterns of growth plate closure. Physeal closure begins at 4 months and is usually completed at 7 to 9 months of age. However, final closure of the distal radial physis in cats can occur as late as 20 months of age.[14] Studies in dogs have been

performed to evaluate the relative contribution of each epiphyseal plate to total growth.[15,16] Table 90-1 summarizes the results of these studies.

Whenever the function of the growth plate is severely impaired, anatomic deformity is likely to develop. Trauma, dietary, hormonal, and genetic etiologies are clinically important to growth deformity in the dog. The following paragraphs will focus on the effect of trauma to the growth plate.

Fractures of the Growth Plate

Prevalence

Growth plate fractures are the result of

trauma. Of dogs with fractures of long bones, 50 to 55% have been reported to be younger than 1 year of age.[17,18] Among the reported cases of long-bone fractures, 30% had trauma to the growth plate, and 7% subsequently developed growth deformities. In a study of 92 dogs with growth deformity as result of trauma, 75% showed a disturbance of the ulna or radius. The tibia had 4% and the femur 8% of the deformities reported.[19]

Biomechanics

Any material, including bone or a specific area of the bone such as the growth plate, can be exposed to disruptive forces such as tension,

compression, torsion, shear, and bending (see chapter 126). Depending on the amount of applied stress, bone may deform and return to normal configuration when the stress is reduced. This is known as elastic deformation. If the stress exceeds the elastic limit, the deformation persists. This is known as plastic deformation. When the point of failure is surpassed, the material breaks. The growth plate of immature animals is more prone to failure than either the ligamentous structures supporting the joint or the relatively elastic bone in these young animals.[20] Therefore, it is common to see growth plate injury without distortion of the joint or fracture of the bone. Although Salter and Harris

applied shear stress in their original experiments, Salter fractures can also be caused by bending, torsion, tension, or compression.[1,5,18,21]

Classification Systems

Salter-Harris Classification

Salter and Harris described a classification for fractures involving the growth plate, mostly intended for use in human patients, which categorizes fractures in relation to the epiphyseal plate, the epiphysis, and the metaphysis (Figure 90-1).[1] This same report explains results of an experimental study in rodents, demonstrating that fractures commonly developed through the zone

of hypertrophy, which is mechanically the weakest zone of the growth plate. Salter and Harris also investigated healing of the different fracture types and suggested that the higher the fracture grade, the worse the prognosis for normal growth. They also postulated that interference with blood supply to the epiphysis is associated with a poor prognosis. The Salter-Harris classification is also commonly used in veterinary medicine.

Table 90-1. Closure Times and Contribution of Growth of the Different Growth Plates in the Canine

Appendicular Skeleton

Forelimb				Hindlimb			
Growth Plate	Closure		Growth (%)	Growth Plate	Closure		Growth (%)
	Earliest	Latest			Earliest	Latest	
Scapular tuberosity	12w	5m		Greater trochanter	6m	11m	
Proximal humerus	10m	12m	80	Proximal femur	6m	12m	30-40
Distal humerus	5m	8m	20	Lesser trochanter	9m	12m	
Proximal ulna	5m	8m	0-15	Distal femur	6m	11m	60-70
Anconeal process	4m	5m		Proximal tibia	6m	12m	55
Distal ulna	6m	11m	85-100	Tibial tuberosity	11m	12m	
Proximal radius	5m	9m	25	Distal tibia	5m	11m	45
Distal radius	6m	11m	65	Medial malleolus	4m	5m	
Accessory carpal bone	10w	5m		Proximal fibula	6m	11m	60
Metacarpal bones	5m	7m		Distal fibula	5m	11m	40
Phalanges	4m	7m		Tuber calcaneous	11w	8m	
				Metatarsal bones	5m	8m	
				Phalanges	4m	8m	

w = weeks; m = months; % = percent.

Salter and Harris describe five types of fractures (Figure 90-1).[1,5,18,21,22] Type I represents complete epiphyseal separation through the zone of hypertrophy. The reserve zone (germinal layer of the growth plate) is usually intact.

In a type II injury, the fracture occurs

partially through the growth plate and partially through the metaphysis. Type I and type II Salter fractures represent 65.5% of growth plate fractures in small animals and, therefore, are the most common types seen.[22]

Type III is an intraarticular epiphyseal fracture. The fracture line is not limited to the hypertrophic zone but also includes a small area of the reserve zone. Salter Type IV fractures are also intraarticular, but the fracture line extends into the metaphysis, thus completely crossing the growth plate. Type III and IV fractures often represent condylar fractures and occur most commonly in the distal humerus.[22] Salter types III and IV

represent 25.5% of all growth plate fractures in the dog.[22]

Type V Salter fractures are characterized by partial or complete compression of the growth plate. This crushing injury is uncommon. It is difficult to diagnose on the basis of radiographs. It may help to compare the width of the growth plate with the contralateral side, and to repeat the radiographic study at 2-week intervals to better assess damage.

Some investigators have suggested adding a type VI fracture to the traditional Salter-Harris classification system.[21,23,24] A type VI fracture involves the peripheral region of the

growth plate, the zone of Ranvier. More commonly, it results from a localized contusion or avulsion of that specific portion of the growth mechanism. Peripheral osseous bridge formation commonly occurs, leading to peripherally localized epiphysiodesis and subsequent angular deformity.[21,24,24]

Ogden Classification

The classification proposed by the human surgeon John Ogden is one concerned with injury to the growth mechanism rather than only physeal or epiphyseal injury. It is a more detailed scheme that permits further understanding of the injury to the

growth mechanism as a whole. Ogden subdivided the Salter and Harris classification in order to better predict a prognosis for growth disturbances.[24] Salter type I lesions are divided into three subtypes (1A-C), type II lesions into four subtypes (2A-D), and type III lesions into three subtypes (3A-C), type IV lesions into four subtypes (4A-D). The subdivisions are made according to the injured zones and specific fracture pattern of the growth plate (Figure 90-3). For example, in contrast with type 1A where the fracture is primarily through the zone of hypertrophic cartilage, type 1B fractures occur through the zone of degenerating cartilage and primary spongiosa, whereas type 1C fractures are

associated with injury to the germinal portion of the physis. Subdivisions for type two to four injuries are according to the size and amount of fragments, and specific location of the fracture. Ogden also introduced new lesions (types VI – IX), describing injury of the ossified or nonossified epiphyseal nucleus, the fibrous structures of the growth plate, and multiple fractures of the epiphysis. In people, this classification system has been shown to provide a better prognosis for injuries of the growth plates, compared with the Salter-Harris system.[25-27] While further description of this system is beyond the scope of this chapter, this grading scheme may help to predict more accurately a prognosis for small

animals with growth plate injuries.[24]

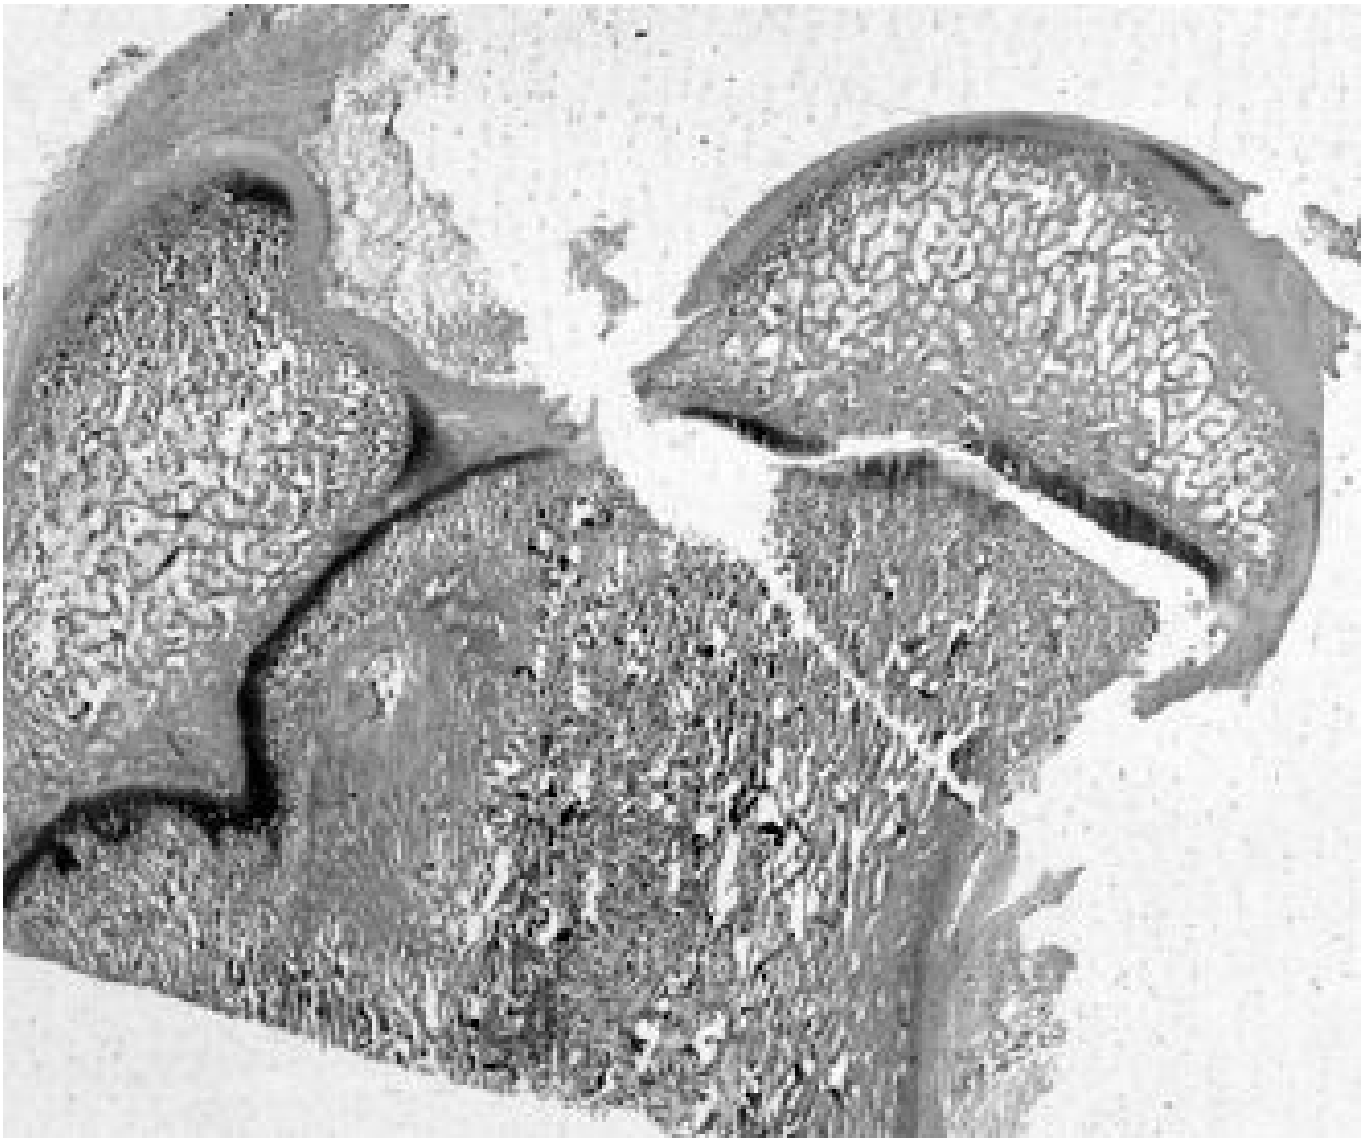

Figure 90-3. (Courtesy: Dr. Ann L. Johnson, University of Illinois). Fracture of the proximal femoral physis, showing the fracture line going through the zones of reserve, proliferation, and hypertrophy. Destruction of cells in the reserve zone and the zone of proliferation increases the risk for a poor prognosis.

Classification Based on Blood Supply

Although the Salter-Harris classification is useful for a radiographic description of the growth plate fracture, this system does not consistently correlate with the clinical and histologic findings, nor does it predict the normality or abnormality of future growth.[28] An additional classification for fractures of the epiphyseal plate has been suggested in human medicine.[15] This system is based on the integrity of epiphyseal and metaphyseal blood circulation. Radiography is used to assess displacement of the fracture fragments, and scintigraphy is used to assess the

degree of vascular damage. Type A fractures are described as having the circulation intact, with no displacement of the fragments. Type A fractures are not expected to have a negative effect on subsequent growth. In type B1 fractures, there is mild displacement of the fragments but some areas are still in direct bony contact. Type B2 fractures show more severe fragment displacement. In type B1 and type B2 fractures, epiphyseal and metaphyseal vessels intermingle through vertical fissures across the epiphyseal plate. In these fractures, bony bridges may form and lead to cessation of longitudinal growth. Type C fractures are described as having complete disruption of the epiphyseal

circulation. These fractures carry a poor prognosis for normal growth.[15,29]

Histologic Findings in Traumatic Growth Plate Injuries in Dogs

A study of the histologic appearance of traumatic canine physeal injuries that had been radiographically classified as Salter-Harris type I or type II fractures showed that in 10 of 13 cases, the fracture disrupted cells in the proliferative zone, rather than in the hypertrophic zone (Figure 90-4).[30] Destruction of cells in the proliferative zone may worsen the prognosis for continued growth, in contrast to the expected favorable outcome

established by the Salter-Harris classification. Other experimental studies showed that the fracture sites do not always occur at the level of the hypertrophic zone, as described by Salter and Harris, but can also involve other zones of the growth plate.[31,32] These differences may be explained by the fact that force impact occurred from only one side in the Salter and Harris experiments, whereas in vivo, combined forces may be acting, resulting in a variety of fracture patterns through the growth plate. As a result of these histologic findings, it can be suggested that the Salter-Harris classification of fractures, as described for humans and rodents, may not be fully comparable to clinical and

experimental evidence in dogs.

Vertical septa connecting the metaphysis and epiphysis at 6 days after trauma to the epiphyseal plate of a rat. These septa develop into bone bridges between the metaphysis and epiphysis, which can eventually lead to cessation of growth and the development of angular limb deformity.

Epiphyseal Bone Bridge

Formation

Physeal bone bridges connect epiphyseal and metaphyseal marrow compartments, and are thought to be responsible for cessation of localized growth and development of angular limb deformities attributed to asymmetrical restriction of longitudinal growth across the physeal plate.[32-36] Although fracture healing generally occurs without complication when the fracture is contained within the cartilage of the physis, cellular debris and the formation of vertical septa followed by physeal bone bridge formation are seen when the fracture extends to the physeal–epiphyseal border. Experimental studies found

that fractures may involve all regions of the growth plate.[32,37] In one study of 20 rats, the periosteum was elevated from the proximal tibiae.[37] A fracture through the growth plate was then created. The authors reported histologic evidence of vertical septa within the growth plate extending from the epiphysis to the metaphysis as early as 6 days after injury, (Figure 90-4), which were followed by the formation of bony bridges across the physis by days 10 and 21 in 65% and 75% of the rats, respectively. The presence of bone bridges after trauma to the epiphyseal plate has previously been described; however, it was not known that physeal bone bridge formation starts to occur so soon after

injury.[32-36]

Diagnosis

Most types of Salter fractures can easily be diagnosed using radiography;[38] although sometimes it is difficult to determine the amount of damage, especially with Salter-Harris type V fractures. Whenever trauma to the growth plate is suspected, serial radiographs are recommended at 1- or 2-week intervals to detect abnormalities in growth. Magnetic resonance imaging (MRI) has been shown to be superior to plain radiographs and computed tomography as a means of diagnosing injuries to the growth plate.[39-41] MRI

provides accurate mapping of physeal bone bridges and associated growth abnormalities that may have already developed.[39] It has been shown that an excellent correlation exists between MRI and histologic findings.[42] Knowledge obtained from MRI studies provides an accurate diagnosis that may change the initial treatment plan. Scintigraphy provides early and accurate evidence of disturbance of epiphyseal blood flow, which, in turn, may cause growth plate injury.[29] As described above, scintigraphy may be a useful alternative means for the classification of growth plate injuries.

Prognosis

About 5 to 17% of all growth plate injuries in dogs are reported to have clinically significant sequelae.[18,19,36,43] The sequelae in altered growth following growth plate fracture depend on many factors, including which physis is injured; the type and severity of injury, including displacement; the stage of physeal maturation (i.e., the age of the animal) at the time of injury; the promptness of proper diagnosis; and the method of treatment. In general, the younger the animal, especially those younger than 6 months of age, the more serious the consequences to longitudinal bone growth.[43] The degree of retardation in bone growth following physeal injury is roughly proportional to the degree

of destruction to the region or zone of the epiphyseal plate.[36]

Clinical lameness as a sequala to growth plate injury occurs only if the length discrepancy between legs is more than 2 centimeters in animals under 20 kilograms or more than 3 centimeters in animals over 20 kilograms.[44]

Although the Salter-Harris classification system provides a good description of epiphyseal fractures, the prognosis should always be guarded. Although the majority of patients with types I and II fractures have an excellent prognosis for normal growth, radiographically undetectable physeal

damage may exist that can only be diagnosed retrospectively. Damage to the epiphyseal vessels and to the fibrous component of the physis may occur in both Salter fracture types I and II, but when early reduction and fixation are possible, uncomplicated healing is expected within 3 to 4 weeks. The prognosis for type III fractures may be good if early reduction and good reconstruction of the joint surface are achieved, and if the epiphyseal blood supply is not severely disrupted. In contrast, more severe trauma carries a guarded prognosis because malalignment and arthritis may develop. Damage to the germinal layer, the joint cartilage, and to the vascular supply in type IV

fractures is common, therefore, the prognosis is guarded. Type V fractures are always associated with a poor prognosis if they happen during a period of rapid growth, because of destruction of the cells in the germinal layer.[45] Partial or complete premature closure of the growth plate and the development of bone deformities are frequently observed.

In a study of distal femoral Salter I or II injuries in 17 dogs, 82.4% showed some degree of femoral growth disturbance, and the mean extent of decreased growth was 6.7%.[43] However, clinical lameness was observed in only 3 dogs evaluated.[43] The authors suggested that

compression, injury to the blood supply of the germinal layer, and fissuring through the growth plate with secondary formation of bone bridges may have possibly contributed to the high incidence of decreased femoral growth. The results of this study showed that prognosis for normal growth cannot be based solely on the Salter-Harris classification system.

It has been shown that the initial displacement, number of reduction attempts, and treatment method did not significantly affect the incidence of premature closure of the growth plate in people.[46] However, it has also been shown that improved anatomic reduction decreases the incidence of

premature physeal closure.[46] For example, evidence of a residual gap following reduction is associated with a 66% incidence of premature closure, whereas with no gap the incidence decreases to 17%.[46] Residual gaps may be due to entrapment of periosteum; therefore, open reduction to remove entrapped periosteum and thus prevent development of length discrepancies or angular limb deformation has been suggested.[46,47]

As a general guideline, patients with injuries to the growth plates should be reevaluated at 2-week intervals for least for 6 to 8 weeks following treatment or until complete closure of the growth plates occurs. This will

ensure early detection and correction of abnormalities.[5]

Summary

Salter fractures involve the growth plate and may result in cessation of bone growth or development of angular limb deformities. This may lead to impaired joint function and abnormal gait. Salter and Harris developed a classification system based on radiographic appearance in order to better describe growth-plate fractures and better predict a prognosis. This radiographic description of growth-plate fractures is well accepted in veterinary medicine. However, it has been shown that the

prognosis does not always correlate well with the Salter fracture type. Although it was believed in the past that the germinal layer and the zone of proliferation are not affected in types I or II Salter fractures, histologic studies have shown that injury to these zones can be found even in these “low grade” fracture types. Therefore, the initial prognosis for any Salter fracture should be guarded, and frequent reevaluation until healing and/or complete growth plate closure is recommended. Advanced imaging techniques such as MRI and scintigraphy may become useful diagnostic and prognostic tools for managing animals with Salter fractures.

Chapter 91

Nonunion, Delayed Union, and Malunion

Ross H. Palmer

Bone is unique in its tremendous ability for repair via regeneration rather than scarring. Indeed, fracture healing typically proceeds in an orderly fashion provided the necessary systemic factors and local environment are present.[1] In fact, bone healing often occurs without veterinary intervention, although the convalescent and long-term morbidity

may not be ideal. It is, thus, the veterinarian's role to determine when and how to intervene so that patient morbidity is minimal and functional outcome is maximized. Simplistically, the veterinarian must provide the fracture zone with biologic and mechanical environments that are conducive to the natural reparative process. Failure to provide either of these prerequisites predictably results in failure to achieve bone union and restore limb function.

Union

Bony union refers to a healed fracture. Although it sounds simple enough, considerable "gray area" exists as to

when union is achieved depending on the measurement tool being used. “Radiographic union” refers to a subjective assessment of radiographs where the evaluator is satisfied that adequate amounts of new reparative bone have been deposited to achieve bridging of the fracture. “Histologic union” and “mechanical union,” where the healed bone is indistinguishable from the bone prior to injury, may take many months to years. A clinician often refers to “clinical union” where he or she is convinced by the radiographs, an appropriate healing time period, and the patient’s use of the limb that functional healing has occurred.

Delayed Union

A delayed union is defined as slower than anticipated healing compared with similar fractures treated with similar methods in similar patients. This term is vague because numerous variables exist, including patient age, systemic health, degree of soft tissue injury, presence of concurrent injuries or disease, patient size, fracture configuration and location, treatment method, and surgeon expertise, that may all affect the healing rate.[2] When delayed union is diagnosed, the veterinarian must determine whether treatment intervention is indicated. This determination is based on serial evaluations of radiographic

appearance, patient comfort, and limb function. Delayed union is a diagnosis of a dynamic process that may either progress to complete union or culminate in nonunion. Because delayed union can be a transitional state between injury and nonunion, the distinction between delayed union and nonunion may be subtle in some instances.

Nonunion

Delayed union may culminate in nonunion. A nonunion fracture is one in which progression of healing has ceased and union is unlikely without further intervention.[2,3] Nonunions are classified as viable or nonviable based

on the biologic activity detected at the fracture site. This distinction directs subsequent treatment strategies.[2,3]

Terminology

Viable Nonunions

Viable nonunion (also called **reactive** or **vascular** or **biologically active** nonunions) are biologically active at the fracture site and have evidence of bone reaction and callus formation.[2-4] Because radiography is the traditional instrument used for assessment of fracture healing, viable nonunions are further subclassified based on the degree of radiographic callus present (Figure 91-1).

Hypertrophic nonunions, often called "elephant's foot nonunion" have an abundant amount of radiographic callus and are often caused by inadequate fracture stabilization in a highly vascularized region of a young animal. **Moderately hypertrophic nonunions** are characterized by lesser degrees of radiographic callus formation, often referred to as "horse hoof callus," and are often associated with fracture instability in a bone with less soft tissue attachment and/or in a more skeletally mature animal. **Oligotrophic nonunion**, although considered biologically active, produces little callus and can be difficult to distinguish from nonviable nonunion. Nuclear scintigraphy may

demonstrate biologic activity of the fracture zone where it is not evident on radiographs.[5,6] When scintigraphy is not readily available, it is clinically advisable to err toward classification as nonviable nonunion as these fractures are treated more comprehensively.

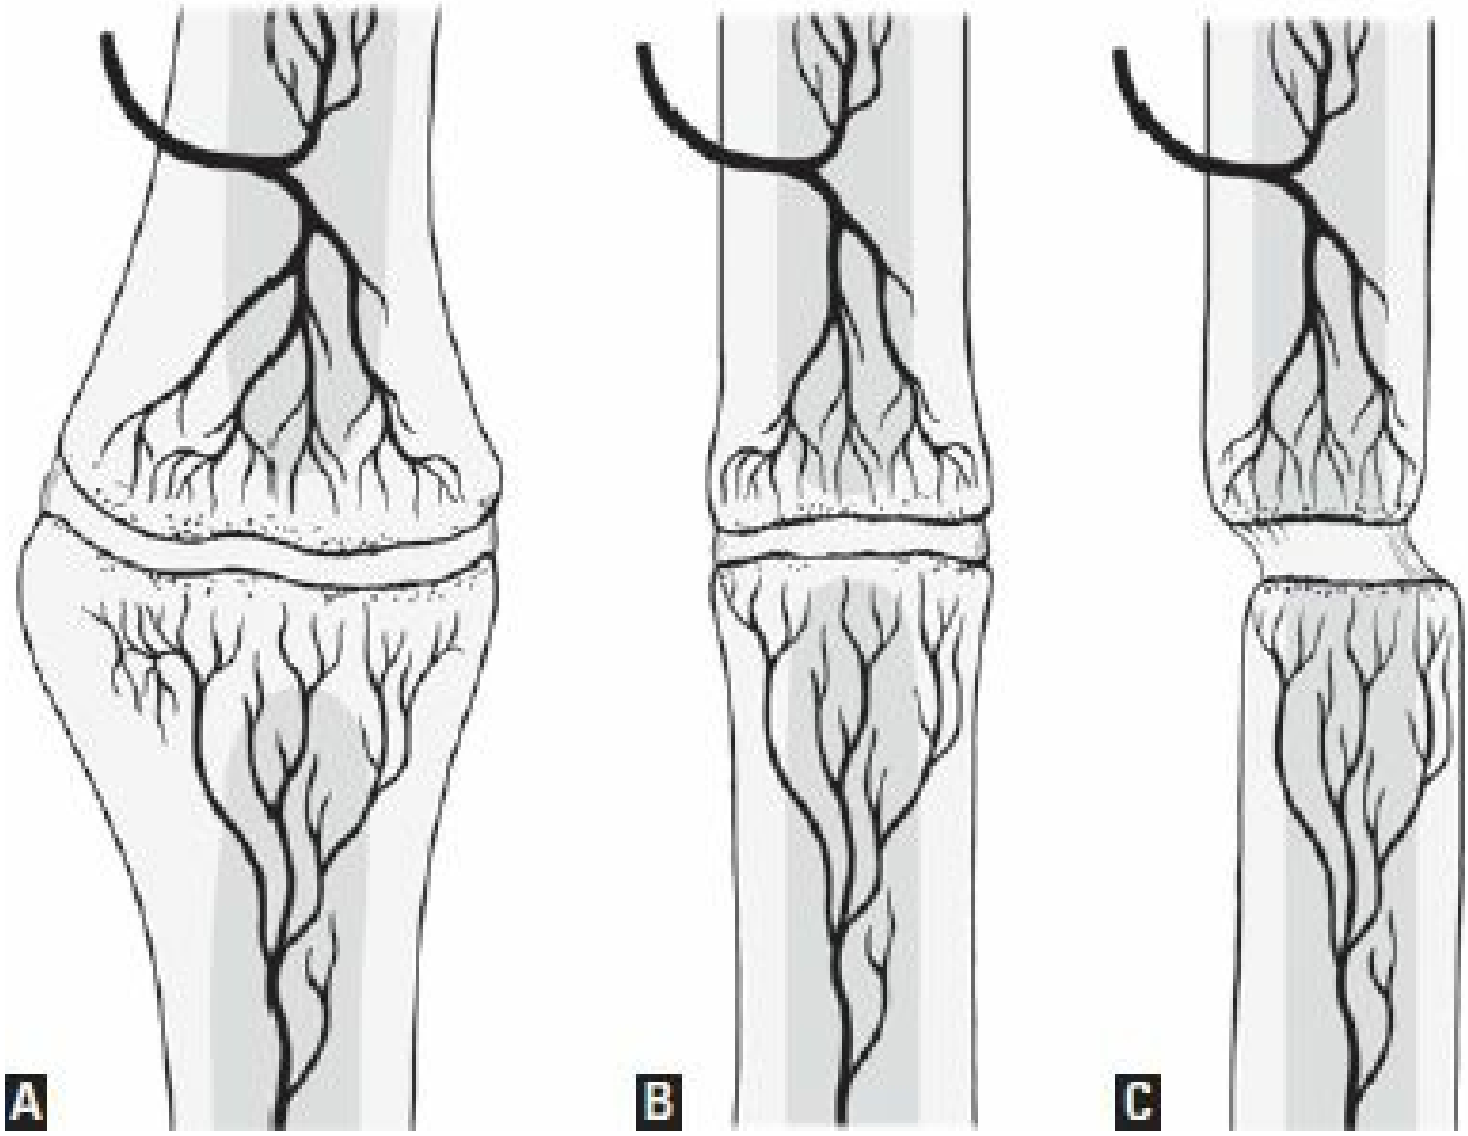

Figure 91-1. Types of viable nonunions. (A) Hypertrophic ("elephant's foot") have an abundant amount of radiographic callus; (B) Moderately hypertrophic ("horse-hoof") have a moderate amount of radiographic callus; and (C) Oligotrophic have minimal to no detectable radiographic callus (making them easy to confuse with nonviable nonunions).

Nonviable Nonunions

Nonviable nonunions (also called **biologically inactive** nonunions) have a severe interruption of blood supply and lack callus production and osteogenic potential. Nonviable nonunions are subdivided into four categories (Figure 91-2).[2,3] **Dystrophic nonunion** is nonunion in which the blood supply to an intermediate fragment is compromised. The fragment heals to one of the main fracture segments, but not to the other. The area of nonunion is biologically inactive as evidenced by a lack of callus, a persistent fracture gap, and rounded, sclerotic fracture ends. **Necrotic nonunions** have one or more

avascular bone fragments within the fracture zone. These avascular bone fragments, called *sequestra*, have no union with any surrounding bone and have sharp margins and sclerosis on radiographs. Necrotic nonunions in dogs and cats are nearly always the result of excessive elevation of soft tissues from a bone fragment combined with bacterial contamination and inadequate stabilization. Conversely, necrotic nonunion seldom occurs when closed or "open but do not touch" treatment strategies are employed to highly comminuted fractures. **Defect nonunions** occur when there is a large gap at the fracture site as a result of the original trauma or from bone fragment loss owing to sequestration,

resorption, or surgical removal. Regardless of the specific cause of the defect nonunion, a critically sized defect exists and callus cannot bridge the gap. **Atrophic nonunion** is the end result of the preceding types of nonviable nonunion. The bony defect is filled with scar tissue and the fractured bones are partially resorbed. Poor limb use leads to osteoporosis and muscle atrophy.

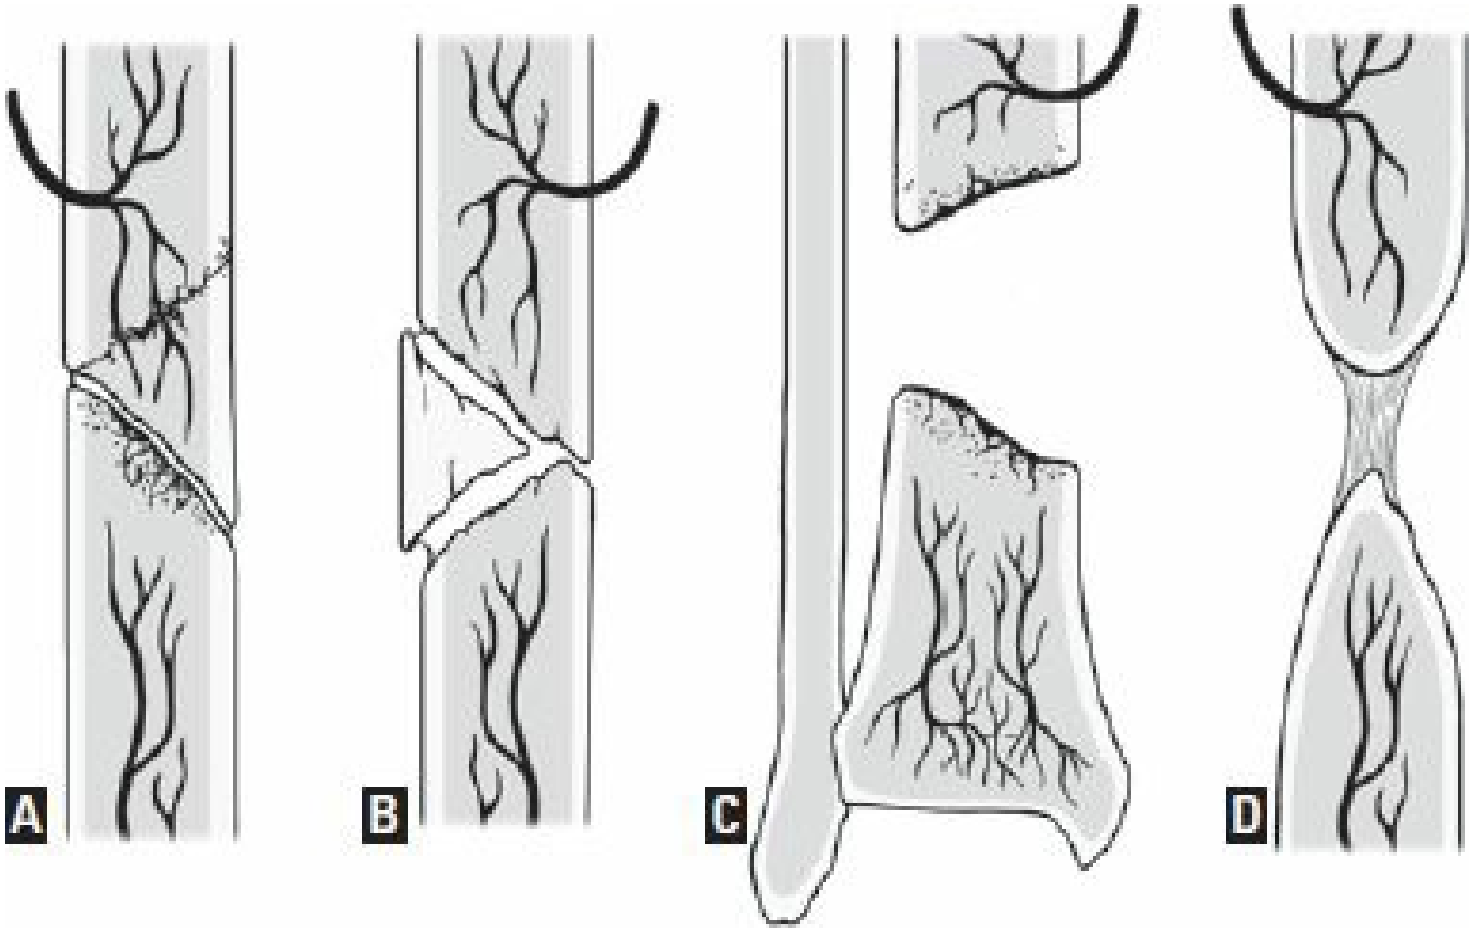

Figure 91-2. Types of nonviable nonunions. (A) Dystrophic nonunion has healing of an intermediate fragment to one of the main segments, but not the other; (B) Necrotic nonunions have one or more isolated, nonhealing, avascular bone fragments ("sequestra") that appear as radiodense fragments with sharp margins; (C) Defect nonunions have a large, nonhealing fracture gap; (D) Atrophic nonunions have defect filled with scar tissue and partial resorption of adjacent fractured bone ends.

A **pseudoarthrosis** may occur with

time as a result of motion at the site of the nonunion.[2,3] The clinical conditions are sclerosis of the bone ends, formation of fibrocartilage between the bone ends, and a fibrous capsule filled with serum. Periarticular fibrosis may cause stiffness of the adjacent joint such that much of the motion is concentrated in the pseudoarthrosis, especially if it is near a joint.

Etiology

A complex array of local and systemic factors is necessary to achieve predictable bone healing.[1,7,8] Systemic factors include the patient's nutritional state, hormonal balance, age, general health, and medications. Local factors

include the conditions within the fracture zone such as health of the soft tissues, size of the fracture gap, stability, contamination/infection, and foreign materials.

The local environment of the fracture zone must be suitably stable (mechanical environment) and viable (biologic environment) in order for bone healing to occur. Although many local and systemic factors may contribute to the development of nonunion, more often than not, an imbalance in the mechanical and/or biologic conditions of the fracture zone is the major contributor to nonunion.

Poor blood supply to the fracture zone

is a common contributing cause of delayed union or nonunion. Blood supply to healthy, intact diaphyseal long bone is primarily from centrifugal flow outward from the intramedullary space.[9] The outer one third of bone is supplied by periosteal vasculature arising from the soft tissues surrounding the bone. When a bone is fractured, the normal blood supply is disrupted and the initial vascular supply for bone healing comes almost entirely from the surrounding extraosseous tissues. Being a viscoelastic material, bone is stiffer and capable of absorbing larger amounts of energy prior to failure when it is more rapidly loaded.[10] Once the failure point is reached, however,

the bone fractures and releases this absorbed energy to the surrounding soft tissue envelope, disrupting the blood supply to the fracture zone. Such high energy absorbed to failure often produces a highly comminuted fracture pattern. A surgeon who attempts to anatomically reconstruct the highly comminuted fracture pattern often compounds the vascular compromise to the injured bone.[11] During the extensive manipulation of each fracture fragment, the soft-tissue envelope is further disrupted. If cerclage wire is used in these efforts, it must be used properly because improperly used wire typically loosens and cleaves off any developing extraosseous blood supply.[12] Because

even the most delicately performed open approach to the fracture zone induces some injury to the fracture zone's blood supply, the surgeon should contemplate the biologic impact of the treatment plan before starting surgery. Poor blood supply may also be inherent to the region of the fracture. Whereas the femur has a strong muscular attachment along its caudal margin at the linea aspera, the distal tibia has minimal surrounding muscular envelope. Indeed, fractures of the tibia accounted for approximately 60% of all appendicular nonunions in cats in one study.[13] Toy and miniature breeds of dogs have decreased vascular density at the distal diaphyseal-metaphyseal junction of the radius as

compared with large breeds of dogs.[14]

Fracture zone instability is another common contributing cause of delayed or nonunion in small animal patients. Strain is a measure of fracture zone motion. Osteoblastic cells have low strain tolerance, consequently direct bone union cannot progress in the presence of excessive fracture zone motion.[15] Callus and fibrocartilage are more strain tolerant and, logically, formation of these tissues is an intermediate step of callus bone healing. However, if formation of these tissues does not effectively reduce fracture gap strain down to tolerable levels, osteoblastic activity cannot occur and a nonunion develops.

Indeed, persistence of fibrocartilage in the fracture zone produces a typical histologic appearance of a nonunion.[16] It is important for the surgeon to understand the forces acting on a fracture and the ability of the selected fixation to constrain those forces. A relatively common nonunion scenario arises when a single large Steinmann pin is used to stabilize a transverse, slightly interdigitating, femoral diaphyseal fracture.[17] What appears to be adequate rotational stability intraoperatively is soon discovered to be inadequate as the patient's recovery continues. The torsional moments induced during weight-bearing and muscular contraction exceed the torsional stability provided by the

interdigitation of the fracture ends and the negligible frictional interaction of the smooth IM pin surface against the endosteal bone surface. The highly vascularized femoral diaphysis attempts to heal by developing exuberant periosteal callus, but is incapable of reducing strain levels down to a level conducive to osteoblastic activity. Predictably, a hypertrophic viable nonunion develops.

Conversely, fracture zone hyperstability may also contribute to nonunion.[2,3] Although the exact mechanical environment required for optimal bone healing is not known, axial micromotion appears to be

beneficial in stimulating bone healing.[18,19] The desired mechanical environment is apparently dynamic, with rigid stability desired early in healing followed by controlled axial micromotion in later stages. It may well be that hyper-rigid fixations may delay or halt healing in these later stages. Indeed, one study suggested that the use of oversized, rigid type II external skeletal fixation contributed to the development of nonunion in cats.[13]

Large fracture gaps, which may result from inadequate fracture reduction or bone loss owing to the original trauma, excision at surgery, or removal of a sequestrum, may contribute to the

development of nonunion. Recent emphasis in the treatment of highly comminuted fractures has been on the use of biologic strategies in order to maintain the viability of all bone fragments within the fracture zone.[11,20] These approaches certainly do not advocate surgical removal of vascularized bone fragments, and the development of sequestra appears rare when such strategies are employed in dogs and cats. However, one must be sure that, in the shift of emphasis away from anatomic reduction of these comminuted fractures, large fracture gaps do not remain. Surrounding soft tissues may become interposed within the fracture zone and impede callus formation. There is a species-specific

critical-size bone defect greater than which bone healing is not likely. Key's hypothesis states that a long-bone defect greater than 1.5 times the diaphyseal diameter exceeds the regenerative capacity of bone in skeletally mature dogs, thereby causing nonunion.[21,22] Indeed, a 21-mm long defect in the femur stabilized with a bone plate induced atrophic nonunion in dogs.[23] Key's hypothesis appears to overestimate the regenerative capacity of bone in the adult cat.[22] When large fracture gaps are unavoidable, appropriate autogenous or allogeneic bone grafting is indicated to prevent soft-tissue interposition and provide some biologic stimulus for healing within the gap.[8,11,24-29] Alternatively,

an osteotomy can be performed adjacent to the fracture gap, and bone transport combined with callus distraction used to fill the large fracture gap.[30-33]

Infection within the regional soft tissues or the bone itself is a relatively uncommon cause of delayed bone healing in dogs.[34] Nonetheless, appropriate aseptic surgical technique must be employed to minimize the incidence of surgical infection. Particular care should be given to the treatment of open fractures as they have a greater incidence of delayed and nonunion.[35] When adequately stabilized, bone can heal in the presence of infection, but healing may

be delayed by bone lysis and/or implant loosening.[2,36] Neovascularization of the fracture zone, critical for bone healing, may be impeded by the presence of infection.

In addition to the basic clinical prerequisites for predictable bone healing (fracture zone stability and viability), a complex cascade of events must take place. Local and systemic mediators stimulate the differentiation of precursor mesenchymal cells into new fibroblasts, chondroblasts, osteoclasts, and osteoblasts needed for neovascularization, soft callus, and bone formation.[1,4] One study found fewer committed mesenchymal stem cells in the early stages of

experimental nonunions and suggested that the differentiation of mesenchymal stem cells is inhibited in states of chronic nonunion.[37]

Although alterations in the local environment of the fracture zone are more frequently recognized contributors, systemic factors may also delay fracture healing. Hyperparathyroidism, whether primary or secondary to renal or nutritional causes, delays bone healing as a result of calcium and phosphorus imbalance. Hyperadrenocorticism, whether primary or iatrogenic, may alter calcium absorption and deposition enough to delay callus formation. Bone healing may be

delayed by administration of corticosteroids, some antineoplastic agents, and possibly some fluoroquinolones and NSAIDs.[38-44] Elderly patients exhibit delayed bone healing as compared with younger, especially skeletally immature, patients.

Diagnosis

Patient signalment and fracture location influence the likelihood of a delayed or nonunion. A study of 2825 fractures in dogs showed a 3.4% incidence of nonunion. The incidence of nonunion was highest in the radius/ulna (40.6%) and femur (38.5%), whereas the humerus (12.5%)

and tibia (4.2%) developed nonunion less commonly.[34] A study of 422 fractures in cats showed a 4.3% incidence of nonunions.[13] This fact highlights that, contrary to popular opinion, cats are every bit as prone to major complications of fracture healing as are dogs. Nonunion in cats was most common in fractures of the tibia/fibula (61.1%), radius/ulna (16.7%), and proximal ulna with intact radius (16.7%). Older cats, heavier cats, cats with open fractures, cats with comminuted fractures and cats with fractures stabilized with type II external skeletal fixation were more likely to develop nonunion.[13]

Although radiography is the principal

assessment tool for bone healing, one should not lose sight of the importance of physical examination and history taking when making patient assessments and therapeutic decisions. Instances often arise where the radiographic progression of healing is slow, but patient function and comfort are optimal. In such instances, surgical intervention may not be warranted, particularly if fracture healing is progressive, albeit slower than anticipated. Conversely, some patients exhibit lameness, muscle atrophy, pain on fracture-site palpation, stiffness, and even gross fracture instability. These findings are usually associated with some loss of the original fixation through implant migration, implant

breakage and/or ensuing fracture instability. Surgical site infection is usually associated with draining tracts originating from the fracture zone, swelling and pain on deep palpation of the fracture zone, or limb manipulation.

Radiographs made at 4- to 8-week intervals are commonly used to assess fracture healing, implant stability, and maintenance of bony apposition and alignment. Making a definitive diagnosis of delayed union is difficult. In delayed union, radiographs indicate progressive healing, but at a slower rate than initially expected. Radiographs may show early bone resorption of the fracture ends,

periosteal bone reaction, endosteal and periosteal callus formation, and finally, bridging callus. The radiographic diagnosis of nonunion is based on the lack of progressive fracture healing during a period of 3 or more months and the persistence of a fracture gap. The characteristic radiographic appearance of a nonunion is varied as previously described for each classification. Viable nonunions have variable amounts of callus, but no callus bridging of the fracture zone. Nonviable nonunions lack callus formation. The distinction between viable and nonviable nonunion is critical as this directs the therapy. The distinction between an oligotrophic, viable nonunion and a

nonviable nonunion can be particularly challenging. Alternative imaging modalities such as ultrasonography, nuclear scintigraphy, dual x-ray absorptiometry, computed tomography, and magnetic resonance imaging have each been used to assess fracture healing and may have roles in distinguishing viable from nonviable nonunions.[5,45-51] However, as with traditional radiography, each imaging modality has its limitations. Recent investigations have evaluated the predictive value of serum biomarkers in making an early diagnosis of nonunion.[52] In the absence of definitive distinction between viable and nonviable nonunions, clinicians should assume nonviability as this will

direct a more aggressive and comprehensive course of action.

Treatment

Identification and treatment of all factors contributing to nonunion are the keys to effective management. Treatment of nonunion typically consists of removal of all loose implants, anaerobic and aerobic bacterial culture (of the fracture zone and/or removed implants/sequestra), and application of a fixation capable of providing long-term stability to the fracture zone. Sequestra, if present, should be removed. Nonviable nonunions require additional specific interventions to stimulate the biologic

activity of the fracture zone. These traditionally include reestablishing the intramedullary canal of the main bone fragments, decortication/shingling of the regional main bone segments, and autogenous cancellous bone grafting.[2-4] One study described successful treatment of nonviable nonunions by limited en bloc ostectomy of the nonunion site and compression plate fixation.[53] In this report, autogenous cancellous bone grafting was only used if significant bony defect remained after ostectomy. Other modifications of the traditional treatment strategies for nonviable nonunions include use of demineralized bone matrix allografts, autogeneic and allogeneic mesenchymal stem cells, human

recombinant bone morphogenetic protein – 2 (rhBMP-2), other growth factors, autologous bone marrow injections, pulsed electromagnetic fields, low-intensity pulsed ultrasound, extracorporeal shock-wave therapy, and hyperbaric oxygen administration.[24,25,54-71]

Malunion

A malunion fracture is a fracture that has healed in a nonanatomic position. Some degree of malunion is present in most instances of closed-fracture stabilization. Malunion may also be present when biologic strategies for spatial alignment are employed for treatment of highly comminuted

fractures. Malunion can occur following anatomic reduction if implants fail prior to complete bone union. Mild degrees of malunion often are tolerated with no apparent short-term or long-term patient morbidity.

Terminology

Malunions are described by their displacement (Figure 91-3). **Overriding malunions** occur when the major bone segments have slid past one another, but normal axial and rotational alignment has been maintained. Minor overriding is usually well tolerated, especially in the pelvic limb, and surgical correction may not be warranted. One study

showed that dogs can adapt to 23.5% loss of femoral length without inducing significant patient disability.[72] **Angular malunions** occur when deviation from normal axial alignment is significant. Angular malunion may be in the mediolateral plane (varus or valgus deviation) or the craniocaudal plane (recurvatum or antecurvatum deviation) or any plane in between. Minor recurvatum or antecurvatum is relatively well tolerated, but minor varus or valgus deviation can cause significant locomotor disability. Femoral varus malunion may cause medial patellar luxation and valgus malunion may cause lateral patellar luxation. **Rotational malunions** occur when torsional malalignment is

present. Minor torsional malunion is often well tolerated, but excessive torsion can alter a patient's gait and place abnormal stresses on adjacent joints. Excessive femoral torsional malunion may cause patellar luxation or contribute to coxofemoral osteoarthritis.

Etiology

Gravitational, ground reaction forces and muscular pull on the bone segments determine the deviation that occurs with malunion formation. Collapse of the pelvic canal is relatively common when ilial body fractures are treated non-surgically or with insufficient internal fixation.[73-75]

External torsional deformity of the proximal femur is common when the pull of the external hip rotator muscles (iliopsoas, gemelli, internal obturator, and quadratus femoris muscles) is not neutralized by intramedullary pin fixation or the rotational displacement is not recognized at the time of fracture reduction and rigid stabilization.[17] After fracture healing, patients tend to hold the hip in a normal position such that the distal limb is internally rotated. Valgus and external torsional deviation of the distal limb is common when applying closed fixation to fractures of the antebrachium and crus.[76,77] Hanging limb positioning has been advocated for surgical fixation of diaphyseal

fractures of the radius/ulna and tibia/fibula. Using a large pointed reduction forcep anchored to the malleoli or talus seems to reduce the tendency for cranial angulation of the distal segment in tibial diaphyseal fractures.

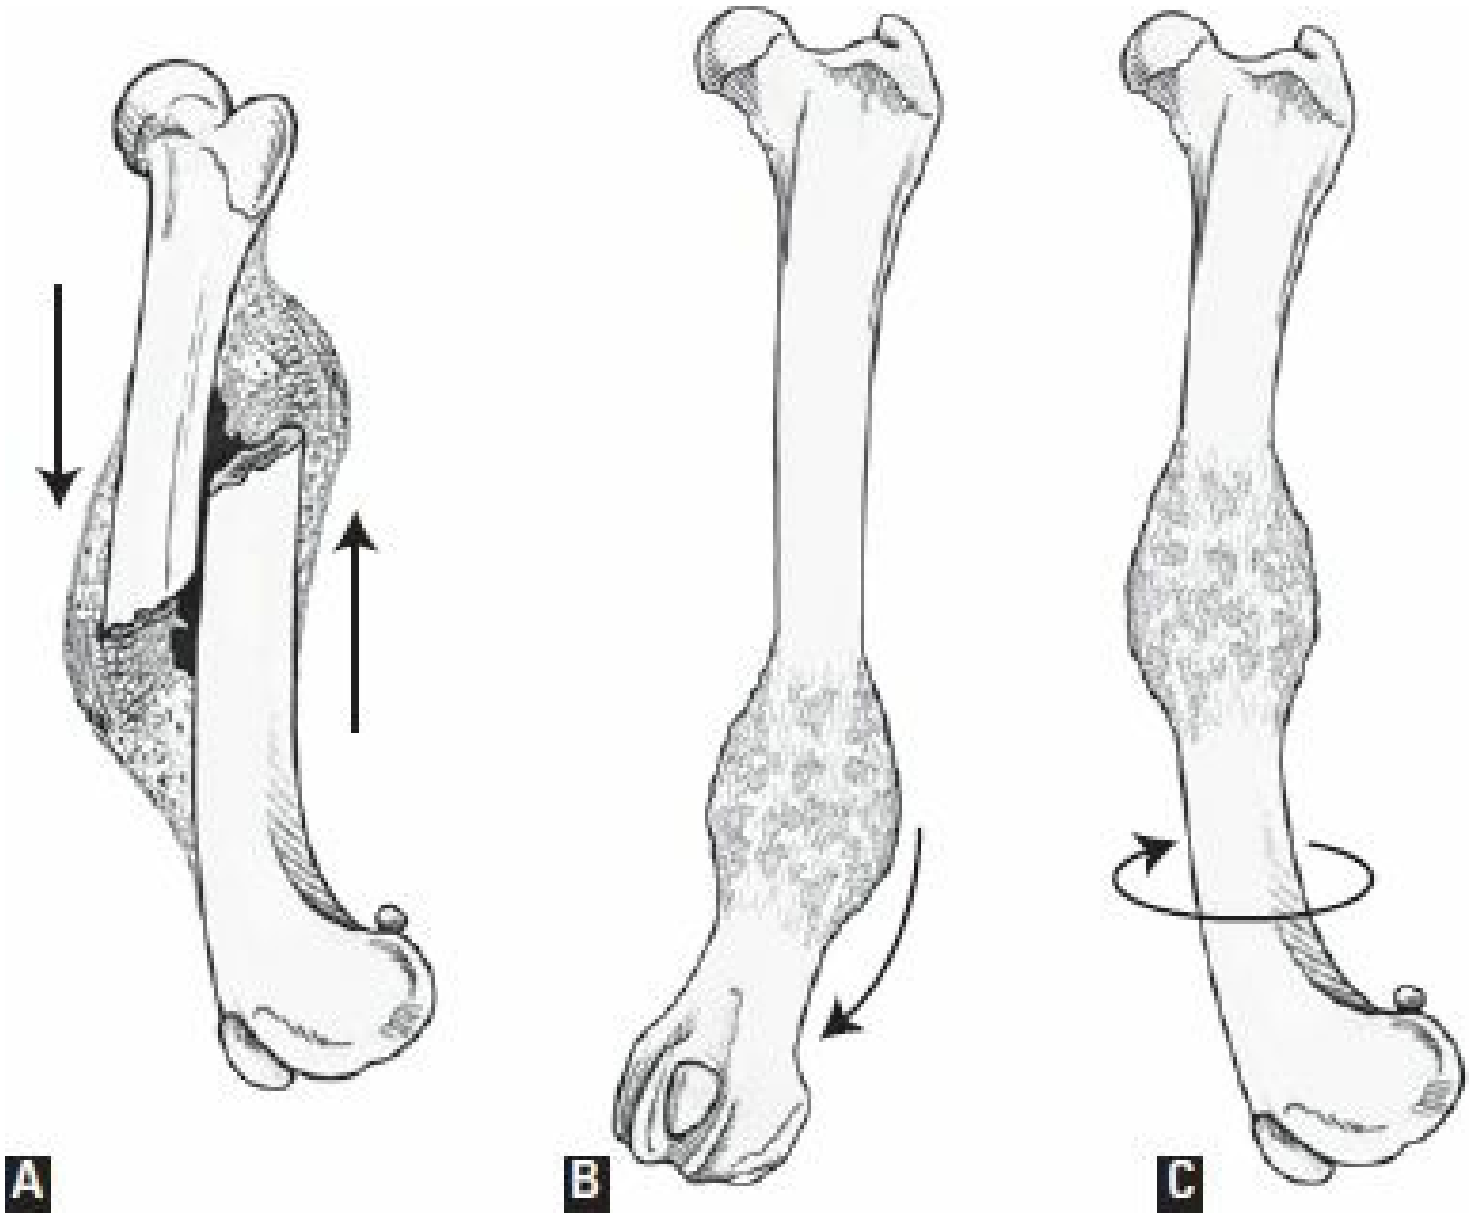

Figure 91-3. Malunions are described by their displacement. (A) Over-riding malunion; (B) Angular malunion; (C) Rotational malunion.

Diagnosis and Treatment Plannning

Careful gait observation, physical examination, and radiographic assessment are needed prior to surgical corrective osteotomy procedures. Mild alterations in limb position during radiography can induce artifactual limb alignment measurements on radiographs because radiographs reduce a three-dimensional structure to a two-dimensional image.[78,79] Placement of the affected bone parallel to and as close to the radiographic cassette as possible should reduce radiographic artifact.[78] Care should also be taken to place the limb in neutral rotation and include the joints proximal and distal to the affected bone. It is advisable to perform repeated radiographs with the limb

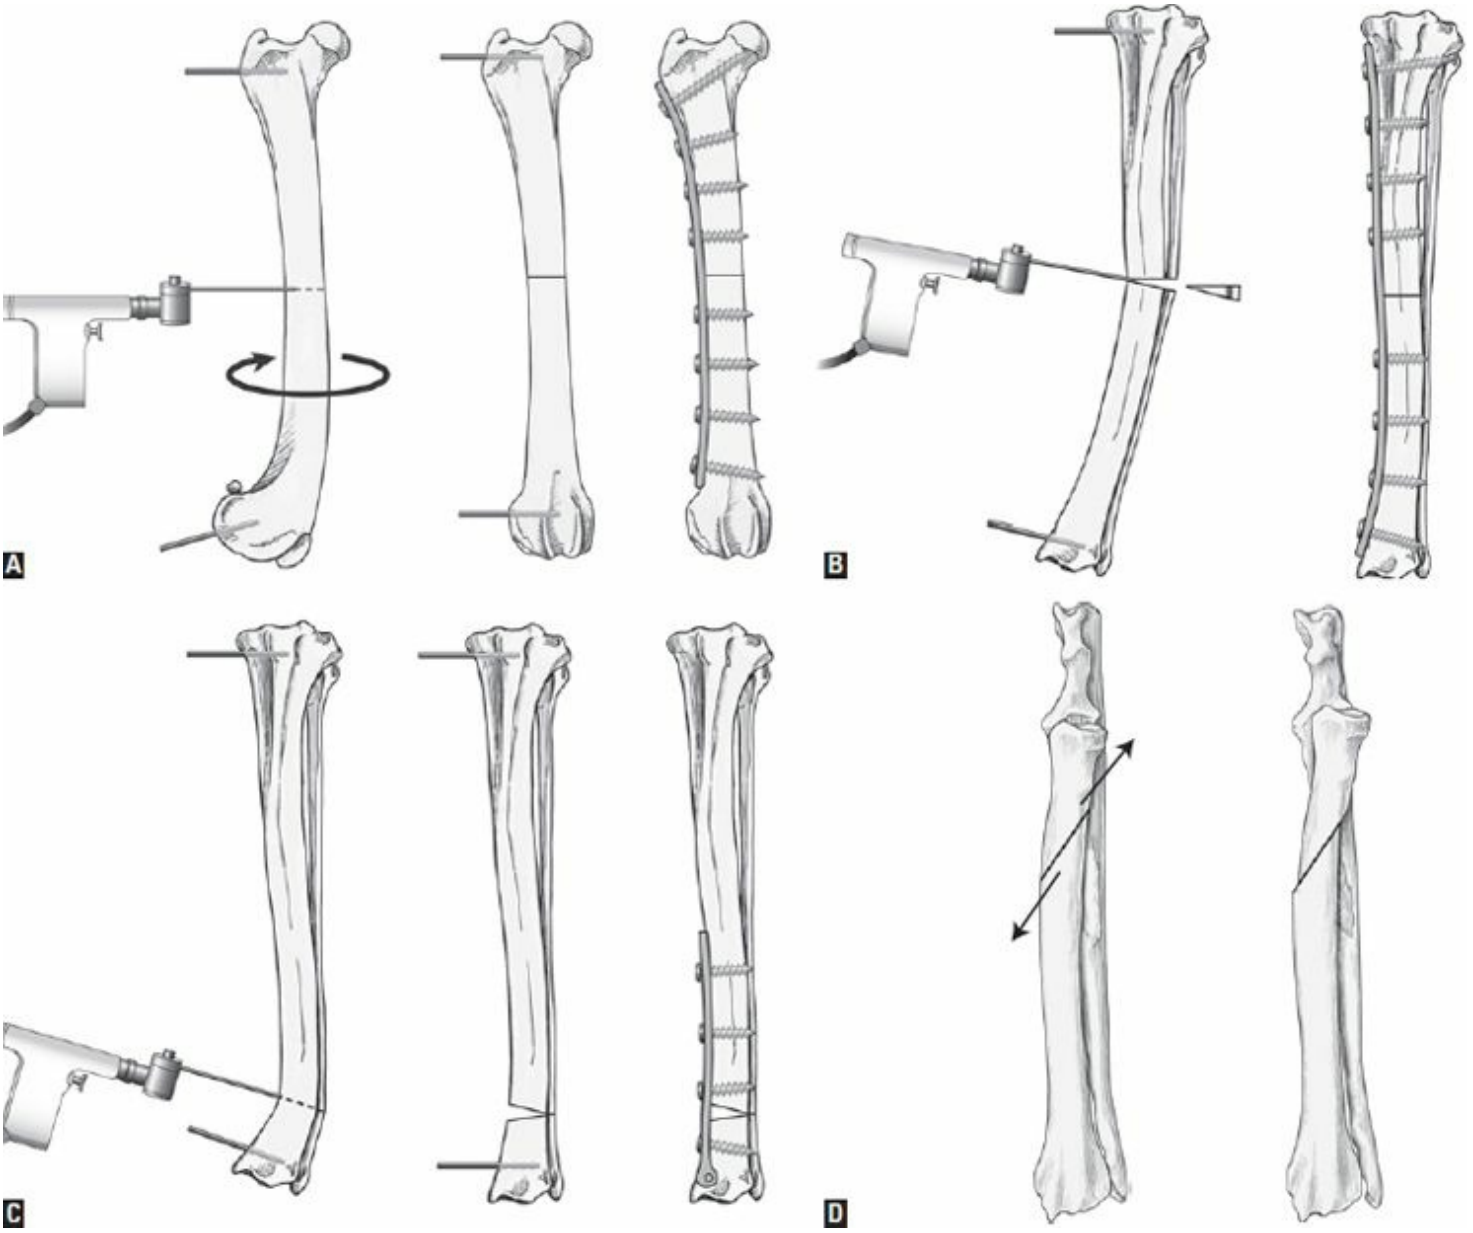
held in the proper position to be certain that malalignment measurements are repeatable. It is essential that the surgeon think three-dimensionally when studying the radiographs. Alternatively, computed tomography including three-dimensional reconstructions can be used.[79-82] In fact, three-dimensional models can be made commercially from these CT studies.[83]

Treatment

Surgery is indicated when the patient does not have acceptable function. The goals of surgical correction of malunion are to improve limb function by restoring more normal alignment

and length, thereby correcting abnormal stresses in adjacent joints. If only minor improvements in alignment, limb length, and most importantly, limb function are anticipated, then the morbidity, risks, and costs of the procedure may preclude surgical treatment. When surgical treatment for malunion is indicated, a corrective osteotomy is usually performed at the point of maximal deformity. Ideally, the osteotomy would allow maximal bony contact at the osteotomy and preserve or restore normal limb length and limb alignment. Different forms of osteotomies can be performed, each with their own advantages, disadvantages, and indications.

Commonly performed osteotomies include transverse, closing wedge, opening wedge, oblique, step, and dome osteotomies (Figure 91-4).



A
B
C
D

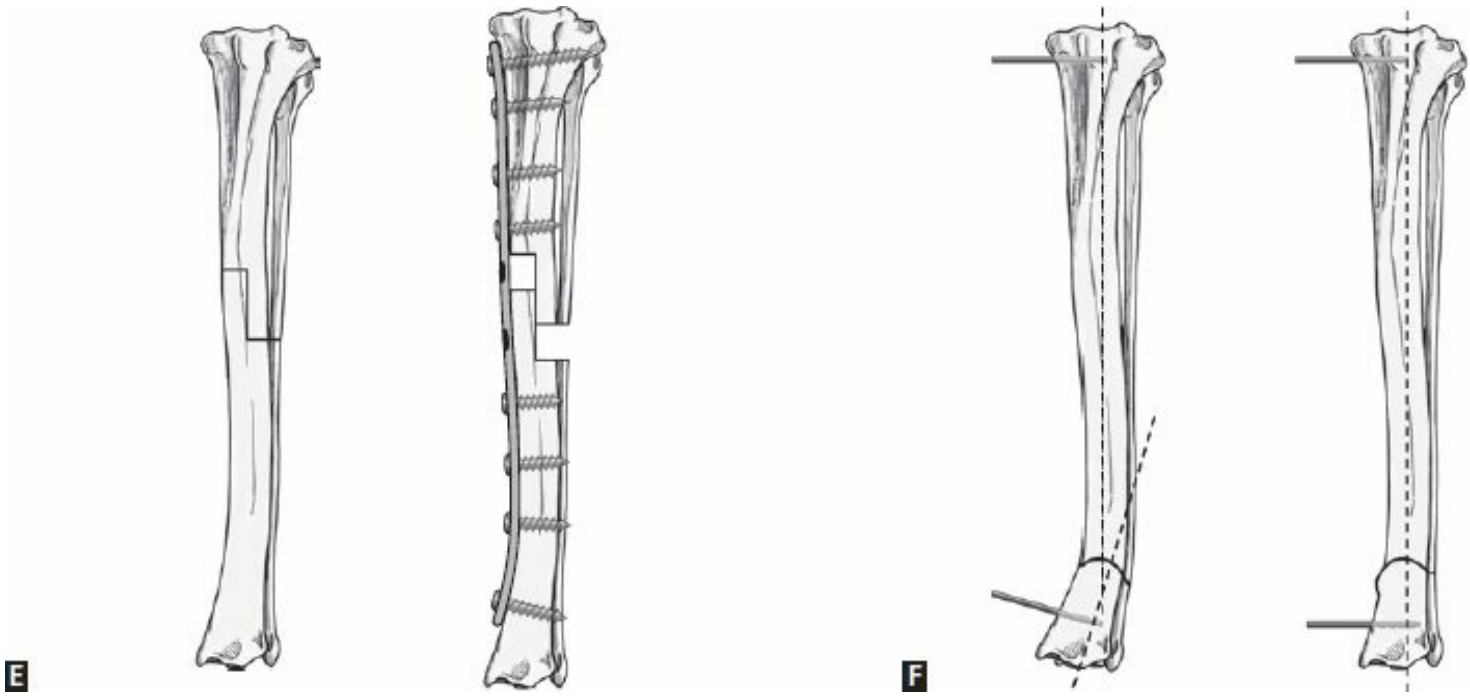


Figure 91-4. Corrective osteotomies. (A) Transverse; (B) Closing wedge; (C) Opening wedge; (D) Oblique; (E) Step; (F) Dome.

Transverse osteotomies are indicated for correction of simple torsional malunions. Closing and opening wedge osteotomies are used for correction of angular malunions. **Closing wedge osteotomies** maximize bony contact, but may result in some loss of limb length. **Opening wedge osteotomies** sacrifice bony contact at the osteotomy

in favor of increasing limb length. Sliding of **oblique osteotomies** can be used to correct translational deformity and to achieve some lengthening (or shortening) of the limb. **Step osteotomies** are relatively complex and are, on rare occasions, used to obtain acute limb lengthening. **Dome osteotomies** are used to correct angular deformity while maximizing bony contact and preserving limb length. Dome osteotomies have been described for correction of malunions of the femur, radius and ulna.[84,85] Conceptually, a three-dimensional dome osteotomy would function similar to a ball-in-socket joint and would easily allow for three-dimensional corrections in limb

alignment prior to application of the fixation. In reality, most dome osteotomies are made in two dimensions such that three-dimensional corrections sacrifice some bony contact at the osteotomy.

Osteotomies can be used for acute limb alignment correction with static fixation or for slow progressive limb alignment correction using dynamic fixation methods. Static fixation is most often obtained with external fixators, bone plates, or interlocking nails. External fixators offer several advantages for corrective osteotomies: (1) placement of the fixation pins parallel to the adjacent joints prior to osteotomy helps the surgeon visualize

when the joints are properly aligned; (2) complex contouring of a bone plate is not required; (3) fixation pins can be placed into a relatively small bone segment.[76,86,87] Locking screw/plate designs may simplify the use of bone plate stabilization of corrective osteotomies because the interlock between the screw head and the plate obviates the need for precise plate contouring.[88] Bone plates and interlocking nails can be of limited use when the osteotomy leaves a relatively small bone segment. On occasion, cross-pin fixation can be used in young dogs in osteotomies performed in the metaphyseal region. Rarely, coaptation has been used with dome osteotomies.[84]

If significant limb lengthening and angular correction are required, progressive callus distraction (callotasis) is indicated.[89-91] Often correction of angular malalignment can be performed acutely, but restoration of large discrepancies in limb length must be performed gradually. Callus distraction involves stabilizing an osteotomy with a specially designed external fixator that utilizes linear motors to induce distraction. Ring fixators with linear motors are commonly employed for such osteotomy distractions and provide the surgeon with several key advantages: (1) the rings placed around the limb allow the surgeon to correct complex three-dimensional

malalignment with relative ease; (2) corrections to alignment can be made after the fixation is applied; and (3) the use of small-diameter, tensioned fixation wires allows the system to be applied to small bone segments. After allowing a lag period for initial callus formation, the osteotomy is gradually distracted at a rate of approximately 1 mm per day. Once the desired limb length is achieved, daily distractions cease and the static fixation (1 month per cm distraction) allows regenerate bone in the osteotomy gap to consolidate.

Chapter 92

Septic Arthritis

Loretta J. Bubenik

Septic arthritis refers to an active joint infection, usually bacterial in origin. It is not common in companion animals, but when it occurs, it can be devastating for the joint. Treatment and outcome depend on the source, organism involved, and duration of infection.

Etiology

Septic arthritis occurs from exogenous inoculation or hematogenous spread of bacteria to the joint. Penetrating injuries, surgical procedures, and intraarticular injections are common exogenous sources. Hematogenous infection occurs when bacteria from distant sites, such as the respiratory tract, oral cavity, umbilicus, genitourinary tract, or heart, localize in the joint.[1] Preexisting disease or conditions causing immunosuppression predispose to joint infection.[2,3] Young animals are often affected, although no breed or age predilection exists.[4]

Escherichia coli, Staphylococcus, Streptococcus, and *Pasteurella* species are commonly isolated from septic

joints, with staphylococcal infections being most prevalent.[5,6] *Borrelia burgdorferi,* bacterial L-forms, *Mycoplasma spumans, Mycobacterium tuberculosis,* fungi, protozoa, and rickettsial organisms have also been implicated.[2]

Pathophysiology

Once exposed to bacteria, a cascade of events initiates the potentially destructive process within the joint environment. Bacterial infiltration results in synovial tissue edema, activation of the immune system, and initiation of the inflammatory cascade. Inflammation of the synovium, capillary rupture, and necrosis

promote extravasation of fibrin, clotting factors, polymorphonuclear leukocytes, and proteinaceous fluid into the joint.[7] Intraarticular pressure increases, potentially leading to ischemia, subluxation, or avascular necrosis of intraarticular structures. Lysosomal enzymes and enzyme by-products released during activation of the inflammatory cascade degrade cartilage, disrupt synovial fluid dynamics, and impair cartilage nutrition.[7] Granulation tissue formed as a result of inflammation can penetrate and undermine the cartilage, causing further joint destruction.[8] As the process progresses and cartilage is destroyed, subchondral bone can also become involved.[8] Destruction of

articular cartilage and degenerative joint changes combined with thickening and scarring of periarticular tissues leads to restricted joint mobility, and in severe cases, loss of joint function. Early therapeutic intervention is imperative to minimize destructive joint changes.[8,9]

Diagnosis

Isolation of bacteria from the joint in question is necessary for definitive diagnosis of septic arthritis, but this is not always possible and degree of suspicion plays a role. Attempt at bacterial isolation is made by aseptic arthrocentesis followed by cytologic evaluation and culture of the synovial

fluid. Abnormal cytologic findings consistent with septic arthritis include increased numbers of white blood cells (40,000/μL or greater, mostly neutrophils that may or may not be degenerate), loss of fluid viscosity, presence of intracellular bacteria, and increased fluid turbidity (Table 92-1).[5,6,10] Direct plating of synovial fluid for culture is not ideal because this leads to frequent negative results.[11,12] Culture of the synovium has been clinically shown to be more beneficial than culture of synovial fluid alone,[5,13] but reports are conflicting in that experimental tests have not shown the same.[11] Submission of synovial fluid on a culture swab has the potential to inhibit some organisms, resulting in

decreased yield,[14] although reasonable success can be achieved using the technique.[11] To facilitate bacterial growth, synovial fluid should immediately be placed in blood culture media at a 1:9 ratio. The synovial fluid-culture media combination is incubated for 24 hours at 37 C (98.6 F) before being plated for identification of organisms.[11]

Other diagnostics depend on the suspected type of infection. In all cases a complete blood count, chemistry panel, and urinalysis should be performed to evaluate the animal as a whole and to look for systemic disease, although yield might be low. In cases of aspergillosis, fungal hyphae might

be seen and can be cultured from synovial fluid.[15] Special stains such as India ink, periodic acid-Schiff, and silver nitrate stains, or treatment of preparations with 10% potassium hydroxide can improve visualization of fungal organisms.[16,17] Synovial fluid from cats with calicivirus infection can be normal or can have elevated cell counts with a predominance of mononuclear cells; virus isolation is possible from synovial fluid and tissues of affected joints.[18] Polymerase chain reaction with DNA isolation can be useful in some cases of septic arthritis in which definitive diagnosis is difficult, such as mycobacterial infections.[19] The source of infection should be isolated in cases of

hematogenous seeding of the joint with bacteria.

Table 92-1. Characteristics of Synovial Fluid from Normal and Septic Joints for Comparison.[5,6,10]

	Normal Joint	Septic Joint
Color	Clear to light straw	Pink-tinged to yellow/white
Turbidity	None	Turbid
Viscosity	Viscous, 2-5 cm string test	Low viscosity, < 2 cm string test
N. cell count	≤ 500 to 3,000 cells/μL	≥ 40,000 cells/μL
Cell type	10% Neutrophils 60-90% Mononuclear cells	> 80% Neutrophils, may or may not be degenerate
Volume	Minimal (< 0.25 to 1ml)	Large (often > 1ml)

N. = Nucleated

Early radiographic changes associated with septic arthritis include joint effusion and soft-tissue swelling. With progression of disease, bone lysis, joint surface irregularity, bone sclerosis, ankylosis, and subluxation can be

seen.[20] Nuclear scintigraphy provides earlier diagnostic information than does conventional radiography. Positive joints do not specifically indicate infection;[21-23] however, newer scintigraphic agents have the potential to differentiate infection from other forms of inflammation.[24] Advanced imaging through computed tomography or magnetic resonance imaging might also be beneficial in the diagnosis of joint infection.[20,25]

Clinical Findings

In animals suffering from septic arthritis, the affected joint is usually swollen and painful. Only one joint is typically involved. The joint might be

warm to the touch and the animal is often severely lame or unable to bear weight. Systemic signs such as malaise, inappetence, and fever are variable in cases of exogenous disease, but with hematogenous infection, they are more likely to be present.[13] In addition to fever, anorexia, depression, and oral ulcerations, cats affected with calicivirus can exhibit acute swelling and pain of the distal joints and may be reluctant to move.[18,26]

Treatment

Therapy is directed at minimizing cartilage destruction and eradicating the infection. Antimicrobials are administered after synovial fluid for

cytologic evaluation, culture, and susceptibility testing has been obtained. Intravenous administration of a broad spectrum, bactericidal antimicrobial is indicated initially, but a favorable initial response permits a change to oral antimicrobial administration within the first 3 to 5 days of therapy. Long-term antimicrobial administration is based on culture and bacterial susceptibility testing. If culture results are negative, antimicrobial therapy is continued based on positive clinical response to treatment. Antimicrobials should be continued for a minimum of 4 weeks or at least 2 weeks beyond the resolution of clinical signs.

Final antibiotic choice is based on culture and antimicrobial susceptibility testing. If empiric antibiotic administration is necessary, care should be taken in antibiotic selection because antimicrobial resistance of commonly isolated organisms is constantly changing. Staphylococci, in one report, showed 18% resistance to first-generation cephalosporins.[27] Clinical response to treatment should always be monitored. Common first-line defense antimicrobials would include first-generation cephalosporins and penicillins supplemented with β-lactamase inhibitors because Staphylococci are most commonly isolated from joint infections.[27] Tetracycline is recommended for those

animals with infectious arthritis secondary to *Borrelia*, rickettsial infections, *Mycoplasma*, and bacterial L-forms.[2,13]

Antibiotic penetration into joint cavities and efficacy against the causative organism is necessary for resolution of infection. Synovial fluid and serum antibiotic kinetics are similar, with synovial fluid concentrations gradually increasing as serum concentrations rise.[28,29] Final synovial fluid concentration depends on the molecular size of the antibiotic and inflammation-dependent changes in synovial membrane permeability.[28,29] Synovial fluid antibiotic concentrations decrease as

joint inflammation resolves, but therapeutic antibiotic concentrations within the joint likely remain.[12,30] Following equilibration, antibiotic concentration within the joint is the same or higher after systemic administration when compared with intraarticular injection, so systemic therapy alone is typically sufficient.[31] Furthermore, intraarticular injection of antibiotics can cause chemical synovitis with worsening of the pathologic process and should be avoided.[32,33]

Medical management consisting of appropriate antimicrobial therapy, passive range of motion exercises, and pain management can result in

resolution of infection and return to function if the animal is treated aggressively and early in the course of disease.[34] However, joint lavage is essential to remove cellular and enzymatic constituents in some cases. In young animals, decompression can be especially important to reduce pressure within the joint and preserve epiphyseal vascularity.[7] Needle aspiration and lavage alone do not adequately remove deleterious materials from the joint, but can provide some benefit if surgical lavage is not an option.[34] Arthrotomy or arthroscopy with surgical debridement and copious lavage of the affected joint is indicated for postoperative joint infections, septic joints untreated

for 72 hours or more, joints that have not responded to 72 hours of appropriate medical management, or joint infection secondary to penetrating wounds.[9,34] At the time of surgery, the joint is explored, cultured, debrided of necrotic debris, and lavaged with large volumes of an isotonic solution. Joints with healthy appearing tissues after debridement and lavage are closed primarily at the time of surgery. If the tissue appears unhealthy, open-joint management or ingress-egress systems may need to be utilized.

An ingress-egress flushing system allows for continued joint lavage during the postoperative period and is

considered for animals with severe infections and extensive tissue damage. However, intraarticular drainage systems can be difficult to maintain. Open-joint management is an effective alternative. Open joints and lavage systems should be managed aseptically and the drains removed or the joint closed when drainage is minimal and less purulent to decrease the chance of nosocomial infection. Open joints should be kept moist until they are closed. Cytologic evaluation of exudate can be helpful in deciding when to remove the drain or close the joint.

Fluid therapy and nutritional supplementation should be instituted as needed. The inciting cause in cases

of hematogenous seeding of the joint with bacteria must be found and treated appropriately. Pain medication is imperative to facilitate joint mobility and patient comfort. It is also important to maintain joint mobility through passive range of motion activity, yet limit heavy weight-bearing to prevent undue stress on the already weakened articular cartilage. Swimming or underwater treadmill activity would be beneficial because joint stress is reduced through these activities. In severe cases that have not responded to antibiotic therapy or surgery and in cases with irreversible, severe joint damage or stiffness, amputation is a feasible alternative. For some joints, arthrodesis is

indicated if the infection, but not the severe destructive changes within the joint, can be eliminated.

Prognosis

Prognosis is variable and depends on the degree of cartilage destruction and duration of disease. Arthritis is expected following joint infection, but the severity and resulting disability are difficult to predict. Up to 50% of people suffer permanent joint dysfunction and 75% have residual disabilities after treatment of septic arthritis.[35,36] Many animals recover with minimal deficits, but others suffer permanent joint dysfunction.[6,34] Furthermore, some animals will have a

residual lameness secondary to a continued immune response to lingering microbial antigens within the joint, even though the infection has been eradicated.[37] These animals might respond to corticosteroid therapy, but treatment should only be initiated after repeated negative joint cultures.[2] Calicivirus infection in kittens is usually self-limiting, but can be associated with a 25% mortality rate in adults cats.[18,26]

In summary, septic arthritis can lead to severe joint destruction and debilitation if not treated aggressively and early in the course of the disease. Parenteral antibiotic therapy followed by long-term oral antibiotic

administration is imperative. Surgical intervention is necessary in some instances to decompress the joint, debride devitalized tissue, and lavage. Arthritis is expected after joint infection, but early treatment can minimize joint destruction.

Chapter 93

Osteomyelitis

Loretta J. Bubenik

Osteomyelitis usually results from open fractures or open fracture repair. The term simply means inflammation of the bone and marrow contents, but bacterial infection is often implied when the word is used. Endogenous and exogenous modes of infection occur, with exogenous being more frequent. Treatment varies depending on the source of infection, the organism involved, and duration of

infection.

Etiology

A variety of organisms has been implicated in bone infections. A single organism is usually involved.[1] Beta-lactamase-producing staphylococcal species, streptococcal species, and gram-negative aerobic bacteria are most commonly isolated,[2-4] with staphylococcal species, usually *Staphylococcus intermedius*, isolated 46 to 74% of the time.[2,4,5] Multiple organisms are isolated 33 to 66% of the time.[4,6]

Isolation of anaerobic bacteria can be difficult, but isolation rates as high as 70% have been reported.[1] Isolation of

anaerobes is site–dependent, with the radius/ulna, mandible, and tympanic bulla commonly involved.[1] Anaerobic bacteria should be suspected in cases of apparent infection but lack of growth on culture, infection secondary to disruption of tissue normally inhabited by anaerobic bacteria, or when infection from an external source has occurred.[1,7-9] Common anaerobic isolates include *Bacteroides, Fusobacterium, Actinomyces, Clostridium, Peptococcus,* and *Peptostreptococcus* species.[1,8,10]

Mycotic bone infection also occurs, but usually results from hematogenous spread.[9] Isolated fungal organisms include *Cryptococcus neoformans,*

Coccidioides immitis, Aspergillus species, Penicillium species, Blastomyces dermatitidis, Histoplasma capsulatum, and *Phialemaenium.*[11-16]

Pathophysiology

Osteomyelitis comes from endogenous or exogenous sources. Acute hematogenous osteomyelitis is the endogenous form; bone infection develops from an infectious focus at a distant site within the body such as the skin, respiratory system, heart, oral cavity, or genitourinary tract. Alternatively, exogenous bone infection (infection from nonhematogenous routes) may occur from direct inoculation (e.g., bites,

punctures, or surgery), open fractures, foreign body migration, or gun shot wounds. Osteomyelitis from exogenous sources is divided into acute and chronic forms.

Acute hematogenous osteomyelitis typically affects the metaphyseal region of long bones, but diaphyseal infections can occur.[2,17] Bacteria lodge in the metaphysis where the capillary endothelium is discontinuous and blood flow slows in the veins.[18,19] After localizing in the metaphysis, bacteria and activated platelets cause inflammation and thrombus formation, producing an ischemic environment that is conducive to bacterial proliferation.[19] Infection either

progresses or is walled off by the immune response.[20] Cellular debris, inflammatory by-products, and bacteria cause thrombosis, abscessation, and compromise of blood supply to the bone. Sequestration, formation of a walled off, devitalized portion of bone, can occur when exudate reaches the outer cortex and elevates the periosteum, compromising cortical blood supply to that area of bone.[19] The isolated bone fragment is usually surrounded by purulent debris (lacuna) and can form an opening for escape of purulent material outside the walled off area (cloaca). Chronic osteomyelitis can result when the infection is walled off, but not eliminated by the body.

Fungal organisms typically gain entrance to the body via inhalation or spread from the gastrointestinal tract. Hematogenous dissemination occurs after localization of the organisms in areas away from the bone.[11,14-16,21-23] Hence, fungal osteomyelitis is usually considered hematogenous in origin, although primary fungal osteomyelitis and direct bone inoculation occur on occasion.[15]

Nonhematogenous acute and chronic osteomyelitis occur when an organism invades osseous tissue by overwhelming the immune system or by seeding compromised tissue. Normal bone is resistant to infection, but soft-tissue injury, bone devitalization,

surgical implants, instability of bone fragments, prolonged wound exposure, and immunosuppression increase the risk of infection.[24,25]

Acute nonhematogenous osteomyelitis is usually a complication of surgical fracture repair and clinical signs are typically apparent 5 to 7 days after surgery. Long bones are more often affected than axial bones, probably owing to increased occurrence of fracture in long bones.[2,4,6] The degree of soft-tissue devitalization, fracture stability, type of fracture repair, organism virulence, and immune system competence influence development of fracture site infection.[6,9,24] Trauma from fracture

generation and/or surgery and implants applied during fracture repair disrupt blood supply and provide foreign material for bacterial adherence and proliferation.[24] Implants decrease the quantity of bacteria needed to establish an infection and provide a site for bacterial adherence that can escape immunosurveillance and antibiotics.[24,26] Moreover, devitalized bone fragments increase the risk of infection for both virulent and nonvirulent strains of bacteria.[27] Bullet penetration and bites cause soft-tissue injury and are a means of bacterial inoculation. Shrapnel, migrating foreign bodies, and occasionally bites leave material behind that allow

bacteria to evade host immune responses and proliferate.[9]

Nonhematogenous, chronic osteomyelitis develops from inadequate treatment of acute osteomyelitis, hidden infections associated with implants or other foreign material, and/or isolation of bacteria from the immune system.[24,28,29] In fractures with prolonged infection, granulation and fibrous tissue isolate devitalized bone (sequestration) and cause delayed healing and/or persistent infection.[19,27] The sequestration of fracture fragments occurs because the fragment of bone is devitalized at the time of fracture owing to trauma and

is walled off instead of being resorbed or incorporated into the fracture callous. However, devitalization and sequestration of bone after fracture can also occur through the same mechanism as with acute hematogenous osteomyelitis. Persistent, chronic infection is enhanced by the presence of metallic implants/foreign material and through bacterial biofilm production, which protects bacteria from immunosurveillance.[24,26,30]

Clinical Findings

Acute hematogenous osteomyelitis is not common but most often affects young animals.[2,4] Findings can include

soft-tissue swelling over the affected site, moderate to severe lameness, inappetence, malaise, fever, and debilitation. The source of bone infection may or may not be found during initial examination, but the animal should be examined for such. The oral cavity, integument system, urogenital tract, lungs, and heart should be carefully examined. Draining tracts occur uncommonly.[19]

Acute osteomyelitis of nonhematogenous sources has no breed or sex predilection and typically occurs after fracture repair. In such cases, the surgical wound may be edematous, erythematous, and warm, and the limb is painful during manipulation.

Animals are often febrile and have a substantial lameness. Draining tracts are not common during the acute phase, but incisional drainage might be obvious. Signs of systemic illness such as inappetence and lethargy might also be apparent.[9]

Animals suffering from chronic nonhematogenous osteomyelitis usually present with an insidious lameness and varying degrees of pain at the fracture site. If the fracture is not healed, the degree of fracture instability can influence the degree of pain and lameness. Moderate to severe muscle atrophy is usually present in the affected limb and a draining tract might be apparent. It is common for

drainage to dissipate with antimicrobial administration only to return once antimicrobials are discontinued. Muscle fibrosis and contracture owing to the effects of long-standing infection on the soft tissues might contribute to the lameness.[9] Signs of systemic involvement, such as fever and inappetence, are less likely to be present than with acute infections.

The clinical presentation of animals suffering from fungal osteomyelitis is similar to those suffering from bacterial osteomyelitis. Signs include lameness, swelling, and pain associated with the affected area, and the presence of draining tracts.

However, animals with fungal osteomyelitis often have disseminated disease and systemic signs such as general malaise, inappetence, respiratory compromise, lymphadenopathy, weight loss, and fever.[11,31] Any age, breed, and sex can be affected, but German shepherd dogs may be overrepresented, possibly owing to genetic factors involving altered immune function.[11]

Diagnosis

History and signalment play a role in diagnosis of bone infection. Concurrent or prior infection elsewhere in the body in conjunction with sudden lameness, pain, heat, and swelling

over the affected bone is suggestive of acute hematogenous osteomyelitis. For acute nonhematogenous osteomyelitis, a history of recent fracture repair, animal bite, evidence of foreign body migration, or puncture wound is more suggestive. Chronic osteomyelitis is usually associated with a history of previous fracture repair or implantation of foreign material and may also be linked to a previous diagnosis of osteomyelitis.

Radiography is commonly employed in the evaluation of suspected osteomyelitis. Radiographs alone have a sensitivity of only 62.5% and a specificity of 57.1% for diagnosis of osteomyelitis, but are commonly used

in conjunction with clinical signs to make a diagnosis.[32] For an acute infection, soft-tissue swelling without alteration in bone architecture predominates,[9,33] but with chronic infection, periosteal new bone proliferation, cortical bone resorption, cortical thinning, implant loosening, and bone sequestration might be apparent (Figure 93-1).[2,4,33,34] Osteolytic and proliferative changes generally lag behind the actual time of infection by 10 to14 days, so obtaining a second radiograph several days later may aid in diagnosis of questionable cases.[35] Radiographic evidence of sequestration may be delayed by several weeks, but in chronic situations, the presence of a

sequestrum can be common (Figure 93-2).[36] Contrast radiography (fistulography) of draining tracts might help identify sequestra or foreign bodies.[9] Scintigraphy with Technetium-99 methylene diphosphonate can provide early information regarding active bone and joint remodeling; however it is not specific for infection.[33,37] New scintigraphic techniques offer distinction between infection and other inflammatory processes and might hold some benefit in the future.[38] Magnetic resonance imaging and computed tomography can also aid in early diagnosis of osteomyelitis.[34,39,40]

To obtain a definitive diagnosis, tissue

samples, direct swabs, and/or needle aspirates should be aseptically collected from the affected area for cytology, aerobic and anaerobic culture, and antimicrobial susceptibility testing. Gram staining of samples can provide early information for empiric treatment while awaiting culture results. Percutaneous aspiration of tissues around and in the affected site can have isolation rates as high as 86%,[41] although some reports do not concur with that high a rate.[2,4] If an abscess is present, the chances of obtaining organisms is likely higher. Tissue culture or direct swabbing through a surgical approach might be more likely to result in a positive culture. In chronic cases, needle

aspiration might be less rewarding because bacteria can adhere tightly to surrounding structures with minimal exfoliatation.[24,29,42] Ideally, antibiotics should be withheld for at least 24 hours before sample collection to improve yield in chronic cases and should be initiated after sample collection in acute cases unless the animal's condition dictates otherwise.[43] Culturing draining tracts should be avoided because contaminants rather than the causative organism are often isolated.[44] If systemic involvement or hematogenous osteomyelitis is suspected, blood cultures should be performed.[45] In people with hematogenous osteomyelitis, approximately 50% of blood cultures

grow the causative organism.[46]

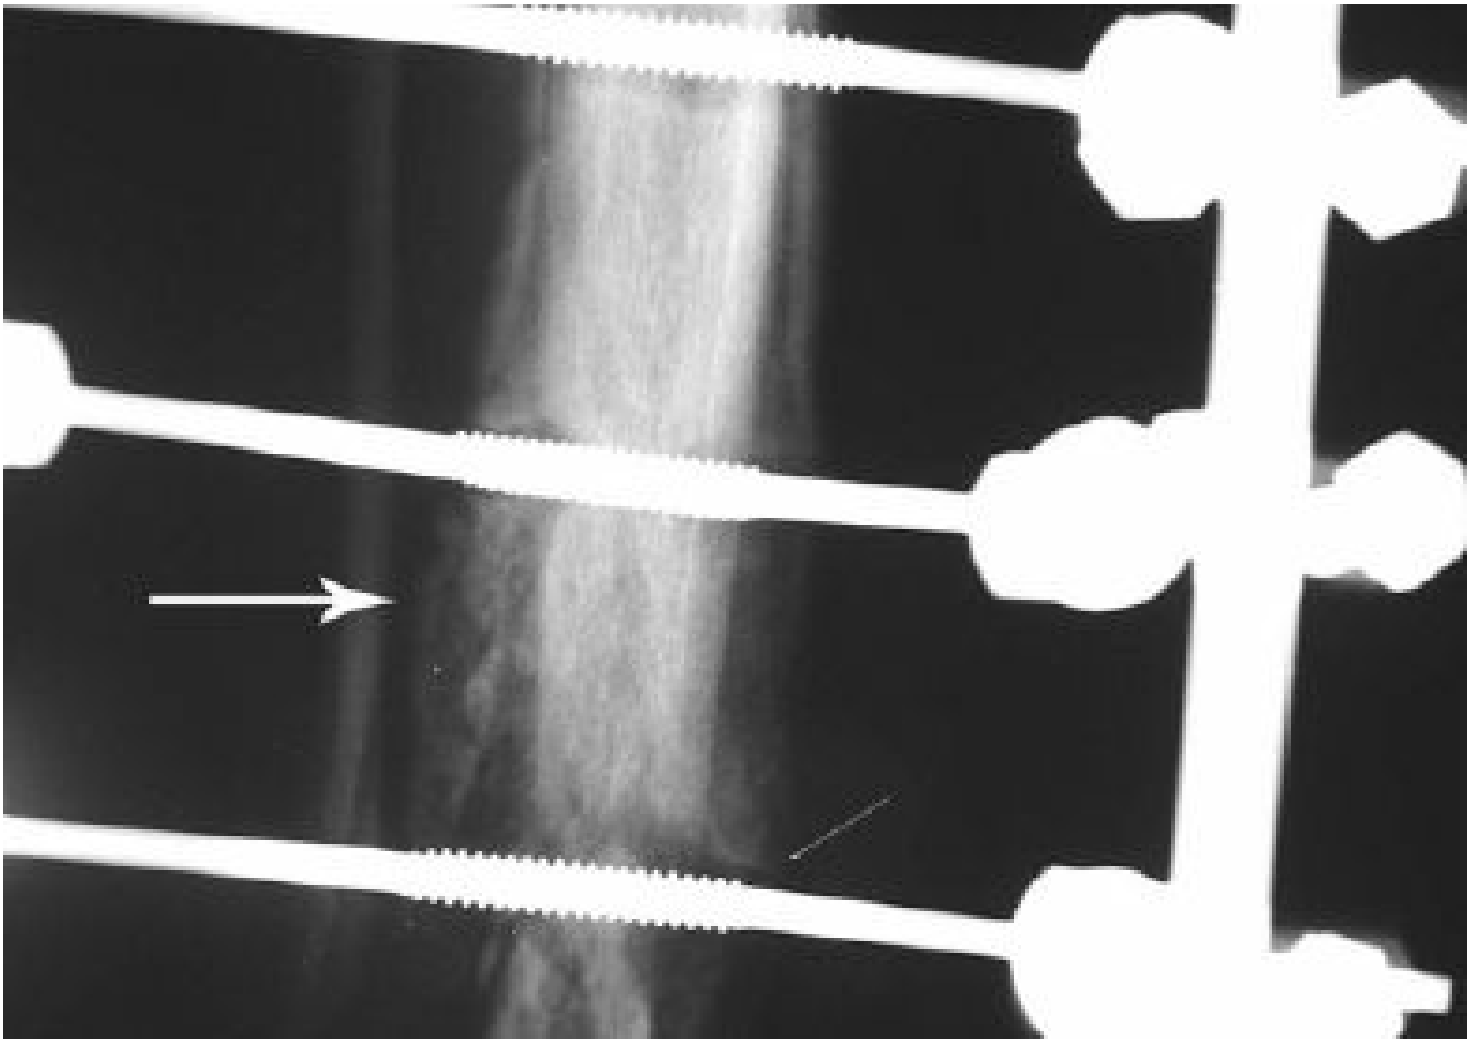

Figure 93-1. Chronic Osteomyelitis. This is a radiograph from a 2-year-old dog that developed osteomyelitis from an open fracture sustained 1 month earlier. Note the periosteal proliferation (solid white arrow) and the radiolucent line along the fixators pin (small line arrow) indicating implant loosening.

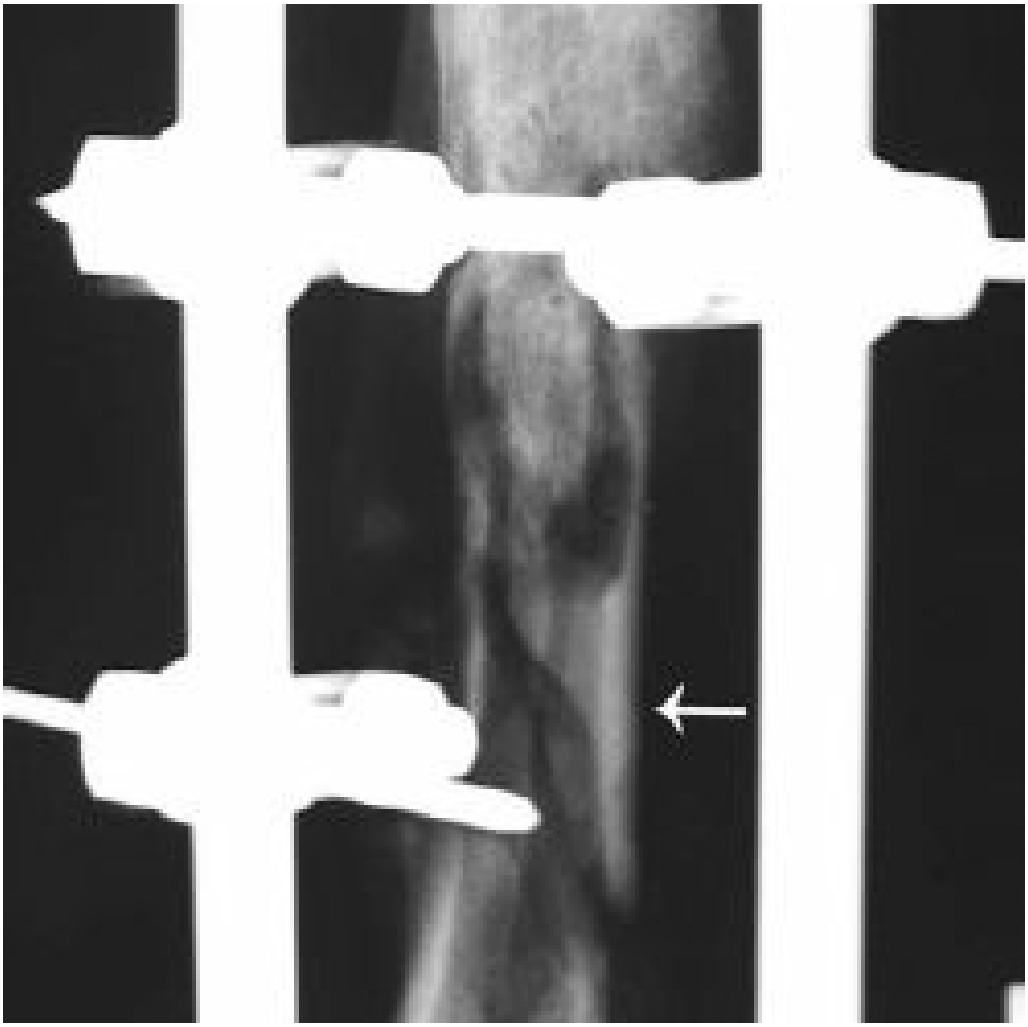

Figure 93-2. Sequestrum. This is a radiograph from a 2-year-old dog that developed osteomyelitis from an open fracture sustained 1 month earlier. Note the lack of periosteal reaction and remodeling of the devitalized portion of bone (solid white arrow).

Supportive diagnostics including a complete blood count, biochemistry panel, and urinalysis might show other organ-system involvement, be

suggestive of infection, or not reveal anything of significance. For acute infections, especially hematogenous osteomyelitis, thoracic and abdominal radiographs, abdominal ultrasound, and/or echocardiogram can elucidate the source of infection and determine the animal's systemic condition.

A diagnosis of fungal osteomyelitis is often made from cytologic or histologic evaluation of affected tissues. Cytology of affected areas mostly consists of pleocellular infiltration, including macrophages, lymphocytes, plasma cells, neutrophils, and multinucleated giant cells; lesions are pyogranulomatous in nature.[31] Fungal hyphae or intracellular organisms are

often apparent on preparations.[11,14-16,21-23] Special stains such as India ink, periodic acid-Schiff, and silver nitrate stains, or treatment of preparations with 10% potassium hydroxide can improve visualization of organisms.[21,31] Serologic testing is helpful to identify exposure.[31] Fungal culture is necessary for definitive diagnosis. In cases of aspergillosis, fungal hyphae can be seen in the urine sediment and can be cultured from urine of some infected animals.[11] Bone biopsy should be performed to rule out neoplasia and to obtain samples for culture and histopathology. Radiographic changes include soft-tissue swelling, periosteal and endosteal bone proliferation, and bone

lysis. Lesions are typically below the elbow and stifle, but may be anywhere and must be differentiated from bone tumors.[11,14-16,21-23] Complete blood count and biochemistry profiles are not specific for fungal disease, but findings include nonregenerative anemia, leukocytosis, hyperglobulinemia, and eosinophilia.[11,14-16,21-23]

Treatment

Antibiotic penetration into bone and efficacy against the causative organism are necessary for resolution of infection. Ultimately, antibiotic choice is based on culture and antimicrobial susceptibility testing. Empiric therapy is initiated while culture and

antimicrobial susceptibility are pending or when cultures fail to offer an appropriate therapeutic strategy. If the causative organism cannot be identified, continued antimicrobial administration is based on appropriate response to the initial therapeutic regimen. Intravenous therapy is always initiated for acute infections, and a favorable initial response permits a change to oral antimicrobial administration within the first 3 to 5 days of therapy. Oral therapy is appropriate in chronic cases, but is typically combined with surgical intervention. In cases of severe soft-tissue destruction, microvascular muscle flaps can provide increased blood supply and improved delivery of

antibiotics and healing factors to the wound bed.[47]

Care should be taken in antibiotic selection because antimicrobial resistance of commonly isolated organisms is constantly changing and antibiotic effectiveness is dependant on many factors. Penicillins and penicillin-combination drugs, cephalosporins, and aminoglycosides readily penetrate normal and infected bone.[48-52] Staphylococci isolated from canine infections are often resistant to pure penicillins because of β-lactamase production, so β-lactamase-resistant drugs are preferred.[53] Staphylococci showed 18% resistance to first generation cephalosporins in one

report,[54] although cephalosporins are a commonly used antibiotic in the first line of defense against bone infections.[54] Aminoglycosides lose some effectiveness in hypoxic or acidotic conditions and in the presence of white blood cells, so efficacy should be monitored during treatment.[55] Fluoroquinolones have good bone penetration and are beneficial for many gram-negative infections.[56] However, fluoroquinolones are not effective under anaerobic conditions and should be avoided in immature animals owing to potential deleterious effects on cartilage.[57,58] Clindamycin penetrates normal bone and is useful for gram-positive and anaerobic osteomyelitis.[59-61]

Duration of antimicrobial therapy depends on the severity of the infection, but antibiotics should be continued for at least 2 weeks beyond radiographic and clinical resolution of infection, which typically requires weeks to months of therapy.[55,62-66] Recurrence is lower in people with acute osteomyelitis if antibiotics are continued for a minimum of 30 days.[63] Owners should be warned that treatment will likely require long-term commitment and can be expensive.

Surgery is a necessary component of treatment in some cases of osteomyelitis. Palpable abscesses must be drained, cultured, debrided, and lavaged. In animals with

nonhematogenous osteomyelitis, loose implants and foreign material must be removed.[64] For chronic osteomyelitis, surgery is often necessary to promote resolution of infection and involves aggressive debridement of devitalized bone fragments and necrotic soft tissue, removal of sclerotic bone occluding the medullary canal, and removal of loose implants or foreign material.[65] If debridement is adequate and the wound bed is healthy, closure over an active drain can be considered, otherwise the wound should be left open and closed at a later time once the tissues appear healthy. Multiple operations might be necessary to resolve infection in refractory cases of osteomyelitis.[6]

Stabilization of an unstable fracture is essential in nonhematogenous osteomyelitis. For amendable fractures, external fixators can be applied with minimal disruption of blood supply and have an added advantage of being easily removed.[66] If the soft tissues are healthy and the surgical procedure has consisted primarily of sequestrectomy and debridement of a fistulous tract, internal fixation can be considered.[67,68] However, all implants should be removed once the fracture is healed because they can harbor organisms and lead to recurrent osteomyelitis.[26] In fracture cases, bone grafting should be considered, but delayed grafting might be necessary in excessively exudative wounds because graft resorption can

occur.[5,20]

Fluid therapy, nutritional supplementation, and analgesics should be instituted as needed and when systemic involvement is present. The inciting cause in cases of hematogenous osteomyelitis must be found and treated appropriately. Rehabilitation of the affected limb is also important, especially in chronic osteomyelitis, because inflammation of the soft tissues secondary to infection can lead to considerable muscle atrophy, fibrosis, and contracture, and prevent return to function. In severe cases that have not responded to antibiotic therapy or surgery and in cases with irreversible muscle damage

and excessive joint stiffness, amputation might be necessary.

Although systemic antibiotic therapy is essential in the treatment of orthopedic infections, local antibiotic therapy provides another means of treatment that has some advantages when combined with systemic therapy.[41,69-71] Local antibiotic administration maintains a higher local drug concentration at the site of infection for a prolonged period of time with reduced systemic toxicity.[72-75] Local delivery of antibiotics usually involves temporary implantation of antibiotic-impregnated polymethylmethacrylate (AIPMMA) at the site of infection, but biodegradable delivery systems have

also been investigated.[76-79] Local antibiotic delivery systems work by gradual release of antibiotics to the site of infection via antibiotic elution out of the implanted material. Tissue antibiotic concentration and elution rate depend on multiple factors including the antibiotic used, cement configuration, type of antibiotic carrier, and tissue environment.[69,73-75,80-83] AIPMMA is most often used in the form of preformed beads that are bought or handmade. The beads are placed at the site of infection and are left there for a duration based on the expected elution rate of the impregnated antibiotic. Beads can be replaced serially to maintain an adequate local antibiotic

concentration, but implanted cement should ultimately be removed from the infected site because it can harbor bacteria and result in recurrent osteomyelitis.[84]

Treatment of fungal osteomyelitis is difficult and expensive. Animals require long-term antifungal therapy (months) and are treated at least a month beyond resolution of clinical signs.[85] Some animals require life-long therapy[85] or amputation.[21] Antifungals include fluconazole, ketoconazole, amphotericin B, and itraconazole, but itraconazole is associated with fewer side effects.[85] Amputation is a reasonable alternative to therapy for fungal osteomyelitis if the systemic

fungal disease is under control but the local bone infection cannot be cured.

Prognosis

Osteomyelitis typically carries a favorable prognosis unless fungal organisms are involved. Most animals respond favorably to treatment if antibiotic therapy is appropriate and the inciting cause is treated. Most infected fractures will heal in the face of infection so long as appropriate antibiotic therapy is used and the fracture is stable. For acute osteomyelitis, aggressive early intervention is necessary for resolution and prevention of chronic osteomyelitis. The inciting cause must

be eliminated in cases of hematogenous spread or foreign body migration for complete resolution of disease.[6,62] In chronic cases, a favorable response to treatment occurs in up to 90% of affected dogs, but recurrence is possible.[6,62]

For fungal disease, prognosis is guarded to poor, although some animals respond to therapy. Systemic disease worsens the prognosis. Recurrence is possible[16,85] and varies from 20 to 25% in cases of blastomycosis.[85] On the other hand, histoplasmosis infection in cats often responds favorably to itraconazole.[85]

Although uncommon, complications

can also affect the ultimate prognosis in cases of osteomyelitis. For acute cases, recurrence and progression to chronic disease can occur. Infections near the epiphysis can rarely lead to concurrent joint infection, and septicemia can result from inappropriate local bacterial control. Finally, chronic osteomyelitis, and some cases of acute osteomyelitis, can lead to refractory or recurrent osteomyelitis, nonunion, restricted joint motion, and loss of limb function.

In summary, many factors contribute to the formation, progression, and prognosis of osteomyelitis. The cause must be identified and treated appropriately. Diagnosis is based on

culture and suspicion of disease, whereas treatment depends on the severity and type of infection present. For bacterial infections, the prognosis is favorable as long as treatment is appropriate for the type of disease, but fungal osteomyelitis carries a guarded to poor prognosis.

Chapter 94

Hypertrophic Osteodystrophy in Dogs

Ron Montgomery

Hypertrophic osteodystrophy (HOD) is a readily diagnosed, inflammatory, and osteoclastic disease process on the metaphyseal side of active physes, predominantly of large and giant breeds.[1-21] The distal radius and ulna are the most often and most severely affected sites with clinical signs. HOD was first reported in dogs in 1935 and was initially called Barlow's disease.[2,7]

HOD has had the synonyms of metaphyseal osteopathy, idiopathic osteodystrophy, osteodystrophy II, canine skeletal scurvy, Barlow's disease, and Moeller-Barlow disease.[1,2,7] The first two synonyms are accurate descriptors, whereas canine skeletal scurvy is not accurate based on comparison of clinical signs, pathophysiology, and etiologies.[2]

Etiology

HOD has a cryptogenic etiology despite extensive investigation. Etiologies considered include excessive dietary vitamins and minerals,[1-14] vitamin C deficiency,[2,10] infectious agents (viral and bacterial)[10,14]

immune-mediated inflammatory disease,[10,11] a form of osteochondrosi,[10] vascular anomalies,[8,10] and genetic or familial predisposition.[3,10,12] Whether the etiology is from exogenous (e.g., infectious agents), endogenous (e.g., abnormal metabolism), or a combination of influences is unclear.[1,2,10] However, many proposed etiologies have been ruled out or determined to be unlikely as sole causes.

Dietary causes of HOD that are unlikely include excessive vitamin D, excessive mineral supplementation, excessive calories, and deficient vitamin C (only primates and guinea

pigs require dietary vitamin C).[1,2] Abnormal metabolism of vitamin C remains a possibility.[1,2] Many dogs with HOD have not had vitamin and mineral supplementation, and many dogs on high levels of vitamin and mineral supplementation do not develop HOD. High calorie diets are also much more common among young dogs than is HOD. It appears that, at most, diets that promote rapid growth and/or affect bone formation may contribute to, but not cause, HOD.

Respiratory and/or gastrointestinal disease a few weeks prior to some cases of HOD has prompted consideration of infectious agents as etiologies.[2,12] Distemper and distemper

vaccination (modified-live) have been prominent etiologic considerations.[2,12,18,19] Experimentally, evidence of canine distemper virus in bone cells of the metaphyseal region of dogs has been reported.[18,19] However, Koch's postulates have never been satisfied with regard to HOD. A comparison of multiple risk factors for HOD and canine distemper virus infection based on a Veterinary Medical Database (VMDB) survey concluded that the risk factors were not similar.[3] Although dogs less than 6 months old were identified to be at greatest risk for both diseases, distemper cases occurred over 12 times more often than HOD.[3]

Nevertheless, specific vaccination protocols using killed virus, or modified-live measles instead of modified-live distemper virus, or vaccinating separately for distemper, parvovirus, and adenovirus have been proposed for Weimaraners.[12,13] Bacterial infection has also been reported in conjunction with HOD.[14] Which came first was undeterminable, although the debilitating effects of HOD were speculated to allow an opportunistic E. coli bacteremia.[14] An autoimmune or hyper-inflammatory etiology has also been proposed, perhaps initiated by infection.[11] The relative infrequency of HOD compared with suspected infectious agents plus the predominant clinical signs being at

the distal radius and ulna make an infectious agent difficult to explain, at least as a sole etiology.

When considering osteochondrosis as an etiology for HOD, details of endochondral bone formation should also be considered. Osteochondrosis affects all physes and includes microscopically visible loss of distinct chondrocyte columns and excessive thickness of the zone of chondrocyte hypertrophy. HOD affects a later step of in endochondral osteogenesis the process than osteochondrosis affects and has a different pathophysiology. HOD pathology occurs in the metaphysis immediately adjacent to the physis where primary spongiosum

is located and transformation to the secondary spongiosum begins. The area affected by HOD normally has rapid growth, high lysosomal enzymatic activity, and high osteoblast and osteoclast activity.[5] Although vessels do not cross the physis, the metaphyseal side of the physis has an extremely rich blood supply from the nutrient artery and peripherally from metaphyseal arteries (Figure 94-1A).[2,8] The normal vascularity of this region is so extreme during rapid bone growth that the distinction between normal and inflammatory is subtle, and based mainly on the lack of pathology. A multitude of small arterioles approach perpendicular to the physis, then make a “hairpin” turn away from the physis

(Figure 94-1B),[8] which affects laminar blood flow. The hairpin turns have been postulated to be "clinically important in growth deformities."[8] Capillary structure here also includes "buds" or dead end capillaries with endothelium that lacks a basement membrane and in places may be open, which allows extravasation of blood into the inter-trabecular sinuses immediately adjacent to the physis (Figure 94-1C).[5,6] Ironically, the area immediately adjacent to the last transverse septum of the physis is reported to have low oxygen tension and localized vascular stasis,[5] despite the nearby hypervascularity.

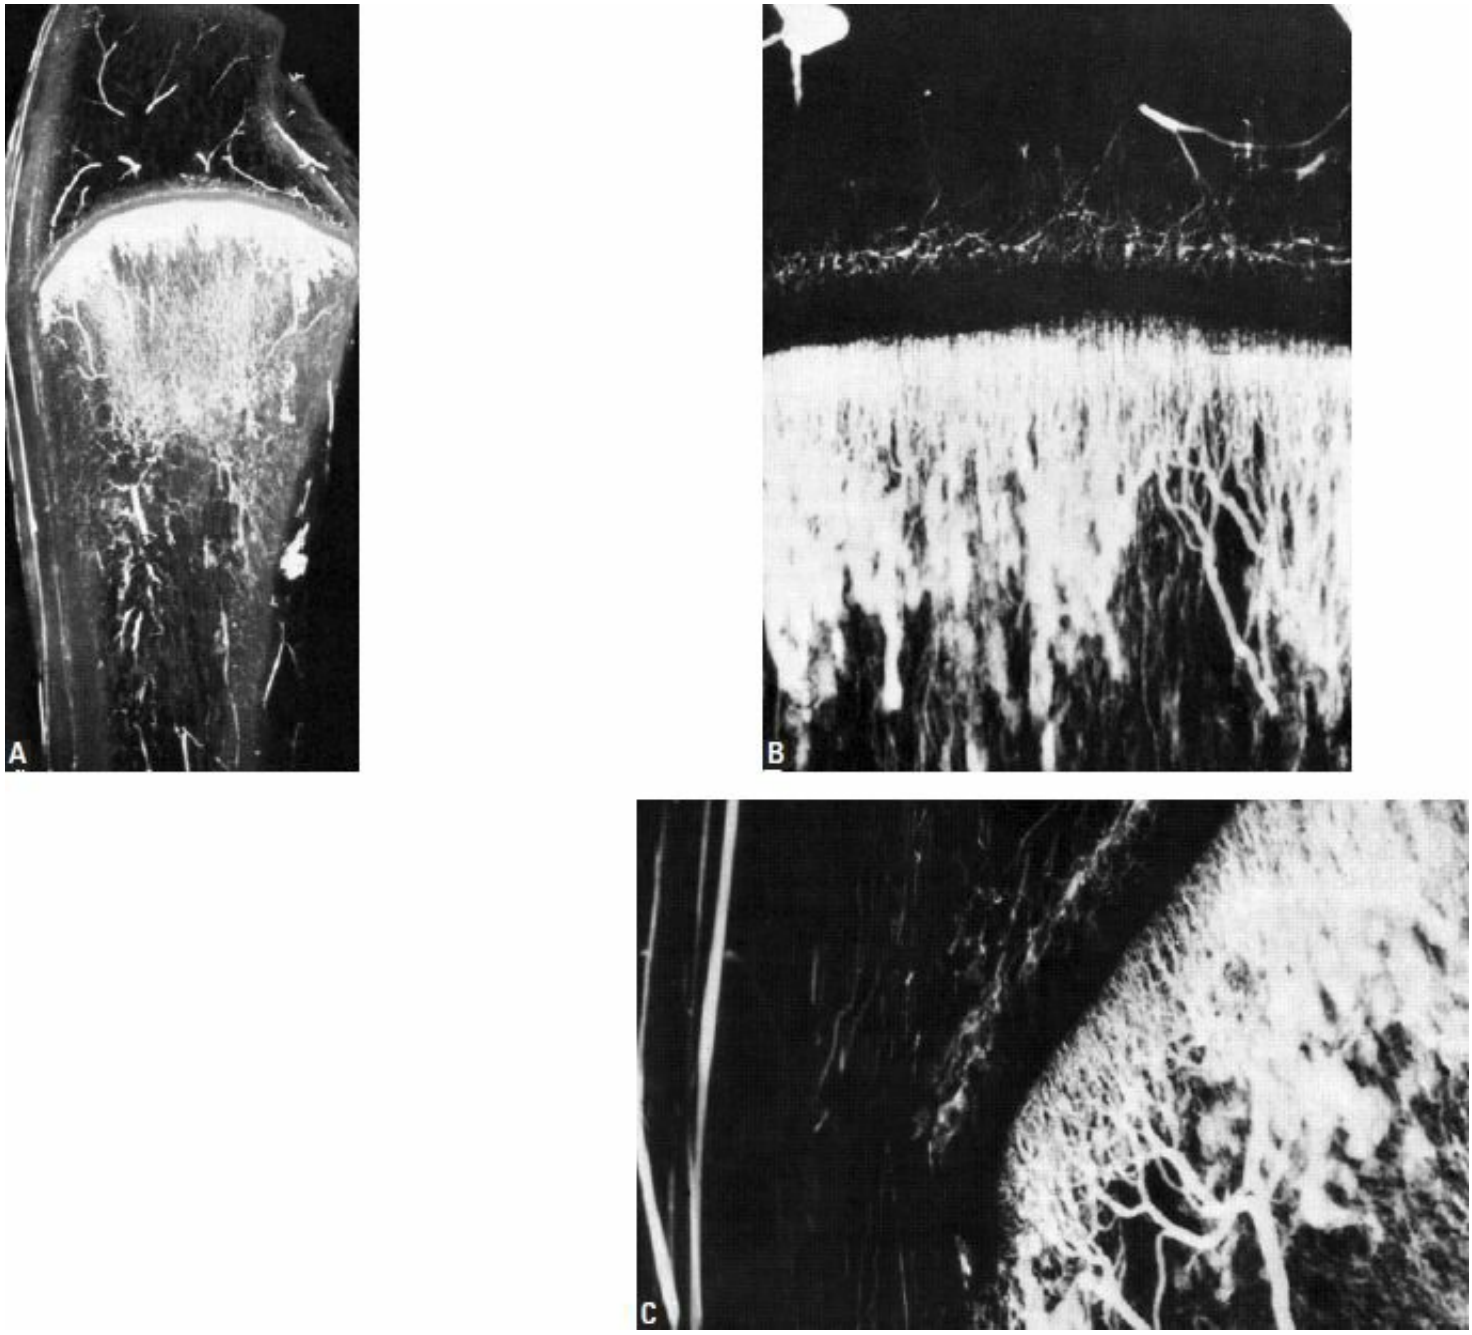

Figure 94-1. Microangiograms of normal immature canine radius. A. Note the extreme hypervascularity in the normal growing dog at the area where HOD occurs. B. Higher magnification shows vascular vessels make a 1800 turn at the physis, which slows laminar blood flow. C. Higher magnification demonstrates some vessels appear to be "open-ended"

to sinusoidal space of relatively stagnant blood.

Rapid endochondral bone formation ostensibly plays a role in HOD, based on the disease's location and the signalment of affected individuals. HOD occurs only in dogs with open physes. Furthermore, HOD tends to coincide with peak metabolic activity of the physis, i.e., at 3 to 5 months of age, in large and giant breeds, and more often in males.

Predispositions for breed and gender were determined for this chapter by a retrieval from the Veterinary Medical Data Base including all participating institutions and from 1994-2004 inclusively (Table 94-1). Seven breeds (Great Danes, Weimaraners, Labrador

retrievers, golden retrievers, German shepherd dogs, mixed breed dogs, and boxers) accounted for about two thirds (64%) of all reported cases. The 20 breeds listed in Table 94-1 accounted for almost 90% of all cases of HOD, the majority of which were large or giant breeds. Nineteen other breeds had 1 case of HOD each. The number of HOD cases per breed is influenced by the breed's popularity.

Great Danes and Weimaraners appear to be greatly overrepresented, whereas mixed breed dogs appear to be under represented, based on HOD cases/100,000 of the breed, which does adjust for breed popularity (calculated for breeds with > 1000 in the survey).

For example, the VMDB survey had 2460 Great Danes, 2510 standard poodles, and 2336 border collies, yet Great Danes had 1016/100,000 whereas the latter two breeds had 80/100,000 and 171/100,000 respectively. Weimaraners had 1279/100,000, while 4 breeds with a comparable number of individuals did not exceed 186/100,000. Mixed breed dogs were ostensibly under represented with only 17/100,000. Labrador retrievers (63/100,000) accounted for 30,248 individuals in the VMDB survey (~10% of all dogs), second only to mixed breeds with 63,974 individuals (Table 94-1). Two publications based on the VMDB, but using different methods and different years surveyed,

also reported a strong predisposition for Great Danes to have HOD, both in number of cases presented and at high risk when adjusted for breed popularity.[3,4] These articles also reported the 7 breeds listed above as having predilection for HOD between 1980-1989, and 1986-1995.[3,4]

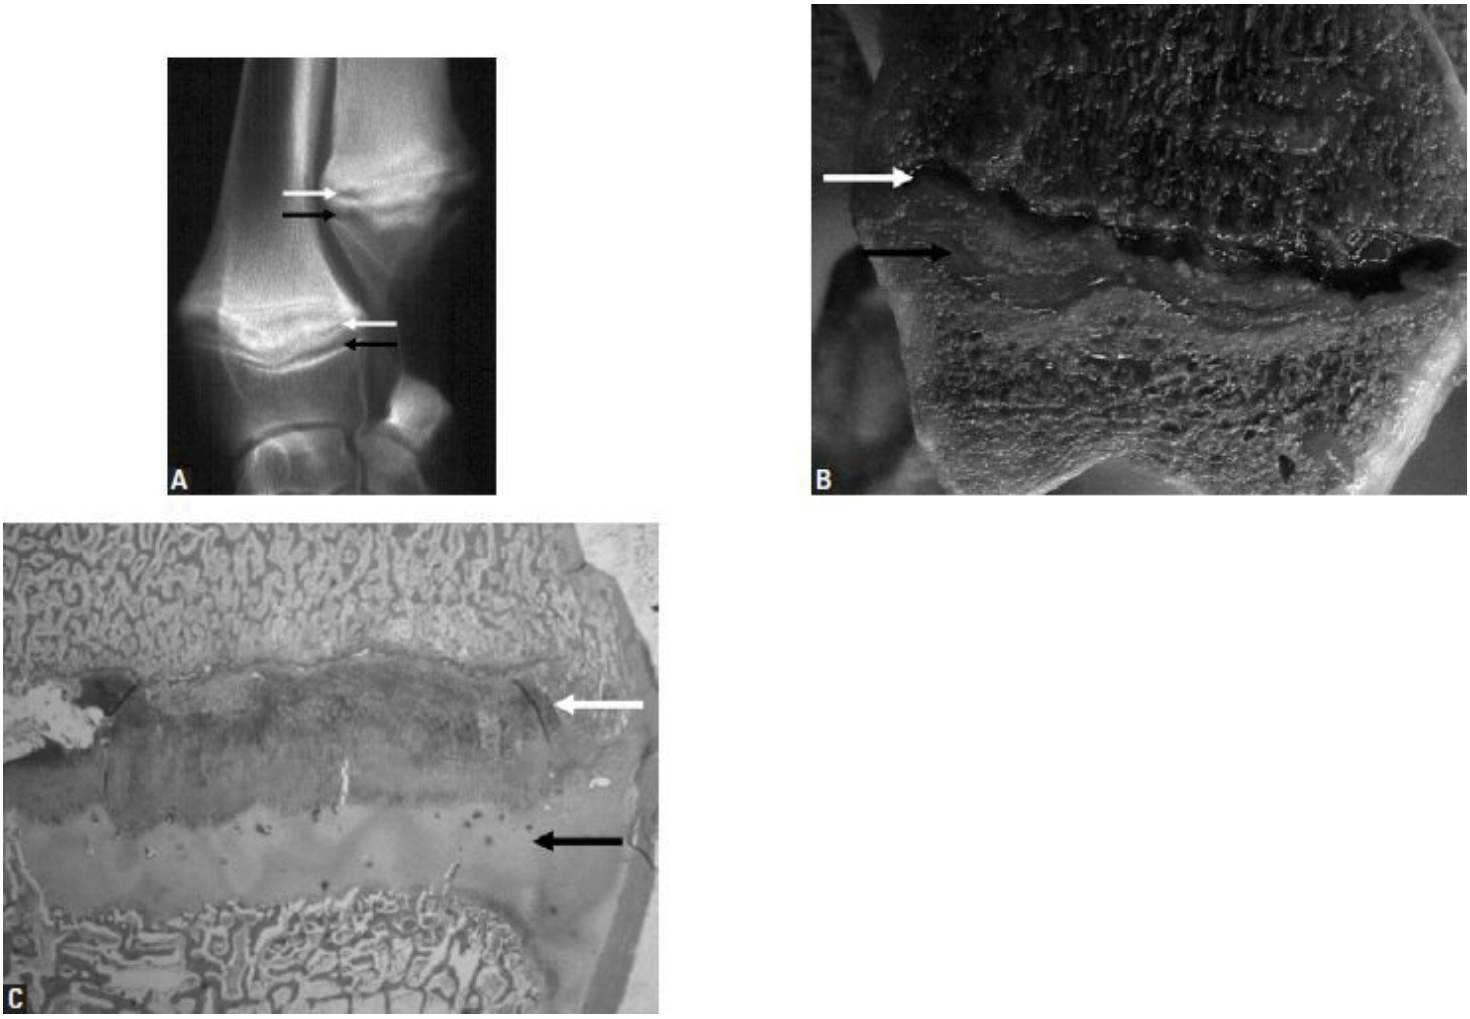

Figure 94-2. A. Pseudophyseal line (solid arrow) just proximal to the physis (hollow arrow) is pathognomonic for HOD. B. Gross sagittal section showing area of bone lysis (solid arrow) on the metaphyseal side of the physis (hollow arrow) which corresponds to the radiolucency of the pseudophyseal line. C. Microscopic section (low magnification/H & E stain) of same area showing necrosis of mineralized primary spicules and massive inflammation (solid arrow) adjacent to the normal physis (hollow arrow).

Table 94-1. Breeds with Multiple Cases of Hypertrophic Osteodystrophy from the Veterinary Medical Data Base, 1994-2004.

Breeds	Total Individuals	Total H.O.D. Cases	% of All H.O.D. Cases	H.O.D. cases/100,000 dogs
All Breeds	307,168	166	100.0%	54
Great Dane	2,460	25	15.1%	1,016
Labrador Retriever	30,248	19	11.4%	63
Weimaraner	1,485	19	11.4%	1,279
Golden Retriever	18,167	14	8.4%	77
German Shepherd	12,617	11	6.6%	87
Mixed Breed	63,974	11	6.6%	17
Boxer	5,002	7	4.2%	140
Irish Setter	820	6	3.6%	< 1,000 of breed
Rottweiler	9,287	6	3.6%	65
Border Collie	2,336	4	2.4%	171
Kuvasz	167	4	2.4%	< 1,000 of breed
Blue Heeler	1,641	3	1.8%	183
German Shorthaired Pointer	1,875	3	1.8%	160
Irish Wolfhound	514	3	1.8%	< 1,000 of breed
Anatolian Shepherd	82	2	1.2%	< 1,000 of breed
Bullmastiff	698	2	1.2%	< 1,000 of breed
Chesapeake Bay Retriever	1,075	2	1.2%	186
English Springer Spaniel	3,736	2	1.2%	54
Mastiff	1,122	2	1.2%	178
Poodle (Standard)	2,510	2	1.2%	80

Males are slightly more likely to develop HOD, which is irrelevant to diagnosis. However, predisposition toward males may relate to etiology, e.g., males tend to be slightly larger, hence endochondral osteogenesis is more rapid. The male:female ratio was 48:52 for the total population, and was

53:47 for cases with HOD in the VMDB 1994-2004 survey for this chapter. Most other reports indicate no gender predilection, or a slight predilection for males. A study of the VMDB study from 1980-1989 reported males were 2.3 times more likely to develop HOD than were females.[3]

Pathology

Inflammation is the overwhelming characteristic seen in HOD. HOD affects a transverse zone of the metaphysis immediately adjacent to the physis, which corresponds to the radiolucent line referred to as a pseudophyseal line (Figure 94-2). This diseased area consists of massive

infiltration of neutrophils and mononuclear cells, hemorrhage, osteoclastic resorption of trabeculae, fibrosis, and necrotic trabeculae (Figure 94-2C).[2] Osteoid, which should be developing on the calcified cartilage spicules, is absent.[2] In a few cases, the physis may be of irregular width or abnormally wide, owing to increased length of the zone of hypertrophy.[2] In more severe cases, subperiosteal hemorrhage beginning near the affected metaphysis can occur.

New bone formation can occur subsequent to subperiosteal hemorrhage, which elevates the periosteum (Figure 94-3). The new bone may persist as permanent

deformity (abnormally enlarged metaphyseal region, valgus deformity) (Figure 94-4). The extent of subperiosteal hemorrhage and periosteal new bone formation can be extensive, but this is rare. All bones that develop primarily via endochondral ossification (i.e., long bones, metacarpi) can potentially be affected by HOD.[2] Bone remodeling after HOD results in normal bones in the vast majority of cases. Necropsies performed on fatal cases have reported HOD lesions at the ends of other long bones, ribs, and vertebrae plus diffuse mineralization of pleura, pericardium, aorta, and lungs.[10] Hypertrophic bone lesions concurrent with classic HOD have also been reported in the axial

skeleton (calvarium, maxilla, mandible, scapula, vertebrae, costochondral junction of ribs, and ilial wing).[2,10,15,20,21]

Clinical Diagnosis

Signalment

HOD typically occurs in 3- to 5-month-old (range 2 to 8 months old), large-breed dogs of either gender.[1] The age at clinical presentation for HOD is typically younger than for other juvenile bone and joint diseases of large-breed dogs, although there is overlap.[1,2] Great Danes have a greater incidence of HOD than any other breed, and along with Weimaraners are at greatest risk when adjusted for

breed popularity (1016 HODs/100,000 Great Danes and 1279 HODs/ 100,000 Weimaraners). Great Danes, Weimaraners, Labrador retrievers, golden retrievers, German shepherd dogs, mixed breed dogs, and boxers account for the majority of HOD cases. Mixed breed dogs ostensibly have a lower risk, with only 17 HOD cases/100,000 mixed breed dogs (Table 94-1).

Figure 94-3. Severe case of HOD which, in addition to pseudophyseal line, has subperiosteal hemorrhage and subsequent osseous metaplasia.

Figure 94-4. Mature Great Dane with deformity owing to severe HOD as a juvenile, which included extensive periosteal hemorrhage and subsequent new bone formation.

Patient History

Dogs with HOD typically present with

either acute or peracute onset of signs, often of a day or less duration. Mild HOD cases occur, with less severe clinical signs and longer duration prior to presentation; however, mild HOD cases are uncommon in the author's experience. History typically includes malaise, pain (vocalization), reluctance or inability to stand, and anorexia. HOD is most often a single event in a dog's life, but can be episodic until skeletal maturity. Because clinical signs of HOD are obvious to owners, a diagnosis of HOD as a juvenile would be expected in the history of the rare adult dog with musculoskeletal deformity due to HOD (Figure 94-4).

Examination Findings

Bilaterally symmetrical swelling of the distal radius/ulna area is obvious via palpation and often readily visible (Figure 94-5A). Swelling of the distal tibia/fibula area may also be present but is typically less severe (Figure 94-5B). Other locations (see **Pathology**) are uncommon or unnoticed owing to less clinically detectable signs. Gentle palpation of the swollen areas results in a painful to extremely painful response, and excessive warmth of the area is often appreciated. Core body temperature in excess of 104° F is a consistent finding. Dehydration is often present as a consequence of malaise and reluctance or inability to stand. Arthrocentesis of the carpii will

yield inflammatory synovial fluid indicative of and owing to the extreme inflammation of the adjacent area; the adjacent joints (carpii and perhaps tarsii) are otherwise not involved in the pathophysiology. Arthrocentesis is not indicated but, if HOD is not recognized, may be performed owing to suspicion of infectious arthritis (infectious arthritis typically occurs in older dogs, affects one joint, and has less pronounced swelling, which is centered over the joint).

Figure 94-5. A. A 4-month-old Labrador retriever with HOD. Note the bilateral enlargement just proximal to the carpii. B. A 6-month-old golden retriever with atypical clinical presentation of HOD affecting the distal tibia more prominently than the radius/ulna.

Radiographic Findings

A pseudophyseal line is pathognomonic for HOD (Figure 94-2) and is located adjacent to and on the diaphyseal side of the physis of the distal radius and ulna (and distal tibia if affected). The radiolucency is due to the attending osteoclasia and osteonecrosis plus the increased fluid density of inflammation characteristic of HOD's pathophysiology. Subperiosteal hemorrhage and/or calcification may be observed in the

metaphyseal area adjacent to the pseudophyseal line (Figure 94-3). Pseudophyseal lines can potentially be identified on the metaphyseal side of any physis. Osteopathy at other locations (see **Pathology**) when classic HOD lesions are present may be identified radiographically.

Treatment

Treatments ranging from nothing to corticosteroids have been reported, depending on the severity of clinical signs.[2,21] Treatments limited to correcting diet, symptomatic supportive care, and/or nonsteroidal anti-inflammatory drugs tend to be unacceptably slow or completely

ineffective. The author prefers intravenous prednisolone sodium succinate (Solu-Delta-Cortef; Pharmacia & Upjohn Company, Kalamazoo, Michigan 49001 USA) because of its speed and reliability in reversing clinical signs. Other injectable corticosteroids are acceptable, including long-acting corticosteroids. However, it is often unnecessary to repeat even the short-acting prednisolone sodium succinate. Such short-term use of corticosteroids makes side effects unlikely. Nonsteroidal anti-inflammatory drugs may be adequate for mild cases, but are not preferred over corticosteroids.

Supportive care is indicated for severe

or refractory cases until clinical signs abate, including adminstering intravenous fluids, providing a well padded area to lie on, and alternating sides of recumbency at 2-3-hour intervals. Refractory cases may dictate forced feeding. Stress and anorexia may potentiate opportunistic bacterial infections, so blood cultures and/or antibiotics may be warreanted.[14] Stopping excessive dietary supplements is probably appropriate. Dietary supplementation with vitamin C and vitamin D may be contraindicated for HOD because of the possibility of promoting dystrophic calcification.[2,9,10]

Prognosis

HOD is a single-episode, completely reversible disease in the vast majority of cases. Relapses are infrequent and are treated in the same manner as described above. HOD only occurs while physes are present, primarily in rapidly growing dogs (a function of age and the breed's size). Cases that develop after 8 months of age are unknown in the author's experience. Death in treated cases is exceedingly rare. Euthanasia, although uncommon and usually unjustified, is the most common cause of death.

Deformity owing to HOD is rare (Figure 94-4), but when present is accompanied by lameness. Lameness is

caused by mechanical dysfunction, valgus deformity, and perhaps degenerative arthritis caused by the malformations (ostensibly not directly owing to HOD affecting the joint). The acute pain and other signs associated with HOD are not present in adult dogs with deformity caused by HOD.

Chapter 95

Panosteitis

Ron Montgomery

Panosteitis is one of the most common causes of lameness in young, large breed dogs, and is common worldwide.[1-20] Panosteitis is a self-limiting disease of the bone marrow of long bones in which the adipose and hematopoietic tissue is temporarily replaced by fibrous tissue.[1-20] Osseous changes also occur affecting the trabeculae, endosteum, and in more severe cases, the cortex and

periosteum.[4,15] Pain and lameness of the affected limb(s) are the consistent clinical signs that last 2 weeks or less.[4,15] Panosteitis typically recurs episodically, and is the classic cause of "shifting leg lameness."[4,15] It is unusual for panosteitis to affect the same bone twice (1%), but it can affect the same leg multiple times.[4] Clinical signs of panosteitis are uncommon after 18 months of age, although in one study 18% of the patients were older than 18 months.[4] Panosteitis spontaneously regresses, so treatment is usually limited to short-term administration of NSAIDs or corticosteroids as needed for adequate pain control.

Synonyms for panosteitis include:

enostosis, eosinophilic panosteitis, juvenile osteomyelitis, and canine panosteitis.[9,15] Enostosis is defined as "morbid bony growth of endosteum or within the medullary cavity."[14] This, along with fibrosis and destruction of normal medullary cellularity, describes the most common pathologic features of panosteitis.[4,15] Early reports of panosteitis were associated with eosinophilia, but subsequent reports indicate only 1% to 5% have eosinophilia.[4,9,15] Juvenile osteomyelitis is a misleading nomen (see etiology). Canine panosteitis is redundant because, to the authors knowledge, it has only been reported in dogs.[15] Panosteitis is the commonly used name. One sage author has

proposed that any name change should await definitive identification of the etiology.[4]

Panosteitis was first described in 1951 in young German shepherd dogs in Europe.[15] Panosteitis was reported in the United States in 1960, and was reported to spread rapidly.[15] However, the "spread" of panosteitis is thought to be a result more of increased awareness than epidemiologic spread.[15]

Etiology

The etiology of panosteitis is unknown.[2,15] Along with HOD and cranial mandibular osteopathy, panosteitis is a disease of unknown

etiology in juvenile dogs that is characterized by osseous proliferation and excessive bone remodeling.[9] However, panosteitis is a unique disease with characteristics unlike any other known disease.[4]

Proposed etiologies for panosteitis include bacterial infection, viral infection (e.g., distemper), genetics, stress, metabolic disease, vascular anomalies, allergy, hyperestrinism, parasite migration, autoimmune reaction after viral infection, and hemophilia.[3,13,15] Some reports of potential etiologies had convincing circumstantial evidence, but subsequent cases did not support the connection. Medical advances (e.g.,

improved microbiology diagnostics, parasite control, vaccines, etc.) have made several proposed etiologies unlikely. Other proposed etiologies remain possible, but proof is lacking. Attempts to isolate causative infectious agents from dogs with panosteitis have been unsuccessful.[20]

Bacterial infection was the originally proposed etiology.[15] Panosteitis was thought to be a result of purulent hematogenous osteomyelitis caused by streptococcus.[15] However, necropsy of 18 dogs failed to identify any bacteria at the lesions.[9,18] Other studies also reported negative cultures associated with panosteitis lesions.[4] The few blood and bone marrow cultures have

been negative for aerobic and anaerobic bacteria.[15] Histopathology consistently fails to implicate a bacterial etiology, and **WBC** counts are typically normal.[4,15] Antibiotic therapy is ineffective.[15] Furthermore, the long clinical history with panosteitis does not support a readily contagious agent as the sole cause.[1-20]

Viral etiology has been strongly supported by some authors,[9] and it remains a potential cause. Initial reports of panosteitis in 1951 roughly corresponded to the common use of live distemper vaccination, and a connection was suspected.[9] Most dogs are vaccinated against canine distemper and never develop

panosteitis. Nevertheless, some authors recommend vaccination with killed distemper or adenovirus vaccine rather than modified live which may still "allow transcription into messenger RNA."[9,19] Viral etiology of panosteitis was suggested by a report of successfully inducing panosteitis via medullary aspirates (filtered or unfiltered to remove bacteria) from dogs with panosteitis and injected intramedullary into unaffected dogs.[18] Panosteitis-like lesions were reported in the inoculated bones 2 to 3 weeks later and also developed in one bone of a marrow recipient that was not inoculated.[18] Transmission was reported to be more readily accomplished in male dogs;[18] however,

the validity of this report has been questioned.[15] Host response to inoculated foreign material likely caused the observed lesions. In addition, bone marrow and buffy coat samples from dogs with panosteitis were placed in kidney cell lines without cytotoxic effects, which would refute a viral etiology.[15,20] Reports of panosteitis with concurrent clinical findings of pyrexia, tonsillitis and leukocytosis also suggest viral infection;[9] however, the numerous cases of panosteitis without pyrexia, tonsillitis, and/or leukocytosis makes it likely that these signs were coincidental.

Genetic influence or cause of

panosteitis is a consideration because of predilection for certain breeds (Table 95-1). Panosteitis is most common in German shepherd dogs, but can occur in almost any large breed.[11] A purely genetic cause is doubtful because so many breeds are affected (n = 59 in our VMDB[1] survey. The VMDB does not give number of cases at every month, or year, of age. Cases within an age range are reported as "0-2 wks; 2wks-; 2mn; 2-6mn; 6-12mn; 1-2yr; 2-4yr; 4-7yr; 7-10yr; 10-; 15yr; and 15yr+." The number of cases for VMDB data in Figure 95-1 was placed at the center of the age ranges, with cases > 4 years old placed at 60 months on the chart).[9] One report stated that English pointer pups and

German shepherd pups were raised in the same pen, yet only German shepherds routinely developed panosteitis.[15] This limited report supports lack of an infectious agent even more than it suggests genetic influence.

Hemophilia A was reported in three male German shepherd dogs with panosteitis. Histopathologic and gross pathologic studies showed typical panosteitis plus hematomas. The signalment is the same for both diseases. However, the author stated it was “unwarranted to conclude that all dogs suffering from enostosis have bleeding disorders,” but suggested that “bleeding disorders should be

considered when discussing the etiology of enostosis."[13]

A frequent correlation exists between the first estrus and the first episode of panosteitis, which has led to speculation of hyperestrinism as a cause of panosteitis. Stress is thought to often precipitate panosteitis episodes.[15] Stress is a common factor in estrus, metabolic disease, allergy, parasite migration, and autoimmune reaction after viral infection, all of which have been speculated as causes of panosteitis. The inability to identify a single cause of panosteitis over 5 decades suggests that panosteitis may be caused by the confluence of multiple factors.

Pathology

Panosteitis is a self-limiting disease of the metaphysis and diaphysis of long bones of juvenile dogs, predominantly large breeds.[4,15] Panosteitis has never been reported to affect the epiphysis.[15] Panosteitis begins with loss of medullary adipose tissue, followed by fibrous proliferation, intramembranous ossification, osteoclastic removal of trabeculae, and in more severe cases, periosteal proliferation and cortical changes.[9,11,15] The process then regresses to normal or near normal architecture in the vast majority of cases.[15] This cycle is typically 60 to 90 days, but may be up to 190 days.[3,15,16]

Panosteitis has been characterized as a

disease of adipose bone marrow with secondary osseous effects.[15] As supportive evidence, the reaction to fractures and to irradiation to remove bone marrow are examples given of adipose bone marrow damage, with histologic and radiographic responses similar to panosteitis.[15] In addition, these events also follow a 90-day pattern.[15] Pathology begins with vascular leakage of protein-rich edema from congested medullary blood vessels and degeneration of adipose tissue.[3,9,11,15,16] Increased leucocytes and plasma cells are typically not observed.[2,4,9,17]

As the edema quickly organizes, fibroblastic reticular cells of bone

marrow stroma produce a marked and highly cellular fibrosis in the medullary canal.[2,4] Hematopoietic tissue is replaced by massive amounts of fibrous tissue, which is rich in fibroblast, osteocytes, osteoblast, and osteoclast, but which is usually not inflammatory.[4,9] Osteoclasts remove much of the preexisting trabeculae, which are replaced by formation of a haphazard trabecular system of woven bone.[4,9,15] These new trabeculae tend to be short and thick, and may obliterate the medullary canal.[9] In addition, areas of acellular calcified material and intramembranous woven bone are scattered throughout the medullary cavity.[2,4,15] High osteoblast and fibroblast activity also occurs

along the endosteum, and in some cases, the cortex and periosteum.[3,4,16] Cortical bone may be replaced with woven bone, especially around the nutrient foramen, and appear as a zone of decreased density.[9] Hyperemia of periosteum and adjacent soft tissues commonly provokes a mild periosteal reaction that may not be detected in most dogs, but can result in periosteal new bone a few millimeters thick.[2]

During late stages, woven bone trabeculae are replaced by fewer lamellar bone trabeculae, which tend to be fewer and thicker than normal.[15] Remnants of the pathologic changes may persist for months.[2,4] Components of the histologic appearance of

panosteitis are not unique or pathognomonic (e.g., also seen at borders of bone tumors and focal bone infections);[2] however, no evidence of inflammatory cell exudate, necrosis, or neoplasia exists.[2,17] The amount of remodeling varies between dogs and even between episodes.[9] Repeated attacks make marrow aplastic, with little to no hematopoietic bone marrow.[15]

Clinical Diagnosis

Signalment

The quintessential case of panosteitis is a 10-month-old male German shepherd dog. Although the signalment has strong predispositions, the range of

breeds and ages represented is broad. Ranges of and predispositions for age, breed, and gender were determined for this chapter by literature review and a retrieval from the Veterinary Medical Data Base, including all participating institutions, and from 1994-2004 inclusively. Cases per 100,000 were calculated for breeds with more than 1000 in the total population.

Age

The majority of panosteitis patients are 5 months to 12 months old; however, the age range is 2 months to 5 years old and older. The VMDB survey for this chapter had 662 cases of panosteitis, of which 380 dogs (57%)

were 6 to 12 months old.* This VMDB survey further indicated that 64% were ≤ 12 months old, and 89% were ≤ 2 years old (n = 590). The VMDB survey had a case at 2 months old, but also reported 14 cases between 7 years old to more than 15 years old (2%) (Figure 95-1).

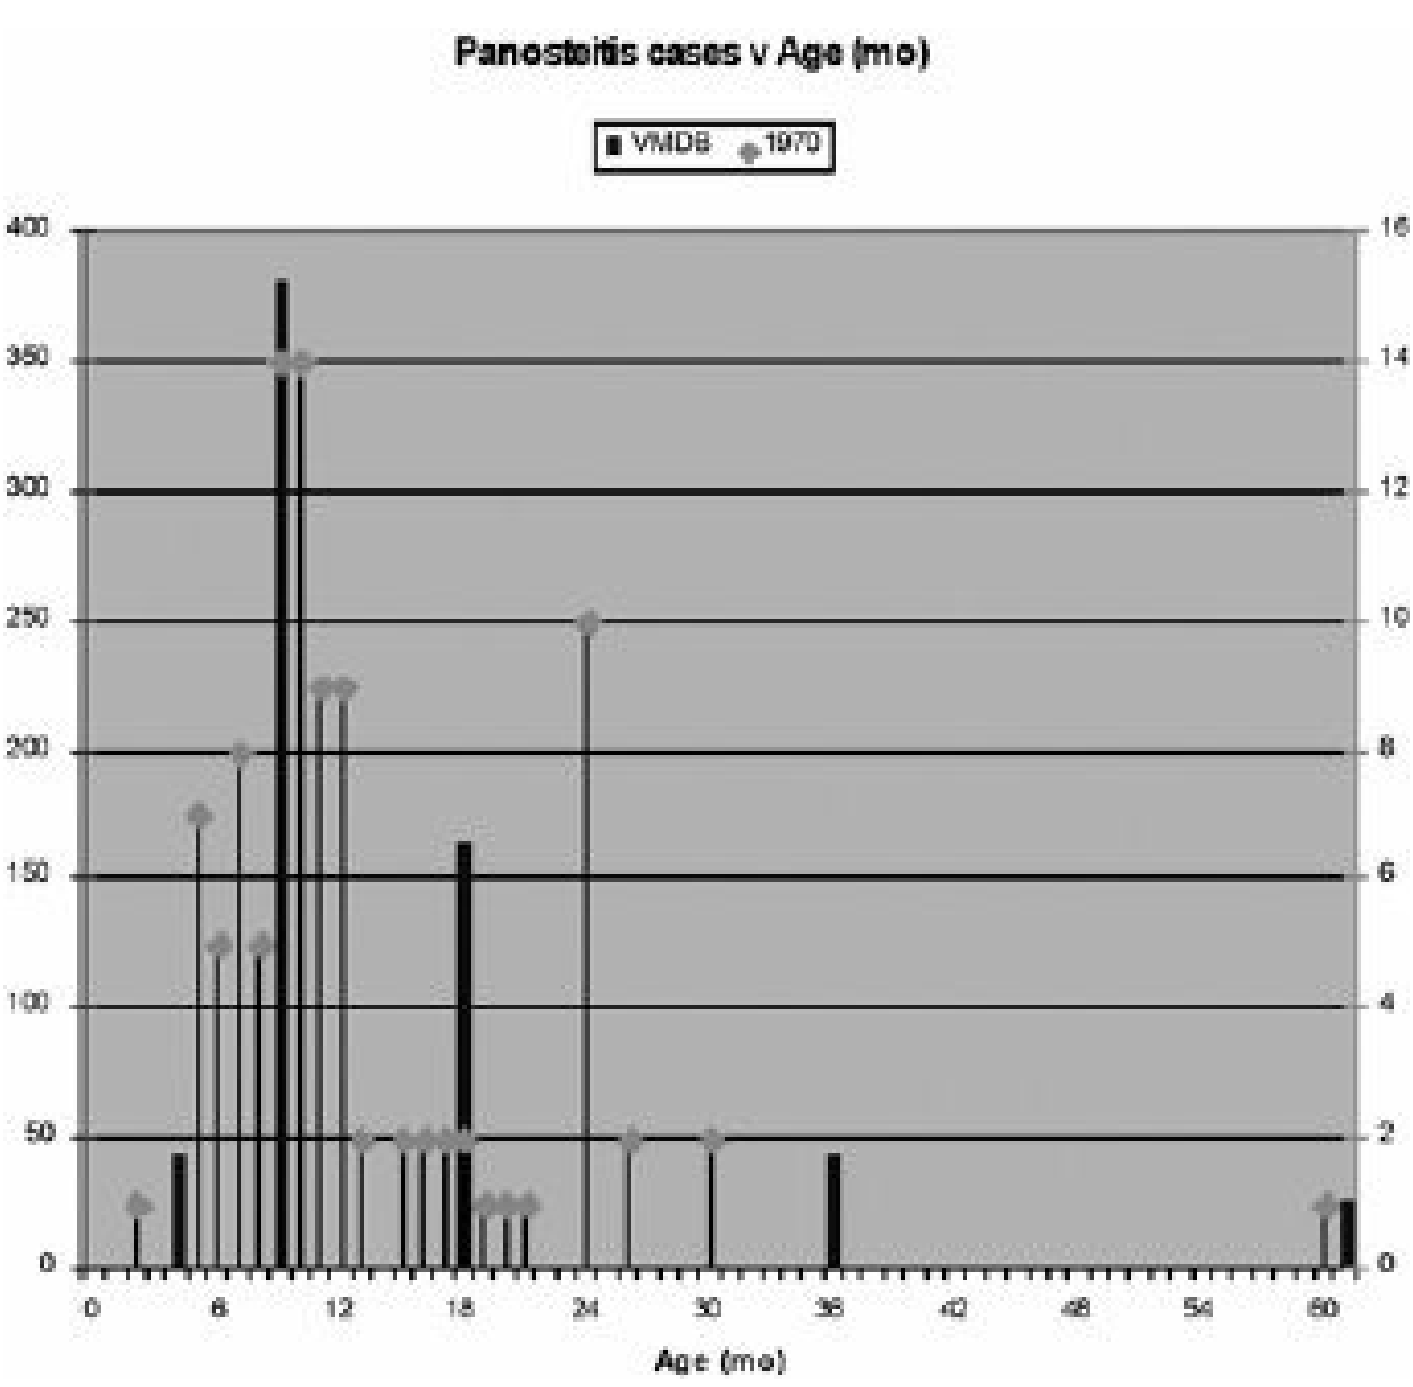

Figure 95-1. Age distribution of dogs with panosteitis from VMDB (662 dogs) and Bohning et al report (100 dogs) indicates panosteitis is predominantly a juvenile disease.

The literature cites age ranges typical

for panosteitis from 5 months to 12, 18, 20, or 24 months old.[3,4,11,15] An excellent 1970 study of 100 consecutive cases of panosteitis reported the peak occurrence was at 9 months and 10 months (n = 14 each month) (Figure 95-1). This study also reported that 71% were 5 to 12 months old, 82% were ≤ 18 months old, and 95% were ≤ 2 years.[4] The reported mean age at initial diagnosis was 12 months 2 weeks old, but the mean calculated from their data by this author was 10 months old.[4] Female German shepherds accounted for the single cases at 2 months and 5 years old.[4] The second youngest was 5 months old (n = 7), and the second oldest was 30 months old (n = 2).[4] Hence, the age

range or mean that constitutes "typical" depends on what percentage of cases is included. Results of the VMDB survey for this chapter and the 1970 study of 100 dogs with panosteitis are comparable (Figure 95-1).

Breed

German shepherds are most commonly afflicted with panosteitis, whether based on number of cases, % of all cases, or cases per 100,000 of the breed (Table 95-1). Our VMDB survey indicated German shepherds had the most cases (n = 259), the highest percentage of cases (39%), and the highest risk (2053 cases of

panosteitis/100,000 German shepherds). A 1970 study of 100 consecutive cases of panosteitis had 79% German shepherds.[4] An earlier VMDB survey is the only report with German shepherds having the second highest number of cases (n = 648); mixed breed dogs had the most cases (n = 945).[1]

Basset hounds had the second highest risk (1999 cases / 100,000 bassets), were tied for 3rd most cases with 53 (Table 95-1), and accounted for 8% of all cases in our VMDB survey. Labrador retrievers had the second highest number of cases with 72 and accounted for 11% of all cases, but had lower risk with 238 cases / 100,000 Labrador

retrievers (Table 95-1).

Eight breeds (Table 95-1) account for 81% of all cases of panosteitis in our VMDB survey. These or similar lists of prevalent breeds being previously reported.[1-4,8,9,15] Panosteitis occurred in 59 breeds in our VMDB survey, but 25 breeds had only 1 case. Twelve breeds, including mixed breeds, had fewer than 100 cases/100,000 of the breed, indicating low risk.

Table 95-1. Breed Prevalence of Panosteitis

Breed	# cases	% of all cases	# Cases / 100,000 of breed
All Breeds	666	100%	217
German shepherd	259	39%	2,053
Labrador retriever	72	11%	238
Bassett hound	53	8%	1,999
Golden retriever	53	8%	292
Mixed breed	53	8%	83
Rottweiler	22	3%	237
Great Dane	16	2%	650
Doberman pinscher	14	2%	297

81% of all cases are in one of these 8 breeds.

Small breeds with panosteitis had a total of 12 cases, or 1.8% of all dogs with panosteitis, in our VMDB survey. Cardigan Welsh corgis had the most cases with 3, blue heelers accounted for 2 cases, whereas the American cocker spaniel, Maltese, Norwich terrier, miniature schnauzer, Shetland

sheepdog, Pembroke Welsh corgi, and wirehaired pointing griffon had 1 case of panosteitis each. A previous study likewise reported 99% of dogs with panosteitis were large breed (miniature schnauzer was the exception).[4]

Gender

The predilection for males to have panosteitis is consistent and noteworthy. Our VMDB study showed males accounted for 70% of all cases of panosteitis, yet the overall population was only 48% males. Males account for 67% to 84% of all cases of panosteitis based on the literature.[3,4,6,11,12,15] One study of 100

dogs with panosteitis had 79% males, with German shepherds and 1 Saint Bernard accounting for all the females.[4] Panosteitis recurrences have been reported to be more predictable in males.[15] Females usually have the first episode of panosteitis associated with the first estrus.[15]

Patient History

An acute onset of mild to moderate lameness is the typical history, although severe lameness is also commonly reported.[4,9,11,15] Duration of lameness is up to 14 days (rarely, 3 weeks in severe cases), although lameness from panosteitis is often as short as 2 days.[2,4,9,15] Decreased

appetite and activity may be reported coinciding with the lameness.[2,3,4,11,12] Lameness is not affected by rest or exercise, but lameness usually increases during the first few days of an episode.[15] Pain is most likely from stimulation of pain receptors in the periosteum and/or owing to medullary hyperemia and congestion.[2] The initial episode of panosteitis most often affects a front leg, followed by rear leg, then returns to a front leg.[15] "Shifting leg lameness" is a classic historical description for panosteitis (see Prognosis for more detail).[2,3,9,11,12] Lameness can also affect one or more legs simultaneously or sequentially (Figure 95-2).[2,4,15] The initial onset of lameness owing to panosteitis is

uncommon (~10%) over 2 years of age (see Signalment for more detail).[4,15]

Examination Findings

Lameness ranges from mild to non-weight bearing.[15] Diagnosis is primarily via palpation.[15] Pain of affected bone is exacerbated and localized by deep palpation of the bone, with painful responses ranging from mild to severe.[2-4,9,11,12,15] Panosteitis tends to start at the nutrient foramen (approximately at the junction of the proximal third with the distal two thirds of long bones), but panosteitis can also occur elsewhere in the diaphysis or metaphysis.[4,9,12,15]

Care should be taken not to compress soft tissues, other than skin, to avoid a false positive response. Panosteitis is easily overlooked, and probably often, unless direct palpation of long bones is a routine part of the orthopedic examination for dogs at risk.[4] Muscle atrophy is rarely present owing to panosteitis because of its acute onset and short duration of clinical signs.[4] Confirmation via radiographs is recommended, although initial radiographs may only rule out other etiologies.[3,4] One report indicated minimal radiographic signs in 5 of 100 dogs with panosteitis.[4] In addition, radiographic signs of panosteitis may not be observed for 10 to14 days after onset of clinical signs, yet there may

be more sensitivity during the first few days (i.e., the patient may be more likely to be presented for examination).[2,12,15] A poor correlation exists between severity of clinical signs and radiographic changes with panosteitis.[2,4,9,11,15]

Figure 95-2. Radiographic signs of panosteitis evident in ihe humerus, radius and ulna of the same leg (arrows). The ulna has the earliest radiographic signs (see insert) of radiolucency at the endosteal surface.

The later radiographic sign, which is most often the first appreciated, is radiodensity of the medullary canal which is patchy (humerus) or generalized (radius).

The most commonly affected bone differs among reports. One report lists in descending order the ulna (42%), radius (25%), humerus (14%), femur (11%), and tibia (8%).[15] A different report lists the most commonly affected bones as the humerus (68%), femur (68%), ulna (54%), radius (27%), and tibia (24%).[4] The latter reported panosteitis of the contralateral bone in 31% (humerus) to 60% (tibia) of the cases, with only 1 of 100 dogs having panosteitis in the same bone more than once.[4] Different phases of the disease may be occurring

concurrently in the same dog at the same time (Figure 95-2).[15]

Concurrent orthopedic diseases are common (26% in one report)[4] in dogs with panosteitis.[2-4,9,11,15] Hence, a complete orthopedic examination, and radiography as indicated, should always be performed. Other findings are rare, but may include pyrexia, anorexia, tonsillitis, eosinophilia, muscle atrophy, and elevated white blood cell counts, none of which are unique to panosteitis.[3,4,9,15] Fever, anorexia, tonsillitis, and eosinophilia have each been reported to occur in only about 1% of panosteitis cases.[4,9] Most cases of panosteitis are in otherwise healthy dogs.[3]

Radiographic Findings

Four radiographic stages are associated with panosteitis, three of which are commonly observed. These stages are in reality a continuum of pathology, and various authors differ on the arbitrary points of delineating stages. The radiographic stages of panosteitis are 1) radiolucency of the medullary canal, 2) radiopacity of the medullary canal, 3) endosteal, cortical, and periosteal reaction, and 4) recovery.

The earliest radiographic sign of panosteitis is increased radiolucency of the medullary canal (Figure. 95-2).[4,8,12,15] The radiolucency corresponds to the early pathologic changes to medullary adipose tissue,

occurs early, and is rarely observed.[2,12,15] Radiolucency can be recognized 10 to 14 days after onset of clinical signs.[12] High quality radiographs are necessary to see changes that are present when clinical lameness begins.[9] If uncertain, additional radiographs should be taken 2 to 3 weeks later to show more obvious changes.[9]

The second stage of radiographic change, and typically the first observed, is increased density of the medullary canal in a patchy or mottled pattern, most frequently starting near the nutrient foramen (Figure 95-3).[4,11,12,15] The radiopacity corresponds to the pathologic changes of

proliferating stromal and adventitial cells in the medullary canal, and their subsequent calcification and intramembranous bone formation.[2,9,12,15] This radiographic stage typically begins 10 to 14 days after initial clinical signs.[15] Initially, these changes can be subtle (Figure 95-2).[9] Radiographic changes of this stage usually last 4 to 6 weeks.[4] Consistent early changes in this stage are loss of normal trabecular pattern, loss of medullary-cortical contrast (owing to increased medullary radiodensity), plus a variable number of intramedullary granular densities.[3,4,9] Early changes that may also be observed are accentuation of the trabecular pattern prior to or adjacent to increased

medullary radiodensity, and the cortical changes around the nutrient foramen which accentuates the foramen (Figures 95-2 and 95-3).[4,9] Midway in this radiographic stage the appearance is patchy or mottled, with sclerotic densities of various size and extent.[3] Granular density can be seen in the medullary canal early to late in this stage.[4] Homogenous radiodensity fills the medullary canal in some cases.[4] As this stage progresses toward the next, the endosteal surface becomes roughened, with coarse trabeculae extending into the medullary canal.[4] In about a third of cases, usually those with extensive medullary involvement, periosteal roughening is followed by periosteal new bone (Figure 95-4).[4]

The third radiographic stage, typically the second observed, includes endosteal, cortical and periosteal reaction (Figures 95-2 and 95-4). The radiographic signs of endosteal, cortical, and periosteal bone changes correspond to the pathologic changes described for the previous stage and formation of woven bone that progress to affecting cortical bone.[9] There is continuation of the obvious patchy or mottled radiodensity, and often an increased radiodensity approaching that of the cortex.[4,9] Endosteal roughening and then periosteal roughening may precede new bone formation, and a coarse trabecular pattern may be present.[9,15] Periosteal new bone is seen in 15 to 25% of

affected cases, ostensibly the more severe cases.[2] Periosteal and endosteal new bone yields the appearance that the cortex is thicker in that region and margins are indistinct.[9] Cortical bone may be replaced with woven bone in some areas.[9] Cortical osteoporosis, if seen, is due to enlargement of the osteonal canals.[15] Thickening of areas of the cortex occurs in about a third of cases.[4] Radiographic diagnosis of panosteitis is easiest in this stage.[4]

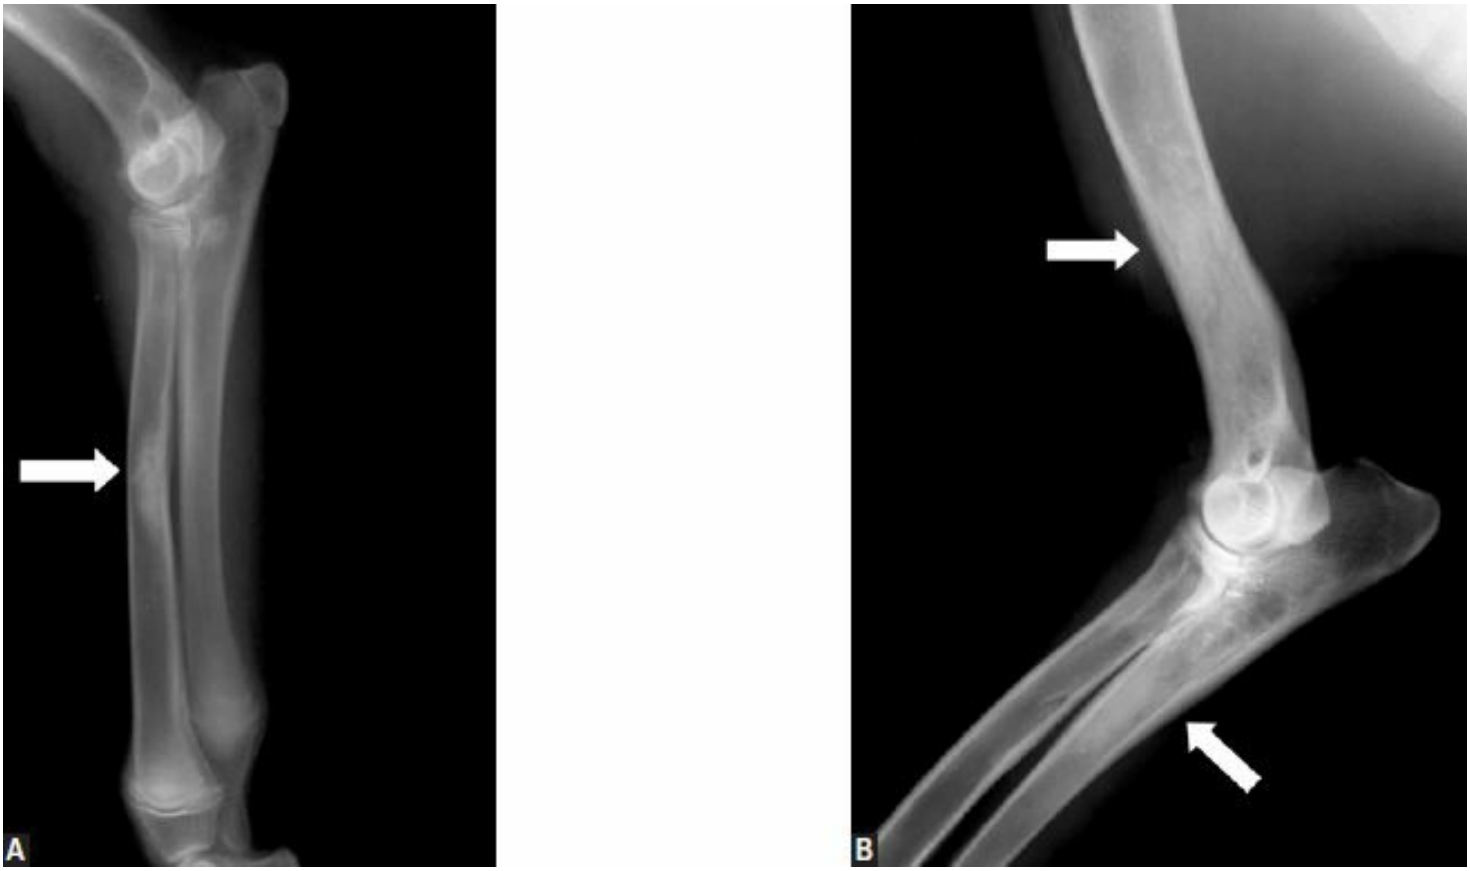

Figure 95-3A. Discrete patchy area of medullary radiodensity characteristic of panosteitis which is later than seen in the ulna of Figure 95-2.

Figure 95-3B. Radiodensity of the medullary canal of the radius is patchy and limited in area, compared to the more advanced humerus which is patchy but nearing gerneralized radiodensity of the entire diameter and over a larger area.

Figure 95-4A. Radiodensity of the medullary canal typical of panosteitis has progressed from patchy and limited areas, as seen in figure 95-3, to involve almost the entire length of this tibia.

Figure 95-4B. This tibia has medullary radiodensity plus the perioosteal proliferation, indicating even further progression compared to figures 92-94A. Not all dogs with panosteitis progress to this severity of radiographic changes.

The fourth radiographic stage,

typically the third observed, is recovery. The radiographic signs correspond to the reversal of the pathologic changes, plus evidence of residual changes. These changes include a decreased number of granular densities, return to normal medullary appearance, and cortical and trabecular remodeling, with regression toward the nutrient foramen (reverse order of formation).[2,3] The medullary canal progresses to a more normal appearance over a 2- to 3-month period.[9] Regression of bony changes is via osteoclastic removal of trabeculae that do not serve a biomechanical function, and requires months.[2] Persistent changes can include slightly increased density of the

medullary canal, granular densities, fewer and coarser trabecular bone, roughened endosteum, and increased cortical thickness (Figure 95-5).[2,4]

The severity and extent of radiographic changes with panosteitis varies greatly.[2,4,15] The overall cycle of radiographic changes for a given bone with panosteitis is typically 60 to 90 days, but may last up to 190 days.[3,15,16] Different stages of panosteitis often occur concurrently in the same dog at the same time (Figure 95-2).[2,4,15] One study reported radiographic changes consistent with panosteitis in 2 or more bones at the same time in 24 of 25 dogs that had radiographs of all limbs.[4] As many as 7

bones have been affected at one time by panosteitis.[15] Radiographic changes owing to panosteitis often center around the nutrient foramen.[4,9,12,15] One report stated that changes affect the diaphysis only in 75% of dogs, with extension to include the metaphysis in 25% of dogs.[4] There has not been a report of panosteitis affecting the epiphysis.[15] Panosteitis affecting the same bone twice is rare (1%).[4] Repeat episodes of panosteitis can result in bones becoming cuboidal and "lose their graceful appearance" owing to repeated remodeling.[15] Although panosteitis almost always affects the long tubular bones, 1 dog was reported to have radiographic lesions typical of panosteitis in the ilium.[4]

Figure 95-5. Fewer and courser trabeculae are long term radiographic indicators of prior panosteitis in this humerus. NOT all episodes of panosteitis have as severe, or any, chronic radiographic changes. These changes are seen after the clinical signs of panosteitis.

Treatment

Because panosteitis is self-limiting,

with clinical signs limited to lameness because of pain, appropriate therapy is typically limited to NSAIDs. Treatment can be on an as-needed basis for the duration of clinical signs, which may be a short as 2 days to as long as 3 weeks.[2,4,9,15] Aspirin has been frequently recommended, but other NSAIDs would also be appropriate.[4,9,15] Corticosteroids may be used in refractory or severe cases.[2,15] Other analgesics may be used but are rarely necessary.[15] Exercise or rest does not affect the severity of lameness,[15] although two reports suggest restricted activity as part of the treatment.[2,9] Concurrent orthopedic problems or other signs (e.g., anorexia) are treated separately.[2,3]

Other treatments that have been tried with minimal success include antibiotics, vitamin and mineral supplements, dietary changes, and irradiation of diseased bone and adrenal glands.[15]

Prognosis

The prognosis for a given episode of panosteitis is excellent. Lameness and pain last from 2 days up to 3 weeks, with or without treatment.[2,4,9,11,15] However, pain may be severe, and even less than severe cases warrant pain relief. Medication such as NSAIDs or corticosteroids almost always provide excellent relief from clinical signs. The severity of attacks tends to

decrease as age increases.[15]

The long-term prognosis for panosteitis is also excellent.[2,4,9,11] However, recurrences are common in dogs up to about 18 months old.[2-4,15] Approximately 5 to11% of panosteitis cases occur in dogs over 2 years old (Figure 95-1).[4] Although it is rare for panosteitis to afflict the same bone a second time (1%), panosteitis will often afflict one or more other long bones in the same or different legs.[4]

The initial episode of panosteitis most often affects a front leg, followed by rear leg, then returns to a front leg.[15] “Shifting leg lameness” is a classic historical description for

panosteitis.[2,3,9,11,12] In many cases lameness shifts every 2 to 4 weeks, with lapses of up to 1 month or more.[4,9,15] The frequency of recurrence has been reported to be more predictable in males.[15] It is not uncommon for a dog to have 1 or just a few episodes, rather than repeated and frequent episodes up to age 18 to 24 months; at least not enough episodes affecting the dog for veterinary attention to be sought. In a report of 100 consecutive dogs with panosteitis, multiple leg involvement occurred in 49%, and multiple bone involvement in 53%.[4] Multiple leg involvement was equally distributed between front and rear legs.[4] Lameness can also affect one or more

legs simultaneously.[4] The frequency and severity of clinical lameness tend to decrease with age.[15]

Chapter 96

Craniomandibular Osteopathy

Ron Montgomery
Brenda Austin Simmons

Craniomandibular osteopathy (CMO) is an uncommon inflammatory disease of juvenile dogs characterized by bone proliferation and remodeling of the mandibles.[1-31] The temporomandibular joint is often affected, and involvement (thickening) of other bones of the cranium is common. Pain associated with CMO is typically moderate to severe. Difficulty eating,

deformity, and/or pain when opening the mouth are common presenting complaints. West Highland terriers and Scottish terriers are the predominant breeds affected. Long bones may also infrequently be affected, with or without clinical signs of lameness and/or pain with palpation. CMO typically regresses as normal bone formation ends at about 1 year of age.[1]

CMO was first reported in 1958 in five West Highland terriers, and in 1959 in West Highland white and Scottish terriers.[1,2] Clinical and radiographic diagnosis was initially neoplasia. However, histopathology indicated non-neoplastic mandibular periostitis with osseous and chondromyxomatous

proliferation.[1] Synonyms for CMO include mandibular periostitis, calvarial hyperostosis, idiopathic hyperostosis of the calvaria, and lion jaw.[1,3,4]

A Veterinary Medical Data Base (VMDB) survey was perform for this chapter from 1994-2004 and reported a total of 29 CMO cases. Review of the literature reported 65 CMO cases,[4-24] some of which predated the years of the VMDB survey whereas others may have also been included in the VMDB study. In addition, cases have been reported in the literature that may be atypical CMO cases. Pastor et al reported a disease he termed calvarial hyperostotic syndrome (CHS).[4] Five

unrelated bull mastiff males between 5 and 9 months old had asymmetrical bony proliferation of the frontal, temporal, and occipital bones, with one dog having bony proliferation of the tympanic bullae.[4] All dogs with CHS recovered. Trowald-Wigh reported 12 Irish setters with confirmed canine leucocyte adhesion deficiency (CLAD).[23] The pathogenesis of CLAD includes absence of granulocyte adhesion proteins and the inability of neutrophils to migrate from blood vessels into the tissues.[23] Similar diseases have been reported in humans and bovines.[23] CMO-like lesions were reported; however, CLAD lesions also include various osteopathies of long bones, purulent infections, and multi-

organ involvement. These 12 Irish setters with CLAD were between 8 weeks and 15 weeks old at the onset of clinical signs, and all were euthanized owing to the severity and recurrence of clinical signs.[23] Two litters each had 4 CLAD dogs, the remaining 2 were unrelated.[23]

Etiology

CMO's etiology is unknown.[1,27-31] Etiologies considered include congenital,[1,25] and infectious,[21,26] and inherited.[1,25] Neither case histories nor the literature indicate that CMO is present at birth, which by definition means it is not a congenital disease.[27] Rather, CMO ostensibly develops at 3

to 9 months of age (Figure 96-1). Infection does not appear to be the cause of CMO. Microscopic evaluation of affected tissues does not show infectious organisms. Bacterial cultures (n = 26) from 4 West Highland white terriers were negative.[22] Antibiotics used in CMO cases have not be reported as an effective treatment.[1-31] Schulz reported E. coli was cultured from a boxer's mandible affected with CMO,[13] which was probably incidental. The predominance of CMO cases occurring in terriers, especially West Highland and Scottish, strongly suggest a genetic etiology. Conversely, CMO occurring in multiple other breeds, including some large breed dogs, causes some doubt regarding a genetic

etiology, assuming these other breeds were pure bred and that CMO was not confused with a similar disease.

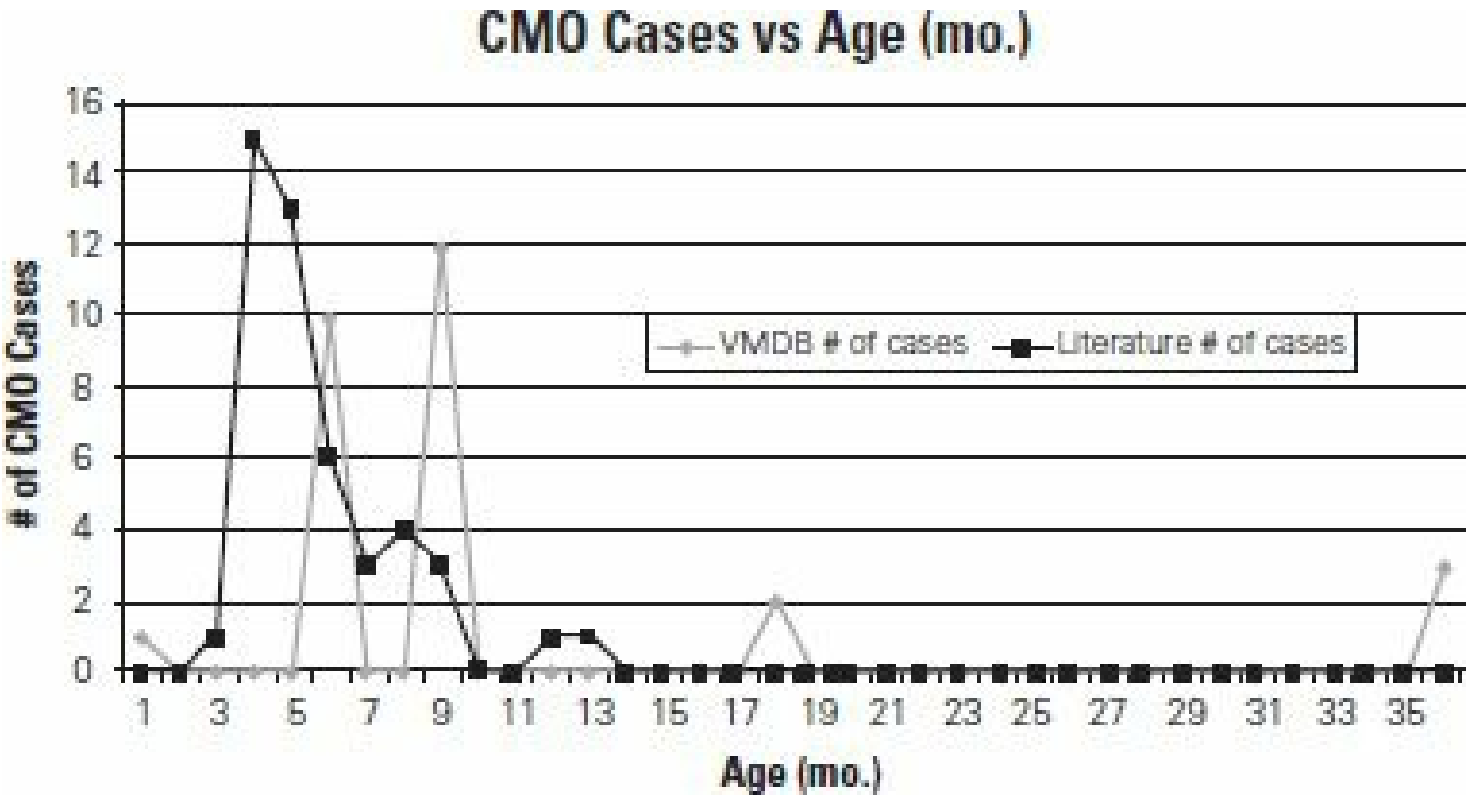

Figure 96-1. The VMDB does not give number of cases at every month, or year, of age. Cases within an age range are reported as "0-2 wks; 2 wks-; 2 mn; 2-6 mn; 6-12 mn; 1-2 yr; 2-4 yr; 4-7 yr; 7-10 yr; 10-; 15 yr; and 15 yr+". The number of cases for VMDB data in Figure 96-1 was placed at the center of the age ranges, with cases > 4 years old placed at 60 months on the chart. 8 West Highland terriers with CMO reported by Riserx did not report age, but were included in breed

assessments.

Pathology

Normal lamellar bone is removed by osteoclasts and may be accompanied by massive numbers of inflammatory cells (predominantly lymphocytes, plasma cells, and neutrophils). Muscle and connective tissue along the normal bone surface are also destroyed by this pathologic process. New bone formation is coarse and/or woven, and extends well beyond the normal periosteum. The marrow spaces are filled with highly vascular fibrous tissue, and occasionally, islets of cartilage. The new bone can have a "mosaic pattern…indicating the sporadic and rapid deposit and

resorption of the abnormal bone."[1] Similar pathologic changes can be observed with some osteosarcomas, hyperparathyroidism, and callous formation.[1] The pathologic changes vary with the bone involved. Mandibular changes are characterized by large, irregular exostosis, whereas changes of the calvarium and tympanic bullae most often result in thickening while maintaining a relatively smooth inner and outer surface.[1]

Gross changes are readily apparent, especially of the mandibles (Figure 96-2). Visible and palpable enlargement of the mandibles is hallmark for CMO. Bilateral symmetry is the rule, but there are many exceptions. The

tympanic bullae are usually involved, with enlargements by 2 to 3 times normal size caused by massive amounts of new bone.[1] In addition, variable amounts of fusion between the enlarged tympanic bullae and the angle of the mandible are common.[1]

Figure 96-2. Gross bony changes owing to CMO. Note the large amount of irregular bony proliferation of the mandibles. In some cases, the tympanic bullae, temporomandibular joint, and flat bones of the calvarium may also be affected.

Clinical Diagnosis

Signalment

The quintessential case of CMO is an intact male Scottish terrier or West Highland white terrier up to 12 months old.

Age

Dogs aged up to 12 months accounted for 82% of the cases in our VMDB survey (Figure 96-2). The age range was from 0 to 2 weeks to 15 years old (one dog in each) (Figure 96-1). CMO is generally considered a juvenile disease, with cessation of clinical signs with osseous maturity. Because similar pathologic changes can be observed

with some osteosarcomas, hyperparathyroidism, and callous formation,[1] misdiagnosis is a possibility for the 5 mature dogs indicated to have CMO out of a total population over 300,000 dogs.

The age of the 65 dogs with CMO reported in the literature ranged from 3 months to 13 months old at presentation, plus 1 dog at 24 months old with bone proliferation of the frontal sinus and polyarthritis.[4-24]

Breed

West Highland white terriers and Scottish terriers were by far the most common breeds to have CMO, and had the greatest risk per 100,000 of the

breeds (Table 96-1). Although West Highland white terriers had the most cases of CMO, Scottish terriers had the highest risk based on number of CMO cases per 100,000 of the breed. Mixed breed dogs had the lowest number of cases (n = 2) and the lowest risk (2 CMO cases / 100,000 mixed breed dogs). However, the risk for CMO overall was low, as indicated by only 9 CMO cases per 100,000 of all breeds. In addition, the low number of CMO cases per 100,000 for the breeds at highest risk was also low compared witih risk factors for other diseases (i.e., hypertrophic osteodystrophy and panosteitis). Terriers accounted for 16 of the 29 CMO cases (55%) reported in the literature.[4-24] However, large breed

dogs such as the bulldog, bassett hound, Weimaraner, bull mastiff and Great Dane were also reported to have had CMO (Table 96-1).[4-24]

Table 96-1. CMO Cases from VMDB Survey 1994-2004 and Reported in the Literature

Breeds	total of Breed	CMO Cases	per 100,000	Literature
All Breeds	307,168	29	9	
West Highland White Terrier	2,039	8	392	35
Scottish Terrier	1,374	6	437	16
Labrador Retriever	30,248	4	13	1
Bulldog	2,808	3	107	0
Cairn Terrier	957	1	*104*	2
Boston Terrier	2,465	1	41	1
Basset Hound	2,651	1	38	0
Welsh Corgi, Cardigan	569	1	*176*	0
Mixed Breeds	63,974	1	2	0
Weimaraner	1,485	1	67	0
Bullmastiff	698	1	*143*	1
Great Dane	2,460	1	41	1
English Mastiff				1
Doberman Pinscher				2
Catahoula				1
Redbone Hound				1
Boxer				1
Shetland Sheepdog				1
Pyrenean M				2

The numbers italicized under "per 100,000" indicates < 1,000 of breed in the VMDB survey.

Gender

Males are more likely to have CMO based on the VMDB survey for this chapter (Table 96-2). The male:female ratio was 48:52 for all dogs, while those with CMO had a male:female ratio of 64:36. A strong predilection

appears to exist for intact dogs to have CMO (85%) (Table 96-2). However, the vast majority of dogs with CMO were 12 months old or younger, and for all dogs up to 12 months old the percentage of intact dogs (76% of males and 69% of females) was closer to the percentage of dogs with CMO that were intact.

Patient History

CMO has an insidious onset. The dog's presenting complaint(s) are most often pain when a person opens the dog's mouth and decreasing ability to open the mouth (decreased range of motion of the temporomandibular joint). More advanced cases also have visible

enlargement of the mandible, decreased eating, and perhaps weight loss. Other dogs of that litter may also be affected.

Table 96-2. Number of Dogs with CMO Based on VMDB Survey

	All dogs	CMO cases	Ratio All	Ratio M:F
Male	150,665	18	48	64
Female	161,119	10	52	36
	All dogs	**CMO cases**	**% of All Dogs**	**% of CMO**
Intact	121,331	23	39	85
Neutered	190,267	4	61	15

Whether or not a female was spayed was unknown for 186 dogs of the total population, and for 0 cases of CMO. A dog's gender was unknown for 1700 dogs of total population and for 1 case of CMO. For dogs ≤ 12 months old, 76% of males were intact and 69% of females were intact.

Examination Findings

The presenting complaints are confirmed. Palpation of the mandibles can reveal an irregular surface and enlargement. The animal has pain on attempting to open the mouth and an inability to open the mouth to a normal widtheven with sedation/anesthesia. A complete examination should be performed to rule out retrobulbar abscess, fracture, and oral lesions (e.g., tooth disease, foreign body, etc.).

Radiographic Findings

Enlargement of the mandibles is the earliest and most obvious radiographic abnormality (Figure 96-3) and may be

extreme in advanced cases. Enlargement of the tympanic bullae is predominantly via thickening of the bony wall and may be several times normal size. Radiodensity and/or bone proliferation between the tympanic bullae and the angle of the mandible may be observed. Flat bones of the calvarium (especially the frontal and parietal bones) may be markedly thicker, but tend to maintain smooth cortical surfaces.

Figure 96-3. Radiographs of CMO. Note the large amount of bony proliferation of the mandibles. The tympanic bullae, temporomandibular joint, and flat bones of the cranium may also be involved in some cases.

Treatment

Corticosteroids titrated against the

clinical signs are the primary treatment for CMO. Various analgesics have also reportedly been used for pain control; however, aspirin has been specifically and repeatedly reported to be ineffective. Antibiotic use has been reported infrequently and shown to be without notable effect. Soft, high-caloric diets are indicated to decrease the pain associated with eating and to maintain body weight. Supportive care, especially fluids and caloric supplementation, may be necessary. Physical therapy aimed at maintaining temporomandibular range of motion has not been reported, but could potentially be beneficial.

Prognosis

Outcome of the disease in 42 dogs has been reported in the literature. Thirty (30) dogs survived, ostensibly with resolution of the CMO lesions. Age at resolution was given in only one dog, at 11 months old.[5] Five dogs with CMO were euthanized.[6-9] Two dogs died, one during the first night of hospitalization and the other after 9 weeks of treatment.[10,14] Fourteen other dogs had follow up examinations between 10 weeks and 9 years after initial treatment, and had lesions that were ostensibly either resolved or resolving.[6,8-13] Insufficient information exists to determine whether prognosis is related to age at onset, age at which

treatment begins, severity of clinical signs at the time of initiating treatment, speed of progression of clinical signs, or other factors.

Chapter 97

Canine Angular Limb Deformities

Denis Marcellin-Little

Epidemiology

Angular limb deformities are common in dogs. They are seen primarily in dogs of chondrodystrophic breeds. Chondrodystrophic dogs have a genetic make-up that leads to variable impairment of the growth of their appendicular skeleton and skull.[1] Their axial skeleton is spared. Most

chondrodystrophic dogs have symmetrically deformed forelimbs and pelvic limbs. The forelimbs of chondrodystrophic dogs initially and primarily have a premature closure of the distal ulnar physes that may lead to a valgus (i.e., abaxial or lateral) deformity, caudal angulation, and slight external rotation of the distal portion of the antebrachia originating at the distal radial physes. Most likely as a consequence of that primary closure, chondrodystrophic dogs often have a varus (i.e., axial or medial) deformity originating at the proximal radial physes (Figure 97-1). The pelvic limbs of chondrodystrophic dogs also have angular and rotational deformities, specifically varus and

caudal angulation and external rotation originating from the proximal portion of the tibiae, coxa vara, and medial patellar luxation. Breeders and owners of chondrodystrophic dogs anticipate a certain degree of curvature in the limbs of their dogs and they may not seek medical care to treat the consequence of these deformities unless the dogs are limping consistently.

Angular deformities occur as a result of injuries, most often injuries to growing long-bone physes but also as a result of fracture malunions. Most angular limb deformities or traumatic origins affect the antebrachium. These deformities represent approximately 1% of the

orthopedic problems of dogs,[2] and may include valgus or varus angulation of variable severity. The purpose of this chapter is to review the assessment, therapeutic decision-making, and surgical management of canine angular limb deformities, particularly antebrachial deformities.

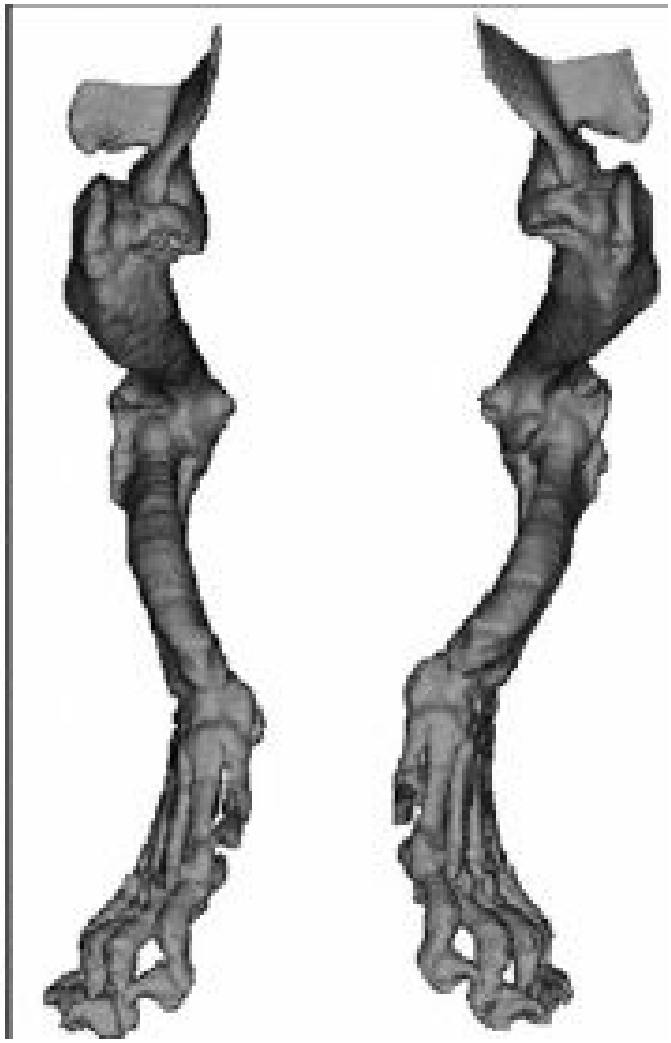

Figure 97-1. This 1-year-old basset hound (left) has a deformity of both forelimbs that includes valgus angulation of the distal portion of his antebrachia and varus angulation of the proximal portion of his antebrachia. These angulations are visible on a 3D rendering of his forelimbs that is based on a computed tomography scan (right).

Preoperative Assessment

The preoperative assessment of patients with limb deformities is complex and includes a variety of factors: limb use and cosmesis, range of motion, static rotation, pronation, supination, mediolateral (ML) and craniocaudal (CC) angulation, length deficit, joint effusion, pain, and osteoarthritis (OA) in the joints adjacent to the deformity. It is important to proceed with a complete

assessment of deformity in patients as rapidly as possible because growth and time will negatively impact the deformed limb. In a study, the average delay before the time of a deformity was noticed and the time corrective osteotomies were performed was 18 weeks.[3] Some clinicians have the misguided impression that monitoring (i.e., reevaluating every few weeks) a deformity is a valid form of management. This form of conservative management is rarely medically advisable.

The owners' motivation when bringing in patients with limb deformities is primarily enhancing limb use and function, but also enhancing overall

mobility, alleviating limb pain, and improving limb cosmesis. Limb use, cosmesis, and overall mobility may be graded (Table 97-1).[3] It is critically important to make sure that these grades are agreed upon by owner and clinician to avoid discrepancies in perceived severity of the problem. Some owners underestimate the severity of the problem, others overestimate it. Angular limb deformities, for example, tend to be noticed later in life and underestimated in dogs with long or curly hair compared with dogs with short hair. Owners may underestimate the severity of a developmental humeroradial (caudolateral) luxation in a young puppy because they may

perceive limb use as acceptable. Some owners are primarily motivated by limb cosmesis of their pets (i.e., show dogs). The optimal management of limb deformities will improve both function and cosmesis of treated patients.[3] Poor limb use per se is not a clear indication for surgery or does not mean that one specific surgery should be performed. For example, a dog with an antebrachial deformity and a developmental humero-ulnar luxation leading to absence of ulnar trochlear notch may have poor limb function but may not be a candidate for a corrective osteotomy. A dog with severe OA combined with an angular limb deformity may not function better if the deformity is corrected because of

the presence of OA-induced pain.

All measurements from the affected limb should be compared with measurements from the opposite limb, with measurements of dogs of similar age and conformation, or with values reported in the scientific literature.[4] The range of motion of affected limbs should be carefully assessed before surgery, and the cause of any anomaly of motion should be understood before therapy is initiated (Figure 97-2).[4] Range of motion is an important aspect of the assessment of the affected limb because loss of joint motion may have a profoundly negative impact on limb use. For example, a dog with loss of carpal extension may not be able to

bear weight on his forelimb. Loss of motion is common with developmental antebrachial deformities, particularly loss of carpal flexion as a result of a developmental subluxation and loss of elbow flexion as a result of humero-ulnar or humeroradial subluxation or OA.[3]

Angulation

Limb (radial) angulation is assessed in patients with limb deformities.[5] Valgus and varus ML deformities have a more significant impact on limb use than do CC deformities. The forelimb has few adaptive options in adjusting for the presence of ML deformities compared with CC deformities, where an increase

of decrease in elbow and shoulder joint flexion may offset a deformity. When standing and walking, dogs most likely load their forelimbs so the center of their shoulder joint and the metacarpal pad form a vertical line, as seen from the front of the dog. That line is named the ML mechanical axis of the limb (Figures 97-2 and 97-3). Having a vertical mechanical axis leads to the lowest energy expenditure and optimizes the effectiveness of locomotion. Valgus deformities are often visually more striking than varus deformities and may have a higher negative impact on limb use because the normal limb most often has 5° to 10° of valgus. For example, a medial deformity of 20° in a dog with an

initial valgus of 10° will lead to a manus orientation of approximately 10°, a reasonably discrete deformity; but a lateral deformity of 20° will lead to approximately 30° valgus, a significant deformity. It is not possible to accurately assess CC angulation of the antebrachium during stance or palpation. It is assessed on radiographs. ML angulation should be assessed while the patient is not sedated and is bearing weight on his affected limb. ML angulation during stance overestimates the actual angulation of the antebrachium, particularly in patients with valgus deformities, because joint subluxation may occur in addition to bone angulation when the joint is loaded

asymmetrically. Angulation may also occur when patients place their limbs in pain-relieving positions, to decrease the load placed on a joint or on part of a joint. ML angulation is also assessed when the patient is relaxed (often under sedation). ML angulation measured on a relaxed limb tends to be the most accurate assessment of limb angulation. Whereas many patients have a single (unifocal) angular limb deformity, some patients have two (bifocal, Figures 97-1 and 97-4) or more complex angular deformities (Table 97-2). Others have a uniformly angled bone, resembling a bow, described as multifocal deformities.[5]

Table 97-1. Assessment of Limb use, Cosmesis, and Overall Mobility in Patients with Limb Deformities

	Limb use (lameness)	Cosmesis (difference with opposite limb)	Mobility (activity level, performance)
Excellent	None	None	Normal
Good	Mild, intermittent	Minor	Mild restriction
Fair	Constant	Significant	Severe restriction
Poor	Toe-touching to NWB	Major	Very limited mobility

Abbreviation: NWB = non weight-bearing.

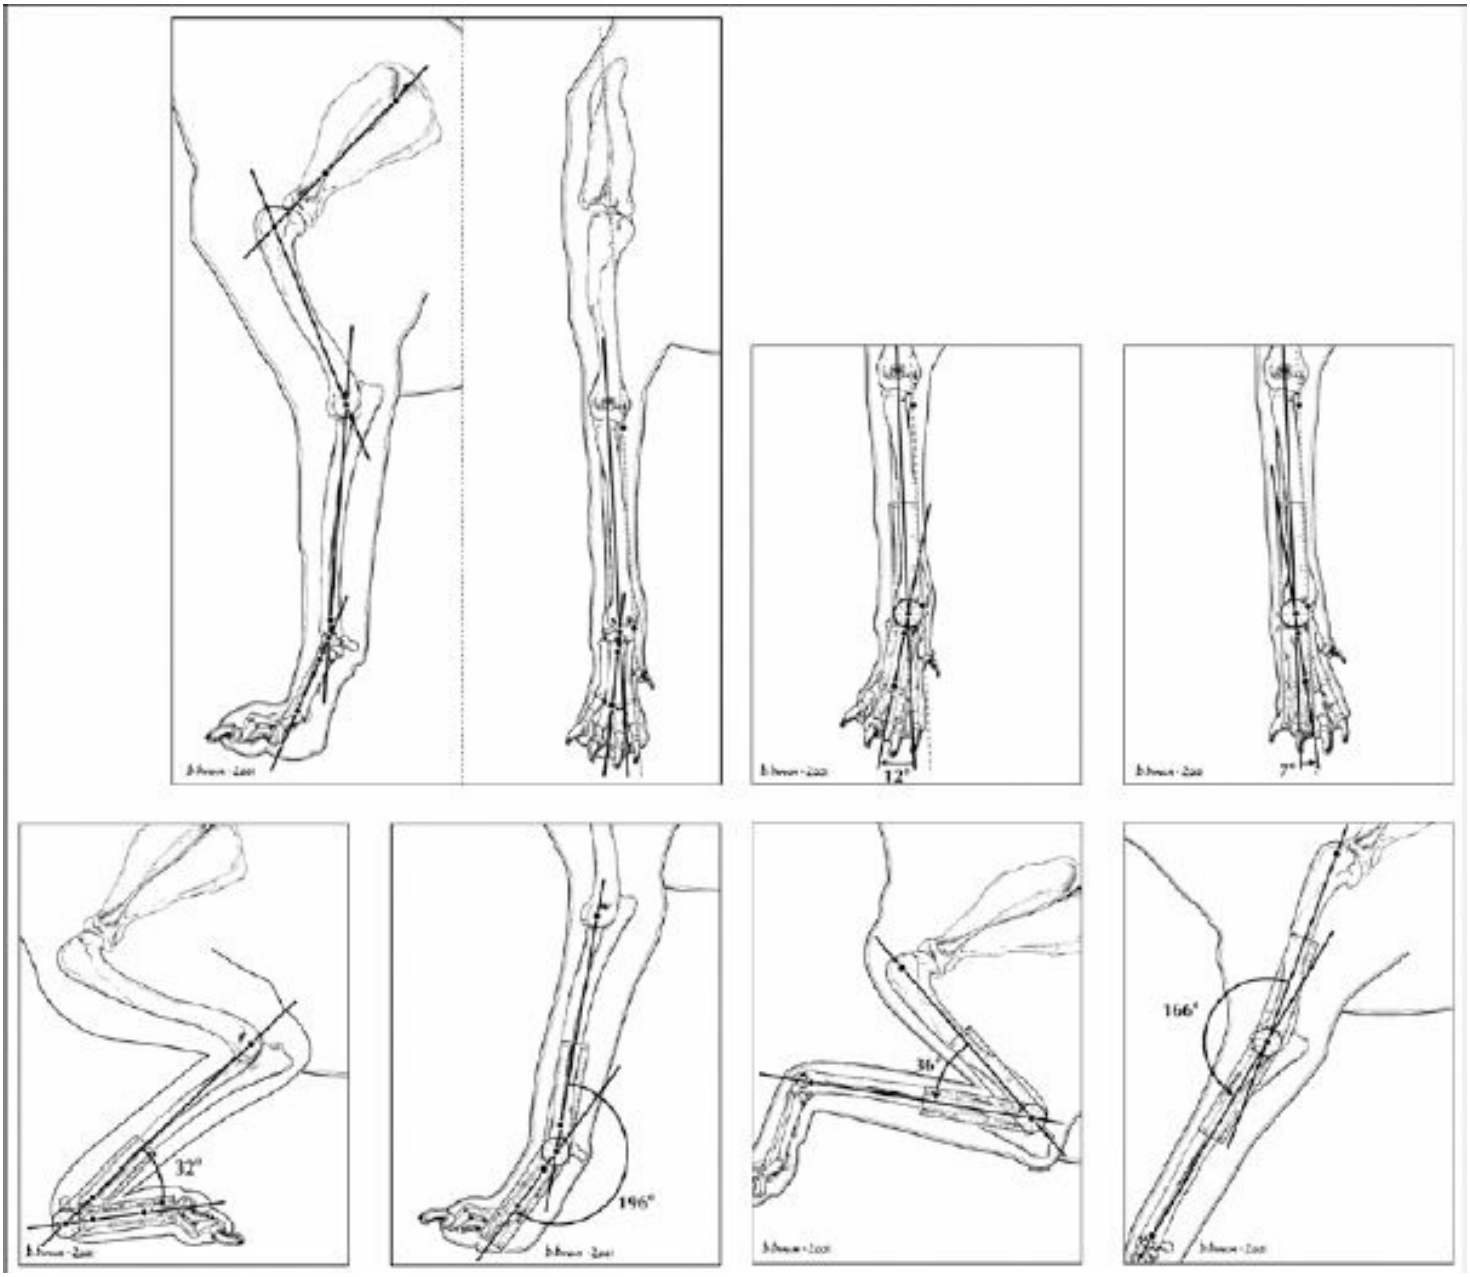

Figure 97-2. Normal range of motion of the carpus and elbow joint in Labrador retrievers as measured using a plastic goniometer aligned with the metacarpal, craniocaudal midpoint of the distal portion of the antebrachium, lateral epicondyle, cranio-caudal midpoint of the proximal portion of the humerus, and spine of the scapula (upper left). Nineteen degrees of motion are available in a

mediolateral direction (upper right), 164° in a craniocaudal direction for carpal motion (lower left), and 130° of elbow motion. (From Jaegger G, Marcellin-Little DJ, Levine D: Am J Vet Res 63:979-986, reproduced with permission < requested from AVMA, pending >).[4]

Figure 97-3. This Yorkshire terrier has valgus deformity of the distal portion of the radius. On the

right, dots have been placed on the approximate centers of the shoulder, elbow, carpus, and metacarpal pad. The centers of the shoulder joints and metacarpal pads appear to form a line perpendicular to the ground.

Rotation

Pronation (internal rotation) and supination (external rotation) are assessed preoperatively. This is primarily done to evaluate the antebrachium for the presence of restrictions in motion and synostoses. Synostoses are confirmed on radiographs. Synostoses, when present in patients with growth potential, may have devastating consequences on elbow joint congruity and, to a lesser extent, on carpal joint congruity.

Synostoses are unusual in dogs with developmental antebrachial deformities resulting from premature closure of the distal ulnar and radial physis or resulting from chondrodystrophy. Synostoses are much more common in patients who previously underwent segmental ulnar ostectomies or in patients with prior radio-ulnar shaft fractures. Pronation and supination may also be used as a predictor of rotational deformities. Dogs have approximately 45° of rotational motion in their antebrachium, with a pronation of 0° and a supination of 45°. Cats have twice as much supination as dogs.

Figure 97-4. This dog has a bifocal angular radial deformity with a valgus deformity of the distal portion of the radius and a varus deformity of the proximal portion of the radius. The radial and ulnar physes do not appear closed.

Rotational deformities are assessed preoperatively. Rotation is a common component of antebrachial deformities: valgus deformities are often associated with external rotation and varus deformities with internal rotation. Rotation is difficult to assess because the presence of angulation influences the perceived angulation of an extremity and because dogs may use their available pronation or supination to enhance their limb function and decrease their perceived pain. Dogs with severe valgus, for example, tend to purposefully rotate their limbs externally to improve the contact of their digits on the ground during stance. Looking at the direction of the footfall as a sole measure of rotational

deformity is inappropriate because it greatly overestimates the rotation present in the antebrachium. Instead, rotation should be assessed on a relaxed (or sedated) patient by comparing the direction of the plane formed during flexion and extension of the carpus with the direction of the plane formed during flexion and extension of the elbow joint.[5] Rotational deformities cannot be assessed reliably on radiographs.

Length Deficits

Radial-length deficit is assessed on the patient by comparing the distance between the radial head, palpable proximally and laterally, with the

medial styloid process of the radius, palpable distally and medially. Ulnar-length deficit is assessed on the patient by comparing the distance between the olecranon, proximally and caudally, with the lateral styloid process, medially and distally. Length deficits are assessed more accurately on radiographs. Compensatory humeral overgrowth may be assessed on the patient by comparing the distance between the greater tubercle, proximally and cranially, with the lateral humeral epicondyle, laterally and distally. If a humeral-length discrepancy between the affected and control limb is suspected, it may be assessed more accurately on radiographs.

Translation

Translation is a displacement of a limb segment in relation to another limb segment in a direction parallel to the long axis of that limb. Translation may be present as a consequence of a fracture malunion. It is rare in dogs. Dogs with severe caudad deformity of the radius originating in the distal portion of the bone compensate for these deformities by hyperextending their carpus. This results in a perceived caudal translation of the carpus in relation to the radius.

Joint Subluxation

Careful assessment of the joints adjacent to the deformity should be

performed. Joint effusion may be present as a consequence of a severe subluxation or cartilage damage. Crepitus may be present as a consequence of cartilage wear or osteophytes at the articular margins. A pain response may be suspected based on activity level, weight shift toward the opposite forelimb or away from the forelimbs, or during manipulation (flexion, extension, pronation, supination, valgus, or varus stress). Assessing pain is critically important because the presence of pain suggests articular damage (cartilage erosion, synovitis, subluxation, OA) and that damage should be assessed as objectively as possible and factored in the preoperative planning and surgical

recommendations made to the owner. Subluxation and OA are confirmed on radiographs.

Table 97-2. Common Components of Classic Canine Antebrachial Deformities

Type of deformity	Length deficit	Angulation	Rotation	Other components*
Chondrodystrophy (mild)	None	U valgus, distal radius	External	Distal HU subluxation
Chondrodystrophy (severe)	None	U valgus, distal radius U varus, proximal radius	External	Distal HU subluxation
Chondrodysplasia	None	U valgus, distal radius U varus, proximal radius	External	Distal HU subluxation
Traumatic PPC, distal ulna	Mild	U valgus, distal radius	External	Distal HU subluxation
Traumatic PPC, distal radius, medial	Moderate	U varus, distal radius	Internal	Distal HR subluxation
Traumatic PPC, distal radius, lateral	Moderate	U valgus, distal radius	None	Distal HR subluxation
Traumatic PPC, distal radius, complete	Severe	None	None	Distal HR subluxation
Radial fracture malunion	Moderate	U valgus, radial midshaft	External	Synostosis
Osteochondrodystrophy†	Severe	M valgus, radial midshaft	External	None

Abbreviations: U = Unifocal; PPC = premature physeal closure; HU = humero-ulnar; HR = humeroradial.

*** Other components assessed include elbow and carpal subluxation and synostoses.**

† Deformity associated with retained dwarfism,

retained cartilaginous core, and hypertrophic osteodystrophy in skeletally immature dogs of giant breeds.

Radiographs are an important step in the assessment of antebrachial deformities. CC and ML views of the antebrachium are made and compared.[3] A magnification marker or object with known length should be placed along the antebrachium and be parallel to the plate when these radiographs are made using digital radiography in order to accurately calibrate these radiographs and assess length deficits. Radial- and ulna-length deficits are measured in millimeters and as a percentage of radial and ulnar length.[3] Dogs in which a premature closure of the radius or the

ulna precedes a premature closure of the other antebrachial bone have a larger deficit present in the bone responsible for the initial closure. For example, a dog with primary closure of the distal ulnar physis and secondary closure of the distal radial physis may have a 10% length deficit in the ulna and a 4% length deficit in the radius. Understanding the primary closure site impacts the therapeutic decision. Radiographs are used to assess the shape of the radius and the ulna and the type (i.e., uni-, bi-, or multifocal) and origin (i.e., proximal physis, shaft, or distal physis) of the angular deformity in the ML plane. The radial angular deformities as in the ML and CC planes often have different origins.

The classic angular deformity that results from chondrodystrophy, for example, includes a unifocal valgus deviation originating at the distal radial physis and a multifocal caudal deformity involving the radial midshaft. Priority will be given to the ML angulation when planning the correction of antebrachial deformities because dogs can compensate for CC angulation much more than for ML angulation. The radiographic appearance of the radial and ulnar physes should be assessed on radiographs. Partial or complete closure may be seen. Interestingly, the correlation between growth potential and radiographic appearance of the physes is low. Some physes appear

open but do not appear to lead to bone growth. Other physes appear closed but have appeared to contribute to bone growth (unpublished data). Radiographs are assessed for the presence of carpal and elbow joint subluxation or luxation (Table 97-3). Elbow (sub)luxation appears to have a larger impact on limb use than does carpal subluxation and is easier to assess on radiographs. In experimental models of antebrachial deformities caused by premature physeal closure of the distal ulnar physis induced by submitting the distal portion of the ulna to high doses of radiation, cartilage damage in the elbow joint occurs within 2 weeks of ulnar premature physeal closure (Figure 97-

5).

Because conservative and surgical management of antebrachial deformities has a limited power in improving joint geometry (with the exception of circular external fixation, see further on for additional information), it is critically important to address joint subluxation as rapidly as possible in skeletally immature patients with antebrachial deformities. The presence and severity of OA are also assessed on radiographs. Severe OA is irreversible and may limit the positive impact of corrective osteotomies. Its presence should be taken into account when choosing therapy. The presence, location, and

length of a radio-ulnar synostosis should be assessed on the ML radiograph.

Computed tomography (CT) may be used to further assess the shape of a deformed antebrachium. The digital information contained in cross-sectional CT may be imported into computer-aided design (CAD) software to make 3D renderings (Figure 97-1). CAD is used to enhance the contrast of these images, eliminate data collection artifacts (i.e., beam hardening in CT scans), and select specific information for the creation of specific 3D renderings (Figure 97-1). The 3D rendering is oriented in space, and a support structure may be created.

These 3D renderings may be kept at their original size or may be resized. Making half-sized models requires only one eighth of the material required to make a full-sized model because length, width, and depth are halved in a smaller model. Decreasing the size of the model may be necessary to make a model of a structure too large for specific manufacturing methods or to decrease the model cost. The creation of physical models based on 3D renderings is named free-form fabrication (FFF). Approximately 25 different types of FFF methods are used, making models ranging from wax to titanium. Stereolithography apparatus (SLA) was the first commercially available FFF method

(Figure 97-6). SLA relies on an ultraviolet laser to cure a photopolymer. SLA is slow but precise. Its speed depends on the power of its laser beam. The maximal size of prototypes in SLA machines ranges from 250 x 250 x 250 mm to 500 x 500 x 500 mm (VIPERsi SLA, 3D Systems, Valencia, CA).

Treatment Decisions

Several options are available to help manage antebrachial deformities, ranging from conservative management to corrective osteotomies. The decision tree for management of limb deformities is complex.

Table 97-3. Common Joint Anomalies resulting from Abnormal Antebrachial Growth

Joint Anomaly	Cause	Potential Consequences
Distal humero-ulnar subluxation	PPC distal ulna	Nonunited anconeal process, severe elbow OA
Distal humeroradial subluxation	PPC proximal radius	Fragmentation of the medial coronoid process
	PPC distal radius	Severe elbow OA
Caudolateral radial luxation	Unknown	Severe elbow incongruity, loss of elbow flexion
Proximal radio-ulnar subluxation	PPC distal ulna	Loss of carpal flexion, mild carpal OA

Abbreviations: PPC = premature physeal closure; OA = osteoarthritis.

Figure 97-5. A distal humero-ulnar subluxation is present in the dog on the left with a premature closure of the distal ulnar physis. The dog in the center has a distal humeroradial subluxation with a premature

closure of the proximal radial physis. The dog (on the right) with a premature closure of the proximal radial physis has a severely abnormal trochlear notch.

Figure 97-6. Side view of the basset hound seen on Figure 97-1. Although his antebrachial deformities are similar in angulation and rotation between left and right forelimbs, his left forelimb is often held in a

position incompatible with comfortable weight bearing (right). While the right side may be managed conservatively, the left side will benefit from a corrective osteotomy.

Conservative Management

Conservative management may be a valid option for the management of an antebrachial deformity if the patient has little or no residual growth potential, if joint subluxation is minimal, and if current limb use is deemed acceptable. As a general rule, conservative management is ineffective at improving limb deformities. Splinting is sometimes used with the intent to positively affect an angular limb deformity by protecting limbs from impact or

limiting their future angulation or rotation. Splinting, however, has not been proven effective and does not appear to offer clinical benefits to patients with angular limb deformities. Splinting also has side effects: it limits limb use, promotes muscle atrophy, and may lead to skin abrasions or necrosis. We do not recommend splinting patients with limb deformities. Specific thresholds that could be used to recommend conservative management over surgical management are sometimes reported (i.e., 20% of limb length deficit) but do not have practical benefits in clinical patients because specific impairment to limb use results from the complex combination of

angulation, length deficit, rotation, and joint subluxation associated with the patient's size, body conformation, and fitness level. It would be beneficial to determine the specific influences of these factors on limb use to predict whether surgical management would be indicated in dogs with developing deformities. For example, most basset hounds have severe antebrachial deformities resulting from their chondrodystrophic appendicular skeleton. Some basset hounds, however, have a combination of angular and rotational deformities that lead to hyperextension of their digits combined with a flexion of their carpus that lead to a significant impairment of these affected limbs (Figure 97-7).

Whereas their specific deformities most often resemble a classic form of chondrodystrophy, a small increase in angulation or rotation may lead to a dramatic decrease in limb use. Although most basset hounds are managed successfully without surgery, some will benefit dramatically from a corrective osteotomy. Conservative management should be avoided in dogs with joint subluxation, even in the presence of seemingly acceptable limb use, because the negative impact of joint subluxation on the articular cartilage is profound and occurs within 2 weeks after the occurrence of that subluxation.

Surgical Management

Conservative management should also be avoided in dogs with deformities and with a large remaining growth potential because growth will most likely to lead to joint subluxation and to the increase in the severity of the deformity. The presence of an angular limb deformity, even in without limb disuse, predisposes the adjacent joints to the development of OA even in the absence of joint subluxation. This is likely because with an angular deformity abnormal stresses are placed on the articular cartilage of the adjacent joint. The development of OA as a result of bone angulation has been reported in people with proximal tibial (varus) deformities and within seven

months after the experimental creation of angular deformities in young dogs. Therefore, it seems indicated to discuss the consequence of angulation on the potential development of OA with owners, especially in large and giant breeds when large abnormal forces placed on articular cartilage may lead to OA.

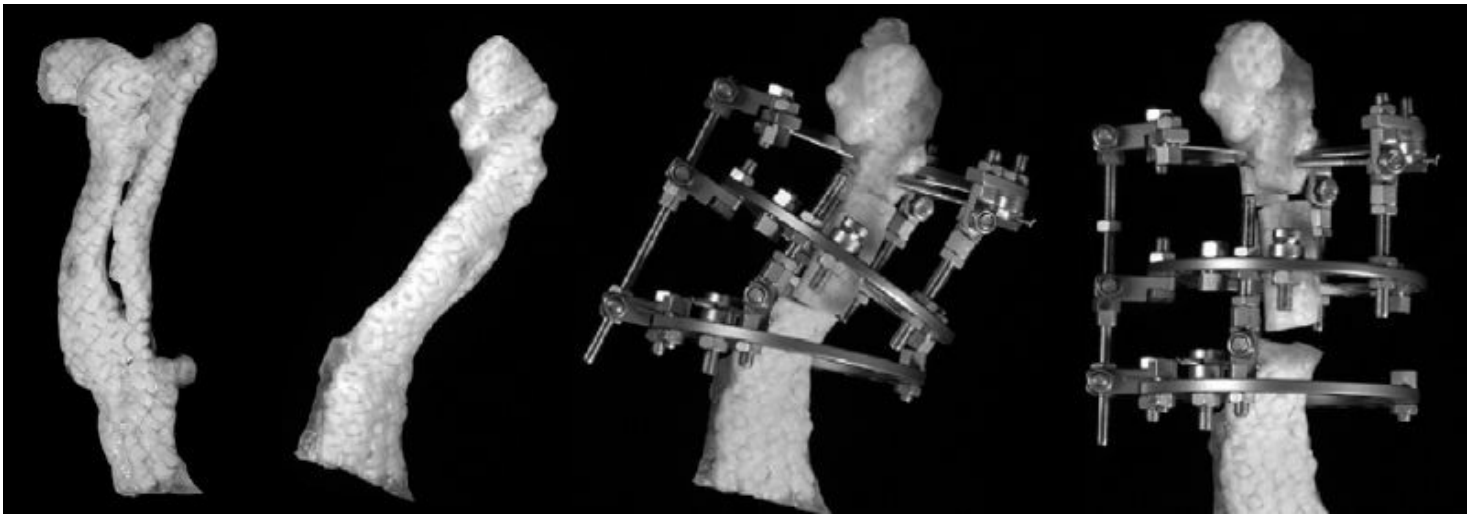

Figure 97-7. The 3D rendering in Figure 97-1 was used to make a full-sized stereolithography model of the left forelimb of the basset hound using rapid protyping methods. The model is used to assess the components of the deformity and to rehearse a

corrective osteotomy. A circular external skeletal fixation frame with two sets of hinges allowing a simultaneous correction of both deformities with a single angular motor adjustment is placed on the model and adjusted to correct the antebrachial deformity.

Some surgeries are performed with the intent to promote corrective or compensatory growth. They generally rely on release osteotomies. Corrective growth is growth that leads to a decrease in abnormal limb angulation. It occurs when limb angulation occurs early in life. For example, if a 3-month-old puppy has a green-stick fracture leading to a 30° angulation of his radius, corrective growth will occur to decrease that angulation over time. To be effective, corrective growth requires a large growth potential. It

appears ineffective in puppies more than five months old. Compensatory growth is growth that leads to a decrease in joint subluxation or limb-length deficit. For example, in a puppy with premature closure of the distal radial physis occurring late in growth when growth potential is less than 5% of final bone length. Compensatory growth in the proximal radial physis may prevent the occurrence of a distal humeroradial subluxation. Compensatory overgrowth also occurs in bones adjacent to the bones with length deficits. For example, a dog with a short radius and ulna could have overgrowth of his humerus. In humans, overgrowth is a routine complication after fracture of long

bones in children. Overgrowth after fracture has not been reported in dogs, to our knowledge. Ulnar osteotomies are a convenient, minimally invasive surgical option allowing corrective growth in young dogs with deformities and with a large remaining growth potential. The ostectomy should not be made near the elbow joint, where it could lead to a caudal displacement of the distal aspect of the proximal ulnar segment that would lead to elbow subluxation. The osteotomy should not be made too distally where it could lead to a weakness in the site of origin of the lateral collateral ligament. When an ulnar ostectomy is performed in a very young patient, the surgery should be minimally traumatic because

a future surgery may take place in that site and minimal tissue changes will facilitate the future surgery, and because a radio-ulnar synostosis should be avoided. Bone healing will occur after most ulnar ostectomies. This healing may be delayed or stopped through removal of the periosteum during the procedure and through placement of a fat graft collected from the axilla. If the osteotomy heals prematurely, a prompt decision should be made as to whether the premature healing predisposes the patient to long-term problems and interferes with future bone growth. A second osteotomy may be performed based on these factors. Short segmental ulnar ostectomies are most effective at

addressing distal humeroulnar subluxations compared with distal humeroradial subluxations. In my experience, distal humeroulnar subluxations of up to three mm may be addressed though ulnar ostectomies. The corrective growth that occurs after an ulnar ostectomy is the result of the growth potential remaining in the radius at the time of the procedure. This means that ulnar ostectomies should be performed as early as possible when a premature closure of the distal portion of the ulna is diagnosed. Some surgeons perform radial osteotomies or ostectomies with the intent to decrease distal humeroradial subluxations. I do not recommend them because they may

lead to limb disuse or additional angular deformities owing to malunion, or they may fail to improve elbow joint congruity.

Periosteal stripping is more popular in horses than in dogs. The information regarding the specific benefits of periosteal stripping in dogs with deformities is scant. Periosteal stripping is based on the fact that the thick periosteum present in puppies (the younger, the thicker) restricts longitudinal bone growth. Dogs may be candidates for periosteal stripping if they have a significant angular deformity in the absence of severe rotation or joint subluxation. I have personally used periosteal stripping in

two patients with acceptable results (unpublished data).

Surgical stapling has been used to restrict the longitudinal growth of one aspect of a distal physis, while the opposite aspect of that physis still grows. Staples are curved metal implants that bridge the physis. Staples are removed after a few weeks to avoid permanent growth cessation of the stapled side. Stapling has been effective in specific patients to induce corrective growth. These patients must be very young at the time of initial diagnosis; they must have a partial premature closure; and they must not have subluxation of the joints adjacent to the deformity. They should be

followed carefully after the procedure to avoid under- or over-correction and to monitor complications.

Linear fixators may be used to correct deformities, when the deformity does not include a significant length deficit, when angulation and rotation may be acutely corrected during the procedure, and when subluxation is not present in the joint adjacent to the deformity. When acute corrections are performed, lengthening is often limited to the length gained through the angular correction. Anatomically, that length roughly equals half of the maximal gap present at the transcortex. Functionally, though, a limb may be longer once an angular correction is

performed because the anatomic and functional axes of the limb are realigned after the correction of an angular deformity. Linear fixators do not appear to be effective at correcting the craniocaudal component of an angular limb deformity when treating antebrachial deformities. Attempting to distract a linear fixator may place a large amount of stress on the fixator and on the patient's soft tissue. The creation of a gap will also require the fixator to function as a buttress; therefore, increasing the bending and axial loads present at the osteotomy site. The practical consequences of that are that frames used for acute angular corrections should have flawless mechanical properties.

Bone plates may be used to treat antebrachial deformities when significant lengthening is not necessary and when the subluxation of adjacent joint does not require specific treatment. Bone plates are deceivingly simple in theory: the radius and ulna are osteotomized, the angular, rotational, and minor length deficits are corrected, and the bone is fixed in place with a plate. In large dogs, a plate may also be placed on the ulna. Like linear ESF frames, plates often have to be used in buttress fashion when correcting antebrachial deformities because the contact between bone ends is likely minimal after deformity correction. Unfortunately, the irregular nature of

the bone surface requires complex contouring of the plate. This is a process easier to achieve in relatively small and thin plates, but the buttress use of that plate requires a relatively large and thick (i.e., stiff) plate. Bone plate fixation has significant limitations in patients with bifocal (varus, proximally, and valgus, distally) deformities because the optimal correction of these deformities requires a proximal and distal osteotomy, whereas the optimal plate placement requires a single midshaft osteotomy.

Circular external skeletal fixation frames are the most versatile method used to treat antebrachial deformities

in dogs. This is because circular ESF may be used to simultaneously correct angulation in one or two locations in a deformed bone, eliminate a length deficit, eliminate a rotational deformity, and decrease the subluxation present in adjacent joints.

In some patients with limb deformities, however, simpler management methods may be used. With circular ESF, the frame consists of rings connected together by threaded rods. The method for placement of circular ESF frames is termed the Ilizarov method, from the name of the Russian surgeon who popularized it. The frame is fixed to the bone with tensioned small-diameter wires and, potentially,

with half-pins. Circular ESF offer unlimited geometric adaptability. The ring size and number, threaded rod size, length, and number, and wire size, number, and orientation can be tailored to the purpose of fixation and the anatomy of the patient. The circular ESF systems with widest use are the small bone fixator and the circular external skeletal fixation systems.[5,6] Linear and circular ESF frames may be combined to form hybrid ESF frames. Unifocal deformities are the simplest deformities to treat. Multifocal deformities tend to be treated like unifocal deformities by focusing or realigning the proximal and distal joints.[5] Bifocal deformities are most challenging to address

because they are generally the combination of a proximal and distal physeal deformity, usually in short bones. Their treatment potentially requires making two independent juxta-articular osteotomies and angular corrections (Figure 97-6).

Circular external fixators are made of individual parts that can be assembled into an unlimited number of configurations. Ilizarov frames can be used to treat bone deformities and fractures, to perform arthrodeses, to transport bone segments, and to treat joint contractures, with varying frame configurations. Ilizarov frames have been used in multiple species ranging in size from the rat, used as an animal

model for research, to the horse. Most frame components remain constant, regardless of the use of the frame and the size of the patient. These components include fine wires, fixation elements, supporting elements, connecting elements, assembly elements, and sliding elements. Tensioning devices and wrenches complete the Ilizarov instrumentation.[7,8] The fines wires used with the Ilizarov method have a diameter ranging from 1.0 to 1.6 mm in animals and 1.5 to 2.0 mm in humans. One-millimeter-diameter wires are used in dogs weighing less than 10 kg, 1.2-mm-diameter wires in dogs weighing 10 to 20 kg, and 1.5-mm-diameter wires in dogs weighing

more than 20 kg. Different wire points are available: half point, bayonet point, or trocar point. Wires with optimal bone penetration should be used in order to minimize thermal trauma to the limb. In our clinical experience, the half-point wires have the best bone penetration. Half-point wires, olive wires, also called stopper wires, have a larger diameter ball in their midpoint. They can be used to prevent translation of the bone fragment on the wire. When two olive wires are placed on opposite sides of the bone across a fracture site, the bending strength of the bone-frame construct is increased. Twisted wires or bent wires can potentially be used as an alternative to olive wires. However,

they have several disadvantages: they are weaker and may be difficult to remove once bone healing is complete and bone growth surrounds the twisted portion of the wire.

Fixation elements allow wire fixation onto the Ilizarov frame. They include cannulated bolts, with a central hole or slotted bolts with an eccentric slot. The wires should always be kept straight to avoid frame migration, wire rupture, bone stress, or potential fracture during wire tensioning. When placing a wire, a cannulated bolt is used on the near side, the wire is then placed through the limb, and a cannulated or slotted bolt is used on the far side. Washers can be used to offset the wire

from the ring by one mm or more or to potentially connect a wire to a connecting rod. The supporting elements include rings, plates, and posts, where the bolts attach. The rings are currently available with inside diameters ranging from 40 mm to 120 mm. For the small bone fixator system (SBF, Hofmann srl., Monza, Italy), nine ring sizes are available in 10-mm increments. For the circular fixator system (IMEX, Inc., Longview, TX), four ring sizes are available. They are made of stainless steel, aluminum, or carbon composite material. A space of no less than one cm should be present between the inside edge of the rings and the skin. Partial rings should be used on the flexion side of joints to

allow unrestricted range of motion after frame placement. Plates and posts are used to offset wires from rings to fix short bone fragments. The connecting elements connect the supporting elements. They include threaded and telescopic rods. The diameter of the rods determines the size of all other Ilizarov elements. Rods of 4-, 5-, or 6-mm-diameter are commercialized. Their pitches are 0.66, 0.8, and 1 mm, respectively. Their length ranges from 30 to 200 millimeters. Systems of five mm can be used in cats and dogs of all sizes. Systems of six mm can be used in man and in medium to giant dog breeds. At least three connecting rods are used to connect the rings. With hinged

fixation, two connecting elements have hinges and a third element, used for distraction, is named the angular motor. Hinged connecting rods are made with two male posts rotating around a bolt. The angular motor is connected to the ring with two twisted plates.

With conventional, straight Ilizarov fixation, all connecting rods can be used as linear motors for distraction. The assembly elements include bolts and nuts used to assemble supporting elements and connecting elements. Some nuts have dots or marks on their faces to facilitate adjustments. With hemispherical washers, the direction of the connecting rods in relation to the

rings can vary. This feature is helpful when ring fixators are used for fracture repair. Nylon-insert nuts may be used to secure hinges and other points of rotation. The sliding elements include buckles. Originally, the buckle was Ilizarov's first fixation element. Buckles now are used mainly as points of rotation between two rings. Tensioners are used to tension the wires. They come in multiple forms: mechanical and pneumatic. They are a critical part of the Ilizarov instrumentation. No tension is placed in animals weighing less than one kg. Twenty to 30 kg of tension are placed in animals weighing 5 to 10 kg, 30 to 60 kg in animals weighing 10 to 20 kg, and 60 to 90 kg in animals weighing more than 20 kg.[9]

Graduated and nongraduated tensioners are available, but only graduated tensioners provide information on the amount of tension placed on the wires.

Box wrenches and flat wrenches are used to perform frame adjustments. Wrenches of 7, 8, and 10 mm are used with 4-, 5-, and 6-mm systems, respectively. Although they were not part of the original Ilizarov instrumentation, fixation cubes have been developed to connect half-pins to the rings, creating hybrid frames. Half-pins can be added to the frames to enhance fixation of short bone fragments or to fix partial rings to the proximal part of the humerus and

femur, where full rings cannot be used. To our knowledge, five manufacturers make circular external fixation systems of various complexity for canine use. Four systems are made in Europe (two in Italy, one in France, and one in England) and one in the United States.

Ilizarov frames should be built so dogs can bear normal weight after frame placement. The frames should have four rings, whenever possible. The outer rings should span the bone and the inner rings should be close to the fracture or osteotomy site, creating a "far-near-near-far" pattern. The specific frame design has been described in detail in several reports.[3,5,8] This includes choosing the number of rings,

their size, their type, the type of hinge or hemispheric washers, their location, the number and location of osteotomy, the type and location of wire and pin fixation, and the presence of sliding or traction components for correction of elbow joint subluxation. Partial rings, placed on the flexion side of joints, decrease the interference of the frame with normal joint range of motion. The rings should have the smallest diameter that maintains a centimeter-wide gap between their inside edge and the skin.

Circular external fixators are particularly complex. Having a comprehensive preoperative plan enhances case management by: 1) requiring a full understanding of the

current pathophysiology and its anticipated evolution; 2) requiring evaluation of all anatomic constraints 3) requiring evaluation of the biomechanical characteristics of the situation; 4) ensuring availability of frame components; and 5) decreasing surgical time. The preparation of hinged frames ideally includes a drawing showing a cross-section of the limb at the level of the planned osteotomy, the ring, the hinges, the angular motor, and the wires.[3] With advances in 3D data collection and rapid manufacturing methods, digital images of affected bones may be collected and used to make models. These models may be used for operative rehearsal. We currently

make models for complex multifocal bone deformities using helical CT scanning and stereolithography, ink-jet, or electron-beam melting rapid prototyping methods (Figure 97-6).[10] These models appear to improve the accuracy of diagnosis and the precision of the surgical placement and postoperative corrections. They also appear to decrease the duration of surgery. Silicon molds of first-generation models may be made to reproduce bones of interest for educational or experimental use.

Ilizarov frames have the advantage of relying on tensioned fine wires with a diameter ranging between 1.0 to 1.6 mm in small animals and between 1.5

to 2.0 mm in humans. Even though these fine wires are less disruptive than conventional external fixation pins with a larger diameter, they have to be placed carefully to optimize the biomechanics of fixation while minimizing soft-tissue interference or potential injury. As a general rule, patients should be able to function normally while the fixator is in place. This is only possible when the fixator is stable and when neurovascular bundles and major muscle groups are unaffected by the transosseous wires. The frames should not interfere with the skin of the limbs, axilla, or groin, during locomotion. It is imperative to leave at least a one cm space between the skin and the inside edge of the

rings to avoid skin irritation and necrosis. In small animals, the placement of full rings around the limbs is limited to the radius and tibia, and, in some instances, the distal portion of the humerus and femur. As a consequence, the use of conventional Ilizarov frames, with two rings above and below the osteotomy or fracture site, is limited to the radius and tibia. Partial rings are often used on the flexion side of joints, with a cranial opening for the proximal aspect of the radius and caudal opening on the proximal aspect of the tibia. The principles of Ilizarov fixation can be applied to the femur and humerus but the frames have to be modified to include arches, plates, and cubes for

half-pin fixation. These hybrid frames are challenging to conceive, to place, and to maintain.

Few reports provide information about wire placement in small animals. Marti and Miller reported on safe, hazardous, and unsafe corridors for placement of linear external fixators.[11,12] Putod described the cross-sectional anatomy of dog limbs. Software packages with cross-sectional and 3D anatomic representations are becoming available for human anatomy and, to a lesser extent, for dogs. The medial aspect of the radius is safe, distal to the insertion of the pronator teres muscle (distal two thirds of the bone). Laterally, the radial head can be palpated

subcutaneously. The lateral aspect of the radial shaft is a hazardous corridor, because of the presence of the extensor muscles. The radial nerve is on the caudomedial aspect of the limb. Practically, wire placement in the radius is craniomedial to caudolateral and caudomedial to craniolateral, with wire angles of 90° in the distal third and 45° to 60° in the proximal two thirds. When hybrid fixation is made necessary by the presence of a short bone fragment, half-pins can be placed in the distal part of the radius, caudomedially, medially, or craniomedially, or in the proximal part of the radius, laterally. Wire placement through the proximal part of the radius in a craniocaudal direction, in a

slightly laterally offset position, has been described (by Dr. Yves Latte), but is not used by the author. This wire placement has several drawbacks: transfixation of the extensor muscles and transfixation of the ulna, eliminating the ability to pronate and supinate. In our experience, the clinical function is better if transfixation of the ulna is avoided, because the elimination of pronation and supination appears to negatively impact limb use and also appears to lead to premature loosening of the pins and wires. The ulna has two safe zones: the olecranon, proximally and caudally, and the lateral styloid process, distally and laterally. Wire placement in the ulna is generally

limited to wires used for displacement of the ulna in relation to the radius. One or two wires can be placed on posts, from a medial to lateral direction, across the caudal aspect of the proximal portion of the ulna. The posts can be adjusted progressively to treat proximal or distal humero-ulnar subluxations.

Ferretti designed the SBF fixator and was the first clinician who used the Ilizarov method in veterinary medicine. He established guidelines for wire size and tension. Wire tension should not exceed 30 kg when the wires are placed on partial rings or posts, away from the rings. Several biologic factors strongly influence the

stability of Ilizarov frames. For correction of deformity, the preservation of the periosteum helps stability at the osteotomy site. The regeneration of callus or new bone helps to create an internal support for the bone (bio-buttress). The bone healing rate at the osteotomy site is enhanced by the presence of an increased blood supply at the osteotomy site (in young dogs, with large bone, and metaphyseal osteotomy). It is also enhanced by a minimally traumatic osteotomy, a long resting period after osteotomy and before distraction, a small amount of daily distraction, and a high frequency of distraction.

For fracture treatment, bone healing seems enhanced when fractures are treated closed. Enhanced bone healing also creates a beneficial bio-buttress. Sharp wires are used to decrease thermal trauma to the limb. The wires are placed with a low-speed power drill. A 2- to 3-mm-long skin incision may be made at the entry and exit sites of the wires to decrease skin trauma. The author has abandoned the use of such incisions. Drilling is generally started on the side of the bone that provides maximal control for wire positioning and safest wire placement - the medial aspect of the radius and tibia. Once the transcortex has been pierced, the wire can be tapped with a mallet to avoid rotation of the wire

through the tissues on the opposite side of the limb. The use of a drill with an oscillating function also helps to protect soft tissues. The soft tissues can be gently reflected by digital pressure. Tension should not be present on the skin after wire placement. If tension is present, the wires may be moved below the skin surface and a new hole in the skin may be made with a more relaxed skin placement. A releasing incision may also be made in the skin to eliminate a minor amount of tension.

Postoperative Management

The postoperative management of dogs after surgical correction of

antebrachial deformities focuses on wound care, maintaining limb use, avoiding excessive stress placed on the bone and external fixation frame, and maintaining range of motion in the carpus and elbow joints.

It is important to maintain limb use during the early postoperative period by giving pain medications, rapidly eliminating swelling, using protected weight-shifting and weight-bearing exercises, and avoiding trauma. Swelling may be present in the extremity and around the surgical site in the early postoperative period, particularly in patients undergoing intraoperative derotation of the extremity. Swelling is controlled by

enhancing lymphatic and venous drainage through elevation of the extremity, passive range of motion of the carpus, gentle finger massage (effleurage), and cold therapy. Swelling is most often eliminated in 2 to 3 days. In patients with circular external fixators undergoing distraction osteogenesis, distraction starts on the third day after surgery.[3] Distraction tends to increase tissue tension and leads to loss of range of motion, particularly carpal joint motion, in the late treatment stages. The distraction rate is often decreased when tissue tension increases, and activities promoting joint motion and stretching are routinely performed. Bandages and braces may be used to

regain joint motion in specific instances.

The soft-tissue complications of Ilizarov fixation are comparable to the soft-tissue complications of conventional external fixation. In most cases, the complications are a consequence of improper surgical technique. Neuropraxia results from nerve trauma. Hemorrhage can result from a vascular injury. In most cases, hemorrhage is intraoperative, but it may occur several weeks after surgery, when wires abrade blood vessels. Skin irritation or necrosis can result from ring placement in contact with the skin or from the contact of the frame with the groin or axilla. Focal drainage

occurs at the skin wire interface, especially when wires are loose. Muscle contracture may result from decreased limb use or from the tension generated during limb lengthening. In our experience, the soft-tissue complications associated with Ilizarov fixation are common, but they are generally minor and rarely affect the outcome of surgery.

Rotation is most often corrected acutely, intra-operatively. Angulation is most often corrected first, progressively after surgery. Mild lengthening is combined with angular correction in dogs likely to heal rapidly (i.e., young dogs). Lengthening is accelerated after angular correction is

complete, generally 15 to 30 days after surgery. The distraction rate is often 1 to 2 mm per day at the point of maximal distraction, divided in 2 to 4 increments.[3] Radiographic follow-up is done at the end of angular correction, and every 3 to 4 weeks afterward until bone healing is complete. Circular external fixation frames are removed under sedation. The long-term outcome of the correction of antebrachial deformities has been good to excellent, from cosmetic and functional standpoints.[3,8] Circular ESF has been used to treat antebrachial deformities that include a severe elbow joint subluxation, a limb-length deficit, and an angular limb deformity of the distal portion of the radius and ulna. Placing

a circular external fixator with a single set of hinges and making two osteotomies (one used to correct angulation and limb length and one to eliminate elbow joint subluxation) had lead to excellent clinical results. Distal humeroradial subluxations of up to 13 mm have been reduced using this method in 5 dogs. Circular ESF has been used to treat bifocal antebrachial deformities that include a severe varus defornity of the proximal portion of the radius and a valgus (generally combined with a multifocal caudal deformity) of the distal portion of the radius (Figure 97-6).

Chapter 98

Miscellaneous Orthopaedic Diseases

Ron Montgomery

Asynchronous Growth of the Radius And Ulna

Normal synchronous growth of the radius and ulna yields a straight antebrachium with normal articular surfaces at the elbow and carpus. Growth in length of the radius and ulna comes from the physes, or growth plates. The distal radial physis

accounts for 60% to 70% of the radius length, while the distal ulnar physis accounts for 100% of the ulna length distal to the elbow (80% - 85% of the overall ulna length).[1,2] Therefore, the diaphyses of the radius and ulna must slide past each other to maintain a straight antebrachium (Figure 98-1).[1]

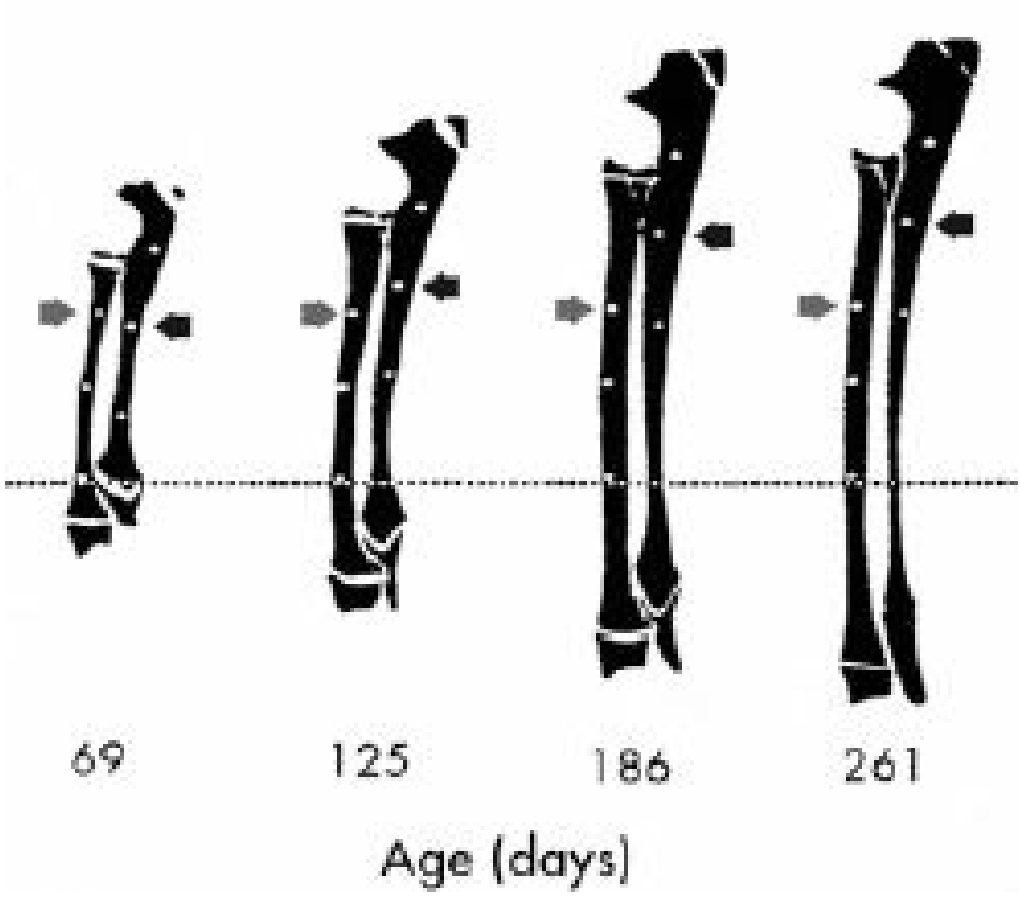

Figure 98-1. Adapted from Carrig CB, Vet Clin N Am

13,91, 1983 (Ref 2). Growth of the radius and ulna is depicted at ~2 months, ~4 months, ~ 6 months, and ~9 months of age. Following the radiographic markers (arrows) as age increases shows that the radial and ulnar cortices must slide past each other during growth. Also noteworthy: the fastest growth occurs between 4 months and 6 months of age; the vast majority of growth is complete by 6 months of age; from the level of the elbow distally (note proximal ulnar marker) virtually 100% of the ulnar length comes from the distal ulnar physis.

Asynchronous growth of the radius and ulna (AGRU) results in an antebrachium that is shortened and has angular, rotational and/or bowing deformity (Figure 98-2).[1-5] Less obvious, but more significant, are the articular malformations of the elbow and/or carpus.[1-6] The articular surfaces are sculpted for each individual during growth via Wolff's law.* Forces that

are normal in direction and proportion yield a congruent, healthy, and mechanically effective joint. Abnormal forces, as occur with AGRU, yield an incongruent, unhealthy, and mechanically ineffective joint that cannot be corrected and often not even significantly improved with contemporary techniques.[6] AGRU has numerous etiologies, each with specific clinical abnormalities reflecting which part(s) of the synchronous growth is abnormally effected.[1-6] Regardless of the specific etiology, however, all forms of AGRU have the pathologies described above to some extent.

The most recognized form of AGRU is premature closure of the distal ulnar

physis, also referred to as radius curvus (Figure 98-2).

Figure 98-2. Puppy with AGRU of the right foreleg which is shortened, bowed, and externally rotated.

The distal ulnar physis is cone shaped, which concentrates compressive forces.

Excessive compressive forces, i.e., when a dog jumps down from a relatively high place and lands first and most forcefully on its front leg(s), can result in Salter-Harris V (compression) fractures. (Other Salter-Harris fracture types can also occur.) This inciting trauma is often not witnessed by the owner, or is soon forgotten because the duration of lameness is short. If radiographs are taken soon after the trauma, the nondisplaced Salter-Harris V fracture is not detectible. Radiographs when AGRU is present, but before normal physeal closure, show premature closure of the distal ulnar physis. The distal ulnar physis stops growing and becomes an anchoring point for the

distal radius, tethered via fibrous connective tissue. The pathology is mechanically analogous to a moving boat tethered to an anchor caught on the bottom. Premature closure of the distal ulnar physis results in the radius deviating laterally with supination (remember the distal ulna is caudolateral to the distal radius). Additionally, there is cranial bowing of the distal radius (the radius is growing in length while the ulna is not), malarticulation of the radiocarpal joint with valgus deformity, humeroulnar subluxation with varus deformity, and shortening of the antebrachium (Figure 98-3). Similar deformity occurs if the lateral part of the distal radial physis stops growing prematurely (partial

closure), which is the second most commonly observed form of AGRU.[6]

Complete closure of the distal radial physis results in relatively minor angular deformity, decreased length of the antebrachium, and malarticulation of the carpus and elbow. Premature closure of the proximal radial physis results in a substantial widening of the radiohumeral joint, radioulnar malarticulation, and shortening of the antebrachium (Figure 98-4). An additional but uncommon cause of AGRU is a radius and ulna fracture that heals in a single mass (synostosis), which prevents the sliding of the diaphyses (Figure 98-5).

Figure 98-3. Radiograph showing premature closure of the distal ulnar physis causing antebrachial shortening, substantial curvature and humeroulnar subluxation.

Figure 98-4. Radiograph showing premature closure of the proximal radial physis resulting in substantial widening of the radiohumeral joint (arrow), radioulnar malarticulation and shortening of the

antebrachium.

Figure 98-5. Photo of synostosis due to prior fracture

and subsequent union of the radius and ulna to each other. Note the large step deformity of the radial head and coronoid processes with accompanying degenerative joint disease.

The severity of deformity depends on the potential growth remaining at the time of physeal damage (premature closure). Potential growth is a combination of the dog's age and adult size. Approximately 90% of bone length is obtained by 6 months of age in all but giant breed dogs, with the most active growth occurring between 3 and 4 months of age. A 3-month-old dog has more potential bone growth than a 5-month-old dog of the same adult size. Similarly, a 4-month-old Labrador retriever has more potential growth than a 4-month-old Chihuahua.

The more potential bone growth, the worse the deformity will be if left untreated. The most effective treatment is removal of a section of the ulna (anchor rope) on the same side of the interosseous ligament as the pathology as soon as AGRU begins.

Ulnar osteotomy is most effective if performed early and enough potential bone growth remains to correct the pathologies.

Atraumatic etiologies of AGRU also exist.[4,5] The most common cause of AGRU is selective breeding, which creates and perpetuates achondroplastic/chondrodysplastic breeds such as basset hounds, English

bulldogs, and dachshunds. Although the condition is generally accepted in these breeds, the pathologies exist nevertheless. AGRU is also present in dogs with dwarfism, an inherited condition reported in the Labrador retriever, malamute, Norwegian elkhound, and Samoyed breeds.[4] A mild form of AGRU also occurs with retained cartilaginous core.[4,5]

Retained Cartilaginous Core

Retained cartilaginous core (RCC) is an abnormality of endochondral ossification in which conversion from physeal cartilage to bone is delayed at the distal ulnar physes. The etiology is most likely a clinical manifestation of

osteochondrosis. Clinical abnormalities are usually limited to lateral deviation of the carpii, usually up to 10° (Figure 98-6). Radiographically, the distal ulnar physis extends an excessive distance proximally. RCC predominantly affects juvenile Great Danes, although the condition may persist into adulthood and/or affect other large breeds. Treatment is typically not indicated.[4,5]

Puppy Carpal Laxity Syndrome

Puppy carpal laxity syndrome is carpal hyperextension or hyperflexion in the absence of an identifiable cause (e.g., tendon rupture or fractures) (Figure

98-7).[7] Puppies with this condition are not in pain and have a full range of motion of the carpus. The condition can be unilateral or bilateral, and typically occurs at 2 to 5 months of age. Multiple puppies in a litter may be affected, suggesting an etiology of nutrition, environment, husbandry, or inheritance. A breed predilection is not recognized, however, and mixed breeds are affected at least as often as pure breeds. The etiology is unknown. The pathophysiology appears to be an imbalance in muscle tone between the extensor and flexor muscles of the carpus. Correction of the condition occurs spontaneously in the vast majority of dogs in less than or up to 2 weeks, although the condition will

persist into adulthood in rare cases. Encouraging exercise has been recommended. Treatment with splints prolongs correction to about 6 weeks.[4-6]

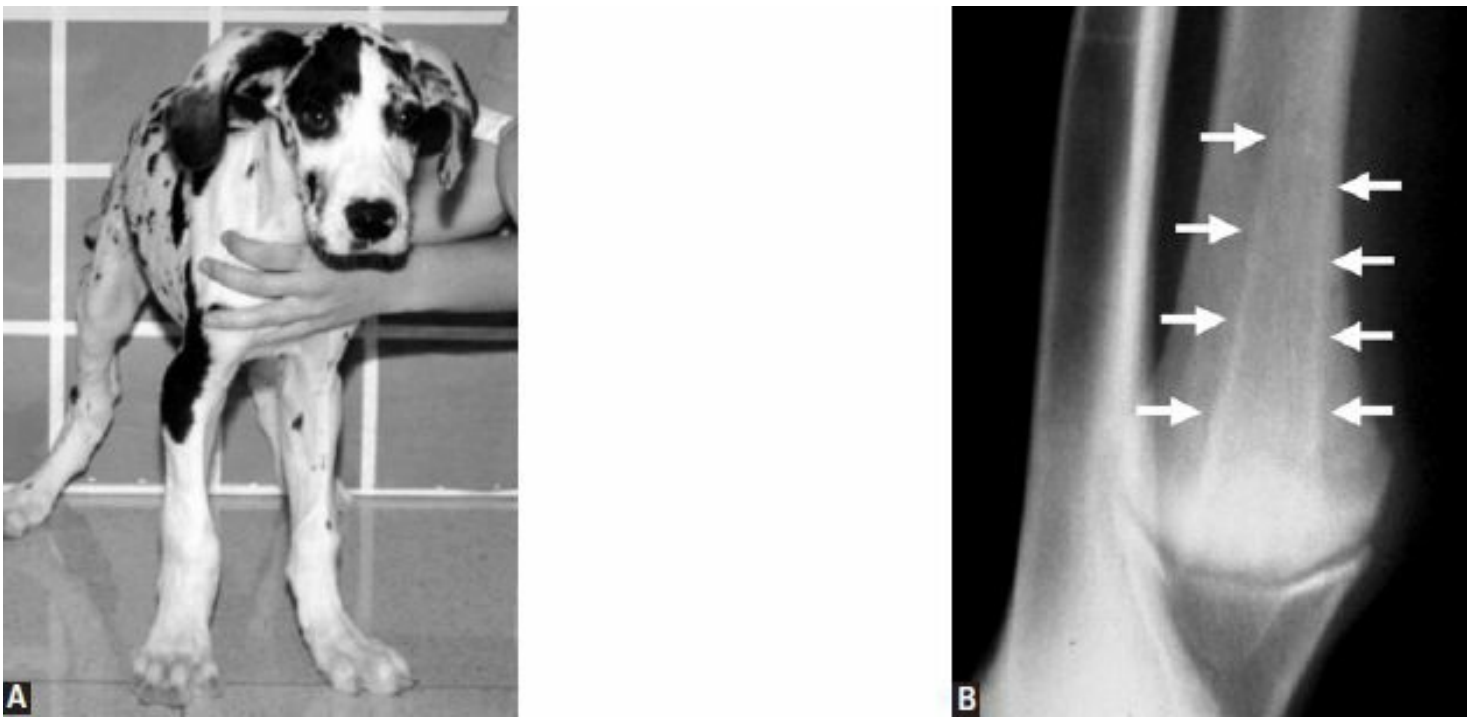

Figure 98-6. (A) Retained cartilaginous core (RCC) of distal ulna causing slight carpus valgus. (B) Radiograph of distal antebrachium showing RCC, seen as excessive proximal extension of the distal ulnar physis (arrows) in shape of a flame.

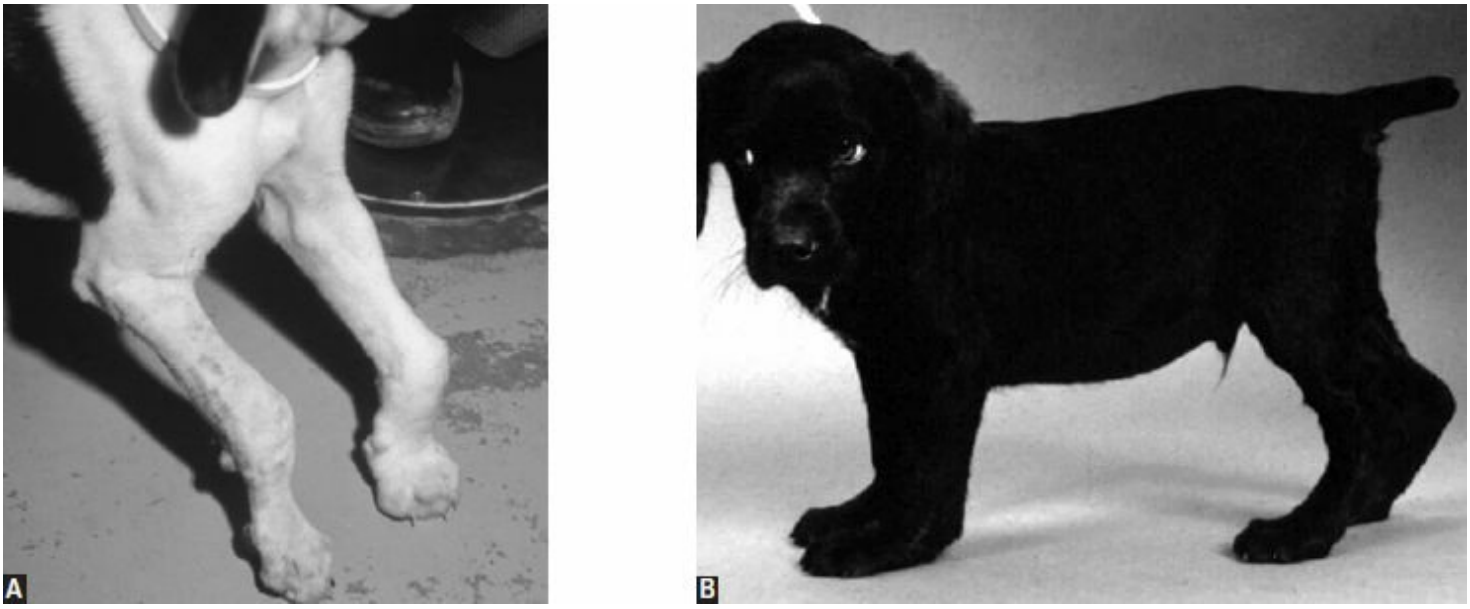

Figure 98-7. (A) "Bucked" carpii or carpal hyperflexion in a juvenile. (B) "Dropped" carpii or carpal hyperextension in a juvenile.

Ectrodactyly

Ectrodactyly is a true congenital deformity (present at birth) wherein the paw's shape is that of two large toes rather than four normal sized toes (Figure 98-8), giving rise to the synonyms of "lobster claw" and "split-hand deformity."[4,5,8] Typically only one front paw is affected. Subluxation

of the ipsilateral elbow occurs in slightly less than half the cases of ectrodactyly. Radiographs of the foot reveal various bizarre combinations of fused and absent metatarsal and phalanges bones. Ectrodactyly has been proven to be of an inherited etiology in humans and cats, and is probably inherited in dogs as well. Medium and large breed dogs (especially mixed breed dogs) have been reported with ectrodactyly thus far in the literature. Treatment is usually not necessary, as most dogs with ectrodactyly have few if any clinical signs other than the anatomic deformity.

Dwarfism

The most common form of “dwarfism” in dogs is intentional selection of the autosomal dominant trait to create and perpetuate “toy” and “miniature” breeds, as well as breeds such as the basset hound. The term “dwarf” is not conventionally used to describe intentional dwarfism, and the condition is not generally considered pathologic. However, clinical problems do occur that are attributable to the selective breeding owing to conformation (especially joint malarticulation). Dwarfism will refer to unintentional.

Dwarfism has been reported in the beagle, cocker spaniel, English pointer,

French bulldog, Great Pyrenees, Labrador retriever, malamute, Norwegian elkhound, miniature poodle, Samoyed, Scottish deerhound, and Scottish terrier.[4,5] The author has observed dwarfism most often in the Labrador retriever, almost certainly influenced by the breed's current popularity (i.e., number of Labrador retrievers and ill advised breeding practices). Dwarfism can occur owing to a variety of anomalies and modes of inheritance, each yielding a characteristic phenotype and associated pathologies. Achondroplastic dwarfism is the term used for humans. It results in a phenotype of short limbs and a normal trunk, which is the most common form

of dwarfism in dogs (Figure 98-9). Autosomal recessive inheritance is the etiology in breeds in which the mode has been studied.[4] Dogs with dwarfism appear normal at birth, but the condition becomes obvious in a few months. Individual bones can be affected equally or unequally, resulting in straight or curved legs, and/or the front legs versus rear legs being equal or unequal in length. Associated pathologies include retinal dysplasia (Labrador retriever), retinal detachment and cataracts (Labrador retriever and Samoyed), and hemophilia (malamute). Owners are often unaware the conformation is abnormal (if the dog is pure breed) and should be informed. In addition,

owners should be advised to have the dog evaluated for associated pathologies and the reasons that neutering the dog is important.

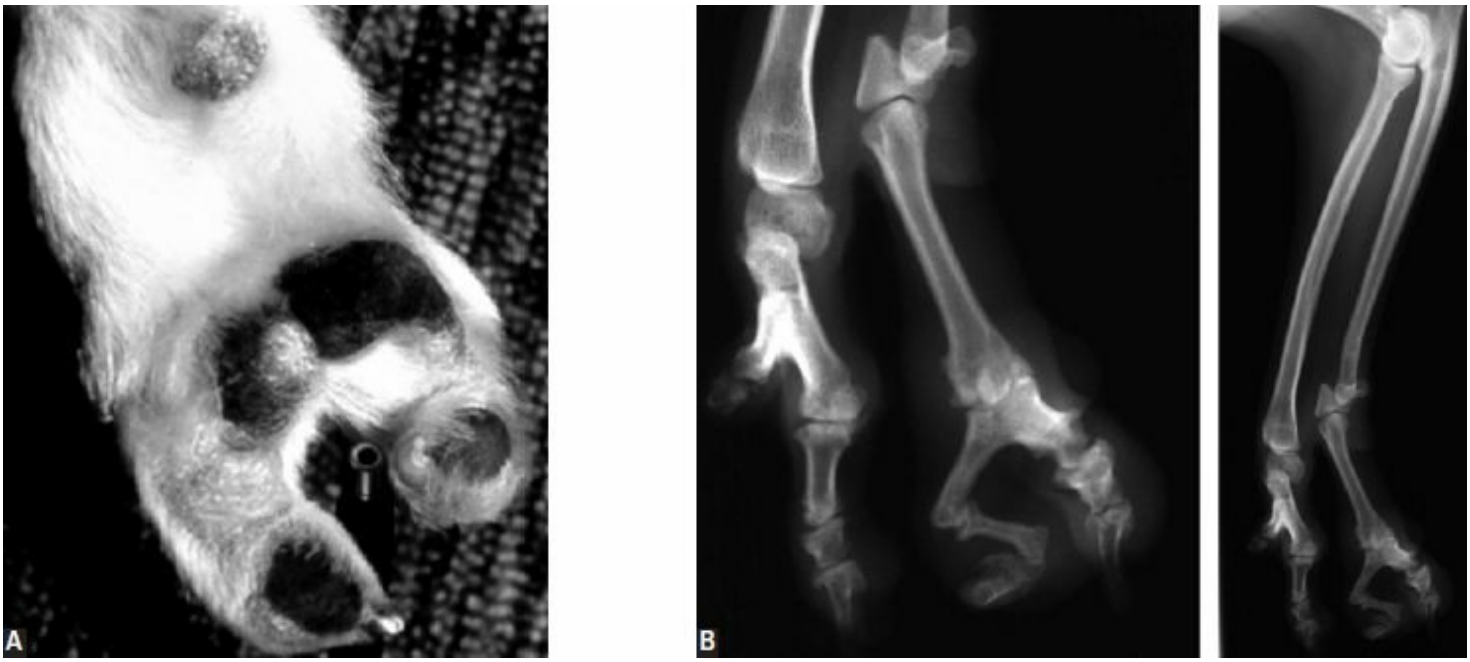

Figure 98-8. (A) Ectrodactyly (a.k.a. "Lobster Claw", or "split hand" deformity) shown from the ventral perspective. (B) Radiograph of ectrodactyly showing bizarre combination of fusion and absence of bones.

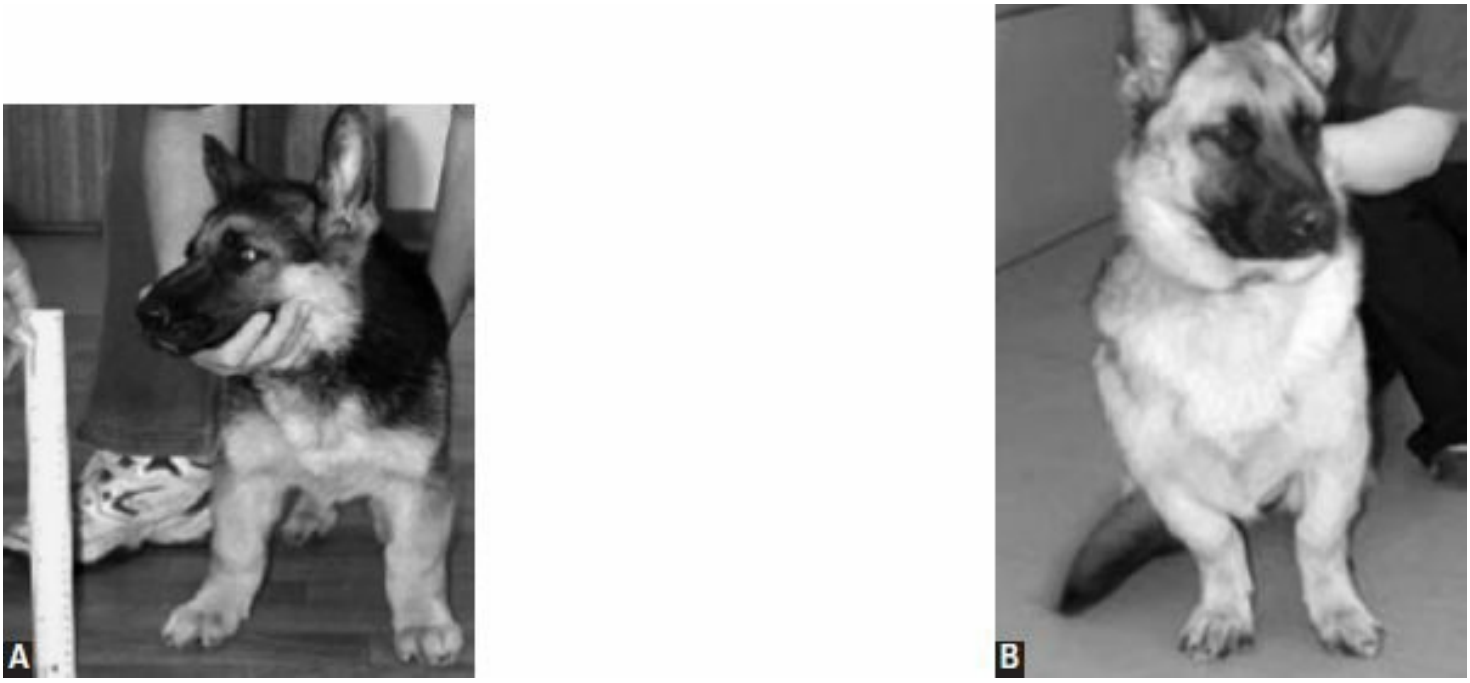

Figure 98-9. Achondroplastic dwarfism in German Shepherd dog at (A) 3 months old and (B) 9 months old. Note the normal appearance of the trunk and abnormally short legs. Photographs courtesy of Mr. Fred Lanting, AKC Judge, Willow Wood Consulting.

Pituitary dwarfism (also called hypophyseal infantilism) is caused by under secretion of growth hormone and gonadotropin deficiency, resulting in a proportional dwarfism with retention of infantile characteristics (Figure 98-10). The most obvious

infantile characteristic is the failure of an adult hair coat (primary hairs) to develop, and easy epilation of the puppy (secondary) hair, resulting in alopecia in areas of high friction such as the caudal thighs, caudal forearms, and around the collar.[5]

Hemimelia/Amelia

In dogs and cats, congenital agenesis of the diaphysis of the radius is the most common form of this rare condition.[4,5] Conventional nomenclature indicates the affected bone first (i.e., radius, ulna, tibia, fibula), followed by amelia (complete agenesis) or hemimelia (complete agenesis of the diaphysis). In addition to dogs and cats, humans, goats, rats, and chickens have been reported to have hemimelia.

The pathogenesis of hemimelia is failure of the radius to develop in utero. The etiology is unconfirmed, although inheritance is generally postulated. One breeding pair of cats

reproduced kittens with amelia over multiple litters (three of eight kittens affected). Other proposed etiologies include accidents in utero, irradiation, drug toxicities, vaccines, and dietary deficiencies (especially minerals, e.g., zinc, copper, manganese). Unilateral occurrence being more common than bilateral obscures the proposed etiologies.

Cats are reported to have radial hemimelia more often than dogs. No size or breed predilection exists. History indicates that the owners noticed the deformity (Figure 98-11) (shortened antebrachium with varus deformity and/or carpus valgus) at or soon after birth. In older dogs, the

appearance of the deformity could be confused with one form of AGRU (distal radius closure), although palpation reveals the lack of a radius diaphysis. Radiographs confirm the diagnosis. Limb function is commensurate with the deformity, ranging from not weight-bearing to good (albeit abnormal). Effective treatment has not been devised, nor is heroic surgery indicated as the condition is ostensibly not painful. Amputation can be performed for cosmesis or treatment of chronic decubital ulcers. Neutering affected animals is recommended, and arguably others in the genetic lineage as well.

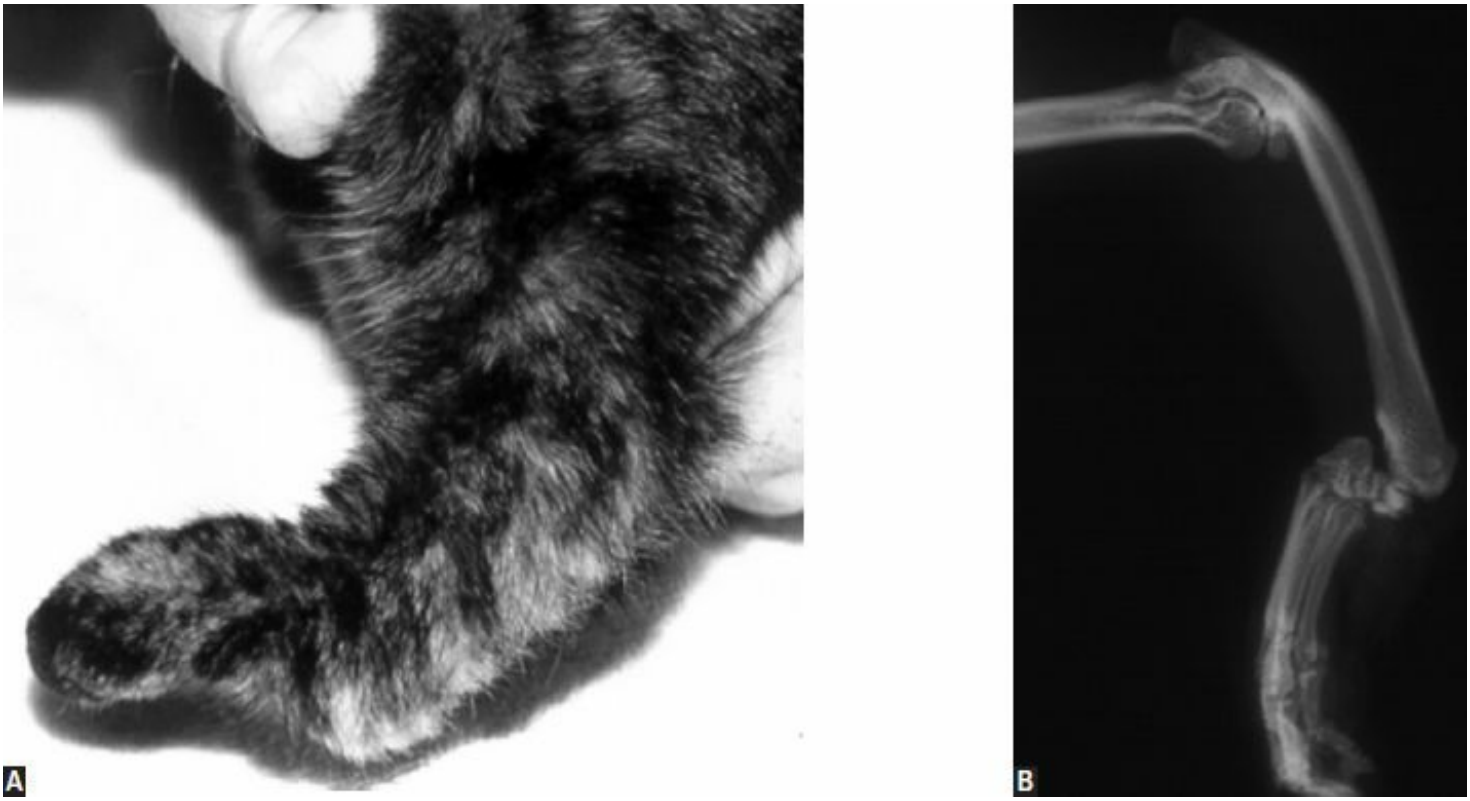

Figure 98-11. Hemimelia/ Amelia. (A) Cat with hemimelia showing carpal subluxation and gross deformity of foreleg (thumb is on shoulder and other hand is behind the elbow). (B) Radiograph showing absence of the radius with malarticulation of the carpus and elbow.

Rickets and Osteomalacia

Osseous deformity and hypomineralization owing to abnormal metabolism of vitamin D, calcium, and phosphorus from various etiologies is

referred to as “rickets.” Osteomalacia is the adult onset form, although conventional use often substitutes the term rickets. “Renal rickets” is probably the form seen most often clinically in dogs. Inappropriate all-meat diets in “big cats” (tigers, lions, etc.), especially juveniles, causes severe hypomineralization. A group of related juvenile vizslas (Figure 98-12) was studied at Auburn University’s College of Veterinary Medicine over a period of several months. Affected dogs had pronounced curvature and shortening of the long bones, which also affected range of motion of adjacent joints. Nutritional and concurrent renal failure were effectively eliminated as causes, and rickets was tentatively

diagnosed.

Bone Cyst

Bone cysts in dogs are rare and include subchondral, simple (cystic), and aneurysmal forms.[4,5] Subchondral bone cysts are relatively small and identified radiographically. Simple and aneurysmal bone cysts are relatively large and often readily palpable. Differential diagnosis between neoplasia and simple bone cyst or aneurysmal bone cyst can be difficult. Therefore, confirming a diagnosis and case management should be performed with due diligence.

Subchondral bone cysts are an osteochondrosis lesion most commonly

identified in horses. Subchondral bone cysts are lined with synovial membrane and contain serosanguineous fluid, myxoid, or fibrous tissue. Forage obliterates the cyst and establishes a new blood supply to initiate healing. It is performed if the cyst is large enough or causing a clinical problem and prior to development of significant degenerative joint disease.

A

B

C

Figure 98-12. Vizsla with rickets. (A) Note the curvature of the front legs and shortened stature. (B) In these radiographs of the distal radius and ulna at approximately 8 weeks of age, there is the characteristic marked widening of the physis in the distal radius and ulna. (C) Several months later there continues to be abnormal appearing metaphysis though the physis have a more normal appearing physeal width.

Simple bone cysts contain serosanguineous fluid and are lined with fibrous tissue. They can occur in the metaphysis of any long bone or multiple long bones (polyostotic). The most common presentation is a single simple bone cyst (monostotic) located in the distal radius or distal ulna of a juvenile or young adult, large breed dog. Doberman pinchers and German shepherd dogs appear to be over-

represented. The etiology of simple bone cysts is uncertain, although the typical signalment of juvenile or young adult dogs suggest an aberration of, or insult during, bone growth. A hereditary predisposition has been suggested for Doberman pinschers. Clinical signs include lameness and painful swelling of the affected metaphysis (with or without pathologic fracture of the bone cyst). Radiographs image a large, expansile mass, absence of osteolysis and/or osteogenesis, variable amounts of cortical thinning, and a fluid density center (Figure 98-13).

Figure 98-13. Bone cyst in the distal ulna demonstrating an expansile, multi-trabeculated appearance with thin cortices.

Simple bone cysts do not usually cross the physis or involve the epiphysis. A

bone cyst may also be asymptomatic and identified as an incidental finding. Asymptomatic cases of simple bone cyst may not require surgery, especially if the ulna is involved as it is not a major weight bearing bone. Surgery is indicated if biopsy is desired to confirm the diagnosis, the simple bone cyst is causing clinical problems (e.g., lameness), and/or if preemptive intervention to avoid a pathologic fracture is desirable (especially a bone bearing significant weight such as the radius). Surgical correction can be via forage of the cyst and into the adjacent medullary cavity, or curettage and bone grafting. With either technique, fracture stabilization devices such as bone plates or external fixators

minimize the risk of pathologic fracture. In humans, injection of simple bone cyst with corticosteroid has been reported as a successful treatment.

Aneurysmal bone cysts contain large vascular sinusoids, are expansile, osteolytic and locally invasive of adjacent bone and soft tissue. Aneurysmal bone cysts have been classified as probably intraosseous arteriovenous shunts, but have also been classified as neoplastic. Aneurysmal bone cysts have been diagnosed in young adults to geriatric dogs. Clinical signs are localized pain and swelling, usually of several months' duration. A predilection exists

for the axial skeleton, although any bone can be affected. Treatments are intended to decrease vascularity while maintaining structural strength, and include debridement with bone grafting, radiation therapy, and cryotherapy. Aneurysmal bone cysts have been reported in dogs, cats, horses, and people.

Congenital Shoulder Luxation

Congenital shoulder luxation is a disease of small and toy breed dogs that, in the author's opinion, is in many ways analogous to congenital medial patella luxation, albeit much less common. Clinical signs are first

observed when the puppy begins to walk, or in young adults, depending on severity. Clinical signs range from non-weight-bearing and constant luxation, to the more common intermittent luxation and associated intermittent lameness (Figure 98-14). Palpation may reveal a medial luxation. Applying medial pressure on the proximal humerus and abducting the elbow with one hand while palpating the relative position of the acromion process with the other hand should diagnose medial shoulder luxation or subluxation. Radiographs are indicated to access the changes to the glenoid cavity and humeral head, with craniocaudal stress radiographs if used for the purpose of diagnosis or

documentation.

The condition is presumed not to be of traumatic etiology, and by convention is called congenital, but may be developmental. Medial luxation or subluxation of the shoulder dictates coexisting insufficiency of the medial collateral ligament and joint capsule, with possible involvement of the subscapularis muscle/tendon. Because congenital shoulder luxation involves abnormal forces in a juvenile, Wolff's law dictates that the glenoid cavity and humeral head develop an abnormal shape. The glenoid cavity may be more shallow, flat, or even convex, with or without identifiable erosion of the medial brim; the

humeral head is flattened to varying extents.

Treatment should be proportional to the severity. Various surgical techniques have been described to stabilize the luxation, with relatively low success rates. A flat or convex glenoid cavity would logically predict poorer results of medial stabilization, as would complete luxation and the presence of osteoarthritis. Shoulder arthrodesis is a reasonable option in dogs owing to the high mobility of the scapula. However, the presence of the infraspinatus nerve and the sparse amount of scapular bone (i.e., decreased ability of implants to hold) makes arthrodesis problematic in these

small and toy breed dogs. Dogs with infrequent intermittent lameness that appears to the owner to be non-painful may be harmed more by surgery than helped.[4,5]

Congenital Elbow Luxation

Congenital elbow luxation occurs predominantly in English bulldogs, basset hounds, Yorkshire terriers, Pekingese, and other small and toy dogs.[4,5] A hereditary etiology has been suggested, but not confirmed. The pathogenesis has been speculated to be an in utero insufficiency of the elbow's medial collateral ligament and perhaps annular ligament. The luxation is lateral in all but one documented

case,[9] and can be unilateral or bilateral. The critical pathologies with congenital elbow luxation are the lateral location of the triceps muscle insertion (hence, contraction does not extend the elbow), and malarticulation in a young dog, causing gross osseous deformities of the joint (see Wolff's law). Congenital elbow luxation causes an obvious deformity (Figure 98-15) consisting of lateral luxation, flexion of the elbow, and pronation of the antebrachium. Appearance of affected dogs has been compared to the praying mantis insect. Gait is likewise overtly abnormal, since inability to extend the elbow(s) causes the dog to crawl (Figure 98-16). A craniocaudal radiograph of the affected leg yields a

Cr-Cd image of the humerus and a lateromedial image of the radius and ulna (Figure 98-17), as opposed to adult dogs with traumatic elbow luxation in which the radius and ulna are not typically rotated.

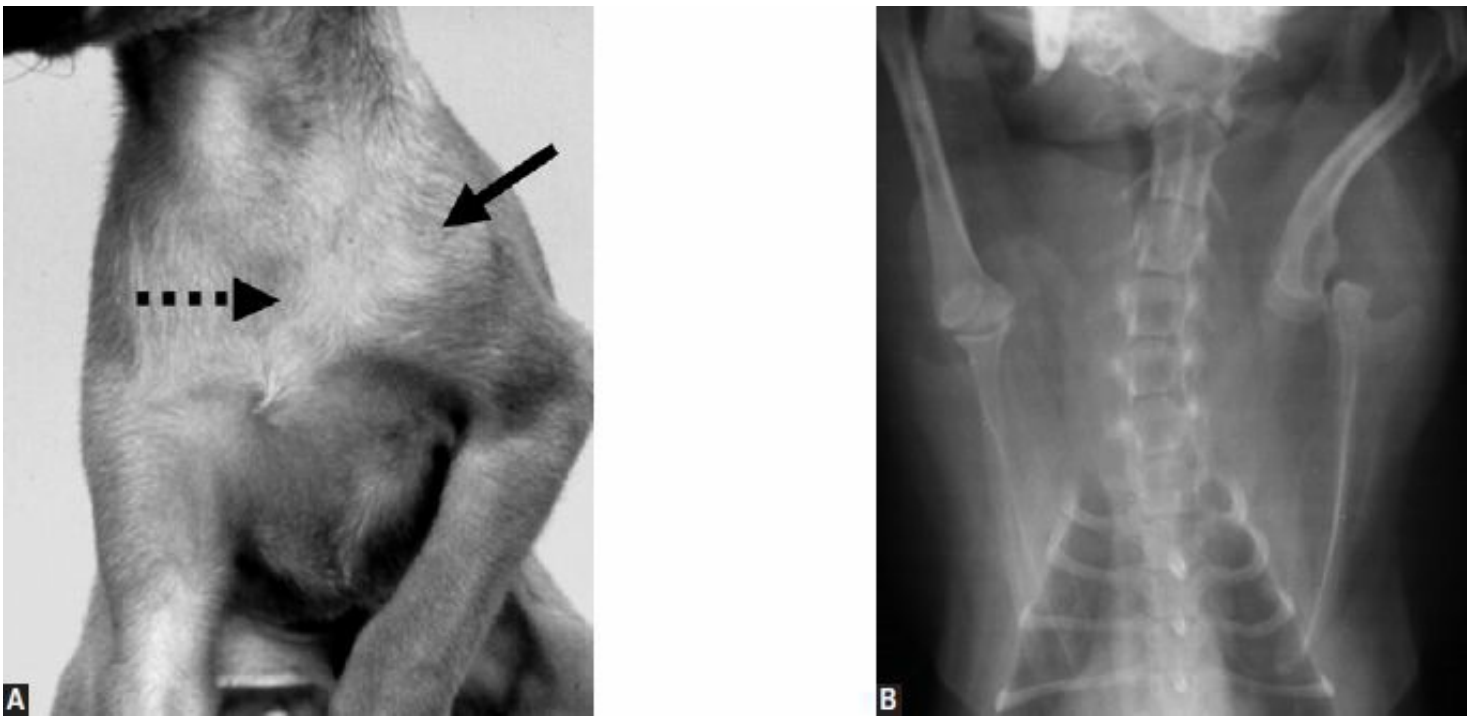

Figure 98-14. Congenital shoulder luxation (left) in a puppy. (A) Note the Abduction of the arm, with lateral position of elbow, prominent acromial process (solid arrow) and medial placement of humeral head (dashed arrow). (B) Radiograph showing congenital medial shoulder luxation. Note the flat to convex

shape of the affected glenoid cavity.

Satisfactory treatment of congenital elbow luxation depends on age at the time of surgery and adult weight of the dog. If treated when only a few weeks old, a modified external fixator (Figure 98-18) typically results in a functional joint (although radiographically abnormal). A small K-wire (e.g., 0.062”) is placed mediolaterally through the olecranon near the triceps insertion; a second K-wire is likewise placed transcutaneously across the distal humeral epicondyles, and a rubber band of appropriate tension is placed externally from the lateral tip of the olecranon pin to the medial tip of the transepicondylar pin, which

rotates the olecranon to the correct functional position caudally. The dog is encouraged to walk on the leg normally (i.e., not splinted) until reduction is maintained without the rubber band present (typically a couple of weeks).[9,10] Success of this technique is fairly reliably predicted based on the ease of manually reducing the luxation. For older dogs, in which the luxation is not readily reduced, transposition of the olecranon can yield reasonable function in some cases. Heavier dogs (e.g., English bulldogs), especially if not treated early, have a poor prognosis for a functional joint; arthrodesis is an option for unilateral cases.

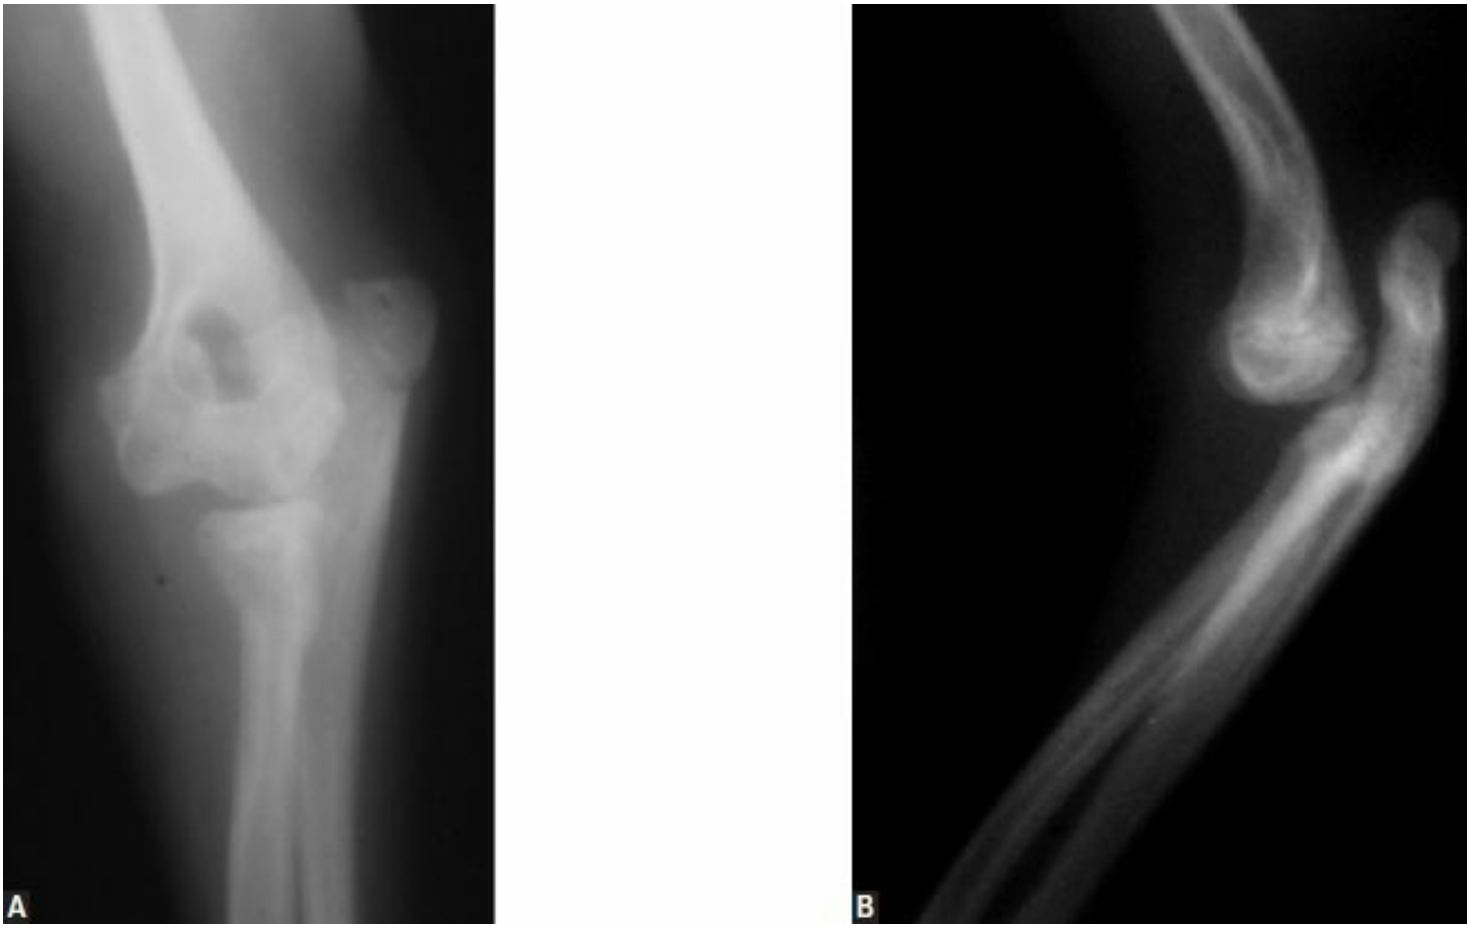

Figure 98-15. Congenital elbow luxation. Note that in the craniocaudal radiograph of the elbow there is a lateromedial view of the radius and ulna. (B) In mediolateral radiograph of the elbow there is a craniocaudal view of the radius and ulna.

Figure 98-16. Congenital elbow luxation is a juvenile. Note the "Praying Mantis" appearance of the front legs due to inability to extend the elbows. There is also internal rotation of the antebrachii and abnormal topographic anatomy of the elbows.

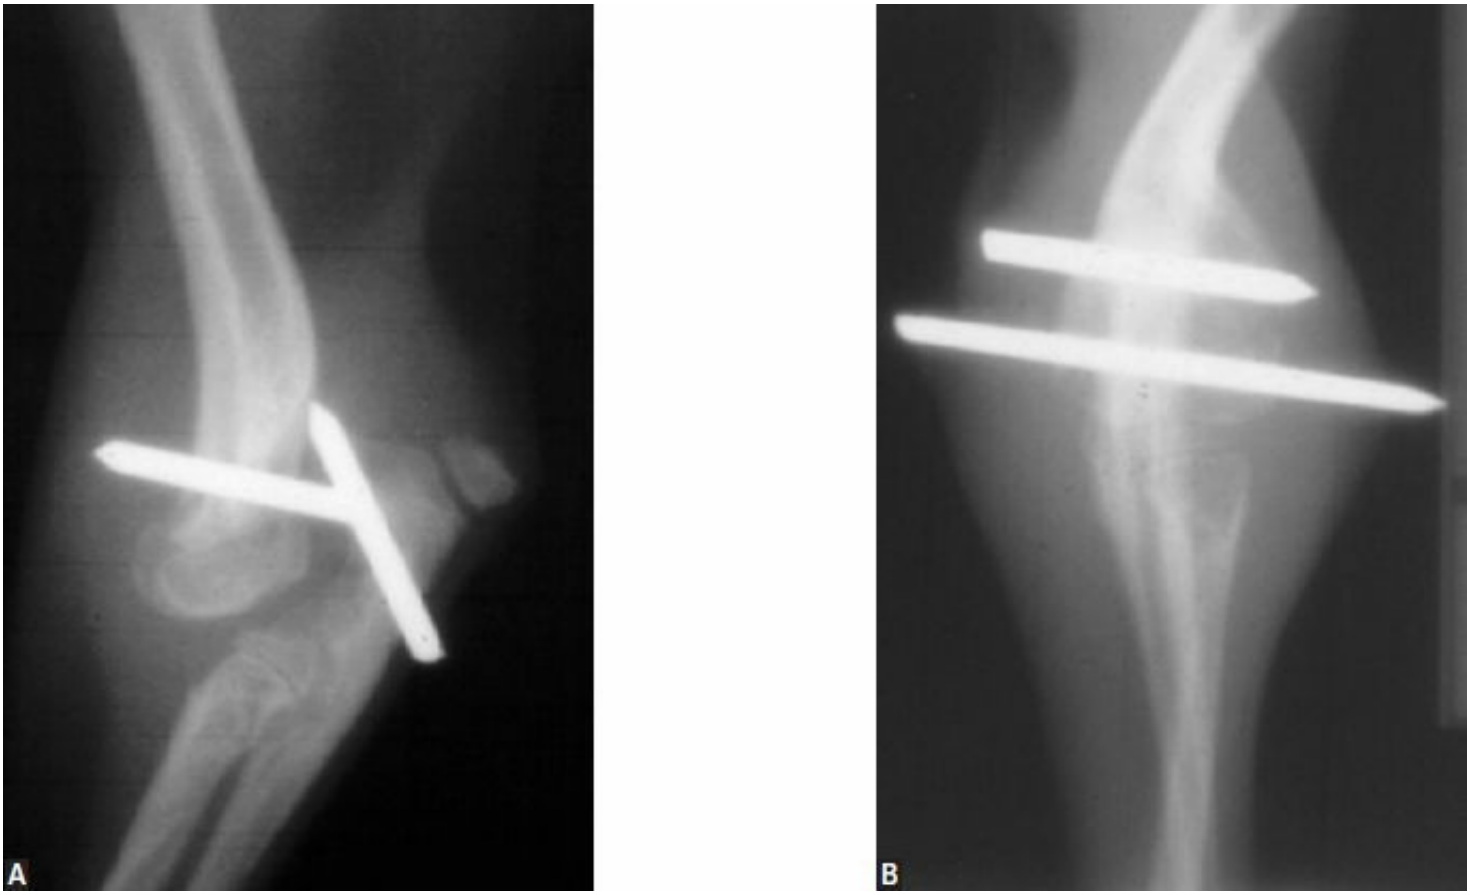

Figure 98-17. Radiographs of dog with congenital elbow luxation. (A) Pin placement for modified external correction. (B) Placement of rubber band on the pin tips (external to the skin) of appropriate tension reduces the luxation while allowing flexion and extension of the elbow joint necessary for juvenile joint health.

Figure 98-18. Multiple cartilaginous exostosis occurred in multiple other locations in this dog. Cartilage covering the exostosis (arrow) was visible on histopathology.

Figure 98-19. Osgood-Schlatter disease in a hunting dog. There is an increased width of the physis of the tibial crest.

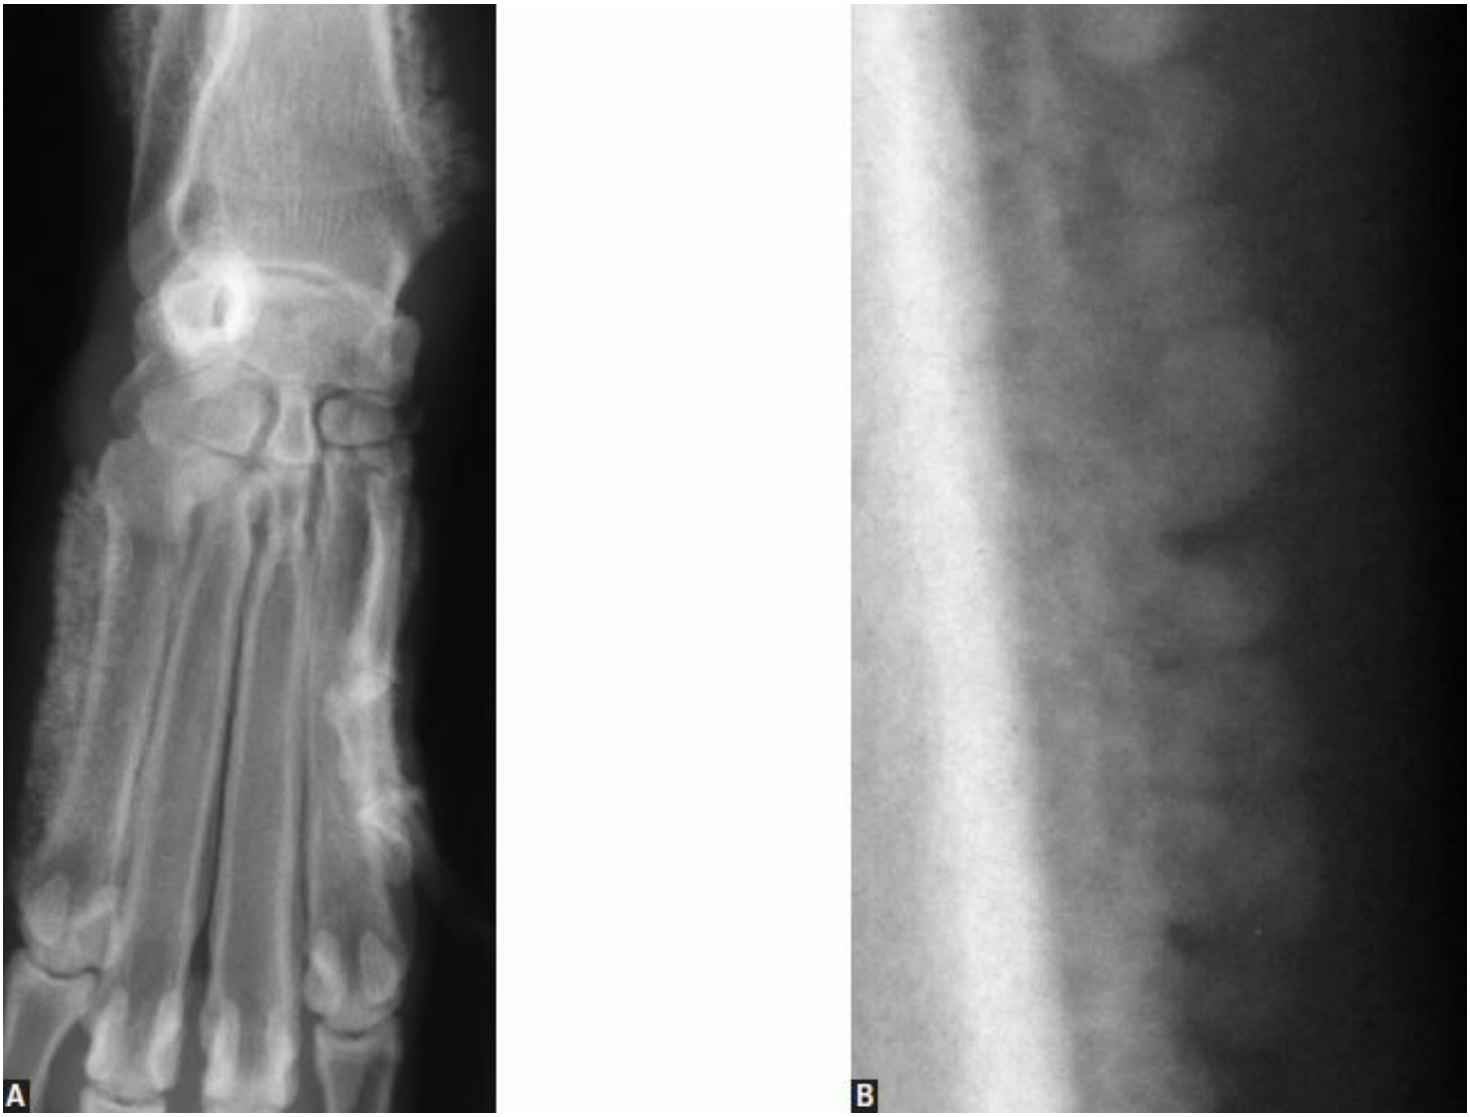

Figure 98-20. Hypertrophic Osteopathy in an adult dog with lung tumors. (A) Periosteal reaction is present along the metacarpi and distal radius and ulna. Note that the joints are unaffected. (B) Close up of the unique "Palisades" periosteal reaction associated with HO.

Multiple Cartilaginous

Exostosis

Multiple cartilaginous exostosis (MCE) is a rare disease with the interesting pathogenesis of extra physes or articular-epiphyseal complexes* that are aberrantly located on, and usually perpendicular to, cortical bone (Figure 98-19).[5,11,12] The pathogenesis most widely accepted is that the MCE originated from the physis before separating. Any bone of the axial or appendicular skeleton formed by endochondral osteogenesis may have MCE, with the involvement of multiple bones being typical. As the juvenile dog grows, so do the cartilaginous exostoses. MCEs are mushroom shaped, with the stalk consisting of bone

formed by endochondral osteogenesis, and the top being cartilage covered and comparable histologically to an A-E complex. Growth continues until osseous maturity, when the MCEs, the normal physes, and A-E complexes cease growth and ossify. Onset of clinical signs is predictably while the dog (and exostoses) are undergoing rapid growth (2 to 5 months of age). Clinical signs associated with MCE depend on their location and what damage (primarily via pressure) the exostoses cause to adjacent tissue. Clinical signs range from a palpable mass, to lameness (pressure on muscle, nerve and/or vessels) to paralysis (compression of the spinal cord). Diagnosis is confirmed via radiographs

of multiple bones with characteristic bone lesions. The bone lesions show bone of variable shape and size extending perpendicular to the metaphysis with radiolucent areas (hyaline cartilage) capping the end. Biopsy results indicate a typical physis consistent with the age of the animal. The marrow portion of the MCE (stalk) contains adipose or hematopoietic marrow. Most cases of MCE have good outcomes unless the MCE has caused irreparable damage (e.g., to the spinal cord), because the MCE ceases growth when the normal physes cease growth. Multiple cases of MCE metamorphosis into chondrosarcomas or osteosarcomas have been reported in the literature; hence, monitoring or

removal would be judicious.

Osgood-Schlatter's

Osgood-Schlatter's disease is a physitis of the tibial crest.[5,13] It has been observed in juvenile dogs, specifically active hunting breeds (e.g., pointers). Osgood-Schlatter's disease is a condition in juvenile boys (~8-15 years old) also called "football knee". It most commonly occurs in larger, athletically active boys. The physes of the tibial crests become inflamed, painful, and radiographically abnormal (i.e., widened and irregular) (Figure 98-20).[17] Adjacent soft tissues are also inflamed in the acute phase. Osteochondrosis has been a proposed

etiology. The more likely and more widely accepted etiology is repetitive trauma. Tension from the patellar tendon, especially strong and repetitive forces, can overload the adjacent physis, resulting in physitis. Rest is the preferred treatment for most cases, followed by avoiding the causative activity until skeletal maturity. Fixation is required only for a displaced tibial crest (determined by flexing the stifle and palpating a lax patellar tendon and unstable tibial crest).

Hypertrophic Osteopathy

Hypertrophic osteopathy (HO) is the only disease reviewed in this chapter

that occurs typically in mature dogs. The most common cause of HO is a mass within the thorax. The likely pathogenesis is stimulation of the vagus nerve, which subsequently alters vascularity to the periosteum of the distal limbs, which promotes periosteal proliferation.[14] This proposed pathogenesis is supported by research in which transection of the vagus nerve resulted in reversal of the periosteal lesions of the distal limbs. HO was originally called hypertrophic pulmonary osteoarthropathy (HPOA). Rhabdomyosarcomas of the urinary bladder have also been reported to cause HO, and the joint is not directly effected.[15-17]

Dogs with HO are typically presented for a firm, non-painful swelling of the metacarpus, metatarsus, and phalanges. The swelling may progress more proximally in some cases. Radiographs show a characteristic, if not pathognomonic, periosteal proliferation characterized as “palisades” (columns, similar to numerous tall buildings) (Figure 98-20B). HO is not treated per se. Rather, treatment is directed toward the underlying cause. Although neoplasia (metastatic or primary) in the thorax is the most common inciting cause of HO, other diseases have been reported to result in HO (e.g., spirocerca lupi parasitism, emphysema, etc).[4]

Chapter 99

Metabolic, Nutritional, and Endocrine Bone Disorders

Herman A.W. Hazewinkel

Metabolic diseases of the skeleton can be due to inborn errors of metabolism or be acquired. The former includes abnormalities in collagen synthesis and, as a consequence, abnormal growth or mineralization of the skeleton, whereas the latter includes a variety of hormonal diseases with or without a nutritional cause. Here we will limit ourselves to three examples

of collagen disease, which are important to recognize as the differential diagnoses of diseases of endogenous and of nutritional origin.

Multiple Epiphyseal Dysplasia

Although different types exist, the major features of multiple epiphyseal dysplasia are irregular epiphyseal growth, with little vertebral involvement and a mild dwarfism, and an irregularly shaped acetabulum.[1] In humans, this genetic trait is autosomal dominant as well as recessive, whereas in dogs it seems to be autosomal recessive.

The clinical signs become obvious at the age of 2 to 3 months and are seen in a variety of breeds including Labrador retrievers, viszlas, and Rottweilers. The owner will notice that the dog does not grow as fast as the litter mates. The elbow joints may be abducted and the gait abnormal in cases with joint deformities, however, this is not always the case. The dog will have short legs and a normal skull and vertebral column. Radiology will reveal shortening of the long bones when compared with litter mates and, in some cases, abnormal joint alignment (Figure 99-1A). Concomitantly, osteochondrosis and other developmental diseases can be present, but so far we have not seen it

in conjunction with ocular diseases like retina dysplasia.

In cases of abnormal joint alignment, the prognosis is extremely poor. In other cases, the disturbed growth will not have a major impact on the dog's well being.[2]

Osteogenesis Imperfecta

The disorder is first noticed at about 3 to 4 weeks of age, when dogs with osteogenesis imperfecta (OI) reveal a reluctance to move. They are well proportioned, with blue sclera, translucent and fragile teeth, and legs with hyperlaxity at different joints and possibly with multiple fractures. Blood biochemistry and calciotropic hormone

plasma levels are normal. The etiology is a genetic defect, probably autosomal recessive, which encodes for procollagen molecules of collagen type I, resulting in an abnormal collagen structure affecting the formation and stability of bone mineral associated with this collagen.[3] Because collagen type I represents 90% of the organic substance of bones, teeth, and tendons, this genetic defect has consequences for osteoid and dentin mineralization, and for connective-tissue strength at multiple sites including the chordae tendiniae. The rupture of the latter may cause sudden death of the patient. The disease has been reported in golden retrievers, collies, poodles, beagles, Bedlington terriers,

dachshunds, and domestic cats.[4]

The diagnosis can be made by a clinical and radiologic investigation. Radiographs show poorly mineralized bones (long bones and ribs) with only some contrast in the area bordering the growth plates, which are of normal width, and fractures of long bones and ribs (Figure 99-1B). The diagnosis can be confirmed by pathologic investigation, which reveals regular growth plates, with some disturbed mineralization of the primary mineralization zone, but with absence of secondary spongiosa, as well as with irregularly arranged woven bone without Haversian systems in lamellar bone.[4] Sometimes dentinogenesis

imperfecta, owing to poor mineralization of collagen type I of the dentine, is concomitantly present. Differential diagnoses include (1) alimentary secondary hyperparathyroidism (discussed later), although this does not go together with flexible joints, blue sclera, or transparent teeth, and the diet of the patient does not differ from that of its normal litter mates; (2) hypovitaminosis D, although that is characterized by the increased width of growth plates; (3) hypothyroidism, although these patients are mobile, do not have fractures, and reveal delayed skeletal maturation with otherwise normal mineralization.

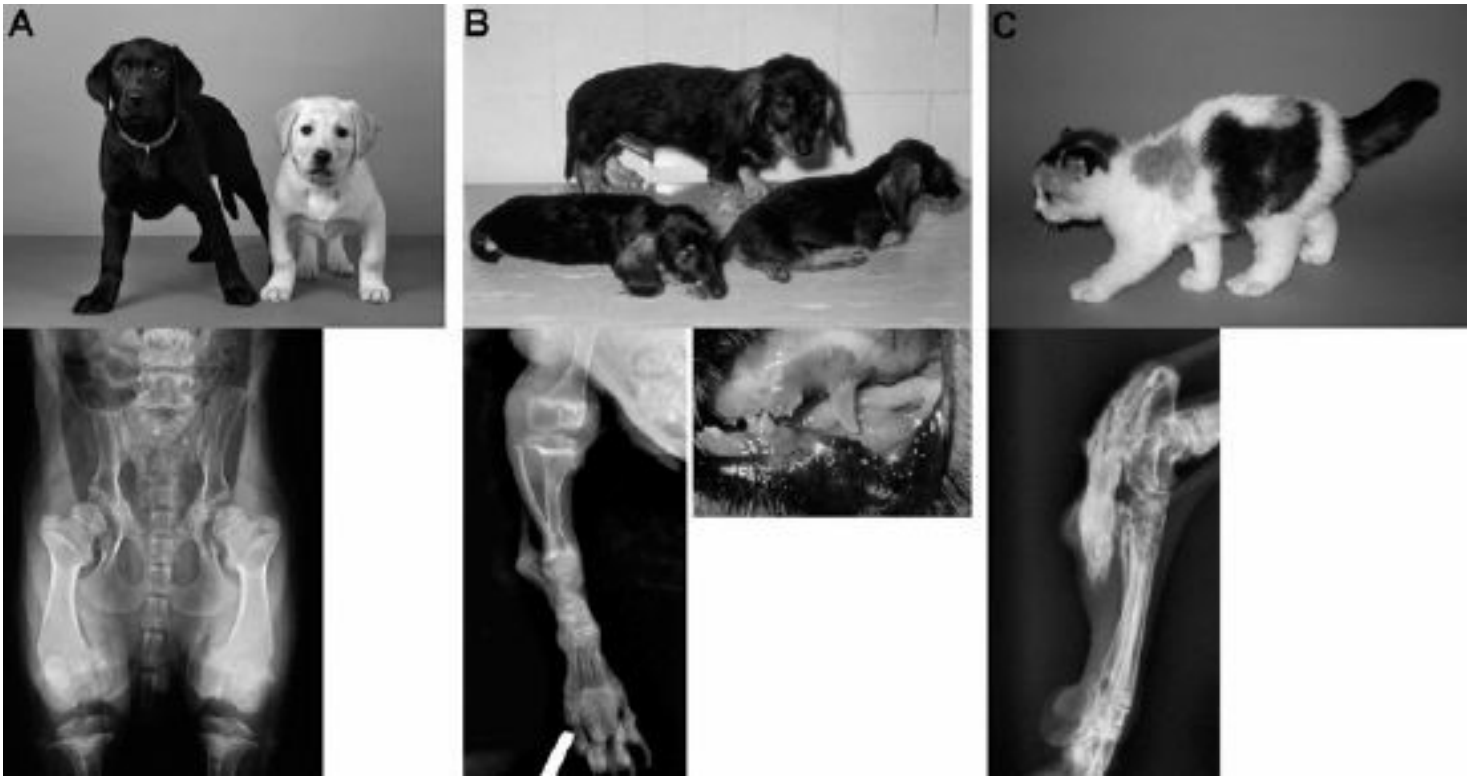

Figure 99-1. Metabolic bone disorders. (A) Disproportional Labrador pup with multiple epiphyseal dysplasia revealing short long-bones, abnormal physeal growth, and irregularly shaped acetabulum with normally shaped vertebrae. (B) Dachshund pup with osteogenesis imperfecta with poor mineralization of long bones and slight widening of growth plates. (C) Offspring of Scottish fold cat with osteochondrodysplasia revealing short misshapen distal limbs with exostosis plantar to and distal of the calcaneus.

Treatment of osteogenesis imperfecta for human patients includes

biphosphonate supplementation to strengthen the bone, and allogeneic mesenchymal stem cell or bone-marrow transplantation with acceptable success;[5] but for companion animals, the prognosis is poor.

Osteochondrodysplasia in Cats

Osteochondrodysplasia is a generalized skeletal disease characterized by short, misshapen distal limbs; exostosis plantar to the calcaneus; and round joints of distal limbs with diffuse osteopenia of adjacent bone; and short, thick inflexible tails (Figure 99-1C). It occurs in offspring of both genders originating from the mating of

a Scottish fold with a normal cat. The Fold-ear is a dominant trait but does not always coincide with these skeletal abnormalities. The patient reveals lameness, a stiff gait, and a reluctance to jump, starting at a young age. Histologically, cartilage maturation seems to be disturbed.[6] Differential diagnosis is hypervitaminosis A, although this reveals exostosis around the proximal joints.

Treatment of single cases varies from expectative, radiation of exostosis,[7] and pantarsal arthrodesis,[8] to injections with pentosan with oral dosage of glucosaminoglycans,[6] all of which have been described as producing some success. However,

breeding with Fold-eared cats can be prevented, because prognosis of this disease is poor.

Vitamin A

Vitamin A is essential in bone metabolism, especially in reducing chondrocyte proliferation in growth plates, decreasing periosteal osteoblast activity, and stimulating osteoclast activity, in addition to a variety of functions in reproduction, epithelization, and retina integrity. Vitamin A is present in animal fat, for example in ground beef (1400 IU/kg dm), raw egg (40,000 IU/kg dm), bovine liver (1,500 000 IU/kg dm), and cod liver oil (850,000 IU/kg dm).

In dogs, but not in cats, vitamin A ($C_{20}H_{29}OH$) can be synthesized out of β-carotene ($C_{40}H_{56}$) by cleavage with the aid of carotenase present in the intestinal mucosa and liver cells. Approximately 1 μg of carotene is equivalent to 0.5 IU of vitamin A. Therefore, the dietary requirement of vitamin A for cats is higher than for dogs (10,000 IU and 5000 IU per kg dm food, respectively). The upper limit of vitamin A for cats is reported to be 100,000 IU/ kg dry matter (i.e., 10 times the requirement). Another difference between dogs and cats regarding vitamin A metabolism is in inactivation; dogs but not cats can form retinyl esters to inactivate vitamin A and are able to excrete 15 to

60% of the daily intake as retinyl palmitate in the urine. Therefore, hypervitaminosis A is seen more frequently in cats than in dogs, especially at an older age (3 to 13 years).[9]

Hypervitaminosis A

Hypervitaminosis A can be caused in kittens and puppies after several weeks of over-supplementation. They reveal reduced growth in length and osteoporosis of long bones together with flaring of metaphyseal regions. Hypervitaminosis A in dogs results in anorexia, decreased weight gain, narrowing growth plate cartilage, decreased new bone formation, and

thin cortices. Concentrations of vitamin A in plasma serum exceed the normal ranges for dogs (i.e., 1800-18,000 IU/L).

Hypervitaminosis A in cats may produce a stiff neck and/or enlarged joints in the front and hind legs (mainly elbow and stifle joint) owing to ankylosis, dull hair coat, change in character (probably owing to hypersensitivity and/or bone pain), anorexia, and weight loss (see Figure 114-3 in Chapter 114, Nutrition in Orthopedics). To confirm the diagnosis bone biopsies can be taken, but a liver biopsy, which is easier, will show fatty infiltration.[9] In addition, retinol levels of the liver are increased, in contrast

to plasma retinol levels, which were normal in 20% of the cases in a study in cats with hypervitaminosis A.[10]

In dogs, a history of supplementation with cod liver oil will help to make the diagnosis. In cats, the history can indicate a prolonged preference for raw fish, raw liver, or supplements, but this is not always the case, suggesting an individual predisposition.[9] On the other hand, a diet with 10^6 IU vitamin A per kg given to adult cats failed to produce the classic skeletal signs of hypervitaminosis A in 2 years' time.11 Both 0.5* 10^6 and 10^6 IU vitamin A per kg diets (92% dm) given to pregnant queens coincided with a 1.7- and 9-fold

incidence increase of kittens with malformations, including neural tube defects, cleft palate, and pelvic hypoplasia, when compared with controls receiving 19,800 IU vitamin A per kg food.[11]

The therapy should be instituted as soon as the diagnosis is made and includes analgesia and food adaptation. Because all commercially available balanced foods include at least the required amount of vitamin A, it is better to prescribe a balanced home-made diet without vitamin A added to it. Such a diet should have a low animal-fat content (lean meat such as veal, lamb, or poultry, or cottage cheese). Per 100 g of cooked meat

(including its boiling water with taurine in it) and 60 g of cooked rice should be added 2 tsp of corn oil, 0.5 tsp iodized salt, and 1 tsp bone meal to prevent deficiencies.[12] Because cats will often have hepatic lipidosis, the dosage of analgesia should be on the lower side. General improvement can be seen 4 weeks after the start of the therapy; ankylosis will not disappear so the cats will stay lame, although not from pain.[9]

Vitamin D

The importance of vitamin D (vitD) for skeletal development was reported in dogs even before it was described in humans.[13] The skeletal abnormalities,

including thin cortices, curved bones, and enlarged growth plates, that developed in dogs raised on oatmeal could be prevented and cured by the administration of cod liver oil. Sunlight was found to prevent rickets in children and to cure rickets in a goat based on the ability to synthesize cholecalciferol in the skin under the influence of ultraviolet-B light. This ability has been developed in amphibians, reptiles, birds, herbivores, and omnivores, but not in dogs and cats.[14] The cutaneous level of the vitamin D_3 precursor 7-dehydrocholesterol (7-DHC) is low,[14] because of a high level of 7-DHC reductase, an enzyme with high activity converting 7-DHC into

cholesterol.[15] Thus, dogs and cats are solely dependent on dietary resources to meet their vitamin D requirement. Balanced dog and cat food does not need any vitamin D supplementation, irrespective of the season or the latitude.

Vitamin D_3 is absorbed in the intestine by passive diffusion, transported in plasma bound to chilomicrons, lipoproteins, and vitD-binding proteins (DBP), and routed to the liver where 40% to 60% will be absorbed.[16] Here $vitD_3$ is hydroxylated into 25-hydroxy-cholecalciferol ($25OHvitD_3$). Eventually, this metabolite is further hydroxylated at different places, thus forming a variety of metabolites with

different or no activity. Two metabolites are considered to be the most active: 1,25dihydroxy-cholecalciferol (1,25 $(OH)_2vitD_3$) and 24,25dihydroxy-cholecalciferol ($24,25(OH)_2vitD_3$). Other metabolites are considered metabolites of the oxidation pathway and can be increased in case of vitamin D intoxication.[17] A 1000-fold difference in plasma concentration exists between $25OHvitD_3$ (nmol/L) and $24,25(OH)_2vitD_3$ (nmol/L), versus $1,25(OH)_2vitD_3$ (pmol/L), but the latter is the most active metabolite. Under normal circumstances, only 0.4% of the latter is not bound to transport proteins and thus it is

biologically active. In vitD intoxication, $1,25(OH)_2vitD_3$ is freed from the binding protein, resulting in high vitD activity without a severe increase of the total plasma concentration of $1,25(OH)_2vitD_3$.[18] The hydroxylation into 24,25 or $1,25(OH)_2vitD_3$ in the kidneys is reflected in the plasma concentration, whereas other hydroxylation sites (such as intestine, growth plates, and placenta) are not. A variety of factors, related to breed, age, and dietary contents, influence the plasma concentrations of these main metabolites (Table 99-1).[19-27] The main role of $1,25(OH)_2vitD_3$, the biologically most active metabolite, is the mineralization of newly formed

cartilage and osteoid. Its increase of active intestinal and renal calcium and phosphorous absorption and its stimulation of the parathyroid hormone-induced osteoclastic bone resorption should be seen in the light of making calcium and phosphorous available for the mineralization process. The main role of 25OHvitD_3, the most abundant metabolite in plasma, is to become hydroxylated, although it has biologic activity, which mainly increases active calcium absorption. The main roles of 24,25$(OH)^2$vitD_3 are decreasing the actions of 1,25$(OH)_2$vitD_3 on the intestine, but working in concert in cartilage maturation and possibly suppression of osteoclast activity.[19]

Table 99-1. Factors Influencing the Subsequent Steps of VitD Hydroxylation

$VitD_3$ → 25OHvit D_3

• The amount of $vitD_3$ in the plasma and thus the $vitD_3$ intake. Dogs raised on a diet deficient of $vitD_3$, revealed significant lower plasma levels of $25OHvitD_3$.[19] In cats, a linear correlation could be demonstrated between $vitD_3$ intake and plasma levels of $25OHVitD_3$.[15] In young Great Danes, however, an 8-fold increase of $vitD_3$ was not reflected in the plasma concentration $25OHvitD_3$, whereas a 100-fold intake was.[20]

• Growth hormone (GH) plasma level: in miniature poodles (MPs) the 25OHvitD_3 plasma levels were significantly lower than in MPs injected daily with GH or in Great Danes with known juvenile acromegaly, all on the same diet.[21]

• Influenced by the further hydroxylation process and thus by the calcium requirement, i.e., an excessive calcium intake in dogs with hypoparathyroidism causes an increased plasma 25OHvitD level, without changes in plasma levels of the dihydroxylated metabolites.[19] Calcium supplementation in alimentary secondary hyperparathyroidism

increases 25OHvitD_3 synthesis.[22]

• A disturbance in the enterohepatic cycle and/or intestinal fat absorption coincides with a decreased level of 25OhvitD.[23]

25OHVIT D_3 → 24,25$(OH)_2$VIT D_3

• Amount of vitD in the food: in vitD deficiency, the plasma level of 24,25$(OH)_2$vitD_3 is extremely low (3% of normal value),[19] whereas if the intake of vitD is 100 times the recommended dosage for 3 months, the plasma level of 24,25$(OH)_2$vit increases to 16-fold.[24]

• Breed differences, mainly owing to GH plasma levels. In Great Danes the ratio is between 25OHvitD:

$24,25(OH)_2vitD_3$ = 1-3: 1, whereas this ratio in MPs is 1:1-3 owing to a down-regulating effect of GH and/or IGF-I on 24-hydroxylase activity.[19,21]

• Calcium status of the animal. In case of nutritionally induced hyperparathyroidism, plasma $1,25(OH)_2vitD_3$ levels are increased and $24,25(OH)_2vitD_3$ levels are decreased, both in large and small breed dogs.[19] This is due to decreased activity of renal (but not intestinal) 24-hydroxylase.[25]

• Dietary restriction of phosphorous decreases renal 24-hydroxylase activity.[26]

25OHVITD → $1,25(OH)_2$VITD

• Insufficient amount of vitD in the diet will moderately decrease total plasma $1,25(OH)_2vitD_3$ concentration.[19] Based on the 1000 concentration difference, only a small amount of $25OHvitD_3$ is necessary to produce an adequate amount of $1,25(OH)_2vitD_3$, especially because the 24-hydroxylation is almost stopped.[19] However, an increased protein-binding percentage of $1,25(OH)_2vitD_3$ can be anticipated, and thus less biologically active $1,25(OH)_2vitD_3$ is available.

• An increased $vitD_3$ intake will stimulate $1,25(OH)_2vitD_3$ synthesis and as a consequence, 24-hydroxylase activity will increase, leading to an

augmented hydroxylation of $1,25(OH)_2vitD_3$ into $1,24,25(OH)_3vitD_3$, as has been shown by Tryfonidou et al. (2003) in a study in 2 groups of Great Danes with 100-fold difference in $vitD_3$ dietary intake.[20]

• The breed and age of the animal; young, fast-growing dogs with their increased levels of GH and insulin-like growth factor I, reveal a higher $1,25(OH)_2vitD_3$ plasma concentration than small breed dogs, even when raised on the same diet.[19,21]

• Calcium can directly or via parathyroid hormone (PTH) influence the 1α-hydroxylation of $25OHvitD_3$.

PTH stimulates $1,25(OH)_2vitD_3$ production. Hypophosphatemia can stimulate 1α-hydroxylase directly and thus form a positive feedback loop with increased $1,25(OH)_2vitD_3$ production, and as a consequence, an increase in phosphate absorption in the intestine, reabsorption in the kidneys, and resorption from the bone.[27]

Hypovitaminosis D

Hypovitaminosis D in young growing animals is called rickets. It is characterized by thin cortices, wide growth plates, broad osteoid seams, and a low plasma concentration of

most of the vitamin D metabolites. Rickets is seen only under extreme circumstances, including in dogs fed unsupplemented vegetarian food, in dogs with an inability to absorb fat and thus also vitamins soluble in fat,[23] and in dogs with inborn errors of vitamin D_3 metabolism.

The diagnosis can be made with radiographs, revealing thin cortices and wide ("mushroom shaped") growth plates (see Figure 114-1C of Chapter 114, Nutrition in Orthopedics). Because active calcium and phosphorous absorption will be decreased in hypovitaminosis D, plasma concentrations of these minerals will be lowered. As a consequence, more

PTH will be synthesised and secreted, thus increasing activity of 1α-hydroxylase. However, owing to the lack of sufficient substrate, the total $1,25(OH)_2vitD_3$ plasma concentration will be lowered (with even less unbound, biologically active metabolite). Under the influence of hyperparathyroidism, the osteoclasts will increase bone resorption to compensate for the decreased active calcium absorption, and thus osteoblasts will increase osteoid production as well. Osteoid will seal off the mineralized bone, preventing osteoclasts from resorbing more bone; the decreased bone and increased amount of collagen explain the bowing of the legs rather than the pathologic

fracturing seen in hyperparathyroidism.

Treatment depends on the underlying cause. Because the vegetarian diet is often unbalanced at multiple points, a balanced diet is the treatment of choice. Restoration of the skeleton can be noticed in 3 weeks' time because cartilage and osteoid are present and ready to become mineralized.[14] Atresia of the bile bladder can be corrected surgically.[23] Inborn error of vitamin D metabolism is resistant to even prolonged vitamin D therapy.

Hypovitaminosis D in mature dogs is called osteomalacia. It can be expected in mature dogs raised on a vegetarian

diet (without sufficient vitD supply) or in case of severe kidney failure with decreased 1α-hydroxylation of the 25-OHvitD metabolite. The latter can occur despite the renal secondary hyperparathyroidism. Because of hypovitaminosis D, newly formed osteoid will not mineralize, but in older animals this activity is reduced, leaving alone the osteoclast activity. Generalized osteoporosis will occur. This will seldom cause clinical problems, because the animal will already be suffering from its renal failure, but microscopically widened osteocyte lacunae can be noticed. Especially in the jaw, bone resorption can cause noticeable weakening (the “rubber jaw syndrome”) with loosening

of elements.

Hypervitaminosis D

Hypervitaminosis D in dogs is not easy to induce. Dogs developed an efficient 24-hydroxylase-induced mechanism to increase hydroxylation of $1,25(OH)_2vitD_3$ in case of its overproduction owing to increased vitD intake.[20] Only after 3 months of very high levels of dietary vitD content (100 times the required amount of 500 IU/ kg food) was the 24-hydroxylation mechanism not efficient, eventually leading to increased calcium absorption. In the dogs with the excessive vitD intake, bone trabecules were thicker, bone remodelling was

decreased, and endochondral ossification was severely disturbed, the latter even before calcium absorption increased (Figure 99-2A).[20] This led to the conclusion that excessive vitD intake is a direct cause of disturbance of endochondral ossification, and that the mechanism is not via hypercalcemia as was hypothesised earlier.[20] Disturbance of endochondral ossification in distal growth plates of the ulna caused radius curvus syndrome in most of these dogs.

Parathyroid Hormone

Parathyroid hormone (PTH) is synthesized in and secreted from the four parathyroid glands, lying in or

near the thyroid glands. Its synthesis is increased by decreasing plasma concentrations of calcium; chronic calcium deficiency causes enhanced synthesis per chief cell as well as hyperplasia of chief cells. Phosphorus does not have a direct effect on chief cell activity, whereas $1,25(OH)_2vitD_3$ executes a negative feedback on chief cell activity. In case of decreasing plasma $1,25(OH)_2vitD_3$ concentration, PTH acts directly on bone and kidneys to mobilize and reabsorb calcium, respectively. The second phase is increased osteoclast activity; PTH has no direct effect on osteoclasts but acts indirectly via the shrinkage of osteoblasts, thus exposing bone to the osteoclasts. Osteocytes under the

influence of PTH enlarge their lacunae, indicating osteocytic osteolysis.[27] Owing to coupling of osteoclast and osteoblast activity, mediated by local factors, osteoblast activity eventually increases. An important effect of PTH on renal tubuli is the decrease of the tubular maximum for phosphorus.

Alimentary Secondary Hyperparathyroidism (or All-Meat Syndrome)

In fast growing animals the calcium requirement is much higher than in mature animals. Insufficient chronic calcium intake, owing to imbalanced food (especially meat based) will

induce hyperparathyroidism with increased osteoclastic and osteocytic bone resorption and increased osteoblast activity: bone turnover is severely increased. This explains the radiologic and pathologic findings in the skeleton: normal growth in width of the bone, but an excessively increased osteoclastic bone removal especially in the endosteum and in the areas of cancellous bone (i.e., metaphyses, diaphyses, vertebrae). The cortex can become so thin that it cannot withstand normal muscle contraction or the bodyweight of the animal, leading to pathologic fractures (i.e., greenstick and compression fractures) (see Figure 114-1B in chapter 114, Nutrition in Orthopedics).

Compression fractures of vertebrae can cause paralysis and can determine the prognosis of the animal, although complete restoration can occur when additional trauma is prevented and adequate therapy is instituted.[9] The increased $1,25(OH)_2vitD_3$ plasma level in alimentary secondary hyperparathyroidism (ASH) explains the normal mineralization of the growth plate cartilage, visible as a white area bordering the growth plates of normal width.[16] This is the most important clinical finding to differentiate between rickets (wide growth plates) and ASH (narrow growth plates), both with thin cortices and possibly greenstick fractures.

Figure 99-2. Nutritional bone disorders. (A) Young dogs with access at weaning to food with high calcium content developed panosteitis at the age of 4 months, characterized radiologically by increased mineral density in the medulla at different sites.32 (B) Excessive calcium intake causing hypophosphatemia and hypoparathyroidism with decreased activation of 25OHvitD_3 caused rickets-like disease with poorly

mineralized cortical and cancellous bone and increased width of growth plates.[33] (See also Figure 114-1C of Chapter 114, Nutrition in Orthopedics). (C) Excessive vitamin D intake causes disturbances of endochondral ossification including retained cartilage cones in (especially fast growing) growth plates, even before it causes increased calcium absorption with hypercalcemia.[20] (See also Figure. 114-1D of Chapter 114, Nutrition in Orthopedics).

The therapy includes strict rest to prevent more damage and normalization of the diet. Normalization of the diet can be accomplished with a complete, balanced food; extra calcium carbonate (50 mg calcium per kg body weight per day) can be added. Because the endogenous $1,25(OH)_2vitD_3$ is increased in hyperparathyroidism, calcium absorption is highly efficient

and extra vitamin D is contraindicated in order to avoid further increasing osteoclast activity.[9]

Fractures should be treated only conservatively, i.e., even splints cannot be applied, because the bone will break at the proximal margin of the splint. After mineralization of the skeleton, which is completed within a month, corrective surgery can be considered.

Differential diagnoses are rickets, osteogenesis imperfecta, and renal hyperparathyroidism.

Calcitonin

In the dog calcitonin (CT) is

synthesized mainly in the parafollicular or C-cells in the thyroid glands. The synthesis of calcitonin is increased in case of calcium intake and gastrin. Chronic excessive calcium intake, especially at a young age, caused hyperplasia of C-cells.[28] Phosphorus has no known effect on the C-cells, whereas $1,25(OH)_2$vitD suppresses CT gene expression.[29]

The main function of CT is the storage of calcium in the skeleton. thus preventing (post-)prandial hypercalcemia. It does so via an instant release of secretory granulae filled with CT after stimulation by calcium or gastrin followed by instant retraction of the ruffle border of

osteoclasts. Chronic hypercalcemia causes hypercalcitoninism, characterized by an increased CT plasma concentration and/or increased response on calcium intake, not directly related to the total amount of absorbed calcium.[30] As a consequence, osteoclast activity is decreased. In addition, chronic hypercalcemia will suppress parathyroid synthesis and activity, including suppressed osteoclasia.

Nutritional Hypercalcitoninism

Induction of hypercalcitoninism depends on the growth rate of the dog, the age of the animal when the

excessive calcium intake starts, and the duration of the period the excessive calcium intake lasts.

Miniature poodles (MPs) raised on a diet with excessive calcium content (3.3% calcium on dry matter base [dmb], which is 3 times the calcium requirement according to NRC 1974 and 6 times the requirement of NRC 1985 (based on an average growing beagle puppy) developed no clinical or radiologically detectable skeletal abnormalities.[31]

Great Dane (GDs) puppies with access to the bitch's diet, which had increased calcium (3.3% on dmb) in order to prevent eclampsia puerperalis (milk

fever), during only the period of partial weaning (i.e., 3-6 weeks of age) developed hyperplasia of C cells with excessive response of CT release following a calcium bolus injection. Despite the fact that at 6 weeks of age all pups got standard food (with 1.1% calcium), the dogs with access to the calcium supplanted food at partial weaning revealed this excessive response until 4 months of age. All these dogs developed enostosis (panosteitis eosinofylica) characterized by shifting lameness and white confluent areas in the medullary cavities (Figure 99-2B), whereas the pups with access to the control food from partial weaning onward had normal skeletal development.[32]

GDs with access to the above described bitch's diet (3.3% calcium on dmb) during partial weaning and continued thereafter, developed severe hypercalcemia, hypophosphataemia, and hypoparathyroidism. Calcification of newly formed osteoid and cartilage was much disturbed both as a result of the hampered phosphate absorption causing hypophosphataemia and the disturbed vitamin D metabolism owing to hypoparathyroidism (Figure 99-2C). The skeleton revealed rickets-like abnormalities with thin cortices and wide growth plates. After normalization of the diet, the chief cells became active again and the skeleton mineralized completely.[33]

GDs raised on food with an increased calcium or calcium plus phosphorous content (i.e., 3.3% calcium and 0.9% phosphorous or 3.3% calcium and 3.0% phosphorous, respectively) starting at weaning (i.e., 6 weeks of age) revealed decreased bone remodeling owing to decreased osteoclast activity and disturbances in endochondral ossification, i.e., osteochondrosis. Decreased remodeling was not expressed as a proportional widening of foramina in the cervical area, leading to the so-called wobbler syndrome, as was also described by Hedhammar et al. (1974) who raised GDs with excessive food intake and compared them with restrictedly fed dogs.[34] The disturbances of

endochondral ossification were noticed as osteochondrosis in joint cartilage (in the centrocaudal area of the humeral head) and as retained cartilage in the growth plates of ribs, distal ulnae, distal radius, and crus. Disturbances in growth in length developed in these dogs with radius curvus syndrome, elbow incongruities, and deviation of the hind paws[33,35] (see Figure 114-1D and Figure 114-4 of Chapter 114, Nutrition in Orthopedics).

The diagnosis of hypercalcitoninism can only be confirmed by a provocation test with determination of the plasma calcitonin concentration, which warrants a homologous radioimmunoassay for CT.[36] A

thorough history with special emphasis on diet composition will not even be informative in many cases, because the calcium intake at pre-weaning is not known to many owners. After weaning calcium intake is often not known either because labels of commercial dog food usually state the “minimal content” rather than the actual content of calcium, unlike special diets with a maximum-claim for calcium (per kg food or per energy content). The diagnosis of hypercalcitoninism refers to the known cause of a series of entities characterized by decreased skeletal remodelling (panosteitis, canine wobbler syndrome) and disturbed endochondral ossification (osteochondrosis, retained cartilage

cones) in growth plates and joint cartilage. Although genetics may play a role in the occurrence of these entities (although this is not yet proven), high calcium intake plays an important role in their expression and so far no other causative factor has been indicated.

Therapeutic measures should include normalization of the diet. With osteochondrosis and radius curvus syndrome surgery may be indicated.

Growth Hormone

Growth hormone (GH) originates from the somatotrophic cells in the anterior lobe of the pituitary. Its release is characterized by rhythmic pulses,

reflecting the pulsatile delivery of growth hormone-releasing hormone, and intervening troughs. The GH level is under primary control of somatotropin-release inhibiting factor, both of which originate from the hypothalamus. The effects of GH can be divided into rapid or metabolic and slow or hypertrophic actions. The rapid effect includes insulin resistance, inducing enhanced lipolysis and restricted glucose transport across cell membranes. The slow effects are mediated through insulin-like growth factor I (IGF-I), which is synthesized in the liver and in other GH-target cells including chondrocytes. At growth plate level, GH stimulates cell differentiation after clonal expansion

through the locally produced IGF-I. IGF-I reached higher levels in growing dogs fed free choice compared with restricted feed controls, whereas dietary protein or carbohydrate content fed iso-energetically to growing dogs did not influence IGF-I levels.[37,38]

GH Excess

Basal plasma concentrations of GH are significantly higher in young dogs of large breeds than in dogs of the same age but of small or miniature breed.[39] The levels of GH in large breed dogs decrease during maturation and are not significantly different from that of small breed dogs at 6 months of age 38

and reach the level range for adult dogs.[38] Prior to that time the pups of giant breed dogs go through a period of plasma GH concentrations comparable with those known to cause acromegaly in adult dogs. The plasma IGF-I levels are higher in large breed young dogs and, although decreasing during life, stay higher in large than in small breed dogs.[38] The heavy overgrowth features known in young puppies of giant breeds are the result of transient juvenile gigantism.[39]

Research dogs, receiving supraphysiologic doses of porcine GH (which has a structure identical to canine GH) in a dosage of 0.5 IU per kg body per day, revealed a steep 2.5-

to 3.5-fold increase in plasma IGF-I levels immediately after starting administration of GH at the age of 13 weeks. In addition, a significant increase in weight gain (112 ± 15 vs. 76 ± 10 g in controls [$p < 0.05$]), in alkaline phosphatase, and in mineralization but not in bone resorption could be noticed at 21 weeks of age.[21] This uncoupling of mineralization and resorption may be the cause that, in 2 out of 5 GH-treated dogs and none of the controls, panosteitis-like lesions were noticed on the radiographs. The length of the radius and ulna were 10% greater in the GH-treated dogs than in the controls at 21 weeks of age, with microscopically noticeable thickening

of the growth plates without any signs of osteochondrosis. This finding makes it likely that it is not the physiologic transient juvenile gigantism in puppies of large breeds that makes them susceptible to osteochondrosis.[21] Long-term administration of IGF-I did not result in increased body size in miniature poodles.[40]

GH-excess is known as acromegaly and occurs in middle-aged female dogs and middle-aged and elderly, predominantly male, cats. Acromegaly in companion animals is characterized by soft-tissue overgrowth rather than by bony overgrowth, as is characteristic for acromegaly in humans. In dogs, endogenous

progesterone or exogenous progestogens induce GH secretion from hyperplastic ductular epithelium in the mammary gland. In dogs, soft-tissue hypertrophy of the mouth, tongue, and pharynx may cause snoring, thickening of the skin, and prognatism, and owing to that, wide interdental spaces.[37,38] In cats, GH excess originates from primary pituitary adenomas and reveals less pronounced physical changes than in dogs with GH excess. In cats, acromegaly may be complicated by diabetes mellitus, neurologic signs owing to tumor growth, and degenerative arthritis with periarticular periosteal reaction.[38] The diagnosis is made by measuring plasma GH concentrations or, even

better, by measuring the less fluctuating plasma IGF-I concentration, although hyperglycemia (in cats) and high alkaline phosphate levels in mature dogs can be indicative. The medical history in dogs and imaging techniques in cats can support the diagnosis. Discontinuation of exogenous progestins and/or ovario(hyster)ectomy in dogs, and hypophysectomy in cats are indicated.[33, 41]

GH Deficiency

Congenital growth hormone deficiency causes a retardation of growth. This genetic disease, with autosomal recessive inheritance, is seen in

different dog breeds but mainly German shepherd and Carelian bear dogs, as well as in cats.[38] A deficiency exists in both GH and thyroid-stimulating hormone, resulting in short but proportional statue (Figure 99-3A) with growth-plate closure before 1 year of age. Owing to concomitant deficiency of luteinizing hormone and follicle-stimulating hormone, female dwarfs come frequently into heat without ovulating, thus preventing breeding, whereas males produce motile sperm. Owing to developing hypothyroidism, the hair coat is lost and the dogs become dull and inactive at a later age.[37,38]

Figure 99-3. Endocrine bone disorders. (A) Congenital growth-hormone deficiency results in proportional dwarfism as revealed from the skeleton and

phenotype, respectively, of two adult German shepherd dogs with this genetic disease. (B) Hypothyroidism in a 6-month-old St.Bernard with mental retardation, puffy facial features, and a skeleton with delayed maturation. Skeletal development normal for its age could be reached in 1 month of thyroxine therapy (see anconeal process which should be fused at 6 months of age). (C) Bilateral femoral neck metaphyseal osteopathy in a 14-month-old, early castrated, male cat with gradual progression of lameness and radiologically demonstrated lucency in the femoral necks, which may result in pathologic fractures.

The diagnosis is made based on the typical habitus, and the low GH- and IGF-I-plasma levels. Differential diagnosis is cretinism owing to hypothyroidism (but those dwarfs are disproportional (legs too short), dull, and have a retarded skeletal maturation) and a variety of cardiac,

hepatic, gastrointestinal, and renal diseases causing growth failure.[42] Treatment with porcine GH is advocated, but limited experience is available. Progestins, known to induce GH secretion in the mammary gland in both genders with release into systemic circulation, can be used with growth-stimulating effects on the skeleton and hair coat.[37] Without therapy, the prognosis is poor because most dwarfs die at an average age of 4 years from a variety of dysfunctions.

Thyroid Hormones

The thyroid glands secrete tetraiodothyronine (L-thyroxine or T_4) and triiodothyronine (T_3) in a ratio of

5:1, with T3 being 3 to 4 times more biologically potent than T_4. Iodine is actively transported from the extracellular fluid into the thyroid follicular cells. In iodine excess, organic binding in the thyroids is blocked, whereas in iodine deficiency thyroid function is increased. Thyroid hormone in circulation is coupled to binding proteins. The iodine content of meat is less than 10 µg per 100 gram on dmb and decreases even more after cooking, whereas dry dog food has an iodine content of 50 to 100 µg per 100 gram on dmb; for cats the requirement is at least 100 µg per 100 gram on dmb.[7,38]

Hypothyroidism in Young Animals

Hypothyroidism at a young age is characterized by disproportional dwarfism and mental retardation (cretinism). It can be caused by iodine deficiency (owing to a strict carnivore diet without supplementation), lymphocytic thyroiditis, or congenital hypothyroidism (owing to thyroid dysgenesis or defective thyroid hormone synthesis) as described in dogs and cats.[38] In complete athyrosis, symptoms manifest at 2 to 2 months of age with hypoactivity, hypothermia, puffy and retarded facial features, retarded growth in length, and delayed loss of puppy hair (Figure 99-3B). The

skull is broadened, the tongue may be too big for the mouth, and mental dullness and retardation are reported by the owners. Since thyroid hormone influences both the activity of chondrocyte progenitors and the maturation of chondrocytes during endochondral ossification, hypothyroidism leads to skeletal abnormalities. Radiographic investigation of long bones and vertebral bodies reveal retarded skeletal maturation with delayed appearance of secondary ossification centers, delayed growth in length, but normal cortices and growth plates.[43]

Differential diagnoses can include dwarfism (although proportional and

lively), owing to GH deficiency, rickets (with thin cortices, wide growth plates), secondary hyperparathyroidism (thin cortices, normal growth plate) and chondrodysplasia (normal cortices, normal growth plate, abnormal alignment and/or joint congruities).

The diagnosis can be made by measuring plasma concentrations of thyroid hormone, thyroid scintigraphy, measuring an increased endogenous thyroid-stimulating hormone plasma level, and by comparing radiographs of the patient with breed- and age-matched controls.[38]

The therapy includes normalization of

the diet (in case of iodine deficiency) or thyroxine therapy at a dose rate of 10 μg/kg body weight twice daily for dogs and half that dosage for cats.[38] After 1 month the skeleton is expected to reach the stage of the biologic age of the animal (Figure 99-3B), although radiologic control may reveal pathologic abnormalities, and mental retardation can stay manifest.

Hypothyroidism in Adults

Often as a result of autoimmune disease, thyroid tissue disappears, leading to a slowly occurring hypothyroidism, characterized by slowing of mental and physical activities, disinterest, thin hair coat,

thick skin with puffy appearance owing to myxedema. The patient can reveal lameness because of myositis in the skeletal muscles and increased plasma creatinine kinase activity.[38] It has been demonstrated that skeletal muscle in a hypothyroid cat is more fatigable, with changes in the isometric twitch speed properties.[44] In addition, lameness characteristic for osteoarthrosis can be seen owing to mucopolysaccharide accumulation in the joint capsules; often this occurs in multiple joints, leading to a stiff gait rather than to lameness. In some cases severe front leg lameness, eventually non-weight bearing, is seen owing to myxedema formation in the carpal tunnel, with median nerve entrapment

as can occur around the facial nerve. It is the author's experience that the front legs are never equally affected. The diagnosis is made by excluding tumor (e.g., osteosarcoma, neurofibroma) in the affected leg and by diagnosing hypothyroidism.[43]

With medical treatment of hypothyroidism (see earlier) the prognosis for animals with myositis and nerve impingement is good, whereas it is guarded for those with osteoarthrosis. In fact, the dog will improve mentally earlier than its joint capsules heal, and thus over-use can make the complaint of osteoarthrosis even worse. In the healing period, the dog should be leash restricted.[43] Other

neurologic disorders that may coincide with hypothyroidism (including myasthenia gravis, vestibular disease, laryngeal paralysis) may not result in resolution of the signs.[45]

Sex Hormones

Skeletal growth and puberty are connected as the sex hormones testosterone and estrogen play a role in cartilage growth and endochondral ossification. Although both hormones are not essential, they play a role in growth, skeletal development, and maintenance of the adult skeleton. Androgens stimulates both chondrocyte hyperplasia and maturation. The anabolic effects of testosterone are

associated with augmentation of pulsatile GH secretion. This drives longitudinal bone growth and epiphyseal growth-plate maturation, which culminates in cessation of skeletal elongation. The effect of estrogens (following aromatization of androgens and stimulation of estrogen receptors) depends on its concentration: low concentration stimulates cartilage growth, whereas high concentration stops cartilage growth. It has been demonstrated that many of the growth-promoting effects of the sex steroids are mediated through estrogens rather than androgens. In addition, skeletal maturation with growth-plate closure is also estrogen-dependent in both

sexes.[46] Androgens stimulate osteoblast proliferation and antagonize osteoclast-activating effects of PTH, leading to increased cortical bone formation. Estrogens repress osteoclastogenesis and stimulate endosteal and trabecular bone formation, both increasing bone strength.[46]

Sex Hormone Deficiency

Estrogen or testosterone deficiency owing to castration occurs soon after surgery. Especially in female dogs, investigations have been performed to study bone strength and composition following ovariohysterectomy, as a model for osteoporosis in

postmenopausal women. However, dogs differ considerably in this regard, perhaps owing to the mean estric cycle of 6 months in dogs. In a study in beagle dogs it revealed that 10 months postovariohysterectomy, cancellous bone remodeling was not significantly different from presurgical levels.[47] No reports show that early castration will cause osteoporosis or its related pathologic fractures in companion animals.

In a study comparing early (at 7 weeks), late (at 7 months), and no castration in dogs, it revealed that growth-plate closure was postponed in case of castration, even more so in early castration. Because growth

velocity did not differ among groups, but the growth period was elongated, the final bone length was increased in both sexes especially in the early castrated dogs.[48] Similarly, in cats, gonadectomy in both genders either at 7 weeks or 7 months of age revealed a delayed closure of the distal radial physis compared with the intact cats.[49] In cats, the growth plates of the proximal femur normally close at 7 to10 months of age, but this occurs much later in early gonadectomized males. This can increase the vulnerability of early castrated cats for physeal fractures in the proximal or distal femur even at adult age.

Femoral neck metaphyseal osteopathy is

seen incidentally, mainly in early castrated male cats. The cat has a vague onset of hind-limb lameness with progression to severe lameness with pain on extension of the hip. Radiologic investigation reveals lucency in the proximal metaphyseal area of the femur with pathologic fracture in a limited number of cases (Figure 99-3C). Histopathologic evalutaion may reveal thickening and splitting of the articular cartilage with necrotic bone and vascular congestion at the epiphysis, with an increased number of osteoclasts. Damage to the blood supply of the femoral head and neck is hypothesized with secondary osteoporosis and pathologic fracture,[50] although the pathophysiology of this

entity needs to be further elucidated.

Chapter 100

Canine Osteochondrosis

Jennifer L. Lansdowne
Curtis W. Probst

Osteochondrosis (OC) is a disorder affecting the process of endochondral ossification in growing people and animals including dogs, horses, pigs, and chickens.[1] Although the clinical manifestations associated with OC are well described, the etiology and pathogenesis are not yet completely understood. Osteochondrosis affects the articular-epiphyseal and physeal

cartilage cells and can be expressed clinically as osteochondritis dissecans lesions, fragmentation of the medial coronoid process of the ulna (FCP), ununited anconeal process (UAP), retained cartilage cores, Osgood-Schlatter syndrome (OC of the tibial tuberosity), slipped epiphysis, or incomplete ossification of the humeral condyle. All these conditions are considered to have a similar pathogenesis. Osteochondrosis is a common cause of secondary osteoarthritis in people and domestic animals.[2] Osteochondritis dissecans (OCD) is the most common clinical manifestation of osteochondrosis. Although osteochondritis is a misnomer because it implies inflammation of

bone and cartilage, it has become entrenched in veterinary medical terminology. Synonyms for OCD found in the literature include osteochondrosis dissecans and dyschondroplasia. Regardless of the terminology, to the veterinarian OCD indicates a dissecting cartilaginous lesion between the bone epiphysis and articular surface. Lesions of canine OCD have been described on the cervical vertebrae, glenoid surface of the scapula, proximal humerus, distal humerus, distal radius, femoral head, distal femur, tibial tarsal bone, and most recently, the lumbosacrum.

This chapter is an overview of the normal growth and ossification of the

canine appendicular skeleton, followed by an in-depth review of the pathology and pathogenesis of osteochondrosis. Pathogenic factors specific to the shoulder, elbow, stifle, tarsus, lumbosacrum, and incomplete ossification of the humeral condyle are also described.

Normal Growth and Ossification of the Canine Skeleton

The growing canine skeleton is composed of cartilage and bone. Three distinct embryonic lineages are responsible for the formation of the skeleton.[3,4] The craniofacial skeleton arises from cranial neural crest cells,

the vertebral skeleton is derived from paraxial mesoderm (somites), and the limb skeleton is formed from the lateral plate mesodermal cells.[3,4] Cells from each lineage migrate to locations in the embryo where bone will eventually form and there they develop into characteristic mesenchymal condensations of high cell density.[3,4] These condensations develop into osteoblasts or chondrocytes.[3,4] The cells in the region of the craniofacial skeleton develop into osteoblasts and directly form bone by intramembranous ossification. In the remaining skeleton, chondrocytes develop first and provide a framework of cartilage models. The cartilage models are replaced by bone and bone

marrow through the endochondral ossification process.

The cartilage models of future appendicular bones grow by appositional and interstitial growth and quickly resemble the future bone in shape and relative size.[3,5] As capillaries enter and supply the surrounding perichondrium, osteoblasts are formed from circulating progenitor cells and begin to lay down a thin layer of bone around the cartilage. At the same time, the chondrocytes in the center become hypertrophic. As the collar of bone and area of hypertrophy continue to enlarge, the matrix surrounding the hypertrophic chondrocytes begins to calcify by

incorporating hydroxyapatite. This results in a network of trabeculae with a cartilaginous core, called primary spongy bone. Primary spongy bone is rapidly resorbed and secondary spongy bone with new trabeculae is formed. The actual process of replacing calcified cartilage (endochondral ossification) occurs in the mid-diaphysis of long bones first. The initial area of ossification is called the primary ossification center and extends in each direction toward the end of the cartilage model. As the process continues, secondary ossification centers develop in each epiphysis. A plate of cartilage remains between the ossified secondary and primary centers and is responsible for the longitudinal

growth of long bones.[3] This plate is called the physeal growth plate (Figure 100-1). The cartilage on the end of the secondary ossification center that is closest to the joint is termed the articular-epiphyseal cartilage complex (AECC). Epiphyseal cartilage of this complex is responsible for growth of the epiphysis and the development of its shape. At maturity in normal dogs, articular cartilage is all that remains on the surface of the bony epiphyses.

The process of ossification starts at weeks 3 to 4 in the canine fetus, but cannot be detected radiographically until 3 weeks prior to parturition. When a puppy is born, the epiphyses are still cartilaginous with no or only

small secondary centers of ossification present. By 2 to 4 months of age, depending on breed, only the physeal growth plates and articular cartilages remain unossified.[6]

Normal Growth of the Articular-Epiphyseal Cartilage Complex

Articular cartilage is divided into three regions: superficial, middle and deep (Figure 100-2).[7] The superficial region is immediately under the surface of the joint and consists of the lamina splendens (composed of filamentous proteins that bind proteinaceous material and provide lubrication for joint surfaces) and the gliding zone

(cells are parallel to the surface).[8] The middle region has cells arranged perpendicularly to the surface of the articular cartilage and is divided into the transitional zone (characterized by cell activity and interstitial growth, allowing the articular cartilage to cover the epiphysis during growth) and the radial zone (composed of cells lined up in irregular columns). The superficial and middle regions are responsible for the expansion of the articular surface during development. The deep region is composed of calcified cartilage and subchondral bone supporting the articular cartilage. Vascular invasion of calcified tissue occurs here, followed by endochondral ossification. The deep region is

responsible for the development of epiphyseal bone. A thin wavy hematoxylin-stained line called the tidemark can be seen histologically separating the non-calcified tissue of the middle region from the calcified tissue of the deep region in adults.[5]

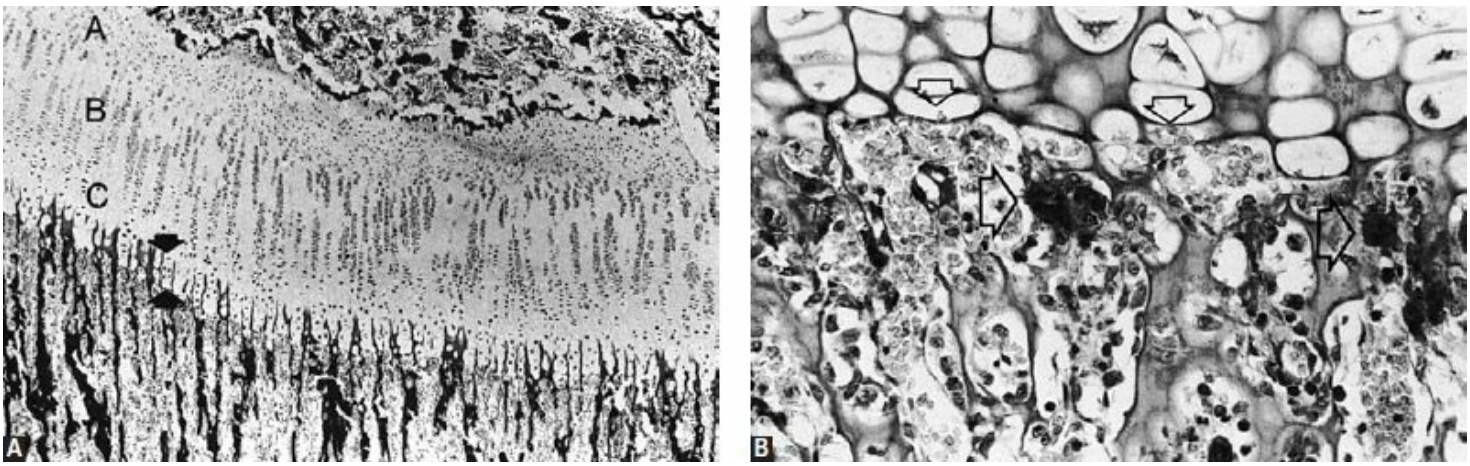

Figure 100-1. Histologic sections that demonstrate the mechanism of longitudinal growth as seen morphologically in the growth plate and the metaphysis. (A) Undecalcified section of the proximal tibial metaphyseal growth plate with part of the epiphysis (above) and the metaphysis (below) from a 9-day-old rabbit. In the growth plate, the zone of germinal (resting) cells (A), proliferating (columnar)

cells (B), transitional (hypertrophying) cells (C), and vesiculated cells (between arrows) are seen. The matrix in the longitudinal bars separating the columns of vesiculated cells is calcined (von Kossa's stain; 50x). (B) Section of the junction between the proximal tibial metaphyseal growth plate (top) and the metaphysis (bottom) in a newbom puppy. It illustrates how the horizontal bars of the cartilage matrix are eroded by vascular sprouts (small arrows) and how chondroclasts (large arrows) resorb calcified matrix in the longitudinal bars (Hematoxylin and eosin (H&E) stain; 250x). (From Summer-Smith, G. (Ed.): Bone in Clinical Orthopedics. Philadelphia, W.B. Saunders, 1982.)

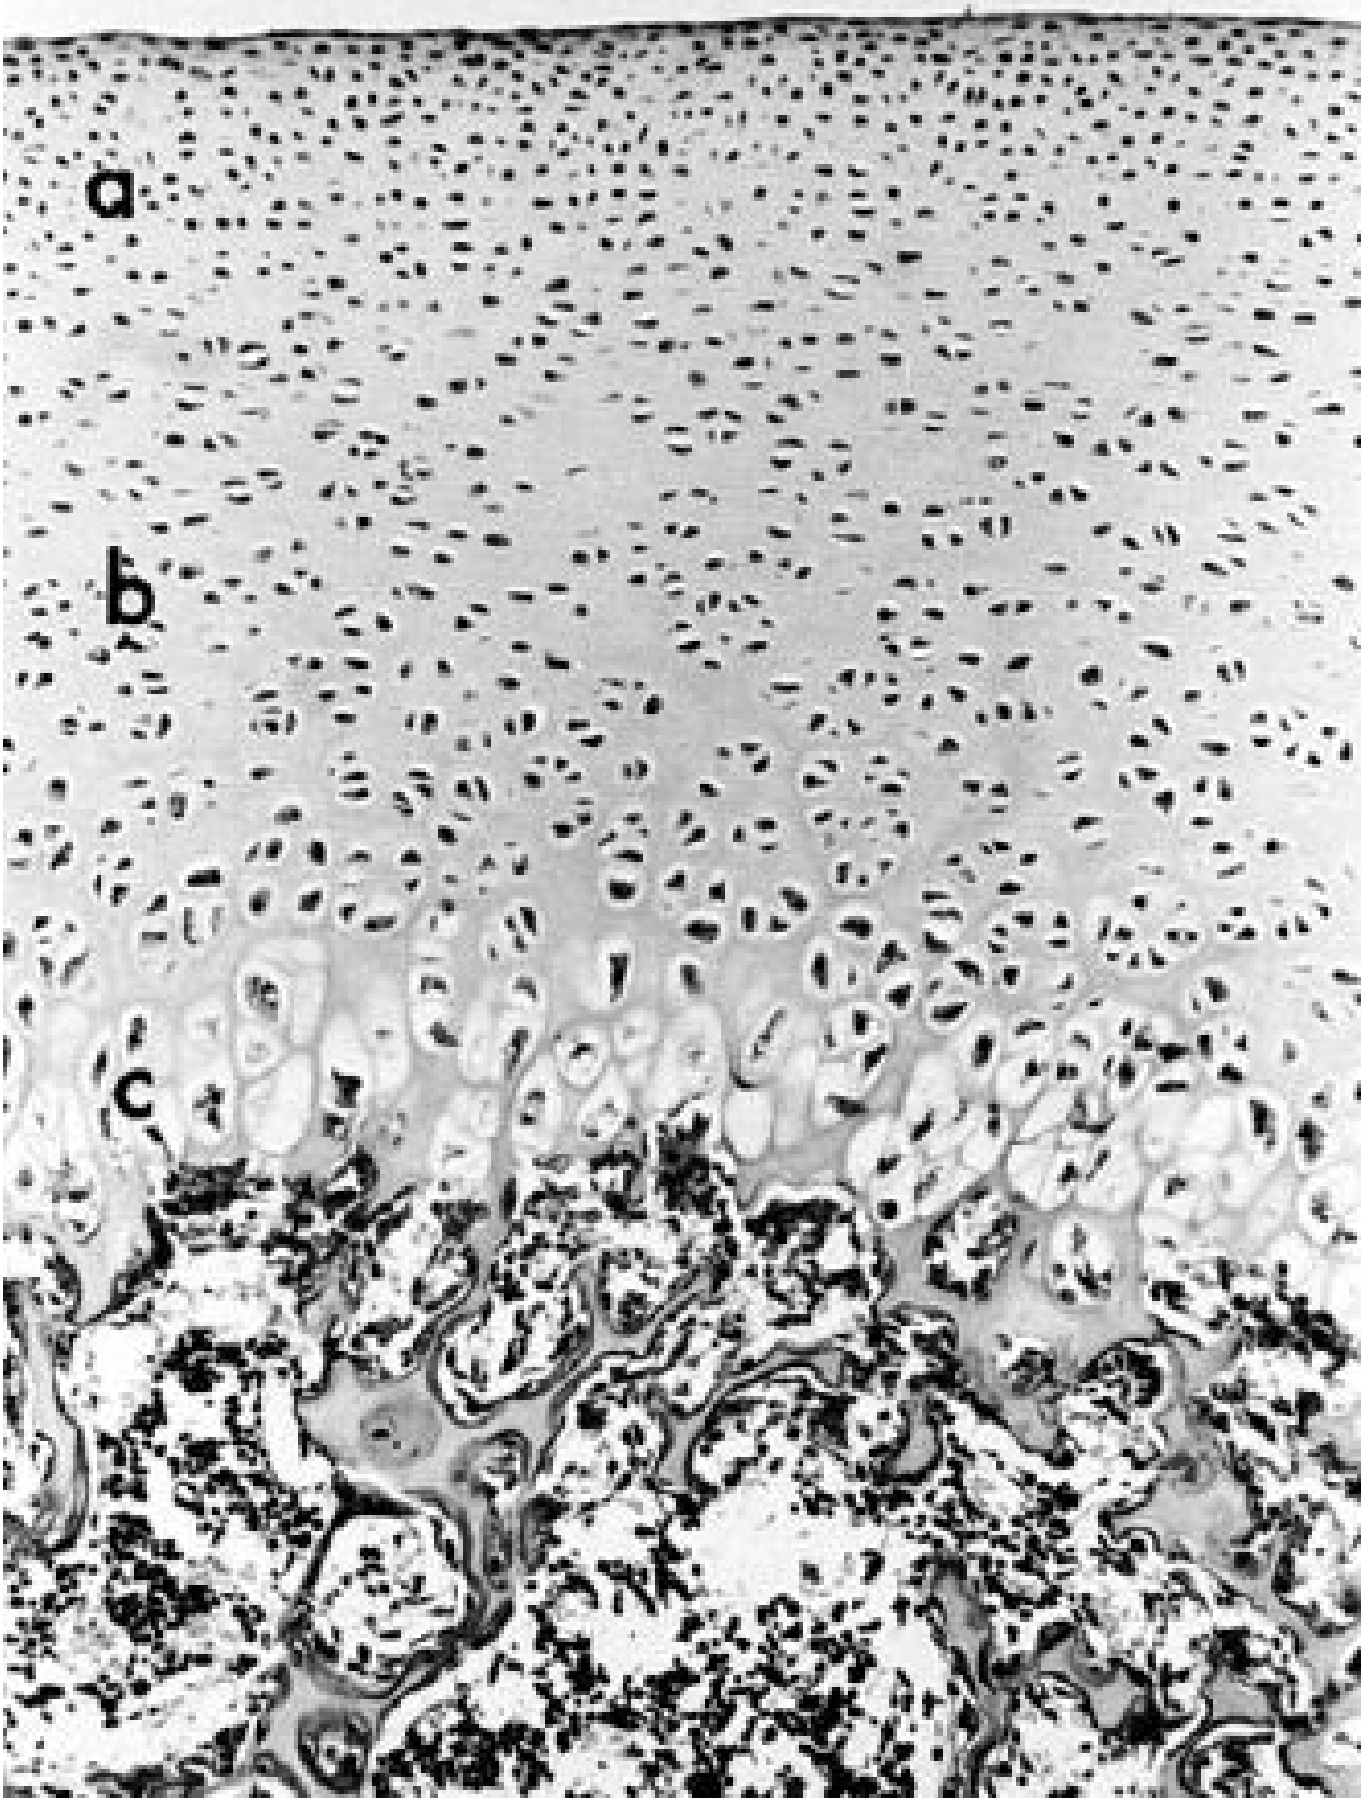

Figure 100-2. Histologic section of the articular

cartilage of the proximal humerus from a 9-day-old rabbit. The immature joint cartilage is the growth cartilage of the epiphysis. The germinal (resting) cells (a) are located about four or five cell layers away from the joint surface. Deeper in the cartilage is the zone of proliferating cells (b), and then the zone of hypertrophying (vesiculated) cells (c), where the cartilage is invaded by vessels paving the way for ossification (H&E stain; 50x). (From Summer-Smith, G. (Ed.): Bone in Clinical Orthopedics. Philadelphia, W.B. Saunders, 1982).

Normal Growth of the Physeal Growth Plate

The physeal growth plate and the epiphyseal component of the AECC differentiate into four morphologically and chemically distinct zones during development (Figure 100-3). From the epiphysis toward the metaphysis, they are the resting (reserve or germinal),

proliferative, hypertrophic, and calcifying zones; orderly maturation of cells in these zones is required for proper endochondral ossification.[1,3] The cells of the resting zone are small and relatively inactive. The proliferative adjacent zone has both local and systemic growth factors that stimulate chondrocyte proliferation. In this zone clonal expansion of proliferated cells takes place toward the metaphysis (cartilage-bone junction) where the cells enlarge, arrange in columns and eventually hypertrophy.[3] The cells of the hypertrophic zone are highly metabolically active, but do not divide. The matrix surrounding the hypertrophic cells continues to calcify,

and the lowermost cells undergo apoptosis (regulated cell death).[3] Osteoclasts and osteoblasts, which have developed from progenitor cells brought in by invading blood vessels, remove the calcified cartilage and deposit bone, respectively. When maturity is reached, the metaphyses and diaphysis are united and the cartilaginous portion is completely replaced by bone. With few exceptions, in mature animals the only remaining cartilage is the hyaline cartilage of the joint surfaces.

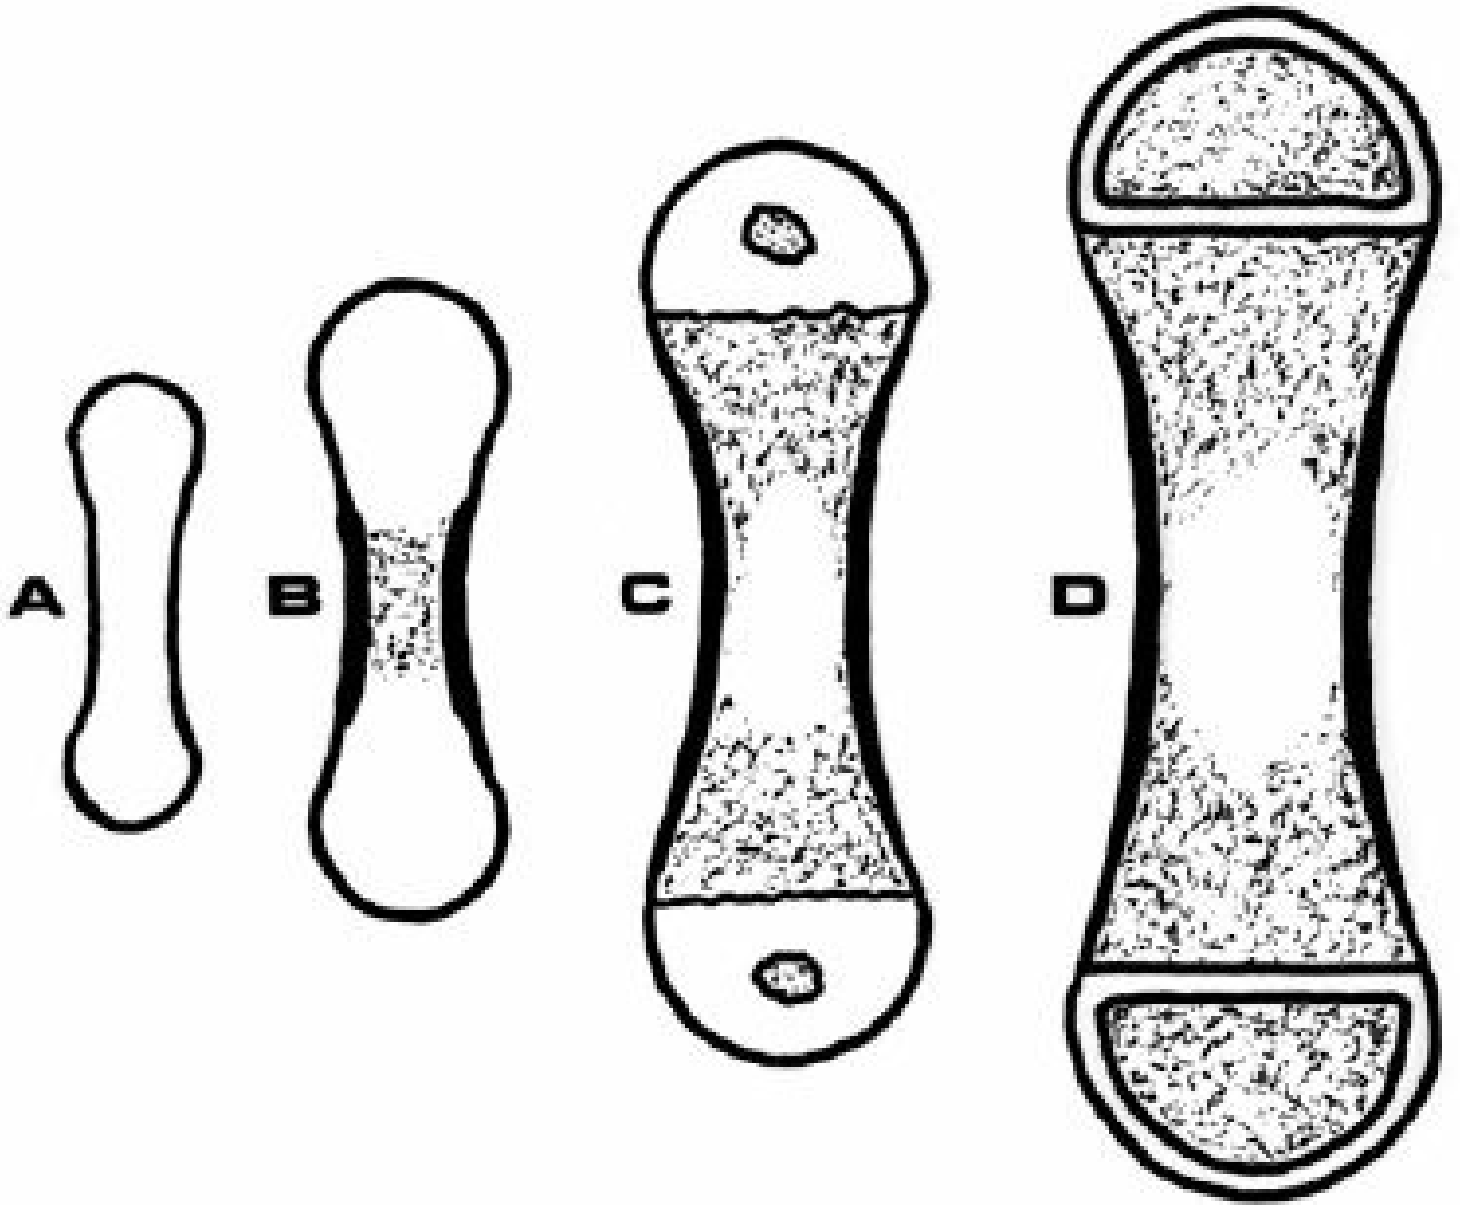

Figure 100-3. Schematic drawing of the development of a long bone. A, Early in fetal life, the long bone consists only of cartilage. B, When the fetus is about 30 days old, it has some cortical and trabecular bone at midshaft. The cortical bone is formed by periosteal apposition, whereas the trabecular bone is formed by endochondral ossification. C, In the newbom puppy, the entire diaphysis (which includes the two metaphyses) is made of cortical and trabecular bone

including bone marrow, while the epiphyses have just begun to ossify. D, When the puppy is a few months old, the only cartilage left in the long bone is the one in the growth plates and in the immature joint.

Vascular Supply and Nutrition of Epiphyseal Cartilage

The epiphyseal cartilage of both the physeal growth plate and the AECC have a well developed blood supply through a network of cartilage canals.[1,9,10] The cartilage canals regress as the animal ages and the growth cartilage becomes thinner. The physiologic process of this regression is termed chondrification.[10] Chondrification causes the vessels, nerve fibers, and stromal cells within

the canals to be substituted with cartilage without pathologic effects on the surrounding tissue.[10] Nutrition is supplied to the AECC by these blood vessels, in addition to synovial fluid.[1] The contribution of each source depends on age, species, and anatomic location.[1] In the adult, articular cartilage receives a minor contribution from vessels of the subchondral bone, obtaining most of its nutrients from the synovial fluid.

Pathophysiology

Pathology and Morphology

Osteochondrosis is characterized by failure of normal differentiation of cartilage to bone during endochondral

ossification; neither matrix calcification nor vascular penetration occurs in focal areas of the growing epiphyseal/articular cartilage, resulting in retention of cartilage rather than conversion to bone.[1] Although abnormal focal regions of retained cartilage are avascular, they receive nutrients from diffusion of synovial fluid and continue to grow. This results in focal abnormally thickened cartilage, which is less resistant (more compliant) to mechanical stresses. The increased thickness eventually prevents adequate diffusion of nutrients and results in a disturbance of the metabolism of the basal layer. Degeneration and necrosis of the chondrocytes at the base of the

OC lesion are the ultimate outcome, which can lead to the separation of the retained cartilage from the underlying calcified tissue. This phenomenon occurs along the tidemark and rarely involves subchondral bone.[11] The resulting fragments are characteristic of OCD lesions when they develop in the AECC.

In the AECC the earliest identifiable histologic lesion is termed *osteochondrosis latens* and is identified as focal necrosis of the cartilage canal vessels and the surrounding cartilage of the resting zone of the epiphyseal cartilage.[10] If the necrotic cartilage resists resorption and persists as a cone of dead tissue surrounded by bone it is

termed *osteochondrosis manifesta* and appears grossly as an area of delayed endochondral ossification.[10] Because this necrotic cartilage is soft and friable, it does not provide a suitable foundation for the over-laying AECC; thus, even minimal trauma can lead to fissure and fracture formation. When these fissures and fractures extend from the necrotic tissue to the articular surface it is termed *osteochondritis dissecans*.[10] In pigs and horses, early lesions of OC of the AECC have been associated with abnormalities in cartilage canal blood vessels.[10,12-15] These abnormalities have been hypothesized to cause local ischemia and chondronecrosis.

Spontaneous repair attempts of the OCD lesions usually occur beneath the cleft with granulation tissue production, fibrogenesis, and osteoblastic and osteoclastic activity. Subchondral bone formation occurs at the base of the granulation tissue, but does not extend past the tidemark. The granulation tissue undergoes chondrification and may even develop some hyaline cartilage. Continuous passive motion during healing may encourage hyalinization of the fibrocartilage.[5] The success of the reparative process is related to the size and extent of the defect as well as time from development. Small defects can completely heal through matrix flow and intrinsic repair (chondrocytes,

proliferation and increased extracellular matrix production). In large defects, however, fibrocartilage degenerates within one year, which leads to secondary osteoarthritis from release of breakdown products.[5,16]

Osteochondrosis of the AECC can lead to OCD lesions in the shoulder, elbow, stifle, hock, and vertebral articular facets, and FCP.[17] Two types of OCD lesions of the AECC exist. Type I OCD lesions are the classic form and occur when the lesion is in or near the center of a convex joint surface. In these cases, the cartilage flap does not have contact with any vascular tissue, such as the joint capsule. As a result, the flap eventually becomes detached and

floats in the joint. This flap may be resorbed or may increase in size as a result of nourishment from synovial fluid. When the flap is free in the joint and becomes ossified it is termed a loose body or “joint mouse.” These lesions typically occur in the humeral head, medial condyle of the humerus, and the lateral and medial femoral condyles.

Type II OCD lesions occur at the periphery of the joint surface providing contact between the cartilage flap and the joint capsule or ligament. Eventually the flap will undergo endochondral ossification and not produce a joint mouse. Osteochondritis dissecans lesions of the

medial or lateral ridge of the talus and sacrum, as well as fragmented coronoid process and ununited anconeal process, are typically type II lesions.[6]

Clinically, OC lesions can be divided into four grades, with grade I the most mild and grade IV the most severe. Grade I classification is given in cases with grossly normal articular cartilage and a small defect in the subchondral bone, whereas grade IV is given when a cartilage flap is separated from the bone. Grades II and III are given subjectively to cases that fall between mild and severe. Because animals are not in pain until the fissure reaches the articular cartilage, grade IV (OCD

lesion) is the most common form diagnosed by veterinarians.

In the physeal growth plate, early lesions of OC are much less obvious than in the AECC until after failure of endochondral ossification has occurred. In the growth pate, retained cartilage is composed of viable hypertrophic chondrocytes. Retention of cartilage in the growth plate usually does not lead to necrosis, probably owing to the presence of vessels in the cartilage. The majority of these lesions heal uneventfully. Clinical signs may manifest if a pathologic fracture occurs within the thickened cartilage or, more importantly, if it occurs at the distal end of the ulna. Incongruity of the

radius and ulna can occur owing to slowed growth of the ulna relative to the radius. Occasionally, incongruity can be seen as a result of OC of the distal radial growth plate. Osteochondrosis of the physeal growth plate can result in UAP, retained cartilaginous cores of the distal ulna, and genu valgum (knock-knee).[17]

Pathogenesis

The underlying lesions of osteochondrosis occur in the growing animal, although they may not show clinical signs until adulthood.[1] The primary lesion of OCD is a dissecting cartilaginous separation between calcified and noncalcified tissues.[5] The

necrotic base of the OC lesion is the starting point for fissures. If the necrotic cartilage is large enough and/or there is sufficient trauma has occurred, a cleft will form from the articular cartilage to the subchondral bone. This results in synovitis from release of inflammatory mediators, joint effusion, and clinical evidence of lameness. It has been suggested that premature disruption of the nutritional function of the vasculature of the cartilage canals results in cartilage necrosis (osteochondrosis latens).[18] Recently it has been shown that there is premature cessation of blood supply to the epiphyseal growth cartilage caused by focal interruption of the vessels leading from the bone marrow

into the cartilage canals.[10] This study proposed that OC occurs secondary to ischemic necrosis caused by microtrauma to the vessels of the cartilage canals in the transition zone between bone and cartilage.[10] It has also been suggested, based on the finding of an increased amount of lipid in OCD cartilage flaps, that delayed calcification may be a result of a lipid metabolism defect.[19]

The effects on the subchondral bone adjacent to the OCD lesion are typically myelofibrosis and trabecular remodeling. It can be quite extensive, but necrosis of the bone is not a prominent feature of OCD. Subchondral bone cyst formation is a

possible, but uncommon, sequela to OCD.

Suggested contributing factors for OC development are trauma, familial/hereditary predisposition, ischemia, rapid growth, and dietary factors.[1] The etiology is likely multifactorial, with no single factor accounting for all aspects of the disease. Our current understanding of the contributions of trauma and genetic factors is discussed below.

Trauma is the most widely considered factor in all species regarding the etiology of OC[1] and is important in the progression of OC to OCD. Trauma does not have to be severe to cause

separation of cartilage and bone in the abnormal cartilage of OC. The gross and histologic appearances of the chronic lesions (lesions with a cartilaginous flap) support this theory. The usual locations are in areas with increased biomechanical stresses.[1] It has been hypothesized that epiphyseal cartilage is inherently weaker and thus more vulnerable to trauma than articular cartilage,[20] however, no research currently supports this concept. Research in swine has shown that, although both the medial and lateral condyle can be affected with OC, the most clinically relevant lesions occur on the medial condyle.[21] Indeed, the medial condyle receives most of the weight-bearing forces. Most cases of

OC have an insidious onset and although purely traumatic osteochondral fractures can occur, particularly in people following severe automobile accidents, they are not considered to be OC. Olsson hypothesized that local traumatic factors within joints, which vary with location, was a principal cause of canine OC.[6] He theorized that repeated microtrauma in predilection sites was crucial to the development of OC.[22] Examples of local microtrauma include impingement of the dorsolateral area of the humeral head in the shoulder joint or forced contact between the medial aspect of the lateral femoral condyle and lateral part of the intercondylar eminence in the stifle

joint of animals with genu valgum. Olsson also hypothesized that transient incongruence in growth rates between the radius and ulna was a factor in ununited coronoid and ununited anconeal process as well as distal humeral OC. Further support for local microtrauma comes from studies performed in calves, which found that when they were housed on hard surfaces the prevalence and severity of OC was increased.[23] Another study compared pigs that were loaded into crates by dropping them from varying heights under 1 meter to pigs that were not loaded.[24] This study found that OC lesions were more severe and prevalent in pigs that were loaded. Unfortunately these theories have only

been evaluated in the chronic stages of the disease and not in the early stages, thus the true pathogenesis remains unknown. However, because most early lesions heal, it is possible that, if joints are protected from trauma during the vulnerable development stage, clinically relevant disease could be reduced.[1] Trauma may be influenced by heritable factors, such as anatomic conformation and/or quality of the surrounding bone and cartilage, and facilitated and/or aggravated by mechanical stress to the area in the limited time period that important blood vessels exist.[10]

Familial cases of OC have been reported in people, including cases in

identical twins.[1] Domestic pigs, which have been genetically selected for certain traits, have a high prevalence of OC, regardless of breed, whereas wild and miniature pigs do not.[25] A polygenetic mode of inheritance of elbow joint OCD in Labrador retrievers has been shown.[26] Dog breeds that reach a mature weight of more than 20 kg tend to be more commonly affected with OC.[1] This prevalence appears to be increased in animals in which rapid growth is emphasized. There also tends to be a greater male incidence, possibly owing to a more rapid growth rate when compared with females. It has been proposed that low serum concentrations of the main metabolites of vitamin D3 found in growing large-

breed dogs fed standard dog food may play a role in disturbances in endochondral ossification.[27,28] Thus, other contributing factors result in OC, not just overall growth rate and feeding regimen. It is unlikely that nutrition, hormonal influences, and trauma alone could account for the development of OC.

In general, the larger the defect the more likely a dog is to have a persistent lameness. In addition, the larger the lesion the more likely the opposite joint surface is to develop a "kissing lesion." The kissing lesion occurs as a result of lack of normal physiologic compression on the opposite articular surface, which is

necessary for maintenance of healthy cartilage. If motion is present between the bone and cartilage flap, synovitis and pain will ensue. Healing will not take place owing to the motion and the presence of synovial fluid between the flap and bone. Healing will only occur if the flap is stabilized or removed.

Specific Osteochondritis Dissecans Lesions

In most cases, diagnosis is based on signalment, history, clinical signs, and physical and orthopedic examination, and confirmed with bilateral radiographs of the affected joint. Not uncommonly, advanced imaging such as computed tomography or

exploratory arthroscopy or arthrotomy is required to make a definitive diagnosis. Contrast arthrography is rarely necessary.

Although most cases are presented as young dogs, any aged dog can be seen. Lameness ranges from sudden to insidious onset, from barely appreciable to non-weight bearing. Dogs can present with any degree of joint effusion, reduced range of motion, muscle atrophy, and pain associated with the OCD lesion. In most cases, regardless of treatment, development of secondary osteoarthritis is inevitable.

Shoulder Joint

Osteochondritis dissecans of the scapulohumeral joint is a common cause of lameness and is the most commonly seen form of OC in dogs in the United States.[17] Surgical removal of the cartilage flap is the preferred method of treatment in dogs with clinical signs. Long-term prognosis following surgery is good to excellent.

The most common site for OC lesion development in the shoulder is the caudal central or caudal-central-medial region of the humeral head (Figure 100-4). Lesions of the glenoid occur rarely.[29] Although the particular susceptibility of the caudal central aspect of the humeral head is not fully

understood, it has been suggested that it is due to the increased thickness of cartilage normally present in that area in dogs.[30,31] It has been suggested that trauma from contact between the humeral head and the glenoid cavity of the scapula predisposes any abnormally developed cartilage to vertical fractures.[30,31] In 1965, it was proposed that the particular location of the OC lesion of the shoulder was caused by the repeated impingement of the caudal part of the humeral head by the scapula during full extension.[6,32] Olsson later suggested that this could be supported by the finding in dogs with shoulder osteoarthritis that osteophytes on the caudal region of the humeral head are often attached to the

scapula by fibrous tissue, indicating a dynamic component to their development.[6,32]

Many cases of shoulder OCD heal spontaneously.[6] The pedicle of the cartilage flap may rupture, thereby dislodging the flap and allowing fibrocartilage to grow from the floor of the defect. The dislodged flap may develop into a joint mouse, become resorbed, or continue to grow. It is possible that the flap(s) can become a large calcified body/bodies in the caudal pouch of the joint. If the calcified body remains in the caudal pouch it may not give rise to clinical signs; however, if it becomes entrapped between the scapula and

humerus it can cause sudden pain and locking of the shoulder joint. If the calcified piece migrates to the sheath of the biceps tendon it can cause persistent lameness.

Humeral head OCD most commonly affects large and giant breed dogs with 56 different breeds being identified in a study of 626 affected dogs.[33] While some large breeds such as the Swiss mountain dog, Great Dane, German shepherd, Newfoundland, Rottweiler, Labrador retriever, golden retriever, and Bernese mountain dog, are at a high risk of developing OCD of the humeral head,[34,35] some large breeds such as the doberman pinscher, collie and Siberian husky are considered to

be at low risk.[33] Small and medium-sized breeds can also be affected.[33,36-39]

Although most dogs present for unilateral lameness, approximately 50% (range 20% to 85%) have radiographically detectable lesions bilaterally.[5,31,33] In one study, only 24% of dogs diagnosed with bilateral lesions on radiographs had clinically bilateral disease.

Elbow Joint

Several lesions of the elbow joint can be classified as manifestations of OC including fragmented coronoid process (FCP), OCD, and ununited anconeal process (UAP) (See Chapter on elbow

dysplasia). Of all these, the most common cause of elbow arthrosis is some abnormality of the coronoid process (fragmented or fissured) and, less commonly, OCD of the humeral condyle.[17] The most common site for OCD in the elbow is along the medial aspect of the humeral condyle (Figure 100-5). Careful examination must be performed to definitively diagnosis OC or OCD. Long-term prognosis following surgical treatment for OC of the elbow is guarded. Early treatment may decrease lameness, but will not prevent progression of secondary osteoarthritis.

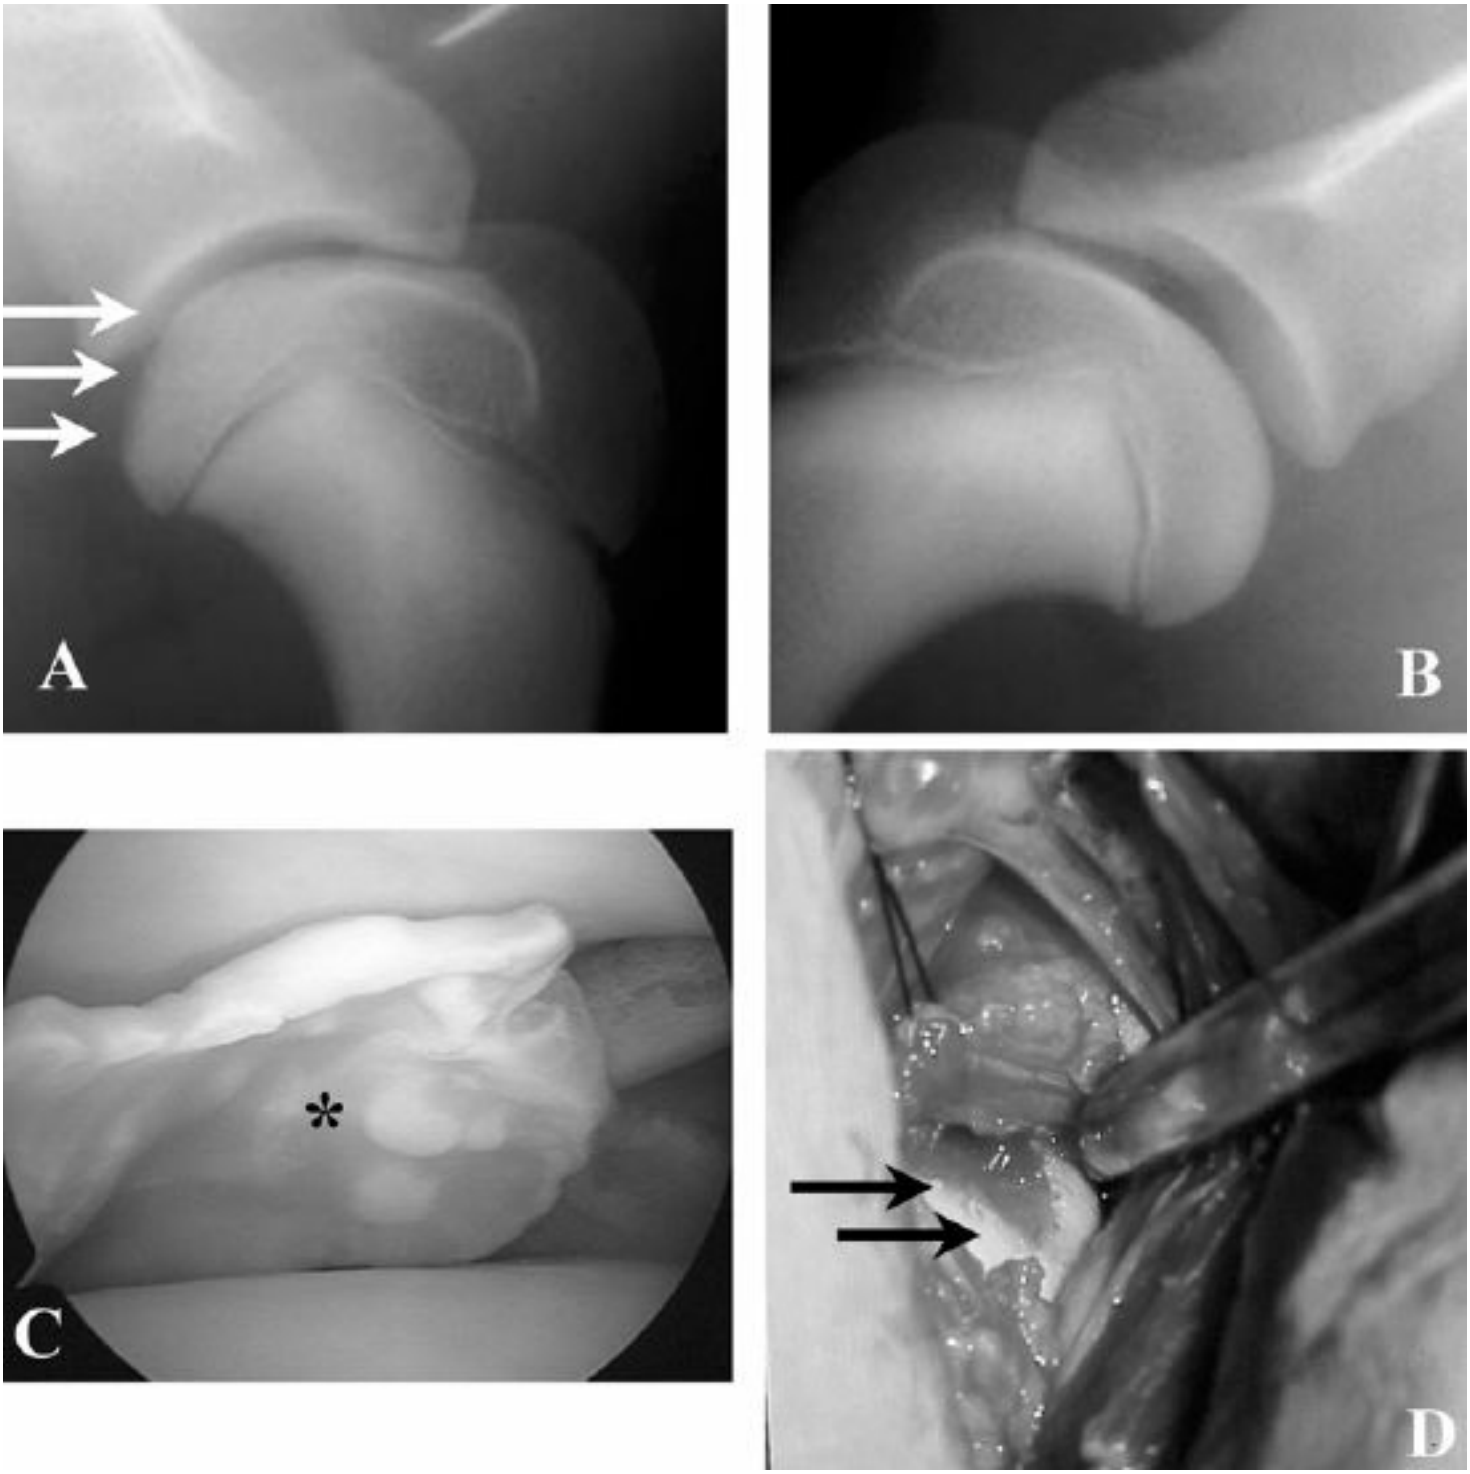

Figure 100-4. A series of images illustrating OCD of the caudal humeral head. (A) Lateral radiographic view of the affected side. Note the flattened area of subchondral bone (white arrows). (B) Lateral radiographic view of the normal side. Note the

curved, smooth surface of the caudal humeral head. (C) An arthroscopic view of a cartilage flap (asterisk) involving the caudal humeral head. (D) An intra-operative view of the caudal humeral head showing the subcondral bone (black arrows) after flap removal.

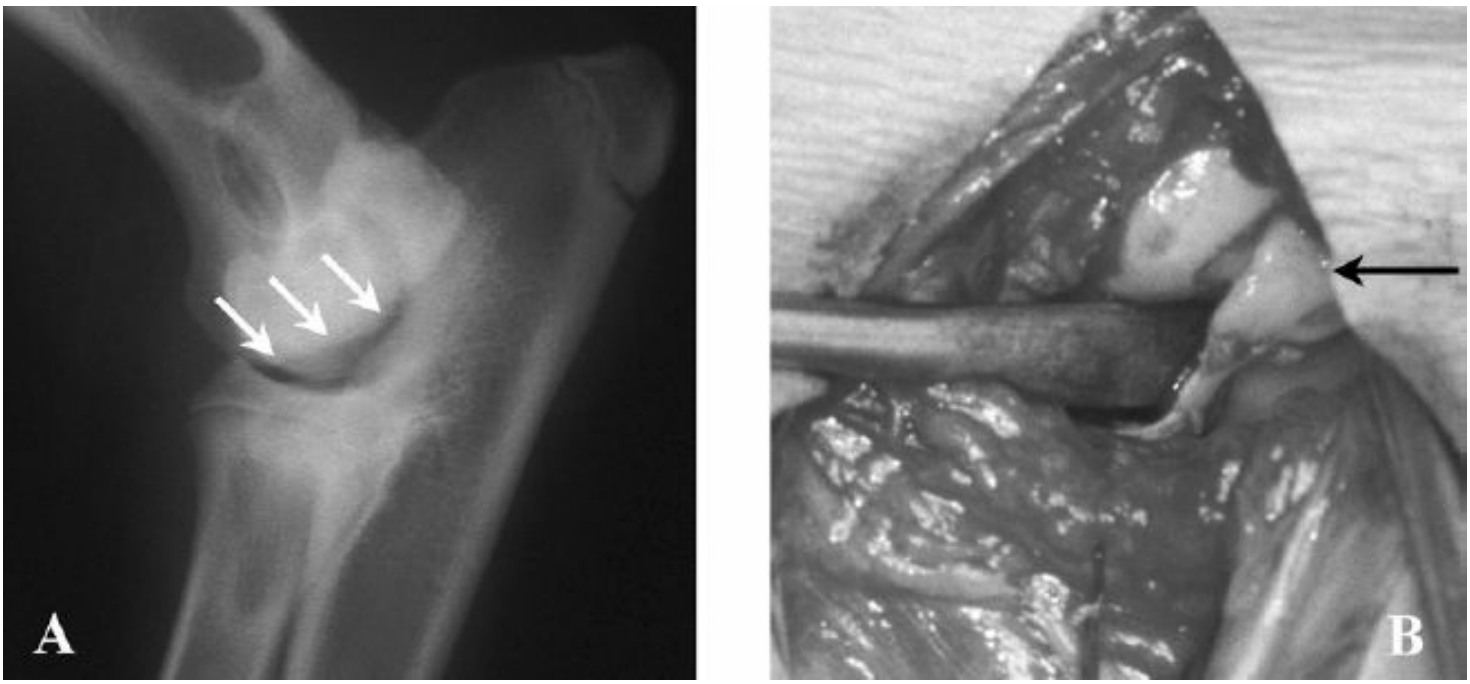

Figure 100-5. A radiographic and intra-operative image illustrating OCD of the medial humeral condyle. (A) Lateral radiographic view of an elbow joint. Note the flattened area of the medial humeral condyle (white arrows) that has resulted in a widened joint space. (B) An intra-operative view, via a medial approach, showing the elevation of a cartilage flap (black arrow) from the medial humeral condyle.

Osteochondrosis of the elbow occurs less commonly tha; shoulder OC, however, the signalment is similar. Large- and giant-breed dogs are most commonly affected, with the highest prevalence in Bernese mountain dogs, golden retrievers, Labrador retrievers and Rottweilers. In a study on 1247 Labrador retriever puppies in an Australian breeding colony producing guide dogs, 15% had OC of the elbow.[40] The Newfoundland, flat-coated retriever, chow chow, Great Dane, and German shepherd have also been found to be over-resented breeds with elbow OC.[6,34,35] Most dogs are presented when they are less than 1 year of age, however ages ranging from 4 months to 12 years have been

reported.[41-43] Males are affected more often than females (2:1). Right and left elbows are affected equally, with bilateral disease in 20 to 50% of patients.[41,44]

Stifle Joint

Osteochondrosis of the femorotibial joint is uncommon in dogs.[42,45] It occurs most commonly along the lateral femoral condyle, but can also occur on the medial femoral condyle (Figure 100-6). Surgical treatment of stifle OCD is required, and although prognosis depends on the size of the lesion, it is generally only fair.

Young, large-breed dogs usually

present between 4 and 9 months. Breeds at risk include: boxers, Great Danes, German shepherds, Labrador retrievers, Rottweilers, bullmastiffs, bulldogs, Irish wolfhounds, golden retrievers, and Newfoundlands.[34,35] Approximately 66% of cases occur in male dogs and approximately 72% of cases are bilateral.[45]

Tibiotarsal Joint

Osteochondritis dissecans of the tibiotarsal joint is well known, but uncommon. It occurs along the medial or lateral talar ridge in a cranial to caudal direction (Figure 100-7). The medial ridge is more commonly affected. Prognosis is guarded and

lameness is likely to persist even without strenuous exercise. Prognosis is improved in cases with small lesions that are treated early. Moderate to severe osteoarthritic changes are expected.

(B) A caudocranial radiographic view showing a flattened area of the medial femoral condyle (white arrow). (C) A CT scan three-dimensional reconstruction showing the extent of a medial femoral condyle OCD lesion (black arrow). (D) An intra-operative photo showing an OCD flap (hemostat is pointing to the flap) involving the medial femoral condyle.

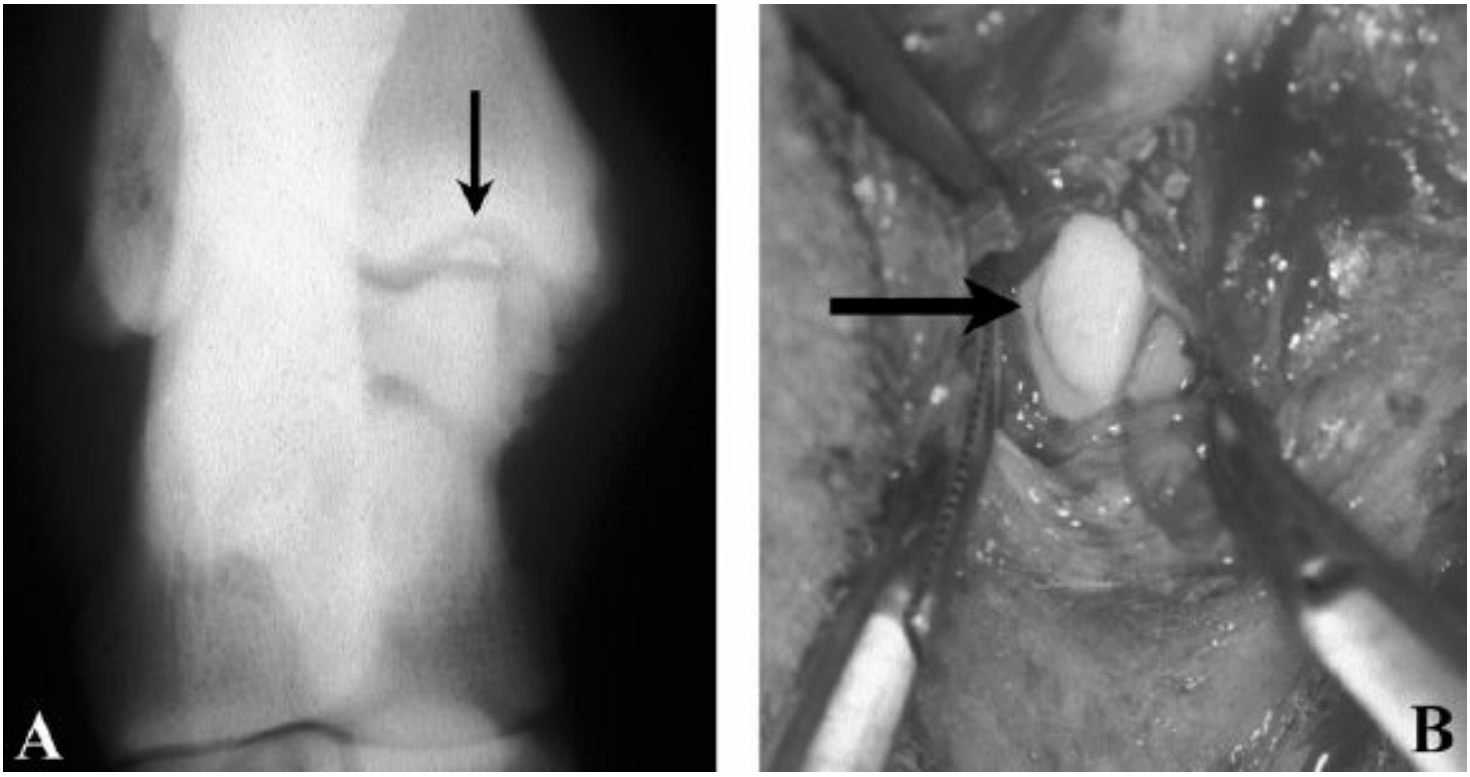

Figure 100-7. Radiographic and intra-operative

images illustrating OCD of the troclear ridge of the talus. (A) A caudocranial radiographic view of the tarsus showing the OCD lesion (black arrow) of medial trochlear ridge and secondary osteoarthritis. (B) An intra-operative view showing a nondisplaced OCD lesion (black arrow) of the lateral trochlear ridge of the talus.

A histologic study of 38 OCD flaps removed surgically from the hock joint concluded that OCD of the talus follows the same sequence of events as OCD of other joints. The one difference is that the cartilage flaps do not only undergo calcification, but also ossify and attach to the synovial membrane and/or the collateral ligament (Type II). This is likely owing to the relatively rich vascular supply from the surrounding synovial membrane and collateral ligament. Olssen suggested

that the reason for the increased incidence on the medial trochlear ridge is local pressure by the tendon of the flexor hallucis longus muscle and pull by the short branch of the medial collateral ligament.[6]

Most dogs present when they are less than 1 year of age, although a range of 4 months to 4 years has been reported.[46] The incidence in males and females is almost equivalent.[44] Large-breed dogs, particularly the Labrador retriever, Rottweiler, and bullmastiff are over represented.[34,35,44,46] Tarsal OCD is bilateral in approximately 60% of cases (range 54% to 69%).[45,46] Most tarsal OCD lesions (79%) occur on the medial trochlear ridge of the talus.[44,47]

Of these lesions, 80% occur on the plantar aspect of the ridge. Conversely most lesions that occur on the lateral trochlear ridge are present on the dorsal aspect of the ridge.[44] It has been reported that lesions of the lateral trochlear ridge occur more often in Rottweilers than in other breeds.[48,49]

Lumbosacrum

Lumbosacral OCD is a form of cauda equina syndrome.[50] Lesions of vertebral OCD vary from cartilaginous overgrowth to flaps of cartilage that separate from the underlying bone and cavitation of the vertebral epiphysis.[51] Sacral OCD is a developmental disturbance of the sacral end plate,

with subsequent separation of hyaline cartilage with a bone center from the dorsal corner.[52,53] Lesions are usually on the craniodorsal corner of the sacral body, or less commonly, on the caudal endplate of the seventh lumbar vertebra (91% and 9%, respectively).[51] Of dogs presenting with cauda equina neuropathy, 15 to 30% have been reported to have lumbosacral OCD.[51,54]

Lumbosacral OCD lesions most commonly affect German shepherds, with male dogs being over represented (4:1, male:female).[51] Dogs are usually diagnosed when they are older than 14 months (range 14 months to 13 years; mean 6.3 years).[51] It has been suggested that despite radiographic

evidence, clinical signs do not appear until dogs are over 18 months of age.

Incomplete Ossification of the Humeral Condyle

Forelimb lameness caused by a radiographically visible radiolucent line in the center of the humeral condyle was first described by Meutstege in 1989.[55] It subsequently became known as incomplete ossification of the humeral condyle (IOHC) and is an uncommon cause of forelimb lameness in dogs.[56]

The pathogenesis of incomplete ossification of the distal intercondylar humerus epiphyseal plate (IOHC) is

unknown. In normal dogs, two separate centers of ossification appear in the humeral condyle at 14 +/- 8 days after birth.[57] One ossification center includes the capitulum and the lateral aspect of the humeral condyle and one ossification center develops into the trochlea and the medial aspect of the condyle. The two centers of ossification normally unite at 70 +/- 14 days after birth.[56] The fissure line seen in IOHC of adult dogs coincides precisely with the cartilaginous remnant between the lateral and medial centers of ossification of the humeral condyle present in immature dogs (Figure 100-8).[56] For this reason it is thought that the source of the problem is failure of complete

ossification of the humeral condyle.[56] Another possible cause is a form of stress fracture, in which the condylar fissure develops after ossification of the condyle is complete.[58] It has been proposed that incongruency in the elbow joint creates stress within the humeral condyle that either prevents ossification or promotes a stress fracture.[58] If an incongruency is the underlying factor, then IOHC may be a manifestation of elbow dysplasia. Fragmented coronoid process and OCD lesions have been found to co-exist in some cases of non-fractured condyles, suggesting that the pathogenesis is linked.[56,59] It is suspected that IOHC has a genetic basis with a recessive mode of inheritance in spaniels.[56] It

has also been suggested that chondrodystrophic dogs are at greater risk;[58] however, normotrophic dogs can also be affected.[59,60] Biopsies taken from the intercondylar area during surgery usually reveal fibrous tissue, with high osteoclastic activity and plasma cell numbers suggesting chronic inflammation.[56,59] Regardless of the etiology, dogs with IOHC are predisposed to humeral condylar fractures, particularly following minor trauma. Most dogs present with a humeral condylar fracture following major or minor trauma, or following normal activity such as jumping from a height of 1 meter or less, climbing stairs, or running.[56] A radiolucent line between the condyles of the

contralateral humerus is reported to be present in 44% to 86% percent of dogs,[56,59] indicating that bilateral disease is common.

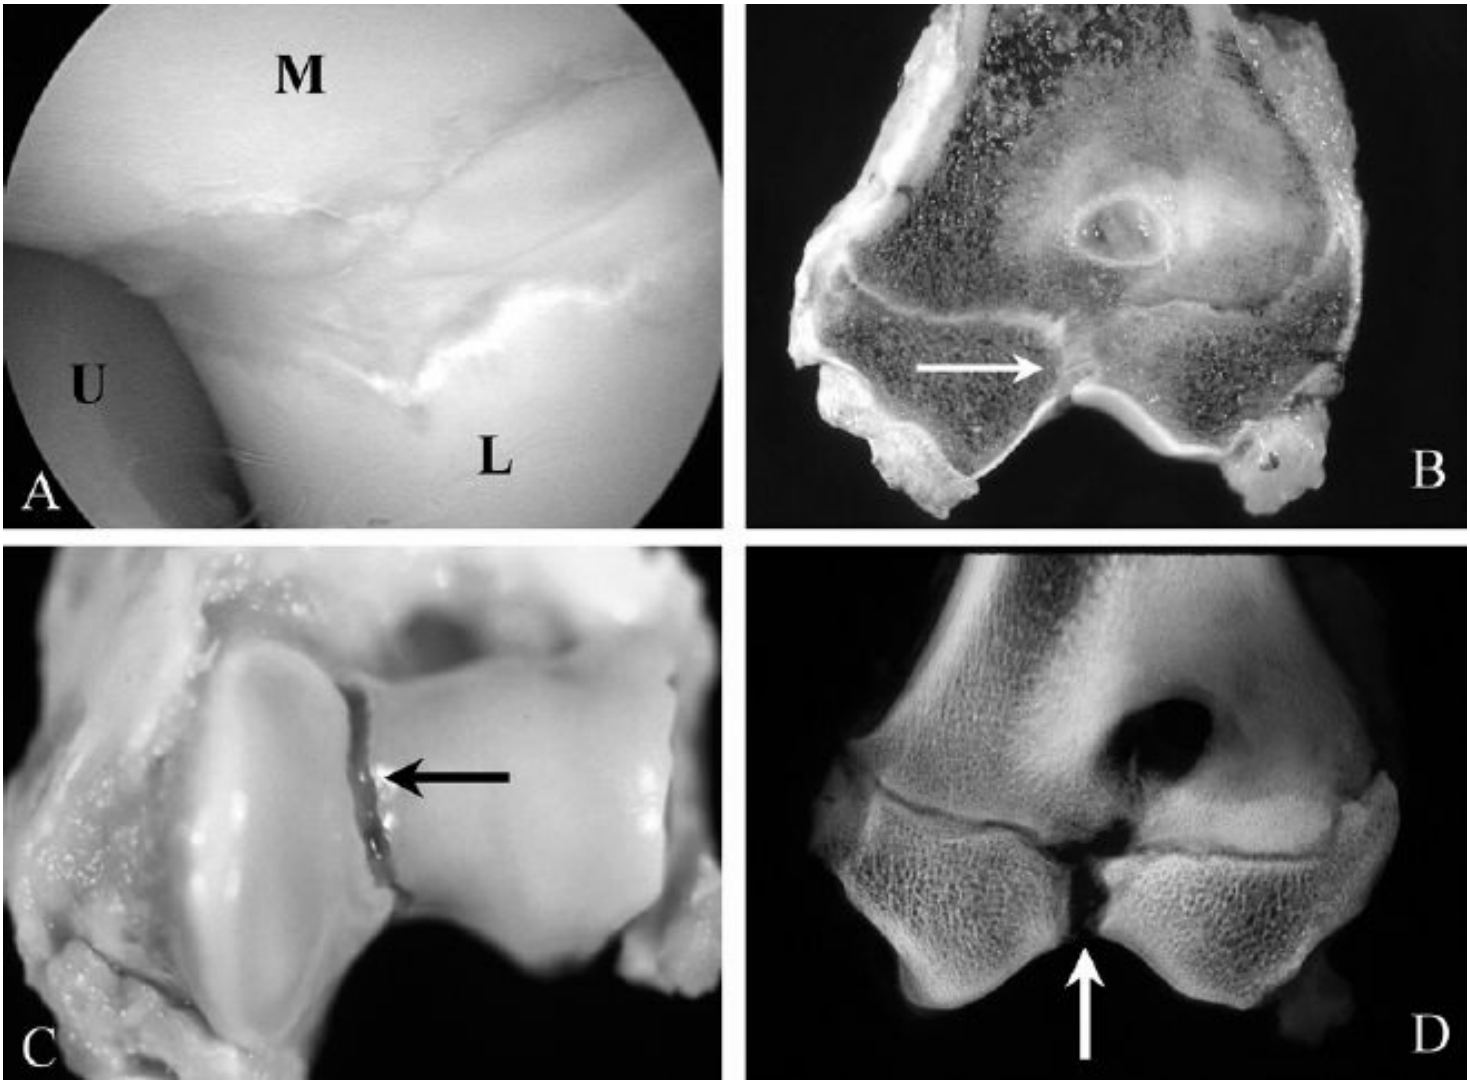

Figure 100-8. A series of images illustrating incomplete ossification of the humeral condyle. (A) An arthroscopic view showing the incomplete disruption in the articular surface between the medial humeral condyle (M) and the lateral humeral condyle (L). A portion of the ulnar notch (U) can be seen. (B) A postmortem specimen showing the retained cartilage (white arrow) between the medial and lateral humeral condyles. (C) A postmortem specimen showing complete disruption of the articular surface

(black arrow) of the humeral trochlea. (D) A faxitron radiograph showing the retained cartilage (white arrow) between the medial and lateral humeral condyles.

Spaniel breeds are at highest risk of developing IOHC, however it has been described in several other breeds. It has been reported in cocker spaniels, Brittany spaniels, springer spaniels, Cavalier King Charles spaniels, clumber spaniels, and a pug, a Yorkshire terrier, a Tibetan mastiff, a Rottweiler and several Labrador retrievers.[56,58,60-62] A recent study from Germany also reported the German wachtell, German shepherd, and mixed breed dog as being at high risk.[59] Interestingly, although spaniels were well represented at the practice in this

study, none were presented for IOHC.[59] Regardless of breed, males have been found to be at higher risk than females.[56,59]

Age of animals that present for associated non-fracture lameness range from 4 months to 5 years, with 54% presented when they are younger than 1 year.[59] Duration between first clinical signs and presentation in dogs with non-fracture lameness was 4 weeks to 12 months, with an average of 4 months.[59]

Chapter 101

Conditions of the Adult Canine Shoulder

Derek B. Fox
James L. Cook

Several conditions can affect the canine shoulder joint. Often the signalment of the animal helps to distinguish those diseases that typically occur in the juvenile patient, such as osteochondritis dessicans, from those that are more common in adult animals. This chapter discusses four

disease conditions that are sources of shoulder lameness more commonly affecting the adult, large-breed dog.

The Rotator Cuff

Many of the conditions of the adult canine shoulder involve components of the rotator cuff. The term “rotator cuff” was initially used in reference to four muscles of the human shoulder that are responsible for the motion of the brachium and for providing active shoulder stability. The four muscles include the supraspinatus, infraspinatus, teres minor, and subscapularis. The canine shoulder differs in form and function from the human shoulder owing to the

quadripedal nature of the dog, however the presence and importance of these four muscles persist. Whereas in the human, the cuff muscles are largely responsible for abduction and rotation of the brachium, these muscles serve predominantly to flex and extend the canine shoulder, in addition to providing active stability to the joint.

Calcification of the Supraspinatus

Calcification or mineralization of the supraspinatus tendon of the canine shoulder is a well documented condition, yet it remains controversial with respect to its etiopathogenesis, relationship to clinical signs, and

treatment. The supraspinatus muscle originates from the supraspinous fossa of the scapula and inserts on the greater tubercle of the humerus, extending to the medial aspect of the tubercle through a broad tendon. The muscle acts to extend the shoulder. Microangiographic studies have revealed an area of the central tendon of the insertion over the greater tubercle that is completely devoid of blood vessels.[1]

Etiopathogenesis

Much of what is known about the etiopathogenesis of rotator cuff calcific tendinopathy must be extracted from the human literature. The two

causative agents that are discussed most frequently are tissue hypoxia and localized pressure.[2] Most researchers concur with a theory describing the process of calcification to be reactive in nature rather than primarily degenerative.[2] Furthermore, it has been suggested that the disease evolves in various stages: precalcific, calcific, and postcalcific. During the precalcific stage, fibrocartilaginous metaplasia occurs in avascular areas of the tendon and the new chondroid cells produce glycosaminoglycan-rich extracellular matrix.[2,3] The calcific stage is subdivided into three phases: formative, resting, and resorptive.[4] The hallmark of the formative phase is the formation of chalky deposits of

coalescing matrix vesicles containing calcium crystals.[2] Histopathologic analysis will reveal positive staining of the calcific clumps with Von Kossa's stain. The resting phase of the calcific stage marks the cessation of calcium deposits that are surrounded by fibrocartilagenous tissue without evidence of inflammation. The resorptive phase may occur nonpredictably following the resting phase, and is so named for the presence of macrophages and multinucleated cells that begin to phagocytose the calcified deposit, resulting in a granulomatous appearance to the lesion.[3] The chalky clumps previously detected change into a toothpaste-like substance during the

resorptive phase. The postcalcific stage is one of remodeling that occurs through the formation of granulation tissue, neovascularization, and deposition of type III collagen in an attempt to heal the void left after the resorption of calcium deposits.[2]

Clinical Relevance

Several reports now document the occurrence of calcification of the supraspinatus tendon in dogs.[5-8] Adult Labrador retrievers, Rottweilers and German shepherd dogs are the most frequently reported affected animals, however this may indicate breed popularity rather than true prevalence.[5-8] Other than the

speculation of localized tissue hypoxia within the avascular portion of the supraspinatus tendon, no definitive risk factors have been determined in reported canine populations. The relationship between clinical signs and the presence of calcific deposits in the supraspinatus is not clear. Supraspinatus calcifying tendinopathy may be an incidental finding and result in no clinical signs.[6,8] Interestingly, Bardet reports that 11% of dogs affected with shoulder instability concurrently possess supraspinatus calcification.[9] In another study assessing 13 dogs positively diagnosed with calcification of the supraspinatus that also underwent radiographic examination of the

elbows, 69% had evidence of fragmented coronoid processes, elbow osteoarthritis, or both.[6] What cannot be determined from these studies is if the diagnosis of supraspinatus calcification is related to other orthopedic conditions within the same joint or limb, or if its incidence reflects coincidence. From reports of humans who are symptomatic from calcific tendinopathy of the supraspinatus alone and the successful resolution of clinical signs following calcific deposit dissolution or removal in some dogs, one may conclude that the presence of the disorder is responsible for lameness in a certain percentage of dogs. However, concurrent sources of forelimb pain should always be

pursued and addressed appropriately.

Diagnosis

Pain may or may not be elicited on palpation of the tendon of insertion of the supraspinatus over the greater tubercle and on shoulder flexion.[5,7] Because of the concurrence of supraspinatus calcification and other shoulder pathology, the biceps tendon should also be palpated for evidence of pain or inflammation, and the joint examined for signs of instability. Similarly, the elbow should be thoroughly palpated to examine for signs of pain, effusion, and decreased range of motion.

The most common diagnostic tool is radiography. However, mineralization of the supraspinatus may be indistinguishable from that of the biceps tendon if only mediolateral radiographs are taken. Therefore, a flexed cranioproximal-craniodistal tangential view of the intertubercular groove, or "skyline" view, should also be taken to distinguish the location of the calcific density (Figure 101-1).[8] Depending on the stage of the disease process, the affected area of the tendon may not be detectable with radiographs. Ultrasonography can be used successfully to detect disruption or inflammation within tendon fibers. Furthermore, if present, calcification is easily recognized as hyperechoic foci

with distal acoustic shadowing.[10] If magnetic resonance imaging is used, T1-weighted images will show calcifications as areas of decreased signal intensity and T2-weighted images may demonstrate a perifocal band of increased signal intensity associated with edema.[2]

Figure 101-1. Lateral and craniproximal – craniodistal or "skyline" radiographic views showing two calcific deposits in the supraspinatus tendon. The skyline view allows localization of the pathology to the supraspinatus tendon versus the biceps tendon. (photos courtesy of Dr. Loic Dejardin)

Treatment

Various treatments have been described for lameness attributable to calcification of the supraspinatus in the dog, including conservative management, surgical removal of the calcific deposits and extracorporeal shock-wave therapy. Surgery consists of accessing the deposits through longitudinal incisions in the tendon for their subsequent removal. Interestingly, in a long-term follow-up study of four operated cases, Laitinen noted that that the calcific depositis had reoccurred in all the dogs after a mean follow-up time of 5.1 years after surgery.[6] However, despite the reformation of the calcium-based deposits, resolution of lameness has

been reported following their surgical removal in the majority of cases.[6-8] In the human, conservative management is the favored initial treatment and surgery is indicated only if 1) clinical signs progress, 2) the pain appears to be consistent and interfering with quality of life, and 3) if conservative management fails.[11] Current opinions from veterinary orthopedic researchers have become similar, recommending a period of conservative management including rest, administration of nonsteroidal anti-inflammatory drugs (NSAIDs), and physical therapy for 3 months from the time of diagnosis before attempting surgery.[6] Lameness attributable to calcification of the suprapinatus has been shown to

resolve in some dogs with conservative management.[6] Another advantage of this approach is to allow other sources of underlying lameness to manifest and be appropriately diagnosed because the incidental occurrence of supraspinatus calcification appears to be high and may serve as the proverbial red herring.

Another treatment strategy that has been reported in the dog is extracorporeal shock-wave therapy, which employs low-frequency, high-pressure pneumatic impulses that are generated outside of the body but delivered to the affected area through a hand-held applicator in a noninvasive, but site-specific fashion.[5]

Success with this technique in alleviating clinical signs has been demonstrated in a small population.[5]

Other techniques described in the human literature include ultrasound-guided needle aspiration and lavage, and arthroscopic-assisted aspiration and debridement.[2] These authors have had success with using arthroscopy to assist in the debridement of focal calcium deposits in a small population of dogs. However, the use of needle aspiration has not been described in the dog to the knowledge of the authors.

Infraspinatus Contracture

The infraspinatus is a fusiform muscle

of the shoulder rotator cuff that originates from the infraspinous fossa of the scapula and inserts on the lateral aspect of the greater tubercle over a small bursa. It can either flex or extend the shoulder depending on the joint's position when the muscle contracts.

Etiopathogenesis

Contracture of the infraspinatus represents a chronic process by which initial injury to the muscle and tendon eventually results in severe fibrosis and adherence to the underlying joint capsule. The condition was first described in 1970,[12] and is a well recognized disorder occurring in

medium- to large-breed working dogs.[13] The initiation of the process can either be self-inflicted through vigorous activity or a result of a traumatic event. Most typically, affected dogs present with acute pain and swelling over the lateral aspect of the shoulder after a period of strenuous activity, although this phase of the disease frequently goes unnoticed. Palpation of the supraspinatus and infraspinatus muscle groups during this acute injury phase reveals swelling and elicits a painful response. During the ensuing weeks, the dog is typically reluctant to bear weight and flex or extend the affected limb at the level of the scapulohumeral joint. Over time, the tendon can undergo irreversible

and severe contraction with marked concomitant muscle atrophy. The result is the adoption of a classic posture of the affected forelimb consisting of adduction of the elbow, abduction of the antebrachium, and external rotation of the limb with extension at the level of the shoulder (Figure 101-2). Research has demonstrated that the suprascapular nerve is not involved in this process and that fibrous tissue eventually replaces the vast majority of affected normal muscle fibers.[14,15] The supraspinatus muscle can be simultaneously or independently involved in a similar process.[16]

Figure 101-2. A dog affected by infraspinatus contracture with classic position of the limb. (photos courtesy of Dr. James Tomlinson)

Diagnosis

A presumptive diagnosis can be made based on patient history, the characteristic positioning of the affected limb, and orthopedic examination. Dogs affected by this

condition will carry the limb in a similarly characteristic fashion during ambulation in which the lower limb swings out in a circumducted fashion while advancing the foot forward. Careful palpation will reveal atrophy of the infraspinatus and possibly the supraspinatus muscles with subsequent prominence of the scapular spine and acromial process. Attempts to internally rotate or adduct the proximal humerus will result in noticeable scapular excursion away from the thoracic wall. Radiographs of the shoulder may be normal or reveal a narrowing of the scapulohumeral joint space, particularly evident on the craniocaudal view. Ultrasonographic examination of the infraspinatus

muscle and tendon can be completed to substantiate the diagnosis, as findings associated with both the early and late stages of the disease have been described.[17]

Treatment

If the disorder can be diagnosed in the early stages, in which the tendon has been strained prior to any secondary fibrotic response, conservative management consisting of rest and NSAIDs has been reported to be successful.[17] Ultrasound examination of these injuries will greatly assist with this early intervention.[17] However, if pursuing conservative management, owners should be advised about the

risk for contracture to occur. Once the muscle and tendon have undergone fibrosis and contracture, only surgical release has been shown to be successful. The infraspinatus is released through tenotomy and partial excision of the tendon close to its insertion on the lateral aspect of the greater tubercle. Adhesions to the underlying joint capsule must be examined for and freed. A dramatic release and recession of the proximal myotendinous junction with immediate restoration of joint range of motion should be detected once the tendon is completely released. Prognosis with this treatment appears to be good to excellent.

Biceps Tendon Pathology

Pathologic conditions of the biceps tendon reported to occur in dogs include tenosynovitis, partial or complete rupture, avulsion, tendinitis, tendinosis, displacement, and bipartite tendon.[18-25] Most often, these conditions occur in middle-aged medium- and large-breed dogs that participate in athletic activities. No documented gender predisposition exists to the authors' knowledge. Apart from rupture or avulsion, dogs with biceps tendon pathology are presented for unilateral forelimb lameness of insidious onset. Dogs typically bear weight on the affected limb. Rupture or avulsion may result in more acute and

more severe lameness.

Etiopathogenesis

Bicipital tenosynovitis (also called tendinitis or tendinosis), with or without partial tearing, appears to be the most common pathologic condition of the biceps tendon in dogs.[18-25] The etiology likely involves chronic overuse with superimposed "micro" or "macro" traumatic episodes involving the tendon. The problem is chronic inflammation of the portion of the biceps tendon that crosses the shoulder joint. Histologically, synovial villous hypertrophy, hypervascularity, and lymphocytic-plasmacytic infiltration are noted.[21,24] Long-term, this

condition can result in tendon fibrosis, necrosis, fibril disruption, collagenolysis, metaplasia, and calcification; enthesiophytosis; and secondary osteoarthritis.[21,24]

Avulsion or rupture of the biceps tendon can occur at the tendon's origin at the supraglenoid tubercle or can include avulsion of the tubercle from the scapula.[18,19,26,27] Avulsion of the tubercle can occur as a Salter-Harris fracture at the supraglenoid ossification center in immature dogs.[26,27] Rupture of the tendon can also occur at mid-substance or the musculotendinous junction. Avulsion and ruptures of all types are most often associated with trauma from

jumping, falling, or blunt impact (i.e., vehicular trauma).

The etiology and significance of displaced and bipartite biceps tendons are not known.[18,19] These conditions may involve genetically based anatomic variations and appear to have a variety of manifestations from incidental findings to overt pain and lameness.

Diagnosis

Physical examination of dogs with biceps tendon pathology is similar regardless of specific cause. The most consistent examination findings reported include lameness, mild to

moderate atrophy of the affected spinatus muscles, pain on shoulder flexion (especially with the elbow extended), and pain on direct palpation of the biceps tendon, and/or manual tensioning of the biceps muscle.[18-25,28,29]

Definitive diagnosis and characterization of the type of pathology of the biceps tendon typically requires more advanced imaging modalities such as contrast arthrography, ultrasonographic evaluation, and/or arthroscopic visualization.[18-25,28,29] Plain radiographic views of the affected shoulder joint provide relevant information regarding secondary bone

and soft tissue changes and should be included in the diagnostic database. “Skyline” radiographic views may aid in evaluating the biceps groove.[20,23] In cases of bicipital tenosynovitis, radiographs may show evidence of osteophytosis and enthesiophytosis associated with the biceps tendon and groove (Figure 101-3). Contrast arthrography provides additional information regarding the anatomy and integrity of the biceps tendon. Contrast arthrography is reported to be sensitive for identifying biceps tenosynovitis,[23] but generally does not delineate type or extent of the pathology or give information regarding changes within the tendon tissue.[18-25] Ultrasonography of the

biceps tendon, performed by an experienced individual, provides for assessment of intratendinous pathology, associated effusion, and pathologic changes of the biceps groove (Figure 101-4).[23,25,29] Ultrasonography is helpful for determining the type and severity of the pathology in the majority of cases.[25,29] Arthroscopic evaluation of the shoulder joint allows for visualization and assessment of all intra-articular structures, providing definitive evidence of visible biceps pathology as well as involvement of other tissues (Figure 101-5). More advanced imaging techniques such as computed tomography and magnetic resonance imaging are currently being

investigated for their usefulness for diagnosis of shoulder joint pathology in dogs.

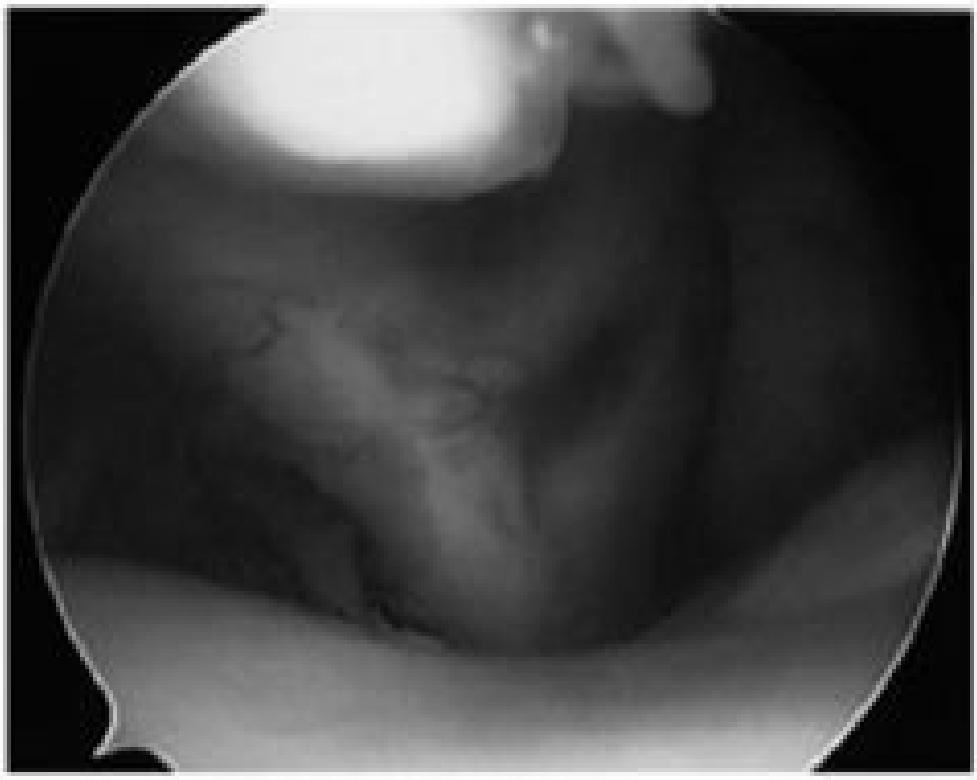

Figure 101-5. Arthroscopic views of a biceps tendon with tenosynovitis and partial avulsion.

It is critical to perform a comprehensive diagnostic evaluation of dogs suspected, or even confirmed, to have biceps tendon pathology. Biceps tendon pathology can be a secondary or incidental finding. Many dogs with biceps tendon problems also have elbow pathology, neurologic dysfunction, or neoplasia. It is vital to look for other pathology in every dog diagnosed with biceps tendon disorders as these other problems are often more clinically important and will greatly affect treatment and prognosis. The authors recommend performing a complete neurologic examination and obtaining radiographs of the elbows in

all cases.

Treatment

When biceps tendon pathology is determined to be a significant cause of pain, lameness, and/or dysfunction in dogs, treatment is indicated. Nonsurgical management of biceps tendon pathology consisting of activity modification, nonsteroidal anti-inflammatory drugs, analgesics, and/or intra-articular injections may be effective in many cases.[18-20,22,25] Exercise restriction appears to be a critical component of successful nonsurgical management. Success rates for nonsurgical treatment of biceps tenosynovitis range from 41% to

73%.[20,25] This variability in outcome is likely due in part to the inability to fully assess the cause and severity of tendon pathology preoperatively. Optimizing comprehensiveness and consistency in diagnosis and characterization of biceps tendon pathology in dogs may lead to more definitive algorithms for decision-making regarding indications for various treatments in these patients.

Surgical management is deemed necessary in a significant number of dogs with biceps tendon pathology.[18-20,22-26,28-30] The reported surgical treatment options for biceps tendon disease include tenodesis, tenotomy, primary repair, debridement,

transposition, and lavage.[18-20,22-26,28-30] In the authors' experience, primary repair, debridement, and transposition are rarely indicated for primary lesions of the biceps tendon. However, these treatment options have been reported to result in successful outcomes, and may warrant consideration in selected cases. Avulsions that include an adequate portion of supraglenoid tubercle can be successfully treated using open or closed reduction techniques and stabilized with internal fixation, such as pin and tension band wiring, divergent pinning, and/or lag screw fixation (Figure 101-6).[26,27]

For surgical treatment of biceps tenosynovitis with or without partial

tears, biceps tenodesis via an open approach and open or arthroscopic biceps tendon release (tenotomy) are the most common surgical procedures used to treat biceps tendon problems in dogs.[18-20,22,25,28-30] Each of these techniques has been reported to be a successful means of treatment for biceps disorders in dogs. Arthroscopic biceps tenotomy was reported to result in good to excellent results in 5 dogs in a series based on subjective measures over a 6-month follow-up period.[28] Open tenodesis has been be associated with good and excellent outcomes in more than 90% of dogs treated.[20,22] Six dogs treated by arthroscopic tenodesis were judged to have good or excellent outcomes in another reported series.[29]

Figure 101-6. Postoperative radiographic views of a dog with avulsion of the biceps tendon origin at the supraglenoid tubercle treated by lag screw fixation after arthroscopically and fluoroscopically guided and performed reduction.

The published literature regarding surgical treatment of biceps tendon pathology suggests that postoperative protection of the repair or treatment, weight management, and physical rehabilitation are critical for a successful outcome when treating biceps tendon problems using any

modality.[18-20,25,28-30] It is important to counsel owners that maximal function may not be reached until 6 months following surgery in the majority of cases, and that these are typically chronic problems requiring compliance in treatment, careful monitoring, and most of all, patience. However, when these factors are addressed, the prognosis for the vast majority of biceps tendon disorders is good to excellent for pain-free, "pet-level" function, and guarded to good for high-level athletic function.

Shoulder Instability

Shoulder instability owing to periarticular soft-tissue pathology is a

commonly diagnosed problem in humans. Bardet has described a shoulder instability syndrome in dogs.[9] Although lateral and multidirectional shoulder instabilities have been described,[9,31] medial shoulder instability (MSI) appears to be the predominant type of shoulder instability seen in dogs.[9,32,33] Characterization of epidemiology, pathology, diagnosis, indications for treatment, treatment options, outcomes, and prognosis for MSI are currently a major focus in veterinary medicine. Dogs diagnosed with MSI are most commonly middle-aged, large-breed dogs with a history of chronic unilateral forelimb lameness.[32,33] Dogs with MSI typically have an intended

purpose of work, performance, or active pet-level function.[32,33]

Etiopathogenesis

The etiology of MSI is not known, but available data suggest that this problem occurs as a result of chronic overuse injury with episodes of "micro" trauma to the shoulder occurring during the development of disease. The pathology associated with MSI includes lameness, shoulder joint laxity, pain on manipulation of the shoulder, and abnormalities of the medial joint capsule, subscapularis tendon, and medial glenohumeral ligament observed via arthroscopy.[9,32-34]

Diagnosis

Signalment, complete history, complete orthopedic and neurologic examination, blood work, radiographs, and ultrasonography are integral to the comprehensive diagnostic approach. Ultrasonographic evaluation is recommended for all potential MSI patients to rule out primary or concurrent musculotendinous pathology. Definitive diagnosis of MSI is based primarily on palpation and exploratory arthroscopy.

Palpation under sedation is a key component of preoperative diagnosis of MSI. Range of motion in flexion, extension, and rotation, the “shoulder drawer sign” as described by Bardet,[9]

and the shoulder abduction test[32,33] should be assessed in each limb. Shoulder abduction angles measured under sedation have been reported to provide objective data for diagnosis of MSI in dogs.[32,33] Shoulders with clinical and arthroscopic evidence of MSI have significantly higher angles (53.7 ± 4.7°) compared with shoulders considered normal (32.6 ± 2.0°).[33]

Currently, arthroscopic exploration provides the most definitive diagnosis of MSI and allows assessment of cartilage damage and other key structures in the shoulder joint. Arthroscopic identification of tearing and laxity of the subscapularis tendon, medial glenohumeral ligament, and

joint capsule are consistent findings in reported cases of MSI (Figure 101-7).[32,33]

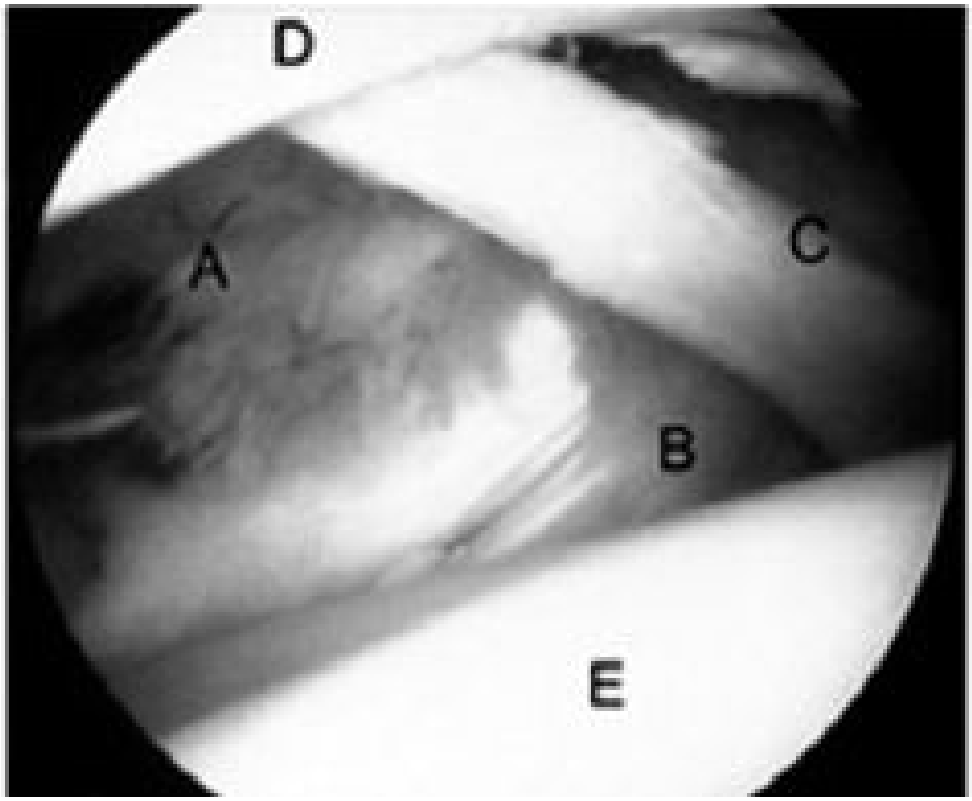

Figure 101-7. Arthroscopic view of the pathology of the medial joint capsule (A), subscapularis tendon (B), and medial glenohumeral ligament (C) typically seen in dogs diagnosed with medial shoulder instability. The distance between glenoid (D) and humeral head (E) also appears excessive.

It is vitally important to rule out

separate or concurrent causes of shoulder lameness. Dogs with MSI may also have elbow pathology, neurologic dysfunction, or neoplasia. It is vital to look for other pathology in every dog presumptively diagnosed with MSI as these other problems are often more clinically important and will greatly affect treatment and prognosis. The authors recommend performing a complete neurologic examination and obtaining radiographs of the elbows in all cases.

Treatment

Few data are available regarding indications for treatment, treatment options, and prognosis for shoulder

MSI in dogs. Treatment recommendations are based on extent and severity of instability, concurrent shoulder pathology, concurrent orthopedic problems, the overall health of the patient, the intended use of the patient, and the commitment of the owner.[9,31-35] The use of radiofrequency-induced thermal capsulorrhaphy (RITC) for treatment of MSI in dogs has been reported to be successful.[32,34] RITC treatment resulted in improved clinical function in 93% of cases, with 79% considered to have excellent outcomes and 7% considered to be failures.[32] Appropriate postoperative care appears to be a critical factor in realizing success in these cases. It is imperative that the

dogs be kept in a non-weightbearing sling for 3 to 4 weeks after RITC treatment in order to protect the treated tissue. It is vital that careful attention to sling and limb management is employed during this period. Severe complications, primarily skin wounds and carpus and elbow contracture, can occur if the sling is not properly cared for and range of motion exercises are not performed at the time of sling change (at least once weekly). For the subsequent 6 weeks, strict exercise restriction with physical rehabilitation is recommended, followed by a progressive return to full function. Dogs do not reach improved function until 12 to 16 weeks after treatment and do not reach full post-

treatment function until 5 to 6 months after treatment.[32] Bilateral shoulder instability, complete tears of the MGL, a single major traumatic episode as the cause of the MSI, concurrent forelimb orthopedic pathology, neurologic dysfunction, and shoulder osteoarthritis are reported to be contraindications for RITC treatment of MSI.[32] For complete tears of the MGL, ST, or MJC, open or arthroscopic reconstruction of the medial compartment by direct tissue reapposition and tissue anchor and suture or imbrication suture reinforcement is recommended.[35] Excision arthroplasty and arthrodesis may also be viable options in a subset of patients with severe MSI. For those

cases that do not fit the inclusion criteria for any surgical treatment, non-surgical treatment consisting of weight management, activity modification, and medical therapy is recommended. No study in which any of these treatments for MSI were compared has been reported to date.

Shoulder instability appears to be a documented problem in dogs that can result in pain and lameness. However, our understanding of etiopathogenesis, clinical versus subclinical pathology, optimal diagnostic tools, indications for treatment, surgical decision making, and prognostication for shoulder instability in dogs is lacking, and a significant amount of work

needs to be done to further characterize and make definitive recommendations regarding this entity.

Chapter 102

Elbow Dysplasia

Stéphane Bureau
Jean-François Bardet

Originally, the term “elbow dysplasia” was introduced to describe a generalized osteoarthritis of the elbow joint in which an ununited anconeal process occurred in some but not in all of the affected joints.[1] Later, fragmentation of the medial coronoid process of the ulna and osteochondritis dissecans of the medial aspect of the humeral condyle were recognized to

also be associated with this generalized osteoarthritis.[2] The modern concept of elbow dysplasia means a complex of polygenic hereditary developmental abnormalities of the elbow, including ununited anconeal process (UAP), fragmented medial coronoid process (FMCP), osteochondrosis of the medial humeral condyle (OCD), and elbow incongruity (EI).[3-5] The term elbow dysplasia has been accepted to describe all conditions resulting in arthrosis of the elbow joint regardless of the underlying cause (1990, International Elbow Working Group meeting, San Francisco).

The same form of dysplasia may be found in both elbows or a combination

of forms may be observed, such as FMCP and OCD.[6-11] Breeds may be predisposed to a particular form of elbow dysplasia. The German shepherd dog suffers more from UAP.[12-14] FMCP and incongruity are the most common findings in the Bernese mountain dog.[15-16] Rottweilers most frequently have FMCP but are rarely affected by OCD.[6,8,11] The Labrador retriever is most likely to have OCD and FMCP.[11,17] The suggestion that different patterns of disease exist within breeds or within families is extremely important in gaining a complete understanding of this complicated syndrome.[18]

The pathogenesis of this disease

remains poorly understood and controversial.[4,19] The finding of all forms of dysplasia within both elbows of a single dog, plus the finding of various forms of elbow dysplasia within the same elbow suggests a common etiology.[18] Incongruity exists in the different forms of elbow dysplasia.[20] Three major pathogenetic mechanisms proposed to explain the development of elbow dysplasia are asynchronous growth of the radius and ulna, osteochondrosis, and trochlear notch dysplasia.

Ununited Anconeal Process

The pathogenesis of UAP is controversial. The heritability in the

German shepherd dog was reported early and conclusively.[1,21,22] The lesion in other breeds has not been so well studied; however, it is thought that it is probably inherited in these dogs as well.[18]

Ununited anconeal process has been described as a manifestation of osteochondrosis.[3] Osteochondrosis (OC) is disturbed endochondral ossification of articular or physeal cartilage.[23,24] The cartilage continues to grow and it becomes abnormally thick and obviously less resistant to mechanical stress.[23,24] In other cases, OC causes retarded growth or premature closure of a growth plate.[24] Retention of cartilage in the distal ulna

may occasionally lead to retarded growth of the ulna; overgrowth of the radius with a relatively shorter ulna could be the cause of UAP (Figure 102-1).[24,25] The radius that is too long relative to the ulna forces the trochlea of the humerus in a proximal direction, which exerts more pressure than normal on the anconeal process, resulting in damage to the joint cartilage and to the ossification center of the anconeal process.[3,25] If OC is present, the entire structure is less resistant to trauma and a tear in the weakened cartilage prevents osseous bridging of the gap.[3] Measurements made of the olecranon in German shepherd dogs with UAP showed a significantly shorter olecranon in

affected limbs.[12] The UAP may be completely separated or joined to the ulna by fibrous or fibrocartilaginous tissue.[19] In large-breed puppies, deformed anconeal processes with degenerated articular surfaces have lesions such as ischemia, degeneration, and multifocal dystrophic mineralization, which were apparently a result of pressure exerted by an upward thrust of the condylar surface of the humerus.[4] In a study on dogs with UAP this pressure on the anconeal process was eliminated by lengthening the ulna through osteotomy.[19]

Although asynchronous growth of the radius and ulna may play a role in the pathogenesis of UAP, breeds of dogs

having secondary centers of ossification at that location are most likely predisposed to develop that lesion. In the German shepherd dog, the separate ossification center of the anconeal process appears at 11 to 14 weeks and the anconeal process is united with the olecranon at 20 to 22 weeks.[9] In the greyhound, UAP is unknown; this is assumed to be because the anconeal process of the ulna ossifies more rapidly than that in the German shepherd dog.[26] Bony union is completed in approximately 2 to 3 weeks in the greyhound against 6 to 8 weeks in the German shepherd dog.[26] Surgical specimens of UAP from breeds with secondary centers of ossification of the anconeal process

had a well formed articular surface of the proximal trochlear notch in which the articular cartilage was supported by an oriented cancellous bony base.[4] The fracture line travelled along what appeared to be a fenestrated closing growth plate. By contrast, surgical specimens of UAP from large-breed dogs that did not have separate secondary centers of ossification of this process were deformed, had less ordered cancellous bone architecture, and did not have the remnants of a closing growth plate along the base. The fracture lines of these specimens had the disordered appearance of a fatigue or stress fracture.[4]

Fragmented Medial Coronoid Process – Osteochondritis Dissecans

Fragmented medial coronoid process is commonly seen with OCD or erosive lesions.[2,7,11] Nevertheless, the lesions can occur independently and one does not lead on to the other.[27] Olsson proposed that both FMCP and OCD are manifestations of OC and could result in overgrowth of the ulna.[3,9] No histologic evidence was found that the medial coronoid process of the ulna has a separate center of ossification.[28] The cartilaginous medial coronoid process ossifies from its base to the tip and ossification is completed at 20 to 22 weeks.[9] This delay in ossification of

the medial coronoid process may predispose it to fragmentation when mechanical stresses are applied.[25] There is no step between the coronoid process and the radius during the stance phase of the gait cycle.[29] A study of the distribution of forces between the articular surface of the humerus and radius, and between the humerus and ulna in normal canine joints shows that the ulna is an important structure in the transfer of load. The ratio of the mean forces between the proximal articular surfaces of the radius and ulna remained close to a 50:50 distribution regardless of the applied load.[30] In human elbow joints the coronoid process appears to be an essential

osseous block to prevent posterior subluxation.[31]

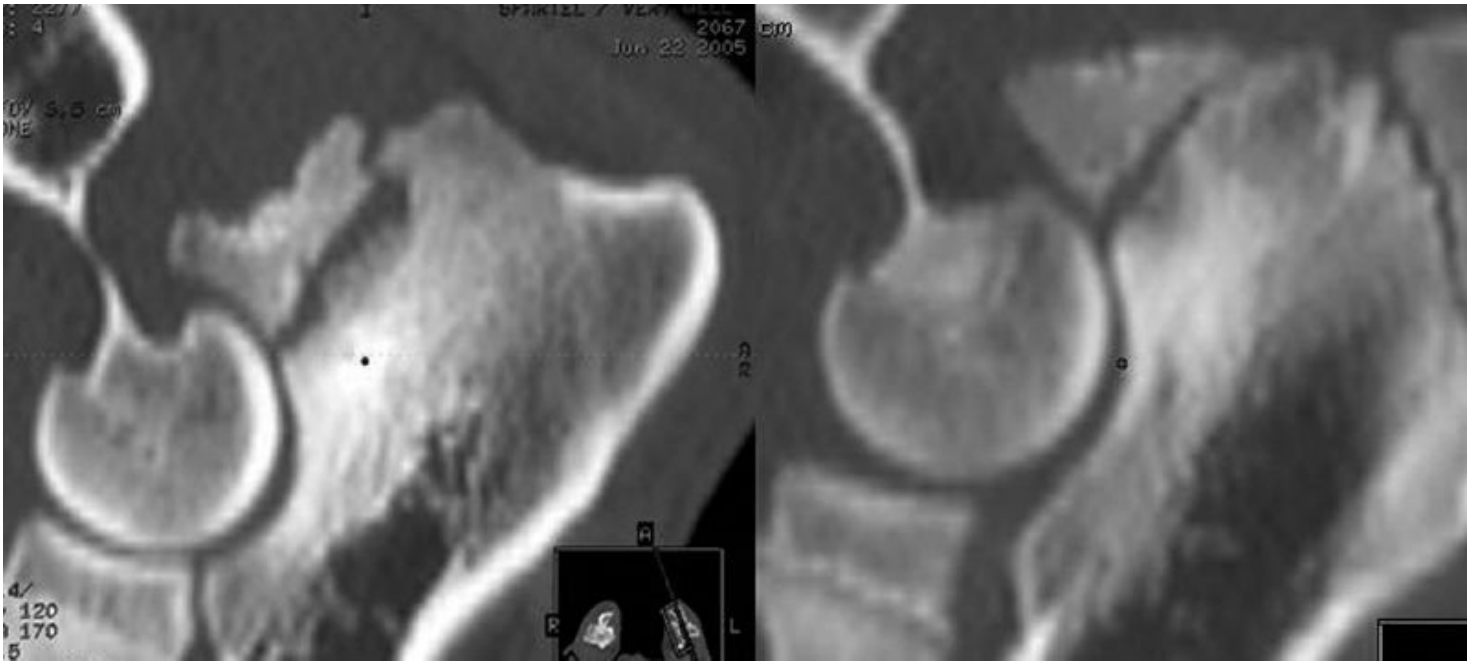

Figure 102-1. CT scan of two dogs affected by UAP. Overgrowth of the radius with a relatively shorter ulna could be the cause of UAP (right) but is not systematically observed (left).

In puppies up to 5 months of age, the bones would move past one another along the longitudinal axis over a distance of about 1 to 2 mm. In puppies older than 5 months,

longitudinal movement of the radius and ulna was limited. No movement could be elicited in any of the specimens older than 6 to 7 months. This may be due in part to the natural slowing of longitudinal bone growth as skeletal maturity is approached, but it may also be due in part to the restraining effect on growth plates exerted by the maturing intraosseous membrane and the ligament that begins to mature and resist longitudinal movement at about this time.[4]

Overgrowth of the ulna places an abnormal load on the medial coronoid process and the medial condyle of the humerus; FMCP, OCD, or both in

combination could appear.[3] The resulting malalignment of the proximal ulna and radius caused much of the weight that was transferred from the humeral condyle to the antebrachium to be transmitted through the small, elevated medial coronoid process, leading to fragmentation or abnormal ossification of the coronoid process.[3,29] Owing to mechanical stress, fissures can result within the thickened cartilage of medial condyle that eventually leads to the formation of a cartilage flap or OCD lesion.[25] If the overgrowth of the ulna develops late, the development of the skeleton has reached a stage of near maturity that does not provide the ground for the appearance of FMCP and OCD. In that

case, the increased load on the humeroulnar compartment of the elbow joint leads only to erosion, or “kissing lesion” that may extend into the underlying bone.[3]

The split line reveals the prevailing alignment of collagen fibers in subchondral bone. An interrelation exists between development and differentiation of connective and supporting tissues and the load acting on them.[32] The orientation of the split line denotes the direction of maximal tensile strength. Three main types of split-line pattern could be differentiated and correspond well with the different fissure and fragmentation line pattern of the

medial coronoid process.[32] These similarities may indicate an association between orientation of the split line and type of lesion.[32]

Up to seven types of lesions of the medial coronoid process are described, with articular cartilage of the medial coronoid process at the same level as that of the radial head or elevated (Figure 102-2).[33] A decrease of the height of the step between the articular surface of the coronoid and radial head is obtained after a proximal ulna sliding osteotomy.[33,34] The damage to the medial coronoid process varies widely. It may remain cartilaginous, have a delayed ossification, or may ossify at a more normal time. The

lesion may appear as a fissure within the cartilage with complete separation of the cartilage fragment or it may appear as a fissure within the bone, with an incomplete fracture or complete separation of a bony fragment.[18] A FMCP might be separated from the fracture bed and remain viable because it is loosely attached to the joint capsule from which it continues to maintain its blood supply. Thus, if displaced, the fragments may remain unchanged or, because of a persistent blood supply, the fragments of cartilage may become larger and may ossify or fragments of bone may enlarge.[9] The OCD lesion lies opposite the medial coronoid process. The fragment may remain in

situ. If it is not removed surgically, it gradually becomes free but rarely mineralizes; it may detach and form a joint mouse.[9]

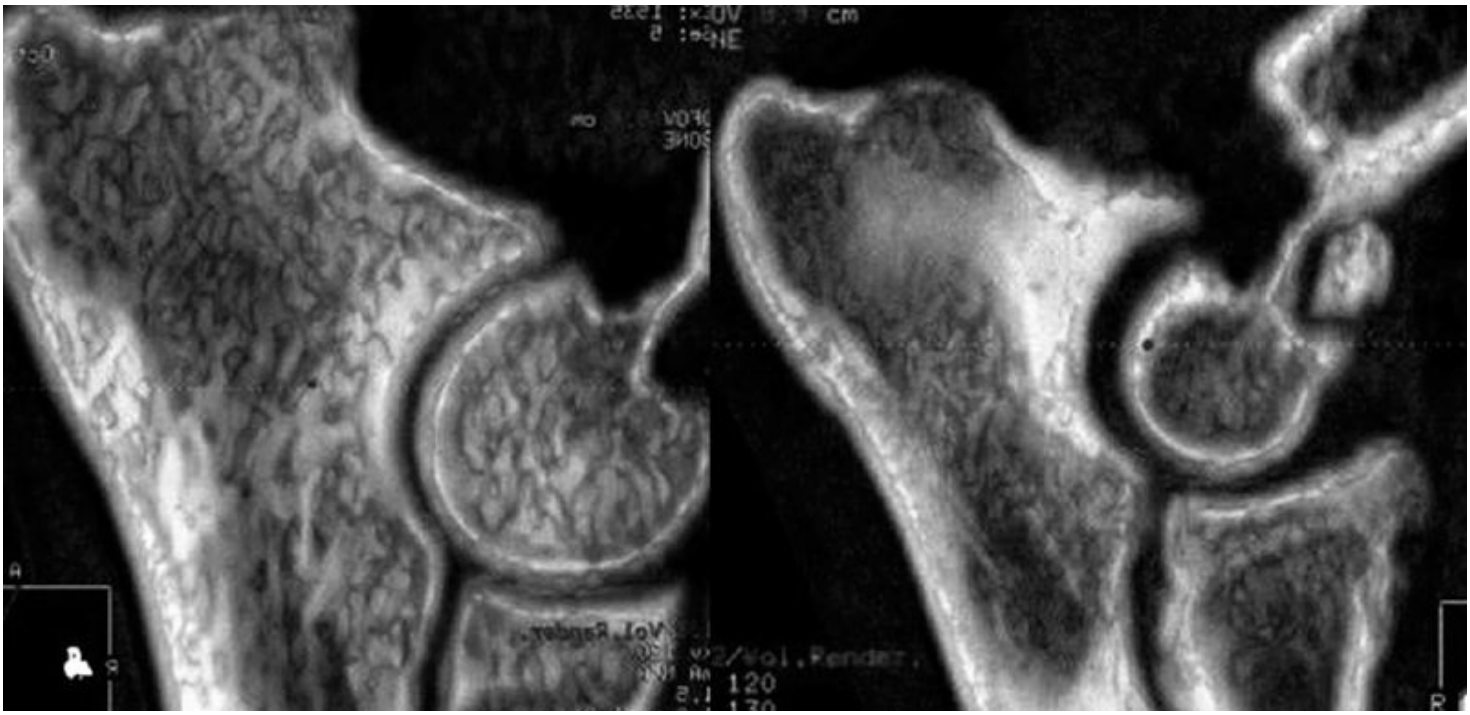

Figure 102-2. CT scan of two 2 dogs affected by FMCP. The medial coronoid process could be at the same level as that of the radial head (left) or could be elevated (right).

Medial compartment osteoarthritis with eburnation of the medial humeral condyle is currently diagnosed by

arthroscopy. The canine medial compartment osteoarthritis is similar to medial compartment osteoarthritis of the human knee.[35] Research shows an association of the medial compartment osteoarthritis with a varus deformity of the elbow similar to what is described in the knee in people. The humeroulnar angle in normal dogs measured on craniocaudal radiographs varies from 0.53° to 9.09°.[35] Dogs with medial compartment osteoarthritis have a varus deformity with this angle greater than 7°.[36]

The cartilaginous growth disturbance is likely to have genetic and environmental, and mainly nutritional

and traumatic causes.[23,25] However, the theory that the lesions are caused by OC is not supported by consistent findings of histologically defective cartilage at early lesion sites. Histologic evidence of thickened degenerated cartilage is reported in less than 20% of 120 dogs with elbow dysplasia.[37] In a multiyear necropsy study, histologic lesions consistent with OC lesions are observed in elbows from 3- to 5-month-old puppies.[4] Both the medial humeral condyle and medial coronoid process have compressed the subchondral capillary bed, disrupted subchondral spongiosa, and focally thickened cartilage lesions. In puppies older than 5 months of age, focal lesions on the medial humeral condyle

were roughened and fibrillated but had an intact articular surface. Although the lesions in these older puppies were located at the same site on the medial condyle as were the lesions in the younger puppies, they more closely resembled osteoarthritis than OC.[4] Differences in the histologic and ultrastructural appearance of the OCD and FMCP lesions tend to suggest that they are two separate disease entities. It is hypothesised that OCD results from incorrect cartilage maturation and endochondral ossification, and the etiology of FMCP is subchondral fracture with an ineffective fibrous repair in some cases.[27]

Joint Incongruity

The normal canine joint showed a continuous arc formed by the central ridge of the trochlear notch and the proximal radial articulation.[20] Specific areas of articular contact were identified on the radius, the craniolateral aspect of the anconeal process, and the medial coronoid process.[29] The medial coronoid and radial contact areas were continuous across the radioulnar articulation.[29] The incongruity observed between the radius and the ulna suggests either a lagging growth rate of the radius or an ulnar trochlear notch of smaller diameter.

The most obvious abnormality was the

finding that the distal edge of the trochlear notch of the ulna with its medial coronoid process lay approximately 2 mm proximally to the articular surface of the radius.[20] Measurements of radial and ulnar length have indicated a statistically significant relative increase in length of the proximal ulna in middle-size and large-breed dogs during a vital period of limb development (before 16 to 20 weeks of age). The ulna was temporarily up to 3 mm longer than the paired radius.[38] Incongruity may not always be evident owing to compensatory adjustment during growth.[38] Examples of bilateral FMCP were found in which a 1- to 2-mm elevation of the medial coronoid

process above the radial articular surface remained in one elbow joint.[4] This degree of incongruity, although compatible with a lagging radial growth, is in itself insufficient to explain the relative increase in the length of the proximal ulna.

Disparity in radial and ulnar lengths were noted in both normal and lame dogs and failed to correlate with obvious radiographic joint incongruity.[39] This indicates that variation in the length of these bones may be a normal variation of growth and a common finding in large-breed dogs. Only 5 of 15 lame dogs demonstrated obvious disparity in radial and ulnar length, although it is

possible that joint incongruity might have temporarily occurred during growth yet was not apparent at presentation.[39]

Another explanation for the incongruity between the radius and ulna is an abnormal development of the ulnar trochlear notch, resulting in a slightly elliptic joint surface with an arc of curvature insufficient to encompass the humeral trochlea. This creates a joint with major contact points in the areas of the anconeal process and medial coronoid process but without a point of contact between the trochlear notch and the humeral trochlea (Figure 102-3).[20] Underdevelopment of the trochlear

notch may be temporary or persistent and becomes evident between the ages of 4 to 6 months.[20] If the incongruity is present at the age of 4 to 6 months, the skeleton at that time is as yet incompletely ossified. Fracture, fragmentation, or fissure of the medial coronoid process could occur owing to the increased weight-bearing forces on the too-high lying parts of the ulna.[20] For the same reason, the lesion could be an OCD lesion.[20] The humeral condyle is pressed against the anconeal process and causes micromovement of the cartilage bridge and partial to complete separation of the articular process.[20,38] If the incongruity is present after 6 months, it may be present on its own and interferes with

the formation of the articular surfaces and the manner in which they articulate; consequently, with time, osteoarthritis develops as a secondary joint disease.[20] Nevertheless, the grade of arthrosis is not always higher in the older dog than in the young dog. Dogs over 5 years of age were identified suffering from FMCP even in the absence of osteophyte formation.[40] It is possible that a different etiopathogenesis such as traumatic fracture or persistent physeal cartilage may have been involved.[40]

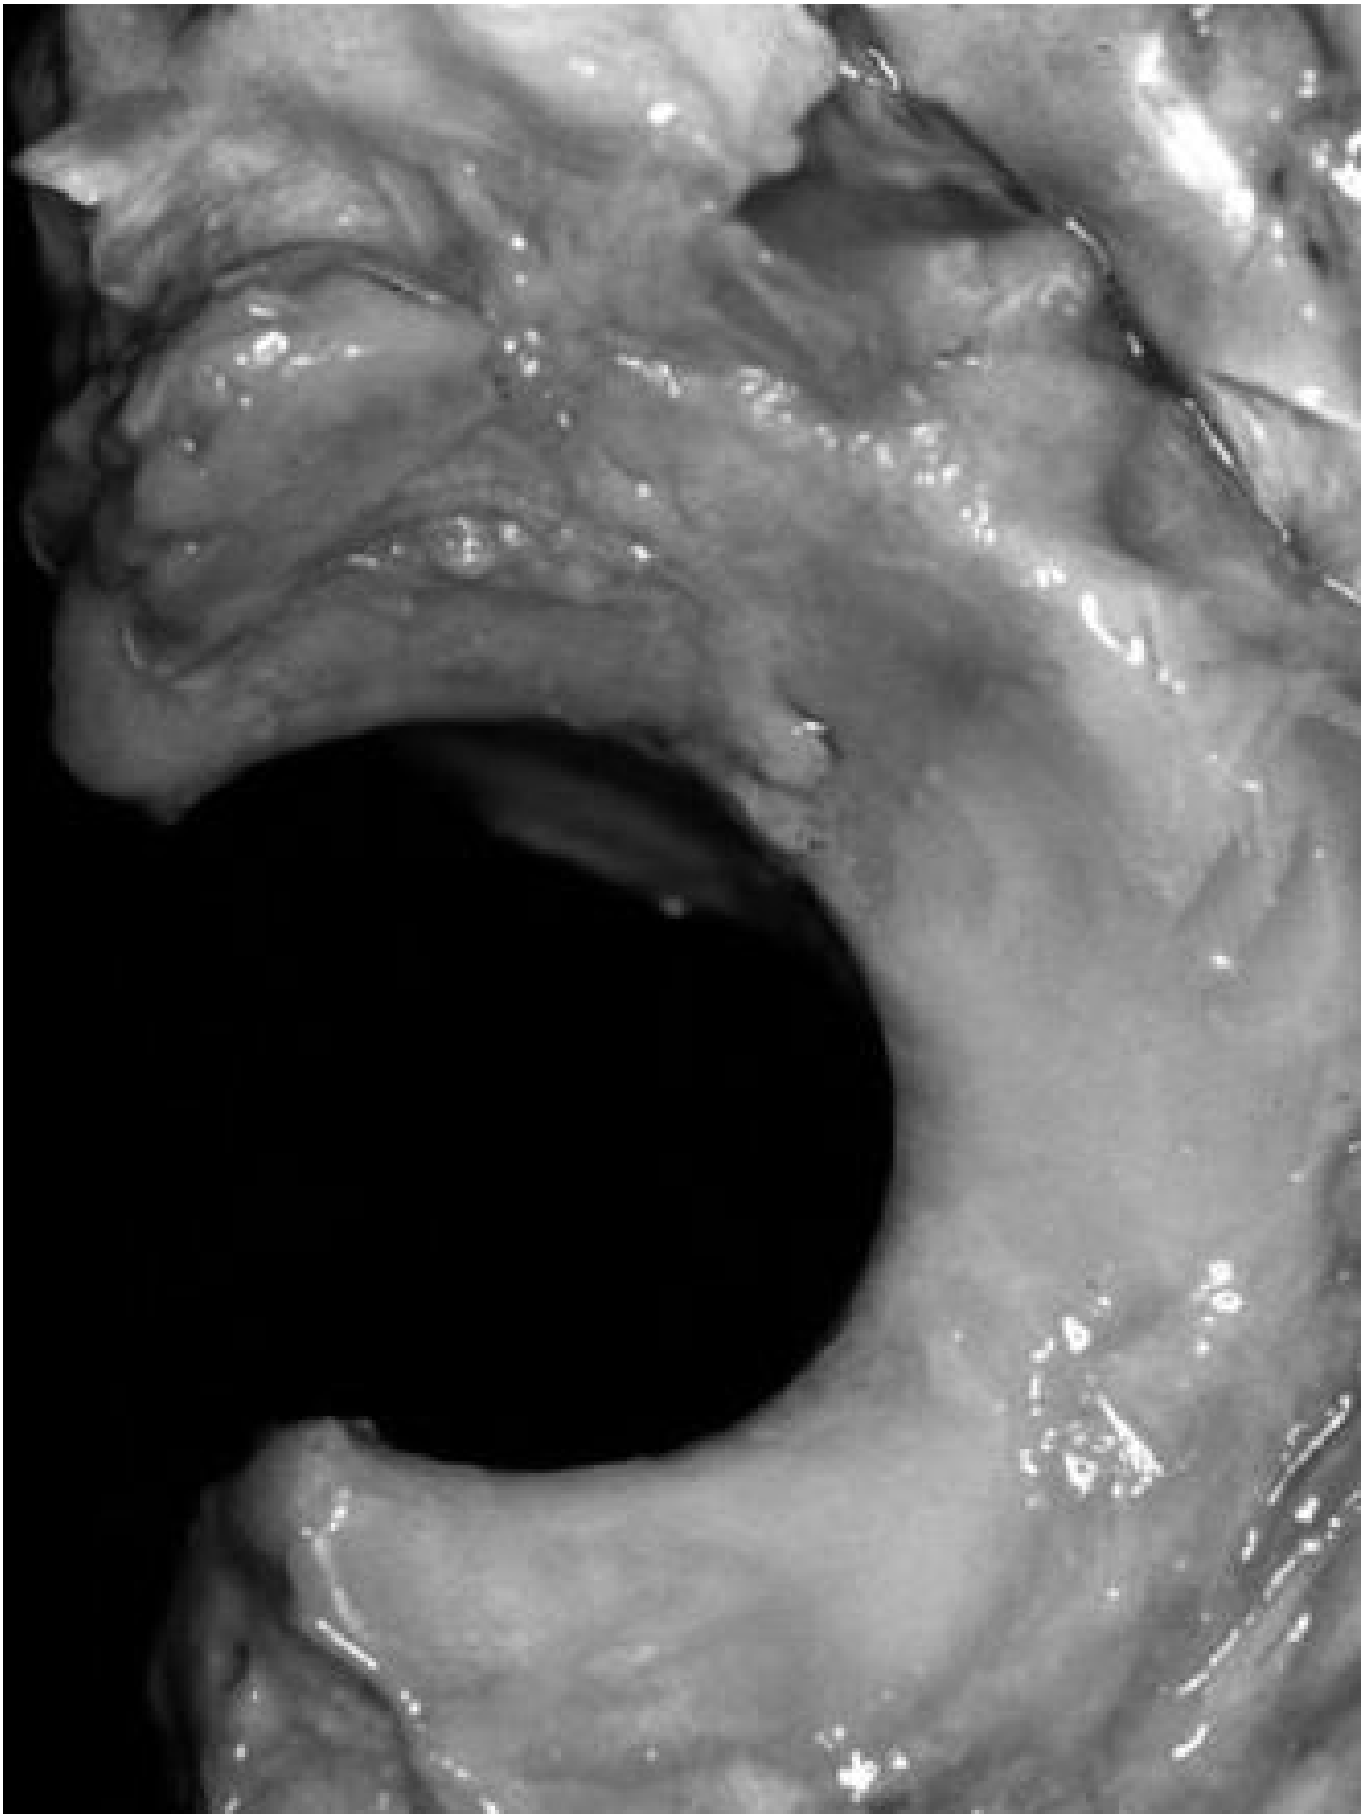

Figure 102-3. An abnormal development of the ulnar

trochlear notch with an arc of curvature insufficient to encompass the humeral trochlea creates a joint with major contact points in the areas of the anconeal process and medial coronoid process.

The increase in the relative size of the proximal ulna in heavier breeds could be necessary to accommodate a larger trochlear notch for articulation with a heavier humerus.[38] This need for rapid growth may also be a contributing factor for the failure of the trochlear notch to reach the required arc of curvature to encompass the humeral trochlea.[38]

In severe cases, it is obvious that the increased load on the medial coronoid process has led to remodelling of the ulnar part of the elbow joint, leading

to a more open trochlear notch.[3] This observation however does not support the hypothesis that an elliptic trochlear notch makes it too small for the trochlea of the humerus. Moreover, the hypothesis of an abnormally developed, slightly elliptical trochlear notch seems unlikely to be a major contributing factor, as combined UAP and FMCP should then occur in much larger numbers of dogs and ulnar ostectomy would have no effects in cases with UAP.[3,19]

One study compared the radius of curvature of the ulnar trochlear notch of the Rottweiler, a breed predisposed to FMCP, to that of greyhound, a breed that has never reported be affected by

this disease.[41] The greater radius of curvature within the distal part of the trochlear notch in the Rottweiler results in a more open elliptical shape. It may result in dynamic or positional instability of the cubital joint, increasing stress leading to FMCP. It may also be formed as a result of asynchronous growth of the radius and ulna.[41]

Heritability

Elbow dysplasia is inherited as multifactorial or polygenic traits.[5,42,43] Osteochondritis dissecans and FMCP were found to be inherited independently as polygenic traits.[17] Fragmented coronoid process and

incongruity were found to be genetically separate diseases.[16] If elbow dysplasia is the phenotypic effect of independent genetic diseases, the phenotype may behave polygenetically even though the underlying components are monogenous.[16] The incidence of elbow dysplasia was found to be strongly breed-specific statistically and was higher in intermediate and heavy-set breeds when compared with sight hounds and setter-type breeds.[38] The exact nature of the environmental contribution to the disease remains unclear, although several putative factors have been put forward such as nutrition and exercise.[5,16]

Males generally are more frequently affected.[7,10,11,42,44] Heritability in Labrador retrievers was 0.77 for males and 0.45 for females.[45] In Rottweilers, estimation of heritability for elbow dysplasia was 0.34 +/- 0.04.46 Reported incidence for this breed in Norway was 40%.[8] In Bernese mountain dogs and Rottweilers, heritability based on regression of sons on sires was 0.34, and the estimated heritability based on regression of daughters on dams was 0.28 and 0.4 respectively.[43] An inherited basis for elbow osteochondrosis has also been reported in the Labrador retriever with a greater contribution of the dam suggesting a "maternal effect."[10] The differences in the prevalence can be

explained by a direct effect of genes on the sex chromosomes or by an effect of secondary sex characteristics such as differences in growth rate, sex hormones, or behavioral patterns. For a polygenic trait such as arthrosis in the elbow joint, the effect of secondary sex characteristics is a more plausible explanation.[43]

Conclusion

Elbow dysplasia describes all conditions (UAP, FMCP, OCD, EI) resulting in arthrosis of the elbow regardless of the underlying cause. A genetic predisposition is widely recognized. All forms of elbow dysplasia were initially thought to be

secondary to osteochondrosis but the research of the last 20 years using histology, traumatic tactile pressure sensor, computed tomography, and subchondral split-line patterns clearly indicates a biomechanical basis as the major pathophysiologic mechanism of UAP, FMCP, and EI. Differences in the pathology and ultrastructural appearance of the OCD and FMCP lesions tend to suggest that they are two separate diseases. The proximal joint surface of the ulna contributes substantially to load transfer through the canine elbow joint. Anomalies that increase this load appear to contribute to canine elbow dysplasia, mainly fragmentation of the medial coronoid process. Because of the great interest

in this common invalidating pathology and the modern tools of investigation, we share a better understanding on how elbow dysplasia might appear, but more research is needed to refine the latest knowledge and to design prevention techniques for elbow osteoarthritis.

Chapter 103

Legg-Calve-Perthes Disease

Michael G. Conzemius
Peter Lotsikas

History

In 1910, Legg, Calve, and Perthes independently described a condition of the hip in children.[1-3] Calve thought that the condition was due to rickets.[2] Perthes thought that it was related to degenerative arthritis, probably of an infectious nature.[3] Legg, however, hypothesized that impairment of blood

supply to the femoral epiphysis was the cause of the condition; a hypothesis that parallels our current understanding of the pathogenesis.[1] Of historical interest, Waldenstrom described a case of tuberculosis of the hip in 1909 that may have actually been a case of Legg-Calve-Perthes (LCP) disease.[4] In 1935, LCP disease was first described in the veterinary literature by Tutt.[5] Later, Spicer (1936), Schnelle (1937), and Moltzen-Nielsen (1938) described the condition, using some form of a synonym of LCP disease, in the veterinary literature.[6] Common synonyms for this condition are avascular necrosis of the femoral neck, aseptic necrosis, osteonecrosis, coxa plana, osteochondritis deformans

juvenilis, and osteochondrosis.

Pathogenesis

The main histologic feature of LCP disease in both dogs and humans has been described as ischemic necrosis of the center of ossification of the femoral head.[7] Ponseti et al described histologicl, histochemical, and ultrastructural observations of biopsy specimens from the lateral aspect of the femoral head and neck of children with LCP disease.[7] They reported that beneath normal cartilage was thickened epiphyseal cartilage that contained areas of hypercellular and fibrillated cartilage with prominent blood vessels.[7] Ultrastructural

examination of these areas revealed irregularly oriented collagen fibers and variable amounts of proteoglycan granules. Hypercellular areas suffered from a decrease in proteoglycans, glycoproteins, and collagen compared with that of normal epiphyseal cartilage. These findings suggest that the disease could be a localized expression of a generalized transient disorder of epiphyseal cartilage that is responsible for delayed skeletal maturation. The collapse of the femoral head likely results from a mechanical failure of this necrotic area that heals as a disorganized epiphyseal cartilage matrix with abnormal ossification. The severe deformity of the femoral head is a consequence of

collapse of this mechanically inferior repairing cartilage. What remains unclear is whether the abnormalities of the epiphyseal cartilage are primary or secondary to ischemic events.[8]

In the dog, three histologically distinct stages of the disease have been described: ischemic, early repair, and advanced repair.[9]

The ischemic (necrosis) stage is characterized by empty osteocyte lacunae and the absence of viable marrow. The chondrocytes of the articular and physeal cartilages are histologically and ultrastructurally normal during this stage. The metaphyseal trabeculae may be

thickened, but the process of endochondral ossification is generally uninterrupted.

In the early repair stage, the articular cartilage develops clefts and fissures as the subchondral bone begins to collapse beneath it, and the overall shape of the femoral head appears flattened (coxa plana). The repair process begins with revascularization at the periphery of the epiphysis. Fibrovascular tissue composed of capillaries, macrophages, fibroblasts, and histiocytes advances toward the center, resorbing the necrotic marrow debris and dead trabeculae. The articular cartilage appears thickened, especially in the zone of calcification,

and the physeal cartilage becomes invaded with fibrovascular repair tissue.

In the advanced repair stage, the articular cartilage becomes markedly thickened with clefts and infolding, and the entire femoral head appears enlarged, with eventual loss of its normal spherical shape. Areas of osteoclastic absorption and extensive new bone formation can be seen histologically at this stage. The disease is considered irreversible at this point because the collapse and repair permanently change the contour of the femoral head. Ultimately, progressive osteoarthrosis develops. The etiology for the ischemia, subsequent

fragmentation, and protracted reformation of the femoral head observed in this disorder remain unknown.[7]

Etiology

Many theories as to the etiology of LCP disease have been proposed and disproved since the disease was first described in the dog in 1935. Because the disease affects primarily small and toy breeds, heritability or anatomic variations in small breeds would seem to be factors contributing to the development of the clinical disease. Indeed, Vasseur et al[9] demonstrated that LCP disease was a heritable condition in the Manchester terrier. To

understand the exact pattern of inheritance for LCP disease, additional investigation of affected pedigrees must be performed. Intuitively, this condition is likely heritable in similar dog breeds. Supporting information is found in a study comparing the vascular anatomy of the hip in a miniature dog with that in a normal-sized mongrel.[10] This study demonstrated a distinct difference between the two groups in the channel of the superior retinacular vessels. In the miniature dog, the vessels coursed through a shallow neck and appeared as a suspended bridge as compared with a deep fossa of the femoral neck in the mongrel dog.[10] The consequence of the difference in vascular supply

may be that the femoral heads of miniature dogs are more susceptible to vascular compromise or insults from trauma, synovitis, or vascular abnormalities.

A more recent suggestion is that LCP disease arises after ischemic infarction, venous or arterial, of the capital femoral epiphysis. Vascular compromise leading to LCP disease has been experimentally demonstrated in animal models by several authors.[11-13] Coagulation disorders as a source of infarction were examined in both humans and dogs. Evidence of thrombocytosis and hypofibrinolysis secondary to a protein C and S deficiency was reported in 1997 by

Glueck et al.[14] However, other investigators have failed to reproduce their findings.[13] The largest study that evaluated coagulation abnormalities involved a population of 139 children in Northern Ireland with LCP disease. Of the children afflicted with the condition, 38% had a prolonged activated partial thromboplastin time compared with 5.9% in a control group of 220 children.[13] However, no significant differences existed in antithrombotic factors protein C, protein S, or antithrombin (AT) III, or resistance to activated protein C. An association between the prolonged partial thromboplastin time and a clotting factor deficiency was not demonstrated.[13] Likewise, Brenig et al

were unable to demonstrate any alterations in protein C, protein S, activated protein C, factor II, factor V, factor VIII:C, or AT III activities in plasma samples of 18 dogs with histopathologically confirmed LCP disease.[15] The cause for prolonged activated partial thromboplastin time in some of these patients remains unknown. Genomic DNA from 15 dogs affected with LCP disease has also been evaluated for mutations in the protein C gene, however no mutations were found.[16]

Diagnosis

Patients generally present in the first year of life with the owner

complaining that the dog has a limp. High-risk breeds include terriers, toy poodles, chihuahuas, Lhasa Apsos, miniature pinschers, pugs, and other toy breed dogs.[17] Although LCP disease in people affects males more often than females, no sex predilection has been identified in the dog. Depending on the stage of the disease, the severity of lameness can range from subtle to non-weight bearing. Clinical signs can also vary if the disease is bilateral, which reportedly occurs in 12 to 16% of cases.[18,19] Physical examination findings generally include lameness, muscle atrophy, and pain on extension and abduction of the affected hip joint(s). Given the breeds affected with LCP disease, medial patellar luxation is

also a common incidental finding.

Confirmation of examination findings can be performed using radiography. Radiographic findings depend on disease stage (Figure 103-1). Early findings can include evidence of an increase in radiopacity as new bone is laid down on empty lacunae. Progression of the disease includes resorption of necrotic bone. Loss of bone is faster than the production of new bone in this pathologic process and radiographic evidence of osteolysis will be present as the disease progresses. As the femoral head begins to collapse, it will lose its spherical shape and an increase in the joint space may be present. Following

collapse, osteoarthritis will rapidly form and osteophytes will be present on radiographs. If both LCP disease and a medial patellar luxation are present and one needs to identify which is most likely causing the clinical signs, nuclear scintigraphy can be performed. Empirically, LCP disease is almost always a bigger contributor to clinical lameness than is a medial patellar luxation. If the etiology of the radiographic findings is in question, arthrocentesis with cytology and a culture should be performed. However, given the infrequency of idiopathic septic arthritis in the dog, this is rarely needed.

Figure 103-1. Hip-extended radiographs of a 10-month-old Cairn terrier (left) with evidence of sclerosis in the femoral neck and collapse of the femoral head. Radiographic progression of the disease is evident when the dog is 14 months old (right) with complete collapse of the femoral head and severe osteoarthritis.

Treatment

Nonsurgical management consists of strict exercise restriction. In an effort

to enforce exercise restriction of unilateral LCP disease a non-weight-bearing sling can be applied. The authors would suggest the use of a Robinson sling, however, the use of an Ehmer sling has been reported to be successful in at least one case report.[20] The duration of exercise restriction varies, but it has been reported that if nonsurgical management is going to be successful it generally takes longer than 2 months.[18] Monthly radiographs should be taken to follow the progression of the disease, and immobilization of the limb continued until complete resolution of the radiolucent areas. In a retrospective report of dogs diagnosed with LCP disease that were treated

nonsurgically, only 25% had resolution of their lameness.[18] It is important to note that, even though the prognosis with nonsurgical management is guarded, it remains a reasonable first option (when the radiographic progression of the disease shows no loss of the spherical nature of the femoral head) because surgical management is via a salvage procedure.

A patient that presents with collapse of the femoral head and incongruency of the coxofemoral joint should be treated surgically by femoral head and neck excision. This salvage procedure can be performed simply, is relatively[18] inexpensive, and provides for an

improved prognosis. Junggren reported that 30 of 36 dogs that had LCP disease treated with femoral head and neck excision had complete resolution of their clinical signs. In addition, the vast majority of these dogs (80%) had fully recovered within 2 months of surgery. Following femoral head and neck excision, the patient should have exercise restriction until suture removal (7-14 days). After this period, the dog can return to its regular activities. Postoperative rehabilitation including cold and hot packing of the area, passive range of motion, and swimming may further improve the number of dogs that respond favorably to treatment. Several commercially available total

hip replacement systems now offer miniature implants. This is no longer true. Patients that have bilateral LCP disease can be treated with bilateral, simultaneous femoral head and neck excision. A ventral approach to the hip for bilateral surgery may reduce morbidity if the surgeon is familiar with the technique.

Chapter 104

Pathogenesis of Hip Dysplasia

Dr. U. Krotscheck
Dr. T. Tohundter

Canine hip dysplasia (CHD) is one of the most common orthopedic complaints in dogs. The severity of clinical signs can vary from occasional lameness to severe dysfunction. It is a complex, polygenic or multifactorial disease which results in osteoarthritis (OA) of the hip joint. This developmental trait is inherited quantitatively and is expressed

clinically and morphologically in response to heritable and environmental influences.[1-3]

Dogs affected with hip dysplasia seem to have normal hip joints at birth, but joint laxity accompanied by incongruity develops as early as the first few weeks of life.[2,4-6] It is postulated that initial joint laxity leads to subsequent subluxation of the hip joint during weight-bearing, causing tension on the joint capsule. This trauma is followed by joint capsule thickening, osteophytosis, and enthesiophyte formation.[7] The underlying etiology of joint laxity unknown.

In this chapter we provide an overview of the etiology and pathogenesis of canine hip dysplasia, discuss the proposed genetic and environmental causes of the disease, and discuss hip screening by means of radiography.

Etiology

Historically, CHD has been characterized by the following factors: joint laxity,[8-11] abnormalities of pelvic musculature,[12] chondrosseous factors such as delayed onset of capital femoral ossification,[13-15] altered composition of the chondroepiphysis,[16] and incongruity between the acetabulum and femoral head resulting in dorsolateral subluxation.[17,18] Which

of these is the initiating factor is still unknown. Today, two broad etiologies are proposed: hip laxity and abnormal progression of endochondral ossification in multiple joints. These are not mutually exclusive as both could result in an abnormal mechanical environment in the hip that results in OA.

Both the hip joint capsule and the chondrosseous conformation of the hip are major contributors toward the stability of the hip joint during loading and, therefore, must be taken into account when considering an underlying etiology of joint laxity. The round ligament of the femoral head may be the main supporting structure

of the hip joint in dogs up to 1 month of age,[7] after which the joint capsule assumes this function. The joint capsule originates in the lateral acetabular rim and inserts into the femoral neck. The strength of the capsule is predominantly due to its fibrillar collagen content and organization, whereas its compliance is due to the extracellular matrix composite of collagen, proteoglycan, water, and elastin.[19-23] As age increases, collagen cross-linking and content increase,[24] contributing to the strength and stiffness of the joint capsule. When load is applied to a normal hip joint capsule, it returns to its original configuration when the load is removed. In the lax capsule, the

stress-strain curve is shifted to the right compared with the tight capsule, resulting in further deformation for an equivalent stress than in a tight hip capsule.[25] As a result, the femoral head can undergo lateral translation relative to the acetabulum, a movement that jeopardizes the structural integrity of articular cartilage. This lateral and dorsal translation can be observed in the passive state in the dorsolateral subluxation position. Joint effusion can also cause hip laxity.[17,26]

The joint capsules of dysplastic hips contain a higher ratio of type III to type I collagen in comparison with those of normal greyhounds.[27,28] Whether this is because of tissue

immaturity, injury,[29,30] endocrine imbalance,[31] or a genetic abnormality is unknown. These results could be explained by capsular injury;[32] type III collagen is expressed after tissue injury and the dogs in this report were mature and some had been referred for total hip replacement, indicating that OA was advanced.[28] Transmission electron microscopy was used to compare the joint capsules of a dog with hip instability (distraction index 0.8) to one without instability (distraction index 0.4). A heterogeneous group of collagen fibrils was found in the dog with hip laxity and homogeneous collagen fibrils in the capsule of the dog without hip laxity. These same structural

differences in collagen fibrils of the ligament of the femoral head were observed in the same loose-hipped and tight-hipped Labrador retrievers. It was not ascertained whether the capsular laxity preceeded or was coincident with synovitis, but it is considered a precursor and risk factor for the development for OA.[6,20,33] Dorsolateral hip luxation cannot develop without passive hip laxity.[17] Dysplastic dogs have abnormal round ligaments of the femoral head. It was shown initially that, in young pups with moderate to severe OA, the volume of this ligament increases.[34] A more recent study comparing the volume of the round ligament of the femoral head and the degree of radiographic OA in adult

German shepherds demonstrated that no difference exists between the volume of the ligament of the femoral head in normal joints and those with only “mild” OA (shallow acetabulum/marked dorsal rim attenuation, moderately osteophytic acetabular margin, rounded femoral head, and minimal osteophytes on the femoral neck).[35] An inverse correlation exists between the severity of radiographic OA and the volume of the round ligament of the femoral head.[35]

The second broad etiologic category of CHD is an abnormality in endochondral ossification. The developing hip is composed of two articulating surfaces: the proximal

femoral capital chondroepiphysis (including the articular epiphyseal complex, the region where the secondary center of ossification appears and the growth plate) and the acetabulum (Figure 104-1).

In the developing acetabulum are four anlagen that give rise to the ilium, ischium, pubis, and acetabular bone, all contributing to the mature acetabulum. Each anlage has a primary center of ossification and a growth plate that results in growth of each anlage away from the center of the acetabulum. The ilium, ischium, and pubis all have a common epiphysis within which the primary center of ossification of the acetabulum appears.

As mineralization proceeds, the growth centers localize in the acetabular cup. This creates the inverted Y shape on a lateral view termed the triradiate growth plate. The acetabular anlage ossifies between the two ventral arms of this growth plate and a secondary center of ossification develops in the common epiphysis prior to closure of the triradiate growth plate. This growth plate closes radiographically at 4 to 5 months of age in medium- to large-breed dogs, whereas the capital physeal growth plate closes between 9 to 11 months of age. This closure is delayed in dysplastic hips.[15] For normal hip joint formation and conformation to occur, proper contact, load, and congruency between the

femoral head and the acetabulum are required. This is demonstrated by the success of pelvic harnesses for the treatment of dysplastic human hips. In CHD, this contact is interrupted.

Dogs with the genetic predisposition to CHD have grossly normal hips at birth, but this changes within the first few weeks of life. Whether laxity precedes osseous disconformity or vice versa is unknown. As the hip joint matures, the secondary centers of ossification and the femoral head and acetabular growth plates become histologically apparent and can be seen by diagnostic ultrasound, with radiographs, with computed tomography, and with magnetic

resonance imaging (Figure 104-1). Any femoral head dislocation affects the direction, magnitude, and distribution of the resultant femoral head force,[36] leading to a lag in development of the craniodorsal acetabular rim.[37] Additionally, femoral capital chondroepiphyseal ossification is detected later in dysplastic hips than in normal hips.[13,15] It is likely that this early neonatal stage of development is the critical time in hip development when even small perturbations in the mechanical environment and gene expression sequence result in long-term detrimental effects.[38] Serial imaging in this early stage of development may hold the key to early diagnosis of CHD.

Epidemiology and Pathogenesis

The prevalence of canine hip dysplasia in one teaching hospital in the United States was 19.7% in purebreds and 17.7% in mixed breed dogs. There was

no significant difference in the prevalence of CHD between sexes or between purebreds and mixed breed dogs.[39] The top four breeds presented to teaching hospitals that have been reported to be at increased risk for CHD in comparison with mixed breeds are the Bernese mountain dog, German wirehaired pointer, the kuvasz, and Newfoundland.[40] Hip dysplasia affects dogs of all breeds but is clinically more common in large-breed dogs.[41-46] The prevalence of CHD within breeds is 1% to 75%, as estimated by the OFA (http://www.offa.org/hipstatbreed.htm The estimate may be low because radiographs of normal dogs are more likely to be submitted for certification than are those of dysplastic dogs, thus

biasing the data base.

The age of the dog at clinical detection of CHD varies depending on the severity of the disease and owner acuity. Dysplastic dogs often develop gait abnormalities and/or lameness during growth (between 3 and 8 months of age). Examination by palpation and radiographs may reveal subluxation of the hip joint(s). Synovitis, joint capsule thickening, and articular cartilage injury are uniformly present if subluxation is detected. The cartilage and soft-tissue changes characteristic of OA in dysplastic hips have been defined.[47,48] The initial cartilaginous lesion occurs perifoveally, suggesting that abnormal

direction or magnitude of load results in increased focal stress in this area.[47,49] The result is joint pain, articular cartilage degeneration, and bony remodeling characteristic of OA (Figure 104-2). As abnormal weight-bearing continues to cause excess articular cartilage wear, the underlying bone is also damaged, possibly causing painful microfractures and sclerosis. In young dogs, perifoveal articular cartilage lesions are accompanied by increased subchondral and femoral head bone density.[50] As the animal ages, the hip laxity decreases as the capsule undergoes fibrosis and the synovial effusion resolves.

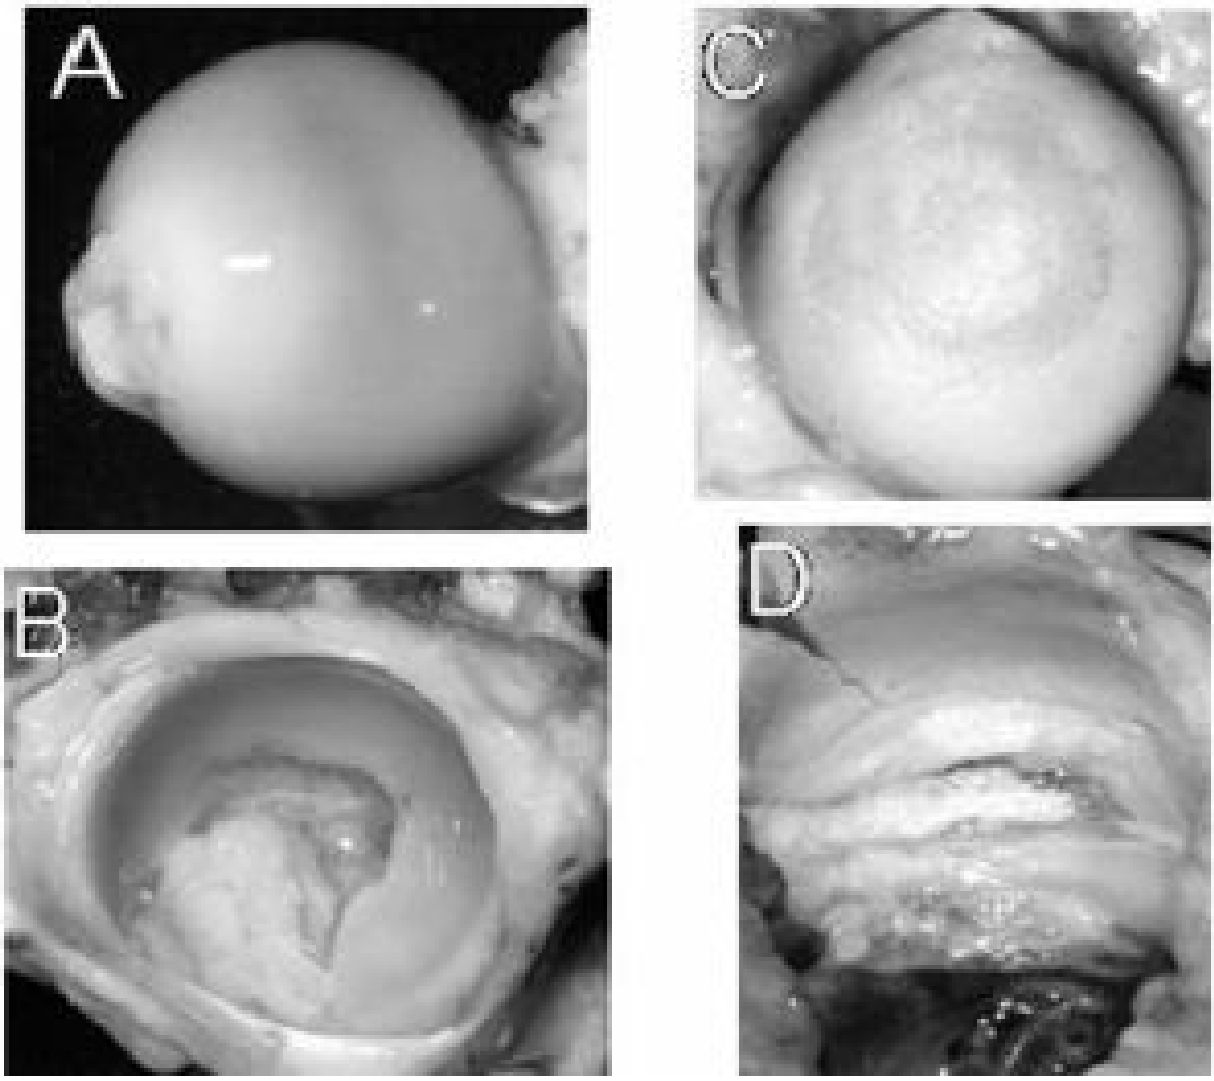

Figure 104-2. A. Dorsal surface of a normal femoral head of a dog. B. Lateral aspect of a normal acetabulum of a dog. C. Medial surface of the femoral head of an 18-month-old dog with full-thickness erosion of the articular cartilage and loss of the round ligament of the femoral head. D. Lateral aspect of the acetabulum of the same dog as in C, with secondary OA from hip dysplasia.

Osteoarthritis remains and is a

debilitating chronic condition characterized by loss of articular cartilage, fibrosis, bony remodeling, and eventual loss of function. Radiographic evidence of OA can be clinically apparent as early as 5 to 9 months of age in some dogs, whereas in other dogs it is not evident until 2 years of age or later.[51] Early OA changes such as synovitis, partial or complete tears of the ligament of the femoral head, and partial- to full-thickness articular cartilage abnormalities cannot be radiographically detected (Figure 104-2).[5,52,53] Using arthroscopy to directly evaluate the hip joint grossly in dogs undergoing a triple pelvic osteotomy, only 50% of dogs with Grade 2 to 3

arthroscopic lesions (articular cartilage surface fibrillation and deep fissuring, respectively) had radiographic evidence of OA in the extended hip view.[52]

Genetics

Two main factors are associated with development of CHD: genetics and environment. A dog's phenotype is the result of a complex interaction of its genotype and the environment to which it is exposed.[18,37,54-56]

Canine hip dysplasia is considered a quantitatively inherited, complex, polygenic, or multifactorial disease that results in OA of the hip.

Quantitatively inherited genetic traits vary along a continuum from one individual to the next and are influenced by two or more genes in addition to environmental factors.[18] The phenotypic and population genetic correlation is moderate and positive (0.24)[57] and the signs of subluxation reveal the highest heritability estimates.[58] Larger breeds share a heritable tendency to CHD and hip OA, yet many dogs with the genetic susceptibility do not show the clinical phenotype.[46] The heritability estimates (h^2) of CHD vary among authors and study population. Based on radiographic screening studies, the heritability estimates for CHD range from 0.1 - 0.68.[41,45,46,55,57-62] The

maternal effect is additive (h_m^2 (additive genetic maternal effect) = 0.1 +/- 0.02),[60] dam and sire hip scores have a significant effect on progeny conformation scores.[63] No significant difference exists in progeny hip conformation scores between the sexes,[63] nor between mixed and purebred dogs.[39] The higher the heritability estimate, the more likely we are to make phenotypic improvements using selective breeding programs.

Using genetic selection to improve the phenotype has been achieved in controlled populations such as the Seeing Eye Inc., Morristown, NJ, by combining individual phenotypic

information with parental and offspring information to obtain estimated breeding values.[55] One of the best genetic improvements reported is that of one standard deviation during 10-year period in Finland.[57] Screening programs through open registries such as those conducted in Sweden have resulted in improvement in hip quality,[62] but in other countries[44,64-66] the improvement in phenotypes has been minimal. As CHD has a polygenic mode of inheritance, future attempts to control the disease using tests based on a single genetic marker would not be immediate,[67] unless there was a major contributing locus and it was shown that mutations at that loci had to be

present to express CHD. At our present knowledge level of its molecular genetics, this seems unlikely.

The pattern of inheritance indicates that CHD is controlled by several genes located at quantitative trait loci (QTLs) and the expression of which is influenced by environmental factors. Inductive or protective QTLs that control expression of hip OA may exist independent of those controlling the dysplastic phenotype.[68,69] Some dog breeds appear to display different susceptibilities to CHD based on their distraction indices and may tolerate more passive hip laxity than do other breeds.[70,71] Other breeds may develop radiographically detectable hip OA as

a result of antecedent CHD faster than others.[70] A major locus contributing to CHD has been implicated in German shepherds, golden retrievers, Labrador retrievers, Rottweilers, and greyhound-dysplastic Labrador retriever crosses based on statistical models.[55,72,73] Using Portuguese water dogs to identify the QTL that regulates CHD, two separate QTLs were found, both on chromosome 1 separated by about 95 Mb, one associated with the Norberg angle of each hip and contributing up to 16% of the phenotypic variance. A major locus is thought to contribute 20% of the phenotypic variance so that molecular genetic results and population genetics are currently at odds.[74] It is interesting

to note that any asymmetry in subluxation during extended hip radiographs was not heritable.[74] Alleles contributing to a complex trait such as CHD may be dominant or additive. The magnitude of their effect is independent of its mode of inheritance.[75]

Environment

Many nongenetic and/or environmental factors influence the development and severity of hip dysplasia in genetically predisposed dogs. Not one of these has been shown to cause CHD in dogs that do not have the genetic predisposition. Factors such as body size, growth rate, the season of

birth, nutrition, dietary anion gap, in utero endocrine influences, and muscle mass are considered to influence the development and clinical signs of CHD.[18,33] High caloric intake, excess protein intake, excess calcium intake, rapid growth rate, lack of or excessive exercise all result in increased severity of CHD.[18,37,54,55]

Maternal/Litter Effects

Hormones and growth-promoting peptides such as insulin, cortisol, epidermal growth factor, insulin-like growth factors (IGFs), parathyroid-hormone-related peptide, relaxin, estrogen, and estrogen precursors are present in canine colostrum and

milk.[76,77] These peptides, absorbed through the gastrointestinal tract particularly in the early postnatal period,[78] have the ability to influence the connective tissue metabolism, especially that of genetically susceptible tissues. Relaxin, estrogen, and estrogen precursors are abundant in the milk of Labrador retrievers.[31] Relaxin persists in the serum of dysplastic Labrador retriever bitches throughout lactation but is detectable for only the first 1 to 2 weeks of lactation in nondysplastic bitches. Relaxin is a potent inducer of neutral matrix metalloproteinase 1 (collagenase 1) and 3 (stromelysin 1) and plasminogen-activator expression. These activated enzymes degrade the

extracellular matrix and, therefore, affect the structure and metabolism of joint capsule and ligaments. Local relaxin activity on estrogen-primed tissues may contribute to the capsular and ligamentous laxity associated with CHD. The total serum estrogen is similar in pups born of dysplastic and normal matings, but testosterone was detected only in the milk of dysplastic Labrador retriever bitches, and estradiol-17β appeared only in the serum of pups born to dysplastic matings. Injection of an aromatase inhibitor (preventing the conversion of testosterone to 17β-estradiol) into pups from birth throughout lactation significantly reduced hip joint laxity at maturity in dysplastic-bred Labrador

retrievers.[79] Dosing estrogen repetitively during the growing period can induce CHD.[2,80]

The litter effect has been reported to contribute 4% of phenotype variation; this percentage includes all environmental and genetic effects common to members of same litter, but also contains the breed effect.[57] Therefore, it appears that the maternal effect is almost negligible (1.5%).[57,61]

Abundant food consumption shortens the time to first appearance and increases the severity of CHD.[34] Whereas overfeeding itself does not cause CHD, it does maximize trait expression in genetically susceptible

individuals. The frequency and severity of CHD and concomitant OA in affected hips were greatly reduced in Labrador retrievers by limiting food consumption to 25% of ad libitum-fed control litter mates.[81-83] Reduction of food resulted in a 67% reduction of CHD at 2 years of age 83 and substantially reduced the prevalence and severity of hip joint OA at 5 years of age.[82] The dogs on the restricted diet had significantly less OA in their hips, shoulders, and lumbar vertebrae when maintained on this diet.[81] One study showed that a dog's body mass at birth is an important factor in determining the age of onset of femoral head ossification as well as the laxity of the immature joint, with dogs of greater

body mass having reduced femoral head coverage.[38] The mechanism of operation of these nutritional effects remains unknown, but may be explained by mechanics (maximizing growth allows maximum load to be placed on genetically susceptible hips), or by the effect of nutritional components on local gene expression. Lower body weight (i.e., restricted feeding) delays onset and limits severity of radiographic signs of OA.[81-83] Perinatal nutrition can have long-term effects on metabolism. Bottle-feeding, compared with breast feeding, of puppies predisposed to CHD after caesarean section resulted in reduced growth rate and a low incidence of the trait. Ad libitum feeding of Great

Danes induced the expression of several unwanted orthopedic traits including CHD when compared with dogs on restricted feeding.[43] It has also been suggested that excessive exercise in dogs with much joint laxity is likely to cause or worsen CHD, but there is no scientific evidence to support this impression.[84]

Besides reduced food intake, systemic polysulfated glycosaminoglycan (Adequan) is the only treatment that has been shown to significantly reduce the expression of hip OA in CHD when administered to dysplasia-prone Labrador retrievers from 6 weeks to 8 months of age.[85] Polysulfated glycosaminoglycans are inhibitors of

neutral matrix metalloproteinase activity and also significantly reduce pubic symphyseal relaxation in estrogen-primed guinea pigs.[86]

Many large-scale studies have attempted to evaluate the environmental factors that affect the incidence of CHD expression. In one study of Rottweilers in Finland (n = 2764), the environmental effects influencing CHD were age (the older the dogs, the worse the condition), birth year (1998 best, 1995 worst), birth year x season interaction (season by itself was not a factor as in other studies,[45,59,61] and the experience of veterinarian radiographing the dog (but with no clear trend and small

differences between classes).[57] In a more recent study of British Labrador retrievers and gordon setters, the mean hip scores of dogs born between June and October were lower than those of dogs born during the rest of the year. These results are similar to those of Hanssen 1991 and Olerth et al 2001.[87] One hypothesis for this effect is that dogs born during the warmer season can exercise on soft ground, creating a supportive musculature and preventing HD.[88] Many other factors probably influence the results regarding season of birth. Body mass at birth was a significant predictor of age at onset of proximal capital ossification (the greater the mass, the earlier the onset) and of 4-month-old femoral head

subluxation (the greater the birth weight, the more reduced coverage in the dorsolateral subluxation position).[38]

Results of studies conflict when trying to determine whether gender influences the expression of CHD. Increased frequency in females,[1,62] males,[59] and equal sex distribution,[71,89] have all been reported. Therefore, it is unknown if the influence of sex is a direct expression of genes on the sex chromosomes or a result of the secondary effects of sex (hormones, weight).[62] The estrus cycle of a dog had no significant effect on hip laxity as measured by the distraction index.[90]

Diagnostics

Dogs with CHD present most commonly at two different ages: as pups at 5 to 9 months of age and as mature adults. Dogs as young as 16 weeks of age with hip joint laxity as measured by the distraction index are at risk for OA.[71] The most common findings on physical examination in young dogs with CHD are discomfort on extension or abduction of the hip and/or a positive Ortolani sign. In 6-month-old dogs, the angle of reduction is repeatable, suggesting that it may be used by multiple examiners with comparable and consistent results.[91] A positive Ortolani sign is thought to be a risk factor for development of OA

later in life, but the significance of its presence or absence has not been evaluated long-term.[49] As dogs age, those with subclinical lameness secondary to hip OA will compensate by shifting their weight between trotting pairs rather than within them.[92] As the pain of chronic OA increases, the effects are best judged by an owner or a person familiar with the dog after receiving training regarding the clinical signs of this disease.[93]

Prevention and Radiographs

Radiography is the most common tool used in the diagnosis of CHD, but it also has great utility in determining the likelihood the development of CHD

in pups. Several radiographic techniques have been researched extensively to determine their sensitivity and specificity in determining which dog will develop radiographic, clinical, or histopathologic evidence of CHD. The problem with all radiographic techniques is that a dog's phenotype is no guarantee of its genotype. Much of the information published is conflicting or not comparable owing to different study scenarios and end-points. We will give an overview of the different radiographic techniques and the indications for them.

Several radiographic signs have been reported to occur first in CHD. Femoral

head subluxation and a lag in the development of the acetabular rim seen as early as 2 to 9 months of age was reported in 1973,[37] and delayed ossification of the femoral head was reported to be the earliest radiographic predictor of CHD on a population basis.[13,15] Later OA changes secondary to CHD include subchondral sclerosis, osteophytosis, joint deformity, proliferative and lytic changes at attachments of joint capsule and supporting ligaments, and intra-articular bodies.[94-96] Radiographic OA can be apparent at 5 to 9 months of age, but some are not evident until at least 24 months of age or later.[51]

All of the available radiographic tests

are considered to be inaccurate at 4 months of age or earlier, most likely owing to ongoing endochondral ossification and the inherent difficulty of imaging cartilage with standard radiographic techniques.[9,11,15,97] Diagnostic methods are more accurate at 8 months of age or later;[9,11,15,97,98] once the hip joints are fully mature after the period of rapid growth is complete.[99] When evaluating any dog radiographically for CHD, one must keep in mind that not all dogs with radiographic subluxation develop radiographic evidence of OA by 2 years of age.[97]

Extended-Hip Radiograph

The extended-hip radiograph (EHR) is frequently used for CHD screening purposes.(Figure 104-3) It is performed with the dog in dorsal recumbency, usually heavily sedated. The femurs are pulled parallel to the table top and each other, and the knees extended and rotated such that the patellae are centered in the trochlear grooves. The Orthopedic Foundation for Animals (OFA, www.offa.org) uses this view to grade CHD. (The radiographic view allows determination of the presence of OA, its severity, and of certain degrees of subluxation. Using the EHR, evaluations earlier than 2 years of age are considered preliminary because younger widely affected dogs may not have evidence of subluxation when

radiographed in the extended position.[11,33] Findings suggest that the strength of the EHR at 8 months of age is its specificity.[98] It is commonly accepted that the OFA-type hip scoring method is the most specific (96%),[53] but it underestimates the susceptibility to CHD.[100] Smith et al (1995) found that the Norberg angle, obtained from EHR, is not a significant risk factor for subsequent radiographic hip OA.[71]

Ventrodorsal radiograph of the pelvis of a dog with hip OA secondary to hip dysplasia.

One finding on the EHR that has shown predictive value in later OA development is the caudolateral curvilinear osteophyte (CCO). First identified in 1961, it appears at the insertion of the joint capsule into the femoral neck.[101] The importance of its appearance has been questioned,[7,96,102-104] as it is often present without any other evidence of OA, and has prompted questioning of its use as an early sign indicating that

OA will develop later.[84] It must be differentiated from what has been termed the "puppy line," which resembles the CCO but is thought to be nonpathologic.[84] The puppy line is found in dogs up t oabout 18 months of age and either disappears or transforms into a CCO.[105] No statistical relationship exists between the puppy line and later development of OA. The original hypothesis was that the CCO develops secondary to increases in stress on the joint capsule insertion in dogs with excessive laxity.[96] Other studies have shown that, in Labrador retrievers, a relationship exists between the CCO and subsequent OA development. Dogs with a CCO are 3.7 times more likely to develop

radiographically evident OA than are those without a CCO.[105] The CCO was the first radiographic sign in 76% of dogs that later developed radiographic OA and 95% of dogs with histopathologic OA had a CCO.[105] Another study showed that dogs with a CCO are 7.9 times more likely to have radiographic OA than are those without a CCO. The animal's distraction index, weight, and age are significant risk factors for the CCO,[84] but this contemporaneous relationship does not predict ultimate OA development. When evaluating the CCO in relation to feeding group (ad libitum contol group or restricted-fed group), it was found that 100% of control dogs with a CCO and 55% of

restricted-fed dogs with a CCO developed later radiographic OA.[105] Regardless of the feeding group, dogs with a puppy line were not more likely to develop OA or a CCO compared with dogs without a puppy line. Diet did not influence the frequency of the CCO, only the time of onset of CCO. This may suggest that the CCO is a more sensitive radiographic marker for susceptibility for OA that is not confounded by environmental factors such as restricted feeding.[105]

Distraction Index (PennHip) and Dorsolateral Subluxation Score

The distraction index (DI) (Figure 104-4A) and the dorsolateral subluxation score (DLS) (Figure 104-4B) assess the laxity of the hip joint. The DI is also measured in dorsal recumbency. For the DI radiograph, the hips are flexed so that the patellae point to the ceiling. A custom-made levering device is placed over the coxofemoral joints between the femurs and an inward force is applied to the stifles to determine the amount of laxity present in the hip joint. The DI is calculated between these views and is used to predict the likelihood of the development of CHD. Individual logistic regression curves can be established for each breed to relate DI to the presence of hip OA secondary to

CHD. The operator must have received special training to perform this technique and submit the radiographs for evaluation. However, this ensures a complete unbiased registry. Additionally, the DI can be artificially increased by increasing intra-articular volume, as well as cavitation, without affecting DLS score.[17,106] The DLS view is also performed under heavy sedation or general anesthesia. The animal is placed in sternal recumbency on a pad with a cutout for the rear legs, such that the knees are flexed and weight-bearing. The radiograph is centered over the hip joints and shows the conformation of the hip joints as the animal bears weight. The advantages of the DLS are that it is easy to

perform, requires only one radiograph, can be done with the animal anesthetized or sedated, and does not require the operator to hold the dog during radiography. The method and measurements are reproducible.[49] External factors such as dorsal hip loading and whether the test is performed under general anesthesia or heavy sedation do not have marked clinical effects on the DLS score, although loading the hips does increase the DLS score in some cross-breeds.[107] The 6% change between loaded and unloaded DLS scores overall is statistically significant but is unlikely to be clinically significant.[107] The DLS score is an objective measurement of coxofemoral subluxation, whereas the

OFA score is subjective.

The DI and DLS scores are associated, but likely represent distinct features of hip joint structure and evaluate different components of joint stability.[17] Several studies have suggested that both the DI and DLS scores remain constant after 8 months of age.[9,18,98] In a mature hip, the laxity (DI) can change independently of the DLS score.[17] The use of either the DI or the DLS score improves the detection of subtle cases of CHD compared to the EHR. The specificity of the DLS score for prediction of hip OA at 8 months of age is similar (84%, DLS score $<$ 55%) to the DI (89%, DI $>$ 0.7) in dysplastic Labrador retrievers, greyhounds, and

their cross-bred offspring.[73] The sensitivity appears to be better for the DLS score than the DI: depending on the cut-off used for the DI ($>$ 0.7) and the DLS score ($<$ 55%), the former had a sensitivity of 50% and the latter a sensitivity of 83%. At 8 months of age, dogs with DLS scores less than 42% suffered from hip OA at early maturity, whereas those with DLS scores over 55% were highly likely to have normal hips. We have argued that the DLS score represents a component of hip joint conformation independent of passive laxity, yet both are important to subsequent OA development.[49,108]

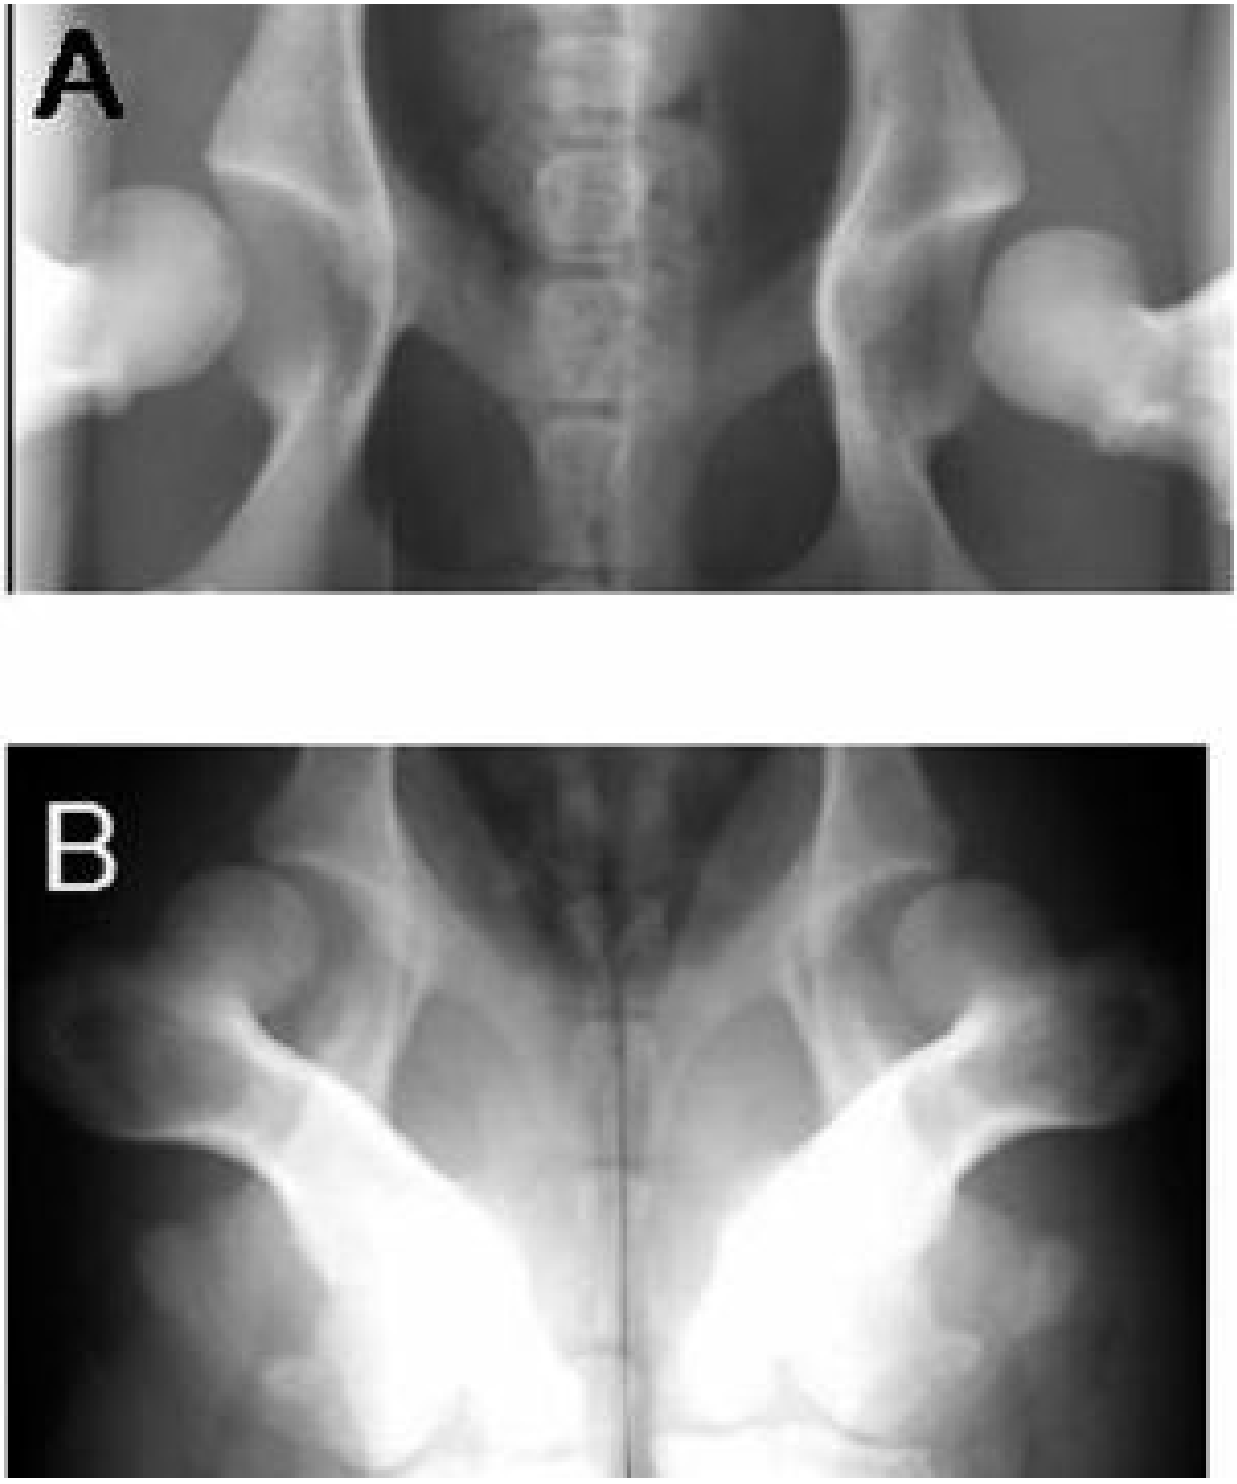

Figure 104-4. A. Ventrodorsal radiograph of the pelvis of a dog in the distraction (PennHip) position. B. Dorsoventral radiograph of the pelvis of a dog in the dorsolateral subluxation position. Both of these dogs have hip laxity, and the dog in 4B has hip

dysplasia and subluxation.

Several studies have compared a multitude of radiographic techniques with different endpoints – radiographic evidence of OA, gross necropsy findings, and histopathologic OA. One such study compared the EHR, DI, and DLS in 8-month-old dogs and used gross necropsy findings as the endpoint. All radiographic findings were significantly correlated with the gross findings. Specificities were similar for all 3 methods, but the DLS score had higher sensitivity and, therefore, fewer false negatives.[96] Another more recent study also compared the radiographic findings in 8-month-old dogs with gross necropsy

findings. Specifically evaluated were the EHR, DI, DLS score, and the Norberg angle (NA). The DLS score and the NA together were best at determining normal joints versus joints with OA, and all models excluding the DLS score were worse than those that included it. The conclusion of this study suggested that two tests were better than one, especially if one was the DLS score, with no improvement if a third test was added for detection of CHD.[109]

Treatment and Prognosis

Two different treatment options are commonly recommended for CHD: medical management and surgical management. Surgical management

consists of juvenile pubic symphysiodesis, triple pelvic osteotomy, excision arthroplasty, and total hip replacement. These are discussed elsewhere. Medical management is multifaceted and consists of preventative measures early in the animal's life and treatment to ameliorate the progression and clinical signs of OA later in life.

The two main preventative measures that can be taken in a dog genetically predisposed to CHD are the administration of systemic polysulfated glycosaminoglycans (PSGAG) and limiting the food intake. Administration of systemic PSGAG at 5 mg/kg during growth can significantly

ameliorate progression of CHD and secondary OA in susceptible dogs.[85] In dogs with severe OA secondary to CHD, there was no statistically significant difference between the treatment groups with PSGAG at 3 increasing doses or the placebo. The authors attributed this either to a lack of response or a response too small to be detected by the physical examination used to determine effectiveness.[110] PSGAG have chondroprotective effects when used prophylactically or therapeutically.[111-118] Polysulfated glycosaminoglycan (Adequan®) is derived from bovine lung and tracheal tissue, which is structurally similar to the glycosaminoglycans found in hyaline

cartilage.[119,120] In vitro, PSGAG can inhibit the rate of collagen and glycosaminoglycan degradation.[121-123] Other in vitro studies suggest that PSGAG treatment may modify the progression of OA in articular cartilage by maintaining chondrocyte viability as well as protecting against extracellular matrix degradation.[124] Similar serum and joint concentrations of PSGAG are achieved after intramuscular and intra-articular administration.[125]

Another method of decreasing the severity of CHD is by limiting food consumption starting at 8 weeks of age. Reduction of food intake by 25% compared with ad libitum-fed controls

resulted in a 67% reduction of CHD at 2 years of age 83 and substantially reduced the prevalence and severity of hip-joint OA at 5 years of age.[82] Osteoarthritis also affected multiple joints significantly less commonly in limit-fed dogs.[81] Once a dog is suffering from CHD-induced OA, several recommendations to the owner are suggested: weight reduction to the breed's ideal bodyweight if the animal is overweight; moderate exercise, which increases the supporting muscle mass of the hip joints; and the addition of nonsteroidal anti-inflammatory medications if they can be tolerated by the animal. The addition of a supplement containing glucosamine and chondroitin sulfate or injection of

PSGAG is also recommended, especially in younger dogs.

Rigorous application of any detection method for CHD combined with progeny testing seems to be as important as the method of hip evaluation itself in reduction of trait incidence. Simply breeding animals with better hips than the average for the breed will not eliminate the trait.[65] Until genetic screening is available, the best indication of a dog's genetic makeup is the phenotype of its parents and grandparents, its offspring, and its siblings and half siblings. Prospective purchasers of puppies should request from breeders phenotypic information on the puppies' relatives. In the end,

the best solution to eliminating the trait from a breed is to know the linked genetic markers and ultimately the mutations at the major contributing loci in that breed. That could lead to genetic screening of pups before purchase and breeding and informed decisions regarding breeding programs.

Chapter 105

Cranial Cruciate Ligament and Meniscal Injuries in Dogs

Kei Hayashi
Jennifer L. Lansdowne
Loïc Déjardin

Cranial cruciate ligament (CCL) rupture is one of the most common causes of lameness in adult dogs. The CCL plays a crucial role in limb function by maintaining stability of the stifle joint throughout the range of motion, thus injury to the CCL will

result in joint instability and predispose the joint to degenerative changes. In dogs, the majority of CCL ruptures occurs under normal activity, likely owing to structural deterioration of the ligament and not because of a traumatic injury. Rupture of the CCL owing to degeneration can manifest acutely even in young dogs and eventually is often bilateral. Osteoarthritis, meniscal injury, and persistent lameness commonly occur with CCL rupture. Therefore, the debilitating pathologic condition related to CCL rupture is often referred to as “cruciate disease.” Cranial cruciate ligament rupture is particularly common in large and giant breed dogs; however, any breed,

size, or age of dog may be affected. Although clinical features and treatment options have been well discussed in the veterinary literature, the disease mechanisms for CCL rupture are poorly understood.

Cranial Cruciate Ligament

Anatomy

The cranial cruciate ligament is a dynamic structure and its anatomy and spatial arrangement are directly related to its function as a constraint of joint motion.[1] The CCL attaches proximally to the caudomedial part of the lateral condyle of the femur, within the intercondylar fossa of the femur, and courses cranially, medially, and

distally across the joint as it passes from femur to tibia, and turns on itself in an outward lateral spiral of approximately 90° (Figure 105-1). The CCL extends distally to attach to the cranial intercondylar area of the tibia, beneath the transverse intermeniscal ligament. The caudal cruciate ligament crosses the CCL medially in the middle of the joint. The CCL fans out proximally and distally at its attachments and is narrowest in the middle.[2]

The cranial cruciate ligament is a collection of parallel and twisted collagenous bundles, or fascicles (Figure 105-1). These fascicles have been divided into two groups: the

relatively thin craniomedial band that is rotated into an outward spiral (craniomedial spiral), and the caudolateral band that forms the bulk of the CCL (caudolateral bulk) (Figure 105-1). The craniomedial band arises more proximally in the intercondylar fossa of the femur and inserts more cranially in the cranial intercondylar area of the tibia.[1,2] The caudolateral band is shorter and straighter.

When the stifle is extended, both craniomedial and caudolateral bands are tight, and when the stifle is flexed, the craniomedial band is tight and caudolateral band is relatively lax. However, the CCL is actually a continuum of collagenous fascicles,

and a different portion of the CCL is taut throughout the range of motion; therefore, this grouping scheme may oversimplify the structure and function of the CCL.[1]

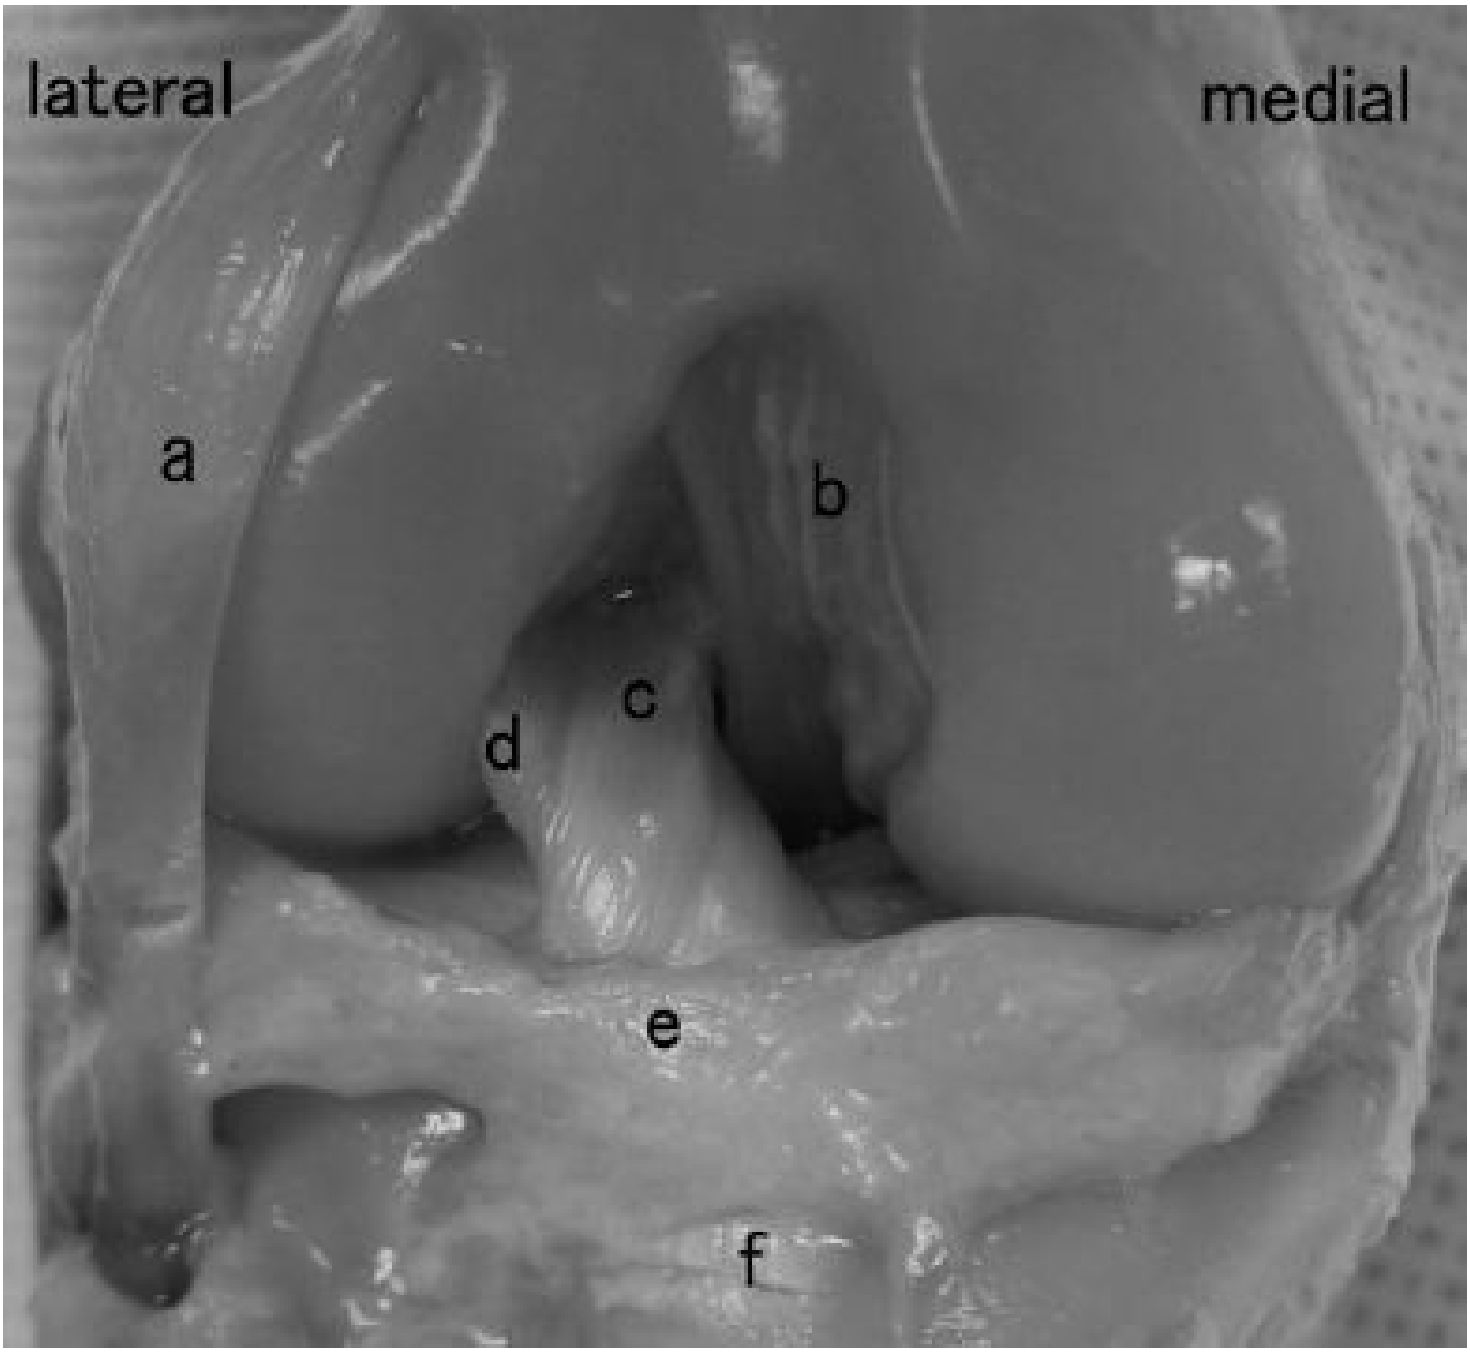

Figure 105-1. Normal anatomy of the canine stifle in flexion. A. long digital extensor tendon, B..caudal cruciate ligament, C. craniomedial band of CCL, D. caudolateral band of CCL, E. intermeniscal transverse ligament, F. distal part of tibial attachment of CCL.

Mechanics

Stifle mechanics are governed by muscular force and constrained by ligaments and joint capsule as well as by the geometry of the menisci and condyles.[1] The stifle is classified as a hinge joint with a combined motion primarily in two planes. Flexion and extension take place about the transverse axis, whereas rotary movement of the tibia on the femur occurs about the longitudinal axis. Slight craniocaudal and mediolateral

movements also occur. The rotary motion is controlled by the condylar geometry and ligamentous constraints; internal rotation of the tibia is mainly limited by the anatomic relationship of cranial and caudal cruciate ligaments. The primary function of the CCL is to prevent cranial displacement of the tibia on the femur (cranial drawer), internal rotation of the tibia, and hyperextension of the stifle. Because the craniomedial band of the CCL is taut in both flexion and extension, it provides the primary check against cranial drawer motion, and because the entire CCL is taut in extension, it serves as the primary check against hyperextension of the stifle.[1] Together the cranial and caudal cruciate

ligaments are responsible for craniocaudal stability of the stifle; the CCL prevents cranial drawer motion, and the caudal cruciate ligament prevents caudal displacement of the tibia on the femur (caudal drawer motion).

It has been suggested that the cranial cruciate ligament also functions to resist a force called “cranial tibial thrust”.[3] Cranial tibial thrust is hypothesized to occur during weight bearing by compression of the femoral condyles against the tibial plateau. The magnitude of cranial tibial thrust is dependent on both the degree of compression during weight bearing and the slope of the tibial plateau. The

amount of tibial compression is variable and depends on the size, muscular force, and activity level of the dog. The tibial plateau slopes caudodistally and varies among dogs owing to anatomic and conformational differences. The CCL, together with the caudal horn of the medial meniscus and flexor muscle groups of the stifle, balances this force, preventing cranial translation of the tibia.

Histology

The cranial cruciate ligament is a complex structure consisting of an extracellular matrix and a diverse population of cells. The CCL has two histologically distinct regions: an

epiligamentous region, composed of cellular synovial intima and loose connective tissue, and a core region, which is the major axial tissue component composed of collagen fiber bundles.[4,5] The collagen fibers are primarily composed of type I collagen and a smaller amount of type III collagen. Bundles of collagen fibers are longitudinally oriented, mostly running parallel to one another. Normal CCL collagen fibers have a recurrent undulating wave or crimped structure. During tensile loading of the ligament's collagen fibers, the crimp is lost before the fiber ruptures. Crimping is a distinct structural feature of organized collagen fibers in dense connective tissue and is an important

determinant of the biomechanical properties of the tissue. From a biomechanical standpoint, the loss of crimping reflects the viscoelastic properties of the cruciate ligament and corresponds to the “toe region” on a load/deformation curve.

The predominant cell type in the CCL is the fibroblast. Ligament fibroblasts are arranged in long parallel rows between collagenous fiber bundles. Three different types of fibroblasts have been described: fusiform or spindle-shaped, ovoid, and spheroid.[5] The cytoplasm of fusiform fibroblasts is intimately attached to the extracellular collagen and follows the crimped waveform of the fibers. Ovoid and

spheroid fibroblasts are situated in the loose connective tissue between collagen fibers. It is currently unclear whether these cells represent differing metabolic states of the same cells or whether they are distinctly different fibroblasts.

The CCL has a relatively tenuous microvasculature, which arises predominantly from the infrapatellar fat pad and periligamentous tissue, as opposed to the proximal and distal attachment sites.[1] The CCL receives its blood supply from branches of the middle genicular artery, which forms a vascular synovial envelope around the ligament. The innervation of the CCL regulates vasomotor tone and

proprioception. The greatest density of mechanoreceptors is found in the proximal region of the CCL. These may function to send impulses during flexion/extension and rotation. The role of these receptors in proprioception is unknown.

Histopathology

The cranial cruciate ligament appears to experience chronic and irreversible degeneration with aging.[4] Idiopathic degeneration is a common histologic finding of the intact CCL, despite its grossly normal appearance. Degenerative changes are generally characterized by a decreased number of normal ligament fibroblasts,

chondroid metaplasia of ligament fibroblasts, and loss of the normal fibrous architecture of the extracellular matrix.[4,5] These changes result in a partial transformation of ligamentous tissue into fibrocartilage (Figure 105-2). More severe changes such as hyalinization, mineralization, and cloning of chondrocyte-like cells can also occur; however, inflammatory or reparative responses are not observed. The degenerative changes can occur at a young age, particularly in large dogs, and progresses with aging. The severity of changes is usually similar in both stifle joints and affects the mechanical properties of the CCL.

The interior “core region” of the CCL

deteriorates earlier than the surface epiligamentous region, and the midportion of the CCL deteriorates earlier than areas close to bony attachments.[4] These findings may be related to the hypovascularity and ischemic environment of the core region of CCL. Histopathologic changes of CCL degeneration are more prominent in larger dogs weighing more than 15 kg; the onset of the degenerative changes occurs at an earlier age in these large dogs. Increasing body size may also exacerbate the rate and severity of the degenerative process.

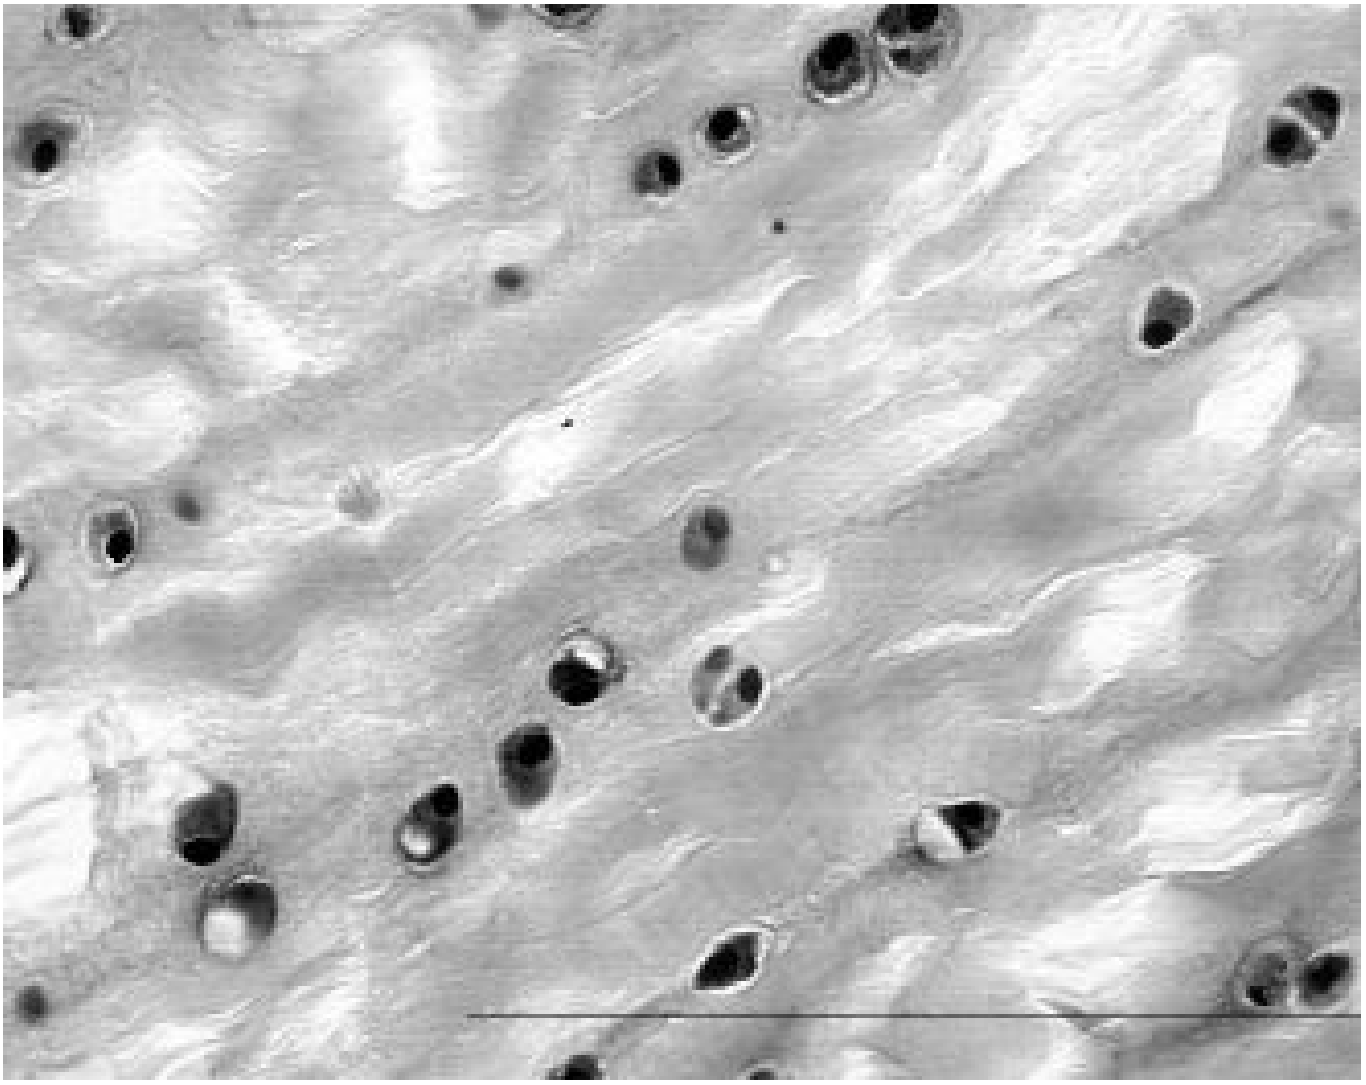

Figure 105-2. Histology of ruptured CCL demonstrating loss of fibrous structure and decreased number of ligament fibroblast with chondroid metaplasia. Note the cloning of chondrocyte-like cells (center and top right corner) - (bar = 100 μm).

Pathogenesis and Epidemiology of CCL Rupture

Exact causes and disease mechanisms of CCL ruptures are undefined and remain controversial; therefore, cruciate disease has been referred to as the "enigma of the canine stifle."[1] Although acute CCL rupture does occur with trauma, it is generally accepted that the majority of CCL lesions are the result of chronic degenerative changes in the ligaments themselves. Rupture of the CCL associated with major traumatic injury is usually unilateral and often involves multiple ligamentous injuries of the stifle and can lead to joint luxation. Isolated traumatic injury to the CCL is rare in dogs, is seen most often in puppies, and typically is associated with avulsion of the ligament at the tibial

attachment site distally. In contrast, most pathologic cranial cruciate ligament ruptures are bilateral, midsubstance, incomplete or complete tears. Evidence is conflicting as to whether the degenerative changes seen in CCL are primary or secondary or a combination of multiple factors. Several risk factors have been proposed for CCL rupture; **Table 105-1** summarizes the findings of recent epidemiologic studies.[6-10] Rupture of the CCL has significant association with breed, body weight, and neutering. Other factors, such as aging, gender, conformational variation, medial patellar luxation, inactivity, and obesity have also been associated with CCL rupture. Although the effect

of the tibial plateau angle (TPA) on cruciate ligament stresses has been recognized in people, the effect of TPA on CCL rupture in dogs has yet to be established. The risk of CCL rupture is higher in certain breeds, such as the Rottweiler, Labrador and Chesapeake Bay retrievers, Newfoundland, Akita, Neapolitan mastiff, Saint Bernard, and Staffordshire bull terrier. Dog phenotype may have a significant effect on the structural properties of the CCL, as the CCL of certain breeds (e.g., Rottweiler) appears more vulnerable to mechanical overload. Material properties of the CCL from Rottweilers are inferior to those of rarely affected breed dogs (greyhounds), although craniocaudal

laxity is similar in both breeds throughout the range of motion. Commonly affected breeds tend to have abnormal posture such as straight stifle, genu varum (bow-leg), or genu valgum (knock-knee). Larger dogs weighing more than 22 kg are at greater risk of cruciate disease and tend to develop CCL rupture at younger ages. It remains unclear whether obesity is a risk factor for the disease independent of the dog's size. Neutering also increases the risk for cruciate rupture, particularly in female dogs, although the cause of this effect is not understood. The effect of hormonal status and endocrinopathy on CCL weakness and rupture are being investigated. The prevalence of

CCL rupture increases with age and reaches a peak incidence at around 7 years.

The mechanism of traumatic CCL rupture can be related to its function as a constraint for joint motion. As stated above, the CCL serves to prevent cranial displacement of the tibia on the femur, to limit internal rotation of the tibia on the femur, and to prevent hyperextension of the stifle. Excessive forces during extremes of these motions can result in damage to the CCL. Common mechanisms of CCL injuries include sudden rotation of the stifle with the joint in 20° to 50° of the flexion, which can occur when the dog makes a sudden outward turn on the

weight bearing limb, and hyperextension of the stifle, which can occur when a dog steps into a hole while running. Direct trauma to the stifle in any direction may cause damage to the CCL as well as to other joint structures.

Chronic degeneration and progressive weakening of the CCL appear to make it more susceptible to damage from minimal trauma, thereby predisposing the CCL to rupture. Despite extensive efforts in epidemiologic and clinical investigation, instigating causes of CCL degeneration and structural deterioration are not fully understood. Aging, hypovascularity of the CCL, abnormal conformation of the stifle,

immune-mediated joint disease, and inflammatory joint disease have been proposed as contributing causes of CCL degeneration and rupture.[11-13] The degenerative changes in cellular and matrix components that develop in a ruptured CCL may result from the effects of remodeling and adaptation to various factors, such as ischemia, mechanical loading, and ligament microinjury.

Idiopathic degeneration of the CCL appears to begin within the central core portion and may be related to the ischemic nature of the tissue, complex mechanical environment (tension, compression, and shear) within the CCL, or both.

In degenerate ligament, the numbers of typical fibroblasts (i.e., fusiform and ovoid cells) are decreased, and the numbers of cells exhibiting chondroid transformation (i.e., spheroid cells) are increased.[5] These cellular changes are associated with extensive disruption of the ligamentous matrix, transforming the ligament into cartilage-like structure. This type of tissue transformation is often attributed to altered oxygenation status and mechanical environment. Inadequate blood supply of the central region of the CCL may be exacerbated by the twisting of the cruciate ligaments on themselves during flexion. This, in turn, may reduce blood flow and may account for the CCL transformation.

For ligament fibroblasts to persist under increasingly ischemic conditions, these cells may be undergoing metaplasia to form chondrocytes, which can survive by using anaerobic metabolic pathway. The complex mechanical environment within the CCL, which includes compression and shear, as opposed to simple tension, can also contribute to the tissue transformation. Cartilage-like tissue is more vulnerable to disruption under normal tensile forces; therefore, the degeneration with fibrocartilaginous transformation may predispose CCL to pathologic rupture. However, areas of fibrocartilage are observed in grossly normal CCL in rarely affected breeds (greyhounds), which may represent

successful physiologic adaptation to ischemic environment.[11] It is currently unclear whether CCL degeneration and transformation into fibrocartilage constitute a pathognomonic condition causing CCL rupture.

Conformational variation such as straight stifle, narrow intercondylar notch, steep tibial plateau slope, MPL, valgus and varus deformities of the stifle, and repeated stress and microinjury can result in progressive degenerative joint disease and CCL rupture. These changes are frequently bilateral and have been referred to as "postural arthrosis." Postural abnormalities may also be a result of other orthopedic conditions. Straight

stifle and narrow intercondylar notch, together with excessive rotation of the tibia and extension of the stifle, may cause constant impingement and abnormal compression of CCL against the cranial aspect of the intercondylar notch. Medial patellar luxation, genu varum, and excessive internal rotation of the tibia, or a steep tibial plateau slope may cause increased stress, micro injury, and degeneration of the CCL. These conformational variations and abnormalities may predispose the CCL to rupture. Although anatomic differences in the shape of the proximal tibia have been documented in dogs with cruciate disease, their role in cruciate disease is unclear because many dogs with a steep tibial plateau

angle do not develop cruciate disease. Indeed, although the mean TPA in dogs varies between 23° and 25°, a wide range of TPA has been reported (13° to 34°) in normal dogs. Furthermore, because the functional TPA is approximately parallel to the ground in most dogs, the true effect of TPA on CCL stresses in vivo is unknown. Finally, although the correlation between CCL rupture and pathologic increases in TPA (> 55°), possibly secondary to gross plate injuries, seems established, the association between TPA and CCL rupture in a normal canine population remains controversial. Muscular force, body size, obesity, rapid weight gain, relative inactivity, and exercise can

also modify the amount of stress sustained by the CCL. The beneficial effect of activity on ligament strength in dogs is well documented, although the roles of activity and inactivity in CCL rupture are not well understood.

Table 105-1. Epidemiologic and Clinical Features of CCL Rupture

Benett et al (1988), UK[6]

50% < 4 years old (mean 1.8 years)

Mostly large dogs (mean body weight 34.1kg), 25% Rottweiler

42% female, 18% spayed female, 38% male, 2% neutered male

53% sudden onset, 47% gradual

onset

31% bilateral

50% > 4 years old (mean 6.8 years)

years)

30% bilateral vs. 27% bilateral

15% meniscal tear vs. 48% meniscal tear

Jerram and Walker (2003), New Zealand[10]

Proposed grouping of dogs based on clinical observation

Small dogs with medial patellar luxation

Large to medium-sized active dogs with trauma (hyperextension or excessive internal rotation)

Young large dogs with conformational abnormalities (impingement of CCL owing to

	hyperextended stifle and narrow intercondylar notch, increased strain on CCL owing to steep tibial plateau slope)
Middle-aged, medium to large dogs with chronic inflammatory joint disease	

Inflammatory disease may be involved in the initiation of CCL rupture.[13,14] Cruciate disease in dogs is often associated with infiltration of leukocytes into the synovial membrane of the stifle joint and the development of inflammatory changes in the synovial fluid. Anti-collagen antibodies, immune complex, and rheumatoid factors have been

identified in synovial fluid of the joint with CCL rupture; therefore, involvement of immune-mediated disease has been proposed as a cause of CCL degeneration. However, anti-collagen antibodies are not likely the major factor of CCL degeneration and rupture, because the increase of anti-collagen antibodies is not specific for the type of joint disorder. More recently, collagenolytic enzyme expression has been found in the ruptured CCL and synovial fluid, and synovial macrophage-like cells that produce matrix-degrading enzymes have been identified. These findings suggest that inflammatory arthropathy predisposes the CCL to rupture, by release of proteolytic enzymes during

inflammatory process. Release of collagenolytic proteases from the synovium into the stifle synovial fluid can significantly degrade the structural properties of the CCL and increase the likelihood of a pathologic midsubstance rupture. However, these inflammatory changes could be a secondary phenomenon, in response to the tissue damage during CCL rupture and osteoarthritis.

Genetic and breed predisposition have recently been implicated in the pathogenesis of CCL rupture.[15,16] Early studies suggest that 1) collagen turnover may be increased in dogs predisposed to CCL rupture (Labrador retrievers) compared with dogs not

predisposed to CCL rupture (greyhounds); 2) collagen fibril of greyhounds are larger than those of Labrador retrievers; and 3) craniocaudal joint laxity is greater in Labrador retrievers compared with greyhounds. Whether cranial cruciate ligament weakness could be part of generalized collagen abnormality remains uncertain because weakness in other ligaments and joints is not commonly seen in dogs with CCL rupture. These differences may be influenced by genetics and may account for the differential predisposition of the two breeds to CCL rupture. Further studies have revealed the high incidence of CCL rupture in Newfoundlands (22%) and suggested

that CCL rupture has a potential recessive mode of inheritance with 51% penetrance in a population of Newfoundlands. A genetic association was also determined between CCL rupture status and a large number of statistically significant microsatellite markers on canine chromosomes 3, 10 and 23 in this population.

Cruciate Ligament Pathology

Pathology of CCL disease appears to involve a gradual degeneration of the CCL itself, inflammatory disease in the stifle joint, partial rupture, progressive rupturing, complete rupture, and secondary disease such as progressive osteoarthritis and meniscal injury.

Partial ruptures can occur at any part of the CCL, although it has been suggested that the relatively thinner craniomedial band of the CCL is more susceptible to rupture. Complete ruptures appear to occur near the tibial attachment, although location of the rupture is often indeterminable.

An initial pathology with slight weakening or stretching of the CCL may not cause lameness, but can produce mild instability within the joint and, therefore, initiate the osteoarthritis process. Dogs with early cruciate disease (i.e., minor partial CCL rupture) may have little or no palpable instability, but they are often presented with lameness, effusion of

the stifle joint, and mild osteoarthritis. Major partial or complete CCL ruptures produce marked instability of the stifle joint, resulting in pain, lameness, and progressive degenerative changes within the joint. Clinical observations have demonstrated that these changes consist of periarticular osteophyte formation, capsular thickening, and meniscal degeneration. As these changes progress, the joints become less unstable. Advanced or end-stage cruciate disease may have little palpable stifle instability because of extensive periarticular fibrosis.

After a partial or complete CCL rupture, some degree of tissue repair

responses arise in the periligamentous region of the ligament. Distinct phases of tissue repair, including an inflammatory phase, a periligamentous repair phase, a proliferative phase, and a remodeling phase, occur after rupture of the anterior cruciate ligament in humans. Whether similar phases exist in dogs is unknown. Expansion of the volume of the periligamentous tissue does occur in the dog during a repair phase that lasts many weeks; however, a bridging scar does not form in the rupture site. Eventually, synovial tissue covers the ruptured ends of the CCL. The extracellular matrix of ruptured CCL has an increased turnover indicated by increased collagen and

glycosaminoglycan synthesis, and increased levels of proteolytic enzymes. This response may represent a degrading and remodeling phase of the CCL after rupture.

Rupture of the CCL causes various degrees of inflammation in the stifle. The inflammatory changes within synovium are variable even within the same joint. Plasma cells, lymphocytes, and macrophages are commonly seen in the synovium, although the infiltrate is not noticeable in some cases. Although partial CCL rupture has been associated with moderate synovial fluid inflammatory changes, synovial fluid analysis in dogs with CCL rupture generally shows a non-inflammatory

process. This suggests that CCL rupture is a progressive condition with an early inflammatory component. Several studies have investigated osteoarthritic parameters associated with CCL rupture.[17] Proinflammatory factors, cytokines, nitric oxide, degradation products of matrix, epitopes of cartilage matrix, and degrading enzymes have been shown to increase with osteoarthritis in the stifle with CCL rupture; however, no specific marker for CCL rupture is known.

Meniscal Injury

Pathophysiology

Primary lesions of the meniscus are

rare in dogs, however meniscal injuries secondary to rupture of the cruciate or collateral ligaments are common. Most frequently the medial meniscus is affected following cranial cruciate ligament rupture. Damage to the menisci can be either acute or degenerative and usually involves the caudal and medial portions of the medial meniscus.[18] A general understanding of the anatomy and biomechanics of the menisci is important in understanding the pathophysiology of injury.

Anatomy

Each stifle contains a medial and lateral meniscus, which are C-shaped

fibrocartilaginous disks interposed between the articulating surfaces of the femur and tibia. In cross section, menisci are wedge shaped with a thin, concave central edge and a thick periphery. The lateral meniscus forms a slightly greater arc and is more concave than the medial meniscus, corresponding to the articular surfaces of the femur and tibia. The menisci are anchored to the tibia and femur via five meniscal ligaments and to each other by the intermeniscal ligament (Figure 105-3). The lateral and medial menisci are each firmly anchored to the tibia by a cranial and caudal meniscotibial ligament. The caudal horn of the lateral meniscus is also attached to the lateral aspect of the

medial femoral condyle by the meniscofemoral ligament. The medial meniscus is not directly linked to the femur, however. Because of extensive fibrous attachments to the joint capsule and medial collateral ligament, it is intimately attached to the tibia. In contrast, the lateral meniscus is more mobile in part because of the popliteal hiatus (imprint of the popliteal tendon and bursa on the lateral edge of the lateral meniscus) and subsequent lack of peripheral connection with the lateral joint capsule and/or collateral ligament. The intermeniscal ligament lies just cranial to the tibial attachment of the cranial cruciate ligament and joins together the cranial portions of the lateral and medial meniscus.[19,20]

The meniscus is a fibrocartilage that is composed of 60 to 70% water. Collagen accounts for 60 to 70% of the dry weight (15-25% wet weight), with type I collagen predominating (> 90%). Type II collagen, proteoglycans, matrix glycoproteins and small amounts of elastin make up the rest of the dry weight.[21] The articulating surface of the meniscus is composed of fine fibrils arranged in a random mesh-like woven matrix. This random distribution is effective against shear stresses. Immediately below the meniscal surface, large collagen fiber bundles are arranged circumferentially, which optimizes meniscal resistance against hoop stresses. Finally, smaller radially

oriented fibers are found throughout the meniscal tissue, tying the large circumferential bundles together. This fibrillar orientation provides the structure to the meniscus and predominates throughout the peripheral two thirds of the tissue. In contrast, the inner third of the region resembles hyaline cartilage in that it contains smaller collagen fibers arranged in a more random pattern.[22] Unlike the meniscal body, which is relatively avascular, the meniscal horns have an abundant blood supply, which arises from branches of the medial and lateral genicular arteries. Further branching supplies the joint capsule, which provides vessels to the periphery of the meniscus. However,

vessels penetrate the menisci for only 10 to 25% of their width, the remainder of the meniscus being totally avascular.[21,23] The clinical relevance of this vascular distribution has lead to the recognition of three zones with decreasing healing potential, namely - from the periphery to the center - the red, red-white, and white zones.[23] Owing to the meager blood supply, meniscal injuries occurring axial to the peripheral rim rarely heal. In addition, a layer of vascular synovial tissue, apparently continuous with the sheath that surrounds the cranial cruciate ligament, covers the cranial and caudal horn attachments of both menisci. The caudolateral portion of the lateral

meniscus, adjacent to the popliteal tendon and the inner aspects of both menisci, lacks vessels and relies on diffusion of synovial fluid for nutrition. The innervation of the menisci follows the vascularization pattern, with the meniscal horns being more richly innervated with mechanoreceptors and free nerve endings than the body of the menisci.

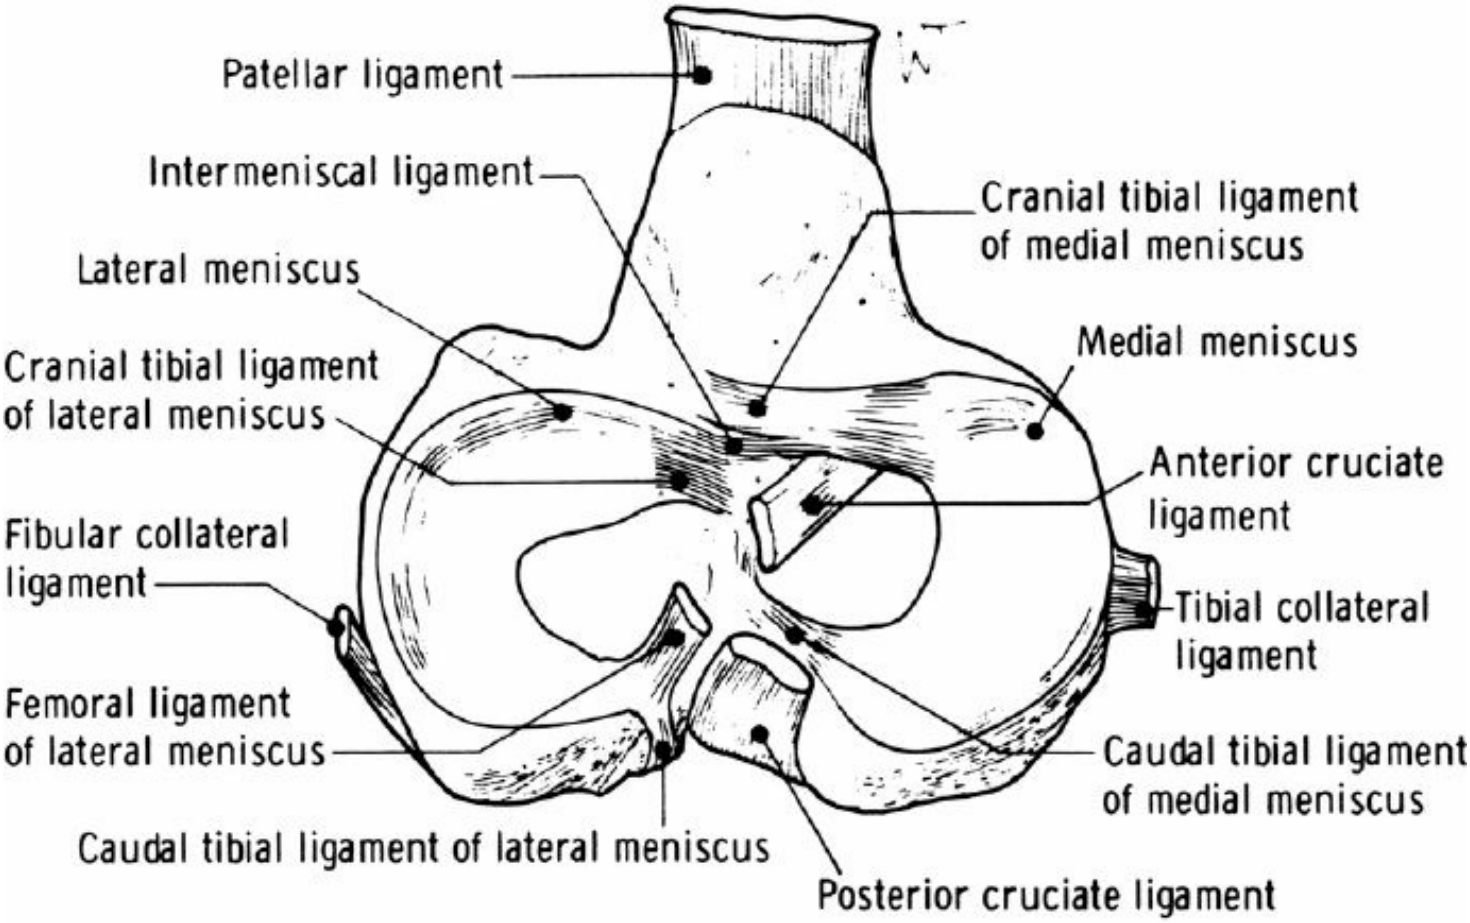

Figure 105-3. Drawing of the dorsal aspect of the tibia showing the menisci and their attachments.

Function

The menisci are thought to participate in four main functions: namely shock absorption, joint stability, sensation, and hydrostatic lubrication.[19,20] The menisci distribute approximately 65%

of the joint force through load transmission (shock absorption). The circumferential arrangement of the collagen fibers and the strong ligamentous attachments of the menisci help convert compressive loads across the joint into hoop stresses, thus absorbing most of the energy generated during weight bearing. The viscoelastic behavior of the meniscal tissue further contributes to the shock absorption function of the menisci, thereby sparing the articular cartilage of the tibia and femur from excessive stresses. The menisci also act as elastic movable washers and contribute to joint stability by improving congruity between the femur and tibia. Because of their firm attachment to the tibia

and/or femur, the menisci further contribute to limiting the relative motion of the femur with regard to the tibia. The sensory function of the meniscus is achieved via an abundant nerve supply to its periphery. In addition, because mechanoreceptors located in the cranial and caudal horns can detect pressure changes within the joint, it is believed that the menisci can receive and transmit proprioceptive information. Additionally, due to a feedback mechanism to myotactic receptors, the menisci allow specific muscle actions to occur in response to acute changes in intra-articular stresses, which in turn contribute to the protection of intra-articular structures during extreme range of motion. The

menisci are also thought to provide hydrostatic lubrication of the articular cartilage. It has been shown that following meniscectomy the intraarticular friction coefficient is increased by up to 20%. As a minor function, the menisci act as space fillers, preventing synovial entrapment between the weight-bearing articular surfaces of the femur and tibia.[19]

Mechanism of Meniscal Injury

The stifle functions as a hinge joint with axial rotation of the tibia on the femur through the range of motion. During range of motion, the displacement of the menisci within the

joint is dictated in part by their specific attachment to the tibial plateau and (for the lateral meniscus) to the femur. During extension, the menisci slide cranially on the tibial plateau then return to a more caudal position as the stifle flexes. With extreme flexion the excursion of the medial meniscus is such that the caudal horn may protrude beyond the caudal aspect of the tibial plateau. In such cases, the caudal horn of the medial meniscus may be acutely crushed between the femoral condyle and the tibial plateau. Because the lateral meniscus is more mobile (less firmly attached to the tibia), the lateral meniscus undergoes considerably more displacement than does the medial meniscus during range of motion.

Excessive compressive and/or shear stresses, resulting from stifle instability, whether acute or chronic, lead to meniscal degeneration.[24,25] The degenerative process is associated with structural alteration of the meniscal tissue such as mucoid degeneration of the cartilage matrix, fragmentation of the collagen bundles, and fibrillation. This alteration in fibrocartilage microstructure makes the menisci more vulnerable to injury and tear after minimal trauma. In chronic cases, calcification within the fibrocartilage can also occur secondary to degenerative change. In addition, modification of the biochemical composition of the meniscal tissue characterized by an increase in water

content and a decrease in collagen content has also been reported and seems to correlate with the degradation of its biomechanical properties, including a decrease in compressive stiffness to ~ 60% of normal. It has been suggested that the extent of theses changes correlates with the loading of the meniscal tissue and, therefore, varies between the cranial, central, and caudal regions of the meniscus. Interestingly, shifts in weight bearing following CCL rupture also affect the mechanical properties on the contralateral normal medial meniscus. As the weight-bearing forces increase on the sound limb, so do loads to which the healthy meniscus is subjected. Adaptative remodeling is

reflected by an increased compressive stiffness of the normal meniscus.

Most commonly, meniscal injuries occur secondary to stifle instability resulting from CCL rupture, with injury to the medial meniscus being reported in at least 50% of cases.[24-26] Although acute meniscal injuries can happen, delayed lesions occurring weeks to months after cruciate rupture are far more typical. Instability in the cruciate-deficient stifle results in a combination of excessive internal tibial rotation and cranial tibial translation. This combined motion induces disproportionately high compressive and shear stresses on the relatively immobile medial meniscus. With

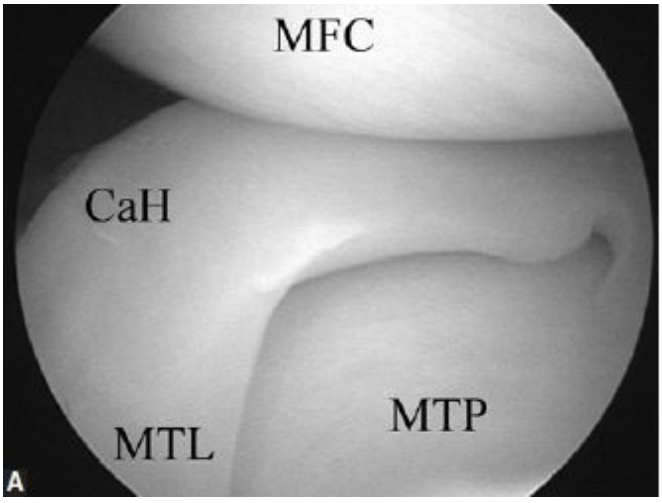
cranial displacement of the tibia/medial meniscus complex, the concave inner border of the meniscus may be stretched to the point of creating a transverse tear. It has been estimated that normal meniscal tissue fails at strain levels exceeding 5% and that degenerative menisci could likely tear at lower strain levels. Eventually, shear stresses generated at the surface of the meniscus by the repetitive sliding of the tibia are transmitted to the meniscal stroma, creating a deep horizontal cleavage. Ultimately, this pathologic cleavage plane propagates toward either surface of the meniscus, creating a grossly visible longitudinal tear (Figure 105-4). The term bucket-handle tear has been used to describe

the displaced medial portion of a longitudinal tear. Alternatively, the caudal horn of the medial meniscus may become crushed or pushed cranially between the medial femoral and tibial condyles as cranial translation of the tibia occurs during weight bearing. In such cases, the caudal meniscotibial ligament may be severed, which in turn allows the caudal horn of the medial meniscus to move freely between the caudal and cranial compartments of the joint. In some cases, the caudal meniscotibial ligament remains intact and the caudal horn alone is damaged. The alternate motion of the caudal horn is initially associated with a characteristic clicking or snapping sound when the dog is

walking or the joint is manipulated. Eventually, the degenerate horn may become fibrotic and even calcified and may interfere with complete range of motion.

In contrast, damage to the lateral meniscus has seldom been reported. However, with the increased popularity of arthroscopic stifle exploration, lateral meniscal lesions are being recognized.[26] In a retrospective evaluation of 100 cruciate-deficient stifles, 77% of the joints had gross structural alteration of the lateral meniscal structure, generally observed as a series of small radial tears of the cranial horn (Figure 105-5). The clinical significance of

these minor tears is unknown. Because of the lack of connection between the lateral meniscus and the joint capsule or collateral ligament, severe lesions of the lateral meniscus seem unlikely and have yet to be reported. Isolated injuries to either meniscus, in the absence of a cruciate rupture, are rare although theoretically possible following sudden compressive force directly on the meniscus, such as jumping from a height and landing with the stifle in full extension.



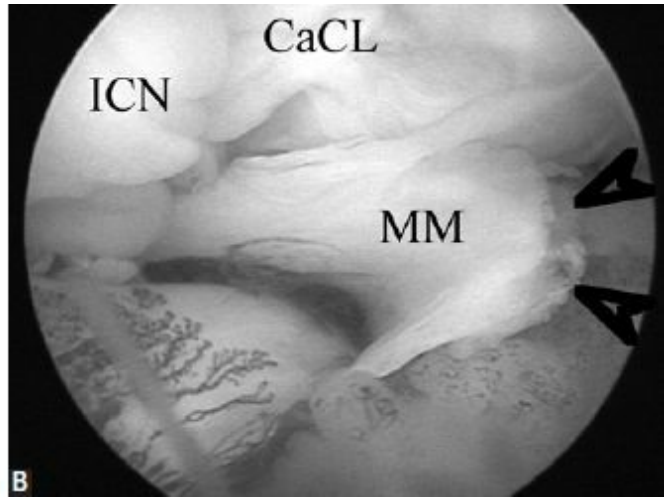


Figure 105-4. Arthroscopic views of a normal medial meniscus immediately following experimental transection of the cranial cruciate ligament (left) and 8 months postoperatively (right). The normal meniscus is viewed from the tibial plateau eminences toward the medial aspect of the joint (along the transverse plane). The torn meniscus is viewed in a cranial to caudal direction (along the sagittal plane). Note the circumferential tear at the limit of the "red-white" zone (arrow heads). Also note the extent of the synovial reaction compared with a normal stifle. MFC: medial femoral condyle, CaH: caudal horn, MTL: meniscotibial ligament, MTP, medial tibial plateau, CaCL: caudal cruciate ligament, ICN: intercondylar notch, MM: medial meniscus.

Menisectomy

The relative benefit of partial versus total removal of either meniscus remains controversial because both result in gross and microscopic degenerative changes of the articular

surfaces of the femur and tibia.[27-29] Although a partial meniscectomy may have a protective effect on articular surfaces, it has been associated with limited tissue regeneration, particularly if the resected segment is entirely located within the avascular center (white zone) of the meniscus. Furthermore, experimental studies in humans have demonstrated that, after partial meniscectomy, the femorotibial articular contact area decreased by approximately 10%, while peak local contact stresses increased by 65%. Conversely, total meniscectomy lead to a 75% decrease in contact area and an approximately 235% increase in peak local contact stresses.[25] The reported advantages of a complete

meniscectomy, however, include a more extensive regeneration of the resected meniscus if the excision line runs through the peripheral vascularized (red zone) portion of the meniscal tissue. In such cases, the regenerated meniscal tissue, derived from the synovial membrane, is generally formed within 3 to 6 months. Unfortunately, the regeneration process is somewhat inconsistent and the regenerated fibrocartilage is ineffective in preventing the development of secondary osteoarthritis, which will occur in almost 100% of cases.

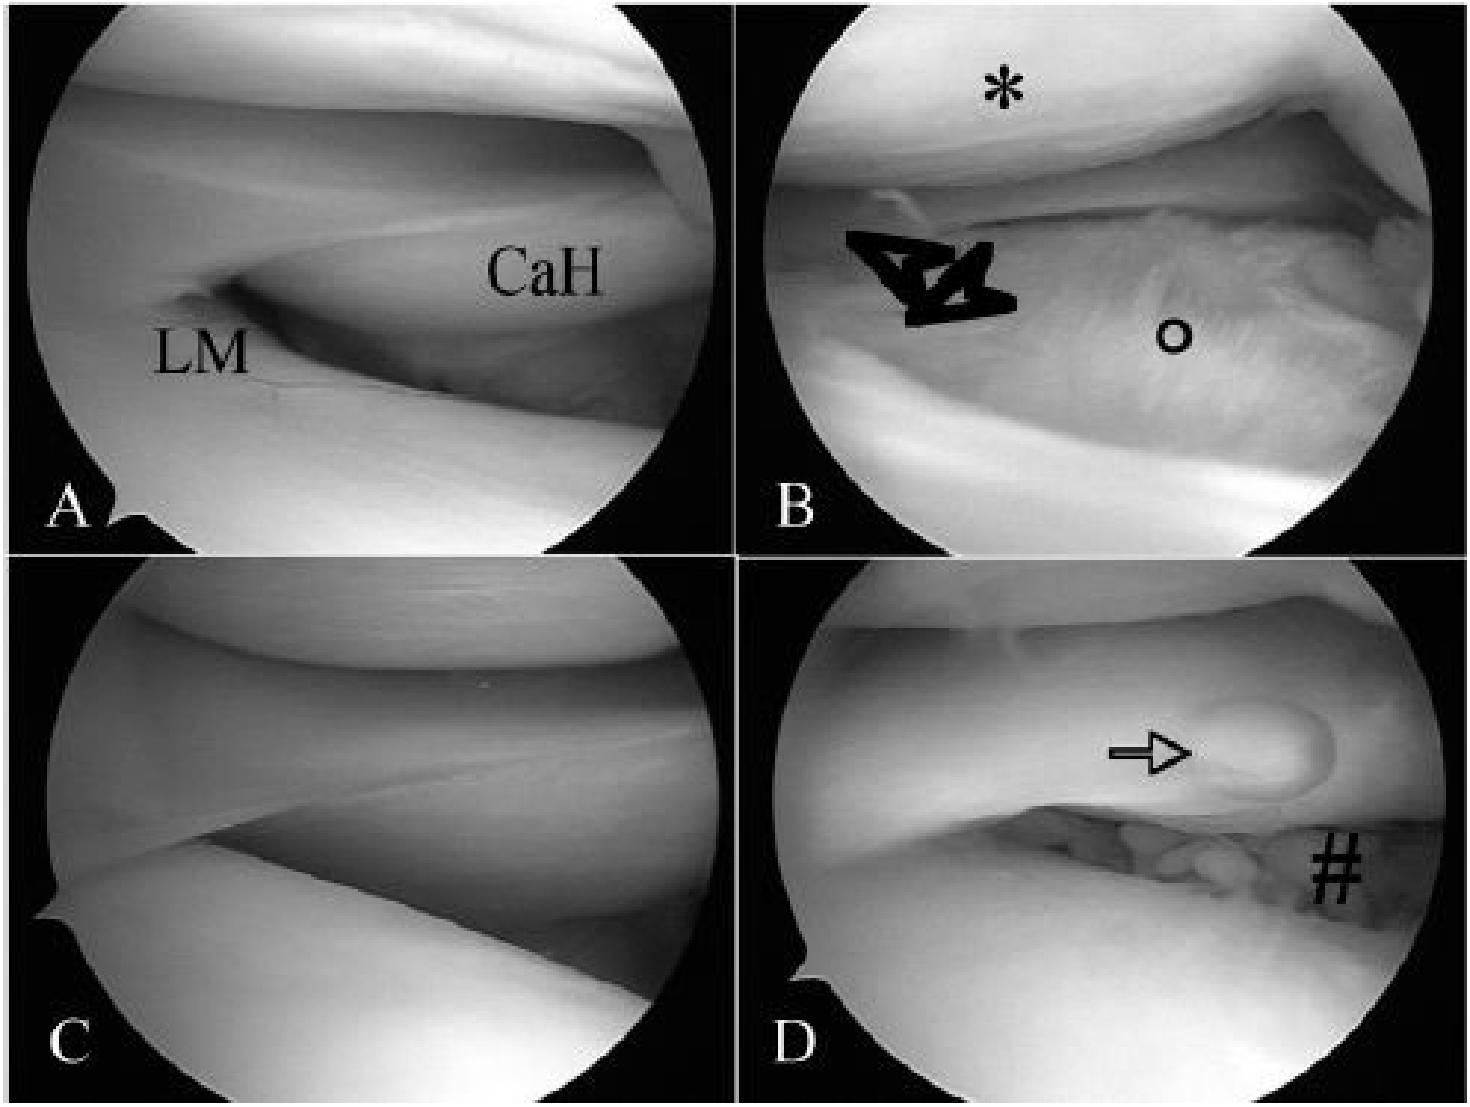

Figure 105-5. Arthroscopic view of normal lateral menisci (A & C) and 8 months following experimental transection of the CCL (B & D). Note (B) the series of small radial tears at the free edge of the meniscus (arrow heads) and the damage to the articular cartilage of the femoral condyle (chondromalacia*) and of the tibial plateau (fibrillation °). Also note (D) the presence of a cartilaginous nodule (open arrow) at the level of the caudal horn and the severe synovial proliferation (#). CaH: caudal horn, LM, lateral

meniscus.

Chapter 106

Patellar Luxation in Dogs

Kei Hayashi
Jennifer Lansdowne
Loïc Déjardin

Patellar luxation, defined as the displacement of the patella out of the trochlear groove of the femur, is a common problem in both small and large dogs. The condition may be congenital, developmental, traumatic, or iatrogenic in origin. The pathology can vary from mild instability of the

patella within the trochlear groove to severe permanent luxation of the patella, either medially or laterally, with skeletal deformities. Medial patellar luxation (MPL) is more common in all sizes and breeds of dogs. Anatomic deviation of the patella interferes with its normal function, resulting in skeletal deformities of the pelvic limb, contracture of pelvic muscles, loss of normal mechanics of the stifle, degenerative changes of the joints, and impairment of limb function. Clinical signs vary with many factors, including degree of luxation, age of patient, degree of musculoskeletal abnormalities, and degree of degenerative joint disease. The majority of patellar luxations

likely have a hereditary basis and genetic predisposition; however, the exact disease mechanisms have not been defined.

Anatomy

The patella is an ossification in the tendon of insertion of the quadriceps muscle group and the largest sesamoid bone in the body.[1] The patella is ovate: the proximal blunt surface is the base and may extend beyond the articular surface, whereas the distal pointed end, the apex, does not (Figure 106-1). The articular surface of the patella is smooth and convex in all directions, and articulates with a wide concave articular groove on the cranial surface

of the distal femur called the femoral trochlea. The medial and lateral trochlear ridges, with the medial ridge usually being thicker than the lateral, bound the femoral trochlea.

The patella is held in the trochlea of the femur primarily by the joint capsule, thick lateral femoral fascia (fascia lata), and thinner medial femoral fascia (Figure 106-1). The cranial part of the sartorius and biceps femoris blend into the femoral fascia at the stifle and may contribute to the medial and lateral stability of the patella. The medial and lateral femoropatellar ligaments also aid in stability of the patella within the trochlea. The lateral femoropatellar

ligament can be traced from the lateral side of the patella to the lateral fabella. The medial ligament is weaker than the lateral and blends with the periosteum of the medial epicondyle of the femur. The edges of the patella are connected to the femoral fascia via the medial and lateral parapatellar fibrocartilages (Figure 106-1). The parapatellar fibrocartilages ride on the ridges of the femoral trochlea and aid in patellar stability through contact with the ridges of the femoral trochlea. The vastus medialis muscle and vastus lateralis muscle of the quadriceps muscle group are fixed to the patella by the medial and lateral parapatellar fibrocartilages, respectively. A suprapatellar fibrocartilage may also

be present in the tendon of the rectus femoris.

The quadriceps muscle group is formed by the rectus femoris, vastus lateralis, vastus intermedius, and vastus medialis. The rectus femoris arises from the ilium cranial to the acetabulum, the vastus lateralis and intermedius arise from the proximal part of the lateral lip of the caudal rough surface of the femur, and the vastus medialis arises from the medial side of the proximal femur. This muscle group converges on the patella and continues as the patellar ligament to insert on the tibial tuberosity distally.

Function

The extensor mechanism is composed of the quadriceps muscle group, patella, trochlear groove, patellar ligament, and tibial tuberosity. Physiologic (near straight) alignment of these structures, together with normal gliding articulation of the patella and trochlea, are essential for smooth and efficient movement of the stifle during its extension.[2] Muscular

forces of the vastus medialis and vastus lateralis control medial and lateral movement and stability of the patella. The patella is an essential component of the extensor mechanism, serving to alter the direction of the pull of the quadriceps mechanism, preserving even tension of the extensor mechanism during stifle extension, and acting as a lever arm, increasing the mechanical advantage of the quadriceps muscle group. The patella also protects the tendon of the quadriceps muscle group during movement, provides a greater surface area for the tendon to engage the trochlea of the femur, and provides cranial and rotary stability to the stifle joint in the extensor mechanism. The

location and prominence of the tibial tuberosity are important for the mechanical advantage of the extensor mechanism.

Epidemiology

Patellar luxation can be congenital, developmental, iatrogenic, or traumatic, although the majority of luxations are congenital and are often related to other musculoskeletal abnormalities.[3,4] It is a common problem of both small and large dogs and is the most common congenital abnormality in dogs.[5] In a study that examined 1679 pet store puppies, 253 had at least one congenital effect (15%) among which 121 were patellar

luxation (7.2%).[6] These puppies were mostly small breeds: 48.8% would likely weigh less than 7 kg when mature. Patellar luxation is diagnosed most commonly in small breed dogs as a congenital or developmental problem within 6 months of age. However, as many as 32 breeds, including large breeds such as Akita, Great Pyrenees, and Labradors have been identified as at increased risk for patellar luxation.[7] Toy and miniature breeds are affected approximately 12 times more frequently than are large breed dogs, with toy poodles, Yorkshire terriers, Pomeranians, Pekingese, Chihuahuas, and Boston terriers being at increased risk for medial luxation.[4]

Medial Patellar Luxation

Medial patellar luxation is more common in all sizes and breeds of dogs than is lateral patellar luxation (LPL). In a study of 124 dogs that were referred for patellar luxation, the majority of dogs had a congenital form (82%), as opposed to acquired patellar luxation (15%), and the majority (89%) had MPL, as opposed to lateral luxation.[3] MPL accounted for 98% in small breeds (< 9.1 kg), 81% in medium breeds (9.1-18.2 kg), 83% in large breeds (18.2-36.4 kg), and 67% in giant breeds (> 36.4 kg). In one study of 70 referred large breed dogs, MPL accounted for 97% and LPL accounted for 2.8%.[8] That study also suggested that in large breed dogs MPL

occurs more frequently in males (male:female sex ratio of 1.8:1). In contrast, other studies have shown that in small breed dogs females are more frequently affected (male:female sex ratio of 1:1.5).[4] Although females are more likely to be affected than males, prevalence is similar among spayed females, neutered males, and intact females, with intact males being at a lower risk. Bilateral luxations are significantly more common (65%) than unilateral luxations (35%).[3,8]

Three groups of patients were identified based on clinical pattern by Brinker, Piermattei, and Flo: 1) neonates and older puppies with abnormal hind-leg carriage and

function from the time of ambulation; 2) young to mature dogs with intermittent and/or progressively abnormal gait; and 3) older dogs with an acute onset of lameness associated with degenerative changes and cranial cruciate ligament rupture.[9]

Lateral Patellar Luxation

Lateral patellar luxation occurs infrequently in dogs. Although LPL can occur in any size breed, it is proportionally seen more frequently in large breed dogs. The reported incidence of LPL varies widely between studies from 3%[8] to 8.9% of patellar luxations in large breed dogs[4] to 38.7% of patellar luxations when all small

and large dogs are included.[3] The male to female ratio of patellar luxation is 1.5:1, with intact males being at lowest risk.[3,4]

Pathophysiology

Medial Patellar Luxation

The cause of MPL remains unclear. Because toy and miniature breeds are affected with MPL approximately 12 times more than large breeds, a hereditary basis and genetic predisposition of this condition is likely. In addition, because many affected dogs are presented at 3 to 6 months of age, in absence of trauma, often with a bilateral condition, a congenital or developmental disorder

rather than an acquired disorder is likely. It is also possible that congenital patellar instability predisposes an animal to traumatic luxation.

It is generally accepted that MPL is a multifactorial anatomic anomaly, not only of the stifle but of the entire pelvic limb. Although the sequence of structural remodeling and variety of deformities of the pelvic limb have been well described, information regarding cause and effect relationships in MPL is limited in the veterinary literature. Specific musculoskeletal abnormalities such as coxofemoral anomalies, malalignment of the extensor mechanism, muscular

pathology in the quadriceps, and shallow trochlear groove have been proposed as underlying causes of MPL.

Coxofemoral abnormality may cause MPL and related limb deformities, however no correlation has been found between hip dysplasia and MPL. Based on Putnam's hypothesis, it has been proposed that primary changes in the coxofemoral joint and resultant postural abnormalities lead to compensatory mechanisms more distally, resulting in the eventual malformation in the distal part of the limb and patellar luxation.[10] Development of MPL has been linked to the radiographic appearance of coxa vara (decreased angle of inclination of

the femoral neck) and decrease in femoral anteversion (relative retroversion), which in turn leads to genu varum, medial displacement of the extensor mechanism, and further anatomic changes during growth by abnormal medial tension of the extensor mechanism (Figure 106-2). In a theory extrapolated from human literature, it was hypothesized that the reduced anteversion causes external rotation of the coxofemoral joint, which requires compensatory internal rotation of the distal limb to place the foot properly. As a result, the lateral soft tissues supporting the stifle joint are stretched and a lateral torsion force is exerted on the distal femoral growth plate, causing lateral torsion of

the distal femur. This lateral rotation of the distal femur displaces the femoral trochlea lateral to the line of contraction of the quadriceps. The compensatory internal rotation of the limb simultaneously causes displacement of the quadriceps muscle group medially, which in turn results in a medial displacement of the patella.

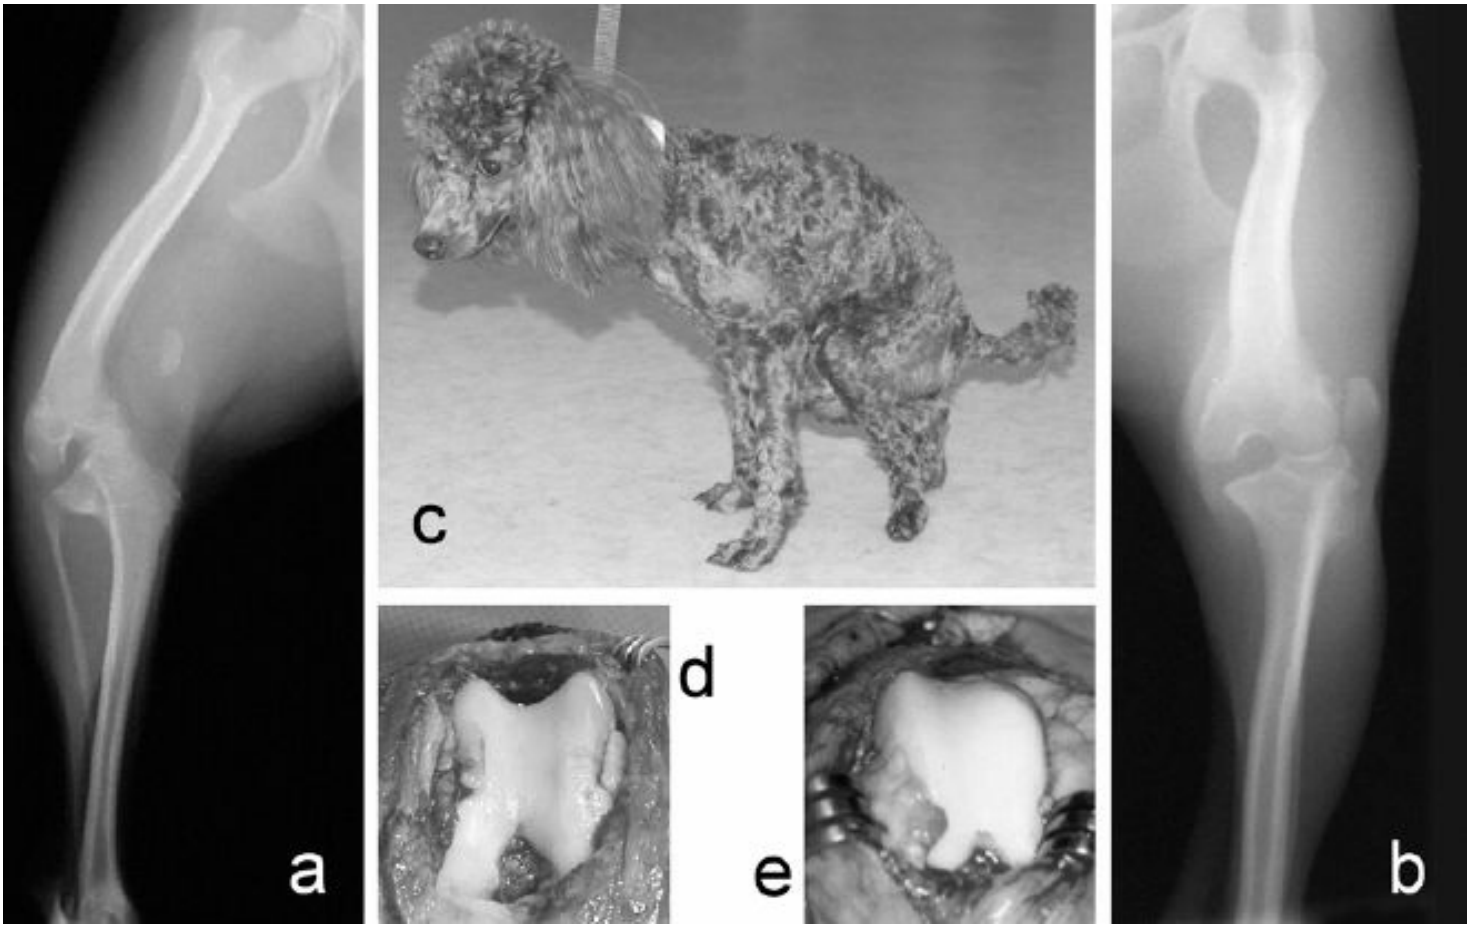

Figure 106-2. Radiographic appearance of grade 4 medial (a) and lateral (b) patellar luxation. Note the extreme internal (a) and external (b) rotation of the tibia as well as the ectopic position of the patella. Clinical signs associated with bilateral grade 4 LPL (c). In such an advanced case, stifle extension is prevented in part because of periarticular adhesions and fibrosis of the periarticular tissues. Permanent stifle flexion may be seen with severe grade 4 LPL and MPL. Intraoperative skyline views of a normally shaped trochlea (d) and a shallow trochlea (e) secondary to juvenile grade 4 patellar luxation.

Contrary to this hypothesis, a study of anteversion angle of the femoral neck using magnetic resonance image (MRI) did not reveal any correlation between patellar luxation and anteversion angle.[11] This study also demonstrated that anteversion angle measurement based on radiographs is not reliable. In another radiographic study of 100 papillons, there were no significant differences in angle of anteversion and inclination of the femoral neck between those with patellar luxation and normal dogs.[12] Interestingly, there were significant differences in weight and size between these groups: dogs with patellar luxation were significantly smaller and lighter. In addition, morphologic analysis of the

pelvis showed that the origin of the cranial part of the sartorius muscle lies significantly more medially in dogs with MPL than in normal dogs. Such conformational variation may lead to increased medial traction on the patella and medial displacement of the patella. Various deformities of the pelvic limb can cause deviated direction of force of the quadriceps group. The deviation between the direction of force of the quadriceps group (from origin of the quadriceps to the center of the trochlea or patella) and the patellar ligament is referred to as the quadriceps angle or Q-angle (Figure 106-3).[11] The Q-angle has been measured using MRI in dogs with varying degrees of MPL, and dogs with

MPL have significantly greater Q-angle, although the cause and effect relationships have not been established.

Malalignment of one or more structures in the extensor mechanism of the stifle may cause MPL. As indicated above, the location and stability of the patella during range of motion are governed by regional anatomic structures about the patella. Quadriceps muscles and other structures in the extensor mechanism, soft-tissue constraints of the patella, and conformation of femoropatellar articulation dictate patellar tracking on the stifle, which is influenced by anatomic relationships among the

pelvis, hip joint, femur, tibia, and tarsal joint. Proper anatomic alignment of the extensor mechanism with the underlying skeleton is the primary component of patellar stability.[2] During stifle extension, strong tensile forces within the quadriceps seek to align the patella between the muscular origin and insertion. If the long axis of the quadriceps muscle is not centered over the trochlea, there is an imbalance in muscular force favoring patellar luxation.

Muscular imbalance among the quadriceps may be a primary cause of malalignment of the extensor mechanism and MPL. A clinical study

reported grossly evident atrophy and fibrosis of vastus medialis (tight band-like appearance) in puppies with severe MPL.[13] As puppies grow, medial displacement of the patella and the quadriceps muscle group, and underdevelopment of the patella and trochlear groove occur. Abnormal tension from the pathologic vastus medialis and medially displaced extensor mechanism may produce a "bowstring effect," causing lateral bowing of femur and internal rotation of tibia. Clinical observation that skeletal deformities can be completely reversed in young puppies (less than 2 months of age) by the release of tight vastus medialis suggests that muscular pathology is the primary cause of MPL

and related deformities of the pelvic limb.

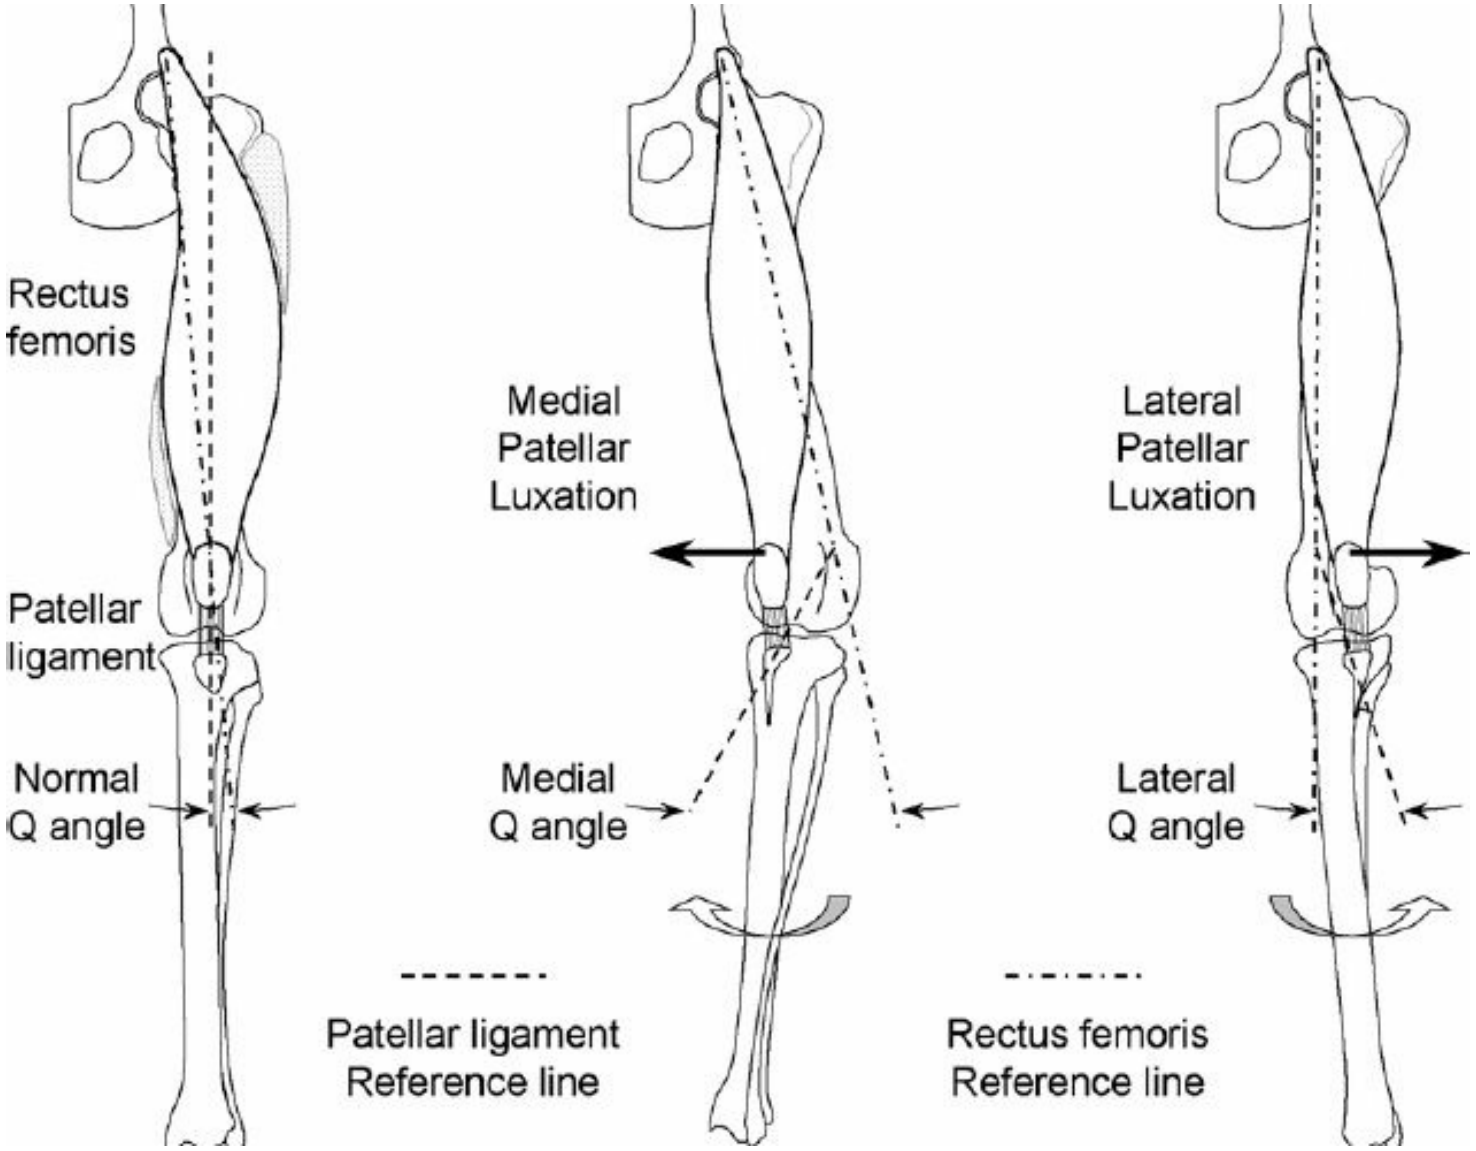

Figure 106-3. In humans, the quadriceps angle (Q-angle) is defined as the angle between the line of action of the quadriceps and the line formed by the patellar ligament and patella in normal limbs. Similarly, the Q-angle in dogs with PL has been defined as the line from the origin of the rectus femoris muscle to the center of the trochlea and the line between the center of the trochlea and the tibial tuberosity. Deviation of the course of the patellar ligament in one direction generates a resultant force (arrow) that pulls the

patella in the same direction, resulting in patellar luxation (the greater the Q-angle, the greater the risk of luxation). The average Q-angle increases with the severity of the luxation from ~11° (normal dogs) to ~12° (grade I), ~24° (grade II) and ~37° (grade III). (Adapted from: Kaiser S, Cornely D, Golder W, et al: Magnetic resonance measurements of the deviation of the angle of force generated by contraction of the quadriceps muscle in dogs with congenital patellar luxation. Vet Surg 30(6):552-558, 2001.)

Regardless of primary etiology, medial displacement of the extensor mechanism causes increased pressure on the medial femoral cortex, and thus unequal growth between the medial and lateral aspects of the distal femoral growth plate. Subsequent to this asymmetrical stress distribution, the growth rate on the lateral side of the distal femoral physis is relatively greater than on its medial side. This

results in more growth on the lateral side of the bone, and thus lateral bowing of the distal femur (bowstring). Similarly, this increased pressure on the medial part of the distal femur slows the growth of the medial femoral condyle, causing dysplasia of the femoral epiphysis. The proximal tibia compensates with greater bone growth medially, which causes medial bowing of the proximal tibia.

Formation of a shallow femoral trochlea has also been proposed as a primary cause for subsequent dislocation of the patella and extensor mechanism. However, because the femoral trochlea does not develop normally in the absence of normal

patellofemoral compression, underdevelopment of the trochlear groove is believed to be a secondary deformity.

The degree of musculoskeletal pathology depends on age and the degree and duration of patellar luxation. Medial patellar luxation often causes progressive deformation of both bony and soft tissues (Table 106-1). Skeletally immature animals develop angular and torsional deformity secondary to abnormal forces directed against open physes, and older animals with MPL may develop degenerative joint disease. Both hip and tarsal joints are also affected. Dogs may show bowlegged

appearance with the feet turned inward, with severely decreased range of motion of the stifle and extended tarsal joints (Figure 106-2). Increased rotational laxity of the stifle joint, bidirectional (medial and lateral) instability of the patella, and extensive cartilaginous erosion on the medial trochlear ridge may also be present. In addition to these abnormalities, the stifle joint may have concurrent problems of instability such as rupture of the cranial cruciate ligament. Because one of the functions of the cranial cruciate ligament is to limit tibial internal rotation during flexion, it has been suggested that MPL and subsequent increased tibial internal rotation amplify the stress on the

cranial cruciate ligament, predisposing to stretching and rupture. In addition, one can speculate that the loss of the quadriceps support cranially (a secondary constraint against tibial cranial translation) further increases cranial cruciate ligament stresses. The association between MPL and cranial cruciate ligament rupture remains uncertain. Although some studies have reported concomitant cruciate ligament rupture in up to 20% of MLP cases, others found that the prevalence of cranial cruciate ligament injury in dogs with patellar luxation was similar to that of dogs with other orthopedic conditions.[14]

Table 106-1. Musculoskeletal Abnormalities Associated with Medial Patellar Luxation

Femur/Tibia
External rotation of the distal third of the femur

Contracture/scarring of medial joint capsule and muscular tissues

Stretching of lateral joint capsule and retinacular tissues

Varying degrees of hyaline cartilage erosion and degenerative joint disease

Tarsal Joint

Compensatory hyperextension

Lateral Patellar Luxation

Owing to the paucity of scientific and clinical studies of LPL in veterinary orthopedics, the proposed pathophysiology of LPL in dogs has often been extrapolated from the human literature where LPL is the most frequent form of patellar luxation. Although several pathologic factors have been associated with LPL, whether these are causative or result from the luxation remains unclear

(Table 106-2). Although in rare cases, no apparent factor other than LPL is identified, in most instances (95%) LPL is associated with one or more structural defects.[1,15,16]

As seen with MPL, the normal development of the femoral condyles and trochlear groove depends on the balance between gravity and muscle forces during normal weight bearing.

Table 106-2. Possible Pathologic Factors Leading to Lateral Patellar Luxation.

See text for more information.

1) Increased anteversion angle
2) Coxa valga

3) Femoral deformity with torsion

4) Genu valgum

5) Lateral condylar dysplasia

6) Shallow trochlear groove

7) Lateral rotation of the tibia

8) Lateral displacement of the tibial tuberosity

9) Vastus medialis hypoplasia

10) Pes varus

Anatomic alterations such as angular and torsional malalignment of the femur and tibia may result from an abnormal distribution of growth-plate stresses during growth. Similarly, alteration of the normal anatomy such as coxa valga and excessive

anteversion of the femoral neck may induce relative medialization and internal torsion of the distal femur, respectively. An increased anteversion angle either can be compensatory as the dog adjusts the position of the hip, or fixed because of a femoral deformity. Both neck anteversion and coxa valga may contribute to medialization of the trochlea with regard to the line of action of the quadriceps (lateral Q-angle) and, therefore, to lateral luxation of the patella (Figure 106-3). Subsequently, the lateral aspect of the distal femoral growth plate may become overloaded, thus contributing to a slower rate of growth of the lateral femoral cortex compared with the medial one and,

over time, to lateral bowing of the distal third of the femur. The lateralization of the compressive loads across the joint may also constrain the development of the tibia, leading to a lateral deviation of the limb at the stifle, a condition known as genu valgum. With genu valgum, although the medial condyles and tibial plateau develop normally, increased forces through the lateral aspect of the distal femoral physis can lead to lateral condylar dysplasia and luxation of the patella. In turn, the absence of patellar pressure during growth interferes with the development of the trochlea, which becomes shallow. Under contraction of the quadriceps, the unconstrained patella is able to move laterally,

leading to wear and erosion of the lateral trochanteric ridge, thus exacerbating the problem.

It has been theorized that, in humans, LPL may be initiated by hypoplasia of the vastus medialis muscle.[17] As the vastus medialis becomes hypoplastic, it cannot counteract the antagonist vastus lateralis, resulting in lateral patellar luxation. Phylogenetically, the vastus medialis is the last muscle to develop in humans.[18] It is also the first to undergo atrophy if it is injured or immobilized, and the last to respond to rehabilitation. Although hypoplasia of the vastus medialis may be present in dogs with LPL, this theory is currently unproven.

As with any developmental condition, the anatomic malformations will be more severe if initiated in a younger animal. It has been shown experimentally that alterations in the lines of force produced by soft-tissue restraints in young animals can lead to permanent recognizable bone deformities within 2 weeks.[19] These conformational alterations, including lateral displacement of the tibial tuberosity, are fixed after 4 weeks in 6- to 8-week-old puppies.[19] The permanent lateralization of the quadriceps results in unbalanced strain on the lateral condyle, medial retinaculum, and joint capsule. The lateral retinaculum tightens, and the medial retinaculum stretches further,

exacerbating lateral patellar luxation.[19]

Three cases of pes varus resulting in LPL and lameness in miniature dachshunds have been reported.[20,21] Pes varus describes the inward rotation of the distal tibia secondary to the asymmetrical premature closure of the medial aspect of the distal tibial growth plate.[21] As pes varus progresses, compensatory righting of the tarsus and paw placement lead to lateralization of the limb, laxity of the stifle, and eventually, LPL. In two cases, pes varus was thought to be the result of autosomal recessive inheritance;[21] in the third case, it was thought to result from an injury to a

distal tibial growth plate.[20] Although the distal tibial physis is affected in 3% of all traumatic physeal injuries,[22] resultant pes varus does not occur in all cases.

Clinical Signs

Clinical signs associated with MPL vary with degree of the pathology of the pelvic limb. A classification of MPL was designed by Putnam and adapted by Singleton.[10,16] Grades l and 2 represent reducible luxations, whereas grades 3 and 4 represent the permanent luxations.

Grade l: Patella can be manually luxated on full extension, with spontaneous reduction on release.

Minimal skeletal deformity.

Grade 2: Patella luxates on stifle flexion or manual manipulation, and remains luxated until stifle extension or manual reduction. As much as 30° of medial tibial rotation.

Grade 3: Patella remains luxated continuously but can be reduced manually; 30° to 60° of medial tibial rotation.

Grade 4: Patella luxated permanently and cannot be reduced; 60° to 90° of medial tibial rotation.

Conclusion

The patella/trochlea arrangement acts as a pulley system that optimizes the function of the quadriceps during stifle

extension. By moving the patella away from the axis of flexion/extension of the stifle, the trochlea provides a lever arm to the quadriceps muscle, thus minimizing muscle contraction during extension. Any reduction of the trochlear leverage owing to patellar luxation results in a relative increase in the magnitude of the contractile force necessary to produce stifle extension. In extreme cases, such as severe grade IV MLP or LPL, the line of action of the quadriceps may become caudal to the stifle axis of flexion/extension. The net result is flexion rather than extension of the stifle during quadriceps contraction (Figure 106-4). This severe alteration of the stifle biomechanics along with

the development of fibrous adhesions between the patella and the retinaculum precludes stifle extension and clinically results in dogs walking in a permanently crouched position (Figure 106-2).

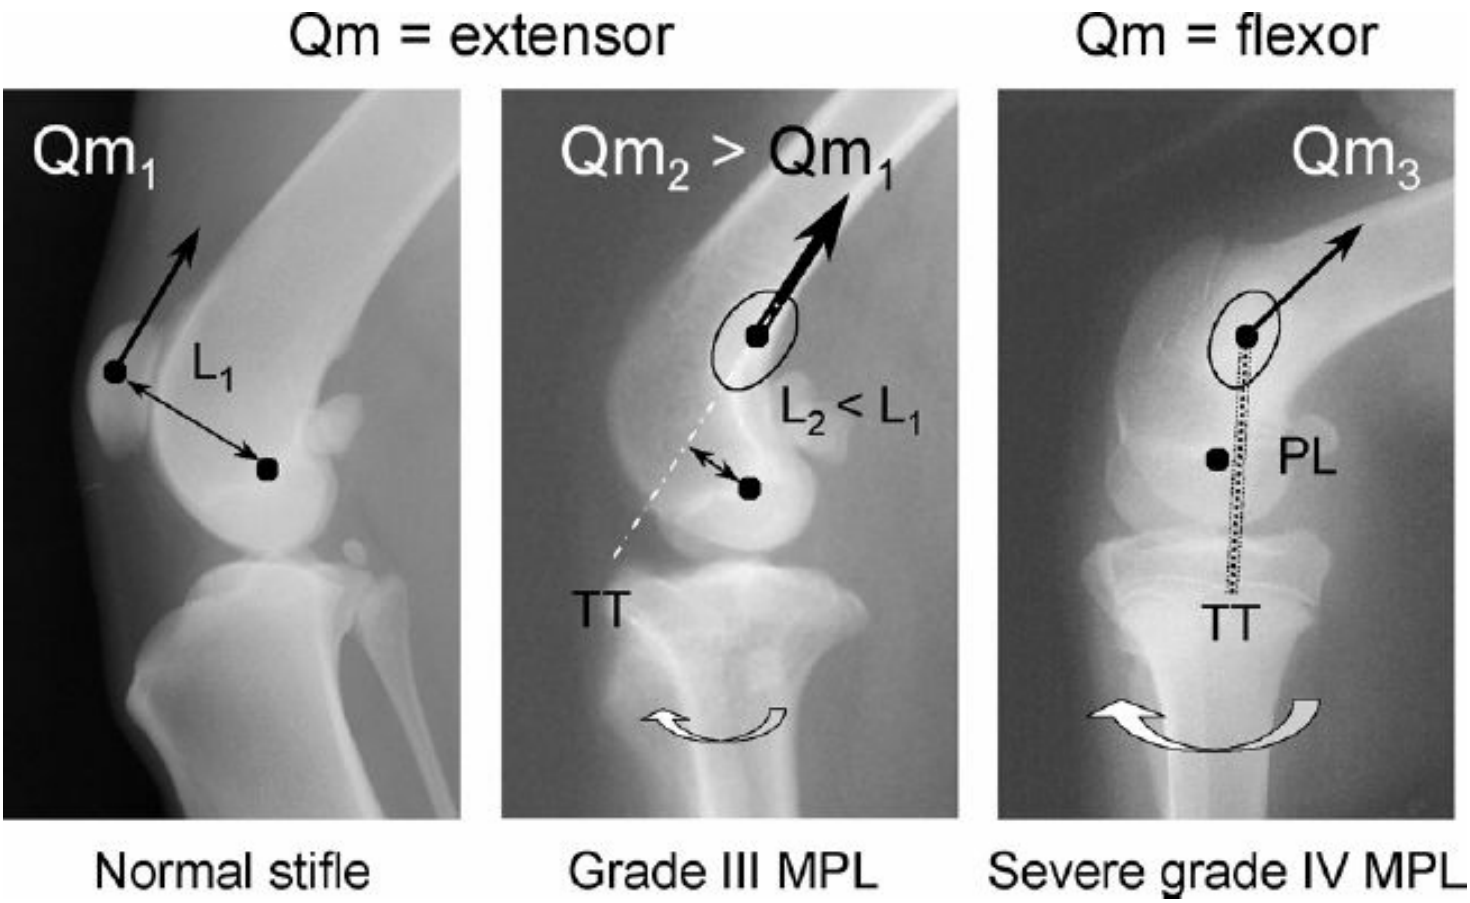

Figure 106-4. The patella and trochlea form a pulley system that optimizes the function of the extensor mechanism by providing a lever arm to the quadriceps muscle (Qm). Patellar luxation reduces the

trochlear leverage (L), which in turn induces a relative increase in the quadriceps muscle force needed to achieve stifle extension. Similarly, the quadriceps muscle force has been shown to increase by 15% to 30% following patellectomy in people. In extreme cases, such as severe grade IV luxations, the quadriceps line of action moves caudally to the stifle axis of flexion/extension, thus transforming the quadriceps into a flexor muscle.

Various surgical procedures have been proposed to treat patellar luxations with the common objective of restoring the alignment of the extensor mechanism through a combination of corrective osteotomies and soft-tissue procedures. Until the pathophysiology of patellar luxation is more completely understood, surgeons must be content to repair the apparent structural abnormalities of their patients.

Chapter 107

Spinal Fractures and Luxations

Brigitte A. Brisson

Fractures and luxations are classified as traumatic or pathologic. Spinal injury in small animals is most commonly associated with blunt force trauma from vehicular accidents.[1-4] Other traumatic causes include gunshot injuries, encounters with other animals, falling from a height and injuries caused by falling objects.[1,3,4] Pathologic fractures and luxations are often associated with congenital

vertebral anomalies, metabolic disorders, and neoplasia. In this chapter we discuss traumatic vertebral fractures and luxations. Secondary spinal cord injury and its treatment are discussed in a separate chapter. Conditions such as atlantoaxial luxation, “wobblers” (caudal cervical spondylomyelopathy), and traumatic disc extrusion are not included. Surgical repair of spinal fractures is discussed with regard to biomechanical properties but techniques are not presented in detail.

Anatomy and Biomechanics of the Normal Spine

The spine is composed of bony

structures (the vertebrae) and soft tissues (all associated ligaments, muscles, etc.). Normal spinal motion includes flexion and extension (most important) as well as lateral bending and rotation. Violent forces applied to the spine can lead to fracture or luxation.

Models that divide the spine into bony and soft-tissue compartments have been developed to help predict the stability of various fracture configurations and guide surgeons with respect to treatment. Using a two-compartment theory,[5] ventral and dorsal compartments were described. In this model, the ventral compartment consists of the vertebral body, the

intervertebral disc (annulus and nucleus pulposus), and the ventral and dorsal longitudinal ligaments. The dorsal compartment contains the dorsal lamina (pedicles and lamina), the articular facets, the joint capsules, the dorsal spinous process, the interspinous and supraspinous ligaments, and the ligamentum flavum. The paraspinal musculature adds stability to both compartments. Lesions that affect both compartments occur most commonly and are generally considered unstable.[6] Traumatic lesions to a single compartment (dorsal or ventral) are rare. When they occur, lesions involving the ventral compartment only are considered more stable than those that involve only the

dorsal compartment.

A three-compartment model (three-column) modified from the human literature has also been described.[7,8] In this model, the dorsal compartment remains the same while the structures contained in the ventral compartment are further divided into the following: a middle compartment that contains the dorsal longitudinal ligament, the dorsal half of the disc, and the dorsal half of the vertebral body (basically the floor of the spinal canal), and a ventral compartment that contains the ventral longitudinal ligament, the ventral half of the disc, and the ventral half of the vertebral body.[7] Using the three-compartment model, injuries

involving two or more compartments are considered unstable.[8]

Biomechanics of Fracture

During trauma, forces are exerted onto the spinal column that can lead to vertebral subluxation, luxation, fracture, or fracture-luxation. Forces associated with specific fracture-luxation patterns include: compression (axial loading), bending (flexion or extension), torsion (rotation), and shear.[9] Although a traumatic event can result in a single force being applied to the spinal column, most fractures result from a combination of forces; flexion and rotational forces are most common.[6,8]

Axial loading (or compression) develops when a force is applied along the axis of the spine. Pure axial loading is rare but can occur when a standing dog is struck straight from behind or head-on, creating high compression forces across the intervertebral discs and vertebral bodies. Experimental studies performed in human spinal segments show that increased compression across the vertebral segments leads to increased pressure within the normal intervertebral disc and the vertebral endplates.[9] As the pressure increases, blood is squeezed out of the vertebral endplates, which bulge and eventually crack, allowing nucleus pulposus to be displaced within the vertebral body.[9]

The intervertebral discs and vertebral endplates are considered important shock-absorbers of the spine.[9]

True compression injuries can occur only in portions of the spine that are in a straight line with the force of trauma at the time of impact. This generally results in a "burst" compression fracture of the vertebral body with or without disruption of the intervertebral disc (Figure 107-1).[20] If damaged, the intervertebral disc can extrude dorsally or into the adjacent vertebral body.[11] If the dorsal compartment remains intact, fractures of this configuration are considered relatively stable.[10] However, bony fragments (from the floor of the spinal

canal), disc material, and redundant annulus fibrosus can be driven into the spinal canal, causing spinal cord compression. Studies using segments of spine with normal and degenerate intervertebral discs suggest that compression by extrusion of nucleus pulposus occurs only when the disc is abnormal to begin with.[9]

Pure hyperflexion and hyperextension injuries are rare. Hyperextension injuries occur when a force is applied directly onto the dorsal aspect of the spine, creating compression forces on the structures of the dorsal compartment and tensile forces on the structures of the ventral compartment.[10] With enough force, the

ventral longitudinal ligament and the ventral portion of the annulus fibrosus may rupture, leaving the dorsal ligamentous structures intact. These lesions are stable and often reduce spontaneously, making them difficult to diagnose.[10,11]

Pure hyperflexion injuries are rare.[10] Excessive hyperflexion results in a wedge fracture whereby the ventral portion of the vertebral body is crushed, often sparing the ligamentous structures of the spine (Figure 107-2).[20] When referring to the three-compartment model, this type of fracture tends to affect only the ventral compartment, leaving the dorsal portion of the disc and vertebral body

intact.[7] Sparing of the middle and dorsal compartments prevents subluxation and compression of the spinal cord by bony fragments.[7] These fractures are considered relatively stable.[7,10]

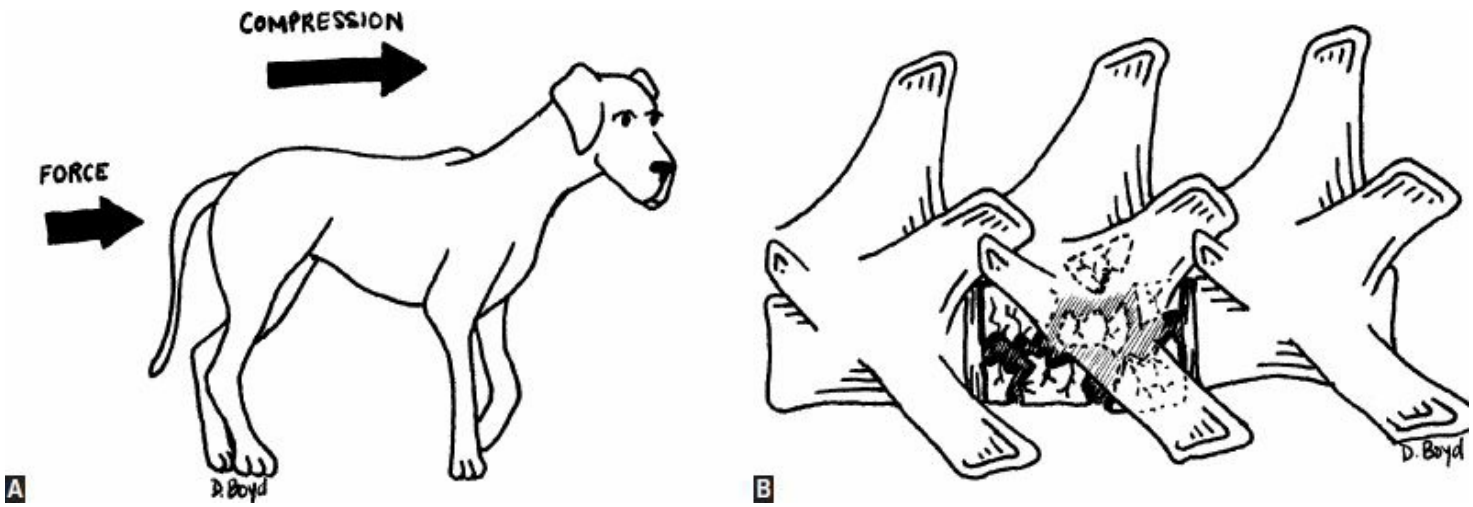

Figure 107-1. Compression injuries occur when the affected vertebrae are in a straight line with the force of trauma at the time of impact. This generally results in a "burst" compression fracture of the vertebral body with or without disruption of the intervertebral disc. Pure compression injuries are rare.

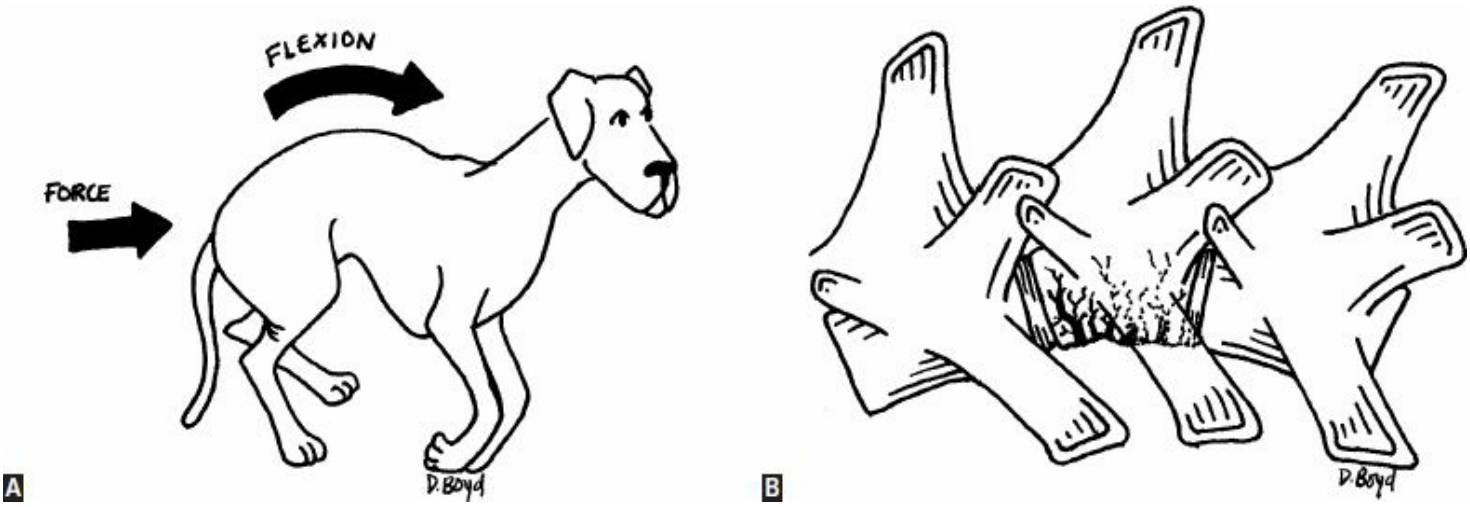

Figure 107-2. Excessive hyperflexion of the spine results in a wedge fracture whereby the ventral portion of the vertebral body is crushed, often sparing the ligamentous structures of the spine. Pure hyperflexion forces are rare.

Torsional forces are typically accompanied by flexion of the spine. These forces often cause trauma to bony and ligamentous structures of the ventral and dorsal compartments (two compartment model) and result in unstable fracture-luxations of the spine. When flexion is the primary force applied to the spine and

simultaneous rotation occurs, luxation is the typical outcome (Figure 107-3).[8,11,12] When rotation is the primary force applied to the spine with concurrent flexion, fracture-luxation generally occurs (Figure 107-4). Owing to their inherent instability, these lesions are often treated with surgical stabilization.[11,13]

Spinal Cord Trauma

Spinal trauma leads to primary spinal cord injury (concussion, compression, and distraction) caused by the initial impact and by repeated motion at the fracture site. Secondary spinal cord injury involves a series of events that begin soon after the initial injury and

include complex vascular, biochemical, and inflammatory processes.[8,14] Because the clinician has no control over the initial spinal cord trauma (primary injury), therapeutic efforts must be aimed at decreasing repeated injury owing to instability and halting or attenuating the secondary processes that begin at the time of injury. The pathophysiology of spinal cord injury and its treatment are discussed in a separate chapter.

Diagnosis

If spinal injury is suspected, patient manipulation should be limited; compliant patients should be strapped to a board to prevent further

displacement of an unstable fracture and repeated spinal cord trauma during patient evaluation. A depression or vertebral malalignment along the spine and possible crepitation may be noted on physical examination. A cursory neurologic examination is performed in an attempt to localize the lesion and determine the severity of the spinal cord injury. Sedation of non-compliant patients and administration of analgesics is considered after a rapid assessment of the neurologic status. Concurrent injuries should be taken into consideration when interpreting the neurologic examination to prevent overstating the neurologic dysfunction and prognosis.[4,15] If possible, survey

radiographs should be performed with the patient awake or under light sedation in order to maintain paraspinal muscle tone and decrease the risk of further fracture displacement. It is important to remember that radiographs may not necessarily reflect the maximal displacement that occurred at the time of trauma.[16,17] This helps to explain why correlation is poor between radiographic displacement and neurologic deficits.[2] Lateral radiographic views are recommended first and, if available, horizontal-beam ventrodorsal views should also be performed. Survey radiographs of the entire spine are recommended to rule out multiple spinal lesions.[1-4,18] The

benefits of performing more thorough radiographic views once the patient is under general anesthesia must be weighed against the potential risks associated with spinal manipulation. Myelography is recommended when no radiographic evidence exists of vertebral displacement and when the neurologic signs do not correlate with the radiographic lesion. In such cases, myelography can help localize the injury by outlining an edematous section of spinal cord or slight vertebral canal subluxation. In addition, myelography can provide information on the degree of spinal cord compression caused by fracture fragments or hematoma. Some authors recommend myelography for all spinal

trauma patients.[19] Advanced diagnostic imaging (CT and MRI) is also useful in cases where vertebral displacement is not evident on survey radiographs. Compared with survey radiography, CT provides an accurate assessment of spinal canal compromise[20] as well as superior detail of the fracture lines and bone fragments. This is especially true for fractures that involve the pedicles and articular facets and for displaced bone fragments that may compress the spinal cord. MRI provides good soft-tissue imaging and may help to determine the severity of spinal cord injury, the presence of spinal cord hemorrhage or edema, and whether disc herniation and spinal cord

compression are present.[21] As with survey radiography, the risks associated with patient manipulation and positioning under general anesthesia as well as the additional anesthetic time must be weighed against the potential diagnostic value.

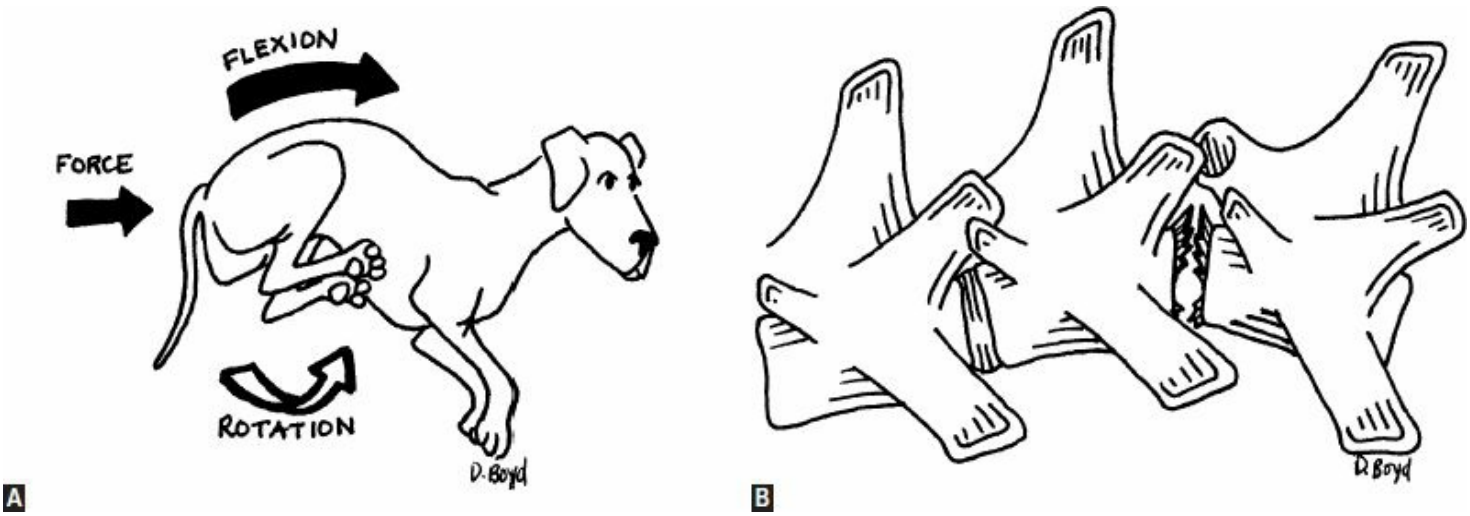

Figure 107-3. When flexion is the primary force applied to the spine and simultaneous rotation occurs, luxation is the typical outcome.

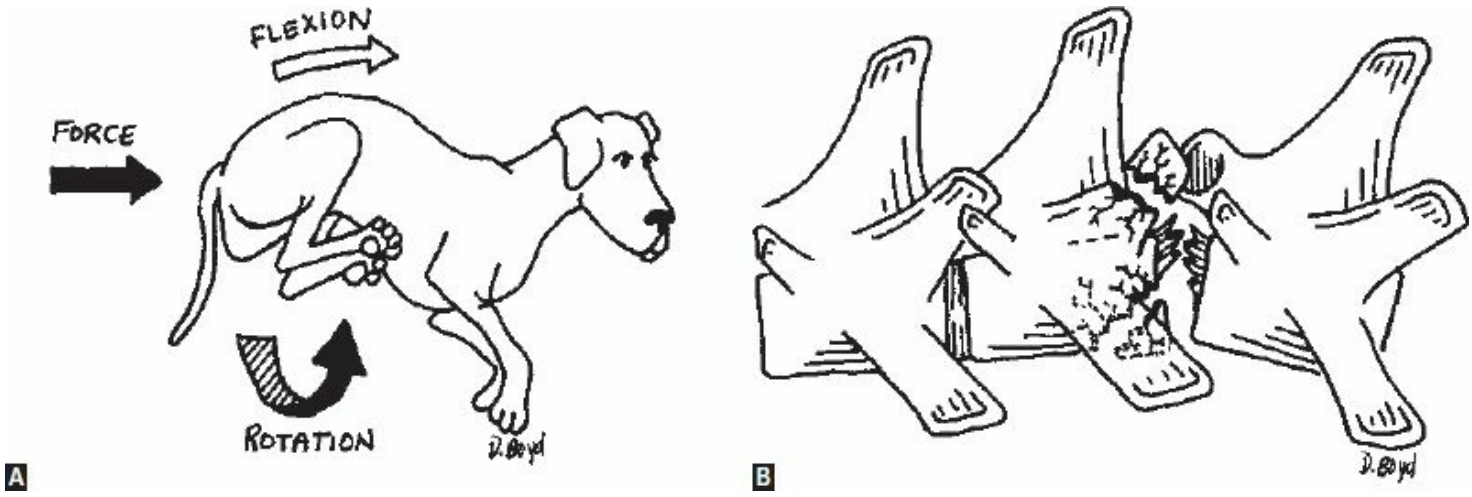

Figure 107-4. When rotation is the primary force applied to the spine with concurrent flexion, fracture-luxation generally occurs.

All trauma patients, especially those with spinal pain or neurologic dysfunction should be evaluated for possible vertebral fracture or luxation. Patients should be assessed and appropriately treated for other concurrent injuries such as pneumothorax, pulmonary contusions, diaphragmatic hernia, and fractures of the pelvis, ribs, and apendicular skeleton. Previous reports indicate that

approximately 50% of patients with spinal trauma have injuries to other systems,[1-4] and that approximately 48% of patients with a lumbar fracture or luxation have a fracture elsewhere in the body; most frequently a pelvic fracture,[4] Owing to a high rate of concurrent pulmonary injuries, thoracic radiographs are recommended for all patients that are to undergo general anesthesia for fracture fixation.[4]

Incidence and Distribution of Spinal Fractures

Spinal fracture-luxations in dogs have been reported to affect the lumbar vertebrae most commonly, followed by

sacrococcygeal, thoracic, and cervical vertebrae.[2,3,18] In cats, the sacrococcygeal region is the most common site for vertebral fracture and/or luxation.[18] Stress concentration at or near the junction between mobile and relatively immobile regions of the spine is thought to result in an increased rate of fracture-luxations at the thoracolumbar and lumbosacral junctions;[18] however, studies have also described a relatively even distribution of fractures along the lumbar spine.[4,22]

The vertebral body has been identified as the most commonly fractured portion of the vertebrae.[2,18] Disc herniation associated with fractures or luxations is fairly uncommon and was

reported in fewer than 12% of cases in one study.[18] The presence of more than one spinal lesion has been reported, but this is rare and tends to involve two adjacent vertebrae.[18] These lesions most commonly involve the lumbosacral and sacrococcygeal junctions.[18] Despite their rare occurrence, radiographic evaluation of the entire spine is recommended to rule out multiple lesions.[1-4,18]

Cervical Fractures

Cervical fractures and luxations are associated with various degrees of neurologic dysfunction but do not typically lead to loss of pain perception caudal to the lesion. The

main reasons for this may be that: 1) the larger cervical spinal-canal to spinal-cord ratio allows for more displacement without severely damaging the spinal cord, and 2) cervical trauma severe enough to cause loss of pain perception generally causes respiratory failure and death at the time of injury.[12,23] Although some have reported that most dogs with cervical fractures present with mild neurologic deficits and often only neck pain,[23] a study reviewing 56 cases of cervical fracture-luxation revealed that 57% of cases presented with non-ambulatory tetraparesis.[1]

The axis (C2) is most frequently fractured (50-78% of cases) followed

by the atlas (C1) (approximately 25% of cases).[1,2,23] The higher incidence of C2 fractures in dogs is thought to relate to the anatomy of the proximal cervical region. It has been hypothesized that the axis acts as a point of leverage between the cranial and caudal cervical regions. This is thought to be due to the close relationship of the vertebral body of the axis with the atlas and the intimate soft-tissue attachment of the dorsal spinous process and caudal articular facets of the axis with the caudal cervical vertebrae.[12,23] One study reports that fractures of C3-7 are more common after dog fights or unknown trauma than after being hit by a car and that fractures involving the caudal

cervical vertebrae typically affect more than one vertebra.[1]

High perioperative mortality (36%) has been reported with surgically treated cervical fracture-luxations.[1] However, most patients that survive through surgery and the immediate postoperative period achieve functional recovery.[1] In addition, almost 90% of patients treated conservatively obtain a functional outcome, suggesting that many cervical fractures are amenable to conservative therapy.[1] Negative predictors for recovery include a non-ambulatory status at presentation and being referred more than 5 days after the initial trauma.[1]

Thoracic and Lumbar Fractures

The lumbar and thoracic regions of the spine are common sites for vertebral fracture and/or luxation in dogs and cats.[2,3,18] Although fractures reportedly occur more commonly at the thoracolumbar and lumbosacral junctions,[18] a study by Turner and others revealed that fractures of L2, L4, and L7 were more common than fractures of the other lumbar vertebrae; no statistical difference was found when all lumbar vertebral segments were compared.[4] Fractures between T1 and T9 are less common, typically minimally displaced, and relatively stable. The inherent stability

of this section of the spine is thought to be due to the additional support provided by the ribs and their attachments. Neurologic dysfunction varying from alterations in conscious proprioception to loss of pain perception has been reported in as many as 85% of patients with lumbar fractures.[4] Based on previous reports, 45% of patients with lesions between T1 and S1 and as many as 62% of patients with lumbar injuries were euthanized without treatment.[3,4] The decision to euthanize was often based on the severity of the neurologic dysfunction or on surgical confirmation of severe spinal cord injury.[3,4] The high rate of neurologic dysfunction associated with

thoracolumbar injuries compared with cervical injuries is likely related to the relatively small spinal-canal to spinal-cord ratio of the thoracolumbar spine.[15] In contrast, fracture-luxations of L6 and L7 only affect nerve roots (cauda equina); these can tolerate a greater amount of displacement without severe neurologic dysfunction.[24] Unlike fractures of the lower thoracic and lumbar regions, which often require surgical fixation, fractures of L6, L7, and the lumbosacral region often heal satisfactorily without surgical intervention.[15]

Sacrococcygeal Fractures

Sacrococcygeal fractures are the most common spinal fracture diagnosed in cats,[18,25] and they occur relatively frequently in dogs.[18,26] Clinical signs associated with these fractures range from sacral pain to loss of sensation and motor function to the tail and perineal area, along with urinary and fecal dysfunction. Although neurologic deficits to one or both hind limbs are possible with traction lesions (tethering) of the cauda equina and spinal cord, these lesions are rare and difficult to differentiate from those associated with concurrent pelvic fractures.[26,27] In dogs, sacral fractures that occur medial to the foramina (axial) are more frequently associated with urinary or fecal incontinence, loss

of perineal sensation, and tail analgesia than are sacral fractures that occur lateral to the foramina (abaxial).[26] In addition, dogs with axial fractures have more severe neurologic dysfunction at presentation and discharge than do dogs with abaxial fractures.[26] Additional orthopedic injuries are reported in 76 to 88% of cats and 74 to 97% of dogs, which emphasizes the need for a complete assessment in order to provide an accurate prognosis.[25-27] In cats, sacral fractures are often associated with sacroiliac luxation, whereas in dogs, they are more commonly associated with ilial fracture.[27] More than 70% of cats in one study had temporary or permanent

urinary incontinence, but the prognosis for recovery of normal urinary function was good when cats retained anal tone and perineal sensation at presentation.[25] Return of neurologic function to the hind limbs, bladder, and rectum reportedly occurs within 1 month; cats that have not recovered urinary function 1 month after trauma are unlikely to recover.[25] In a canine study, patients with abaxial fractures had a better prognosis for recovery than those with axial fractures.[26] Based on the results of this study, little neurologic improvement should be expected during hospitalization.[26] Surgical treatment of sacrococcygeal fractures has been associated with worsening of the neurologic status in

approximately 40% of dogs; this is likely owing to iatrogenic injury.[26]

Principles of Fracture Fixation

Whether to treat spinal fractures conservatively or surgically is a topic of great controversy. Surgical intervention aims toreduce and realign vertebral bone fragments, which in most cases will effectively decompress the spinal cord; and to provide rigid fixation of the affected vertebral segments to prevent continued instability. In some cases, laminectomy is necessary to assess the spinal cord for visible damage and to relieve compression caused by hematoma, disc

material, or bony fragments. Because decompressive procedures have the disadvantage of potentially destabilizing the spine, pediculectomy and hemilaminectomy are preferred over dorsal laminectomy because they produce less instability.[2,28] Although the general consensus is that fractures that involve both the dorsal and ventral compartments (two-compartment model) are unstable and should be stabilized surgically, some studies have demonstrated up to 94.4% functional recovery (walking) with non-surgical management.[1,2,22] Although patients with a range of neurologic dysfunction were included in published retrospective studies, reported recovery rates should be

interpreted with caution because patients with severe neurologic dysfunction are more likely to have undergone surgical stabilization, whereas patients with less severe neurologic dysfunction are more likely to have been treated conservatively. Despite this, patients retaining even minimal neurologic function should be given the benefit of conservative management if surgery is not an option and the owners are willing to perform supportive care and rehabilitation.[3,22]

Conservative management and external splinting have demonstrated good success in the treatment of some cervical and thoracolumbar

injuries.[3,22,29] Because it provides relatively limited immobilization of the fracture site, this treatment option has typically been recommended for patients with relatively stable fractures causing mild neurologic dysfunction or when financial constraints limit treatment options.[5] Experimental bending of a back splint designed for the treatment of lower thoracic and lumbar fractures revealed it could withstand bending moments in excess of those shown to cause failure of commonly used internal fixation techniques and those experienced by large paralyzed veterinary patients undergoing nursing care.[29] This splinting technique is considered suitable for patients that retain some

degree of voluntary motor function and have lesions that affect mostly the dorsal compartment; lesions with loss of ventral buttress are not considered ideal for this technique.[29] External splints should extend well beyond the fracture site on either side of the affected vertebral segments to prevent a fulcrum effect at the level of the fracture. Patients should be monitored daily for slippage of the splint and other related complications such as urine scalding, skin abrasion, ulceration or abscessation, and overheating.[22,29] Although conservative management requires significantly more supportive care and generally leads to a longer recovery period, the cost of treatment is often lower and

the duration of hospitalization shorter than for surgical stabilization.[3]

Surgical management should be considered for exploratory purposes in patients that have lost pain sensation, and in order to provide stable fixation across the fracture site in all patients with severe neurologic deficits (non-ambulatory patients).[25,30] Surgical stabilization is also recommended for patients with unstable fractures (determined radiographically or by palpation of a “click” during ambulation or patient movement), those that fail to improve or continue to deteriorate neurologically despite conservative therapy, and patients with severe pain beyond the first 48 to

72 hours after injury.[25,30]

Various surgical techniques have been described for fracture stabilization in all regions of the spine. Vertebral body cross-pinning was described for stabilizing fractures of the articular facets, epiphyseal body fractures, and spinal luxations. This technique is considered inadequate for fixation of severe compression or multifragmented fractures[31] and is no longer recommended. Spinal stapling involves applying parallel stainless steel pins through and along the dorsal spinous processes on either side of the fracture, with additional wire stabilization through the dorsal spinous processes spanned by the repair.[32] This technique

is only applicable for patients weighing less than 10 kg and requires intact dorsal spinous processes.[5,32] Similarly, modified segmental spinal instrumentation involves placing Steinman pins around and along the dorsal spinous processes of several vertebrae and wiring these pins to the dorsal spinous processes and the cranial articular facets of the vertebrae spanned by the repair.[33] This technique is reportedly applicable for all sizes of dogs but should be reserved for fractures that do not involve the ventral compartment. Modified segmental spinal instrumentation and spinal stapling frequently fail by tearing through the spinous processes and are rarely used. Application of a

metal bone plate to the dorsolateral aspect of two or three consecutive vertebral bodies is referred to as vertebral body plating. This technique is limited to the caudal thoracic and cranial lumbar vertebrae because application may require dislocation or removal of any associated rib head and transection of nerve roots (rhizotomy) exiting below the bone plate, precluding its use in the lower lumbar spine.[34]

Dorsal spinous-process plating using plastic (Lubra plate, Lubra Co., Fort Collins CO 80521) or metal (Auburn spinal plate, Richard Manufacturing Co., Memphis, TN 38101) spinal plates has been described as an option to

stabilize dorsal compartment instability in regions with prominent dorsal spinous processes.[30,35,36] This technique has been used extensively but appears to be of limited use on its own. Dorsal spinal plating is most commonly applied in combination with other methods such as transilial pinning and vertebral-body plating to stabilize fractures of the lumbar vertebrae that do not involve the dorsal spinous process or lamina.[30,35,37] Reported complications include fracture of the dorsal spinous processes, ischemia of the dorsal spinous processes as a result of over-tightening, and plate slippage owing to insufficient tightening of the bolts.[30,38] The use of screws or pins

plus polymethylmethacrylate (PMMA) has been described for stabilization of spinal fractures in all locations, including those that are less amenable to ventral compartment fixation such as the thoracic and lower lumbar region.[39-42] This procedure requires minimal instrumentation, however, an excellent knowledge of vertebral anatomy is essential to ensure accurate implant positioning. This technique is compatible with decompressive techniques as long as the surgeon carefully applies and irrigates the PMMA during polymerization. Pins and PMMA, unlike several other stabilization techniques, can be applied even when perfect alignment is not achieved.[2] Stabilization using pins and

PMMA is currently the most popular technique used to stabilize vertebral fractures. External skeletal fixation has been reported for stabilization of lumbar fractures.[43,44] Advantages include that implants are inserted away from the fracture site and that removal of all implants is possible once healing has occurred.[43,44] Again, excellent knowledge of vertebral anatomy is essential to ensure accurate placement of pins into the vertebral bodies; this can be facilitated by fluoroscopic guidance.[45]

Experimental comparison of the biomechanical characteristics of various surgical techniques used to stabilize spinal fractures has been

performed. A drawback of these studies is that they typically evaluate a small number of fixation techniques and cannot be compared with each other because differing methods are used for each evaluation.

It is well accepted that techniques providing stability to both the ventral and dorsal compartments are superior to those that stabilize only a single compartment. When the stability and strength of five internal fixation methods used for lumbar fracture stabilization were compared, vertebral body plating was found to be stronger than all other methods including dorsal spinal plating, pins and methylmethacrylate, and crossed

pins.[46] The combination of dorsal spinous-process plating and dorsolateral vertebral-body plating provides the most rigid and strong repair.[46] Similarly, a more recent study comparing five methods of fixation for thoracolumbar instability reported that the application of vertebral body plates or the combination of pins and PMMA was strongest.[47] A biomechanical study comparing five configurations of pins or bone screws with PMMA for internal stabilization of lumbar instability revealed that 8 pin fixations were more rigid and stronger than 4 pin fixations and that the orientation of the pins impacted on rigidity depending on the number of pins used.[48] Furthermore, this study

revealed that pins were more rigid and less likely to fail than screws.[48] Finally, a study showed that external skeletal fixation has mechanical properties comparable to internal fixation techniques that use a combination of pins and PMMA.[44]

Prognosis and Recovery

Similar to other spinal disorders, the loss of pain perception caudal to the lesion is the single most accurate prognostic indicator when evaluating patients with spinal fracture and/or luxations.[5,16,49] Patients that have no deep pain have less than 50% chance of recovery, and the rate of recovery decreases to less than 5% if pain

sensation has been lost for more than 48 hours.[50] Despite having a positive impact on the prognosis, the presence of pain perception does not guarantee complete neurologic recovery.

Based on previous reports, it appears that the degree of radiographic vertebral displacement does not correlate well with the neurologic status.[2,16] Although survey radiographs are of limited use when trying to determine prognosis in patients with little vertebral displacement, correlations have been made between the degree of radiographic vertebral malalignment and the loss of pain perception caudal to the injury.[16,22] Patients with 80% vertebral

displacement in the thoracic spine and 60% displacement between L1 and L5 do not typically maintain pain perception caudal to the lesion.[16] Caudal to L5, survey radiographs are less helpful in determining outcome because the nerve roots at this level can tolerate significant displacement without severe neurologic dysfunction.[16] In general, vertebral displacement of greater than 80% caudal to L5 is associated with LMN signs.[16] Unlike the cervical and thoracolumbar regions, full recovery is possible in patients with severe vertebral displacement if the lesion is caudal to L5.[16]

Patient recovery is difficult to predict,

although patients that retain pain perception and purposeful movement are likely to recover functional neurologic status. Based on previous reports, the hospitalization time for surgically treated cases tends to be longer than for cases treated conservatively.[3] However, the overall rate of return to a functional neurologic status is similar for both treatment regimens.[2,3]

Chapter 108

Fracture Biomechanics of the Appendicular Skeleton

Ross H. Palmer
Susan P. James

Bone Structure and Function

The purpose of the skeletal system is to protect internal organs, and to provide rigid kinematic links and muscle attachment sites to facilitate body movement. These functions are supported by the unique structural and mechanical properties of bone. Bone is

a hard, tough material, metabolically active, capable of self-repair, and adaptive to the mechanical demands placed upon it.

Like other connective tissues, bone consists of cells and an organic extracellular matrix. Bone is unique among mammalian tissues because of its high content of inorganic mineral salts, primarily calcium and phosphorus. This inorganic mineral accounts for 65 to 70% of bone's dry weight and gives bone its solid consistency and rigidity. The organic extracellular matrix, composed primarily of collagen and, to a lesser extent, proteoglycans, gives bone its flexibility and resiliency. Abundant

amounts of water, which also contribute to bone's flexibility and resiliency, are also present in bone, mostly in the extracellular matrix, but also in the canals and cavities of bone.

Microscopically, bone is composed of multiple osteons or haversian systems (Figure 108-1). In the center of the osteons are haversian canals that form the primary circulatory network in bone. Each osteon consists of concentric layers of mineralized matrix called lamellae that surround the haversian canal. Each osteon is separated from, yet bonded to, surrounding osteons by a cement line composed of a cementing ground substance consisting predominantly of

glycosaminoglycans. Collagen connects one lamella to the next within an osteon, but does not cross from one osteon to the next. Interstitial lamellae, which are of the same material as the osteons but oriented differently, are continuous with the osteons and span regions between complete osteons. In long bones, osteons usually run longitudinally.

Biomechanical Properties of Bone

The fracture behavior of whole bones is influenced by both their material and structural properties. Mechanically, bone behaves as a biphasic, composite material with mineral (hydroxyapatite)

as one phase and the collagen and ground substance as another.[1] Collagen toughens the bone, preventing the stiff mineral from undergoing brittle fracture, and the hydroxyapatite mineral prevents flexible collagen from excessive deformation and increases the bone's elastic modulus (~stiffness) beyond that of collagen alone. Except for minor differences, all bone is formed of identical material. Two distinct macroscopic bone structures observed are cortical (compact) and cancellous (trabecular) bone. The major differences in these two structures of bone are their porosity and structural dimensions. The dense outer shell, or cortex, is made of cortical bone with

5% to 30% porosity. Inside this outer shell, cancellous bone is a fine lattice of thin bony plates with a porosity of 30% to 90% (Figure 108-2).[1] In either case, the hierarchical structure of bone is key to its mechanical performance and multifunctionality.[2] For example, bone's excellent toughness (energy-absorbing capability) is due in part to its hierarchy from the level of the amino acid sequence in collagen and the coiled-coil structure of collagen up through the various haversian, lamellar, and other intermediate-sized structures, to the more macroscopic cortical shell around cancellous bone structures. The large surface area resulting from all the interfaces and levels of hierarchy enable bone to

absorb energy as these interfaces, which are widely distributed throughout the structure, fail.

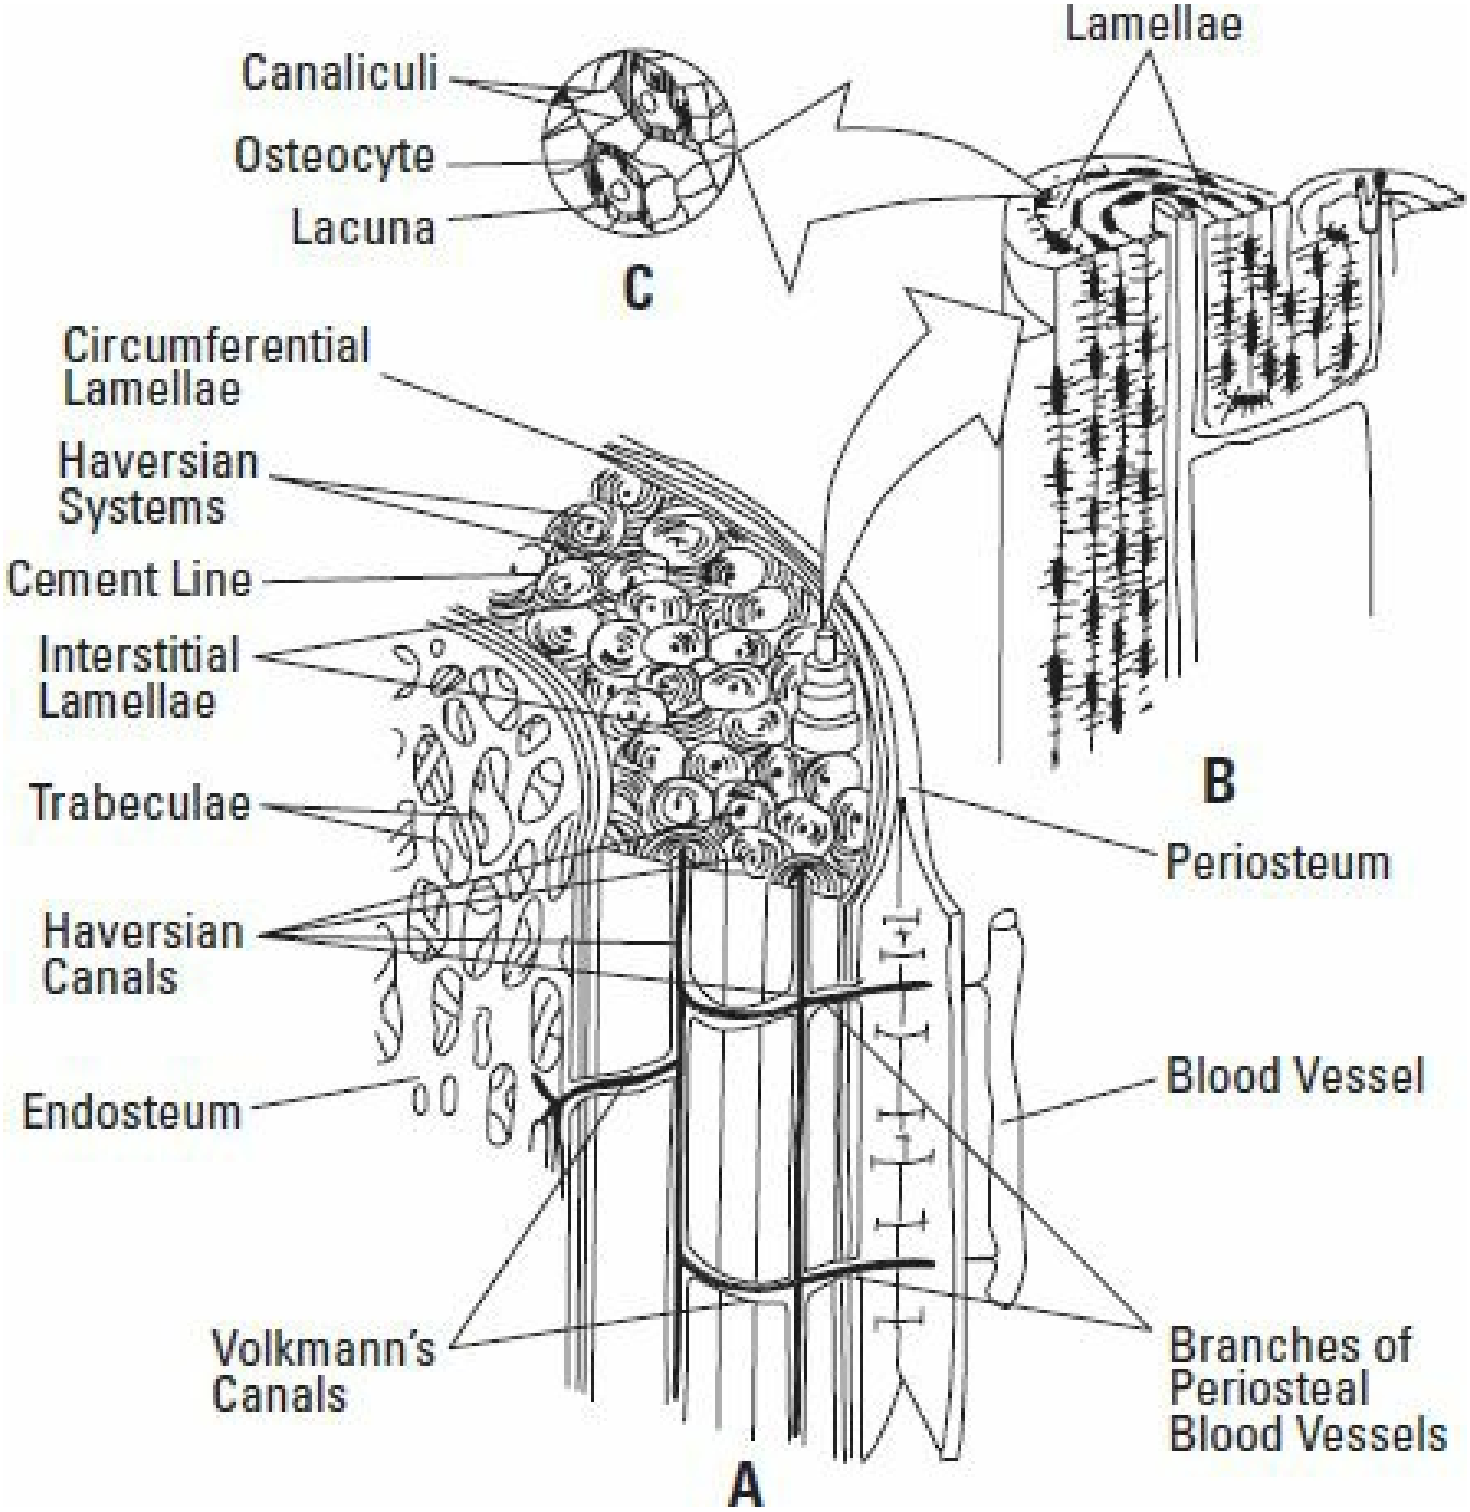

Figure 108-1. Schematic illustration of the fine structure of a section of long bone depicting multiple osteons (also called haversian systems) as the structural units. Haversian canals at the center of each osteon form the primary circulatory network. Each osteon consists of concentric lamellae interconnected by collagen. Each osteon is distinct from, yet bonded to surrounding osteons, by a cementing ground substance. Note the longitudinal orientation of the osteons.

The mechanical performance of whole bones, as for any structure, is understood by measuring its deformation under the influence of externally applied forces. As increasing loads are applied to a bone, it begins to deform until finally, failure occurs. Deformation is the measured change in dimensions of the structure under conditions of known loads and can be plotted on a load-deformation curve

(Figure 108-3).[1,3-5] Much can be revealed about a structure (such as a whole bone) by study of its load-deformation curve. Under conditions of low-level loading, a structure typically deforms in direct relation to the load applied. This linear portion of the curve is called the elastic region and reveals the elasticity of the structure, because when the load is removed the structure returns to its original shape. The point at which the applied load causes permanent deformation of shape is called the yield point. Living bone loaded to this degree will sustain microstructural damage. As applied load exceeds the yield point, the structure exhibits plastic behavior, revealed in the load-deformation curve

between the yield point and the ultimate failure point. This region of the curve is called the plastic region and removal of applied loads at this point will no longer allow the structure to return to its original dimensions (structural damage has occurred). If loading is progressively increased, the structure will fail at some point (gross bony fracture), which is indicated by the ultimate failure point on the curve.

Figure 108-2. Longitudinal section through the proximal end of an adult canine femur. A shell of

cortical bone surrounds a fine lattice of cancellous bone. Note how cancellous bone is concentrated in the irregularly shaped epiphyseal and metaphyseal segments and diminishes in the more regularly, cylindrical, thick-cortical diaphyseal segment.

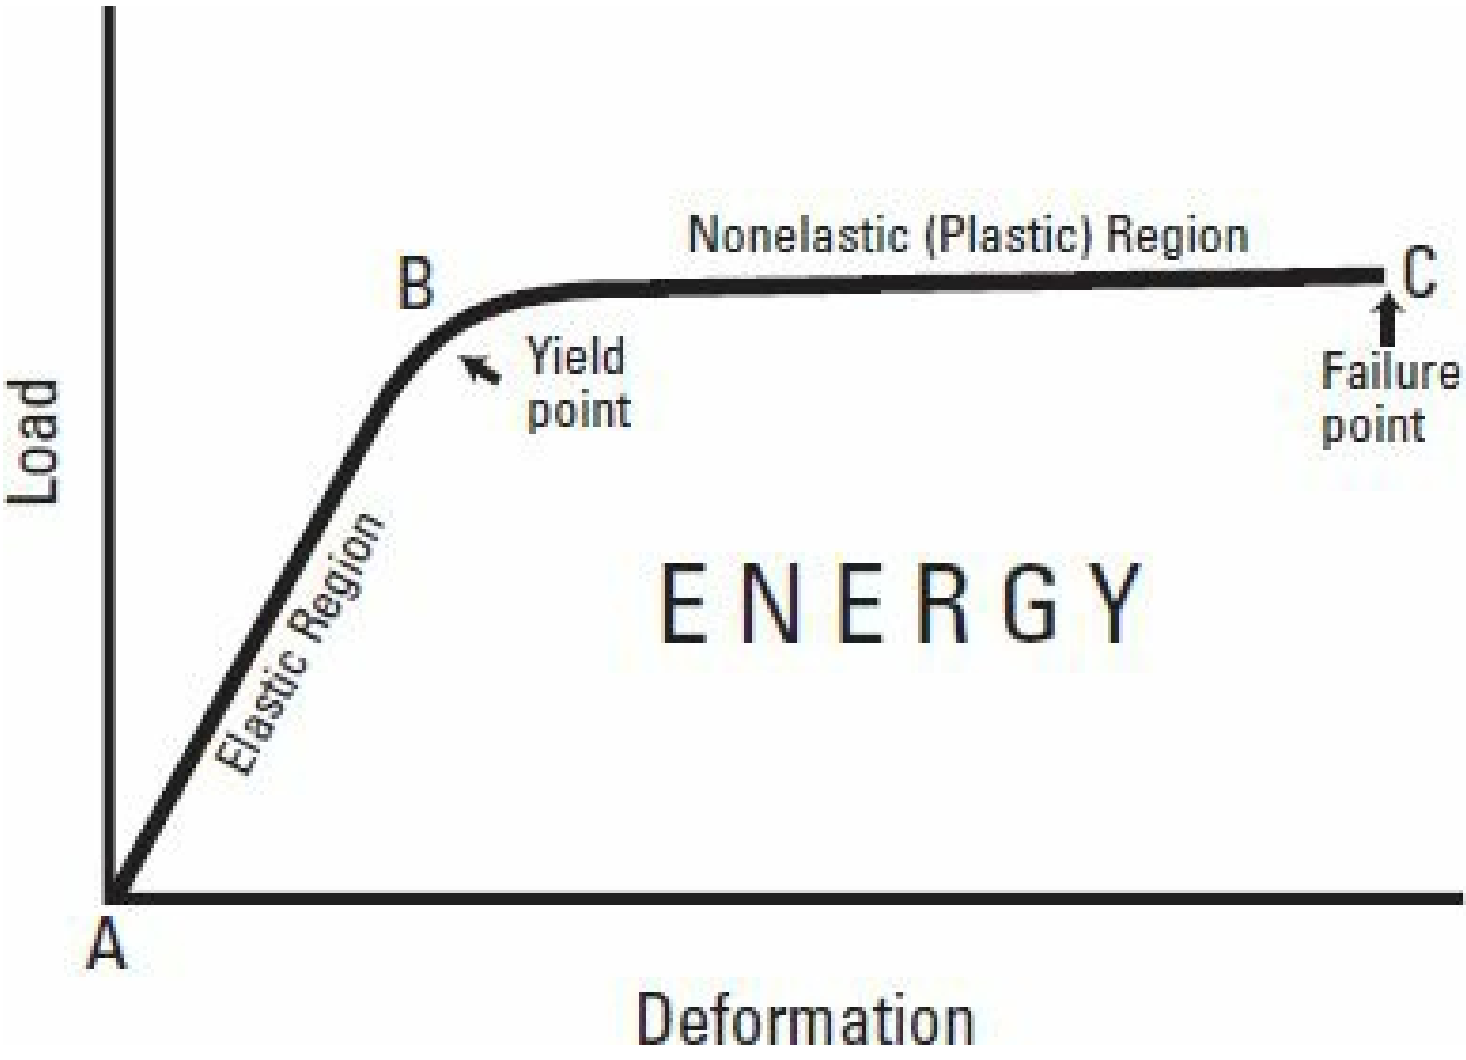

Figure 108-3. A theoretical load-deformation curve for a whole bone. Under conditions of low-level loading (elastic region, A-B), the structure deforms in direct relation to the applied load and returns to its original shape when the load is removed. Loading past

the yield point (B) induces permanent deformation of shape (plastic region, B-C) even when the load is removed. If loading is progressively increased, the bone will grossly fail (fracture) at the ultimate failure point (C). The slope of the elastic region of the load-deformation curve indicates the stiffness of the studied bone. The area under the curve indicates the amount of energy absorbed by the bone prior to failure.

Functionally, two of the most important structural properties of bone are its stiffness and its load-bearing capacity. The stiffness of a structure is indicated by the slope of the elastic region of its load-deformation curve. The steeper the slope is, the stiffer the structure. Three parameters are typically used to determine the load-bearing capacity of a structure: (1) the load that the structure can sustain

before failing (ultimate load), (2) the deformation that the structure can sustain before failing (ultimate deformation), and (3) the energy absorbed by the structure prior to failure. The energy-absorbed-to-failure is measured as the area under the load-deformation curve and, because it is indicative of both the load and deformation-to-failure, it provides an approximate measure of the toughness of the bone. These structural properties, from analysis of a load-deformation curve, depend on both the material composition and the dimensions of the tested bones. As an example, a large femur from a Rottweiler and a small femur from a Chihuahua are loaded in torsion to the

point of gross fracture (Figure 108-4). The larger Rottweiler femur deforms less at a given load and fractures at a larger ultimate load than does the smaller Chihuahua femur. Since both bones were from mature, healthy, nonosteoporotic animals, one can assume that the material composition of both bones is then similar. Thus, the observed differences in structural properties can be attributed to the larger size (larger outer diameter and thicker cortical wall) of the Rottweiler femur.

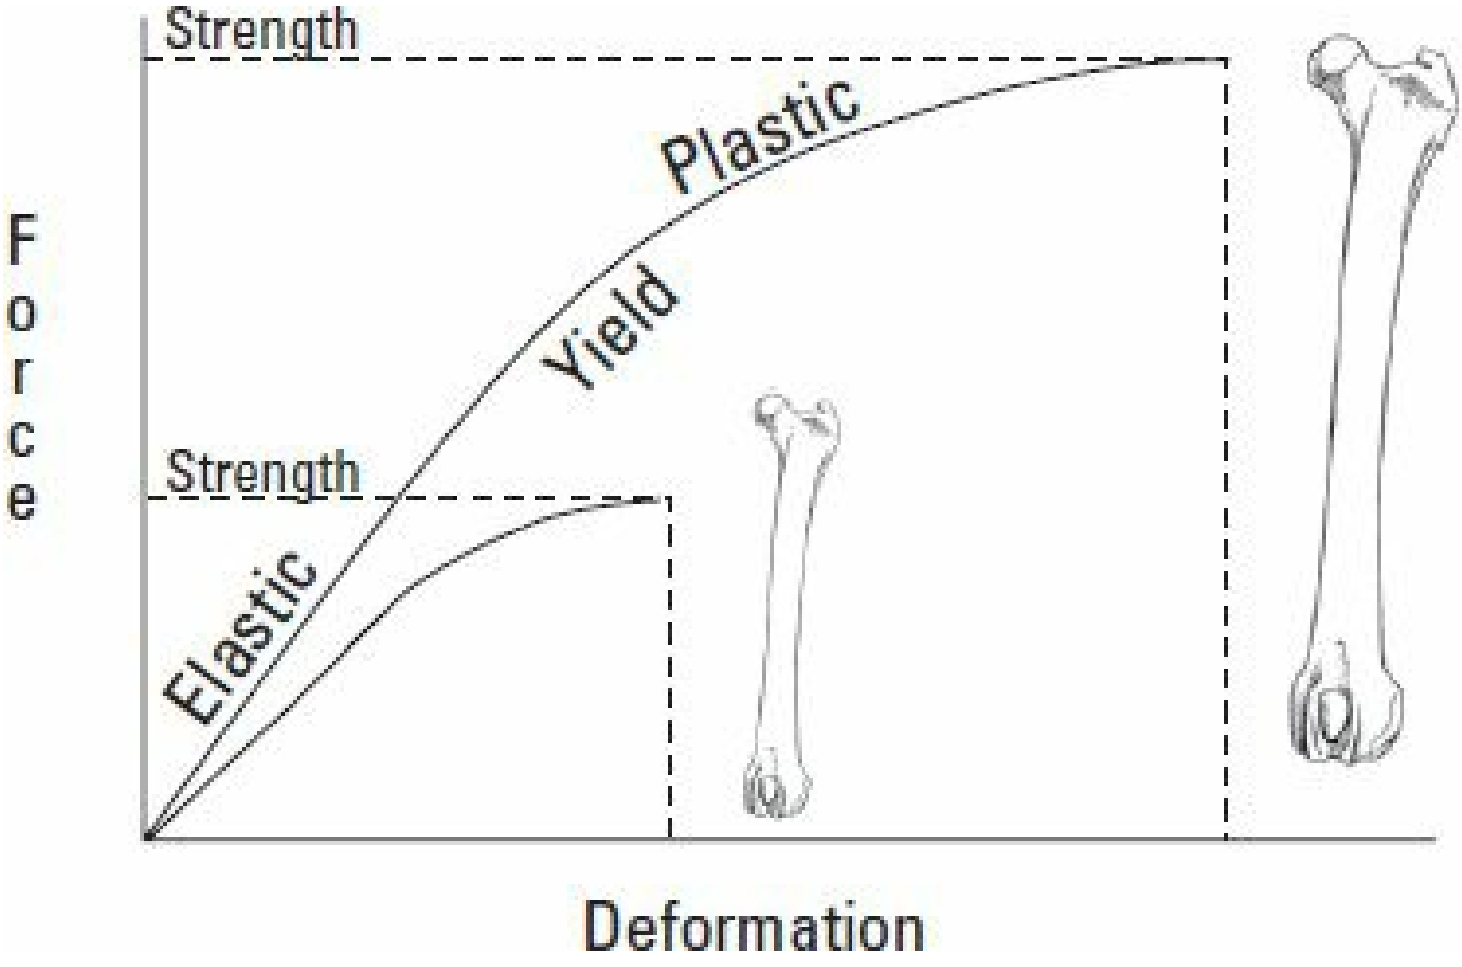

Figure 108-4. Idealized load-deformation curves for femora from a Rottweiler and a Chihuahua tested under torsion. The larger Rottweiler femur deforms less at given load (is stiffer) and fractures at a larger ultimate load (is stronger) than the smaller Chihuahua femur. Since both bones were from mature, healthy, non-osteoporotic animals, one can assume that the material composition of each bone is similar. Thus, the observed differences in mechanical behavior of each bone are attributed to structural differences (outer diameter, cortical thickness, etc).

The length of the bone, the cross-sectional area, and the distribution of bone about the neutral axis (cross-sectional shape) are important geometric dimensions that influence these whole bones' biomechanical behavior under various loading conditions. When the geometric dimensions of these whole bones are normalized, most often by testing simple-geometry samples of material cut from the bone, the load-deformation curve from mechanical testing can be converted to a stress-strain curve.[1,3-5] Bones of similar composition, like the Rottweiler and Chihuahua femurs above, have similar biomechanical characteristics as expressed in a stress-strain curve

(Figure 108-5). Thus, whereas a load-deformation curve reveals properties of structure and material composition, a stress-strain curve reveals the biomechanical properties of a material (independent of geometric dimensions). Stress is defined as load (or force) divided by cross-sectional area, and the units most commonly used for measuring stress in standardized samples of bone are Newtons per centimeter squared (N/cm^2) or Newtons per meter squared (N/m^2). One N/m^2 is equivalent to one Pascal (Pa). Because Pascals are a small unit of measure with regard to bone testing, multiples of this unit are often employed including the kilopascal ($1kPa = 1 \times 10^3$ Pa), the

megapascal (1mPa = 1 x 10^6 Pa), and the gigapascal (1gPa = 1 x 10^9 Pa). Bone typically fails at stresses in the megapascal range.[6]

Strain is the deformation (change in dimension) that develops in response to externally applied loads, divided by its original dimension. The two basic types of strain are linear (or normal) strain, in which a stress that is applied perpendicular to the test axis of an object causes a change in length of the specimen, and shear strain in which a stress applied parallel to the test axis of an object causes a change in angular dimension within it (Figure 108-6).[1,3-5] Linear strain is measured as the amount of linear deformation

(lengthening or shortening) of the specimen divided by its original length and is, therefore, expressed as a dimensionless number or percentage (e.g., 1cm/10cm = 0.1 strain or 10% strain). Often, although not necessarily, the units are listed (e.g., cm/cm) for clarification. Shear strain is measured as the amount of angular change in a right angle lying in the plane of interest within a specimen and is expressed in radians (1 radian equals approximately 57.3 degrees).

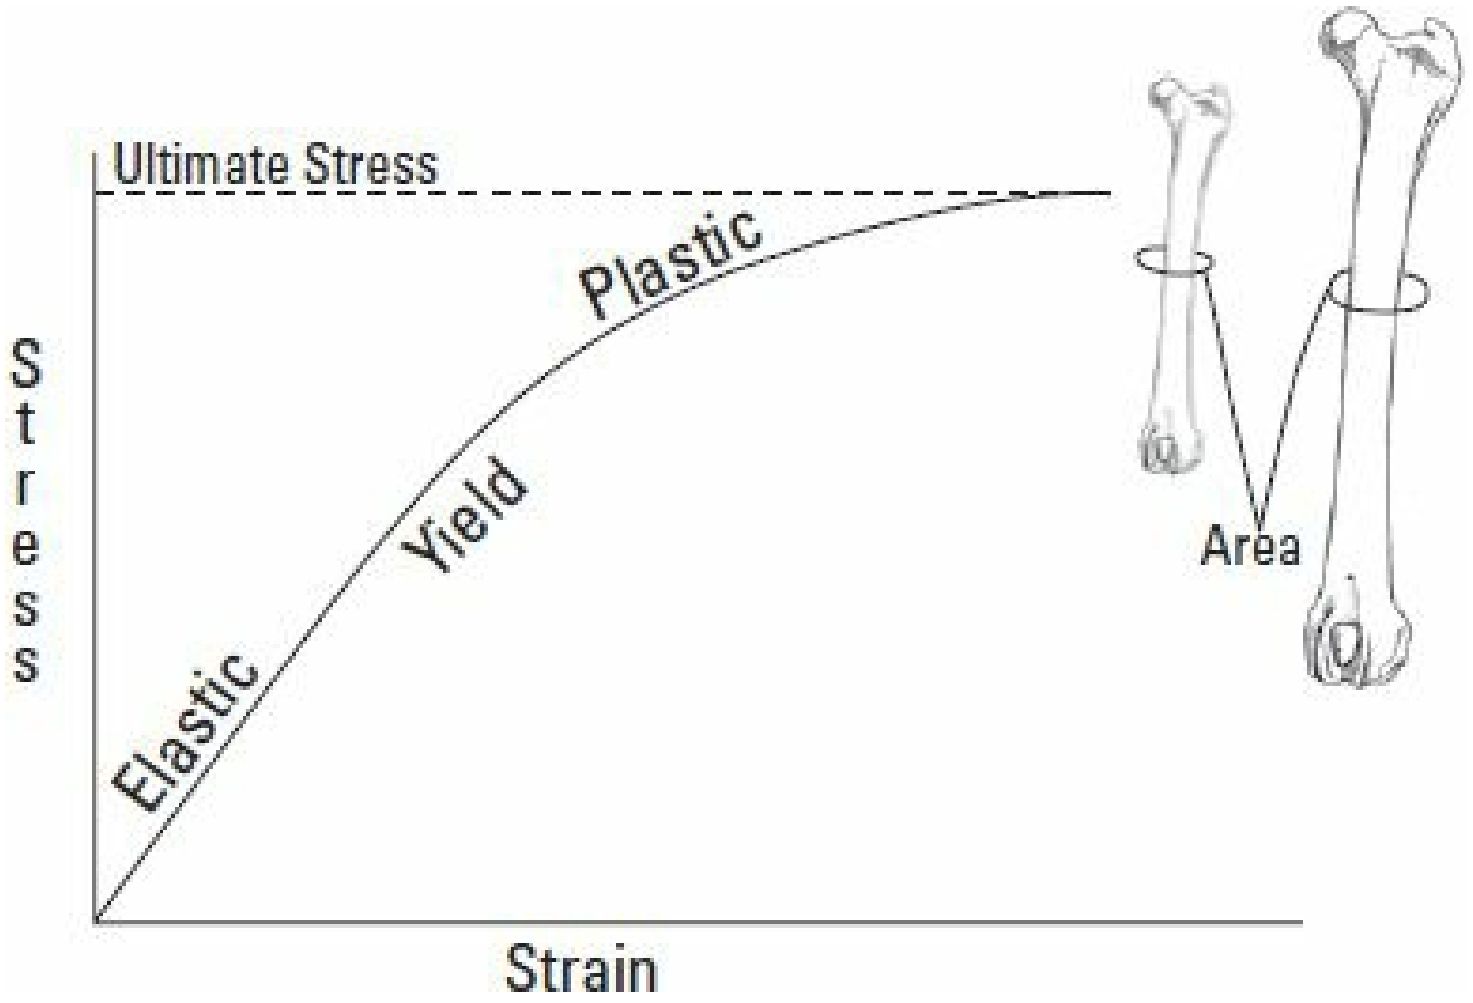

Figure 108-5. Idealized stress-strain curves for simple normalized samples harvested from femora from a Rottweiler and a Chihuahua tested under torsion reveal biomechanical properties of the bones' material (independent of geometry). Stress is the load divided by the cross-sectional area of the specimen. Strain is the measured change in dimension under the externally applied load, divided by its original dimension.

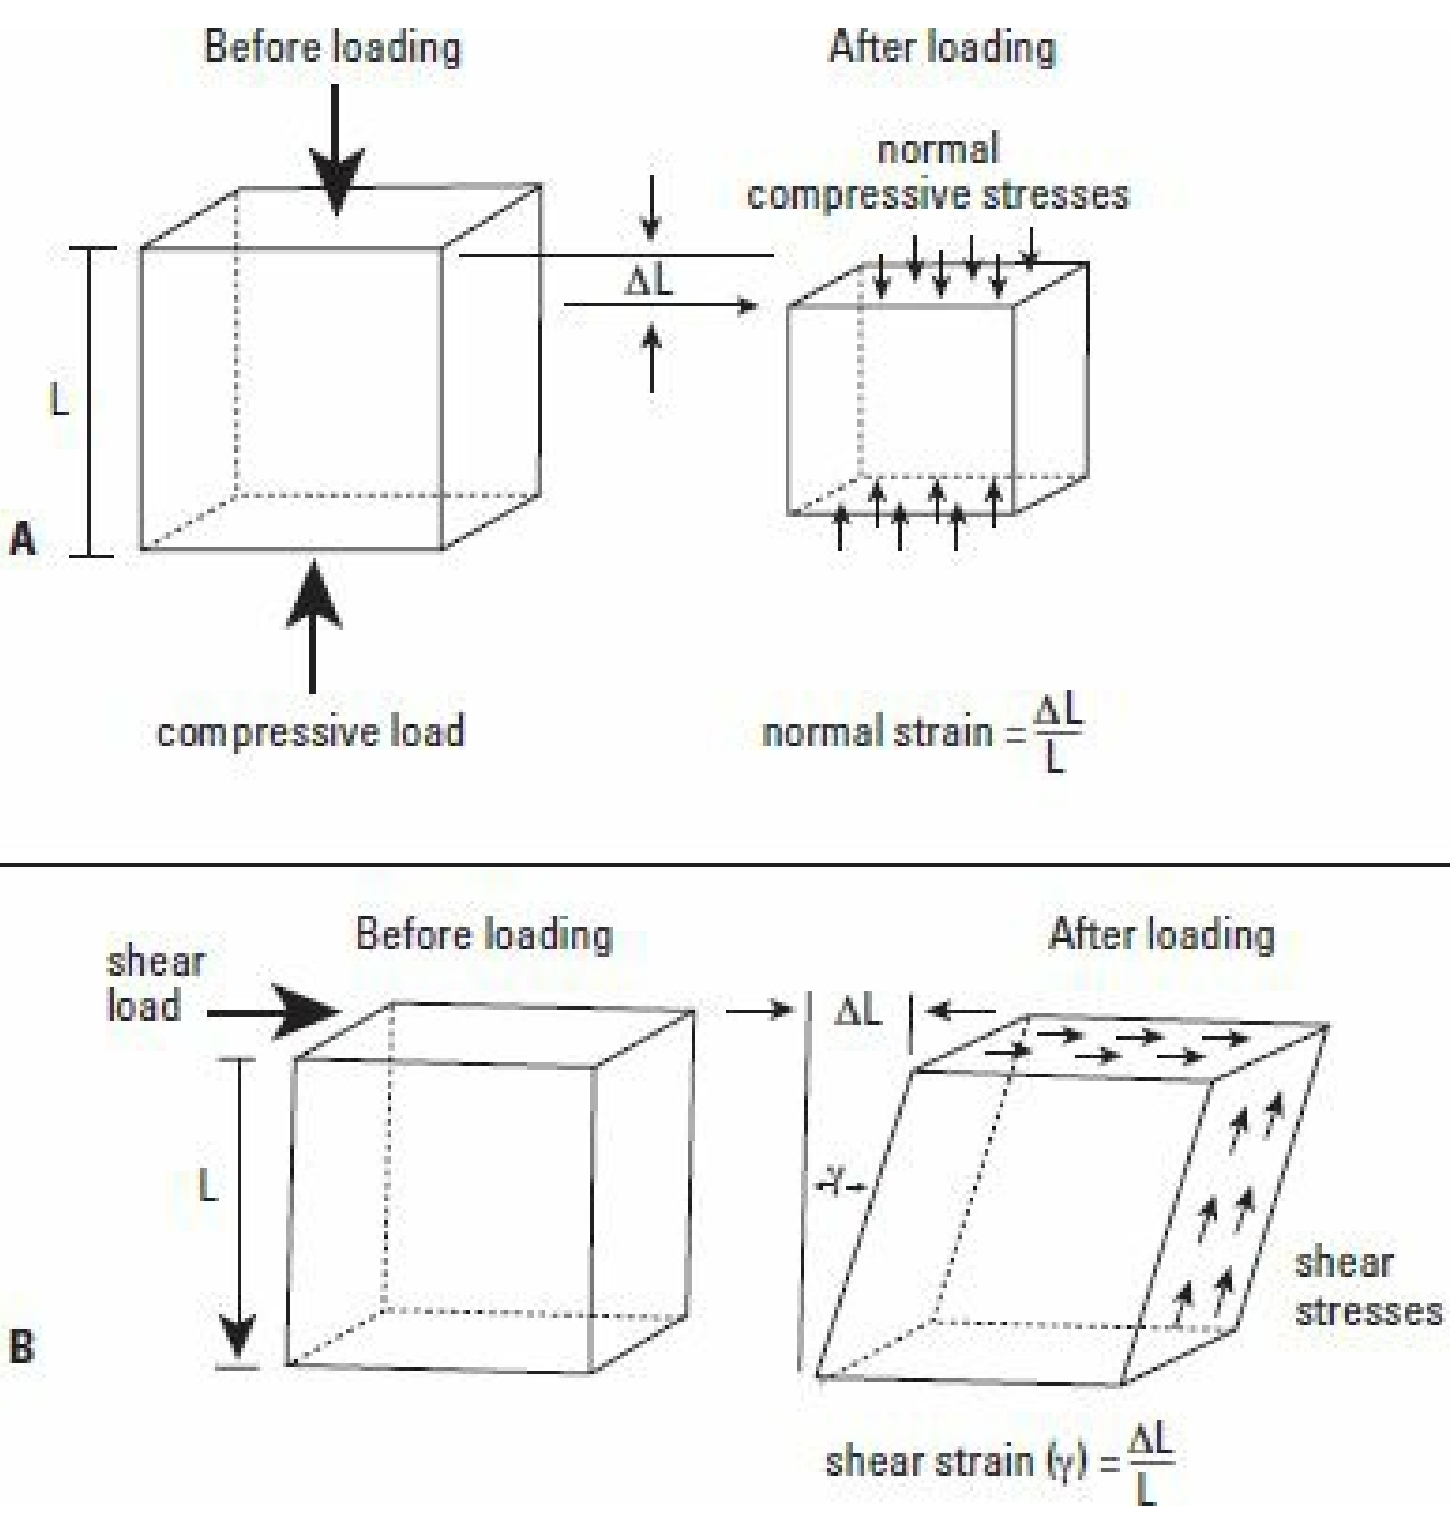

Figure108-6. A. Loading of bone perpendicular to a surface (compressive or tensile force) induces normal stress and strain within the sample. Linear strain is measured as the linear deformation (shortening or lengthening) of the specimen divided by its original

length, often expressed as a percentage. B. Loading of bone parallel to a surface causes one part of the bone to slide past an adjacent part, resulting in shear stress and strain within the sample. Shear strain is measured as the amount of angular change in a right angle lying in the plane of interest within the specimen, and is expressed in radians.

A stress-strain curve can be produced by placing a standardized specimen of bone tissue into a testing jig and then loading it to failure in tension, compression, shear, or bending (see Biomechanics of Bone Fracture section further in the chapter for definitions of these loading regimens). The regions of this curve are similar to those of a load-deformation curve in that the curve has elastic and plastic regions, a yield point, and an ultimate failure point. The slope of the linear elastic

region of a stress-strain curve is referred to as the elastic modulus or Young's modulus of elasticity. Stiffer materials have a higher Young's modulus.

Mechanical Behavior of Bone

The fracture behavior of bone is influenced by its viscoelastic, anisotropic, and heterogeneous properties. Materials such as bone, the stress-strain behavior of which is dependent on the rate of loading, are viscoelastic.[1,3-5] If bone is loaded at a high rate, such as occurs with vehicular trauma or gunshot injury, its stiffness (Young's modulus), ultimate strain,

and energy-to-failure increases (Figure 108-7). The clinical significance of the high toughness of healthy bone is that, if a high-rate loading actually causes macroscopic failure or fracture, as opposed to just distributed microscopic interfacial failures, the large release of the absorbed energy will cause marked comminution and injury to surrounding soft tissues.[7] Bone is also an anisotropic material, meaning that its strength and stiffness are dependent on the orientation of the applied load relative to the bone's microstructure and macrostructure (Figure 108-8).[1,3-5]

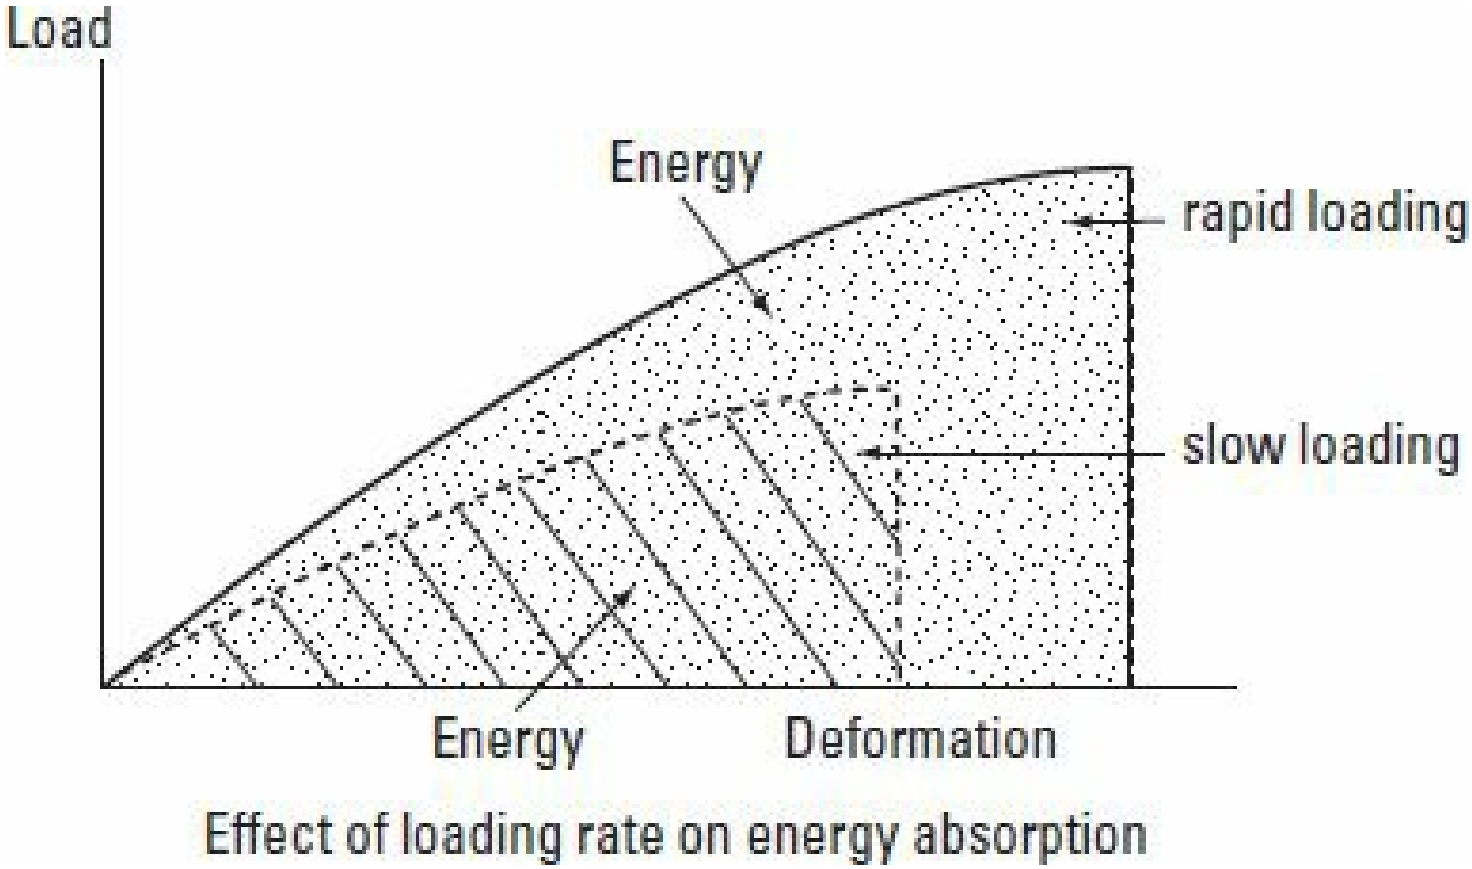

Figure 108-7. Viscoelasticity of bone. Idealized stress-strain curves depicting the effect of rate of load application on bone's stiffness and ultimate strength. The energy absorbed by the bone prior to fracture (area under the curve) is greater when it is rapidly loaded. Much of this absorbed energy is released to the surrounding soft tissues on gross fracture.

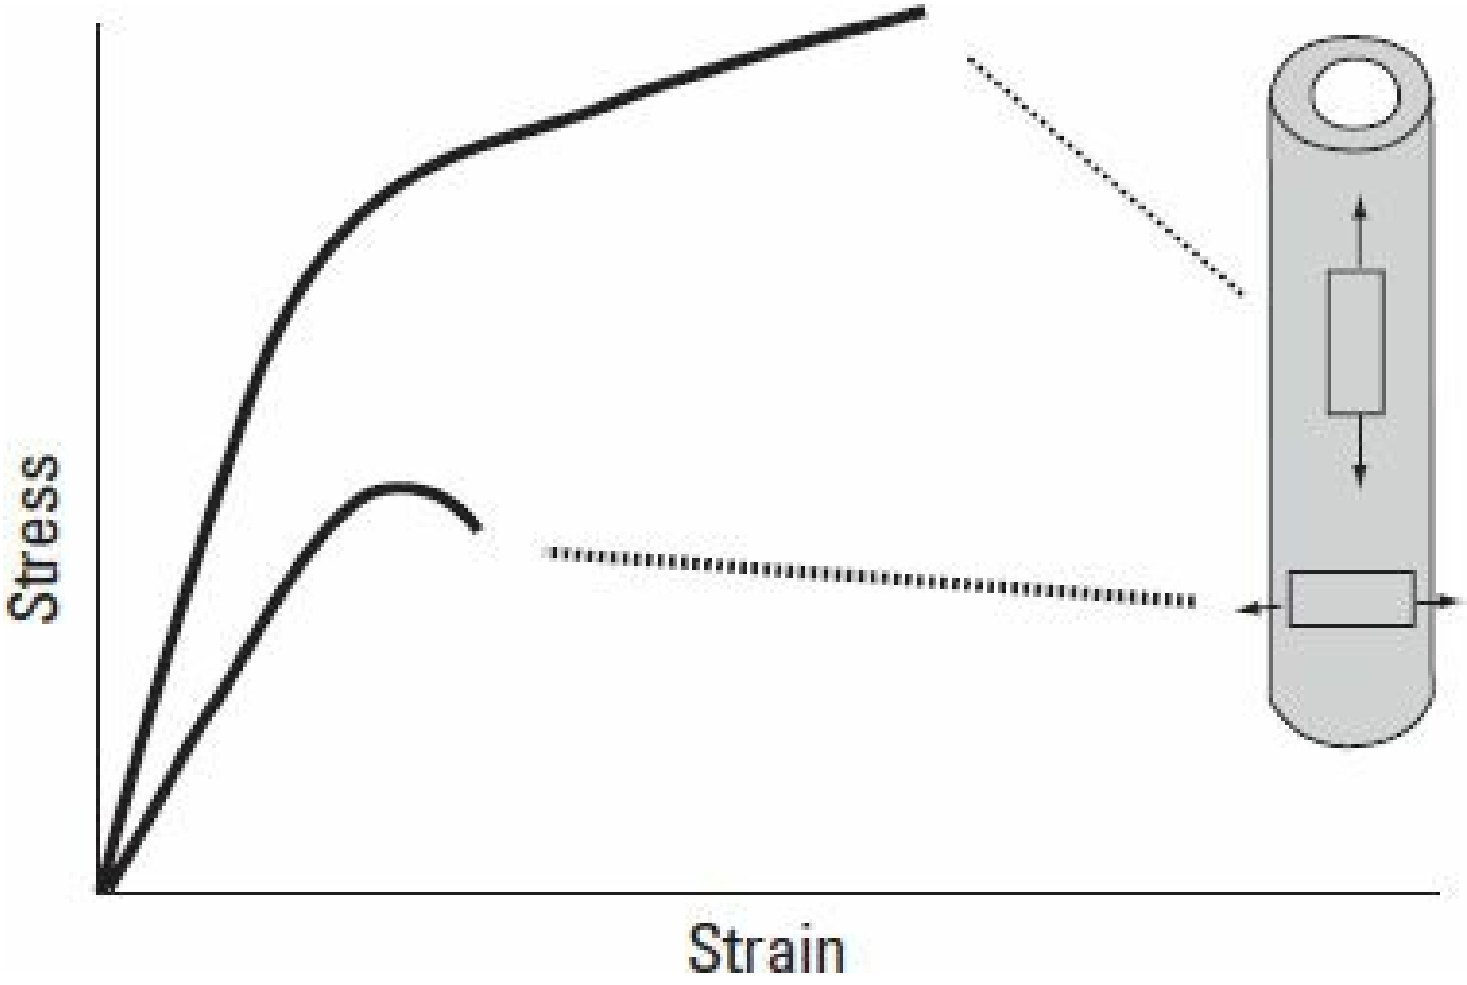

Figure 108-8. Idealized stress-strain curve depicting the anisotropic behavior of bone. Harvested samples are tested in tension in two different orientations: (a) with the longitudinal axis (parallel to the osteonal orientation) and (b) perpendicular to the longitudinal axis.

Cortical bone is stiffest and strongest when loaded parallel to osteon long axis, rather than perpendicular to the

osteon long axis. Thus, long bones are better able to resist loads applied parallel to their long axis (compression and tension) than loads applied perpendicular to their long axis (shear). As predicted by Wolff's law, bone is generally stronger and stiffer in the direction in which the greatest loads are most commonly imposed (e.g., the long axis of the femur).[8,9] Being a heterogenous structure, the mechanical properties vary within a given bone. Porosity has a profound effect on the compressive stress-strain behavior of bone (Figure 108-9). Porosity is the volume of bone occupied by nonmineralized tissue.[4,5] Apparent density, a related measurement, is the mass of bone

tissue divided by the bulk unit volume of bone tissue including mineralized bone and marrow space. Apparent density of bone is directly related to its inorganic mineral content. Cortical bone is composed predominantly of inorganic mineralized matrix and, therefore, has a higher apparent density and a lower porosity (varying from 5 to 30%) than cancellous bone.[1,4,5] In contrast, cancellous bone has a lower apparent density and a higher porosity (ranging from 30 to 90%) than does cortical bone.[1,4,5] Under compressive stress, cancellous bone behaves similarly to other porous materials. Under low levels of stress, cancellous bone exhibits elastic behavior. Then, after its yield point is

reached, progressive collapse of trabeculae produces a long plateau in the plastic region of the curve. With continued compression, compaction of the compressed trabeculae causes an increase in material stiffness until its ultimate failure point is reached. Under compression, highly porous cancellous bone is capable of absorbing significant amounts of energy and tolerating up to 7% strain prior to failure.[4,10] Conversely, cortical bone with its low porosity, has a more brittle behavior under compressive stress, similar to glass. Cortical bone, which undergoes little plastic deformation prior to failure, absorbs less energy and tolerates little strain ($< 2\%$) before fracture as compared

with cancellous bone. However, cortical bone has greater ultimate strength and increased stiffness and can tolerate more stress prior to fracture than can cancellous bone.[4,10,11]

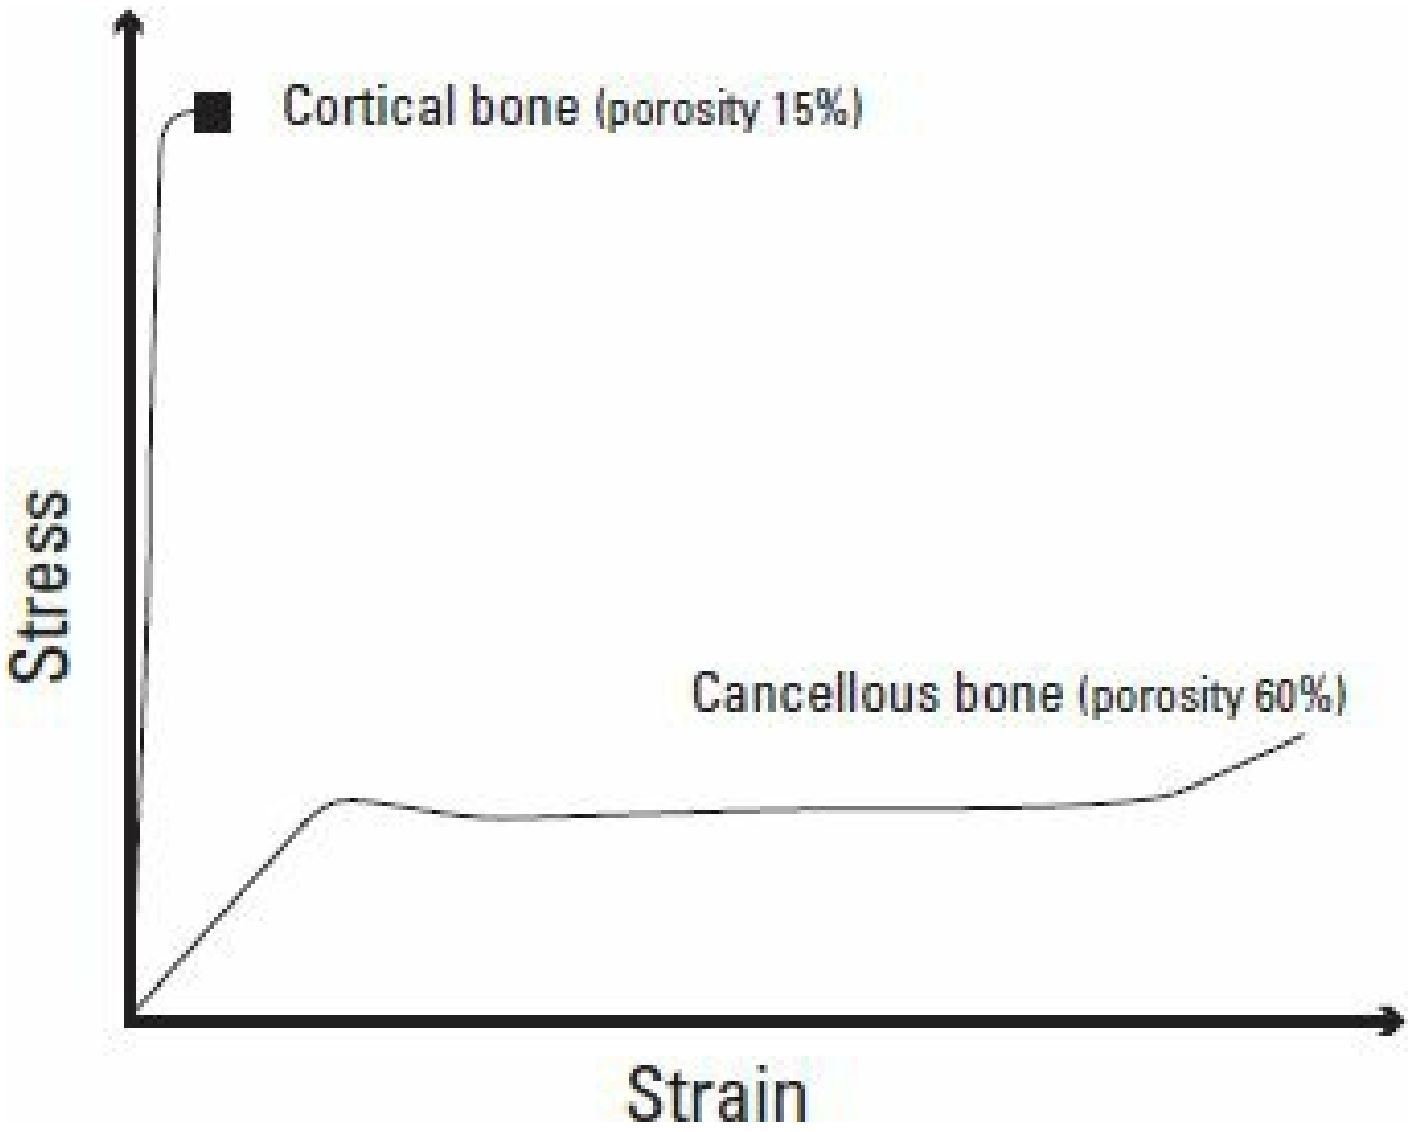

Figure 108-9. Idealized compressive stress-strain

curve of cortical and cancellous bone samples depicting the effect of bone porosity on bone's mechanical behavior. Note that porous cancellous bone exhibits elastic behavior prior to its yield point. Following yield, progressive collapse of the bony trabeculae produces a long plateau of plastic deformation followed by a region of increased stiffness as the fractured trabeculae are compressed. This behavior allows cancellous bone to absorb great amounts of energy and tolerate significant strain prior to failure. Conversely, cortical bone, with its low porosity, displays brittle behavior where it is capable of tolerating great amounts of stress in the elastic region of the curve, but then fails abruptly.

There are many clinical implications of the relationship between bone's apparent density and its mechanical behavior. Large changes in tissue strength and modulus of bone can result from small changes in its apparent density. In the clinical setting this is important because changes in

apparent density may not be evident on radiographs until it is altered by 30% to 50%.[4,5] Thus, minor reduction in bone density detected on radiographs is associated with greatly reduced stiffness and strength. Conversely, greatly enhanced fracture zone stiffness and strength may be present when even the most minor increases in fracture zone density are detected on radiographs.

Functional Structural Design of Long Bones

Another clinical implication of the relationship between bone porosity and its mechanical behavior is that it allows the clinician to better

understand the functional design of long bones. Long bones are supremely designed structures well suited to their function as rigid kinematic links. The distinction between the mechanical behaviors of cancellous and cortical bone comes into play during weight bearing, as the ends of long bones must be able to absorb the tremendous compressive stresses and energy of weight bearing and distribute these to the diaphysis. The relatively high content of porous cancellous bone in the epiphyseal/metaphyseal regions provides bone with this unique capability. Further, the expanded cross-section of many bone ends provides additional strength and stiffness in compression because these properties

are proportional to the cross-sectional area of bone. In contrast, both the cross-sectional area and the distribution of bone tissue about the neutral axis affect a structure's resistance to bending and are quantified in the structural parameter called the *area moment of inertia* (AMI). In bending, one side of the bone experiences tension and the other side compression. No stresses or strains are produced at the neutral axis (Figure 108-10).

Bone oriented further from the neutral axis is better able to resist bending loads. This is why an I-beam is an efficient structure for resisting bending forces applied in one direction (within

the plane of the height of the beam). When bending is applied within the opposite plane, however, the AMI (and thus bending stiffness) of the I-beam decreases dramatically. Diaphyseal bone, on the other hand, must endure a complex array of bending moments in many directions as a consequence of varied activities, terrains, and muscular contraction. Thus, the cylindrical shape of the diaphysis of most long bones affords resistance to bending moments in all directions (the AMI of a cylinder is proportional to the radius raised to the 4th power). The tubular shape (versus a solid cylinder) of diaphyseal bone distributes much of the bone tissue at a distance from the neutral axis, thus providing

considerable resistance to bending (and torsion) with a minimum of bony mass. The factors that affect bone strength and stiffness in torsion are the same as for bending, the cross-sectional area, and the distribution of bone around the neutral axis. The polar moment of inertia (PMI) is used to calculate a structure's resistance to torsion. The larger the PMI is (which for a cylinder is also proportional to the radius raised to the 4th power), the stronger and stiffer the bone is against torsional moments.

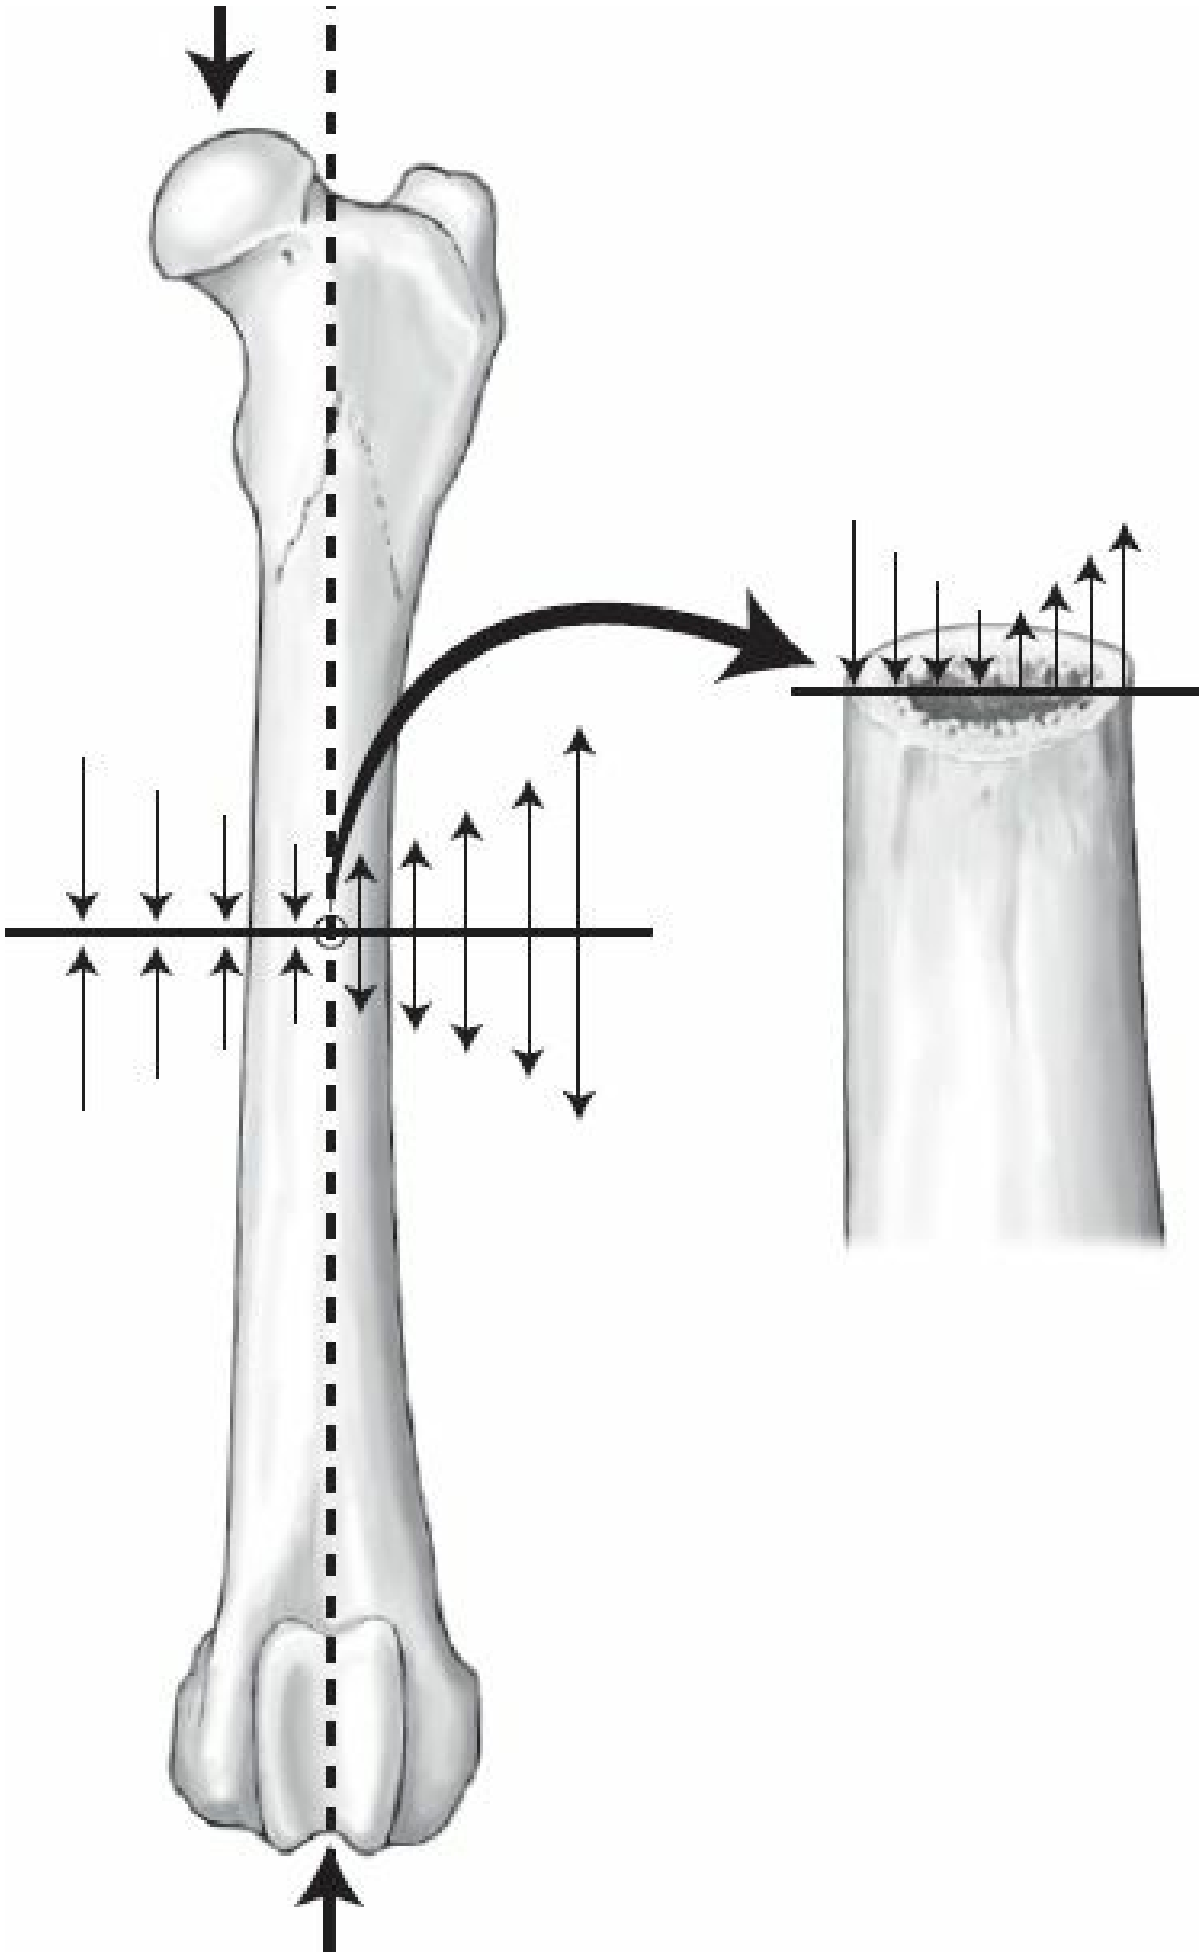

Figure 108-10. During weight-bearing, load applied to the femoral head produces bending forces at the femoral diaphysis. Here, the concave medial side experiences compressive stresses and strains while the convex lateral side experiences tensile stresses and strains. Because the magnitude of these stresses is proportional to their distance from the neutral axis of the bone, the neutral axis is subjected to neither tensile nor compressive stresses and strains.

Biomechanics of Bone Fracture

Bones are subject to physiologic and non-physiologic forces. Physiologic forces are generated through weight-bearing and muscular contraction. Physiologic forces that are applied in a uniaxial direction (compression or tension) can give rise to torsional or bending moments in bone. Physiologic

forces rarely exceed the yield point of healthy bone, or in other words they do not cause plastic (permanent) deformation of bone. On the other hand, non-physiologic forces are the result of some externally applied load (vehicular trauma, horse kick, fall from deck or pickup truck bed, gunshot) and may easily exceed the yield point and load-bearing capacity of bone, creating a fracture. Forces and moments applied to bone in various directions can produce tension, compression, bending, shear, and torsion (Figure 108-11). Bone in vivo is subjected to all these loading modes.

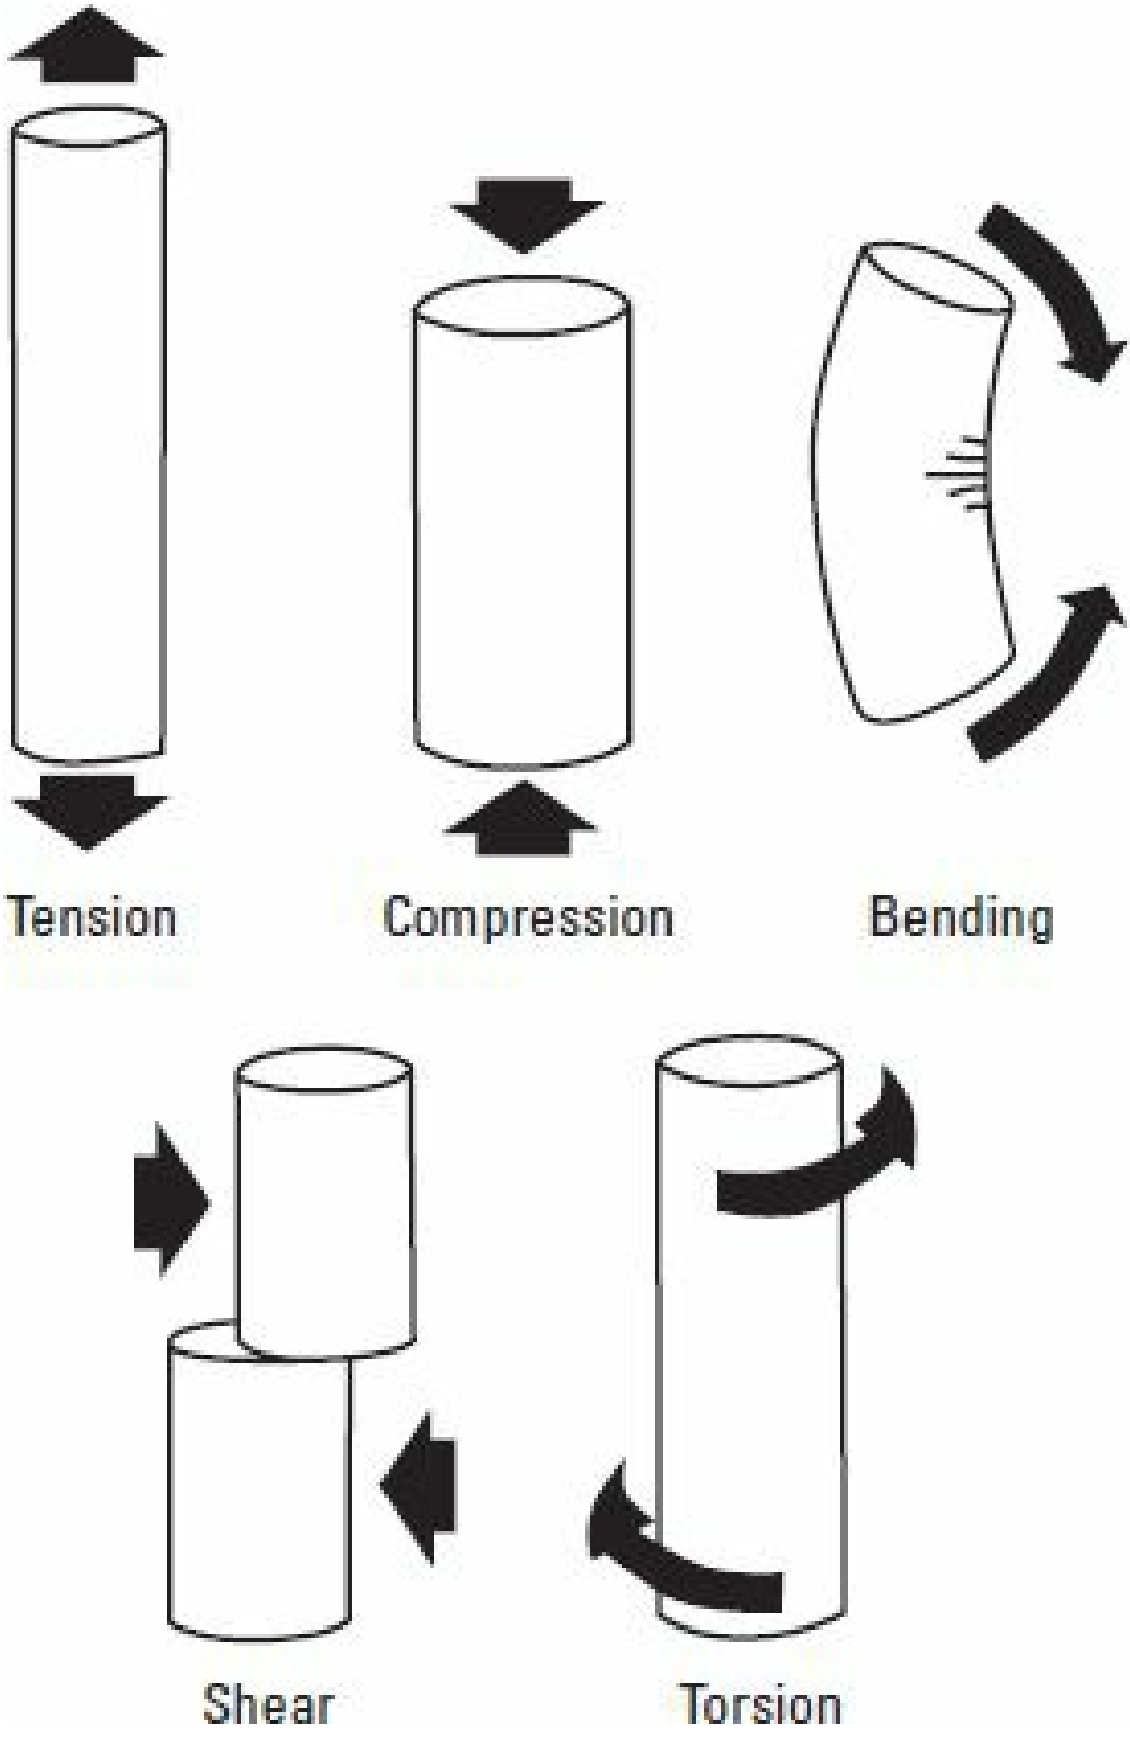

Figure 108-11. Schematic illustration of tensile, compressive, bending, shear, and torsional loading

modes.

Compression

During compressive loading, equal and opposite loads are applied toward the center of the structure and parallel to the axis of the structure, causing compressive stress and strain within the bone (Figure 108-12A). Compressive loads cause most structures to shorten and widen. Maximal compressive stress occurs on a plane perpendicular to the applied load and can be thought of as many small forces directed toward the center of the bone that could potentially compact or crush the bone. Intuitively, one might expect compression

fractures to develop perpendicularly to the applied compressive load and to crush or buckle the bone much like an empty soda can that is stepped on. However, compression loading also produces internal shear stresses and strains that develop oblique to the longitudinal axis and are maximal on a plane 45° from the axis of compressive loading.[1,3-5] Microscopically, the failure of bone loaded under compression is usually oblique cracking of the osteons created by these internal shear stresses, generated partly because of the bone's anisotropy and the fact that bone is weaker in shear than in compression. These oblique fracture configurations produced by compressive loading are commonly

seen clinically with jump-down injuries of the tibia and radius (bones that are loaded along their central axis).[3,4]

Tension

During tensile loading, equal and opposite loads are applied away from the center of the structure, causing tensile stress and strain within the bone. Under tensile loading, most structures lengthen and narrow (Figure 108-12B). Maximal tensile stress occurs on a plane perpendicular to the applied load and can be thought of as many small forces directed away from the center of the bone that could potentially distract or pull apart the bone. Microscopically, the failure

mechanism of bone loaded in tension is mainly debonding at the cement lines and other interfaces and pulling out of the osteons.[1,3-5] Grossly, bone tends to fail within a plane that is oriented perpendicularly to the applied tensile force. Clinically, fractures produced by tensile forces are typically at traction apophyses such as the tibial tuberosity, olecranon, tuber calcis, and attachment sites for ligaments.

Shear

During shear loading, equal and opposite loads are applied parallel to the surface of the bone, with the shear forces acting in opposite directions on opposing surfaces, causing shear stress

and strain within the bone (Figure 108-12C). Under shear loading, a structure deforms in an angular manner (right angles within the structure are deformed to acute or obtuse angles). Shear stress can be thought of as many small forces acting on the surface of the bone on a plane parallel to the applied load. Not so intuitive is the observation that a geometrically complex and microscopically heterogenous structure loaded in compression or tension experiences internal shear stress (Figure 108-12A and B). Bone is weakest when subjected to shear stresses and tends to fracture in metaphyseal regions rich in cancellous bone along the lines of maximal shear stress.[1,4,5] A clinical

example is the fracture of the lateral aspect of the humeral condyle that develops when a cocker spaniel falls from a height and lands on his thoracic limbs. The compressive load applied from the radial head to the lateral aspect of the humeral condyle produces shear stress in excess of the ultimate shear strength of the humeral condyle and lateral epicondylar crest, creating fracture in these structures.

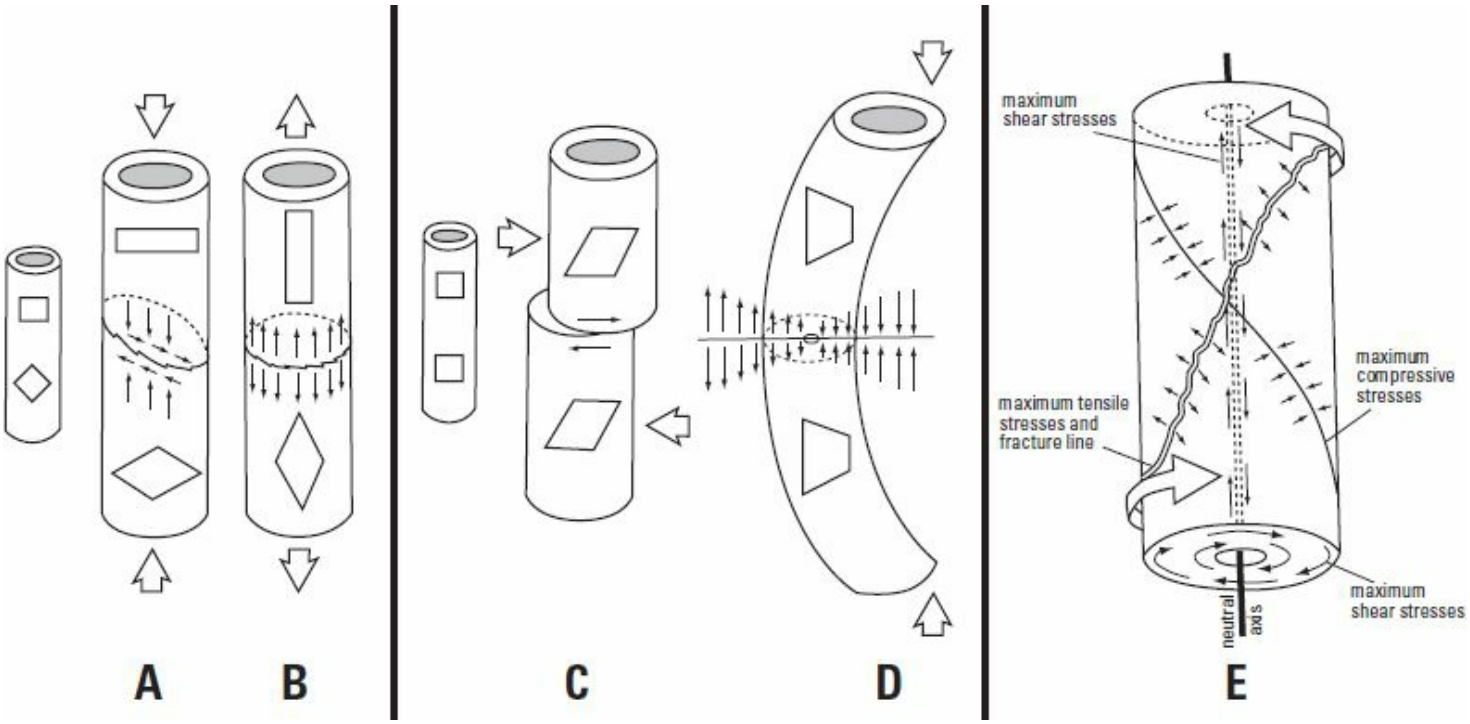

Figure 108-12. Illustration depicting stresses and strains produced by various loading modes on a cylindrical long bone. A, Compressive loading induces compressive and shear stresses and strains that, if excessive, may induce a short oblique fracture. B, Tensile loading induces tensile stresses and strains, which if excessive, induce a transverse fracture. C, Shear loading induces internal shear stresses and strains causing angular deformations. D, Bending loading induces tensile stresses and strains along the convex surface and compressive stresses and strains along the concave surface. There is a continuous gradient from maximal tensile stress, to neutral, to maximal compression. E, Torsional loading induces shear, tensile, and compressive stresses and strains, which if excessive, produce a typical spiral fracture configuration.

Bending

In bending, loads are applied to the surface of the bone in a manner that causes it to bend about an axis (usually

the long axis of the bone). Under bending loads compression is generated on one side of the neutral axis and tension is produced on the opposite side (Figure 108-12D). During weight bearing, eccentrically loaded bones such as the femur and humerus experience physiologic bending forces that typically produce internal compressive stresses on the concave surface of the bone and tensile stresses on the convex surface.[1,3-5] No stresses or strains are produced at the neutral axis. The magnitudes of the stresses are proportional to their distance from the neutral axis such that the gradation is continuous from maximal compressive stress down to no stress at the neutral axis and then increases to maximal

tensile stress at the opposite bony surface. Because bone is weaker in tension than in compression, the fracture plane generally begins on the tensile surface and transversely migrates toward the compressive surface.[1,3-5] Clinically, these fractures tend to be transverse or short oblique configurations. The obliquity is the result of accumulated internally generated shear stresses causing fracture along the line of maximal shear stress. A large wedge-shaped "butterfly" fragment is often produced when compression is combined with bending because two oblique divergent planes of maximal shear stress cause fracture on the compression side.[1,3-5]

Torsion

In torsion, loads are applied to the surface of the bone in a manner that causes it to twist about an axis (usually the long axis of the bone). Torsion results in shear stresses that are distributed throughout the bone (Figure 108-12E). As in bending, the magnitude of these stresses is proportional to their distance from the central (long) axis. Under torsional loading, maximal shear stresses act on planes perpendicular and parallel to the central axis. Furthermore, the maximal tensile and compressive (normal) stresses resulting from the torsion/shear act on a plane diagonal to the central axis. The spiral fracture pattern seen under torsional loading

suggests that bone fails first in shear, with formation of an initial fracture line parallel to the neutral axis. A second crack usually forms along the plane of maximal tensile stress.[1,3-5] Clinically, spiral fractures are commonly seen in the narrow diameters of the distal tibial and distal humeral diaphyses where the polar moment of inertia is relatively small (thus the resultant shear strain from torsional stress is relatively high).

Combined Loads

Although we have considered each mode of loading individually, non-physiologic loads-to-failure in living bone are seldom so pure. In vivo,

loading of bones is complex owing to their irregular shape and the constant barrage of multiple, coincident loads. Further, the hierarchical structure of bone allows it to absorb considerable energy prior to failure, particularly under rapidly applied loads. Thus, the energy of complex, rapidly applied non-physiologic loads is rapidly dissipated through the formation of multiple fracture lines (comminution).

Stress Concentration

Alterations and defects in bony structure or density owing to such conditions as drilled holes (biopsy tract, bone graft collection, or screw removal) or neoplasia cause stress

concentrations in bone that can initiate failures.[12-14] These stress concentrations can lead to local stresses in the bone near the defect that are many times higher than the nominal applied stress on the bone. One way to think of the stress concentration effect is that the applied force must “flow” through the bone and, in a defect-free, homogenous bone, it can flow equally through all regions, creating equal stress throughout. However, in bone with defects (e.g., holes from removed screws), the force cannot flow through the areas with the holes and thus must flow around the holes. This leads to a build up of force flow (or higher stress) in the regions adjacent to defects and

heterogeneities. The result is that a bone with stress concentrations fails at much lower loads or appears weaker than defect-free bones. The weakening effect of a stress concentrator is particularly marked under torsional loading where the decrease in strength may approach 90% and is proportional to the defect size.[13] Although defects smaller than 10% of the bone diameter may be of negligible significance in torsional resistance, larger holes are more problematic and remain so for an extended period of time.[13,15,16] This may be of particular concern in regions such as the distal humeral and distal tibial diaphyses where a relatively small polar moment of inertia already places these regions at

risk of torsional failure (spiral fracture).

Another form of stress concentration comes from a mismatch in the elastic moduli (stiffness) of two materials (e.g., stainless steel and bone) placed in close proximity to one another and under load. The stress concentration results from the mismatch because the modulus of a material determines its response to an applied force: high moduli materials deform (strain) much less than do low moduli materials under the same load. The mismatch interrupts homogenous force flow and results in stress concentrations. Common clinical examples are cemented total joint replacement or

stainless steel bone plating. As the materials are loaded, the bone exhibits greater elastic deformation, creating a shear stress at the bone-implant interface (Figure 108-13).

Figure 108-13. Craniocaudal radiograph of a feline femur 7 days following plate fixation of a distal metaphyseal fracture. The new fracture has occurred at the junction of the proximal end of the stainless steel plate with healthy bone and is attributed to stress concentration resulting from modulus mismatch.

Biomechanics of Callus Bone Healing (Indirect Healing)

Bone union can occur by one of two different repair mechanisms, direct healing (osteonal reconstruction) or indirect healing (intermediate callus formation).[3] Direct healing occurs primarily under conditions of anatomic alignment and rigid stability. Fracture line strain is less than 2%, and cutting cones are formed at the ends of the osteons nearest the fracture. Osteoclasts line the tip of the cutting cones for bone resorption and osteoblasts line the sides for bone formation. Resorption and formation of bone occur simultaneously as the

cutting cones advance directly from one osteon to the next across the fracture line.

Indirect bone healing occurs through transformation of fibrous tissue or cartilage into osseous tissue in instances when impaired blood supply, fracture instability (deformation), or fracture-gap width do not allow direct formation of lamellar bone. Early events of indirect healing include the formation of granulation tissue in the fracture zone. This loose fibrous and vascular tissue tolerates strain as high 40%. Bone resorption at the fracture ends may be seen early in healing as this increased fracture-gap width effectively decreases fracture-gap

strain (strain = change in gap dimension under load/original gap dimension). Fibrous tissue forms at the periphery of the fracture gap where blood supply is adequate, and fibrocartilage forms toward the center of the callus where blood supply is limited. Greater fracture-zone instability stimulates more abundant callus production extending further from the bone's neutral axis. Profound increases in resistance to bending and torsional moments accompany modest increases in external callus deposition because the AMI and the polar moment of inertia are both exponentially related to the radius of a cylindrical structure. Resistance to compression and tension are also related to the

cross-sectional area of the filling fracture gap.

This soft callus is able to bridge the fracture gap, but cannot decrease deformation to a level conducive to osteoblast survival. This fibrous and fibrocartilage tissue is stiffer than granulation tissue, but is also less tolerant of strain. Once the soft callus deposition is sufficient to adequately reduce fracture-gap strain, mineralization and woven bone formation begin, starting from the regions with the least motion. Once this stiffer mineralized cartilage and woven bone adequately reduce fracture-gap strain, these tissues are replaced by cancellous bone. After

complete bridging by abundant cancellous bone has occurred, the fracture zone can enter into a stage of remodeling where longitudinally oriented lamellar bone and more normal bony contour are restored. In general, during callus healing, the extensive circumferential distribution of the soft callus provides structural strength and stiffness to the fracture to compensate for the relatively weak material properties of the soft callus. As the material properties of the callus strengthen and stiffen, the structural properties of callus become progressively weaker through remodeling.

Appendicular Fractures±

Fractures of the Scapula

The scapula is a thin, flat bone shaped like an I-beam through much of its body. The shape of the scapular body combined with its support by extensive musculature protect it from fracture except in the case of high-energy trauma such as vehicular and gunshot injury.[15] Many of these fractures are effectively treated nonsurgically as a function of both the mechanical and biologic support afforded by the surrounding musculature. In selected scapular-body fractures with excessive displacement (folding), fixation with 1 or 2 inverted semitubular plates and screws placed adjacent to the scapular

spine allows for restored alignment and maximal screw purchase in the thin bone without the need for supplemental coaptation.[16] Fractures of the acromion process and supraglenoid tuberosity are subject to pure tensile forces resulting from their musculotendinous attachments. Treatment of acute fractures in these locations should usually incorporate tension-band fixation to counter these tensile forces.[17] Fractures of the glenoid cavity are typically treated with internal fixation because rigid fixation and anatomic reduction are prerequisites for mitigation of osteoarthritis following articular fracture.[17]

Fractures of the Humerus

Fractures of the humerus represent approximately 12% of long-bone fractures and most often involve the distal half of the bone.[15,17-19] Fractures of the proximal humerus, which is larger in diameter than the distal end, are relatively uncommon and are typically the result of high-energy trauma or elastic modulus mismatch inherent to physeal fractures. Low-energy trauma associated with jumping down from an elevation often causes spiral fracture configurations in the narrow distal diaphyseal region. Another common "jump down" fracture of the distal humerus is the fracture of the lateral aspect of the humeral condyle frequently seen in cocker

spaniels.[20-26] On landing, axial compressive loads are transmitted from the radial head to the lateral aspect of the humeral condyle (capitulum) and the lateral epicondylar crest. The resultant shear forces in the condylar and epicondylar bone may be excessive, particularly in conditions of incomplete humeral condyle ossification, and result in fracture.[24,25] Simple supracondylar fractures and more complex "Y" fracture configurations are also relatively common and are the result of excessive compression and/or shear stresses within the narrow dimensions of the humeral condyle and epicondylar crest regions.

Fractures of the humerus can, potentially, be treated with most any surgically applied fixation system, depending on fracture location, configuration, disruptive forces, and other factors. The extensive envelope of musculature surrounding the humerus complicates application of external skeletal fixation (ESF) by itself because the connecting elements are placed extremely eccentric to the neutral axis. However, when ESF can be "tied-in" to intramedullary pin fixation, the bending resistance is dramatically increased by virtue of increased AMI.[27,28]

Fractures of the

Antebrachium

Fractures of the radius and/or ulna comprised 22% of all long-bone fractures in dogs and cats in one study.[18] Fractures of the diaphyseal segments of these bones are most common. As with any bone, fractures of the physes of immature dogs and cats is relatively frequent owing to the modulus mismatch at these locations. Further, the unique conical shape of the distal ulnar physis appears to predispose it to crushing injury of the resting cells of the physis. "Jump down" injury may disrupt the resting cells along the margins of the conical physis by shear forces, and compression may be focused on the

resting cells at the tip of the conical distal ulnar physis. Fractures of the radius and ulna are more common in the distal diaphyseal region where the smaller diameter and lateral position of the ulna combined with the craniocaudally flattened shape of the radius (decreased AMI) may predispose it to fracture from excessive craniocaudal bending moments associated with falls, being stepped on, etc. The cross-sectional geometry of these bones may be disproportionately small in toy breeds of dogs, thereby predisposing them to distal-third antebrachial fracture.[29] Of course, high-energy trauma associated with gunshots and vehicular trauma may be more extensively distributed

throughout the two bones. The olecranon is the most common location of fractures involving the proximal antebrachium.[18] Olecranon fractures should usually be stabilized using the tension-band principle because of the pure tensile load applied by the triceps muscle group insertion on the olecranon.[17] Application of a bone plate to the caudal surface of the ulna, using the tension-band principle, may be advantageous in complex olecranon fracture scenarios.[30]

Fractures of the Pelvis

The pelvis (os coxae, sacrum, and first coccygeal vertebra) protects intrapelvic structures from trauma

while allowing for load transmission from the pelvic limbs to the spine. Although protected by extensive surrounding musculature, fractures of the pelvis are common, representing 20% to 30% of all fractures in dogs.[17] The pelvis' box-like shape predisposes it to fracture, most often multiple fractures. Displacement of one side of the rectangular box places stress on another side of the box. Although the blood supply provided by the surrounding musculature aids healing for most pelvic fractures even when treated nonsurgically, surgical treatment is often indicated to hasten restoration of locomotor function and to ensure adequate pelvic canal dimensions when healing is complete.

Surgical stabilization is indicated for fractures involving the acetabulum, fractures causing excessive pelvic canal collapse, and many fractures in which load transmission from the pelvic limb to the lumbar spine is interrupted.[17] Anatomic reduction and stabilization of the acetabulum are paramount and can be achieved with bone plate/screw (with or without plate luting) or with screw/wire/polymethylmethacrylate fixation along the dorsal acetabular rim.[31-33] This implant placement creates a tension-band effect because the impact of the femoral head into the acetabulum creates tension along the dorsal acetabular rim. Fractures of the ilium are also commonly treated surgically. The tension surface of the

canine ilium is dynamic through the gait cycle, shifting from ventromedial to neutral.[34] Standard lateral plate/screw placement for fixation of longitudinal fractures (relatively parallel to the spinal axis) of the ilium may ignore the tensile stress on the bone's ventromedial aspect.[34-36] Use of ventral-to-dorsally oriented screws alone or in combination with bone plate fixation has been advocated to address this concern. The effects of lateral-to-medial screw purchase in the body of the sacrum are debated.[34-36] Some studies of triple pelvic osteotomies show that screw migration was reduced when substantial sacral screw purchase was achieved.[37,38] Other studies suggested that sacral

body screw purchase should be avoided as low-level sacroiliac joint movement may induce screw migration.[35,39] The authors of one study suggested that addition of ventral screws is a better way to increase overall screw purchase and avoids patient morbidity that may be associated with iatrogenic immobilization of the sacroiliac joint.[35]

Fractures of the Femur

Fractures of the femur represent approximately 45% of all long-bone fractures in the dog and cat.[18] Approximately half of these involve the diaphysis, and the other half are evenly divided between the proximal and distal epiphyseal/metaphyseal

regions.[18,40] In the proximal region, fractures of the femoral neck are most common. Weight bearing likely generates significant shear stress within the narrow diameter of the femoral neck. These shear stresses may be particularly problematic when transmitted across the physis of the femoral head and neck. Indeed, delayed closure of this physis associated with early neutering has been hypothesized as a predisposing cause of excessive and repetitive shear stress leading to physeal disruption in overweight cats.[41]

Fractures of the femoral diaphysis may be of most any configuration, thus reflecting the wide array of loading

leading to fracture. External rotators of the hip (gemelli, internal obturator, quadratus femoris, and iliopsoas muscles) typically produce profound external rotation of the proximal femoral segment that must be corrected during surgical stabilization. Owing to eccentric loading of the femur during weight bearing, the medial surface is the compression side and the lateral surface is the tension side. Indeed, diaphyseal fractures producing medial "butterfly" fragments are relatively common, and this fracture configuration is predictable when strong mediolateral bending forces are generated with compression loads along the medial surface. Further, surgeons must be especially

aware of the impact of eccentric loading when surgically stabilizing femoral fractures, particularly with bone plates. With traditional bone-plate application on the lateral surface of the femur, defects present on the medial surface drastically reduce the AMI of the bone/plate construct, thus increasing the likelihood of fixation failure.[28,42] Simple combination of an IM pin to the plate fixation dramatically increases the fatigue life of the fixation by profoundly increasing the AMI of the composite fixation.[43,44] Common fixation methods used for femoral diaphyseal fractures include intramedullary pin plus cerclage wires, IM pin plus ESF, interlocking nail, bone plate, and

plate/pin systems. The most appropriate fixation depends on a comprehensive assessment of pertinent biomechanical, biologic, and clinical factors that influence bone healing and return of locomotor function. External skeletal fixation of the femur is complicated by the extensive surrounding musculature (that shifts the ESF's connecting elements far eccentric to the neutral axis) and adjacent body wall (that prevents utilization of many traditional frame configurations). Innovative ESF frame configurations, often in combination with an intramedullary pin "tie-in", are often advisable when applied to the femur.[27,45] Distal femoral physeal fractures are relatively common.[46] This

physis has a unique “4 pegs in 4 cups” configuration. Three or 4 of these metaphyseal pegs are often intact (Salter I or II fractures) in dogs and cats. Reduction of 3 or more pegs into their respective cups provides some inherent stability, particularly against torsional moments.[47] These fractures are often surgically stabilized with relatively simple single IM pin, cross-pin, or dynamic pin (“Rush-fashion”) fixation.

Tibia/Fibular Fractures

Fractures of the tibia and fibula consist of 22% of all long-bone fractures in the dog and cat.[18] The majority of these fractures are located in the diaphyseal

region. The smaller diameter of the distal diaphysis reduces the bones' AMI and polar moment of inertia. Clinically, low-energy bending injury often produces short, oblique fractures or fractures with a small butterfly fragment. On occasion, in young, skeletally immature animals, the traumatic injury produces only a greenstick (incomplete) line in the tibia or a complete fracture of the tibia, but leaves the fibula intact (but sometimes plastically deformed). Low-energy trauma and torsional injury commonly produce spiral fractures in the narrow diameter of the distal tibial diaphysis where the polar moment of inertia is relatively small (thus the resultant shear strain from torsional

stress is relatively high). Higher energy trauma, such as vehicular accidents, commonly produces highly comminuted fracture patterns that may extend more proximally than is typical for the lower energy fractures. Simple fractures in the distal tibial physeal region are also common and may reflect the stressconcentrating effect of modulus mismatch. Fractures of the tibial crest are subject to pure tensile loading from the patellar ligament and are best treated with tension band fixation.

Fracture Assessment

The mechanical goal of fracture fixation is to provide appropriate

spatial limb alignment and sufficient fracture gap stability to allow for bone healing and full restoration of limb function. In order to achieve this goal, the fixation must effectively neutralize the disruptive forces acting on the fracture. Clinically, this mechanical goal must be tempered against the biologic requirements for bone healing and inherent patient- and client-related factors.

Compression, generated by weight bearing and muscular contraction, must be neutralized in the treatment of diaphyseal fractures of all long bones. In instances in which reconstruction of the bony column is advisable, the reconstructed bony column will

provide some resistance to collapse of the fracture zone. When transverse or interdigitating short, oblique fractures are purposefully compressed, the end-to-end bone contact may improve fracture stability and actually aid bone healing. In other instances, however, open anatomic reconstruction of the bony column is not advisable. In these instances, the fixation itself must resist all of the compression forces that tend to cause axial collapse via adequate purchase of the main proximal and distal fracture segments.

Tensile forces result in distraction of fracture fragments and are primarily the result of musculotendinous or ligamentous insertions on the ends of

long bones. Tensile forces are best neutralized by application of the tension-band principle using a tension-band wire or tension-band plate. Tension band implants are applied opposite the direction of pull on the fragment. As an example, tensile forces from the triceps insertion on the olecranon tend to pull the proximal segment cranially and proximally. A tension-band wire is placed by initially reducing the olecranon with paired Kirschner wires. The bending force on these wires is neutralized by addition of a taut figure-of-8 tension-band wire placed on the caudal aspect of the olecranon (opposite the direction of pull). Alternatively, a plate applied on the caudal aspect of the olecranon can

exert the same tension-band effect.

Bending is inherent to diaphyseal fractures of all long bones and must be neutralized if predictable, low-morbidity healing is to be realized. Bending forces in long bones result from combinations of their curvature, eccentric loading, and contraction of surrounding muscles in addition to a variety of extrinsically applied loads. Bending forces tend to cause collapse on the concave (compression) side of the bone. Loss of cortical contact on the compression side exaggerates the bending forces acting on the fracture fixation system. Neutralizing bending forces must always be a consideration in treating diaphyseal fractures of long

bones.

Torsion is induced by muscular contractions, by changes in direction of the body while the foot is planted, and by extrinsic sources. Failure to neutralize torsional forces is a relatively common cause of delayed or nonunions and malunions when intramedullary pinning is used without supplementary fixation. Torsional forces are most predictably neutralized by fixation that purposefully achieves implant-bone purchase on both the proximal and distal main fracture segments. Torsional forces can seldom be adequately resisted by interdigitation of the fractured bone ends and this is only feasible in the

smallest and fastest healing of patients.

Fracture Treatment

Fracture treatment must effectively address the mechanical goals stated earlier, the biologic requirements for bone healing, and the inherent clinical concerns such as patient temperament, client compliance, cost, and surgeon expertise. The following description is an overview of the inherent mechanical strengths and weaknesses of various fracture treatment methods.

Full-Cylinder Cast

External coaptation includes soft

padded bandages, slings, splints, and casts. The full-cylinder cast is the most rigid form of external coaptation and is capable of effectively neutralizing bending and rotational forces when applied correctly and in the proper situations. A full-cylinder cast must span the joints above and below the fracture (note: this is not feasible for fractures of the humerus and femur), must conform to the limb, and must be sufficiently thick to withstand weight bearing. A full-cylinder cast is not capable of neutralizing axial collapse (compression) or tension. Thus, casting is not ideally indicated for fractures in which end-to-end contact of transverse diaphyseal fractures cannot be accomplished. Likewise, casts do not

neutralize the pure tensile forces acting on traction apophyses.

Splints and casts encase the limb, but do not directly interact with the bony segments. Thus, an interface of soft tissue and cast padding exists between the fixation and the bony segments. More stability is provided when there is less soft interface between the cast and the bone(s) being stabilized. Clinical practicality, however, dictates that some soft interface must be present to minimize the risk and severity of cast sores. Increasing cast thickness is the easiest way to increase resistance to bending (by virtue of increased AMI), but this also increases its weight substantially. Alternatively,

reinforcement of the cast in one region can be used (i.e., the I-beam effect) if unidirectional bending is anticipated.

Intramedullary Pin Fixation

Intramedullary (IM) pinning, when properly performed, effectively neutralizes bending forces because of their large AMI. Since AMI is a function of radius raised to the 4th power, the diameter of the pin greatly influences its bending strength. Furthermore, theoretically, complete fill of the intramedullary canal with an IM pin would effectively neutralize shear forces resulting from weight bearing on noninterdigitating oblique fractures. Complete (100%) filling of

the intramedullary canal with an IM pin is neither realistic (because of the irregular shape of bones) nor desirable (because complete canal filling prevents intramedullary blood supply from redeveloping).[48,49] Instead, filling of 60% to 70% of the intramedullary canal by the IM pin is frequently recommended. Pinning of the radius is seldom recommended; one reason is that the intramedullary canal is so narrow that an appropriately sized IM pin provides neglible bending strength such that the fixation must be supported with coaptation anyway. In selected instances, intramedullary pinning of small bones such as metacarpals or metatarsals is recommended, but these fixations must

always be protected with suitable coaptation owing to the small diameter of the pins. Proper pinning technique also requires the IM pin to be well seated into the proximal and distal metaphyses. Unfortunately, IM pin fixation alone lacks the ability to effectively neutralize axial compression or torsion because each of these requires a system that gains purchase of the bone and the connecting element(s) of the fixation system on each side of the fracture (i.e., interlocking nails, bone plates, or external skeletal fixation). Frictional hold between the smooth surface of the IM pin and the endosteal surface of the bone is insufficient to resist torsional moments. Increasing the IM pin

diameter or addition of threads does not improve torsional resistance.[50] A trilaminar fluted nail in which the flutes engage the endosteal surface to resist torsion forces has been described in the veterinary literature but has not found widespread clinical application.[51] Use of multiple, smaller diameter pins ("stack pinning") only slightly increases rotational stability and should not be relied on in fractures that are not inherently stable.[52] Supplementing the IM pin with a bone plate or an external skeletal fixator is a common strategy to complement the pin's inherent ability to resist bending forces, with the latter systems' abilities to resist axial collapse and rotation. Fracture fixation with only a single IM

pin is seldom recommended – only in instances of interdigitating transverse fractures of very small and rapidly healing patients.

Techniques of cross pinning or dynamic pinning are commonly used for fixation of metaphyseal and epiphyseal fractures where rapidly healing, interdigitating transverse fractures are frequently encountered.[47] These fractures are inherently resistant to collapse. With each of these paired pinning methods, the pins are typically angled such that they cross on the diaphyseal side of the fracture. In this manner, the 2 pins cross the fracture in different pathways, thereby imparting some resistance to rotational moments.

With cross pinning, each of the pins passes from one side of the bone and penetrates the far-cortical surface. In contrast, dynamic pins (pins placed in "Rush fashion") are placed such that they deflect off the far endosteal surface rather than penetrate it. The pins are then advanced to seat in the distant metaphyseal region. The interaction of these dynamically placed pins helps resist rotation moments, but not to the same degree as the cross-pinning technique.[47]

Interlocking Nails

Interlocking nailing is an intramedullary system that addresses the axial collapse and rotational

instability weaknesses of IM pin fixation while utilizing its inherent ability to resist multidirectional bending loads. By virtue of the interlock between the bone and intramedullary nail on each side of the fracture, the interlocking nail system is capable of resisting axial collapse and torsional moments.[53-56] Interlocking nails, themselves, are weakest at their screw holes (lowest AMI and a stress concentrator).[28] Unlike bone plates, a locking screw through a nail does not reduce the stress-concentrating effects of the hole because the locking screw does not interact rigidly with the nail.[56] Therefore, these screw holes should not be placed in close proximity to the fracture zone with or without an

interlocking screw. When used to span nonreconstructed fractures, the interlocking screws resist axial collapse by “tethering” the main bone segments to the level of the nail holes. As nail diameter decreases, the AMI decreases of both the nail and of the corresponding interlocking screws that can be used. When one manufacturer used a relatively large 3.5-mm screw diameter in their 6-mm nail, breakage of nails was the most common mode of clinical failure.[57] As they reduced the size of the screw hole to accept 2.7-mm screws (thus increasing the AMI of the nail), nail breakage became less common but screw failure was noted.[58]

As an alternative to the use of

interlocking screws, bolts are now manufactured such that positive-profile threads engage only the near-cortical surface during insertion, and the core diameter of the "tethering" portion of the bolt is maximized (Table 108-1). One does not have to be overly concerned about premature "backing out" of the bolts because they are not subjected to pull-out forces as are screws placed through a bone plate. Whereas unicortical thread engagement of the bolt is sufficient, bicortical penetration of the interlocking screws or bolts is important, particularly when functioning as a tether in nonload-sharing situations. Further, in such instances, the longer screw lengths

required for use in metaphyseal regions increases their susceptibility to bending or breaking.[59] Eccentric loading of these screws, such as occurs when the nail is not centralized within the metaphyseal region, appears to improve screw fatigue life.[59] Interlocking nail systems compare favorably with bone plate and plate-pin combinations when used to stabilize gap models except with regard to torsional resistance.[53,54] The lack of a rigid interlock between the locking screw and/or bolt and the nail permits slight rotational movement.[54] One way to augment the interlocking nail system's resistance to rotation is to use it in conjunction with external skeletal fixation.[60-62] This can be done

by virtue of a connecting bar “tie-in” between the proximal extension of the interlocking nail and the ESF frame or by use of special external fixation pins designed for dual use as an ESF pin and the interlocking bolt.[60,61] One would expect such fixation to dramatically increase both bending resistance (in the plane of the frame by increasing AMI) and torsional resistance (by increasing PMI). Interlocking nails can be dynamized, if desired, by removing the interlocking devices on one side of the fracture, thus exposing the fracture zone to both axial compression and torsional stresses.[60-62]

Table 108-1. Area Moment of Inertia of Screws and Locking Bolts of Varying Size. (Area moment of inertia = $\pi r^4/4$ where r = radius = 0.5 x core diameter).

Implant	Core diameter (mm)	Area moment of inertia (mm^4)
2.0 screw	1.5	0.25
2.0 bolt	2.0	0.79
2.7 screw	2.0	0.79
2.7 bolt	2.7	2.61
3.5 screw	2.5	1.91
3.5 bolt	3.5	7.37
4.0 screw (cancel.)	2.0	0.79
4.5 screw	3.2	5.15
4.5 bolt	4.5	20.13

Orthopedic Wire and Cerclage

Orthopedic wire is malleable stainless steel that is formed into monofilament wire of varying dimensions. Applications in small animals typically vary from as large as 16-gauge to as little as 24-gauge wire. Full-cerclage wire is placed around the full circumference of a completely and anatomically reconstructed bony column. As the wire is tightened, the fracture lines are compressed (much like the staves of an oak barrel are compressed as the band surrounding them is tightened). If perfect anatomic reduction is not achieved, wire tightening will tend to collapse

fragments into the intramedullary canal and the wire will be prone to premature loosening. Stabilization of two main fracture segments requires that the fracture line be a long oblique configuration in which the length of the fracture line is at least 2.5 times greater than the bone diameter in that location. When sufficient obliquity is present, a minimum of two properly applied wires is capable of providing excellent compression of the fracture surfaces (interfragmentary compression). When improperly applied to a short oblique fracture, full-cerclage wire creates shear stress at the fracture and, because there is only room for one wire, concentration of bending stresses. Although one should

avoid the use of cerclage wire in short oblique fractures, the following “escape strategy” can be employed if alternatives are not available: use of 1 or 2 K-wires oriented perpendicularly to the plane of the fracture can minimize the shear forces created by tightening of the full-cerclage wire. The cerclage wire is placed so that, as it is tightened, the K-wire prevents its orientation perpendicular to the long axis of the bone and directs compression across the fracture line.[63]

Cerclage wires can be tightened and secured in a number of ways and their relative mechanical merits are measured by comparisons of the compression achieved and the

resistance to knot loosening.

Twist-knots are properly formed when each of the two ends of the wire wrap evenly around the other (improper formation is one wire wrapped around the core of the other – like a snake wrapped around a stick). Tensioning and securing the wire occur simultaneously with this method. In most instances, it is advisable to cut the knot short rather than bending it over because any manipulation of the knot decreases tension in the wire.[64,65] Resistance to knot failure under loading is determined by the frictional interface between the two wires. The number of twists to leave in the knot has not been clearly established, but

cutting the knot with three twists remaining is common. If the twist-knot must be flattened, the flattening process and the final twisting should be simultaneous to minimize loss of loop tension.[64,66] Twist knots untwist when loaded past the yield point and do not exert as much loop tension as other methods.[64,67] Twist-knots sustain greater load to failure than single-loop knots, but similar load to loosening.[63,64]

Single-loop knots are formed using a wire with a loop on one end. After passing the free end of the wire around the bone, it is passed through the loop. The free end is then passed into the end of a purpose-specific tightening

instrument. The wire is tensioned by rotating a crank on the tightening instrument. The wire is tightened in the first phase of application; then the knot is locked in the second phase by bending the free end over the loop. This method achieves greater initial loop tension than the twist-knot, but has a similar load resistance before loosening.[66] The single-loop knot fails by unbending of the free end.[67]

Double-loop cerclage is formed from a segment of wire bent 180° in the middle. The bent end is passed around the bone and the 2 free ends are passed through the loop created by the bend. The free ends are tightened with a 2-crank wire tightener. The knot is

locked in a similar manner as the single-loop method. The double-strand and double-knot increase the loop tension and knot security. The double-loop knot generates 3 times as much tension as the single loop and resists twice the distracting load prior to wire loosening.[64]

Bone Plates and Screws System (DCP, LC-DCP, Locking-Plate Systems)

Screws convert insertion torque into compression along their shaft such that any structures bone plate, washer, or bone fragment underlying the screw head are compressed during tightening

(provided the hole diameter in that underlying structure exceeds the screw-thread diameter such that it may glide freely along the screw shaft). Individual screws may be used in positional or lag fashion. When screws are used as positional screws, their threads engage both the near and the far segments such that the position of each fragment is held in a specific location, and compression of the fracture line is not achieved. When screws are used as lag screws, their threads engage only the far bone segment. Screw tightening compresses the near segment against the far segment because the near bone segment is free to slide along the screw shaft. The amount of interfragmentary

compression achieved with the lag screw method is primarily a function of the bone strength, outer-thread diameter, and insertional torque. Screws must often resist significant bending forces. The bending strength of a screw is determined by its AMI which is related to its core radius raised to the fourth power.[28] Therefore, small increases in screw core-diameter profoundly increase its bending strength. For example, a 3.5-mm cortical screw (2.5-mm core diameter) is nearly 2.5 times stronger than a 2.7-mm cortical screw (2.0-mm core diameter) (Table 108-1).

The most common use of screws is to fasten a bone plate to the bone. Unlike

an ESF connecting bar, traditional bone plates are not mechanically linked to fixation screws. With traditional plating, the fixation only becomes stable when the screw is firmly tightened, thereby compressing the plate against the underlying bone. Properly applied bone plates resist compression, tension, bending, and torsional and shear forces especially when used to compress a two-piece transverse fracture of a long bone. In this instance, a dynamic compression plate (DCP) is desirable. The DCP screw hole is designed such that tightening of the screws compresses the fractured bone ends together. The DCP screw holes are oval and the surface that comes into contact with the

underneath side of the screw head slopes downward and toward the fracture line (much like a playground slide). When the screw is inserted on the "high" side of the oval sloped DCP hole, the screw head comes into contact with the sloped hole as the screw is tightened. The screw is fixed in the bone and is not free to slide down the slope. Instead, the interaction between the screw head and the oval sloped DCP hole draws the plate toward the screw. Using the playground slide analogy, rather than a child sliding down a fixed playground slide, the slide is free to move and is drawn backward as the child descends. Once a traditional bone plate is secured with screws, the plate

acts as the connecting element that spans the fracture.

Bone plates are most susceptible to bending forces because of their eccentric position relative to the bone's neutral axis. Their mode of placement determines the likelihood of fixation failure. If a transverse fracture is anatomically reduced and the plate compresses the fracture segments, the plate and the bony column share the loads and their large combined AMI creates a highly rigid construct. If the bone, especially the cortex opposite the plate, is not reconstructed, the plate alone must resist considerable bending forces. The bone plate is weakest at its screw holes (lowest AMI). Further, an

open screw hole centered over the fracture functions as a stress concentrator and dramatically increases the risk of failure under bending loads. Several methods can be used to increase the AMI of the fixation. Lengthening plates are available where the middle section of the plate is solid (without screw holes). Another method is to combine an intramedullary pin with bone-plate fixation.[43] The bone plate constrains axial collapse and rotational forces, while the IM pin resists bending forces. By adding the pin, the AMI of the combined fixation is greatly increased and the fatigue life of the plate is greatly extended.

The limited-contact dynamic compression plate (LC-DCP) was designed with a scalloped profile to the underneath side of the plate that contacts the bone.[68] One effect of this scalloped contour is minimized stress-concentrating effect of an open screw hole because the AMI is similar over the length of the plate.[68] Granted, the solid section (between screw holes) of the LC-DCP is significantly weaker than the solid section of a traditional DCP, however, when screw holes are left unfilled the plate is only as strong as its weakest point.[69] Another advantage of the LC-DCP is that the scalloped "footprint" of the plate against the bone may allow for improved vascular supply to the

healing bone, but other factors such as bone-surface topography also influence the relative significance of this feature.[70]

Whereas traditional plating depends on firm screw-insertion torque to compress the plate against the bone to ensure rigid fixation, newer locking-plate technology utilizes a locking screw mechanism to link the plate firmly to the fixation screw.[71] These locked screw-plate systems can be thought of as internal skeletal fixators. Because traditional plating does not link the plate and the screw, the screw is free to microtoggle within the plate hole. Bicortical purchase of traditional screws helps to reduce this

microtoggling, which among other things, can lead to fretting failure of the plate or screw. Locking screws are rigidly fixed between the bone on one end and the plate on the other. For this reason, bicortical screw purchase is theoretically less important with locking screw-plate- systems. This may be a function of cortical bone thickness that is relatively thin in small animal patients. Pullout of locked screws is not just a function of the strength of their thread interlock in the bone, because the screw is also locked in the plate. Thus, premature screw loosening of a single locking screw is not likely. Further, the linkage between the fixation screw and the plate as a connecting element eliminates the

mechanical need for compression of the plate against the bone surface. Because the threads on the screw head correspond to those in the screw hole of the plate, angling of screws is not possible and locking screw-plate systems are fixed-angle constructs. Further, dynamic compression cannot be achieved when only locking screws are used. Combined conventional and locking-screw techniques can be used, but require plate contouring on the end(s) of the plate where conventional screws are used. When conventional and locking screws are combined within a bone segment, the conventional screws are applied first to compress the contoured plate to the bone segment and to achieve the DCP

effect (if desired). Locking screws are subsequently applied. If locking screws have been used to fix a plate to a fragment, subsequent insertion of conventional screws should not be performed without first loosening the locking screw (it can be retightened after insertion of all the traditional screws are in place). Dynamic compression can be achieved after one segment has been fixed with locking screws by using conventional screws in the dynamic compression portions of the plate hole.

External Skeletal Fixator

Linear ESF

The external skeletal fixation (ESF) system makes use of fixation pins, connecting bars, and pin-bar linkages. Each component of the system represents a mechanical variable that can be adjusted to the mechanical needs of the patient. Long-term stability of the pin-bone interface is foundational to success with ESF. Threaded pins provide much greater resistance to pin pullout than do nonthreaded pins.[72,73] Pins with a negative-thread profile have less pullout resistance than positive-profile pins in some but not all implantation sites.[74] Negative-thread profile pins are also more prone to breakage as a result of their decreased AMI and the stress concentration at the threaded-

nonthreaded junction. Pin rigidity is also a function of pin diameter. As pin diameter increases, so does its AMI and flexural rigidity, but the impact of pin size on bone strength must also be considered. Proportionate loss of bone strength occurs with each increase in circular cortical defect size greater than 20% of the bone diameter.[13] ESF fixation strength and stiffness are increased by increasing the number of fixation pins in each fracture segment (unless the connecting column is the weakest component) up to a maximum of 4 pins per bone segment.[75,76] Evenly distributing pins throughout each main bone segment maximizes resistance to bending in the plane orthogonal to uniplanar ESFs.[75,77] Angling pins

closest to the fracture zone in order to decrease the working length of the connecting bars may be advisable for highly comminuted, nonreconstructable fractures because the bending stiffness of the connecting bar is inversely related to its working length raised to the third power. The concept of working length and stiffness also applies to pin length. The connecting bar should be linked to the fixation pins as close as possible to the skin without causing skin irritation (usually a finger's width).[75,76] Linkage clamps should be oriented such that the working length of the pin is minimized.[75]

The rigidity of the connecting bar(s)

significantly influences the strength and stiffness of the ESF-bone construct.[78-80] Elastic deformation of the connecting bar of unilateral-uniplanar (type Ia) frames places “to and fro” axial loads on the fixation pins.[80] Elastic deformation of the connecting bar can be minimized by using more rigid materials, increasing bar diameter, adding supplemental bars or plates, or utilizing more complex frame configurations.[78,79] Static strength evaluation of different configurations showed that unilateral-uniplanar (type Ia), unilateral-biplanar (type Ib), bilateral-uniplanar (type II), and bilateral-biplanar (type III) frames to be successively stronger in resisting axial compression and

torsion, and bending in the plane of the ESF.[78,81] The ability of the pin-connecting bar linkage to rigidly maintain this interface is essential. In addition to clinical factors such as proper clamp assembly and tightening, clamp design also must be considered.[82,83]

Circular ESF

Circular ESF (CESF), like linear ESF, consists of fasteners (tensioned wires), connecting rods and wire-connecting rod linkages. Variations in these components can be manipulated to alter the mechanical properties of the CESF-bone construct. Unlike linear ESFs, CESFs utilize small-diameter

wires tensioned between clamps positioned on rings rather than using traditional fixation pins to fasten the device to the bone. This design feature accounts for a fundamental difference between the load-deformation behavior of linear ESFs and CESFs.[84] Linear ESFs using half-pins loaded in cantilever bending have a linear elastic region of their load-deformation curve followed by plastic deformation to failure with progressive loading.[84,85] CESFs using small-diameter tensioned wires loaded in three- or four-point bending show initial nonlinear elasticity with increasing rigidity followed by linear progression to yield.[84,85] This characteristic difference reveals how CESF devices allow axial micromotion

of the bone segments.

Ring diameter, which dictates wire length, profoundly influences the mechanical properties of CESF. As ring diameter increases, so does the length of the tensioned fastening wires, thereby decreasing fixation rigidity.[84-87] Although ring diameter affects stability in all loading modes, its most profound influence is on axial stability.[84,86] This influence is most evident at lower axial loads because self-tensioning of the wires develops during loading, resulting in a progressive increase in stiffness.[84] The smallest diameter ring possible should be used allowing about 2 cm between the skin and the ring for pin-tract care,

soft-tissue swelling, etc. Ring diameter has a greater effect on gap stiffness and gap displacement than does wire tension, and the effect of increasing wire tension decreases for larger rings.[87] Complete rings are stiffer than incomplete rings.[88]

As for linear ESF, the bone fasteners (tensioned wires) should be spread over the length of each major bone segment; increasing the number of fasteners up to four per segment is advisable.[85,86,89] In CESF, tensioned wires are distributed over the bone using rings. Where possible, blocks of two rings distributed over the bone-segment length significantly increases the stability of the fixation when

compared with configurations that secure individual bone segments at only one level (using a single ring).[85,86,89] Typically, one tensioned wire is placed above each ring and another below each ring for a total of two tensioned wires per ring. When only one ring can be used owing to a short bone-segment length, “drop wires” spanned from posts extending from the ring can be used to increase the number of fasteners and increase resistance to bending.[90]

Whereas much of the wire stiffness is a function of tensioning, wire stiffness is greater in larger diameter wires than in similarly tensioned smaller diameter wires. Wire diameter also influences

how much a wire can be tensioned. Wire tension should not exceed 50% of its yield strength to minimize the possibility of breakage.[85] Wire tension affects the overall rigidity of the fixator construct, most notably axial stiffness during low load application. The relationship between wire tension and construct stiffness is nonlinear because of the self-tensioning effect of the wire.[84,85] Tensioning wires before loading increases the axial stiffness of a CESF at low loads, mitigating much of the displacement during physiologic loading. The practical limits of wire tensioning are associated with wire breakage, ring deformation, slippage of the wire within the clamp, and a "ceiling effect" beyond which the gain

in axial stiffness is nominal.[84,85] During fixator application, sequential tensioning of wires on the same ring can cause loss of tension in the first wire owing to ring deformation. Simultaneous tensioning of wires on the same ring mitigates this effect, especially for large rings.[85] Subsequent study using 84 mm diameter rings faied to detect any, differences in wire strains or construct stiffness when compairing simultaneous and sequential wire tensioning methods.[91]

Ideally, tensioned wires are placed at 90° angles to one another to maximize stability and shear, but regional anatomy seldom allows this. Reducing the separation from 90° down to 45°

particularly reduces the CESF's resistance to bending in the orthogonal plane.[90,91] Reducing this separation further can also lead to plastic deformation of the ring during wire tensioning.[90,92]

Hybrid linear and CESF has been used for stabilization of juxtaarticular fractures. Clinically, a linear ESF is utilized on the larger main fracture segment, and the tensioned wires and ring block are used on the small juxtaarticular segment. Combining fixation pins and tensioned wires within a segment is not advised because the axial motion permitted by the tensioned wires can place excessive stress on the pin-bone interfaces when

few pins are used.[85]

Conclusion

A basic understanding of the biomechanics of the appendicular skeleton should include the material and structural properties of bone, the generation of internal stresses caused by applied loads, and common modes of failure under these applied loads. These understandings combined with knowledge of basic biomechanics of various fixation systems enhance the surgeon's ability to create an appropriately stable fracture zone that is conducive to rapid bone healing and restoration of patient function.

Chapter 109

Growth Plate Injuries

Derek B. Fox

Growth plates, or physes, are composed of several merged layers that produce longitudinal growth of the long bones by the method of endochondral ossification. Physeal damage is not uncommon in the small animal and can result from trauma, genetic disorders, nutritional imbalances, or other medical disturbances. The physis can be either completely or partially damaged and

injuries can vary in their subsequent extensiveness from total growth arrest to retardation. Common sequelae of physeal injury include shortened limbs, angular limb deformation, and adjacent joint subluxation. Angulations can occur in multiple planes depending on the location of the growth plate damage and whether the affected bone is anatomically paired with another long bone, as with the radius and ulna. Malalignment can be in the frontal plane, resulting in varus and/or valgus deformities, or in the sagittal plane, causing pro- or recurvatum and rotationally causing internal or external bone torsion. A thorough understanding of the resulting pathology from physeal injury

necessitates a discussion of the anatomy and physiology of the growth plate.

Growth Plate Anatomy

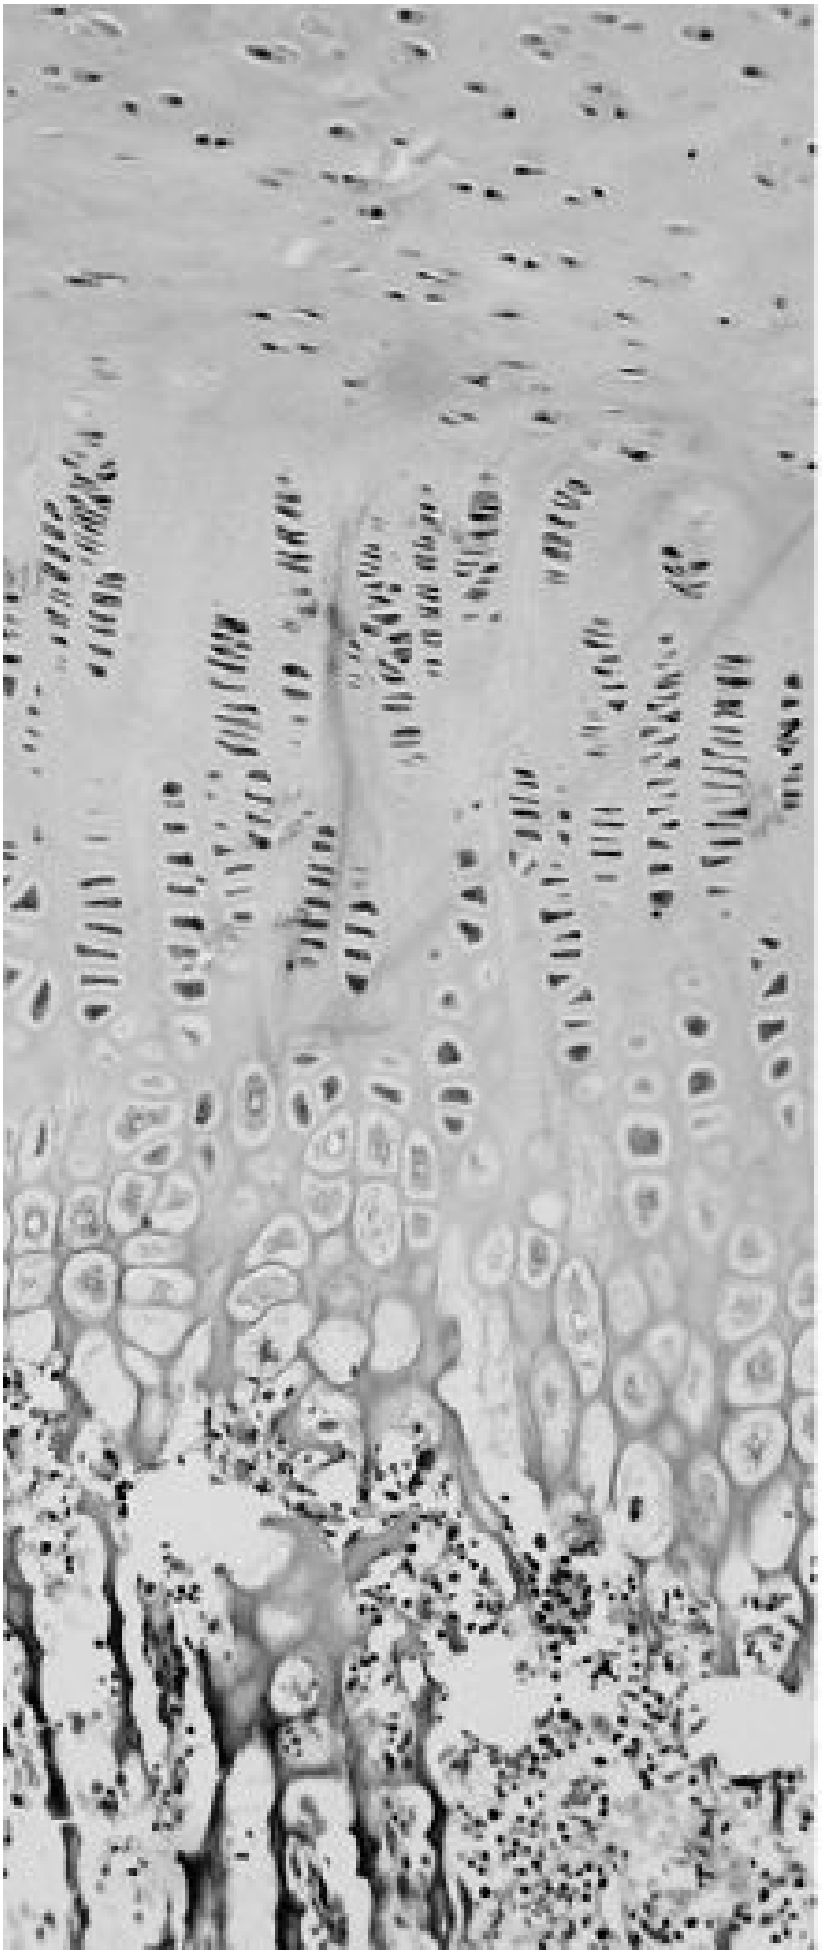
Although the physiology of the individual layers of the growth plate is unique, the functional unit of the physis can be summarized as a column of chondrocytes that proliferate, hypertrophy, and synthesize matrix before ultimately undergoing apoptosis.[1] These functions are intimately regulated intrinsically by growth factors and mechanical forces and extrinsically both hormonally and mechanically. The growth plate can be divided into its various layers both

morphologically and functionally. As such, a standard set of descriptive terms for the layers does not exist and will vary widely depending on the author. For purposes of this discussion, a functional scheme of evaluation is presented including the 1) germinal zone; 2) columnar zone with upper proliferating area and lower maturation area; 3) hypertrophic zone with an upper four fifths possessing nonmineralized matrix and lower one fifth with mineralized matrix; and 4) outer metaphysis (Figure 109-1). The cells within the germinal zone are also frequently referred to as resting cells because they do not proliferate.[2] The small, irregularly spaced cells in the germinal zone contain a high

concentration of lipid within their vacuolar contents, suggesting their important role in nutrient storage.[3]

The upper portion of the columnar zone represents the only aspect of the growth plate in which chondrocytes undergo division. The active division in this area results in the stacking of flattened cells into columns that are separated from each other by large conglomerations of type II collagen. This proliferating portion of the columnar zone is high in oxygen content and undergoes active glycogen storage by the chondrocytes.[4,5] The high concentration of rough endoplasmic reticulum within chondrocytes in the lower half of the

columnar zone dictates their role in extensive matrix synthesis.[1]



Germinal Zone
Columnar Zone
Hypertrophic Zone
Outer Metaphyseal Zone

Figure 109-1. Photomicrograph of a normal canine growth plate stained with hematoxylin and eosin and labeled for the four primary functional zones: germinal zone, columnar zone, hypertrophic zone, and outer metaphyseal zone. The proximal aspect of the bone is at the top of the photograph. (Courtesy of Dr. Keiichi Kuroki.)

The hypertrophic zone of the physis is the driving force of longitudinal bone growth through cell expansion. The chondrocytes of this zone increase their intracellular volume anywhere from 5- to 10-fold. Variation in the rate of chondrocyte hypertrophy is now thought to be the main reason for different anatomically located physes to grow at different rates.[6] Like the lower half of the columnar zone, the cells of the hypertrophic zone also possess a highly active metabolism that

is responsible for large quantities of matrix synthesis. In addition to abundant type II collagen, both type X collagen and vascular endothelial growth factor (VEGF) are produced in the hypertrophic zone. The production of these elements is a hallmark for cellular differentiation and the ceasing of cellular division. These processes occur in an environment that is lower in oxygen tension and in which glycogen is consumed by the chondrocytes until depleted.[4,5] In the lower one fifth of this zone, the matrix is modified for calcification and vascularization. Whereas recruitment for vessel ingrowth is signaled by the release of VEGF, matrix mineralization is mediated by budding vesicles formed

from the chondrocyte plasma membrane.[7] The vesicles contain calcium and enzymes, including both alkaline phosphatase and matrix metalloproteinase (MMP).[1] Newly deposited matrix then forms in longitudinal septa between the columns of chondrocytes and primarily consists of crystalline hydroxyapatite. The septa eventually become primary trabeculae as the upper two thirds are resorbed by chondroclasts and the distal third acts as a scaffolding for osteoid deposition from osteoblasts.[7] Within the mineralized cartilage, matrix forms a transverse septum that is invaded by capillary loops from the metaphysis as they penetrate the distal hypertrophic chondrocyte lacunae. The

differentiated chondrocytes then undergo caspase-mediated programmed apoptosis.[8]

Finally, the zone of the outer metaphysis is the area where the endochondral ossification process yields true bone tissue through remodeling of the primary trabeculae into trabeculae of lamellar bone, or secondary trabeculae.[7] This remodeling is mediated by a variety of cells, including undifferentiated mesenchymal cells, preosteoblasts, and osteoblasts in addition to the metaphyseal vascular system.[1] The combined areas of the distal hypertrophic zone and proximal metaphysis are also often referred to

as the zone of provisional calcification.

Whereas the layers described above provide for longitudinal growth, they do not account for the necessary increasing width of the physis during bone development. The growth plate zones are thus circumscribed by a wedge-shaped area of chondrocyte progenitor cells known as the perichondrial ossification groove of Ranvier, which contributes germinal cells to allow expansion of the bone's width at the physis. Within this groove is the fibrous ring of LaCroix, which contains fibers arranged vertically, circumferentially, and obliquely to provide mechanical support in response to compression, tension, and

shear loads on the physis.[1,7]

During the late embryonic phase of development, the epiphyseal cartilages of the long bones are well vascularized, with vessels frequently crossing the physes either partially or completely.[1] Following birth, the transphyseal vascular bridging is eliminated resulting in the physeal vasculature arising from two separate sources. Epiphyseal vessels supply the germinating, proliferating, and upper hypertrophic zones through diffusion, and separate metaphyseal vessels permeate to the level of the distal hypertrophic zone. The epiphyseal and metaphyseal vessels normally only anastomose once the physis has closed,

marking the onset of skeletal maturity.[9] Premature vascular anastomosis across the physis results in pathologic closure of the growth plate. Alteration in this specific vascular pattern can result in aberrant long-bone development at the level of the physis. Disruption of the epiphyseal blood supply is the most devastating injury to the physeal growth plate vasculature. Epiphyseal vessel damage can cause avascular necrosis of both the germinal chondrocytes and secondary ossification center of the epiphysis, resulting in ossification of the growth plate and premature cessation of growth. To the contrary, injury of the metaphyseal vasculature can result in transitory increases in

physeal growth.[1,7]

Growth Plate Physiology

A complex and multifactorial array of factors regulate control over a variety of growth-plate functions including cell proliferation, maturation, hypertrophy and apoptosis, matrix synthesis and mineralization, vascular infiltration, and ultimately physeal closure. Ongoing studies elucidating many of these processes are shedding new light on the disease processes that result in growth-plate dysfunction. Major regulating factors are hormones, growth factors, vitamins, and biomechanical forces.

Chondrocyte proliferation within the

growth plate is believed to be under the primary control of a local negative feedback loop involving three signaling molecules synthesized by growth-plate chondrocytes: parathyroid hormone-related peptide (PTHrP), Indian hedgehog (Ihh), and transforming growth factor-beta (TGF-β).[5,7,10] The release of Ihh by cells newly undergoing hypertrophic differentiation triggers the release of TGF-β by the perichondrium, which in turn stimulates perichondrial and juxtaarticular cells to increase synthesis of PTHrP, thus slowing the progression of proliferating cells expressing the PTHrP receptor from advancing into the hypertrophic stage.[10] This feedback loop is not

exclusive in its control of cell proliferation within the growth plate and is greatly modulated by a number of other systemic and local signaling molecules including the fibroblast growth factor (FGF) family and its receptors.[11] In addition, growth hormone (GH) produced in the anterior pituitary, and its mediator, insulin-like growth factor (IGF), play important roles in physeal chondrocyte proliferation. Chondrocyte maturation and hypertrophy appear to occur spontaneously largely through the actions of the bone morphogenic proteins (BMPs) and their receptors.[12] The peptide hormone thyroxine (T4) can only induce chondrocyte maturation and production of type X

collagen through induction of BMP-2.[13] Because hypertrophy can occur spontaneously, negative inhibitors are likely to be crucially important in the regulation of growth-plate kinetics. Once the chondrocytes have terminally differentiated, their purpose is to foster matrix calcification in preparation for osteoblastic bone formation.[7] Subsequent death and removal of the chondrocyte then allows space for infiltrating vasculature and bone marrow stromal cells.[14] It is now accepted that the death of terminally differentiated chondrocytes occurs through highly regulated apoptosis, or programmed cell death. Alteration in the normal caspase-mediated apoptotic process through mutation of regulating

FGF receptors is now suspected to be the cause of achondroplasia, or dwarfism.[15] The administration of both glucocorticoids and radiation to juvenile animals has been shown to increase the rates of hypertrophic chondrocyte apoptosis, and can alter the shape and normal activity of the growth plate.[16,17,18]

Matrix synthesis in the growth plate is thought to be regulated by many of the same factors that direct the development and differentiation of physeal chondrocytes. One transcription factor in particular, Sox 9, binds with various related proteins to specific enhancer regions in the promoter regions of genes expressing

types II, IX, and XI collagen and aggrecan.[19] Mineralization of the secreted matrix is an essential precursor to the conversion of the chondroid nature of the growth plate to bone. As previously stated, matrix vesicles serve as the principal site for matrix mineralization within the lower hypertrophic zone largely through their accumulation of calcium and alkaline phosphatase. The accretion of calcium is dependent on the calcium channel molecule family of annexins.[20] An interesting relationship exists between type X collagen and annexin V. Type X collagen, present exclusively within the hypertrophic zone of the physis, is able to bind to matrix vesicles with the assistance of annexin V and

subsequently stimulates its activity, thus facilitating calcium deposition.[7,21] Although still incompletely characterized, the likely function of the vesicular alkaline phosphatase is the hydrolysis of pyrophosphate, an inhibitor of hydroxyapatite crystal formation, into two molecules of orthophosphate.[22] Vitamin D is well known for its critical influence on increasing both alkaline phosphatase and MMPs within the chondrocyte. In particular, MMP-13, present within matrix vesicles, is important for the cleavage of type II collagen and the activation of latent TGF-β, both of which are associated with the onset of matrix mineralization.[23,24]

Following matrix mineralization, vascular invasion from the metaphyseal side of the physis is an essential precursor to ossification. The process of vascularization is multifactorial but is largely mediated through the actions of VEGF expressed by hypertrophic chondrocytes and targeting vascular endothelial cells, stimulating their proliferation and migration.[25] Another growth factor that has been shown to possess pro-angiogenic characteristics is basic FGF.[26] Failure of appropriate vascularization results in disruption of normal physeal architecture and widening of the hypertrophic zone with diminished trabecular bone formation.[7] Physeal closure is

associated with a decrease in chondrocyte proliferation, resulting in a diminished height of both proliferative and hypertrophic zones. In most mammals, the epiphysis and metaphysis become fused with resorption of the growth plate following sexual maturity. Some evidence suggests that physeal closure is estrogen-mediated through promotion of chondrocyte-replicative senescence and not through vascular invasion or ossification.[27]

Fractures of the Growth Plate

A thorough understanding of the mechanical properties of the growth

plate has yet to be achieved. Large variation exists among studies, attributable to differences in animal models and their respective ages, test parameters, and the anatomic locations tested. Because the physes represent both the sole source of skeletal longitudinal growth as well as the weakest point of the juvenile skeleton, an understanding of growth-plate biomechanics and modes of failure is essential. Growth-plate fractures are common and can result in significant alteration of physiologic growth function. A close relationship exists between the ultrastructural properties of the physeal extracellular matrix and its mechanical behavior. In cadaveric testing, the germinal and

proliferating portion of the columnar zones are somewhat protected from excessive external force owing to a more random organization of collagen fibers and overall higher concentration of collagen.[28] Experimentally, the hypertrophic zone may represent the weakest region within the growth plate during tensile loading owing to the lower concentration and more regular organization of collagen in addition to the parallel chondrocyte orientation with respect to the longitudinal axis of the bone.[5] The clinical situation may differ greatly, however, with differences in anatomic sites and complexity of offending forces.

A commonly used classification system

of growth-plate fractures intended to correlate the characteristics and prognoses of each fracture configuration was proposed by Salter and Harris.[29] Salter-Harris fractures have been covered in more detail previously within this text but are briefly discussed here in the context of physeal injuries. Using this classification system, physeal fractures can be categorized into one of five types. Type I fractures represent a displacement of the epiphysis from the metaphysis with no associated bone fracture as a result of shearing and tensile forces. Type I fractures are more common in younger animals (< 6 months of age) and were classically thought to carry more favorable

prognoses owing to the larger thickness of the physis at this age and limitations of the fractures to the hypertrophic zone.[30] Several clinical reports now contradict this, however, and important exceptions should be noted. A high incidence of damage to the proliferating portion of the columnar physeal zone has been reported in naturally occurring type I fractures in the dog, explaining the common clinical observation of growth retardation.[31] Additional exceptions occur with specific anatomic sites including the femoral capital physis, which may see direct disruption of ascending epiphyseal vasculature along the femoral neck, resulting in secondary femoral neck resorption.

This has been documented to occur in as many as 70% of affected patients following surgery and ultimately necessitated femoral head and neck excision in 20% of cases in one report.[32,33]

Salter-Harris type II fractures occur along the length of the growth plate but extend into the metaphysis, resulting in a wedge-shaped metaphyseal fragment that remains attached to the epiphysis. The side on which the metaphyseal fragment occurs is related to the direction of the impacting force and subsequent bending of the bone. Most metaphyseal fragments remain adhered to the epiphyseal component on the concave

aspect of the deformed bone during impact.

Type III fractures are intraarticular in that an epiphyseal fracture communicates with the fissure extending along the growth plate. With disruption of the articular cartilage and subchondral bone, a higher likelihood exists for postoperative osteoarthritis. Goals for surgical treatment include accurate reduction and fixation of the articular components to reestablish the joint surface.

Type IV fractures consist of type III fractures with the addition of a metaphyseal extension of the

epiphyseal injury. Like type III fractures, type IV fractures are intraarticular and thus require perfect anatomic reduction to reduce the risk of secondary osteoarthritis. Displaced type IV fractures must also be accurately reduced to minimize the risk of formation of a bone bridge along the fracture line that extends from the joint across the physis and into metaphysis, resulting in subsequent growth retardation.[5]

Type V Salter-Harris fractures are classically described as compression fractures of the growth plate. The offending compression is theorized to result in necrosis of proliferating chondrocytes of the growth plate,

resulting in overall growth arrest of the bone if the entire physis is affected or angular limb deformities if only a portion of the physis is involved. The most commonly affected location in the dog is the distal ulnar physis because of its unique conical shape. In cases in which the distal ulna is affected without concomitant involvement of the distal radius, antebrachial deformation ensues in the form of excessive procurvatum, external rotation, and carpal valgus.

Again, caution should be used in extrapolating prognosis based on radiographic interpretations of fracture configurations. Numerous other factors that are difficult or impossible to assess

radiographically have a tremendous impact on the response of the bone as it heals, including the post-traumatic status of epiphyseal vasculature, the physeal zone affected, and the nature of insulting forces creating the fracture.

Pathologic States Affecting the Growth Plate

Irradiation

Although much more frequently diagnosed in people, juvenile osteosarcoma has been reported in dogs.[34] Palliative treatment of bone tumors with various forms of radiation has been investigated in several juvenile animal models, elucidating the

negative impact radiation has on growth-plate physiology. It has been determined that the proliferating cells of the upper portion of the columnar zone and epithelial cells of the metaphyseal vasculature are the most radiosensitive cellular populations of the growth plate.[35,36] Studies investigating the effects of a β-particle-emitting radionuclide on physeal growth and development in skeletally immature rabbits revealed decreased production of type X collagen and MMP-13 in hypertrophic chondrocytes with subsequent limb shortening in treated animals.[18]

Bacterial

Bacteria are capable of invading the metaphyseal portion of the growth plate causing microabcessation through vascular sinusoids. Although it is not clearly understood why these infections occur, theories include reduced blood velocity through the torturous vascular system, low oxygen tension, and deficiencies in the reticuloendothelial system.[5] Likely to be more common in the horse and human, bacterial physitis has been reported to occur in the dog most frequently in the lumbar vertebra, where it causes lucent widening of the growth plate and loss of definition of the physeal margins.[37] Although collapse of the physis and subsequent sclerosis typically ensues, secondary sequestration has been

reported requiring sequestrectomy and long-term antimicrobial therapy.[38]

Endocrine

As previously described, the physes function under intimate guidance by the various components of the endocrine system. Endocrine diseases, therefore, can result in alteration of normal growth-plate physiology and secondary skeletal deformities. It is important to note that some features typical of endocrine disorders are often accepted as breed characteristics in the dog.[39] Increases (gigantism) or decreases (dwarfism) in body size can be considered normal and classified as constitutional, as the result of complex

genetic effects, or abnormal, as the result of endocrinopathies or other complex disorders. Each condition can exist either proportionately or disproportionately, depending on whether the appendicular and axial skeletal components are altered in synchrony.

The anterior pituitary gland, under the stimulation of the hypothalamus, releases growth hormone, which plays an important role in chondrocyte proliferation, physeal development, and bone growth. Alterations in available concentrations of growth hormone result in developmental skeletal disorders. Reduction in levels of growth hormone production by the

anterior pituitary gland typically results in proportionate dwarfism, which is a rare but well documented disorder in the dog, most frequently affecting the German shepherd dog (Figure 109-2). In this breed, hypopituitary dwarfism is known to be an autosomal inherited disorder.[40] In most of these cases, intrapituitary cysts exist and enlarge with age; suprapituitary stimulation does not increase the release of GH or thyroid stimulating hormone (TSH).[41] Hypopituitary dwarfs demonstrate retarded bone development and delayed epiphyseal fusion.[42] The growth plates may remain open for years, and possess architectural derangement of the proliferating

chondrocyte arrangement and intercellular matrix.[42]

Figure 109-2. Photograph of three German shepherd dog littermates, aged 6.5 weeks. The two puppies on the left represent proportional hypopituitary dwarfs. (Courtesy of Ms. Susie Zeiner and Mr. John Walker.)

True hyperpituitary gigantism (acromegaly) is rare in small animals. Normal giant breeds of dogs represent proportional constitutional gigantism, and may possess the features frequently associated with acromegaly in humans, including bone thickening of the supraoribtal frontal bones and enlarged paws manus and pedes. Interestingly, GH levels are normal in these dogs, but concentrations of IGF-1 may be elevated.[43] An acromegalic syndrome in cats is documented, which occurs in middle-aged to older animals, associated with GH-secreting tumors of the pituitary gland with many clinical sequelae; however, the age of onset obviates growth-plate involvement.

Congenital or juvenile-onset hypothyroidism has been frequently documented in the dog. The skeletal manifestations of this disorder include delay in time of ossification of the epiphyseal centers (epiphyseal dysgenesis) and physeal closure, stunted growth, and disproportionate dwarfism (Figure109-3).[42,44] Familial congenital hypothyroidism has been documented in Scottish deerhounds,[45] giant schnauzers,[46] boxers,[47] and toy fox terriers.[48] Some evidence suggests that, if a diagnosis can be made at an early age (< 4 months), appropriate treatment can result in remission.[46]

A close association exists between the sex steroids, estrogen and testosterone,

and the onset of skeletal maturity. Whereas androgen alone does not affect growth-plate closure, estrogen accelerates physeal fusion and terminates linear growth.[49] Androgens are converted to estrogens via aromatization in the male, such that estrogen mediates growth termination in both genders. Thus, prepubertal surgical gonadectomy can affect bone development. Salmeri et al determined that radial and ulnar growth-plate closure was delayed in dogs by 4 months if surgical gonadectomy was completed at 7 weeks of age, and by 3 months if gonadectomy was completed at 7 months of age.[50] Although not examined in this study, it was suspected that animals neutered prior

to skeletal maturity might be more susceptible to sustaining traumatic Salter-Harris fractures for a longer time.[50] Subsequently, spontaneous, atraumatic fractures of the capital physis in male cats have now been shown to be linked with prepubertal gonadectomy.[51] This population of cats still possessed open growth plates at a mean age of 94.5 weeks, suggesting that the diminished presence of androgens could have resulted in delayed growth-plate closure and thus posed a higher risk for fractures.[51]

The animal was diagnosed with congenital hypothyroidism. Note the complete lack of ossification of the epiphyseal centers (epiphyseal dysgenesis). (Courtesy of Dr. Valerie Samii.)

Chondrodysplasias

Chondrodysplasia is a general term referring to any number of disturbances in the development of the cartilaginous growth plates, primarily of the long bones. It frequently results in achondroplasia, which is disproportionate dwarfism, where the long bones of the appendicular skeleton are shortened but the axial components, including skull and vertebral column, are of normal size. Many types of chondrodysplasia have been documented and are cited as specific entities particular to certain breeds. Again, these disorders are distinguished from constitutional dwarfism owing to chondrodystrophy, which is accepted as a nonpathologic breed standard in many types of dog

(e.g., Basset hounds, Welsh corgis, and beagles). Brief descriptions of various reported chondrodysplasias are discussed; however the reader is referred to pathology texts and listed references for more detailed descriptions of each.

Pseudoachondroplastic dysplasia has been documented in both miniature poodles and Scottish deerhounds, although the disease has characteristics unique to each breed.[52,53] However, the condition is likely to be autosomal recessive in both breeds and is first recognized when the animals are several weeks old. Although histologic changes of the physeal derangements are specific and well described for the

different breeds, linear growth of the long bones only reaches approximately 65% of that of normal dogs of like breed.[52,53,54] By the time the animals achieve skeletal maturity, severe angular limb deformities are noted, with subsequent marked joint laxity.

A condition has been documented to affect young beagle dogs called *multiple epiphyseal dysplasia*, in which stippled mineralizations can be radiographically detected in the epiphyses of the femur, humerus, and carpal and tarsal bones.[55,56] Clinical and radiographic signs are first detected at 3 to 4 weeks of age; however, they typically resolve with development and are no longer

apparent by 5 months of age.[42] Affected dogs may possess osteoarthritis as adults, attributable to the abnormal epiphyseal development.

Specific chondrodysplasias have now been documented for several canine breeds. The condition is well documented in the Alaskan malamute, in which a disproportionate dwarfism with concurrent macrocytic hemolytic anemia results from the autosomal recessive disorder. Among other clinical sequelae, hallmarks of the disease include derangement of the proliferative zone of the physes and abnormal endochondral ossification that is radiographically most apparent as flattened distal ulnar physes and

retarded ossification of cuboid bones detected between 4 and 12 weeks.[42,57] A similar chondrodysplasia causing disproportionate dwarfism in Norwegian elkhounds has been documented, with a distinguishing characteristic being shortened vertebral bodies.[58] Chondrodysplastic dwarfism with vertebral malformation has been described in great Pyrenees, which also exhibit concurrent deafness.[59] Dwarfism has also been reported as autosomal rececssive traits owing to chondrodysplasia in the English pointer and Irish setter breeds.[42,60]

Oculo-skeletal dysplasia has been reported in both the Labrador retriever

and Samoyed breeds.[61,62] Aside from the ocular pathology, which includes cataracts and retinal dysplasia, affected animals may also be chondrodysplastic dwarfs with more severely affected forelimbs. Secondary changes can include fragmented coronoid processes, ununited anconeal processes, and hip dysplasia. In the Labrador, the severity of dwarfism is positively correlated with the extent of microscopic degeneration of the physeal chondrocytes, detected in part by the presence of cytoplasmic inclusions.[63]

Nutritional

Many nutritional disorders can affect

bone physiology, and with respect to the growth plate specifically, it is well documented that certain dietary alterations can cause pathologic changes to physeal architecture and development. Diets low in vitamin D and phosphorus can result in rickets, causing derangement of the normal chondrocyte columns within the physes, an inability to appropriately calcify the matrix surrounding the hypertrophied cells, and diminished vascular invasion from the metaphysis necessary for physeal closure.[39] Large projections of uncalcified cartilage subsequently protrude into the metaphysis and are occasionally bypassed by the irregular ingrowth of vascularized, ossifying tissue, resulting

in a tortuous metaphyseal junction.[42] Angular limb deformities can occur secondary to the growth-plate disturbances. Hypervitaminosis A has been reported to cause exuberant and premature calcification of growth-plate cartilage, resulting in early physeal closure.[64]

Idiopathic

Retardation of endochondral ossification and the formation of apparent retained cartilage cores have been reported to affect most frequently the distal canine ulnar growth plate (Figure 109-4).[65] These lesions consist of a cone of unmineralized hypertrophic cartilage projecting from

the growth plate into the metaphysis. Although the etiology is unknown, it is speculated that they arise either from a process similar to osteochondrosis or an interruption to the metaphyseal blood supply.[42] They typically occur bilaterally and can be associated with premature closure of the distal ulnar physis with secondary antebrachial angular limb deformities.

Figure 109-4. Lateral radiograph of a distal canine radius and ulna exhibiting a retained cartilage core apparent as a longitudinal radiolucent projection extending from the open physis proximally into the metaphysis.

Chapter 110

Biomechanics of Luxation

Dr DA Hulse

Luxations are a common occurrence in small animal veterinary medicine. Decisions on appropriate treatment strategies are based on many factors. One of the most important of these factors is an understanding of the biomechanics of joints. Armed with this knowledge, mechanisms of injury can be understood and sound decisions relative to treatment methods can be made to restore normal function. In

this section, we address biomechanics, which is the science of the action of forces, internal and external, on the living body, an unfamiliar topic for many veterinarians.

Diarthrodial or synovial joints are complex structures loacated at the ends of long bones. Each joint is a composite made of hyaline ar¬ticular cartilage, synovial lining tissue, joint capsule, and ligaments. Tendons and muscles cross joint articulations, lending substantial support to the joint. The sequence of events encountered by the joint during trauma and the sequelae of these events are discussed in this chapter. It is important to realize, however, that

most forces are exerted indirectly on the joint, and the resultant deformation of anatomic structures depends on many factors, such as (1) the direction of the force, (2) the speed of the force, (3) the attitude (position) of the animal, (4) the age of the animal (e.g., open or closed physes), (5) the configuration of the bones and joints (e.g., bones of basset hounds versus those of a greyhound), and (6) preexisting joint disease (e.g., laxity, hip dysplasia).

Forces singularly or coupled (e.g., rotation and bending) directed at the appendicular skeleton of the animal are transmitted along the limb and may result in a joint subluxation or

complete joint luxation. Additional injuries may combine with joint trauma; these may include: bone fracture, tendon tear, capsular tissue avulsion, or physis separation in young animals. The veterinarian should maintain a high degree of suspicion when examining animals subjected to trauma. A clearly evident fracture in a limb may be associated with a less noticeable luxation in the same limb. An example would be a fractured distal tibia with dislocation of the hip in the same limb. The shoulder, elbow, carpal, hip, stifle, and tarsal joints are discussed here, and a set of events that may lead to luxation of the particular joint is outlined. Surgical considerations that deal with the

damage done by luxation are discussed when applicable.

Shoulder Joint

Anatomy

Being a ball and socket joint, the shoulder joint is well suited for movement in all directions. Although capable of movement in all directions, the shoulder primarily moves in flexion and extension. Joint stability is provided through a combination of passive and active mechanisms (Figure 110-1). Passive mechanisms include the medial and lateral glenohumeral ligaments, surrounding joint capsule, joint conformation, and synovial fluid cohesion. The medial collateral

ligament (MCL) commonly appears as “Y” shaped with the cranial arm coursing caudally from its origin at the medial surface of the supraglenoid tubercle. The caudal arm of the MCL originates from the medial surface of the scapular neck and joins the cranial arm to insert onto the humeral neck. The MCL and associated joint capsule are major factors in providing joint stability. Complete medial luxation occurs following transection of the medial glenohumeral ligament (MGHL). (1) The lateral collateral ligament (LCL) originates from the lateral rim of the glenoid and extends ventrally to insert onto the humerus at the caudal region of the greater tubercle. The joint capsule originates

from the periphery of the glenoid cavity. Medially, the joint capsule forms a synovial recess owing to its attachment several millimeters proximal to the glenoid rim. The concavity of the glenoid and the fit of the humeral head into the glenoid provide joint stability. This is particularly true when compression across the joint is enhanced by active muscle contraction. Dynamic active glenohumeral stability is provided by contraction of the surrounding cuff muscles. These include the biceps brachii, subscapularis, teres minor, supraspinatous, and infraspinatous muscles. Active contraction of all or selective cuff muscles induces compression across the shoulder joint

as well as increasing tension in the joint capsule. When tested in a neutral position, the cranial, lateral, and medial translation of the humerus was significantly increased after biceps tendon transection. In the flexed position, translation of the humerus in the cranial and lateral directions was significantly increased after biceps tendon transection. In the extended position, the medial translation of the humerus was significantly increased after biceps tendon transaction.[1]

Figure 110-1. Photograph of the passive and active restraints of the shoulder joint. Passive restraints are the medial collateral ligament, lateral collateral ligament, and surrounding joint capsule. Active restraints are the surrounding cuff muscles, which include the biceps, supraspinatus, infraspinatus, and supscapularis muscles.

Examination of the shoulder for stability should be done under anesthesia. Flexion, extension, abduction, adduction, and rotational stability of the shoulder joint should be assessed. Normal ranges of flexion and extension are 40° for flexion and 165° for extension. A normal abduction test is approximately 25°; abnormal abduction is considered present when abduction exceeds this degree and there is a difference in the abduction angle between the injured side and the

normal side. Note that dogs with long-standing forelimb lameness often present with laxity. In the majority of these cases, approximately 45° of abduction exists on the affected side with a normal abduction on the sound limb (25°).

Biomechanics

A fall or jump from a height may produce a shoulder subluxation or luxation. An example in a toy breed would be the dog jumping from an owner's arms. Another mechanism of injury causing subluxation/luxation of the shoulder would be if the animal is bearing weight at the time that a blunt force is applied to the proximal area of

the humerus. The direction of subluxation/luxation is dependent on the direction of force application (i.e., anterior to posterior, medial to lateral). Because the limb is bearing weight, it forces the proximal humerus to accept most of the blow. If the foot is off the ground, the leg is able to swing in the direction of the force, diminishing the chance of a subluxation or luxation. In addition, when the limb is bearing weight, the humerus is down and away from the chest wall, and no medial, shock-absorbing protection is available from the chest wall. With a laterally to medially directed force, the humeral head can be driven medially, rupturing the medial restraints (MCL,

subscapularis tendon, and joint capsule). The humeral head lies medial to the glenoid of the scapula, resulting in a medial luxation (Figure 110-2).

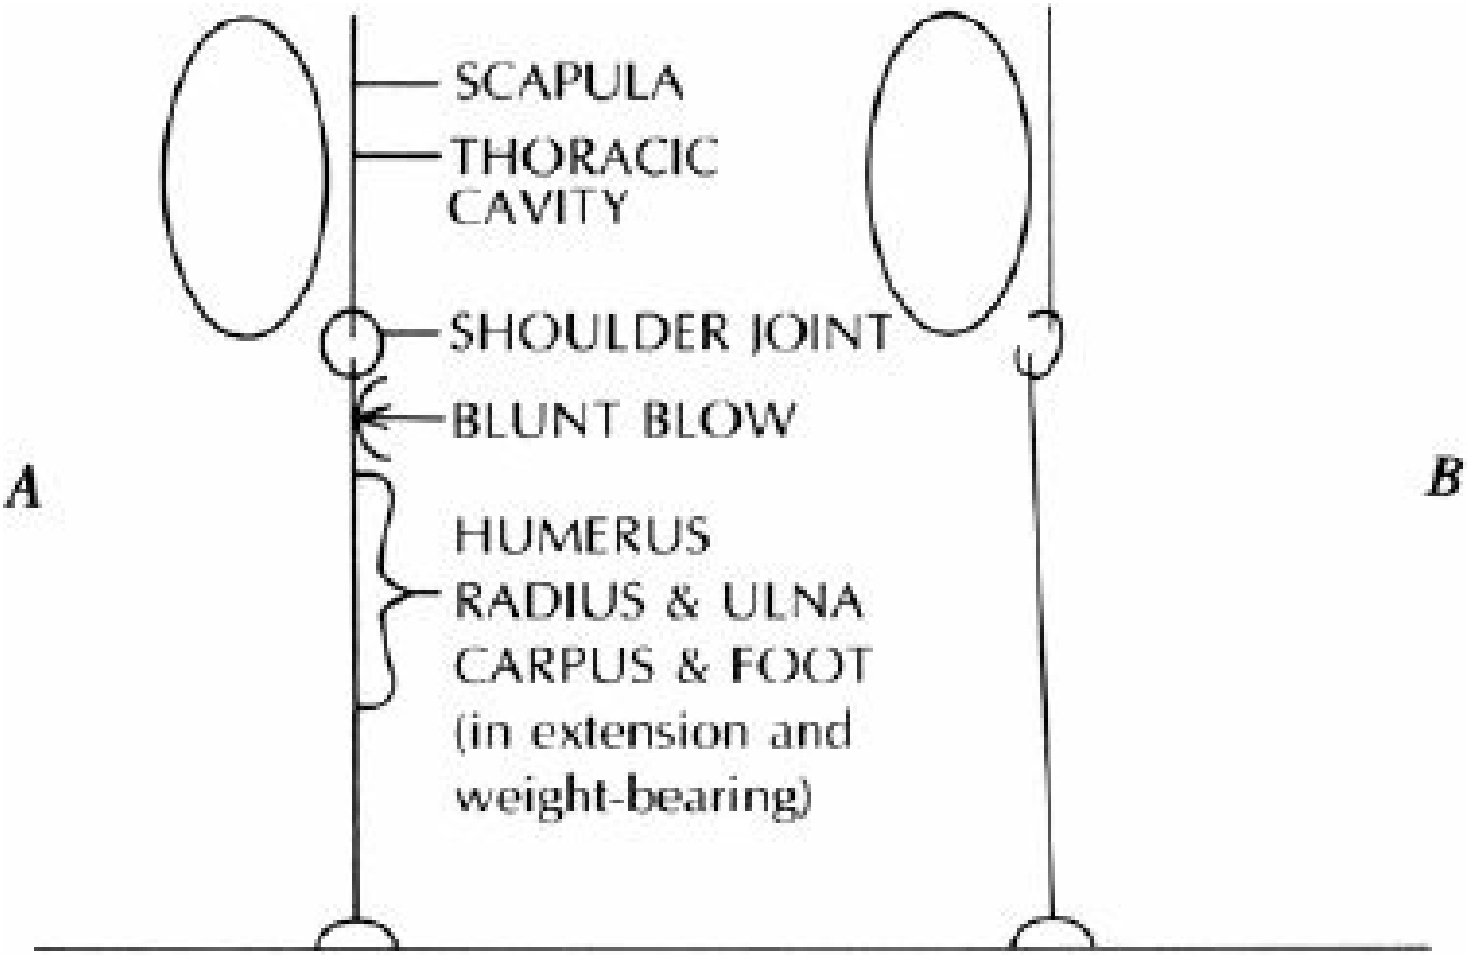

Figure 110-2. A and B, Schematic drawings of an animal seen in an anteroposterior view. A medial luxation of the humeral head is due to a blunt blow to the proximal lateral surface of the humerus.

Medial Luxation

A medial to lateral force directed against the body may result in a medial subluxation or luxation if, when the force is applied, the foot is in contact with the ground. In this position, the leg starts to abduct as the body moves toward the ground. This action may be caused by a blow from a moving vehicle or a fall from a height. As the extended limb starts to abduct, a long lever arm is created from the foot to the shoulder. The greatest stress occurs on the medial side of the shoulder joint, rupturing the medial restraints (Figure 110-3).

Treatment Strategies

CLOSED REDUCTION: If, following reduction, the shoulder joint maintains the correct position, reduction can be maintained with a Valpeau sling. The elbow should be taped to the chest wall, producing a lateral force at the shoulder joint. A Valpeau sling should remain in place for 3 weeks. Once the splint is removed, the attending veterinarian should radiograph the shoulder and examine the joint under anesthesia. Either palpation to detect subtle subluxation with rotation or the abduction test is performed.

OPEN REDUCTION: A medial approach with careful identification of all injured tissue is required. Placement of suture anchors at the origin and

insertion of the Y-shaped medial collateral ligament is achieved. Nonabsorbable suture is used to reconstruct the MCL.

Lateral Luxation

Lateral luxation occurs when the limb is in full extension and is forced into adduction during weight bearing. This action can be caused by a blow from a moving vehicle or a fall. The force is applied principally to the lateral surface of the shoulder. The force injures the lateral cuff muscles and collateral ligament, allowing the humeral head to luxate laterally to the glenoid (Figure 110-4).

Another mechanism for injury is a blow to the proximal end of the humerus. The blow is directed from cranial to caudal. Because the joint is in midflexion, the humeral head is more easily driven out of the glenoid cavity. The tendons surrounding the joint are fairly relaxed, and the greater tubercle is below the scapular tuberosity and glenoid. If the force of the blow is sufficient, the humeral head is driven out of the glenoid cavity. Depending on which tendons rupture first (subscapularis or infraspinatus), the humeral head eventually lies on either the medial or lateral side of the glenoid.

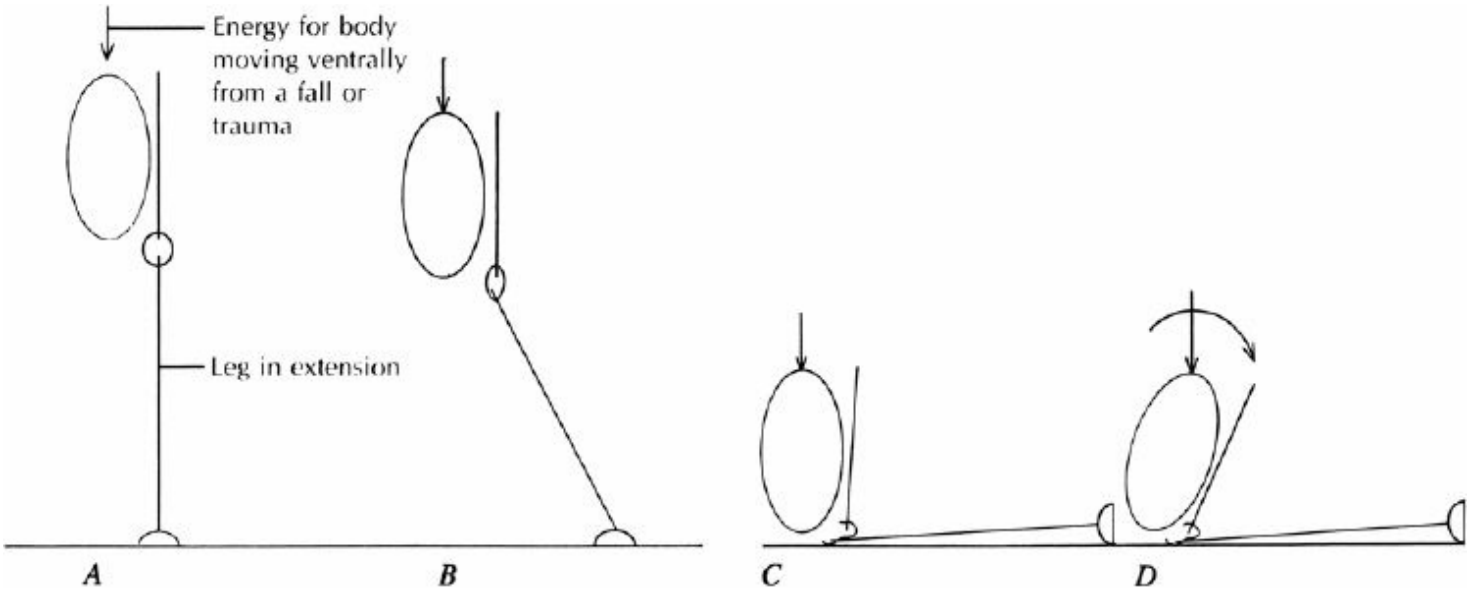

Figure 110-3. A, The animal's body is moving ventrally while the forelimb is in extension and weight-bearing. B, As the chest continues ventrally, the limb begins to abduct, putting stress on the medial side of the shoulder joint. C, As the chest nears the ground, the medial side of the joint ruptures, allowing the humeral head to luxate medially. D, The stress on the medial side of the joint can be greatly exaggerated if at the same time the body is moving ventrally it is also rotating toward the affected limb.

Treatment Strategies

CLOSED REDUCTION: Measures are the same as for medial luxation, except that padding is placed between the

elbow and chest wall, producing a medial force at the shoulder joint.

OPEN REDUCTION: A lateral approach with careful identification of all injured tissue is required. Placement of suture anchors at the origin and insertion of the lateral collateral ligament is achieved. Nonabsorbable suture is used to reconstruct the LCL.

Elbow

Anatomy

The elbow is a composite ginglymoid (hinge) joint formed by the humeral condyle, the head of the radius and the semilunar notch of the ulna. The entire joint consists of three separate

articulations enclosed within a single joint capsule. The humeroradial joint occurs between the humeral capitulum and the radial head and is thought to transmit the majority of weight through the elbow. The humeroulnar joint occurs between the humeral trochlea and olecranon fossa of the humerus and the articulating surface of the semilunar notch and anconeal process of the ulna. The humeroulnar joint, along with the collateral ligaments, provides stability to the elbow, particularly in extension. The proximal radial head fits into the coronoid processes of the ulna and allows some supination and pronation. In the normal Labrador retriever, the elbow joint functions primarily in

flexion and extension, allowing up to 36° of flexion and 166° of extension.[2] It has been reported that, with the elbow and carpus flexed to 90°, the collateral ligaments limit internal rotation to 60° and external rotation to 40°.[3] The collateral ligaments originate from the medial and lateral humeral epicondyles and split into cranial and caudal crura as they course distally to insert on the proximal radius (cranially) and the lateral ulna or the caudal radius, annular ligament, and medial interosseous space.

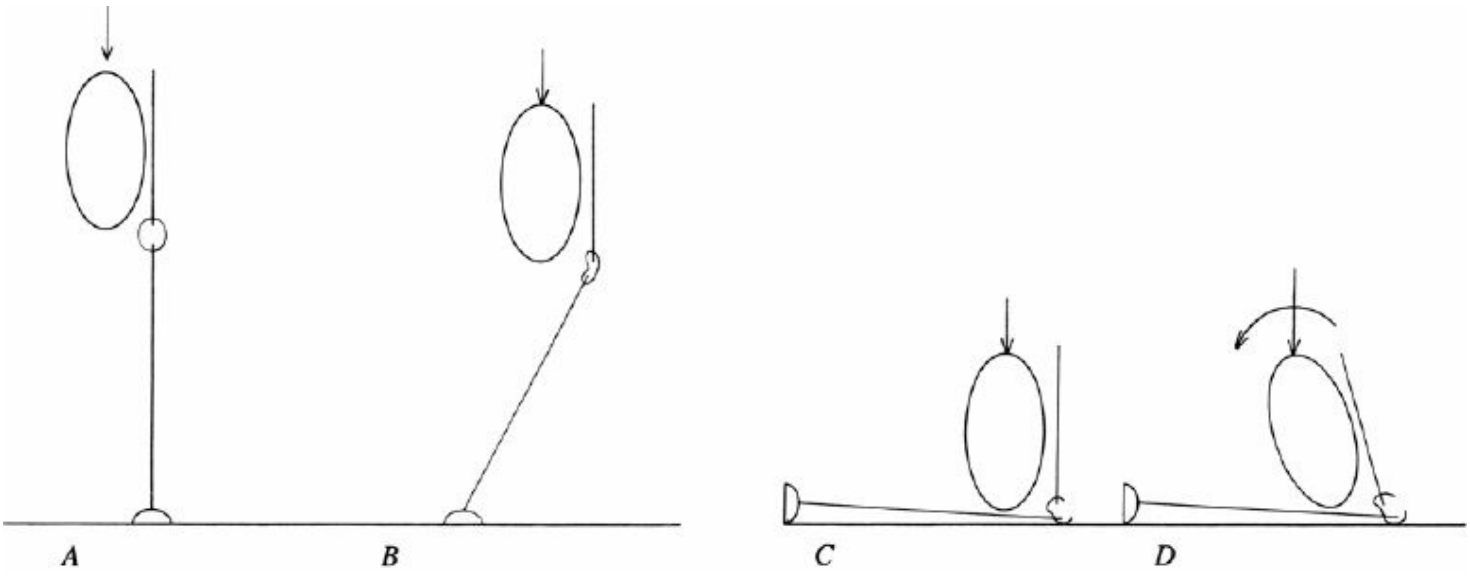

Figure 110-4. A, The animal's body is moving ventrally. The forelimb is in extension and is weight bearing. B, As the body continues ventrally, the limb moves into abduction causing stress on the lateral side of the shoulder joint. C, As the chest nears the ground, the lateral side of the joint ruptures, allowing the humeral head to luxate laterally. D, The stress on the lateral side of the joint can be greatly exaggerated if at the same time the body is moving ventrally it is also rotating away from the side of the affected limb.

Acquired Elbow Joint Luxation

Elbow luxation is much less common

than fractures involving the elbow, likely because of the inherent stability of the anatomy of the joint. When elbow luxation occurs in the dog, it is thought to be caused primarily by rotation of the body around a flexed, weight-bearing limb rather than by a direct blow to the elbow or by landing on an extended forelimb (Figure 110-5). In the dog, lateral luxation occurs in over 90% of cases, although medial and caudal luxation have been reported.[4] The larger shape and orientation of the medial condyle make medial luxation much more unlikely. The one reported case in a cat was a medial elbow luxation.[5] The diagnosis of elbow luxation is almost always associated with significant impact,

such as being hit by a car, although luxation has been reported after fighting or rough play. The animal will be severely lame, usually unable to bear weight, will have a swollen elbow with limited range of motion, and painl on attempted manipulation of the joint. Although luxation of both the radial head and the anconeal process laterally are most commonly seen, in about 20% of cases the ulna is not completely luxated. In addition, the clinician should be aware that a caudal blow to the ulna may result in radial head luxation and concurrent ulnar fracture (Monteggia fracture). Monteggia fractures, discussed elsewhere in this text, can be challenging to repair and are handled

differently from a straightforward traumatic elbow luxation.

Treatment Strategies

ACUTE LUXATION: A complete physical examination should focus on other major orthopedic or thoracic injuries, which can be present in up to 30% of cases. The affected forelimb should be assessed carefully to assure intact innervation and vascular supply. Radiographs of the antebrachium should be carefully examined for ulnar fracture (which may be very distal) and fractures of the anconeal process, fragmented coronoid process, and avulsions of the epicondyles where the collateral ligaments attach. Once the

animal is stable, closed reduction should be performed under general anesthesia. Reduction should be radiographically confirmed, and the elbow should be fairly stable once reduced. Post-reduction coaptation is controversial; a variety of recommendations can be found in the literature, from no bandaging at all to 4 weeks in a Spica splint, incorporating the shoulder joint. At a minimum, bandaging in flexion (for example, a Valpeau sling) should be avoided as the elbow is more likely to reluxate in that position. The animal should be confined to leash walks and crate rest for a minimum of 2 weeks. If malalignment or instability are present after reduction, or if reluxation occurs,

open reduction is recommended. Some authors also recommend surgical repair of collateral ligaments even after closed reduction if it is radiographically apparent that one or both epicondyles have avulsed. Although the majority of reductions performed early after luxation give good to excellent results, the owners should be warned that degenerative joint disease and lameness can be the end result.

CHRONIC LUXATION: Luxations of over 1 to 2 weeks' duration are generally considered chronic. All chronic luxations require open reduction. The amount of cartilage damage, muscle contracture, and

fibrosis present will dictate whether the luxation can be reduced and also correlate with decreasing prognosis for normal use of the limb. In all cases of chronic elbow luxation, the surgeon should warn the owner that arthrodesis or amputation may be an option.

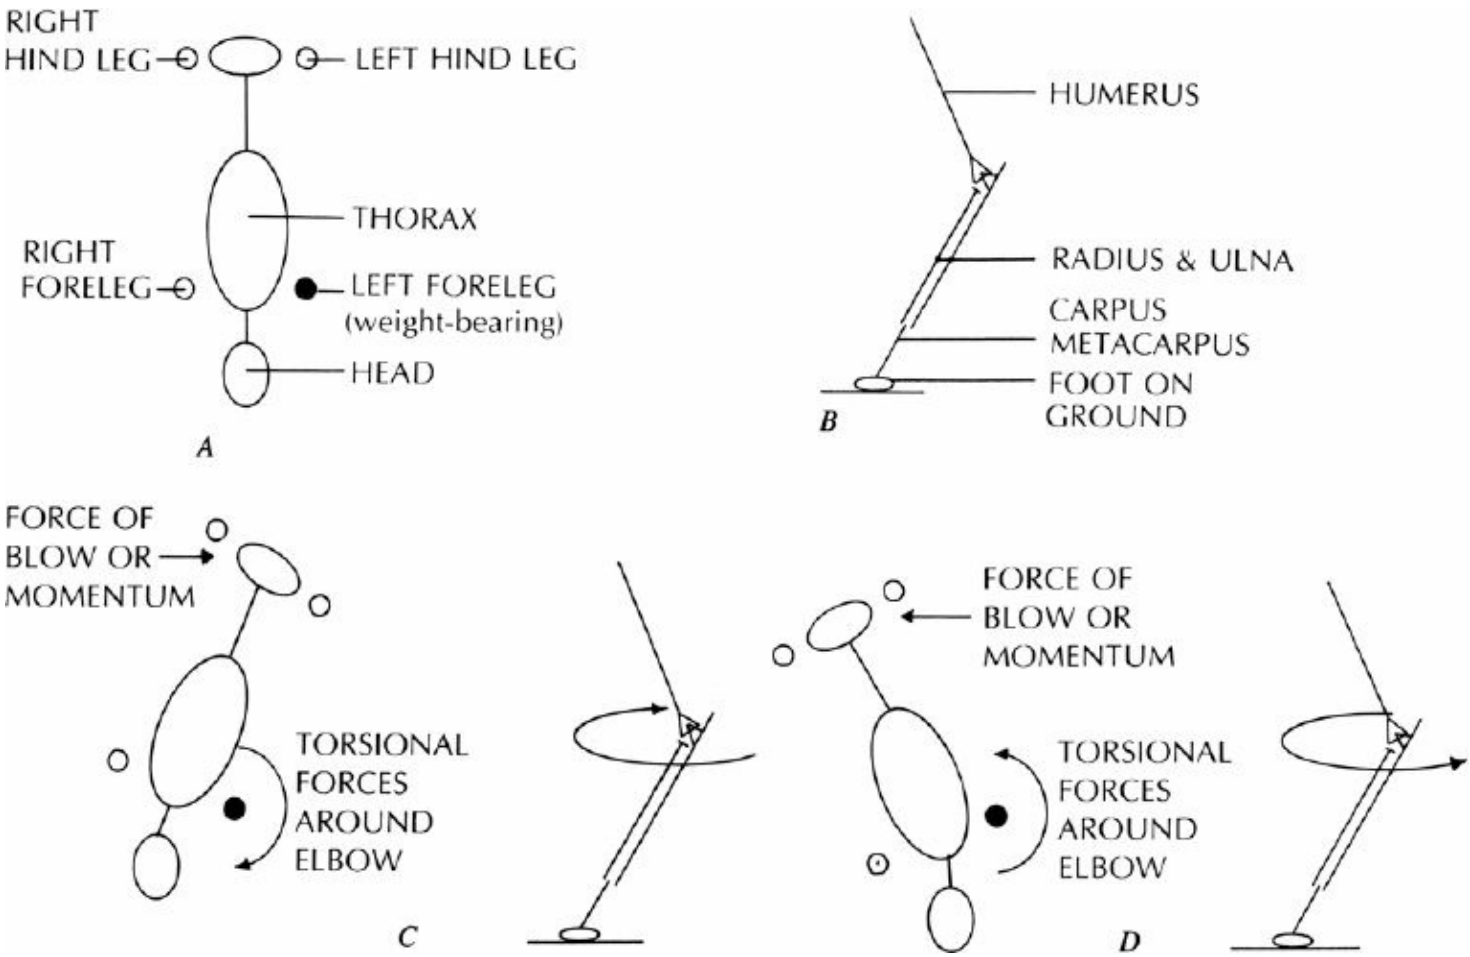

Figure 110-5. Schematic drawings show the animal from two views. A, A top view shows the left foreleg circled in solid black because that will be the weight-bearing limb. B, A lateral view of the forelimb. C, The forces acting on the animal cause the rotational forces to be in a clockwise direction as viewed from above. D, The force acting on the animal's body causes the rotational forces to be in a counterclockwise direction as viewed from above.

Carpus

Anatomy

The carpus consists of seven bones arranged in two rows. The radial carpal and ulnar carpal bones make up the proximal row, while the first, second, third, and fourth carpal bones make up the distal row. The accessory carpal bone lies caudally and articulates with the ulnar carpal bone. The radial carpal bone and ulnar carpal bone articulate with the radius and styloid process of the ulna to form the radiocarpal joint. This joint has the greatest amount of movement. The middle carpal joint, formed by the articulation of the proximal and distal rows of carpal bones, accounts for 10% to 15% of carpal motion. Little motion occurs in the carpometacarpal and

intercarpal joints. Collateral ligamentous support arises from the short radial collateral ligament medially and from the short ulnar collateral ligament laterally. Additionally, sleeves of collagenous tissue that house tendons provide medial and lateral collateral support. Palmar support is from the flexor retinaculum proximally and palmar fibrocartilage distally. Multiple small ligaments cross the intercarpal articulations between carpal bones to provide additional collateral and palmar support. Two of these, the palmar radiocarpal ligament and the palmar ulnar carpal ligament are important structures in providing palmar support for the radiocarpal

joint (Figure 110-6). Two accessory ligaments originate from the free end of the accessory carpal bone and insert onto the palmar surface of the fourth and fifth metacarpal bones. The caudal position of the free end of the accessory carpal bone, in conjunction with the accessory carpal ligaments, serves to act as a moment arm to balance the vertical force produced when the paw strikes the ground.

Carpal hyperextension injuries are divided into the following three categories. Type I injury is a subluxation or luxation of the radiocarpal joint (may include damage to the middle carpal and carpometacarpal joints). A Type II

injury is a disruption of the accessory carpal ligaments, palmar fibrocartilage and palmar ligaments of the middle carpal and carpometacarpal joints. The result is a subluxation of the middle carpal and/or carpometacarpal joints with dorsal displacement of the free end of the accessory carpal bone and ulnar carpal bone. A Type III injury is a disruption of the accessory carpal ligaments, carpometacarpal ligaments, and the palmar fibrocartilage. In these injuries, a subluxation of the carpometacarpal joint occurs without disruption and displacement of the accessory carpal and ulnar carpal bones.

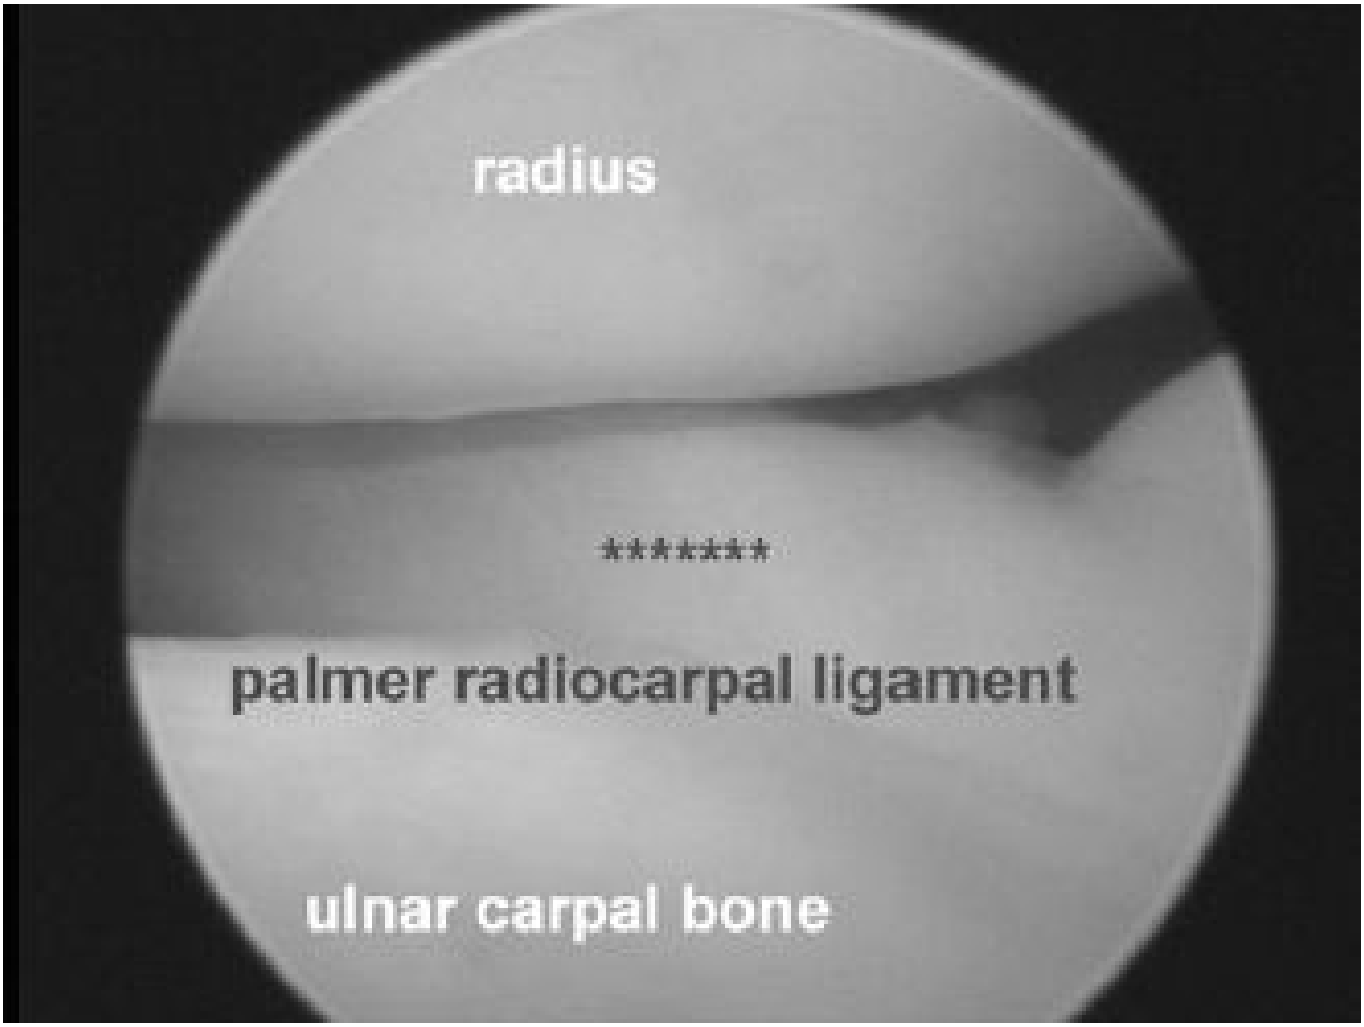

Figure 110-6. Photograph showing the palmar radiocarpal ligament and the palmar ulnar carpal ligament. These ligaments are important in providing craniocaudal and rotational support for the radiocarpal joint.

With an acute injury, ligamentous disruption is complete and the patient presents with a nonweight-bearing lameness. Swelling, pain, and

instability are evident on examination. In Type I injuries, the patient generally remains nonweight bearing until definitive treatment is achieved; in Type II or Type III injuries, the patient may begin to bear minimal weight with the limb after the injury. However, as the patient increases the amount of weight placed on the limb, collapse and hyperextension of the carpus are evident. Standard craniocaudal and medial-to-lateral radiographs are indicated to determine the presence of bone fractures and/or joint malalignment. To accurately assess the integrity of the carpus, however, stress radiographs should be taken. The purpose of stress radiography is to assess the point of

injury and to determine if the integrity of the radiocarpal joint is intact. If the integrity of the radiocarpal joint is intact, then a partial arthrodesis is indicated; if the integrity is lost, a pancarpal arthrodesis is preferred. Although stress radiographic evaluation is a valuable tool, false positives (i.e., radiocarpal joint not intact) are possible. Another valuable tool to assess the integrity of the radiocarpal posterior ligamentous support is arthroscopic examination prior to deciding on a partial carpal or pancarpal arthrodesis.

Biomechanics

The carpus is a complex structure.

Type I luxations of the carpus are uncommon, and when they occur they usually involve the antebrachiocarpal joint. Luxations can be found with severe shearing injuries involving the carpus. Subluxation associated with hyperextension is the most common form of luxation in the carpus. The energy needed to cause luxation often comes from the animal's falling or jumping from a height or jumping out of a fast-moving vehicle and landing on a fully extended limb. As the foot makes contact with the ground, the carpus hyperextends, allowing the volar aspect of the proximal metacarpal bones to strike the ground. This transmits a violent force proximally through the carpal bones

toward the radius. At the same time, the force of the weight of the animal travels ventrally through the radius toward the carpus. When sufficient opposing forces travel through the column of bones held together by ligaments, luxation of one or more the carpal joints is possible. On some occasions, when an animal is falling to the ground as in the previous situation, the foot knuckles over into flexion. As the radius continues to drive ventrally, the foot is forced into extreme flexion, causing severe stress on the anterior side of the carpus. In this case, any or all of the joints of the carpus may open anteriorly, rupturing the joint capsule and interosseous ligaments. When an animal is struck by a vehicle, the

carpus may be dragged along the road, causing severe shearing injury to the medial or lateral side. Generally, all the collateral support structures (skin, ligaments, tendons, joint capsule, and sometimes a considerable amount of bone) are lost. Again, the antebrachiocarpal joint is the most susceptible to luxation.

Treatment Strategies

CLOSED REDUCTION: If the damage is not too severe, it is possible to obtain healing and stability with the use of splints or casts. External coaptation must be rigid for the initial 4 weeks and then gradually stabilized over the next 4 weeks. The carpus is originally

placed in mild flexion and gradually extended to a normal standing position. External coaptation is more successful with injuries to the anterior (dorsal) restraints as compared with injuries of the caudal restraints.

OPEN REDUCTION: Primary ligamentous repair, i.e., suturing the ligament ends is not successful. Likewise, reconstruction with autogenous or autologous tissue has not been rewarding. The common method for surgical repair is fusion of the injured joint(s). The method of surgical intervention depends on the classification of injury. Type I carpal injury requires a pancarpal arthrodesis; Type II injury can be

repaired with a pancarpal or partial carpal fusion, whereas Type III injury requires a partial fusion. Good to excellent results can be expected when this procedure is done correctly.

Hip Joint

The hip is by far the most common site of traumatic luxation in dogs and cats. No collateral ligaments exist, and the muscles that attach to the proximal end of the femur allow a great deal of motion in the joint. The major stabilizing feature of this joint is the ball-and-socket configuration itself. Contraction of the surrounding muscles is of primary importance in lending stability to the hip joint as is the

anticavitational effect of synovial fluid. The round ligament and the joint capsule are the major soft-tissue structures providing passive stability and are not of primary importance in preventing subluxation of the hip joint. These structures may become stretched, as with hip dysplasia, allowing subluxation and predisposing the hip to complete luxation. The different classifications of hip luxations are named by the location of the femoral head relative to the acetabulum. For example, with a craniodorsal luxation, the femoral head lies cranial and dorsal to the acetabulum, whereas with a ventral luxation, the femoral head lies beneath the acetablum (often lodged in the obturator foramen).

Craniodorsal Luxation

One of the most common causes of luxation of the hip is a strong blow delivered from the rear or side of the dog or cat. As the animal starts to fall toward the hip to be luxated, the center of gravity moves lateral to the hip joint. Simultaneously, with the foot on the ground, the rear leg moves into adduction. As the hip moves ventral and laterally toward the ground, the lever action of the adducted femoral shaft subluxates the femoral head out of the acetablum (Figure 110-7). The center of gravity of the animal moves lateral to the hip joint. This position is exaggerated in dysplastic animals, where the hip joint conformation is poor and the passive restraints (round

ligament and joint capsule) are already stretched. The dorsal rim is remodeled, further contributing to instability. When the greater trochanter strikes the ground, the energy of the blow is transmitted through the femoral neck to the femoral head. The femoral head is driven over the dorsal rim, shearing the joint capsule or teres ligament. Sometimes the teres ligament avulses from the femoral head, causing a small fragment to pull from the femoral head. Rarely, a piece of bone is chipped off the dorsal rim of the acetabulum. The femoral head comes to rest in its most common position of luxation craniodorsal to the acetabulum. The strong pull of the

gluteal muscles also helps to pull the femoral head to this position. Muscular force and passive restraints (capsule and round ligament) are unable to maintain the reduced state of the joint.

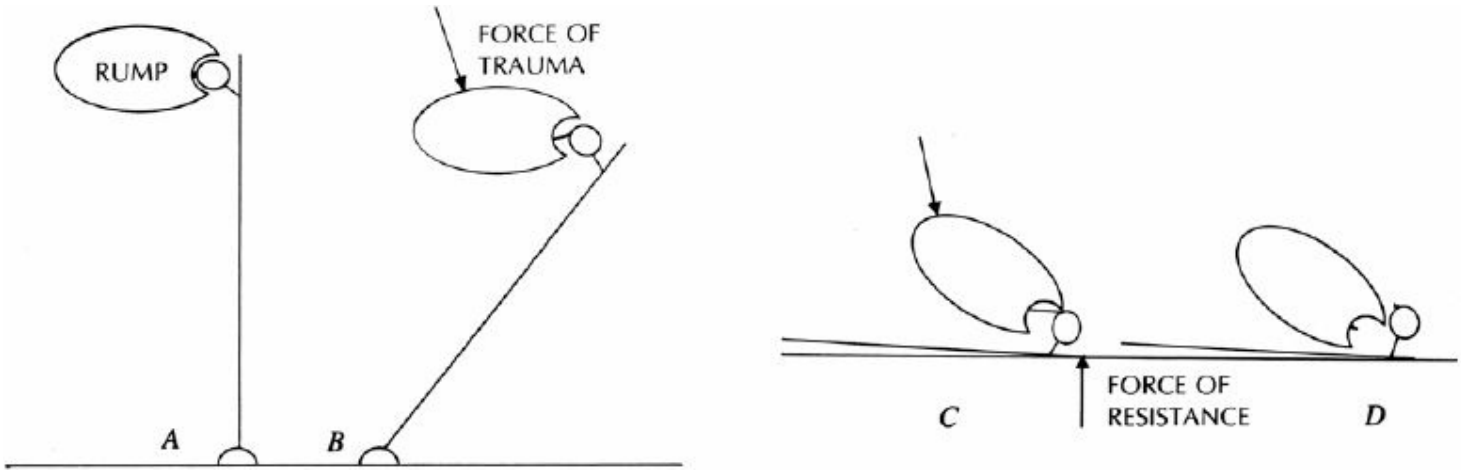

Figure 110-7. A, The hip joint and hind limb viewed from the front. The leg is in extension and is weight bearing. B, A blow is struck to the rump causing the limb to go into adduction. C, Just as the greater trochanter is about to hit the ground, the femoral head is subluxated against the dorsal rim of the acetabulum. D, As the hip hits the ground, the teres ligament ruptures and the femoral head luxates to a dorsoanterior position.

Another way in which hip luxation may occur is when the body is driven ventrally toward the ground. The hind leg is extended and the foot is bearing weight. As the pelvis is forced ventrally, the knee and hip begin to flex. At some point before the pelvis strikes the ground, the knee makes contact with the ground. As the pelvis continues to move ventrally, the hip begins to rotate externally. If the force is sufficient, the teres ligament and joint capsule rupture, allowing the femoral head to luxate. The strong pull of the gluteals causes the femoral head to luxate in a craniodorsal position.

Treatment Strategies

CLOSED REDUCTION: Several techniques are used to reduce hip luxations. The longer the hip is dislocated, the more difficult it is to reduce, owing to muscle contraction and local fibrosis. Generally, the leg must be put into a sling to prevent reluxation. Reported success rates vary from 30% to 85%. Animals with hip dysplasia, severe degenerative joint disease, or avulsion fractures in the hip joint are poor candidates for closed reduction.

OPEN REDUCTION: If the luxation cannot be reduced or if the joint repeatedly reluxates, surgery is indicated. Many techniques are available to the surgeon. Procedures

include capsulorrhaphy, iliofemoral suture, trochanteric transposition, transarticular pinning, teres ligament replacement (including a toggle), and triple pelvic osteotomy. Alternatives to preserving the in situ hip joint are excision arthroplasty and total hip replacement.

Ventral Luxation

A distinction may be made between cranial and caudal ventral luxation. The biomechanics are the same for both, except for the position of the femoral head as it is being forced ventrally under the acetabulum. If the leg rotates inward as the hip is luxating ventrally, the femoral head

ends up in the obturator foramen. If the leg rotates outward, the femoral head ends up in front of the pubis. It has been reported that a ventral luxation can be created by overzealous reduction of a craniodorsal luxation. Those that occur naturally are usually associated with the trauma of jumping or falling and landing with the leg abducted. As the leg contin¬ues to abduct during the fall, eventually the femoral neck and greater trochanter strike the dorsal aspect of the acetabulum. This forces the femoral head out of the acetabulum, rupturing the teres ligament and ventral joint capsule. An animal with a ventral luxation carries the leg abducted and inwardly rotated and is unable to put

the foot on the ground.

Treatment Strategies

CLOSED REDUCTION: Not many cases of ventral luxation have been reported, but they do appear to respond well to closed reduction. If reduction alone leaves the joint unstable, hobbles or an adduction sling may be used to prevent abduction.

OPEN REDUCTION: Any of the techniques mentioned for craniodorsal luxation that prevent luxation in any direction (e.g., transarticular pinning) could be considered. The ventral restraints may be reconstructed by advancement of surrounding soft tissue. If none of these methods works,

femoral head and neck excision arthroplasty or total hip replacement should be considered.

Stifle Joint

Anatomy

The stifle joint is a complex diarthrodial (synovial) joint that allows movement in three planes. The stifle consists of three intimately associated joint spaces: the femorotibial (between the femoral and tibial condyles), the femoropatellar (between the patella and the femoral trochlea), and the proximal tibiofibular joints.

The primary motion of the joint is

flexion and extension; however, the articulation of the femoral condyles with the surrounding supportive structures, menisci, and proximal tibial surface allows cranial and caudal translation, internal and external rotation, varus and valgus angulation, and medial and lateral movement of the femur in relation to the tibia. The medial and lateral menisci are C-shaped, fibrocartilagenous structures interposed between the articular surfaces of the femur and tibia (Figure 110-8). They perform a load-transmitting function, improve joint stability by providing congruity between the femur and tibia, assist in lubrication of the joint, and are thought to provide a sensory function

so they may aid in joint proprioception. The menisci are firmly attached to the femur, tibia, and joint capsule by six ligaments.

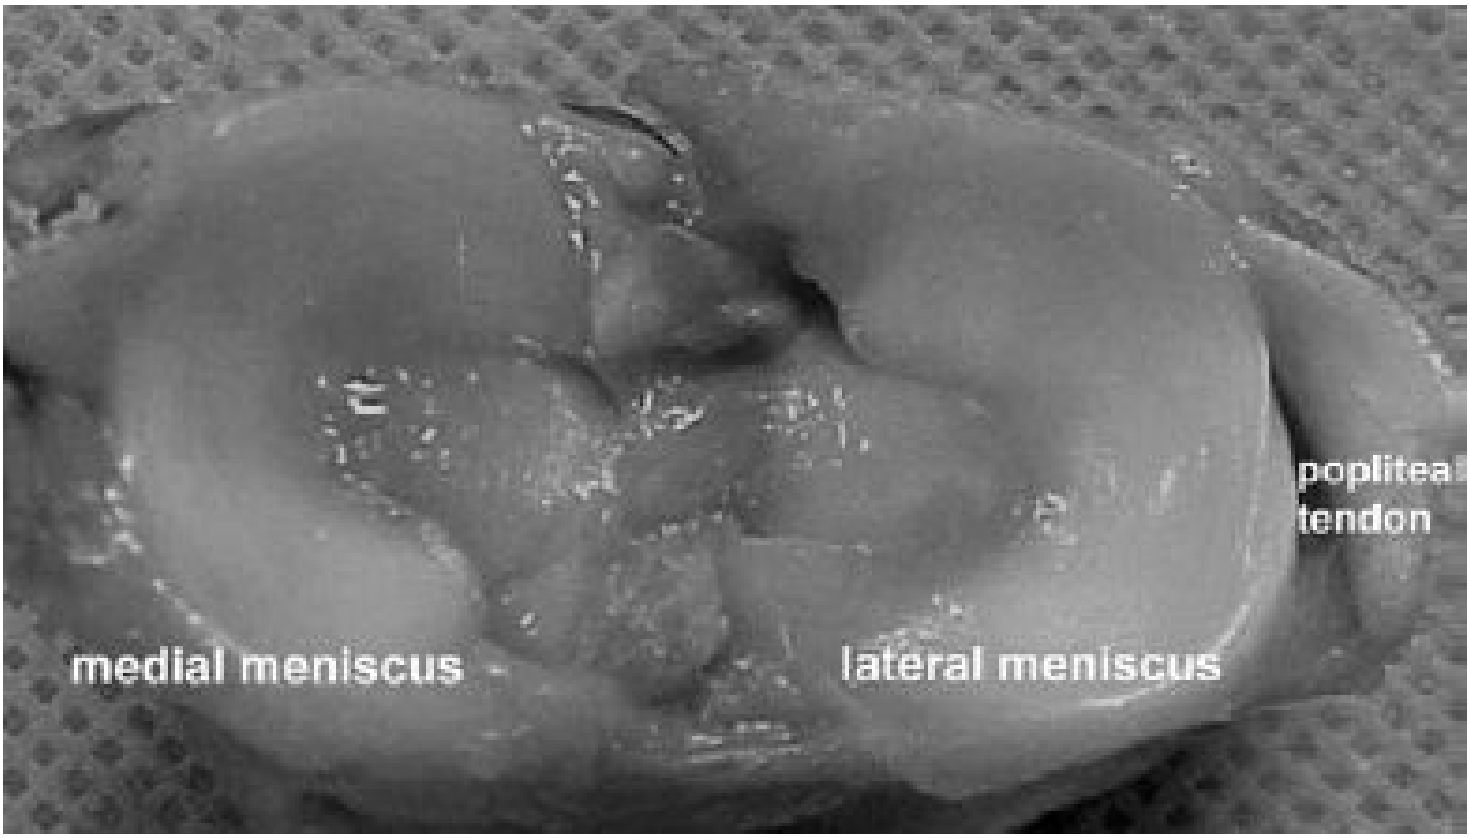

Figure 110-8. Photograph of the medial and lateral meniscal ligament. Both are important intra-articular structures providing joint stability and load transmission.

Primary ligamentous support of the

stifle is provided by medial and lateral collateral ligaments, as well as cranial and caudal cruciate ligments. The lateral collateral ligament originates proximal to the origin of the popliteal muscle on the lateral femoral epicondyle and inserts on the fibular head. The medial collateral ligament originates from an oval area on the medial femoral epicondyle and forms a distal attachment to the medial meniscus and surrounding joint capsule. Collateral ligaments are responsible for preventing varus (lateral collateral) and valgus (medial collateral) motion of the tibia and as a secondary stabilizer against rotational forces of the stifle. The cranial cruciate ligament originates on the

caudomedial portion of the lateral condyle of the femur and courses in a spiral orientation cranially, medially, and distally through the intercondylar fossa to the cranial intercondyloid area of the tibia. It functions primarily to prevent cranial and caudal translation of the tibia in relation to the femur, to provide rotational stability by preventing internal rotation of the stifle, and also to assist in preventing hyperextension of the stifle. The caudal cruciate ligament begins at the lateral aspect of the medial femoral condyle and extends caudally and distally to the lateral edge of the popliteal notch of the tibia. The caudal cruciate ligament prevents excessive cranial and caudal translation of the tibia in

relation to the femur and provides assistance in prevention of hyperextension of the stifle.

Other soft tissues that lend themselves to the stability of the stifle joint include the popliteal muscle, the semitendinosus and semimembranosus muscles, quadriceps femoris, straight patellar ligament, and joint capsule.

Biomechanics

Because of the dynamic variety of muscular and ligamentous structures and the articulation of the femur, tibia, and menisci, movement of the stifle is complex and does not limit itself to a single plane. During flexion of the

stifle, the tibia internally rotates slightly because of the relaxation of the lateral collateral ligament and subsequent caudal displacement of the lateral femoral condyle. During extension, the tibia externally rotates because of the cranial displacement of the lateral femoral condyle as the lateral collateral ligament tightens. Cranial and caudal movement of the femur in relation to the tibia is seen in a sagittal plane during flexion and extension; a slight varus and valgus movement of the tibia is also seen but is limited by the ligamentous structures of the stifle.

The most common cause of stifle subluxation is associated with the

rupture of the cranial cruciate ligament. Stifle luxation or total derangement of the knee is an uncommon injury in dogs and cats, but has been documented to have a higher incidence in cats.[6] Significant damage to multiple ligaments of the stifle is typically associated with high-energy injury, such as with a fall or vehicular truama. Rupturing of the articular structures is most likely associated with a direct blow to a weight-bearing limb, resulting in a cranial and lateral luxation of the stifle and subsequent rupture of the cranial cruciate, caudal cruciate, and medial collateral ligaments.[7] Also, it is common to see damage to the secondary structures of the joint, such as the joint capsule,

menisci, and patellar ligmament. Ipsilateral fractures of the femur and pelvis were also cited as having been seen in 8 of 27 cases (30%).[7]

Damage to the cruciate ligaments and medial collateral ligament is theorized to occur because of the vulnerability of the lateral portion of the limb to blunt trauma or perhaps owing to the resistance of medial and caudal luxation by the quadriceps, hamstring, gastrocnemius, and popliteal muscles.[8] Because of the magnitude of the blow that is necessary to luxate the stifle joint, vascular and nerve complications are a consideration, especially with cranial luxations.

Treatment Strategies

CLOSED REDUCTION: Nonsurgical reduction of a stifle luxation is not recommended. The prognosis for return to function is poor.

OPEN REDUCTION: Return to good function can be expected if primary and secondary joint restraints can be restored. Multiple techniques for open reduction and repair of articular and periarticular structures have been described.[9] Even under general anesthesia, it is difficult to assess the extent of damage without direct visualization of the ligamentous and soft-tissue structures. Consequently, complete exposure and exploration of the joint is recommended.[10] Thorough

examination of articular structures is important. Repair or debridement of damaged menisci and repair of the joint capsule should be the first steps in the surgical therapy.

Repair of the stifle depends on immediate repair and stabilization and long-term periarticular fibrosis. Reconstruction of collateral ligaments or placement of prosthetic ligaments using screws and spiked washers is suggested to maintain stability so that stabilizing sutures can be placed. Both intra- and extra-articular repair for the cranial and caudal cruciate ligaments have been used to provide immediate stifle stability. Reconstruction of the caudal cruciate ligament was not found

to be necessary in a review of 12 cases of multiple ligamentous injuries of the feline stifle of working dogs, but methods of stabilization must be addressed on a case by case basis.[11] With extensive soft-tissue damage, it is proposed that a strong inflammatory reaction incites significant collagen-repair stages of healing, leading to long-term stability of the joint.

External skeletal fixation has been used as an adjunct therapy to support extra-articular techniques used for the repair of collateral and cruciate ligament damage. The use of a transarticular external fixator provided joint stability and return to function during the period of periarticular

fibrous tissue formation. Complications seen with the external fixator are associated with pin loosening, fracture through pin sites, and severe breakdown of repair as was seen with animals that escaped from confinement. Lateral splints may also be used to provide support to surgical procedures. Use of a temporary transarticular pin without reconstruction of the damaged soft tissues has also been successfully used in small dogs and cats to provide support and allow periarticular fibrosis to form and stabilize the stifle.

Regardless of the surgical method used, mild to moderate stifle osteoarthritis is expected and can be attributed to the

initial injury, as well as resultant altered biomechanical forces. Lastly, arthrodesis or amputation can be used as an option for acute severe trauma, chronic instability, or a painful joint.

Luxations involving the Tarsus and Metatarsus

The tarsal joints are composite articulations, in which more than two joint surfaces are enclosed within the same joint capsule. The tarsus and metatarsus are frequently involved in trauma and subluxations, and complete luxations are common. The regional anatomy is complex, and most surgeons consider instability at four different horizontal levels from

proximal to distal: the talocrural joint, the proximal intertarsal joint, the distal intertarsal joint, and the tarsometatarsal joint. In addition, a multitude of vertically oriented intratarsal joints are considered to be more rigid than the horizontally oriented joints, although instability can occur in these joints as well.[12]

Talocrural Joint Subluxation and Luxation

This joint permits the largest degree of movement (maximum flexion in normal Labrador retrievers is 38°, with maximal extension measured at 165°).[2] The trochlea of the talus (or tibial tarsal bone), with two distinct articular

ridges, fits into reciprocal grooves found in the cochlea of the tibia, providing some stability; however, the rest of the stability relies on the medial and lateral collateral ligaments and the plantar ligaments.

In dogs and cats, luxations of the talocrural joint are most commonly associated with trauma, and injuries can be classified as either closed (without soft-tissue injury) and open or as shearing injuries. Most of these injuries are presumably caused by trauma, although in many cases the actual event is not observed. The type of trauma is thought to be forced rotation around the long axis of the joint or a severe blow directly to the

joint, most often to the medial aspect. If luxation of the talocrural joint results, either the medial or lateral malleoli (or both) may fracture. In our experience, the lateral malleolus is more likely to fracture and the medial collateral ligament complex is more likely to tear without fracture. Although most injuries to the collateral ligaments involve both the short and long components, injuries to the short collateral (fibulocalcanear and fibulotalar or distal and proximal short lateral collateral ligaments, respectively) can occur and may be difficult to diagnose without careful palpation under anesthesia. Radiographic changes associated with these injuries may be confused with

osteochondrosis dissecans.[13,14] Damage to the lateral collateral ligaments may be more likely when the animal rotates at speed around the hindlimb in a flexed, weight-bearing position.[13] In adult cats, a torn medial collateral ligament complex is frequently associated with lateral instability caused by fracture of the fibula at the origin of the lateral collateral ligament;[15] whereas a Salter-Harris 2 fracture of the distal tibia will result in the appearance of a complete luxation of the tibiotarsal joint in the immature cat.

Treatment Strategies

CLOSED INJURY: Using a combination

of traditional orthogonal and stressed-view radiography, in addition to careful palpation, the surgeon should identify whether the medial collateral, lateral collateral, or palmar ligamentous support to the talocrural joint has been damaged. For complex injuries, computed tomography should be considered as well.[16] Although closed reduction and coaptation can be attempted, the forces applied to the joint usually exceed the ability of the scar tissue to stabilize the joint, and the joint will not become stable enough for the animal to bear weight.

Surgical repair usually involves reconstruction of the collateral ligaments. It has been shown that

reconstruction of both the long and short parts (double prosthetic repair) will give a much better clinical outcome than single prosthetic repair.[17] Although the traditional method of screws and washers using nonabsorbable suture gives good results, alternative methods using bone tunnels[18] and bone anchors can also be used. Regardless of the method used, it is important to support primary repair of the collateral ligaments with either a transarticular external fixator or cast/splint for up to 6 weeks. If excessive damage to the articular surface of the tibiotarsal joint is found during surgical exploration, pantarsal arthrodesis should be done, typically by application of a dorsal plate

combined with an intramedullary pin.[19]

SHEARING INJURY: Shearing injury of the hock involves the medial aspect in two thirds or more of cases.[20] Treatment is somewhat controversial and can include immediate or delayed prosthetic reconstruction of the damaged ligaments, immediate or delayed pantarsal arthrodesis, or primary management of the wound with support from either an external fixator or cast alone.[20] If immediate arthrodesis is performed, an external fixator may be preferable to a plate, which may have to be removed owing to chronic infection that cannot be avoided when a large open wound is

present.[21]

Proximal Intertarsal Subluxation and Luxation

The proximal intertarsal joint is composed of the talocentral and calcaneoquartal joints, which do not allow noticeable motion in the normal dog and cat. This joint can fail in either hyperextension, which may result in damage to the dorsal ligaments, or more commonly, from failure of the plantar ligaments with or without fractures and luxations of the associated tarsal and metatarsal bones. The Shetland sheepdog appears to be predisposed to proximal intertarsal joint luxation, presumably caused by

chronic degeneration of the plantar ligaments of unknown cause.[22] The condition may be bilateral.

Treatment Strategies

HYPEREXTENSION: Because during normal weight-bearing hyperextension injuries tend to be held in reduction, and because most of the support to the joint comes from the plantar ligaments, these injuries can generally be treated with a cast.

HYPERFLEXION: Calcaneoquartal arthrodesis is recommended for hyperflexion injuries, as external coaptation has been shown to be ineffective. Arthrodesis may be effective in a variety of ways (e.g.,

lateral plate, Steinmann pin, and tension band), use of a tension band in combination with the primary repair and external coaptation until radiographic evidence of arthrodesis is achieved is recommended.[22]

Tarsometatarsal Luxation and Subluxation

The four distal tarsal bones, numbered from medial to lateral first through fourth, articulate with the metatarsals I through V, forming the tarsometatarsal joints. These joints are considered to be low-motion joints in the normal dog and cat. Subluxation and luxation of the tarsometarsal joints usually occur as a result of trauma and may be

associated with concurrent fractures of the proximal metatarsal bones.

Treatment Strategies

External coaptation may be appropriate for minor injuries involving only one or two metatarsal bones with minimal displacement. However, if the entire tarsometatarsal articulation is luxated, or if significant displacement is present even if only a lateral or medial injury is noted, arthrodesis is recommended. Although many forms of arthrodesis have been reported, plate fixation is likely to be the most successful. Usually the plate is applied laterally,[23] and a hybrid (either 2.0/2.7 or 2.7/3.5 mm)

dynamic compression plate may be advantageous.[24]

Talocalcaneal Luxation

The talocalcaneal joint is maintained by two ligaments crossing the tarsal sinus between the two bones, and is considered to be a low-motion joint. Luxation has been reported in the dog after trauma, and may be difficult to see on standard radiographic views.

Treatment Strategies

The reports of this injury are limited, but success has been observed both with reduction and external coaptation and lag screw fixation.[25]

Chapter 111

Tendon Injury and Repair

Simon Timothy Kudnig

Function of Tendons

Tendons are a vital component of the locomotor system and are a vital link between muscle and bone. Tendon function includes the transfer of force developed by muscles, joint movement, limb support, gliding motion, and the storage and release of energy. Tendons do not possess contractile elements; however, their elasticity may serve to

attenuate sudden forces, thereby protecting the associated muscle, and to enable a final velocity of movement to be attained that is greater than that of the contracting muscle.[1] Muscles possess a tendon attachment whenever their point of insertion is distant or when the muscle must exert its forces of contraction across a joint. Tendons are highly resistant to extension but are relatively flexible and, therefore, can be angulated around bones or a joint.

Tendon Anatomy

The tendon is a complex composite material consisting of collagen fibrils embedded in a matrix of

proteoglycans.[2] Collagen fascicles are oriented parallel to the long axis of the tendon, with type I collagen being the major constituent.[2] Fibroblasts are the predominant cell type within the tendon and are arranged in parallel rows in the spaces between the parallel collagen bundles. Collagen chains are arranged in a left-handed configuration, with three collagen chains combined into a collagen molecule. The tertiary structure of type I collagen consists of three collagen chains coiled together in a right-handed triple helix held together by hydrogen and covalent bonds.[2] Collagen molecules are then arranged in a quarter stagger, forming the quaternary structure with the

alignment of oppositely charged amino acids providing a great part of the strength of the structure.[2] Five collagen molecules combine to form ordered units of microfibrils, which are arranged to form subfibrils, and these in turn are combined to form fibrils. Collagen fibrils are bound together by a matrix consisting of proteoglycans and glycoproteins in combination with water to form fascicles. A loose connective tissue called the endotendon binds the fascicles within the tendon together and permits longitudinal movement of collagen fascicles as well as support for blood vessels, lymphatics, and nerves. The epitenon covers the surface of a tendon; with tendons that are enclosed

by a tendon sheath, a mesotenon originates on the side opposite the pulley friction surface and joins the epitenon. Tendons that are not enclosed within a synovial sheath are surrounded by a looser areolar connective tissue called the paratenon. A tendon sheath surrounds a tendon in areas where there is a marked change in direction, when tendons pass under ligamentous bands or through fascial slings, or when tendons pass across a joint. The tendon sheath consists of a visceral (inner) layer and a parietal (outer) layer and is lined by a secretory endothelium. Sesamoid bones are osseous or cartilaginous structures that protect the tendon as it passes over a bony surface, and the opposed

surfaces of the sesamoid and underlying bone are covered by cartilage. This entire structure is enveloped in a bursa or sheath. Tendons receive their blood supply from surrounding tissues via vessels in the paratenon or mesotenon. Tendons surrounded by paratenon have been described as “vascular tendons,” with multiple points of vessel entry from the periphery; these vessels anastomose with a longitudinal system of capillaries. Tendons surrounded by a tendon sheath have been described as “avascular tendons” in which the blood supply in the mesotenon is reduced to vessels in the vincula, which divide into dorsal, proximal, and distal branches and vascular loops into the

tendon substance.

Pathophysiology of Tendon Injury

Tendon injury results from both direct and indirect trauma. Direct trauma includes lacerations and contusions; indirect trauma results from tensile overload resulting in sprains, rupture, avulsions, and displacements. Most tendons can withstand larger tensile forces exerted by their muscles or sustained by bones, resulting in avulsion fractures of the bone to which the tendon is attached, avulsions of the tendon attachment to bone, or ruptures at the muscle-tendon junction. Preexisting pathology in the tendon

can result in midsubstance tears from mechanical overload. Underlying conditions that can predispose to tendon injury include hyperadrenocorticism, excessive administration of corticosteroids, and intratendinous injection of corticosteroids.[3,4] Repeated microstrains and mechanical overload with hyperthermia, free-radical production, and hypoxia are pathophysiologic mechanisms important in the development of tendinitis. Tendon sprains are more commonly diagnosed in horses; however, it is likely that many tendon injuries are unrecognized in small animals. Tendon sprains seen in dogs include the insertion of the flexor carpi

ulnaris in racing greyhounds, the deep digital flexor tendon to the digits, and various components of the Achilles mechanism. Tendons commonly undergoing displacements include the biceps tendon, the superficial digital flexor tendon, and the long digital extensor tendon. Tendon avulsions commonly involve the long digital extensor tendon and the gastrocnemius tendon.

Tendon Biomechanics

The presence of collagen and the arrangement of collagen fibers parallel to the direction of the tensile forces provide tendons with considerable tensile strength. As with other

collagenous soft tissues such as ligaments, the load-deformation curve of tendons is characterized by a toe region, which corresponds to the straightening of the crimped fibrils and orienting of the fibers in the direction of loading. The toe region for tendons, however, is relatively small owing to the preexistence of collagen fibers nearly parallel with the long axis of the tendon. The toe region is followed by a linear region, and the slope of this region represents the elastic modulus of the tendon. The yield point is the point of the load deformation curve that is followed by the failure region in which plastic deformation leads to irreversible changes in the tendon. Tendons do have viscoelastic

properties, with the elongation depending not only on the amount of force applied but also on the rate of force application.[2]

Tendon Healing

Tendon healing is an important area of orthopedic research to maximize strength and rate of repair to facilitate early and complete return to athletic function. Tendon healing is important to enable both sufficient tendon strength and to maintain appropriate tendon length to ensure appropriate function. A healing tendon must also maintain the ability to glide, which is the most difficult aspect of tendon repair to preserve. Healing tendons, as

other tissues, undergo four overlapping phases of wound healing, which are inflammation, debridement, repair, and maturation. Immediately after injury, the wounded tendon fills with inflammatory products, neutrophils, and fibrin. The remnants of disrupted tendon are removed during the inflammatory phase, resulting in demarcation of the lesion.[5] The inflammatory and debridement phases of healing delay the onset of the repair phases, necessitating gentle tissue handling, wound lavage, surgical debridement, and resolution of infection to shorten the duration of the inflammatory phase. During the repair phase, undifferentiated mesenchymal cells from the surrounding connective

tissues migrate into the wound and differentiate into fibroblasts. The fibroblasts secrete ground substance and collagen, which together with capillary buds, form granulation tissue between the tendon ends. The growth and migration of collagen fibers between the tendon ends are oriented perpendicularly to the long axis of the tendon; however, by the third and fourth weeks, the fibroblasts and collagen fibers orient themselves along the lines of stress.[2] The reorganization of collagen fibers is part of the maturation phase and is partly responsible for the increase in tensile strength. An increase in intermolecular bonds between collagen fibers also contributes to an increase in tensile

strength, and this, as well as fiber orientation and collagen production, depends on the application of stresses to the healing tendon.[2] As the maturation phase ensues, the fibroblasts switch from type III collagen to type I collagen.

A distinction has been made with regard to the healing of unsheathed, vascular tendons versus sheathed, avascular tendons. With unsheathed tendons, the undifferentiated mesenchymal cells and capillary buds migrate from the paratenon and blend with the epitenon. With sheathed tendons, contrary to previous investigations indicating that the fibroblasts were derived only from the

tendon sheath, tendon cells themselves do have some intrinsic capabilities of repair. The intrinsic response originates from the epitenon and is stimulated by passive range of motion, which results in less adhesion formation and an improvement in healing over the traditional "one wound one scar" theory of avascular tendon healing. Revascularization of ensheathed canine flexor tendons in conjunction with passive range of motion has been shown to occur from vessels in the epitenon, in the absence of ingrowth of peripheral adhesions.[6] Thus repair of sheathed tendons in the correct environment can occur with minimal contribution from cells of the tendon sheath or surrounding

connective tissue, thereby avoiding restrictive adhesion formation.

More recent research, particularly in the human and equine fields, has focused on molecular techniques for the improvement in tendon healing. Important growth factors that are involved in tendon healing include insulin-like growth factor-1, transforming growth factor- beta1, growth and differentiation factors (GDFs), epidermal growth factor, platelet-derived growth factor, vascular endothelial growth factor, and bone morphogenic proteins 2 and 7.[7-10] These growth factors form the basis of molecular techniques and gene manipulation techniques to enhance

tendon healing.[11] Mesenchymal stem cells found in the bone marrow have been shown to stimulate healing and have additive effects with growth factors.[12] Other therapies to optimize tendon repair have included tissue engineering, extracorporeal shock-wave therapy, therapeutic ultrasound, low-level laser therapy, hyperbaric oxygen therapy, and nitric oxide.[13-17]

Tendon Repair

Tendon repair techniques must follow certain principles to ensure a successful outcome. These include the apposition of the severed ends with minimal disruption of blood supply, minimum amount of suture material for repair,

elimination of gap formation, and use of suture techniques with maximum mechanical strength. Gap formation of greater than 3 mm at the site of tendon repair has been shown to delay healing and significantly increase the risk of rupture during the first 6 weeks of rehabilitation.[18] A gap of less than 1 mm is required for a tendon to heal without scar and adhesion formation.[19] Tendon suturing techniques have followed the principle that sutures passed between the fascicles are easily pulled out of the tendon, whereas maximum mechanical strength has been achieved with the placement of sutures perpendicular to the tendon before passing across the site of injury. The optimum rehabilitation of tendon

injuries is difficult to achieve in small animals. Excessive activity early in the repair process will result in gap formation and failure of the repair, whereas controlled early passive mobilization stimulates repair and increases the strength of the tendon in the first few months following repair. Early motion also limits adhesion formation and, therefore, enhances the gliding function of the tendon. Vascular tendons achieve 56% and 79% of the original strength at 6 weeks and 1 year, respectively, following repair.[20] Normal forces associated with muscle contraction stress the tendon to approximately 25 to 33% of maximum strength, indicating that by 6 weeks postoperatively the repair should be

able to withstand limited exercise.[1,21,22] Numerous suture patterns for the repair of tendons have been developed. The Bunnel-Mayer technique is limited by compromise of the blood supply and a resultant decrease in tensile strength.[23] The Kessler technique was developed to maximize strength by the placement of suture bites perpendicular to the tendon, and the modified Kessler or locking-loop technique allows the knot to be placed at one end of the tendon rather than between the tendon ends. Superior tensile strength has been demonstrated by the three-loop pulley technique over a single and double locking-loop technique.[24] The three-loop pulley technique, owing to its

superior tensile strength, is recommended for larger weight-bearing tendons and round tendons, and also for collateral ligament repair. The locking-loop technique is useful for flat tendons, although a continuous cruciate pattern has been shown to be superior to the locking-loop technique for tenorraphy of canine deep gluteal tendons.[25]

Specific Tendon Injuries

Luxation of the Tendon of the Biceps Brachii Muscle

Luxation of the tendon of the biceps muscle occurs because of a displacement of the tendon out of the intertubercular groove as a result of

rupture of the transverse humeral ligament.[26] Affected dogs present with forelimb lameness; flexion of the shoulder with external rotation can promote luxation of the tendon. Surgical treatment involves placement of sutures between the remnants of the transverse humeral ligament to the insertion of the supraspinatus muscle, or it involves using a prosthetic suture to replace the transverse humeral ligament.[26]

Severed Superficial and Deep Digital Flexor Tendons

Severance of the digital flexor tendons commonly occurs on the palmar or plantar aspect of the distal extremity

where the tendons are superficial; the injury is commonly the result of a penetrating wound. Severance of the deep digital flexor tendon(s) causes hyperextension of one or more digits with hyperextension of the distal interphalangeal joint and dorsal elevation of the claw from the ground during weight bearing. Surgical apposition of the transected tendon ends with a monofilament nonabsorbable locking-loop suture or three-loop pulley suture; an appositional pattern in the tendon sheath has been recommended.[27] Postoperative management should involve a cast or splint designed to maintain the digits in flexion for 6 weeks.[27] Although early passive range

of motion is recommended for human tendon repair, such controlled activity is difficult to achieve in canine patients.

Avulsion of Proximal Tendon of the Long Digital Extensor Muscle

Avulsion of the long digital extensor muscle from the lateral femoral condyle commonly affects young, large and giant breeds. Affected dogs present with a weight-bearing pelvic limb lameness with pain and crepitus palpated in the stifle.[28,29] Diagnosis can be made via radiography, computed tomography, or magnetic

resonance imaging.[28,29] The avulsion is repaired by reattaching the avulsed bone to the origin on lateral femoral condyle.[28,29] If no bone remains for fixation, the tendon can be sutured to the stifle joint capsule near its point of penetration.

Achilles Mechanism Injury

The Achilles tendon is composed of the gastrocnemius tendon, the common tendon of the biceps femoris, gracilis and semitendinosus muscles, and the superficial digital flexor tendon. Injuries to the Achilles mechanism result in tarsal hyperflexion and a flaccidity of the Achilles tendon when the tarsus is flexed. Flexion of the

digits with tarsal hyperflexion resulting in a “claw” appearance occurs when the superficial digital flexor tendon is intact. Ruptures of the Achilles mechanism commonly occur at the musculocutaneous junction rather than the muscle belly. Primary tenorrhaphy of each of the three tendon components is recommended, with additional support provided by a fascia lata autograft or polypropylene mesh. A modified three-loop pulley suture pattern has been shown to be a superior technique for reattachment of the tendon to bone than the lockingloop suture.[30] Postoperative immobilization is important to protect the repair from excessive weight-bearing forces and can be achieved

with external coaptation using a cast, orthotics, linear external fixator, or a circular fixator.

Luxation of Superficial Digital Flexor Tendon

The superficial digital flexor tendon can become luxated as it crosses the tuber calcanei. Lateral luxation owing to breakdown of the medial retinaculum is more common. It appears that Shetland sheepdogs[31] are predisposed. Possible contributing factors include exercise, trauma, obesity, rotation around the joint with the tarsus in a flexed position, structural deformities of the calcaneus, and a weaker medial attachment of the

tendon to the calcaneus.[31,32] Palpation of instability of the superficial digital flexor tendon during talocrural manipulation is pathognomic for the injury.[32] The injury is repaired by suturing the retinaculum opposite the side of luxation. With lateral luxations, appositional sutures are placed in the medial retinaculum, and bone tunnels can be placed in the calcaneus for additional purchase if required. Polypropylene mesh has been used for failed repairs to reinforce the medial calcaneal retinaculum.[33]

Chapter 112

Tendinitis and Bursitis

Simon Timothy Kudnig

Tendinitis

Lower intensity trauma can result in tendon sprains or tendinitis rather than complete rupture. Such injuries are more commonly diagnosed in horses; however, they are recognized in canine athletes and are probably under-diagnosed in active dogs. Tendinitis refers to inflammation of the tendon with a few or many tendon

fibers being torn; however, total discontinuity of the tendon is not produced. Hypoxic tendon injury can result in fibrocartilaginous metaplasia, which can interfere with tendon function and be a source of pain. Repeated microstrains and mechanical overload with hyperthermia, free-radical production, and hypoxia are pathophysiologic mechanisms important in the development of tendinitis. Goals of treatment of tendinitis are to increase the number of fibroblasts, increase matrix production, increase the proportion of type I collagen versus type III collagen, and increase the organization of collagen fibers. This will allow an increase in tensile strength, a decreased incidence

of reinjury, and a decreased rehabilitation time. Restoration of structurally normal tendinous tissue with normal tensile strength and elasticity is the goal of tendon repair rather than promoting a connective tissue scar.

Mineralization of the Tendon of Insertion of the Supraspinatus Muscle

Mineralization of the tendon of insertion of the supraspinatus muscle or calcifying tendinopathy of the supraspinatus tendon can result in a chronic, intermittent, or progressive weight-bearing lameness that worsens

after exercise. Pain is elicited on shoulder extension. Mineralization of soft tissues to the level of the greater tubercle of the humerus cranial to the scapulohumeral joint on a craniproximal-craniodistal radiographic view is suggestive of the disease. A poor correlation between the size of the lesion and lameness has been identified.[1] Hypoxia of the tendon is considered the primary initiating factor in the deposition of calcium. The tendon undergoes fibrocartilaginous transformation; calcium crystals are then deposited in the matrix and coalesce to form deposits. The location of the injury may be related to a hypovascular area of the tendon adjacent to the major

tubercle that may be predisposed to hypoxic injury. Treatment options include rest, nonsteroidal anti-inflammatory therapy, intralesional steroid injections, surgical excision, and extracorporeal shock-wave therapy. The mineral deposits commonly reform; however this is poorly correlated to a recurrence of lameness.[1]

Bicipital Tenosynovitis

Biceps tendon injury is a common cause of forelimb lameness and shoulder pain in dogs. Biceps tears commonly occur within the glenohumeral joint, outside the bicipital groove and adjacent to the

supraglenoid tubercle, as this is a relatively avascular zone.[2] Inflammation of the biceps tendon can occur as a primary lesion or secondary to intraarticular disease such as glenohumeral instability. The cause of primary bicipital tenosynovitis is unknown and may include overuse or chronic repetitive trauma resulting in an inflammatory response. Gross pathologic changes include hyperemia of the bursa, leading to joint effusion; chronic synovitis, causing synovial hyperplasia of the bursa; chondromalacia of the intertubercular groove with osteophyte formation at its margins; and metastatic calcification of the biceps tendon. Adhesions between the tendon and the

tendon sheath may develop. Hypoxia of the tendon as a result of damaged blood supply promotes chondroid metaplasia and calcification, with the normal synovial space and smooth gliding surface of the intertubercular groove typically being replaced by proliferative synovium and fibrotic adhesions. Fibrocartilaginous metaplasia, however, can be seen in normal dogs,[3] and the relationship between histopathologic findings and clinical findings is inconsistent.[4] Diagnosis of bicipital tenosynovitis can be made via an orthopedic examination, by eliciting a positive "biceps test" (pain on palpation of the biceps tendon with the shoulder in a flexed position), and with plain

radiographs including a skyline view of the bicipital groove, contrast arthrography, ultrasonography, or MRI. Treatment includes rest and nonsteroidal anti-inflammatory treatment, intraarticular or intralesional steroid injections, open tenodesis, arthroscopic tenodesis, and arthroscopic biceps tenotomy. Results of tenodesis are excellent,[5,6] however, arthroscopic tenotomy offers a less demanding approach with apparently good results.[7] The indications and long-term results for tenodesis versus tenotomy in dogs has not been established.[6]

Calcaneal Tendinitis

Inflammation of the area of the insertion of the calcaneal tendon onto the calcaneus may progress to avulsion and failure of the Achilles mechanism. It is recommended that evaluation of the opposite calcaneal tendon be performed in cases of a unilateral injury to ensure that calcaneal tendinitis is not present in the contralateral limb. Ultrasonography has been shown to be a useful tool for imaging lesions of the Achilles tendon.[8]

Stenosing Tenosynovitis of the Abductor Pollicis Longus Muscle

The abductor pollicis longus muscle

abducts the first digit. Injury of this tendon can result in forelimb lameness, a swelling on the medial aspect of the carpus, and pain on carpal flexion.[9] Connective tissue proliferation leads to stenosis of the synovial sheath and pain associated with constriction of the tendon within the tendon sheath. Radiographically, proliferative bone reactions at the distal radius in the area of the fibro-osseus canal of the abductor pollicis longus can be found in advanced cases of the disease.[9] Conservative treatment involves injection of corticosteroids in the area of the synovial sheath; however, nonresponding cases benefit from surgical release of the tendon rather than tenotomy.[9]

Tendinitis of the Insertion of the Flexor Carpi Ulnaris

This injury commonly occurs in the tendon of insertion of the flexor carpi ulnaris muscle to the accessory carpal bone in racing greyhounds. Chronic inflammation with repeated bouts of lameness is common.[10]

Bursitis

Bursae are connective tissue sacs that are lined by a synovial epithelium and contain synovial fluid. A bursa serves to reduce friction between moving parts such as tendons, ligaments, or muscles or to cushion the effects of excess pressure between these movable structures and bony prominences. True

bursae are normal anatomic structures and can be described as subtendinous, submuscular, subfascial, or interligamentous. Bursae are abundantly supplied with vessels and nerves and tendon injuries involving a bursa, therefore, are extremely painful. False bursae are acquired structures secondary to repeated trauma over pressure points and consist of a nonepithelial-lined sac full of fluid, also known as a hygroma.

Many anatomic bursae have been described in the dog.[11] In the forelimb are located bursae associated with the infraspinatus muscle and the caudal part of the greater tubercle of the humerus, where the tendon of the

triceps brachii muscle crosses the proximal end of the olecranon (bursa subtendinea olecrani), under the tendon of the extensor carpi radialis tendon at the carpus, under the tendon of origin of the extensor carpi ulnaris muscle, and also between its tendon of insertion and the distal ulna and where the abductor pollicis longus passes over the extensor carpi radialis muscle. A bursa also exists between the tendon of origin of the superficial digital flexor muscle and the underlying medial epicondyle of the humerus and beneath the tendon of origin of the deep digital flexor muscle. In the hindlimb, bursae are located under the tendon of origin of the rectus femoris muscle, between the distal third of the rectus femoris

muscle and the femur, under the insertion of the vastus lateralis and medialis muscles, under the superficial digital flexor tendon as it passes over the tuber calcanei, between the internal obturator muscle and the ischial ramus, and at the insertion of the internal obturator muscle in the trochanteric fossa. Many dogs also have bursae beneath the deep and superficial gluteal muscles at the insertion on the greater trochanter of the femur. Projections of joint capsules can also function in a similar manner as bursae, some examples include the projection of the glenohumeral joint capsule beneath the tendon of origin of the biceps brachii muscle, the projection of the elbow joint capsule

beneath the origin of the flexor carpi radialis muscle, the projection of the patellar joint capsule under the tendon of the quadriceps muscle, the projection of the stifle joint capsule under the origin of the long digital extensor muscle, and a communication between the joint capsule between the third and fourth tarsal bones and the bursa of the tendon of insertion of the peroneus longus muscle.

Acquired bursae occur as a result of trauma to the skin and subcutaneous tissue over bony prominences. The pressure on bony prominences is transmitted from the surface to the underlying dense bone, compressing all intervening tissues, and this in turn,

can obstruct blood flow, leading to cell death. A spectrum of injury exists from a pressure sore, which is a dilatation of blood vessels, inflammatory edema in the skin and subcutaneous tissue over bone, to a false bursa where a hematoma has formed in the subcutaneous tissues and has become enclosed in a well delineated sac. The progression to a false bursa is dependent on the persistence of the underlying trauma and failure of a protective skin callus to protect the underlying tissues.

Specific Injuries of Anatomic Bursae

Bursitis of the Bursa Associated with the Extensor Carpi Radialis

This injury occurs in racing greyhounds and causes lameness after racing and a palpable fluid swelling.[12]

Bicipital Tenosynovitis (Bursitis)

This condition is described above under specific tendon sprains.

Chronic Calcification of the Bursa over the Greater Trochanter of the Femur

This is commonly seen as an incidental

finding on radiographs, and lameness is not evident.

Specific Injuries of Acquired Bursae

Acquired bursa have been described over the olecranon (elbow hygroma) and other pressure points including the acromion of the scapula, tuber ischii, tuber coxa, greater trochanter of the femur, lateral malleolus of the tibia, tuber calcanei, and over the fifth digits and the sternum. Acquired bursae are generally sterile unless organisms are introduced via centesis or corticosteroid injection.[13] Treatment of hygromas involves removal of the inciting trauma by providing soft

bedding and protective padding. Drainage followed by protective padding is considered for persistent swelling or when the bursa has become infected.

Chapter 113

Gait Analysis

Michael Conzemius
Richard Evans

Quantitative analysis of animal motion can provide unique insight into normal and abnormal limb function. This information is useful clinically for the diagnosis of disease and as a measure of outcome following treatment intervention. In addition, gait analysis is commonly used in the development and subsequent use of animal models of disease. Historically, gait analysis

has been extremely cumbersome and time-consuming. Routine clinical use was impractical because of the time required for set-up, data collection, and evaluation as well as using bulky and/or awkward equipment. Dramatic computational and equipment improvements over the past 10 years, however, have made these techniques readily available and now allow for routine assessment of gait in a modern-day laboratory or hospital. Perhaps the most attractive draw to gait analysis is that it produces objective, reproducible data of limb function.

Several techniques are available for the analysis of gait. The most common method in veterinary medicine is visual

observation of gait. Objective measures of ground reaction forces (GRF) using a force platform, however, is an attractive alternative that is also commonly utilized. Publications of analysis of joint and body movements using two- and three-dimensional stereometric methods and visible markers also exist. These techniques attach markers to the skin on rigid segments of the body structure and track their motion using imaging equipment. Less frequently used methods of analyzing gait in animals include accelerometers, electromyography, electrogoniometry, and roentgenographic and magnetic coupling. Simultaneous use of a combination of evaluation methods

should be considered.

Visual Observation of Gait

For most species the entire gait cycle lasts for only one second; thus, a systematic and disciplined approach must be used to clinically evaluate a patient's gait. The animal should be viewed from the front, side, and back. The observation of gait begins with a general assessment, noting symmetry and smoothness of movements of the various body parts. During stance, the clinician should take note of the position of the patient's center of mass, as the center of mass will shift toward a normal or less affected side to reduce the force applied to more painful joints

or muscles. In addition, it is important to look at the base width. In general, if the forelimbs are apart and the rear limbs near each other, the animal is shifting its weight to the front; the opposite is also true. Finally, as the patient stands, one should observe for excessive internal or external rotation of a limb. In my experience, external rotation of a limb is associated with an abnormality in that limb, and internal rotation of a limb is associated with an abnormality in a different limb. Of course, disorders that have caused a permanent rotation of the skeleton make this point moot. Watching a patient sit and move from a sitting to standing position is also helpful. The "sit-test" is sometimes advocated. When

a dog sits, it is considered abnormal for a foot to be pointed outward. In fact, some consider that position pathognomonic for knee pain. Although this concept frequently holds true, many normal dogs also sit with a foot or feet externally rotated. When a dog rises from a sitting position, the focus should be on the shift of weight onto the front limbs. With experience, one will notice excessive shifts.

As the animal walks, attention to the stance phase of gait is helpful. If lameness is present because of pain, the animal will avoid placing weight on the affected limb. When this occurs, the stance phase of gait will be shorter. For example, if a dog is suspected of

having a unilateral forelimb lameness, the observer should watch how much time the dog spends with each of the front feet in contact with ground. The foot that is on the ground for the shortest period of time may be more painful. Some clinicians prefer to observe the position of the head when observing for a forelimb lameness. The concept is similar; the patient will place more weight on the less painful side; as the foot on this side is positioned firmly on the ground, the shoulder and head will drop. Alternatively, the foot on the more painful side will not be in contact with the ground as much and the shoulder and head will be elevated. Circumduction of a limb is abnormal. It

is most likely present because of a painful joint; the patient resists flexion because of this pain and swings the limb instead. A preference for observing a patient's gait at several different velocities is common. In addition, some gait abnormalities may be observable only after the patient has been exercised.

The largest concern with the use of visual observation of gait is its subjective nature. Clinical and personal experiences can influence interpretation, thus introducing opinion, which, in the author's point of view, reduces precision, accuracy, and reproducibility. For example, in one publication when the sensitivity of

visual observation of gait was compared with that of force platform gait analysis, visual observation was found to be vastly inferior.[1] In this comparison, they evaluated 148 adult Labrador retrievers; 17 were free of orthopedic and neurologic abnormalities, and 131 were 6 months after surgery for unilateral CCL injury. The observer was blinded to the dog's group assignment. Of the 17 normal dogs, the observer correctly identified all as having no gait abnormality, as did the force platform. However, the observer identified only 15 of the 131 dogs that were 6 months after knee surgery as not being normal. Using ground reaction forces from force platform gait analysis, 75% of the 131

dogs failed to achieve GRFs consistent with sound Labradors. In effect, if a dog looked lame it was lame; but if it looked normal to the observer, it may in fact have been abnormal. It should not be surprising that a computational gait analysis is more sensitive than our powers of observation. This fact should be remembered when we inform an owner that a dog "has returned to normal" after a clinical examination.

Force Platforms

A force platform measures the ground reaction forces (GRFs) exerted when it is stepped on during the stance phase. It consists of a metal plate that is mounted level with the surrounding

floor or walkway that is separated from a bottom frame by force transducers near each corner. Forces in an X, Y, or Z direction that are exerted on the top surface are transmitted through the force transducers. Commercially available force plates are frequently grouped into either piezoelectric or strain gauge. Although subtle differences exist in the capabilities and cost of the two types, for clinical gait applications, the type used probably has little influence on the data generated. Piezoelectric force plates utilize quartz transducers, which generate an electric charge when stressed. Strain-gauge force plates utilize strain gauges to measure the stress in load cells when a force is

applied. Piezoelectric force plates are a bit more sensitive, have a built-in amplifier, and allow for a greater force range than do strain-gauge types. However, they may have some drift, which requires resetting of the charge amplifiers just prior to data acquisition, and they are usually more expensive. There are several different manufacturers to choose from and aside from cost, the potential for customization of a system is something that should be factored into the decision-making process. The size of the force platform, transparency (if photography under the platform is desired), portability, and use with a treadmill (only z direction forces can be measured) are all potential options.

Although all of the manufacturers offer compatible software, for veterinary use most clinicians and researchers use commercially available veterinary-specific software. A final consideration is professional installation in an area that encourages frequent clinical and research use but avoids abuse from general hallway traffic.

Pressure Platforms and Walkways

Pressure platforms are comparatively new systems that allow investigators to measure both temporal and spatial gait parameters. In general, pressure platforms are a bit larger (2 square feet) than a traditional force platform.

Pressure walkways, which consist of multiple platforms in series, can be customized to virtually any length. These platforms function using a sensor pad that is an ultra thin (~0.1mm), flexible printed circuit. Contained within the circuit are thousands of pressure-sensing locations, or elements, arranged in rows and columns along the length and width of the platform or walkway. The sensing elements act as variable resistors within an electrical circuit. When the sensors are loaded, their resistance is low; when the force is reduced, resistance increases. The output resistance created is then converted to a raw sum for use in analysis. In effect, this allows one to

measure ground reaction forces in the z-force direction. Sensors can be produced with pressure ranges from as low as 0-5 psi to as high as 0-25,000 psi. Perhaps it is important to note that ground reaction forces generated from normal dogs on pressure walkways have been shown to be nearly identical to those of force platforms.[2]

Several advantages exist to using a pressure walkway. First, because of its extended length, multiple readings and simultaneous, consecutive, and contralateral foot-strikes can be recorded with a single pass over the walkway. Some of this advantage can be attenuated if a laboratory is

equipped with multiple force platforms. A single force platform, however, can only measure on half of a gait cycle in a single pass or trial. Thus, by increasing the length of the measuring field, one not only gathers data that are more reflective of the patient's gait but fewer trials are needed to generate an adequate amount of data for statistical comparison. Reducing trial repetition is important because it saves time, because some weak or lame patients may not be able to physically perform many trials, and because the majority of variance in force platform data is attributable to trial repetition.[3] Second, because the geometry of the mat is known, spatial parameters of

gait can be calculated. Patient stride length and width for each limb can be measured for consecutive steps, allowing the clinician to look for inconsistencies, improvements, or disease progression. Limb velocity and acceleration can be calculated using these data or they can be measured using a speed gun or photoelectric cells. Third, the distribution of pressure from the entire foot can be investigated.[4] Both types of platforms measure cumulative force(s) over the cell. For pressure platforms the cell is usually 0.25-square centimeters and for a traditional force platform the cell is 3-square feet. This difference allows for clinicians to estimate changes in load over the patient's foot (e.g. is load

being shifted to the left side of the foot because of an injury on the right). Fourth, because of the small size of the cell in pressure platforms, there are few limitations to the size of the animal for which data can be accurately collected. Using a traditional force platform, a dog's stride length must be long enough that it place only one foot on the platform at a time. In general, dogs weighing less than 20 kg have a difficult time accomplishing this. Likewise, an extremely tall dog with a long stride may step over a traditional force platform. Increasing the animal's velocity through the gaited area will increase its stride length but this methodology creates other limitations.

Because pressure platforms allow for data collection in animals with a very short stride length they provide the opportunity to measure limb function in small dogs and cats,[5,6] or in large dogs that have a short stride length because of disease or because they are recovering from surgery.[7] An added benefit to this advantage is that pressure platforms allow users to create, view, and save data in the form of a "continuous framed movie." Movies are recorded over a specified time period, at a specified frame per second speed. These gait movies allow for clinicians to measure load-bearing while the animal stands still.[7] Finally, pressure platforms are easy to set up, break down, and move to a different

location. This portability provides opportunities to measure limb function that would otherwise be impossible with a traditional force platform.

Unfortunately, pressure platforms have some disadvantages. One drawback is that they can only measure total ground reaction force. Forces are not deciphered between the x-, y-, and z-direction. Second, our experiences with the software are that it is easy to work with but requires the user to invest much more time to extrude the data from each trial. For example, when using a traditional force platform, the software immediately provides peak vertical force and vertical impulse numbers. The pressure platform would

require approximately one minute of additional work to gather that data. In effect, data are not automatically tabulated and summarized; this must be done manually. Furthermore, although some platform systems have components that incorporate velocity and acceleration data for each trial, most pressure platform systems do not. Again, these values, to date, must be manually calculated and added to the database. Pressure platforms are also not nearly as durable as a metal force platform and would not last long if used to measure limb function in a horse. Finally, the many advantages of pressure platforms come with a significant cost.

Technical Aspects of Force Platform Gait Analysis

Documentation of patient kinetics generates an enormous amount of data. Forces in the x-, y-, and z-direction are expressed in both peak and impulse forms, and average rising and falling slope are just a few of the points available. One obvious question is what data the clinician or investigator should focus on. Forces in the z-direction are generated by a vertical compression of the platform, and these forces are dramatically larger than those of the other two directions. Forces in the y-direction (second largest) are generated by cranial-caudal tipping of the platform

and are closely related to acceleration or deceleration, which can be measured or controlled in other ways. Forces in the x-direction are generated by medial-lateral tipping and are extremely small in the quadruped. Peak vertical force (PVF) is the single largest force during the stance phase and represents only a single data point. Vertical impulse (VI) is the total area under the stance-phase curve. The results of these facts are that most veterinary publications have focused on z-direction PVF and VI forces. Although this method of expressing the data is reasonable and common, it may not be ideal. Evaluation of the force-time curves that are provided by the software is likely the best

representation of limb function. Unfortunately, the statistical methods associated with this can be complicated. A simple method to mathematically explore gait analysis is to use a multivariate, as opposed to a univariate, statistical approach. In one report, the optimal set of GRFs was selected using logistic regression, with normal or not normal as the binary dependent variable and GRFs as candidate explanatory variables.[8] This method built a descriptive yet economical model that evaluated most candidate combinations of GRFs that best discriminated between the GRFs of normal Labrador retrievers and those of Labrador retrievers that had unilateral lameness from a torn cranial

cruciate ligament. A cutoff that maximized Youden's index (sensitivity + specificity -1) was established and then a receiver operating curve (an ROC is a plot that represents the relationship between sensitivity and specificity of a diagnostic test) was used to assess the diagnostic properties of GRFs obtained from the force platform. These values were then applied to a group of Labrador retrievers that were 6 months after unilateral CCL-rupture surgery. The probability that an individual Labrador could be discriminated from the normal population of Labradors was calculated from data collected from visual observation of gait and from GRFs generated by force platform gait

analysis. There are several advantages to this methodology. Limb function is determined by evaluating all GRFs. In comparison, if clinicians use z-direction PVF, they truly are looking at only 1/1200 (this assumes a sampling frequency of 1200 samples per second and a stance phase of 1second) of the data. In addition, this technique allows clinicians to estimate the probability of normal function after gait analysis and communicate that to an owner. For example, we now know that 6 months after some surgical procedures the probability of normal limb function is only 20%.[9] This does not mean that function after surgery is not improved or that surgery wasn't successful, only that function is not normal. This is an

important step toward differentiating outcomes between treatment options.

Subject velocity influences most GFR measurements. For example, as patient velocity increases, z-force PVF increases because the patient hits the platform harder, and z-force VI decreases because the patient spends less time on the platform. Historically, for force platform gait analysis, patient velocity has been recorded via the use of photoelectric cells that project a beam of light across the runway and are set up at a known distance apart from one another with the center photoelectric cell centered at the center of the platform. When a subject interrupts the first photoelectric

cell's beam of light, the system is triggered to begin recording time as the subject passes across the force platform. When the last cell's beam of light has been interrupted, the recording system stops. The patient's average velocity through the runway is then calculated. If three or more photoelectric cells are used in the system, patient acceleration can also be calculated. Velocity can also be measured using a speed gun. One limitation of the photoelectric cell system is that the cells are often aligned so that the subject's torso is the trigger of the system. Thus, photoelectric cells measure average torso velocity rather than limb velocity. The significance of this can be

envisioned if one were to compare velocities of a Great Dane to that of toy poodle. If both dogs have similar torso velocities, the limb velocity of the smaller dog would have to proportionally increase relative to its shortened stride length. This limitation can be averted by comparing data from dogs of similar stature. The other, perhaps easier, method for controlling for this problem is to standardize stance time on the platform.[10]

Given the importance of subject velocity, it is common for investigators to control this parameter when evaluating and comparing a group of dogs. For walking trials, 1.0 to 1.3 meters per second, and for trotting, 1.7

to 2.0 meters per second, are used. It has been suggested by some that a trotting velocity should be used because it is more of a challenge to the dog and thus more lameness will be detected. This argument may have merit if the patient population being studied has only a subtle limp. However, in one study the effect of patient velocity on GRFs was studied and a walking velocity was clearly superior.[8] Several important messages came from that study. First, GRFs collected at a walk were linearly related and highly correlated to those collected at a trot. Second, in this investigation of dogs with lameness from a torn cranial cruciate ligament, data could be collected from all dogs at

a walking velocity but only 62% of the dogs at a trotting velocity. The large proportion of dogs that failed to obtain acceptable trotting trials would dramatically impact a study. Ground reaction forces at a walk were significantly different among dogs that could and could not successfully trot; this occurred because the dogs that were the most severely lame failed to trot (most likely because as velocity increased, force increased, and thus pain increased). These dogs would be eliminated from a clinical study, and the study would be biased toward dogs that were less lame. This may make a study group that received a certain treatment appear less lame than if they were studied at a walking

velocity. Use of trotting velocity would affect subject accrual because more candidate dogs would be necessary to reach the sample size required for the study. For example, for a study in which 50 dogs are required, 81 candidate dogs would be needed to perform the study by use of trot velocity (assuming the 38% failure rate reported). In contrast, a similar study to evaluate 50 dogs at a walk would likely require only 50 candidate dogs. Third, among dogs that could walk and trot, fewer trials were required to obtain acceptable walking data than trotting data and walking data had a smaller coefficient of variation, suggesting that walking has less inherent variation than trotting.

Interestingly, the ideal velocity should probably not be determined by the investigator but the subject. If one dog is most comfortable walking through the runway at 1.1 meters per second then that is arguably the speed that you will gather data that is most reflective of that dog's normal gait. If a second dog in the study wants to go 1.8 meters per second that also should be allowed. The velocity of these dogs for subsequent trials should remain the same. The velocity, and/or stance time of these dogs can vary and their influence on GRFs can be calculated and adjusted mathematically.

Kinematic Analysis of Gait

A trained observer may be able to make critical judgments about a patient's gait, but by viewing a video recording, especially if viewed in slow motion, more subtle abnormalities may be detected. Thus, one of the simplest pieces of gait instrumentation, a picture video system, also is one of the most useful. It is also useful to document gait prior to applying any instrumentation so that differences can be resolved if, after equipment has been attached to the animal, motion data do not correspond to the clinician's initial visual image of the subject. In addition to motion photography, automated stereometric systems are commonly used. Other technologies, such as electromechanical

linkage and electrogoniometry, which use an exoskeleton that is applied to the patient, are too cumbersome for most animals.

The stereometric method employs visible markers that are attached to the skin on rigid segments of the body (e.g., joints, centers of rotation, or bony prominences) and tracks their motion using imaging equipment. The markers are either infrared light-emitting diodes for active marker systems or solid shapes covered with retroreflective tape for passive marker systems. Digital image analysis allows the horizontal and vertical coordinates of each marker to be computed as the subject moves within the field of view.

Using triangulation of the views from an array of cameras and the known location of each camera, computer software computes the coordinates for each marker. This technique has minimal impact on the natural motion of the subject and two- or three-dimensional methods can be employed. Two-dimensional methods have a diminished time and financial investment for the laboratory or clinic that will only perform this method occasionally, but joint motions can only be determined in one plane. Three-dimensional methods generally employ the use of 3 to 8 cameras that are mounted to the ceiling or wall and create a semi-permanent field of view. It is important to note that, in order to

document three-dimensional kinematics, each body segment must be defined by at least three markers, each joint center must be defined, and Euler angles calculated. Although these systems allow for collection of state-of-the-art motion data, they are relatively expensive and, if the methods are not well understood, they can be intimidating.

Motion data allows for calculation of time/distance parameters (velocity, cadence, stance, and swing times, etc.) and the angular position of the joints (hips, knees, and ankles) during the different phases of gait. These methods have been well described and demonstrated in normal dogs at a trot,

in dogs with orthopedic disease, and in dogs that are swimming.[11-13] Although historically these methods have been used more in the field of veterinary orthopedics, applications for patients with a neurologic disorder that quantify deviation from normal may offer the greatest clinical treatment potential for this technology. Three-dimensional kinematics, when collected simultaneously with force (kinetic) data can provide useful information about the force around a joint.

Electromyography (EMG)

EMG provides a representation of the contribution from muscles during gait.

EMG can be useful to the clinician, but detailed attention to the instrumentation and techniques must be made to provide high-quality EMG signals. Surface electrodes have gained widespread use owing to their ease of application and because skin penetration is not required. However, results for deep muscles can be reliably obtained only with intramuscular wire electrodes. As with many of the other techniques described in this chapter, collaboration with an experienced group early on will pay long-term dividends.

Chapter 114

Nutrition in Orthopedics

Herman AW Hazewinkel

Bone is a specialized form of connective tissue with a complex chemical and physical composition. Apart from its cellular fraction and the water phase (10%), it is composed of an organic matrix and a mineral phase. The cellular fraction includes osteoblasts (organic-matrix forming cells), osteoclasts (calcified-matrix resorbing cells), and osteocytes (embedded osteoblasts with bone-

resorbing capacity). The organic matrix, which is about 20% of the bone volume, is composed of 90% collagen fibers with a high content of hydroxyproline and 10% aminopolysaccharides, noncollagen proteins, and a small quantity of lipids. The mineral phase encompasses about 70% of the bone volume, mainly in the form of hydroxyapatite crystals and amorphous calcium phosphate, as well as small quantities of other elements. The total amounts of body calcium and phosphorus, 99% and 80%, respectively, are present in the skeleton. Although zinc, copper, manganese, and other elements may influence the development of skeletal abnormalities,[1] they seem of minor

significance in small animal practice. The availability of calcium, phosphate, and vitamins A and D has direct and indirect influences on skeletal mineralization. This will be discussed later in the chapter.

This chapter is limited to the recognition and management of orthopedic problems that are significant in small animal practice in which nutritional management is either a causative or a therapeutic factor. The quantity and quality of the food (including the main minerals and vitamins) are discussed in relation to skeletal diseases in growing, and in adult dogs and cats. In addition, nutrition is reviewed in relation to

osteoarthrosis and fractures.

Nutrition and Skeletal Growth

Skeletal growth includes cartilage maturation as part of enchondral ossification and osteoid formation and mineralization, as well as bone modeling influenced by skeletal homeostasis and calcium homeostasis. The latter is under the influence of parathyroid hormone (PTH), calcitonin, and vitamin D metabolites.

A food of good quality and palatability that has been shown to be nutritionally adequate for growth should be given. Requirements for a number of

nutrients are listed in Table 114-1. Young dogs and cats should have sufficient food during the growth phase to meet their needs, which can be two-and-one half to three times the adult maintenance value.[1] Optimal nutrition in an otherwise satisfactory environment permits optimal growth as ordained by the genotype.

In the following sections the orthopedic consequences of deficient or excessive intake of protein, energy, minerals, and vitamins for young dogs and cats are described.

Restricted Caloric Intake

Slight underfeeding may slow the

growth of puppies but will not influence the adult size of the dog. In a controlled study of Great Dane dogs raised on a mixture of balanced complete commercial diets, the animals fed ad libitum had early skeletal maturation and advanced growth, but at 7 months of age the length of long bones of litter-mates fed a restricted diet (two-thirds of the caloric intake) was identical.[2] After a period of inhibited growth owing to malnutrition or illness of short duration, the animal will grow at a greater rate than average for its age (i.e., catch-up growth). Influences of growth factors other than nutrition must be considered when judging an animal that is small for its age,[3] including the

extent of variation in growth patterns of normal healthy animals. From different studies of young dogs raised on food with carbohydrate content of 0 to 62%, protein 20% to 48%, and fat 13% to 76% as percentage of metabolizable energy, it was concluded that, so long as adequate protein and essential fatty acids exist in a palatable diet, it does not appear to matter in growing dogs what proportion of energy comes from carbohydrate, fat, or protein.[1] A study revealed that in 3 groups of Great Danes each fed iso-energetic diets only differing in their dietary protein levels (i.e., 15%, 23%, or 32% protein on dry matter base[dmb]), with carbohydrates exchanged for proteins, and diets fed

in equal energetic amounts to all dogs, the 32%-protein-fed dogs had significantly higher body weight without a difference in length of the antebrachial bones than the dogs fed the 15%-protein diet at half a year of age. This lead to the conclusion that a high quality and quantity content of proteins in the diet stimulates soft tissue growth in young dogs, but does not increase skeletal growth or increase the risk for developmental orthopedic diseases.[4]

Table 114-1. Nutrient Requirements for Growing Dogs and Cats Expressed as Amount of each Nutrient

per 1000 kJ or 100 kcal of Metabolizable Energy (ME)

	Dogs		Cats	
	Per 1000 kJ	Per 100 kcal	Per 1000 kJ	Per 100 kcal
Protein (g)	14	5.8	17	7.0
Fat (g)	4	1.7	5	2.1
Linoleic acid (g)	0.7	0.3	0.7	0.3
Calcium (g)	0.7	0.3	0.	0.25
Phosphorous (g)	0.5	0.2	0.5	0.2
Vitamin A (IU)	300	125	300	125
Vitamin D (IU)	30	12.5	30	12.5

Expression of nutrients per 1000 kJ ME or per 100 kcal ME allows for comparison of different product labels. ME can be calculated from the label as follows1: (g protein x 14.64 kJ) + (g fat x 35.56 kJ) + (g carbohydrates x 14.54 kJ) or (g protein x 3.5 kcal) + (g fat x 8.5 kcal) + (g carbohydrates x 3.5 kcal).

Example: product label states that diet has a calcium content of 2.5% on dmb with a calculated ME=1500 kJ per 100 g diet. Is this enough calcium? 1000/1500 x 2.5=1.7 g/1000 kJ; this is too much calcium. It should have been 1500/1000 x 0.7=1.05% on dmb.

Low Calcium Intake

Young animals have a great need for calcium to mineralize newly formed cartilage and osteoid. Depending on the dietary regimen and hormonal status, 225 to 900 mg/kg body weight (bw) per day is deposited in the growing skeleton of young dogs, of which 100 to 225 mg/kg per day

should be absorbed from the intestine.[1,5,6] The minimal requirement for dietary calcium in growing dogs is 0.4 to 0.6% on dmb in small breed dogs, 0.5% on dmb for growing kittens, and 0.7 to 1.2% for fast-growing dogs of large breeds.[1] Low calcium absorption, either from low calcium content of the food or poorly available calcium (complexes with phytic acid or oxalate, high phosphate content of the food, inadequate vitamin D status), can cause a decrease in the circulating calcium concentration. This situation can be created by feeding an all-meat diet. The decrease in circulating calcium concentration will be counteracted by the increase in PTH secretion, with

eventually increased osteoclasia and increased synthesis of the active vitamin D metabolite 1,25-dihydroxycholecalciferol (or 1,25$(OH)_2$ vitamin D_3). The latter stimulates calcium (and phosphate) absorption with a total efficiency of up to approximately 80 to 90% of the digested amount in puppies and kittens.[5-7] Subsequently, the high PTH and vitamin D metabolite levels will stimulate calcium and phosphate resorption from bone. When this situation continues for weeks, massive osteoclasia will weaken the skeleton to such an extent that it can withstand neither body weight nor muscle forces. The result is the development of skeletal deformities, which include

bowing of long bones and calcaneus, compression fractures in cancellous bone (metaphyseal and epiphyseal areas), deformation of the pelvis and vertebrae, and greenstick fractures of long bones (Figure 114-1B and Figure 114-2). No changes occur at the growth plates (Figure 114-1B). Compression fractures of the vertebrae can result in compression of the spinal cord that may be severe enough to cause posterior paresis or paralysis in the acute phase.

The bones cannot withstand the stress or load of a splint or cast, and additional greenstick fractures may result proximal to the cast or splint. Therefore, therapy is limited to good

nursing care and a diet that fulfills the requirements according to the nutrient requirements of dogs[1] without any injections of vitamin D. This allows the skeleton to become sufficiently mineralized within 3 weeks. Corrective osteotomies of long bones or symphysis pelvis can be considered once the skeleton has become mineralized to acceptable levels. For example, narrowing of the pelvic canal by deformation may result in chronic constipation (Figure 114-2). Failure of the obstipation to respond to medical management may require pelvic osteotomy at a later date.

Low Vitamin D Intake

Vitamin D metabolites stimulate increased plasma levels of calcium and phosphate to mineralize newly formed osteoid and cartilage. Vitamin D is absorbed by the intestine, hydroxylated in the liver to 25OH vitamin D, and then further hydroxylated in the kidney to 24,25$(OH)_2$vitamin D_3 or to the most active metabolite, 1,25$(OH)_2$vitamin D_3. Puppies fed a semipurified balanced dry dog food without added vitamin D did not synthesize sufficient vitamin D when they were irradiated daily with ultraviolet (sun) light under con¬trolled circumstances. This is in contrast to other species, including herbivores and omnivores.[8] Biochemical, radiographic, and

histologic evidence showed that these dogs developed rickets within 3 months. Thin cortices and broad physeal growth plates (Figure 114-1C) returned to normal when a commercial dog food was given.

Clinical cases of rickets in dogs and cats are exceedingly uncommon and can be diagnosed by measuring circulating vitamin D_3 metabolites,[8] or by determining the width of the growth plates as seen radiologically and histologically. An increase in width is not seen with low-calcium-high-phosphate diets, but is a strong indication of rickets. In rickets, the bowing of the legs predominates over the number of pathologic fractures.

Dietary therapy consists of commercial food with adequate amounts of calcium, phosphate, and vitamin D_3. No injections of vitamin D_3 are indicated, especially because commercial pet foods may contain more than the minimal recommended amounts.[9] When indicated, corrective surgery can be considered later.

High Energy Intake

Young animals have less tendency to become obese with excessive energy intake before 30 weeks of age than do older animals. Free-choice feeding of young dogs coincides with higher plasma levels of thyroid hormone, and thus stimulation of metabolic processes

including heat production.[10] Young Great Danes overfed with a palatable, balanced, complete commercial diet did not show evidence of obesity, but rather advanced increases in weight and height when compared with their littermates fed a restricted diet. The dogs fed restricted diets reached the identical length of long bones at 7 months of age.[2] In another study, Great Danes had an even higher energy intake and a greater growth rate, but again without signs of obesity.[11] These Great Danes, as well as German shepherd dogs and retrievers, suffered from more severe developmental orthopedic diseases (including osteochondrosis, panosteitis, and hip dysplasia) when raised on a

high caloric intake, in comparison with littermates raised on a restricted energy intake.[11-13] Dogs grow slower and have less fat deposition when fed a low density food with 8% instead of 24% fat, both offered free of choice.[10] Overweight owing to high energy intake may cause biomechanical stress, which, preceeding or following cartilaginous lesions, may be held responsible for these orthopedic diseases.[10]

C

Figure 114-1. Radiographs of the left radius and ulna of five different young dogs used as a diagnostic aid for nutritionally induced skeletal abnormalities by evaluation of the growth plate (gp) width, the metaphyseal (m) aspect, cortical (c) thickness, and length of ulna when compared with the radius (position of styloid process (sp)).

Age & Breed	Growth plate width	Metaphyseal aspect	Cortical thickness	Length of ulna vs. radius	Nutritional history
A 8 weeks, Rottweiler	normal	normal	normal	normal	normal
B 16 weeks. Great Dane	normal	relatively dense	thin greenstick fracture	normal	low Ca, normal P
C 22 weeks, mongrel	enlarged	mushroom-shaped	thin	normal	low vitamin D
D 24 weeks. Great Dane	central enlarged	retained cartilage in ulna	normal to thick	short ulna radius curvus	high Ca, normal P
E 24 weeks, boxer	normal	lucent line parallel to gp	normal	normal	high Ca, high P
F 28 weeks, boxer	normal	subperiosteal thickening	normal	normal	hypertrophic osteodystrophy, healed by rest and corrected diet

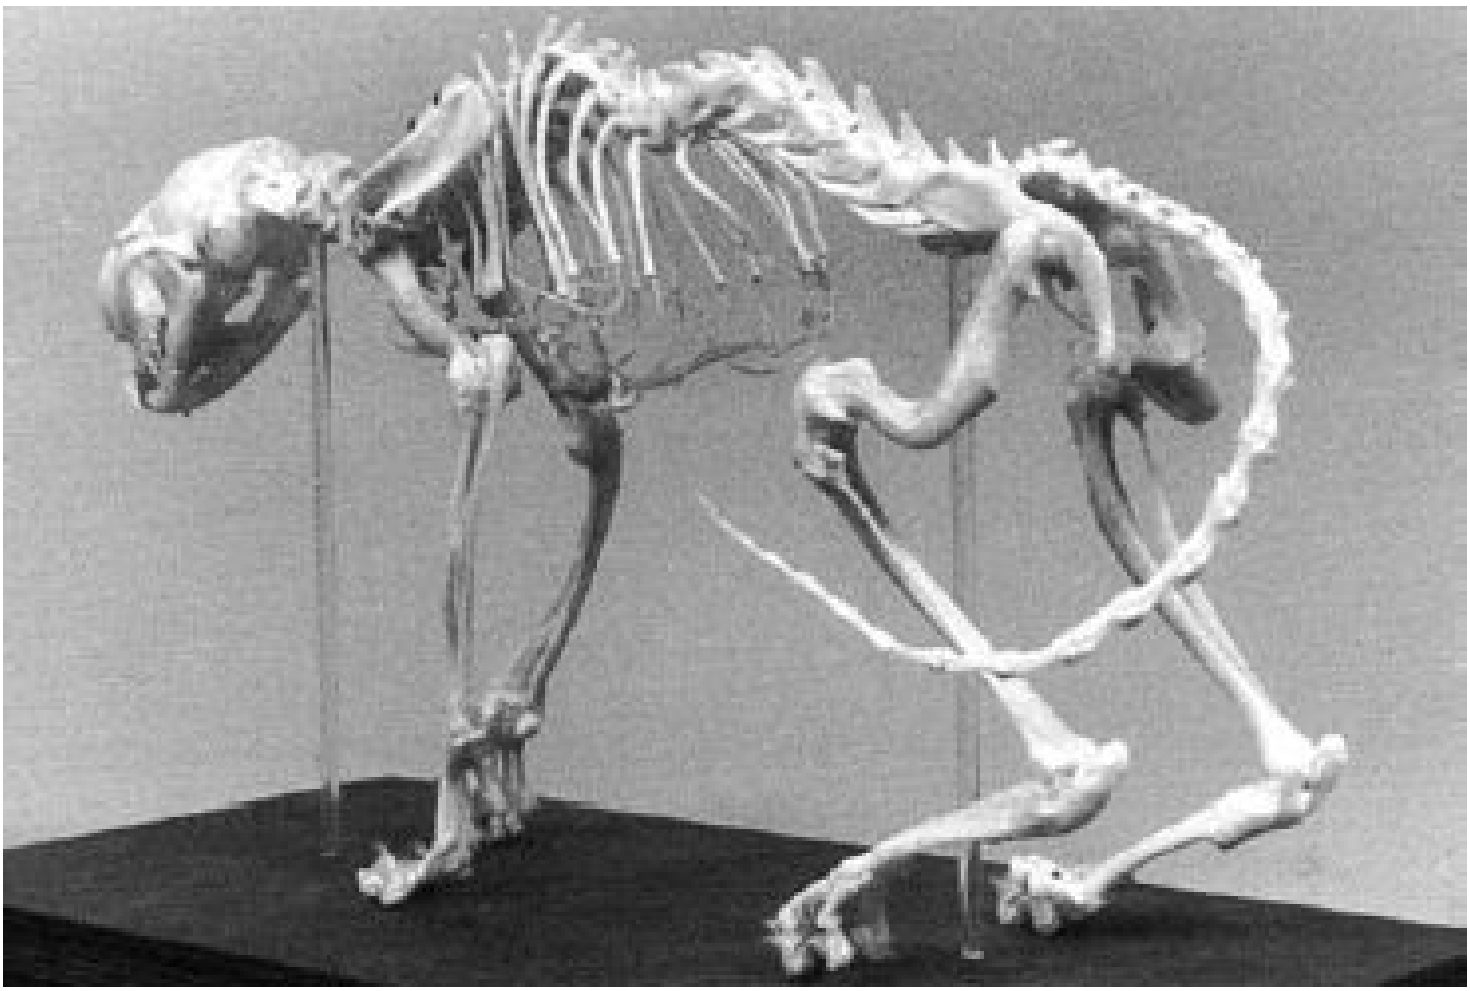

Figure 114-2. Low-calcium diet. Skeleton of a cat fed an all-meat food on a long-term basis. The cat has had severe skeletal abnormalities and recurrent

constipation. Note the abnormal alignment of the long bones (especially the femurs), the calcanei, the vertebral column, and pelvis.

The owner of a young dog should monitor growth rate rather than body fat deposition and compare this with the average for that breed. The owner should realize that rapid growth will not lead to a larger adult dog, but will probably increase the risk of orthopedic problems, including hip dysplasia.

High Mineral Intake

To avoid the classic skeletal diseases that are a result of lack of calcium, too much phosphate, or too little vitamin D (as described previously), some

owners, as well as some dog food manufacturers, tend to over-supplement with calcium, with or without a proportional addition of phosphate.[9] A high calcium content increases the circulating calcium concentration and eventually increases calcitonin secretion and decreases PTH secretion (for details see Chapter 99). A chronic hypercalcitoninemic state causes decreased activity of osteoclasts, which are of utmost importance for skeletal modeling during growth. Bony foramina should be widened by the osteoclasts in proportion to growth of soft tissues, such as the spinal cord and nutritional vessels of bones. In several studies, Great Danes fed a diet with a high calcium content (2 g/1000 kJ),

with or without excess of other constituents such as protein or phosphate) developed an inadequately expanded cervical vertebral canal in proportion to the growth of the cervical cord.[5,11] This causes compression of the cord with clinical, radiographic, and pathologic signs of canine wobbler syndrome.

Decreased diameter and alteration in the course of the nutritional foramina in the diaphyses restrict venous return, leading to edema in the medullary cavity and subperiosteal. Ultimately, this edema leads to intramedullary fibrosis and bone formation, as well as subperiosteal edema and new bone formation. This entity is known as

panosteitis.

Disturbance in enchondral ossification, termed osteochondrosis, was more frequent and more severe in young Great Danes receiving a supplementation of calcium when compared with Great Danes with a calcium intake of 0.8 to 1.1% on dmb.[5,11,14] Not only was the weight-bearing cartilage affected, but also the non-weight-bearing growth plates of ribs; therefore, microtrauma owing to overweight could be excluded. Severe signs of osteochondritis dissecans in the proximal humeral head and retained cartilage cones in metaphyseal growth plates (Figure 114-1D), with eventual radius curvus

syndrome (Figure 114-3) and deviation of the hind legs[8,11,14] were observed in the dogs whose calcium intake was high. In less severe cases, nutritional correction may restore normal position of the legs (Figure 114-3); more severe cases may have to be treated surgically.

Hypertrophic osteodystrophy (HOD) can be characterized as a massive disturbance of enchondral ossification of growth plates. Typical is the osseous discontinuity in the metaphyseal area of many long bones, close to and parallel with the growth plates. This zone is composed of remnants of cartilage and bone trabeculae, blood, fibrin, and debris. This area becomes

visible on radiographs when it is surrounded by mineralized tissue (Figure 114-1E). At a later stage, a superfluous periosteal reaction becomes visible on clinical and radiographic evaluation, as evidenced by bulging (Figure 114-1F). Pathologic signs of this disease were found in different controlled studies in well vaccinated Great Danes (a breed with a high prevalence for HOD) but all raised on food with a high mineral content.[5,11,15] Vitamin C supplementation may be expected to aggravate HOD more than to cure it.[16] Owners of young, fast-growing dogs should be aware of the severe consequences of high mineral intake on skeletal development.

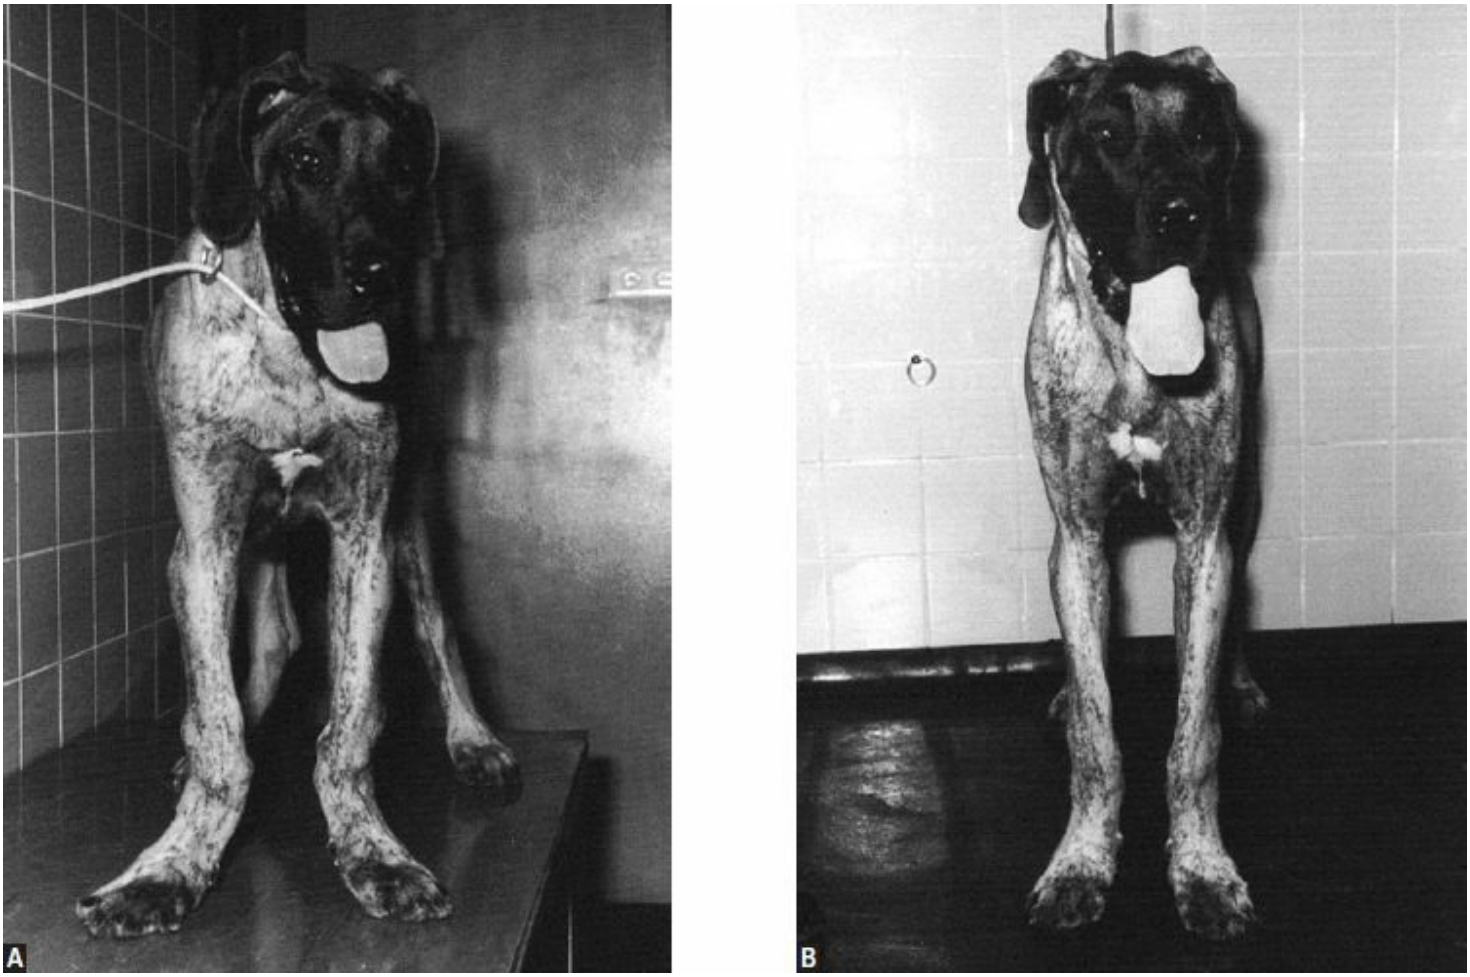

Figure 114-3. A, A 25-week-old Great Dane with both front legs in valgus position and with radiologic evidence of retained cartilage cones. B, The position of both front legs at age 1 year is normalized after the dog was fed a controlled amount of a balanced diet.

Vitamin D Excess

The first hydroxylation of vitamin D_3 to 25OHvitamin D_3 in the liver is

relatively poorly controlled, whereas the second hydroxylation to $1,25(OH)_2$vitamin D_3 in the kidney is under exquisite control. The allowance for vitamin D_3 is 500 IU/kg food on dmb for dogs (growth and maintenance alike) and 750 IU/kg food for kittens (but possibly as low as 250 IU/ kg food) and 500 IU/kg food for adult cats for maintenance.[1] In case of over supplementation of vitamin D_3, 25OHvitamin D_3 will be metabolized into the less biologically effective $24,25(OH)_2$vitamin D_3 and is the formed $1,25(OH)_2$vitamin D_3 quickly hydroxylated into the non-effective $1,24,25(OH)_3$ vitamin D_3.[17] In a controlled study in Great Danes,

vitamin D excess of 100 times the recommended level of 500 IU per kg food, given during a 5-month period, caused plasma concentrations of $1,25(OH)_2$vitamin D_3 lower than controls, coinciding with severe osteochondrosis with radius curvus syndrome[17] with a similar radiologic appearance as in Figure 114-1D. Massive intakes of vitamin D_3 (or even more so of its metab¬olites) can cause hypercalcemia together with hyperphosphatemia, anorexia, polydipsia, polyuria, vomiting, muscle weakness, and lameness.[1] The circulating high levels of calcium and phosphate are a result of increased bone resorption, increased absorption from the gastrointestinal tract, and

eventually, tubular mineralization. Vitamin D intoxication in dogs and cats is marked by mineralization of soft tissues, including blood vessels, alveoli, and renal tubules, together with pathologic changes in the gastrointestinal tract and the heart.[1]

Pet foods can contain from 2 to more than 10 times the NRC-recommended amount of vitamin D.[9] Extra supplementation with vitamin D can cause increased calcium and phosphate absorption with *deleterious effects on skeletal development* (see Chapter 99) and probably on kidney function.[9] Owners of young dogs and cats should be aware of the severe effects of clinical and subclinical vitamin D_3

intoxication with cumulative effects owing to vitamin over-supplementation.

Excessive Vitamin A Intake

Because development of hypervitaminosis A demands prolonged intake of vitamin A-rich food stuffs such as raw liver, intoxication is rarely seen clinically in young animals. Metabolism of an excess of vitamin A is more complete in cats than in dogs, so hypervitaminosis A is more likely to occur in kittens than in puppies (see Chapter 99).

Experimentally, massive doses of

vitamin A given for several weeks caused profound depression of bone growth, owing to degenerative changes of the growth plates, in addition to decreased osteoblast activity and osteoporosis in both kittens and puppies.[9] Osteophyte formation and periosteal reactions are present but of minor importance in these young animals.[9] The recommendation for vitamin A is 5000 IU/kg of food dmb for dogs (both for growth and for maintenance) and 3333 IU/kg food dmb for kittens and 6000 IU/ kg food for adult cats;[1] supplementation of commercial pet food with a vitamin additive can result in giving 100 times the normal requirement.[9] Owners of young companion animals, especially

kittens, should be aware of the severe skeletal abnormalities that can result from over-supplementation with vitamin A.

Nutrition and Skeletal Maintenance

Permanent bone turnover occurs in the adult dog and cat and consists of bone resorption as well as new bone formation. In the adult dog, calcium deposition and resorption are equal in magnitude: approximately 4 to 8 mg/kg bw per day. Daily losses of calcium by endogenous fecal and urinary excretion (i.e., 10 to 30 and 1 to 7 mg/kg bw per day, respectively) can easily be compensated for by a

balanced diet.

Natural menopause and other causes of estrogen deficiency in women are characterized by bone loss leading to pathologic fractures of the vertebrae, proximal femur, and wrist. This explains the extensive concern for nutrition in elderly women. Although ovariectomy is a common practice in female cats and dogs, and some osteoporotic changes are noticeable 17 to 36 weeks after surgery,[17,18] this practice does not result in a problem of practical significance in companion animal orthopedics (see Chapter 99).

Feeding adult animals a diet based on some variation of the dietary

requirements prescribed for growing animals usually does not result in serious problems. The major clinical problems in relation to orthopedics in adult companion animals are excessive energy intake, low vitamin D or excessive phosphorus intake together with decreased renal function, and excessive vitamin A intake, especially in cats.

Excessive Energy Intake

Superfluous energy content will increase the risk of obesity for the normally active companion animal. In addition to high energy intake, the following factors may underlie an abnormal gain in body weight: the

dietary composition (protein-energy ratio), breed and strain differences, hormonal status, the number of adipocytes present, and changes in household circumstances. Between 24% and 44% of dogs and at least 9% and 25% of cats are said to be overtly obese.[1] The females of the species are more frequently obese. About 25% of obese dogs have orthopedic problems, whereas only 10% of all dogs seen in 11 veterinary practices had orthopedic problems.[19] These problems included arthritis, herniated intervertebral disks, and ruptured anterior cruciate ligaments. In a risk assessment study for hip dysplasia in German shepherd dogs, golden retrievers, Labrador retrievers, and Rottweilers, high body

weight was shown to be an important risk factor.[20] (see "Osteoarthrosis" later in this chapter). No known dietary aberration is responsible for these diseases, but rather the mechanical effect of the increased weight on the skeleton.[19]

Excessive Mineral Intake

The calcium and phosphate content of ordinary commercial pet foods can significantly exceed the recommended levels, and although this may not have deleterious effects on healthy adults, it is certainly unneccessary.[9] In dogs and cats with severe loss of kidney function, phosphate will accumulate and thereby decrease circulating

calcium concentrations. Hyperphosphatemia can go together with decreased 1-α hydroxylation of 25OHvitamin D, resulting in diminished production of $1,25(OH)_2$vitamin D_3 and thus in decreased active calcium absorption. As a result, the parathyroid glands will secrete more PTH (renal secondary hyperparathyroidism), causing an increase in osteoclastic activity to normalize circulating calcium concentrations, with eventual development of osteodystrophy and loosening of teeth in the mandible and maxilla. Of greater clinical significance are the systemic effects of renal failure. Renal osteodystrophy is characterized microscopically by increased osteoclast

and osteocyte activity and inadequate mineralization of normal osteoid. High phosphate intake will aggravate the situation by (1) promoting mineral depositions in soft tissues, not only the kidney but also periarticular tissue, tendon sheaths, and foot pads; and (2) decreasing circulating calcium concentrations and subsequently boosting hyperparathyroidism.[21]

Low Vitamin D Intake

Because young dogs are not able to fulfill their need for vitamin D by biosynthesis in the skin via stimulation by ultraviolet light, it seems reasonable to suggest that adults also need dietary vitamin D. Hypovitaminosis D, causing

osteomalacia in adult dogs and cats and characterized by increased osteoclasia and unmineralized osteoid layers, is seldom recognized clinically. The deleterious effects of vitamin D intoxication are the same as those previously described for young animals.

Excessive Vitamin A Intake

Hypervitaminosis A is seen more frequently in cats than in dogs, especially at an older age (2 to 9 years). Radiologically, hypervitaminosis A is characterized by new bone formation rather than by osteoporosis or bone loss. New bone formation starts at the points of

insertion of ligaments, muscles, and joint capsules, causing narrowing of intervertebral foramina in the cervical area and ankylosis of vertebral, shoulder, elbow, hip, and stifle joints (rarely carpal and tarsal joints). In addition to lethargy, pain on palpation, and changes in character, such changes as stiffness of the neck or of one or more large joints can be the first clinical signs. For further details and treatment see Chapter 99.

Nutrition and Osteoarthrosis

Cartilage contains chondroblasts, proteoglycans, and collagen. Proteoglycans are build out of

glycosaminoglycans (GAGs) and a core protein. Aggrecan is an important proteoglycan in joint cartilage, with keratin sulphate and chondroitin sulphate as GAGs. About 200 aggrecan molecules are bound via a glycoprotein to a hyaluran molecule, binding a large quantity of extracellular water, determining the compressability of cartilage. Collagen molecules in cartilage contain large amounts of hydroxyl proline and hydroxyl lysine. The molecules form a triple helix structure, bound to fibrils and these to fibers, with great strength against pull and which form a labyrinth holding proteoglycans in its place. During aging, the length of GAGs decrease, the proteoglycan content decreases, and

thus the water content and the flexibility to withstand loading decrease. GAGs may be damaged by reactive oxygen species (ROS), i.e., free radicals formed during different metabolic processes, trauma, infection, and irradiation.

Regeneration of cartilage can occur after microtrauma by proliferation of undamaged chondrocytes and by de novo synthesis of proteoglycans and collagen. Severe cellular damage will lead to a scar without cells, a fibrotic cartilage scar with a low content of proteoglycans.

Under normal circumstances proteolytic enzymes, mainly matrix

metalloproteinases (MMPs), will be suppressed by tissue inhibitors of MMPs (TIMPs). In osteoarthrosis (OA), however, MMPs will be formed under the influence of cytokines interleukin-I (IL-I) and tumor necrosis factor-α, released by synovial membrane cells, monocytes, macrophages, and T-cells. These cytokines also stimulate chondrocytes and osteoclasts to produce MMPs as soon as their surrounding cartilage has been destroyed. In addition, IL-I stimulates the release of arachidonic acid (AA) metabolites including prostaglandin PGE_2 from chondrocytes and synovial membrane as well as leukotriene B_4 (LTB_4).[5]

Causative Role of Nutrition

Osteoarthrosis (OA) can be divided into primary OA, i.e., without any other cause than aging, and secondary OA, which has a variety of causes, including incongruency or loose bodies in the joint, joint instability, and infection, immune disease, or hemarthrosis. This wide variety of diseases will eventually result in clinical OA. The age of onset and severity of occurrence of primary OA may depend on the breed (Patronek et al, 1997). Many orthopedic developmental diseases have a low h^2 (as in elbow dysplasia, $h^2 = 0.4\text{-}0.7$), leaving a large influence on the environment. Fragmented coronoid process (FCP) and osteochondrosis of

the elbow joint have been explained by Olsson[22] as a disturbance of endochondral ossification and, as such, expressions of the same disease. Osteochondrosis is seen more frequently in certain breeds and subpopulations and can be aggravated by high food intake and excessive calcium intake,[5,8] as well as by over-supplementation of balanced food with vitamin D.[23] Rations rich in protein will not have a disturbing influence on skeletal development;[4] however, Great Danes raised on food with an increased calcium and phosphorous intake but with the same Ca:P ratio (3.3 Ca and 3.0% P versus controls on 1.1% Ca and 0.9% P) also developed disturbances in endochondral ossification in the

growth plates of the distal radius or ulna (Figure 114-1D).[14] As a consequence, elbow incongruity developed, owing either to a severe disturbance of growth in length of the radius or to a severe radius curvus syndrome with disturbed growth in length of the ulna (Figure 114-3).[8,14] The latter may coincide with an ununited anconeal process or the painful distraction cubiti; both will lead to OA of the elbow joint. In studies in Labradors,[2,13] Great Danes,[11] and German shepherds[12] it has been demonstrated that OA develops in hip joints in overweight dogs and less frequently in restricted-fed dogs. The frequency and severity of the occurrence of OA can thus be

prevented by dietary management, including a food with a lowered calcium-to-energy ratio, or a quantitative restriction of food intake, and without adding minerals or vitamin D to a balanced diet.

Therapeutic Role of Nutrition

The nonsurgical therapy of OA includes adaptations and medicaments. First the body weight of the patient should be adapted. Decrease of weight, gained during the period of decreased mobilization but not with a simultaneous adaptation of energy intake, will be the primary goal. A significant improvement was recorded by Impellieri et al in dogs with HD,

following a decrease in body weight by 11 to18%.[24] This clinical finding was supported by the objective score by force-plate analysis by Burkholder et al.[25] Adaptation to the amount and the kind of activity that does the least possible harm to the joint, preferably hydrotherapy (i.e., swimming), should coincide with the weight reduction program.

Corticosteroids suppress phospholipase activity, consequentially with stabilization of blood vessel walls and lysosomes. The joints will be less painful and less synovia is produced. Because regeneration of cartilage will be decreased under the influence of corticosteroids, long-lasting or

repetitive use of corticosteroids, especially intraarticular and at higher doses, is contraindicated. Nonsteroidal anti-inflammatory drugs (NSAIDs) have actions against cyclooxygenase (COX) enzymes; COX1 stimulates the production of prostaglandins (PGs), which protect the body, whereas COX2 stimulates the production of PGE_2, which is responsible for clinical signs such as pain and hyperemia (with resultant warm joint and overproduction of joint fluid). Selective COX2 inhibitors with or without suppressive action on lipoxygenase are claimed to be available for dogs, with fewer side effects than most inhibitors of COX1 and COX2. NSAIDs with low incidence of side effects will be

prescribed for a prolonged period, not to mask pain but to improve the metabolic condition of the diseased joint.[26]

In order to support regeneration of joint cartilage and to shorten or lower the dosage of NSAIDs, a search continues for nutritional support of patients with OA. These supplements or diseases-modifying osteoarthritis agents (DMOAs) include chondroitin sulphate, glucosamines, polyunsaturated fatty acids, and antioxidants.

Chondroitin sulphate increases in vitro the production of proteoglycans and, therefore, the regeneration of

cartilage.[27] When given prophylactically in rabbits, it prevents synthesis of MMPs by IL-3 and thus cartilage damage.

Glucosamines, precursors of GAGs, will stimulate synthesis of GAGs, prostaglandins, and collagen by chondrocytes in vitro.[27] In case of substitution of glucosamines in the medium of chondrocytes, mRNA content for aggrecan increased, and for MMPs decreased and synthesis of proteoglycan increased.[28] In rabbits with a cranial cruciate ligament (CCL) rupture, 120 mg/kg body weight of prophylactic glucosamine decreased the amount of chondropathy in comparison with controls.[29] In a study

in dogs with CCL rupture as a model, it has been demonstrated that these dogs had less cartilage swelling, less total and active metalloproteinase (MMP), and lower pathologic scores when injected with 4 mg/kg bw glucosaminoglycan polysulfuric acid (GAGPS) twice weekly for 4 to 8 weeks, starting 4 weeks after the CCL rupture.[30] It is suggested by Altman et al that GAGPS suppress proteoglycan breakdown by MMPs or by directly inhibiting MMP in cartilage, rather than by increasing synthesis of proteoglycans by chondrocytes.[30] De Haan et al demonstrated in a clinical double-blind, placebo-controlled trial that, in dogs with hip dysplasia, 4.4 mg GAGPS per kg bw (IM for 3 to 5

days) revealed an improvement in lameness score, range of motion, and joint pain and no side effects after 8 injections, with only small improvement in the placebo group of dogs.[31]

Combinations of chondroitin sulphate and glucosamines given to dogs with OA subjectively allowed for more normal locomotion and joint movement than in untreated controls.[32] Prophylactically provided, this combination decreased inflammation in dogs with induced arthritis,[33] possibly owing to a modulated metabolism of the articular cartilage. The latter was suggested to occur in dogs with CCL ruptures,

supplemented with a mixture of chondroitin sulphate, glucosamine hydrochloride, and manganese ascorbate.[34]

The polyunsaturated free fatty acid (PUFA) component of mussels or plant seeds has a potentially beneficial role in immune-related disorders and OA.[35] Leukotrienes are formed out of arachidonic acid (AA; 20:4Ω -6) and eicosapentaenoic acid (EPA; 20:6Ω-3), originating from cellular membranes, under the influence of the enzyme 5-lipogenase. Pro-inflammatory LTB4 originates from AA, anti-inflammatory LTB5 originates from EPA. The amount and type of these eicosanoids are determined by the availability of the

PUFA precursor. A higher Ω–3 intake results in decreased membrane AA levels and thus a decreased synthesis of eicosanoids from AA and an increase in eiconoids derived from EPA. In joints with OA, the LTB4 content is increased.[36] In 36 dogs with elbow OA owing to elbow dysplasia, a double-blind efficacy study was performed by feeding balanced foods with increased Ω-3 content (Ω-3 of 4%, and Ω-6 of 20%) versus a high Ω-6 content (Ω-3 of 0.8%, and Ω-6 of 38%) revealed significant increase in plasma LTB5 concentrations in the former group, although ground reaction forces did not differ between the two groups of dogs.[37] A clinical trial including force-plate analysis performed in two groups

of dogs fed either a control food or an EPA-supplemented diet for a 90-day period revealed that 31% of the controls and 82% of the EPA-supplemented group improved their weight-bearing ability.[38] In addition, in vitro studies of canine cartilage indicated that cartilage exposed to EPA stopped further degradation.[39]

Antioxidants may decrease the damage of synovial cells by reactive oxygen species (ROS). For this purpose, vitamins A, C, and E and β-carotene content in the diet can be increased.[40]

Combinations of chondroitin, glucosamine and PUFAs are present in green-lipped mussels (GLM). The flesh

part of the GLM, separated from the shell, contains saturated, monounsaturated, and polyunsaturated fatty acids. Of the latter, a large amount is Ω-3 fatty acid, mainly EPA, and docosahexaenoic acid (DHA), with a final ratio of Ω-6: Ω-3 = 1: 10. GLM powder is claimed to be a 5-lipoxygenase-pathway inhibitor. Freeze-dried GLM powder contains in addition a variety of nutrients that may have a beneficial effect on joint health, including amino acids (glutamine, methionine), vitamins C and E, and minerals (zinc, copper, and manganese). The combination of Ω-3, PUFA, and other ingredients may have the synergistic potential to limit the progression of OA. In a double-blind,

randomized, controlled trial in dogs with OA, 17 dogs were given GLM supplement powder and 15 dogs were given GLM supplement oil (both in a daily dosage of 1000 mg when bw was more than 34 kg; 750 mg when bw was 34 to 25 kg; 450 mg when bw was less than 25 kg) and both groups were compared with 15 controls. A nonobjectivated score of arthritic signs grading from no signs to severe was given for mobility and for all major joints individually before the start of the study and at 6 weeks. Joint swelling, pain, and crepitus were reported to improve in only the GLM-powder supplemented group in comparison with the controls.[41] In addition, Bierer and Bui reported on a

dose-response in alleviating arthritis score in 4 groups of dogs: 3 dosage groups (1:2:4) receiving GLM-power and 1 control group.[41] All 3 dosages resulted in a similar improvement in total arthritic score and all significantly different from the controls. However, no significant effects were observed with regard to mobility and range of joint movement with the addition of GLM in any of the groups. Longer study period and more sensitive assessment methods may be helpful in detecting any possible effects in these parameters.[41]

There is great interest in the discovery of natural products to be used as DMOAs, based on the aversion to

“chemical substances” (i.e., NSAIDs) that exist among many dog owners, as well as on the less restricted efficacy-control of supplements in terms of dosage and purity, and the approval to add these substances to dog food. There is a growing need to double-blind clinical-efficacy studies with objectivated criteria to demonstrate the evidence gathered in vitro that these DMOAs, “neutraceuticals” and “supplements” may be beneficial to patients suffering from OA. Meta-analyses of the efficacy of glucosamine and chondroitin sulphate for treatment of OA in humans, led to different conclusions: supplementation with glucosamine or chondroitin sulphate demonstrated some efficacy in some

symptom-relieving parameters, but the ability to modify the structure of articular cartilage was not confirmed.[42] Research is scarcely available to demonstrate a direct therapeutic effect in support of the treatment of OA in dogs at the level these substances are included in most pet foods.[32,38] Claims for different levels or different combinations of neutraceuticals, or the period before efficacy can be expected, the use in particular breeds or sizes of dogs, or the indication for their use in different joints with OA or at certain stages of OA will be a matter of debate until the onus of proof is laid in the hands of those who claim the efficacy.

Nutrition and Fractures

The skeleton is under the influence of calcium homeostasis. Low calcium or high phosphate intake or low vitamin D intake can cause pathologic fractures owing to poor mineralization of the skeleton (Figure 114-1). These pathologic fractures include compression fractures of cancellous bone and greenstick fractures of cortical bone. In the latter, the abnormal alignment (Figure 114-2) can be corrected only after the bone has achieved normal mineralization. Therefore, the first phase should consist of good nursing and feeding of a balanced diet. Because a great deal of osteoid (and cartilage, in the case of

hypovitaminosis D) has to be mineralized in this first phase of treatment, this “bone hunger” can be compensated for by supporting the balanced food with calcium salts (i.e., bone meal) up to 0.7 g calcium and 0.5 g phosphorus per 1000 kJ. Radiographic evaluation (Figure 114-3) will demonstrate dramatic improvement. If the improvement does not occur, other rarer causes of abnormal skeletal development, including osteogenesis imperfecta (see Chapter 99), should be considered. When posterior paralysis or paresis occurs, the prognosis for improvement is guarded.

Spontaneous fractures, especially of

the mandibles, in old dogs can be the first sign of severe renal dysfunction and they require treatment.

When properly treated in a healthy animal, traumatic fractures heal via the process of primary or secondary bone healing. The latter has much in common with enchondral ossification and thus needs the same nutritional support. Optimal circumstances can be reached with a balanced commercial pet food containing optimal levels of calcium, phosphate, vitamin A, and vitamin D. Excessively high doses of these nutrients have been demonstrated to retard enchondral ossification[39] and bone healing.[40] Pain owing to trauma or surgery may cause

distress, which depletes reserves of protein and diminishes immune competence. In addition, the dietary requirements of ascorbic acid and probably of other nutrients are increased.[1] In surgical patients, the fasting period before and after anesthesia may be detrimental. Therefore, a palatable food formulated to meet the needs of young, growing animals must be considered. Even obese patients should be kept in a positive energy balance, although this demands special management of fracture treatment and postoperative mobilization.

Chapter 115

Articular Cartilage Healing

C. Wayne McIlwraith

General Concepts

Healing refers to restoration of the structural integrity and function of the tissue after injury or disease. Repair refers to the replacement of damaged or lost cells and matrix with new cells and matrix, a process that does not necessarily restore the original structure or function of a tissue.[1] Regeneration may be considered a

special form of repair in which the cells replace lost or damaged tissue with a tissue identical to the original tissue. It has been suggested that, with exception of bone fractures, most injuries and diseases of musculoskeletal tissues do not stimulate regeneration of the original tissue. The limited potential of articular cartilage for regeneration and healing has been appreciated for over 2 centuries. In 1743, Hunter stated “From Hippocrates to the present age, it is universally allowed that ulcerated cartilage is a troublesome thing and that when once destroyed it is not repaired”. The response of cartilage to tissue damage is limited, and natural repair responses from adjacent tissues are unable to

produce tissue with the same morphologic, biochemical, and biomechanical properties of articular cartilage.

Some of the earlier experimental work provided us with classic concepts. Bennett, Bauer, and Maddock studied the repair of articular cartilage defects, as well as the reaction of normal joints of adult dogs to surgically created defects of articular cartilage and implantation of joint mice. No defects completely healed in the 28-week period. Calandruccio and Gilmer studied the healing of defects in immature dogs.

They recognized the phenomena of

matrix flow, proliferation of superficial cartilage cells, proliferation of connective tissue from the base of the defect, and formation of new chondrones as phenomena in the healing process. Using radioactive labeling, other research has recognized increased collagen synthesis, as well as increased proteoglycan synthesis adjacent to the area of cartilage injury. However, despite this evidence for increased proteoglycan and collagen synthesis, no significant contribution was made to the healing of lacerated defects in mature rabbit cartilage. Biochemical studies have been directed at characterization of the collagen types in the repair tissue. Furukawa et al were the first to recognize the early

formation of type I collagen with later increases in type II collagen content (the characteristic collagen for articular cartilage). Although type II later predominated, type I collagen always persisted significantly. It addition, there was less hexosamine in the repair tissue, suggesting that the fibrous nature that usually developed in the healing tissue was due to a lack of proteoglycans rather than a change in the type of collagen.[7]

Natural Healing of Articular Cartilage Defects

The major limiting factor in the successful rehabilitation of any joint after injury and disease is the failure of

osteochondral defects to heal. Three mechanisms have been recognized as possible contributors to articular cartilage repair. Intrinsic repair (from within the cartilage) relies on the limited mitotic capability of the chondrocyte and a somewhat ineffective increase in collagen and proteoglycan production. Extrinsic repair comes from mesenchymal elements from the subchondral bone participating in the formation of new connective tissue that may undergo some metaplastic change to form cartilage elements. The third phenomenon known as “matrix flow” may contribute to equine articular cartilage repair by forming lips of cartilage from the perimeter of the

lesion that migrate toward the center of the defect.[9,10] A publication has suggested that it is possible for synovial membrane (and the subsynovial tissue) to act a source of repair.[11] This experimental study was done with partial-thickness defects in rabbits. With the use of chondroitinase ABC to digest the GAG chains of cartilage proteoglycans (which enhances adhesions) an addition of growth factors and mesenchymal cells that were considered synovial in origin came into the defect. There was no transformation of these cells into chondrocytic elements and at this stage it would seem, although synovial membrane could be a potential source of cells, effective healing is not going

to be achieved.

The depth of the injury (full or partial thickness), size of defect, location and relation to weight-bearing or non-weight-bearing areas, and the age of the animal influence the repair and remodeling of an injured joint surface.[4,6,12]

With a partial-thickness defect, some degree of repair with increased glycosaminoglycan synthesis and increased collagen synthesis occurs.[6] However, the repair process is never completely effective. It has been reported in humans that complete repair of chondromalacia of the patella is thought to occur if matrical

depletion and surface breakdown are minimal.[13] However, more recent work with arthroscopic debridement of partial-thickness defects in humans questions any actual regeneration.[14] It should also be recognized that superficial defects are not necessarily progressive and do not necessarily compromise joint function.

With full-thickness defects, the response from the adjacent articular cartilage varies little from that of superficial lesions and provides only limited repair necessary to replace dead cells and damaged matrix at the margins of the wound. These defects heal by in-growth of subchondral fibrous tissue that may or may not

undergo metaplasia to fibrocartilage.[9,12,15-17] Subchondral bone defects either heal with bone that grows up into the defect or fill in with fibrocartilagenous in-growth. Duplication of the tide mark in the calcified cartilage layer is rare, and adherence of the repair tissue to surrounding non-injured cartilage is often incomplete.

The size and location of articular defects have a significant effect on the degree of healing achieved; several studies in the horse demonstrate this. Convery et al first reported that large defects were less likely to heal.[12] A more recent study distinguished between large (15 mm^2) and small

(5mm^2) full-thickness lesions in weight-bearing and non-weight-bearing areas of the radiocarpal, intercarpal and femoropatellar joints.[9] At 1 month, small defects were filled with poorly organized fibrovascular repair tissue; by 4 months, repair was limited to an increase in the amount of organization of this fibrous tissue; and by 5 months, small radiocarpal and femoropatellar lesions were hardly detectable because of the combinations of matrix flow and extrinsic repair mechanisms. Large lesions showed good initial repair but at 5 months perilesional and intralesional subchondral clefts developed.

It has also been demonstrated that

induced osteochondral defects (6.5 mm) on the non-weight-bearing aspect of the distal lateral trochlea in the horse healed with fibrocartilagenous tissue at a faster rate, and more completely, than those on the weight-bearing proximomedial trochlear ridge of the talus.[18]

The repair tissue that forms after full-thickness injury to hyaline cartilage, or as a natural repair process in joints with OA, is primarily composed of type I compared to type II collagen at least at 4 months.[19,20] Identification of type II collagen is a critical biochemical factor distinguishing hyaline cartilage from repair fibrous tissue and fibrocartilage. It is believed that the

presence of an abnormal subchondral bone plate and the absence of a tide mark reforming may create a stiffness gradient, and that shear stresses of the junction of the repair tissue and underlying bone develop. The propagation of such shear stresses would lead to the degradation of repair fibrocartilage and exposure of the bone. This mechanical failure has been observed experimentally and clinically.[9,21] Of some interest are data from the author's laboratory on the analysis of tissue 12 months after creation of full-thickness articular cartilage defects in a weight-bearing area. In a study looking at the effectiveness of sternal cartilage grafting long-term, the repair tissue in

the non-grafted defects at 12 months consisted of fibrocartilaginous tissue with fibrous tissue in the surface layers, as had been seen in control defects at 4 months (Figure 115-1). On biochemical analysis, the repair tissue of the non-grafted defects had a mean type II collagen percentage of 79% compared with being non-detectable at 4 months.[20] On the other hand, the glycosaminoglycan content expressed as milligrams of total hexosamine per gram of dried tissue was 20.6 +/- 1.85 mg/gm compared with 26.4 +/- 3.1 mg/gm at 4 months and 41.8 +/- 4.3 mg/gm DW in normal equine articular cartilage.[20,22]

The fibrocartilaginous repair seen in

normal full-thickness defects, therefore, is biomechanically unsuitable as a replacement-bearing surface and has been shown to undergo mechanical failure with use. The lack of durability may be related to faulty biochemical composition of the old matrix and incomplete remodeling of the interface between old and repaired cartilage or to increased stress in the regenerated cartilage because of abnormal remodeling of the subchondral bone plate and calcified cartilage layer. Although some work implies that it may be possible to reconstitute the normal collagen type in articular repair,[22] it is clear that low levels of glycosaminoglycan persist and these are important components in the

overall composition of the cartilage matrix.

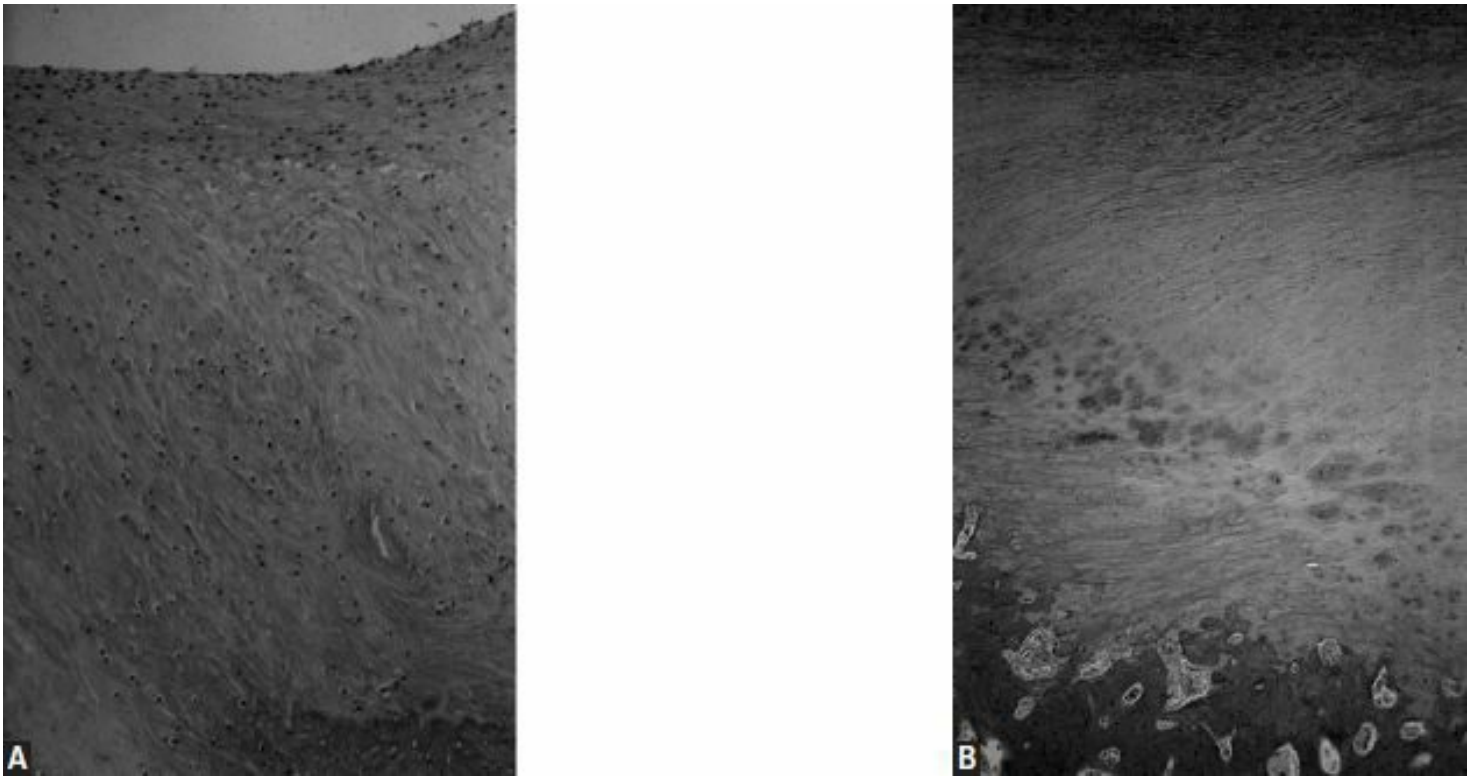

Figure 115-1. Photomicrographs of repair tissue in full-thickness articular cartilage defects in equine radial carpal bone. (A) at 4 months, (B) at 12 months. There is a mixture of fibrous (superficially) and fibrocartilagenous (deeper) tissue in the defect.

It does need to be recognized that the presence of a cartilage defect may not represent clinical compromise. In the

equine carpus, it has been shown that up to 30% of articular surface loss of an individual bone may not compromise the successful return of a horse to racing.[21] However, a loss of 50% of the articular surface or severe loss of subchondral bone leads to a significantly decreased prognosis.

It is also to be recognized that the inadequate healing response may not necessarily apply to immature animals nor to non-weight bearing defects. An example is the young patient after surgery for osteochondritis dissecans (OCD) in which impressive healing responses or at least functional responses are obtained. This may be related to increased chondrocytic

capacity for mitosis and matrix synthesis and the presence of intracartilaginous vascularity. Complete restoration of the ultrastructure and surface configuration in a hinge-like gliding joint surface such as the femoropatellar joint may be unnecessary for clinical soundness compared with the more severe loading on an osteochondral defect located on the weight-bearing portion of the medial condyle of the femur, for instance. It has been suggested that increasing age may affect the response of cartilage to injury in humans because the ability of the chondrocytes to synthesize and assemble matrix micromolecules could decline with age.[1] Buckwalter and

Mow cite a study of transplanted chondrocytes, suggesting that older chondrocytes produce a more poorly organized matrix than do younger chondrocytes,[1] and other studies demonstrate that the proteoglycan synthesized by the chondrocytes change with age.[5,23]

Techniques Attempted for Modulation of Articular Cartilage Healing

Defect Debridement

An old clinical generalization is that superficial defects in articular cartilage do not heal and that full-thickness defects heal through metaplasia of

granulation tissue arising at either the articular margin or from the subchondral marrow spaces below.[16] This led to the common practice of clinicians curetting partial-thickness defects into full-thickness ones to stimulate "healing." As mentioned previously, the importance of small partial-thickness defects has been questioned and the quality of the new replacement tissue after full-thickness curettage is now recognized as uncertain and commonly defective.[8] In addition to experimental work, arthroscopic observations (follow-up examinations) by the author of the healing of clinical articular defects confirm the failure of these defects to heal effectively in weight-bearing

areas. Because of this inadequate healing response, it is suggested that debridement of partial-thickness defects to full-thickness defects in aggressive debridement to bone is contraindicated.[24] This opinion is also influenced by the observation that superficial defects are not necessarily progressive and do not necessarily compromise joint function.

Having said that, cartilage and bone debridement are common during arthroscopic surgery. As a simple rule, loose fibrous tissue or exposed loose bone should be removed from full-thickness defects. If cartilage is elevated or separated from the bone, it should be debrided back to where it

attaches. Debridement should continue down to firm, normal-appearing subchondral bone. Maintaining as much subchondral bone as possible keeps the bone plate and overlying cartilage repair tissue contoured to the normal congruency of the opposing joint surface, thereby enhancing the chance of healing cartilage tissue persisting. It is important, however, that the remaining bone is viable. Crumbly, brownish bone should also be removed by debridement, either using hand instruments or motorized equipment. As has been mentioned, consensus appears to favor not debriding partial-thickness fibrillated cartilage. An argument exists that chondroplasty reduces the possibility of

damaged cartilage leaching degraded cartilage-matrix fragments, including collagen, proteoglycan, and cellular components, to the synovial fluid where they increase synovitis and concurrent lameness.[25]

Full-thickness cartilage lesions are debrided to remove residual portions of the calcified cartilage layer. Research has confirmed that persistence of calcified cartilage retards the development of well attached cartilage repair tissue from the subchondral bone and surrounding cartilage (Figure 115-2).[26]

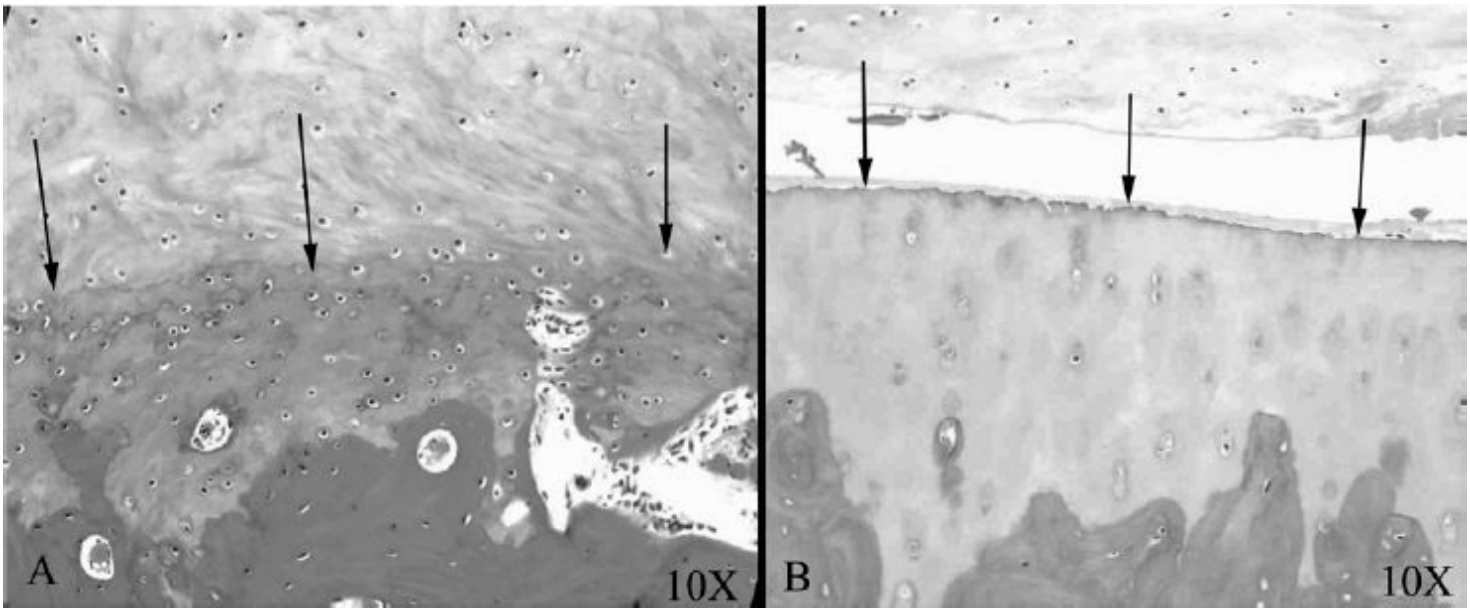

Figure 115-2. Photomicrographs of repair tissue at 12 months in full-thickness articular cartilage defects on the medial femoral condyle where (A) the calcified cartilage layer has been completely removed, and (B) the calcified cartilage layer has not been removed.

Chondroplasty

Resection of the protruding surface strands of partial-thickness cartilage fibrillation has been promoted as a mechanism to reduce cartilage-derived debris entering the synovial environment.[25,27-29] Motorized

synovial abraders are used smooth the surface of the more seriously damaged cartilage. The residual cartilage then presents a more uniform non-clefted surface, which may be more durable and incite less synovitis than the large surface area presented by multiple strands of fibrillated cartilage. Although this seems a simple concept, a paucity of evidence exists documenting any discrete benefit, either in reducing synovial levels of fragmented proteoglycan and collagen or in decreasing the symptoms of synovitis. Clinically, chondroplasty to smooth articular cartilage in areas of fibrillation seems to reduce the evidence of persistent effusion when patients go back into exercise, but

because of a lack of controlled experimental data, the technique is controversial. It is important that, if done, resection should only involve the fibrillated surface and not be aggressively pursued down to the subchondral bone for reasons previously discussed. Articular cartilage was shaved on the underside of the rabbit patella with no evidence for repair (and no evidence of degenerative changes) in either the superficially or deeply shaved areas.[23,30] Ultrastructural studies after arthroscopic cartilage shaving however, question any regeneration and suggest deleterious effects.[14]

Spongialization

Removal of sclerotic subchondral bone from the base of full-thickness defects has been advocated to achieve the formation of new tissue in the defect.[31] In defects associated with OA, the subchondral plate is often sclerotic and ischemic, and complete removal of the subchondral plate (spongialization) could potentially provide an increased opportunity for tissue filling of cartilage defects. However, long-term follow-up of experimental defects in horses with significant debridement of subchondral bone implies that the biomechanical changes result in stresses that disrupt the new repair tissue.[22] Spongialization has been replaced by less invasive techniques,

particularly microfracture.

Subchondral Bone Drilling

Subchondral bone drilling has been used with rationale similar to spongialization (access to cancellous bone through a sclerotic or ischemic subchondral bone plate). Controlled studies have been done with experimentally created full-thickness and partial-thickness defects in horses.[32,33] Subchondral bone drilling of full-thickness cartilage defects of the equine third carpal bone was followed by fibrocartilagenous repair tissue of quality and quantity superior to the fibrous tissue of non-drilled defects, but satisfactory functional healing was not

achieved.[32] Subchondral drilling did not significantly improve partial-thickness cartilage healing.[33]

Abrasion Arthroplasty

The use of superficial intracortical debridement (arthroscopic abrasion arthroplasty), as opposed to deep cancellous debridement, for sclerotic degenerative lesions has been advocated in humans.[34] The concept is somewhat controversial and argues the necessity to expose cancellous bone to reach both bone supply and pluripotential cells. Abrasion arthroplasty is an arthroscopic technique used to remove eburnated bone by exposing intracortical vessels

in the tibial and femoral surfaces of the knee. The organizing hematoma forms over these abraded surfaces and then differentiates into fibrocartilage. The abrasion goes approximately 2 mm into cortical bone. Deep exposure into cancellous bone with removal of subchondral bone is considered counter-productive as it causes a fibrous repair without cartilage.[35] Microfracture is the favored technique for gaining access to cancellous bone elements now.

Subchondral Bone Microfracture

The use of microfracture, or micropicking, as it has been referred to

in equine arthroscopy, has many of the advantages associated with subchondral drilling, including focal penetration of the dense subchondral plate to expose cartilage defects to the benefits of cellular and growth-factor influx, as well as improving anchorage of the new tissue to the underlying subchondral bone and, to some extent, surrounding cartilage.[36-38] The simplicity of microfracture comes from the use of a tapered awl (Linvatec, Largo, FL; Arthrex, Naples, FL) instead of a parallel-sided twist drill. Using the awl eliminates the need for powered instrumentation and gives accurate control. A tapered entry into the subchondral marrow space is achieved. The microfracture awl should penetrate

the subchondral bone deeply enough to provide ready access to the marrow spaces, thereby maximizing cellular and anabolic growth-factor delivery (Figure 115-3). The microfracture awl also tends to make a crater in the subchondral bone, which may play a role in better attachment of the cartilage repair tissue.[39] Microfracture holes are generally placed 3 to 5 mm apart and cover the entire debrided area in a cartilage lesion. It is also important to microfracture the subchondral bone on the perimeter of the cartilage lesion to encourage new tissue at the junction of repair tissue and residual cartilage. The technique has become popular in human arthroscopy and is now frequently

compared to chondrocyte transplantation as one of the two most frequently employed techniques to improve cartilage healing.[36,40,41] One study compared use of microfracture to autologous chondrocyte implantation in a randomized trial. At 2 years' follow-up, both groups had significant clinical improvement, but according to the SF-36 physical component score, the improvement in the microfracture group was significantly better than that in the autologous implantation group.[42]

An experimental study in the horse documented improvement in the quantity of tissue and the type II collagen content at 4 and 12 months

after microfracture of full-thickness cartilage defects (Figure 115-4).[37] Improvements in early gene expression of type II collagen and mRNA at 8 weeks have also been demonstrated.[43]

Figure 115-3. Arthroscopic view of a microfractured articular defect.

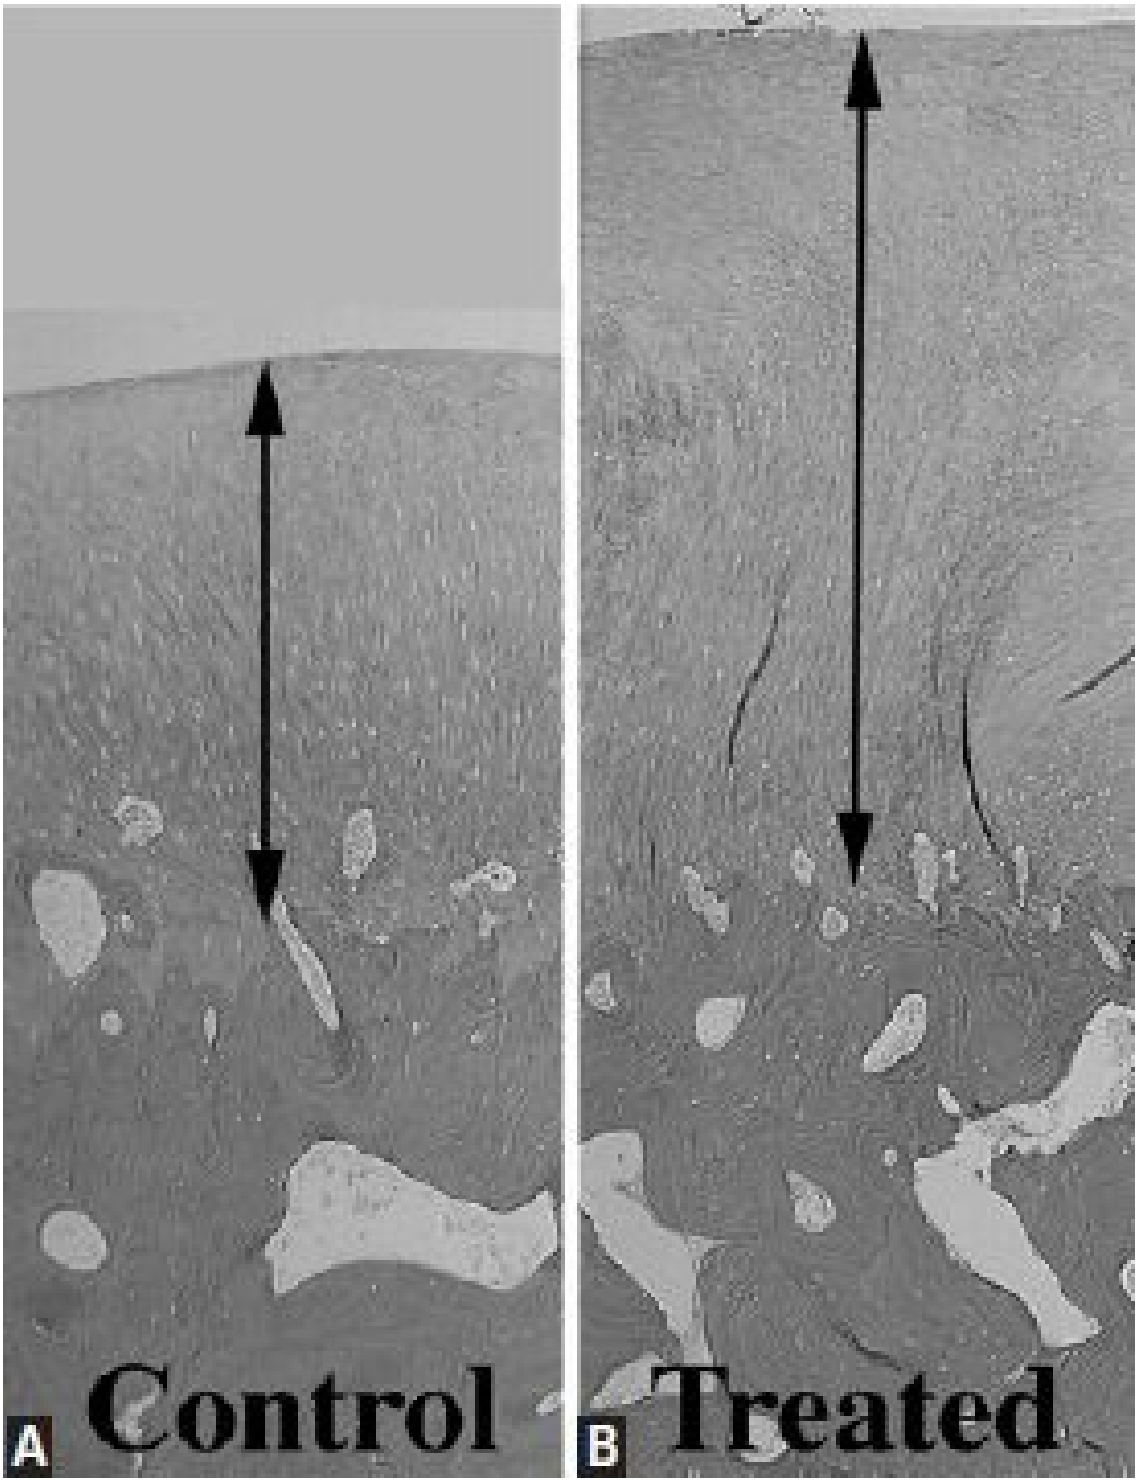

Figure 115-4. Photomicrographs (same level of magnification) of full-thickness defects on the medial femoral condyle that have been (A) simply debrided and (B) debrided and microfractured, demonstrating signficiantly more filling of articular defect that has

been microfractured.

The technique clearly has advantages over forage and transplantation methods, including ease of application using arthroscopy, use of a simple hand tool, the relative economics of the equipment required, and the apparent increase of cartilage repair tissue that develops after the procedure.

Transplantation Procedures

It is generally accepted that most debriding and marrow-stimulating techniques result in fibrocartilage formation with modest biomechanical capabilities. The use of supplemental free cells, various vehicles containing

cells or entire tissue such as periosteum or cartilage grafts have been advocated to improve on the modest impact that local manipulative procedures have on both the quality and quantity of cartilage repair tissue. Transplantation procedures can be classified according to the origin of the transplanted tissue: 1) periosteal grafting; 2) periochondral grafting; 3) autogenous cartilage (articular, sternal, or auricular transplantation); 4) osteochondral transplantation; 5) chondrocyte transplantation; and 6) pluripotential stem cell transplantation. These transplantation techniques have practical limitations. Arthrotomy is required for insertion of periosteum, perichondrium, intact

cartilage, and osteochondral grafts. Similarly, tissue-engineered analogs such as chondrocytes cultured on collagen, PGA or PGA/PLA, or other synthetic materials such as hyaluronan membranes are also difficult or impossible to implant arthroscopically.

Periosteum

The chondrogenic potentials of perichondrium and periosteum have been used experimentally to restore large osteochondral defects in the rabbit and dog.[44-47] Work in the horse showed that chondroid tissue could be produced after implantation of free periosteal autografts (but not perichondreal autografts).[48] However,

when periosteal autografts were placed into osteochondral defects and fixed with fibrin glue, results were unsatisfactory, with the predominant tissue in most defects being fibrous tissue. The poor results and high type I collagen content were related to the formation of adhesions.[17]

Sternal Cartilage Autografts

The use of sternal cartilage autografts has been investigated in horses with fixation of the autografts using biodegradable pins.[20,22] On histologic examination at 4 months, the repair tissue appeared morphologically similar to hyaline cartilage compared with the non-grafted tissue, which was

fibrocartilage tissue with fibrous tissue on the surface. On biochemical analysis, the repair tissue with sternal grafting was composed predominantly of type II collagen (non-grafted predominantly type I collagen) and the total GAG content of repair tissue (42.6 =/- 5.9 mg/g DW) was not significantly different from that of normal articular cartilage and was significantly greater than that of non-grafted defects (26.4 +/- 3.1 mg/g DW). Unfortunately, a long-term (12-month) study (together with high-speed treadmill exercise) resulted in repair tissue degenerating and the formation of horizontal and vertical clefts. The type II collagen content was not significantly different from control

defects and the mean total GAG content had dropped to 29.1 mg/g DW in grafted defects compared with 19.1 mg/g DW in controls.

Osteochondral Grafts

The use of osteochondral autografts and allografts has cycled through several periods of clinical interest. Originally, autogenous osteochondral shell allografts were used, but there were major problems of limited availability of autogenous osteochondral graft tissue and donor site morbidity. Few locations in humans or animals can sacrifice considerable areas of a joint as osteochondral grafts. The use of

osteochondral shell allografts overcomes the limitations of donor site morbidity, and fresh osteochondral hemiarthroplasty shell allografts have been used for advanced degenerative osteoarthritis in humans.[49] These are entire femoral condylar grafts and immunogenicity is always of concern.

Mosaicplasty using autogenous osteochondral dowel grafts has become popular. Osteochondral dowels are harvested arthroscopically from less weight-bearing regions of the same joint, and these dowels are inserted to reconstruct a relatively congruous joint surface with articular cartilage.[50-53]

Several instrument systems are

available for the harvest and implantation of osteochondral dowels in humans and animals, including the mosaicplasty system (ACUFEX-Smith and Nephew, Andover, MA); the osteochondral autografts transfer system (OATS-Arthrex, Naples, FL); and the consistent osteochondral repair system (COR-Innovasif BE). Frequently "mosaicplasty" is used as an umbrella term when it is specific to the Smith and Nephew instrumentation. The benefits of this technique include immediate weight-bearing capabilities, relatively good integration of the bony portion of the dowel, and the long-term data available from clinical trials.[52,53]

The mosaicplasty technique has been used in the horse and it has also been shown that age influences the outcome.[54] A case report has been published of the use of mosaicplasty for the repair of a subchondral bone cyst in the medial femoral condyle in the horse.[55] The technical difficulties associated with careful graft harvesting and the precision and crafting needed for heterotopic graft insertion in the recipient bed will probably detract from wider clinical application.[56] Also empty spaces that naturally form between inserted osteochondral dowels heal poorly and allow synovial fluid entry into the bony tunnels of adjacent dowels.

Chondrocyte Transplantation

Autogenous chondrocyte implantation is one of the few FDA-approved tissue engineering techniques to treat articular cartilage injury in humans. It is a two-stage procedure in which articular cartilage biopsies are harvested arthroscopically from minimally weight-bearing regions of the injured knee, propagated ex vivo in cell culture, and later implanted under an autogenous periosteal tissue flap.[57] The indications include focal defects and osteochondritis dissecans.[58,59] The delivery of cells requires an arthrotomy and the harvest and suture attachment of a periosteal flap, which is tedious and technically demanding. One study compared

chondrocyte transplantations secured with a periosteal patch to defects treated with periosteal patches without chondrocyte implantation and found no difference between the healing tissues after 1 year.[60] Long-term studies for patients treated with autogenous chondrocyte repair have reported good outcomes.[61-63]

In horses, chondrocyte implantation techniques have been examined in a variety of matrix carrier vehicles.[64-66] Initial research trials indicated enhancement of healing with chondrocyte implantation using a fibrin vehicle,[64] but further tissue engineering approaches with collagen matrix scaffolds did not provide a

satisfactory improvement in repair.[65]

Experimental work in the horse with a modified ACI technique (culturing of chondrocytes on a collagen membrane) has yielded positive results at 12 and 18 months.[67] However, more recently, even better results have been obtained with re-implantation of morselized autogenous articular cartilage particles in a one-step procedure.[68] Such techniques have real potential application in dogs and horses.

Pluripotential Mesenchymal Stem Cell Transplantation

The use of pluripotent cells to enhance cartilage repair has been investigated

for several years. Initial studies in the rabbit indicated mesenchymal stem cells (MSCs) could enhance cartilage repair.[69] Follow-up work in small animals demonstrated that MSCs can be partially induced down chondrocyte lineages.[70] Studies in the horse indicate bone marrow-derived MSCs can be harvested and cultured for sufficient time and defined media to differentiate toward a chondrocytic lineage,[71] but in vivo studies in the horse report little advantage in the healing at 8 months in a femoral trochlear ridge cartilage defect model.[72] Further work is being done in this area.

Growth Factors

Several naturally occurring polypeptide growth factors play an important role in cartilage homeostasis. The differentiating and matrix anabolic-promoting activity of IGF-1 and TGF-beta are particularly important in counteracting the degradatory and catabolic activities of cytokines, serine proteases, and neutral proteinases. Studies in the horse have largely focused on IGF-1 as TGF-beta has shown synovitis and osteophyte development in animal studies. Slow release of IGF-1 from fibrin composites has been shown to allow for enhanced cartilage repair;[73] however, ideal repair tissue is not obtained and it has been suggested that IGF-1 seems to have better

application in combination chondrocyte implantation where more complete cartilage repair develops.[74]

Conclusion

At the present time most cartilage repair techniques in small animals would revolve around endogenous manipulation of healing, such as the use of debridement and microfracture. More advanced techniques including cartilage transplantation and autogenous chondrocyte implantation, as well as autogenous osteochondral grafting techniques, show promise.

Chapter 116

Osteoarthritis

Michele A. Steffey
Rory J. Todhunter

This chapter is dedicated to Dr. Nancy Burton-Wurster, Cornell University, whose intellectual drive and hard work continues to inspire young minds to pursue investigations into the basic science of osteoarthritis in dogs.

Osteoarthritis (OA) is a degenerative process that leads to changes in all components of a synovial joint:

articular cartilage, subchondral bone, synovial membrane, synovial fluid, and periarticular soft tissues. Osteoarthritis affects up to 20% of dogs over 1 year of age.[1] Although idiopathic (primary) osteoarthritis is rare in dogs and cats, secondary osteoarthritis is common and usually due to underlying factors such as prior trauma, joint incongruency, joint instability, inflammation, or developmental conditions. Pathologic changes typically consist of variable synovitis, joint capsule thickening, cartilage destruction, subchondral sclerosis, and the production of new bone (osteophytes and enthesiophytes). Because several reviews of OA have been written in

veterinary textbooks, this chapter focuses also on information on the subject especially related to biomarkers.

Anatomy and Normal Joint Physiology

Diathrodial joints are an articulation between adjacent bones of the skeleton that are characterized by a surface of articular cartilage, a joint capsule, and synovial fluid secreted into the joint cavity that lubricates the contact surfaces of the joint. Synovial joints can be classified according to the number of articular surfaces they contain (simple or compound joints), the shape or form of the articulating

surfaces (plane, ball and socket, ellipsoidal, hinge, condylar, trochoid, or saddle joints) or by the function of the joint.[2]

The fibrous joint capsule of a diarthrodial joint is lined by a synovial membrane. The outer fibrous layer consists primarily of collagen but also contains the vascular and nervous supply to the joint. It attaches peripherally to the articular cartilage and blends with the periosteum of each bone.[2] The synovial membrane is vascular and consists primarily of loose areolar tissue with an inner layer of cells that is one to two synoviocytes thick (Figure 116-1). The two types of synoviocytes are type A, which are

primarily phagocytic, and type B, which are primarily secretory. The synovial membrane covers all structures within the joint except the articular cartilage and the contact surfaces of any fibrocartilaginous plates (menisci) and blends with the periosteum as it reflects onto bone.[2]

The primary functions of articular cartilage are to promote motion with minimal friction and to transmit load to the underlying subchondral bone. Hyaline cartilage is composed primarily of matrix and contains relatively few cells (Figure 116-1). Chondrocytes make up less than 5% of the tissue volume.[1] Each chondrocyte, in association with its pericellular

capsule and pericellular matrix, forms a unit described as a “chondron.”[3] Cartilage is composed of 70% to 80% water by weight, and is avascular, aneural, and alymphatic (Figure 116-2). The primary large molecules comprising articular cartilage matrix are collagen and proteoglycan, and it is these two molecules that give cartilage its unique biochemical and functional properties. Collagen provides tensile strength, whereas proteoglycan provides compressive strength. Both molecules are produced and secreted locally by chondrocytes.

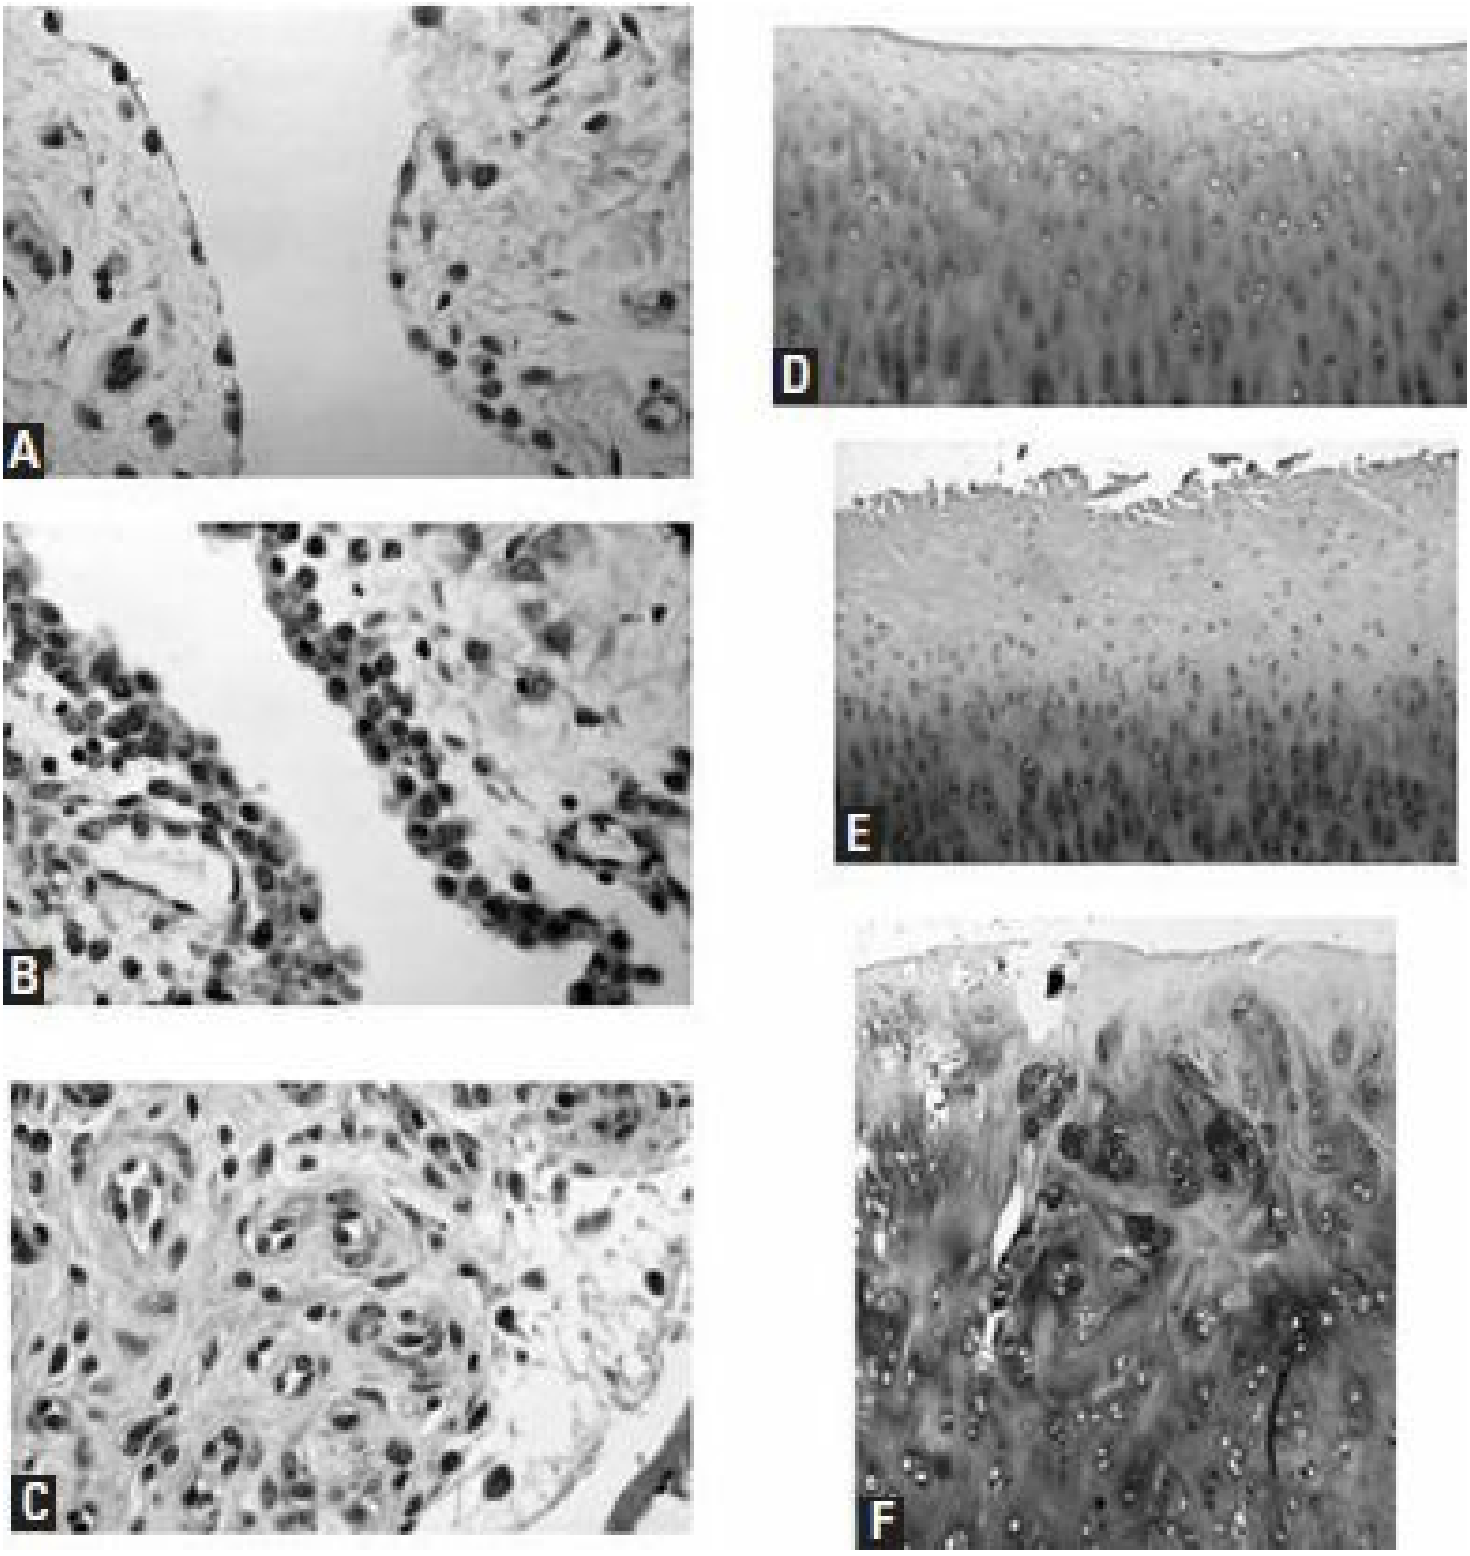

Figure 116-1. A. Photomicrograph of a cross-section of normal synovial membrane. The synovial cavity is between the two pieces of synovial membrane on each side of the photograph. B. Synovial hyperplasia

characterized by synovial lining proliferation. C. Chronic synovial hypertrophy characterized by fibroplasia. *(A,B,C: Hematoxylin and eosin, X160.)* D. Photomicrograph of normal articular cartilage showing tissue sparsely populated with chondrocytes that elaborate a profuse extracellular matrix. Chondrocytes in the deep zone tend to align perpendicular to the articular surface (on top). More intense uptake of stain (which binds the sulfated glycosaminoglycan) is seen pericellularly in the deeper layers. E. Photomicrograph of fibrillated articular cartilage showing decreased staining of the extracellular matrix in a dog in the early stages of hip dysplasia. *(D,E: Safranin O/fast green stain, X180.)* E. Cloning of chondrocytes in advanced osteoarthritis. F: Photomicrograph of articular cartilage from a dog with advanced osteoarthritis secondary to hip dysplasia. Surface irregularity, fissures, and chrondrocyte cloning can be seen *(safranin O/fast green stain, X200)*.

The classic zonal description of articular cartilage is based on

chondrocyte organization, orientation of collagen fibrils, and proteoglycan distribution. Zone one, the tangential zone, is the most superficial region and is characterized by relatively few flattened cells, low proteoglycan content, and collagen fibrils that are oriented tangentially to the articular surface (Figure 116-2). This distribution of collagen and proteoglycan provides the superficial layers of cartilage matrix the greatest ability to withstand tensile forces and resist the swelling pressure exerted by proteoglycan located in the deeper zones.[1] Zones two and three comprise most of the matrix volume. In this region, the density of chondrocytes and proteoglycan content increase with

increasing depth in the tissue (Figure 116-1). The cells become more ovoid and in zone two, the transitional zone, are randomly distributed. The direction of the collagen fibrils changes gradually from a tangential orientation to an oblique orientation, and ultimately the fibrils become radially aligned to the articular surface (Figure 116-2). In zone three, the radial zone, the cells line up in vertical columns within the matrix. It is the increased proteoglycan content in these deeper regions that provides most of the ability of cartilage to resist compressive load. A distinct separation, known as the tidemark, exists between zones three and four, at the upper limit of zone four, the

calcified zone. It contains radially oriented collagen fibrils, but little proteoglycan. The calcified cartilage is separated from the underlying subchondral bone by a cement line. The osteochondral junction is maintained by the morphology of the interdigitating boundary, the undulating nature of which allows shear stresses to be converted into potentially less damaging compressive forces on the subchondral bone.[4]

Collagen composes 50% of the dry weight of mature articular cartilage. There are at least 27 different types of collagen.[5] Collagen fibrils are composed of collagen monomers, which in turn are composed of three polypeptide alpha chains arranged in a triple helix. Genetically different alpha chains lead to different types of collagen monomers. Type II collagen is the primary form of collagen in

articular cartilage. Other types of collagen that are known to be important in the normal function of articular cartilage are types VI, IX, X, and XI. Type VI collagen is found in the pericellular region of the chondron and may be involved in binding the cell surface to matrix constituents. Type IX links type II fibrils together and is important in the association of collagen and proteoglycan within the matrix. Type X collagen is found during development in the hypertrophic cartilage and in the calcified zone of adult cartilage.[1]

Proteoglycans make up 22% to 28% of the dry weight of adult articular cartilage (Figure 116-2). A

proteoglycan molecule is composed of a core protein with glycosaminoglycan side chains. The glycosaminoglycans are chains of repeating disaccharide units of variable length and are negatively charged owing to carboxyl and sulfate groups.[4] This intrinsic ionic charge leads them to repel one another, resulting in the "bottle brush" conformation of the proteoglycan molecule and contributing to its hydrophilic nature. The most common glycosaminoglycans in articular cartilage are chondroitin-6-sulfate (mature articular cartilage), chondroitin-4-sulfate (immature articular cartilage), keratan sulfate, and dermatan sulfate. Proteoglycans may be classified as aggregating or

non-aggregating, depending on the ability of the proteoglycan monomer to attach to a hyaluranon backbone by a glycoprotein link. The major aggregating proteoglycan of articular cartilage is aggrecan, whereas the major non-aggregating proteoglycans are decorin and biglycan. Hyaluronan is a non-sulfated glycosaminoglycan that has no core protein. It is found in both the articular cartilage extracellular matrix and the synovial fluid. Hyaluronan is secreted into the extracellular matrix by chondrocytes, where it forms a chain by the noncovalent interaction of hyaluronon monomers, and can aggregate with aggrecan monomers. Hyaluranan is secreted into the synovial fluid by type

B synoviocytes where it functions in boundary lubrication, but does not appear to be important in cartilage-on-cartilage lubrication.[1]

The ionic charge of proteoglycan attracts water (Figure 116-2). Proteoglycans can occupy a volume up to 50 times their dry weight volume when hydrated.[1] However, because proteoglycans are trapped in a collagen matrix, their expansion is limited to within 20% of their potential volume, keeping cartilage turgid. It is this relationship between proteoglycan and collagen and the free motion of fluid that allows cartilage to resist deformation and transmit load. When cartilage experiences a compressive

load, fluid flows slowly through the collagen meshwork and the pores created by the proteoglycan molecules. The ability of the cartilage to tolerate load is dependent on the interconnections of collagen fibrils (Figure 116-2). If these connections are broken, propagation of fissures through the matrix occurs, leading to morphologic changes characteristic of OA. To a certain extent, articular cartilage adapts to the predominant stress level it experiences and is stiffer in areas of high stress and has increased proteoglycan content.[4] Excessive stress in areas of softer cartilage may result in matrix damage and OA.

Because adult articular cartilage is avascular, it is dependent on the synovial fluid for delivery of nutrition, removal of waste, and circulation of synovial lining cells and leukocytes. Synovial fluid is an ultrafiltrate of plasma, to which large molecules such as hyaluranon have been added by synoviocyte secretion. The viscosity of synovial fluid depends on the molecular weight and concentration of hyaluranon.[4] Joint motion leads to the mechanical compression of cartilage and encourages diffusion of nutrient molecules into the cartilage matrix. In immature animals, nutrients may diffuse into the deep zones of articular cartilage from metaphyseal blood vessels because the calcified cartilage

and subchondral plate have not formed. Joint lubrication and the ability of cartilage surfaces to deform under load produces a low coefficient of friction. Under conditions of load, some water is forced out of the matrix, resulting in a weeping of fluid onto the articular surface (hydrostatic lubrication), until an equilibrium is reached between the osmotic force of proteoglycans and the compressive force applied.[1] During weight bearing, articular cartilage lubrication is hydrostatic (squeeze-film) and most important under heavy load whereas boundary lubrication predominates under light load. Load leads to fluid exudation from the matrix, resulting in a thin film of fluid that separates

articular surfaces. Boundary lubrication is adherence of a molecular film of lubricant to surfaces of articular cartilage and synovium, which separates opposing surfaces. The boundary lubricant of synovial membrane is hyaluronan. The boundary lubricant of articular cartilage is a glycoprotein called lubricin and its associated protein.

Pathophysiology and Pathology of Osteoarthritis

Osteoarthritis can originate by one of two mechanisms: normal forces acting on an abnormal joint (e.g., in the case of osteochondrosis, hip or elbow dysplasia, or patellar luxation) or

abnormal forces acting on a normal joint (e.g., joint trauma resulting in fracture or luxation) (Figure 116-3). Regardless of the specific inciting cause, alterations in the function of the joint lead to specific molecular and cellular changes that result in the ultimate dysfunction of cartilage and periarticular structures that is observed clinically.[1] Changes in cartilage gene expression have been detected as early as 2 weeks after cranial cruciate ligament transaction in a canine model of OA, prior to detectable changes in glycosaminoglycan or collagen content, or evidence of gross or histologic pathology.[6] Joint insult results in release of pro-inflammatory agents such as interleukin 1α (IL-1α)

and β and tumor necrosis factor-α (TNF-α) by chondrocytes, synoviocytes, and infiltrating inflammatory cells, resulting in synovitis. The synovitis is marked by synoviocyte proliferation more than neutrophilic infiltration. Synovial lining cells and leukocytes release destructive enzymes, free radicals, cytokines, and prostaglandins. Persistent inflammation alters cartilage metabolism and cartilage degradation follows. At least some of the pain associated with OA has been attributed to the synovitis.[7]

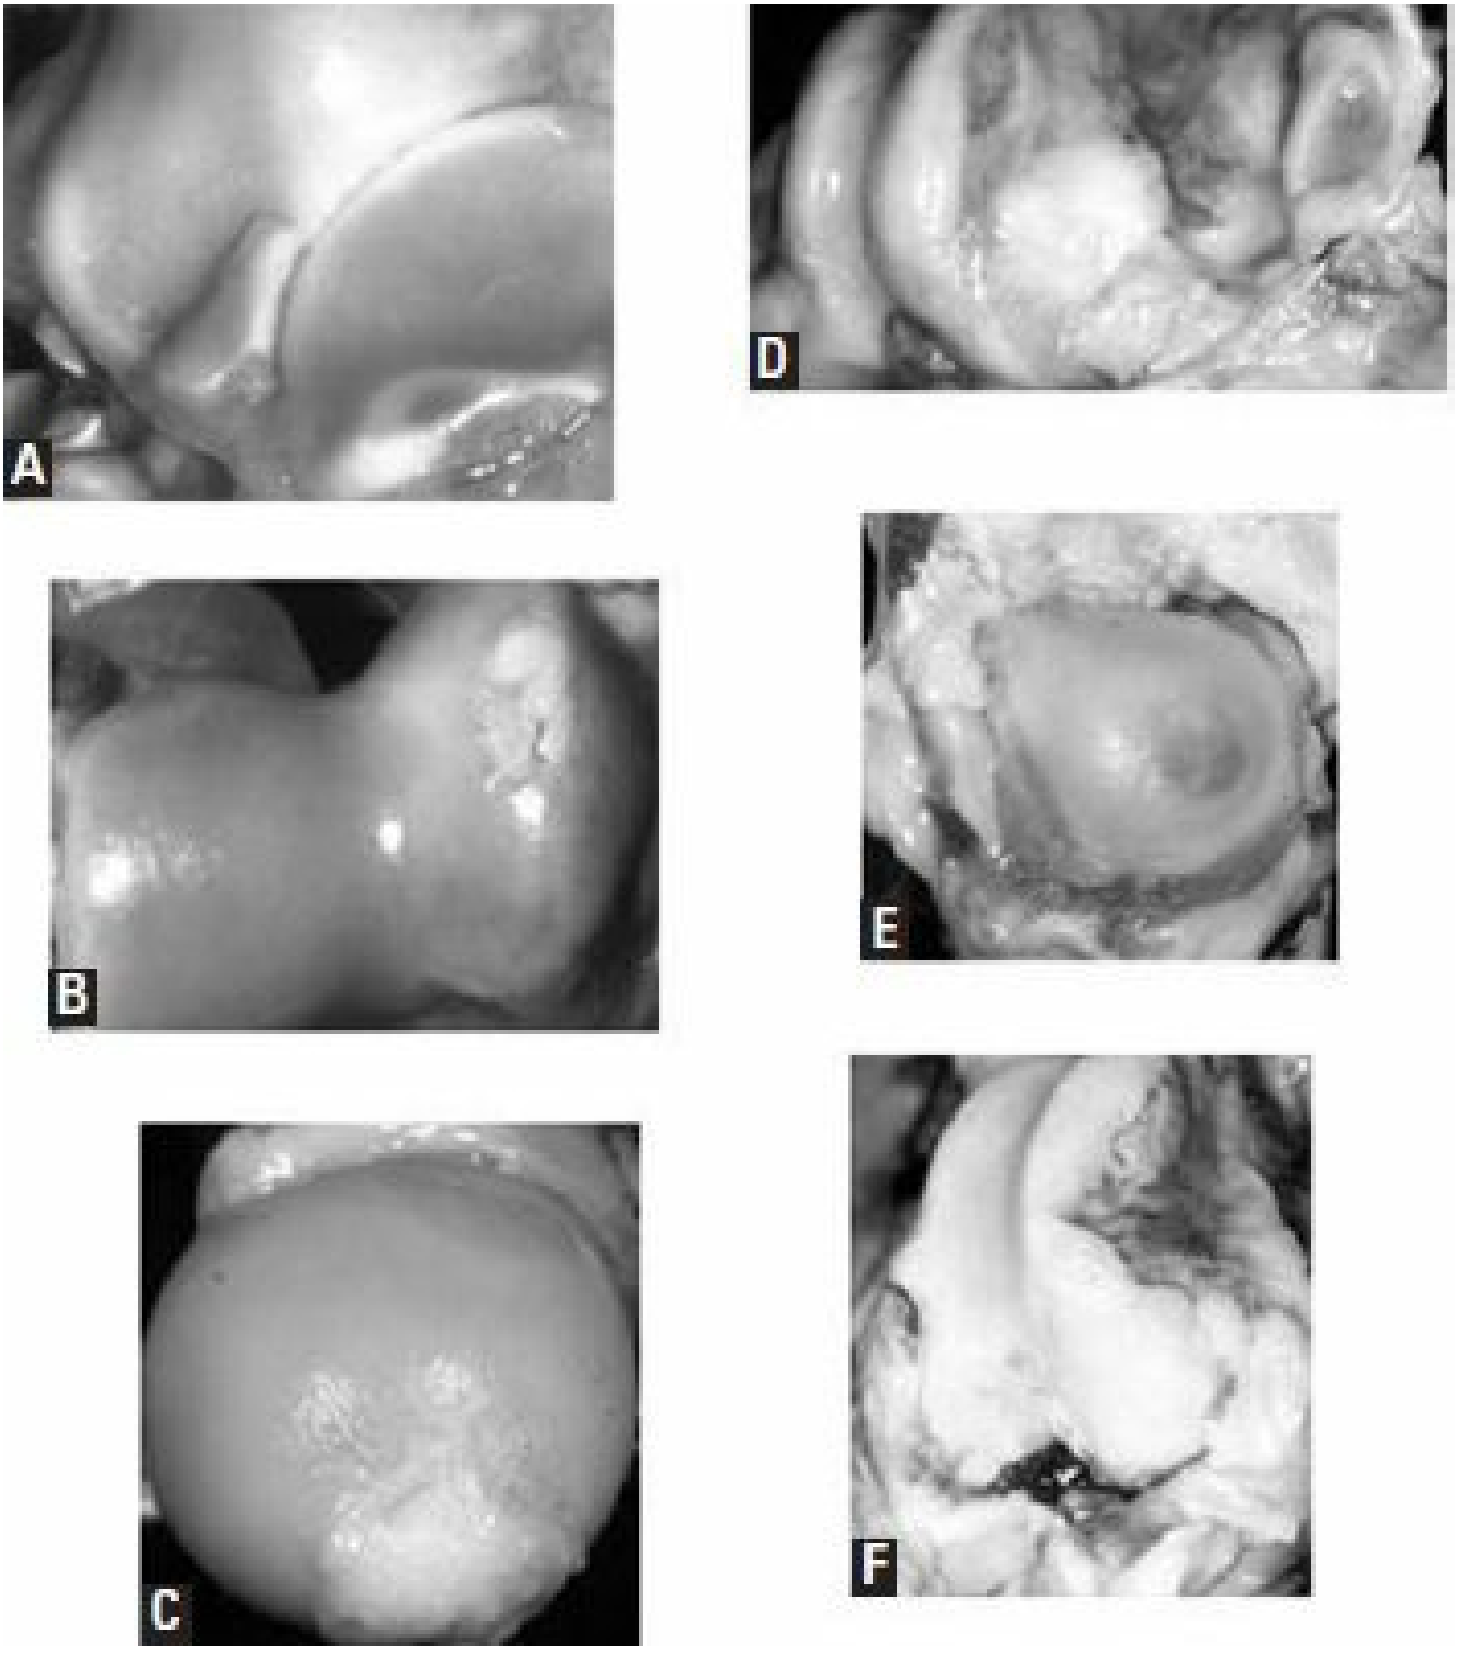

Figure 116-3. Photographs of joint with developmental orthopedic conditions that all result in secondary osteoarthritis owing to surface irregularity

or abnormal mechanical loading. A. Photograph of a stifle joint taken 6 months following experimental transaction of the cranial cruciate ligament. Osteophytes are present along the medial trochlear ridge. (Compliments of Dr. Steven Budsberg, University of Georgia.)

Synovial fluid becomes less viscous as hyaluronan concentration drops and

joint lubrication suffers. Release of cartilage fragments and proteinases worsens the inflammatory response and induces further breakdown of collagen cross links.[8] Changes in synovial membrane and synovial fluid may be reversible. Articular cartilage damage is usually irreversible and self-perpetuating. Osteoarthritis is a self-perpetuating destructive cycle involving all components of the joint. The release of leukocytes, prostaglandins, lysozomal enzymes, hyaluronidase, interleukin-1, leukotrienes, and proteinases propagate joint tissue destruction. Synovial fluid viscosity decreases owing to alteration, breakdown, and dilution of hyaluronan and other

proteins. Biomechanical properties of synovial fluid are altered with suboptimal lubrication, and decreased diffusion of nutrients into articular cartilage ensues.

Biochemically, OA is characterized by reduction in aggrecan content, alteration in collagen fibril size and structure, and increased synthesis and degradation of matrix macromolecules in cartilage. Proteoglycan synthesis by chondrocytes increases initially but then proteoglycan levels drop.[9] Finally, interleukin-1 and TNF-α induce proteoglycan depletion in articular cartilage by increasing the rate of proteoglycan degradation, decreasing synthesis by chondrocytes, or both.

Matrix catabolism is mediated by the effects of matrix metalloproteinases, aggrecanases, cathepsins (acidic proteinases), interleukin-1, TNF-α, hyaluronidase, and prostaglandins. Decreased proteoglycans are accompanied by increased water content, increased compressibility, and decreased stiffness of the articular cartilage. Loss of matrix support that results from collagen fibril degradation permits the matrix to swell.

In the early stages of OA, cartilage fibrillation occurs. Fibrillation (loss of the superficial layer [zone 1]) fundamentally alters the biomechanical properties of articular cartilage.[10] Fibrillation occurs early in

the pathogenesis of OA; full-thickness articular cartilage loss follows. Abnormal stresses cause fissures to propagate to deeper layers (Figure 116-1). Chondrocytes cluster and increase in cell size (Figure 116-1). Erosion (uniform surface loss of articular cartilage) follows. Finally, in regions of full-thickness cartilage loss, subchondral bone becomes exposed and eburnated (the polished appearance of sclerotic subchondral bone).

In young dogs with articular cartilage fibrillation owing to hip dysplasia (Figure 116-3), the subchondral and epiphyseal bone mineral content is increased as measured by quantitative

computed tomography.[11] In dogs with cranial cruciate ligament deficiency, a marked and sustained rise in urinary excretion of collagen pyridinium cross links was reported, which are thought to derive at least in part from the degradation of mature collagen in bone. Calcitonin, a potent inhibitor of osteoclastic bone resorption, markedly reduced the urinary levels of pyridinium cross links in OA dogs.[12] In canine experimental OA, subcutaneous injection of calcitonin reduced the severity of cartilage osteoarthritis lesions assessed both grossly and histologically.[12] Interestingly, mean bone mineral density of the placebo group was 80% of the calcitonin-treated group.[13]

Periarticular osteophytes can be seen as early as 2 weeks from the onset of osteoarthritis (Figures 116-4 and 116-5). Osteophytes are bony exostoses typically developing at sites of joint capsular attachment. Osteophytes probably represent an attempt by the body to compensate for increased tension on joint capsular attachments owing to chronic synovial effusion, concomitant joint capsular distension, persistent joint instability, and a proliferative repair response. Osteophytes eventually become canalized and the marrow cavity communicates with that of the epiphyseal bone. Enthesiophytes are bone growths or dystrophic mineralization that extends into

capsular, ligamentous, and regional soft tissue attachments (Figures 116-4 and 116-5).

Synovial Fluid Analysis

Laboratory evaluation of synovial fluid may be useful in confirming a diagnosis of OA and ruling out other inflammatory or infectious joint diseases. Synovial fluid is evaluated grossly for color, clarity, and viscosity, and microscopically for cell count, cell type, and the presence of infectious agents.[4] The amount of synovial fluid varies according to the joint sampled and the size of the patient. The average volume of synovial fluid in the normal stifle joint of adult dogs, for

example, ranges from 0.2 to 2.0 mL.[2] Synovial fluid volume in OA is generally increased, but may vary according to the chronicity of the condition and the degree of synovitis. Normal synovial fluid is clear, colorless to pale yellow, and contains less than 1000 nucleated cells/μl, whereas synovial fluid from an OA joint may be a clear to hazy pale yellow with nucleated cell counts ranging between 3000 and 5000 cells/μl. The predominant nucleated cell observed in both normal and OA synovial fluid should be the monocyte, and neutrophils should account for less than 10% of the nucleated cells observed (Figure 116-6).[14] Nucleated cell counts in synovial fluid greater

than 5000 cells/μl, or cell counts with a higher proportion of neutrophils, indicate arthritis of an infectious or inflammatory etiology that may include an acute exacerbation of a chronic condition. In dogs, the normal synovial fluid cell counts may vary among joints, with the highest cell counts found in synovial fluid from the shoulder and stifle joints.[15] Synovial fluid cell counts from normal and OA stifle and shoulder joints in cats fall within the ranges described above.[16]

(Compliments of Dr. Peter Scrivani, Cornell University.)

Biomarkers

Because significant limitations exist in the ability of routine diagnostic methods to detect OA in its early stages or to evaluate subtle changes in progression of the disease in an individual, interest in the identification of endogenous substances as biomarkers for the OA process has arisen. Non- or minimally invasive evaluation of one or more of these substances may eventually allow better identification of individuals in the early stages of the disease, quantification of the severity of the disease and its progression, and objective evaluation of the efficacy of

treatment. Biomarkers are typically products of articular cartilage synthesis or degradation. Biomarkers may be anabolic (a product of a synthetic process) or catabolic (a product of degradation) indicators. Alterations in the biomechanics or biochemistry of the joint lead to an imbalance of matrix degradation and synthesis, and the resulting substances that are released may be measured in cartilage, synovial fluid, and in other body fluids such as blood or urine. Concentrations of biomarkers in individual samples of synovial fluid are affected by the presence of joint effusion, clearance of the marker from the joint, exercise level, and circadian rhythms.[4] Although serum concentrations of

markers are less affected by dilution, the value of systemic biomarker concentrations in the diagnosis and monitoring of an OA joint is controversial, as the concentrations in urine or blood will more likely reflect cartilage turnover in all joints and not solely a joint or joints of interest.[17] Additionally, although differences exist in the average values of these markers between normal and OA populations, the variation between individuals is large and the extensive overlap limits their use as a solitary diagnostic tool in any one individual patient. Better discrimination is obtained when markers are evaluated longitudinally or multiple markers are used in combination.[18,19]

Three broad categories of molecular markers have been identified based on

their origin and function during the OA process: agents related to mechanisms of cartilage degradation (matrix metalloproteinase-1, matrix metalloproteinase-3, tissue inhibitors of metalloproteinase [TIMPs], interleukin-1, and interleukin-6), the degradation products of cartilage (keratan sulfate, chondroitin sulfate, aggrecan fragments, cartilage oligomeric matrix protein, cartilage matrix glycoprotein), and components of articular cartilage released as part of an anabolic response to OA (chondroitin sulfate epitopes 3B3(-) and 7D4, link protein, collagen X, fibronectin) (Table 116-1). Fibronectin is an extracellular matrix glycoprotein through which cells interact with their

surrounding matrix. Fibronectin isoforms ED-A and ED-B have previously been described as biomarkers in the rheumatic diseases.[20,21] Total fibronectin concentrations have been demonstrated to be elevated in the cartilage of dogs with OA secondary to hip dysplasia,[22] and in the synovial fluid of dogs with OA secondary to cruciate ligament insufficiency.[23] In the latter study, total fibronectin concentration in synovial fluid was inversely correlated with the duration of clinical signs, suggesting that this marker is an indicator of early repair phase post-injury.[23] Elevation of total fibronectin in the synovial fluid of human patients with OA has also been

reported.[24] However, because fibronectins are found in nearly all body tissues, this lack of specificity makes the total fibronectin concentration in serum a poor solitary biomarker for osteoarthritis. (V+C)-fibronectin is a splice variant specific to cartilage so that its presence in bodily fluids implies a cartilage origin.[25] It constitutes 50% to 80% of the total fibronectin present in articular cartilage.[26] A 10-fold elevation of this isoform in OA cartilage has been reported; however, a study of spontaneous OA in the stifles of clinical canine patients failed to demonstrate a significant elevation in synovial fluid (V+C)- concentration as compared with synovial fluid from a

control population.[27,23] However, like cartilage oligomeric matrix protein (COMP) evaluated in the same study, (V+C)- fibronectin was elevated in the contralateral stifles, and its elevation could be an indicator of early disease.[23]

Cartilage oligomeric matrix protein (COMP) is a pentameric matrix protein in the thrombospondin family. It is found primarily in cartilage, but has also been identified in ligament, synovium, tendon, and meniscus.[28] Its function is not known, but it may have a role in chondrogenesis and the interaction of the chondrocyte with its surrounding matrix.[23] Increases in serum and synovial fluid COMP have

been reported in human and canine patients with OA.[29-31] Another canine study found that COMP levels in the synovial fluid of stifles with OA secondary to cranial cruciate ligament insufficiency were not significantly elevated compared with synovial fluid from a control population, but that COMP was elevated in the contralateral (unaffected) stifles of these patients. Given the increased risk of cranial cruciate ligament injury in the contralateral stifle when one stifle is already affected, this elevation may indicate preclinical disease and COMP may be a marker of early cartilage injury.[23] However, within the joint, COMP is also secreted by the synovium and increased concentration of COMP

may reflect synovitis. Additionally, owing to its presence in other tissues, serum elevation of COMP is not considered specific for cartilage degradation and individual variation is high; therefore, the utility of COMP as a solitary biomarker is limited.

Chondroitin sulfate is a glycosaminoglycan that is a major constituent of aggrecan. In early OA, newly synthesized aggrecan molecules

contain chondroitin sulfate side chains with increased chain length and altered structure that are identifiable utilizing monoclonal antibodies.[32] Two epitopes (3B3(-) and 7D4) have been most thoroughly investigated, but significant difference exists in the timing of elevation in synovial fluid concentration of these epitopes between species. Multiple canine studies have demonstrated significant elevations in the concentration of synovial fluid chondroitin sulfate after experimental induction of OA. Significant increases in the 3B3(-) epitope of chondroitin sulfate have also been demonstrated in the synovial fluid from OA joints in humans.[17] Expression of 7D4 appears to be more

prevalent in OA cartilage and synovial fluid from humans, monkeys, and guinea pigs with OA joints and was found to be more elevated in patients with acute injury and early osteoarthritis.[32] In another study, synovial fluid concentrations of 3B3(-), but not 7D4, were elevated in human patients with chronic knee OA.[33] Although the 3B3(-) form of chondroitin sulfate is absent in healthy canine articular cartilage, it has been identified in canine cartilage during early OA.[34,35] A longitudinal study in a canine model found that an increase in 7D4 concentration preceeded the rise in 3B3(-) concentration.[36] A correlation between 3B3(-) and 7D4 epitope concentrations in synovial fluid from a

canine model of naturally occurring OA contradicted a study in humans that found that the synovial fluid concentrations of these two epitopes varied independently of each other.[32,37]

Keratan sulfate is a glycosaminoglycan that is a major constituent of aggrecan. Numerous studies with different models of induced and naturally occurring OA have produced a wide variation in results, with synovial fluid concentration of keratan sulfate rising significantly post-injury in some models, a lack of significant change, and even a significant decrease in keratan sulfate concentrations in others.[17]

Matrix metalloproteinases (MMPs) are a family of zinc-dependent endopeptidases. They and their inhibitors, tissue inhibitors of matrix metalloproteinases (TIMPs), play an important role in normal degradation of the extracellular matrix. Once activated, MMPs become susceptible to inhibition by TIMPs, which are secreted by chondrocytes and synoviocytes. Because MMPs appear to play a substantial role in OA, potential treatment strategies include regulation of their activity by control of gene expression and secretion, deactivation of pro-MMPs, and inhibition of active MMPs.[38] Most MMPs are present in articular tissues in an inactive form,[39] but during OA, MMPs are present in

higher concentrations than the TIMPs and the latent forms of MMPs become activated.[40] Aggrecanases are members of the ADAMT (a disintegrin and metalloproteinase with thrombospondin motif) family. Several aggrecenases have been described, 6 of which have been associated with aggrecan core protein cleavage. Current thinking is that as many as 11 MMPs are responsible for normal articular cartilage matrix turnover, and the aggrecanases contribute to pathologic degradation.[41]

Stromelysin (MMP-3) degrades collagen II, IX, and X, proteoglycan, and fibronectin. This MMP is released from chondrocytes during OA in

response to cytokine stimulation. Stromelysin concentrations have been demonstrated in a number of in vitro and in vivo studies to be elevated in the tissues and synovial fluid of OA joints in dogs, horses, and humans,[39,42-45] so that stromelysin concentration in articular cartilage and/or synovial fluid may be a biomarker for OA.[17] Collagenase (MMP-1) also degrades collagen II, IX, and X. Gelatinases (MMP-2 and MMP-9) were detected in the synovial fluid of healthy joints, while a canine study demonstrated elevated MMP-2 and MMP-9 activity in the synovial fluid of OA joints that paralleled the increase in MMP-9 activity seen in horses with OA.[40,46,47] Although molecular markers

of osteoarthritis do not currently have direct clinical application, numerous substances are under investigation as potential biomarkers, and significant advances in understanding the molecular processes of OA have been made. Further identification and understanding of the OA process may ultimately allow for earlier diagnosis and treatment opportunities.

Genetics

Many developmental diseases in dogs are a result of a complex interaction between genetic susceptibility, nutrition, and other environmental factors. Polygenic modes of inheritance have been proposed for hip dysplasia,

osteochondritis dissecans, and elbow dysplasia.[4] Osteoarthritis is a secondary disease process that occurs as a result of these joint abnormalities, but these developmental diseases result in variable degrees of OA in a given individual. Heritability of elbow dysplasia has been reported at 10% to 45%, and osteochondrosis of the shoulder joint has been estimated at 55% to 70% in various breeds of dogs. One study showed dogs with hip OA to be predisposed to elbow and stifle osteoarthritis.[48] For further information on the genetics of developmental and acquired orthopedic traits in dogs, see other reviews.[4,49]

Diagnostic Imaging

Radiography

In one study, radiographic evidence of DJD was evident in 90% of older cats evaluated as part of a diagnostic workup for other disease. Other studies of cats of varied ages have reported overall incidences of OA of 20% to 30%.[50] The elbow is the most commonly affected joint in cats.[16,50] In radiographic evaluation of human knee OA, within-observer reproducibility is greater than between observers, and osteophyte score, joint space narrowing, and bony contour are acceptably repeatable, but subchondral sclerosis and subchondral cyst scores suffer from poor

reliability.[51] To meaningfully assess joint-space narrowing, a weight-bearing radiograph is required.[52] In assessment of progression of OA in canine stifles, effusion, osteophytosis, and intra-articular mineralization were found to be more reliable than assessment of subchondral sclerosis.[53]

Computed Tomography

When conventional radiography fails to demonstrate changes characteristic of OA, or fails to reveal the underlying etiology when OA is recognized, computerized tomography can be employed to help identify the underlying cause of lameness. Perhaps the most common use of this modality

is to identify fragmented medial coronoid process of the elbow. Computed tomography is more sensitive than conventional radiography to early bone changes and three dimensional reconstructions can be useful in evaluating the extent of bone lesions.

Nuclear Scintigraphy

Nuclear Scintigraphy is most useful when the cause of lameness is unknown. A bone-seeking radionuclide compound, such as technecium-99m-labeled methylene diphosphonate, will be taken up in areas of increased bone and periarticular metabolic activity. Therefore, itreflects both the vascular

supply to the region and the rate of mineralization as it is adsorbed to the mineralization front. Any process that disturbs the normal balance of bone production and resorption can produce an abnormality on a bone scan. A bone scan is a highly sensitive but relatively nonspecific diagnostic tool. When administered to an animal with a non-localized lameness, areas of increased activity aid in identifying the affected joint(s) and allow for more specific evaluation using conventional radiographic techniques, computerized tomography, or magnetic resonance imaging in order to further identify the underlying etiology.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is infrequently used as an imaging tool for clinical cases of joint disease in veterinary medicine. However, this modality may have its greatest potential use for the evaluation of subtle lesions and assessing cartilage thickness or damage as part of a clinical research protocol. MRI can detect subtle changes in cartilage structure and subchondral bone long before changes in the underlying bone or periarticular structures are detected by conventional radiographic methods. Well hydrated tissues are best imaged with MRI. Changes including cartilage thinning, surface irregularities, and increased signal intensity (called a

bone bruise) in subchondral bone have been noted at 4 weeks post-injury in a canine experimental model of OA.[6]

Treatment

Osteoarthritis leads to decreased patient flexibility, increased joint stiffness, and pain; the resultant disuse atrophy of periarticular supporting muscle results in decreased overall strength. As a result, treatment goals include pain relief, reduction of any inflammatory component, improvement of joint function, maintenance of muscle mass, and if possible, preventing or minimizing progression of disease. If an underlying cause of the OA can be

identified, treatment is aimed both at correction of the initiating cause and management of the subsequent degenerative cartilage changes.

Surgical management of OA is primarily aimed either at manipulation of joint congruency and stability (e.g., stabilization of a cruciate-deficient stifle or removal of a fragmented coronoid process) early in the disease process in an attempt to minimize progression of OA, or by salvage procedures in end-stage disease (total hip replacement, pancarpal arthrodesis) to reduce pain and improve overall limb function. Medical management of OA may be broadly conceptualized as having four main

components: weight management, pharmacologic treatment with analgesics and anti-inflammatories, exercise modification/physical therapy, and slow-acting disease-modifying osteoarthritis agents (SDMOAs). Slow-acting, disease-modifying agents are also described as chondroprotective agents and are purported to have three primary effects: enhancement of chondrocyte and synoviocyte metabolism, inhibition of degradative enzymes within the synovial fluid and matrix, and inhibition of thrombus formation in the small blood vessels supplying the joint.[54]

Obesity is a significant risk factor for the development and progression of

OA in people, and may be associated with increased stresses on weight-bearing joints or metabolic alterations.[55] Weight loss in dogs with OA has been demonstrated to have a profound positive effect on the clinical management of the disease.[55] In addition, it has been demonstrated that long-term limitation of caloric intake results in decreased radiographic prevalence and severity of OA in dogs.[48,56] Management recommendations to clients should include long-term efforts to keep patients as lean as possible to reduce force transmission through OA joints. More recently, nutritional supplements and commercial diets with specific ratios of omega-3 and omega-6 fatty

acids have been introduced as components of management of the OA patient. By shifting the prostaglandin synethesis pathway from arachidonic acid metabolites to dihydroxyeicosapentanoeic acid metabolites, omega-3 fatty acids are thought to decrease inflammation and decrease the expression and activity of proteoglycan degrading enzymes.[57] The ideal dietary ratio of omega-6:omega-3 fatty acids for dogs is controversial but the current recommendation is between 10:1 and 5:1.[54]

Nonsteroidal Anti-inflammatory Drugs

(NSAIDs)

Although the inflammation associated with OA is variable, NSAIDS are used to reduce pain and synovitis as a result of OA. Nonsteroidal anti-inflammatory drugs decrease prostaglandin synthesis by inhibition of cyclooxygenase (Figure 116-7). The two primary isoforms described as cyclooxygenase, COX-1 and COX-2, are simplistically described as the constitutive form and the inducible form, respectively. NSAIDs inhibit sensitization and stimulation of peripheral nociceptors and spinal cyclooxygenase activity. NSAIDs reportedly inhibit nitric oxide-induced apoptosis independent of cyclooxygenase activity. These signalling pathways involve nuclear-

factor kappaB and caspase activation. COX-2 and PGE_2 production are affected by the non-COX mechanism.[58]

Nonsteroidal anti-inflammatory drugs can be divided into COX nonspecific, COX-2 preferential, and COX-2 specific. The COX nonspecific drugs include aspirin, phenylbutazone, ibuprofen, and naproxen. Aspirin (acetylsalicylic acid), a first generation NSAID, is a nonspecific COX inhibitor. It has adverse effects on the gastrointestinal tract, inhibits platelet aggregation, can cause renal failure in susceptible patients, and is used at an approximate dose of 1 adult aspirin (375 mg) per 60 lb body weight up to 3 times a day with a little food.

COX-2 preferential drugs are generally well tolerated by dogs, with fewer side effects reported. Their analgesic action is related to inhibition of spinal nociceptive transmission and attenuation of peripheral inflammation. They include carprofen (Rimadyl, Pfizer), which is approved for use in dogs at 2.2 mg/kg twice daily or 4 mg/kg once daily; etodolac (Etogesic, Fort Dodge), which is approved for use in dogs at 10 to15 mg/kg once daily; and meloxicam (Metacam, Merial/Boehringer Ingelheim) used at 0.2 mg/kg as an oral liquid suspension. Carprofen is generally considered to be either COX 2 preferential or nonselective. In cell culture, it has low COX-2 inhibition. It

may have an alternative pathway for its analgesic activity. Peak plasma concentration is reached in 1 to 3 hours and plasma elimination half-life is 7 to 9 hours. Carprofen has good analgesic, antipyretic, and anti-inflammatory properties. Idiosyncratic hepatic toxicity has been reported, especially in Labrador retrievers. Minimal gastrointestinal toxicity has been observed in experimental studies. Carprofen probably has no negative impact on articular cartilage metabolism. In the cranial cruciate transaction model of OA in dogs, carprofen was given 4 weeks after induction of disease and continued for 8 weeks at 2.2 and 4.4 mk/kg bid. Carprofen reduced morphologic

changes in articular cartilage and subchondral bone normally associated with OA.[59] Carprofen improves limb function in dogs based on both subjective and objective gait evaluation.

Etodolac reaches peak plasma concentration in 1 hour, with an elimination half life of 10 to 14 hours, and is generally considered COX-2 preferential but that is debated. It has been shown to improve hind limb function in dogs with hip OA.[60] Etodolac is reported to spare collagen synthesis by chondrocytes but data conflict on its effect on proteoglycan synthesis. It exhibits minimal gastrointestinal toxicity. Meloxicam

exhibits peak plasma concentration at 8 hours and has an elimination half life of 23 hours. It performs comparably to carprofen in clinical trials for lameness in dogs with minimal side effects reported.[61] Derracoxib (Derramax, Novartis) is a COX-2 selective drug which reduced postoperative pain and lameness in dogs given at 1 to 2 mg/kg. Celecoxib (Celebrex) had a positive effect on hyaluronan and proteoglycan synthesis in human OA cartilage explants. Minimal side effects have been so far reported.

In an acute stifle synovitis model in dogs, butorphanol (0.2 mg/kg, IV), etodolac (17 mg/kg, PO), carprofen (4 mg/kg, PO), and meloxicam (0.2

mg/kg, PO) were compared. A Latin cross-over design and 3-week washout was followed. Treatments were given 3 hours after monosodium urate injections into the stifle joint. Ground reaction force (GRF), orthopedic exams, and C-reactive protein were measured.[62] The greatest improvement in vertical GRF was in the carprofen group. Etodolac had the fastest onset of action. Compared with butorphanol, only carprofen and etodolac had decreased stifle pain scores. There were fewer non-responders in the carprofen and meloxicam groups.

Leukotrienes can also be inhibited by combined cyclooxygenase/lipoxygenase

inhibitors (Figure 116-7). Leukotriene B_4, for example, induces chemotaxis, aggregation, degranulation, and increased cytokine production by leukocytes, hyperalgesia, and bone resorption. Other leukotrienes affect smooth muscle function, mucus secretion, vascular permeability, and airway inflammation. Cysteinyl leukotrienes may enhance gastric mucosal injury by causing local vasoconstriction. Prostaglandins and leukotrienes have complementary effects but lipoxins can inhibit the inflammatory effects of leukotrienes. Tepoxalin (Zubrin, Schering Plough) inhibits both COX activity and lipoxygenase 5, the activity of which results in leukotriene synthesis. It has

potent anti-inflammatory activity with excellent gastric tolerance. The tables are rapidly disintegrating. A similar drug used in human medicine called licofelone given for 8 weeks beginning the day after surgery in a model of OA induced by cranial cruciate ligament transaction prevented abnormal subchondral bone cell metabolism, reduced PGE2 production in synovial fluid, inhibited collagenase 1 production in articular cartilage, interleukin 1-β, and leukotriene B_4 in synovial membrane, and reduced chondrocyte cell death (decreased caspase 3 activity) probably owing to lower nitric oxide and PGE_2.

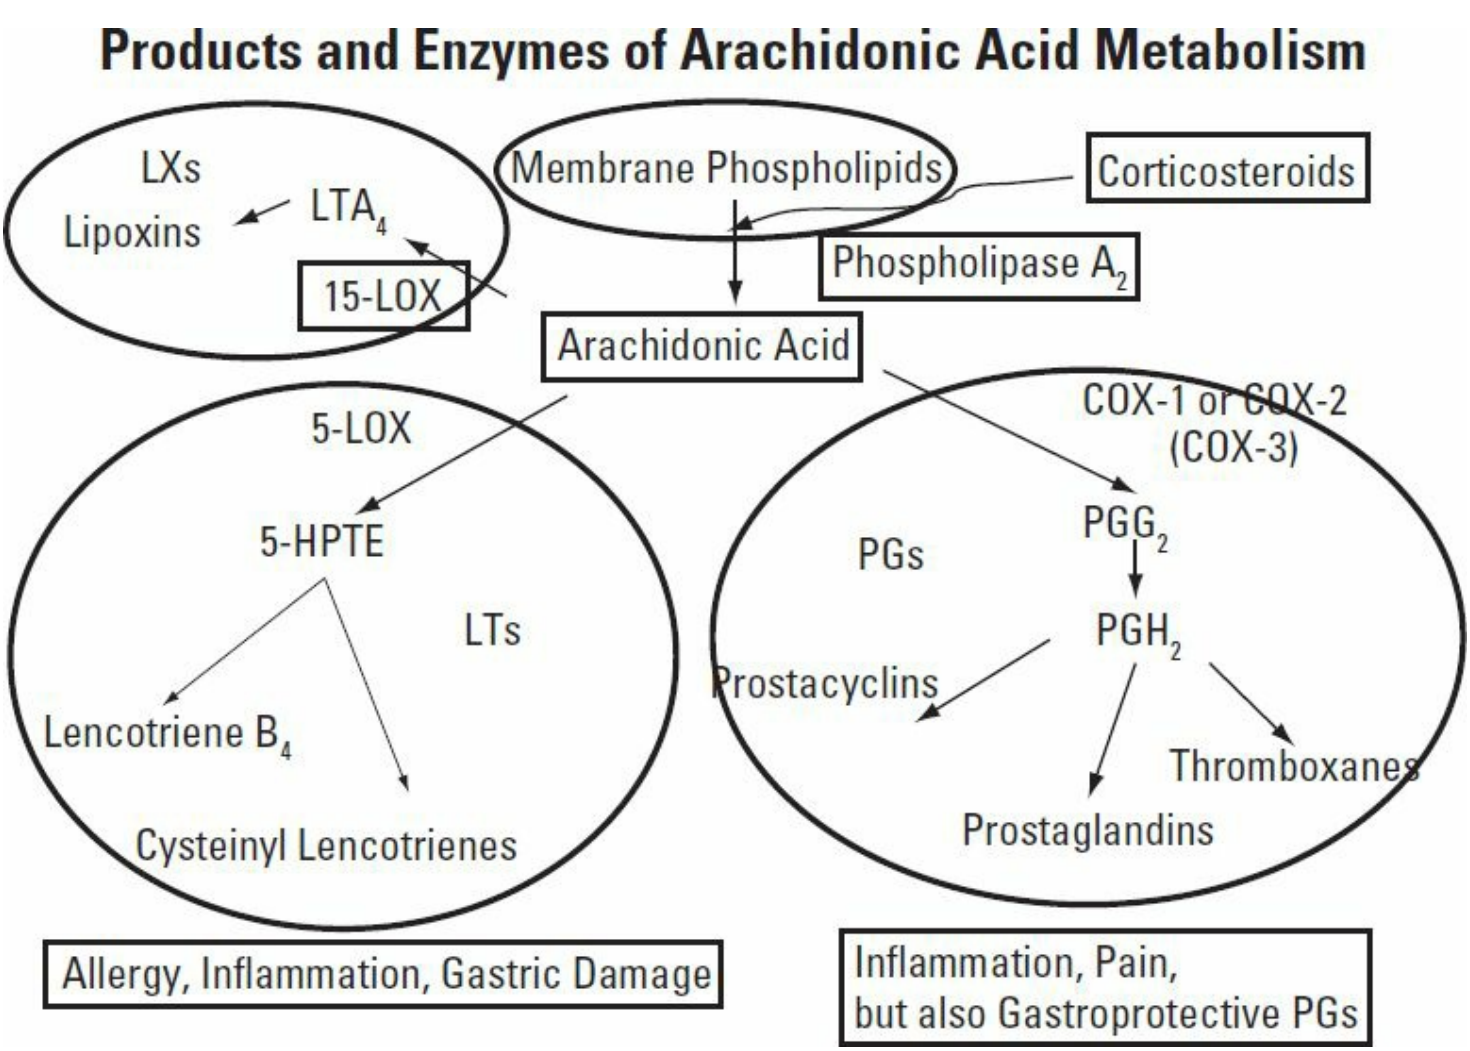

Figure 116-7. Products and enzymes of arachidonic acid metabolism.

Whether NSAIDs can affect the progression of OA is an open question. Prostaglandin inhibition by NSAIDS may have a negative effect on chondrocytes and the cartilage matrix.[63] The detrimental effects of

NSAIDs on chondrocytes are partly mediated by inhibition of glycosyltransferase activity, uncoupling of mitochondrial oxidative phosphorylation, activation of cAMP-dependent kinase A, and disruption of protein interactions at the cell surface. The majority of positive effects are due to suppression of inflammation characterized by inhibition of COX-2, which is highly expressed in OA tissues, the inhibitory effects on IL-1 production or IL-1 receptor expression, decreased PGE_2 production, reduced inducible nitric oxide synthase (iNOS) synthesis by interleukin-1, and decreased nitric oxide. Nitric oxide enhances MMP activity, decreases proteoglycan synthesis, and inhibits

interleukin 1β receptor antagonists. Inhibition of matrix metalloproteinase activity will encourage maintenance of the extracellular matrix and inhibit chondrocyte apoptosis, a critical feature of OA progression.

Slow-Acting Disease-Modifying Osteoarthritis Agents

Disease-modifying agents of OA comprise a large, diverse group of compounds, many of which are poorly characterized as to their efficacy and/or mechanism of action, and their production and administration are poorly regulated, with varying degrees

of quality control. Disease-modifying OA agents are also commonly referred to as “nutraceuticals”; however, the only thing shared in common is that they are neither foods nor drugs recognized by the FDA, and as such undergo no pre-market approval process.[64] The only FDA-approved SDMOA in dogs is injectable Adequan (Luitpold Pharmaceuticals), which is a polysulfated glycosaminoglycan (PSGAG). Because it is a heparin analogue, injectible PSGAG has the potential to affect coagulation. In cats, injectable PSGAG has been demonstrated to produce a prolongation in the activated partial thromboplastin time and should be avoided in animals with bleeding

disorders or on concurrent NSAIDs that exhibit antithromboxane effects.[65] The proposed mechanisms of action include inhibition of serine proteases, PGE_2, elastase, stromelysin, MMPs, and hyaluronidases.[66] In one study, dogs treated with an injectable PSGAG from a young age and studied until skeletal maturity had better hip conformation and fewer joint abnormalities than did controls.[67] Pentosan polysulfate is a polysaccharide sulfate ester and is thought to modify disease progression by its antithrombotic and fibrinolytic effects in addition to improving subchondral and synovial membrane blood flow.[4,68] However, a clinical study evaluating the effects of pentosan polysulfate failed to

demonstrate a significant clinical improvement over control in the postoperative progression of OA after surgical stabilization of canine stifles with cranial cruciate ligament insufficiency.[68] Glucosamine salt supplements are commonly found in combination products with chondroitin sulfate and manganese ascorbate. Glucosamine is an amino sugar that is a precursor to matrix glycosaminoglycans.[54] Chondroitin sulfate is a glycosaminoglycan found naturally within the extracellular matrix of articular cartilage. It has been proposed that glucosamine supplementation benefits OA articular cartilage by promoting formation and repair of cartilage, whereas

chondroitin sulfate is thought to promote water retention and elasticity in cartilage as well as to inhibit degradative enzymes. Clinical and experimental studies support the use of glucosamine-chondroitin-manganese combinations or as individual components.[54] Oral glucosamine-chondroitin sulfate formulations may be obtained over the counter. However, clients should be warned about significant variations among measured concentrations and label claims in both glucosamine and chondroitin sulfate in products on the market.[69,70] In addition, differences in the bioavailability of these substances may be significant between formulations and between species.

Oral bioavailability of glucosamine hydrochloride in humans is 84%, but the bioavailability of the sulfate salt is only 47%.[64] The oral bioavailability of glucosamine in dogs was reported to be 10%.[71] The oral bioavailaibility of chondroitin sulfate varies inversely with molecular weight, and molecules of chondroitin sulfate with a molecular weight of 17000 have the most favorable permeability coefficient.[64] In addition to concerns about variations in formulation and bioavailability, accurate pharmacokinetic and pharmacodynamic information for most products is lacking, as are studies on safety and efficacy. Efficacy in veterinary patients is particularly difficult to assess; however, the

placebo effect in animals is likely equal or greater than the 30% to 40% placebo effect that is reported in human studies evaluating pain. Recently, it was shown that glucosumine and chondroitin sulfate regulate expression of matrix-degrading enzymes and the inhibitors at the transcriptional level.[72] Products containing glucosamine and chondroitin sulfate have been shown to cause significant decreases in red blood cell and platelet indices in dogs and cats, but these differences stay within clinically normal ranges and are unlikely to be clinically relevant.[73,74]

The use of other nutritional supplements such as elk velvet antler,

green-lipped mussels, type-II collagen, and milk protein concentrate have been preliminarily described in veterinary patients for the treatment of OA; however, further evaluation is needed before these substances can be recommended.[75-78] Hyaluronan, methylsulfonylmethane, dimethylsulfoxide, and doxycycline have all been used to treat osteoarthritis, but supporting evidence of their success is lacking.

Chapter 117

Immune Mediated Polyarthritis

Autumn P. Davidson

Immune-mediated polyarthritis (IMPA) is a noninfectious form of inflammatory arthropathy in the dog and cat. IMPA is characterized by inflammation of the synovial membranes reflected by inflammatory cell infiltrate in the synovial fluid and accompanied by systemic signs of illness. Classically these include lethargy, arthralgia, and fever.

Accompanying signs of systemic illness can be subtle and vague, making the diagnosis elusive. Polyarticular involvement is reportedly more common than monarticular. Distal joints have been suggested to be more frequently affected; however, proximal joint synovitis is more challenging clinically to document, and may be overlooked.[1-9]

Categorization of IMPA

IMPA is commonly categorized as nonerosive, which is nondeforming and usually proliferative, and erosive, in which a progressive destructive deformation of joints occurs. Nonerosive IMPA occurs more

commonly than erosive disease in both the dog and cat. Nonerosive canine IMPA has been further classified into subtypes based on the identification of associated contributory or causative disorders. These subtypes include type I, or idiopathic (no identifiable associated factors); type II, or reactive (associated with systemic infectious or inflammatory disease, most commonly of the respiratory, urinary, and reproductive systems, as well as of the eye and the skin); type III, or enteropathic (associated with gastrointestinal or hepatic disease); and type IV, or paraneoplastic (associated with neoplasia distant from the joints, or with myeloproliferative disease). Additionally, the nonerosive

IMPA category includes arthropathy associated with systemic lupus erythematosis (SLE), the polyarthritis/polymyositis syndrome, the polyarthritis/meningitis syndrome, polyarteritis nodosa, Akita juvenile onset polyarthritis, the Shar-Pei fever syndrome, and that associated temporally with the administration of drugs or vaccination.[1-9]

Canine erosive IMPA is characterized by a progressive, refractory, and protracted joint destruction most pronounced in the distal joints. Canine erosive IMPA has been categorized into rheumatoid-like arthritis, idiopathic erosive polyarthritis, and Greyhound polyarthritis.[1-9]

Feline IMPA is classified as progressive polyarthritis (PPA) and has a nonerosive proliferative form and an erosive destructive form. Both generally cause serious systemic illness. The disease most commonly affects young (1 to 5 years of age) male cats and can be associated with feline syncytium-forming viral infection and its associated chronic antigenic stimulation.[1-9]

Pathogenesis

Primary nonerosive polyarticular arthritis, type I, is the most common form of IMPA reported in the dog. Nonerosive types II, III, and IV IMPA are less common. Identification of

concurrent significant medical conditions is important for determining prognosis and in therapeutic decision making. Treatment of type I IMPA is directed at immunosuppression and its associated clinical scenarios (opportunistic infection, myelosuppression, and individual side effects of immunosupressant drugs). Treatment of types II, III, and IV IMPA is specifically directed at the associated systemic disorder in anticipation that joint inflammation will improve once the primary disorder is effectively treated or resolves with time.[1-9] Many type II polyarthridities associated with an infectious disease (i.e., coccidioidomycosis) are actually a

granulomatous synovitis (“desert rheumatism”) or vasculitis (ehrlichiosis, Rocky Mountain spotted fever (RMSF), Lyme disease) rather than a direct extension of the infectious organism into the synovium.[10] Some forms of nonerosive IMPA have been reported to have an underlying genetic predisposition associated with certain histocompatibilty genotypes.[1] Resolution of synovitis in types II to IV IMPA can be delayed when compared with that in type I and is dependent on the degree to which the contributory disorder is resolved.

The pathogenesis of erosive IMPA is better understood than its etiology. As a consequence of either defective

immunoregulation (failure of self tolerance) or production of an immunogenic IgG-antigen molecule, the pathogenic autoantibody rheumatoid factor (RF) is formed. Plasma cells and activated B lymphocytes produce RF which circulates into synovial fluid. The synovium functions as a phagocytic tissue; as a consequence, immune complex ingestion occurs, triggering the activation and proliferation of synoviocytes. Activated synoviocytes release inflammatory mediators and enzymes (interleukin 1, collagenases, peptidases, and prostaglandin E_2). Osteoclasts are activated, resorbing subchondral bone. Subchondral bone cysts form as a consequence of this

osteolysis. Intraarticular formation of granulation tissue arising from the inflamed synovium forms a pannus. Lymphocytes, plasma cells, neutrophils, and proliferating activated synoviocytes compose the pannus. Fibroblast proliferation promotes fibrosis with scarring and contracture. Joint deformation results.[1-4,11]

Clinical Presentation

IMPA should be part of the differential list for any dog or cat with fever of unknown origin or inexplicable lethargy. Arthralgia can be subtle or obvious, ranging from a simple reluctance to move to a peculiar,

stilted, and crouching gait indicative of pain in numerous joints. Fever is common, generally in the range of 103.5 to 104.5° F. Palpation of joints can elicit pain, and the joints can feel effusive and warm, especially later in the course of the disease. With chronicity, the joint capsule may become thickened. Arthralgia can be misinterpreted clinically as myalgia, neuralgia, abdominal discomfort, or even neuropathic or myopathic disorders. Anorexia is variably present, and has been reported to be a poor prognostic sign.[3] Atypical house soiling can occur if the animal is reluctant to move outdoors or to a litter box for defecation or urination. Altered disposition, even aggression, can occur

as a result of marked pain. The arthropathic signs of types II to IV IMPA can be completely masked by those of the primary, associated disorder. Incomplete response to therapy for the primary disorders associated with types II to IV IMPA should prompt evaluation of the joints for inflammatory changes. Alternatively, a poor response to immunosuppression for suspected type I IMPA should prompt consideration that the condition could be type II to IV, and clinical evaluation for associated disorders should be pursued.

Some generalizations exist. Type I IMPA is most commonly but not exclusively diagnosed in dogs less than

6 years of age, of either gender. A breed predilection may exist in German shepherds, Doberman pinschers, collies, spaniels, retrievers, terriers, and poodles. Polyarthritis associated with SLE is reported more commonly in German shepherds, collies, Shetland sheepdogs, beagles, and poodles, of any age. Females are more commonly affected.[12,13] Atypical cases of cranial cruciate ligament rupture (young, otherwise fit individuals of large breeds) can belong to a subclass of dogs with plasmacytic-lymphocytic synovitis/tendonitis.[7] Young (less than 3 years), large-breed dogs are more commonly affected with plasmacytic-lymphocyticsynovitis/tendonitis, most

frequently diagnosed in the stifle and associated with damage (often bilateral) to the cranial cruciate ligament (ACL). Acute lameness associated with rupture of the ACL occurs and presents as a sudden worsening of lameness and reluctance to ambulate in an individual otherwise successfully under therapy for IMPA. Drug-associated polyarthritis, a vasculitide, has been reported to be associated with Doberman pinschers and Labrador retrievers.[14,15] Vaccine-associated IMPA is suspected clinically if the syndrome occurs within 3 to 4 weeks of vaccination.[7]

Erosive IMPA in the dog typically affects young to middle-aged members

of toy and small breeds. A semierosive polyarthritis of greyhounds has been reported, generally in dogs between 3 and 30 months of age. Feline chronic progressive polyarthritis typically affects male cats from 1 to 5 years of age.[1-4]

Diagnostics

Evaluation of veterinary patients with unexplained lethargy, arthralgia, or fever should include arthrocentesis for cytologic evaluation of synovial fluid. Arthrocentesis can be performed in most medium to large dogs with minimal sedation/analgesia. Small dogs and cats usually require sedation or anesthesia to obtain synovial fluid

samples without iatrogenic hemorrhage secondary to inadvertent trauma to the synovium during collection. Synovial fluid contaminated with hemorrhage markedly limits conclusive cytology.[8]

Arthrocentesis should be performed on a minimum of four joints. Usually the carpi, stifles, tarsi, and elbows are preferred sites for synovial fluid collection. The site of centesis should be clipped and prepared with aseptic technique. Carpal arthrocentesis is generally performed with a 25-gauge needle and 3-ml syringe. Fluid is aspirated from the joint space between the distal medial radius and the radial carpal bone joint, approached medially

(Figure 117-1). Tarsal arthrocentesis is usually performed with a 22-gauge needle and 3-ml syringe, aspirating fluid from the joint space between the fibula and the calcaneus bone of the tarsus, approached laterally (Figure 117-2). Stifle arthrocentesis usually requires a longer needle to penetrate the patellar fat pad; a 20-gauge needle and a 3-ml syringe are typically used, aspirating the joint space between the lateral femoral epicondyle and the lateral tibial intercondylar area (Figure 117-3). Elbow arthrocentesis is technically more difficult. A 22-gauge needle and a 3-ml syringe are used to aspirate the joint space between the radial articular fovea and the ulnar lateral coronoid process (Figure 117-

4). Synovial fluid should be immediately evaluated for color and clarity, as well as viscosity. Normal synovial fluid is clear, with viscosity producing a strand when dabbed with a gloved finger or needle. Abnormal synovial fluid is opaque to hemorrhagic with watery consistency.[8,11]

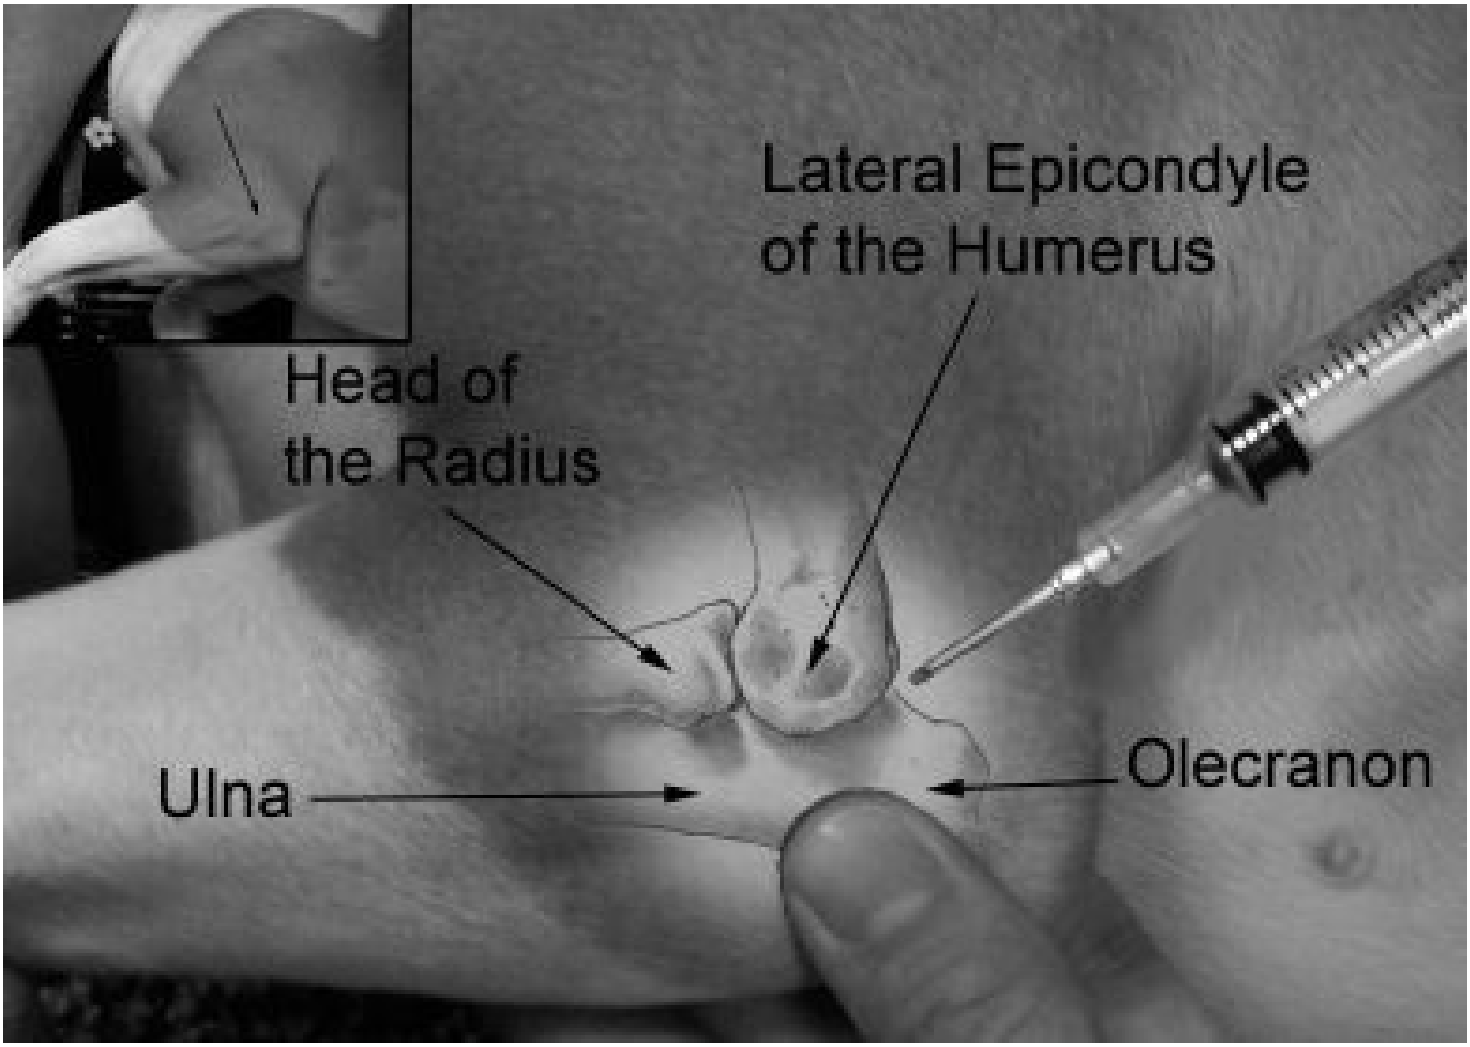

Figure 117-4. Arthrocentesis of the lateral elbow joint (radial-ulnar). (Courtesy of Alexander J. Frederick, University of California School of Veterinary Medicine, Class of 2009.)

Cytology of synovial fluid can be performed in the clinical setting or submitted to a commercial or academic laboratory for evaluation. Normal

synovial fluid is poorly cellular (< 2500 nucleated cells/ml). The majority (> 90%) of cells in normal synovial fluid are large and small mononuclears. Synovitis associated with IMPA is characterized by suppurative cytology, with more than 5000 cells/ml, and with neutrophils accounting for more than 10 to 25% of the total cell count. The white blood cell count of synovial fluid can be estimated by counting the number of cells per high dry field and multiplying by 1000. Synovial fluid contaminated iatrogenically with hemorrhage from a traumatic arthrocentesis will have a white blood cell differential similar to peripheral blood, and synovial neutrophilia cannot be readily

determined.[8,16]

Careful history-taking and a thorough review of physical examination findings can assist in the characterization of IMPA. Once inflammatory synovitis has been identified, collection of the minimum data base (complete hemogram, serum chemistries, urinalysis with culture) should be accompanied by specific, appropriate diagnostics to identify contributory and concurrent significant disease. Because immunosuppression is the goal of therapy for type I IMPA, prior evaluation for concurrent infectious disorders is important. Hyperglobulinemia and an inflammatory leukogram can be the

only clinicopathologic abnormalities with type I nonerosive IMPA, other than suppurative, sterile synovial fluid.[9]

Survey thoracic and abdominal radiographs, serum titers for tick-borne diseases (ehrlichia, RMSF, and Lyme), abdominal and cardiac ultrasonography, and radiography of the thorax and affected joints can be performed. Culture of synovial fluid is performed if sepsis is suspected, but blood and urine cultures are usually more rewarding.[5,8]

Heartworm infection, pyometra, periodontal disease, chronic bacterial endocarditis, discospondylitis, chronic

Actinomyces infections, juvenile cellulitis, chronic salmonellosis, and occult urinary tract infection have all been associated with nonerosive type II arthritis, and should be considered.[5,7,8] Idiopathic arteritis causing meningitis can be accompanied by distal joint inflammation. Enteropathic type III arthritis can be associated with inflammatory bowel disease, and hepatopathic arthropathy can be associated with chronic active hepatitis.[5,8]

Differentiation of nonerosive from erosive forms of IMPA can be made with radiography, and should always be pursued if response to therapy for

presumed nonerosive IMPA is less than anticipated. Viral serology for feline leukemia can be positive in 66% of cats with progressive polyarthritis associated with feline syncytium-forming virus, and may exacerbate the disease.[4,8]

Review of the physical examination findings and clinical pathology results should identify criteria of SLE if it is present: cytopenia (hemolytic anemia and/or thrombocytopenia), dermatologic lesions, protein losing nephropathy (urine protein: creatinine ratio), myositis, myocarditis/pericarditis, pleuritis, or glossitis. The presence of antinuclear antibodies and LE cells can help

confirm the diagnosis of SLE, but are not specific for it. Similarly, a positive Coomb's test can support the diagnosis of SLE.[12,13]

Rheumatoid factor testing is neither sensitive nor specific for erosive polyarthritis in the dog. Serologic testing for the presence of rheumatoid factor is reported to be positive in 25% to 75% of dogs with erosive polyarthritis when performed using the Rose-Waaler test. Additionally, the mucin clot test may support the diagnosis of erosive arthritis. Mucin levels in synovial fluid are typically lowered in patients with erosive arthritis owing to the action of inflammatory substances. Synovial

biopsy can support the diagnosis if histopathologic changes typical of erosive arthritis are found: periarticular fibrosis, synovial hyperplasia and villous hypertrophy, and the formation of pannus.[4,11]

Therapeutics

Type I IMPA and SLE-associated polyarthritis are successfully treated in most cases with immunosuppressive levels of corticosteroids alone. One to 2 weeks after initiation of therapy, repeat arthrocentesis and synovial fluid cytologic evaluation should be performed. Effective control of IMPA is reflected by normalization of gross characteristics of synovial fluid and

cell counts with return to a predominance of mononuclear cells, in addition to clinical improvement. Gradual tapering of corticosteroid doses should occur in concert with continued improvement of clinical signs and normalization of synovial fluid. Serial arthrocentesis for cytologic evaluation of synovial fluid is important in assessing response to therapy and maintenance of remission. The typical course of immunosuppression in type I idiopathic IMPA is 6 to 12 weeks. Combination therapy as described for erosive IMPA (see below) can be necessary if the initial response (within 2 weeks) to corticosteroids is incomplete, if tapering results in

relapse, or if unacceptable side effects are associated with prednisone administration.

IMPA associated with significant concurrent systemic disease warrants treatment of the primary disorder first and synovitis second. Antimicrobial, antiparasitic, antineoplastic, immunomodulatory, and nutritional therapies should prevail Figure 117-5. Analgesic and anti-inflammatory therapy can accompany treatment of the primary disorder if dictated by the level of discomfort associated with arthritis. The use of nonsteroidal anti-inflammatory drugs in combination with corticosteroids is not advised owing to the risk of gastric ulceration.

Combination antimicrobial and immunosuppressive therapy can be cautiously instituted if clinically indicated, while awaiting serologic and microbiologic results, but this demands close patient monitoring.

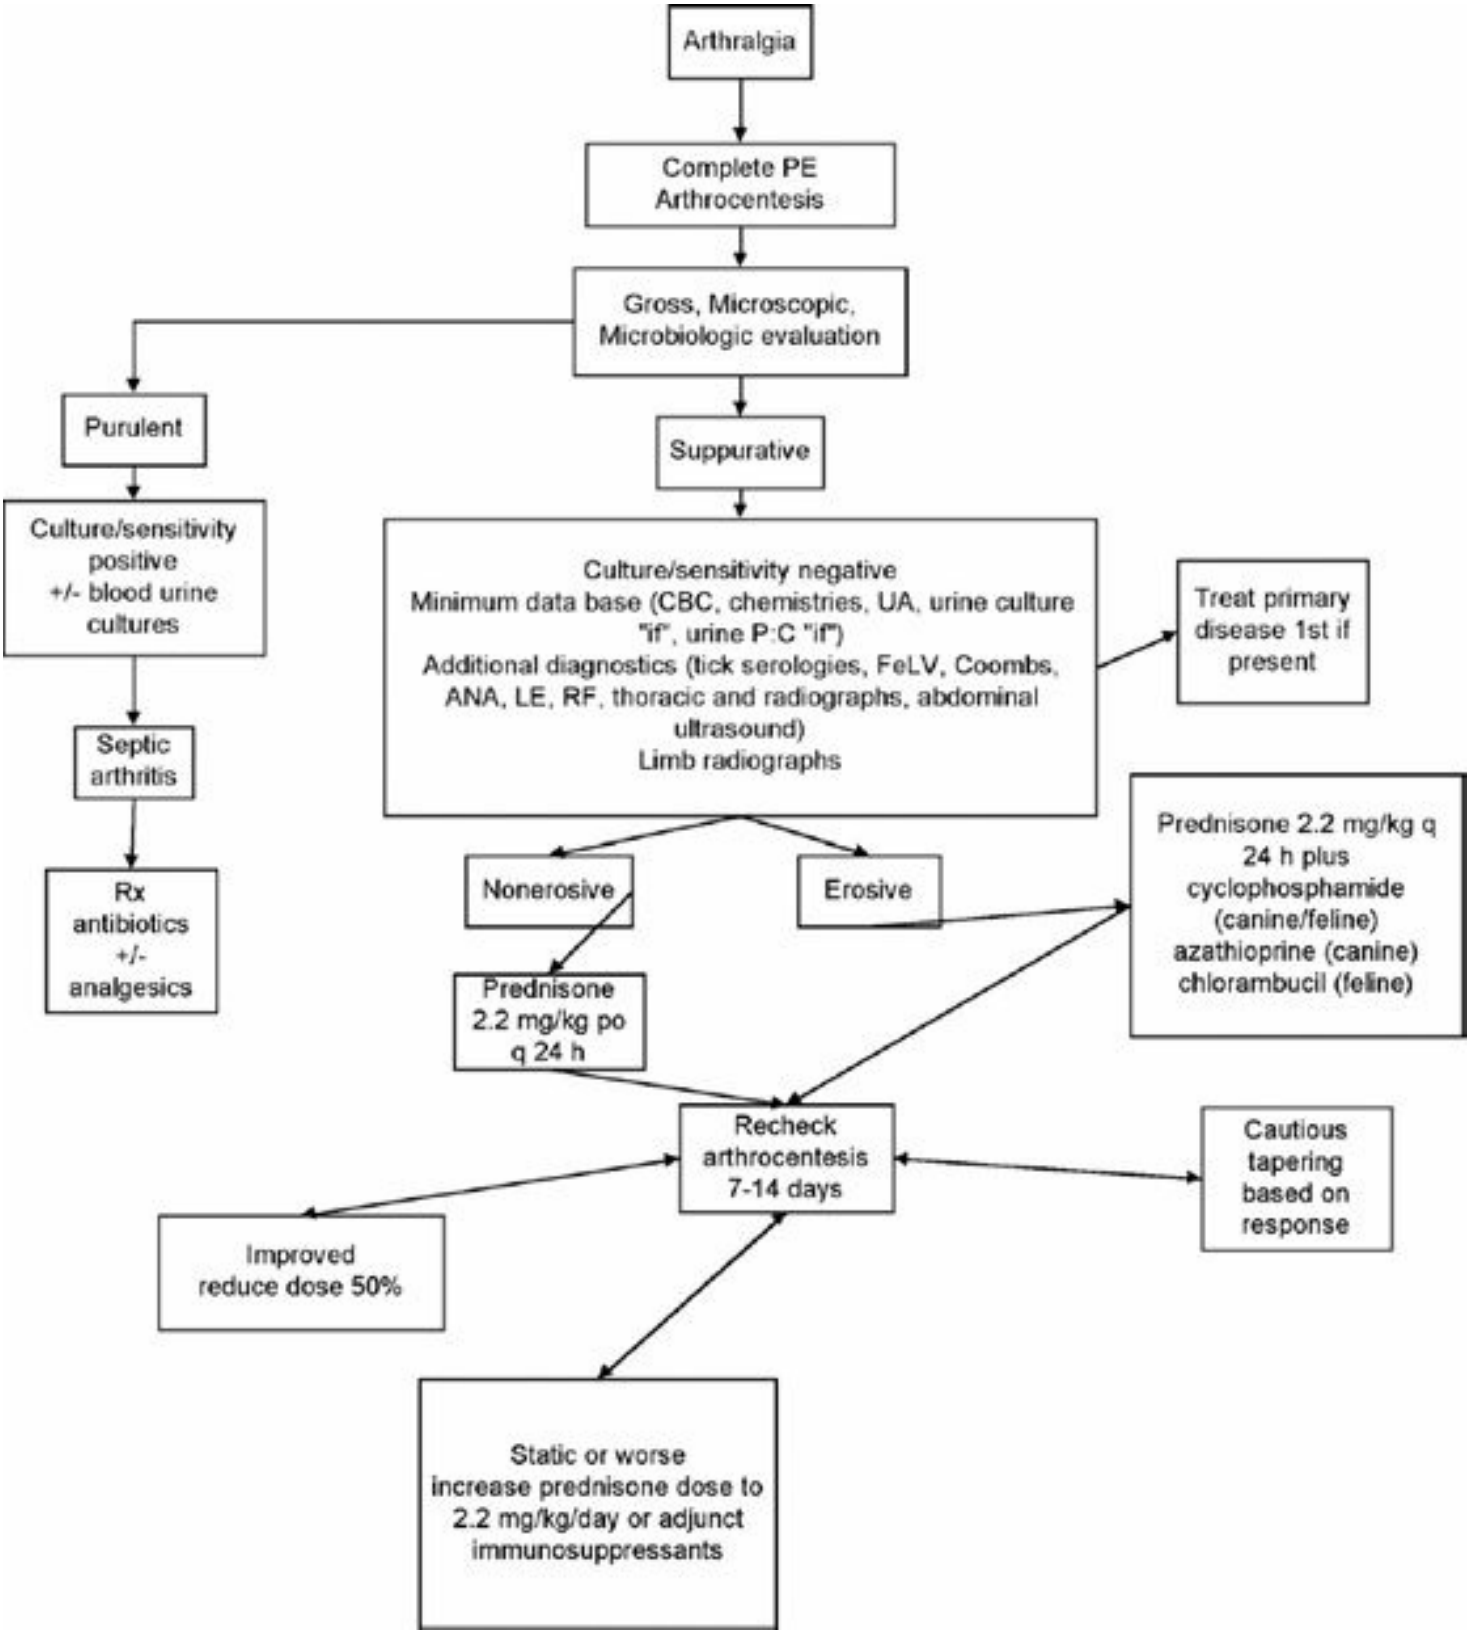

Figure 117-5. Flow chart for clinical evaluation of arthralgia and IMPA.

Current recommendations for therapy of erosive IMPA dictate combination corticosteroid and cytotoxic drug administration. Immunosuppressive doses of prednisone (2.2 mg/kg/day) are combined with cyclophosphamide (Cytoxan, 50 mg/M^2 PO every 24 hours x 4 days each week, or MWF), azathioprine (Imuran, 50mg/M^2 every 24 hours for 7-14 days, then every 48 hours), or cyclosporine (10 mg/kg). Generally, cyclophosphamide is not used for longer that 4 months in dogs owing to its association with sterile hemorrhagic cystitis. Cats are much more susceptible to azathioprine toxicity, and its use is generally not recommended. Chlorambucil (1-2 mg/cat every 24-72 hours) is used as

an alternative. Both cyclophosphamide and azathioprine require close monitoring for myelosuppression. Hepatic enzyme elevation can occur with azathioprine. Chlorambucil (Leukeran, 2-6 mg/M^2 every 48 hours canine) can be substituted for cyclophosphamide once remission has been attained, if necessary, in the dog. Side effects of cyclosporine include gastrointestinal upset, anorexia, and gingival hyperplasia. Cyclosporine reversibly inhibits immunocompetent lymphocytes in the G_0 - or G_1 – phase, affecting T-helper cells, T-suppressor cells, and reducing lymphokine production and release. Cyclosporine has variable bioavailability, and the various formulations do not have equal

efficacy or dosing. Microemulsified products have improved oral absorption (Neoral, Novartis, Greensboro NC, 5-10 mg/kg/day divided bid). Ketoconazole (10 mg/kg/day divided tid PO with food) can be used concurrently to decrease cytochrome P-450 clearance of cyclosporine, permitting a lower dosage to be effective and saving client expenses. Serum levels should be monitored starting 2 to 3 days after the initiation of therapy; trough levels of 200 to 500 ng/ml are advised.[17] Leflunomide (4mg/kg every 24 hours, with dosage adjustment based on trough plasma levels of 20 µg/ml) is a new immunosuppressive agent showing promise in the treatment of

refractory immunologic disease in dogs and cats. Leflunomide can be considered for IMPA unresponsive to conventional therapy. Other than repair of ruptured cranial crucial ligaments, surgical intervention (synovectomy, arthrodesis) for IMPA is unrewarding and uncommon. As with type I IMPA, immunosuppressive drug withdrawal should be performed in concert with clinical signs of remission coupled with synovial fluid evaluation, as improvement in gait does not always correlate with normalization of synovial fluid.

Prognosis

The prognosis for dogs and cats with

IMPA varies. The prognosis for nonerosive forms of IMPA is better than that for erosive forms. Early appropriate immunosuppressive therapy, tapered carefully based on clinical and clinicopathologic evaluations, can result in resolution and discontinuation of medication in 1.5 to 3 months.[5,7,8]

The prognosis for polyarthritis associated with concurrent disease (types II-IV) depends on the potential for resolution of the primary, contributory disorder. IMPA associated with infectious/inflammatory diseases responsive to therapy (rickettsial infections, enteropathies) carries a better prognosis than that associated

with more refractory disorders (mycoses, viruses, neoplasia).[7]

Erosive forms rarely resolve, but remission with continued medical therapy is possible. Feline erosive progressive polyarthritis carries a poor prognosis. Canine erosive polyarthritis has a fair prognosis if diagnosed and treated early in its course, but is generally considered to be a more aggressive condition than the similar disease in humans (rheumatoid arthritis). Semierosive polyarthritis of greyhounds is reported to have a poor prognosis. Aggressive combination immunosuppressive therapy is indicated to slow progression of erosive IMPA, and postpone joint

subluxation, luxation, ankylosis, and collapse, and to minimize periarticular osteophyte production. These changes are irreversible. Caution must be taken that therapy does not result in serious complications such as refractory sterile hemorrhagic cystitis, viral relapse, myelosuppression, or opportunistic bacterial sepsis. Therapy can be expected to continue at high doses for 3 to 6 months, and at maintenance levels for months to years.[4,7]

Part XIV

Exotics

Chapter 118

Surgical Diseases of the Ferret

SJ Mehler
RA Bennett

It is estimated that 7 to 10 million ferrets are owned as pets in the United States.[1] Besides traumatic injuries and gastrointestinal foreign bodies, the majority of surgical diseases in ferrets are neoplastic conditions. A group of black-footed ferrets that spent their entire lives in a captive setting had a 100% incidence of cancer at necropsy.[2] It is also common for more than one

type of tumor to be present simultaneously in a ferret, with one type usually diagnosed as an incidental finding at surgery.[3-8] The most commonly reported tumors in ferrets are endocrine tumors, with an incidence of 39.7% to 53%.[6,7,9,10] Pancreatic beta-cell tumors or insulinomas are the most common endocrine tumors, and adrenal tumors are the second most common.[8-10]

Surgical procedures in ferrets are similar to those performed in dogs and cats. Because of the small body size of ferrets, microsurgical instruments, magnifying loupes, smaller suture sizes, body-temperature support devices, and smaller retractors (Lone

Star retractor, Lone Star Medical Products, Stafford, TX) are important (Figure 118-1). For a majority of the surgical diseases described in this chapter, a ventral midline laparotomy is indicated. Ferrets have relatively thick skin, little subcutaneous tissue, and a wide, thin linea alba.[11]

In the United States, 2 years represents 25% of the average lifespan of ferrets.[8] If the goal of treatment is to prolong life and improve the quality of life of the ferret, then a 1- to 2-year survival with a good quality of life is considered a success.

Figure 118-1. Lone Star retractor being used in the abdomen of a ferret.

Insulinoma

Pancreatic beta-cell tumors are the most commonly reported endocrine tumors in ferrets, with a reported incidence of 21.7% to 25%.[6,7,10,12-16] The median age of ferrets with

insulinomas is 5 years (range 2-7 years), with males being diagnosed more frequently than females.[7,17,18]

Disease Mechanism

The four types of islet cells are beta cells (insulin secretion), alpha cells (glucagon secretion), delta cells (somatostatin secretion), and F cells (pancreatic polypeptide secretion).[19] Islet cell tumors in ferrets arise from the beta cells and produce insulin, which, when present in excess amounts, leads to hypoglycemia.[6,8,9,19,20] Functional insulin-secreting conditions in ferrets include pancreatic hyperplasia, adenoma, and adenocarcinoma.[6,7,17,21]

Neuroglucopenic signs occur because cells in the central nervous system have a higher metabolic rate and glucose is their primary energy source.[19,22] Prolonged and severe hypoglycemia can cause brain damage and, clinically, patients present with neurologic dysfunction.[9,19,22]

Clinical Signs

Clinical signs may not be apparent and the tumor is sometimes diagnosed on health screen biochemical examination or at exploratory laparotomy for another reason. Clinical signs are related to the systemic effects of hypoglycemia, the rate of decline of the blood glucose concentration, and

the duration and degree of hypoglycemia.[19] Clinical signs in ferrets with hypoglycemia include hind limb ataxia, paresis or paralysis, seizures, weight loss, ptyalism, gagging, vomiting, and pawing at the mouth.[6,7,12,14,17,21,23,24] Pawing at the mouth is thought to be associated with nausea, but may lead owners and clinicians to believe there is a foreign object in the mouth or throat.[8,25] Owners may report a prolonged waxing and waning history of lethargy and episodes of collapse. They often describe the ferret as having a "glazed" eye appearance.[19] Physical examination of ferrets with an insulinoma may be unremarkable as the hypoglycemia can be episodic.

Diagnostics

The reference range for resting blood glucose concentration in ferrets is 94 to 207 mg/dL and normal fasting blood glucose levels are 90 to 125 mg/dL.[19] Insulin levels can be run concurrently but will only be diagnostic if the patient is hypoglycemic at the time of sampling.[19,26,27] If serum glucose levels are normal and a high clinical suspicion for insulinoma exists, a controlled fast can be performed for no more than 4 hours to better establish hypoglycemia. It is best to fast the ferret in the hospital in case a hypoglycemic crisis occurs. Because ferrets have a rapid gastrointestinal transit time (3-4 hours), a shorter fast

than in dogs and cats is diagnostic. A 4-hour fasting glucose concentration less than 60 mg/dL is consistent with a pancreatic islet cell tumor in a ferret.[20,21,27] Typically, abdominal radiography and ultrasonography are not helpful in detecting these masses as they are usually only millimeters in diameter.[8,19]

Treatment

Treatment is aimed at increasing blood glucose levels by both medical and surgical means. It is common (> 50% of surgical cases) that after surgical excision, medical management is still indicated.[17] Only 14% to 15% of ferrets with insulinoma are cured long-

term with surgery.[7,17,19,28] This may be due to the high recurrence rate or micrometastatic rate of ferret insulinoma to other regions of the pancreas, regional lymph node, spleen, or liver; however, some have found the metastatic potential to be low.[17,24]

Surgical excision is the treatment of choice for ferrets under 6 years of age or for those suspected of having concurrent adrenal disease.[19] Surgery is indicated for confirmation of insulinoma, for decreasing the tumor burden, and to better evaluate for metastatic and concurrent disease (Figure 118-2).[27] Removal of the left lobe of the pancreas is technically less challenging than removal of the right

lobe because of the close proximity of the right lobe to the pancreatic ducts, duodenum, and adjacent blood vessels.[21,29]

Figure 118-2. An insulinoma removed from the left limb of the pancreas of a ferret. This was an unusually large tumor. Most insulinomas in ferrets are less than a centimeter in diameter.

The pancreas of ferrets is similar to

that of cats in that there is typically a common pancreatic duct that joins with the common bile duct and enters the duodenum at the major duodenal papilla. An accessory pancreatic duct is present in about 2.5% of ferrets.[11,13] Medical management can be used concurrently with surgery or as the sole modality for treatment. Ferrets with insulinomas managed medically without surgery have a shorter survival than those treated with surgery or a combination.[17] Medical management is aimed at increasing blood glucose levels. Glucocorticoids increase hepatic gluconeogenesis and decrease glycogenolysis.[19,27,30] Liquid formulations of prednisone or prednisolone are available for more

accurate dosing. It is important that the solution does not contain sugar or alcohol that can exacerbate the hypoglycemia.[8,19]

Diazoxide is a nondiuretic benzothiadiazide that effectively increases serum glucose levels by different mechanisms. It inhibits pancreatic islet cell insulin secretion and enhances hyperglycemia by stimulating the beta-adrenergic system and inhibiting the uptake of glucose by cells.[15,31,32] Diazoxide has no antineoplastic activity nor does it affect the synthesis of insulin.[31,32] Glucocorticoids and diazoxide can be given alone or in combination as needed to combat the effects of

systemic hypoglycemia. Streptozotocin is a chemotherapeutic agent that exhibits a diabetogenic effect on pancreatic beta cells in dogs but not in humans and has not been evaluated in ferrets.[8,32]

Diet is also important in the medical management of insulinomas in ferrets. Feeding a high-protein, low-carbohydrate diet at frequent intervals is necessary. Treats and snacks, especially those containing sugar, should be avoided.[8,19,27] It has been recommended that serial blood glucose concentrations be taken at 2 weeks post surgery and at 1-4-month intervals for the life of the ferret.[11,19]

Prognosis

The prognosis for ferrets with insulinomas varies but is generally better than for that of dogs with insulinomas.[7,12,21,23,24,26] Young ferrets without metastatic disease that are diagnosed early in the disease process have the best prognosis.[27] With partial pancreatectomy, mean survival time is 668 days; multiple surgeries are sometimes needed to achieve longer survival times.[7,8] The duration of clinical signs before diagnosis may negatively affect survival time and disease-free interval after surgery.[14] No difference in survival time has been identified between ferrets with benign versus metastatic disease.[12,17]

Adrenal Disease

Adrenocortical cell tumors are the second most common tumors in ferrets.[3,6,10,18,30,33-36] The occurrence of hyperadrenocorticism in domestic ferrets in the United States is common and may be present in up to 25% of all ferrets.[3,6,37] The first report of hyperadrenocorticism in a domestic ferret was in 1987.[38] Since then several reports identifying the hormones elevated in ferret hyperadrenocorticism and the pathophysiology of the disease have been published.[3,33,34,39] The mean age of affected ferrets is 3.4 to 4.8 years, with females having a predilection for the disease,[3,30,35] although one study

refutes this finding.[37]

Disease Mechanism

These are adrenal cortical reticularis tumors, which produce excessive levels of androgenic hormone precursor and estrogenic hormones. Increases in serum cortisol levels are typically not a feature of this disease in ferrets, nor is primary pituitary disease likely.[8,19,27,35,40-42] These tumors histologically are characterized as adrenal cortical hyperplasia, adenomas, or adenocarcinomas, and it is possible that this is a continuum of a disease process.[3,43] The clinical signs and prognosis are the same regardless of the histopathologic

diagnosis.[2,3,8,30,37] Adrenocortical spindle-cell tumors and pheochromocytomas have also been reported alone and concurrently with functional adrenocortical cell neoplasms in ferrets.[9,18,19,30,44] The incidence of adrenal disease in ferrets in Europe and Australia appears to be much lower than in the United States. It has been speculated that adrenal gland hyperplasia and tumor development are due to the early neutering of ferrets.[27,45,46] This has been shown to occur in mice.[45] Other suggested causes include feeding a commercial brand ferret food (instead of whole prey items), inbreeding, and the lack of a natural light cycle for ferrets in the United States.[19]

Clinical Signs

Clinical signs in ferrets with functional adrenocortical tumors are primarily a result of the hypersecretion of estrogenic and other steroid hormones by tumor cells.[9] Clinical signs are variable in affected animals and may include a bilaterally symmetrical endocrine alopecia which may be seasonal, pruritis (sometimes the only clinical sign), vulvar enlargement in females, prostatic enlargement in males, aggressive sexual behavior, comedones on the tail, and mammary gland enlargement (Figure 118-3).[3,19,20,28,33,37,39,47] Males with prostatic disease secondary to hyperadrenocorticism may present with dribbling urine or straining to

urinate and defecate. Prostatic abscessation, paraurethral cysts, and urinary obstruction can also accompany the disease in males. Large tumors can be palpated in the cranial abdomen.

Figure 118-3. The ventral abdomen of a female ferret diagnosed with hyperadrenocorticism. Notice the

alopecia of the ventral tail and abdomen. Moderate swelling of the vulva is secondary to an increase in circulating estrogens and androgens.

Diagnostics

Hyperadrenocorticism in ferrets is diagnosed based on a combination of clinical signs, abdominal ultrasound, and plasma concentrations of estrogens and androgens.[19,34,35,40,41] Serum chemistry and hematologic profiles are usually normal except for the occasional thrombocytopenia and anemia, thought to occur owing to estrogen-induced bone marrow suppression.[3] In ferrets with anemia and pancytopenia, a packed cell volume less than 15% is associated with a grave prognosis.[19] A serum

androgen profile has been established and is commercially available at the University of Tennessee. The assay measures levels of 17-hydroxyprogesterone, androstenedione, and estradiol. An elevation of any one of these hormones is considered diagnostic for hyperadrenocorticism in ferrets.[19,33,34] Elevations in dehydroepiandrosterone may also be detected in ferrets with adrenal disease.[40] Urine cortisol:creatine ratios are not useful in diagnosing hyperadrenocorticism in ferrets because serum cortisol is not elevated in these patients,[3,41] although one study disagrees with this.[35]

History and physical examination

appear to be the most useful in diagnosing the disease. Abdominal radiographs are usually unremarkable unless the mass is large or if mineralization of the affected adrenal gland has occurred.[3] Adrenal lesions are the most commonly found ultrasonographic abnormalities in ferrets.[8,48,49] Ultrasound has been reported to have an 84% sensitivity for detecting adrenal disease in ferrets, with histopathology being the gold standard.[43] Ultrasound findings in ferrets with hyperadrenocorticism may also include a prominent uterus or uterine stump, or a prominent prostate with or without prostatic cysts.[43] The authors have also observed ultrasonographic evidence of urinary

tract dilation (urethra, bladder, and ureters) owing to an enlarged prostate obstructing the prostatic urethra.

Treatment

Currently, medical management of adrenal disease in ferrets is focused on controlling abnormal hormone levels and their effects. These treatments do not cure the condition but may help alleviate clinical signs. Medical management is recommended if the owner is unable to afford surgery, if the ferret is a poor surgical candidate, or if the ferret has bilateral adrenal tumors that cannot be resected.[19] The use of leuprolide acetate, a repositol gonadotropin releasing hormone

(GnRH) analog, causes a transient increase and then a rapid decrease in luteinizing hormone, follicle-stimulating hormone, and testosterone levels.[19,50] It is rare that patients become refractory to leuprolide acetate treatments.[8] Other hormone therapies include bicalutamide, anastrazole, and melatonin.[8,19,51]

A ventral midline and a lateral celiotomy have been described for adrenalectomy in ferrets (Figure 118-4).[20,52-59] In 85% of ferrets with hyperadrenocorticism, one adrenal gland is enlarged and the other is small to normal. In the remaining 15% of cases, bilateral adrenal enlargement is identified.[3,37] In unilateral

enlargement, disease may occur in the contralateral gland after the affected adrenal is removed.[37] In some cases, both adrenal glands will appear grossly normal and direct visualization of the entire gland via careful dissection of surrounding retroperitoneal fat is necessary. Historically, the recommended surgical treatment for bilateral adrenal disease in ferrets has been total adrenalectomy of the one side and partial resection of the contralateral side.[40,57] This will ultimately lead to recurrence of the disease as the remaining adrenal tissue proliferates, and it may not even temporarily relieve clinical signs.

The prostate is not grossly visible in a

normal male ferret. If the ferret presented with a urinary obstruction from prostatic disease, a urinary catheter should be left in place for a couple of days until voluntary urinary function returns.

Figure 118-4. A 2 cm x 1.5 cm right adrenal mass is being removed from the caudal vena cava and liver. A

combination of blunt dissection with sterile cotton tip applicators, hemoclips, and bipolar electrocautery facilitate removal of these tumors.

If both glands are abnormal, bilateral adrenalectomy is achievable and preferred. Removing both adrenal glands can lead to iatrogenic hypoadrenocorticism (Addison's disease); however, most ferrets do well on glucocorticoid supplementation only and do not need long-term mineralocorticoid therapy. Most ferrets will not require long-term steroid administration.[20] Many ferrets are concurrently diagnosed with insulinoma and already on glucocorticoid therapy for that disease process. Periodic electrolyte analysis of ferrets having had a bilateral

adrenalectomy is recommended because some patients will require mineralocorticoid therapy.

Prognosis

Following complete surgical removal of the affected gland or glands, prostatic and vulvar enlargement decreases within days and hair regrowth occurs within 3 months.[8] The prognosis for adrenal gland disease in ferrets is good, if the gland is completely excised, owing to a low metastatic potential.[3,8,27,30]

Splenomegaly

Splenomegaly is a common finding in

adult ferrets but is poorly understood.[11,60,61] The spleen in ferrets increases gradually and slightly in size with increasing age[30] but can also enlarge owing to proliferative lesions, reactive processes, compensatory mechanisms, or certain anesthetics.[29,60] The most common cause of splenomegaly is extramedullary hematopoesis (EMH) in the presence or absence of anemia or other hematologic dyscasias.[60-62] Other causes include lymphoma, insulinoma, cardiomyopathy, adrenal disease, systemic mast cell tumors, Aleutian disease, eosinophilic gastritis, hemangiosarcoma, primary splenic neoplasia, hypersplenism, and splenitis.[54] Most causes of

splenomegaly are not surgical diseases and should be evaluated with clinicopathologic data and imaging modalities before splenectomy is considered. Percutaneous splenic biopsy is contraindicated in ferrets suspected of having splenic hemangiosarcoma, although this condition is rare in ferrets.[54] Ultrasound is useful in determining the safety of percutaneous biopsy. Ultrasound is also useful in guiding biopsy needles or smaller gauge needles for obtaining a sample of the spleen. Fine-needle aspiration is simple, carries little risk, is associated with low morbidity, and provides useful samples.

Indications for splenectomy in ferrets include splenic neoplasia, splenomegaly or hypersplenism causing compression of abdominal viscera, splenic torsion, and non-self-limiting traumatic fractures of the spleen. Splenectomy is contraindicated in ferrets with bone marrow hypoplasia because the spleen is the primary site of hematopoiesis in these patients.[54] Ferrets with splenic extramedullary hematopoiesis may develop chronic anemia after splenectomy because of the absence of splenic production of erythrocytes.

Gastrointestinal (GI) Foreign Body

In pet ferrets, foreign body ingestion is common.[11,63] Ferrets are inquisitive and have a propensity to chew on rubber and plastic.[64,65] Ingestion of foreign objects usually occurs in ferrets under the age of 2 years, whereas trichobezoars are more commonly observed in older ferrets.[64] Linear foreign bodies are rarely seen in ferrets.

Disease Mechanism

Ferrets have a rapid GI transit time compared with other carnivores.[25] This is likely owing to a lack of the proximal-to-distal digestive-enzyme gradient seen in other carnivores, resulting in a continuous exposure of

nutrients to digestive enzymes during GI transit.[25] Most GI foreign bodies lodge in the stomach or jejunum.[64]

Clinical Signs

Clinical signs of gastrointestinal foreign bodies in ferrets include anorexia or inappetance, diarrhea, ptyalism, facial rubbing, and vomiting (although this is not commonly reported by the owners).[63-65] Abdominal palpation may elicit discomfort. Palpation of the foreign body is usually possible, especially if it is in the intestinal tract.[10,63,65]

Diagnostics

Diagnosis is based on signalment, history, and physical examination. Ferrets have an abdomen that is easy to palpate, making most foreign bodies readily palpable within the gastrointestinal tract.[54] A complete blood count, serum biochemistry panel, and urinalysis should be performed. Abdominal radiographs and ultrasonography are useful in confirming the diagnosis and determining the location of the obstruction (Figure 118-5). The ferret should be stabilized with intravenous fluids before surgical removal is pursued.

Figure 118-5. A right lateral abdominal radiograph of a 1-year-old ferret with decreased appetite and lethargy. Notice the numerous, circular, soft-tissue opacities in the jejunum. Fluid and gas dilation of the small intestine is present. This ferret had a jejunal foreign body obstruction.

Treatment

Most GI foreign bodies in ferrets must be removed surgically. Gastrointestinal foreign bodies in ferrets rarely pass on

their own. The use of gastrointestinal lubricants and fluid replacement therapy may allow smaller nonobstructive materials to pass, especially hairballs.[65]

A ventral midline abdominal exploratory surgery should be performed in any ferret with a GI foreign body. Ferrets lack a grossly obvious ileum, and the jejunoileum extends from the duodenojejunal flexure to the ascending colon.[11,13] A gastrotomy and/or enterotomy are usually indicated, with intestinal resection and anastamosis less frequently necessary.

Prognosis

In general, ferrets have an excellent prognosis after surgery for foreign body removal as long as a perforation and septic peritonitis are not present. Intestinal necrosis or perforation seem to occur less frequently in ferrets compared with dogs and cats with foreign body obstruction. Preventing foreign body ingestion can be difficult in ferrets. Usually by 2 years of age, ferrets ingest foreign bodies less frequently. The routine use of GI lubricants to prevent trichobezoars is helpful.

Gastrointestinal Neoplasia

GI neoplasia has been reported in

ferrets,[6,10,18,30,66-69] but it is not a common site for primary neoplasia.[65] Pyloric adenocarcinoma has been described in ferrets and clinical signs include those associated with an upper GI obstruction: vomiting, weight loss, anorexia, and lethargy.[6,67,68]

The anatomy of the ferret stomach is similar to that of dogs, but is physiologically more like the human stomach.[13,25] Blood gas analysis commonly reflects a hypochloremic metabolic alkalosis. Ultrasound is useful in diagnosing the presence and location of the mass. Attempts at surgical resection with a Bilroth have been made but were unsuccessful.[67,68] Palliative stenting across the pylorus of

a ferret with adenocarcinoma was successfully performed and alleviated clinical signs.[69]

Obstructive Urolithiasis

Urolithiasis in ferrets can be characterized by solitary or multiple renal or cystic calculi or by the presence of sandy material in the urinary bladder and urethra.[70] Clinically, obstructive urolithiasis tends to be less common now than it was 10 years ago.[70] Obstructive urolithiasis is more common in male ferrets than in female ferrets owing to the narrow diameter of the urethra as it passes through the os penis in males. The most common type of stone identified

in ferrets is magnesium ammonium phosphate (struvite).[70]

Disease Mechanism

Although not studied as extensively as in dogs and cats, the pathogenesis of struvite urolithiasis in ferrets is probably related to diet.[70] Ferrets are carnivores with a normal urine pH of about 6.0.[71] Struvite crystallizes when the urine pH rises above 6.4. Although the mineral content of the food was once thought to be the cause of urolithiasis in ferrets, it is now thought to be caused by ingestion of plant proteins.[70] The metabolism of organic acids in plant protein produces an alkaline urine that results in the

formation of struvite crystals.[71] This was demonstrated in a group of pregnant jills fed a diet high in plant protein (mainly corn) and in a group of ferrets fed a commercial dog food.[71,72] Historically, the prevalence of the disease in the American ferret population was probably related to feeding poor quality dog and cat diets that contained a high percentage of plant-based protein. In recent years, many commercial ferret diets have become available and ferrets are not commonly fed dog and cat foods with plant proteins.

Clinical Signs

The systemic effects of obstructive

urolithiasis in ferrets are the same as those in dogs and cats. Dysuria, hematuria, stranguria, frequent licking of the perineum, and urine dribbling are reported clinical signs in ferrets with urolithiasis.[70] Ferrets with obstructive urolithiasis may strain violently or cry when attempting to urinate, or they may present depressed, moribund, or comatose. Rarely, ferrets present with lethargy and inappetance without lower urinary tract signs.

Diagnostics

The presence of lower urinary tract signs and palpation of a firm, distended, unexpressable urinary

bladder confirms an obstruction. Obstructive urolithiasis can be identified with abdominal radiographs because struvite stones are radioopaque. However, sand is not always visible radiographically. Abdominal ultrasound is often useful as the fine sand-like crystals are easily identified. It is also helpful if another cause is suspected (prostate disease secondary to adrenal neoplasia) and to identify radiolucent urinary calculi. Serum chemistry and hematologic profiles should be run to determine the extent of azotemia and electrolyte abnormalities, as well as to look for concurrent disease.

Treatment

If severe cardiac arrhythmias and electrolyte abnormalities are present, they are treated before attempting to unobstruct the urethra. Once intravenous fluids and supportive care have been initiated, the urethra should be unblocked. The treatment of obstructive urolithiasis in male ferrets is challenging because it is difficult to pass a urinary catheter in males. Males have an operculum covering the distal urethra and a hook directed dorsally at the tip of the os penis, making it difficult to identify the urethral opening.[58] The technique for urinary catheterization in ferrets has been described.[54,73]

If the distal urethra cannot be cleared of stones or if the ferret has recurrence of obstruction, an emergency cystotomy, percutaneous tube cystostomy, or perineal urethrostomy (PU) can be performed if the ferret is stable.

The anatomy of a ferret penis is similar to that of a dog.[58] The penis exits the pelvic canal, runs subcutaneously along the ventral pelvis, and lies along the caudal ventral abdominal body wall.[58] The opening of the prepuce is just caudal to the umbilicus. The PU site should be between the caudal portion of the os penis and the pelvic urethra. The stoma should be perineal and not

ventral to avoid trauma to the site during normal ambulation. The penis is not resected as is done in cats. A 3.5 to 5.0 Fr red rubber catheter is then placed in the proximal urethrostomy site to assess the diameter of the urethra and make sure it is patent. Fine monofilament suture (6-0 to 8-0) is used to appose the mucosa of the urethra to the skin. The urethral drain board should be at least 1 cm. This technique works well in ferrets and is well tolerated long term.

Prognosis

If the ferret is on an inappropriate diet it should be changed to a commercial ferret diet with no plant protein

source. The ferret should be monitored for struvite urolithiasis every 3 to 6 months with a urinalysis and abdominal radiographs. The prognosis is good for ferrets with obstructive urolithiasis if they are stabilized before general anesthesia. Recurrence can happen but is uncommon when dietary changes are made.

Blood Products

Many of the surgical diseases presented in this chapter require aggressive and challenging operative procedures. The use of perioperative blood products may be needed in some cases. Whole blood or packed red blood cell transfusions have been used in

clinical patients. Ferrets have only one blood type and transfusion reactions have not been reported in ferrets, but minor cross-matches are still recommended by some.[8,25,74] Oxyglobin (Biopure, Cambridge, Massachusetts) is a hemoglobin replacement product that increases the oxygen carrying capacity of the blood and has been used in ferrets with no reports of adverse reactions. The beneficial effects are still speculative.

Chapter 119

Surgical Diseases of the Rabbit

SJ Mehler
RA Bennett

Rabbits can be challenging surgical patients. Fear, pain, and stress have a profound effect on survival in the perioperative period. Anorexia, depression, and death can occur following minor surgical procedures. This is believed to be a result of increased catecholamine release.[1]

Rabbits ferment cellulose in their

cecum. Stress, antibiotics, anesthetics, and diet can alter gastrointestinal function and physiology, which can lead to serious gastrointestinal (GI) complications, especially gastrointestinal ileus, postoperatively. Rabbits are unable to vomit so fasting to prevent aspiration pneumonia is not necessary. Rabbits have a relatively large GI volume. A fast prior to laparotomy in rabbits is not routinely performed; however, some suggest a fast of 6 to 12 hours prior to laparotomy in order to decrease GI volume, improve surgical visualization and exposure, and improve the ability to manipulate GI structures. Yet, a fast of this duration will have little effect on cecal volume where the majority of

ingesta (about 40%) is located.[2,3]

It is important to have airway and venous access during anesthesia in the event of cardiac and/or respiratory arrest. Intubation is recommended for major surgeries in rabbits, and is essential during thoracotomies and procedures lasting greater than 20 minutes. Techniques for intubation are not covered in this chapter but are found elsewhere.[4] Repeated attempts to intubate rabbits can result in swelling and edema of the glottis that can result in fatal upper airway obstruction. If the intubation is not successful after 3 or 4 attempts, the rabbit should be maintained on mask anesthesia or, if appropriate, the

procedure should be postponed for 2 to 3 days, allowing the glottis to recover.

Rabbits have a blood volume of 57 ml/kg body weight.[5] Loss of 15 to 20% of total blood volume in a rabbit causes massive cholinergic release. An acute blood loss of 20 to 30% of the total blood volume causes hemodynamic collapse and shock.[5] Fresh whole blood can be collected and prepared from donor rabbits for transfusion. Rabbits do have blood groups and transfusion reactions do occur, because of this a cross match is recommended before a blood transfusion is given. Purified bovine hemoglobin with oxygen-carrying capacity can be used temporarily to

restore tissue perfusion and oxygenation while hemorrhage is controlled intraoperatively.

The success of surgery is often dependant on minimizing pain, stress, and fear. The use of analgesics, sedatives, anxieolytics, and shorter hospitalization times will minimize the negative effects of increased catecholamines on the surgical outcome. A positive outcome is also dependant on getting the rabbit to eat within 1 to 2 hours after surgery. If the rabbit is not eating after surgery, it should be force fed every few hours. Intravenous or subcutaneous fluids should be administered and continued until the rabbit is eating and drinking

on its own.

Uterine Adenocarcinoma

Endometrial adenocarcinoma is the most common tumor of female rabbits.[6,7] In intact female New Zealand White rabbits that are greater than 3 to 4 years of age, incidence approaches 80%.[6,8]

Disease Mechanism

As the rabbit ages, the endometrium of the uterus undergoes cellular changes, characterized by increases in endometrial collagen content.[9] The increase in collagen and decrease in cells are considered senile changes and

are associated with the development of uterine adenocarcinomas.[9,10] An identical process occurs in humans.[11]

Uterine adenocarcinomas in rabbits tend to be slow growing tumors and are slow to metastasize (Figure 119-1A and B). Local invasion of the tumor into the myometrium can occur early in the development of the tumor, and the neoplasm can extend through the uterine wall to invade other visceral structures.[6] Relevant medical history may include reproductive abnormalities such as decreased litter size, abortion, retention of feti, and stillbirth.[8,10]

Clinical Signs

Clinical signs include depression, anorexia, hematuria, and bloody vaginal discharge.[8,10] Hematuria is the most common presenting complaint but the hemorrhage is from the reproductive tract. Owners are usually not able to differentiate between hematuria and a hemorrhagic vaginal discharge. Cystic mammary glands can also develop concurrently with uterine endometrial hyperplasia and adenocarcinoma.[11,12]

Diagnostics

Larger tumors are easily palpated on physical examination. Adenocarcinoma is often present in both horns at the

time of diagnosis.[6,9,13] A complete blood count, serum biochemistry panel, and urinalysis should always be performed. Abdominal and thoracic radiographs are useful in detecting primary tumors as well as metastatic disease. Metastatic uterine carcinoma has been reported in the lungs, liver, bone, brain, and throughout the peritoneal cavity (Figure 119-2).[8,13-15] Hypertrophic osteopathy associated with metastasis to the lungs has also been reported in rabbits.[8] Abdominal ultrasonography is useful in differentiating between uterine masses and other causes of reproductive tract enlargement or disease (endometrial hyperplasia, endometrial polyps, pyometra, and endometritis),

metastatic disease in the abdomen, or concurrent abdominal disease.

Treatment

Prevention is the best treatment for uterine adenocarcinoma. It is recommended that rabbits undergo ovariohysterectomy (OHE) between the ages of 6 and 12 months.[10] The treatment of choice for rabbits with uterine adenocarcinoma is OHE.[8,13-15] The uterus of young rabbits is found just dorsal to the bladder, coiled in the caudal abdomen. In older rabbits, the cervix is dorsal to the bladder and the horns extend laterally but not very cranially. The doe reproductive anatomy lacks a uterine body. The

uterus is bicornuate and each horn has its own cervix that empties into the relatively large vagina. The mesometrium is a major adipose storage site in rabbits, which makes identification of the ovarian and uterine vessels difficult during OHE. The oviduct in rabbits encircles the ovary and must be removed during OHE. If a remnant of the oviduct is present, it can become cystic.[16] The cranial vagina is ligated caudal to the cervices to avoid the development of cervical aneurysms, which may rupture resulting in fatal hemorrhage.[16]

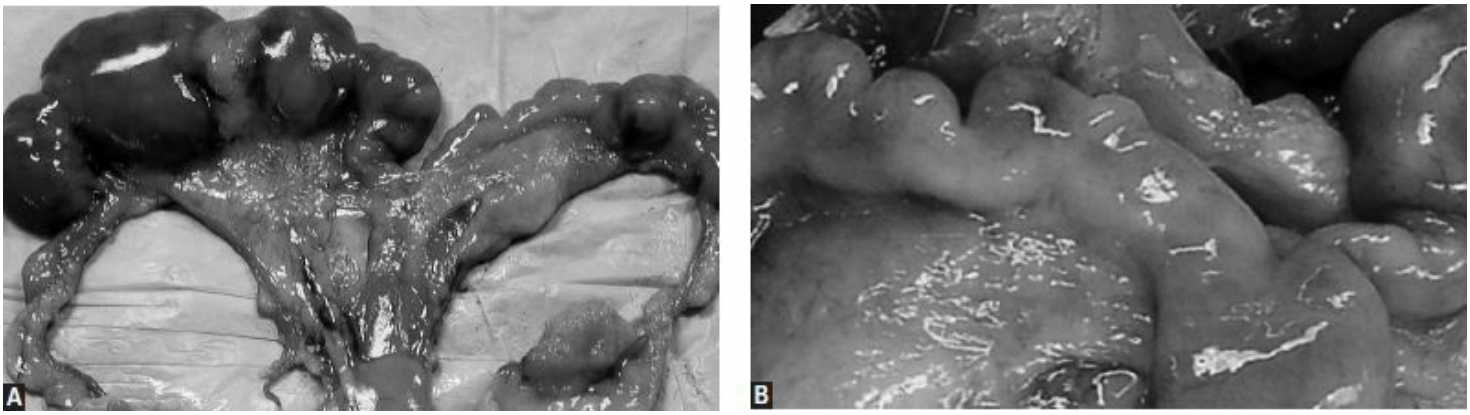

Figure 119-1A and B. Uterine adenocarcinoma in the rabbit. At the time of diagnosis, the tumor is commonly found in both uterine horns. Note the bicornuate uterus in figure B.

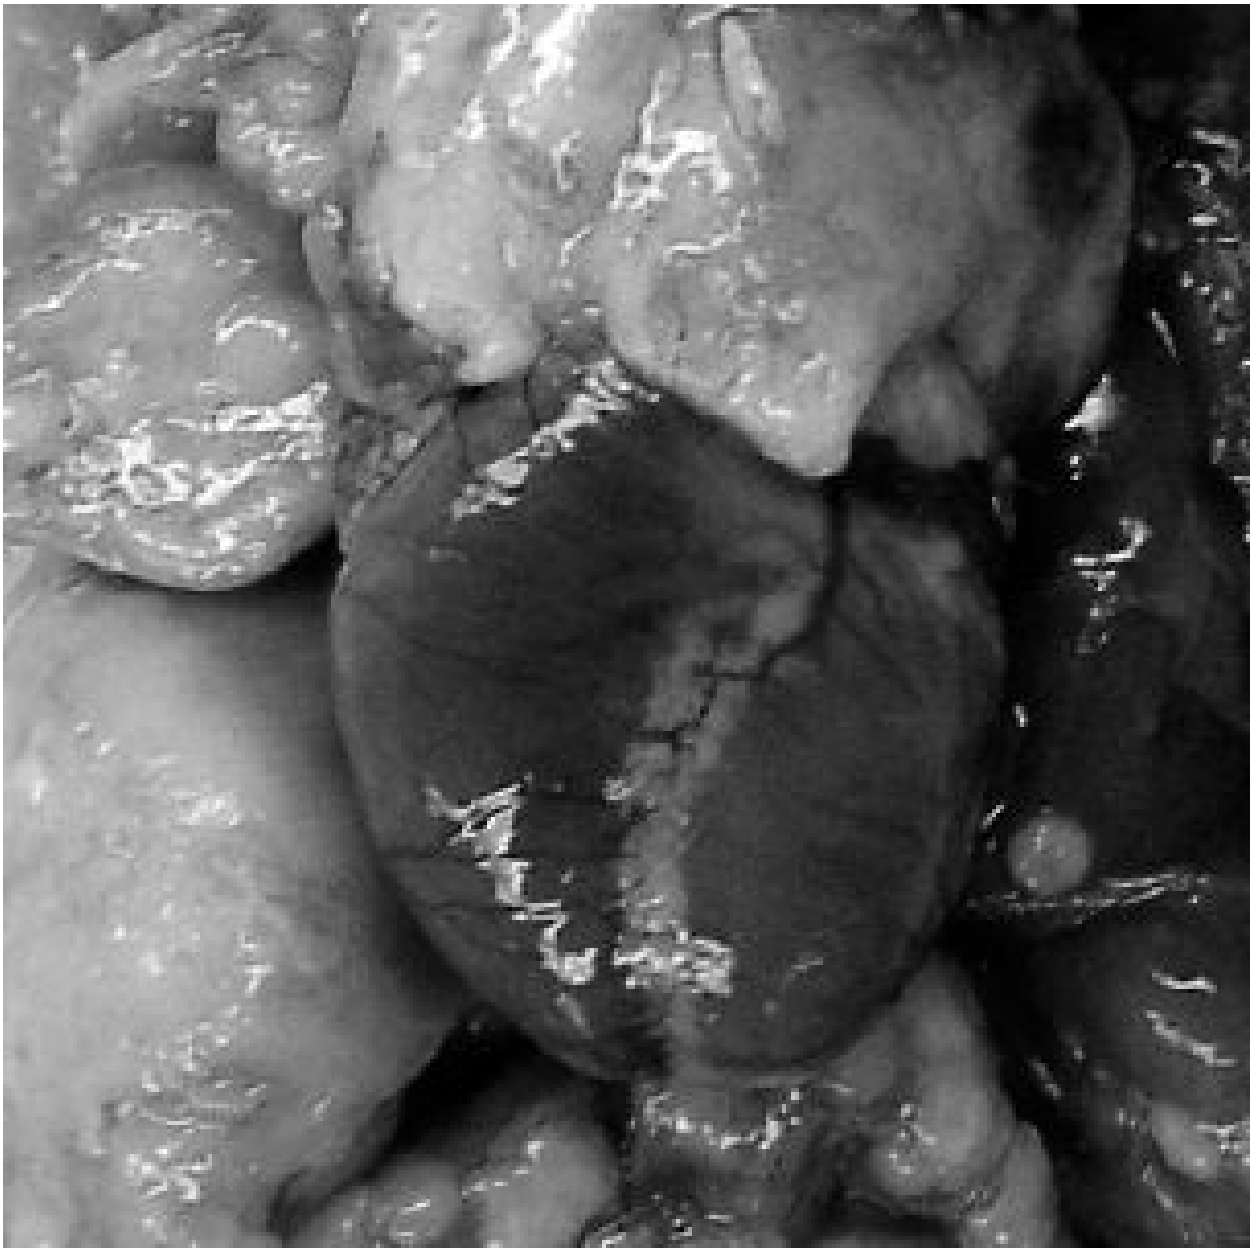

Figure 119-2. Metastatic uterine carcinoma in the rabbit. Note the circular white lesions in the lungs. Although metastatic spread of uterine adenocarcinoma in the rabbit is uncommon, disseminated disease can be found in the lungs, liver, bone, brain, and throughout the peritoneal cavity.

Prognosis

If no macro/micrometastatic disease is present at the time of surgery, OHE may be curative. If pulmonary metastatic disease is present, the rabbit is given a grave prognosis.[10] It has been suggested that rabbits with uterine adenocarcinoma at the time of OHE be examined for pulmonary and abdominal metastasis every 2 to 3 months after OHE for 1 to 2 years.[10]

Urinary System and Cystic Calculi

The urine of normal rabbits varies in color from yellow, to creamy, to red or brown, which can be linked to pigments in the diet. The reddish hue

of some rabbits' urine is normal but will lead rabbit owners to present their rabbit for hematuria.[2] The most common surgical disease of the urinary tract in rabbits is urinary bladder sludge and associated cystic calculi. Both conditions are likely related to the diet of the rabbit. Urinary sludge and calculi are composed mostly of calcium carbonate.

Disease Mechanism

It is reported that the total serum calcium levels in rabbits reflects the level of calcium in the diet and is not regulated within a narrow range;[2] however, recent research has identified that both ionized and total serum

calcium concentrations in rabbits are maintained in a narrow reference range regardless of diet, although normal levels are higher than those in dogs and cats (personal communication, KR Rosenthal). Urine is a major route of calcium excretion in rabbits. The fractional excretion of calcium in rabbits is 20 to 30 times that of most mammals.[2] The calcium carbonate excretions may accumulate in the urinary bladder and form a thick sludge or cystic calculi. The color and consistency of rabbit urine can be greatly affected by dietary calcium levels, often appearing thick and white while ingesting high levels of calcium. Prolonged ingestion of a diet high in calcium levels can lead to

mineralization of the aorta and kidneys.[2]

Clinical Signs

Clinical signs of cystic calculi may include straining to urinate, decreased appetite with subsequent decreased fecal production, or, if a lower urinary tract obstruction is present, the rabbit may become depressed, anorectic, and recumbent.

Diagnostics

Routine diagnostics should be performed in any rabbit demonstrating signs of lower urinary tract disease. These include a complete blood count,

serum biochemistry profile, urinalysis, abdominal radiographs, and abdominal ultrasound. Mineralized calcium excretions (sludge) are commonly detected in the bladder on abdominal radiographs as an incidental finding while another disease process is being investigated. The material in the bladder is usually radiopaque because the composition is mainly calcium carbonate (Figure 119-3). Abdominal ultrasound is also helpful in evaluating the entire urinary tract, especially if a partial or complete urinary tract obstruction is suspected.

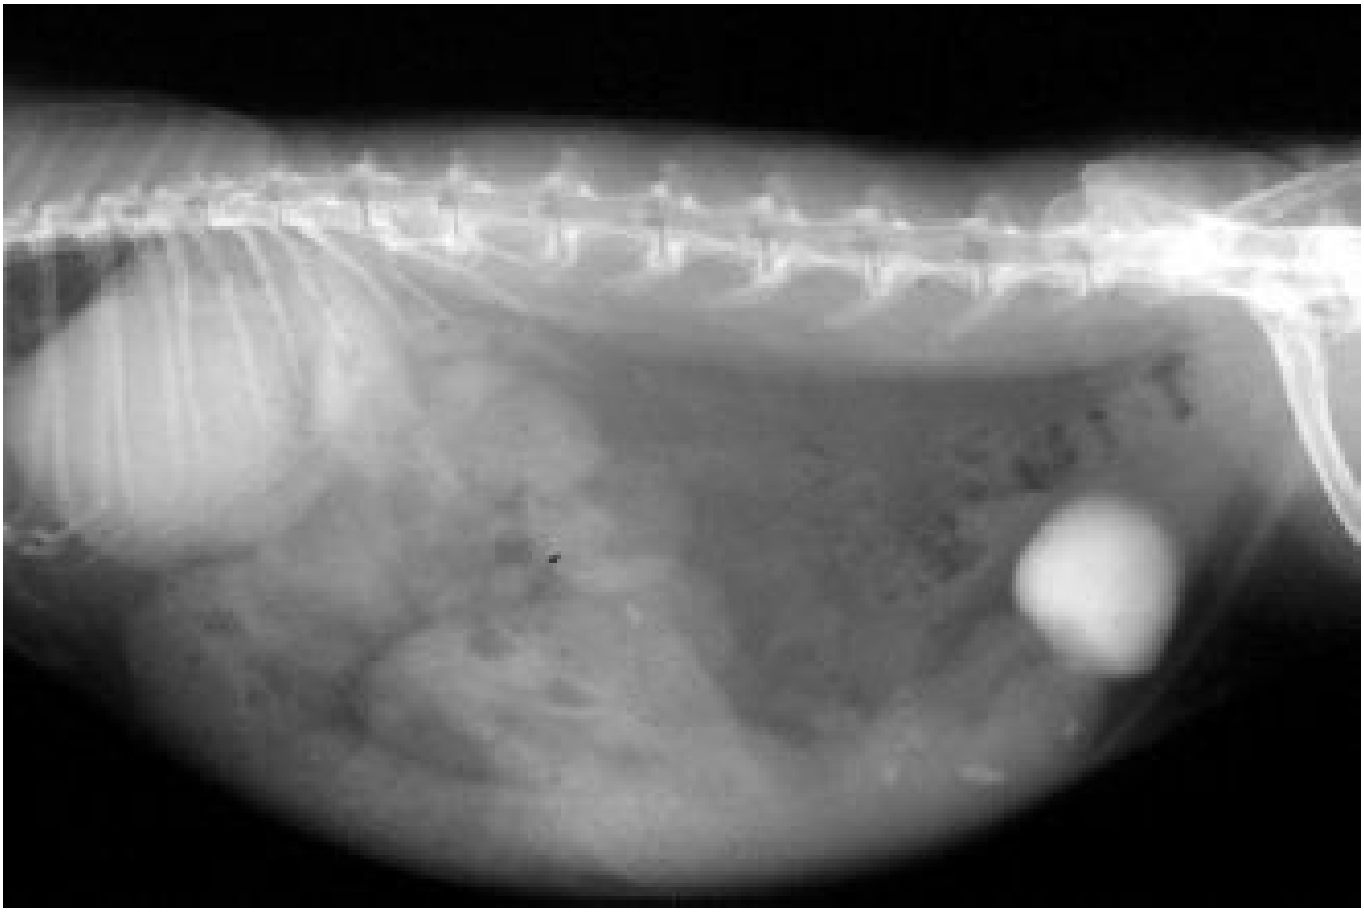

Figure 119-3. A right lateral radiograph of a rabbit with cystic calculi. The material in the bladder is usually radiopaque because the composition is mainly calcium carbonate.

Treatment

In some patients, this sludge-like material can be removed by lavaging the urinary bladder using a urinary catheter, sterile saline, and manual

expression. This procedure is performed under general anesthesia. Occasionally, the material becomes thick enough that it will not pass or it forms a stone and causes lower urinary tract obstruction. Cystotomy in rabbits is analogous to that in other species.

Prevention and Prognosis

Some controversy exists as to whether dietary calcium restriction is beneficial in preventing urinary sludge or stone formation in rabbits. Commercial alfalfa pellets and alfalfa hay are relatively high in calcium. They were originally formulated for meat-production rabbits to cause rapid weight gain. As such, they are also

high in protein and can predispose to obesity. Reducing the daily intake of pelleted alfalfa diets and feeding rabbits a diet composed mostly of timothy hay and timothy hay pellets, which are lower in calcium, is currently recommended. Additionally, treats high in calcium should be avoided. The prognosis is good after cystotomy but recurrence of sludge and of calculi formation is common.

Dental Abscesses

The dental formula in rabbits is 2 x (I 2/1 C 0/0 PM 3/2 M 3/3), making the total number of teeth 28.[17,18] The rostral incisors of the upper and lower jaw are modified to form a chisel-like

cutting tool.[2,3] Rabbits keep these teeth sharp by gnawing on objects in their environment. The thicker enamel on the labial surface of the incisors allows the front surface of the teeth to wear down more slowly, creating the sharp edge.[3] The peg teeth (maxillary I_2) are smaller than the other incisors and are just caudal to the rostral incisors. The points of the lower incisors rest on the peg teeth. Therefore, in a normal rabbit's mouth, the lower incisors rest caudal to the upper incisors. The premolars and molars are often grouped together and called cheek teeth. The diastema is the toothless space between the last incisor and the first cheek tooth.[2]

The rabbit's nasolacrimal duct narrows at the maxilla bone and as it passes over the roots of the upper incisor teeth. The duct opens at a nasal punctum, depositing tears in the nostril as in dogs and cats. Abscessation of the upper incisors can lead to occlusion of the ipsilateral nasolacrimal duct.

All rabbit teeth grow continuously, and the permanent teeth are completely erupted by 3 to 5 weeks of age.[2] The teeth continue to grow from the highly metabolically active apical germinal cells. The cheek teeth of adult rabbits consist mostly of crown. The clinical crown is exposed in the oral cavity.[18] The reserve crown makes up most of the tooth but is within the bone of the

mandible or maxilla. In rabbits, the growth of the permanent teeth is never completed, so no tooth roots are formed. The process of continual growth leaves rabbits susceptible to dental disease throughout their lives.

Disease Mechanism

In rabbits eating natural vegetation, the power stroke of chewing, the lingual edges of the mandibular cheek teeth occlude against the food on the buccal edges of the maxillary cheek teeth.[18] This repetitive movement of the cheek teeth during chewing enables even wear. Rabbits being fed a pellet diet have a decreased lateral excursion of the cheek teeth against the pellet

and an increase in the vertical movement of the teeth. This altered motion of the jaw leads to abnormal tooth wear. Abnormal tooth wear can lead to erosions or ulcerations of the oral mucosa (maxillary cheek teeth) and tongue (mandibular cheek teeth) from the sharp points that develop. Anorexia, oral pain, arrested tooth development, and infection of the oral cavity occur secondary to abnormal tooth wear and growth. Systemic disease and metabolic abnormalities may also lead to inappropriate tooth growth and development.

The most common cause of periodontal disease in rabbits is the impaction of food debris into the peridontium.[18]

This occurs secondary to abnormal or arrested tooth growth from inappropriate diet and systemic disease. The inflamed and infected peridontium, periodontal ligament, and surrounding tissues remodel and reabsorb. Tissue loss leads to deeper periodontal pockets, advanced infection into surrounding tissues, and local spread of bacteria toward the apex and bone of the mandible and maxilla. If not addressed, osteomyelitis and abscessation ensue.

Historically, abscesses in rabbits were thought to be caused by *Pasteurella multocida*; however, a variety of other organisms are routinely cultured. It is actually rare to isolate Pasteurella sp.

from abscesses in rabbits. Anaerobic bacteria, Staphylococcus sp. and Streptococcus sp. are most commonly cultured.[19] Abscesses of the head in rabbits may develop secondary to dental disease, food or foreign body impaction between the gingiva and tooth, periodontal disease, tooth fracture, or tooth root abscess. Abscesses occur in rabbits of all ages and can be soft or firm. When the bone is involved, there is often bony swelling owing to the periosteal reaction. If the maxillary cheek teeth are involved, ocular discharge is observed owing to the involvement of the ipsilateral nasolacrimal duct. The wall of the abscess is commonly thick and contains bacteria. The pus is

usually caseous, thick, and creamy-white in appearance. Of all the abscesses occurring in rabbits, retrobulbar and dental abscesses are likely the most difficult to cure.

Diagnostics

Many rabbits with dental abscesses present with a swelling or a mass palpable during a physical examination. During a routine physical examination, the ventral mandible is palpated for any bumps. Bumps or scalloping along the ventral mandible is indicative of mandibular cheek teeth root disease resulting in cortical penetration.

Clinical work up includes a minimum data base including a complete blood count, serum biochemistry panel, and urinalysis. An oral examination is helpful in evaluating the crowns of the teeth for elongation, points, and other structural abnormalities; however, the extent of involvement of the reserve crowns, germinal tissue, and bone cannot be assessed by oral examination alone. Additionally, many attempt to evaluate the crowns in an awake rabbit. This is often difficult because the rabbit's mouth does not open very far, it chews constantly while the oral examination is being attempted, and it is difficult to evaluate all surfaces of the crowns. Because some type of imaging

modality (radiography or computed tomography) is essential when evaluating dental abscesses, an oral examination is best conducted under general anesthesia.

Skull radiographs under anesthesia are useful to evaluate for the presence and extent of infection. The four or five views recommended are a ventrodorsal or dorsoventral, a lateral, a left lateral oblique, and a right lateral oblique at a minimum. A rostrocaudal projection allows evaluation of the occlusal surface of the cheek teeth and for any bony proliferation of maxillary bone. Computed tomography (CT scan) has become more available in veterinary medicine and is far more useful for

evaluating the extent of dental disease.

Aspirates of the abscess are obtained to confirm the presence of pus and for cytologic and microbiologic evaluation. Cultures of aspirated pus have yielded higher quantities and more species of bacteria than intraoperative cultures of the abscess walls.[19] A positive preoperative culture is useful for starting antibiotic therapy prior to surgery as well as for deciding which antibiotics would be best for local therapy. Cytology, including a Gram's stain, is useful to confirm that the mass is an abscess and define the types of bacteria present. This is useful in deciding on antibiotic therapy prior to receiving culture results. Additionally,

some aspirates will fail to grow bacteria and the Gram's stain may be the only objective data on which to base antibiotic therapy.

Treatment

A variety of surgical therapies has been used in treating dental abscesses in rabbits with variable results. The traditional treatment of abscesses in mammals (lancing, draining, and flushing) is not effective in rabbits because the pus is too thick to drain effectively. Also typically fibrous tracts are present that contain bacteria, making recurrence common. As a result, the skin surface usually heals over before the infection has

completely been eliminated. This traps infected tissue below the skin surface and a new abscess develops at the same site. Failure to completely remove any teeth that are associated with the abscess will result in recurrence of the abscess regardless of the technique used because bad teeth and surrounding infected bone will serve as a nidus of infection.

The basic principles employed when treating a dental abscess in a rabbit are to remove all infected soft tissue including the abscess capsule, debride all infected bone, remove any teeth involved, minimize contamination of remaining tissues with pus, irrigate extensively, implant antibiotic-

impregnated polymethylmethacrylate (AI-PMMA) beads (Figure 119-4A, B, and C), and administer systemic antibiotic to treat any bacteremia that may result from the surgery.

The use of antibiotic impregnated polymethylmethacrylate beads, which release relatively high concentrations of antibiotic locally with little systemic absorption, is currently the recommended surgical option for rabbits with oral cavity abscesses.[20-25] It appears that antibiotics that are not safe when administered systemically in rabbits, such as cefazolin and clindamycin, are safe in AI-PMMA beads. Different antibiotics should not be mixed together in the same bead as

this has been shown to unacceptably alter the elution rate.[22] It is also important to refrain from using antibiotics in beads for which the elution rate and appropriate concentration are unknown, for example, enrofloxacin will not mix into PMMA. The rabbit should still be placed on systemic antibiotics for 2 to 3 weeks but long-term therapy is not needed as the beads release antibiotic for many months. The antibiotics chosen are based on culture and sensitivity or Gram's stain results.

Some teeth, even after they are removed, will grow back if the germinal bud remains viable. Because rabbit teeth grow continuously, the

question arises, if teeth are removed, is it necessary to remove the opposing teeth? This is not usually necessary. The maxillary teeth tend to grow and erupt at a slower rate than the mandibular teeth. Often, after the mandibular teeth are removed, the maxillary teeth stop erupting.[18] Some removed cheek teeth grow back because the germinal tissue is still healthy. Because of the extensive movement during chewing, even 2 to 3 teeth are often enough to wear the opposing teeth. Sometimes, the opposing teeth overgrow, in which case they either need to be trimmed on a regular basis (every 6 to 8 weeks) or they need to be removed.

Even after aggressive surgical debridement, rabbits recover quickly. Most begin eating within a couple of hours of surgery. It appears that removing the abscess helps resolve the pain associated with the abscess.

Figure 119-4. A. AI-PMMA is rolled out into fine tubular strips. B. The tubular strips are then cut into appropriate size pieces for the wound. The pieces are cut before the PMMA hardens. A scalpel blade works well for this. Bead makers are also available but are limited to one bead size. C. The beads are then placed in the wound. In this photograph, the beads are being used in a thoroughly debrided mandibular abscess in a rabbit.

Prognosis

In general, the prognosis for complete recovery without recurrence is fair to good using this technique. The best chance for surgical cure is with the use of CT imaging, aggressive removal of all grossly abnormal tissue including teeth and bone based on the CT images, and the implantation of PMMA beads impregnated with an appropriate antibiotic based on preoperative culture and sensitivity results. Even with all of this, dental abscesses in rabbits can be difficult to completely eliminate. Owners should be advised before surgery about the nursing care, frequency of follow-up visits, and financial commitment involved.

Gastric Stasis Syndrome (Ileus), Trichobezoar, and Gastrointestinal Foreign Body

The most common clinical problems in rabbits involve the gastrointestinal tract. Most of these are directly or indirectly related to diet.[26] Rabbits are unable to vomit because of the anatomic arrangement of the cardia and stomach.[26,27] The pylorus is easily compressed by the duodenum because it exits the stomach at a sharp angle.[2] The ileocecal junction is a common site for foreign body obstruction in rabbits.[2] The cecum of rabbits is thin-walled and holds 40% of the total gastrointestinal contents.[2] Rabbits are

hindgut cecal fermentors that efficiently ingest large quantities of poorly digestible fiber that is essential for normal peristalsis more than it is important for nutrition.[26,27]

Disease Mechanism of Trichobezoar and Gastric Stasis

It has previously been suggested that, when rabbits are fed a diet deficient in fiber or if gastric stasis occurs for another reason, trichobezoars can become a clinical problem by obstructing the pyloric outflow tract and proximal duodenum.[28,29] Although trichobezoars are described as a

clinical problem, it is now accepted that the presence of a trichobezoar is normal in rabbits and the illness is not directly related to the presence of a mass of hair and fiber. Rabbits that present with clinical signs of anorexia, lethargy, and mild abdominal distention that have radiographic evidence of a hairball are commonly ill for other reasons, most likely gastrointestinal ileus. Historically, rabbits with a trichobezoar were treated by gastrotomy to remove the hairball. Most of these rabbits did not survive because the mass of hair was not causing the illness and little attention was paid to managing the underlying ileus and dehydration. It is now accepted that the hairball is an

incidental finding and this syndrome is more accurately termed gastric stasis. It is best managed medically, not surgically.

In rabbits with dental disease, the discomfort associated with chewing food will cause rabbits to quickly decrease daily food intake and appears to be a common cause of ileus. Ileus is also commonly associated with a high-carbohydrate/low-fiber diet, stress, pain, and a lack of exercise.

Clinical Signs

Gastric stasis syndrome (ileus) is common in rabbits and is defined clinically by anorexia, decreased or no stool production, and a large stomach

typically containing a mass of fiber and hair along with gastric fluid.[26] If an underlying disease is present, clinical signs associated with that condition should be evaluated and treated concurrently with the gastric stasis.

Diagnostics

A detailed dietary history is an important part of the diagnostic investigation in rabbits with GI ileus. A complete blood count, serum biochemistry panel, and urinalysis should be performed to look for the underlying cause for the ileus. A dental examination should also be performed. If indicated, abdominal radiographs

and ultrasound should be performed.

Treatment

The most important aspects of medical management for rabbits with gastrointestinal stasis are fluid support, getting fiber into the GI tract to stimulate motility, administering GI motility-enhancing drugs, and providing nutritional support to minimize the risk of secondary hepatic lipidosis. Medical management usually includes intravenous fluid support because rabbits with GI stasis are typically dehydrated. Although most patients have a decreased appetite, many will still eat fresh leafy green vegetables. Eating such materials will

provide additional fluids, compared with dry hay or pellets, as well as fiber. If the patient will not eat, nasogastric intubation for alimentation may be necessary. Analgesics are often beneficial to palliate concurrent abdominal discomfort and increase the activity level of the rabbit, which may help stimulate GI motility.

The condition may be complicated by the presence of hepatic lipidosis secondary to the anorexia. Pelleted diets are relatively high in protein and carbohydrates, resulting in obesity and predisposing to hepatic lipidosis. Correcting the nitrogen balance will decrease the acidosis and ketosis, and counter the negative effects of the lipid

hepatopathy.

Disease Mechanism of Gastrointestinal Foreign Body

Carpet fiber is a common cause of foreign body obstruction seen in rabbits. Another cause of intestinal foreign body is a piece of gastric hairball that breaks off and migrates into the duodenum. Rabbits with GI foreign body obstruction can present with clinical signs similar to those of ileus, and both conditions can occur simultaneously. The disease process associated with GI foreign body is generally an acute condition that does

not allow time for the rabbit to adjust systemically. The acute distention of the stomach with gas and fluid, the inability of rabbits to vomit, and the pain associated with a foreign body obstruction make this disease in rabbits a rapidly life-threatening emergency.

Clinical Signs

Rabbits with gastrointestinal foreign body obstruction commonly present with acute depression and severe and rapid abdominal distention. They are typically much more critically ill than are rabbits with GI ileus alone.

Diagnostics

A complete blood count, serum

biochemistry panel, and urinalysis should be performed. Abdominal radiographs and ultrasound are useful in determining the presence of a foreign body obstruction. The presence of a mass of hair in the stomach is considered normal in rabbits and does not confirm a diagnosis of obstruction. Obstruction can cause an ileus pattern on radiographs; however, if the obstruction is at the pylorus or orad duodenum, only the stomach will be distended.

Treatment

Systemically ill rabbits must be stabilized with intravenous fluids and analgesics before definitive surgery is

performed. Gastric decompression by nasogastric or orogastric intubation or by trocharization is vital in critically ill patients. Routine exploratory laparotomy and gastrotomy with two-layer closure, as performed in dogs and cats, should be performed in rabbits with a gastric foreign body causing pyloric outflow obstruction. For an intestinal obstruction, enterotomies and intestinal resection and anastamosis are performed as needed. The small intestine of rabbits has a much thinner wall than that of dogs and cats. Surgical magnification and appropriate suture and atraumatic needle sizes are used. Postoperatively, rabbits should be treated with analgesics and for gastrointestinal

stasis as previously described.

Prognosis

Rabbits with GI foreign body obstruction do poorly postoperatively and have a high perioperative mortality rate compared with dogs and cats. These patients need to be rapidly stabilized and decompressed on presentation. Short anesthesia and operative times, aggressive analgesia, fluid therapy, and postoperative nutritional and GI motility support are vital.

Thymoma

The thymus in rabbits persists into

adult life, lies ventral to the heart, and extends to the thoracic inlet.[2] Thymomas in rabbits are infrequently reported, but make up as much as 8% of all neoplasms.[8,30] Two age groups appear to be affected. Genetically based thymomas occur in rabbits 1 to 4 years of age and have been associated with a systemic immunopathy and hemolytic anemia.[6,8] Older rabbits, 7 to 9 years of age, are affected with primary thymoma. Most of these tumors are diagnosed post mortem.

Disease Mechanism

The thymus is responsible for the normal development and regulation of the immune system.[31] Thymomas are

uncommon tumors in rabbits, dogs, and cats.[8,30,32,33] In dogs, cats, and humans, paraneoplastic syndromes associated with thymoma include myasthenia gravis, cytopenia, thyroiditis, hypogammaglobulinemia, and polymyositis.[32,33] Potential paraneoplastic conditions associated with thymoma in rabbits include hypercalcemia, systemic immunopathy, and hemolytic anemia.[6,8]

Clinical Signs

Clinical signs are variable and are related to a space-occupying mass in the cranial mediastinum or to the paraneoplastic processes. Rabbits can present with clinical signs including

respiratory distress and precaval syndrome (swelling of the head, exopthalmos, and prolapse of the third eyelids).[34-36]

Diagnostics

Complete blood count, serum biochemistry panel, and urinalysis should be performed. Thoracic radiographs of rabbits with thymoma reveal a cranial mediastinal mass (Figure 119-5). Because the radiographic density of the mass is the same as the heart, it is difficult to distinguish the two structures.[34-36] Ultrasound-guided transthoracic fine-needle aspiration and needle-core biopsy are helpful to evaluate the

extent of the mass, and to evaluate the heart and other thoracic structures as well as to rule out other causes of a cranial mediastinal mass. Although cystic and necrotic areas are commonly associated with thymomas, a diagnosis via fine-needle aspiration or needle-core biopsy is usually possible with ultrasound guidance.

CT or MRI is highly useful in evaluating the invasiveness of the mass and its association with vital thoracic structures. This can be valuable in planning the surgery and offering a prognosis.

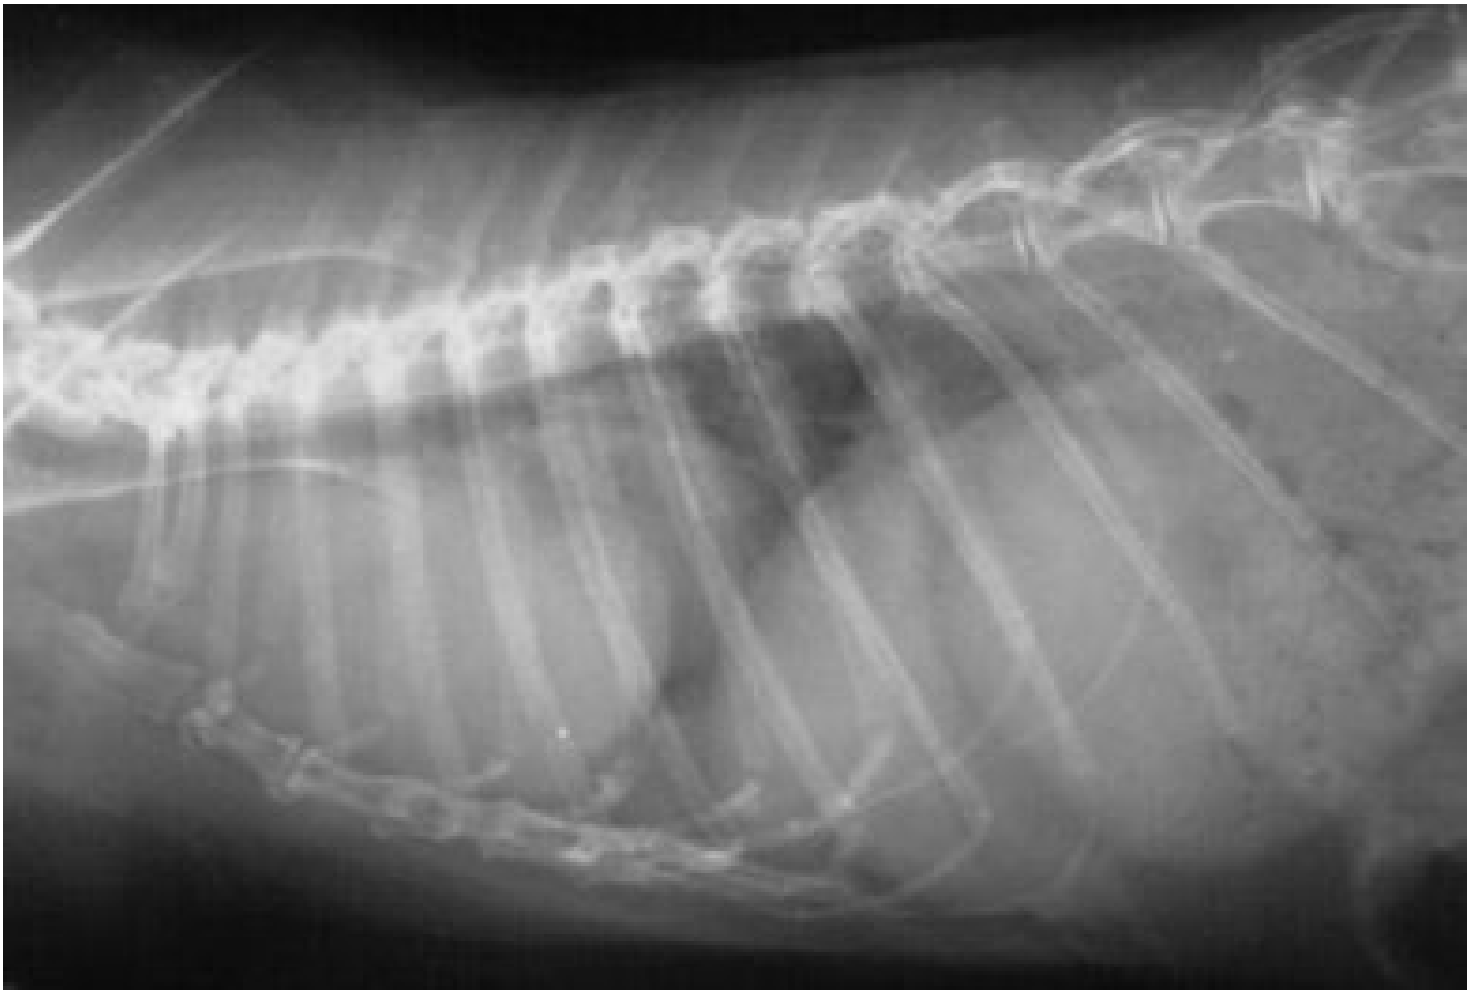

Figure 119-5. A right lateral thoracic radiograph in a rabbit with a thymoma. The cranial borders of the heart are obscured by a soft tissue opacity in the cranial mediastium.

Figure 119-6. A ventral approach to the thoracic cavity has been performed in a rabbit. The sternebrae of rabbits are usually too narrow to be able to split longitudinally. Therefore, it is best to disarticulate the ribs from the sternebrae on one side allowing the chest to be opened. A cranial mediastinal mass is noted with adhesions to the pericardium, aortic root, and cranial aspect of the heart.

Treatment

Thymomas are surgically resected using a ventral midline approach (Figure 119-6). The sternebrae of rabbits are usually too narrow to be able to split longitudinally. Therefore, it is best to disarticulate the ribs from the sternebrae on one side, allowing the chest to be opened. Invasion of the thymic capsule, vena cava, pericardium, pleura, and lung parenchyma can make complete resection difficult in some cases.[31] Care is taken to avoid important neurologic and vascular structures in the cranial thorax. Complications of thymoma removal include fatal hemorrhage, pneumothorax, and inadvertent damage to vital thoracic structures.[8,34-36]

Prognosis

If rabbits survive the postoperative period and the mass is completely removed, prognosis is good. Radiographic rechecks are recommended every 3 to 4 months for the first year to assess for evidence of recurrence. Recurrence following complete excision of a thymoma in rabbits has not been reported.

Vertebral Fracture, Subluxation, or Luxation

The most common cause of acute paraparesis or paraplegia in rabbits is vertebral body fracture, subluxation, or luxation.[37] Fractures are more common than luxations, with the most common

site of injury being the caudal lumbar vertebral bodies.

Disease Mechanism

Injury results from improper handling, from accidentally stepping on the rabbit, or when a caged rabbit is startled while in its enclosure. The heavily muscled hindquarters are allowed to twist at the lumbosacral junction, which acts as a fulcrum in applying leverage to the caudal lumbar vertebral column.[38] Also, the bones of rabbits are hard and brittle compared with those of dogs and cats. The bones of rabbits comprise only 8% of the total bodyweight, compared with 13% in cats.[39] The spinal cord in rabbits

extends all the way to the sacrum so even lower lumbar vertebral fractures in rabbits can results in upper motor neuron signs.

Clinical signs

Clinical signs are dependant on the location and severity of the injury to the spinal cord. In addition to paraparesis or paraplegia, loss of urinary and fecal continence, urine retention, and myelomalacia can occur. Again, it is important to note that, because the spinal cord ends at the sacrum, neurolocalization is dissimilar to that in cats and dogs.

Diagnostics

Diagnosis is based on a thorough neurologic examination and survey spinal radiographs. Magnetic resonance imaging (MRI), myelography, and/or computed tomography (CT scan), are useful for defining the nature of the injury and prognosis for neurologic recovery in preparation for surgery. MRI is preferred if available.

Treatment

Both medical management and surgical intervention have been applied to rabbits with spinal cord injury. Medical management includes strict cage rest, management of urine retention (UMN

lesion) or dribbling (LMN lesion), analgesics, nonsteroidal anti-inflammatories, and physical therapy. Surgical options depend on the location of the injury and whether the injury involves a fracture, instability, or both. Fixation of vertebral body fractures or instabilities can be performed with plates, pins and polymethylmethacrylate, screws and polymethylmethacrylate, or spinal stapling.

Prognosis

Prognosis depends on the severity of the neurologic deficits present during the perioperative period and the degree of displacement of the fracture

and/or luxation. Owners should be informed that nursing care will be intensive regardless of whether medical or surgical options are pursued. Loss of deep pain perception in the limbs is usually considered a poor prognostic indicator for the return of neurologic function in rabbits suffering from a vertebral body luxation or fracture.
