Numbers in parentheses are percentage of strains giving positive reaction.

in patients with underlying disease.[749,898,1018] It has been reported that *A. xylosoxidans* colonizes the respiratory tract of intubated children and patients with CF and that colonization of patients with CF is associated with an exacerbation of pulmonary symptoms.[305,942] *A. xylosoxidans* has been shown to be the predominant *Achromobacter* species isolated from CF patients around the world.[25,68,263,882,1023]

A. ruhlandii was originally described as a soil commensal and not thought to be pathogenic to humans.[553] However, in a study by Spilker and colleagues on the distribution of *Achromobacter* species in CF patients, *A. ruhlandii* was found to be the second most commonly isolated species after *A. xylosoxicans* accounting for 23.5% of the isolates.[1023]An exceptionally resistant clone of *A. ruhlandii*, designated the Danish epidemic strain (DES), spread among CF patients in Denmark in 2006 and could not be stopped despite aggressive infection control measures.[904,905] Species of *Achromobacter* recovered from CF patients are frequently misidentified using biochemical reactions.[904,905] 16S rRNA sequencing is also not able to discriminate

among different *Achromobacter* species.[825,1022] Papalia reported that identification of *A. ruhlandii* can be achieved by sequencing a single OXA gene (gene $bla_{\text{oxa-258}}$).[825]

Four new saccharolytic species of *Achromobacter* representing different MLST genogroups have recently been named. The new species are *A. insuavis* (genogroup 2), *A. aegrifaciens* (genogroup 5), *A. anxifer* (genogroup 7), and *A. dolens* (genogroup 14). All have been isolated from human sputum in patients with and without CF.[1112]

Genus *Advenella.* *Advenella* is in the family *Alcaligenaceae* and consists of four species: *A. faeciporci, A. incenata, A. kashmirensis,* and *A. mimigardefordensis* that are mainly found in soil, sludge, and compost. Only *A. incenata* has been isolated from various human and veterinary clinical samples.[224] *Advenella incenata* is a gram-negative, small (1 to 2 μm), rod-shaped or coccoid bacterium that occurs singly, in pairs, or in short chains.[224] On nutrient agar, colonies are flat or slightly convex with smooth margins and appear light brown in color.[224] They are oxidase and catalase positive. Motility and oxidation of OF glucose are strain dependent. They are uniformly negative for amylase, lysine and ornithine decarboxylase, arginine dihydrolase, gelatinase, DNase, ONPG, esculin hydrolysis, and indole production (Table 7-16). Isolates have been recovered from human blood, sputum, and wound specimens.[224]

Genus *Bordetella.* Currently the genus *Bordetella* comprises eight species, four are motile with peritrichous flagella (*B. avium*, *B. bronchiseptica*, *B. hinzii*, *B. trematum* [Table 7-16]) and four are nonmotile (*B. holmesii*, *B. pertussis*, *B. parapertussis*, *B. petri* [Table 7-18]). The three most common human species, *B. pertussis*, *B. parapertussis,* and *B. bronchiseptica*, cannot be differentiated genotypically through DNA homology studies and are likely subspecies or strains of a single species with different host adaptations.[827] Phenotypically they behave quite differently, however. *B. bronchiseptica* is motile by means of peritrichous flagella and grows readily on ordinary media, whereas *B. pertussis* and *B. parapertussis* are both nonmotile. *B. pertussis* requires special media for growth, whereas *B. parapertussis* will grow on blood, chocolate, and MacConkey agars. *B. pertussis* and *B. parapertussis* are the etiologic agents of whooping cough and are discussed in detail in Chapter 9 with the fastidious gram-negative rods.

Bordetella bronchiseptica. Colonies of *B. bronchiseptica* grow well on blood and MacConkey agar and in 24 hours appear as smooth, translucent, colorless colonies about 1.5 mm in diameter. On Gram's stain, the organisms appear small and coccobacillary. They have the distinguishing biochemical feature of rapidly converting Christensen's urea agar (Image Plate 7-2A). Other distinguishing features are given in

Table 7-16. *B. bronchiseptica* is found in the respiratory tract of domestic and wild mammalian animals including dogs, cats, rabbits, rodents, horses and pigs ("bronchiseptica" is derived from the Greek word *bronchus*, meaning "trachea"). It is an infrequent isolate in the clinical laboratory, and only a few human infections have been reported in the literature.[364] Pedersen and coworkers[829] reported the recovery of only 12 strains of *B. bronchiseptica* from a total of 565 nonfermenters, all of which were from respiratory specimens obtained from patients who were free of infections. Most symptomatic infections have been in animal caretakers who presented with mild pertussis-like symptoms. Ghosh[364] reported fatal *B. bronchiseptica*-induced septicemia and bronchopneumonia in a malnourished patient with alcoholism, which indicates that the organism can be virulent under the right circumstances. Woolfrey and Moody reviewed 25 cases of human *B. bronchiseptica* infection associated with sinusitis, tracheobronchitis, acute pneumonia, pneumonia with septicemia, septicemia, and whooping cough.[1191] For the whooping cough cases, it is likely that *B. bronchiseptica* acted as a colonizer and not as the cause. *B. bronchiseptica* has been reported to cause pneumonia in patients with AIDS,[23,267,272,307,351,664,727,782,1189] acute leukemia,[383] CF,[1154] and thoracic trauma[889] and following bone marrow[79,194] or heart transplantation.[175] There have been two reports of bronchitis caused by *B. bronchiseptica*, one in an elderly woman[841] and one in an immunosuppressed patient.[723] Two patients with meningitis,[84,169] one patient with endocarditis,[359] and one patient with a pancreatic abscess with associated bacteremia[714] due to *B. bronchiseptica* have also been reported. These highlight the fact that *B. bronchiseptica* can be associated with severe disease. A review of the microbiolgic and clinical aspects of respiratory infections associated with *B. bronchiseptica* has been provided by Garcia-de-la-Fuente et al.[349] Most strains of *B. bronchiseptica* are susceptible to most antibiotics, with the exception of ampicillin, cefamandole, and cefoxitin.[385,593]

Bordetella ansorpii. *B. ansorpii* was first described in 2005 and was isolated from a purulent epidermal cyst but its pathogenic significance was unclear.[580] A second report was published in 2007 wherein an 88-year-old man with leukemia developed positive blood cultures.[340] The organism is described as a motile, gram-negative bacillus that grows on both blood agar and MacConkey agar and is oxidase negative. It is also negative for indole production, urease, arginine dihydrolase, esculin and gelatin hydrolysis, ONPG, nitrate reduction, and is asaccharolytic.[580]

Bordetella avium. *B. avium* is a pathogen for birds causing coryza or rhinotracheitis in poultry, especially in turkeys.[554] Similar to the species in the *B. bronchiseptica* complex, *B. avium* exhibits a strong tropism for the ciliated epithelium of the upper respiratory tract.

Bordetella hinzii. *B. hinzii* was formerly referred to as *Alcaligenes faecalis* type II, or *B. avium*–like, and has been isolated from the respiratory tracts of chickens and turkeys in various parts of the world. Human isolates have been recovered from blood,[228,544] and sputum,[347,1109] including repeated isolations from the sputum of a patient with CF.[345] *B. hinzii* has also been isolated from multiple biliary specimens collected over 6 months from a liver-transplant recipient with cholangitis.[45] *B. hinzii* are motile and oxidase positive and must be distinguished from phenotypically similar organisms, as shown in Table 7-16.

Bordetella holmesii. Strains of *B. holmesii* have been recovered mostly from human blood.[405,646,717,747,786,978,1058,1171] Shepard and colleagues at the CDC analyzed the clinical histories of 30 patients with *B. holmesii* bacteremia whose isolates were submitted to CDC for identification. Of the 26 patients for whom data were available, 22 (85%) were anatomically or functionally asplenic. *B. holmesii* was the only organism isolated from the blood samples in 25 (96%) of the 26 patients.[978] Despite initial reports that *B. holmesii* does not cause respiratory disease, patients may be either infected or colonized with *B. holmesii* in their nasopharynx. Scientists from the Massachusetts State Laboratory Institute reported the isolation of *B. holmesii*, but not *B. pertussis*, from 32 nasopharyngeal specimens collected over a 3-year period from patients with pertussis-like symptoms.[717,1207] Several studies have shown that *B. holmesii* can give strong positive results with PCR assays targeting IS *481* of *B. pertussis*, thus confounding the diagnostic reliability of such assays.[659,660,896] Russell and colleagues reported a patient with interstitial and lobar pneumonia with progression to pulmonary fibrosis caused by *B. holmesii*.[933] *B. holmesii* is reported to be susceptible to amikacin, ampicillin, cefazolin, cefotaxime, ceftazidime, chloramphenicol, gentamicin, mezlocillin, trimethoprim–sulfamethoxazole, imipenem, ciprofloxacin, and piperacillin–tazobactam.[1058] *B. holmesii* was formerly classified as CDC Group NO-2 and is nonmotile and oxidase negative, making it phenotypically similar to *Acinetobacter* species and CDC Group NO-1 (Table 7-18). Additional morphologic and phenotypic characteristics are given under the heading "Organisms That Are Nonmotile and Oxidase Negative."

Bordetella petrii. *B. petrii* is nonmotile and oxidase positive. It has been isolated mainly from the environment and is the only member of the genus capable of anaerobic growth.[1152] More recently *B. petrii* has been isolated from clinical specimens linked to sinusitis,[767] septic arthritis and osteomyelitis,[788] mandibular osteomyelitis,[341] mastoiditis,[1027] and chronic pulmonary disease[616] and from respiratory samples and a postmortem spleen sample of a patient presenting with

bronchiectasis and cavitary lung disease associated with a nontuberculous mycobacteria infection.[1215] *B. petrii* has also been reported in respiratory specimens from patients with CF.[737,1020]

Bordetella trematum. *B. trematum* is oxidase negative and motile with peritrichous flagella. Growth occurs on

MacConkey agar and malonate is utilized. Other biochemical reactions are given in Table 7-16. Strains have been isolated from ear infections and wounds of humans, but not from respiratory specimens.[1105] Dorittke et al.[294] had described the isolation of a "*B. avium*-like organism" from a patient with chronic otitis media, whereby the respective isolate (strain LMG 13506) was later reclassified as *B. trematum*.[1105] Daxboeck et al.[259] reported the isolation of *B. trematum* from a diabetic foot ulcer; however, there was no evidence for a causative role of the organism in the foot infection. A summary of *B. trematum* reported cases human infection has been

provided by Almagro-Molto et al.[12]

Genus *Kerstersia*

Kerstersia gyiorum. Coenye and colleagues have described a novel genus, *Kerstersia* gen. nov. with a single species *K. gyiorum* (Greek *gyion,* meaning "limb": referring to the fact that the majority of strains were isolated from human leg wounds).[217] These bacteria appear as gram-negative, small (1 to 2 μm long), coccoid cells that occur singly, in pairs or in short chains. On nutrient agar, colonies are flat or slightly convex, with smooth margins and color ranging from white to light brown. Growth occurs at 28°C and 42°C, motility is strain dependent, and all strains are asaccharolytic. All strains are catalase positive but are negative or slow positive for oxidase. Arginine, lysine, and ornithine decarboxylase, β-galactosidase, gelatinase, urease, DNase, reduction of nitrate and nitrite, esculin, and starch hydrolysis are all negative (Table 7-16). In our experience, *K. gyiorum* grows well on both BAP and MacConkey, producing characteristic dull, flat, spready colonies that give a swarming appearance (Image Plate 7-5F, 7-5G). In the original description, *K. gyiorum* was isolated from various human specimens, including feces, sputum, and leg and ankle wounds; however, the clinical significance was unknown.[217] Serious infections caused by *K. gyiorum* have subsequently been reported and include chronic ear infections,[15,765,836] chronic leg wound[836] and bronchoalveolar lavage fluid from a patient with a chronic tracheostomy.[282] We have isolated three strains at Loyola University Medical Center from urine, leg wound, and tracheal aspirate. Our strains and those from three published reports were unambiguously identified with MALDI-TOF MS using the Bruker BioTyper (software version 3.1).[282,765,836]

Kerstersia similis. A second species of *Kerstersia*, *K. similis*, has been described for a genospecies that biochemically resembles strains of *K. gyiorum*. Identification can only be obtained with genetic typing or carbon assimilation using the Biolog GEN III system.[1101]

Genus *Oligella*

The genus *Oligella* consists of two species: *O. urethralis* (formerly *Moraxella urethralis* and CDC group M-4) and *O. ureolytica* (formerly CDC group IVe).[925] One species is oxidase positive and motile with pertitrichous flagella (*O. ureolytica*), whereas the other species is oxidase positive and nonmotile but will be discussed here for the purpose of continuity.

Oligella ureolytica. Colonies of *O. ureolytica* are first seen as slow-growing on blood agar medium, producing pinpoint colonies after 24 hours but large colonies after 3 days of incubation. Colonies are white, opaque, entire, and nonhemolytic. *O. ureolytica* strains phenotypically resemble asaccharolytic *Achromobacter* species, *Bordetella bronchiseptica* and *Cupriavidus pauculus*, in that they are

nonsaccharolytic, oxidase positive, and motile by means of peritrichous flagella. They differ from *Achromobacter* species by their ability to rapidly hydrolyze urea in Christensen's urea agar. Additional differentiating features are shown in Table 7-16. Most isolates have been obtained from human urine, often in patients with long-term indwelling catheters. *O. ureolytica* bacteremia has been reported in several patients with varying predisposing conditions, including a patient with obstructive uropathy,[913] a patient with AIDS,[689] an 18-month-old child with pneumonia,[615] a newborn infant[275] and a cancer patient.[70] *O. ureolytica* tends to be susceptible to most antibiotics, although there is one report of a highly resistant strain that demonstrated in vitro resistance to the penicillins, cephalosporins, imipenem, meropenem, ciprofloxacin, and trimethoprim–sulfamethoxazole, but was susceptible to the aminoglycosides, tetracycline, and levofloxacin.[615]

Oligella urethralis. *O. urethralis* is similar to *Moraxella* species in that isolates are coccobacillary, oxidase positive, nonmotile, and gram-negative bacteria. Colonies are smaller than those of *M. osloensis* and are opaque to whitish. *O. urethralis* and *M. osloensis* share additional biochemical similarities (e.g., accumulation of poly-β-hydroxybutyric acid and failure to hydrolyze urea), but can be differentiated on the basis of nitrite reduction, growth at 42°C, and alkalinization of formate, itaconate, proline, and threonine (all positive in *O. urethralis*, negative in *M. osloensis*).[853] Cellular fatty acid analysis can also be used to differentiate these two species.[1172] Biochemical features that help differentiate *O. urethralis* from *Moraxella* species are shown in Table 7-21. As the name indicates, *O. urethralis* is most frequently recovered from urethral specimens and is considered a commensal of the genitourinary tract; however, in rare cases it may lead to urosepsis.[871] There has been one report of *O. urethralis* infectious arthritis in a patient wherein the presentation clinically mimicking gonococcal arthritis.[728]

Family Rhodobacteriaceae

Genus *Pannonibacter* and *Achromobacter* Groups A–F. Holmes and colleagues separated achromobacters into six groups (A–F) based on genetic patterns.[457] *Achromobacter* groups A, C, and D constitute a single species and were found to be identical to *Ochrobactrum* anthropi (discussed later in this chapter).[465] *Achromobacter* groups B and E constitute biotypes of a single genus and species.[455,456,459] that was confirmed by Holmes et al.[466] to be identical to a previously described taxon, *Pannonibacter phragmitetus*.[112] *Achromobacter* group F, however, is genetically distinct from groups B and E and is currently unnamed.[455,456] The biochemical tests useful for separation of *Achromobacter* groups A–F from phenotypically similar

bacteria have been reported by Holmes and coworkers.[464] *P. phragmitetus* can be separated from *O. anthropi* by the properties of being ONPG and esculin positive and failing to produce acid from adonitol and dulcitol.[459] *Achromobacter* Group F are similar to *O. anthropi* except that they do not produce gas from nitrite and fail to grow on MacConkey agar (Table 7-17). *P. phragmitetus* biovar B has been isolated from the blood of patients with septicemia[455,458,512] and one patient with

replacement-valve endocarditis.[721] Isolates of *P. phragmitetus* biovars E and F have also been recovered from blood.[455,456]

Family Rhizobiaceae

The only medically important member of the family *Rhizobiaceae* is the genus *Rhizobium*. However, members of the genus *Rhizobium* are phenotypically similar to saccharolytic *Achromobacter* species and *Ochrobactrum anthropi*, from which they must be differentiated. Characteristics that are useful in separating these organisms are given in Table 7-17.

Genus *Rhizobium* (Formerly *Agrobacterium*). The former genus *Agrobacterium* contained several species of plant pathogens occurring worldwide in soils.[552] As a result of a large number of comparative studies, four distinct species of *Agrobacterium* were recognized: *Agrobacterium radiobacter* (formerly *A. tumefaciens* and CDC group Vd-3), *Agrobacterium rhizogenes* (subsequently transferred to the genus *Sphingomonas* as *S. rosa*),[1054] *Agrobacterium vitis*,[803] and *Agrobacterium rubi*.[952] The separation of the phenotypically indistinguishable species *A. tumefaciens* and *A. radiobacter* was based on the presence of a plant tumor-inducing plasmid, present in *A. tumefaciens* and absent in *A. radiobacter*. Genetic studies showed that the two species were the same, and a proposal was made to reject the name *A. tumefaciens* and to designate *A. radiobacter* as the type species for the genus *Agrobacterium*.[952] Young and colleagues[1210,1211] proposed an emended description of the genus *Rhizobium* to include all species of *Agrobacterium*. Following this proposal, the new combinations are *Rhizobium radiobacter, R. rhizogenes, R. rubi,* and *R. vitis*.[1210] Farrand and colleagues have presented evidence from classical and molecular comparisons that support the conclusion that agrobacteria biovars 1 and 3 are sufficiently different from members of the genus *Rhizobium* to warrant retention of the genus *Agrobacterium*.[323] No doubt, the final chapter on the classification of *Agrobacterium radiobacter* has not been written, and the controversy is likely to

continue for some years; however, for the purposes of this textbook, we have decided to accept the arguments set forth by Young and colleague[1211] and will refer to this bacterium as *Rhizobium radiobacter*.

Rhizobium radiobacter. The key biochemical tests used in differentiating *R. radiobacter* from the closely related species *Ochrobactrum anthropi* are given in Table 7-17. Key features for this group of organisms are a rapid urease reaction and a positive test for phenylalanine deaminase. Colonies of *R. radiobacter* grow optimally at 25°C to 28°C, but will grow at 35°C as well. They appear circular, convex, smooth, and nonpigmented to light beige on blood agar. Colonies may appear wet and become extremely mucoid and pink on MacConkey agar with prolonged incubation (Image Plate 7-4B). *R. radiobacter* is occasionally isolated from clinical specimens but only rarely linked with human infection. In reports of human infection, *Rhizobium* has been most frequently isolated from blood,[105,142,306,309,311,336,418,687,860,867,916,1178] followed by peritoneal dialysate,[425,914,916] urine,[21,916] and ascitic fluid.[879] The majority of infections have occurred in patients with transcutaneous catheters or implanted biomedical prostheses, and effective treatment often requires removal of the device.[105,306,309,311,336,418,860,867,916,1178] Lai and colleagues examined the medical records of 13 patients with *R. radiobacter* infections during a 7-year period. Ten (76%) had underlying hematologic malignancy or solid-organ cancer. Six (46%) had febrile neutropenia during the course of their infection. Fifty-four percent of the infections were catheter-related bacteremia, and 92% were hospital-acquired.[601] Two cases of *R. radiobacter* endophthalmitis subsequent to cataract extraction have also been reported.[736,769] Antimicrobial susceptibility is variable, and requires testing of individual isolates. Lai et al.[601] reported that all isolates tested in their series were susceptible to cefepime, piperacillin–tazobactam, carbapenems, and ciprofloxacin.

Family Brucellaceae

Genus *Ochrobactrum*

Ochrobactrum anthropi. *O. anthropi* is the name given to the urease-positive "*Achromobacter*" species formerly designated CDC group Vd-1 and Vd-2 and *Achromobacter* groups A, C, and D of Holmes et al.[464,465] Subsequent studies have shown, however, that biogroup C and some strains belonging to biogroup A constitute a homogeneous DNA–DNA hybridization group separate from *O. anthropi* that has been given the new species designation of *Ochrobactrum intermedium*.[1132] Both *Ochrobactrum* species are closely related to *Brucella* spp., with *Ochrobactrum intermedium* occupying a phylogenetic position that is intermediate between *O. anthropi* and *Brucella*.[1132] The two species share identical phenotypic properties. They are oxidase positive, saccharolytic and motile by means of peritrichous flagella.

Good growth is observed on routine media in 24 hours. Colonies are about 1 mm in diameter and appear circular, low convex, smooth, shining, and entire. Isolates we have observed grow readily on MacConkey agar, and colonies appear mucoid. Key tests useful in distinguishing *O. anthropi* from related organisms include their ability to hydrolyze urea, inability to hydrolyze esculin, and a negative ONPG test. Additional biochemical tests useful in differentiating *O. anthropi* from *Rhizobium* species and saccharolytic *Achromobacter* species are shown in Table 7-17.

All strains of *O. anthropi* have thus far been recovered from human clinical specimens (*anthropi* is derived from Greek and means "of a human being"). Strains have been isolated predominantly from blood, wounds, urogenital tracts or urine, respiratory tracts, ears, feces, an eye, and CSF.[36,69,133,167,465,511,686,1124] Of particular concern are recent reports of CVC-related sepsis caused by *O. anthropi*.[20,198,393,415,550,573,937,1031] Isolation of this organism from blood should raise suspicion of CVC-related infection. Opportunistic infections and nosocomial outbreaks of *O. anthropi* are being increasingly reported. There has been one report of a patient who developed septic shock following peripheral venous infusion of a solution contaminated with *O. anthropi*,[555]and another of nosocomial bacteremia in five organ-transplant recipients following infusion of contaminated anti-thymocyte globulin.[321] Patients with infective endocarditis due to *O. anthropi* have also been reported.[683,919] The clinical characteristics of *O. anthropi* bacteremia have been reviwed by Hagiya and colleagues.[416] A review of *O. anthropi* infection in immunocompetent hosts has been provided by Vaidya et al.[1093]

376

O. anthropi is reported to be susceptible to aminoglycosides, carbenicillin, fluoroquinolones, imipenem, tetracycline, and trimethoprim–sulfamethoxazole, but resistant to other antimicrobial agents.[101,367,550,1146]

Ochrobactrum intermedium. There are no biochemical tests currently available that separate *O. intermedium* from *O. anthropi*; however, it has been suggested that colistin (polymyxin E) and polymyxin B resistance can be used to separate *O. intermedium* (resistant) from *O. anthropi* (susceptible).[1132] One patient with a pyogenic liver infection due to *O. intermedium* has been reported[741]; however, because of the close phenotypic similarity between *O. anthropi* and *O. intermedium*, it is possible that certain infections thought to be caused by *O. anthropi* were actually caused by *O. intermedium*.

Organisms That Are Nonmotile and Oxidase Positive

Family Flavobacteriaceae

Vandamme and colleagues have reported that none of the established species of flavobacteria were closely related to the type species *F. aquatile*; therefore, they proposed that the generically misclassified organisms *F. balustinum*, *F. gleum*, *F. indologenes*, *F. indoltheticum*, *F. meningosepticum,* and *F. scophthalmum* be included in a new genus, *Chryseobacterium,* with *C. gleum* as the type species.[1098] These same authors reported that *Flavobacterium breve* represented a distinct genetic taxon and proposed the name *Empedobacter brevis* for this species.[1098] Furthermore, *Flavobacterium odoratum* was found to comprise two distinct species, which have been renamed *Myroides odoratus* and *Myroides odoratimimus*.[1096] In 2005, Kim et al.[566] proposed the transfer of *C. meningosepticum* and *C. miricola* to a new genus, *Elizabethkingia* gen. nov., with the names *Elizabethkingia meningoseptica* and *Elizaethkingia miricola*. An outline of the current classification and nomenclature for the medically important members of the family *Flavobacteriaceae* is given in Box 7-10.

Interestingly, none of the remaining *Flavobacterium* species are found in human clinical specimens, and none are indole positive—a feature that has been synonymous with the genus *Flavobacterium* in the past. The key differentiating features of the clinically significant members of the family *Flavobacteriaceae* and related bacteria are given in Tables 7-19 and 17-20. Most species produce yellow-pigmented colonies on blood agar medium, and all are oxidase positive. All species are nonmotile and negative for nitrate reduction, and most species fail to grow on MacConkey agar. Most species (except *Weeksella virosa*) are polymyxin-resistant, a property they share with the pseudomallei group discussed elsewhere in this chapter. Only the clinically significant members of the *Flavobacteriaceae* will be discussed further in this chapter. The taxonomic dilemma of *Flavobacterium* and *Sphingobacterium* has been reviewed in detail elsewhere.[92,981,1098,1195]

Genus *Chryseobacterium*. These former *Flavobacterium* species occur naturally in soil, water, plants and foodstuffs. In the hospital environment they exist in water systems and on wet surfaces. They are readily distinguished from other nonfermenters by their ability to produce indole in tryptophan broth (Image Plate 7-2C). Often the indole reaction is weak and difficult to demonstrate; therefore, the more sensitive Ehrlich method (discussed earlier in this chapter) should be used. *C. indologenes* is easily recognized by the production of dark-yellow colonies (Image Plate 7-4C). *E. meningoseptica*, in contrast, produces colonies with a very pale yellow pigment that

may not be evident on initial examination of colonies at 24 hours. Colonies of *Empedobacter brevis* are pale yellow. Pigment production may be augmented by incubating the culture for an additional 24 hours at room temperature. The *Chryseobacterium* species generally grow poorly, or not at all, on MacConkey agar and are considered to be glucose oxidizers, although most strains will slowly ferment glucose after prolonged incubation. Microscopically, cells of *E. meningoseptica,*

BOX 7-10

Description of Medically Important Members of the Family *Flavobacteriaceae*

Genus: *Flavobacterium*

Type genus consisting of 121 species isolated from aquatic environments. Not associated with human infection

Genus: *Bergeyella*

B. zoohelcum
B. cardium

Genus: *Capnocytophaga*

C. canimorsus
C. cynodegmi
C. gingivalis
C. granulosa
C. haemolytica
C. leadbetteri
C. ochracea
C. sputigena

Genus: *Chryseobacterium*

87 species described but only two associated with human infection
C. gleum
C. indologenes

Genus: *Elizabethkingia*

E. anophelis
E. meningoseptica
E. miricola

Genus: *Empedobacter*

E. brevis

E. falsenii

Genus: *Myroides*

Eight species described but only two associated with human infection

M. odoratus

M. odoratimimus

Genus: *Weeksella*

W. virosa

377

C. indologenes, and groups IIe, IIh, and IIi are thinner in their central region than in their peripheral portions and include filamentous forms; IIh cells are significantly smaller than those of other species. It should be emphasized that test results (e.g., DNase, indole, urea, starch hydrolysis) in this group are dependent on the choice of medium, reagents, and length of incubation.[847] *Chryseobacterium indologenes, C. gleum*, and CDC Group IIb are tabulated individually in Table 7-19. Group IIb is genetically heterogeneous and includes strains of *C. indologenes, C. gleum*, and probably additional genomospecies. Additional DNA–DNA hybridization studies will be required to resolve this issue. Phenotypic separation between *C. indologenes* and *C. gleum* has been difficult; however, acid production from xylose and growth at 41°C are consistently positive in DNA groups clustering around the type strain of *C. gleum*.[1091] Additional characteristics separating the members of this group of organisms can be found in Table 7-19.

Chryseobacterium indologenes. *C. indologenes* (formerly *F. indologenes* and CDC group IIb) is the most frequent human isolate, although it rarely has clinical significance.[1146] It has been documented to cause bacteremia in hospitalized patients

with severe underlying disease, although the mortality is relatively low even among patients who were administered antibiotics without activity against *C. indologenes*.[484] Nosocomial infections due to *C. indologenes* have been linked to the use of indwelling devices during a hospital stay.[487,490,779,793] Rare instances of pneumonia,[487,490,779] meningitis and central nervous system infection,[315,435,798] wound infection,[487,490] keratitis,[670] urinary infection,[5,487] peritonitis,[6] and bacteremia[56,317,397,484,487,490,720,793] have been reported.

Chryseobacterium hominis. *C. hominis* is a new species of *Chryseobacterium* proposed in 2007 for a collection of clinical isolates that were characterized biochemically as being similar to CDC groups IIh and IIc.[1121] All strains are nonmotile, oxidase, and catalase positive. Growth occurs at 30°C and 37°C with optimal growth at 30°C. No growth occurs on MacConkey agar, cetrimide agar, or 3% NaCl agar. Colonies are circular and mucoid; some are also sticky. Some strains exhibit a pale yellow or tan pigment. Acid is produced in OF glucose and OF maltose, but not OF mannitol. All strains are positive for indole production, hydrolysis of esculin, starch, and gelatin. Acid production from sucrose and reduction of nitrate and nitrite are variable.

379

All strains are negative for growth at 42°C, urease, H_2S on Kligler's agar, ornithine and lysine decarbosylase, arginine dihydrolase, alkalinization of Simmons' citrate, L-phenylalanine deaminase, and ONPG.[1121] Clinical isolates in the initial report were recovered from blood, dialysis fluid, pus, infraorbital drain, eye, and aortic valve. The clinical significance of these isolates was not reported.[1121] A 58-year-old man with Parkinson's disease who presented to the emergency room at Loyola University Chicago Medical Center with a 2-day history of nausea and vomiting was found to have *C. hominis* bacteremia. He reported having intermittent abdominal pain localized to the epigastric region. He was dizzy upon standing or sitting up, and his serum lactate was elevated. Review of systems was otherwise normal. Blood cultures from the day of admission grew coagulase-negative *Staphylococcus* (likely contaminant) and an indole-positive, glucose nonfermenting gram-negative rod. The isolate was identified by MALDI-TOF MS as *C. hominis* (top rank) with a value score of 1.695 using the Bruker Daltonics MicroFlex LT instrument, biotyper software 3.1. The identification was confirmed by 16S rRNA sequencing as *C. hominis* (Schreckenberger P, personal communication).

Genus *Elizabethkingia*

Elizabethkingia meningoseptica. *E. meningoseptica* (formerly *Flavobacterium*

meningosepticum and CDC group IIa)[566] is the species most often associated with significant disease in humans. In adults, it has been reported to cause pneumonia, endocarditis, wound infections, postoperative bacteremia, and meningitis, usually in patients with severe underlying illness.[50,104,190,233,342,424,443,526,617,640,688,801,811,908,979,1066,1168] It is highly pathogenic for premature infants and has been associated with neonatal meningitis.[190,233,358,427,462,568,677,861,908,1072] Although neonatal meningitis is only rarely encountered, it is important to diagnose the disease accurately because epidemics may occur in nurseries, and a mortality rate as high as 55% has been reported.[1146] *E. meningoseptica* has increasingly been reported as a cause of healthcare-associated infections. A cluster of four patients with ventilator-associated pneumonia was reported in an intensive care unit traced to contaminated humidifier water.[176] *E. meningoseptica* has also been reported to cause infections in patients receiving hemodialysis[837] and healthcare-associated bacteriuria primarily in elderly patients with diabetes.[1220] Jean et al.[508] have reviewed the incidence, predisposing factors, clinical features, and measures for the prevention and control of infections caused by *E. meningoseptica.*

Elizabethkingia miricola. *E. miricola* is a nonmotile, nonfermenting rod that was first described in 2003 when it was isolated from condensation water on the Russian space station Mir.[639] It was initially named *Chryseobacterium miricola* but was reclassified as a species of *Elizabethkingia* in 2005.[566] The only confirmed clinical isolate of *E. miricola* was from the sputum and blood of a man with mantle cell lymphoma who had undergone stem cell transplant and chemotherapy and required ventilator support.[398] Good growth is observed on MacConkey agar. Colonies are very sticky on solid medium. Indole is produced and urea is hydrolyzed. Acid is produced from fructose, glucose, lactose, maltose, mannitol, and trehalose, but not from arabinose, cellobiose, raffinose, sucrose, salicin, or xylose.[566] *E. miricola* has a biochemical profile similar to *E. meningoseptica*, but can be differentiated by a positive urease reaction. (Table 7-19) Several authors have reported misidentification of *E. meningoseptica* as *E. miricola* when performing MALDI-TOF MS using the Bruker Daltonics MicroFlex LT instrument, biotyper software 3.0 and 3.1.[14,724,960]

Elizabethkingia anophelis. *E. anophelis* is a recently discovered bacterium isolated from the midgut of the *Anopheles gambiae* mosquito.[536] It is a gram-negative, nonmotile, non–spore-forming rod. Oxidase and catalase are positive. Colonies on nutrient agar are smooth, yellowish, translucent, and shiny. No growth occurs on MacConkey agar. Acid is produced from glucose, lactose (weak), mannitol, maltose, rhamnose, sucrose, trehalose, and cellobiose (weak). Esculin, indole, and ONPG are positive. Urease, hydrolysis of gelatin, starch, DNA, and tyrosine are negative. Arginine dihydrolase, lysine and ornithine decarboxylase, and utilization of malonate

are negative.[536] (Table 7-19) *E. anophelis* has been reported in three patients with sepsis involving two neonates who had meningitis and one neonate's mother who had chorioamnionitis.[612] It has also been reported to cause meningitis in an 8-day-old girl delivered by cesarean section in the Central African Republic.[333] A nosocomial outbreak of *E. anophelis* was reported in an intensive care unit in Singapore.[1065] The outbreak involved five patients who were ventilated via tracheostomy and had CVCs. Isolates recovered from the sputum and blood specimens of the infected patients were related to strains isolated from hand hygiene sink aerators in the cardiothoracic and surgical ICUs where the patients were housed.[1065]

The appropriate choice of effective antimicrobial agents for treatment of *Chryseobacterium* and *Elizabethkingia* infections is difficult. Species in this group are inherently resistant to many antimicrobial agents commonly used to treat infections caused by gram-negative bacteria (aminoglycosides, β-lactam antibiotics, tetracyclines, chloramphenicol), but are often susceptible to agents generally used for treating infections caused by gram-positive bacteria (rifampin, clindamycin, erythromycin, sparfloxacin, trimethoprim-sulfamethoxazole, and vancomycin).[324,1017,1146] Although early investigators recommended vancomycin for treating serious infection with *E. meningoseptica*,[427,861] recent studies have shown greater in vitro activity of minocycline, rifampin, trimethoprim–sulfamethoxazole, and quinolones.[104,335,1017] Further complicating the choice of appropriate antimicrobial therapy is the fact that MIC breakpoints for resistance and susceptibility of this group have not been established by the Clinical Laboratory Standards Institute and the results of disk diffusion testing have been shown to be unreliable in predicting antimicrobial susceptibility to *Chryseobacterium* and *Elizabethkingia* species.[3,168,335,1148] The Etest has been shown to be a possible alternative to the standard agar dilution method for testing cefotaxime, ceftazidime, amikacin, minocycline, ofloxacin, and ciprofloxacin, but not piperacillin.[483] Definitive therapy for clinically significant isolates should be guided by individual susceptibility patterns determined by an overnight MIC method.

Genus *Empedobacter.* The genus *Empedobacter* includes two species, *Empedobacter brevis* (formerly *Flavobacterium*

breve) and *Empedobacter falsenii* (formerly *Wautersiella falsenii*) containing two distinct genomovars.[532,1098,1216,1217] These two species are rarely recovered from human clinical specimens and little is known about their capacity to cause disease.

Empedobacter brevis. Janknecht et al.[505] reported an outbreak of *E. brevis* endophthalmitis in a series of patients who had cataract extractions performed on the same day by the same surgeon, suggesting that the source of infection may be anything from the lens to the sterilization process. *E. breve* was also recovered from a foot lesion in a patient with anaphylactoid purpura,[785] and from the blood of a patient following right knee cellulitis.[877] All strains produce yellow colonies on nutrient agar. Some strains are pale yellow or opaque gray and nonhemolytic on blood agar.[467] All strains are nonmotile, oxidase, catalase, DNase, and gelatin positive. All strains produce indole, but a sensitive method (utilizing Ehrlich reagent) is necessary to demonstrate the presence of indole.[467] Most strains oxidize glucose and maltose but not mannitol. Additional biochemical reactions are shown in Table 7-19.

Empedobacter (Wautersiella) falsenii. The clinical origins of *E. falsenii* isolates used in the original species description were from blood, ear, oral cavity, pleural fluid, pus, respiratory tract, surgical wound, and vaginal swab, but the clinical significance was not provided.[532] There is one report of *E. falsenii* isolated from the urine of an infant with a complicated urinary tract infection.[1114] *E. falsenii* has also been found in a respiratory sample from a CF patient with unknown clinical significance.[696] *E. falsenii* can be separated into two distinct clusters or genomovars based on molecular characterization and biochemical reactions. All strains are gram-negative, nonmotile, nonfermenting rods, and grow aerobically at 20°C, 30°C, and 37°C on blood agar. Some strains display yellow-pigmented colonies after prolonged incubation. All strains are oxidase and catalase positive and produce acid from glucose and maltose.[532] All strains produce indole and urease. Nitrate reduction is negative and nitrite reduction is variable. All genomovar 1 isolates rapidly hydrolyze gelatin and esculin, but are ONPG negative. All genomovar 2 isolates but one are esculin negative, ONPG positive, and weak gelatin positive.[532] Additional reactions are given in Table 7-19.

Genus *Weeksella* and Genus *Bergeyella.* The genus *Weeksella* as originally proposed contained two species, *W. virosa* (formerly CDC group IIf) and *W. zoohelcum* (formerly CDC group IIj).[470,471] Vandamme and colleagues have shown that these two species represent separate genetic taxa and thus proposed the reclassification of one of these species, *W. zoohelcum*, as *Bergeyella zoohelcum*.[1098] Both species are oxidase positive, usually grow on MacConkey agar, are nonpigmented, nonsaccharolytic, and indole positive. Both species have the unusual feature of being susceptible to penicillin, which allows them to be easily differentiated from the related genera (Table 7-19).

Weeksella virosa. *W. virosa* (derived from the Latin word for "slimy") forms mucoid, sticky colonies that are difficult to remove from agar. Colonies are at first observed to be nonpigmented but further incubation may result in a butterscotch

pigmentation. *W. virosa* is urease negative and polymyxin B susceptible. It has been recovered primarily from the urogenital tract of women, but there is little evidence that it can play a pathogenic role.[470,697,892,893] There have been published reports of spontaneous peritonitis[108] and septicemia caused by *W. virosa*.[1001] A review of infections caused by *W. virosa* along with in vitro susceptibility data has been provided by Slenker et al.[1001]

Bergeyella zoohelcum. A key differentiating feature of *B. zoohelcum* is the production of an intense urease reaction in Christensen's urea agar. *B. zoohelcum* forms sticky colonies that are at first nonpigmented, but may form tan to yellow-colored colonies with prolonged incubation. It is penicillin susceptible, but polymyxin B resistant. *B. zoohelcum* is part of the normal oral and nasal flora of dogs and cats.[951] It is not surprising, therefore, that the majority of human isolates have been the result of dog or cat bites,[128,471,744,891,951,986,1172] or in patients who had significant exposure to dogs or cats.[408,643,787] It has been a cause of septicemia in elderly patients with severe skin infections,[577,643,787] and in two cases, the patients reported that they allowed their cat to sleep on top of their legs,[577,787] *B. zoohelcum* has also been reported to have caused pneumonia in a patient exposed to a dog that was a carrier of the organism,[408] and to have caused bacteremia in another patient after ingestion of a dish prepared with goat blood.[85] There is one report of meningitis owing to *B. zoohelcum* following multiple dog bites.[128]

Bergeyella cardium. Recently, a new species of *Bergeyella, B. cardium*, was reported as a causative agent of infective endocarditis in two patients from two differen hospitals in Korea.[1013] The organism was reported to grow slowly on blood and chocolate agars at 37°C and 41°C, but did not grow at 24°C and 30°C. 16S rRNA gene sequencing of the two strains demonstrated sequence similarity of 94.9% to *B. zoohelcum* strongly suggesting that the isolates belonged to a novel bacterial species on the genus *Bergeyella*.[1013] Additional biochemical properties of the isolates were not reported. The organisms were reported susceptible to many commonly used antibiotics incuding penicillin.[1013]

Genus *Myroides*. Vancanneyt et al.[1096] determined that the organism formerly classified as *Flavobacterium odoratum* consisted of a heterogeneous group that comprised two distinct species for which they proposed the names *Myroides odoratus* and *Myroides odoratimimus*. Cells of both species are gram-negative rods 0.5 µm in diameter and 1 to 2 µm long. Various colony types may occur, but most colonies are yellow pigmented and form effuse, spreading colonies that may be confused with the colony morphology of a *Bacillus* species (Image Plate 7-4D). A characteristic fruity odor (similar to that of *A. faecalis*) is produced by most strains. *Myroides* grow on

most media, including MacConkey agar. Growth occurs at 18°C to 37°C, but not at 42°C. They are asaccharolytic but are oxidase, catalase, urease, and gelatinase positive. Indole is not produced, and nitrite (but not nitrate) is reduced (Table 7-20). There are no routine phenotypic tests for differentiating the two *Myroides* species, their differences being confined to assimilation tests and cellular fatty acids.[1096] Organisms identified as *M. odoratus* have been reported mostly from urine but have also been found in wound, sputum, blood and ear specimens.[468,1201] Clinical infection with *Myroides* spp. is exceedingly rare; however, patients with rapidly progressive necrotizing fasciitis and

bacteremia have been reported,[236,491] as well as individuals with recurrent cellulitis with bacteremia.[57,396] A review of skin and soft tissue infections caused by *M. odoratus* has been provided by Crum-Cianflone and colleagues.[236] Most strains are resistant to penicillins, cephalosporins, aminoglycosides, aztreonam, and carbapenems.[468]

Unnamed CDC Groups IIc, IIe, IIg, IIh, and IIi

The unnamed CDC groups IIc, IIe, IIg, IIh, and IIi are phenotypically related indole-positive glucose nonfermenting rods.[1172] Holmes et al. performed DNA–DNA hybridization and 16S rRNA gene sequence analysis of 182 phenotypically similar isolates that phenotypically resembled species from *Chryseobacterium, Elizabethkingia, Empedobacter* or belonged to CDC groups IIc, IIe, IIh, and IIi. They reported that there was little correlation with genomic data and members of the CDC groups since members of each group belonged to at least two different DNA–DNA hybridization groups (three groups in the case of CDC Goup IIi), although one group was comprised almost entirely of strains of CDC Group IIe.[469] In another study, Wauters et al.[1161]reported that CDC group IIi strains belong predominantly to *Sphingobacterium mizutaii*, and in yet another study, Vaneechoutte et al.[1121] reported that CDC groups IIh and IIc belong predominantly to *Chryseobacterium hominis*. The disposition of the various groups identified by these researchers and their correlation to the CDC phenotypic groups remains unresolved. For laboratory identification purposes, the authors have chosen to maintain the CDC group designations in the current edition of this text (Table 7-19) The CDC groups are rarely recovered from clinical material, and little is known about their involvement in clinical disease. One patient with meningitis caused by CDC Group IIe has been reported,[1157] and the phenotypic characteristics of several clinical isolates of CDC groups IIc and

IIg have also been reported.[449,451] Group IIg isolates are easily distinguished from the other CDC groups by their ability to grow on MacConkey agar and failure to produce acid in OF glucose[449] Phenotypic characteristics useful for separating the CDC groups are shown in Table 7-19.

Family Sphingobacteriaceae

Genus *Sphingobacterium*. The sphingobacteria are yellow pigmented, oxidase positive, and nonmotile. They are differentiated from chryseobacteria and weeksellae by their failure to produce indole from tryptophan, and are separated from *Myroides* species by their ability to produce acid in OF glucose. As of this writing, there are 34 species in the genus *Sphingobacterium. S. multivorum* (formerly *Flavobacterium multivorum*, CDC group IIk-2), and *S. spiritivorum* (includes species formerly designated *Flavobacterium spiritivorum, F. yabuuchiae*, and CDC group IIk-3), are the two species most frequently recovered from human clinical specimens. They can be distinguished from the similar organism *Sphingomonas paucimobilis* (formerly IIk-1) by lack of motility and resistance to polymyxin B. Additional differentiating features of these bacteria are given in Table 7-20. *S. multivorum* has been isolated from various clinical specimens, but has only rarely been associated with serious infections, including peritonitis and septicemia.[42,284,338,463,865] Blood and urine have been the most common sources for the isolation of *S. spiritivorum*.[461,700,1079] *S. thalpophilum* has been recovered from wounds, blood, eye, abscess, and an abdominal incision.[1172] A positive nitrate test and growth at 42°C differentiates *S. thalpophilum* from other *Sphingobacterium* species. *Sphingobacterium mizutaii* (formerly *S. mizutae*, and *Flavobacterium mizutaii*)[191,473,1161,1195] has been isolated from blood, CSF, and wound specimens and can be differentiated from other *Sphingobacterium* species by its failure to grow on MacConkey agar and its usual lack of urease activity.[1172] *Sphingobacterium* species are generally resistant to aminoglycosides and polymyxin B, while they are susceptible in vitro to the quinolones and trimethoprim–sulfamethoxazole. Susceptibility to β-lactam antibiotics is variable, requiring testing of individual isolates.[1017]

Family Moraxellaceae

The family *Moraxellaceae,* contains three genera of clinical importance: *Moraxella*, *Acinetobacter*, and *Psychrobacter*.[842]

Genus *Moraxella*. Several key features make one suspect that an unknown nonfermenter may belong to the genus *Moraxella*. After 24 hours on blood agar, the colonies tend to be small and pinpoint (usually less than 0.5 mm in diameter), with

poor or no growth on MacConkey agar. The bacterial cells appear as tiny, gram-negative diplococci or diplobacilli in Gram-stained preparations, and have a tendency to resist decolorization.[254] Both the cytochrome oxidase and catalase reactions are positive (the former rules out *Acinetobacter* species; the latter rules out *Kingella* species). The inability of *Moraxella* species to form acid from carbohydrates also eliminates most *Neisseria* species from consideration. Most *Moraxella* species are extremely susceptible to low concentrations of penicillin. Examination of Gram-stained smears prepared from the outer zone of inhibition around the penicillin susceptibility disk can be used to distinguish *Neisseria* species (which retain their coccal morphology) from *Moraxella* species (which produce elongated, pleomorphic forms) (Image Plates 7-4E and F).[159] All *Moraxella* species are nonmotile.

The *Moraxella* species of medical importance are *M. lacunata*, *M. nonliquefaciens*, *M. osloensis*, *M. atlantae* (CDC group M-3), and *M. catarrhalis*. *M. catarrhalis* is covered along with the pathogenic *Neisseria* species in Chapter 11. CDC groups M-2 and M-4 have been named *Psychrobacter phenylpyruvicus* and *Oligella urethralis*, respectively, and are covered later in this section. CDC groups M-5 and M-6 have both been placed in the genus *Neisseria*, even though their microscopic appearance is that of gram-negative rods. Group M-5 has been designated *Neisseria weaveri*,[454] and group M-6 has been named *Neisseria elongata* subsp. *nitroreducens*.[394] These species, along with other recently described *Moraxella* species such as *M. canis*[506] and *M. lincolnii*,[1102] are difficult to distinguish from the established species of *Moraxella*. Animal species include *M. bovis*, isolated from healthy cattle and other animals, including horses, *M. boevrei* and *M. caprae* (goats), *M. caviae* (guinea pigs), *M. cuniculi* (rabbits), and *M. ovis* (sheep).

Table 7-21 provides some useful differential tests for identification of the medically important *Moraxella* species. *M. atlantae*, *M. lacunata,* and *M. nonliquefaciens* are similar in many of their features. Growth of *M. atlantae* is stimulated by bile salts and sodium desoxycholate, whereas the growth of *M. lacunata* and *M. nonliquefaciens* is not. Only *M. lacunata* liquefies gelatin, whereas both *M. lacunata* and *M. nonliquefaciens* reduce nitrate to nitrite.[122,850] Separation of *M. lacunata* and nonspreading *M. nonliquefaciens* may prove difficult, because gelatin hydrolysis (with any method) and liquefaction of Loeffler slants may take more than 1week. In some instances, fatty acid analysis may help determine the species.[1172] Because many strains of *Moraxella* are somewhat fastidious and biochemical reactions are often negative or equivocal, many laboratories choose to simply report members of this group as "*Moraxella* species."

383

Moraxella species are normal flora on mucosal surfaces and are considered to have low pathogenic potential. They occur most frequently in the respiratory tract and less commonly in the genital tract and occasionally may cause systemic infection. *M. lacunata*, which has been known for over a century to cause conjunctivitis, is fastidious and requires either enriched nonpeptone media or the addition of oleic acid or rabbit serum to counteract a toxic proteolytic effect. In addition to conjunctivitis, this species has been reported to cause keratitis, chronic sinusitis, and endocarditis.[766,907,1075] *M. nonliquefaciens* also may require serum supplements for optimal growth. It is part of the normal flora in the human upper respiratory tract and is frequently isolated from the nasal cavity. It has been isolated from the blood, eye, CSF, lower respiratory tract, and other local sites[121,392,1075] and has been associated with endophthalmitis[308,613,658] and septic arthritis.[518] Atypical mucoid strains of *M. nonliquefaciens* have been recovered from sputum samples of three patients with chronic lung disease.[257] *M. osloensis* is commonly recovered from clinical specimens

and does not require growth supplements. It is usually not pathogenic when isolated from humans; however, isolated cases of sinusitis, conjunctivitis, bronchitis, septic arthritis, osteomyelitis, peritonitis, meningitis, endocarditis, CVC infection, and septicemia have been reported.[136,325,421,922,975,1042] *M. atlantae* grows slowly in culture medium, producing colonies with a tendency to form a spreading zone after 48 hours of incubation.[122] They are a rare cause of bacteremia in immunocompromised patients.[135,261]

M. canis is a new species that resides in the upper respiratory tracts of dogs and cats. Human isolates have been from blood,[506] lymph node[1116] and a dog bite wound.[506] *M. canis, M. catarrhalis*, *M. cuniculi*, *M. caviae,* and *M. ovis* belong to the coccoid moraxellae, which in contrast to the bacillary moraxellae, all exhibit DNase activity. Isolates of *M. canis* resemble *M. catarrhalis* on Gram's stain; however, their colony morphology on sheep blood agar more closely resembles that of members of the *Enterobacteriaceae* (large, smooth colonies).[506] Some isolates may also produce very slimy colonies resembling colonies of *Klebsiella pneumoniae*.[506] The production of a brown pigment on starch-containing Mueller-Hinton agar is also typical of most *M. canis* strains.[506] *M. lincolnii* has been isolated mainly from the respiratory tract of humans.[1102]

Most *Moraxella* strains are susceptible to penicillin and its derivatives, cephalosporins, tetracyclines, quinolones and aminoglycosides.[324,923,1017] Production of β-lactamase has been reported only rarely in *Moraxella* species other than *M. catarrhalis*.[518,766,923] Because of the fastidious nature of many *Moraxella* species and the predictability of the antibiotic profile, antibiotic susceptibility testing, except for β-lactamase testing, is usually not performed on clinical isolates.

Genus *Psychrobacter.* The *Psychrobacter* species that are important clinically are *P. immobilis* and *P. phenylpyruvicus* (formerly *Moraxella phenylpyruvica*).[125]

Psychrobacter phenylpyruvicus. *P. phenylpyruvicus* is both urea and phenylalanine deaminase positive, features that help to distinguish it from *Moraxella* species and *Oligella urethralis* (Table 7-21). Students and laboratorians should be aware that *P. phenylpyruvicus* can phenotypically resemble *Brucella* species, and there have been several reports of *Brucella* species misidentified as *P. phenylpyruvicus* in commercial identification systems.[65,75,833] The differentiation of *P. phenylpyruvicus* and *Brucella* spp. requires microscopy (*Brucella* are tiny coccobacilli) and tests for acidification of xylose and glucose.[849,852] *P. phenylpyruvicus* is asaccharolytic, whereas *Brucella* spp. utilize xylose and usually glucose when a sufficiently sensitive method for detecting acidification of glucose is used.[849] *P. phenylpyruvicus* is a rare cause of infections in humans, but has been reported to cause bacteremia,[630] endocarditis,[413,1078]

peritonitis[165] and a fungating lesion of the foot.[563]

Psychrobacter immobilis. Most strains of *P. immobilis* grow slightly or not at all at 35°C and grow best at 20°C.[493] *P. immobilis* is divided into saccharolytic and asaccharolytic strains. Saccharolytic *P. immobilis* strains share all of the characteristics of the asaccharolytic strains (Table 7-22), except that glucose, xylose and lactose, but not sucrose and maltose are oxidized. Asaccharolytic strains are phenotypically similar to *P. phenylpyruvicus*. The diagnosis of *P. immobilis* can be confirmed by transformation studies, cellular fatty acid profile, and optimal growth temperatures <35°C.[756,1172] Many strains of *P. immobilis* have an odor resembling that of phenylethyl alcohol (PEA) agar (i.e., roses)[493] and are resistant to penicillin but susceptible to most other antibiotics.[376,657] *P. immobilis* septicemia has been reported in a 16-year-old boy with CGD and fulminant hepatic failure.[1025] One patient with an ocular infection and one infant with meningitis have also been reported to be caused by *P. immobilis*.[376,657]

Family Neisseriaceae

Genus *Neisseria*. Some *Neisseria* species appear rod-shaped on Gram's stain and as such may not be recognized initially as *Neisseria* species. Two such species are *N. weaveri* and *N. elongata*, both of which must be differentiated from other phenotypically similar NFBs (Table 7-21). The coccoid members of the genus *Neisseria* are covered in Chapter 11.

Neisseria elongata. *N. elongata* subsp. *elongata* and *N. elongata* subsp. *glycolytica* are considered to be transient colonizers of the human upper respiratory tract and urogenital tract; however, *N. elongata* subsp. *elongata* has been reported to cause human endocarditis,[33,771] and *N. elongata* subsp. *glycolytica* has been isolated from human wounds and blood cultures.[29,476] Most human infections are due to *N. elongata* subsp. *nitroreducens*, which has been

[a]Data from reference 1172.
[b]Saccharolytic *P. immobilis* strains share all of the characteristics of the asaccharolytic strains listed here except that glucose, xylose, and lactose, but not sucrose and maltose are oxidized.[1172]
+, 90% or more strains positive; −, 90% or more strains negative; V, 11%–89% of strains positive; NA, results not available. Numbers in parentheses are percentage of strains giving positive reaction.

associated with a variety of human infections, but diseases most commonly produced include bacteremia and endocarditis,[291,394,414,446,498,539,581,729,839,854,920,998,1036,1184] and rarely with osteomyelitis.[353,1184] This organims was first known as CDC group M-6, but was recognized as a unique subspecies of *N. elongata* named "*nitroreducens*" because it reduces nitrates and nitrites to amines without the formation of gas.[394] Other characteristics of the organism include negative catalase, urease, and indole reactions; a positive oxidase reaction; and lack of acid production from carbohydrates (Table 7-21). *N. elongata* subsp. *nitroreducens* is typically susceptible to aminopenicillins, carbenicillin, cephalosporins, aminoglycosides, trimethoprim–sulfamethoxazole, and polymyxin and it is variably susceptible to penicillin.[291]

Neisseria weaveri. *N. weaveri* is found as normal oral flora in dogs and is associated with human wound infections resulting from dog bites.[28,67,392,454] It has also been isolated from blood,[28,149] sputum, and bronchial washings,[28,817] and from eye, peritoneal, and chest fluids.[28] There is one report of a wound infection in a child after being bitten by a white Siberian tiger.[148] *N. weaveri* appears as aerobic, gram-negative, broad, plump, medium-to-large, straight rods of varying length, with a tendency to grow in chains or longer rods in broth cultures.[28] Growth occurs at 25°C and 35°C, and most strains grow at 42°C. Colonies are gray-white, with an entire

border, flat, somewhat glistening, and smooth. *N. weaveri* is nonmotile, strongly positive for oxidase and catalase, and negative for carbohydrate utilization. Nitrite is reduced, but not nitrate, and it is weakly positive for phenylalanine deaminase (Table 7-21).[28] It is susceptible to penicillin, colistin, and vancomycin.

***Neisseria zoodegmatis* (EF-4b).** *Neisseria animaloris* and *Neisseria zoodegmatis* are the new names for the CDC Group Eugonic Fermenters (EF)-4a and EF-4b, respectively.[1106] *N. zoodegmatis* (EF-4b) does not ferment glucose, does not hydrolyze arginine, and does not produce gas from nitrate, which separates it from the glucose-fermenting strains now designated *N. animaloris* (EF-4a) which is covered in Chapter 9 of this text. *N. zoodegmatis* strains are coccoid to short rods that are nonmotile, and oxidase and catalase positive. Colonies on culture plates are nonpigmented and reported to smell like popcorn. Additional characteristics are given in Table 7-22. Most isolates have been recovered from human infections following dog and cat bites.[1172]

Unnamed Species

Gilardi Rod Group 1. This group consists of nonfastidious, nonoxidative, gram-negative, oval to medium-length, and sometimes pleomorphic rods. The cultural and biochemical characteristics of these organisms are most similar to CDC group M-5, now called *Neisseria weaveri*. All Gilardi rod group 1 strains are strongly positive in the phenylalanine deaminase reaction, producing a deep green color in the agar slant, whereas N. weaveri isolates, when positive, give a weak to moderate reaction. All N. weaveri reduce 0.01% nitrite,

whereas all Gilardi rod group-1 isolates are negative.[367,754] Other differentiating characteristics are given in Table 7-21. Isolates of Gilardi rod group-1 have been recovered from a variety of human sources, including leg, arm, and foot wounds; an oral lesion; urine; and blood; however, their pathogenic potential has yet to be determined.[754]

Family Rhodobacteriaceae

Genus *Paracoccus* and CDC Eugonic Oxidizer (EO) Groups

***Paracoccus yeei* (EO-2) and CDC Groups EO-3 and EO-4.** Members of this group are aerobic, gram-negative (sometimes appearing gram-variable), coccoid to short, thick or slightly thick rods that grow, sometimes poorly, on MacConkey agar. All are strongly oxidase positive, nonmotile, and indole negative and utilize glucose,

xylose, and lactose[756] (Table 7-22). Daneshvar et al.[251] proposed the name *Paracoccus yeeii* (later changed to *yeei* in accordance with the international code for bacterial nomenclature)[320] for the former CDC group EO-2. CDC groups EO-3 and EO-4 remain unnamed. *P. yeei* grows on both BAP and MacConkey agars and appears as mucoid to very mucoid, nonpigmented colonies after 48 hours incubation (Image Plate 7-4G). *P. yeei* also has a distinctive O-shaped cellular morphology on Gram's stain examination owing to the presence of vacuolated or peripherally stained cells (Image Plate 7-4H).[756] This O-shaped morphology is not observed with *P. immobilis* or EO-3 or EO-4 strains. EO-3 and EO-4 strains have a definite yellow, nondiffusible pigment that is not observed with either *P. immobilis* or *P. yeei*.[756] *P. yeei* has been isolated from various human wound infections and blood.[251,343] It has also been reported to cause keratitis in a contact lens wearer,[232] corneal graft rejection in a patient following corneal transplant,[537] myocarditis in a transplanted heart,[961] and peritonitis in an ambulatory peritoneal dialysis patient.[1153] EO-3 has been reported to cause peritonitis in a patient on continuous peritoneal dialysis.[239] EO-4 has been recovered from blood, urine, and a nasal sinus, but the clinical significance of these isolates is unknown.[1170]

Genus *Haematobacter*. *Haematobacter* is a new genus of aerobic gram-negative rods that phenotypically most closely resembles *Psychrobacter phenylpyruvicus*. The genus consists of two named species, *H. massiliensis* (formerly *Rhodobacter massiliensis*) and *H. missouriensis*, and one unnamed species, *Haematobacter* genomospecies 1.[434] They are obligately aerobic, nonmotile rods and grow at 25°C and 35°C, but not at 42°C. Microscopically, cells appear as gram-negative serpentine pleomorphic rods with filaments. The Gram stain appearance can be viewed in the publication by Helsel et al.[434] *Haematobacter* species are nonhemolytic and nonpigmented on blood-containing media. Some strains produce green discoloration under areas of moderate to heavy growth on BAPs.[434] Some strains grow on MacConkey agar. All strains are asaccharolytic. They produce catalase, oxidase, urease, phenylalanine deaminase, and H_2S (lead acetate paper), but do not produce indole, reduce nitrate or nitrite, or hydrolyze gelatin or esculin. ONPG is weakly positive.[434] Additional phenotypic properties are given in Table 7-21. Strains received at CDC were mainly recovered from blood cultures, but the clinical significance is unknown.[434] One additional isolate *H. massiliensis* was recovered from the blood of a patient in France.[299] There is also a report of the isolation of a *Haematobacter*-like species from the blood of a 65-year-old man who suffered from probable aortic valve endocarditis.[139] *Haematobacter* strains have low MICs values for amoxicillin, fluoroquinolones, aminoglycosides,

carbapenems, but variable MICs for cephalosporins, monobactams, and piperacillin.[434]

Organisms That Are Nonmotile and Oxidase Negative

Family Moraxellaceae

Genus *Acinetobacter*

Taxonomy. The genus *Acinetobacter* is currently classified in the family *Moraxellaceae* and consists of bacteria that are nonmotile, oxidase-negative, gram-negative coccobacilli.[354,926] In 1986, Bouvet and Grimont provided a new classification that distinguished 12 different groups (genomospecies) within the genus *Acinetobacter* based on DNA–DNA hybridization and nutritional characteristics.[117] In 1989, Tjernberg and Ursing[1073] described three additional DNA groups coded 13 through 15; concurrently, Bouvet and Jeanjean[119] described five DNA groups of proteolytic *Acinetobacter* species that they number 13 through 17. However, two of the DNA groups described by Tjernberg and Ursing differ phenotypically from the DNA groups described by Bouvet and Jeanjean. Thus, different DNA groups have the same number, which adds to the confusion surrounding the present subdivision of the genus. There are also two provisional genomospecies designated, "Between 1 and 3" and "Close to 13TU."[362] The name *Acinetobacter seifertii* has recently been proposed for the "Close to 13TU" strains.[776] At the time of this writing there were 41 named species described within the genus *Acinetobacter* (http://www.bacterio.net/acinetobacter.html).[496,772,773,1016] Many of the original *Acinetobacter* genomospecies have been named and are delineated in Box 7-11.[117,362,592,776–,784,1073] The remaining genomospecies are unnamed. A scheme of phenotypic tests useful for identifying *Acinetobacter* genomospecies 1 through 12 has been described.[117]

One initial clue that a nonfermenter isolate may belong to the genus *Acinetobacter* is the Gram stain morphology: gram-negative coccobacillary cells often appearing as diplococci (Image Plate 7-5A). This similarity in appearance to *Neisseria gonorrhoeae* led to the archaic taxonomic genus designation "*Mima*" (to mimic). Students and laboratory workers should also be aware of the fact that *Acinetobacter* species may initially appear as gram-positive cocci in direct smears of clinical specimens and in smears prepared from positive blood-culture bottles.[254,423] After 24 hours of growth on blood agar, the colonies are between 0.5 and 2 mm in diameter, translucent to

opaque (never pigmented), convex and entire. Most strains grow well on MacConkey agar and produce a faint pink tint (Image Plate 7-5B). Certain glucose-oxidizing acinetobacters may also cause a unique brown

BJ, Bouvet and Jeanjean; TU, Tjernberg and Ursing.

discoloration of heart infusion agar with tyrosine or blood agar into which glucose is incorporated.[987,1172] We have also observed this phenomenon on MacConkey and Mueller–Hinton agars with a clinical isolate of *A. baumannii* (Image Plate 7-5C). Differential and selective media have been described for isolation of *Acinetobacter* spp. from contaminated specimens.[475,507] Presumptive identification of *Acinetobacter* species can be made on the basis of the lack of cytochrome oxidase activity, lack of motility and resistance to penicillin.

A variety of human infections are caused by *Acinetobacter* species including pneumonia (most often related to endotracheal tubes or tracheostomies),[141] endocarditis, meningitis, skin and wound infections, peritonitis (in patients receiving peritoneal dialysis) and urinary tract infections. Sporadic cases of conjunctivitis, osteomyelitis, and synovitis have also been reported.[379] It is now recognized that *Acinetobacter* spp. play a significant role in the colonization and infection of hospitalized patients. They have been implicated in a variety of nosocomial infections, including bacteremia, urinary tract infection, and secondary meningitis, but their predominant role is as agents of nosocomial pneumonia, particularly ventilator-associated pneumonia in patients confined to hospital intensive care units.[90,834,1137,1180] Comprehensive reviews of *Acinetobacter* infections have been provided by Bergogne-Berezin and Towner[90] and Munoz-Price and Weinstein.[761]

***Acinetobacter calcoaceticus–Acinetobacter baumannii* (ACB) Complex.** The ACB complex consists of five phenotypically and genotypically related species with valid names: *A. baumannii, A. nosocomialis, A. pittii, A. calcoaceticus, A. seifertii*, and a provisional genomospecies called "Between 1 and 3."[776,777] Because of problems in separating the saccharolytic strains belonging to the ACB complex using phenotypic tests,[94,360,363,619] most laboratories have chosen to report members of this group as "*Acinetobacter calcoaceticus–A. baumannii* complex."[363,834] Although *A. baumannii* is the most clinically important species and is frequently involved in nosocomial infections,[332,350,834,1140,1181] including outbreaks associated with multidrug- and pandrug-resistant strains,[107,285,486,522,591,628,762,775,1044] there are an increasing number of reports of non- *A. baumannii* species of the ACB complex causing nosocomial infections.[93,265,481,540,1077,1115,1181] These species differ from *A. baumannii* in characteristics regarding infectious potential, antimicrobial susceptibility and mortality rates, which dictates the need for precise identification to guide therapy and improve clinical outcome.[600,1016] Therefore, it may be important in the future for laboratories to adopt nonphenotypic-based test methods for use in identifying members of the ACB complex. In this regard, a number of genotypic methods have been proposed for *Acinetobacter* identification.[285] The most widely used approaches include PCR, amplified rRNA gene restriction analysis (ANDRA),[1119] amplification

and sequencing of species-specific DNA regions, such as the intrinsic oxacillinases from *Acinetobacter* species,[1086] partial *rpoB* gene sequence analysis,[411] Fourier transform infrared spectroscopy (FTIR),[1016] and MALDI-TOF MS. Of these methods, MALDI-TOF MS seems to be the most practical for incorporation into routine use in the clinical microbiology laboratory. Several studies have demonstrated that MALDI-TOF MS can provide rapid and accurate identification of *Acinetobacter* species including those in the ACB complex.[22,316,485,965,1015]

Acinetobacter baumannii. *A. baumannii* is saccharolytic and acidifies most OF carbohydrates; in particular, definitive identification is made by demonstrating the rapid production of acid from lactose (1% and 10% concentrations). Additional identifying characteristics can be found in Table 7-18. *A. baumannii* is the most commonly found species in human clinical specimens, followed by *A. lwoffii, A. haemolyticus, A. johnsonii*, genomospecies 3 and genomospecies 6.[120,531,969,1073] *A. baumannii* is the species most often responsible for hospital-acquired infections,[82,332,350,665,834,1137,1140] and is increasingly being reported as a significant pathogen causing sepsis, wound infections, and pneumonia in both hospitalized patients and in the community setting.[172,179,187,693,735,762,970] *A. baumannii* has also been associated with combat injuries in Iraq and Afghanistan.[44,258,963,964] A fatal outbreak of extensively drug-resistant *A. baumannii* with enhanced virulence (so-called Clade B strains) has been reported in a cohort of relatively immunocompetent patients raising concerns that the low virulence potential of *A. baumannii* may need to be reevaluated.[522] A biotyping system for differentiating 17 biotypes of *A. baumannii* based on the utilization of six substrates has been established and may be useful for epidemiologic studies.[118]

Other *Acinetobacter* Species. *A. johnsonii, A. lwoffii* and *A. radioresistens* are nonsaccharolytic *Acinetobacter* species that occur as natural inhabitants of human skin[120,969] and may be commensals in the oropharynx and vagina.[120]

387

A. junii is a rare cause of ocular infection[868] and bacteremia, particularly in pediatric patients.[93,540,644,1077] *A. lwoffii* has been more commonly associated with meningitis than other *Acinetobacter* species.[989] *A. nosocomialis* clinical isolates have been reported from tracheal secretions[265] and blood.[265,1181] A nosocomial outbreak of *A. nosocomialis* infection was reported in a neurosurgical intensive care unit where 5 of 23 patients who became colonized with the outbreak strain developed an infection.[1115] *A. pittii* has been reported to cause infections in a neonatal intensive care unit,[481] and

nosocomial bloodstream infections.[743,1181] In one study, the clinical profile of patients colonized or infected with *A. pittii* was noticeably different from that observed for patients with *A. baumannii* infections. *A. pittii* was more frequently found in skin and soft tissue infections, including surgical wound infections, while colonization and infection of the respiratory tract was less frequent than observed for *A. baumannii*.[740] *A. radioresistens* has been reported in an HIV-positive patient with community-acquired bacteremia.[1141] *A. schindleri* has been recovered from a variety of human specimens (vaginal, cervical, throat, nasal, ear, conjunctiva, and urine), but are mostly regarded as clinically nonsignificant.[296,772,774] *A. ursingii* has been shown to cause bloodstream infections in hospitalized patients.[296,666,772,774]

A. lwoffii and *A. radioresistens* are asaccharolytic. *A. johnsonii* is also asaccharolytic but can be separated from all other *Acinetobacter* species by its failure to grow at 37°C. Additional biochemical characteristics of *A. lwoffii* are given in Table 7-18. Additional differentiating features of the other genomospecies can be found in the article by Bouvet and Grimont.[117]

Acinetobacter species tend to be resistant to a variety of antibiotics, although one species, *A. lwoffii*, tends to be more sensitive than the others. There is almost universal resistance to penicillin, ampicillin, and cephalothin, and most strains are resistant to chloramphenicol.[672,968] Variable susceptibility to second- and third-generation cephalosporins and to trimethoprim-sulfamethoxazole has been reported. We have noticed an increased trend toward aminoglycoside resistance among the *Acinetobacter* species in recent years and multidrug-resistant strains, including carbapenem-resistant *Acinetobacter* species have been reported in nosocomial outbreaks.[107,115,289,486,591,661,690,743,762,775,1138,1188] Antimicrobial susceptibility testing for *Acinetobacter* species is problem-prone. Swenson and colleagues at the CDC have shown that results obtained using standardized microbroth dilution do not agree with results obtained with the standardized disk diffusion method for certain antibiotics. Very major errors were frequent with the β-lactam and β-lactam inhibitor combination antibiotics with the microbroth dilution method typically showing greater resistance.[1048] Additionally, susceptibility testing via Etest for *Acinetobacter* has been reported to give falsely high MIC values for tigecycline.[695] Hope et al.[478] reported that MICs of minocycline, tetracycline and tigecycline were one or two dilutions higher in Mueller–Hinton broth than Mueller–Hinton agar. Thamlikitkul et al.[1068] reported that tigecycline MICs for *Acinetobacter* species determined by the Etest method were usually fourfold higher than those determined by the broth microdilution method and that Etest might not be an accurate method for in vitro susceptibility testing of tigecycline and *Acinetobacter*. Susceptibility breakpoints for tigecycline and *Acinetobacter* have not been published by either the FDA or the CLSI, because the prescription of tigecycline for treating *Acinetobacter* infections remains a nonindicated

use. However, realizing that tigecycline is being used to treat *Acinetobacter* infections when limited therapeutic options are present, Jones et al. tried applying the FDA disk diffusion breakpoints ≥19 mm (susceptible) and ≤14 mm (resistant) listed for *Enterobacteriaceae* to *Acinetobacter* species, but found that this led to an unacceptable error rate of 23.3%; however, an adjustment of the tigecycline disk diffusion breakpoints for testing *Acinetobacter* to ≥16/≤12 mm (susceptible/resistant) reduced errors to an acceptable level.[523] At present, there are no data to indicate which methods for testing susceptibility to *Acinetobacter* provide more clinically relevant information. Students and laboratorians are advised to use caution when performing and interpreting susceptibility testing results with *Acinetobacter* species. A review of the antimicrobial susceptibilities of *Acinetobacter* species and the main mechanisms of antimicrobial resistance has been provided in two separate reviews by Van Looveren et al.[1127] and Perez et al.[838]

Combined treatment with an aminoglycoside and ticarcillin or piperacillin is synergistic and may be effective in serious infections. For multiply-resistant *Acinetobacter* infections, several studies have demonstrated clinical efficacy of sulbactam in combination with ampicillin or cefoperazone.[441,510,515,631,818] Moland et al.[739] showed *in vitro* synergy between tigecycline and amikacin against multidrug-resistant *A. baumannii*. Old drugs like minocycline are also being brought back into use for treating infections caused by multidrug-resistant *A. baumannii*.[157,380] The only other antibacterial agents that have been shown to be active against multidrug-resistant *Acinetobacter* are colistin and polymyxin B.[158,516,543,561,562,632] Castanheira et al.[157] reported that among 17 antimicrobial agents tested and considered as candidates for treating *A. baumannii*, minocycline and colistin were the only 2 agents that had susceptibility rates (as per CLSI criteria) exceeding 50% (79.1% and 98.8%, respectively). Bowers et al.[123] reported that the intracellular concentration and *in vitro* bactericidal effect of minocycline were both enhanced by polymyxin B suggesting the clinical utility of these two drugs when used in combination. Scheetz et al.[953] have shown that polymyxin B, minocycline and tigecycline are the most active antimicrobials *in vitro* against carbapenem-intermediate or resistant *A. baumannii*. Of increasing concern are reports of the emergence of colistin-resistant and heteroresistant strains of *A. baumannii* in association with previous colistin therapy.[428,628,637,862,873,895] Reviews of the currently available antimicrobial agents and data supporting the use of various agents for treatment of *Acinetobacter* infections has been provided by Fishbain and Peleg,[330] and Neonakis et al.[780]

Family Alcaligenaceae

Genus *Bordetella*

***Bordetella holmesii* (CDC Group NO-2).** *B. holmesii* was formerly classified as CDC Group NO-2, and is described as a gram-negative, small coccoid and short rod, with medium-width longer rods occasionally observed. They are

asaccharolytic, oxidase negative, nonmotile, and fastidious, and they produce a brown soluble pigment (Table 7-18).[1171] The lack of oxidase activity and the production of a brown soluble pigment differentiate *B. holmesii* from *B. pertussis, B. bronchiseptica* and *B. avium*; the lack of urease activity differentiates this species from *B. parapertussis*. A negative nitrate reaction differentiates it from NO-1 strains, and the production of a brown soluble pigment differentiates it from *Acinetobacter* species. Information on the clinical significance of *B. holmesii* and its association with disease in humans was presented elsewhere in this chapter under the heading "Organisms That Are Motile With Peritrichous Flagella—Genus *Bordetella*."

Unnamed Species

CDC Group NO-1. An unnamed species of a fastidious, nonoxidative, gram-negative rod, designated CDC Group NO-1 (nonoxidizer-1), has been isolated from human wounds resulting primarily from dog or cat bites.[58,450,530] This organism is nonmotile, oxidase negative, and asaccharolytic. They appear as coccoid to medium-sized gram-negative rods that form small colonies on sheep blood agar. They resemble *Acinetobacter* spp. phenotypically but can be readily separated from *Acinetobacter* by a positive nitrate reduction test. Cellular fatty acids and ubiquinone analysis are also useful in differentiating NO-1 from *Acinetobacter* species.[450] Other phenotypic characteristic are given in Table 7-18. They are susceptible to a variety of antimicrobial agents, including the aminoglycosides, β-lactam antibiotics, tetracyclines, quinolones, and sulfonamides. Fifty percent of isolates are reported to be resistant to trimethoprim.[450]

CDC Group EO-5. CDC EO-5 are glucose-oxidizing gram-negative rods that have a biochemical profile similar to *A. baumannii*.[249] They are nonmotile and oxidase negative, but unlike *Acinetobacter* species, they fail to grow on MacConkey agar. Some strains produce a yellow soluble pigment. Cellular fatty acid analysis is also useful in differentiating EO-5 strains from *Acinetobacter*. Other characteristics are given in Table 7-18. Isolates have been recovered from blood, peritoneal fluid, transtracheal aspirate, gallbladder, and an arm wound.[249] Antibiotic susceptibility data are not available.

PART III: APPROACH TO RECOVERY AND IDENTIFICATION OF NONFERMENTERS

Levels of Service in Identification of Nonfermenters

The level to which species identification of nonfermenters is performed depends on the size and purpose of the individual laboratory. Reference laboratories, or universities and clinics where students and residents are being trained, may be required to identify all clinically relevant nonfermenters to the species level. Laboratories that provide services primarily for the medical community may be prepared to identify only the more frequently encountered species, sending the rare isolates to a reference laboratory. In the analysis of bacteriology specimens circulated by the CDC for their microbiology performance evaluation programs, Griffin and associates[406] found that laboratories for which the volume of specimen testing is small (fewer than 80 samples per week) average about double the error rate of laboratories handling more than 1,200 specimens per week. They conclude that this difference in performance is constant and that a laboratory cannot necessarily correct its performance, for many of the reasons listed in Box 7-12. They recommend that laboratories limit testing to procedures that can be done well and make arrangements with a reference laboratory to provide services for testing specimens that are received infrequently. Factors that contribute to the difficulties in identifying nonfermenters are listed in Box 7-12.

BOX 7-12

Factors Contributing to the Difficulties in Identifying Nonfermenters

1. Most species are only infrequently encountered.
2. Because of this infrequency, laboratory personnel may not be familiar with many of the nonfermenters.
3. Many of the conventional culture media are not suitable for identifying nonfermenters.
4. Many species grow slowly, and biochemical reactivity is weak, requiring considerable experience to interpret equivocal reactions.
5. Quality control of culture media may be difficult, and, because of infrequent use, outdating becomes a problem.
6. Packaged commercial kit systems often have low accuracy in the identification of

the more fastidious strains of nonfermenters, requiring the use of additional media.

Several commercial packaged systems for the identification of nonfermenters (discussed later in this chapter) are currently available[453,576,797,912,1158]; however, because these systems depend on bacterial growth and on the formation of biochemical products in conventional media or in marginally nutritious substrates, only the more biochemically active species can be identified with an acceptable degree of accuracy. The accuracy of performance is also improved with the use of one of several automated or semiautomated bacterial identification systems, primarily because they rely on automatic instrument readings and recording of results, eliminating the subjective bias inherent in the visual interpretation of equivocal end points. These instruments have the advantage of making identifications several hours faster than conventional methods.

389

Guidelines for Recovery of Nonfermenters

With the previous discussion in mind, each laboratory director must develop a logical approach to the identification of nonfermenters in his or her laboratory. The following guidelines are helpful in the laboratory approach to the recovery and identification of nonfermentative gram-negative bacilli:

1. Except for *P. aeruginosa* (and the rarely encountered *B. mallei* and *B. pseudomallei*), the nonfermenters have a low degree of virulence and most often cause nosocomial infections in patients who are debilitated or immunocompromised. This narrow niche of infectivity indicates that infections will be uncommon (except for the relatively high incidence of *P. aeruginosa* and *Acinetobacter baumannii*, as discussed earlier). However, because an increasingly higher proportion of hospitalized patients have serious underlying illness, nonfermenters are being recovered with increasing frequency from clinical specimens and must be considered as important agents for many infectious diseases. Specific conditions or diseases predisposing patients to infection with nonfermenters include the following:
   a. Malignancies (particularly of the reticuloendothelial system) and instrumentation and surgery—catheterizations (particularly urinary tract and indwelling intravascular), tracheostomy, lumbar puncture, dialyses, lavages,

and the placement of shunts and prostheses.

b. Prolonged corticosteroid, antibiotic, antimetabolic and anticancer therapy.

c. Underlying metabolic or chronic infectious diseases (e.g., an apparent link exists between CF and infections caused by *B. cepacia*, mucoid *P. aeruginosa* and *A. xylosoxidans*).

d. Burns, open wounds, and various exudative lesions.

2. Most nonfermenters have their natural habitat in several environments that serve as potential reservoirs for human infections:

a. Various water reservoirs that are prevalent in hospitals—humidifiers, mist tents and nebulizers, water baths, disinfectant and irrigation solutions, distilled water lines, hand creams, body lotions, and so on. These solutions often come in direct contact with mucous membranes and other body surfaces in the course of patient treatment.

b. Implements, such as anesthetic equipment, forceps, and thermometers, that may be stored in disinfectant solutions; and mops, sponges, and towels.

c. Moist intertriginous parts of the skin, such as the toe webs, groin, axilla, and antecubital fossa. Infections from these sources tend to be more prevalent in the summer.

d. Various domestic animals predisposing caretakers to infection.

3. Certain nonfermenters have a propensity for causing specific infections, discussed elsewhere in this chapter. Septicemia may be found with virtually any species; pneumonitis or bronchitis, septic arthritis, urinary tract infections, postoperative and posttraumatic wound infections, and conjunctivitis may also be caused by most species of nonfermenters. Some species, particularly of *Pseudomonas*, may produce cytotoxic and lytic toxins that make some of these infections locally severe and potentially life-threatening.

4. Clinical isolates that are gram-negative bacilli on Gram's stain can be suspected of being nonfermenters if they produce small colonies on blood agar, grow poorly or not at all on MacConkey agar, do not produce acid in either the slant or the deep portion of KIA or TSI medium, and are cytochrome oxidase positive.

5. Many species of nonfermenters also tend to have certain patterns of multidrug-resistance to antibiotics. These patterns are learned through experience and may provide an initial clue that one is dealing with one of the nonfermenters, or may point to a specific genus.

Identification of the Most Common Species

The identification of the three most commonly recovered clinical species,

Pseudomonas aeruginosa, *Acinetobacter baumannii* and *Stenotrophomonas maltophilia* is addressed first. Most strains can be identified easily on the basis of only a few observations and chemical tests. Not only does the rapid identification of these common isolates provide the physician with immediate information, but it also relieves the laboratory of performing a battery of time-consuming and expensive secondary tests.

Pseudomonas aeruginosa

More than 95% of *P. aeruginosa* strains recovered from clinical specimens can be identified by observing the presence of the following primary characteristics:

- Gram-negative rod
- Oxidase positive (within 10 seconds)
- Typical fruity grapelike odor, or corn tortilla
- Recognizable colony morphology
  - On blood agar or chocolate agar appear as large colonies with metallic sheen; may be mucoid, rough or pigmented (showing pyocyanin), and often β-hemolytic (Image Plate 7-2F)
  - On MacConkey, appear as lactose negative with green pigmentation, or metallic sheen; may be mucoid (Image Plates 7-2G, 7-2H)

When these characteristics are present, a definitive identification of *P. aeruginosa* can be made with no further testing.[208]

Most strains of *P. aeruginosa* produce pyocyanin, a water-soluble green phenazine pigment that imparts a greenish color to the culture medium. In fact, observing the presence of pyocyanin may be the only characteristic required to identify *P. aeruginosa,* because no other nonfermenter synthesizes this pigment. Reyes and coworkers[899] have shown that 98% of the *P. aeruginosa* strains isolated in their laboratory

produced pyocyanin on Tech agar[569] within 48 hours and suggest that the use of Tech agar is a satisfactory alternative to the use of extensive identification schemes when *P. aeruginosa* is suspected (Image Plate 7-1G). They note that some mucoid strains of *P. aeruginosa* from patients with CF may not produce pigment and, therefore, may be misidentified if pigment production is the only criterion used for identification of these aberrant strains. A few strains of *P. aeruginosa* may produce pigments with other colors—pyorubin (red), pyomelanin (brown to black), and pyoverdin (yellow).

Fluorescein pigment can be visualized by observing the growth on certain media

using a long-wavelength ultraviolet light source (e.g., Wood's lamp; Image Plate 7-1H). Media containing proteose peptone 3 (Difco Laboratories, Detroit, MI) and cations, such as magnesium or manganese, enhance fluorescein synthesis. King's medium B, Sellers' medium, and Mueller-Hinton agar are also suitable for demonstrating fluorescence. Fluorescence may be enhanced if cultures are incubated at 20°C to 30°C rather than at 35°C to 37°C. The following additional characteristics are helpful in identifying non–pigment-producing strains of *P. aeruginosa*:

- Growth at 42°C
- Alkalinization of acetamide
- Denitrification of nitrates and nitrites
- Motile with polar, monotrichous flagellum

Variants producing mucoid or dwarf colonies with atypical biochemical reactions may also be encountered, occasionally making identification difficult.

In summary, most strains of *P. aeruginosa* can be identified easily by observing the typical large colonies, with a blue–green discoloration on primary isolation media, and further confirmed by detecting a typical grapelike odor. Demonstration of fluorescein pigment and cytochrome oxidase activity helps to confirm the final identification, and additional tests are usually not required. The typical characteristics by which *P. aeruginosa* are identified are shown in Table 7-5.

Acinetobacter baumannii

A. baumannii is the second most frequent nonfermenter encountered in clinical laboratories, but with only about one-tenth the frequency of *P. aeruginosa*. The following are the characteristics by which a presumptive identification can be made:

- Appears as cocci or coccobacilli on Gram's stain
- Grows well on MacConkey agar (colonies may have a slightly pinkish tint, a helpful characteristic when present)
- Does not produce cytochrome oxidase
- Exhibits rapid utilization of glucose, with production of acid
- Exhibits rapid utilization of 10% lactose, with production of acid
- Are nonmotile
- Are penicillin-resistant

The initial clue is the observation of tiny (1.0 × 0.7 μm) bacilli on Gram stains prepared directly from clinical materials. When Gram stains are prepared from agar or broth cultures, the cells may appear larger and more like coccobacilli (Image Plate 7-5A). *Acinetobacter* species are not pigmented when grown on blood agar, a helpful characteristic in differentiating them from certain other nonfermenters, such as

occasional oxidase-negative, nonmotile strains of *Burkholderia cepacia*. However, colonies growing on MacConkey agar may produce a faint pink tint or a deeper cornflower blue when observed on eosin methylene blue agar (Image Plate 7-5B). Resistance to penicillin helps distinguish *A. baumannii* from the highly penicillin-sensitive *Moraxella* species, which also usually appear as coccobacilli on Gram stain. Most strains of *Moraxella* species are also cytochrome oxidase positive. *A. lwoffii* is nonsaccharolytic and can be differentiated from *A. baumannii* because it produces no acid when grown in media that contain carbohydrates.

Stenotrophomonas maltophilia

S. maltophilia is the third most frequently encountered nonfermenter in clinical laboratories. The following are the characteristics by which a presumptive identification can be made:

- Good growth on blood and MacConkey agars
- Does not produce cytochrome oxidase (or very delayed reaction)
- Produces acid in OF maltose but may be negative in OF glucose
- Lysine decarboxylase positive
- DNase positive
- Some strains have yellow pigment

The antibiotic susceptibility pattern can also be a clue to the identification of *S. maltophilia*, which is typically resistant to most antibiotics, including the aminoglycosides, but is susceptible to trimethoprim-sulfamethoxazole and usually colistin.

Methods for Identification Using Conventional Biochemical Tests

If an unknown nonfermentative gram-negative bacillus is not *Pseudomonas aeruginosa*, *Acinetobacter baumannii,* or *Stenotrophomonas maltophilia*, additional characteristics must be determined to make a species identification. The two most widely used identification schemes based on phenotypic biochemical reactions are those of Weyant and associates (CDC)[1172] and Schreckenberger.[958] Which approach to select is largely one of personal preference, past experience, and the local availability of the culture media required to perform the various tests, providing the criteria listed in Box 7-13 are met.

CDC Scheme—Weyant and Associates

In answer to the problem of how to identify nonfermenters in the clinical laboratory without doing all the tests that are done in a reference laboratory, Weyant and colleagues[1172] have published a three-part guide that includes (1) an identification key for gram-negative aerobes, (2) a set of 12 identification

BOX 7-13

Approach to Selecting a Conventional Test

1. Positive and negative reaction results delineated in the identification table must be based on the procedures and formulas listed in the laboratory procedure manual. That is, the media and procedures must be the same as those used to generate the results in a table of reactions used for identification.
2. All of the reactions listed in the identification table must be at a confidence level of 90% or higher and derived from a database of a sufficiently large number of organisms to be statistically significant.
3. All tests must be performed under standard quality-control surveillance to ensure that the reagents, reactions, and end points are as close as possible to those on which the table was originally based.

tables, and (3) a numerical code book by which derived biotype numbers can be linked to species names. They also include procedures and media formulas for all of the biochemical tests cited in the identification manual. To correctly interpret results from a given identification table, one must use the same procedures on which the reactions are based. The manual is entitled: "Identification of Unusual Pathogenic Gram-Negative Aerobic and Facultatively Anaerobic Bacteria," and is available from Lippincott Williams & Wilkins.[1172]

Practical Approach to Identification of Nonfermenters—Schreckenberger

The approach used in this book was devised by Schreckenberger[958] and requires that the various clinically important nonfermentative bacilli be divided into four functional groups based on an immediate assessment of their motility and ability to produce cytochrome oxidase (Table 7-23). Once having accomplished this subgrouping,

definitive identifications can be made by referring to the identification Tables 7-23 through 7-37 and following the instructions given with the tables. The biochemical tests used in this identification guide are all conventional biochemical formulations and are available commercially from most media manufacturers. Note that in working with these tables, a given species of a nonfermenting bacillus may appear in more than one table because a particular organism may not be 100% positive or negative for a given characteristic; therefore, some redundancy is built into the scheme so that an unknown bacillus will be identified regardless of the test result obtained with the variable screening test. By following these tables, the microbiologist should be able to definitively identify over 95% of nonfermentative bacilli that will be recovered from clinical specimens.

Computer-Aided Schemes

ASHEX Web ID Program. When a large battery of tests is performed, it is often difficult to determine the most likely organism identification by using tables or algorithm-based diagrams. For this reason, Schreckenberger has developed an organism identification application called WIP (Web ID Program).[957] WIP is a free online program (developed by Adam Schreckenberger 2014) that can be used to identify bacteria without the use of downloaded software. The WIP application works on any PC, Apple or smartphone system with an active internet connection. Since the program runs within an internet browser, it requires no additional downloads. One merely needs to enter available phenotypic characteristics into the online Web form to calculate a likelihood probability and modal score. If the likelihood score is less than 95%, a list of phenotypic tests that distinguish the top two candidates will be displayed; likewise, if the modal score is poor, a list of input results that do not match well to the top candidate prediction will be shown. The program provides statistical selection of unknown bacterial isolates through comparisons to phenotypic characteristic matrices of known strains. The program has three major functions: (1) the identification of an unknown isolate, (2) the selection of additional tests to distinguish between possible strains if identification is not achieved, and (3) the storage and retrieval of results. An assortment of WIPs, each of which targets a specific subset of gram-negative bacteria, is available on www.pschreck.com by clicking the appropriate WIP tab of choice on the site toolbar. This collection is referred to as the AID (App Identification) Cloud. Each WIP references a specific characteristic matrix that was created either from a published table in the literature or from the author's own data.

The table associated with the Nonfermenter WIP is named ASHEX and consists of 887 isolate entries representing 93 separate species of NFBs with reactions for 42 phenotypic tests. The table can be downloaded from the website as an Excel spreadsheet. This file includes the characteristic matrix as well as the raw phenotypic

reaction results used to compute each probability. The complete table is reproduced in this chapter as Table 7-3. To access the WIP, go to www.pschreck.com and click the WIP tab of your choice in the tool bar and enter your reactions on the worksheet.

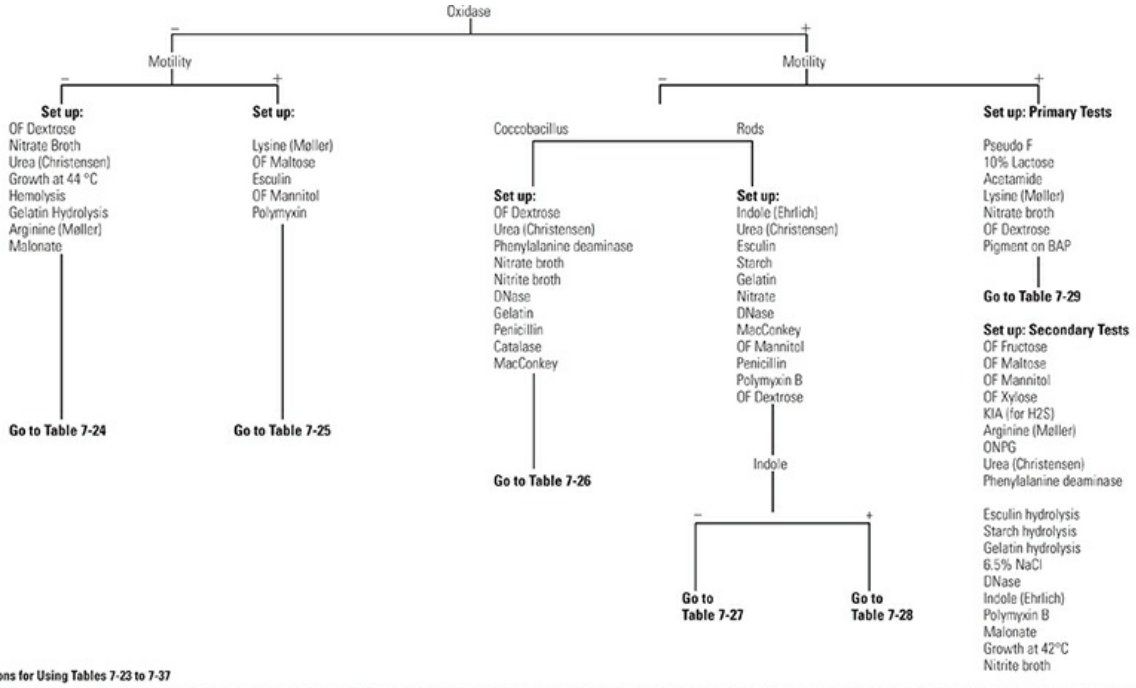
Methods for Identification Using Commercial Kit Systems

Packaged kit systems have been designed for, or adapted to, the identification of the nonfermentative bacilli. These kits share many of the attributes of packaged systems in general; that is, they are convenient to use, have a long shelf life, and preclude the need for fresh supplies of media and reagents. The packaged systems also provide standardized techniques that are accurate and give reproducible results equal to or better than conventional procedures, with the exceptions discussed later in this chapter.

Inherent problems in the use of many of the currently available packaged kits for identifying nonfermenters include

392

TABLE 7-23 Practical Approach to the Identification of Nonfermenters



Instructions for Using Tables 7-23 to 7-37

This approach to the identification of nonfermenters is designed to minimize the number of biochemical tests needed for identification based on a preliminary assessment of the oxidase and motility reactions of organisms to be identified. Once this information is known, a specific battery of tests is performed to complete the identification of the organism. For those organisms that are both oxidase positive and motile, a two-step approach is used based on the reactions obtained in a primary test battery followed by additional supplemental tests that are specified in the designated Tables. Depending on the needs and resources available, the user of this guide may wish to set up all of the tests included in the primary and secondary batteries whenever a motile, oxidase-positive nonfermenter is encountered in order to obtain a definitive identification in the shortest time possible. As a general rule when working with NFBs, a heavy inoculum should be used and reactions should be held 48 hours before the final reading is taken.

Steps to Follow

1. Determine the motility and oxidase reactions and follow the flow diagram in Table 7-23.
2. Set up the specified biochemical tests and go to the Table indicated to complete the identification.
3. To utilize Tables 7-24 to 7-37, begin with the first biochemical test listed on the left hand side of the Table and locate the shaded box or boxes in the upper left hand corner.
4. If a single box is shaded, and if the reaction given matches the reaction obtained with your specimen, you are done. The organism identification is listed in the same row to the left of the box.
5. If multiple boxes are shaded and the reaction matches that of your specimen, use the reactions to the right of the shaded boxes to determine the correct identification.
6. If the reaction obtained with your specimen does not match that in the shaded box or boxes, proceed to the next column on the right and find the shaded box or boxes in this column. Repeat steps 4 and 5 until you reach a definitive identification.
7. Special consideration must be given to shaded boxes that contain a variable (V) reaction sign. In these rare cases, you must treat the variable reaction in the shaded box as both a match and a nonmatch.

the (1) tendency for organisms that exhibit weak or delayed biochemical activity to produce false-negative reactions, (2) less than optimal design of many systems for cultivation of certain nonfermenters, and (3) inclusion of some differential tests that may not be applicable to the identification of nonfermenters. Whereas members of the *Enterobacteriaceae* usually grow rapidly and exhibit active enzymatic activity on a variety of substrates that can readily be detected with kit systems, most nonfermenter species are slow-growing and relatively inactive enzymatically. The microbiologist needs considerable experience to interpret some incomplete or weak reactions that may be encountered in the use of these systems.

It is with these perspectives in mind that the following five kit systems are discussed.

- API 20E (BioMérieux, Hazelwood, MO)
- API 20NE (BioMérieux)
- Crystal Enteric/Nonfermenter System (Becton Dickinson Microbiology Systems)
- RapID NF Plus (Remel)
- Biolog System (Biolog, Hayward, CA)

The API 20E System

The API 20E system, originally designed for identification of the *Enterobacteriaceae,* has been extended to include the identification of common nonfermentative bacilli as well. To maximize the use of the API 20E for nonfermenters, six additional tests were added to generate a nine-digit profile number (Box 7-14). Studies performed with nonfermenters have shown that although the API 20E system identifies *P. aeruginosa*, *S. maltophilia,* and *Acinetobacter* species with up to 99% accuracy, particularly after 48 hours of incubation, the performance with other less common nonfermenters was often less than acceptable.[137,298,748,976] Incorrect identifications occurred most often because of false-negative reactions for citrate, gelatin liquefaction, motility, arginine dihydrolase, ONPG, nitrate reduction, and urease tests.[298] In other cases, identifications were not possible because the biotype number derived from the 20E strip was not listed in the API Profile Index.[298,976]

The API 20NE System

The API 20NE is a modification of the API 20E strip. The construction of the plastic strip is the same as in the 20E system; however, the substrates have been changed to include 8 conventional tests and 12 assimilation tests that are based on the observation of microbial growth in the presence of a single source of carbon (Image Plate 7-5H). A description of the operating procedure and substrates included is given in Box 7-14. Positive and negative reactions are converted to a 7-digit biotype number, and

organism identifications are made either from a computerized database or from a profile list provided by the manufacturer. Users of this system should note that the database is constructed on the basis of reactions obtained at an incubation temperature of 30°C (instead of the conventional 35°C to 37°C) with final

[b]Occasional strains of *S. maltophilia* may be oxidase positive.
+, 90% or more of strains are positive; –, 90% or more of strains are negative.

readings taken after 48 hours of incubation. Kiska et al.[575] tested 150 nonfermenters isolated from patients with CF and reported an overall correct identification rate of 57%, including 43% of the *B. cepacia* isolates. The overall performance of the API 20NE has shown it to be one of the better-performing commercial systems for the identification of nonfermenters.[37,605,709,1151,1158]

The Crystal Enteric/Nonfermenter System

The Crystal Enteric/NonFermenter ID kit was described in Chapter 6. The nonfermenter database includes 24 taxa of nonfermenters representing 10 different genera. Twenty additional taxa are included in a group called "Miscellaneous Gram-Negative Bacilli," that consists of a group of oxidase-positive species that are relatively inactive and indistinguishable from each other in the Crystal E/NF System. Included in this group are some medically relevant species of *Alcaligenes, Burkholderia, Comamonas, Moraxella, Ochrobactrum, Oligella,* and *Pseudomonas*. In a study by Wauters and coworkers,[1158] the overall correct identification of 201 nonfermenters (including 31 different species) was 75.9% with the Crystal E/NF compared with 75.3% for the API 20NE. Of note is that only 36 of 45 *P. aeruginosa* strains were correctly identified by the Crystal E/NF compared with 41 of 45 by the API 20NE. The overall percentage of incorrect identifications for nonfermenters was substantially higher for the API (13.8%) than for the Crystal (6.3%). The authors noted that an advantage of Crystal over the API system is that both fermenters and nonfermenters can be tested in the same panel. In addition, the API 20NE may require 48 hours of incubation, whereas the Crystal E/NF requires only 18 hours of incubation. Robinson and colleagues[912] studied 131 nonenteric bacilli on the Crystal E/NF including 11 species of nonfermenters; however, three species (*P. aeruginosa*, *A. baumannii*, *S. maltophilia*) accounted for 90% of the nonfermenters tested. The Crystal system correctly identified all of the *P. aeruginosa*, *A. baumannii,* and *S. maltophilia* species tested, but correctly identified only 8 of the 13 (61.5%) remaining nonfermenter species tested.

The RapID NF Plus System

The RapID NF Plus System (Remel) is a micromethod using conventional and chromogenic substrates for the identification of medically important glucose nonfermenting gram-negative bacteria and other selected glucose-fermenting gram-negative bacteria not belonging to the family *Enterobacteriaceae*. The tests used in the RapID NF Plus System are based on the microbial degradation of specific substrates detected by various indicator systems. The reactions used are a combination of conventional tests and single-substrate chromogenic tests. The system is described in Box 7-15. In the study by Kitch and colleagues,[576] 90.1% of all strains were identified correctly to species without additional tests. Kiska and associates[575] showed that the NF Plus correctly identified 80% of the NFBs recovered from patients with CF, including 81% of the *B. cepacia* isolates. This was the highest overall identification rate of the four commercial systems included in the study.[575] The RapID NF Plus system is currently the only nonautomated 4-hour test system available for the identification of nonfermenters.

The Biolog System

The Biolog System (Biolog, Hayward, CA) was described in Chapter 6. The newest version of the Biolog system available for manual testing is the GEN III MicroLog M System without computer (MLM). Biolog's latest generation redox chemistry enables testing and microbial identification of aerobic gram-negative and gram-positive bacteria in the same test panel. Gram stain and other pretests are no longer needed. The setup protocol is simple and can be performed in about 1 minute. The Biolog Microbial ID System can rapidly identify over 2,500 species of aerobic and anaerobic bacteria, yeasts, and fungi. Unfortunately, this product is not FDA approved for human in vitro diagnostic use, but can be a valuable resource for use in veterinary microbiology, research, or reference laboratory testing.[256,453,1214]

Methods for Identification Using Automated Identification Systems

The Vitek Legacy System

The Vitek Legacy System (bioMérieux), described in Chapter 6, has also been used with success in the identification of the nonfermenters most frequently encountered in the clinical laboratory. Pfaller and coworkers[844] tested 91 NFBs, with 90.1% identified correctly. Fifteen percent were identified at 4 hours, an additional 45% were identified 5 to 8 hours, and an additional 40% were identified at 9 to 18 hours. Colonna and associates[225] tested 142 NFBs and found 79.6% agreement with the API NFT. Kiska

and colleagues[575] evaluated four identification systems, including the Vitek

405

BOX 7-14

API 20E and API 20NE Systems for Identifying Nonfermenters

Functional Design

Each system consists of a plastic strip with 20 miniaturized cupules containing dehydrated substrates and a plastic incubation chamber with a loosely fitting lid (Image Plates 6-6A and 7-5D). Each cupule has a small hole at the top through which the bacterial suspension can be inoculated with a pipette. Bacterial action on the substrates produces turbidity or color changes that are interpreted visually.

Operating Procedure

For both systems: Add 5 mL of tap water to an incubation tray to provide a humid atmosphere during incubation. Place the strip into the incubation tray. Prepare a bacterial suspension of the test organism by suspending the cells from a well-isolated colony in 5 mL of sterile 0.85% saline. The turbidity must be equivalent to a 0.5 McFarland standard.

API 20E: With a Pasteur pipette, fill each cupule with the bacterial suspension through the

inoculating port. Overlay the three decarboxylase and the urease cupules with sterile mineral oil. The unit is incubated at 35°C for 24 or 48 hours before reading results according to the following rules: after 24 hours, if the glucose is positive add reagents, perform an oxidase test, and generate a 7-digit profile number to look up in the white section of the Profile Index; if glucose is negative, but three or more other reactions are positive before adding reagents, proceed as above; if glucose is negative and fewer than three other tests are positive, do not add reagents, reincubate strip for additional 24 hours and inoculate OF glucose, motility medium, and MacConkey agar. After 48 hours, add reagents, perform oxidase test, and generate a 9-digit profile number to look up in the blue section of the Profile Index.

API 20NE: With a Pasteur pipette, fill the tube portion of the first eight cupules (NO_3through PNPG) with the bacterial suspension. Inoculate an ampule of AUX medium with four drops of the same saline suspension. Mix well. With a new sterile pipette inoculate the assimilation tests GLU through PAC (cupules with colored lines) by filling the tube and cupule until a flat liquid surface without a meniscus is obtained. Add mineral oil to the GLU, ADH, and URE cupules. Incubate strip for 24 hours at 29°C–31°C. After 24 hours, add nitrate reagents to NO_3 cupule and TRP reagent to TRP cupule. Read and record reactions. Assimilation tests are recorded as positive if there is visible growth in the cupule portion of the tube. A 7-digit profile number is generated. If a good identification is not obtained or profile number is not found in codebook, the test strip may be incubated for an additional 24 hours. To do so, immediately cover the $NO_3$and TRP cupules with mineral oil. Record the NO_3, TRP and GLU test results after 24 hours; do not read these tests after 48 hours.

Substrates Included

API 20E:

ONPG

Arginine dihydrolase

Lysine decarboxylase

Ornithine decarboxylase

Citrate

Hydrogen sulfide

Urease

Tryptophan deaminase (add 10% $FeCl_3$)

Indole

Voges–Proskauer (add KOH and α-naphthol)

Gelatin

Glucose

Mannitol

Inositol

Sorbitol

Rhamnose

Sucrose

Melibiose

Amygdalin

Arabinose

Supplemental Tests:

Oxidase

NO_2

N_2 gas

Motility

MacConkey

OF glucose-oxidative

OF glucose-fermentative

API 20NE:

Biochemical Tests:

Nitrate reduction

Tryptophanase

Glucose fermentation

Arginine dihydrolase

Urease

Esculin hydrolysis

Gelatinase

β-Galactosidase

Assimilation Tests:

D-Glucose

L-Arabinose

D-Mannose

D-Mannitol

N-Acetyl-D-glucosamine

Maltose

D-Gluconate

Caprate

Adipate

L-Malate

Citrate

Phenylacetate

406

BOX 7-15

RapID NF Plus System for Identifying Nonfermenters

Functional Design

The system consists of 10 reaction cavities molded into the periphery of a plastic disposable tray (Image Plate 7-5F). Reaction cavities contain dehydrated reactants, and the tray allows the simultaneous inoculation of each cavity with a predetermined amount of inoculum. When the test inoculum is added to the reaction cavity, the test substrate is rehydrated and the test reaction is initiated. After incubation for 4 hours, each test cavity is examined for reactivity by noting the development of a color. In some cases, reagents must be added to the test cavities to provide a color change. The resulting pattern of positive and negative test reactions is used as the basis for identification of the test isolate by comparison of test results to reactivity of known organisms stored in a computer-generated database.

Operating Procedure

Preparation of Inocula: Test organisms must be grown in pure culture and should be examined by Gram stain and oxidase before use in the RapID NF System. Test organisms may be removed from a variety of selective and nonselective agar growth media. Plates used for inocula preparation should preferably be 18–24 hours old. Using a cotton swab or inoculating loop, remove organisms from agar plate and suspend in RapID Inoculation Fluid to achieve a visual turbidity of at least a 1 but not in excess of a 3 McFarland Turbidity Standard. Suspensions should be mixed thoroughly and used within 15 minutes of preparation.

Inoculation of Panels: Peel back the panel lid over the inoculation port. With a Pasteur pipette, gently transfer the entire contents of the inoculation fluid into the upper right-hand corner of the panel. Reseal the inoculation port by pressing the peel tab back in place. After adding the test suspension, tilt the panel back away from the test cavities at approximately a 45° angle. While tilted back, gently rock the panel from side to side to evenly distribute the inoculum along the rear

baffles. While maintaining a level horizontal position, slowly tilt the panel forward toward the reaction cavities until the inoculum flows along the baffles into the reaction cavities. Incubate panels at 35°C–37°C in a non-CO_2 incubator for 4 hours.

Reading Panels: Place panel on benchtop and peel back the label lid over the reaction cavities. Without the addition of any reagents, read and score cavities 1 through 10, reading from left to right and record on report form. Record color of cavity 10 (GLU) in space provided on report pad. Then add two drops of NF Plus Reagent to cavities 4–8, two drops of Innova Spot Indole Reagent to cavity 9, and two drops of Innova Nitrate A reagent to cavity 10. Allow 30 seconds but no more than 3 minutes for color development. Record results in appropriate boxes on report form. Look up in Code Compendium or computer database.

Substrates Included

Arginine dihydrolase
Aliphatic thiol utilization
Triglyceride hydrolysis
Enzymatic hydrolysis of glycoside or phosphoester-linked nitrophenyl substrates releases yellow *o*- or *p*-nitrophenol:

p-Nitrophenyl-phosphoester

p-Nitrophenyl- *N*-acetyl-β, D-glucosaminide

p-Nitrophenyl-α, D-glucoside

p-Nitrophenyl-β, D-glucoside

o-Nitrophenyl-β, D-galactoside

Urea hydrolysis
Glucose utilization
Enzymatic hydrolysis of substrate linked β-naphthylamide substrates releases free β-naphthylamine which is detected with the RapID NF Plus Reagent

Proline β-naphthylamide

Pyrrolidine β-naphthylamide

γ-Glutamyl-β-naphthylamide

Tryptophan β-naphthylamide

N-Benzyl-arginine-β-naphthylamide

Tryptophan utilization with formation of indole
Sodium nitrate reduction
The above tests together with oxidase provide 18 test parameters.

GNI card, for identification of NFBs from patients with CF. A total of 150 isolates

were tested including 58 *B. cepacia*, 30 *S. maltophilia*, 24 *A. xylosoxidans*, 14 *P. aeruginosa*, and 24 other NFBs. The Vitek correctly identified only 50% of the *B. cepacia* isolates and 60% of the isolates overall. O'Hara and coworkers[797] tested 23 nonfermenters (8 *Acinetobacter*, 10 *P. aeruginosa*, 5 *S. maltophilia*) and reported 100% correct identification with the Vitek GNI card and version R07.1 software. Rhoads and associates[901] tested 80 *A. baumannii* and 39 *P. aeruginosa* and reported correct identification of 100% and 84.6%, respectively, with the Vitek GNI card and version AMS-R08.2 software. Sung and colleagues evaluated the GNI+ for identification of 301 isolates of NFBs representing 25 different species. Correct identification to the species level at initial testing was 71.8%, improving to 92.3% after additional testing was performed as recommended by the manufacturer's protocol.[1045]

The Vitek 2 System

The Vitek 2 System is described in detail in Chapter 6. The original Vitek 2 card for gram-negative bacteria identification has been redesigned to improve the identification of fermenting and nonfermenting bacilli. The new card contains 47 tests (26 that had been included in the previous card and 21 new tests), compared with 41 in the established Vitek 2 ID-GNB card. The database for the new card has been expanded to 159 taxa compared with only 101 for the original Vitek 2 card. In a study performed by Funke et al.,[344] 133 of 144 (92.4%) NFBs were correctly identified with the new Vitek 2 cards.

407

The Microscan Walkaway-96, Walkaway-40, and Autoscan-4 Systems

These three systems (manufactured by Beckman Coulter, West Sacramento, CA), described in Chapter 6, all have an extensive database that includes many species of NFBs. Pfaller and colleagues,[844] using WalkAway-96 Rapid Gram Negative Panel, reported that 92.3% of the nonenteric bacilli were identified correctly with a likelihood of more than 85%. Tenover and colleagues[1064] evaluated the Walkaway-96 (formerly called the autoSCAN-W/A) for its ability to identify 310 well-characterized non–glucose-fermenting gram-negative bacilli. In their study, two types of identification panels were tested: the dried colorimetric Neg ID type 2 panel (DCP) and the rapid fluorometric Neg ID panel (RFP). Results with the DCP showed that 41.3% of 286 organisms were identified correctly, with a confidence of more than 85%, whereas 22.4% were misidentified with the same degree of confidence (major errors). Fifteen percent of the organisms were reported as unidentified. Problems in identifying

relatively common nonfermentative bacilli, such as *P. fluorescens*, *P. putida* and *S. maltophilia* were reported with the DCP panel. The researchers reported better results with the RFP panels, in which 77.1% of 239 isolates were correctly identified, whereas 25% were misidentified. The researchers further noted that the results with the RFP panels were available in 2 hours; thus, if an organism cannot be identified, additional biochemical tests can be inoculated on the same day, and little time is lost in identifying the organisms. Colonna and colleagues at UCLA tested 142 NFBs using the 2-hour rapid Neg ID panel and reported 74.6% agreement with the API NFT.[225] O'Hara and colleagues[797] at the CDC tested 23 strains of NFBs, including 8 *Acinetobacter*, 10 *P. aeruginosa*, and 5 *S. maltophilia*, and reported 100% accuracy with the Walkaway Neg combo 3 panel and version 17.02 software. Rhoads and coworkers[901] reported 97.5% and 82.1% correct identification of *A. baumannii* and *P. aeruginosa* isolates, respectively, using the Walkaway-96 system with urine combo 6 and negative combo 16 and version 20.20 software. Sung and colleagues compared the MicroScan Walkaway (W/A) using conventional (overnight) Neg Combo type 12 panels, with the Vitek GNI+ for identification of 301 isolates of NFBs representing 25 different species. The W/A correctly identified 71.4% of the isolates to the species level at initial testing improving to 96.0% after additional testing that was recommended by the manufacturer's protocol.[1045] Saiman et al.[941] evaluated the ability of the MicroScan Autoscan to identify *P. aeruginosa* isolates recovered from patients with CF. Using Negative Combo type 15 panels, read after 20 to 24 hours and again at 48 hours of incubation, they were able to correctly identify 57% (108 of 189) of nonmucoid strains and 40% (24 of 60) of mucoid strains. The most common misidentification was *Pseudomonas fluorescens/putida*.[941]

In 1997, MicroScan updated the Rapid Gram-Negative Identification panels from the Type 2 panel to the Type 3 panel in order to improve identification accuracy and to remove the need for mineral oil overlay for the decarboxylase tests, and to increase the shelf life from 1 year to 2 years. The identification database for the revised panel was updated to include 119 taxa. In a multicenter evaluation of the new type 3 panel 91.3% (63 of 69) NFBs were correctly identified to the species level.[72] In a study conducted by Schreckenberger et al.,[959] 92.2% (71 of 77) NFBs representing 10 species were correctly identified to the species level with the Rapid Gram Negative type 3 panels.

The Sensititre AP80 System

The Sensititre AP80 Identification panels (TREK Diagnostic Systems, Cleveland, OH) can be inoculated and incubated offline and then read in the Sensititre Autoreader, or can be inoculated and placed in the ARIS (Automated Reading and Incubation System) Instrument described in Chapter 6. The AP80 panel permits the identification

of gram-negative bacilli in as little as 5 hours, with the option of additional overnight incubation if needed or desired. Colonna and coworkers[225] tested 142 NFBs using the Sensititre AP80 panels and reported 71.1% agreement with the API NFT. Staneck and colleagues[1026] tested 144 nonenteric isolates including 135 nonfermenters representing eight species. Ninety-three percent of the isolates tested consisted of just three species (68 *P. aeruginosa*, 33 *Acinetobacter*, 25 *S. maltophilia*). Correct identification was obtained for 99.2% of these three species and for 95.1% of all nonenterics tested. The small number of nonfermenter species tested in this study makes it difficult to evaluate the performance of this system for routine clinical laboratory testing of the nonfermenters.

The Phoenix System

The Phoenix Automated Microbiology System (Becton Dickinson Microbiology Systems) is a fully automated, identification and antimicrobial susceptibility test system. Details of the system are presented in Chapter 6. To date, only a few studies have been published that evaluate the system for identification of NFBs. Stefaniuk et al.[1029] tested 54 NFBs (22 *P. aeruginosa*, 17 *Acinetobacter*, 15 *S. maltophilia*) and reported 96.3% (52 of 54) agreement with standard methods. Donay and colleagues[293] tested 56 NFBs representing 7 species and reported 89.3% correct identification with the Phoenix compared to a reference ID.

Methods for Identification Using Molecular Systems

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry

MALDI-TOF MS was described in detail in Chapter 6. An overview of this new technology and modern applications in the clinical microbiology laboratory are described in a recent review.[828] Overall performance of MALDI-TOF MS has been reported to be significantly better than commercially available systems for identification of the NFBs although overall performance is still less than satisfactory.[14,270,502,960] Degand et al. evaluated the performance of the Bruker Autoflex spectrometer with flex control software (Bruker Daltonics, Bremen, Germany) using 512 clinical isolates of NFBs (predominantly *P. aeruginosa*) recovered from the

sputum of children with CF plus 47 strains obtained from the Obervatoire National des Cepacia (Toulouse, France) and found 98.2% correctly identified with MALDI-TOF MS versus 91.8% correctly identified by API 20E. The misidentifications by MALDI-TOF MS all occurred with members for the *B. cepacia* complex.[270] Almuzara et al.[14] evaluated the Bruker MicroFlex LT, RUO software version 3.1 and reported 64.65% correct ID to the species level and 28.28% to the genus level (92.95% combined) for 396 clinical isolates of NFB. Jacquier et al.[502] tested 101 NFB clinical isolates excluding *P. aeruginosa*, *A. baumannii* and *S. maltophilia* using the Bruker Autoflex with the flex control software, Vitek-2 and API 20 NE and reported correct ID to the species level of 80.8%, 70.7% and 57.4% respectively. Schreckenberger et al. performed a side-by-side comparison of the Bruker MALDI-TOF MicroFlex LT MS using Biotyper 3.0 software and the Vitek MALDI-TOF MS System using the Vitek MS RUO version 3.5 software and the Vitek MS IVD version 2.0 software. The population studied included 392 less common clinical isolates of NFBs, including 30 genera, 71 species, and 5 unnamed CDC groups of NFBs. Pyocyanin-producing strains of *P. aeruginosa* were excluded. Results obtained with the MALDI-TOF MS systems were compared to results obtained with a 42-test conventional identification procedure as described by Schreckeberger.[958] Discrepancies were refereed with 16S rRNA sequencing or whole genome sequencing (WGS) using Illumina's MiSeq technology. Correct identification to the species level for Bruker RUO, Vitek RUO, and Vitek IVD was 62.1%, 48%, and 54.3%, respectively. Correct identification when genus only IDs and genus and species IDs were combined for the three libraries evaluated were 89.7% for the Bruker RUO, 87.1% for the Vitek MS RUO, 83.3% for the Vitek MS IVD. Both systems gave a low number (<5%) of incorrect IDs; however, the ability to identify NFBs correctly to species level was low for both systems. Improvements are needed in the databases used for identification of NFBs with both systems for accurate identification of NFBs to the species level.[960]

16S rRNA Gene Sequencing

Due to the poor performance of commercially available systems for the identification of NFBs and sometimes less than satisfactory performance of MALDI-TOF MS to identify NFBs at the species level, laboratories have increasingly turned to sequencing methods such as 16S rRNA gene sequencing to determine the identification of clinically relevant isolates. 16S rRNA is a component of the 30S small subunit of prokaryotic ribosomes. The use of the 16S rRNA gene for phylogenetic studies was pioneered by Carl Woese because it is highly conserved between different species of bacteria and archaea and because of the slow rate of evolution of this region of the

bacterial gene.[1182,1183] In addition to highly conserved primer binding sites, 16S rRNA gene sequences contain hypervariable regions that can provide species-specific signature sequences useful for identification of bacteria. As a result, 16S rRNA gene sequencing has become prevalent in medical microbiology as a rapid and inexpensive alternative to phenotypic methods of bacterial identification.[203]

Jacquier et al.[502] tested 188 NFBs collected from 9 French hospitals and were able to identify 92% to species level and 100% to genus level using 16S rRNA gene sequencing. Cloud et al. compared phenotypic identifications of 96 clinical NFB isolates with identifications obtained by partial 5' 16S rRNA gene sequencing using the MicroSeq 500 system (Life Technologies, Grand Island, NY). Sequencing identified 88 isolates (91.7%) with >99% similarity while 8 isolates (8.3%) could be identified confidently only to the genus level by sequencing. Phenotypic testing was performed by conventional phenotypic and commercial methods in use at each of the participating laboratories and included the Vitek or API 20NE systems (bioMèrieux, Durham, NC) or the MicroScan system (Beckman Coulter, Sacramento, CA). Using phenotypic testing, 50/96 (52.1%) NFB isolates were correctly identified to the species level and 11/96 (11.4%) were correctly identified to the genus level (combined 63.5%).[206] The largest number of discrepancies with phenotypic testing occurred with *P. fluorescens* (7/9) and *S. maltophilia* 11/19).[206] In a separate study conducted by Mignard and Flandrois, 683 clinical NFB isolates were analyzed by 16S rRNA sequencing. Species-level identification was provided for 568 (83.1%) isolates, genus-level identification only for 108 (15.8%) isolates and 7 (1%) isolates could not be identified by sequencing.[733] Bosshard et al. in a prospective study compared 16S rRNA sequencing with two commercially available identification systems (API 20 NE, Vitek-2 Fluorescent card; bioMèrieux, Marcy l'Etoile, France) using 107 NFB (non-*Pseudomonas aeruginosa*) strains recovered from blood cultures and from relevant clinical material where identification was required. Using 16S rRNA sequencing, 92% of the isolates were assigned to species level and 8% to genus level (100% combined). Using API 20 NE, 54% of the isolates were identified to the species level, and 7% to the genus level (61% combined), and 39% of the isolates could not be identified. For Vitek-2, 53% could be identified to the species level, 1% to the genus level (54% combined), and 46% could not be identified.[113]

Resolution of 16S rRNA Gene Sequencing. Although 16S rRNA gene sequencing is highly useful in regards to bacterial classification, it has low phylogenetic power at the species level and poor discriminatory power for some genera.[113,503,733] With the NFB this is particularly true for members of the *Burkholderia cepacia* complex, the *Acinetobacter calcoaceticus–Acinetobacter baumannii* complex, and some members of the genus *Pseudomonas*, the genus *Achromobacter*, the genus *Bordetella,* and the

genus *Ralstonia*.[113,503]

As for any identification method, limitations for 16S rRNA gene sequencing exist and students and laboratorians should be aware of these pitfalls when using gene sequencing for bacterial identification in the diagnostic laboratory.[503,733]

Selection of a System

Clinical microbiologists must evaluate parameters such as accuracy, cost-effectiveness, and effects on workflow when deciding whether to use a commercially manufactured system for identifying nonfermenters. The commercial systems perform with levels of accuracy equal to or better than conventional methods in identifying *P. aeruginosa*, *Acinetobacter*

409

species, and *S. maltophilia;* however, these metabolically active organisms can also be identified easily by using a few simple biochemical tests described earlier in this chapter. Many laboratories have adopted one of the commercial systems as a matter of convenience. However, because of the reported low sensitivity and specificity in the identification of many of the more fastidious and biochemically inactive nonfermenters, supplemental conventional differential media must still be retained. Therefore, the definitive identification of most nonfermenters still requires considerable technical experience and access to a variety of fresh culture media kept under strict quality control. Because relatively few nonfermenters, particularly strains of species other than the three mentioned in the foregoing, are encountered in most medium-sized or small laboratories, the services of a reference laboratory should be seriously considered. Identifying nonfermenters is not difficult if the microbiologist is willing to devote the time and dedication necessary to achieve an acceptable level of accuracy. Packaged systems can be recommended, provided one understands their shortcomings and is willing to set up supplemental tests to identify weakly reactive or fastidious strains.

PART I: CURVED RODS: *CAMPYLOBACTER, WOLINELLA, ARCOBACTER, HELICOBACTER,* AND RELATED BACTERIA

Historical Background

The microorganism presently classified as *Campylobacter jejuni* was discovered in 1931 by Jones and coworkers[202] as the causative agent of winter dysentery in cattle. Twenty-six years lapsed before King described a group of microaerophilic, motile curved rods isolated from the blood of children with acute dysentery, which she designated "related vibrios" because they were similar in many respects to *Vibrio fetus.*[225] King astutely mentioned that the vibrios isolated from the blood of children might be closely related to the organism described as *V. jejuni* by Jones in 1931 and that the organism might be more important as a cause of childhood diarrheal syndromes of unknown etiology than previously realized.

This was a prophetic statement; nevertheless, another 15 years passed before this association was substantiated in the laboratory. In 1972, Dekeyser and colleagues[96] isolated the "related vibrios" from the feces of patients with acute enteritis using a filtration technique that allowed the small, curved rods to pass through the membrane but retained larger fecal microorganisms. Several other reports followed, linking related vibrios (*V. fetus,* subsp. *jejuni; C. jejuni*) with

gastroenteritis in humans, with a distribution throughout the world.[40,41,211] This relative incidence has since been the experience in most clinical laboratories, although during the past several years, the rates of recovery have declined to some degree.

The history of the discovery of *Helicobacter pylori* (formerly named *Campylobacter pyloridis* and then *C. pylori*) is even more circuitous. Warren and Marshall are credited with the "discovery" of the organism in Perth, Australia, in 1982[444]; however, many previous descriptions of spiral organisms in biopsy specimens of human gastric mucosa have appeared in the literature dating back to the beginning of the 20th century.[132,232] Only after successful cultivation of this bacterium using the unique "*Campylobacter* atmosphere" has serious attention been paid to this organism, which may be the most common cause of human gastrointestinal (GI) infection as well as the most frequent cause of gastritis.[337]

Classification of *Campylobacter* and Related Taxa

Classification of the microaerophilic gram-negative bacilli has changed considerably over the past few decades. Vandamme and associates,[430,433] using a variety of molecular techniques, including DNA–rRNA hybridization, 16S ribosomal RNA (rRNA) sequence analysis, and immunotyping analysis, determined that the *Campylobacter* species and related taxa belong to the same phylogenetic group, which they named rRNA superfamily VI. Five genera, including *Campylobacter, Arcobacter, Helicobacter, Wolinella,* and "*Flexispira*" (which subsequently has been placed in the genus *Helicobacter*), were included in rRNA superfamily VI. Characteristics that differentiate between these related genera are listed in Table 8-1. Solnick and colleagues described two uncultivable human gastric spiral organisms, "*Gastrospirillum hominis*" 1 and 2, which they identified as helicobacters by 16S rRNA analysis and provisionally named "*Helicobacter heilmannii*."[390] Following the successful isolation of "Candidatus *H. heilmannii*" in vitro in 2012, this organism was given full taxonomic recognition as *H. heilmannii*.[384]

Studies of Thompson and coworkers[421] showed that bacterial species included in rRNA superfamily VI could be separated into three distinct rRNA clusters. They reported that only those organisms comprising rRNA group I (*C. fetus, C. coli, C. jejuni, C. lari, C. hyointestinalis, C. concisus, C. mucosalis, C. sputorum*, and *C. upsaliensis*) were the true campylobacters. Paster and Dewhirst[329] found a close relationship between *Wolinella curva, W. recta, Bacteroides gracilis, B. ureolyticus*, and the true campylobacters that made up the rRNA homology group I and suggested that all members of the campylobacter cluster should be placed in the genus *Campylobacter.* Vandamme and colleagues[433] confirmed the findings of Thompson and coworkers[421] and Paster and Dewhirst[329] and proposed an amended description of the genus *Campylobacter* to include all organisms placed in homology group I and the transfer of *W. curva* and *W. recta* to the genus *Campylobacter* as *C. curvus* and *C. rectus,* respectively. Vandamme and coworkers[428] proposed the reclassification of *B. gracilis* as *Campylobacter gracilis.* However, although *B. ureolyticus* was considered a member of the family *Campylobacteraceae*, it remained as a species *incertae sedis* until finally being reclassified as *Campylobacter ureolyticus* in 2010.[429]

The rRNA cluster II contained a homogeneous group of organisms for which Vandamme and associates[433] proposed the genus designation of *Arcobacter.* At the time of this writing, the genus *Arcobacter* includes 18 species isolated from a wide range of farm animals, shellfish, mussels, water sources, and sewage.

rRNA cluster III contained members of three different genera, *Helicobacter, Wolinella,* and "*Flexispira*", and an unnamed species, CLO-3. Vandamme and

associates[433] emended the description of the genus *Helicobacter* and proposed the transfer of *Campylobacter cinaedi* and *C. fennelliae* to the genus *Helicobacter* as *H. cinaedi* and *H. fennelliae,*

TABLE 8-1 Characteristics for Differentiating *Arcobacter, Campylobacter, Wolinella, Helicobacter*, and "*Flexispira*"

Genus	Nitrate Reduction	Growth on 0.5% Glycine	Hydrolysis of Urea	Growth at			Cell Morphology	Flagellar Sheaths
				15°C	30°C	42°C		
Arcobacter	+	NA	V	+	+	–	Curved and spiral rods	Absent
Campylobacter	+	V	–	–	+	V	Curved and spiral rods	Absent
Wolinella	+	–	–	–	–	W	Spiral	Absent
Helicobacter	V	+	V	–	V	V	Curved and spiral rods	Present
"Flexispira"	–	+	+	–	–	+	Straight fusiform rods	Present

+, 90% or more of strains are positive; –, 90% or more of strains are negative; V, 11%–89% of strains are positive; W, weak reaction; NA, results not available.
Data modified from reference 433.

respectively. "*Flexispira*" is now included in the genus *Helicobacter. W. succinogenes* remains as the only species of the genus *Wolinella* and has not been associated with human infections.

Genus Campylobacter

Campylobacter species are microaerophilic (i.e., require decreased O_2) and capnophilic (i.e., require increased CO_2), curved spiral bacteria that are motile by means of a single unsheathed polar flagellum. These organisms are nonfermentative and nonoxidative in their metabolism, deriving energy from the use of amino acids and 4- and 6-carbon Krebs' cycle intermediates. These organisms were once classified with *Vibrio* species, until DNA homology studies showed that they were unrelated to the vibrios. Even among the currently recognized *Campylobacter* species, much genotypic and phenotypic diversity exists. The organisms inhabit a wide variety of ecologic niches and environments. Most species are found in animals (cattle, swine) and cause infertility and abortion.

Campylobacter jejuni subsp. *jejuni*

Clinical Significance. *C. jejuni* subsp. *jejuni* is the most important human pathogen among the campylobacters. It has worldwide distribution, and in industrialized countries, it is recovered from diarrheal stool samples two to seven times

more frequently than *Salmonella* or *Shigella*.[14] It is also ubiquitous in domestic animals—house pets may carry the organism, and the vast majority of chickens, turkeys, and waterfowl are colonized.[150] Raw milk,[75,439] partially cooked poultry,[150] and contaminated water[67,210] are the common sources for human infections.[134] Enteritis with this organism is characterized by crampy abdominal pain, bloody diarrhea, chills, and fever. For most persons, the infection is self-limited and resolves in 3 to 7 days. The organism may continue to be excreted by convalescing patients for 2 weeks to 1 month. The patient may be treated with oral erythromycin if the disease is severe.

Although enteritis and diarrheal syndromes remain the most common manifestations of *Campylobacter* infections, other diseases have emerged during the past few years. Patients with septic arthritis, meningitis, and proctocolitis secondary to *C. jejuni* have been reported.[347] *C. jejuni* has been described to cause bacteremia mostly in elderly or immunocompromised patients,[323] and a patient with prosthetic joint infection after a diarrheal illness has also been described.[438] There have now been several reports that associate *C. jejuni* infection with Guillain–Barré syndrome (GBS), an acute demyelinating disease of the peripheral nerves.[154,233,362,393] Data from both serologic and culture studies show that between 20% and 40% of patients with GBS are infected with *C. jejuni* 1 to 3 weeks prior to the onset of neurologic symptoms.[15] The risk of developing GBS after *C. jejuni* infection, however, is quite small (<1 case of GBS/1,000 *C. jejuni* infections).[14] There is no relation between the severity of GI symptoms and the likelihood of developing GBS after infection with *C. jejuni*; and in fact, even asymptomatic infections may trigger GBS.[15] In the United States and Japan, 30% to 80% of *C. jejuni* isolates from patients with GBS belong to Penner's serotype 0:19.[15,135] *C. jejuni* infection has also been associated with immunoproliferative small intestinal disease (also called alpha chain disease).[249] A review of the epidemiology, pathogenesis, and clinical features of *C. jejuni* infection has been written by Allos.[14]

Presumptive Identification From Stool. It may be possible to make a presumptive diagnosis of *Campylobacter* enteritis by observing characteristic gram-negative, curved, S-shaped or gull-winged, or long spiral forms in Gram-stained preparations of diarrheal stools (Image Plate 8-1A). One could consider examining wet mounts or stained smears of all diarrheal stool specimens for polymorphonuclear leukocytes and the presence of bacterial forms suggestive of *Campylobacter* species. Stool specimens for *Campylobacter* species are not further processed in some laboratories unless polymorphonuclear leukocytes are present. The rationale for this practice is that it is unlikely that *Campylobacter* species will be recovered in clinically significant numbers in stool specimens devoid of leukocytes. The expenditure of time

and use of special culture media for specimens in which there is little chance to recover significant microbes is not considered cost effective.

Methods for Laboratory Isolation. Successful isolation of *C. jejuni* from stool depends on the use of selective media (e.g., Campy-Thio, Campy-BAP), incubation at an elevated temperature (42°C), and the proper incubation atmosphere (5% oxygen, 10% CO_2, 85% nitrogen). A membrane filtration technique that is used with nonselective blood agar plates has been reported to be as effective as the use of selective media for the isolation of *C. jejuni*.[398] This method has the advantage of allowing the isolation of antibiotic-susceptible campylobacters. For the past several decades, the selective culture media and special incubation conditions necessary to recover *Campylobacter* species have been used in most clinical microbiology laboratories.

Various procedures can be used to provide a suitable gaseous atmosphere for cultivating microaerophilic campylobacters. These include evacuation–replacement procedures, disposable gas generators, and the use of the Fortner principle. Two of these procedures, which have been used successfully by various investigators, are outlined in Table 8-2. The use of a CO_2 incubator is not recommended for cultivating campylobacters because only strains that are very aerotolerant grow in the atmosphere provided. Likewise, a candle extinction jar is not recommended because the oxygen level (12% to 17%) is too high for optimal growth of campylobacters.[259,442]

Several selective media have been developed to allow for the isolation of *C. jejuni* from fecal samples. Merino and colleagues[281] evaluated the efficacy of seven selective *Campylobacter* isolation media. The names of these media, their composition, and a summary of the evaluation of each are included in Table 8-3. Butzler selective medium, Blaser medium (Campy-BAP), and Skirrow blood agar have been used in most clinical laboratories. However, Merino and colleagues[281] found that Preston *Campylobacter* blood-free medium with cefoperazone yielded the greatest number of *C. jejuni* isolations. Karmali and colleagues[212] found that a blood-free, charcoal-based selective medium (CSM) consisting of Columbia agar base, activated charcoal, hematin, sodium pyruvate, cefoperazone, vancomycin, and

435

TABLE 8-2 Procedures Used by Various Investigators to Create a Microaerophilic Environment Suitable for Cultivating *Campylobacter* Species

Investigators	Procedure
Luechtefeld et	

al.[259] Evacuation-replacement	with a mixture of 10% CO_2 and 90% N_2. Six plates of media were incubated in one jar.
Hébert et al.[164] Evacuation-replacement	Evacuated 75% of air from a modified pressure cooker by twice evacuating the container to −15 in. (−38 cm) Hg and refilling with a mixture of 10% CO_2 and 90% N_2 to atmospheric pressure. Plates occupied no more than one-half the volume of the container.

TABLE 8-3 Formulas for Selective Media for Isolation of *Campylobacter jejuni*

Medium	Base	Additives
Butzler's selective medium	Fluid thioglycollate medium (Difco Laboratories, Detroit, MI)	Agar (3%) Sheep blood (10%) Bacitracin (25,000 IU/L) Novobiocin (5 mg/L) Colistin (10,000 IU/L) Cephalothin (15 mg/L) Actidione (50 mg/L)
Skirrow's blood agar	Blood agar base No. 2 (Oxoid)	Lysed horse blood (7%) Vancomycin (10 mg/L) Polymyxin B (2,500 IU/L) Trimethoprim (5 mg/L)
Blaser's medium (Campy-BAP)	Brucella agar base (Becton Dickinson, Microbiology Systems, Cockeysville, MD)	Sheep blood (10%) Vancomycin (10 mg/L) Trimethoprim (5 mg/L) Polymyxin B (2,500 IU/L) Cephalothin (15 mg/L) Amphotericin B (2 mg/L)
		5% Saponin-lysed horse

Preston *Campylobacter*-selective medium	Nutrient broth No. 2 (Oxoid CM67) 1.2% New Zealand agar	blood Trimethoprim (10 µg/mL) Polymyxin B (5 IU/mL) Rifampin (10 µg/mL) Cycloheximide (100 µg/mL)
Preston *Campylobacter* blood-free medium	Nutrient broth No. 2 (Oxoid CM67) 1.2% New Zealand agar	Bacteriologic charcoal Sodium deoxycholate Ferrous sulfate Sodium pyruvate Casein hydrolysate Cefoperazone (32 mg/L)
Butzler's virion medium	Columbia agar base (Oxoid CM331)	Defibrinate sheep blood Cefoperazone (15 mg/L) Rifampin (10 mg/L) Colistin (10,000 U/L) Amphotericin B (2 mg/L)
Modified Preston medium	Nutrient broth No. 2 (Oxoid)	7% Defibrinated horse blood Cefoperazone (32 mg/L) Amphotericin B (2 mg/L) Campylobacter growth supplement (Oxoid)
Charcoal-based blood-free selective medium	Columbia agar base (GIBCO)	Activated charcoal (Oxoid) Hematin (0.032 g/L) Sodium pyruvate (0.1 g/L) Vancomycin (20 mg/L)

	Cefoperazone (32 mg/L) Cycloheximide (100 mg/L)

Data from references 212 and 281.

cycloheximide is more selective than Skirrow's medium and has a higher isolation rate of *C. jejuni* from mixed cultures. Charcoal, hematin, ferrous sulfate, and sodium pyruvate serve as substitutes for blood in growth media for campylobacters. Casein is added to help grow certain strains of nalidixic acid–resistant thermophilic campylobacters that are environmental organisms.

Endtz and colleagues[108] compared a semisolid blood-free selective motility medium[146] with two blood-free CSM, two blood-based media (Skirrow's medium and Blaser's Campy-BAP), and the membrane filter technique. They found that CSM was the single best medium; however, the highest isolation rates were observed when CSM was used in combination with any other media or the filter technique. Endtz and colleagues also reported that extending the incubation time from 48 to 72 hours led to an increase in the isolation rate regardless of the medium used.[108]

Rectal swabs or swab samples of the stool specimen can be inoculated directly to a small area on the surface of one of the recommended selective agar media. Formed stool specimens may also be processed by emulsifying a small portion (peanut sized) in phosphate-buffered saline or broth before inoculating one or two drops to the surface of the agar with a Pasteur pipette; similarly, one or two drops of liquid stool specimens can be inoculated directly.

An outline of a procedure that will allow isolation of enteric campylobacters from fecal samples is shown in Box 8-1. This technique is consistent with current information from the literature about requirements for cultivation of these bacteria and is suitable for use in most clinical laboratories.

An alternative membrane filter technique, as described by Steele and McDermott,[398] may be used in combination with a Campy-selective medium with equivalent results (Image Plate 8-1B and Box 8-2).

Routine use of enrichment selective "Campy broth" is generally not recommended. Enrichment broths may be beneficial if stool specimens are delayed in transit or left at room temperature too long. Each laboratory director must decide whether an enrichment broth will be beneficial based on local disease patterns and how well the collection and transport of quality specimens can be monitored. Since campylobacters

enrichment broth will be beneficial based on local disease patterns and how well the collection and transport of quality specimens can be monitored. Since campylobacters are microaerophilic, they tend to grow best near

BOX 8-1

Procedure for Isolating *C. jejuni* and Other Enteric *Campylobacter* Species From Fecal Specimens

1. Using a fecal sample or a swab sample in Cary–Blair medium, prepare a turbid suspension of the feces in 10 mL of brain–heart infusion broth. Immediately inoculate one or two plates (two plates are preferable) of a *Campylobacter*-selective medium (best results are obtained with CSM as noted in text); streak to obtain isolated colonies; and hold in a nitrogen-holding jar (see Chapter 16) until the remaining media are inoculated.
2. Lightly centrifuge the specimen (at approximately 1,000 *g*) for 5 minutes.
3. Remove about 5 mL of the supernatant with a syringe and filter through a sterile 0.65-µL Millipore filter, as described by Butzler.[58] Discard the first 3 mL of fluid and use 1 or 2 drops of the remainder to inoculate two plates of chocolate agar without selective agents or a blood agar medium such as the Centers for Disease Control (CDC) anaerobe blood agar that will support the growth of *Campylobacter*. Streak for isolation.
4. Incubate one set of Campy-selective agar and chocolate agar plates at 42°C in an atmosphere of 5% O_2, 10% CO_2, and 85% N_2 and the remaining plates at 35°C–37°C in the same gaseous atmosphere.
5. Inspect the plates after 24, 48, and 72 hours of incubation for colonies characteristic of *Campylobacter* species and identify the isolates with the techniques described in the text. Plates not showing growth after 24 or 48 hours of incubation should be returned for an additional 24–48 hours in the same incubator and gaseous atmospheric conditions, as described above.

BOX 8-2

Steele and McDermott Membrane Filter Technique

1. Mix 1 g stool in 10 mL of sterile saline containing glass beads. Vortex for 30 seconds.
2. Place a 47-mm, 0.45 Gelman cellulose triacetate membrane filter (Gelman No. 63069) centrally onto the surface of a nonselective *Brucella* agar plate

pipette. Take care to ensure that the drops do not extend to the edge of the filter.
4. Remove filter and discard 30 minutes after the suspension is applied.
5. Incubate plate in environment suitable for the cultivation of *Campylobacter* species, as described previously.

437

the top of the tube. If a *Campylobacter* broth is used, the following procedure for subculture should be followed:

Use a Falcon brand polyethylene plastic pipette that can be inverted. Place the tip of the pipette 1 inch below the surface of the medium and continuously withdraw sample as you remove the pipette. Invert the pipette to facilitate mixing of the sample, place three drops on a Campy-BAP plate, and streak for isolation. Incubate as you would a primary culture plate.

Identification From Culture. The appearance of colonies on one of the selective *Campylobacter* agars that has been incubated at 42°C in the microaerophilic environment, described previously, is presumptive evidence that the organism is one of the thermophilic *Campylobacter* species (most commonly *C. jejuni*). The morphology of *Campylobacter* species on selective agar varies from flat, gray, irregular-shaped colonies that may be either dry or moist to colonies that are round and convex and glistening with entire edges (Image Plate 8-1C, D). There is a tendency for colonies to form confluent growth along the streak lines on the agar surface. Hemolytic reactions are not observed on blood agar. The identification can be further confirmed by performing rapid catalase and cytochrome oxidase tests (*C. jejuni, C. coli,* and *C. lari* are positive for both these tests.). On occasion, thermophilic bacterial species other than *Campylobacter* species, notably *Pseudomonas aeruginosa,* may break through and grow on the selective media. It is unlikely, however, that *P. aeruginosa* would be confused with *C. jejuni*. The colony morphology of the two organisms is different, and if there were any question, a Gram stain would quickly differentiate *Campylobacter* species from *P. aeruginosa.*

Gram-stained preparations from colonies of *C. jejuni* after 24 to 48 hours incubation on blood agar show characteristic gram-negative, curved, "S"-shaped, gull-winged, or long spiral forms (Image Plate 8-1A). Coccoid forms are more commonly seen in older cultures of *C. jejuni,* particularly after colonies have been exposed to ambient air. Strict adherence to usual Gram stain timing is important because *Campylobacter* species are typically faintly staining. For this reason, one could consider extending the staining time of the safranin counterstain to at least 10 minutes to allow for greater staining intensity.

Once isolated, both subspecies of *C. jejuni* can be easily identified since they are

the only campylobacters that hydrolyze hippurate (Image Plate 8-1E and Table 8-4). In addition, this species is resistant to cephalothin and usually is susceptible to nalidixic acid, although resistant isolates are occasionally encountered (Image Plate 8-1F).

Other *Campylobacter* Species. At the time of this writing, there were 33 species and subspecies of *Campylobacter* described (http://www.bacterio.net/campylobacter.html). Only those species associated with human infections are covered further in this chapter.

Campylobacter coli. *C. coli* is closely related to *C. jejuni* and is also an important foodborne pathogen in humans.[409] It shares several cultural characteristics with *C. jejuni,* including susceptibility to nalidixic acid and resistance to cephalothin. *C. coli* can be differentiated from *C. jejuni* by the hippurate hydrolysis test (*C. jejuni* hydrolyzes hippurate; *C. coli* does not). The report when this organism is recovered in laboratories in which the hippurate test is not performed should read "*C. jejuni/C. coli*." It is estimated that *C. coli* accounts for 5% to 10% of cases of *Campylobacter* enteritis in humans.[299] A patient with a urinary tract infection caused by quinolone-resistant *C. coli* has also been reported.[328]

Campylobacter concisus. *C. concisus* is capable of anaerobic growth and requires hydrogen or formate for growth. The organism is isolated most commonly from human gingival crevices. However, it may also cause GI disease, especially in immunocompromised patients.[1,248,431] *C. concisus* has been suggested as a possible etiologic agent of Crohn's disease.[152,188,243,265,461,462,463] In a study by Zhang et al.,[463] *C. concisus* was more frequently present and higher levels of antibodies to *C. concisus* were detected in children with Crohn's disease than in controls. Recovery of *C. concisus* from stool specimens requires use of the filter method (discussed elsewhere in this chapter).

Campylobacter curvus. *C. curvus* was originally named *Wolinella curva.*[413,433] Cells stain gram negative and are short and slightly curved. Helical or straight cells may also occur. Strains exhibit rapid, darting motility and are asaccharolytic. The organism grows anaerobically and in 5% O_2 atmospheres containing H_2. No growth occurs in air enriched with 10% CO_2. All cultures require formate and fumarate for broth growth. Some strains exhibit a corroding morphology on agar media. Isolates have been recovered exclusively from human sources and include dental root canal, alveolar abscess, liver abscess, bronchial abscess, and blood.[156,413] *C. curvus* and *C. curvus*-like strains have been associated with sporadic episodes of bloody gastroenteritis.[7] Characteristics useful in distinguishing *C. curvus* from similar species are given in Table 8-5.

Campylobacter fetus* subsp. *fetus. *C. fetus* subsp. *fetus* is primarily associated with infective abortion in cattle and sheep and is an infrequent cause of human infections.

Infections usually result in systemic illness and usually affect debilitated persons with chronic hepatic, renal, or neoplastic disease, or individuals with compromised immune function.[68,336] *C. fetus* subsp. *fetus* has been reported to cause proctitis and proctocolitis in homosexual men[99]; premature labor and neonatal sepsis in humans[69]; septic abortion[402]; neonatal meningitis[241]; prosthetic hip joint infection[28,459]; and both native and prosthetic valve endocarditis.[113] *C. fetus* is the most commonly identified *Campylobacter* species to cause bacteremia.[323] In one study, patients with bacteremia due to *C. fetus* were older, were more likely to be male, and were more likely to have both implanted medical devices and no identified cause of immunosuppression compared to patients with bacteremia due to other *Campylobacter* species.[323] *C. fetus* is not believed to cause gastroenteritis, but, because of its susceptibility to cephalothin and its failure to grow at 42°C, it may not be recovered in clinical laboratories where selective media and increased incubation temperatures are used as a screen for *C. jejuni;* therefore, its etiologic role in this infection is not known.[163]

Campylobacter fetus* subsp. *venerealis. *C. fetus* subsp. *venerealis* comprises part of the normal genital tract flora of bulls, but has not been associated with human infection.[385]

Campylobacter gracilis. The name *Bacteroides gracilis* was proposed by Tanner et al.[412] for a group of agar-corroding bacteria that were originally considered to be anaerobic. In 1995, Vandamme and colleagues proposed the transfer of

this organism to the genus *Campylobacter* as *C. gracilis.*[428] These bacteria are found in the gingival crevices of humans and have been isolated primarily from sites of deep tissue infection.[200,251,381,414] Johnson and colleagues have reported that 83% of the specimens in which *C. gracilis* was isolated were obtained from patients with serious visceral or head and neck infections.[200] An 80-year-old man with a history of hypertension, hypertensive nephropathy, and chronic obstructive pulmonary disease (COPD) was reported to have developed fatal bacteremia caused by *C. gracilis.*[380] *C. gracilis* is microaerophilic and asaccharolytic and resembles campylobacters in almost all phenotypic characteristics. Individual cells stain gram negative and are small and unbranched, often having both tapered and rounded ends. Growth is stimulated in broth cultures by formate and fumarate. They may be differentiated from other campylobacters by the absence of flagella and oxidase activity.[412] *C. gracilis* isolates appear less susceptible to antimicrobial agents than the closely related species (e.g., *C. ureolyticus*), with only 67% of the isolates reported to be susceptible to penicillin.[200] A selective medium for isolation of *C. gracilis* has been described that contains tryptic soy agar base, formate, fumarate, nitrate and two selective agents, nalidixic acid, and teicoplanin.[252]

Campylobacter helveticus. *C. helveticus* is a thermophilic catalase-negative *Campylobacter* that has been isolated from the feces of domestic cats and dogs.[395] Of note is the fact that almost half of the *Campylobacter* isolates found in cats are *C. helveticus.*[55] Colonies of *C. helveticus* are adherent on blood agar and can be separated from other thermophilic species (*C. jejuni, C. coli,* and *C. lari*) by virtue of a negative catalase reaction. It is indoxyl acetate positive and susceptible to both nalidixic acid and cephalothin.

Campylobacter hyointestinalis. *C. hyointestinalis,* closely related to *C. fetus* subsp. *fetus,* was initially found only in animals, principally as a cause of ileitis in

swine,[137] but more recently has been reported from human clinical specimens. In one report,*C. hyointestinalis* was isolated from stool specimens of four persons, all of whom were experiencing nonbloody, watery diarrhea. The youngest (8 months) and the oldest (79 years) persons were female, and the other two were homosexual men.[107] A 52-year-old woman with chronic myeloid leukemia and nonbloody, watery diarrhea associated with this organism has been reported from France,[287] and an isolate from the rectal culture of a homosexual man with proctitis has been reported in the United States.[115] *C. hyointestinalis* will not be recovered on many *Campylobacter* media formulations because it is susceptible to cephalosporins, such as cephalothin and cefoperazone. Although it will grow at 42°C, growth is more luxuriant at 35°C.[115] The organism is also resistant to nalidixic acid, is hippurate negative, and produces hydrogen sulfide in triple sugar iron agar. The production of hydrogen sulfide in triple sugar iron agar is dependent on the test being incubated in a microaerophilic environment containing hydrogen.[137]

A group of "*C. hyointestinalis*-like" organisms obtained from porcine stomachs have been described. These isolates are sufficiently different from *C. hyointestinalis* to warrant creation of a separate subspecies classification, *C. hyointestinalis* subsp.*lawsonii*.[319] The creation of this new subspecies necessitates that the description of *C. hyointestinalis* be emended to *C. hyointestinalis* subsp. *hyointestinalis*. *C. hyointestinalis* subsp. *lawsonii* can be separated from subsp. *hyointestinalis* by its failure to grow in 1.5% bile. *C. hyointestinalis* subsp. *lawsonii* has been isolated from the intestines and stomachs of pigs; hamster intestines; and the feces of cattle, deer, and humans; but its pathogenicity is not known.[319]

Campylobacter jejuni* subsp. *doylei. A subspecies of *C. jejuni* has been isolated from human clinical specimens including gastric epithelium biopsies[213] and feces from children with diarrhea.[399] The pathogenicity of the organism remains unknown. *C. jejuni* subsp. *doylei* can be distinguished readily from other campylobacters because it does not reduce nitrates and hydrolyzes hippurate.[399] It is susceptible to cephalothin and therefore will not be recovered on media containing cephalosporin-type antibiotics.

Campylobacter lari. Formerly named *C. laridis,* the organism now known as *C. lari* is thermophilic, halotolerant, and nalidixic acid resistant; otherwise, it shares several

features with *C. jejuni* and *C. coli*.[383] Anaerobic growth in the presence of 0.1% trimethylamine oxide (TMAO) and failure to hydrolyze indoxyl acetate help to identify this species (reagents available from Sigma Chemical Co., St. Louis, MO). *C. lari* is

now considered to be part of a group of closely related *Campylobacter* species referred to as the *C. lari* group and is composed of five species (*C. lari, C. insulaenigrae, C. volucris, C. subantarcticus,* and *C. peloridis*), as well as a group of strains termed the *urease-positive thermophilic Campylobacter* (UPTC) and other *C. lari*-like strains.[283] Many laboratories rely on resistance to nalidixic acid to separate *C. lari* from *C. jejuni* and *C. coli;* however, *C. jejuni* resistant to nalidixic acid is being seen with increased frequency. *C. lari* is endemic in sea gulls but is an infrequent human pathogen. However, occasionally it causes enteritis simulating *C. jejuni* infections and, rarely, bacteremia, especially in immunocompromised persons.[32,79,269,300,415]

Campylobacter mucosalis. *C. mucosalis,* formerly classified as *C. sputorum* subsp. *mucosalis,* produces a yellow pigment and is catalase negative. Phenotypically, this species is very similar to *C. sputorum* bv. *sputorum* and *bubulus,* but is able to grow at 25°C. Unlike the majority of campylobacters, this species requires hydrogen and formate as an electron donor for growth, an essential requirement of *C. concisus, C. mucosalis, C. curvus,* and *C. rectus.*[430] Figura and colleagues[118] reported what was thought to be the first isolation of *C. mucosalis* from children with enteritis. However, this finding has been disputed, and the isolates have been shown by molecular probe studies to be *C. concisus*.[244,246,316] These two species are difficult to separate on the basis of biochemical tests alone, and it has been suggested that molecular methods must be used for the precise identification of these two species.[246] On[316] has suggested the use of several media containing various inhibitory agents for separating *C. concisus* and *C. mucosalis.* There are as yet no confirmed reports associating *C. mucosalis* with human infection.

Campylobacter rectus. *C. rectus* was originally named *Wolinella recta.*[412,433] Microscopically, the cells appear small and straight with rounded ends and stain gram negative. Strains exhibit rapid, darting motility and are asaccharolytic. Growth is anaerobic; however, some strains can grow in a 5% O_2 atmosphere but not in air enriched with 10% CO_2. Growth in broth is stimulated by formate and fumarate. Nitrates and nitrites are reduced, and both oxidase and catalase are negative. Additional identifying characteristics are given in Table 8-5. *C. rectus* is found in the gingival crevices of humans[412] and is reported to cause primary endodontic infections.[381] Spiegel and Telford[394] reported isolating this organism along with *Actinomyces viscosus* from an actinomycotic chest wall mass. *C. rectus* has also been reported as a cause of breast abscess,[156] abscess of the palate in a patient with gastroesophageal adenocarcinoma,[263] and extra-oro-intestinal abscesses.[100]

Campylobacter showae. *C. showae* is a recently described species isolated from human gingival crevices.[110] The organism appears as a straight rod with round ends

and contains two to five unsheathed unipolar flagella—a feature that is unique among campylobacters. The organism grows in a microaerophilic atmosphere in the presence of fumarate with formate or H_2, but prefers to grow under anaerobic conditions. Because of the limited number of reliable biochemical traits that can be used to differentiate closely related *Campylobacter* species, serologic or molecular tests or protein profiles may be required to positively identify isolates of this species.[110] An association with human disease has not been shown.

Campylobacter sputorum. *C. sputorum* is capable of anaerobic growth and can be recovered from the oral cavity and gingival crevices of humans. This organism is not recognized as an agent of human disease, although a few clinical isolates have been reported. Three biovars (bv) are described: *C. sputorum* bv. *bubulus, C. sputorum* bv. *sputorum,* and *C. sputorum* bv. *fecalis.*[361]

Campylobacter upsaliensis. *C. upsaliensis* is catalase negative or only weakly positive and thus has been referred to as the CNW strain of *Campylobacter.* However, because weak catalase reactions may also occur for *C. jejuni* subsp. *doylei,* the CNW designation no longer holds. Except for the lack of or weak production of catalase, this organism shares several characteristics with pathogenic campylobacters. It is thermophilic (i.e., grows at 42°C) and is highly susceptible to drugs that are present in selective isolation media, making them unsuitable for the isolation of *C. upsaliensis.*[400] Goossens and coworkers[145] reported the isolation of 99 strains of *C. upsaliensis* by the filter method, with only four strains recovered simultaneously from selective media.

Domestic pets may serve as the reservoir of this species, which was first isolated from healthy dogs, dogs with diarrhea, and later from asymptomatic cats.[129,371] Data from some reports suggest that this organism may be an opportunistic agent of infections in children. Lastovica and associates[245] reported the recovery of *C. upsaliensis* from blood cultures of 16 patients, 10 of whom were 10 months old or younger. Walmsley and Karmali[441] reported the isolation of this organism from the stools of six children. Other reports have associated the isolation of *C. upsaliensis* from the blood of patients with serious underlying disease.[59,81] There has been one report of *C. upsaliensis* isolated from the blood and fetoplacental material of an 18-week pregnant woman who suffered a spontaneous abortion.[151] The patient had no underlying disease, and her only previous pregnancy was uneventful. Numerical analysis of protein profiles revealed that strains isolated from the patient and a healthy household cat were almost identical, implying that the cat might have been the source of the infection.[151] The only report of *C. upsaliensis* from a site other than blood or stool was from a patient with a breast abscess in which *C. upsaliensis* was recovered along with a *Peptostreptococcus* species from purulent exudate obtained through fine-needle aspiration of the infected site.[136] Sandstedt and Ursing[370] have described *C.*

upsaliensis, including its phenotypic characteristics and clinical significance.

Campylobacter ureolyticus. *C. ureolyticus* was formerly known as *Bacteroides ureolyticus* but was reclassified as a species of *Campylobacter* in 2010.[428,429] *C. ureolyticus* differs from other campylobacters in its fatty acid composition and its proteolytic metabolism. It also differs from most campylobacters in its ability to hydrolyze urea (only some *C. lari* and *C. sputorum* strains are also urease positive).[428,429] *C. ureolyticus* strains have been isolated from patients with superficial ulcers, soft tissue infections, nongonococcal nonchlamydial urethritis, and periodontal disease.[104,105,123,124]

442

C. ureolyticus has also been reported to be an cause of gastroenteritis.[52] In a study by Johnson and colleagues, *C. ureolyticus* strains were found to be uniformly susceptible to penicillins, cephalosporins, erythromycin, clindamycin, chloramphenicol, metronidazole, and aminoglycosides.[200]

Campylobacter volucris. *C. volucris* is a novel species of *Campylobacter* that was first isolated from a rectal swab specimen from black-headed gulls in 2010 in Sweden.[93] A human with *C. volucris* bacteremia has been reported in an immunocompromised patient with polycythemia vera and alcoholic liver cirrhosis.[234] *C. volucris* is gram negative with a curved-rod morphology. It is oxidase and catalase positive and reduces nitrate. Indoxyl acetate and hippurate are not hydrolyzed. H_2S is not produced in triple sugar iron agar. Strains grow on blood agar plate at 37°C and 42°C under microaerophilic conditions, but do not grow aerobically.[93]

Genus Arcobacter

The genus *Arcobacter* belongs to the family *Campylobacteraceae* and includes the former aerotolerant *Campylobacter* species[433,435]; distinguished by their ability to grow in the presence of atmospheric levels of oxygen.[318] Other characteristics useful in distinguishing aerotolerant "*Campylobacter*" species from other campylobacters include hydrolysis of indoxyl acetate; growth at 15°C, 25°C, and 36°C, but not 42°C; and the inability to hydrolyze hippurate (Table 8-4). Three species were immediately associated with both human and animal diseases, namely *Arcobacter butzleri, A. cryaerophilus,* and *A. skirrowii*.

Arcobacter butzleri. Kiehlbauch and colleagues at the Centers for Disease Control and Prevention (CDC)[221] reported that the strains of aerotolerant campylobacters do not make up a homogeneous group. The majority of human isolates, both from within and

outside the United States, make up a distinct DNA homology group that they named *Campylobacter butzleri*, which changed to *Arcobacter butzleri* following the acceptance of the new genus designation for this group of organisms.[435] Strains of *A. butzleri* can be separated from *A. cryaerophilus* by demonstrating aerotolerance at both 30°C and 36°C (*A. cryaerophilus* is aerotolerant at 30°C, but not at 36°C). In addition, *A. butzleri* grows on MacConkey agar and in glycine and nitrate-containing media (reducing nitrate to nitrite) and in 1.5% and 3.5% NaCl. *A. cryaerophilus* gives the opposite reactions.[221] The majority of isolates of *A. butzleri* from humans have been from stools of patients with diarrheal illness[221,254,434]; however, the organism rarely has been isolated from abdominal contents, peritoneal fluid, and blood.[221,456]

Arcobacter cryaerophilus. *A. cryaerophilus* (formerly *C. cryaerophila*) grows well under aerobic conditions, although it may require microaerophilic conditions for initial isolation. Optimal growth occurs at 30°C, and the organism will not grow at 42°C. Biochemically, this species resembles *C. fetus* subsp. *fetus*; however, *A. cryaerophilus* is indoxyl acetate positive, whereas *C. fetus* subsp. *fetus* is not (Table 8-4). Most strains are susceptible to nalidixic acid and resistant to cephalothin. In a report by Borczyk and colleagues[45] comparing growth of *A. cryaerophilus* on CSM, Skirrow's blood agar, and cefsulodin irgasan novobiocin (CIN) agar, it was noted that the most luxuriant growth was obtained on CIN agar incubated for 24 to 48 hours at 25°C and 36°C. *A. cryaerophilus* has been recovered from human stools from healthy, asymptomatic individuals.[181,369] *A. cryaerophilus* was reported from the stool of a man infected with HIV with intermittent diarrhea; however, this strain was subsequently found to be *A. butzleri*.[416,417]

Arcobacter skirrowii. *A. skirrowii* is the most recently described species of *Arcobacter*. Strains have been isolated mainly from the preputial fluids of bulls; other strains have been isolated from aborted fetuses and diarrheic feces from cows, pigs, and sheep. *A. skirrowii* was isolated from the stool of a 74-year-old man with chronic diarrhea; however, there was no association with farm animals or pets, and it was not clear if the strain was etiologically associated with the patient's diarrhea.[454] Samie et al.[369] found *A. skirrowii* in 1.9% of hospital patients and primary school children in a region in South Africa, but it was not found to be associated with diarrhea.

Genus Helicobacter

The genus *Helicobacter* comprises 35 formally validated species at the time of this writing. Proposed names that are not yet validated by the International Committee on Systematic Bacteriology are enclosed in quotation marks. *Helicobacter* species are strict microaerophiles with a spiral or helical morphology. Many species exhibit strong

urease activity. *Helicobacter* species strain "flexispira" (formerly "*Flexispira rappini*") is the name proposed for an organism that is closely related to *Helicobacter,* but this microorganism is cigar shaped rather than curved and fusiform shaped. Species included in the genera *Helicobacter* possess sheathed flagella. No *Campylobacter* or *Wolinella* species possess sheathed flagella (Table 8-1).

Helicobacter pylori. This species was initially called *Campylobacter pyloridis* and then *Campylobacter pylori*. Molecular analysis provided evidence showing that this organism does not belong to the genus *Campylobacter.*[144] Features that distinguish this organism from campylobacters are its multiple sheathed flagella, its strong hydrolysis of urea, and a unique fatty acid profile (i.e., a high percentage of 14:0 acid, a low percentage of 16:0 acid, and the presence of 3-OH-18:0 acid). 16S rRNA sequencing has shown that this organism is closely related to *W. succinogenes.* However, there are many differences in biochemical features and growth characteristics between *H. pylori* and *W. succinogenes*, which indicates that these species should not be in the same genus. *W. succinogenes* is catalase negative, urease negative, does not possess γ-glutamyltranspeptidase or alkaline phosphatase activity, and does not grow at 30°C or on 0.5% glycine; *H. pylori* has the opposite characteristics.

H. pylori is found only on the mucus-secreting epithelial cells of the stomach. *H. pylori* is an important cause of active chronic antral gastritis[268] and is a major factor in the pathogenesis of peptic ulcer disease.[337] Additionally, there is strong evidence that *H. pylori* is linked to gastric adenocarcinoma and to the development of gastric non-Hodgkin's lymphoma (i.e., mucosa-associated lymphoid tissue [MALT] lymphomas).[327,391] *H. pylori* gastritis is widespread in many countries

in the world and may be one of the most common chronic human infections. The case for *H. pylori* as a causative agent of duodenal ulcer remains controversial. *H. pylori* bacteremia has been reported to occur as a rare complication in patients with undiagnosed gastric infection.[155,307]For excellent reviews, see the work of Blaser,[39] Buck,[51] and Dunn and colleagues.[106]

H. pylori strains are microaerophilic (10% CO_2, 5% O_2, 85% N_2) and will also grow in air with increased (10%) CO_2 content. The optimum temperature for isolation is 35°C to 37°C, although some strains will grow at 42°C. High humidity has also been found to favor growth. Most strains take 3 to 5 days to grow, with occasional isolates requiring 7 days of incubation before growth is evident. They can be cultured on nonselective blood-containing media, producing small, translucent, gray colonies. The characteristic Gram stain (small, curved, slightly plump bacilli) and positive reactions

for catalase, oxidase, and urease provide an identification.

Culture and Isolation of *H. pylori*

Specimens for Recovery of *H. pylori*. For the diagnosis of *H. pylori*-associated gastritis, histologic staining and culturing of biopsy specimens has been considered the "gold standard."[27] Image Plate 8-1H Suitable specimens include gastric and duodenal biopsies. Specimens submitted for culture should be fresh and not delayed in transport for more than 3 hours. Specimens may be kept for up to 5 hours if stored at 4°C. Tissue should be kept moist by the addition of 2 mL or less of sterile isotonic saline.

Isolation Procedure. Grinding of specimens in a ground-glass grinder yields heavier growth than mincing or rubbing the specimen onto an agar surface. Material should be inoculated onto a nonselective blood agar medium, such as Brucella, brain–heart infusion (BHI), or tryptic soy agar plates with 5% sheep or horse blood added. Poor growth is observed on commercially prepared chocolate agar plates; therefore, this medium is not recommended. Because these bacteria are susceptible to cephalothin, *H. pylori* will not grow on any selective medium containing cephalosporins. Many laboratories have had good results using modified Thayer–Martin agar as a selective medium for isolation of *H. pylori* in mixed cultures. Plates are incubated at 37°C in a humid, microaerophilic environment. Growth is usually observed in 3 to 5 days. Unpublished data from experiments conducted at the University of Illinois Hospital Microbiology Laboratory are shown in Table 8-6. Because of the potential hazard of using an anaerobic jar without a catalyst, we recommend the use of the Campy GasPak jar (column 2 in Table 8-6). Growth occurred in the Campy GasPak jar but not in the Poly Bag with Campy gas mixture (column 4 in Table 8-6), presumably because the water added in the former system provides the necessary humidity for growth.

Identification of *H. pylori*. Colonies of *H. pylori* are small, gray, translucent, and weakly β-hemolytic. Gram stain reveals pale-staining, curved, gram-negative bacteria with characteristic gull-wing and "U" shapes. Presumptive identification can be made with positive reactions for oxidase and catalase and an extremely rapid (within minutes) urease reaction. Additional identifying characteristics are listed in Table 8-4.

Biopsy Urease Test (*Campylobacter*-Like Organism Test). A more rapid but somewhat less sensitive and specific technique than the previously mentioned tests is the biopsy urease test (*Campylobacter*-like organism [CLO] test). In this test, a medium containing urea and a pH-sensitive dye is inoculated with the mucosal biopsy specimen. If urease is present in the specimen, urea is split and ammonia causes a rise in pH and subsequent change in the color of the indicator. This test may produce false-negative results if only a small number of organisms are present or false-positive results if other urea-splitting organisms are present in the specimen.[275]

TABLE 8-6 Comparison of Culture Media and Atmospheric Conditions for Growth of *Helicobacter pylori*

Agar Media	Conditions of Incubation[a]				
	Anaerobe Jar (No Catalyst)	Campy GasPak Jar	Anaerobe Jar (Catalyst)	Poly Bag (Campy Gas Mixture)[b]	Atmospheric Air With 5% CO_2
Brucella with 5% sheep blood	Best growth β-hemolytic	Very good growth β-hemolytic	No growth	No growth	No growth
Tryptic soy with 5% sheep blood	Very good growth	Good growth	No growth	No growth	No growth
Brain–heart infusion with 5% horse blood	Very good growth	Good growth	No growth	No growth	No growth
Chocolate (Becton Dickinson Microbiology Systems, Cockeysville, MD)	No growth	No growth	No growth	No growth	No growth
Chocolate (GIBCO)	Small colonies	Small colonies	No growth	No growth	No growth
Chocolate (freshly prepared)	Very small colonies	Very small colonies	No growth	No growth	No growth
Campy-BAP (Blaser's)	No growth	No growth	No growth	No growth	No growth

[a]All cultures were incubated at 37°C and read after 5 days.
[b]5% O_2, 10% CO_2, 85% N_2.
Data from K. Ristow, University of Illinois Hospital, Chicago, IL.

Noninvasive Tests to Diagnose *H. pylori* Infection. *H. pylori* infection may be diagnosed by invasive assays that require endoscopy (culture, stain, polymerase chain reaction [PCR], CLO test), or by noninvasive assays in which endoscopy is not necessary. Included in the latter category are the urease method, antigen detection, and serology.

Urease method. Two urease methods have been described. The first method, called the urea breath test (UBT), requires that the patient ingest [^{13}C]-labeled urea dissolved in water, followed by collection of breath samples that are analyzed for the presence of $^{13}CO_2$ at 60 minutes. A second method utilizes radiolabeled urea containing ^{15}N.[452] After oral ingestion, radiolabeled urea is broken down into ammonia and carbon dioxide by *H. pylori* urease in the stomach. The ammonia is absorbed into the blood and excreted in the urine. The amount of [^{15}N] urea, reflecting the magnitude of *H. pylori* infection, is evaluated by measuring the abundance and excretion rate of ^{15}N in ammonia in the urine. The sensitivity of the $^{15}NH_4$ excretion test is reported to be 96%, with 100% specificity when compared with patients who were *H. pylori* positive by culture and Gram stain.[452] The [^{13}C] UBT is very reliable for the diagnosis of *H. pylori* infection in adults and children older than 6 years, but the specificity varies from 82% to 100% for younger children.[30,187,277,346,363]

Antigen detection. A monoclonal antibody–based enzyme immunoassay (EIA) for direct detection of *H. pylori* antigen in stool specimens is commercially available

(Premier Platinum HpSA, Meridian Bioscience, Cincinnati, OH) and has been found to be highly accurate in all age groups, including children.[20,231,264,288,309]

Serologic methods. Serologic tests for detecting antibody to *H. pylori* have been used mainly for epidemiologic studies, but can also be used to monitor the efficacy of treatment. The principle format is the enzyme-linked immunosorbent assay test for the detection of IgG, although latex agglutination tests are available. IgA and IgM can also be detected, but are less useful diagnostically. One inherent problem is attempting to establish a baseline for positivity since the prevalence of persons with elevated antibody titers is relatively high in certain populations. In an extensive study of Army recruits, Smoak et al.[387] found an overall positivity rate of 26.3%. This rate increased from 24.0% in age group 17 to 18 years to 43% in age group 24 to 26 years. Seropositivity for blacks was 44%, for Hispanics 38% and for whites 14%.

Accuracy of Invasive and Noninvasive Tests to Diagnose *H. pylori* Infection. Cutler and colleagues[91] evaluated the accuracy of several tests for determining *H. pylori* infection, including the UBT, measurement of serum IgG and IgA antibody levels and antral biopsy specimens for CLO test, histology, and Warthin–Starry stain. They found that the Warthin–Starry stain had the best sensitivity and specificity, although the CLO test, UBT, and IgG levels were not statistically different in determining the correct diagnosis. They concluded that the noninvasive UBT and IgG serology tests are as accurate in predicting *H. pylori* status in untreated patients as the invasive tests of CLO and Warthin–Starry. The absence of chronic antral inflammation accurately excludes *H. pylori* infection.[91]

Other Medically Important *Helicobacter* Species. Several species of *Helicobacter* other than *H. pylori* have been isolated from humans and are associated with human disease.[122,278,389,390,391] These include *H. bilis, H. canadensis, H. canis, H. cinaedi, H. felis, H. fennelliae, H. heilmannii* ("*G. hominis*"), *H. hepaticus, H. pullorum*, *H. suis*, *Helicobacter* species strain flexispira ("*Flexispira rappini*"), and the unnamed *Helicobacter* species CLO-3 (Table 8-7).

Helicobacter bilis. *H. bilis* is a fusiform bacterium with 3 to 14 multiple bipolar sheathed flagella and periplasmic fibers wrapped around the cell. It grows microaerophilically at 37°C and 42°C, but not at 25°C. Additional characteristics are provided by Fox et al.[130] *H. bilis* includes some of the former "*Flexispira rappini*" strains previously referred to as *Helicobacter* sp. flexispira 16S rDNA taxa 2, 3, 8, and 9.[157] *H. bilis* is an unusual cause of chronic infections in patients with X-linked agammaglobulinemia (XLA) and is notoriously difficult to diagnose and eradicate.[298,425] It has been reported to cause cellulitis accompanied by bloodstream infection in such patients.[141,425] *H. bilis* has also been recovered in the bile and gallbladder tissue of patients with cholecystitis and gallbladder cancer[126,340]; however,

a causative role has not been shown.[325]

Helicobacter canadensis. *H. canadensis* is named after the country of original isolation. Cells are slender, curved-to-spiral rods with one to three spirals. It is gram negative and motile by means of nonsheathed, single unipolar or bipolar flagella. Cultures grown on solid agar media appear as spreading layers. Growth occurs at 37°C and 42°C. Additional characteristics are found in the report by Fox et al.[125] It has been isolated from humans with diarrhea,[125] and from the blood of a 35-year-old man with pyrexia of unknown origin.[419]

Helicobacter canis. *H. canis* is a gram-negative, helically curved, spiral, slender, rod-shaped bacterium with bipolar flagella and is most frequently detected in the GI tract of dogs and cats.[397] *H. canis* has been reported in cases of human bacteremia[8,16,141,253,344,436] and chronic duodenal ulcerations in a patient with Crohn's disease.[411] Human infection with *H. canis* is most likely zoonotic from regular contact with domestic pets.

Helicobacter cinaedi. *H. cinaedi,* originally designated as CLO-1, and formerly known as "*Campylobacter cinaedi,*" has been isolated from rectal swabs taken from symptomatic as well as asymptomatic homosexual men.[116,422] This organism has also been described as a cause of bacteremia in two homosexual men with concurrent tuberculosis,[331] in patients with AIDS,[82,94,367] and in another who was HIV seropositive but did not have AIDS.[308] Reports, however, suggest that *C. cinaedi* infections are not restricted to homosexual or bisexual men. For example, Vandamme and associates[432] have reported the isolation of *H. cinaedi* from the blood of two women without any record of sexual contact with homosexuals and from the stools of three children, two of whom were girls.

H. cinaedi is known to cause diarrhea as well as bacteremia, cellulitis, and other symptoms after gaining entry into the body through the intestinal mucosa. Although these conditions are primarily observed in HIV-infected patients, their occurrence among both immunocompetent[228,242] and other immunocompromised patients[223,224,286,297] has also been reported. Orlicek and colleagues have reported a neonatal patient with septicemia and meningitis caused by *H. cineadi*.[320]

445

TABLE 8-7 *Helicobacter* Species and Related Organisms of Human Origin

Species	Origin	Types of Human Infection
		Cellulitis accompanied by bloodstream infection in patients with

H. bilis	Mice, humans	XLA, bile, and gallbladder tissue of patients with cholecystitis and gallbladder cancer
H. canadensis	Feces of diarrheic humans	Diarrhea and bacteremia
H. canis	Gastric mucosa of dogs and cats	Bacteremia and chronic duodenal ulcerations in patients with Crohn's disease
H. cinaedi	Rectal swabs of homosexual men and intestinal tract of hamsters	Diarrhea, bacteremia, cellulitis, and meningitis in both immunocompetent and immunocompromised patients
H. felis	Gastric mucosa of dogs and cats	Gastric biopsy
H. fennelliae	Rectal swabs of homosexual men	Bacteremia in HIV-infected patients and stools and blood cultures of pediatric patients. Human-to-human transmission has been shown.
H. heilmannii	Cheetahs; gastric mucosa of humans and domestic animals	Chronic gastritis similar to *H. pylori* infection, MALT lymphoma, gastric and duodenal ulcer, and gastric cancer
H. hepaticus	Colons and ceca of mice	Associated with HCC
H. pylori	Gastric mucosa of humans	Gastritis and peptic ulcer disease. Also plays etiologic role in metaplasia and dysplasia of gastric mucosa, gastric adenocarcinoma, and non-Hodgkin's lymphoma of the stomach. Rare cause of bacteremia in patients with undiagnosed gastric infection.

H. pullorum	Intestinal tract and liver of chickens, mice, and humans	Gastroenteritis, chronic hepatobiliary disease, and Crohn's disease
H. suis	Stomach of pigs	Dyspepsia and reflux esophagitis in a pig veterinarian
Helicobacter sp.*flexispira*[a]	Stool of humans, dogs, and from aborted ovine fetuses	Gastroenteritis and bacteremia
CLO-3	Rectal swabs of homosexual men	Diarrhea

[a]Flexispira taxa 1 and 4–6 represent the same species and are named *H. trogontum*,[158] while, Flexispira taxa 2, 3, 8, and 9 represent the same species and are named *H. bilis*.[157] Flexispira taxa 7 and 10 remain unnamed at the time of this writing.
XLA, X-linked agammaglobulinemia; MALT, mucosa-associated lymphoid tissue; HCC, hepatocellular carcinoma.

Since *H. cinaedi* has been identified as a normal intestinal inhabitant of hamsters[138,403] and the mother of the newborn cared for pet hamsters during the first two trimesters of her pregnancy, it is likely that the hamsters served as a reservoir for the transmission of the organism to the mother and that the newborn most likely became colonized with *H. cinaedi* during the birth process.[320] An immunocompetent adult who had daily contact with a kitten for a month developed *H. cinaedi* meningitis.[405] *H. cinaedi* has also been reported to cause infection of an axillobifemoral bypass graft in an immunocompetent 85-year-old man,[404] and was identified in aneurysmal tissues from three patients with abdominal aortic aneurysm.[207] Burman and coworkers[54] have reported the association of skin infections and arthritis due to *H. cinaedi* bacteremia. The most common cutaneous manifestation of *H. cinaedi* bacteremia is superficial cellulitis, which usually takes the

form of painful erythemas or infiltrated erythematous plaques on the extremities.[379] Blood culture isolates are often recovered in automated blood culture instruments only after 5 or more days of incubation. In a report by Araoka et al.,[21] the time required for blood cultures to become positive for *H. cinaedi* was ≤5 days in 69 sets (55%) and >5 days in 57 sets (45%) using the Bactec 9240 and the Bactec FX (Becton, Dickinson, Sparks, MD) blood culture systems. All *H. cinaedi* strains were detected in aerobic bottles only.[21] Since standard laboratory practice is to incubate blood culture bottles for 5 days, the true incidence of *H. cinaedi* bacteremia is likely underreported. In general, organisms are not seen on initial Gram staining of the blood culture material, but can be visualized by darkfield or acridine orange staining. *H. cinaedi* grows only at 37°C, shows intermediate resistance to cephalothin (30-mg disk), and reduces nitrate to nitrite. Additional genotypic and phenotypic characteristics can be found in the report by Kiehlbauch and colleagues.[220] The clinical spectrum of illness associated with *H. cinaedi* infection includes fever, bacteremia, and recurrent cellulitis, with most patients having signs of systemic infection including leukocytosis, and often thrombocytopenia.[222] Kielbauch and colleagues reported that treatment with a penicillin, tetracycline, or an aminoglycoside may be more effective than treatment with cephalosporins, erythromycin, or ciprofloxacin.[222] The only known natural reservoir of *H. cinaedi* found so far is the intestinal tract of hamsters, which may serve as a reservoir of human infections.[138,403] Nosocomial infection

caused by *H. cinaedi* among immunocompromised patients in the same hospital ward has been reported indicating that human-to-human transmission can also occur.[286,356]

Helicobacter felis. *H. felis* is a spiral-shaped, gram-negative rod containing five to seven spirals per cell. Spherical forms are present in older cultures. Cells are motile with a rapid corkscrew-like motion. Growth occurs in microaerophilic atmosphere, but the organism can grow anaerobically. It grows at 37°C and 42°C, but not at 25°C. These organisms are nutritionally fastidious, growing only on media enriched with blood or serum, and are asaccharolytic.[330] These bacteria have been isolated from the gastric mucosa of cats and dogs and also recovered from a gastric biopsy specimen of a 14-year-old girl who presented with persistent epigastric pain of several months duration.[453]

Helicobacter fennelliae. Originally designated CLO-2, and formerly known as "*Campylobacter fennelliae,*"[422] this organism has the distinctive odor of hypochlorite cleaning powders.[116] It is susceptible to cephalothin and does not reduce nitrates to nitrite. As with *H. cinaedi, H. fennelliae* has been isolated from rectal swabs taken

from symptomatic and asymptomatic homosexual men,[116,422] and is reported to cause bacteremia in HIV-infected patients.[218,220,308] Subsequent reports have identified *H. fennelliae* in the blood of a non–HIV-infected heterosexual man with cirrhosis and diabetes,[182] and in stools and blood cultures of pediatric patients in South Africa.[388] Rimbara et al.[355] reported isolation of *H. fennelliae* from the blood of 3 patients from the same hospital ward, which showed the same pulsed-field gel electrophoresis pattern between isolates, suggesting human-to-human transmission.[356] Sharp reported *H. fennelliae* in chronic skin ulcers in a 25-year-old homosexual man with Bruton's XLA.[378]

Helicobacter heilmannii. *H. heilmannii* is a spiral bacterium found in human gastric mucosa that is larger and more tightly coiled than *H. pylori*. The organism is helical, 3.5 to 7.5 μm long and 0.9 μm in diameter with truncated ends flattened at the tips, six to eight tight spirals, and up to 12 sheathed flagella 28 nm in diameter at each pole.[274] McNulty and colleagues proposed the name "*Gastrospirillum hominis*." However, Solnick and coworkers[390] showed that "*Gastrospirillum*" is a member of the *Helicobacter* genus and proposed the name "*H. heilmannii"* after Konrad Heilmann, a German histopathologist who described the first large series of patients infected with the organism.[165] *H. heilmannii* was given full taxonomic status after successful in vitro cultivation in 2012.[384] Heilmann and Borchard reported the prevalence of "*Gastrospirillum*" infection in patients presenting for endoscopy to be less than 1%.[165] *H. heilmannii* appears to be ubiquitous in domestic animals, suggesting that human infection may be acquired as a zoonosis.[103,128,167] Human infection with this bacterium may be accompanied by chronic gastritis similar to that seen with infection by *H. pylori*.[97,120,165,250,274,291,389] Iwanczak et al.[189] recovered *H. heilmannii* from biopsy specimens taken from the gastric mucosa of 22 children with dyspeptic symptoms. In three children, mixed infection with *H. pylori* and *H. heilmannii* was diagnosed.[189] *H. heilmannii* has also been reported to cause gastritis in patients testing negative for *H. pylori*.[272,358] In addition to gastritis, *H. heilmannii* has been associated with low-grade gastric MALT lymphoma,[290,349] gastric and duodenal ulcer,[102,142,199,390,460] and gastric cancer.[147,289,457]

Helicobacter hepaticus. *H. hepaticus* cells are slender, gram-negative, curved-to-spiral rods, which form one to three spiral turns. They are motile by means of sheathed, single, bipolar flagella. Colonies are pinpoint, but cultures often appear as thin spreading layer on agar media.[127] Cells exhibit microaerophilic or anaerobic growth, but there is no growth aerobically. Growth occurs at 37°C, but not at 25°C or 42°C.[127] *H. hepaticus* was originally recovered from the colons and ceca of mice and has been shown to cause chronic active hepatitis and induce hepatocellular carcinoma

(HCC) in mice.[127,443] Yang and colleagues identified *H. hepaticus* infection in patients with primary HCC using serologic and molecular biologic detection, suggesting that *H. hepaticus* infection may be involved in the progression of HCC in humans.[458]

Helicobacter pullorum. *H. pullorum* is a gram-negative, curved, slender, rod-shaped bacterium with a single, unsheathed polar flagellum.[396] It exhibits characteristic darting motility and grows micoaerobically at 37°C and 42°C. No growth occurs under aerobic or anaerobic conditions.[396] It is considered an enterohepatic pathogen that has the ability to colonize the distal intestinal tract and liver of chickens, mice, and humans.[66,396,424] It has been detected in humans with gastroenteritis,[56,396,401] chronic hepatobiliary diseases,[65,126,335,357] and Crohn's disease.[43,236] Sirianni et al.[382] showed that *H. pullorum* has the ability to adhere to and invade human cells and secrete factors that may contribute to the pathogenic potential.

Helicobacter suis. Cells of *H. suis* are gram-negative, tightly coiled spiral rods with up to six turns. In older cultures, coccoid cells predominate. They are motile by means of tufts of 4 to 10 sheathed bipolar flagella. Organisms grow under microaerophilic conditions but not in 5% CO_2, and only weak growth is observed under anaerobic conditions. Growth occurs at 37°C, but not at 25°C or 42°C.[24] *H. suis* is associated with ulceration of the stomach and gastritis in pigs[24] and is reported to infect up to 80% of pigs at slaughter age.[166,326] There has been one report of human infection occurring in a pig veterinarian suffering from general dyspepsia and reflux esophagitis. Biopsy specimens from both the corpus and antrum of the stomach revealed the presence of *H. suis*.[203]

***Helicobacter* sp. Strain *flexispira* ("*Flexispira rappini*").** *Helicobacter* species strain "*flexispira*" (formerly "*Flexispira rappini*") was the proposed name[49] of an organism that is urease positive and possibly genomically closely related to *H. pylori*.[433] However, it is a straight, fusiform-shaped organism rather than a spiral one, and the ultrastructure is highly distinctive: The cell body is cigar shaped, encircled by a complex array of periplasmic fibrils, and has multiple, bipolar tufts of sheathed flagella. It does not possess alkaline phosphatase or grow at 30°C, but does grow at 42°C, and is resistant to metronidazole (5 mg); *H. pylori* has the opposite characteristics.[144] It is separated from the campylobacters by negative reactions for catalase and nitrate and an inability to grow in 1% glycine.[22] *Helicobacter* species strain "flexispira" has been isolated from stool specimens of humans with symptoms of gastroenteritis and from blood cultures, from the stool of dogs,[22,360] and from aborted ovine fetuses.[226,227,360,392,418] Dewhirst et al.[101] examined a collection of *"F. rappini"* strains by using 16S rRNA sequence analysis and found that the strains

fell into 10 taxa, named flexispira taxons 1 to 10, each possibly representing a novel *Helicobacter* species. Two of the taxa corresponded to previously designated *Helicobacter* species, flexispira taxon 6 corresponded to *H. trogontum,*[279] and flexispira taxon 9 corresponded to *H. bilis*.[130] Subsequent phenotypic characterization, analysis of RFLPs of 16S and 23S rDNAs, and SDS-PAGE profiles revealed that flexispira taxa 1, 4, and 5 and the type strain of *H. trogontum* (flexispira taxon 6) represented the same species and are therefore named *H. trogontum*,[158] while flexispira taxa 2, 3, and 8 and the type strain of *H. bilis* (flexispira taxon 9) represent the same species and are therefore named *H. bilis*.[157] Flexispira taxa 7 and 10 remain unnamed at the time of this writing.

CLO-3. An unnamed species originally described by Fennell and coworkers,[116] CLO-3 can be separated from the other CLOs by its ability to grow at 42°C, its resistance to cephalothin, and its inability to reduce nitrate (Table 8-4). One isolate has been reported from a rectal swab obtained from a symptomatic homosexual man.[116]

Other Microaerophilic Gram-Negative Bacilli

Sutterella wadsworthensis. Wexler and colleagues have proposed the name *S. wadsworthensis* for a group of bacteria that were originally identified as *C. gracilis* but differed in genetic and biochemical characteristics from typical *C. gracilis* strains.[447] These organisms are gram-negative straight rods that grow in a microaerophilic atmosphere or under anaerobic conditions. They are differentiated from *C. gracilis* and *Campylobacter* species by being oxidase, urease, and indoxyl acetate negative; resistant to 20% bile disks; and by not reducing tetrazolium tetrachloride under aerobic conditions. They have been isolated mainly from human infections of the GI tract.[447]

Definitive Identification of Campylobacters and Related Bacteria

The colonial morphology and Gram stain characteristics of *C. jejuni*, as described earlier, also pertain to most other *Campylobacter* species. However, definitive species identification depends on the determination of the phenotypic characteristics presented in Table 8-4; when these tests do not provide a species identification, then molecular techniques must be employed.

The differential susceptibility to nalidixic acid and cephalothin may be useful in

differentiating the more commonly encountered *Campylobacter* species according to the scheme in Box 8-3. Because isolates of *C. jejuni* and *C. coli* resistant to nalidixic acid are encountered with increasing frequency, these tests have become less helpful.

Luechtefeld and Wang[260] also found that resistance of *C. jejuni* to triphenyltetrazolium chloride (TTC) is helpful in distinguishing *C. fetus*. The test for hippurate hydrolysis is useful in separating *C. jejuni* from the closely related species *C. coli*. Most strains of *C. jejuni* hydrolyze hippurate to benzoic acid and glycine.[162] The rapid procedure of Hwang and Ederer for hippurate hydrolysis is suitable for testing clinical isolates of *Campylobacter* species. Morris and associates[292] describe a more sensitive method for detecting benzoic acid using gas-liquid chromatography (GLC). This application is an extension of the procedure previously reported by Kodaka and colleagues,[230] who used hippurate formate fumarate medium to detect not only hippurate hydrolysis by GLC, but also the utilization of formate and fumarate.

Mills and Gherna[284] described the use of a rapid test for detecting hydrolysis of indoxyl acetate by *Campylobacter* species. Studies have shown that all strains of *C. jejuni, C. coli, C. curvus, C. helveticus, C. rectus, C. showae, C. upsaliensis, A. butzleri, A. cryaerophilus*, and *H. fennelliae* hydrolyze indoxyl acetate, whereas most other campylobacters are negative.[174,284,317,343] Several additional biochemical and physical characteristics may be helpful in separating the various *Campylobacter* and *Campylobacter*-like species (Table 8-4). An extensive review of identification methods for campylobacters, helicobacters, and related organisms has been published by On.[317]

Rapid Identification of Campylobacters From Colonies Grown in Culture

Morphologic Identification. In most instances, the appearance of small, tan to gray, watery colonies that tend to flatten on *Campylobacter*-selective agar, and that exhibit

BOX 8-3

Definitive Identification of Most Commonly Encountered Campylobacters

	Nalidixic Acid	Cephalothin	TTC	Hippurate Hydrolysis	Indoxyl Acetate Hydrolysis
C. jejuni subsp. *jejuni*	V	R	R	+	+
C. coli	S	R	R	–	+
C. fetus subsp. *fetus*	R	S	S	–	–
C. lari	R	R	S	–	–

TTC, triphenyltetrazolium chloride.

characteristic "S"-shape and gull-wing morphology on Gram's stain and are oxidase and catalase positive, will be sufficient to establish the diagnosis of campylobacteriosis in patients with diarrheal syndromes.

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry. Identification of *Campylobacter* species and related organisms using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) has been shown to be accurate for several species of *Arcobacter, Campylobacter*, and *Helicobacter*.[12,34,267,270,410,448] In a study by Bessède et al.,[34] there was 100% correlation with MALDI-TOF and molecular identification for six species (*A. butzleri, C. coli, C. fetus, C. lari, C. sputorum*, and *C. upsaliensis*) and 99.4% correlation for *C. jejuni*. In a study reported by Martiny and colleagues, 230/234 (98.3%) *Campylobacter, Arcobacter*, and *Helicobacter* isolates representing 12 species were correctly identified by MALDI-TOF.[270]

Commercial Kit Systems. The API Campy (bioMérieux, Marcy l'Étoile, France) is a miniaturized identification system that includes 11 enzymatic and conventional tests and nine assimilation and inhibition tests.[186,270,352] Martiny et al.[270]reported that the API Campy provided correct identification of *C. jejuni* subsp. *jejuni* for 116/125 (92.8%) isolates tested, but overall correctly identified only 167/234 of 12 species of *Campylobacter, Arcobacter*, and *Helicobacter* isolates tested.

The *Neisseria–Haemophilus* (NH) identification card was developed for use on the Vitek 2 system (bioMérieux, Marcy l'Étoile, France). The NH card is based on colorimetric technology utilizing dehydrated media containing chromogenic substrates that are used to identify 27 taxa of gram-negative fastidious bacteria, including *C. jejuni, C. coli*, and *C. fetus*.[270,354,427] In a study reported by Martiny et al.,[270] 101/125 (80.8%) *C. jejuni* subsp. *jejuni*, 47/65 (72.3%) *C. coli*, and 0/7 *C. fetus* isolates were correctly identified to the genus and species level with the Vitek 2 NH

card.

Methods for Direct Detection of Campylobacters From Stool

Non–culture-based methods that allow for the direct detection of *Campylobacter* antigens or DNA in stool specimens have been developed. These include direct immunofluorescence, EIAs, and PCR assays.

Direct Immunofluorescence. Hodge and coworkers[175] advocate the use of direct immunofluorescence techniques in the rapid screening of stool specimens from patients with an acute diarrheal syndrome. This approach has the potential for removing the guesswork involved in interpreting Gram-stained smears. However, these reagents are not commercially available.

Enzyme Immunoassay. There are currently three *Campylobacter* EIA methods commercially available: the Premier CAMPY EIA (Meridian Bioscience, Cincinnati, OH), the ProSpecTCampylobacter EIA (Remel, Lenexa, KS), and the ImmunoCard STAT! CAMPY test (Meridian Bioscience, Cincinnati, OH). In a study conducted by Granato et al.[149] on 485 stool specimens (127 culture-positive and 358 culture-negative) tested by the Premier CAMPY and ProSpecT Campylobacter microwell plate EIAs, both assays had identical sensitivities of 99.3% and comparable specificities (99.3% vs. 98%), with positive and negative predictive values of 95% and 99.7% for each EIA, respectively, after arbitration of discrepancies with culture results by PCR. In a subset of 300 (127 culture-positive and 173 culture-negative) stool specimens tested using the ImmunoCard STAT! CAMPY assay, the sensitivity, specificity, positive, and negative predictive values were 98.5%, 98.2%, 97.8%, and 98.8%, respectively, after arbitration of discordant results with PCR.[149] Several studies have shown that the ProSpecT Campylobacter EIA and ImmunoCard STAT! CAMPY assay can detect *C. upsaliensis* in culture-negative specimens because of the cross-reactivity between *C. upsaliensis* antigen with *C. jejuni/C. coli* antigens.[89,95,172] Bessède et al. evaluated two culture-based methods (culture after filtration and culture on selective medium without filtration) with two different PCR methods and three different immunoenzymatic methods. The main result of their study was the lack of sensitivity of culture methods for detecting *Campylobacter* species, the filtration methods detected only 15 cases (65%) and selective media 13 cases (54.4%).[33] In contrast to these findings, researchers from CDC conducted a study of diagnostic methods used by laboratories within eight states for detection and isolation of *Campylobacter* from stool including four *Campylobacter*-selective media and four EIA assays. They reported that a total of 3.1% (87/2772) of specimens tested were positive by culture of which 13.8% (12/87) were negative in all four EIA tests utilized

by the participants. As compared to culture, the sensitivity/specificity/positive predictive values of four EIA tests were as follows: Premier CAMPY, 81.6/97.6/52.9%, ProSpecT Campylobacter 82.7/97.9/56.7%, ImmunoCard STAT! CAMPY, 72.4/96.3/38.6%, XpecT, 73.6/99.3/76.2%.[121] Given the low incidence of *Campylobacter* disease and the performance data generated in their study, these authors concluded that rapid EIA tests do not appear reliable as standalone tests for direct detection of *Campylobacter* in stool.[121]

PCR. There are currently five commercially available diagnostic systems for the detection of enteric pathogens using multiplex PCR that include targets for one or more *Campylobacter* species. These include Prodesse ProGastro SSCS assay (Hologic Inc., San Diego, CA),[50] Luminex xTag GI pathogen panel (GPP) assay (Luminex Corp., Austin, TX), [83,219,306,332] FilmArray GI panel (BioFire Diagnostics LLC, Salt Lake City, UT),[57,219] Verigene Enteric Pathogens (EP) test (Nanosphere, Northbrook, IL),[312] and BD Max enteric bacterial panel (EBP) (BD Diagnostics, Baltimore, MD).[19,36,161] The Prodesse ProGastro SSCS assay and the BD Max EBP assay detect the same pathogens: *Salmonella* spp., *Shigella* spp., *Campylobacter* spp. (*C. jejuni* and *C. coli*), and Shiga-like toxin genes. In a study of the BD Max EBP performed on 3,401 specimens by Harrington et al.,[161] the positive percent agreement and negative percent agreement for *Campylobacter* was 97.5% and 99.0%, respectively. Biswas et al.[36] reported 100% sensitivity and 100% specificity for *Campylobacter* with the BD Max. The Prodesse ProGastro SSCS panel was evaluated by Buchan et al.,[50] who reported

96.4% sensitivity and 93.5% specificity for *C. coli/C. jejuni*. The Verigene EP test includes seven bacterial and two viral targets, including *Campylobacter* group. In an assessment of 611 prospective and 839 contrived specimens, conducted on the Verigene EP, Novak et al.[312] reported 97.1% sensitivity for *Campylobacter* species. The FilmArray panel contains 23 bacterial, viral, and parasitic targets, including *C. jejuni, C. coli*, and *C. upsaliensis*. In a multicenter study of 1,556 samples, the sensitivity and specificity of the FilmArray GI panel for *Campylobacter* species were 97.1% and 98.4%, respectively.[57] Khare et al.[219] reported 100% sensitivity and specificity with *Campylobacter* species and the FilmArray GI panel, although only three positive *Campylobacter* samples were included in the study. The Luminex xTag GPP assay can detect 15 targets (9 bacteria, 3 viruses, 3 parasites) and includes *C. jejuni, C. coli*, and *C. lari*. Several studies on the xTag GPP assay have been

published with reported sensitivities ranging from 90% to 100%.[83,219,306,332] All of the molecular panels report sensitivities and specificities greater than conventional culture and can be performed directly on stool specimens, with results available in 1 to 5 hours depending on the method. The choice of a particular system will depend on the throughput required for the test volume of the laboratory, the turnaround time of the assay, the technical time and expertise required to perform the assay, and the choice of menu desired depending on whether a focused or broad approach to pathogen detection is desired.

PART II: THE FAMILIES *VIBRIONACEAE* AND *AEROMONADACEAE* AND THE GENERA *PLESIOMONAS* AND *CHROMOBACTERIUM*

Phylogeny of the *Vibrionaceae*

The name *Vibrionaceae* was originally proposed by Veron in 1965 with the intent of grouping a number of nonenteric, fermentative, gram-negative rods that were oxidase positive and motile by means of polar flagella. This grouping was intended as a convenience for the purpose of differentiating these organisms from the *Enterobacteriaceae* and did not necessarily imply a taxonomic relationship among the included species. The *Vibrionaceae* once included four genera: *Vibrio*, *Aeromonas*,*Photobacterium*, and *Plesiomonas*. However, in the past few decades, a variety of methods for nucleic acid analysis have revolutionized microbial taxonomy and have resulted in the restructuring of this family along phylogenetic lines and the establishment of two new genera, *Listonella* and *Shewanella,* and a new family, *Aeromonadaceae.*[88,261,364] The genus *Plesiomonas* is now placed in the family *Enterobacteriaceae*.

Genus Vibrio

Vibrio species have both historical and contemporary interest. *Vibrio cholerae* is the etiologic agent of Asiatic cholera in humans, a potentially severe diarrheal disease that has been the scourge of humanity for centuries. The organism was first described and named by Pacini in 1854; 32 years later Koch isolated the organism, which he called "Kommabacillus" because of the characteristic curved or comma-shaped appearance of the individual bacterial cells.

There have been seven pandemics of cholera in recorded history; the last three pandemics are known to be due to *V. cholerae* serogroup O1. The most recent

pandemic, caused by *V. cholerae* O1, biotype El Tor, began in 1961 in Indonesia, rapidly spread to Asia, Europe, Africa, and the South Pacific, and reached South and then Central America in 1991. In addition, a number of minor epidemics of diarrheal syndromes and extraintestinal infections caused by non-O1 serogroups of *V. cholerae* and by several newly described halophilic species have been reported in the United States in several Gulf Coast states since the early 1970s.[183,209] Most infections have occurred following ingestion of contaminated and poorly cooked seafood. Wound infections have also been reported following trauma while swimming or working in infected waters or on exposure to marine animals.[183]

The point of this discussion is that clinical microbiologists cannot discount *Vibrio* species as a possible isolate from diarrheal stool specimens and must remain informed on how to recover and identify the various species. Those working in inland laboratories will have fewer potential encounters than those working in the Gulf Coast hospitals; nevertheless, with open world travel and shipping of seafoods to inland markets, everyone must remain alert.

Taxonomy. The strains of *V. cholerae* that have been recovered from classic patients with pandemic cholera agglutinate in what has been designated O1 antiserum. Strains not agglutinating in this antiserum are called either non-O1 *V. cholerae* (if this species is determined biochemically) or a variety of other *Vibrio* species names, such as *V. parahemolyticus, V. mimicus,* and so on. Since the non-O1 species usually do not cause diarrheal syndromes as severe or potentially life-threatening as O1 species, or more commonly may be associated with extraintestinal infections, early differentiation between the two groups can be of considerable clinical importance. Although 35 or more distinct *Vibrio* species have been identified, all but 11 are environmental organisms, called "marine vibrio species," and have not been associated with human infections.[197]

Description and Associated Clinical Syndromes of *Vibrio* Species of Human Importance. The species that are recovered from humans and potentially cause disease can be divided into two groups, namely *V. cholerae* and the noncholera vibrios.

Vibrio cholerae. *V. cholerae* is the etiologic agent of epidemic and pandemic cholera in humans. Within the species of *V. cholerae*, there is much dissimilarity among the strains in both their pathogenic and epidemic potential (Table 8-8). The strains can be divided according to differences in their cell wall composition (somatic O antigen), which forms the basis of the serotyping scheme that classifies the organisms into 139 different serogroups. All share a common flagellar (H) antigen. It was determined in the mid-1930s that all of the pandemic strains were agglutinated with a single antiserum that has been designated O1. The O1 type *V. cholerae* strains

can be further separated into one of three serogroups: Inaba,

TABLE 8-8 Characteristics of *Vibrio cholerae*

Classification Method	Epidemic-Associated	Not Epidemic-Associated
Serogroups	O1	Non-O1 (serogroups O2-O138)[a]
Biotypes	Classical, El Tor	Biotypes not applicable to non-O1 strains
Serotypes	Inaba, Ogawa, Hikojima	These three serotypes not applicable to non-O1 strains
Toxin	Produce cholera toxin	Usually do not produce cholera toxin; sometimes produce other toxins[a]

[a]A serogroup designated O139 Bengal emerged in Calcutta, Bangladesh, and parts of India in 1992 that produced cholera toxin in quantities similar to that produced by *V. cholerae* O1, and has spread in epidemic proportions across the Indian subcontinent.

Ogawa, and Hikojima. These serogroups are important for epidemiologic studies. For example, the current pandemic of cholera that began in 1961 is caused by the Ogawa serogroup, whereas a focus of cholera that is endemic in the Gulf Coast region of the United States is associated with a *V. cholerae* O1 Inaba serotype.[215] In January 1991, epidemic cholera appeared simultaneously in several coastal cities of Peru and has since been reported in Ecuador, Chile, Colombia, Brazil, and the United States. This outbreak is apparently also due to a strain other than the pandemic strain and has been identified as O1 serotype Inaba, biotype El Tor.[70]

Epidemic strains of serovar O1 may be further divided into the classic and El Tor bv. El Tor is an actively hemolytic biotype of *V. cholerae* that was isolated at the El Tor Quarantine Station in Egypt. The El Tor strain has been found to be hardier and better capable of surviving in the environment; furthermore, chronic carriers of the El Tor strain have been reported in the literature.[214] The El Tor vibrio is now recognized as a biotype of *V. cholerae* and is responsible for most current epidemic outbreaks of classic cholera. The present pandemic of cholera that began in 1961 is caused by the El Tor bv, as are the Gulf Coast and South American outbreaks. The classic bv has

almost disappeared except for rare isolations in India. Studies from Bangladesh indicate that the classic biotype has reemerged.[197]

Cholera: World history. There have been seven pandemics of cholera in recorded history; the last three pandemics are known to be due to the *V. cholerae* serogroup O1. The seventh pandemic of cholera, caused by the El Tor vibrio, originated in Celebes, Indonesia, in 1961 and subsequently spread worldwide, reaching the South American continent in 1991. The emergence and rapid spread of cholera caused by a new serotype designated O139 Bengal in October 1992 in nine countries (India, Bangladesh, Pakistan, Thailand, Nepal, Malaysia, Burma, Saudi Arabia, and China) suggests the possibility for the beginning of the eighth pandemic.[10,114,266,406] For a synopsis of the cholera pandemics of the 19th and 20th centuries, the reader is referred to the review published by Lacey.[235]

Toxigenic* V. cholerae *0139 Bengal. In October 1992, an epidemic of cholera-like illness began in Madras, India, and spread to Calcutta and Bangladesh and many other places in India and in southeast Asia.[293] The strain could not be identified as any of the 138 known types of *V. cholerae* and thus represented a new serogroup, O139 (synonym Bengal to indicate its first isolation from the coastal areas of the Bay of Bengal).[10] The strain caused large epidemics of cholera in Bangladesh, India, and neighboring countries and, for a time, largely replaced *V. cholerae* O1 strains in affected areas. From 1996 to 2002, most cases of cholera in Bangladesh were caused by *V. cholerae* O1 biotype El Tor, but in March 2002, *V. cholerae* O139 reemerged as the predominant pathogen.[114] There are three important points to consider with regard to this new serotype: (1) the symptoms associated with *V. cholerae* O139 infection suggest that it is indistinguishable from cholera caused by *V. cholerae* 01 and should be treated with the same rapid fluid replacement, (2) the rapid spread of *V. cholerae* O139 suggests that preexisting immunity to *V. cholerae* O1 offers little or no protective benefit and travelers to affected areas should not assume that cholera vaccination is protective against the *V. cholerae* O139 strain, and (3) laboratory identification methods for *V. cholerae* O1 depend on detection of the O1 antigen on the surface of the bacterium, and therefore do not identify this new strain.[72] The phenotypic, serologic, and toxigenic traits of *V. cholerae* O139 Bengal have been reported by Nair and coworkers.[301]

Cholera: Western Hemisphere. In January 1991, epidemic cholera, which had not been reported in South America in the 20th century, appeared simultaneously in several coastal cities of Peru and rapidly spread throughout South and Central America.[153,324]

Cholera: United States. In the United States, a small environmental focus of potentially epidemic *V. cholerae* exists along the Gulf Coast.[216] Cholera caused by this strain has in most cases been linked to undercooked crab or raw oysters harvested

from the Gulf Coast. In 1973, the first patient with cholera in the United States since 1911 was reported from Texas.[446] This was followed in 1978 by the report of 11 patients in Louisiana and in 1981 with two additional outbreaks in Texas involving 18 patients.[37] Crabs harvested from nearby estuaries were found to be the vehicle of infection in the Louisiana cases, whereas the largest of the two Texas outbreaks was traced to contamination of cooked rice following accidental rinsing with water from the environment containing the outbreak strain.[214] It is now known that 44 toxigenic *V. cholerae* O1 infections were acquired in the United States between 1973 and 1987.[197] All resulted from exposures in Louisiana and Texas near the Gulf Coast. In 1991, 26 patients with cholera were reported in the United States; 18 were linked to the South American outbreak.[71] In 1992, 103 patients with cholera were reported in the United States; 75 were associated with an outbreak on board an Aerolineas Argentinas flight between Argentina and Los Angeles in February 1992. In 1993 and 1994,

451

22 and 47 cholera cases were reported in the United States, respectively. Of these, 65 (94%) were associated with foreign travel. Three of these were culture-confirmed cases of *V. cholerae* 0139 in travelers to Asia.[73] From 1995 to 2000, 14 patients with cholera were reported; 6 were associated with the endemic environmental focus and 8 with imported seafood.[294] Through 2015, cholera continues to be rare in the U.S. and is most often acquired during travel to countries where *V. cholerae* is circulating.

Cholera: Non O1. *V. cholerae* non-O1 serotypes have been associated with isolated cases of diarrheal disease, although the majority of non-O1 strains do not produce cholera toxin, they appear to produce an enterotoxin different from cholera toxin. Strains have also been isolated from wounds and systemic infections. Safrin and coworkers,[368] in a review of patients with non-O1 *V. cholerae* bacteremia, reported that the case-fatality rate for 13 cases in which the outcome was known was 61.5%. The majority of known infections have occurred in immunocompromised patients, particularly those with hematologic malignancy or cirrhosis. Pitrak and Gindorf[342] reported a patient with bacteremic cellulitis caused by non-O1 *V. cholerae* that was acquired in a freshwater inland lake in northern Illinois.

Pathophysiology of* Vibrio cholerae *-induced gastroenteritis. *V. cholerae* is the prototype of diarrheal syndromes in which disease is caused not by tissue invasion of microorganisms but through the production of toxins that interrupt normal intraintestinal exchanges of water and electrolytes. Toxigenic strains produce a toxin that binds to a receptor on the epithelial cell membrane and activates adenylate cyclase, causing increased levels of cyclic adenosine monophosphate (cAMP) and hypersecretion of salt and water, resulting in the characteristic “rice water” diarrhea of

cholera. Box 8-4 provides a brief account of the step-by-step sequence for *V. cholerae*-induced gastroenteritis. Figure 8-1 is a schematic illustration of the mode of action of the cholera toxin. For a comprehensive review of cholera including pathogenesis and virulence factors, the reader is referred to publications by Kaper and colleagues and Sack and colleagues.[208,366]

Treatment and prevention of V. cholerae infections. Most *V. cholerae* are rapidly killed by tetracycline; however, fluid secretion may persist for several hours after treatment from the effect of toxin already bound to the mucosal cells. Correction of fluid and electrolyte losses is essential with as much as 1 L or more of fluid per hour required. Antibiotic therapy (e.g., trimethoprim-sulfamethoxazole or tetracycline) will

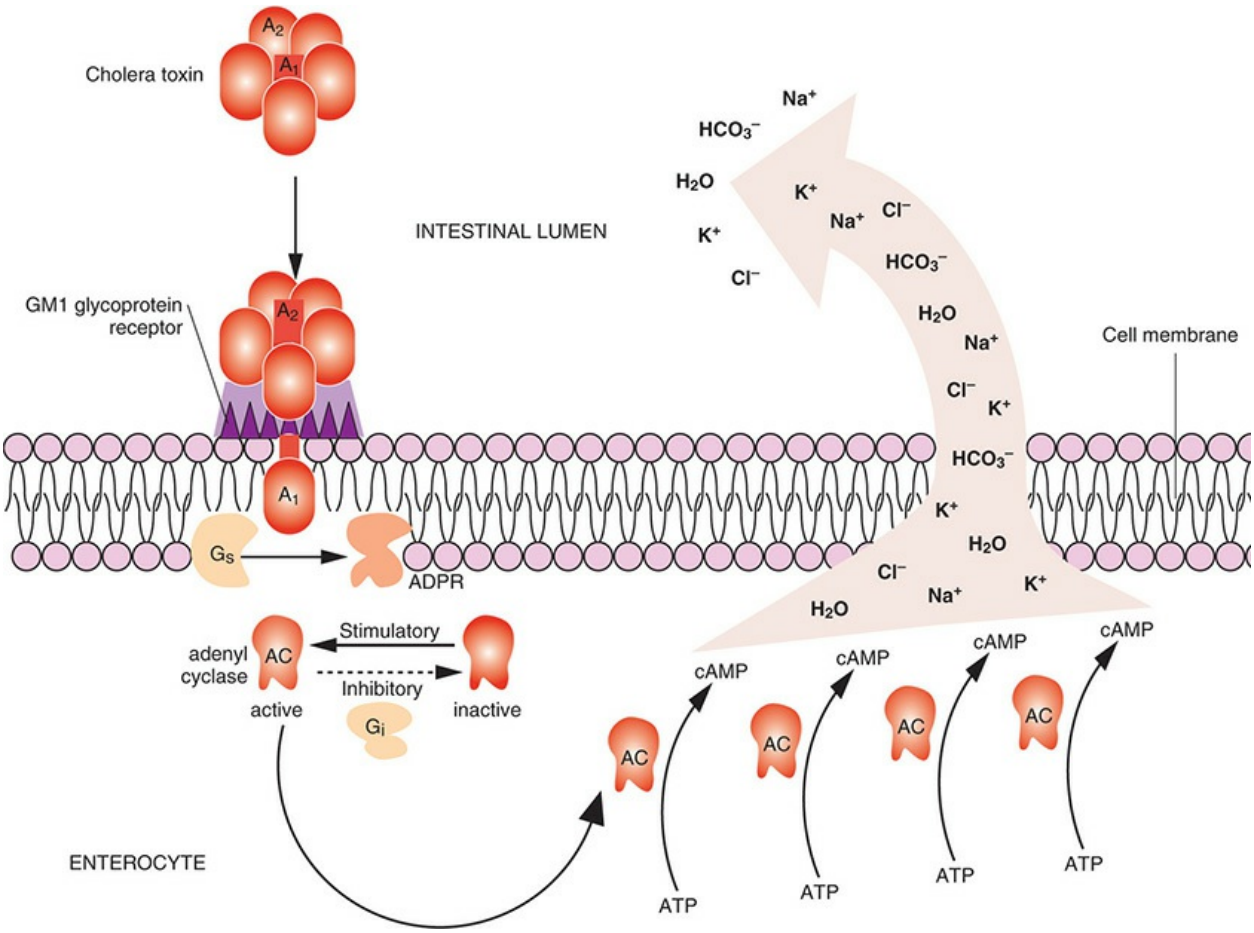
BOX 8-4

Events Leading to *V. cholerae*-Induced Gastroenteritis

1. Organisms ingested in contaminated water must first pass the highly acidic secretions in the stomach. An estimated 10^{10} organisms per milliliter are required to survive gastric passage in healthy persons; only about 100 organisms per milliliter are required in hypochlorhydric persons, either because of previous gastrectomy or from ingestion of antacids in treatment of gastric ulcer disease.
2. To cause disease, *V. cholerae* bacterial cells must adhere to the gastric and intestinal mucosal epithelial cells. These bacteria are motile and secrete mucin, two properties that aid in the penetration of the protective mucin layer that coats the surface of the gastroenteric mucosa. Bacterial attachment is a complex mechanism requiring the recognition by the bacterial cells of a surface marker on the epithelial cells to which they can bind.
3. *V. cholerae* produces an enterotoxin molecule composed of two subunits: an A (active) subunit and a B (binding) subunit. The A subunit is composed of two peptides: A_1 with toxin activity and A_2, which facilitates penetration of the A subunit into the cell. The B subunit binds the toxin molecule to cholera toxin–specific G_{M1} ganglioside receptors on the intestinal epithelial cell membrane. There are five B subunits per toxin molecule, arranged in a ring around a central core that contains the enzyme A1. Initial binding occurs rapidly, followed by a slow conformational change in the toxin molecule, leading to internalization of the A_1 enzyme into the host cell; thus, there is a short lag phase (15–60 minutes) between the time cholera-infected water is ingested and the onset of symptoms. Through a series of steps, A_1 catalyzes the ADP-ribosylation of the G_s (stimulatory) regulatory protein, locking it in the active state. The G_s protein acts to return adenylate cyclase from its inactive to active form, which in turn causes an intracellular rise in cAMP (Figure 8-1).[282]

4. cAMP prevents the reabsorption of sodium ions across the brush-border membrane of the intestinal epithelial cell and the excretion of sodium bicarbonate and potassium into the bowel lumen. The intestinal chyle has high concentrations of sodium and chloride (isotonic), bicarbonate (twice that of plasma), and potassium (three to five times that of plasma). Water, therefore, is passively passed from the epithelial cells into the intestinal lumen in response to high osmotic pressure gradients, following the old adage, "where goes the sodium, there goes the water."
5. Thus, there is diffuse fluid secretion from the gut epithelial cells and the accumulation of large quantities of water in the intestinal lumen. The rate of fluid production increases between 3 and 10 hours after exposure. Fluid loss persists for up to 5 days in patients who receive no antibiotics, after which the bacterial cells are washed from the bowel by an unknown host mechanism. The result is varying degrees of dehydration and electrolyte imbalance, which can lead to metabolic acidosis, hypokalemia, shock, and death in extreme cases.

452



■ **FIGURE 8-1** The action of cholera toxin (see Box 8-4 for details).

help shorten the duration of the diarrhea and reduce the period of carriage; however, antibiotics should be considered ancillary to vigorous rehydration. Additionally, antimicrobial-resistant strains of *V. cholerae* have emerged during the past few decades.[294,366] The risk for cholera and traveler's diarrhea can be reduced by following the general rule "boil it, cook it, peel it, or forget it." In particular, travelers should not consume (1) unboiled or untreated water or ice made from such water; (2) food and beverages from street vendors; (3) raw or partially cooked fish and shellfish, including ceviche; and (4) uncooked vegetables. Cold seafood salads are particularly hazardous. Considerable work has been done regarding development of oral cholera vaccines.[366] Two oral vaccines are licensed in several countries outside the United States. One consists of killed *V. cholerae* plus the cholera B subunit; the other is an avirulent strain of *V. cholerae*. Currently no cholera vaccine is commercially available in the United States.

Noncholera Vibrios. Most *Vibrio* infections in the United States have been caused

by nonepidemic species other than *V. cholerae.* The natural habitat and geographic distribution, the culture media required for optimal recovery, the key biochemical reactions, and the clinical syndromes associated with the noncholera species of human importance are listed in Table 8-9. Although these *Vibrio* species are "noncholera," they should not be dismissed, as many strains can cause severe diarrheal disease in addition to extraintestinal infections that can result in fatal septicemia. In most intestinal infections, however, the symptoms are less severe and of shorter duration than that experienced in classic epidemic cholera.

Certain species of noncholera vibrios can produce enterotoxins similar to those described for *V. cholerae.* In addition, some species cause invasive disease and more closely simulate *Shigella* dysentery; other species, *V. vulnificus* in particular, may invade the intestinal lymphatics and result in septicemia. Extraintestinal *Vibrio* infections are most commonly cutaneous wounds or otitis externa, where breaks in the skin have become contaminated while swimming or boating in marine environments or after handling contaminated raw seafood.[276,377] The following is a brief account of the microbiology and clinical syndromes associated with each of the noncholera *Vibrio* species reported to cause human infection.

Vibrio alginolyticus. *V. alginolyticus* was originally classified as biotype 2 of *V. parahaemolyticus.* Most clinical

TABLE 8-9 Characteristics of Clinically Important *Vibrio* Species Other Than *V. cholerae*

Species	Natural Habitat, Geographic Distribution; Modes of Human Infection	Media for Optimal Growth in Laboratory Cultures	Key Biochemical Reactions		Clinical Syndromes
V. alginolyticus	Habitat: marine environment Infection: exposure of traumatized skin to seawater or infected animals	NaCl supplement needed for growth on nonselective media. Grows on blood agar and enteric media. Yellow colonies on TCBS agar.	Lysine Arginine Voges–Proskauer 8%, NaCl 10%, NaCl	+ – + + V	Associated with soft tissue infections; seems to have also an etiologic role in wound and ear infections
V. damsela CDC Group EF-5 (transferred to genus *Photobacterium*)	Habitat: marine environment Infection: exposure of broken skin or traumatic wounds to infected marine animals or contaminated seawater	Requires 1% NaCl in nonselective culture media. Good growth on blood agar. Green colonies on TCBS agar. Optimum growth 25°C.	Arginine Voges–Proskauer Ferment: Glucose Mannitol Galactose Trehalose	+ + + – + +	Associated with human wound infections
V. fluvialis	Habitat: worldwide—endemic in Bangladesh. In the United States—Gulf Coast, New York, and Pacific Northwest estuaries. Infection: ingestion or contact with contaminated water	Na^+ supplement of culture media less critical than other halophilic *Vibrio* species. Yellow colonies on TCBS agar.	Arginine 6% NaCl Glucose (gas) Hydrolysis of esculin Aminovalerate Glutarate	+ + – – + –	Cholera-like gastroenteritis and diarrheal syndrome—watery diarrhea, vomiting, dehydration; probably enterotoxin induced
V. furnissii	Habitat: endemic in the marine waters and estuaries in Asia Infection: ingestion or contact with contaminated water	Na^+ supplement for optimal growth in nonselective culture media. Yellow colonies on TCBS agar.	Glucose (gas) Hydrolysis of esculin Aminovalerate Glutarate	+ – – +	Isolated from patients with diarrhea and gastroenteritis, particularly tourists returning from Asia
V. hollisae (transferred to genus *Grimontia*)	Habitat: marine environment in Gulf Coast and Chesapeake Bay states Infection: consumption of raw seafood	1%–2% NaCl supplement needed for growth. Poor growth on TCBS or MacConkey agars. Screen for oxidase-positive colonies on blood agar.	Indole Lysine Arginine Ornithine Motility (after 7 days) Urea	+ – – – – –	Isolated from patients with diarrhea and gastroenteritis. Invasion of bloodstream reported in persons with liver abnormalities.
V. metschnikovii	Habitat: worldwide in fresh and brackish marine waters, rivers, sewage; also in shrimp, crabs, and lobsters Infection: cause of fowl cholera; exposure or ingestion of contaminated water or animals	Grows well on most laboratory isolation media. Sodium supplement not as critical as other halophilic vibrios. Yellow colonies on TCBS agar.	Oxidase Nitrate Voges–Proskauer	– – +	Associated with rare and isolated human infections: septicemia, urinary tract infections, wounds, peritonitis
V. mimicus	Habitat: coastal waters, and oysters and shrimp Infection: ingestion of undercooked seafood, particularly oysters	Grows on enteric isolation media. Green colonies on TCBS.	Sucrose Mannitol Ornithine Lipase Voges–Proskauer Polymyxin	– + + V – S	Diarrheal syndrome related to production of heat-labile and heat-stable toxins; also swimmer's ear infections
V. parahaemolyticus	Habitat: worldwide distribution in fresh- and seawaters. Endemic in Japan. Infection: ingestion of contaminated seafood—raw fish and shellfish	Grows slow on nonselective media. Screen for oxidase-positive colonies on blood agar. Green colonies on TCBS agar.	Lysine Arginine Voges–Proskauer Lactose Salicin Urease Indole	+ – – – – V +	Acute gastroenteritis—nausea, vomiting, abdominal cramps, fever, chills. Positive Kanagawa test (i.e., clear hemolysis on specially prepared media). Extraintestinal: wounds and septicemia.
V. vulnificus (lactose-positive *Vibrio*)	Habitat: coastal water and estuaries Infection: ingestion of raw oysters; exposure of traumatic wounds to infected marine animals or contaminated water	1% NaCl needed for growth. Growth good on blood agar. Green (85%) or yellow (15%) colonies on TCBS agar.	Lactose Lysine Arginine Salicin	+ + – +	Life-threatening septicemia; 50% fatality rate. High association with preexistent liver disease. Wounds are painful, with skin and muscle necrosis.

S, susceptible, 90% or greater; +, 90% or more of strains are positive; −, 90% or more of strains are negative; V, 11%–89% of strains are positive.

isolates are recovered from superficial wounds[109,271,338,374] or the external ear.[159,197] Conjunctivitis,[256] acute gastroenteritis,[350] bacteremia,[44,109,194] and necrotizing fasciitis[143] caused by *V. alginolyticus* have also been reported.

Vibrio cincinnatiensis. Human infection caused by this *Vibrio* species is rare. It has been recovered from blood and cerebrospinal fluid of a 70-year-old patient with bacteremia and meningitis.[46] The patient was treated with ampicillin (day 1) and moxalactam for 9 days, followed by an uneventful recovery.

Vibrio damsela (Photobacterium damsela). *P. damsela* was formerly called CDC Group EF-5, *V. damsela*, and *Listonella damsela*. It has been reported as the cause of human wound infections, primarily after exposure to saltwater.[86,177,295] Most strains are resistant to penicillin, but susceptible to gentamicin, chloramphenicol, and tetracycline. MacDonell and Colwell[261] proposed transfer of *V. damsela* to the genus *Listonella.* Subsequently, Smith and colleagues proposed that *L. damsela* should be reassigned to the genus *Photobacterium*.[386]

Vibrio fluvialis. Formerly designated as CDC Group EF-6, *V. fluvialis* has been isolated from humans with diarrhea. This species was isolated from fecal cultures of more than 500 patients with diarrhea at the Cholera Research Laboratory in Bangladesh during a 9-month period from 1976 to 1977.[184] In the United States, the organism has been isolated from a wound of a patient in Hawaii, from water and sediment in the New York Bay, from shellfish in Louisiana, from water and shellfish in Pacific Northwest estuaries, from an 81-year-old man from Laredo, Texas, with diarrheal illness,[408] from the stool of a 1-month-old infant,[169] and from the stool of a 43-year-old man with a history of AIDS.[176]

Vibrio furnissii. Formerly designated *V. fluvialis* biogroup 2, *V. furnissii* has been isolated from patients with acute gastroenteritis in at least two outbreaks of food poisoning[48] and from the stool of a 1-month-old infant.[169]

Vibrio harveyi. *V. harveyi* (formerly *V. carchariae)*[334] is a pathogen of sharks, but has been reported in a human wound infection in an 11-year-old girl who was attacked by a shark while wading in knee-deep water off the South Carolina coast.[333] *V. harveyi* can be differentiated from biochemically similar species (*V. alginolyticus, V. parahaemolyticus*, and *V. vulnificus*) by negative gelatin hydrolysis at 22°C, negative motility at 36°C, and negative ornithine decarboxylase reaction. The other species have the opposite reactions.

Vibrio hollisae (Grimontia hollisae). Formerly designated as CDC Group EF-13, and reclassified as *Grimontia hollisae* in 2003,[420] this species has most commonly been isolated from stool specimens of persons with diarrhea and abdominal pain and a

history of eating raw seafood.[4,168,295] Rare patients with systemic infection caused by *G. hollisae* have been described and most often involve bacterial sepsis in persons with underlying immune deficiencies.[173,258,348] Evidence suggests that *G. hollisae* may share with *V. vulnificus* a predilection for bloodstream invasion in persons with liver abnormalities.[348]

Vibrio metschnikovii. *V. metschnikovii,* formerly CDC Enteric Group 16, is often isolated from the environment but rarely isolated from human clinical specimens. The first documented human infection was from the blood of a patient with cholecystitis at Cook County Hospital in Chicago.[198] More recently, Hansen and colleagues reported patients with *V. metschnikovii* septicemia: one fatal case involving a patient with liver cirrhosis, renal insufficiency, and diabetes; and another in an 82-year-old woman with respiratory problems and an infected leg lesion, who was treated successfully.[160] Human isolates referred to the CDC for identification include two isolates from urine and four isolates from unknown sources.[112]

Vibrio mimicus. Formerly classified as sucrose-negative *V. cholerae, V. mimicus* has been isolated from shellfish and water as well as from human diarrheal stools and ear infections.[92,377]

Vibrio parahaemolyticus. *V. parahaemolyticus* causes gastroenteritis in humans following ingestion of contaminated seafood,[294] the mechanism of which has not been elucidated. Since 1996, pandemic spread of *V. parahaemolyticus* infections due to a single clone has been reported in several Asian countries.[426] Symptoms include watery and sometimes bloody diarrhea, abdominal cramps, nausea, vomiting, headache, low-grade fever, and chills. The illness is usually mild to moderate and self-limiting, with a duration of 2 to 3 days. Extraintestinal infections by *V. parahaemolyticus* have also been described, mostly from wounds in contact with seawater, although primary septicemia rarely has been reported.[294] A urea-positive biotype has appeared and has been the cause of several recent outbreaks, often associated with ingestion of contaminated raw oysters.[5,238,310,313] Janda and associates[197] reveal that 70% of the *V. parahaemolyticus* cultures submitted for identification to the Microbial Diseases Laboratory in the Department of Health Laboratory at Berkeley, California, were urease positive. Similar findings have been reported in the Pacific Northwest.[217]

More than 95% of *V. parahaemolyticus* strains that have been isolated from patients with diarrhea are Kanagawa positive; that is, they hemolyze human erythrocytes on Wagatsuma agar.[206] The hemolysin is both cytotoxic and cardiotoxic. Only about 1% of strains isolated from marine environments are Kanagawa positive.[197] The implication is that Kanagawa hemolysin activity is associated with the pathogenesis of *V. parahaemolyticus* gastroenteritis. However, the association of Kanagawa hemolysin with pathogenesis has never been proven, and in fact Honda and coworkers[180] report

that 11 of 12 *V. parahaemolyticus* isolates recovered from patients in a 1985 gastroenteritis outbreak in the Maldives were Kanagawa negative. Rehydration is usually the only treatment required.

Vibrio vulnificus. Formerly CDC Group EF-3, *V. vulnificus* was first termed *lactose-positive Vibrio* by Hollis and coworkers in 1976.[177] *V. vulnificus* is a particularly virulent species associated with wound infections after exposure to contaminated seawater and primary septicemias and death following consumption of contaminated seafood, most commonly raw oysters.[74,78,294] A high fatality rate (40% to 60%) is associated with septic infections.[197] The organisms reach the bloodstream by invading the intestinal mucosa. Patients with hepatic disease are particularly susceptible to septicemia.[38,111,407]

Medical conditions that predispose to *V. vulnificus* bacteremia include liver dysfunction and syndromes leading to increased iron deposition: chronic cirrhosis, hepatitis, thalassemia major, hemochromatosis, and a history of heavy alcohol consumption.[197] The chief symptoms associated with sepsis are fever, chills, and vomiting, which begin about

455

38 hours after ingesting raw oysters. Diarrhea is often not a component of the syndrome.

Methods for Laboratory Isolation of *Vibrios*. There are four possible laboratory approaches to the isolation of *Vibrio* species from clinical specimens:

1. Use normal procedures, and make no specific effort to search for *Vibrio* species.
2. Use normal procedures and plating media, and look for oxidase-positive colonies.
3. Incorporate thiosulfate citrate bile sucrose (TCBS) agar as an extra plate for stool cultures and also for other likely specimens such as those from wounds, blood, eye, and ear.
4. Use other special procedures to enhance the isolation of *V. cholerae*, *V. parahaemolyticus*, and other *Vibrio* species.

For laboratories in the American Midwest, where positive cultures for *Vibrio* species may be few, the first or second approaches may be most appropriate. In laboratories near oceans, particularly those located in endemic areas, the third or fourth approach may be indicated. However, disadvantages to the routine use of TCBS agar include the increased cost for a relatively low return, and some *Vibrio* species or strains may

not grow well on TCBS agar. It is helpful for laboratory personnel to be informed when clinical cases of cholera or extraintestinal *Vibrio* infections are suspected. In these cases, the use of a selective medium or alkaline broth enrichment, to be discussed in a later section, may still be in order. In such instances, a *Vibrio* culture may be offered. However, when this is considered, education of the medical staff regarding when this test should be ordered is important to assure appropriate utilization.

Specimen Collection, Processing, and Media Selection. Laboratory personnel should be notified if the physician suspects a cholera syndrome or extraintestinal infections with *Vibrio* species. Specimens should be collected as early in the disease as possible. In the acute diarrheal stages of disease, specimens may be collected from the rectum with a soft rubber catheter or a rectal swab or from a small portion of the passed liquid stool. Culturing of vomitus may also be productive of organisms, particularly in the early stages of disease.

Specimens should be transported in closed containers to preserve moisture and transferred to culture media as soon as possible. *Vibrio* species are generally quite sensitive to drying, exposure to sunlight, and the development of an acid pH. They are also easily inhibited by the normal intestinal flora or contaminating organisms. If cultures cannot be set up immediately, *Vibrio* species will remain viable in Cary–Blair semisolid transport medium for an extended time. The use of buffered glycerol saline transport medium should be avoided. If a transport medium is not available, a 2 × 1/2-inch strip of thick blotting paper can be soaked in the fecal specimen, placed in a sealed plastic bag, and then mailed to the nearest reference laboratory.[215] Specimens suspicious for harboring *Vibrio* species should be inoculated to 5% sheep blood and MacConkey agar. Whether to also inoculate a plate of TCBS agar and/or a tube of alkaline peptone water (APW) enrichment must be determined by each laboratory supervisor depending on the prevalence of *Vibrio*-related diseases in any given locale. If TCBS agar is not used, hemolytic colonies that appear on sheep blood agar after overnight incubation should be tested for cytochrome oxidase activity. Either representative colony can be individually touched and spot tested for the oxidase reaction using Kovac's reagent or one or two drops of Kovac's reagent can be dropped in an area on the surface of the plate where suspicious colonies are present. The rapid development of a blue color is indicative of a positive test. Oxidase-positive colonies can be transferred to TCBS agar for further species identification using biochemical and other characteristics.

APW enrichment broths should be subcultured to TCBS agar for further evaluation of colonies that grow after an additional 24 to 48 hours of incubation. APW, which contains 1% peptone and 1% NaCl at pH 8.6, is a simple-to-use enrichment broth that can be recommended in situations where low concentrations of organisms in the specimen are anticipated (e.g., in convalescent stages of disease). The high pH of the

medium serves to suppress the growth of many commensal intestinal bacteria while allowing uninhibited multiplication of *V. cholerae.* Subcultures to TCBS or gelatin agar should be made within 12 to 18 hours, since other organisms can begin to overgrow in the broth after prolonged incubation. APW is also an excellent transport medium if specimens cannot be immediately delivered to the laboratory for processing. It is recommended that about 1 mL of liquid or 1 g of formed stool be placed into 10 mL of APW in a screw-capped tube; alternatively, rectal swabs can be placed into a tube containing 1 to 2 mL of APW.[215]

Presumptive Identification of *Vibrio* Species Based on Colonial and Microscopic Morphology. Vibrios grow readily on most isolation media; growth of all species is enhanced by adding 1% NaCl to the medium. Colonies are typically smooth, convex, creamy in consistency, gray-white, and have entire margins. Rough colonies are occasionally encountered that adhere to the agar. Certain marine vibrios are able to swarm on the surface of agar media, associated with the formation of long cells with lateral flagella. This phenomenon is not seen with most human isolates.

Microscopically, straight or curved gram-negative bacilli are observed (Image Plate 8-2D). The curved character of the cells may be best seen in early stationary phase in broth cultures; in log phase, straight and rounded coccoid forms are intermixed. Although a presumptive diagnosis of cholera can be made by observing large numbers of curved bacilli in direct gram-stained stool specimens, recovery of the organism in culture is needed to make a definitive identification.

The differential reactions on TCBS agar are helpful in making a presumptive identification of *V. cholerae, V. alginolyticus, V. parahaemolyticus*, and *V. vulnificus.* After 18 to 24 hours of incubation on TCBS agar, *V. cholerae* grows as smooth, yellow colonies, 2 to 4 mm in diameter with an opaque center and transparent periphery (Image Plate 8-2A). The colonies of *V. alginolyticus,* which also ferment sucrose, will also produce yellow colonies on TCBS agar; *V. parahaemolyticus* and *V. vulnificus,* which do not utilize sucrose, produce blue-green colonies (Image Plate 8-2B). On gelatin agar, *V. cholerae* grows as transparent colonies surrounded by an opaque halo indicating liquefaction of gelatin (Image Plate 8-2C). O'Brien and Colwell have described a

modified taurocholate–tellurite gelatin agar for the differentiation of *V. cholerae* (β-galactose positive) versus *V. parahaemolyticus* (β-galactose negative) based on the hydrolysis of 4-methylumbelliferyl-β-D-galactose, in addition to determination of gelatin hydrolysis and tellurite reduction.[314]

Biochemical Characterization and Laboratory Identification of *Vibrio* Species.

Members of the genus *Vibrio* are facultative anaerobes capable of both respiratory and fermentative metabolism. However, because they grow and react in carbohydrate test media designed for fermentative metabolism, they are classified with the fermenters. The natural habitat for *Vibrio* species is aquatic, in both fresh and salt water. The growth and biochemical reactivity of most species are enhanced in differential test media supplemented with 1% to 2% sodium chloride.

Most *Vibrio* species produce cytochrome oxidase, a characteristic that separates them from the *Enterobacteriaceae*. Therefore, *Vibrio* species are included in the group of oxidase-positive fermenters—*Aeromonas* species, *Plesiomonas* species, and *Chromobacterium* species—from which they must be differentiated (Table 8-10). Since *V. cholerae* ferments glucose, an acid-deep/alkaline-slant reaction is seen on Kligler's iron agar. Since sucrose is also fermented, an acid-deep/acid-slant reaction is seen on triple sugar iron agar. *V. cholerae* produces both lysine and ornithine decarboxylases.

Those laboratory workers who use lysine iron agar to screen stool isolates will note that *V. cholerae*, *A. hydrophila*, and *Plesiomonas shigelloides* all produce a purple slant/purple deep reaction because of the decarboxylation of lysine. Arginine can be used to separate *V. cholerae* (negative) from both *Aeromonas* and *Plesiomonas* (positive). Most strains of *A. hydrophila* hydrolyze esculin, differentiating it from the other organisms included in Table 8-10. Differences in the utilization of lactose, sucrose, mannitol, and inositol also serve to differentiate these genera.

V. cholerae, including the El Tor biotype, can be distinguished from other *Vibrio* species by the ability to produce a positive string test (Image Plate 8-2E). To perform this test, bacterial colonies are mixed with a few drops of 0.5% sodium deoxycholate on a glass slide. An inoculating loop is immersed into the mixture and pulled away from the drop. *V. cholerae* produces a long string that becomes more tenacious after 60 seconds or more (other vibrios may give an initial string reaction that diminishes or disappears 45 to 60 seconds later). A positive slide agglutination with

polyvalent O antiserum is also helpful in differentiating *V. cholerae* from other closely related strains (Image Plate 8-2F). The El Tor biotype can be distinguished from classic strains of *V. cholerae* by several characteristics (Table 8-11). El Tor strains are actively β-hemolytic on blood agar (Image Plate 8-2G) and are capable of agglutinating chicken erythrocytes (Image Plate 8-2H). The chicken erythrocytes test is performed by mixing a loopful of washed chicken erythrocytes (2.5% suspension in saline) with bacterial cells from a pure culture to be tested. Visible clumping of the erythrocytes indicates the El Tor biotype, in contrast to classic O1 strains of *V. cholerae* that do not have this property. Classic strains of *V. cholerae* are susceptible to 50 IU of polymyxin B in the disk diffusion test; El Tor strains are resistant. El Tor strains are also Voges–Proskauer positive, whereas classic strains of *V. cholerae* are Voges–Proskauer negative. Lesmana and coworkers[255] described using a modified CAMP test to differentiate the classical biotype (CAMP negative) from the El Tor biotype (CAMP strong positive). *V. cholerae* O139 strains also demonstrate a strong positive CAMP reaction, whereas non-O1 and non-O139 isolates give a weak positive CAMP reaction. The test is performed by inoculating a β-lysin-producing *Staphylococcus aureus* strain (ATCC 25178) onto a 5% sheep blood agar plate by making a single straight line streak and then inoculating the *Vibrio* species to be tested in a line perpendicular to and a few millimeters from the *S. aureus* streak. Plates are incubated in a candle jar at 37°C for 18 to 20 hours and observed for zones of synergistic hemolysis (Chart 8-1). For laboratories capable of performing phage IV susceptibility tests, El Tor strains are resistant to this phage.

As an initial first step in the identification of *Vibrio* species, Kelly and colleagues[215] have devised a dichotomous scheme for separating the *Vibrio* species into six groups based on their reactions with seven tests: requirement for 1% NaCl for growth in nutrient broth, oxidase production, reduction of nitrate to nitrite, *myo*-inositol fermentation, and production of arginine dihydrolase, lysine decarboxylase, and ornithine decarboxylase. Their scheme is reproduced in Table 8-12. Grouping the species this way will provide simple presumptive identification of most clinical isolates. Additional key reactions and clinical correlation can be obtained by consulting Table 8-9. Overman and associates[322] recommended the use of the API 20E strip for performing the biochemical tests necessary to make identifications of the more commonly encountered members of the *Vibrionaceae*. However, a more recent evaluation of commercially available identification systems showed that the six methods evaluated correctly identified only 63% to 81% of the *Vibrio* tested to the species level.[315] For *V. cholera* in particular, accuracy ranged from 50% to 97%.

Thus, the authors concluded that extreme care should be taken in interpreting results of commercial systems for identification of *Vibrio* species.

Nonculture Methods. An immunochromatographic dipstick test for rapid detection of *V. cholerae* O1 and O139 from stool specimens has been developed. In an evaluation of the test in Madagascar and Bangladesh, where cholera is endemic, sensitivity ranged from 94% to 100% and specificity from 84% to 100%.[305] Bhuiyan and colleagues modified the procedure by performing a 4-hour enrichment in APW prior to the dipstick assay.[35] With this added step, the sensitivity and specificity, respectively, were 96% and 92% for *V. cholerae* O1 and 93% and 98% for *V. cholerae* O139.

MALDI-TOF MS. Rychert et al.[365] evaluated the Vitek MS v2 MALDI-TOF MS platform with Knowledgebase 2.0 (bioMérieux, Marcy l'Étoile, France). The Vitek MS identified all 42 isolates of *V. cholera* O1 and O139 and 7 of 9 non-O1/O139 isolates. Cheng et al.[77] evaluated the Bruker Biotyper MALDI-TOF MS (Bruker Daltonics Inc. Billerica, MA) for ability to identify genetically confirmed *Vibrio* species that were recovered from patients with bloodstream infections. The Bruker MS identified all isolates of *V. vulnificus* (n = 20), *V. parahaemolyticus* (n = 2), and *V. fluvialis* (n = 1), but none of the isolates of nonserogroup O1, non-O139 *V. cholera* (n = 33) to the species level due to the fact that *V. cholera* was not included among the 53 *Vibrio* species listed in the Bruker Biotyper MALDI-TOF MS library (DB 5627).

Listonella, Photobacterium, and *Shewanella*

MacDonell and Colwell[261] proposed restructuring of the *Vibrionaceae* to include the establishment of two new genera, *Listonella* and *Shewanella,* within the family. Through rather complex 5S rRNA ribonucleotide sequencing studies and cluster analysis, these authors concluded that several *Vibrio* species, notably *V. anguillarum, V. pelagius*, and *V. damsela*, should be transferred to a proposed new genus *Listonella* as *L. anguillara, L. pelagia*, and *L. damsela*. They also conclude from these studies that *Alteromonas* (*Pseudomonas*) *putrefaciens* and *Alteromonas hanedai* should comprise the new genus *Shewanella* along with a proposed new species, *Shewanella benthica.* Subsequent to the work of MacDonnell and Colwell, Smith and colleagues proposed that *L. damsela* be reassigned to the genus *Photobacterium* as *P. damsela* based on phenotypic data.[386] Members of the genera *Listonella, Photobacterium*, and *Shewanella* are associated with marine environment and are pathogenic for fish.

Data from reference 215.

Members of the genus *Shewanella* (notably *S. putrefaciens*) are straight or curved, gram-negative bacilli, motile by means of a single polar flagellum. Characteristic colonies are dome shaped, circular, slightly viscous or mucoid, and usually red-brown or salmon-pink. They possess cytochrome oxidase activity and produce abundant hydrogen sulfide in Kligler's iron agar. Nitrates are reduced to nitrites, and gelatinase, ornithine decarboxylase, and DNase tests are positive. *S. putrefaciens* has been recovered from human clinical specimens and is discussed in detail in Chapter 7 of this text.

Aeromonas and *Plesiomonas*

Several years ago, *Aeromonas* species were included along with *Vibrio* species and *P. shigelloides* in the *Vibrionaceae*.[29] However, based on molecular genetic evidence, *Aeromonas* species have been placed in a separate family, *Aeromonadaceae*.[88,261] It has also been proposed that *Plesiomonas* be placed in the *Enterobacteriaceae* as a member of the genus *Proteus*. Phenotypic differences between *Vibrio, Aeromonas*, and *Plesiomonas* species are listed in Table 8-10.[139]

Genus Aeromonas

As the species name hydrophila ("water loving") indicates, the natural habitat of

Aeromonas species is freshwater or seawater, where they commonly cause infectious diseases in cold-blooded aquatic animals. These bacteria also reside in sink traps and drainpipes and can be recovered from tap water faucets and distilled water supplies, which are potential sources of organisms involved in nosocomial infections.

Taxonomy. The genus *Aeromonas* has undergone considerable taxonomic and nomenclature revisions during the past several years. Only five species were recognized in 1988.[196] By 2000, the number of valid published genomospecies had risen to 14.[204] At the time of this writing, the genus *Aeromonas* includes 32 recognized species and 12 subspecies (http://www.bacterio.net/aeromonas.html). The genus *Aeromonas* is divided into two groups: psychrophilic and mesophilic. *A. salmonicida*, a fish pathogen, is the only species in the psychrophilic group. It is nonmotile and does not grow at 37°C. The mesophilic group of motile species are potential human pathogens. A group of *Aeromonas*-like bacteria that were mannitol, sucrose, and indole negative and known by the vernacular name CDC Enteric Group 501 were found in 1988 to be a new species of *Aeromonas* and were named *A. schubertii*[170] One of the original eight strains of CDC Enteric Group 501 was found to be only 61% related to the type strain of *A. schubertii* and was retained within the vernacular name *Aeromonas* group 501, also named *Aeromonas* sp. HG13. This strain deviated from the *A. schubertii* phenotype by being indole positive and lysine decarboxylase negative[170] and was subsequently assigned to a new species, *A. diversa*.[285]

Clinical Significance. Four categories of human infections have been described: gastroenteritis, cellulitis and wound infections, septicemia, and miscellaneous. However, as our knowledge of *Aeromonas* has grown, the miscellaneous category of diseases they cause has expanded.[191]

Gastroenteritis. Janda and others[190,191,193] have reviewed the infectious disease spectrum of *Aeromonas* species and concluded that there is strong evidence supporting *Aeromonas* species as a causative agent of diarrhea, although the data are not absolute. On one hand, they cite several reports indicating that there is little significant difference between symptomatic and asymptomatic persons who harbor *Aeromonas* species in their stools.[119,178,423] In contrast, other reports link *Aeromonas* species with gastroenteritis.[53,148] Watson and associates[445] proposed that the virulence factors of *Aeromonas* species that cause intestinal infections are similar to those of other enteric pathogens, that is, adherence of bacterial cells to intestinal mucosa, toxin production, and mucosal invasion. About 20% of their patients with intestinal infections from *Aeromonas* species had symptoms of dysentery similar to those caused by *Shigella* species and by invasive strains of *C. jejuni*. Most of the invasive strains included in their study, as determined by invasiveness in cell culture, were *A. sobria*; a minority

were *A. hydrophila.* The majority of *A. sobria* and *A. hydrophila* produce a cholera-like extractable toxin (Asao toxin) that causes watery diarrhea.[80,311] The previous notion that *A. caviae* does not produce an enterotoxin, is not invasive, and is not considered to be a human pathogen[140] may be questioned in light of a few reports in which this species was found to be a cause of gastroenteritis.[17,133,303,304]

Cellulitis and Wound Infections. Wounds, ranging in severity from mild, primarily cutaneous infections (e.g., cellulitis) to severe infections involving muscle, joints, and/or bone, are the second most common type of infection caused by *Aeromonas* species, after gastroenteritis. Clinical settings associated with *Aeromonas* wound infections include lacerations/abrasions associated with water sports, puncture wounds or other penetrating injury, crush injuries (e.g., motor vehicle accident), and invasive medical procedures (e.g., intra-abdominal surgery, catheterization).[191] In a fraction of cases, no preceding trauma or precipitating event is recognized.

Septicemia. Four categories of persons who develop *Aeromonas* septicemia have been proposed, based on portal of entry, underlying disease state, immune status, and exposure to freshwater. The two most common of these groups are immunocompromised adults and infants less than 2 years of age who have complicating underlying medical conditions (e.g., malignancy, hepatobiliary disease, diabetes) and *Aeromonas* in their GI tract. *Aeromonas* septicemia in these groups of patients can be rapidly fatal, especially in those with hepatic cirrhosis or underlying malignancy.[247] A third group are persons who develop secondary *Aeromonas* sepsis from trauma-related myonecrosis. The fourth, and smallest, group includes adults with no underlying defects, who are exposed to freshwater sources. *Aeromonas* bacteremia in burn patients has also been described.[25] *Aeromonas* septicemia is caused in most instances by one of three species: *A. hydrophila, A. veronii*, or *A. caviae.*[191,192,229] *A. schubertii* has also been responsible for infections in a few patients with bacteremia.

Miscellaneous *Aeromonas* Infections. Uncommon presentations of *Aeromonas* infections include urinary tract

infections, hepatobiliary disease, meningitis, ear infections, endocarditis, hemolytic uremic syndrome, peritonitis, respiratory tract disease, and ocular infections.[23,42,64,85,296] Posttraumatic brain abscess caused by *A. hydrophila* was reported in a patient following an assault during which the patient sustained a right frontal scalp laceration.[262] Only a few cases of *Aeromonas* meningitis have been documented in adults. In one patient, meningitis occurred after a craniotomy following head trauma.[345] In other patients with *Aeromonas* meningitis, the infection has occurred in association with medicinal leech therapy,[321] and following exposure to

compost, where inhalation of the organism was the proposed mechanism of entry.[131] Two pediatric patients with *Aeromonas* meningitis have also been reported.[376,455]

Infections Caused by Less Commonly Isolated *Aeromonas* species. A number of less commonly isolated *Aeromonas* species have been described to cause human infections.

- ***A. caviae*** has been reported to cause keratitis associated with contamination of a contact lens case.[339]
- ***A. dhakensis*** (formerly *A. hydrophila* subsp. *dhakensis* and *A. aquariorum*)[31] has been reported in severe soft tissue and bloodstream infections,[117,229,449,450,451]
- ***A. enteropelogenes*** (formerly *A. trota*)[185] has been isolated from human feces and human appendix,[61] and reported to cause gastroenteritis in a child[351] and wound infection accompanied by septic shock in a patient with liver cirrhosis.[237] It has a unique biochemical profile, including negative reactions for esculin hydrolysis, arabinose fermentation, and the Voges–Proskauer test; positive reactions for cellobiose fermentation, lysine decarboxylation, and citrate utilization; and susceptibility to ampicillin.[61,87] This finding may invalidate the use of ampicillin-containing selective media (discussed in the next section) for screening stool specimens for *Aeromonas* species.
- ***A. jandaei*** (formerly genospecies DNA Group 9; *A. sobria*). This organism is sucrose, esculin, and cellobiose negative. It has been isolated from blood, wounds, and stool.[62]
- ***A. schubertii*** (formerly CDC Enteric Group 501)[170] has been incriminated as the cause of wound infections.[63]
- ***A. veronii*** (formerly CDC Enteric Group 77).[171] This organism is ornithine decarboxylase positive and has been reported to cause bacteremia, wound infections, and diarrhea.[6,171,205]

***Aeromonas* Species in Medicinal Leeches.** The medicinal leech *Hirudo medicinalis* has enjoyed a revival as a treatment for venous congestion following microvascular or plastic surgery. Unfortunately, *Aeromonas* species are present in the leech gut, where they aid in the breakdown of ingested red blood cells. As a result, an increasing number of *Aeromonas* infections have been associated with leech application.[201,321,373] Although some of the reported patients had relatively trivial episodes of wound drainage, other patients had significant episodes of cellulitis,

abscess, tissue loss, sepsis, and meningitis.[9,257,280,321] It has been recommended that leech applications be restricted to tissue with arterial perfusion to minimize contamination of necrotic tissue with *Aeromonas*. Furthermore, the prophylactic administration of antibiotics has been proposed when leeches are applied.[257]

Laboratory Recovery of *Aeromonas* Species From Clinical Specimens. Differential or selective agars should be utilized when *Aeromonas* is suspected as the etiologic agent of gastroenteritis or when fecal specimens are submitted for workup on patients whose peak of diarrheal symptoms has subsided (Box 8-5). Most strains grow on selective enteric media as lactose fermenters and, therefore, may be overlooked as unimportant or commensal enteric organisms.

Laboratory Identification of *Aeromonas* Species. *Aeromonas* species are cytochrome oxidase positive and can be quickly excluded from the *Enterobacteriaceae* by performing an oxidase test. A drop or two of tetramethyl-*p*-phenylenediamine-dihydrochloride (oxidase reagent) can be placed on surface colonies and observed for the evolution of a black discoloration characteristic of the colonies of *Aeromonas* species. Mesophilic *Aeromonas* species are motile with polar rather than peritrichous flagella similar to *Pseudomonas* species; however, *Aeromonas* species can be differentiated from the latter because they utilize glucose fermentatively rather than oxidatively, and most *Aeromonas* species are indole positive (*Pseudomonas* species are negative). The phenotypic characteristics of *Aeromonas* species,[60] reviewed by Altwegg and colleagues[18] and more recently by

BOX 8-5

Selective Agars Used to Culture *Aeromonas*

1. *Blood agar with or without ampicillin:* Blood agar can be made selective by incorporation of 10μg/mL ampicillin. Janda and associates[195] recommend the use of a selective sheep blood agar containing ampicillin (SB-A agar) to improve the recovery of *Aeromonas* species from stool specimens.
2. *Alkaline peptone water (APW, pH 8.6):* Initially developed for isolation of *Vibrio* species, APW can be used to recover aeromonads present in low numbers (10 CFU/mL) in stools. After overnight enrichment, APW is subcultured to the agar medium of choice.
3. *CIN agar:* Originally developed for the isolation of *Yersinia enterocolitica*, CIN agar is also suitable for recovery of *Aeromonas* from feces.
4. *Enteric agars:* Deoxycholate, MacConkey, and Xylose Lysine Deoxycholate gave the highest overall plating efficiencies of eight routine enteric agars tested

for recovery of *Aeromonas* species from feces.[98]

461

Abbott and colleagues,[2] are summarized in Table 8-13. Janda and Duffey[196] point out that one pitfall in the identification of *Aeromonas* species is that some of the miniaturized, semiautomated test kit systems cannot efficiently distinguish between *Aeromonas* species and *V. fluvialis.* The latter is only rarely encountered in clinical laboratories, however, and can be differentiated from *Aeromonas* species by demonstrating the ability of *V. fluvialis* to grow in 6.5% salt solutions, to produce yellow colonies on TCBS agar (sucrose positive), and to be sensitive to the vibriostatic agent 0/129.[196]

Lamy and colleagues compared the accuracy of six commercial systems for *Aeromonas* identification including API-20E, API-32GN, ID-GN card with the Vitek2 system (bioMérieux, Marcy l'Étoile, France), the identification portion of the NFC47 panel (MicroScan Walk/Away system, Beckman Coulter, Sacramento, CA), ID69 (Phoenix system; BD Diagnostic Systems, Sparks, MD), and GN2 microplates (Omnilog system; Biolog, Hayward, CA). Correct identification at the genus and species level for the six systems was 77.1%, 91.9%, 82.7%, 80.5%, 73.5%, and 67.8%, respectively.[240] Confusion with *Vibrio* affected 6.9% of results obtained with NFC47 and 16.1% of results obtained with API-20E. Overall accuracy of identification was hampered by outdated databases and taxonomy, weak algorithms, and impractical additional tests. For *Aeromonas* identification, additional tests were not required with the Phoenix and GN2 microplate systems, but were always necessary with the API-20E and NFC47 MicroScan W/A systems. Additional tests were also required with the API-32GN and ID-GN card Vitek2 systems, but only when the probability of identification was below the acceptable minimum defined by the corresponding system.[240]

Namdari and Bottone[302] also describe the suicide phenomenon for the rapid differentiation of *Aeromonas* species. This phenomenon is expressed when unknown strains are grown in broth media containing 0.5% glucose. The supplied glucose suppresses the tricarboxylic acid cycle, resulting in accumulation of acetic acid and cell death. *A. hydrophila* is nonsuicidal, aerogenic, and esculin positive; *A. sobria* is suicide variable, aerogenic, and esculin negative; and *A. caviae* is suicidal, anaerogenic, and esculin positive. Further studies on the biochemical characteristics and serologic properties of the genus *Aeromonas* have been published by Janda and colleagues and Abbott and colleagues.[2,193]

MALDI-TOF MS has been shown to be effective in species identification of *aeromonads*. Lamy and colleagues evaluated the accuracy of MALDI-TOF MS for identifying *aeromonads* with an extraction procedure. Genus-level accuracy was 100%. Compared to *rpoB* gene sequencing, species-level accuracy was 90.6% (29/32) for type and reference strains and 91.4% for a collection of 139 clinical and environmental isolates.[239] Chen et al.[76] reported that MALDI-TOF MS could accurately identify *A. dhakensis, A. hydrophila, A. veronii*, and *A. caviae* with accuracy rates of 96.7%, 90.0%, 96.7%, and 100%, respectively.

Genus Plesiomonas

The term *plesiomonas* is derived from the Greek word meaning "neighbor," indicating a close association with *Aeromonas.* However, as mentioned before, *Aeromonas* species have been reclassified within their own family, whereas *Plesiomonas* is believed to be more closely related to *Proteus* than *Aeromonas,*[261,364] and is now included in the family *Enterobacteriaceae*. *P. shigelloides* is the only species in the genus.

Clinical Significance. *P. shigelloides* is ubiquitous in surface waters and in soil and commonly infects various cold-blooded animals (frogs, snakes, turtles, lizards). Humans become infected primarily by ingesting contaminated or unwashed food. Although less frequently recovered from human feces than *Aeromonas* species, *Plesiomonas*-induced gastroenteritis has been reported in children[273] and in adults.[178] In the latter study, 28 of 31 patients with gastroenteritis had no other organisms to account for the acute symptoms. In Thailand, a carrier rate as high as 5.5% has been reported.[341]

Plesiomonas-related gastroenteritis in humans usually manifests as a mild watery diarrhea in which the stools are free of blood and mucin. Severe colitis or a cholera-like illness may be seen in patients who are immunosuppressed or who have GI malignancies.[359] The infection is more prevalent in the subtropical and tropical regions of the world and during the warm summer months. Pathogenicity is probably related to the production of an enteropathogenic enterotoxin; Sanyal and colleagues demonstrated that 13 clinical strains they studied produced significant fluid accumulation in the ileal loop test.[372] *P. shigelloides*-associated diarrhea has occurred in epidemics but also in isolated cases. It has been described after uncooked shellfish consumption and as a cause of travelers' diarrhea.[179] A few isolated cases of extraintestinal infections including septicemia, neonatal meningitis, cellulitis, septic arthritis, and acute cholecystitis have also been reported.[47,84,353] There are also reports of an overwhelming postsplenectomy infection with *P. shigelloides* in a patient cured of Hodgkin's disease[90] and a *P. shigelloides*-associated persistent dysentery and

pseudomembranous colitis in a 42-year-old Bangladeshi woman.[437] The clinical disease spectrum and pathogenic factors associated with *Plesiomonas* infections have been reviewed by Brenden and colleagues.[47]

Laboratory Isolation and Identification. *P. shigelloides* is a straight-to-rounded, short, motile gram-negative bacillus with polar, generally lophotrichous flagella (*Vibrio* species and *Aeromonas* species are monotrichous). The organism grows well on sheep blood agar and on most enteric media. Isolates are nonhemolytic on sheep blood agar, and in 24 hours at 30°C to 35°C (growth is optimum at 30°C), colonies average 1.5 mm in diameter; are gray, shiny, smooth, and opaque; and may be slightly raised in the center. *P. shigelloides* is readily isolated on enteric agars such as MacConkey, deoxycholate, Hektoen, and xylose lysine deoxycholate. However, ampicillin-containing selective media that are frequently used for the isolation of *Aeromonas* species are not suitable for the isolation of *P. shigelloides*.[440]

Glucose is fermented; therefore, the deep of Kligler's iron agar or triple sugar iron agar tubes will appear yellow. *P. shigelloides* will appear as a nonlactose fermenter on MacConkey agar and may be confused with *Shigella* species. The cytochrome oxidase reaction is positive, and indole is produced. *P. shigelloides* decarboxylates arginine, lysine, and ornithine. It does not produce DNase or extracellular proteases, and it ferments inositol but not mannitol. These are

TABLE 8-13 Differentiation of *Plesiomonas shigelloides* and Clinically Important *Aeromonas* species

key characteristics by which it is separated from *Aeromonas* species. Additional key identifying characteristics are listed in Table 8-13.

P. shigelloides can be resistant to penicillin, ampicillin, carbenicillin, and other β-lactamase susceptible penicillins. Most strains are susceptible to the aminoglycosides, chloramphenicol, tetracycline, trimethoprim-sulfamethoxazole and the quinolones, ciprofloxacin, and norfloxacin.[47,353]

Genus *Chromobacterium*

Brief mention of the genus *Chromobacterium* is made here because some strains are oxidase-positive fermenters and can be confused with *Aeromonas* species and *Vibrio* species. *Chromobacterium violaceum* is the species most commonly encountered in clinical laboratories, although it is seldom associated with human disease. *C. violaceum* grows well on blood agar, and most strains produce abundant violet pigment that makes recognition easy. Select biochemical characteristics are shown in Table 8-10. In addition, the ability of the organism to utilize citrate, reduce nitrates, and strongly hydrolyze casein is also helpful in making a final definitive identification.

Antimicrobial Susceptibility of *Bordetella* Species

Introduction to the Family *Pasteurellaceae*

The family *Pasteurellaceae* was established as a distinct taxonomic family in 1981 and includes a diverse group of gram-negative coccobacilli that are primarily isolated from animals.[1038] Initially, the various genera classified in the family were delineated by phenotypic and metabolic characteristics, and several additional "species" were subsequently assigned to the family based on DNA–DNA hybridization studies.[926]

With the application of more advanced molecular taxonomic methods, the phylogenetic structure of the family began to undergo significant revision beginning in the early 1990s.[339,354] At that time, the family *Pasteurellaceae* comprised three genera—*Haemophilus*, *Pasteurella*, and *Actinobacillus*—that included both human and animal isolates. Early 16S rRNA sequencing studies of these three genera demonstrated that organisms in the *Pasteurellaceae* were phylogenetically diverse and intermixed.[339,354] During the last decade, existing genera and species in the family have undergone reexamination by molecular methods, resulting in reclassification of some species and rejection of others as invalid members of the current genera. Several new genera have been created to accommodate both misclassified species and newly described bacterial isolates. Consequently, the family *Pasteurellaceae* now includes 15 genera, the majority of which are composed of bacteria found in various animals (Box 9-1). These genera are classified in the proposed order "Pasteurellales" in the γ-division of the *Proteobacteria*.

The family *Pasteurellaceae* now includes the following genera: *Haemophilus, Pasteurella, Actinobacillus, Aggregatibacter, Mannheimia, Bibersteinia, Lonepinella, Phocoenobacter, Histophilus, Avibacterium, Gallibacterium, Nicoletella, Volucribacte, Chelonobacter,* and *Basfia*. *Haemophilus* species are part of the normal microbiota of the upper respiratory tract of humans except for *H. ducreyi*, the causative agent of the sexually transmitted infection chancroid. *Pasteurella* species are primarily animal isolates that are occasionally recovered from human infections. With the exception of *Actinobacillus ureae* and *Actinobacillus hominis*, members of the genus *Actinobacillus* are also primarily recovered from animals. The genus *Aggregatibacter* includes the former *Haemophilus* species *H. aphrophilus (Aggregatibacter aphrophilus)*, *H. paraphrophilus (Aggregatibacter aphrophilus), H. segnis (Aggregatibacter segnis),* and *Actinobacillus actinomycetemcomitans (Aggregatibacter actinomycetemcomitans).*[956] The genus *Mannheimia* was created in 1999 to accommodate the trehalose-negative "*[Pasteurella] haemolytica*" complex and *Pasteurella granulomatis*.[46] The "*[Pasteurella] haemolytica*" complex included biovars A and T. Organisms belonging to biovar A were subsequently reassigned to the genus *Mannheimia* and distributed among the six species of *Mannheimia: M. haemolytica, M. granulomatis, M. glucosida, M. ruminalis, M. varigena,* and *M. succiniciproducens*.[46,206,772] Organisms assigned to the T biovar were reclassified [*Pasteurella*] *trehalosi*, despite evidence that this species is not closely related to other organisms in the genus *Pasteurella*. In 2009, [*Pasteurella*] *trehalosi* was placed in the new genus *Bibersteinia* as *Bibersteinia trehalosi*.[137]

BOX 9-1

Members of the Family *Pasteurellaceae*

Genus	Species
Haemophilus	*H. influenzae, H. parainfluenzae, H. haemolyticus, H. parahaemolyticus, H. paraphrophaemolyticus, H. pittmaniae, H. ducreyi*
Pasteurella	*P. multocida* subsp.*multocida, P. multocida* subsp. *gallicida, P. multocida* subsp.*septica, P. dagmatis, P. canis, P. stomatis*
	Species incertae sedis: [*P.*] *aerogenes,* [*P.*] *pneumotropica,* [*P.*] *bettyae,* [*P.*] *caballi,* [*P.*] *mairii,* [*P.*] *testudinis,* [*P.*] *skyensis,* [*P.*] *langaaensis,* [*P.*] *lymphangitidis*
Actinobacillus	*A. ureae* (formerly *Pasteurella ureae*), *A. hominis, A. lignieresii, A. pleuropneumoniae, A. equuli* subsp. *equuli* subsp. *haemolyticus, A. suis, A. arthriditis* (Bisgaard taxon 11),*Actinobacillus* genomospecies 1,*Actinobacillus* genomospecies 2 (sorbitol-negative *A. arthriditis*), Bisgaard taxa 8 and 26
	Species incertae sedis: [*A.*] *muris,* [*A.*] *seminis,* [*A.*] *succinogenes,* [*A.*] *rossii,* [*A.*] *porcinus,* [*A.*] *capsulatus,* [*A.*] *indolicus,* [*A.*] *delphinicola,* [*A.*] *scotiae,* [*A.*] *minor,* [*A.*] *porcitonsillarum*
Aggregatibacter	*A. aphrophilus* (formerly *Haemophilus aphrophilus* and *Haemophilus paraphrophilus*), *A. segnis* (formerly *Haemophilus segnis*), *A. actinomycetemcomitans* (formerly *Actinobacillus actinomycetemcomitans*)
Mannheimia	*M. haemolytica* (formerly *Pasteurella haemolytica*), *M. granulomatis* (formerly *Pasteurella granulomatis*), *M. glucosida, M. ruminalis, M. varigena,* and *"M. succiniciproducens"*
Bibersteinia	*B. trehalosi* (formerly [*Pasteurella*] *trehalosi*)
Lonepinella	*L. koalarum*
Phocoenobacter	*P. uteri*
Histophilus	*H. somnus* (formerly *"Haemophilus somnus," "Histophilus ovis,"* and *"Haemophiilus agni"*)
	A. gallinarum (formerly [*Pasteurella*] *gallinarum*), *A. paragallinarum* (formerly *"Haemophilus paragallinarum"*), *A. avium* (formerly

	[*Pasteurella*] *avium*), *A. volantium* (formerly [*Pasteurella*] *volantium*), *A. endocarditidis*
Gallibacterium	*G. anatis* biovar *haemolytica, G. anatis* biovar *anatis* (formerly [*Pasteurella*] *anatis*), *G. melopsittaci, G. trehalosifermentans, G. salpingitidis, Gallibacterium* genomospecies 1, 2, and 3, unnamed taxon (group 5)
Nicoletella	*N. semolina*
Volucribacter	*V. psittacicida, V. amazonae*
Chelonobacter	*C. oris*
Basfia	*B. succiniciproducens*

Newer genera in the family *Pasteurellaceae* include the genus *Lonepinella*, *Phocoenobacter, Histophilus*, *Avibacterium*, *Gallibacterium*, *Nicoletella*, *Volucribacter, Chelonobacter, and Basfia*. The genera *Lonepinella* and *Phocoenobacter* each include single species named *Lonepinella koalarum* and *Phocoenobacter uteri*, respectively.[437,983] *L. koalarum* is an environmental isolate and has also been recovered from koala bears. *P. uteri* was isolated from the uterus of a dead harbor porpoise found stranded on the Scottish coastline. The genus *Histophilus* also comprises isolates from animals and currently includes the single species *Histophilus somni*.[45] This newly described species includes three isolates that were formerly incertae sedis (i.e., of uncertain placement): "*Haemophilus somnus,*" "*Haemophilus agni,*" and "*Histophilus ovis.*" *Histophilus somnus* causes infectious thromboembolic meningoencephalitis in cattle, while *Histophilus ovis* and *Histophilus agni* cause mastitis, septicemia, synovitis, epididymitis, and vaginitis in sheep. The new genus *Avibacterium* accommodates V-factor-dependent and V-factor-independent avian species formerly classified in the genera *Haemophilus* and *Pasteurella*. The four species in the genus *Avibacterium* form a monophyletic group, showing greater than 96.8% DNA sequence homology with one another, and include *A. gallinarum* (formerly *Pasteurella gallinarum*), *A. paragallinarum* (formerly *Haemophilus paragallinarum*), *A. avium* (formerly *Pasteurella avium*), *A. volantium* (formerly *Pasteurella volantium*), and the new species *A. endocarditidis*.[132,138]

The genus *Gallibacterium* includes former members of the "[*Pasteurella haemolytica*]-"*Actinobacillus salpingitidis*"-*Pasteurella anatis* complex. The genus includes *G. anatis* biovar *haemolytica*, *G. anatis* biovar *anatis*, *G. melopsittaci*, *G. trehalosifermentans*, *G. salpingitidis*, *Gallibacterium* genospecies 1, 2, and 3, and an unnamed taxon (group 5).[134,269] These organisms have been isolated from avian

unnamed taxon (group 5).[134,269] These organisms have been isolated from avian species, including chickens, turkeys, pigeons, parrots, and parakeets. The genus *Nicoletella* was described in 2004 and includes the single species *Nicoletella semolina*, which has been isolated from the airways of horses with respiratory disease.[739] The new genus *Volucribacter* includes members of the formerly unnamed Bisgaard taxon 33 and includes two species, *V. psittacicida* and *V. amazonae*.[267] These species have been isolated

from parrots, budgerigars, parakeets, and chickens with respiratory disease and septicemia. In 2009, genotypic analysis of [*P.*] *testudinis* and other isolates from diseased tortoises resulted in the description of the new genus *Chelonobacter*, which was demonstrated to be a member of the *Pasteurellaceae*.[515] Genus *Chelonobacter* contains a single species, *C. oris*, that is distinct genotypically and phenotypically from [*P.*] *testudinis*, which remains unclassified at this time. The genus *Basfia* is represented by the single species, *B. succiniciproducens*, which was isolated from the bovine rumen.[740] Characteristics for differentiation of the various genera within the family *Pasteurellaceae* are presented in Table 9-1.

Haemophilus Species

Taxonomy

In the 2005 edition of *Bergey's Manual of Systematic Bacteriology*, which reflects bacterial phylogeny based largely on 16S rRNA gene sequence comparisons, 15 *Haemophilus* species are included in the family *Pasteurellaceae*.[702] These species are dispersed among 10 of 21 rRNA "clusters."[975] *Haemophilus* sensu stricto is placed in rRNA cluster 16 and includes *H. influenzae*, *H. aegyptius*, and *H. haemolyticus*. These X-factor (hemin)-dependent species comprise a closely related group. The "Aphrophilus" cluster (rRNA cluster 13) includes *H. aphrophilus*, *H. paraphrophilus*, *H. segnis*, and *Actinobacillus actinomycetemcomitans*. *H. parainfluenzae* and *H. ducreyi* comprise rRNA clusters 2 and 19, respectively. The "Parahaemolyticus cluster" includes *H. parahaemolyticus* and *H. paraphrohaemolyticus*. By 16S rRNA sequencing, *H. parainfluenzae* and members of the "Parahaemolyticus cluster" appear to occupy an intermediate taxonomic position between *Haemophilus* sensu stricto and other genera included in the *Pasteurellaceae*. DNA–DNA hybridization studies, however, clearly indicate the correct placement of *H. parainfluenzae* and the "Parahaemolyticus cluster" within the genus *Haemophilus*. In order to assess the

taxonomists have started to examine the phylogeny of *Haemophilus* species sensu stricto using alternate gene sequences along with 16S rRNA sequencing. These examinations have included partial sequencing of several "housekeeping" genes, including *sodA* and *sodC* (superoxide dismutase genes), *infB* (translation initiation factor 2 gene), *fucK* (fuculokinase gene), *hap* (penetration protein gene), *pgi* (glucose-6-phosphate isomerase gene), *adk* (adenylate kinase gene), and *recA* (recombination protein gene).[207,952,957]

Based on these data, the genus *Haemophilus* can be divided into four clusters, which are shown in Box 9-2. Members of cluster 2 have since been reassigned to the new genus *Aggregatibacter*.[956] *H. ducreyi* differs in several respects from other members of the genus and was originally assigned to genus *Haemophilus* because of its requirement for X factor (hemin). *H. ducreyi*, however, is unrelated to *H. influenzae* by DNA–DNA hybridization studies and is only distantly related to *H. influenzae* and the other haemophili, but 16S rRNA sequencing has confirmed its membership in the *Pasteurellaceae*.[975] *H. ducreyi* will likely be reclassified in the near future. Although traditionally defined by requirements for factors found in blood (i.e., X factor [hemin] and V factor [nicotinamide adenine dinucleotide (NAD), NAD phosphate (NADP)]), these requirements are not exclusive features of *Haemophilus* species. V-factor-dependent avian isolates (e.g., *Avibacterium* [*Pasteurella*] *avium*, *Avibacterium* [*Pasteurella*] *volantium*) are more closely related to the type species of the genus *Pasteurella* (*P. multocida*) than to that of the genus *Haemophilus* (*H. influenzae*).[138] Some animal haemophili (e.g., "*Haemophilus agni*," "*Haemophilus somnus*") have never been validated as *Haemophilus* species; these organisms are now included in the genus *Histophilus*.[45] Sequencing of the *infB* (elongation factor 2) gene from *Haemophilus* species has indicated that all species that require X and V factors are closely related and that *H. parainfluenzae* constitutes a heterogeneous group within the genus. Using 16S rRNA sequencing as well as the various "housekeeping" genes, taxonomists are attempting to determine the relationship of typeable (i.e., encapsulated) *H. influenzae* to nontypeable strains, the phylogenetic relatedness of genospecies of haemophili to *Haemophilus* species sensu stricto, the relationship of *H. influenzae* cryptic genospecies biotype IV and *Haemophilus* sensu stricto, the status of haemophili in the "Parahaemolyticus" and "Parainfluenzae" groups, and the relationship of *H. influenzae* and *H. haemolyticus* to haemophili that are nonhemolytic but phenotypically resemble *H. haemolyticus*.[569,877,920,953,957] During the course of these taxonomic investigations, a new *Haemophilus* species, *H. pittmaniae*, was described.[954] This organism, along with other *Haemophilus* species, is part of the microbiota of the upper respiratory tract of humans.

Haemophilus influenzae

Haemophilus influenzae

Haemophilus species are part of the normal bacterial microbiota of the oropharynx and nasopharynx in more than 85% of adults. Most oropharyngeal isolates are nonencapsulated *H. influenzae* and *H. parainfluenzae*, although encapsulated *H. influenzae* (capsular serotypes a, b, c, d, e, and f) may be found as part of the normal microbiota of the upper respiratory tract of both children and adults. Prior to the availability of *H. influenzae* type b conjugate vaccines, 2% to 6% of children carried capsular serotype b strains and as many as 60% of children in day care centers were colonized in the oropharynx. Recovery of *H. influenzae* from sputum specimens may reflect the presence of these organisms as normal microbiota. However, in chronic respiratory ailments (e.g., bronchitis, chronic obstructive pulmonary disease [COPD]), both encapsulated (typeable) and nonencapsulated (nontypeable) *H. influenzae* may cause severe infections.[919,1171] Infections caused by *H. influenzae* and members of the genus other than *H. ducreyi* are described in Box 9-3.

Among the haemophili, *H. influenzae* serotype b is considered the most pathogenic of the six capsular serotypes (i.e., types a, b, c, d, e, and f). The type b polysaccharide is the only capsular type that contains two pentose monosaccharides rather than hexose sugars as subunit carbohydrates. The native type b capsule comprises a linear teichoic acid containing ribose, ribitol (a 5-carbon sugar alcohol), and phosphate linked by phosphodiester bonds, and is called PRP (polyribosylribitol phosphate) (Fig. 9-1). Although virulence of *H. influenzae* type b is multifactorial, the PRP capsule is

BOX 9-3

Infections Caused by *Haemophilus* Species

Infection	Comments
Meningitis	In the prevaccine era, *H. influenzae* was the most common cause of bacterial meningitis in children between 1 month and 2 years of age, with the peak incidence between 6 and 12 months of age. Between the ages of 2 and 6 years, *H. influenzae* and *Neisseria meningitidis* occurred with equal frequency, and *H. influenzae* meningitis was uncommon in children older than 6 years of age. More than 90% of isolates obtained from these patients belonged to capsular serotype b. Meningitis caused by this agent now occurs most frequently among infants who are either not immunized or who are too young to have completed the primary immunization series.[215] Prior nasopharyngeal colonization in a susceptible host leads to invasion of the bloodstream and subsequent seeding of the meninges.[706] Symptoms of an upper respiratory tract infection of viral etiology and otitis media often precede the development of meningitis.[1014] Onset of signs and symptoms may be abrupt or insidious, with the latter being the most common pattern. Children present with fever, malaise, and occasionally vomiting; nuchal rigidity is often absent. Some children may develop peripheral and/or cranial nerve palsies and seizures. A high index of suspicion, aggressive diagnostic approaches (i.e., lumbar puncture for collection of CSF, collection of blood cultures, early administration of appropriate antimicrobial therapy), and close communication with the laboratory are essential for proper diagnosis. Although relatively unusual, complications of *H. influenzae* type b meningitis include brain and brainstem abscesses, subdural effusion, pericarditis, septic arthritis, and localized infections at other body sites due to hematogenous dissemination.[231,417,1222] *H. influenzae* meningitis in adults is uncommon and usually complicates underlying conditions, such as CSF leakage following head trauma or neurosurgical procedures. Meningitis may also result from direct extension from a contiguous focus of infection in the sinuses or the middle ear.[188,1143] Debilitating underlying diseases, such as diabetes, chronic alcoholism, pneumonia, HIV infection, and other immunodeficiency states, also predispose adults to *H. influenzae* meningitis. Approximately half of the adult patients with *H. influenzae* meningitis have disease caused by nontypeable *H. influenzae* strains, while the other half are caused by type b and other encapsulated strains.[196,381] Rare instances of *H. influenzae* type b meningitis have been reported in children who have completed the primary immunization series and patients with meningitis due to nontypeable *H. influenzae* have been reported.[607,629] *H. influenzae* is spread via respiratory secretions, and an increased risk of secondary, invasive disease exists for unvaccinated or incompletely vaccinated household contacts 4 years of age and younger. Rifampin, the drug of choice for chemoprophylaxis, eradicates oropharyngeal carriage and interrupts transmission. According to the American Academy of Pediatrics (AAP), prophylaxis should be administered to all household members (including adults) when the household contains a contact or contacts younger than 48 months whose immunization status is incomplete.[32] The AAP defines a contact as a child who is a member of the immediate household or who has spent 4 or more hours each day with the index case for at least 5 of the 7 days preceding the onset of disease. The dosage of rifampin for children is 20 mg/kg once daily for 4 days and for adults is 600 mg twice daily for 2 days. Rifampin must be given to close contacts within 7 days after disease onset in the index case in order to be effective. All members of a household with an immunized child less than 12 months of age (i.e., those children who have not yet received the 12–15 month "booster") should receive rifampin. Chemoprophylaxis is not necessary when all household contacts younger than 48 months of age have completed their immunization series. Children attending day care facilities who are contacts of index cases should receive rifampin prophylaxis if they are unvaccinated or incompletely vaccinated and are exposed to the index case for 25 or more hours in the week prior to disease onset in the index case.

	H. influenzae meningitis has been described as a complication of CSF shunt infections.[1364] These infections have occurred primarily in infants and children and have involved ventriculoperitoneal, ventriculoatrial, and lumboperitoneal shunts. While shunt infections caused by *Staphylococcus epidermidis* or *Staphylococcus aureus* usually develop from intraoperative/perioperative contamination of the shunt and ventricular CSF, *H. influenzae* shunt infections result from seeding of the shunt and CSF during bacteremia. Patients presenting with meningeal symptoms often have other infections associated with *H. influenzae* (e.g., otitis media). Bacterial isolates have either been capsular type b or nontypeable. While shunt infections caused by gram-positive bacteria require removal/replacement of the foreign body for cure, systemic antimicrobial therapy without shunt removal is often successful in eliminating type b strains, although antimicrobial monotherapy has been less successful in treatment of shunt infections caused by nontypeable strains.[1364]
Supraglottitis	*H. influenzae* type b has historically been associated with supraglottitis (epiglottitis), a cellulitis of supraglottic tissues that results in obstructive laryngeal edema.[919] Epiglottitis seldom occurs in infants, and is typically seen in children 2–7 years of age and in adult males 20–30 years old. The presentation is acute, with sore throat, dysphagia, fever, and swelling of the epiglottis above the larynx at the base of the tongue.[521,1246] In children, this abrupt onset helps to clinically differentiate epiglottitis from croup caused by viral agents (e.g., respiratory syncytial virus (RSV), parainfluenza viruses) and from pertussis. As the disease progresses, swallowing becomes increasingly difficult, resulting in drooling, inspiratory stridor, and incipient respiratory distress.[521] Nasotracheal intubation and vigorous administration of antimicrobial and supportive therapy may be life-saving in cases of airway obstruction. While posterior pharyngeal cultures are not helpful because of the presence of other nasopharyngeal microbiota, *H. influenzae* type b may be recovered from blood cultures. Epiglottitis also occurs in adults; fever, sore throat, dysphagia, and respiratory distress are the presenting signs and symptoms.[1363] The introduction of effective vaccine strategies has also affected the incidence of epiglottitis. The incidence of pediatric epiglottitis prior to widespread immunization was 3.47–6.0 per 100,000 patients per year and currently is estimated to be 0.3–0.7 per 100,000 patients per year in the postvaccine era.[1173] Disease incidence in adults has remained at 1–4 cases per 100,000 patients per year. Despite effective vaccines, *H. influenzae* type b epiglottitis has been reported in children who have received the entire vaccination series.[1311]
Otitis media	Otitis media refers to inflammation of the middle ear and is clinically categorized as uncomplicated, persistent, recurrent, or chronic.[776] Otitis media occurs most frequently in children aged 6 months to 5 years, with the highest incidence among children less than 3 years of age. The high incidence in young children reflects the underdeveloped protective mechanisms of the eustachian tube. Acute otitis media often occurs as a complication of viral infections (e.g., RSV, parainfluenza viruses). Symptoms include ear pain, hearing loss, and sometimes discharge from the external otic canal, while signs include fever, irritability, headache, and occasionally nausea and vomiting. Otoscopy reveals a red, opacified bulging tympanic membrane that is relatively immobile. Definitive etiologic diagnosis requires needle aspiration of middle ear fluid (tympanocentesis), which is not performed routinely. If drainage is present, however, it should be collected for culture. Culture of CSF and blood may be necessary and helpful if systemic signs and symptoms are present. Common bacterial causes of acute otitis media include *Streptococcus pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis*, with one-quarter to one-third of infections due to *H. influenzae*. The causative agent cannot be differentiated on clinical grounds, although fever, otorrhea, and tympanic membrane inflammation are less commonly seen with *H. influenzae* compared with *S. pneumoniae*.[777,921,1096] Over 90% of *H. influenzae* strains recovered from appropriate specimens are nontypeable, with the remaining 10% being type b. Up to one-fourth of children with *H. influenzae* type b ear infection also have bacteremia and/or meningitis.[141] Complications include recurrent otitis media, persistence of middle ear effusions necessitating insertion of drainage tubes, hearing impairment, mastoiditis, meningitis, chronic otitis media, brain abscess, and sepsis.[786] Amoxicillin clavulanate combined with amoxicillin (PO), cefuroxime axetil (PO), or ceftriaxone (IM) has been recommended as the antimicrobial agents of choice for treatment of recurrent and persistent otitis media.
Sinusitis	Acute sinusitis is characterized by persistent cold symptoms, purulent nasal/postnasal discharge, cough, fever, headache, and often facial pain.[183,878] The acute presentation blends into chronic sinusitis, which is characterized by symptomatic persistence beyond 3 months, with cough and purulent nasal drainage being the principal symptoms.[1149] A sensation of facial fullness or the presence of edema or periorbital discoloration may indicate extension of infection from the sinuses into the soft tissues of the orbit. Diagnosis of sinusitis is made most often by a clinical assessment, with imaging techniques (i.e., radiographs, computed tomographs, magnetic resonance imaging) being used for visualizing ethmoid and sphenoid sinuses and for determining orbital involvement. In studies where specimens were obtained surgically or by needle aspiration of the maxillary sinus spaces, *H. influenzae* and *S. pneumoniae* are the organisms most frequently isolated.[1149] Careful clinical and bacteriologic studies have demonstrated *H. influenzae* as the etiologic agent in 20%–25% of adults and in 36%–40% of children.[183,1205] Most *H. influenzae* isolates from these infections are nontypeable. Serious intracranial infection (e.g., epidural abscess) may arise by direct extension of infection from the sphenoid and ethmoid sinuses.
Bronchitis and COPD	Chronic bronchitis is an ill-defined clinical entity involving bronchial inflammation without significant involvement of the pulmonary parenchyma, and is characterized by a persistent, nonproductive cough, wheezing, and shortness of breath.[1354] This condition is common, particularly among men over age 40 years who smoke. Environmental factors (e.g., air pollution) and viral infections further irritate and inflame the respiratory mucosa, rendering them increasingly susceptible to bacterial colonization

	and eventually leading to the production of purulent sputum. In patients with stable chronic bronchitis, the lower airways are often colonized with multiple strains of nontypeable *H. influenzae*; during acute exacerbations, the numbers of these organisms increase.[86] Chronic cough with sputum production for at least 3 consecutive months for more than 2 years in succession is termed *chronic obstructive pulmonary disease*. COPD classification is currently undergoing characterization using spirometry, which involves measurements of airflow limitations that are progressive and associated with abnormal responses of the lung to noxious gases or particulates. Patients with severe exacerbations of chronic bronchitis and COPD present with dyspnea, hypoxia, and usually a low-grade fever. During exacerbations, sputum production is increased and the consistency changes from mucoid to mucopurulent to purulent. Gram's stains of properly collected sputum specimens generally show many PMNs associated with a particular bacterial morphotype (e.g., the pale-staining coccobacilli of *H. influenzae*).[918] The most common agents recovered from purulent sputum are nontypeable strains of *H. influenzae*, followed by *S. pneumoniae* and *M. catarrhalis*.[1007,1170] In patients with *H. influenzae*-associated disease, nontypeable strains can be isolated from the lower airways between exacerbations of symptoms.[782] During exacerbations, empiric therapy with oral antimicrobial agents are prescribed, along with bronchodilators and other supportive measures. In patients with airway obstruction who are producing purulent sputum, antimicrobial therapy shortens the duration of symptoms. Drugs with demonstrated efficacy in this setting have included extended-spectrum cephalosporins, tetracyclines, quinolones, and newer macrolides. Chronic bronchitis, acute exacerbations of purulent bronchitis, COPD, and pneumonia are a continuum of pathologic pulmonary processes in which nontypeable *H. influenzae* strains are a primary player. Several host factors (e.g., immune status, genetic predisposition, other pulmonary compromises) contribute to the pathogenesis of these ill-defined conditions. Treatment options include second- and third-generation cephalosporins, amoxicillin clavulanate, azithromycin, and the fluoroquinolones.[632]
Pneumonia	*H. influenzae* pneumonia can be a manifestation of systemic *H. influenzae* infection, or may develop as a complication of COPD. *H. influenzae* pneumonia in patients with systemic disease (i.e., meningitis, epiglottitis, bacteremia, otitis media) is lobar, segmental, and purulent; characteristics are similar to pneumococcal pneumonia. In these infections, encapsulated type b organisms are the usual etiologic agents. Nontypeable *H. influenzae* are the important causes of pneumonia with and without bacteremia in elderly patients with underlying respiratory conditions (e.g., chronic bronchitis, COPD, bronchiectasis), or with other underlying diseases (e.g., immunodeficiency, diabetes, alcoholism, neoplasms).[655,1143] Bacteremic pneumonia due to *H. influenzae* capsular types other than type b has also been reported in patients with underlying conditions that impair local or systemic host defense mechanisms. Definitive diagnosis of *H. influenzae* pneumonia through the assessment of respiratory specimens is challenging since the organism is present in the upper respiratory tract of healthy individuals, as well as those with pneumonia. Expectorated sputum specimens may provide inadequate or misleading results; bronchial washings, bronchoscopy, or BAL specimens may be necessary for definitive cultural diagnosis.
Bacteremia and infectious complications of bacteremia	Bacteremia is a frequent, early manifestation of acute *H. influenzae* type b meningitis, but some infants may present with bacteremia without meningitis. Acute presentations are seen mostly in children with underlying disease (e.g., sickle cell disease) and include fever, lethargy, and a high peripheral neutrophil count. Bacteremia may seed soft tissues, joints, and bone, resulting in cellulitis, septic arthritis, and osteomyelitis, respectively.[919] Cellulitis often appears in children as violaceous or reddish blue swellings on the cheeks and periorbital areas. This manifestation of *H. influenzae* type b sepsis has virtually disappeared since the introduction of type b conjugate vaccines.[30,1089] Septic arthritis is characterized by pain, swelling, and decreased mobility of the infected joint. Hematogenous osteomyelitis presents as swelling, bone pain, and constitutional symptoms.[1407] Howard and colleagues reviewed 851 cases of septic arthritis and osteomyelitis from 1977 through 1997 in Ontario, and found that hematogenous *H. influenzae* type b septic arthritis and osteomyelitis accounted for 30% and 3%, respectively, of these infections prior to 1992, but only one patient with type b septic arthritis and no patients with osteomyelitis were seen from 1992 to 1997.[610] Widespread vaccination has resulted in the virtual disappearance of type b organisms as etiologic agents of these complications. *H. influenzae* bacteremia may also occur in neonates and the elderly. In these cases, meningitis may or may not be present. Most cases of neonatal infection result from maternal–fetal or maternal–perinatal transmission (see below), and the majority of isolates from bacteremia in neonates and older children are nontypeable.[978] While *H. influenzae* type b sepsis has been reported in elderly adults, the majority of isolates from these individuals are also nontypeable with the respiratory tract as the usual source. Nontypeable *H. influenzae* bacteremia occurs in older patients with underlying diseases (e.g., alcoholism, SLE, rheumatoid arthritis, diabetes, malignancies) and is associated with a several complications, including cellulitis, septic arthritis, osteomyelitis, empyema, intra-abdominal infections, pyelonephritis, and endocarditis.[1143]
Endocarditis	*H. parainfluenzae* and *A. aphrophilus* (formerly *H. aphrophilus/paraphrophilus*) are the frequently isolated species from patients with endocarditis and intravascular infections, with typeable and nontypeable *H. influenzae* being relatively uncommon.[327,482,613,666] The incidence of endocarditis is highest in young to middle-aged adults. Patients usually have a subacute clinical course with low-grade fever, malaise, chills, and respiratory tract symptoms. Preexisting or underlying valvular disease is found in only about half of the patients, with the presence of a heart murmur being the only suggestive finding. Echocardiography studies have demonstrated that *A. aphrophilus* endocarditis is associated with a high incidence of valvular vegetations and consequent septic complications resulting from embolization. Risk factors for endocarditis with *Haemophilus/Aggregatibacter*

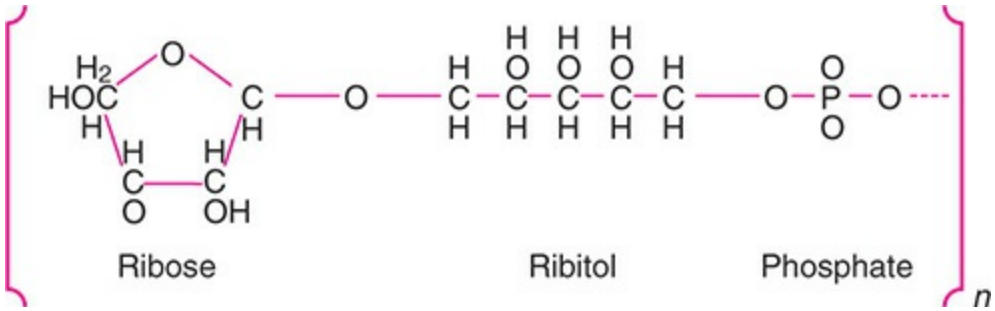
	species include the presence of dental or oral lesions, antecedent dental manipulations, oral surgery, diseased or damaged cardiac valves, and valvular prostheses. *H. parainfluenzae* has also been implicated in cases of endocarditis in persons with no underlying predisposing factors. Intravenous drug users may present with right-sided endocarditis, tricuspid valve vegetations, and clinical and radiographic evidence of septic embolization.[256,275,590,960] *H. parainfluenzae* has also been associated with sustained bacteremia resulting from infection of vascular implants, such as pacemaker wires.[996]
Urogenital, maternal, perinatal, and neonatal infections	*Haemophilus* species, particularly nontypeable *H. influenzae* and *H. parainfluenzae*, are uncommon causes of urethritis, female genital tract infections, vulvovaginitis, obstetrical and gynecological infections, postpartum bacteremia, septic abortion, tubo-ovarian abscess, intrauterine fetal death, and neonatal sepsis with/without meningitis.[78,110,202,313,566,609,675,734,1188,1292] In a study conducted in Houston between 1976 and 1981, *H. influenzae* was recovered from blood cultures of 16 women with postpartum bacteremia and 36 neonates with bacteremia or meningitis.[1316] Another 50 *H. influenzae* were cultured from genital sites (vagina, endometrium, cervix, Bartholin's glands, fallopian tubes, male urethra, and prostatic fluid) and fetal tissues (amniotic fluid, placental tissues). Of these isolates, 94% were serologically nontypeable. Quentin and colleagues recovered *Haemophilus* species from genital cultures of 83 women over a 90-month period.[1051] Forty-two women had significant bacterial genital tract infections, including endometritis, salpingitis, and Bartholin's gland abscesses. Genital tract infection was linked to the presence of intrauterine devices in 62% of the patients with endometritis and in 4 of 6 patients with salpingitis, suggesting that the genital haemophili may behave as opportunistic agents in genital sites. Prenatal and perinatal acquisition of *Haemophilus* species from the maternal genital tract has been associated with premature rupture of membranes, amnionitis, septic abortion, and neonatal sepsis.[246,849,1331] Biotyping of genital isolates has shown that nontypeable biotype IV *H. influenzae* and biotype I and II *H. parainfluenzae* are inhabitants of the genital tract and may be associated with genital tract infections, postpartum maternal, and neonatal systemic infections.[1051] Studies of serologically nontypeable *H. influenzae* strains recovered from these infections have established the existence of a novel, cryptic genospecies of *H. influenzae*.[1049,1050] This novel genospecies types as biotype IV (i.e., indole-negative; urease and ornithine decarboxylase-positive) but is distinct by other morphologic, phenotypic, and genetic criteria (i.e., peritrichous fimbriae, a distinctive outer membrane protein profile, variant outer membrane proteins, unique multilocus enzyme electrophoresis patterns).[922,1050] Molecular studies indicate that these isolates are clonal and genetically homogeneous, share less than 70% of overall genomic similarity with *H. influenzae* sensu stricto, and are most closely related to strains of *H. haemolyticus*.[1050] This cryptic genospecies cannot be phenotypically differentiated from other *H. influenzae* biotype IV strains.
Ocular infections	*H. influenzae* ocular infections vary widely in severity and include conjunctivitis, scleritis, subconjunctival abscess, and endophthalmitis. *H. influenzae* causes a contagious, acute conjunctivitis colloquially called "pinkeye." Localized outbreaks of acute conjunctivitis occur among persons who share towels, handkerchiefs, or other objects that come in direct contact with the skin of the face or eyes. The diffuse pink color of the sclera and the presence of a serous or purulent discharge are virtually diagnostic of *Haemophilus* conjunctivitis. Hemorrhagic conjunctivitis may also occur as part of invasive *H. influenzae* type b disease.[1012] *H. influenzae* endophthalmitis is uncommon but may occur as an iatrogenic complication of ocular surgery.[22,27,1264,1402] Sykes and colleagues reported on three cases of *H. influenzae* scleritis.[1233] These elderly patients had severely decreased visual acuity, pain, and nodular scleral abscesses from which *H. influenzae* was recovered in culture. Brooks and colleagues reported a spontaneous subconjunctival abscess due to *H. influenzae* in a 27-year-old immunocompetent woman with no underlying or preexisting ocular pathology.[184] *H. influenzae* may also be isolated from superinfected herpetic corneal ulcers and from corneal specimens of patients with atopic keratoconjunctivitis.[1191] Historically, isolates from conjunctival infections were designated as a separate species called "*H. aegyptius*." Phenotypically, these isolates are similar to *H. influenzae* biotype III. The distinctive clinical presentation, biochemical characteristics, and serologic studies have been used to support the status of "*H. aegyptius*" as a separate species within the genus. However, genomic nucleotide studies have demonstrated significant sequence homology between "*H. aegyptius*" and *H. influenzae*; so this organism is now called *H. influenzae* biogroup *aegyptius*. A unique, highly virulent clone of *H. influenzae* biogroup *aegyptius* emerged in the early 1980s as a causative agent of a clinical syndrome called Brazilian purpuric fever (BPF; see below).
Brazilian purpuric fever	During the 1980s, a subgroup of strains that were phenotypically indistinguishable from *H. influenzae* biotype III ("*H. aegyptius*") were recognized in association with outbreaks of a severe illness called BPF.[160–162] BPF was first reported in 1984 in Promissão, São Paulo State, Brazil, when 10 children died from an acute illness characterized by a high fever, abdominal pain with vomiting, a petechial/purpuric rash, hypotensive shock, and vascular collapse. A subsequent outbreak among 10 children in the nearby town of Serrana resulted in four additional deaths.[162] Blood cultures from these children grew "*H. aegyptius*." During epidemiologic investigations, cases were found to have had recent or concurrent purulent conjunctivitis. Since the initial outbreaks, sporadic cases have been reported in other areas of Brazil and in central and western Australia.[874,1351] Outbreak-associated "*H. aegyptius*" strains possess several characteristics not found in "*H. aegyptius*" isolated from cases of purulent conjunctivitis without BPF.[562] These strains are nontypeable, possess a unique 24-kDa plasmid, a distinctive 25-kDa outer membrane fimbrial protein, and are resistant to the bactericidal effects of normal human serum. BPF strains possess a

conserved cell surface epitope of the 48-kDa P1 outer membrane protein that is not present in non–BFP-associated strains. Outbreaks of BPF were caused by a unique clone of "*H. aegyptius*" that has been designated "*H. influenzae* biogroup *aegyptius*." In vivo studies using a rat model and studies with a human microvascular endothelial cell line also have shown that BPF-associated *H. influenzae* biogroup *aegyptius* are more cytotoxic than non–BPF-associated *H. influenzae* strains.[1118,1344] Based on multilocus enzyme electrophoresis methods, biogroup *aegyptius* isolates form three distinct lineages within the species *H. influenzae*. The BPF isolates are not closely related genetically to non-BPF biogroup *aegyptius* strains but do show a close genetic relationship with encapsulated *H. influenzae* capsular serotype c.[925]

Miscellaneous *H. influenzae* infections

H. influenzae type b may cause other uncommon infections; in many instances, the recovery of *Haemophilus* species was unexpected. *H. influenzae* has been isolated from abdominal infections (i.e., peritonitis, pancreatic and pelvic abscesses, appendicitis) and hepatobiliary tract infections (i.e., cholecystitis, pyogenic liver abscess).[31,522,852,964,971,1047,1349]

While sporadic infections due to encapsulated non-type b *H. influenzae* occurred in the United States prior to widespread vaccination with type b vaccines, serious infections caused by both non-type b capsular serotypes and nontypeable strains of *H. influenzae* are being increasingly recognized in the vaccine era. In 2001, five cases of invasive disease caused by *H. influenzae* serotype a were seen over a 10-month period in Utah.[4] These children (median age 12 years) presented with meningitis, bacteremia, and, in one instance, purpura fulminans. Examination of 48 invasive non-type b *H. influenzae* by restriction endonuclease typing showed that type a strains segregated into two major clonal groups, while type e and type f strains represented single clones, respectively. In another Utah study, Bender and colleagues reviewed all cases of invasive *H. influenzae* disease in children less than 5 years old from 1998 through 2008 and found that *H. influenzae* serotype a was the most common, representing the etiologic agent in 28% of all infections.[109] Increased incidence of encapsulated non-type b *H. influenzae* may reflect either the emergence of hypervirulent clones or limited genetic diversity among non-type b strains.[976] Serious infections (i.e., meningitis, pneumonia) due to *H. influenzae* serotypes other than type b have been reported.[421,678,703,869]



■ **FIGURE 9-1** Structure of the repeating unit of the *Haemophilus influenzae* type b capsular polysaccharide PRP. This molecule consists of the 5-carbon monosaccharide ribose, linked by an ester bond to ribitol, and a 5-carbon sugar alcohol, which, in turn, is linked to a phosphate group.

of singular importance. Animal studies with isogenic strains transformed with DNA coding for capsule production confirmed that type b strains were more virulent than the other capsular types. The PRP capsule allows the organism to resist phagocytosis and intracellular killing by neutrophils. Anti–type b antibodies promote complement-dependent phagocytosis and killing (opsonization) of these organisms in vitro and in vivo. In addition to the type b capsule, *H. influenzae* possesses several other virulence factors, most of which are related to adherence, colonization, and invasion. Some of these factors are found in both typeable and nontypeable strains, while others are

found only in nontypeable *H. influenzae* isolates.

***Haemophilus Influenzae* Type b Vaccines and Immunity.** Prior to the introduction of effective vaccines against *H. influenzae* type b, this organism was the most common cause of bacterial meningitis in children younger than 5 years, causing approximately 16,000 cases of invasive disease annually. The majority of systemic type b infections occurred in children aged 2 years and younger. Inadequate levels of protective, anti-PRP bactericidal antibodies at this age play a major role in the development of disease. During the immediate newborn period, immunity to *H. influenzae* type b is acquired by transplacental antibodies, but this is lost within the first few months of life. These antibodies reappear following exposure to type b organisms or to other microbial antigens that engender cross-reactive antibodies. Most individuals who develop systemic *H. influenzae* type b disease have low or undetectable levels of anti-PRP capsular antibodies. The antigenic capabilities of native, purified PRP were exploited in the first *H. influenzae* type b vaccine preparations. Purified PRP elicited antibodies in older children, but failed to elicit a response in children less than 2 years of age, the group most at risk for serious illness. PRP also did not predictably elicit a "booster" response on subsequent antigenic challenge. This failure was due to the T-cell-independent nature of the primary immune response to polysaccharide antigens. Clinical trials were subsequently undertaken with four PRP/protein conjugate vaccines. The vaccines consisted of PRP conjugated covalently to tetanus toxoid (PRP-T), to diphtheria toxoid (PTP-D), to an outer membrane protein complex from Neisseria meningitidis (PRP-OMPC), and to CRM197, a "non-toxic" diphtheria toxin isolated from a mutant strain of Corynebacterium diphtheriae (PRP-HbOC). Using this approach, the immunogenicity of the PRP material would likely be enhanced, since conjugation of carbohydrate moieties to proteins as haptens elicits a T-cell dependent immune response with generation of memory cells.

Two conjugate vaccines are currently licensed and available in the United States: PRP-T (ActHIB *Haemophilus* b Tetanus Conjugate Vaccine, Sanofi Pasteur, Swiftwater, PA) and PRP-OMPC (PedvaxHIB *Haemophilus* b Conjugate Vaccine [Meningococcal Outer Membrane Protein Conjugate],

Merck and Company, Inc., West Point, PA). PRP-T is also available as a vaccine containing diphtheria, tetanus, and acellular pertussis vaccine combined with ActHIB (TriHIBit DTaP/Hib, Connaught Laboratories, Swiftwater, PA), and PRP-OMPC is also available in combination with the hepatitis B vaccine (Recombivax). Infants should receive a dose of PRP-T conjugate vaccine at 2, 4, and 6 months of age or two doses of PRP-OMPC administered at 2 and 4 months of age. A booster dose is

recommended at 12 to 15 months of age. The food and drug administration (FDA) also states that TriHIBit (DTaP/Hib) should not be used for dosing at ages 2, 4, or 6 months, but can be used for the final dose in children aged 12 months or older. The PRP-OMPC/hepatitis B combination vaccine can be used for immunizations at 2, 4, 12, and 15 months of age.

In the United States, widespread use of these conjugate vaccines has almost completely eradicated invasive *H. influenzae* type b disease in children aged 5 years and younger. In 1987, the incidence of invasive pediatric *H. influenzae* type b was 41 cases per 100,000 per year, and this incidence decreased to about 0.11 cases per 100,000 per year by 2007 in the same pediatric population.[1225] Large decreases in disease incidence among children less than 18 months of age were noted long before the conjugate vaccines were in widespread use, and it is now recognized that conjugate vaccines not only prevent disease by inducing active immunity, but also decrease oropharyngeal carriage of and, consequently, exposure to *H. influenzae* type b. In premature infants or those with underlying disease (e.g., HIV infection), the vaccines may not be as effective as in term infants with normal immune systems, since antibody responses are less robust, which results in lower levels of anti-PRP antibodies.[833] The reduced antibody responses to the vaccines in HIV-infected infants is likely due to the T-cell-depleted state of the patients and the T-cell-dependent nature of the immune response to the conjugate vaccines. *H. influenzae* type b conjugate vaccines are immunogenic in HIV-seropositive adults, but the ability to develop protective levels of antibody is related to baseline CD4 T-cell counts and IgG levels. Occasionally, severe infections with nontypable *H. influenzae* may occur, as evidenced by the report of a previously healthy 7-year-old boy who developed an intracranial abscess.[1134]

Other Haemophilus *Species*

H. parainfluenzae, *H. haemolyticus*, *H. parahaemolyticus*, and *H. paraphrophaemolyticus* and *H pittmaniae* are part of the normal microbiota of the respiratory tract and are rarely associated with infections. In recent years, however, several reports documenting *H. parainfluenzae* as an important agent of native and prosthetic valve endocarditis have appeared in the literature.[256,275,590,960] *H. parainfluenzae* infections of pacemaker lead wires and an implantable cardioverter defibrillator have also been described.[314,996] *H. parainfluenzae* has been isolated from patients with bronchitis, sinusitis, otitis media, brain abscess, COPD/pneumonia, cellulitis, abscesses, neonatal sepsis, and native/prosthetic joint infections.[159,200,201,243,481,1032,1170,1278] *H. parainfluenzae* has also been isolated as an unusual cause of urinary tract infection.[556] *H. parainfluenzae* may occasionally be isolated from the genital tract and may cause urethritis in men, chorioamnionitis in

women, and early-onset sepsis in the neonate.[408,1008,1079] Rare *H. parainfluenzae* hepatobiliary tract infections, including liver abscess, retroperitoneal abscess, and peritonitis, have also been reported.[29,449,454,863,1008] In these latter infections, it was postulated that *H. parainfluenzae* gained access to the hepatobiliary tree from the intestinal tract rather than via a hematogenous route.

Haemophilus ducreyi

H. ducreyi is the causative agent of chancroid, a highly contagious sexually transmitted infection characterized by painful genital and perianal ulcers and tender inguinal lymphadenopathy (Image Plate 9-2B). Chancroid is a major cause of genital ulcer disease in Latin America, Africa, East and Southeast Asia, and India. In these countries, chancroid accounts for 20% to 60% of genital ulcer disease.[900] Outbreaks of chancroid have been reported in a number of coastal cities in the United States and Canada. In these outbreaks, female sex workers have been the usual reservoir, with the exchange of sex for money or drugs being a major behavioral risk factor.[148] In these outbreaks, male-to-female case ratios of 3:1 to 25:1 have been observed. In undeveloped countries, infection with *H. ducreyi* is associated with transmission of human immunodeficiency viruses (HIV-1 and HIV-2). Studies in Africa have provided evidence that chancroid is a risk factor for sexual transmission of HIV-1. Chancroid facilitates the transmission of HIV due to increased viral shedding into the genital tract from ulcer exudates and bleeding of ulcers during and after intercourse.[426] The lesions of chancroid also disrupt mucosal integrity, thereby providing a portal of entry for HIV. In addition, the cellular immune response to *H. ducreyi* involves infiltration of the lesion tissues with large numbers of CD4-positive T-helper cells in the lesions themselves, thereby increasing the risk of transmission to sexual contacts. Antigens of *H. ducreyi* also stimulate the CD4 T lymphocytes locally, resulting in upregulation of HIV replication and increased titers of infectious virus and virally infected cells in the genital tract.[1295]

Although several potential virulence factors have been identified in *H. ducreyi*, their roles in pathogenesis are poorly understood at the present time. All strains appear to have fine, tangled, surface fimbriae, unique outer membrane proteins, lipooligosaccharide, and a cytotoxin/hemolysin, which contributes to epithelial cell invasion and the formation of ulcerative lesions.[1324] The role of these molecules in disease pathogenesis is not clear. *H. ducreyi* also has a specific growth requirement for iron, and, although it lacks siderophores, the organism has a receptor on its surface that binds hemoglobin and is essential for iron uptake. *In vitro*, *H. ducreyi* is able to attach, invade, and cause cytopathic effects in cultured human foreskin cells, and several animal models for chancroid have been developed to study virulence and pathogenicity, including rabbit, piglet, primate, and human volunteer models. The latter

studies have helped to identify genes and gene clusters that are essential for organism virulence.[99]

Genital lesions caused by this organism are called "soft chancres" because, unlike the primary chancre of syphilis, the borders of the lesion are ragged and pliable rather than sharply demarcated and indurated. Trauma or localized abrasion of the skin or mucosa is required for entry of the organism, and it is estimated that about 10,000 organisms constitute

an infective dose. After an incubation period of 4 to 7 days, the lesions begin as tender erythematous papules that become pustular, eroded, and ulcerated within the next 48 to 72 hours. In males, chancroid lesions are usually tender, painful, and are covered with a yellow-gray exudate overlying a beefy, bleeding base. In males, lesions are usually present on the external genitalia (prepuce, frenulum, coronal sulcus, glans penis, and penile shaft); in uncircumcised men, these lesions are often found beneath the foreskin. HIV-infected males may have increased numbers of genital ulcers that heal more slowly and that become superinfected more readily.[708] In females, multiple lesions may be present on the fourchette, labia, vulva, the vaginal wall, the clitoris, and in the perianal area. Lesions may coalesce to form large ulcerative areas that may become superinfected. Extragenital chancroid is uncommon, but lesions have been described on the glabrous skin of the thighs, the breasts, the oral mucosa, and the conjunctivae. In about half of the infected patients, painful unilateral inguinal lymphadenopathy develops. These enlarged lymph nodes may actually suppurate through the overlying skin to form large inguinal abscesses, draining fistulas, and sinus tracts. Untreated genital ulcers may persist for several months, but the organism does not disseminate via the blood or lymphatics.

Laboratory Diagnosis of Haemophilus *Infections*

Direct Examination of Clinical Specimens

Gram's Stain. A rapid presumptive diagnosis of *H. influenzae* meningitis can be made by direct examination of cerebrospinal fluid (CSF) using the Gram's stain. If sufficient (i.e., more than 1 to 2 mL) CSF is received, the specimen is centrifuged to obtain a pellet of material for examination and culture. Cytocentrifugation of CSF specimens enhances detection of small numbers of organisms and considerably increases the sensitivity of the Gram's stain in comparison with conventionally centrifuged or uncentrifuged specimens.[236] On Gram's stain preparations, *Haemophilus* organisms appear as small, pale-staining, gram-negative coccobacilli (Image Plate 9-1A). Occasionally, slender filamentous cells may be observed.

Although *H. influenzae* may be the likely pathogen on the basis of the Gram's stain appearance and the clinical presentation of the patient, the organisms cannot be identified on the basis of the Gram-stained smear. Furthermore, a negative Gram's stain (i.e., a Gram's stain with no organisms seen) does not rule out the possibility of *Haemophilus* infection because very few organisms may be present in the specimen. Gram's stain smears of other specimen types may also be useful for presumptive diagnosis.

Detection of Type b Capsular Antigen. For rapid diagnosis of *H. influenzae* type b infections, techniques are available for the detection of the type b PRP capsular antigen in CSF, serum, and urine. Commercially available methods include latex agglutination (LA) (e.g., Directigen Meningitis Combo Test, Becton-Dickinson and Company, Sparks, MD) and staphylococcal protein A coagglutination (COA) (e.g., Phadebact CSF test, Bactus AB, Huddinge, Sweden). These kits contain reagents for detecting *H. influenzae* group b PRP antigen along with reagents for *S. pneumoniae*, *N. meningitidis*, and group B streptococcal antigen detection in body fluids. Despite the performance of these tests in clinical trials that led to their approval for use, many laboratories have discontinued offering these tests routinely. Aside from the high cost of the latex/COA reagents themselves, their diagnostic and prognostic utility has not been borne out after years of experience. Perkins et al. reviewed all latex tests performed over a 10-month period at two hospitals and found 57 positive results.[1021] Review of these cases revealed that 31 results were false-positives, 22 were true positives, and 4 were indeterminate. False-positive tests were noted most often with urine specimens. Patients with false-positive test results received unnecessary treatment, resulting in prolonged hospitalization and additional complications. Furthermore, among the 22 patients with true-positive LA results, there was no instance where the antimicrobial therapy or clinical management of the patient was altered on the basis of the LA result. These tests may be most useful in cases of suspected meningitis where the initial Gram's stain is negative and/or where CSF cultures are negative after 48 hours. The recommended method for optimal direct detection of *H. influenzae* in CSF depends on careful inspection of a Gram-stained smear prepared from a cytocentrifuged specimen.

Recovery of *Haemophilus* Species in Culture. Optimal recovery of *Haemophilus* species from clinical specimens depends on proper collection and transport of specimens, and the use of appropriate culture media and incubation environments. Because of their fastidious nature, specimens containing them should not be exposed to drying or to temperature extremes. Crucial specimens such as CSF should be hand-carried to the clinical laboratory as soon after collection as possible. Conventional sheep blood agar is not suitable for recovery of *Haemophilus* species that require V factor for growth because of the presence of V-factor-inactivating enzymes in native sheep blood. Rabbit or horse blood does not contain these enzymes, and agar media

containing either of these blood products will support the growth of most *Haemophilus* species. Isolation of *Haemophilus* requires incubation at 35°C to 37°C in a moist environment with increased CO_2 (3% to 5%). This atmosphere is provided by incubation in a CO_2 incubator or in candle extinction jars. Primary isolation of *Haemophilus* species from clinical specimens is accomplished by using chocolate agar, *Haemophilus* isolation agar, or the *Staphylococcus* streak technique (Image Plate 9-1B).

Chocolate Agar. Chocolate agar is prepared by adding sheep blood to an enriched agar base when the temperature of the medium is high enough to lyse the red cells without inactivating the NAD in the blood lysate (i.e., about 80°C). Most clinical laboratories purchase chocolate agar and other media from commercial vendors. Commercially prepared "chocolate agar" contains a mixture of hemin and chemically defined growth factors that are added to GC (gonococcal) agar base medium. GC agar base contains proteose peptone, cornstarch, phosphate buffers, sodium chloride, and agar. The chemically defined supplement contains NAD, vitamins ($B1_2$, thiamine hydrochloride), minerals (iron, magnesium), amino acids required for growth of fastidious bacteria (cysteine, glutamine), and glucose. These supplements are available commercially under the trade names IsoVitalex (BD Biosciences) and GCHI Enrichment (Remel Laboratories, Lenexa, KS). The disadvantage of using chocolate agar for primary

isolation of *Haemophilus* species is that hemolytic properties of several species (*H. haemolyticus*, *H. parahaemolyticus*, *H. pittmanniae*) cannot be determined. Because *Haemophilus* species are common inhabitants of the upper respiratory tract (including both hemolytic and nonhemolytic species), many laboratories have adopted *Hemophilus* isolation agar for recovery of these organisms from respiratory specimens.

***Haemophilus* Isolation Agar.** These commercially available media contain beef heart infusion, peptones, yeast extract, and defibrinated horse blood (5%) containing both X and V factors. Bacitracin (300 μg/mL) is added to inhibit the other normal respiratory tract microbiota (i.e., staphylococci, micrococci, neisseriae, streptococci). Besides the selective recovery of *Haemophilus* species, hemolytic properties can be determined directly upon primary isolation.

***Staphylococcus* Streak Technique.** Many bacteria and yeasts synthesize and secrete NAD during growth on bacteriologic media. In mixed cultures, *Haemophilus* species that require V factor may grow as pinpoint colonies around the colonies of other microorganisms. This phenomenon is called satellitism (Image Plate 9-1C). Satellitism provides a technique for detecting these organisms in mixed cultures as well

as a presumptive test for genus-level identification. A colony of a possible *Haemophilus* species is subcultured onto a sheep blood agar plate and streaked as a lawn. A single streak of an NAD-producing organism (e.g., *S. aureus*) is made through the lawn inoculum. After overnight incubation in a CO_2-enriched environment at 35°C to 37°C, tiny moist gray colonies of the haemophili may be observed within the hemolytic area adjacent to the staphylococcal growth. X-factor-dependent haemophili will also grow as satellite colonies because hemin and hematin are released from the lysed red blood cells. This method may be used for presumptive identification of *Haemophilus* species when species-level identification is not required or essential (e.g., upper respiratory tract specimens).

Identification of *Haemophilus* Species

Colony Morphology and Cultural Characteristics. On chocolate agar, colonies of *H. influenzae* are smooth and blue-gray in color; heavily encapsulated strains may appear mucoid. Most strains produce convex, smooth, entire colonies of 1 to 2 mm after overnight growth. Some strains will have an "*E. coli*" odor because of the production of indole by some biotypes. *H. parainfluenzae* colonies are usually smaller, light gray, and have a matte appearance on growth media. Oxidase and catalase reactions for these organisms are usually positive, although the oxidase reaction may be delayed.

Identification Procedures. Commonly encountered *Haemophilus* species are identified by hemolytic reactions on horse blood agar and growth requirements for X and V factors. Filter paper disks or strips impregnated with X factor, V factor, or both X and V factors are routinely used to determine these factor requirements (Image Plate 9-1D). The organism to be identified is streaked as a lawn on media deficient in growth factors, such as trypticase-soy agar. It is important when selecting colonies from primary culture plates for this test that none of the chocolate agar or other blood-containing media is transferred to the factor determination plate. Suspending the organism in factor-deficient broth before plate inoculation is one way to reduce carryover of growth factors and consequent false-positive results. The X and V factor disks or strips are placed on the agar surface about 1 to 2 cm apart (Chart 9-1). If a disk/strip containing both factors is also used, the disks may be more widely spaced on the agar surface. The plates are incubated in 5% to 7% CO_2 at 35°C for 18 to 24 hours, and the patterns of growth around the disks/strips are observed. Trypticase-soy agar is the medium of choice for performance of the growth factor determination procedure.[361] Although interpretation of factor requirement tests is generally clear-cut, misidentifications of *H. influenzae* with *H. parainfluenzae* have been reported because of inconsistent results in X factor determinations. Reasons for these inaccuracies include presence of trace amounts of hemin in the basal medium used for the factor determination test, carryover of X factor in inocula taken from growth on

blood-containing medium, and the fastidious nature of some *H. parainfluenzae* strains, with consequent difficulty in reading tests for factor requirement. The δ-aminolevulinic acid (ALA)–porphyrin test circumvents many of these problems as this test is a direct assessment of the ability of *Haemophilus* strains to synthesize protoporphyrin intermediates in the biosynthetic pathway to hemin from the ALA. Strains that require exogenous X factor for growth (i.e., *H. influenzae* and *H. haemolyticus*) cannot synthesize protoporphyrins from ALA and, consequently, are negative with this test. Strains that do not require exogenous X factor for growth (i.e., *H. parainfluenzae* and *H. parahaemolyticus*) possess the enzymes that synthesize protoporphyrin compounds from ALA and are, consequently, ALA–porphyrin test-positive. ALA-impregnated disks (BD Biosciences; Remel Laboratories; Hardy Diagnostics, Santa Maria, CA) or growth media containing the ALA reagent (Remel Laboratories) may also be used to perform the ALA–porphyrin test (Image Plate 9-1F and 9-1G). With the disk method, the impregnated disk is moistened with water and inoculated with colonial growth. After 4 hours' incubation, the disk is observed under ultraviolet light (Wood's light). Brick-red fluorescence on the disk indicates a positive test result; bluish fluorescence constitutes a negative test result. With the ALA agar medium, the organism is inoculated onto the medium and incubated overnight. The next day, growth is examined under a Wood's light for brick-red fluorescence. Phenotypic characteristics for the identification of *Haemophilus* species are presented in Table 9-2.

Tests for hemolysis on horse blood agar, factor requirements, and the ALA–porphyrin test have been incorporated into commercially available sectored-plate systems for identification of *Haemophilus* species. These include the *Haemophilus* ID II Triplate and the *Haemophilus* ID Quad plate (Remel). The triplate is a three-sectored plate containing horse blood agar, agar containing V-factor, and agar containing ALA agar. Following inoculation and overnight incubation, the plate is read by inspecting the blood agar sector for hemolysis, looking for growth in the V-factor sector, and looking for brick-red fluorescent growth in the ALA sector under Wood's light illumination. The quad-plate contains four sectors containing factor-supplemented Müeller–Hinton medium with horse blood, X-factor-enriched medium, V-factor-enriched medium, and medium containing both X and V factors, respectively. Based on hemolysis and the pattern of growth in the remaining quadrants, an identification can be obtained.

[a] Biotyping reactions are identical with those of *H. influenzae* biogroup aegyptius, but biogroup aegyptius strains are xylose-negative.
[b] Biotype V strains are identical to *Aggregatibacter segnis*.
+, positive; –, negative; +[w], weak positive; V, variable; NA, not available; HEM, hemolysis on horse blood agar; ALA, aminolevulinic acid porphyrin test; IND, indole; URE, urease; ODC, ornithine decarboxylase; ONPG, *o*-nitrophenyl-β-D-galactopyranoside; GLU, glucose; SUC, sucrose; LAC, lactose; FRUC, fructose; RIB, ribose; XYL, xylose; MANN, mannose.

486

Serotyping of *Haemophilus influenzae*. The easiest technique for serotyping isolates is slide agglutination. A dense organism suspension is prepared in saline, and single drop of the suspension is placed in each of a series of circles on a glass slide corresponding to the number of sera to be tested, plus a saline control. Type-specific antisera are added to each of the test circles, and the slide is rotated. Rapid (i.e., less than 1 minute) agglutination of organisms by a specific antiserum and the absence of agglutination in the saline control identifies the isolate as a specific serotype. Polyvalent and type-specific antisera for all six *H. influenzae* serotypes are commercially available. Serotyping of clinical isolates by slide agglutination must be carefully performed with reliable reagents that are quality controlled with organisms of known serotype.

A COA culture confirmation test (Phadebact *Haemophilus* Test, Bactus AB) is available for simultaneous identification and serotyping of *H. influenzae* type b from primary culture media. This kit contains a vial of staphylococcal cells sensitized with type b antisera (test reagent) and a second vial of staphylococci sensitized with antisera to type a, c, d, e, and f (control reagent). Colonies from growth media are mixed with each of the two reagents on a cardboard slide. After mixing, the slide is rocked for 30 to 60 seconds. Visible agglutination of the mixture with the type b test

reagent but not the control reagent identifies the isolate as *H. influenzae* type b. A positive reaction in the control reagent indicates that the organism belongs to capsular types a, c, d, e, or f.[511]

Biotyping of *Haemophilus influenzae* and *Haemophilus parainfluenzae*. In his taxonomic study of the genus, Kilian introduced biochemical tests for identifying and characterizing haemophili.[701] Biotypes are determined with three tests: indole production, urease, and ornithine decarboxylase. *H. influenzae* strains could be divided into seven biotypes that were independent of serotype (i.e., type b, non–type b, or nontypeable). Seven *H. parainfluenzae* biotypes have also been described using these methods. Biotyping reactions for *Haemophilus* species are included in Table 9-2.

Biotyping of *Haemophilus* species has demonstrated that specific biotypes are associated with different infections, sources, antigenic properties, and antimicrobial resistance patterns. *H. influenzae* biotype I strains are recovered mostly from CSF, blood, and respiratory tract secretions of infants less than 1 year old.[913,962] *H. influenzae* biotypes II and III are recovered from conjunctival and sputum cultures of children aged 1 to 5 years and from adults greater than 20 years of age. Biotypes II and III are also associated with ocular infections.[22] Biotype IV *H. influenzae* are emergent pathogens in obstetric, gynecologic, perinatal, and neonatal infections. The cryptic genospecies associated with maternal/neonatal infections has biotyping reactions that are identical with *H. influenzae* biotype IV and underscores the shortcomings of phenotypic methods for strain typing. The cryptic genospecies can only be distinguished from biotype IV strains by molecular genetic approaches that are not readily available in clinical microbiology laboratories.

Biochemical and Kit Methods for *Haemophilus* Identification. Carbohydrate fermentation tests can also be used for identification of *Haemophilus* species. These methods bypass technical problems associated with factor requirement tests. Acid production from several carbohydrates (i.e., sucrose, fructose, ribose, xylose, and mannose) can be used to separate *H. influenzae* from *H. parainfluenzae*. A limited battery of tests is also necessary for differentiating and identifying the former *Haemophilus* species *Aggregatibacter aphrophilus, Aggregatibacter actinomycetemcomitans*, and *Aggregatibacter segnis*. Lactose fermentation or *o*-Nitrophenyl-β-D-galactopyranoside (ONPG) hydrolysis is useful for identifying *A. aphrophilus*; other *Haemophilus* species and *Aggregatibacter actinomycetemcomitans* are negative for lactose fermentation and ONPG reaction. *A. segnis* produces weak or delayed acidification of sucrose and fructose, and is negative in all three biotyping reactions. Carbohydrate utilization is determined in heavily inoculated semisolid cystine-tryptic digest agar containing 1% filter-sterilized carbohydrates. Acid production is apparent in 4 to 18 hours. Reagent-impregnated urease and ornithine decarboxylase disks and the spot indole test can be used for rapid biotyping of individual isolates.

Kit identification systems that use modified conventional tests and chromogenic enzyme substrates can also be used to identify and simultaneously biotype *Haemophilus* species. The RapID NH panel (Remel Laboratories), the *Haemophilus-Neisseria* Identification (HNID) panel (Siemens-MicroScan, West Sacramento, CA), the API NH strip (bioMérieux, La Balme-les-Grottes, France), and the Vitek 2 *Neisseria-Haemophilus* card identify these organism within 2 to 4 hours of inoculation (Image Plate 9-2A and 9-2C).[641,916]

Haemophilus ducreyi: *Laboratory Diagnosis of Chancroid*

Specimen Collection and Direct Examination. Cotton, rayon, Dacron, or calcium alginate swabs may be used to collect specimens from chancroid ulcers. Specimens should be collected from the base and undermined margins of the ulcer. For bubo, a needle and syringe may be used to aspirate pus from the bubo through normal, intact tissue. If the bubo has suppurated through the skin, a swab may be used to collect the specimen. However, the organism is often not recoverable from bubo pus. Transport media have not been evaluated for recovery of *H. ducreyi*; so growth media should be inoculated directly. If a transport medium is used, Amies transport medium or Amies with charcoal should be used and the specimen should reach the laboratory within 4 hours of specimen collection. Gram-stained smears of the suppurative exudate from genital lesions of chancroid are usually noncontributory because of low sensitivity (from 5% to 63%) and specificity (51% to 99%). When seen on direct smears, *H. ducreyi* appears as pale-staining, gram-negative coccobacilli, often arranged in clustered groups ("school of fish") or loosely coiled parallel chains ("railroad tracks") (Fig. 9-2). Organisms may be inside and outside of polymorphonuclear leukocytes (PMNs). Since genital lesions and suppurative nodes or abscesses may become superinfected with other bacteria, culture should be attempted. Diagnosis of chancroid is frequently made on clinical and epidemiologic grounds; however, syphilis, genital herpes simplex virus infection, and lymphogranuloma venereum must be included in the differential diagnosis.

Culture. *H. ducreyi* may be difficult to recover in culture, and several media have been evaluated for this purpose. For the

■ **FIGURE 9-2** Gram-stained morphology of *Haemophilus ducreyi*. On Gram-stained smears prepared from lesions of chancroid or from colonial growth, the organisms may appear in loose clusters (i.e., "school of fish" ***[left]***) or as loosely coiled clusters of gram-negative bacilli lined up in parallel (i.e., "railroad tracks" ***[right]***).

highest yield, more than one type of culture medium should be inoculated. GC agar base supplemented with 2% bovine hemoglobin, 5% fetal calf serum, and 1% IsoVitalex, and Müeller–Hinton agar supplemented with 5% chocolatized horse blood plus 1% IsoVitalex enrichment have been used for culture of *H. ducreyi*. In some media formulations, activated charcoal (0.2%) instead of fetal calf serum has been used as an additive to absorb toxic materials from the specimen and the agar. Vancomycin (3 µL/mL final concentration) may be added to inhibit contaminating gram-positive bacteria. Commercial chocolate agar media will generally support the growth of *H. ducreyi*; vancomycin disks may be placed in various quadrants of a chocolate plate to help detect the organisms in mixed cultures. Most strains of *H. ducreyi* have vancomycin minimum inhibitory concentrations (MICs) of 32 to 128 µg/mL, but some strains have MICs as low as 4 µg/mL. Therefore, it may be advantageous to inoculate media with and without vancomycin and to collect multiple appropriate specimens. Media are incubated at 33°C to 35°C in 5% to 7% CO_2 or in a candle jar with high humidity; growth may actually be inhibited at incubation temperatures exceeding 35°C. Better growth may be obtained using a microaerophilic environment, where cultures are placed in a GasPak jar with two carbon dioxide/hydrogen gas-generating envelopes and no catalyst. Cultures are inspected daily for 10 days. Most isolates from clinical specimens produce visible growth in 2 to 4 days.

Colonies of *H. ducreyi* are small, nonmucoid, and gray, yellow, or tan in color. The colonies can characteristically be "nudged" along the agar surface with a bacteriologic loop, are difficult to pick up, and produce a nonhomogenous, "clumpy" suspension in saline. The organisms appear as gram-negative coccobacilli, usually in close association with one another. *H. ducreyi* is catalase-negative and oxidase-positive; the oxidase reaction is usually delayed and develops only after 15 to 20 seconds with the tetramethyl-*p*-phenylenediamine dihydrochloride reagent. Because of the fastidious nature of *H. ducreyi*, growth factor requirements cannot be demonstrated with factor-impregnated disk or strip techniques. The ALA–porphyrin test is negative, indicating that exogenous hemin is required for growth. *H. ducreyi* is biochemically inert, except for positive nitrate reduction and alkaline phosphatase tests. In an evaluation with 25 *H. ducreyi* isolates, Shawar et al. found that all strains produced unique and consistent enzymatic reactions on the RapID ANA (Remel), a 4-hour identification system for clinically significant anaerobic bacteria.[1178] *H. ducreyi* strains are also susceptible to sodium polyanetholsulfonate (SPS) as determined by a disk susceptibility method. Growth characteristics, SPS susceptibility, and aminopeptidase profiles obtained with the enzymatic RapID ANA system may be useful for laboratory identification of *H. ducreyi*. A rapid immunochromatographic strip method for organism identification from culture has also been described.[1009] This assay used monoclonal antibodies directed against the highly conserved outer membrane hemoglobin receptor, HgbA, as the capture antibody. Using this assay, all of 26 *H. ducreyi* isolates tested were correctly identified, while all other bacteria tested were negative. Molecular methods and non–growth-dependent techniques, including direct and amplified nucleic acid probes, have also been developed for identification or direct detection of *H. ducreyi*. Suntoke and colleagues from the NIH developed a sensitive, rapid, and reproducible real-time multiplex polymerase chain reaction (PCR) assay for the direct detection of *H. ducreyi*, *Treponema pallidum*, and herpes simplex virus types 1 and 2 directly in genital ulcers.[1231]

Antimicrobial Susceptibility of Haemophilus *Species*

Until about 1973, antimicrobial susceptibility testing of *H. influenzae* was unnecessary because clinically significant isolates were susceptible to ampicillin, the drug of choice for type b meningitis and bacteremia. By 1974, some strains of *H. influenzae* had become resistant to ampicillin beacuse of acquisition of plasmids carrying genes encoding β-lactamase enzymes. Plasmid-mediated β-lactamases have been found in type b, encapsulated non–type b, and nontypeable *H. influenzae* and in *H. parainfluenzae* strains. These organisms harbor a 3.0 megadalton transposon that carries the gene for a TEM-1 type β-lactamase enzyme. Rare *H. influenzae* strains produce a second type of β-lactamase, called ROB-1.[329] Over the last 25 years, the

prevalence of β-lactamase-positive strains has been increasing throughout the world. In the 2002 LIBRA surveillance project, β-lactamase-positive *H. influenzae* accounted for 32.2% of 2,791 isolates.[658] At that time, more than 99% of the strains were susceptible to amoxicillin clavulanate, regardless of β-lactamase production. Clavulanate inactivates the β-lactamase, rendering the organisms susceptible to the amoxicillin included in this combination antibiotic. *H. influenzae* strains have been isolated that are resistant to ampicillin, but do not produce β-lactamases. In these strains, resistance is due to alterations in cell wall penicillin binding proteins or in permeability of the cell membrane to the agent. These strains also display diminished susceptibility to third-generation cephalosporins and to β-lactam/β-lactamase inhibitor combinations. A 2000 to 2001 *H. influenzae* surveillance study in the United States detected only 9 (0.6%) β-lactamase-negative, ampicillin-resistant strains among 1,434 isolates, suggesting that these strains are relatively uncommon.[683] However, a 2009 report from Japan showed that the proportion of ampicillin-resistant, β-lactamase-positive

488

H. influenzae strains decreased from 9.6% in 1999 to 4.8% in 2003, whereas the proportion of ampicillin-resistant, β-lactamase-negative strains increased from 15.4% to more than 30% over the same time period.[505]

Clinical and Laboratory Standards Institute (CLSI) methods for antimicrobial susceptibility testing of *H. influenzae* and *H. parainfluenzae* recommend the use of *Haemophilus* test medium or *Haemophilus* test medium broth for disk diffusion and broth dilution, respectively.[285] *Haemophilus* test medium contains hematin, yeast extract, and NAD; Müeller–Hinton agar is included for the disk diffusion method.[660,661] Breakpoints for susceptible, intermediate, and resistant categories are available for ampicillin, β-lactam/β-lactamase inhibitor combinations, third- and fourth-generation cephalosporins (including oral and parenteral formulations), macrolides, and trimethoprim–sulfamethoxazole (SXT).[285] Only susceptible category breakpoints are available for aztreonam, the carbapenems, and the fluoroquinolones as the absence of resistant strains precludes defining intermediate and resistant categories for these agents at the present time. A rapid test for detection of β-lactamase provides a simple method for testing susceptibility to ampicillin and amoxicillin. Ampicillin/amoxicillin-resistant, β-lactamase-negative strains are also considered resistant to β-lactam/β-lactamase inhibitor combination agents (i.e., amoxicillin clavulanate, ampicillin sulbactam, piperacillin–tazobactam) and oral cephalosporins (i.e., cefaclor, cefetamet, cefonicid, cefprozil, cefuroxime, loracarbef) even though isolates may test susceptible to these agents in vitro. Since the standard recommendations for antimicrobial therapy

of *Haemophilus* infections are well defined, many laboratories do not perform antimicrobial susceptibility testing on *Haemophilus* species. Furthermore, some strains *H. influenzae* and *H. parainfluenzae* do not grow well on *Haemophilus* test medium.

Currently, third-generation cephalosporins (i.e., cefotaxime, ceftriaxone) are the recommended therapy for treatment of systemic *H. influenzae* type b infections because of the excellent activity of these agents in vitro and in vivo.[919] Treatment for systemic infections is usually continued for 7 to 10 days; those individuals with complicated infections (e.g., endocarditis, osteomyelitis) may require 3 to 6 weeks of parenteral therapy. Infections associated with nontypeable *H. influenzae* (e.g., chronic bronchitis, COPD, otitis media) are often treated with ampicillin or amoxicillin if susceptibility to these agents has been documented. Oral macrolides (i.e., azithromycin, clarithromycin) or fluoroquinolones are also prescribed for these infections. The fluoroquinolones have excellent activity against *H. influenzae*; in a recent 25-year susceptibility survey performed in Japan, greater than 95% of *H. influenzae* isolates had fluoroquinolone MICs of ≤0.06 μg/mL.[505] Nontypeable *H. influenzae* that are β-lactamase-negative are also susceptible to the fluoroquinolones, macrolides, and the extended-spectrum oral and parenteral cephalosporins. *H. parainfluenzae* and other respiratory tract *Haemophilus* species are susceptible to third-generation cephalosporins, the quinolones, tetracyclines, and aminoglycosides. Although most strains are susceptible to penicillin and ampicillin, resistant strains, including β-lactamase-producing strains, have been reported.

In parts of the world where chancroid is endemic, rapid and accurate methods for specific diagnoses are lacking; so a syndromic approach, as recommended by World Health Organization, is used for management of sexually transmitted infections. Chancroid can be treated with a variety of agents, including fluoroquinolones, macrolides (e.g., erythromycin, azithromycin), and cephalosporins (e.g., ceftriaxone).[919] These agents show excellent activity against *H. ducreyi* in vitro, while many strains are resistant to tetracyclines and SXT. Recommended treatment regimens for chancroid from the World Health Organization (WHO), the Centers for Disease Control and Prevention (CDC), and the United Kingdom Clinical Effectiveness Group (CEG) include erythromycin (500 mg, PO, for 7 days, tid or qid), azithromycin (1 g, PO, single dose), ceftriaxone (250 mg, IM, single dose), and ciprofloxacin (500 mg, PO, bid for 3 days).[900] Because of treatment failures in HIV-infected patients, there is some concern about the clinical efficacy of single-dose or short-course therapies (e.g., with IM ceftriaxone or PO azithromycin) in individuals with chancroid who are also immunodeficient.[1274] Symptomatic or asymptomatic sexual contacts of individuals diagnosed with chancroid should be treated if sexual contact occurred 10 days or less after clinical presentation of the index patient.

Genus *Aggregatibacter*

Taxonomy

In 2006, *H. aphrophilus, H. paraphrophilus*, and *H. segnis* were reclassified, along with *Actinobacillus actinomycetemcomitans*, into the genus *Aggregatibacter*.[956] *H. aphrophilus* and *H. paraphrophilus* are now recognized as the same species, *A. aphrophilus*; the V factor dependence of *H. paraphrophilus* is considered a variable characteristic of the single species (Image Plate 9-2F). *Aggregatibacter* species are classified in the family *Pasteurellaceae*.

Clinical Significance

Aggregatibacter aphrophilus. *A. aphrophilus* is indigenous to the oral cavity, where it is a minor component of the healthy periodontal microbiota. *A. aphrophilus*, along with *H. parainfluenzae*, is the species in this group that is most commonly associated with endocarditis.[10,327,613,666,1018] Most people who develop native valve endocarditis with this organism have some preexisting heart valve abnormalities such as aortic valve stenosis, but cases of endocarditis have been reported in those without preexisting cardiac abnormalites.[10,613,1018] *A. aphrophilus* may also be associated with endocarditis involving prosthetic valves.[1329] *A. aphrophilus* has been isolated from various head and neck infections (e.g., sinusitis, otitis media, epiglottitis, ventriculitis, epidural and brain abscesses, and meningitis) and pleuropulmonary infections (e.g., pneumonia, empyema, and lung abscess).[6,60,253,592,666,680,967,1273] Hematogenous dissemination of *A. aphrophilus* may also result in septic arthritis, vertebral osteomyelitis, sponydylodiscitis, cellulitis, endophthalmitis, and intra-abdominal infections.[296,613,700,1005,1371] Neutropenia,

malignancy, and cancer chemotherapy are predisposing factors for infections with these organisms. *A. aphrophilus* culturally resembles other fastidious gram-negative bacteria and are part of the "HACEK" group, which includes *Haemophilus* (H), *Aggregatibacter* (A), *Cardiobacterium* (C), *Eikenella* (E), and *Kingella* (K) species (Image Plate 9-2D).

Aggregatibacter segnis. *A. segnis* is found occasionally in dental plaque and the upper respiratory tract. Infections with *A. segnis* are rare and include periodontal infections, bacteremia endocarditis, cholecystitis, acute appendicitis, and pancreatic abscess.[89,192,203,762,934,1210] Further investigation of these fastidious organisms is

needed for a more complete appreciation of their pathogenic potential.

Aggregatibacter actinomycetemcomitans. *A. actinomycetemcomitans* is a part of the normal microbiota of the oral cavity, particularly in the gingival and supragingival crevices. Based on reactions of specific monoclonal antibodies with exposed, cell surface carbohydrate moieties of the cell wall lipopolysaccharide (LPS), this species can be divided into seven serotypes designated a through g.[1236] Serotypes a, b, and c are the most prevalent, comprising more than 80% of oral strains. A recent study of *A. actinomycetemcomitans* recovered from subgingival plaque samples from 161 patients with and without periodontal disease in the Los Angeles found that serotype c was the dominant serotype, comprising 50% of all strains, followed by serotypes a and b.[240] Serotypes d, e, and f were less frequently found or were not detected. A recent study from Brazilian patients also reported that serotypes c and a were the predominant serotypes.[1105] Some patients may be colonized with multiple serotypes. Although it has been suggested that certain serotypes (e.g., serotype b) may be associated with specific forms of periodontal disease, biotyping and rRNA gene probe studies have demonstrated significant phenotypic and genomic heterogeneity among strains belonging to the same serotype.[73] In a study of 311 strains from 189 periodontology patients, 216 stains were serologically typeable and 95 were nontypeable. Amplification of the serotype antigen-specific genes indicated that the nontypeable strains possessed serotype-specific gene sequences, but the genes were not expressed among the nonserotypeable strains.[677] All of these serotypes and lineages have been isolated from patients with periodontal disease, indicating that all have pathogenic potential.

A. actinomycetemcomitans is well recognized as a major cause of aggressive periodontal disease.[422,578] This organism is causally related to early-onset periodontitis and localized aggressive periodontal disease seen in older children and young adults, generally in the 12 to 26 year age group. This disease is characterized by rapid degeneration and destruction of the alveolar bone supporting the first permanent molars and incisors. Subgingival bone loss in these areas results in the development of deep gingival pockets that readily bleed with probing. Progression of the disease can result in bone destruction along the affected root surfaces with the involvement of adjacent teeth. This severe periodontitis may lead to acute periodontal abscesses and subsequent tooth loss. Periodontal disease associated with *A. actinomycetemcomitans* evokes both systemic and localized immune responses, and high titers of serum IgG are produced against *A. actinomycetemcomitans* serotype antigens, which are O-side chain oligosaccharides in the cell wall LPS. The LPS of the organism also induces localized gingival inflammation and allows the organism to establish itself in subgingival plaque. In addition to LPS, *A. actinomycetemcomitans* produces a potent leukotoxin and several other virulence factors that contribute to its role as a periodontal pathogen.

Certain strains of *A. actinomycetemcomitans* are more pathogenic because of the production of more virulence factors. For example, the JP2 clone of *A. actinomycetemcomitans* has a 530 base pair deletion in the promoter region of the leukotoxin operon that results in enhanced leukotoxin production and augmented virulence.[182,280,564,669] These factors act in concert to cause inflammation, localized immunosuppression, inhibition of phagocytic activity, and resorption of bone. Some of these factors stimulate production of serum and crevicular fluid antibodies that may help to limit the periodontal process. In addition to the described virulence factors, failure to stimulate humoral or cell-mediated responses against the organism and/or its products may be partially responsible for progression to severe, generalized periodontal disease. *A. actinomycetemcomitans* is also implicated in the pathogenesis of Papillon–Lefèvre syndrome, an inherited disease characterized by hyperkeratosis of the palms and soles and extensive periodontal destruction resulting in the loss of both primary and permanent teeth.

Epidemiologic studies indicate that periodontal disease associated with *A. actinomycetemcomitans* has racial and genetic components that predispose individuals to these severe oral infections caused by endogenous microorganisms. For example, studies on the geographic occurrence of the highly leukotoxic JP2 clone have demonstrated that colonization with this pathogen is largely restricted to those of African American descent and is absent, for the most part, in non-African populations from Northern Europe.[564,565] Epidemiologic investigations have distinguished two patterns of periodontal disease associated with *A. actinomycetemcomitans*. Localized aggressive periodontitis in northern European Caucasian populations is associated with non-JP2 clonal populations of *A. actinomycetemcomitans* circulating as opportunistic pathogens, while the JP2 clone is the principal cause of aggressive, juvenile-onset periodontal disease in young adults of North or West African descent.[566] Furthermore, individuals infected with the JP2 clone may have diminished responses to therapeutic interventions, which may include deep scaling and root planning, antimicrobial therapy, and surgery, if necessary.[307] Sporadic reports have documented colonization of Caucasians with the JP2 clone.[280]

The immune response to periodontal infection with *A. actinomycetemcomitans* may also play a role in the pathogenesis of disease. Patients with aggressive periodontitis produce abnormally high levels of prostaglandin E2, and the inflammatory cytokine tumor necrosis factor-alpha (TNF-α) in the crevicular fluids surrounding the teeth.[537] These factors are produced by local monocytes and macrophages in response to bacterial products. Cultured monocytes and macrophages from periodontitis patients produce three to six times the amount of these cytokines than similar cells from noninfected patients on exposure to *A. actinomycetemcomitans* LPS.[1176]

These inflammatory cytokines induce bone resorption by osteoclasts, leading to alveolar bone loss, and downregulation of neutrophil chemotaxis. The immune response to microbial antigens may help to limit the periodontal process and failure to stimulate humoral or cell-mediated responses against the organism, and/or its products may be partially responsible for progression to more severe, generalized periodontal disease.[1130]

A. actinomycetemcomitans is also associated with actinomycotic infections, endocarditis, bacteremia, wound infections, and dental infections. The name of the organisms is derived from its recognized "concomitant" isolation with *Actinomyces* species from abscesses and other infections. *A. actinomycetemcomitans* is a cause of subacute bacterial endocarditis.[1010,1043,1321,1342] Native valve endocarditis usually occurs in individuals with antecedent valvular damage because of congenital heart diseases (e.g., congenital aortic stenosis, bicuspid aortic valve disease, atrioventricular septal defect, mitral valve insufficiency due to rheumatic heart disease). Prosthetic mitral and aortic valve endocarditis have also been reported in individuals with porcine and mechanical valves and pacemakers. Localized complications have included pericarditis and paravalvular abscesses.[1353] Predisposing factors in the development of *A. actinomycetemcomitans* endocarditis include poor dentition or recent dental manipulations. *A. actinomycetemcomitans* endocarditis usually follows an indolent course. Fever, weight loss, chills, cough, and night sweats are common, along with a heart murmur. Hepatosplenomegaly and conjunctival or splinter hemorrhages are variably present. Complications include septic emboli, cerebral hemorrhage, coronary arteritis, vasculitis, congestive heart failure, valvular damage requiring prosthetic valve placement or replacement, pyogenic ventriculitis, and death.[666,789,1010,1182,1353]Other infections caused by *A. actinomycetemcomitans* result from contiguous spread of the organism from its habitat in the oral cavity or from hematogenous dissemination during bacteremia and endocarditis. Head, neck, and pleuropulmonary infections have included epidural and brain abscesses, osteomyelitis, cervical lymphadenitis, cellulitis, pneumonia, chest wall/subphrenic abscess, and lung abscess.[102,238,545,549,1006,1223,1321] Hematogenous dissemination of *A. actinomycetemcomitans* has resulted in osteomyelitis, spinal abscess, vertebral discitis, endophthalmitis, septic arthritis, and hepatic and intra-abdominal abscesses.[125,936,1182,1184,1228] Portals of entry for various types of infections have included oral lesions, prior pulmonary infections, skin abrasions, thoracotomy sites, and urinary tract instrumentation.

Cultural Characteristics and Identification of Aggregatibacter

Species

Colonies of *A. aphrophilus* are small after 24 hours' incubation; 48 to 72 hours' incubation is often required before colony morphology can be ascertained and sufficient growth is available for preliminary identification tests. On chocolate agar, colonies are 0.5 to 1 mm in diameter, convex, granular, and have a faint yellowish pigment. A distinct "grade school paste" odor may be detected. Some strains of *A. aphrophilus* require V factor; V-factor-requiring strains will grow on chocolate agar, but not on sheep blood agar. *A. aphrophilus* is catalase- and oxidase-negative, although weak or delayed positive oxidase reaction may be observed with some isolates. The negative catalase reaction is helpful in separating *A. aphrophilus* from *A. actinomycetemcomitans*, which is catalase-positive. Acid is produced from glucose, maltose, sucrose, lactose, and trehalose. The organism hydrolyzes ONPG and does not produce arginine dihydrolase, lysine or ornithine decarboxylase, indole, or urease. Phenotypic tests for identification of *Aggregatibacter* species are presented in Table 9-3 (Image Plate 9-2H and 9-3C).

TABLE 9-3 Phenotypic Characteristics for Identification of *Aggregatibacter aphrophilus*, *Aggregatibacter actinomycetemcomitans*, and *Aggregatibacter segnis*

[a] Only quantitative differences in the amount of acid produced from carbohydrates may discriminate *A. segnis* phenotypically from stains of *H. parainfluenzae* biotype V (negative for indole, urease, and ODC).
[b] A few strains may produce weak or delayed reactions.
[c] Rare strains may be maltose-negative.
[d] Most strains are mannitol-positive.
+, positive reaction; –, negative reaction; V, variable reaction; +[w], weak positive; HEM SBA, hemolysis on sheep blood agar; OX, oxidase; CAT, catalase; NO_3 RED, reduction of nitrate to nitrite; IND, indole; URE, urease; ODC, ornithine decarboxylase; ONPG, *o*-nitrophenyl-β-D-galactopyranoside; GLU, glucose; MAL, maltose; FRU, fructose; SUC, sucrose; LAC, lactose; XYL, xylose; MNTL, mannitol; MANN, mannose; GAL, galactose; TREH, trehalose; RAFF, raffinose.

A. actinomycetemcomitans grows slowly on chocolate and blood agars, with visible colonies appearing after 48 to 72 hours (Image Plate 9-3B). Colonies are small, smooth, translucent, nonhemolytic, and have slightly irregular edges. Fresh clinical isolates are adherent to the agar and are difficult to emulsify. With prolonged incubation (i.e., 5 to 7 days), colonies may develop a central density that appears as a four- or six-pointed star. This characteristic is lost on repeated subculture, and the colonies become less adherent. As with *A. aphrophilus*, growth in broth is scant and adherent to the sides of the tube. On Gram's stain, the organisms appear as pale-staining, gram-negative coccobacilli (Image Plate 9-3A). Longer cells may be noted with repeated subcultures. Characteristics for identification of *A. actinomycetemcomitans* include lack of growth on MacConkey and other enteric agars, and positive reactions for catalase production and nitrate reduction. The organism is usually oxidase-negative, although occasional strains may be weakly positive, urease-negative, does not produce indole, and does not require X or V factors. Lysine and ornithine decarboxylase and arginine dihydrolase reactions are negative (Image Plate 9-2G). Most strains strongly ferment glucose, fructose, and mannose; acid production from maltose, mannitol, and xylose varies. *A. actinomycetemcomitans* can be differentiated from *A. aphrophilus* in that the former is catalase-positive, ONPG-negative, and acid is not produced from lactose, sucrose or trehalose.

A. segnis grows on chocolate agar but not on sheep blood agar because of its requirement for V factor. This organism is ALA-porphyrin test–positive and is negative for indole, urease, and ornithine decarboxylase production. In carbohydrate test, acid production from glucose, sucrose, and fructose is weak or delayed, and no acid is produced from lactose, ribose, xylose, or mannose.

Antimicrobial Susceptibility of Aggregatibacter *Species*

In 2010, the CLSI published an approved guideline for antimicrobial susceptibility testing of the fastidious members of the HACEK group.[285] This method uses cation-adjusted Müeller–Hinton broth supplemented with 2.5% to 5% lysed horse blood. The inoculum is a dilution of a direct colony suspension of the organism that is equivalent to a 0.5 McFarland turbidity standard. End points are read after 24 to 48 hours' incubation at 35°C in a 5% CO_2 atmosphere. Agents suggested by CLSI for primary testing of these organisms include ampicillin, amoxicillin clavulanate, ceftriaxone or cefotaxime, imipenem, ciprofloxacin or levofloxacin, and SXT. Breakpoints are available for these agents and several others (e.g., meropenem, azithromycin,

clarithromycin, tetracycline, and rifampin) No intermediate or resistant categories are defined for ceftriaxone and cefotaxime due to the absence or rare occurrence of strains belonging to these "nonsusceptible" categories.

Strains of *A. aphrophilus* and *A. actinomycetemcomitans* are susceptible to third-generation cephalosporins, fluoroquinolones, tetracyclines, and aminoglycosides.[738] Agents such as ceftriaxone, cefotaxime, and ciprofloxacin have been effective in patients with serious central nervous system (CNS) infections, brain abscesses, and endocarditis. Although most strains are susceptible to penicillin and ampicillin, resistant strains, including rare β-lactamase-producing strains, have been reported.[659] The third- and fourth-generation cephalosporins are considered the drugs of choice for empiric therapy of serious infections such as endocarditis. *In vitro* studies indicate that combinations of antimicrobials agents for the treatment of *A. actinomycetemcomitans* endocarditis may be synergistic, additive, or antagonistic; so efficacy of combination therapy cannot be predicted and must be determined for individual strains by either an agar dilution technique or Etest.

Treatment of *A. actinomycetemcomitans*-associated periodontal disease involves subgingival debridement, scaling, root planing, and antimicrobial therapy directed against periodontitis-associated bacteria. Successful treatment partially depends on the eradication and suppression of *A. actinomycetemcomitans* and other bacteria from deep periodontal pockets. For advanced periodontal disease, systemic metronidazole or doxycycline, along with mechanical debridement, is usually prescribed.[798] Of course, the administration of systemic tetracyclines is contraindicated in children; so nontetracycline regimens are used in such instances. A formulation of extended-release doxycycline is also available for use as a topical agents, and a powder composed of microspheres containing minocycline has also been approved by the FDA for the treatment of established periodontitis.[958,1080] This compound releases controlled amounts of antibiotic beneath the gums and is used along with root planing and scaling for the treatment of refractory periodontal disease. Although most strains of *A. actinomycetemcomitans* have remained susceptible to tetracyclines, plasmid-associated, *tetB*-mediated tetracycline resistance in *A. actinomycetemcomitans* has been reported. Since most strains of *A. actinomycetemcomitans* are resistant to metronidazole in vitro, the success of this agent may be due to the broad activity of metronidazole against co-infecting anaerobic periodontal pathogens (e.g., *Prevotella species, Porphyromonas* species, *Tannerella forsythensis*).

Cardiobacterium Species

Taxonomy

Cardiobacterium hominis (formerly CDC group IID), the first member of the genus *Cardiobacterium*, was first described in 1964. This organism is classified in the family *Cardiobacteriaceae,* which also includes the genera *Suttonella* and *Dichelobacter*.[353] In 2004, a second *Cardiobacterium* species, *C. valvarum*, was described.[551] The genus *Suttonella* was created to accommodate *Kingella indologenes*, an organism that was shown to be more closely related to *C. hominis* than to other *Kingella* species or other members of the family *Neisseriaceae*, where *Kingella* species are classified.[353] *S. indologenes* is now classified with *Cardiobacterium* in the family *Cardiobacteriaceae*. A second *Suttonella* species, *S. ornithocola,* was described in 2005.[434] This organism was isolated from necropsy specimens of congested lung tissues of birds belonging to the tit families during an investigation of an unexplained die-off of specific avian species in the United Kingdom. The family *Cardiobacteriaceae* belongs to the order *Cardiobacteriales* in the γ-subdivision of the *Proteobacteria*.

492

Clinical Significance

C. hominis is an organism of low virulence and has the unique characteristic of causing endocarditis almost exclusively.[829,1315] The organism is a part of the normal microbiota of the respiratory tract, but, because of its slow growth, it is rarely noted in respiratory tract specimens. *C. hominis* enters the bloodstream and usually infects previously diseased or damaged heart valves (e.g., rheumatic heart disease, ventricular septal defects, aortitis).[781,829] *C. hominis* endocarditis may also develop in individuals with no evidence of previous heart disease.[244,477] About 20% of reported *C. hominis* infections have involved various prosthetic cardiac valves, including aortic homograft tissue valves, porcine xenograft aortic/mitral valves, mechanical aortic/mitral valves, and pacemaker leads.[50,319,829,1185] Patients are usually middle aged to elderly and have poor dentition and/or a history of recent dental procedures. The infection follows a subacute course, with insidious onset, low-grade fevers, and vague symptoms that may linger for several months before a diagnosis is established. *C. hominis* tends to form large, friable vegetations on the heart valves; so the most serious complications include septic embolization, mycotic aneurysms, and congestive heart failure.[312,914]Severe, sepsis-associated thrombocytopenia may be observed in some patients.[66] Isolation of *C. hominis* from specimens other than blood cultures is rare. Francioli and colleagues diagnosed cardiobacterial meningitis in a patient as a complication of endocarditis, and Rechtman and Nadler reported the recovery of *C. hominis* along with *Clostridium bifermentans* from an abdominal abscess in a diabetic

man with adenocarcinoma of the kidney and caecum.[445,1065] In 1998, Nurnberger et al. described a case of pacemaker lead infection and vertebral osteomyelitis due to *C. hominis*.[959] *C. hominis* has also been isolated from peritoneal fluid of a patient on continuous ambulatory peritoneal dialysis and no evidence of endocarditis and from pericardial fluid of a 10-year-old girl.[124,742]

C. valvarum was first described as the cause of bacteremia and endocarditis in a 37-year-old man with congenital bicuspid aortic valve disease that was complicated by a ruptured mycotic aneurysm.[551] The description of this single isolate prompted a search for additional isolates, and four additional strains were found in the Culture Collection of the University of Goteborg in Sweden.[550] These isolates were oral strains recovered from subgingival pockets and a plaque specimen. The 16S rRNA gene sequences of these isolates exhibited 99.3% to 99.6% sequence homology with the original *C. valvarum* isolate. Whole-cell protein electrophoretic profiles, nutritional and growth requirements, and cellular and colonial morphology were also similar. Since the first description of this organism in 2005, four additional cases of native valve endocarditis[154,241,603,1294] and two reports of prosthetic valve endocarditis due to *C. valvarum* have been reported in the literature.[480,594] A fourth report dealt with identification of the organism and contained no patient information.[1029] Among the four patients with native valve endocarditis, three had tricuspid or bicuspid aortic valve involvement and one had mitral valve involvement. Large vegetations and destruction of heart tissue were seen in all cases, and three of the four patients required placement of prosthetic valves. Prosthetic valve endocarditis was reported in a 71-year-old man with a bioprosthetic valve placed 2 years prior because of native aortic valve stenosis and in a 28-year-old woman with a right ventricle-to-pulmonary artery conduit and a porcine pulmonic valve.[480,594] Although replacement of the conduit and prosthetic valve were planned after 6 weeks of chemotherapy in the latter patient, the 71-year-old male developed septic emboli that were detected in the cerebellum by CT and MRI, and expired from septic shock resulting from severe cardiac deterioration. In other instances, *C. valvarum* has also been isolated from subgingival pockets and dental plaque samples.[551]

S. indologenes has been isolated from human corneal infection and was first reported as a cause of prosthetic valve endocarditis in 1987.[646] In 2010, Yang and colleagues reported *S. indologenes* prosthetic valve endocarditis in a 28-year-old Cambodian man with complex congenital heart disease that was complicated by septic pulmonary emboli.[1396] In 2011, Ozcan and colleagues described a fatal case of *S. indologenes* prosthetic valve endocarditis in a 25-year-old man that was complicated by splenic infarction and fatal intracranial hemorrhage.[992]

Cultural Characteristics and Identification

C. hominis and *C. valvarum* are principally isolated from blood cultures, grow slowly, and produce no visible change in the blood culture medium (i.e., turbidity, hemolysis). Gram's stains of positive blood bottles may not reveal the organism; low-speed centrifugation of an aliquot of the medium to remove red blood cells with subsequent high-speed centrifugation to pellet small numbers of organisms may aid in their visualization. On Gram's stains, both organisms may appear gram-variable, with a tendency for the cells to retain the crystal violet dye at the poles. Individual cells may appear swollen at one or both ends, resulting in teardrop-, dumbbell-, and lollipop-shaped organisms. On Gram's stains from blood cultures, cells may aggregate in rosette-like clusters or line up in parallel, picket fence arrangements (Image Plate 9-3D). Cell morphology is influenced by the type of culture medium used; in media containing yeast extract, cells appear as uniform, gram-negative bacilli with rounded ends.

C. hominis and *C. valvarum* grow as very small, glistening, opaque colonies on enriched blood or chocolate agar generally after 48 to 72 hours at 35°C in 5% to 7% CO_2 (Image Plate 9-3E). *C. valvarum* grows more slowly than *C. hominis,* and some strains of both species may show pitting of the agar that is more evident on chocolate agar than on sheep blood agar. Neither species is able to grow on MacConkey agar or other enteric selective or differential agars. Both *C. hominis* and *C. valvarum* are oxidase-positive, catalase-negative, nitrate-negative, urease-negative, and esculin hydrolysis-negative. *C. hominis* is indole-positive, but this may not be noted with the "spot indole" (cinnamaldehyde) reagent, since very small amounts of indole are produced by most strains. *C. valvarum* isolates from reports of patients with endocarditis have been strongly indole-positive (even with the spot indole reagent), while oral strains have been indole-negative.[550] Indole production can best be detected in heart infusion or tryptone broth. These media are heavily inoculated (with a swab) and incubated for 48 hours. Extraction with xylene and use of Ehrlich's reagent rather than Kovac's reagent allow

493

detection of small amounts of indole. Both *C. hominis* and *C. valvarum* produce H_2S by the lead acetate strip method. Phenotypic characteristics for the identification of *Cardiobacterium* species are presented in Table 9-4.

C. hominis produces acid fermentatively from glucose, fructose, sucrose, mannose, and sorbitol; acid production from maltose and mannitol is variable, with most strains producing positive reactions. Like *C. hominis*, *C. valvarum* fermentatively produces acid from glucose, fructose, sorbitol, and mannose, but, unlike *C. hominis*, does not produce acid from maltose, sucrose, or mannitol. Neither species is able to ferment

lactose, galactose, raffinose, or xylose. *S. indologenes* produces acid from glucose, maltose, and sucrose, but not from lactose, and is distinguished by its ability to produce indole. This characteristic should be determined in tryptone broth with xylene extraction and addition of Ehrlich's indole reagent. *S. indologenes* may be differentiated from *C. hominis*, which closely resembles, by appearance on Gram's stain, positive alkaline phosphatase activity and failure to produce acid from mannitol and sorbitol. Phenotypically, *C. hominis* is very similar to *S. indologenes*. *C. hominis* and *C. valvarum* can be differentiated from *S. indologenes*, *E. corrodens*, and *Kingella* species by cellular fatty acid analysis. As with other agents of bacterial endocarditis, molecular methods such as broad-range PCR and DNA sequencing have been used successfully for detection and identification of *C. hominis* and *C. valvarum* directly in clinical specimens.[477,914,946,1029]

Antimicrobial Susceptibility

C. hominis can be tested for antimicrobial susceptibility using the methods in the CLSI-approved standard (see Chapter 17).[286]

494

Despite the availability of these methods, antimicrobial susceptibility testing of *C. hominis* and *C. valvarum* is difficult because of their fastidious requirements and slow growth rates. From the literature, strains of *C. hominis* are susceptible to most antimicrobial agents, including penicillin, ampicillin, cefazolin, third-generation cephalosporins, carbapenems, fluoroquinolones, aminoglycosides, and tetracycline; susceptibility to the macrolides and aminoglycosides is variable.[738] The currently recommended therapy for native valve endocarditis due to *C. hominis* is ceftriaxone, ampicillin sulbactam, or ciprofloxacin for at least 4 weeks.[81] Patients with native valve endocarditis due to *C. hominis* may be successfully treated with antibiotics alone in some instances, but some have required partial valve resection or valve replacement

because of hemodynamic compromise, embolic phenomena, or progressive cardiac failure. The same agents may be used for prosthetic valve endocarditis, but therapy may need to be extended beyond 6 weeks' duration. Although reported, β-lactamase-producing, penicillin-resistant strains of *C. hominis* are rarely encountered.[808] Strains of *C. valvarum* have been tested for antimicrobial susceptibility by Etest methods. Both blood and oral isolates of *C. valvarum* are susceptible to penicillin, ampicillin, ticarcillin/clavulanate, cephalosporins of all generations, fluoroquinolones, carbapenems, tetracyclines, and SXT.[550,551] Patients who have developed *C. valvarum* endocarditis also had similar complications, and survivors have also required surgical intervention and valve replacement.

Eikenella corrodens

Taxonomy

Originally, the genus *Eikenella* (CDC group HB-1) defined isolates considered as facultative strains of *Bacteroides corrodens,* an anaerobic gram-negative rod. Based on genotypic and phylogenetic studies, the species epithet of *B. corrodens* was changed to *Bacteroides ureolyticus* (urease-positive) and the facultative isolates were placed in genus *Eikenella* as the sole species, *E. corrodens*. Based on 16S rRNA sequencing and rRNA–DNA hybridization, *E. corrodens* is related to *Neisseria* species and is in the family *Neisseriaceae* in the β-subgroup of the *Proteobacteria*.

Clinical Significance

E. corrodens is a part of the normal microbiota of the mouth and upper respiratory tract. In the oral cavity, this organism plays a role in some types of periodontal disease. A high prevalence of *E. corrodens* is found in subgingival plaque samples from patients with periodontal disease, whereas prevalence is low in individuals with no periodontal disease.[1227] Among those with periodontal disease, the highest prevalence of *E. corrodens* is found in people under 20 years of age with progressive periodontitis, followed by those with postjuvenile periodontitis, prepubertal periodontitis, rapidly progressive periodontitis, and adult periodontitis. If left untreated, severe periodontitis may become refractory to treatment.[1227] In healthy persons, the prevalence of the organism in deep gingival specimens decreases with advancing age. *E. corrodens* is part of the mixed bacterial microbiota recovered from periodontal and gingival specimens, periapical abscesses, and root canal infections.

E. corrodens has been isolated from a wide variety of infections and clinical specimens.[1011,1181] This organism has been isolated from various types of head and neck infections, including ocular infections (i.e., periorbital cellulitis, corneal ulcers,

endophthalmitis, and lacrimal abscesses), mastoid and submandibular abscesses, and thyroid abscesses.[74,251,577,585,662,663,784,1139,1275,1403] Pleuropulmonary infections involving *E. corrodens* include lung abscesses and empyemas. These occur in settings of immunosuppression, propensity for pulmonary aspiration, and underlying lung disease.[611,704,1366] By extension from periodontal, middle ear, or sinus infections, *E. corrodens* can gain access to the CNS, resulting in meningitis, brain or paraspinal abscesses, subdural empyemas, and osteomyelitis.[53,70,685] Bacteremia and endocarditis usually occur in immunocompromised hosts, intravenous drug abusers, and individuals with previous valvular damage and a history of recent dental work or oral surgery.[572,826,974]Endocarditis has also been diagnosed in healthy people with no recognized risk factors.[1328] Prosthetic valve endocarditis and infections of indwelling vascular prostheses with *E. corrodens* have been reported. *E. corrodens* bacteremia with or without endocarditis may also be diagnosed in patients with rheumatoid arthritis and hematologic malignancies.[409] *E. corrodens* is a recognized cause of subcutaneous abscesses, soft tissue cellulitis, and bacteremia in intravenous drug users.[47,501,974] These infections result from the use of saliva for cleansing of the skin or dissolving the narcotics in saline prior to drug injection. *E. corrodens* can cause cellulitis and osteomyelitis of the hand resulting from "clenched fist injuries" (i.e., fist fights), chronic nail-biting, and human bites.[150,559,1237] Traumatic implantation of the organism into subcutaneous tissue may enable extension of infection into bones and joints, resulting in osteomyelitis and/or septic arthritis.[150,233]Cultures obtained from these infections often grow *E. corrodens* along with other facultative organisms (α- and β-hemolytic streptococci [including the *Streptococcus anginosus/constellatus/intermedius* group], *Staphylococcus aureus*, coagulase-negative staphylococci, enteric gram-negative bacilli) and oral obligate anaerobes. Osteomyelitis of the spine caused by *E. corrodens* has been reported as a result of hematogenous dissemination from an infected site (e.g., severe periodontal disease) or as a complication of spine surgery.[41,775,1055,1267] In 2007, an unusual case of *E. corrodens* cervical spine epidural and retropharyngeal abscess was diagnosed in a 72-year-old man who had swallowed a fish bone.[649] The bone had transversed the esophagus and had lodged in the C3 to C4 intervertebral disk space. Additionally, *E. corrodens* osteomyelitis of the jaw was reported as a complication of radiation therapy for a squamous cell carcinoma of the tonsils.[941] *E. corrodens* may also be isolated in pure or mixed culture from various types of wound infections and abscesses, including necrotizing fasciitis.[889,990,1110,1418] Bacteremia from localized wound infections may result in hematogenous infections and abscesses at many sites, including joint spaces (i.e., septic arthritis), the vertebrae (i.e., discitis, paraspinal abscess), and the female genital tract (i.e., chorioamnionitis).[397,1055] *E. corrodens* can survive in the

gastrointestinal tract and may be isolated

495

from abdominal, splenic, hepatic, and pancreatic abscesses and peritoneal infections along with facultative and anaerobic intestinal microbiota.[67,662,1061,1221] *E. corrodens* has also been recovered from gynecological infections, including chorioamnionitis, amniotic fluid infection, endometritis, vulvar abscess, and cervicitis associated with in situ colonization of intrauterine devices.[39,476,637,730,994] In 2007, an *E. corrodens* urinary tract infection was reported in an 83-year-old women with recurrent anal prolapse and chronic lymphocytic leukemia.[602]

Cultural Characteristics and Identification

E. corrodens grows on blood and chocolate agar, but does not grow on MacConkey agar (Image Plate 9-3G). Colonies are small (0.5 to 1.0 mm) after 48 hours. About 50% of isolates may "pit" the agar during growth; both pitting and nonpitting variants may be observed in the same culture. A pale yellow pigment (observed best on a white swab swept through growth on a chocolate agar plate) is usually produced, and most strains have an odor of sodium hypochlorite (i.e., "Clorox" bleach or a heavily chlorinated swimming pool). On Gram's stain, the organisms appear as regular, slender, gram-negative bacilli or coccobacilli with rounded ends (Image Plate 9-3F).

Biochemical characteristics of pitting and nonpitting *E. corrodens* strains are fairly uniform. *E. corrodens* is oxidase-positive and catalase-negative, although rare strains may be weakly catalase-positive. The organism reduces nitrate to nitrite and does not require X or V factors, although hemin is necessary for aerobic growth. Nonpitting isolates may be mistaken for *Haemophilus* species and, when tested with X and V factor disks, display growth around the X but not the V disk. Indole and urease are not produced, and most strains are positive for lysine decarboxylase and ornithine decarboxylase (Image Plate 9-3H). Unlike the other HACEK organisms, *E. corrodens* is asaccharolytic. Kit systems that address fastidious gram-negative organisms are able to correctly identify *E. corrodens*. *E. corrodens*-specific DNA probes, as well as probes for other periodontal pathogens, have been designed by analysis of 16S rRNA, identification of unique nucleotide sequences, and chemical synthesis of probe molecules that are complementary to these species-specific sequences.[1094,1280] Phenotypic characteristics for identification of *E. corrodens* are shown in Table 9-4.

Antimicrobial Susceptibility

Antimicrobial susceptibility testing of *E. corrodens* can be performed using the CLSI-approved standard for susceptibility testing of fastidious bacteria (see Chapter 17).[286]

E. corrodens strains are susceptible to ampicillin, amoxicillin, second- and third-generation cephalosporins, tetracyclines, and fluoroquinolones, and azithromycin and are resistant to the penicillinase-resistant penicillins, clindamycin, vancomycin, erythromycin, metronidazole, and aminoglycosides.[814,883] Penicillin susceptibility varies from strain to strain. Most isolates are variably susceptible to the first-generation cephalosporins, with cefazolin being the most active. *E. corrodens* is susceptible to cefoxitin, ceftriaxone, cefepime, ciprofloxacin, and carbapenems.[738,1181] Rare β-lactamase-positive strains have been reported.[744]

Kingella Species

Taxonomy

Members of the genus *Kingella* are classified in the family *Neisseriaceae* in the γ-subgroup of the *Proteobacteria* and currently include four species: *K. kingae*, *K. denitrificans*, *K. oralis*, and *K. potus*. The former species *K. indologenes* was demonstrated to be more closely related to *Cardiobacterium* species than to the other *Kingella* species; so this organism was renamed *Suttonella indologenes* and transferred to the family *Cardiobacteriaceae* in 1990.[353] *K. kingae*, the type species of the genus, was formerly a member of the genus *Moraxella,* and *K. denitrificans* was formerly called CDC group "TM-1." In 1993, Dewhirst and colleagues described a new *Kingella* species that was recovered from human dental plaque of a patient with adult periodontitis.[352] This new species was named *Kingella oralis*. This organism constitutes 0.4% of the total microbiota in dental plaque from periodontally healthy individuals and about 4.6% of the microbiota in dental plaque from adult and juvenile periodontitis patients.[239] The fourth *Kingella* species, *Kingella potus*, was isolated in 2005 from an infected wound of a zookeeper who, 3 days earlier, had sustained the bite of a kinkajou (*Potus potus*).[766]

Clinical Significance

Although part of the normal microbiota of the upper respiratory and genitourinary tracts of humans, *K. kingae* is increasingly being recognized as an important human pathogen.[373,1390] Since its initial description, *K. kingae* was considered to be a rare cause of infection in patients with endocarditis. However, during the last 10 to 20 years, *K. kingae* has emerged as a significant pathogen in pediatric patients, causing primarily bacteremia and skeletal infections.[1378] This organism colonizes the upper respiratory tract of infants after about 6 months of age, and the rate of colonization increases to about 10% to 12% between 6 months and 2 years of age. After this time,

colonization rates begin to decline. The prevalence of the organism in the respiratory tract is highest among children aged 6 months to 4 years, which parallels the ages having the highest attack rates for invasive disease.[1385] A large study performed in Israel found that invasive *K. kingae* disease occurred most frequently in previously healthy children during the first 2 years of life.[374] Studies in day care center populations have demonstrated that *K. kingae* can be transmitted from child to child by the respiratory route.[699,1199,1383] A study performed at a day care center over an 11-month period found that, among 48 attendees, about 28% carried *K. kingae* in the upper respiratory tract at any one time and that 73% of these children had at least one positive pharyngeal culture over the study period.[1382] Molecular analysis of respiratory tract isolates of *K. kingae* recovered from a large cohort of carriers showed geographic clustering of isolates with identical genotypes, indicating spread of the organism between siblings, playmates, and schoolmates.[1392] This study also demonstrated that invasive strains of *K. kingae* were maintained within a community over several years by respiratory carriage and transmission among close contacts. The portal of entry for the organism into the bloodstream is likely via breaches in the oropharyngeal mucosa.

496

Bone and joint infections are the most common clinical manifestations of *K. kingae* infection in children.[224,245,264,769] These infections present as bacteremia, septic arthritis, osteomyelitis, discitis, tenosynovitis, and dactylitis.[126,811,1168] With the availability of effective vaccines against *H. influenzae* type b, *K. kingae* has replaced *H. influenzae* as the most common gram-negative bacterium causing osteoarticular infections in children less than 3 years of age.[912] Most infants with systemic *K. kingae* infections present with low-grade fevers; viral upper respiratory tract infections and stomatitis are also frequently present.[33] In most cases, *K. kingae* septic arthritis is an acute infection, with patients usually presenting within 3 days of the appearance of signs and symptoms. These children are usually febrile, and the involved joints are swollen, are tender, and display decreased ranges of motion. Blood cultures from these patients are frequently negative. *K. kingae* septic arthritis is usually monoarthritic, with the most frequently involved joints being the knee, hip, and ankle.[373] Osteomyelitis due to *K. kingae* is usually an indolent infection that follows a subacute course, with patients usually presenting 7 to 10 days after the appearance of symptoms. *K. kingae* osteomyelitis usually affects the femur, other long bones, the tibia, ulna, radius, and calcaneus bones.[373] Patients with osteomyelitis of the long bones usually are unable to bear weight on the affected limb, and there is local tenderness over the involved bone. Hematogenous seeding of the intervertebral disk spaces leads to spondylitis and

intervertebral discitis.[126] Disk space infections may involve the lumbar, thoracic, lumbosacral, or thoracolumbar spaces. Pediatric osteoarticular infections of the lower sternum and the junction between the manubrium and the xyphoid process have also been described.[811] Children with invasive *K. kingae* infections often have significant underlying conditions, such as acute lymphocytic leukemia or congenital heart disease. Although rare, bone and joint infections due to *K. kingae*, including intervertebral discitis and septic arthritis, have also been diagnosed in adults.[395]

K. kingae is also a rare cause of bacteremia and endocarditis.[373,374] *K. kingae* endocarditis primarily occurs in persons with underlying heart disease (e.g., rheumatic heart disease, cardiac malformations) or in those with cardiac prostheses. However, endocarditis in individuals with no previous heart disease has been reported.[158,373,1114,1168,1409] Unlike bone and joint infections, *K kingae* endocarditis occurs more frequently in adults and school-age children.[1378] Complications of *K. kingae* endocarditis occur commonly and include pericarditis, paravalvular abscess, pericardial abscess, embolic phenomena, mycotic aneurysms, cerebral and pulmonary infarcts, septic shock, and congestive heart failure.[719,855] *K. kingae* endocarditis with meningitis has been reported in a woman with systemic lupus erythematosis.[1360] Patients may have poor oral hygiene, pharyngitis, or mucosal ulcerations due to treatment for other conditions (e.g., radiation therapy and chemotherapy). *K. kingae* bacteremia without endocarditis has been reported in immunocompetent adults following dental manipulations. Additional complications of bacteremia and bone infections include meningitis, hematogenous orbital cellulitis and endophthalmitis, soft tissue infection, and corneal abscess.[199,300,1068,1104] The clinical presentation of *K. kingae* bacteremia may mimic systemic neisserial infections (i.e., meningococcemia or disseminated gonococcal infection).[1262] *K. kingae* was also reported as a cause of corneal ulcer in an 11-month-old child, urinary tract infection in a 45-year-old woman with dysuria and postmenopausal bleeding, and peritonitis in a 55-year-old man with advanced hepatic cirrhosis, who performed a paracentesis procedure on himself, resulting in peritoneal infection.[144,903,1059] The other *Kingella* species are rarely isolated from infectious processes. Although *K. denitrificans* has been cultured from the upper respiratory and genitourinary tracts as part of the normal microbiota, it has also been documented as a cause of septicemia and native/prosthetic valve endocarditis.[563] *K. denitrificans* has also been recovered from empyema fluid of a patient with bronchogenic carcinoma, from bone marrow of a patient with AIDS, from the amniotic fluid of a young woman with chorioamnionitis, and from a corneal ulcer.[707,818,893,901] To date, *K. oralis* has not been associated with infections. *K. potus* has only been isolated from the previously mentioned kinkajou bite in a human.[766]

Cultural Characteristics and Identification

Kingella species are plump gram-negative bacilli or coccobacilli that sometimes occur in pairs or short chains. They are oxidase-positive and, unlike *Neisseria* and *Moraxella* species, are catalase-negative. All species grow on chocolate and blood agars and do not grow on MacConkey agar or other enteric media (Image Plate 9-4A and 9-4B). All *Kingella* species and *S. indologenes* are oxidase-positive and catalase-negative; *S. ornithocola* is positive for both oxidase and catalase. All *Kingella* and *Suttonella* species are negative for arginine dihydrolase, lysine and ornithine decarboxylases, urease, esculin hydrolysis, and ONPG hydrolysis. The phenotypic characteristics that are useful for identification of *Kingella* and *Suttonella* species are shown in Table 9-4 (Image Plate 9-4C).

K. kingae is β-hemolytic on sheep blood agar; the hemolytic reaction is "soft," resembling that of group B streptococci, and may only be noted in areas of confluent growth or after the removal of the colony from the agar surface. On prolonged incubation, some strains of *K. kingae* and *K. denitrificans* may "pit" the agar like *E. corrodens*. *K. kingae* produces acid only from glucose and maltose. *K. denitrificans* produces acid only from glucose in supplemented media, rapid carbohydrate degradation tests, and various kit systems. *K. denitrificans* is also prolyl-aminopeptidase-positive, and is able to grow on Thayer-Martin agar. Because of these characteristics, *K. denitrificans* may be misidentified as *N. gonorrhoeae,* particularly in specimens from the oropharyngeal and genitourinary tracts. This organism, unlike the other species in the genus, reduces nitrate to nitrite, and most strains will also reduce nitrite to nitrogen gas on prolonged incubation. *K. oralis* produces acid from glucose only, but may be differentiated from *K. denitrificans* by its failure to reduce nitrate and nitrite and the absence of prolyl-aminopeptidase activity. Unlike other *Kingella* species, *K. potus* is asaccharolytic and DNase-positive. In addition, the colonies of *K. potus* are yellow-pigmented on blood agar. *E. corrodens* may be differentiated from both

497

Cardiobacterium and *Kingella* species by Gram's stain morphology, failure to ferment carbohydrates, and positive ornithine and lysine decarboxylase reactions.

Although identification of these organisms is straightforward once they are isolated, the initial recovery of *K. kingae* from clinical specimens, particularly joint fluid specimens, may present some difficulties. Direct inoculation of plates with fluid from joint aspirates is much less sensitive for recovering *K. kingae* than inoculation of blood culture media. Among 100 specimens cultured by both methods, 34 grew significant organisms; 10 of the 11 *K. kingae* isolates that were obtained grew only in the BACTEC blood culture medium and were not recovered on direct plating.[1381] The

discrepancy in the isolation rate of *K. kingae* was not observed for other organisms causing bone and joint infections. *K. kingae* has also been detected in blood and synovial fluids using the BacT/Alert system (bioMérieux, Inc.), BACTEC 660NR, BACTEC 9240, and the pediatric Isolator 1.5 microbial tube (Wampole Laboratories, Cranbury, NJ).[127,778,1391] Other recent studies have confirmed that the routine use of blood culture bottles significantly enhances recovery of *K. kingae* from joint fluid specimens.[912,1380] Improved recovery of *K. kingae* from joint fluid specimens inoculated into blood culture media may be due to the dilution of inhibitory factors in synovial fluid by the culture medium (e.g., broth-based blood culture systems) or by removal of the organisms from the synovial fluid milieu (e.g., Isolator cultures). In any case, inoculation of osteoarticular fluids into blood culture bottles is now the standard for processing of these specimens in the clinical laboratory. Molecular methods (e.g., real-time PCR) have also been developed and used for the direct detection of *K. kingae* in joint and pericardial fluid.[224,245,264,622,855,1298]

Antimicrobial Susceptibility

K. kingae strains are susceptible to penicillin, ampicillin, cephalosporins of all generations, aminoglycosides, SXT, and fluoroquinolones. Some strains may be relatively resistant to erythromycin, and most are resistant to clindamycin and vancomycin.[127,738]Isolates of *K. denitrificans* have antimicrobial susceptibilities similar to *K. kingae*; growth of *K. denitrificans* on Thayer-Martin agar indicates that they are resistant to vancomycin and colistin. *K. kingae* isolates that produce β-lactamase have been described that were resistant to ampicillin, cefazolin, and ticarcillin, but susceptible to combination drugs containing β-lactamase inhibitors (clavulanate and sulbactam).[1212] Among five patients with *K. kingae* infection reported from Iceland in 1997, three of the five isolates produced β-lactamase enzymes and were resistant to penicillin and ampicillin.[127] Susceptibility of *Kingella* species can be determined using the broth dilution method described in the CLSI document on susceptibility testing of fastidious bacteria.[286]

On antimicrobial susceptibility testing, the single *K. potus* isolate from the kinkajou bite wound was susceptible to penicillin, ampicillin, ceftriaxone, cefotaxime, ciprofloxacin, imipenem, and meropenem, but was resistant to erythromycin, clindamycin, tetracycline, gentamicin, and trimethoprim. The patient responded to treatment with ciprofloxacin and metronidazole.

Capnocytophaga Species

Taxonomy

Capnocytophaga species were originally described by Prevot in 1956 at the Pasteur Institute and were studied further at the CDC during the early 1960s. These facultative, capnophilic, fusiform gram-negative bacilli had been isolated from the human oropharynx and clinical specimens and were given the name CDC group DF-1. DF was an abbreviation for "dysgonic fermenter," referring to the poor fermentative capabilities of these organisms in medium not supplemented with serum. Researchers from the University of Massachusetts and Boston's Forsyth Dental Center published a series of articles on these organisms and addressed their possible role in human periodontal disease. These organisms were named *Capnocytophaga* species, reflecting their "consumption" or requirement for CO_2 for growth.[768] The type species was named *Capnocytophaga ochracea,* and related isolates from the human oropharynx were named *Capnocytophaga sputigena* and *Capnocytophaga gingivalis*. In 1994, two new human *Capnocytophaga* species—*Capnocytophaga granulosa* and *Capnocytophaga haemolytica*—were identified in human dental plaque specimens, and, in 2008, two additional species—*Capnocytophaga leadbetteri* and *Capnocytophaga* genospecies AHN8471—were described among 62 oral isolates from children.[448,1394]

CDC group DF-2 was originally isolated in 1976 from blood and spinal fluid cultures of a patient who had become symptomatic after suffering a dog bite.[142] In 1989, DF-2 and some "DF-2-like" organisms were placed in the genus *Capnocytophaga* based on phenotypic characteristics and DNA relatedness studies. CDC group DF-2 was subsequently named *Capnocytophaga canimorsus* (Latin for "dog bite"), and the "DF-2-like" strains were called *Capnocytophaga cynodegmi* (Greek for "dog bite").[170]Although these organisms are phenotypically different from *Capnocytophaga* species isolated from humans, they are similar with respect to Gram's stain morphology, cellular fatty acid composition, gliding-type motility, and cultural conditions for growth. Chemotaxonomy has been used to differentiate *Capnocytophaga* species from CDC group DF-3 (i.e., *Dysgonomonas*) and aerotolerant strains of *Leptotrichia*.[118] Based on 16S rRNA analysis, human and animal *Capnocytophaga* species are classified in the phylum *Bacteroidetes*, class *Flavobacteria*, and family *Flavobacteriaceae* along with the genera *Flavobacterium, Chryseobacterium*, *Elizabethkingia, Myroides*, and *Weeksella* species.

Clinical Significance

Capnocytophaga species are a part of the normal oropharyngeal microbiota and can behave as opportunistic pathogens under the appropriate circumstances. In the oropharynx, *C. ochracea*, *C. sputigena*, *C. gingivalis*, *C. granulosa*, *C. haemolytica,* and *C. leadbetteri* can be isolated from gingival crevices, periodontal pockets, and

both supragingival and subgingival plaque specimens, but their role in the development of periodontal disease is controversial.[278,279,1394] Survey studies suggest that *Capnocytophaga* species are more prevalent in patients without periodontitis or dental caries than

in those with severe caries or with treatable or refractory periodontal disease.[293,676,1085] As with the HACEK bacteria, head and neck infections with *Capnocytophaga* species may occur by extension from an oral focus to involve the sinuses and the CNS. Wang and colleagues reported a brain abscess due to *C. ochracea* in a 7-year-old boy with recent histories of multiple tooth extractions.[1322] Sepsis due to oral *Capnocytophaga* species is a recognized cause of infection in immunocompromised patients, particularly those with hematologic (e.g., acute/chronic myelogenous leukemia, aplastic anemia, Hodgkin's disease, myeloblastic leukemia, acute lymphocytic leukemia, adenocarcinoma, multiple myeloma, Hodgkin's disease) and solid organ malignancies (e.g., endometrial carcinoma).[147,834,854,891] Bacteremic episodes in these patients coincide with periods of profound neutropenia (especially acute myelogenous leukemia or acute lymphocytic leukemia) and with administration of cytotoxic chemotherapy.[473,479] Mucositis and oral ulcerations are characteristically found in profoundly immunosuppressed patients, thereby establishing an efficient entry route for the organism into the bloodstream.[499] Occasionally, *Capnocytophaga* species may also be isolated from blood of immunocompetent hosts. In 2007, Desai reported severe sepsis and purpura fulminans in a previously healthy 49-year-old man.[348] Rare cases of *Capnocytophaga* pneumonia have been reported in compromised patients as a result of aspiration.[479] Rarely, *Capnocytophaga* species may be recovered from the lower respiratory tract, lung abscesses, wound infections, joint fluid, bone, conjunctival, corneal, and vitreal specimens. *Capnocytophaga* species have been isolated from female genital tract infections as causes of intrauterine, intra-amniotic, and perinatal infections (e.g., endometritis, amnionitis, chorioamnionitis); abortion; preterm birth; congenital bacteremia; and neonatal sepsis.[13,367,802] Endocarditis, cervical lymphadenitis, empyema, lung abscess, sinusitis, vertebral osteomyelitis, iliopsoas abscess, pyonephrosis, liver abscess, and osteomyelitis involving *Capnocytophaga* species have been reported in both immunocompromised and nonimmunocompromised patients.[230,379,539,705,1330] In 1995, the first instance of *Capnocytophaga* species (*C. sputigena*) as a cause of continuous ambulatory peritoneal dialysis-related peritonitis was documented in a 73-year-old man with end-stage renal disease.[405] In 2000, *C. granulosa* was isolated from

an abscess in an immunocompetent patient.[383]

C. canimorsus is the principal human pathogen associated with dog bites and close contact with dogs.[464,1285] Cultural and molecular studies of dogs have shown that 21% to 86% of canines have *C. canimorsus* and/or *C. cynodegmi* in their mouths, but these figures are probably underestimates.[358,830,1232,1286] Although most serious infections have occurred as a consequence of dog bites, several case reports describe infections resulting from dogs licking abrasions, skin wounds, or minor burns.[807,1112] The most serious clinical manifestations occur in individuals with underlying diseases or conditions that predispose them to severe infection with the organism. These conditions include hepatic disease secondary to alcoholism (e.g., cirrhosis), previous splenectomy related to other medical circumstances, Hodgkin's lymphoma, hairy cell leukemia, pulmonary fibrosis, malabsorption syndrome, renal disease, diabetes mellitus, COPD, peptic ulcer disease, Waldenstrom's macroglobulinemia, other malignancies, and the use of systemic or topical corticosteroids. The frequently noted association of systemic *C. canimorsus* infection with asplenia suggests that the reticuloendothelial system (RES) plays an important role in containing the spread of the organism.[376,1127,1226] Although this infection is usually seen in individuals with underlying diseases as outlined above, as many as 40% of patients have no predisposing conditions that place them at higher risk of infection. The mortality associated with severe *C. canimorsus* infection may be as high as 20% to 30%.

Major clinical features of *C. canimorsus* infection include wound infection with cellulitis, meningitis, bacteremia with septic shock, renal failure, hemorrhagic skin lesions suggestive of meningococcal disease, pneumonia with empyema, and both native and prosthetic valve endocarditis.[226,334,455,567,640,780,981,1112,1137] Fulminant *C. canimorsus* sepsis may clinically resemble overwhelming meningococcal disease, with the development of disseminated intravascular coagulation (DIC), purpura fulminans, rapidly evolving hemorrhagic skin lesions, symmetrical peripheral gangrene, and the Waterhouse–Friderichsen syndrome.[190,350,640,897,1313] The clinical presentation of *C. canimorsus* infection can mimic other serious disease syndromes, including tularemia, plague, and hantavirus infection. The disease may progress extremely quickly; in one report, the patient developed DIC that resulted in death over a 4-hour period. Unusual presentations and complications of *C. canimorsus* sepsis have included adult respiratory distress syndrome, myocardial infarction, abdominal symptoms, hemolytic-uremic syndrome, musculocutaneous mononeuropathy, thrombotic thrombocytopenic purpura without DIC, mycotic abdominal aneurysm, vertebral osteomyelitis/discitis, and dialysis-related peritonitis.[424,717,898,942,1255] There is a report of meningitis caused by *C. canimorsus* that was retrospectively diagnosed in a patient who had undergone a CT-guided myelogram. Investigation revealed that the patient, the radiologist, and the radiology technician had prolonged contact with dogs at home, and a procedural

breach in infection control may have resulted in iatrogenic infection of the patient.[1090] *C. canimorsus* was isolated from a prosthetic knee joint infection in a man with Waldemstrom's macroglobulinemia and as the cause of acute tenosynovitis in a patient with systemic lupus erythematosus (SLE), which may be yet another risk factor associated with this organism.[751,779] In 2008, the isolation of *C. canimorsus* from a brain abscess in a patient who had sustained a recent dog bite was reported.[1277] Eye infections, including angular blepharitis, chronic corneal ulcers, corneal ulcer with perforation, and endophthalmitis caused by *C. canimorsus,* have also been reported.[915,999,1030]In one instance, the patient had sustained a scratch on the cornea from his dog that was treated with, among other things, topical prednisone. Interestingly, infections caused by *C. canimorsus*, including keratitis and sepsis with bacteremia, have occurred in individuals who sustained bites and scratches from domestic cats.[255,875] In a 2010 prevalence study, *C. canimorsus* and *C. cynodegmi* were found in 57% and 84% of the oral cavities of cats, respectively.[1232] In 2006, the first documented *C. canimorsus* infection in a nonhuman species occurred in a 2-year-old healthy male pet rabbit that had been bitten on the head by a dog.[1293]

C. cynodegmi is not isolated as frequently as *C. canimorsus*, and in vitro studies suggest that this organism may not be

499

as virulent as *C. canimorsus*. However, several case reports in recent years indicate that this organism may be as pathogenic as its relative *C. canimorsus*. In 2005, Khawari and colleagues described the first instance of fatal sepsis and meningitis due to *C. cynodegmi* in a splenectomized woman who had been bitten on the hand by her pet dog 24 hours before presentation to the emergency department.[698] This organism was recovered from cellulitis of the ankle in a patient with rheumatoid arthritis who had suffered a cat bite; this patient was on long-term corticosteroid and anti-TNF-α therapy.[484] *C. cynodegmi* was isolated as a cause of cellulitis, pneumonitis, and bacteremia in a man with insulin-dependent diabetes mellitus, who had sustained a bite from a stray dog.[1144] *C. cynodegmi* was more recently described as the cause of peritonitis in a 67-year-old man with end-stage renal disease who was on continuous ambulatory peritoneal dialysis.[1023] His only animal exposure was to his neighbor's cat. *C. cynodegmi* may also be a pathogen in animals. *C. cynodegmi* was isolated from lung tissues of a Rottweiler dog with bronchitis and pneumonia due to a retained foreign body and from a bronchoalveolar lavage (BAL) specimen of a 10-year-old cat with a pulmonary carcinoma.[429,1369]

Cultural Characteristics and Identification

Human oral *Capnocytophaga* species are slow-growing, with colonies becoming visible after 48 hours' incubation and developing a characteristic morphology after this time. All species require a CO_2-enriched environment for growth. Colonies of the organism are yellow, tan, or slightly pinkish and have marginal finger-like projections (gliding motility) appearing as a film surrounding the central area of the colony (Image Plate 9-4D). The central part of the colonies also has a moist, mottled appearance. *Capnocytophaga* species grow on blood and chocolate agar, but not on MacConkey agar (Image Plate 9-4F). Good growth may also be observed on modified Thayer-Martin agar because of the resistance of the organism to vancomycin, colistin, and trimethoprim. The organisms are gram-negative, are fusiform in shape, and appear straight or slightly curved (Image Plate 9-4E and 9-4G). Pleomorphism, with swollen or large coccal cells, is seen in older cultures. All species are catalase-negative, are oxidase-negative, and produce acid from glucose, maltose, sucrose, and mannose, but not from ribose, xylose, mannitol, or sorbitol. Indole and urease are not produced. The organism is negative for both lysine and ornithine decarboxylase, as well as arginine dihydrolase. *Capnocytophaga* species produce characteristic, uniform profiles on cellular fatty acid analysis that allow genus-level, but not species-level, identification. Species are identified by an expanded battery of tests (e.g., nitrate and nitrite reduction, starch and dextran hydrolysis, etc.). *C. haemolytica* is β-hemolytic on sheep blood and is the only human hemolytic species. *C. granulosa* strains form intracellular granular inclusions that stain with carbol fuchsin when the organisms are grown anaerobically in peptone-yeast glucose broth under anaerobic conditions. These last two species can also be differentiated from the previously described human *Capnocytophaga* species by determination of various aminopeptidase activities. Phenotypic characteristics for the identification of *Capnocytophaga* species are presented in Table 9-5.

C. canimorsus is usually recovered from blood cultures, wound cultures, aspirates from cellulitis, and CSF. *C. cynodegmi* has been recovered from dogs' mouths and from several types of human clinical specimens, including localized dog-bite wounds, cellulitis, blood, BAL specimens, and peritoneal fluid. In cases of high-grade bacteremia, the bacteria may actually be observed on Wright–Giemsa-stained smears of peripheral blood.[1313] The organism has been recovered in several types of blood culture media, and growth is generally slow. In most reports, blood cultures become positive 3 to 7 days after collection. The organism grows slowly on blood and chocolate agar incubated at 35°C in a CO_2 incubator with increased humidity. Poor growth on routine sheep blood agar has been attributed to the use of a trypticase-soy base; better growth is seen when a heart infusion base is employed. The organisms also grow better in a medium supplemented with cysteine, and addition of rabbit serum to the medium also enhances growth. Commercial supplemented chocolate

agars containing IsoVitalex (which contains cysteine) or other similar enrichments are satisfactory. Pinpoint colonies appear after 2 to 4 days of incubation. After further incubation, colonies appear larger, circular, smooth, and convex. The colonies are nonhemolytic and have a shiny, spreading edge consistent with the gliding motility of the organism. Colonies may have a yellowish or pinkish hue. On Gram's stain, the bacteria appear as medium-to-long, slightly curved bacilli with tapered or spindle-shaped cells. Like the other fastidious bacteria discussed thus far, no growth is observed on MacConkey agar. Both *C. canimorsus* and *C. cynodegmi* are catalase-positive and oxidase-positive; these two reactions differentiate them from the human oral *Capnocytophaga* species, which are oxidase- and catalase-negative. Both canine species are arginine dihydrolase-positive, ONPG-positive, and negative for lysine and ornithine decarboxylase, urease, indole, and nitrate reduction. *C. canimorsus* ferments glucose, maltose, and lactose, but not raffinose and inulin. *C. canimorsus* and *C. cynodegmi* are differentiated by carbohydrate utilization tests, with the latter organism producing acid from a wider variety of sugars. Table 9-5 shows the biochemical reactions of *C. canimorsus* and *C. cynodegmi* along with the general biochemical characteristics of the other *Capnocytophaga* species discussed previously. Broad-range PCR has been used to diagnose *C. canimorsus* osteoarticular and meningeal infections.[284,506,886,1326]

Antimicrobial Susceptibility

Human oral *Capnocytophaga* species are generally susceptible to ampicillin sulbactam, tetracycline, linezolid, imipenem, and other β-lactam/β-lactamase inhibitor combinations, but are resistant to polymyxin, colistin, and trimethoprim. Susceptibility to the penicillins, cephalosporins, aztreonam, erythromycin, fluoroquinolones, aminoglycosides, and metronidazole varies from strain to strain.[479,656,657] *Capnocytophaga* strains that are resistant to β-lactams produce novel β-lactamase enzymes that confer resistance to extended-spectrum cephalosporins and penicillins.[553,854] These β-lactamase-producing strains are highly resistant to penicillin, amoxicillin, and cefazolin; addition of clavulanate results in a 64-fold decrease in the amoxicillin MIC for over 90% of the β-lactamase-producing strains. These strains are also less

susceptible to cefuroxime, cefotaxime, and ceftazidime than β-lactamase-negative strains. Imipenem appears to be active against both β-lactamase-positive andβ-lactamase-negative *Capnocytophaga* isolates.[656] *Capnocytophaga* species are usually resistant to aminoglycosides (i.e., gentamicin, tobramycin, amikacin, netilmicin), trimethoprim, colistin, and vancomycin, although some strains may be susceptible. Gomez-Garces et al.[499] reported a patient with fatal bacteremia caused by a ciprofloxacin-resistant β-lactamase-producing strain of *C. sputigena* that was resistant to all β-lactams (except cefoxitin) and aminoglycosides, but was susceptible to tetracycline, erythromycin, clindamycin, aztreonam, and imipenem. Generally, immunocompromised and granulocytopenic patients are empirically treated with a combination of a β-lactam antibiotic and an aminoglycoside, and cidal levels of antimicrobials are usually required for an optimal therapeutic response. Therefore, rapid recognition of the salient features of this organism by the microbiologist is important. The intrinsic resistance of *Capnocytophaga* species to aminoglycosides and

the production of β-lactamase enzymes by some clinical isolates, which can be detected by the nitrocefin test, should be reported to the physician as soon as possible.

Slow growth of *C. canimorsus* on agar medium and failure of some strains to grow in certain types of broth media have precluded studies of the antimicrobial susceptibility of this organism. Unstandardized studies using disk diffusion procedures designed for more rapidly growing bacteria have found that *C. canimorsus* strains are susceptible to most antimicrobials, including penicillins, third-generation cephalosporins, fluoroquinolones, tetracycline, erythromycin, and imipenem. The organism demonstrates resistance to the aminoglycosides, aztreonam, and SXT, but results for these agents may be method dependent.[1301] Antibiotics that are generally more active against gram-positive organisms, such as vancomycin, clindamycin, erythromycin, and rifampin, were also active against *C. canimorsus*. These data support the clinical efficacy observed with penicillin (mean penicillin MIC = 0.04 μg/mL +/− 0.01 μg/mL for all strains tested).

501

Dysgonomonas Species

Taxonomy

The genus *Dysgonomonas* was created in 2000 to accommodate the former CDC group DF-3 as *Dysgonomonas capnocytophagoides* and a second species, *D. gadei*, which had been isolated from an infected human gall bladder.[596] Members of the genus are gram-negative, facultatively anaerobic coccobacilli that form a phylogenetic cluster within the family *Porphyromonadaceae* of the order *Bacteroidales*. Biochemically, these organisms resemble certain *Capnocytophaga* species, but 16S rRNA sequencing and chemotaxonomic analyses indicate genetic relatedness to *Bacteroides, Prevotella, and Porphyromonas* species, particularly *Bacteroides distasonis* and *Bacteroides forsythus.*[1289]

Clinical Significance

The first two reports of *D. capnocytophagoides* in association with human disease were published in 1988. In one instance, *D. capnocytophagoides* was isolated in pure culture from stool specimens of an elderly woman with common variable hypogammaglobulinemia, and, in the second instance, from blood cultures of a profoundly granulocytopenic man with acute lymphocytic leukemia.[68,1312] In 1991, Gill and coworkers at the National Cancer Institute screened stool specimens from 690

patients and found 11 with moderate to heavy growth of *D. capnocytophagoides*.[488] Of these 11 patients, 4 had a history of prolonged diarrhea and were treated; diarrhea had been documented in the other seven patients, but the organisms cleared spontaneously. Blum and colleagues also recovered *D. capnocytophagoides* from the stool of eight patients during a year-long period.[140] All patients were immunocompromised or had severe underlying disease. Among these patients, the clinical spectrum of *D. capnocytophagoides* ranged from chronic diarrhea with a clinical therapeutic response to an asymptomatic carrier state. Other investigators have also noted the association of enteric *D. capnocytophagoides* infection with both HIV infection and common variable hypogammaglobulinemia.[570,588] This organism has also been isolated from soft tissue, blood cultures, abscesses, decubitus ulcers, and the urinary tract of compromised patients.[88,555,880,1157] In 2002, a third *Dysgonomonas* species,*Dysgonomonas mossii*, was isolated from abdominal drainage fluid, and two other isolates were obtained from other human clinical specimens.[765] In 2006, *D. mossii* was also recovered from multiple specimens obtained from a surgically placed intestinal drainage tube of a patient recovering from resection of pancreatic cancer.[853] A fourth species, *Dysgonomonas hofstadii*, was isolated from a wound, following abdominal surgery, taken from a 72-year-old man in Helsinki, Finland.[763]

Cultural Characteristics and Identification

Dysgonomonas species are nonmotile, facultatively anaerobic gram-negative coccobacilli. All species grow on blood and chocolate agars, but do not grow on MacConkey agar (Image Plate 9-4H). *Dysgonomonas* species are oxidase-negative and catalase-variable. All species ferment glucose with no gas formation, and none of the species reduce nitrate or produce urease, gelatinase, or H_2S. All species are arginine dihydrolase-negative, and do not produce lysine or ornithine decarboxylases. Phenotypic characteristics of *Dysgonomonas* species are shown in Table 9-6.

D. capnocytophagoides grows slowly, with pinpoint colonies appearing after 24 hours' incubation. *D. capnocytophagoides* has been recovered from stool specimens using cefoperazone–vancomycin–amphotericin (CVA) blood agar incubated at 35°C in 5% to 7% CO_2. In these cases, nonselective blood agar should also be inoculated, as some strains fail to grow on this selective *Campylobacter* medium. The organism has also been recovered on blood agar containing kanamycin and vancomycin following anaerobic incubation. After 48 to 72 hours, the colonies are gray-white, smooth, and nonhemolytic, and some strains produce a sweet odor during growth. Oxidase and catalase reactions are negative, but indole is produced in tryptone broth and esculin is hydrolyzed. This bacterium produces acid fermentatively from glucose, xylose, and maltose; most strains also produce acid from sucrose and lactose, but do not produce acid from mannitol. Some "DF-3-like" strains have also been described that are

consistently sucrose-negative and slightly hemolytic.[325] *D. gadei* and *D. mossii* can be differentiated phenotypically from *D. capnocytophagoides* by acid production from mannitol, inositol, sorbitol, raffinose, and trehalose (Table 9-6). Gas-liquid chromatography (GLC) is also useful for identification, since all strains consistently demonstrate 12- and 13-methyltetradecanoate, with minor amounts of tetradecanoate and hexadecanoate in their cell wall.[325,1312]

Antimicrobial Susceptibility

Antimicrobial susceptibility of *D. capnocytophagoides* isolates has been determined by disk diffusion, broth dilution, and Etest methods. *D. capnocytophagoides* isolates are resistant to penicillin, ampicillin, ampicillin sulbactam, aztreonam, aminoglycosides, cephalosporins of all generations, erythromycin, fluoroquinolones, and vancomycin. Most isolates are susceptible to SXT and are variably susceptible to piperacillin, clindamycin, tetracyclines, and imipenem. Patients respond clinically to therapy with SXT, clindamycin, or tetracycline.

Streptobacillus moniliformis

Taxonomy

Streptobacillus moniliformis is the only member of the genus *Streptobacillus,* and its present taxonomic position is uncertain. Based on 16S rRNA sequencing studies, *S. moniliformis* is currently classified in the proposed family "*Fusobacteriaceae*" in the proposed class "*Fusobacteria*" of the phylum *Fusobacteria*.

Epidemiology

Individuals who are at risk for infection with *S. moniliformis* include animal laboratory workers and those individuals who live in urban areas where rats may be prevalent. Additionally,

other urban or rural dwelling domesticated animals that prey on rodents may also become infected and are able to transmit the infection to humans via bites, scratches, or contact with animal urine and excrement. *S. moniliformis* may also cause infections in koala bears, turkeys, and monkeys.[1284]

Clinical Significance

Streptobacillus moniliformis is a fastidious gram-negative bacillus that is normally found in the upper respiratory tracts of wild rats, laboratory rats and mice, and domesticated rodents (e.g., guinea pigs, gerbils, ferrets) and may cause disease in these animals.[463] The organism may also be carried by animals that catch or feed on rodents, such as dogs and cats. As the natural reservoir for *S. moniliformis*, bites from these reservoir hosts or exposure to their urine or feces can transmit the organism to humans. Consequently, *S. moniliformis* infection in humans is termed *rat-bite fever*. Infection may also be transmitted via ingestion and is called Haverhill fever when the bacterium is acquired by this route. The latter name comes from Haverhill, Massachusetts, where this organism was recovered from blood cultures of several patients during a local outbreak of the disease involving ingestion of milk contaminated with rat excrement.[745,1175] Since then, outbreaks of Haverhill fever from ingestion of contaminated water and turkey meat have been reported. At present, most cases involve bites from rats or exposure to rodents, and many of these infections occur in children.[87,664] Infection has also been documented following receipt of several scratches from a rooster.[375] After an incubation period of 7 to 10 days following the infection, there is an abrupt onset of high fever, chills, headache, muscle aches, vomiting, and other constitutional symptoms.[391,463] The incidence and severity of pharyngitis and vomiting is greater when infection is acquired by the oral route.[745] A few days after disease onset, a maculopapular rash usually appears on the distal extremities, with petechiae appearing on the plantar soles and the palms. In some cases, the maculopapular rash may be hemorrhagic or pustular.[87] About 50% of patients may develop severe joint pain, migratory, nonsymmetric polyarthritis, or septic arthritis.[345] Cutaneous and subcutaneous abscesses with pitting edema have also been described in association with this infection.[1261] The disease may resolve spontaneously with no residual symptoms, or may develop into a chronic, periodically febrile condition. Complications related to systemic dissemination via the bloodstream include native and prosthetic valve endocarditis, myocarditis, pericarditis, pneumonia with pleural effusion, septicemia, brain abscess, amnionitis, prostatitis, pancreatitis,

cutaneous and genital tract abscesses, and death.[87,242,357,413,718,1033,1108,1121] Arthritic symptoms may persist for years after resolution and/or treatment of the infection. Without a clue as to the origin of infection, rat-bite fever or Haverhill fever may resemble rheumatoid arthritis, staphylococcal or streptococcal sepsis, acute rheumatic fever, disseminated gonococcal infection, meningococcemia, secondary syphilis, typhoid, brucellosis, leptospirosis, acute enteroviral infection, Lyme disease, ehrlichiosis, anaplasmosis, Rocky Mountain spotted fever, and other rickettsial infections.[391,463] Diagnosis may also be problematic because cases have been reported in patients with no history of rodent bites or direct exposure to rodents.[428] Conversely, review of 45 cases occurring in California over the last 30 years revealed that rat-bite fever was suspected in 75% of the cases where a tentative diagnosis was given.[513] Because of the fastidious nature of the organism and the difficulties involved with culture, retrospective diagnoses of *S. moniliformis* infection have been made on occasion by serologic techniques, including detection of serum agglutinins and complement fixing antibodies against the bacillary form of the organism. However, serologic tests for this infection are not readily available, and most serologic approaches have been used to assess presence of the organism in laboratory rodent colonies.

Cultural Characteristics and Identification

S. moniliformis is a fastidious, pleomorphic gram-negative bacillus that tends to form long, thin, filamentous single cells. These thin cells are about 1 μm in diameter, but may be over 100 μm in length and may fold into loops and coils.[463] Occasionally, these organisms may stain gram-variable. On prolonged incubation, bulbous- or sausage-shaped swelling may appear along the filament, causing the organism to resemble a string of beads. On enriched, serum-containing media, the organisms appear as regular, thin, gram-variable fusiform bacteria with rounded or pointed ends. The organism may also lose its cell wall and exist as an "L-form, which may be related to the lower glucosamine and muramic acid content of the cell wall of the organism. In fact, there is genetic, phenotypic, serologic, and structural evidence suggesting that this organism is taxonomically related to the mycoplasmas and ureaplasmas, which also lack a typical bacterial cell wall.[1373] *S. moniliformis* is microaerophilic, and growth in liquid medium usually requires supplementation with serum (10% to 20%), blood, or ascites fluid.

Diagnosis of rat-bite or Haverhill fever is made by recovery of *S. moniliformis* from blood cultures, synovial fluid, CSF, skin lesions, and abscess material.[87,391,463] Because the organism is inhibited by the anticoagulant SPS, blood (10 mL) must be anticoagulated with citrate (10 mL sodium citrate, 2.5%) prior to processing.[745,1174] The organism has also been successfully recovered in SPS-containing blood culture

media with resins (e.g., BACTEC Peds Plus, BD Biosciences) and in BACTEC Plus Aerobic Anaerobic/F bottles (BD Biosciences), which do not contain SPS. The citrated blood cells are sedimented by centrifugation, and the packed cells are inoculated onto agar medium (heart infusion agar) containing 10% to 20% sterile decomplemented horse serum and 0.5% yeast extract. The inoculum is gently spread over the agar surface. A broth medium of similar ingredients (heart infusion broth with 10% to 20% horse or rabbit serum, defibrinated blood or ascites, and yeast extract) is also inoculated with the packed cells. Isolation of *S. moniliformis* has also been accomplished using a biphasic medium of trypticase-soy broth containing a trypticase-soy agar slant. Medium is incubated at 35°C in a candle jar or a CO_2incubator. Other specimens (citrated joint fluid, aspirates, abscess material, etc.) may be cultured in the same manner. Loridant and colleagues reported successful recovery of *S. moniliformis* from blood culture media by inoculation of shell vials containing monolayers of ECV 304 human endothelial cells. The organisms showed cytopathic effects on the cultured

cells after 24 hours, with subsequent successful subculture on agar media.[806]

In broth medium, the organism grows as small "puff balls" near the bottom of the tube or bottle and overlying the red cells and stroma. Accumulation of acid in broth media may kill the organism; so frequent subculture is necessary to maintain viability. On serum-enriched agar medium, growth may appear within 2 to 3 days, or may require a week or more. Colonies are small (1 to 2 mm in diameter), convex, gray-white, smooth, and buttery in consistency. Microscopic L-phase variants form spontaneously under or around the existing colonies; the typical "fried egg" morphology with a dense center similar to the morphology of *Mycoplasma* species can be observed with a dissecting microscope. Identification of *S. moniliformis* is accomplished by observing the typical gram-negative, filamentous morphology on Gram's staining and by performing biochemical identification tests in serum-supplemented medium. Carbohydrate utilization tests may be performed in nutrient broth containing 1% filter-sterilized carbohydrates and 0.5% sterile horse serum. These tests should be incubated for 3 weeks before the final interpretation, although reliable and reproducible results have been obtained when cultures were incubated for only 1 week before test interpretation. Rapid identification of the organism may also be accomplished by fatty acid profile analyses using GLC, by detection of enzymatic activities for various aminopeptidases and glycosidases using the API-ZYM strip, and by protein patterns obtained by polyacrylamide gel electrophoresis (PAGE).[310,384,1117] Fatty acid methyl esters detected by GLC include hexadecanoic acid (C16:0), linoleic acid (C18:2), and octadecanoic acids (C18:1, C18:0).[384,1117] PAGE techniques may

also be useful for strain typing of clinical isolates.[310] The reactions of *S. moniliformis* in various biochemical identification tests are shown in Table 9-7.

Broad-range PCR-based amplification of a part of the 16S rRNA gene followed by amplicon sequencing has been developed for direct detection of *S. moniliformis* in rodent colonies, turkey flocks, and human clinical speciemens.[112,151] This method was used to diagnose rat-bite fever in a symptomatic 11-year-old boy who developed fever, vomiting, rash, and arthritis after being bitten by his pet rat. Cultures from blood, CSF, and urine were negative, but fluid from a cutaneous blister was positive by the amplification/sequencing assay.[112] 16S RNA sequencing has also been used for the detection of *S. moniliformis* in joint fluid specimens and to confirm the identity of isolates recovered from joint fluid cultures.[237,930,1319]

Antimicrobial Susceptibility

In vitro antimicrobial susceptibility data indicate that *S. moniliformis* is susceptible to penicillin, ampicillin, extended-spectrum and penicillinase-resistant penicillins, cephalosporins, erythromycin, clindamycin, tetracycline, rifampin, imipenem, and vancomycin.[384,1373] The organism is intermediate in susceptibility to aminoglycosides and ciprofloxacin, and is generally resistant to colistin and SXT. The drug of choice for treatment of mild-to-moderate disease is intravenous penicillin G, with oral tetracyclines as an alternative for patients with penicillin allergy. Other antimicrobial agents (e.g., ceftriaxone, clindamycin, erythromycin) have also shown some clinical efficacy. Parenteral therapy may be followed by course of oral therapy in severe disease. Combination therapy with intravenous penicillin plus an aminoglycoside may be warranted for treatment of native valve endocarditis.

Simonsiella Species

Simonsiella species are fastidious, aerobic gram-negative bacilli that have the unusual morphologic characteristic of existing in multicellular arrangements measuring 20 to 50 µm by 4 to 8 µm. These arrangements consist of 6 to 8 cells, with the long axis of the individual bacilli at right angles to the axis of the cell group. The cell group exhibits gliding motility and forms pale yellow colonies on blood agar after 18 to 24 hours at 37°C. The genus *Simonsiella* contains the single species *S. muelleri,* which is found in the human oral cavity. Two former *Simonsiella* species—*S. crassa* and *S. steedae*—have been reclassified in the genus *Alysiella* as *A. crassa* and in the new genus *Conchiformibium* as *C. steedae*, respectively.[1376] These organisms are found in the oral cavities of sheep (*A. crassa*) and dogs/cats (*C. steedae*). *S. muelleri* was isolated from a gastric aspirate from a neonate, but has not been implicated as a human pathogen.[1348] The genera *Alysiella*, *Simonsiella*, and *Conchiformibium* are classified in the family *Neisseriaceae.*[1113]

505

Pasteurella and *Mannheimia* Species

Taxonomy and Characteristics of the Genus Pasteurella

The taxonomic structure of genus *Pasteurella* is complicated, and taxonomists are now attempting to unravel the relationships among members of the described genera and the proper taxonomic assignment of several "species" to *Pasteurella* and other genera.[273] Prior to the mid-1980s, the genus *Pasteurella* included *P. multocida, P. aerogenes, P. ureae,* and *P. pneumotropica* based on phenotypic characteristics. Subsequent additions to the genus occurred during the mid-1980s, when the delineation of genera in genus *Pasteurella* was based on DNA hybridization studies, with strains showing greater than 50% homology being included in the same species with little regard for phylogenetic origin and phenotypic characteristics.[926–928,1148,1202] *Pasteurella*"species" described by these investigators included *P. dagmatis, P. canis, P. stomatis, P. gallinarum, P. anatis, P. langaaensis, P. bettii, P. lymphangitidis, P. mairii, P. trehalosi, P. testudinis, P. avium,* and *P. volantium*. At the same time, other investigators used DNA hybridization and phenotypic methods to demonstrate that *P. ureae* was not closely related to any of these new "*Pasteurella*" species.[404] Subsequently, examination of 16S rRNA sequences showed that the older species of *Pasteurella*—[*P.*] *pneumotropica*, [*P.*] *aerogenes*, [*P.*] *ureae*, and species within the [*P.*] *haemolytica* group—were not closely related to the type species of *Pasteurella* (*P. multocida*) or to each other and probably belonged in genus *Actinobacillus* or in new genera.[354] With the exclusion of these existing "species" from the "genus" *Pasteurella*, specific epithets for these organisms are written with the genus name in brackets as indicated. *Pasteurella* species sensu stricto, [*Pasteurella*] species incertae sedis, and members of the genus *Mannheimia* are presented in Box 9-4.

BOX 9-4

Pasteurella Species Sensu Stricto, [*Pasteurella*] Species Incertae Sedis, and *Mannheimia* Species

Species/Subspecies	Habitat and Clinical Significance in Humans
Pasteurella Species	

P. multocida subsp.*Multocida*	Respiratory tract of nonhuman mammals; clinical isolate from infections in humans
P. multocida subsp.*septica*	Same as above
P. multocida subsp.*gallicida*	Same as above; also associated with fowl cholera
P. dagmatis	Respiratory tracts of dogs and cats; animal bite wounds and systemic infections in humans
P. canis	Respiratory tracts of dogs and calves; dog-bite wounds in humans
P. stomatis	Respiratory tract of dogs; dog-bite wound infections
[*Pasteurella*] Species Incertae Sedis	
[*P.*] *aerogenes*	Normal flora in the intestinal tract of swine; human infection following a pig bite
[*P.*] *pneumotropica*	Respiratory tracts of guinea pigs, rats, hamsters, cats, and dogs; rarely isolated from humans
[*P.*] *bettyae*	Human Bartholin's gland and finger abscesses; may be associated with genital ulcer disease; postpartum bacteremia; pneumonia and pleural effusion in a patient with AIDS
[*P.*] *caballi*	Equine isolate causing pneumonia, wound infection; human wound infections reported
[*P.*] *mairii*	Abortion in sows; sepsis in piglets
[*P.*] *langaaensis*	Respiratory tract flora of chickens and other fowl
[*P.*] *lymphangitidis*	Bovine lymphangitis
[*P.*] *testudinis*	Pathogen in some species of desert tortoises
Former [*Pasteurella*] Species Incertae Sedis	
Avibacterium gallinarum	Formerly [*Pasteurella*] *gallinarum*; respiratory tracts of chickens and hens; two reported cases of bacteremia in humans
Gallibacterium anatis	Formerly [*Pasteurella*] *anatis*; intestinal tract flora of ducks
	Formerly [*Pasteurella*] *trehalosi*; septicemia in

	adolescent lambs
Mannheimia Species	
M. haemolytica	Pneumonic infections in cattle; mastitis in ewes; septicemia in goats and sheep; upper respiratory tract flora of ruminants; rare human infections reported

506

M. granulomatis	Progressive granulomatous disease (panniculitis) in cattle; bronchopneumonia and conjunctivitis in leprine species and deer
M. glucosida	Upper respiratory tract flora in cattle and sheep
M. ruminalis	Normal flora in the rumen of sheep and cattle
M. varigena	Pneumonia, mastitis, and septicemia in cattle; also found as part of the upper respiratory, rumen, and intestinal flora of cattle; respiratory tracts flora of swine; sepsis, enteritis, and pneumonia in swine
M. succiniciproducens	Isolated from the bovine rumen

Restructuring of the *Pasteurellaceae* began when [*P.*] *ureae* was formally reassigned to the genus *Actinobacillus* as *Actinobacillus ureae.*[929] In 1999, members of the "*Pasteurella haemolytica* group" (including *P. haemolytica* sensu stricto, *Pasteurella anatis,* and *P. granulomatis*) were placed in the new genus *Mannheimia* or reclassified as the previously described species *Pasteurella trehalosi*.[46] Based on 16S rRNA sequencing, amplified 16S ribosomal DNA analysis (ARDRA), quinone typing, and sequencing of the *sodA* genes, which encode the manganese-dependent superoxide dismutase enzyme and provide higher discriminatory power for bacterial systematics, the genus *Pasteurella* sensu stricto now consists of *P. multocida* subspecies (*multocida*, *gallicida*, and *septica)*, *P. canis*, *P. dagmatis*, and *P. stomatis*.[672] The other "*Pasteurella*" species were designated as species incertae sedis. New genera will need to be created to accommodate these other "*Pasteurella* species," including [*P.*] *aerogenes*, [*P.*] *pneumotropica*, [*P.*] *bettyae*, [*P.*] *caballi*, [*P.*]

species," including [*P.*] *aerogenes*, [*P.*] *pneumotropica*, [*P.*] *bettyae*, [*P.*] *caballi*, [*P.*] *anatis*, [*P.*] *mairii*, [*P.*] *testudinis*, [*P.*] *skyensis*, [*P.*] *langaaensis*, [*P.*] *lymphangitidis*, [*P.*] *trehalosi*, [*P.*] *avium*, [*P.*] *volantium,* and [*P.*] *gallinarum*.

Reclassification of Other [Pasteurella] *Species*

[*P.*] *anatis*, [*P.*] *avium*, [*P.*] *volantium*, [*P.*] *gallinarum*, [*P.*] *trehalosi*, [*P.*] *testudinis*, [*P.*] *langaaensis*, [*P.*] *lymphangitidis*, [*P.*] *mairii*, [*P.*] *skyensis*, and [*P.*] *lymphangitidis* are animal species incertae sedis that have not been isolated from humans. In 2003, [*P.*] *anatis* and *avian* isolates classified in the "[*P.*] *haemolytica*" group were reclassified in the new genus *Gallibacterium* as *G. anatis*.[269] Unnamed taxa that had been isolated from other avian species were also analyzed and added to genus *Gallibacterium* in 2009 as *G. melopsittaci*, *G. trehalosifermentans*, and *G. salpingitidis*.[134] In 2005, [*P.*] *avium*, [*P.*] *volantium*, and [*P.*] *gallinarum* were transferred to the new genus *Avibacterium* as *Avibacterium avium, Avibacterium volantium,* and *Avibacterium gallinarum*, respectively, along with "*Haemophilus paragallinarum*" (*Avibacterium paragallinarum*).[138] In 2007, a fifth *Avibacterium* species, *A. endocarditidis*, recovered from chickens with valvular endocarditis, was added to this new genus.[132] Also in 2007, the sheep pathogen [*P.*] *trehalosi* was reclassified in the new genus *Bibersteinia* as *B. trehalosi*.[137] In 2009, genotypic analysis of [*P.*] *testudinis* and other isolates from diseased tortoises resulted in the description of the new genus *Chelonobacter*, which was demonstrated to be a member of the *Pasteurellaceae*. This new genus contains a single species, *C. oris*, that is distinct genotypically and phenotypically from [*P.*] *testudinis*, which remains unclassified at this time.[515] In 2004, other unnamed taxa that had been recovered from parrots and parakeets were placed in the new genus *Volucribacter* as *V. psittacicida* and *V. amazonae*.[267] The genera *Lonepinella, Phocoenobacter, Nicoletella,* and *Basfia* include single species that are found in koala bears (*L. koalarum*), harbor porpoises (*P. uteri*), horses (*N. semolina*), and the bovine rumen (*B. succiniciproducens*) and were described in 1995, 2000, 2004, and 2010, respectively.[437,739,740,983] [*P.*] *langaaensis*, [*P.*] *lymphangitidis*, [*P.*] *mairii*, [*P.*] *skyensis*, and [*P.*] *lymphangitidis* remain as species incertae sedis and await reclassification.

Members of the genus *Pasteurella* sensu stricto share certain phenotypic characteristics.[366] *Pasteurella* species are nonmotile, gram-negative, facultatively anaerobic coccobacilli or rods. Most species are oxidase-positive, are catalase-positive, are alkaline phosphatase-positive, and reduce nitrate to nitrite. Most species also produce acid from glucose, fructose, mannose, and sucrose, but none hydrolyze starch or salicin. Several species also produce urease. All *Pasteurella* species are usually

Pasteurella *Species: Clinical Significance, Identification, and Antimicrobial Susceptibility*

Pasteurella multocida. *P. multocida* is the most frequently encountered *Pasteurella* species from human clinical specimens and is also recovered from animals. *P. multocida* organism can commonly be cultured from the oral cavities of healthy domesticated cats (70% to 90%) and dogs (40% to 66%), and is also found in other animals (e.g., cattle, horses, swine, sheep, fowl, rodents, rabbits, monkeys, lions, panthers, lynx, birds, reindeer, and buffalo). In some animals, this organism causes serious infections (e.g., shipping fever and hemorrhagic septicemia in cattle, fowl cholera, atrophic rhinitis in swine and pleuritis, pneumonia, abscess formation, chronic rhinitis, otitis media, and septicemia in laboratory rabbits). The majority of human infections are wound infections and cellulitis usually resulting from cat bites and scratches.[966,1341] Occasionally, *P. multocida* may be found in the nasopharynges

507

of healthy individuals who have frequent animal exposure. Immunocompromised patients, particularly those with liver diseases (e.g., cirrhosis), solid tumors, or hematologic malignancies, may develop bacteremia from localized wound infections, which, in turn, may lead to hematogenous pneumonia, meningitis, or other complications.[1057] This organism has also been found as the cause of cellulitis in a patient with diabetes mellitus.[1410] *P. multocida* may be recovered from a variety of clinical specimens particularly from immunocompromised hosts. Box 9-5 describes infections associated with *P. multocida.P. multocida*, a small gram-negative coccobacillus is oxidase-positive, catalase-positive,

BOX 9-5

Clinical Spectrum of Human *Pasteurella multocida* Infections

Infection	Comments
Wound infections and cellulitis	Local wound infections in humans are associated with cat bites, cat scratches, or dog bites. These infections are characterized by rapid development of pain, erythema, swelling, cellulitis, and purulent or serosanguinous drainage at the site of the wound.[1341] Regional lymphadenopathy occurs in 30%–40% of patients, and systemic signs of infection may or may not be present. Serious localized complications (e.g., septic arthritis, osteomyelitis) most frequently follow cat bites, where the wound may be deep, forceful, and traumatic to underlying tissues. Since most bite wounds are on the hands, bone, and joint complications are usually seen at these sites. Serious wound infections requiring wide excisional debridement (e.g., necrotizing fasciitis) may also develop in patients with underlying diseases (e.g., diabetes) or on immunosuppressive therapy.[235,1410] Occasionally, this organism may be found in wounds that are not associated with animal bites or obvious animal exposure. Wound infections with *P. multocida* have also occurred as a result of a dog or cat licking open or partially healed wounds.[235] The bacterium has been isolated from decubitus ulcers, periocular abscesses, and from postsurgical abdominal and orthopedic wound infections.[301,618]
Bone and joint infections	Bone and joint infections result from implantation of *P. multocida* into bone and joints by traumatic dog or cat bites and scratches, by contiguous spread from an adjacent cellulitis, and, rarely, by hematogenous seeding of the joint space. Infections include septic arthritis, osteomyelitis, or both. *P. multocida* septic arthritis is often associated with preexisting joint disease (e.g., rheumatoid arthritis, corticosteroids, osteoarthritis, implanted prostheses). Infections of total knee and total hip replacements have occurred following dog and cat bites and scratches and licks.[583,584] These infections may necessitate removal and subsequent reimplantation of the prostheses. Osteomyelitis results from either direct implantation at the time of the bite or by extension of cellulitis. Infections are more severe in patients with underlying diseases.[193]
Respiratory tract infections	*P. multocida* can be isolated from the upper and lower respiratory tract, where it may behave as a commensal or as a cause of epiglottitis, pneumonia, empyema, lung abscess, adult respiratory distress syndrome, bronchitis, sinusitis, tonsillitis, and otitis media.[163,491,793,887,982,1357] Individuals with respiratory tract colonization often have a history of occupational or recreational animal exposure. Symptomatic patients usually have some preexisting airway compromise (e.g., COPD, chronic bronchitis, bronchiectasis, lung carcinoma, HIV infection). Symptoms of *P. multocida* pneumonia include an insidious or abrupt onset of fever, malaise, shortness of breath, and pleuritic chest pain. On chest x-ray, lobar consolidation, with mostly lower lobe involvement, is the most common presentation. Complications include development of bacteremia, pleural effusions, and empyema.[847] Upper respiratory tract infection with *P. multocida* may have unusual clinical presentations. *P. multocida* tonsillitis was reported in a woman whose cat habitually licked her toothbrush.[1060] Invasive *P. multocida* sinusitis was described in a kidney transplant recipient whose dog licked her face and ears.[1151]
Endocarditis	*P. multocida* can be a rare cause of both native valve and prosthetic valve endocarditis.[414,461,1296] Patients occasionally have a history of underlying or preexisting heart disease, although a history of cat or dog exposure and underlying disease (i.e., hepatitis, cirrhosis) is commonly found.[461] Infection usually involves the aortic and, less frequently, the mitral valve.[414] In 2007, right-sided endocarditis involving the pulmonary valve due to *P. multocida* was reported to occur in an HIV-negative IV drug user.[508] This patient required homograft replacement of the pulmonary valve because of persistent fever and positive blood cultures. Endocarditis due to *P. multocida* is usually a subacute clinical presentation, as indicated by a 1-week to 4-month time period from onset of symptoms to etiologic diagnosis. The one reported instance of prosthetic valve endocarditis occurred in a 72-year-old woman with a Carpentier–Edwards valve implant for aortic stenosis 3 years prior to the onset of disease.[944] The patient responded to penicillin and ampicillin sulbactam, and valve replacement was not required.

CNS infections	CNS infections caused by *P. multocida* have included meningitis, subdural empyema, and brain abscess.[143,514,932] The clinical presentation of *P. multocida* meningitis is similar to that caused by other agents; the CSF is usually purulent, and gram-negative coccobacilli are observed on Gram's stains. CNS infections have been reported in elderly individuals with underlying disease and in infants.[977] Meningitis in infants has often been associated with nontraumatic exposure to animals via licks from cats and dogs and fomites (e.g., pacifiers) contaminated with cat saliva.[712,932] Vertical transmission has resulted in neonatal bacteremia and meningitis. In these instances, vaginal, blood, or endometrial cultures obtained from the mothers were positive for *P. multocida*.[932] Caregivers of neonates and infants who have animal contact may also transmit the organism. An unusual case report described meningitis and sepsis in twins whose father had slaughtered a sheep for a dinner celebration. Isolates from the twins were identical to those isolated from the father's throat and nares.[525] More recently, sepsis and meningitis was reported in a 44-year-old woman and revealed her habit of kissing her dog and transferring food to the dog with her mouth.[692] Meningitis has also occurred as a complication of *P. multocida* septic arthritis.[767]
Eye infections	*P. multocida* has been isolated in rare instances from patients with conjunctivitis, periocular abscess with cellulitis, keratitis, and endophthalmitis. Purulent conjunctivitis was diagnosed in a poodle owner who did not recall any bites or scratches from the animal.[1251] *P. multocida* keratitis and corneal ulcers usually occur following corneal lacerations from cat or dog scratches.[1234] *P. multocida* endophthalmitis has occurred following penetrating injuries from cat scratches or as an immediate or delayed postoperative complication of cataract or lens implantation surgery.[94,326] These infections may result in loss of visual acuity or the need for enucleation of the eye.
Bacteremia and sepsis	*P. multocida* sepsis and bacteremia may occur by spread of the organism from a localized bite wound, or it may originate from an infected site elsewhere (e.g., cellulitis, arthritis, meningitis, or peritonitis).[1057] In some instances, the initial wound may be so innocuous (e.g., a minor scratch from a dog's paw) that it is ignored until signs and symptoms of sepsis supervene. Bacteremia occurs predominantly in the settings of liver disease (e.g., cirrhosis) or other underlying conditions (e.g., solid neoplasms, hematologic malignancies, lupus, infection).[84,180,194,1057] Profound *P. multocida* sepsis has been seen following animal bites in healthy individuals.[1119] In 2007, *P. multocida* bacteremia was diagnosed in two asymptomatic plateletpheresis donors.[189] The first platelet recipient had a transfusion reaction, and *P. multocida* was recovered from the donor platelet culture. The donor was asymptomatic, but had sustained a cat bite 100 minutes prior to platelet donation. In the second instance, platelet contamination was detected by culture, and the donor, a 74-year-old woman who cared for several feral cats, was diagnosed with *P. multocida* lymphadenitis five days later.
Intra-abdominal infections	*P. multocida* is an infrequent cause of intra-abdominal infections, including postsurgical wound infections, spontaneous bacterial peritonitis, appendicitis, and intra-abdominal/splenic/hepatic abscesses.[500,1058,1240] Patients who develop these infections have underlying diseases such as cirrhosis, solid organ tumors, and/or hematologic malignancies. Clinically, peritonitis caused by *P. multocida* is similar to that caused by enteric bacteria, with abdominal pain, fever, gastrointestinal bleeding, and hypotension. *P. multocida* is recovered from paracentesis fluid on culture, although direct Gram's stains of unconcentrated fluid are often negative. Since most patients with peritonitis usually have concurrent bacteremia, seeding of the peritoneal cavity is believed to occur via the hematogenous route in most cases, although peritoneal infection associated with upper endoscopy has been reported.[713] Although most cases of peritonitis are associated with animal contact, some patients do not recall or have no significant exposure to cats or dogs.[101] Continuous ambulatory peritoneal dialysis–associated peritonitis caused by *P. multocida* is unusual but has been reported.[49,923] In some instances, the organism was introduced into the peritoneal cavity by cat bites or scratches on the peritoneal dialysis tubing.
Obstetric, gynecologic, and urinary tract infections	*P. multocida* may occasionally colonize the female lower genital tract and can cause serious gynecologic or perinatal infections, including meningitis in the newborn. Female genital tract and neonatal infections have included diffuse infection, tubo-ovarian abscess, Bartholin's gland abscess, intrauterine device-related endometritis, intrauterine infection followed by septic abortion, chorioamnionitis with neonatal sepsis, pneumonia, and meningitis.[227,799,1088,1314] Most patients have some sort of underlying disease or immune compromise (e.g.,cranial trauma, neurosurgery, hepatic cirrhosis, postoperative wound infection, cervical carcinoma, or congenital genitourinary tract malformations). Puerperal sepsis, with isolation of the organism from the blood and endocervical discharge, has also been described in a previously healthy woman with nontraumatic exposure to the family cat.[1308] In this instance, PCR "fingerprinting" proved the genotypic identity of the isolates from the patient and from the oral cavity of her cat. Rare urinary tract infections may be caused by *P. multocida*. These are most often cat-associated, and patients usually have underlying renal disease and abnormal urologic anatomy secondary to surgery.[309,794]

ornithine decarboxylase-positive, indole-positive, mannitol-positive, and urease-negative (Image Plate 9-5B and 9-5C). In 2004, Christensen and colleagues demonstrated that bovine isolates of [*P.*] *avium* (*A. avium*) biovar 2 and [*P.*] *canis* biovar 2 were actually strains of *P. multocida* that were negative for ornithine decarboxylase, indole, and mannitol.[265]

P. multocida is not difficult to isolate and identify, although knowledge of the specimen type and an animal exposure history increases the index of suspicion that this organism may be present. *P. multocida* grows well on chocolate and sheep blood agar, forming smooth, gray colonies that are 0.5 to 2.0 mm after 24 hours' incubation in CO_2 (Image Plate 9-5A). The organism is nonhemolytic and does not grow on MacConkey agar, Eosin methylene blue (EMB) agar, or other selective/differential enteric media. Isolates from respiratory tract specimens may be mucoid. A characteristic odor (like *E. coli*, but more pungent) is frequently noted due to the formation of indole. *P. multocida* is oxidase-positive, catalase-positive, ornithine decarboxylase-positive, indole-positive, and urease-negative. The "spot indole" (*p*-aminocinnamaldehyde) reagent is usually strongly positive. *P. multocida* produces acid, but no gas, from glucose, sucrose, and mannitol, but not from maltose or lactose. For typical isolates recovered from likely sources, such as a cat bite or scratch, demonstration of oxidase-positive, gram-negative bacilli that are strongly spot indole-positive and do not grow on MacConkey agar is usually sufficient to identify *P. multocida*. *P. multocida* strains can be identified to subspecies level (i.e., subspecies *multocida*, *septica*, and *gallicida*) based on acid production from sorbitol and dulcitol. Subspeciation is of interest mostly regarding veterinary isolates and usually is not part of the species identification. Phenotypic characteristics for the identification of *Pasteurella* and related genera and species are shown in Table 9-8.

Virulence factors of *P. multocida* that are associated with economically significant animal infections (e.g., atrophic rhinitis in swine) have been actively investigated for years. Some *P. multocida* strains are encapsulated, and five capsular groups—A, B, D, E, and F—have been described.[560] These capsular groups can be divided further by somatic O antigen typing. Most human isolates of *P. multocida* belong to capsular group A and, to a lesser extent, group D. Strains of *P. multocida* that cause atrophic rhinitis produce a chromosomally encoded 145-kDa dermonecrotic toxin that is an essential virulence factor for disease development and progression. Molecular tests have been developed for direct detection of the *toxA* gene in *P. multocida*. The role of the dermonecrotic toxin in human disease is not known.

In 2010, CLSI published guidelines for both microbroth dilution and agar dilution antimicrobial susceptibility testing of *Pasteurella* species.[286] The approved microbroth method uses cation-adjusted Müeller–Hinton broth with lysed horse blood (2.5% to 5%), a direct colony suspension equivalent to a 0.5 McFarland turbidity standard, and incubation in air at 35°C for 18 to 24 hours. Agents to consider for testing include

penicillins, β-lactam/β-lactamase inhibitor combinations (i.e., amoxicillin clavulanate), cephalosporins (specifically ceftriaxone), fluoroquinolones (levofloxacin, moxifloxacin), tetracyclines (specifically tetracycline and doxycycline), macrolides (erythromycin, azithromycin), and SXT. Antimicrobial susceptibility testing indicates that *P. multocida* isolates are broadly susceptible to many antimicrobial agents in vitro. The organism is susceptible to penicillin, ampicillin, amoxicillin clavulanate, broad-spectrum penicillins, extended-spectrum cephalosporins, and tetracyclines. Less activity is noted for first-generation cephalosporins (e.g., cephalothin, cefazolin) and semisynthetic penicillins (e.g., oxacillin, methicillin, nafcillin). Aminoglycosides have moderate to poor activity against *P. multocida* strains in vitro, and the organism is resistant to vancomycin and clindamycin. Azithromycin has greater activity against *P. multocida* than erythromycin. *P. multocida* strains are very susceptible to fluoroquinolones and oxazolidinones, but clinical data regarding the use of chemotherapeutic agents are limited. Animal isolates of *P. multocida* are often tetracycline-resistant due to presence of a transposon-associated *tet(H)* tetracycline resistance determinant. At the present time, penicillin and the expanded-spectrum parenteral cephalosporins remain the agents of choice for treatment of infections caused by *P. multocida*.

Pasteurella dagmatis, Pasteurella canis,* and *Pasteurella stomatis. *P. dagmatis, P. canis,* and *P. stomatis* are members of the oral microbiota of dogs, and *P. dagmatis* is also found in the feline oropharynx. Human infections are associated with bites and scratches from these animals. *P. dagmatis* is a rare cause of bacteremia and endocarditis; in one case, endocarditis was complicated by vertebral osteomyelitis.[349,1111,1211] This patient was a 55-year-old woman who worked in an animal welfare agency and had sustained multiple cat bites and scratches from strays.[1211] *P. dagmatis* bacteremia was also documented in a 50-year-old diabetic man who developed *P. multocida* cellulitis of the toe and bacteremia 1 year earlier; at that time, his infection was traced to his dachshund, who had licked an open foot blister.[410] During a second hospitalization, *P. dagmatis* was isolated from blood cultures; this time the isolate was traced to his Yorkshire terrier! Chronic pneumonia due to *P. dagmatis* and *Neisseria canis* were documented in a 66-year-old man, who was a poodle owner with COPD.[20] Spontaneous bacterial peritonitis and peritoneal dialysis–associated peritonitis caused by *P. dagmatis* have also been reported.[72,1318] In 2009, Guillard and colleagues reported on the recovery of *P. dagmatis* from a dog-bite wound; the organism was misidentified as *P. pneumotropica* by the Vitek 2 system.[524]

Both *P. canis* and *P. stomatis* have been isolated from infected dog-bite wounds.[557,1044] *P. canis* strains are divided into two biotypes: biotype 1 is found in the oral cavity of dogs, whereas biotype 2 has been recovered from calves.[926] In a study

conducted by Holst and colleagues, 28 of 159 strains examined were identified as *P. canis*; all of these were biotype 1 strains from dog-bite wounds.[601] Ten isolates were identified as *P. stomatis*, eight from dog-bite wounds and two from abscesses. In the eight *P. stomatis* wound infections, *P. multocida* and *P. canis* were co-isolated with *P. stomatis*. *P. dagmatis*, *P. canis*, and *P. stomatis* are susceptible to penicillins, cephalosporins, aminoglycosides, tetracyclines, fluoroquinolones, and SXT.

[Pasteurella] *Species Incertae Sedis: Clinical Significance, Identification, and Antimicrobial Susceptibility*

[*Pasteurella*] *aerogenes.* [*P.*] *aerogenes* is found among the oropharyngeal/intestinal microbiota of swine. Rare human infections have resulted from bites, tusk wounds, or secondary to the occupational exposures to pigs and boars.[386] This organism is a cause of abortion and stillbirth in pigs, dogs, and rabbits. [*P.*] *aerogenes* was isolated from the ears and throat of a stillborn child delivered by a women during her 31st week of pregnancy; the organism was also found in vaginal cultures following delivery.[1254] The woman worked on a pig farm in Denmark. Quiles and colleagues reported cervical vertebral osteomyelitis caused by [*P.*] *aerogenes* in a previously healthy 62-year-old man.[1054] [*P.*] *aerogenes* was also recovered from peritoneal dialysate fluid of a 14-year-old girl whose pet hamster had chewed on the dialysis tubing.[452] [*P.*] *aerogenes* grows as smooth, convex, circular, nonhemolytic colonies on sheep blood agar and also grows on MacConkey agar. [*P.*] *aerogenes* is indole-negative and urease-positive, and most isolates produce ornithine decarboxylase. This species is "aerogenic," meaning that gas is produced from glucose during fermentation. [*P.*] *aerogenes* isolates from human specimens have been susceptible to ampicillin, cephalosporins, aminoglycosides, ciprofloxacin, and tetracycline.

[*Pasteurella*] *pneumotropica.* [*P.*] *pneumotropica* is part of the microbiota of the respiratory tract of dogs, cats, rats, and mice. Humans become infected via traumatic exposure via dog and cat bites. Human infections attributed to [*P.*] *pneumotropica* include meningitis, bacteremia with shock, bone and joint infections, wound infection, cellulitis, and upper respiratory tract infection.[450,465,895] Bilateral interstitial pneumonia

due to [*P.*] *pneumotropica* was documented in a 27-year-old person with AIDS who lived with several dogs.[317] [*P.*] *pneumotropica* peritonitis resulting from contamination of dialysis tubing by a pet hamster was reported in a patient receiving continuous ambulatory peritoneal dialysis.[195] [*P.*] *pneumotropica* has been rarely recovered from wound drainage, bone, joint fluid, throat swabs, urine, pleural fluid, and blood. After 24 hours' incubation, colonies of [*P.*] *pneumotropica* on sheep blood agar are variable in size (0.5 to 1 mm in diameter), smooth, convex, and nonhemolytic. They are urease-positive, indole-positive, and ornithine decarboxylase-positive; the last two tests help to differentiate [*P.*] *pneumotropica* from *Actinobacillus ureae*, which is negative for these two reactions. Some strains of [*P.*] *pneumotropica* grow on MacConkey agar. The positive urease test and differential reactions for maltose and mannitol help to differentiate this organism from *P. multocida*.

[*Pasteurella*] *bettyae*. [*P.*] *bettyae* (formerly CDC group HB-5, [*P.*] *bettii*) has been isolated from the human female genitourinary tract and related specimens (i.e., amniotic fluid). In 1989, a cluster of five patients with urethritis, pelvic inflammatory disease, or Bartholin's gland abscesses was identified in Tennessee; [*P.*] *bettyae* was isolated as the etiologic agent.[80] This outbreak suggested that [*P.*] *bettyae* may be a sexually transmitted pathogen. In a study performed in Rwanda, [*P.*] *bettyae* was isolated from 25 (3.6%) of 675 patients (204 women and 471 men) with genital ulcer disease, but from only one of 983 patients without genital ulcer disease.[145] Of 145 men with a urethral

discharge but without genital ulcers, [*P.*] *bettyae* was isolated from one man. In 1996, [*P.*] *bettyae* was reported as the cause of peripartum bacteremia in a 25-year-old woman and as the agent of a fatal pneumonia and pleural effusion in a 40-year-old man with HIV infection.[909,1177] [*P.*] *bettyae* grows on both blood agar and chocolate agar; growth on MacConkey agar is variable. After 24 hours' incubation in a CO_2 environment, colonies are pinpoint, nonhemolytic, smooth, and white. The organism is oxidase variable or delayed, and the catalase reaction is negative. Nitrate is reduced to nitrite, but not to nitrogen gas, and urease is not produced. Acid is formed from glucose and mannose, but not from maltose, sucrose, lactose, mannitol, and xylose. The organism produces indole after overnight incubation in tryptone broth; indole formation may be slight; so xylene extraction of the broth and use of Ehrlich's indole reagent may be required for indole detection. [*P.*] *bettyae* isolates are susceptible to penicillins, cephalosporins, monobactams, carbapenems, fluoroquinolones, aminoglycosides, and SXT. In the Rwanda study, 7 of 24 isolates were ampicillin-

resistant because of β-lactamase production.[145]

[*Pasteurella*] *caballi*. [*P.*] *caballi* inhabits the upper respiratory tract of horses and swine, and has been isolated in pure and mixed culture from equine pneumonia, peritonitis, equine and porcine endocarditis, wounds, abscesses, and genital tract infections.[271,277,1148] Documented human infections caused by [*P.*] *caballi* infection include an inflammatory, fluctuant finger lesion that occurred without any previous traumatic injury in a 28-year-old veterinarian who worked with horses, and from a horse-bite wound infection.[133] [*P.*] *caballi* strains are broadly susceptible to antimicrobial agents; some strains, however, are resistant to penicillin G and sulfonamides.

***Avibacterium* ([*Pasteurella*]) *gallinarum*.** [*P.*] *gallinarum* was reclassified in the new genus *Avibacterium* as *A. gallinarum* in 2005.[138] *A. gallinarum* inhabits the respiratory tract of domestic fowl. The first report of a human infection with *A. gallinarum* appeared in 1995, when it was recovered from blood cultures of a 12-year-old Saudi man who developed endocarditis 10 years after surgical repair of a ventricular septal defect.[16] This isolate was susceptible to penicillin, ampicillin, and cefotaxime; the patient responded to 6 weeks of therapy with the last two agents. The patient did not report any bites, scratches, or contact with any animals. A second report of a human infection appeared in 1999 from Japan, when *A. gallinarum* was recovered from blood cultures of a 34-year-old man with acute gastroenteritis. The isolate was susceptible to penicillins, cephalosporins, macrolides, carbapenems, fluoroquinolones, and aminoglycosides; the patient responded to cefazolin therapy. He had developed gastroenteritis 2 days after eating chicken at a barbecue, and the authors suggested that this meal may have been the source of *A. gallinarum*.[54] The identity of the isolates in these two case reports has been questioned since details on phenotypic characteristics were either not included or the data provided were not sufficient for accurate identification.[451] In 2002, *A. gallinarum* was isolated from blood, urine, and CSF of a 4-day-old neonate as a result of a septic home delivery.[7]

Mannheimia *Species (Formerly the* "Pasteurella haemolytica/Pasteurella granulomatis" *Complex)*

P. haemolytica strains are recognized as prominent pathogens in domesticated animals, causing severe disease and major economic losses in cattle, sheep, swine, and poultry industries. Historically, *P. haemolytica* strains were divided into biotypes designated A (cattle-associated) and T (sheep-associated). Biotype A strains produced acid from arabinose but not trehalose, while biotype T strains produced acid from trehalose but not arabinose. These biotypes were each divided into 17 serotypes: serotypes 1, 2, 5

to 9, 11 to 14, 16, and 17 belonged to biotype A and serotypes 3, 4, 10, and 15 belonged to biotype T. In 1985, *P. haemolytica* sensu stricto was excluded from the genus *Pasteurella* based on DNA–DNA hybridization. DNA–rRNA hybridization confirmed this exclusion from the *Pasteurella, Haemophilus, and Actinobacillus* genera.[926] Genotypic investigations of trehalose-positive "*P. haemolytica*" (biotype T) strains resulted in their reclassification as *Pasteurella trehalosi*, despite marginal genetic affinity with the genus *Pasteurella*. Organisms classified as *Pasteurella trehalosi* have recently been reclassified in the new genus *Bibersteinia* as *Bibersteinia trehalosi*.[137]

Examinations of diverse, trehalose-negative (biotype A) "*P. haemolytica*" strains by phenotypic criteria, multilocus enzyme electrophoresis, ribotyping, and 16S rRNA sequencing resulted in the proposal of a new genus, *Mannheimia*, to accommodate the trehalose-negative isolates of the "*P. haemolytica*" complex and "*P. granulomatis.*"[330,1084] Based on 16S rRNA sequencing, four distinct, related clusters corresponding to five new species were delineated in genus *Mannheimia*: *M. haemolytica* and *M. glucosida* (cluster I), *M. ruminalis* (cluster II), *M. granulomatis* (cluster III), and *M. varigena* (cluster IV).[46] These new species are most closely related to genus *Actinobacillus* (particularly *A. lignieresii*) and *B. trehalosi* ("*P. trehalosi*"). *Mannheimia* species can be separated from the genus *Pasteurella* by failure of the former species to produce acid from mannose and from the animal-associated *Actinobacillus* species by being urease-negative. *Mannheimia* species are mannitol-positive, which separates them from members of the genus *Haemophilus*, which are mannitol-negative. *M. haemolytica* strains are the cause bovine pneumonic pasteurellosis or "shipping fever." This infection is triggered by herd overcrowding, stress, immunosuppression, and concomitant viral respiratory tract infection. *M. haemolytica* strains that cause disease in cattle produce a leukotoxin that is species-specific, having cytolytic activity against ruminant lymphoid cells. The leukotoxin is a 105 to 108 kDa protein that belongs to the RTX toxin family.[1126,1224] At low concentrations, this leukotoxin activates neutrophils, induces formation of inflammatory cytokines, and causes cytoskeletal changes that lead to apoptosis. The toxin also causes pore formation in the cell membranes, leading to cell swelling and lysis.[1224] In vitro, the leukotoxin causes cytopathic changes in the bovine alveoli, where it is associated with membranes of degenerating macrophages and neutrophils. Leukotoxin-negative mutants of *M. haemolytica* have reduced virulence in animal models.[1247]

Members of the former "*P. haemolytica*" complex are rarely isolated from humans; infections have resulted from occupational or recreational animal exposures. Rivera and colleagues

reported an aortic graft infection due to both "*P. haemolytica*" biotype A (*M. haemolytica*) and group C β-hemolytic streptococci in a 50-year-old man.[1091] Yaneza and colleagues reported a patient with endocarditis who had no contact with cattle or other farm animals.[1395] *M. haemolytica* isolates are susceptible to penicillin, ampicillin, amoxicillin clavulanate, macrolides, aminoglycosides, and fluoroquinolones, but are resistant to linezolid. During the study of genus *Pasteurella* systematics using *sodA* gene sequences, an isolate of *M. haemolytica* that was recovered from a sputum specimen from a human was shown to be the first human isolate of *Gallibacterium anatis* (Table 9-8). Another previously undescribed *Mannheimia* species, *Mannheimia succiniciproducens*, was isolated from bovine rumen specimens in 2002.[772]This species was characterized genotypically, but phenotypic characteristics are not available. Phenotypic characteristics that are useful for identification of *Mannheimia* species are presented in Table 9-9.

Genus *Actinobacillus*

Taxonomy

The genus *Actinobacillus* currently includes 22 species and unnamed taxa: 19 of these are associated with the respiratory and genital tracts of animals. *A. pleuropneumoniae, A. equuli* subspecies, and *A. suis* are associated with serious animal diseases, and only two species—*A. ureae* and *A. hominis*—have been isolated from human infections. Based on 16S rRNA phylogenetic analysis, DNA–DNA hybridization data, and phenotypic characteristics, the genus *Actinobacillus* sensu stricto includes *A. lignieresii*,*A. pleuropneumoniae*, *A. equuli* subsp. *equuli*, *A. equuli* subsp. *haemolyticus* (Bisgaard taxon 11), *A. suis*, *A. arthriditis* (sorbitol-positive Bisgaard taxon 9), *A. ureae, A. hominis*, *Actinobacillus* genomospecies 1, *Actinobacillus* genomospecies 2 (sorbitol-negative *A. arthriditis*), and Bisgaard taxa 8 and 26.[266] Based on phylogenetic comparisons of the 16S rRNA, other "species" assigned to the genus *Actinobacillus* may be subcategorized into seven monophyletic groups representing miss-named taxa and do not truly belong to genus *Actinobacillus*. These phyla include the "Rodent group" ([*A.*] *muris*),[131] the "Succinogenes-Seminis group" ([*A.*] *seminis*, [*A.*] *succinogenes*), the "Rossii group" ([*A.*] *rossii*, [*A.*] *porcinus*), the "Capsulatus group" ([*A.*] *capsulatus*), the "Parasuis group" ([A.] indolicus), and the "Delphinicola group" ([*A.*] *delphinicola*, [*A.*] *scotiae*). [*A.*] *minor* (from swine) has no group affiliation, but is closely related to the core *Actinobacillus* genus and to another proposed species, "[*A.*] *porcitonsillarum*."[1260] The revised taxonomy of

genus *Actinobacillus* sensu stricto based on 16S rRNA sequencing is supported by alternate gene sequence comparisons (e.g., sequencing of a 426 base pair fragment of the *infB* gene, which encodes translation initiation factor 2).[955] Members of the genus *Actinobacillus* sensu stricto and *Actinobacillus* species incertae sedis are presented in Box 9-6.

Clinical Significance of Actinobacillus *Species*

Actinobacillus ureae. *A. ureae* is an uncommon commensal of the human respiratory tract and a rare isolate from human infections, including bacteremia, endocarditis, meningitis, bone marrow infection, septic arthritis, pneumonia, conjunctivitis, and peritonitis.[77,335,400, 674,691,709,950,1350] In most cases, an underlying condition is present, such as postsurgical infection, diabetes, periodontal disease, emphysema, and alcohol-associated cirrhosis. Patients with meningitis have been associated with previous skull trauma and with underlying disease, including HIV infection.[674]

Actinobacillus hominis. *A. hominis* is a rare human isolate that has been recovered from sputum and empyema fluid specimens of individuals with chronic lung disease. Wust and colleagues reported on two patients with hepatic failure due to chronic hepatitis B infection and cirrhosis, respectively, in which *A. hominis* septicemia occurred as the terminal event.[1374] In a study conducted in Copenhagen on 36 patients with *A. hominis,* lower respiratory tract infection and/or bacteremia, alcoholism, cardiovascular disease, drug addiction, psychiatric disorders, and COPD were associated conditions.[456]

Other *Actinobacillus* Species. Human infections with animal species of *Actinobacillus* usually occur as a result of animal-related trauma. *A. lignieresii*, *A. equuli*, and *A. suis* have been recovered from human clinical specimens, including horse and sheep bite wounds, joint fluid, blood, and sputum.[71,108,403,1015] The remaining *Actinobacillus* species have not been isolated from human clinical specimens.

Cultural Characteristics of Actinobacillus *Species*

Members of the genus *Actinobacillus* are aerobic, microaerophilic or facultative, gram-negative bacilli or coccobacilli that have an optimal growth temperature of 35°C to 37°C. All members of the genus are nonmotile gram-negative bacilli, urease-positive, indole-negative, ALA-porphyrin test–positive, and phosphatase-positive. All species produce acid from glucose (no gas), maltose, sucrose, fructose, and dextrin, and nitrate is reduced to nitrite and to nitrogen gas. All species in the genus are methyl red-negative and do not produce acetoin, and most species are catalase- and oxidase-

positive. The phenotypic characteristics of *A. ureae* and *A. hominis* are shown in Table 9-10, whereas the characteristics of *Actinobacillus* species isolated from animals are found in Table 9-11.

A. ureae is a pleomorphic gram-negative bacillus; on staining, some strains form distinct filaments. After 24 hours of growth on blood agar in a CO_2-enriched atmosphere, colonies are smooth, 1 mm in diameter, and nonhemolytic. Some isolates may appear mucoid. The organism is oxidase-positive, is catalase-positive, reduces nitrate to nitrite, does not grow on MacConkey agar, and hydrolyzes urea rapidly. Indole is not produced, and the lysine and ornithine decarboxylase, as well as the arginine dihydrolase reactions, are negative. Acid is produced from glucose, maltose, sucrose, and mannitol; no acid is produced from lactose and xylose. The other biochemically similar *Actinobacillus* species may be differentiated from *A. ureae* by acid production from additional carbohydrates and by the abilities of the former species

514

BOX 9-6

Members of the Genus *Actinobacillus* Sensu Stricto and *Actinobacillus* Species Incertae Sedis

Actinobacillus Species Sensu Stricto	Animal Habitats and Diseases
Actinobacillus lignieresii	*A. lignieresii* is a commensal of the oral cavity and pharynx of ruminants (cattle and sheep). Disease results from traumatic inoculation of the organisms into submucosal tissues, with formation of granulomas in the head, neck, gums, and tongue ("wooden tongue" disease of cattle). Dissemination via the lymphatics results in granulomas in the lungs. This organism also causes pneumonic and cutaneous infections in sheep and other ungulates.
Actinobacillus equuli subsp.*equuli*	*A. equuli* causes a equine disease called "sleepy foal disease" ("joint ill").[270,363] The foal acquires the organism from the mare, who may carry the organism asymptomatically in the mouth, respiratory, and alimentary tracts. In the foal, nephritis is the principal associated disease. *A. equuli* can also cause bacteremia, endocarditis, peritonitis, lower respiratory tract infection, and genital tract infection, leading to abortion in adult animals.[1] The organism has also been isolated from swine.
Actinobacillus equuli subsp.*haemolyticus*	This organism was originally described as a hemolytic variant of *A. equuli*, and the species was subsequently amended to include two subspecies.[270] This subspecies is also associated with bacteremia, peritonitis, nephritis, osteomyelitis, endometritis, abortion, and arthritis in horses. RTX toxin activity that has been detected in subspecies *haemolyticus*, but not in subspecies *equuli,* is active against equine lymphocytes. Like *A. pleuropneumoniae*, this species is CAMP test-positive.
	A. pleuropneumoniae is an important agent that causes a highly contagious pneumonia and chronic lung disease in pigs.[1124]Disease usually occurs in outbreaks among animals lacking immunity to the organism. The infection is a necrotizing pneumonia associated with severe congestion and hemorrhage into the lung parenchyma. The most significant virulence factor of *A. pleuropneumoniae* is the production of Apx toxins (pxI, ApxII, and ApxIII), which are

Actinobacillus pleuropneumoniae	encoded by RTX (repeat in toxins) genes. The RTX family of cytolysins also includes *E. coli* hemolysin and the leukotoxin of *Mannheimia haemolytica*, and similar genes are also found in *A. suis* and *A. equuli* subsp. *haemolyticus*. The Apx toxins are cytotoxins that are able to lyse porcine macrophages in vitro and in vivo. *A. pleuropneumoniae* requires V factor for growth and, therefore, does not grow on sheep blood agar. A V-factor-independent biotype of this organism has been described that does not cause overt disease in pigs. The organism also produces a hemolysin that is responsible for β-hemolysis on V-factor-supplemented blood agar and CAMP test reactivity with *Staphylococcusaureus*.
Actinobacillus arthriditis	*A. arthriditis* is isolated from the oropharynx of healthy horses and as a cause of septicemia and arthritis in ill horses.[268]
Actinobacillus suis	This species causes septicemia, pneumonia, gastroenteritis, and arthritis in suckling and newly weaned piglets.[1124]
Actinobacillus ureae	This species is a rare cause of respiratory tract infections in humans (see text).
Actinobacillus hominis	This organism is implicated as a rare cause of respiratory tract infections in humans (see text).
"*Actinobacillus porcitonsillarum*"	This newly described V-factor-dependent organism has been isolated from porcine tonsil, lung, and liver tissues. Based on 16S rRNA sequence analysis, this "species" is most closely related to *A. pleuropneumoniae*.[1260]This organism was originally thought to be nonpathogenic, but in 2007, "*A. porcitonsillarum*" was isolated from the hilar lymph nodes and lung tissue of a slaughter pig with granulomatous lymphadenitis and pneumonia.[970] This organism is β-hemolytic and CAMP test-positive.
Actinobacillus genomospecies 1	This genomospecies is a cause of stomatitis in horses.[268]
Actinobacillus genomospecies 2	This unnamed species causes arthritis and septicemia in horses.[268]
Bisgaard taxon 8	This taxon has been recovered from the respiratory tracts of guinea pigs.[136]
Bisgaard taxon 26	This taxon is implicated as a cause of sinusitis and sepsis in ducks.
Actinobacillus Species	

Incertae Sedis	
[*Actinobacillus*] *muris*	[*A.*] *muris* was isolated from the oropharynges of rodents.[136]

516

[*Actinobacillus*] *seminis*	[*A.*] *seminis* was originally isolated from rams with epididymitis, and may be a cause of infertility in these animals.[1202]
[*Actinobacillus*] *succinogenes*	This "species" has been isolated from cattle.[523]
[*Actinobacillus*] *rossii*	This "species" was originally isolated from the vaginas of postparturient sows.[272,1202]
[*Actinobacillus*] *porcinus*	This V-factor-dependent organism has been isolated from the respiratory tracts of swine.[904]
[*Actinobacillus*] *capsulatus*	This species is a cause of granulomatous arthritis and sepsis in rabbits, hares, and hamsters.
[*Actinobacillus*] *indolicus*	This V-factor-dependent, indole-positive "species" was isolated from the upper respiratory tract of pigs.[904]
[*Actinobacillus*] *scotiae*	This organism was originally isolated from sea mammals.[438]
[*Actinobacillus*] *delphinicola*	This "species" was originally recovered from sea mammals.[436]
[*Actinobacillus*] *minor*	[*A.*] *minor* is a V-factor-dependent isolate found in the respiratory tracts of pigs.[904]

to grow on MacConkey agar. Molecular methods have been used for diagnosis of *A.*

ureae meningitis. *A. ureae* strains are susceptible to most antimicrobial agents, including penicillin, ampicillin, cephalothin, cefoxitin, tetracycline, SXT, and the aminoglycosides.

A. hominis forms nonhemolytic mucoid and nonmucoid colonies on sheep blood agar. The organism is positive for the oxidase, catalase, urease, and ONPG reactions, but negative for indole. Acid is produced from a wide variety of carbohydrates; these characteristics are helpful for differentiation of *A. hominis* from *A. ureae*.

Brucella Species

Introduction

Brucellosis (infection with *Brucella* species) is worldwide in distribution and has been known historically as undulant fever, Bang's disease, Gibraltar fever, Mediterranean fever, and Malta fever. The organism was first isolated in 1887 by Sir David Bruce, who recovered a suspect organism from splenic cultures of British soldiers dying of Malta fever. Later, it was found that milk, cheese, and other foods made with goats' milk were the sources of infection for these soldiers. Similar organisms were recovered from cattle, pigs, and humans exposed to these animals and their products. Brucellosis became recognized as a zoonosis of great economic importance and concern to the livestock industry in many parts of the world. At present, brucellosis still afflicts humans and animals in many parts of the world, including southern Europe, the eastern Mediterranean region, the Middle East, the Arabian Peninsula, Central Asia, the Indian subcontinent, Mexico, and Central and South America.[1002] Animal brucellosis has been successfully eradicated from several parts of the world, including North America, Northern Europe, and northwest Asia. Infections that present in these areas usually result from travel to endemic areas, exposure to infected animals, or accidental laboratory-acquired infections. Brucellosis

is transmitted among animals via the gastrointestinal tract, skin, and mucous membranes. Following infection, organisms reach the lymph nodes and bacteremia ensues. In some animals (e.g., *B. abortus* infection in cattle), the organisms proliferate in the uterus and in the mammary glands. Growth of the organism in the chorionic membranes of the pregnant animal leads to abortion. Many animals recover from the infection spontaneously, but continue to shed the bacteria for varying times in urine, vaginal secretions, and milk.

Taxonomy and Epidemiology

Originally, the genus *Brucella* contained six classical species: *B. melitensis*, *B. abortus*, *B. suis*, *B. canis*, *B. neotomae,* and *B. ovis*. In 1985, Verger and colleagues found that isolates belonging to all six species had greater than 90% homology with each other and proposed that all brucellae belonged to a single species (*Brucella melitensis*) and that the recognized species should be regarded as biovars of *B. melitensis* (i.e., *B. melitensis* biovars *melitensis, abortus, suis,* and *canis*).[1300] This proposal was not accepted by the Subcommittee on *Brucella* of the International Committee on Systematic Bacteriology because of biochemical and serologic differences among the species, their divergent host ranges, recognized differences in virulence, and the presence of species-specific genes and proteins. The gravity of *Brucella* infections, the significance of the various agents in agriculture, and the potential for bioterrorism with the various species further supported the decision to retain the traditional classification scheme.[986]Molecular genetic studies (i.e., restriction endonuclease mapping) subsequently revealed gene polymorphisms that were able to differentiate *B. abortus*, *B. melitensis*, *B. suis*, and *B. canis* along conventional species lines, although these methods could not delineate biovars within species. One of the polymorphic genes that help to differentiate species within the brucellae is the *omp2* porin gene, which codes for a 36-kDa outer membrane protein that is responsible for determining susceptibility to the dyes used for conventional species identification. *Brucella* species are members of the family *Brucellaceae* in the order *Rhizobiales* in the α2-subdivision of the *Proteobacteria*.[532] The order *Rhizobiales* also contains the families *Bartonellaceae*, *Rhizobiaceae*,*Phyllobacteriaceae,* and *Aurantimonadaceae. Brucella* species are related to *Agrobacterium*, endosymbiotic *Rhizobium* and *Mesorhizobium* species, *Bartonella* species, *Ochrobactrum* species, and *Phyllobacterium* species, which are free-living chemoautotrophic pathogens of tropical plants. Brucellae are most closely related to *O. anthropi* hybridization group 2, for which the new species name *O. intermedium* has been proposed.[1152,1297] The genetic relatedness of these organisms is so close that *O. anthropi* is reactive in a PCR-based assay that is supposedly "specific" for *Brucella* species.[320]

Studies on the genetic relationships of brucellae have revealed other unique features

of the genus. The genomes of the five major *Brucella* species have been completely sequenced, and are similar in size and gene structure.[1217] The average genome size within the genus is about 3.29 Mb and consists of two circular chromosomes in all species except *B. suis* biovar 3, which has a single chromosome.[665] Chromosome 1 is about 2.11 Mb, and chromosome 2 is about 1.18 Mb in size.[340,341] Each chromosome encodes functions that are essential for replication and survival of the organism, hence their classification as chromosomes and not plasmids. *Brucella* species have no classical virulence-associated genes, do not have capsules or pili, and do not produce any known exotoxins. Plasmids and genetic exchange via transformation or conjugation have not been described in *Brucella* species.[1166]

Brucella species are named for their primary host species and are further subdivided into biovars based on serologic agglutination with "smooth LPS (S-LPS)"-associated antigens M and A (see below). *B. melitensis* is found primarily in goats and sheep, and may also be found in cattle because of indirect contact with infected sheep and goat flocks. This species is divided into three biovars (1 to 3). *B. abortus* is pathogenic for cattle, but can infect sheep, goats, canines, horses, and humans. *B. abortus* includes eight biovars (1 to 7, and 9). *B. suis* contains five biovars: Biovars 1, 2, and 3 are found in swine, while biovar 4 is found in reindeer and caribou in the Arctic regions of North America and Russia and biovar 5 causes infections in small ruminants.*B. suis* biovar 1 has also become established in cattle herds in Brazil and Columbia. *B. canis* strains comprise a single biovar and occur in dogs (especially beagles) in the United States, Mexico, Argentina, Spain, China, Japan, and Tunisia.[1417] *B. ovis* and *B. neotomae* each contain a single biovar and are found in rams and wood rats, respectively. Antigenic variation among existing biovars has been demonstrated for every *Brucella* species, establishing that biovar classifications require further study and expansion. *B. melitensis*, *B. abortus*, and *B. suis* are associated with human disease, with *B. melitensis* considered the most virulent species, followed by *B. suis* and *B. abortus*. *B. canis* rarely causes infections in humans, and reported infections have often been laboratory associated. *Brucella microti*, a new terrestrial *Brucella* species, was described in 2008 based on two isolates recovered from clinical specimens of the common vole *Microtus arvalis* in the Czech Republic.[1153,1155] These strains contained the *omp2a* gene found in marine brucellae (see below), but the *omp2b* gene was similar to those found in terrestrial *Brucella* species. This species has also been isolated from mandibular lymph nodes of red foxes in Austria and from soil specimens.[1154,1155] More recently, a new *Brucella* species, *B. inopinata*, was isolated from a breast implant wound of a 71-year-old woman with symptoms of brucellosis.[333,1156] This isolate was initially called strain BO1. In 2010, another isolate, called BO2, was isolated from a lung biopsy specimen of a 52-year-old Australian man with necrotizing pneumonia.[1256] Phenotypic characteristics suggested a *Brucella*

species, and 16S rRNA gene sequencing was identical with *B. inopinata* (strain BO1). These two *B. inopinata* strains form a distinct phylogenetic cluster in the genus *Brucella*. Finally, in 2009, a novel *Brucella* isolate was recovered from uterine cultures of two baboons who had stillbirths.[1147] Phylogenetic characterization of the organisms confirmed their membership in genus *Brucella*, with the closest relative being *B. ovis*.

During the 1990s, several *Brucella*-like bacteria were isolated from carcasses of marine animals, including seals, porpoises, dolphins, otters, and whales.[175,283,432,638] Isolates from these marine hosts showed more than 77% relatedness to the genus *Brucella* by DNA hybridization.[1299] IS*711*, a genetic insertion element that is found in all *Brucella* species,

520

was also found in marine mammal isolates, and, based on restriction endonuclease mapping and the detection of multiple copies of IS*711*, the species "*Brucella maris*" was proposed for isolates from marine mammals.[283,287] These strains could also be grouped into biovars based on phenotypic and biochemical characteristics.[638] Other investigators examined the *omp2* gene of these strains and identified polymorphisms at that gene locus that supported and aligned with the biovar designations described by Jahans and colleagues.[288] Recognized *Brucella* species contain two *omp2* genes composed of one copy each of *omp2a* and *omp2b*, or two *omp2a* genes. The marine brucellae carry two *omp2b* gene copies, and sequencing of these genes revealed significant heterogeneity among marine isolates, indicating that these organisms encompass more than a single species ("*B. maris*"), as had been proposed.[283,288]Based on these data and consistent with inclusion of preferential hosts in considering taxonomic classification, at least two new species were proposed for organisms included in "*Brucella maris*": *Brucella pinnipediae*, for isolates from seals, and *Brucella cetaceae*, for cetacean isolates.[288] Isolates obtained from aborted bottlenose dolphin fetuses were also characterized, and the name "*Brucella delphini*" was proposed for these isolates.[890] Serologic surveys of seal, porpoise, dolphin, and whale species have shown that antibodies against these *Brucella* species are widely distributed among marine mammals, and molecular analysis has shown that isolates from whales, seals, porpoises, and dolphins are *Brucella* species but differ from each other and from other extant *Brucella* species in many respects, including LPS structure and outer membrane proteins.[98,175,647] Additional studies involving restriction profiles of the genomes of these bacteria recognized three clonal groups that corresponded to specific organisms hosts—seals, porpoises, and dolphins.[157] In 2007, Foster and colleagues proposed two new species—*Brucella pinnipedialis* and

Brucella ceti—for *Brucella* strains with seals and cetaceans as their preferred hosts, respectively.[435] In these hosts, these brucellae cause CNS, liver, lung, and genitourinary tract disease and abortion.[321,433,638] Characterization of strains from marine mammals by traditional *Brucella* biotyping approaches and novel molecular techniques found that strains originating from cetaceans were in two groups with either dolphins or porpoises as the preferred host.[331] These data were consistent with other studies, showing subgroups within the proposed species *B. ceti*.[157,519,636] Strains isolated from seals were in another group corresponding to the proposed species, *B. pinnipedialis*. In the newest edition of *Bergey's Manual of Systematic Bacteriology*, three new species, *Brucella phocae* (seals), *Brucella phocoenae* (porpoises), and *Brucella delphini* (dolphins), are included.[306]

Evidence also suggests that these new species may have extended pathogenic potential. Rhyan and colleagues inoculated six cattle with a *Brucella* isolate from a harbor seal, and found that all animals seroconverted in tests used for detection of *B. abortus* antibodies. Two of the cattle aborted, and the brucellae were isolated from the stillborn fetuses, indicating that these strains are pathogenic for terrestrial mammals as well.[1083] In addition, there have been reports of human infections (i.e., neurobrucellosis) with strains from marine mammals.[173,873,1204] A laboratory technician working with marine isolates manifested symptoms of brucellosis, which was confirmed by isolation and PCR-restriction fragment length polymorphism (RFLP) identification of a marine *Brucella* species. The individual also demonstrated a serologic response to the organism.[173] Two patients from Peru were diagnosed with neurobrucellosis due to marine mammal brucellae as demonstrated by isolation and confirmation by PCR and sequencing.[1204] In 2006, a man from South Auckland, New Zealand, was diagnosed with spinal osteomyelitis; the isolated organism was initially identified as *B. suis*, but was found to resemble a *Brucella* species originating from bottlenose dolphins by PCR-RFLP and sequencing of the *bp26*, IS*711*, and *omp* genes.[873] Additional work is needed to delineate the phylogenetic relationships among these new species, to ascertain their relationships with currently recognized brucellae, and to determine the virulence factors associated with animal and human infections.

In the United States, the incidence of human brucellosis has declined steadily as a result of control measures implemented in the livestock industry. These measures include vaccination of young animals and slaughter of sick animals or older animals with serologic evidence of infection. At the time that the Federal-State Cooperative Brucellosis Eradication Program and routine dairy pasteurization began in 1945, over 6,000 human cases were reported to the CDC annually. During the 1970s, brucellosis in the United States was attributable to *B. suis* infections among abattoir workers. In 1981, the reported annual domestic incidence of human brucellosis had dropped to 185 cases, and since that time, less than 200 cases per year have been reported. In

2007, for example, 131 cases of brucellosis were reported in the United States, and states with the highest numbers of reported cases were California, Texas, and Florida.[222] Human brucellosis is probably underdiagnosed and underreported, with estimates that at least 25 cases go unrecognized for every case that is diagnosed. Human consumption of sheep or goat milk or contaminated meat containing *B. melitensis* is a principle source of human brucellosis worldwide.[342,1239,1317] Domestically acquired *Brucella* infections have been diagnosed among individuals living in Texas and California who have ingested Mexican cheese prepared from unpasteurized goat's milk.[260] Most cases in the northern states largely represent imported disease acquired through international travel or through the consumption of imported, contaminated food. In the western, south central, mountain, and Pacific states, the disease affects largely Hispanic populations in areas bordering Mexico.[368] With increasing availability and popularity of international travel, many patients with brucellosis that are US residents have visited countries where the organism is endemic in ovine/bovine herds and, consequently, is present in raw, unpasteurized dairy products. Infection partly reflects participation in aspects of foreign cultures that are so appealing to travelers (i.e., "living like the natives do"). Box 9-7 includes a brief discussion on the worldwide epidemiology of brucellosis.

Occupational exposure may occur in abattoir workers, farm workers, veterinarians, ranchers, and meat-packing employees; these individuals acquire infection by contact with infected animals, products of conception, or body fluids from infected animals. Human-to-human transmission is rare, but sexual transmission of *Brucella* has been reported.[840,1375] In 2007, human-to-human transmission was documented in an

BOX 9-7

Global Epidemiology of Brucellosis

Brucellosis is found throughout areas of both the eastern and western hemispheres. In Latin America, Mexico is an area of high endemicity, and the disease occurs mostly in the northern regions bordering the United States, and the northwest and north central regions.[813] *B. melitensis* biovars 1-3, *B. abortus* biovars 1, 2, and 4-6, *B. suis* biovar 1, *B. canis,* and *B. ovis* have been isolated from animals in Mexico. *B. abortus* is found mainly in cattle herds, although coexistence of cattle and goat herds had resulted in some *B. melitensis* infections among cattle. Human brucellosis in Mexico is associated with both occupational exposure and infection via contaminated dairy products, as more than 35% of cow's milk and 85% of goat's milk are consumed

unpasteurized.[813]Among reported human infections in Mexico, 93% are due to *B. melitensis* of caprine origin, 5% are due to *B. melitensis* of bovine origin, 1.5% are caused by *B. abortus* of bovine origin, and 0.5% are caused by *B. suis* of bovine origin. Brucellosis is found throughout Central America, including Guatemala, Belize, Honduras, El Salvador, Nicaragua, Costa Rica, and Panama. Infection rates in cattle herds range from 10% to 25%. Bovine and swine diseases due to *B. melitensis* and *B. suis*, respectively, are found in all Central American countries, and ovine and caprine brucellosis has been found in Guatemala.[908]Guatemala and Costa Rica have the highest disease prevalence, while El Salvador has the lowest prevalence. In South America, brucellosis is not endemic throughout the continent.*B. melitensis* is found predominantly in Peru and west Argentina.*B. abortus* is found in cattle populations in east Argentina and several other countries in South America. During the period from 1994 through 2006, *B. suis* emerged along with *B. melitensis* as the most frequent isolate in Argentina, with a concomitant decrease in the prevalence of *B. abortus*.[809]In Argentina, the estimated prevalence of caprine disease ranges from 20% to 25%, while the prevalence of bovine infection ranges between 11% and 13%.[1133] In Venezuela, the prevalence of brucellosis in cattle and buffalo herds is about 10%, and efforts are underway to control and eradicate the disease.[446]Although little data are available due to under-reporting, Brazil remains at risk for *B. abortus* as this country has the largest commercial cattle population in the world.

In the European Union and western Europe, many countries have successfully eradicated brucellosis, including Sweden, Norway, Denmark, Finland, Austria, the Netherlands, and Great Britain. Germany, Belgium, Luxembourg, and Switzerland are also considered *Brucella*-free countries.[1002]France has successfully eradicated brucellosis, and infections seen there are due to localized outbreaks associated with consumption of dairy products imported from Spain. Spain is considered an endemic area and has a high incidence of brucellosis, but regions within the country have noted substantial, consistent declines in the number of human infections beginning in 1997. Portugal borders the high endemicity regions of Spain, but the rest of Portugal has noted declines in disease since 1999. Disease incidence in Italy showed a steady decline over the past 30 years, but since 2003 this decline has not occurred uniformly throughout Italy. Few infections are reported from northern and central Italy, whereas most infections occur in southern Italy and in Sicily.[846]This disparity in Italy reflects the distribution of wealth and access to health care in northern versus southern regions of the country. Greece, Macedonia, and Albania remain regions of high endemicity, with the last two countries having the highest disease incidence in Europe.[1238]Prior to the 1990s, increases in disease prevalence in Greece were due to the illegal importation of infected animals or dairy products into Greece from Albania. In Greece, cattle herds are infected with *B. abortus* and *B. melitensis*.[1238]By 1995, after internal turmoil and civil wars that resulted in the formation of new countries, the disease was recognized to be highly endemic in Turkey, Croatia, and the

former Yugoslav Republic of Macedonia. The disease is found throughout the Balkan Peninsula, and increases in disease have been seen in Kosovo and Bosnia-Herzegovina.[963] Bulgaria was free of brucellosis from 1958 until 2005, when a reemergence of disease was documented.[1123]

In Asia, the Middle East is a highly endemic area; five of the ten countries with the highest incidence of human brucellosis are in this region. Ongoing wars and famines, lack of infrastructure for surveillance, and unregulated animal transportation across open borders in this part of the world contribute to the lack of disease control and the spread of both animal and human disease.[541] Syria has the highest annual incidence of the disease worldwide, and large numbers of patients becoming infected each year in Saudi Arabia, Turkey, Iran, Afghanistan, Oman, and the United Arab Emirates. In Kuwait, high disease incidence was seen prior to the 1990s due to widespread disease in cattle. During the 1991 Iraqi invasion, large die-offs of livestock resulted in substantial decreases in human infections, but this has not been maintained. Disease control in Jordan, Lebanon, and Israel is improving, although increased numbers of cases have been reported in Palestine in recent years. Among the republics of the former Soviet Union, seven (Kyrgyzstan, Tajikistan, Kazakhstan, Uzbekistan, Armenia, Georgia, and Turkmenistan) are among the top 25 countries with the highest incidence of the disease worldwide, and neighboring Mongolia is ranked second in disease incidence.[1317]Political and social upheaval in this region has resulted in loss of control over livestock populations and has precluded disease recognition and the implementation of interventions that would

522

reestablish disease control. In China, the incidence of human brucellosis declined from 1964 through 1994 as a result of a large vaccination program. Since then, disease in humans and animals has increased, with *B. melitensis*, *B. abortus,* and *B. suis* prevailing in various provinces.[347] Even though the prevalence of brucellosis in China is increasing, a national surveillance network has been put in place to quarantine and eliminate infected animals and to vaccinate domesticated animals.[347] Disease incidence in South Korea is increasing as well. On the Indian subcontinent, brucellosis is an increasing and significant public health problem.[836]Residents, particularly in rural areas, live closely with domestic and wild animal populations, and the organisms are widespread among cattle, goats, sheep, pigs, and canines. Large outbreaks have occurred on dairy farms, leading to infected milk, abortion, and stillbirth; dairy personnel have high rates of infection as determined by serosurveys. Although B. *abortus* is found in India,

B. melitensis is the predominant species recovered from humans, goats, sheep, and milk samples.

Brucellosis is endemic in North Africa, and Algeria has the tenth highest annual incidence worldwide.*Brucella* exists throughout sub-Saharan Africa, but there is little data regarding its prevalence, and health networks, ongoing surveillance, and vaccination programs are nonexistent. Outbreaks of brucellosis in Uganda involving transmission from cattle to humans have been recognized, but proceed uncontrolled due to lack of resources. The high incidences of malaria, HIV, and tuberculosis eclipse the importance and impact of brucellosis on the African subcontinent.[844]Human brucellosis has been documented in Nigeria, Kenya, Ethiopia, Tanzania, Uganda, Cameroon, Burkina Faso, Mali, Namibia, Swaziland, Chad, and the Republic of the Congo. Little data are available regarding disease incidence in Egypt, Morocco, Tunisia, and Libya.

obstetrician who performed an emergency cesarean delivery on a woman in her 24th week of pregnancy.[884] A pediatric resident and a neonatologist who had provided care to the premature infant were also subsequently diagnosed with *Brucella* infection. The same organism was recovered from the mother and from her congenitally infected neonate. *Brucella* infections have been transmitted via blood transfusions, and bone marrow and kidney transplants from infected donors.[18,402,731,1408] Neonatal infection can be acquired by the transplacental route, during delivery or via the ingestion of contaminated breast milk.[997]

Brucella species also pose an occupational hazard to laboratory workers because of laboratory accidents, spills, or inappropriate manipulations of specimens or cultures containing *Brucella* organisms.[220] Infections have occurred from sniffing plated cultures, spilling blood culture bottles, mucocutaneous exposure to organism suspensions, aerosols generated from broken centrifuge tubes, and performance of culture work on the open benchtop.[425,1092] In 2000, seven laboratory-acquired infections caused by *B. melitensis* were reported at a medical center in southern Israel.[1389] This outbreak was caused by three different *B. melitensis* biovars, indicating multiple exposures, and the infections occurred over a 3-month period when 10% of 530 positive blood cultures grew *Brucella* species. On investigation, no sources or breaches in laboratory safety were found. Brucellosis was also diagnosed in 7 hospital employees (6 bacteriology technologists and a pathologist) over a 9-year period at a hospital in Riyadh, Saudi Arabia.[881] Infections were diagnosed by serology, along with compatible clinical signs and symptoms. Resulting morbidity included relapse in two patients and complications (septic phlebitis, infected prostheses, epididymo-orchitis, and lumbar spondylitis) in four others. Infections in the

technologists were traced to the handling of *Brucella* cultures. In a report from Italy, 12 laboratorians became infected after accidental breakage of a centrifuge tube.[425] Although the laboratories involved in these accidents used class II biologic safety cabinets for manipulations of specimens and cultures, the risk for laboratory-acquired infections is significant, particularly in laboratories located in endemic regions. Strict adherence to safety protocols and procedures in all laboratories and vigilance and care when handling specimens/cultures is an absolute requirement for prevention of laboratory-acquired infections of any kind. Biosafety level 3 (BSL-3) practices, containment equipment, and facilities are recommended for all manipulation of *Brucella* cultures.[1279]

Virulence of Brucella *Species*

Brucella species are facultative intracellular organisms, and their disease spectrum is partially explained by their ability to evade host defense mechanisms by taking up an intracellular existence. *Brucella* species have no classical virulence-associated genes and do not produce any classical virulence factors such as capsules, pili, fimbriae, exotoxins, cytolysins, or hemolyins.[447,1167] These organisms do not harbor plasmids or lysogenic bacteriophages, and do not exhibit genetic exchange mechanisms. *Brucella* species undergo antigenic variation or "dissociation"; the colonies switch from a "smooth" to a "rough" morphology, which results in loss of virulence and diminished reactivity with *Brucella*-specific antibodies. Antigenic variation results from decreased expression of genes encoding the glycosylation of the polysaccharide moieties of the cell wall LPS. Organisms that are in the smooth phase possess an S-LPS and are resistant to intracellular killing by macrophages, monocytes, and PMNs.[19] The LPS of *B. melitensis*, *B. abortus*, and *B. suis* contains two major antigenic determinants called A (for "Abortus") and M (for "Melitensis"). In addition to providing markers for biovar determinations, these molecules also have a role in organism virulence. Monoclonal antibodies against S-LPS are protective in animal models, and smooth isolates that have lost S-LPS have attenuated pathogenicity for mice. The S-LPS O (somatic antigen) chains from both smooth *B. melitensis* and smooth *B. abortus* strains are composed of polymers of 4, 6 dideoxy-4-formamido-D-mannose (i.e., *N*-formyl-D-perosamine). In *B. abortus* S-LPS, the O chain contains about 100 residues, nearly all of which are α-1,2 linked, with a small

523

percentage being α-1,3-linked (A determinants). In *B. melitensis* O chains, α-1,2:α and α-1,3 linkages occur in a 4 to 1 ratio (M determinants). The serodominant A antigen tends to be rod-shaped, the shape being determined by the five consecutive α-1,2-

linked residues, while the serodominant M antigen is "kinked" in shape because the fourth residue is linked to the fifth by an α-1,3 linkage. The common expression of nonterminal α-1,2 linked *N*-formyl-D-perosamine is responsible for the cross-reactivity that exists between S-LPS of smooth *B. abortus* and smooth *B. melitensis* strains, and the cross-reactivity that is seen with other species (e.g., *Vibrio cholerae* 0:1, *Yersinia enterocolitica* O:9, *Escherichia coli* O:157, *Salmonella* O:30, and *Stenotrophomonas maltophilia*). Slide agglutination or enzyme immunoassays (EIAs) with polyclonal or monoclonal antibodies specific for A or M epitopes are used to determine A or M antigen predominance and the serovar designations of *Brucella* strains. Strains of *B. abortus*, *B. melitensis*, and *B. suis* can be A antigen-positive, M antigen-positive, or both A and M antigen-positive. A and M antigenic determinants are not found in *B. canis* or *B. ovis*; these species are characteristically rough, do not display phase variation, and have a restricted host range. The unique structure of the *Brucella* LPS renders this molecule several hundred times less toxic than LPS found in enteric gram-negative bacilli.[750]

Brucella species are transmitted to humans by three principal routes: direct contact with infected animal tissues, ingestion of contaminated meats or dairy products, and inhalation of aerosolized organisms. Once inside the host, the organisms are phagocytosed and begin their adaptation to the intracellular environment. Brucellae produce enzymes (e.g., superoxide dismutase, catalase, peroxidase) that neutralize reactive oxygen intermediates produced within the macrophage to inhibit bacterial multiplication.[478] The S-LPS also functions to inhibit the synthesis of immune mediators (i.e., complement, nitric acid, tumor necrosis factor) and alters the ability of the infected cell to process foreign antigens, thereby influencing the host immune response at the cellular level. S-LPS is also able to inhibit the programmed cell death (apoptosis) of infected cells.[517] The two-component quorum sensing system (*BvsR/BvrS*) of brucellae modulates the expression of genes encoding cell surface proteins that are involved in cell binding and intracellular survival. Specific periplasmic proteins termed *osmoregulated periplasmic glucans* (OPGs) interact with lipids in the host-cell membrane and function to interrupt the phagosome–lysosome fusion cycle.[55,804]Intracellular survival is also mediated in part by the *virB* locus, a 12-gene operon that encodes several proteins comprising the type IV secretion system, which is essential for virulence.[152] The *virB* operon proteins interact with the endoplasmic reticulum of the cell and internalized vesicles containing the bacteria, assisting in neutralizing the vesicular pH and further enabling intracellular bacterial replication.[153] Infected cells in the RES eventually degenerate and release the intracellular organisms. The bacteria, in turn, are phagocytosed by other macrophages and monocytes. The waxing and waning fever pattern seen in brucellosis is associated with the periodic release of bacteria and their components from phagocytic cells. The intermittent

bacteremia results in hematogenous seeding of other organs and tissues, leading to the protean clinical manifestations of human brucellosis.

The clinical spectrum of brucellosis depends on many factors, including the immune status of the host, the presence of other underlying diseases/conditions and the species, and virulence of the infecting organism. Relapses and recurrences of illness are controlled to some degree by a balance between the virulence of the organism and the presence of an intact, functional cellular immune response. As with other intracellular pathogens, humoral antibodies are produced, but cellular immune defense mechanisms are required to contain the intracellular bacteria. The greater virulence of *B. melitensis* and *B. suis* has been supported by in vivo studies with experimentally infected animals and by in vitro work examining phagocytosis, intracellular survival, and lymphocyte responses to the different species. Diseases due to *B. abortus* and *B. canis* are insidious in their onset, but tend to cause milder constitutional symptoms and less severe complications.

Because these organisms are infectious via the aerosol route, as evidenced by laboratory-acquired infections, *Brucella* species are one of several bacteria that are viewed as potential agents of biologic warfare and bioterrorism activity. Brucellae could be effectively delivered by aerosol dispersal and are able to survive in both soil and water for several weeks, thereby providing both immediate and delayed periods of infectivity. The United States investigated *B. suis* as a potential weapon during the 1940s and 1950s, and it is likely that other nations have made similar efforts. Reports of unusual clinical presentations, along with spurious serologic tests for *Brucella* antibodies, have prompted investigations involving the CDC and FBI regarding possible bioterrorist activity with *Brucella* species. Vaccination against brucellae is not available, as the existing *B. abortus* vaccine is licensed for veterinary use only. Post-event prophylactic therapy with doxycycline and rifampin has been effective in preventing disease in exposed individuals.

Clinical Spectrum of Brucellosis

Brucella infections may be difficult to diagnose because of the wide spectrum of clinical manifestations associated with them (Box 9-8).[837,1167] Following an incubation period of about 2 to 3 weeks (range, 1 week to 2–3 months), the onset of symptoms may be abrupt or insidious, developing over days to weeks. Fever, night sweats, chills, and malaise, often accompanied by severe headache, myalgias, and arthralgias, are the nonspecific symptoms seen in most infected patients. Most bacteremic individuals present with a febrile illness alone, or with both fever and arthritis. Lymphadenopathy, splenomegaly, and hepatomegaly may also be present. Cutaneous manifestations and vascular complications (e.g., erythema nodosum–like lesions, maculopapular or papulonodular rashes; deep vein thrombosis) may be noted in some patients. "Undulant fever" is synonymous with brucellosis (especially that caused by *B. melitensis*) because of the periodic fevers that occur over prolonged periods. Fevers occur mostly at night, with normal temperatures maintaining during the day, over 2 to 3 weeks. After this, days may ensue when the patient is afebrile and feels relatively well, only to experience another cycle of fevers. Symptoms wax and wane because of containment of the organisms in granulomas and subsequent release of organisms (or LPS) back into the circulation. Brucellosis assume characteristics of a debilitating,

BOX 9-8

Clinical Spectrum of Brucellosis

Infection	Comments
Osteoarticular infections	Bone and joint involvement (i.e., arthritis, bursitis, sacroiliitis, spondylitis, osteomyelitis) is the most commonly described complication of brucellosis, occurring in about 10% of patients. This is seen most often following bacteremia with *B. melitensis*.[15,1078,1400] Arthritis and sacroiliitis are associated with acute disease in pediatric patients, while spondylitis, vertebral osteomyelitis, osteitis, epidural, and paravertebral abscess are seen more frequently in chronic infections in older individuals and in those with underlying disease (e.g., HIV infection).[15,93,469,1400] Arthritis usually involves the hip and knees, but may also affect the smaller joints. Organisms have been isolated from joint fluids

Osteoarticular infections	processed by lysis-centrifugation.[1384] Patients with spondylitis usually present with fever, malaise, lower back pain, and difficulty walking.[1239,1400] Bone scans, computed tomography, magnetic resonance imaging, and newer methods (e.g., fluid-attenuated inversion recovery [FLAIR] modalities) are often helpful for detecting bone invasion, soft tissue lesions, and complications such as paraspinal/paravertebral abscess.[25,93,831] Brucellar osteomyelitis may also involve both joint and nonjoint prosthetic implants.[1249] In 2006, spinal osteomyelitis and bacteremia due to a marine mammal *Brucella* species were documented in a 43-year-old man in New Zealand.[873]
CNS infections	Neurobrucellosis occurs in less than 5% of patients and presents most commonly as a subacute or chronic meningoencephalitis, but it can present as encephalitis, meningitis, meningomyelitis, or cerebellar ataxia.[9,1248] The CSF will usually show pleocytosis, elevated protein, and low to normal glucose. Patients may appear acutely or chronically ill or may actually appear and feel relatively well (i.e., no fever or nuchal rigidity). Some infected patients may develop papilledema, visual symptoms, peripheral neuropathies, cranial nerve palsies, and abducens/optic nerve involvement.[681]Thrombosis of blood vessels may lead to cerebral/thalamic infarction and hemorrhage, encephalitis, myelitis, and peripheral neuropathy.[9,651]Epidural spinal abscesses, subdural empyema, paraspinal abscesses, intramedullary dermoid cysts, and brain abscesses are rare but do occur occasionally.[290,1020,1141,1186] Infection of the CNS resulting in colonization of a ventriculoperitoneal shunt and the subsequent development of *B. melitensis* peritonitis has also been documented.[35] Culture of brucellae from the CSF is negative more than 75% of the time, although blood cultures may be positive. Molecular methods have been useful for detecting brucellae in CSF specimens, and brucellar CNS disease can also be diagnosed by serologic testing of the CSF.[295,681] Treatment usually involves multiple antimicrobial agents, including aminoglycoside, doxycycline, and rifampin, and must be continued for 8–12 weeks.[9]Some patients have responded to third-generation cephalosporins (i.e., ceftriaxone) combined with doxycycline and rifampin.[681]
	Involvement of the respiratory tract is a rare event with *Brucella*

Respiratory tract infections	lungs or by direct inhalation of the organisms in aerosols.[1001]Clinical manifestations of pulmonary brucellosis include bronchitis, bronchopneumonia, lung abscess, pulmonary nodules, hilar lymphadenopathy, interstitial pneumonitis, empyema, and pleural effusions.[3] Patients present with headache, malaise, myalgia, and usually a nonproductive cough. Chest x-rays show typical lobar pneumonia in 32% and interstitial infiltrates in about 40% of patients, and about 10% of patients may have pleural effusions. While sputum specimens usually fail to grow the organism, it has been cultured from pleural effusion specimens.[1001]Diagnosis is usually made by serology unless other clinical manifestations are present that are more typical of brucellosis (e.g., osteoarticular disease).
Gastrointestinal/hepatobiliary tract infections	Gastrointestinal, hepatobiliary, and hepatosplenic involvement occurs as a manifestation of acute systemic infection in over 70% of patients with brucellosis. Symptoms include abdominal pain, nausea, vomiting, anorexia, and diarrhea or constipation. Infections of long-standing may result in more extensive gastrointestinal pathology, including colitis, enterocolitis, spontaneous bacterial peritonitis, pancreatitis, cholecystitis, splenic abscesses, and splenic infarcts.[294,344,619,743,896,1000,1003,1131]Liver involvement may be reflected only by elevations in liver enzymes, but is usually more extensive, particularly in *B. melitensis* and *B. suis* infections.[619] Infections with these two species are associated with the formation of caseating hepatic granulomas and microabscesses, while *B. abortus* tends to produce noncaseating granulomas in the liver. The management of suppurative complications of chronic hepatosplenic brucellosis requires combined surgical and medical approaches for optimal clinical response.[65,1398] *B. melitensis* peritonitis associated with chronic ambulatory peritoneal dialysis has also been described in several patients in Turkey.[21]Patients are usually treated with a 10- to 12-week course of doxycycline and rifampin and require catheter removal until cure is effected.
	Brucellae may infect the genitourinary tract, usually as a consequence of systemic infection, where they may cause epididymitis, prostatitis, orchitis, and renal granulomas.[79,212,670] While renal involvement is fairly uncommon, glomerulonephritis and pyelonephritis have been reported. Brucellae cause abortion in infected animals by localization in the chorioamniotic membranes of the placenta, but there is little evidence supporting a role for these

Genitourinary tract infections	the placenta, but there is little evidence supporting a role for these organisms in spontaneous abortion in humans.[984] However, the organisms may rarely be isolated from amniotic fluid and placental tissues of humans with brucellosis. Malone and colleagues described maternal brucellosis infection that resulted in preterm labor, chorioamnionitis, placental abruption, and delivery of the infant at 25 weeks' gestational age.[832] *B. abortus* was isolated from maternal blood and amniotic fluid. A 1998 case report details the first account of sexual transmission of *B. abortus*.[1250]

525

Cardiovascular infections	Cardiovascular brucellosis is a rare complication, occurring in less than 2% of infected patients.[531,1075]Interestingly, *Brucella* endocarditis is the main cause of death related to this disease.[155,543] Endocarditis may occur with both native and prosthetic valves; aortic valve involvement occurs the most frequently.[11,155,531,623] Complications of *Brucella* endocarditis include septic embolization, mycotic aneurysms, myocarditis, pericarditis, and the necessity for surgical intervention for prosthetic valve placement or replacement.[11,531,623] *B. melitensis* infection of a pacemaker and associated leads has also been reported in a 45-year-old sheep shearer who had just undergone 45 days of therapy for treatment of brucellosis.[337] In 1999, Ying and colleagues described a case of serologically confirmed *B. canis* endocarditis that occurred in a 49-year-old man upon return from Kuwait.[1401]
Ocular infections	Ocular infections are unusual, late complications of *Brucella* infection. Uveitis is the most frequent ocular infection associated with brucellosis.[1102,1103] In a study of 12 patients with brucellar uveitis, culture and serology were performed on vitreous, aqueous, and subretinal humor specimens. Eight patients (66.7%) had positive vitreous fluid serologies for *Brucella* antibodies. Four patients (33%) had negative ocular serologies for *Brucella*, but were serum-positive.[1103]Ocular fluid from 11 patients was cultured, and only one patient had a positive subretinal fluid culture. Ocular *Brucella* infections also include optic neuritis, keratitis,

Miscellaneous infections	endophthalmitis, and infection of the lacrimal glands.[17,104,394] Optic neuritis is associated with loss of vision, fever, temporal headache, and retrobulbar pain. Endophthalmitis results from hematogenous dissemination, and positive cultures have been obtained from both aqueous and vitreous humors. *Brucella* infection transmitted by bone marrow transplantation was reported in an 8-year-old boy who received an allogeneic bone marrow transplant from his HLA-matched sibling.[402] Culture of the infused marrow was positive after 4 days, and the patient subsequently developed fever and had *B. abortus* isolated from blood cultures. The sibling presented on post-transplant day 32 with fever, hepatosplenomegaly, positive *Brucella* serologies (agglutination titer of 1:320), and positive blood cultures with *B. abortus*. Yousif and Nelson reported a patient who developed neurobrucellosis 13 years after receipt of a cadaveric kidney transplant.[1408] Cellulitis and soft tissue infections are uncommon manifestations of brucellosis. The tissues are probably seeded with the organisms during bacteremic episodes, leading to abscess formation. Gluteal, breast, psoas, splenic, and Bartholin's gland abscesses due to *Brucella* species have been reported recently.[123,398,527,1003,1016,1081] Treatment includes draining the abscesses and prolonged antimicrobial therapy. Mucocutaneous manifestations (erythematous papular lesions, purpura, Stevens–Johnson syndrome) can also be part of the clinical presentation.

chronic illness. Patients are often pan cultured to determine an etiology for a "fever of unknown origin." Acute and chronic brucellosis may lead to complications affecting several organ systems (Box 9-8). In immunocompromised hosts on chemotherapy, prolonged febrile neutropenia that fails to respond to broad-spectrum antimicrobial coverage is suggestive of *Brucella* infection, particularly in *Brucella*-endemic regions.

Hematologic abnormalities may be present because of chronic infection of the RES, including the lymph nodes, the bone marrow, and the spleen. Granulomas and abscesses form directly in these tissues or manifest as peripheral hematologic dyscrasias. Small, poorly defined noncaseating granulomas may be found in the bone marrow in about 70% of patients along with nonspecifically reactive histiocytes. Leukopenia, pancytopenia, microangiopathic hemolytic anemia, severe thrombocytopenia, and disseminated intravascular coagulation have all been observed in patients with brucellosis.[1172,1272,1405] Hematologic abnormalities may predominate

in early infection, masking the infectious etiology of the disease and mimicking primary hematologic diseases. Hematologic abnormalities are usually transient and normalize following successful antimicrobial therapy.

Serologic Diagnosis of Brucella *Infections*

Serologic tests are commonly used for the diagnosis of brucellosis. These assays detect antibodies against the O-side chain of the bacterial LPS. The serum agglutination test (SAT) is the most widely used and is the cornerstone of *Brucella* serology.[1370] SAT uses a standardized commercial *B. abortus* antigen (BD Biosciences, Sparks, MD), is performed as a tube dilution test, and detects agglutinating antibodies of both IgG and IgM classes.[61,1404] A standardized volume and concentration of a whole *Brucella abortus* cell suspension is reacted with a standardized volume of serum dilutions ranging from 1:20 to 1:1280. After incubation at 37°C for 24 hours, the agglutination of cells at the bottom of the tubes is inspected visually. The titer is the highest dilution of serum that results in agglutination of 50% of the bacterial cells.[26] Incorporation of 2-mercaptoethanol (0.05M) into the tube test inactivates IgM by disruption of the disulfide bonds of the molecule, providing an IgG-specific agglutinin titer.[191] Upon infection, IgM antibodies are produced during the first 7 to 10 days, followed by a decline in IgM and a switch to IgG production after the second week.[688] The sensitivity and specificity of the SAT depend on the background level of disease in the population and the cutoff value used to determine positive results. The test specificity and predictive value of a positive test are increased by selection of a higher cutoff value in areas of *Brucella* endemicity. However, by selecting a higher cutoff titer, the test sensitivity decreases, and persons with persistent or relapsing disease may be missed. Most patients with active brucellosis will have SAT titers of ≥1:160; these titers subsequently fall with adequate therapy. In areas of high endemicity, the use of a cutoff titer of 1:320 may increase test specificity. However, lower or higher titers can be detected in both active and asymptomatic disease.[812]

526

Test sensitivity may be increased by evaluating paired sera (collected about 2 weeks apart) and looking for seroconversion or for a fourfold or greater increase in titer. The SAT using *B. abortus* antigen cannot be used to diagnose infections caused by *B. canis* or *B. ovis* because these organisms exist only in a rough colony form and do not have antigens that cross-react with other *Brucella* species.[64] For these two agents, major outer membrane protein antigens are used for serologic diagnosis. The SAT can also be performed as a microagglutination test in U- or V-bottomed microtiter wells.

The indirect Coombs' anti-human globulin test is used as a complement to the standard SAT and for the detection of blocking or nonagglutinating IgG antibodies that are not detected in the SAT.[26] Standard tube dilutions that are negative for agglutination of whole *B. abortus* or *B. melitensis* cells are centrifuged, and the bacterial cells are resuspended and washed several times. Anti-human IgG is then added to the resuspended cells, and the tubes are incubated at 37°C for 24 hours. Agglutination of the bacterial cells by the human antiglobulin is observed visually. The Coombs' antiglobulin test is useful for detection of chronic or relapsing disease as it detects agglutinating and nonagglutinating antibodies having both high and low affinity for the antigen.[204]

The Rose Bengal agglutination test is a rapid test that was originally designed to screen animal populations, but is also used as an adjunctive test for rapid diagnosis of brucellosis in humans. Positive results are generally confirmed by the SAT. The test is based on the agglutination of whole smooth-phase *B. abortus* cells that are stained with Rose Bengal dye and buffered at a low pH (3.65), which inhibits nonspecific agglutination of the bacterial cells. This test detects both agglutinating and nonagglutinating antibodies. In an evaluation of the Rose Bengal test using sera from 711 patients diagnosed with brucellosis and 270 controls, the overall sensitivity of the test was 92.9%.[1120] Specificity of the assay, however, was dependent on the characteristics of the group studied. Among those patients with no regular exposure to or history of brucellosis, the specificity was 94.3%, but among those patients infected with *Brucella* who had been treated within the previous year, the test specificity fell to 76.9%. In endemic regions, asymptomatic or self-limiting infections are known to occur, and anti-*Brucella* IgG can persist for months after the completion of therapy. Because of this low specificity and the consequent large numbers of false-positives, the use of the Rose Bengal test for screening in endemic areas is not recommended. Use of this test as the sole determinant of active infection would lead to unnecessary treatment with potentially toxic agents. In addition, the S-LPS shows cross-reactivity with other gram-negative bacteria, including *Y. enterocolitica*, *E. coli* O157, and *F. tularensis*, which may further increase the number of false-positive results and decrease test specificity.

A newer development in the serodiagnosis of brucellosis is the BrucellaCapt immunocapture agglutination assay (Vircell SL, Santa Fe, Granada, Spain).[61,204,205,979] This test uses microtiter wells that are coated with antibodies directed against human IgG and IgA. Patient serum is serially diluted and added to each well. After incubation, antigen (a formalinized colored suspension of *B. abortus* bacteria) is added and the plate is incubated for 24 hours. Positive tests show agglutination of the bacterial suspension over the bottom of the well. Negative tests are indicated by the formation of a condensed pellet of organisms at the bottom of the well. In a study of 321 serum samples from 48 patients with brucellosis (including 20

patients with focal disease and 8 patients with 9 relapses over the previous 18 months), the BrucellaCapt assay had a sensitivity of 100% for the diagnosis of initial infections.[204] In treated patients with good clinical outcomes, the titer decreases determined with the BrucellaCapt were pronounced and rapid. Following the rapid decline, 80% of patients remained positive at low titer for 12 months or more post-treatment; most of the slow decreases in titer were seen in patients with chronic or focal disease. In another evaluation, the sensitivity and specificity of the BrucellaCapt were more sensitive than the SAT (96% vs. 73%), but the specificity of the BrucellaCapt was 97.5% compared with the 100% specificity observed with SAT.[205] In patients with relapsing disease, BrucellaCapt titers remained high (titer ≥640) even though the SAT may be high or low.[979] Results with BrucellaCapt are also influenced by the prevalence of disease in the population being studied. An evaluation of the BrucellaCapt in an endemic region in Spain had a sensitivity of 98% in culture-confirmed case using a cutoff of 1:80 and a specificity of 96% when specimens from healthy individuals were used. However, the specificity fell to 63% at the 1:80 cutoff when specimens from individuals living in the endemic region and diagnosed with other conditions were tested.[979] In this situation, raising the cutoff titer increases test specificity, but decreases test sensitivity. The BrucellaCapt detects primarily high-affinity antibodies and is more specific than the Coombs' test, but in patients with chronic or relapsing disease, the small changes that occur in low-affinity antibodies are still best detected by the Coombs' antiglobulin test.[204]

EIAs have also been developed for serologic diagnosis of brucellosis, and these methods are the tests of choice for complicated and chronic infections.[51] EIAs for detecting IgM, IgG, and IgA antibodies against *Brucella* have been described that use *B. abortus* whole cells, smooth LPS, protein extracts, and *B. melitensis* S-LPS as the solid-phase antigen.[61,64,841,985] Ariza and coworkers compared SAT with EIA methods for detection of *Brucella*-specific IgG, IgM, and IgA in 761 sera obtained from 75 patients with brucellosis. The EIA method in this study incorporated *B. abortus* S-LPS as the antigen. EIA was sensitive and more specific than standard serologic tests for brucellosis. Initial IgM titers were higher in patients who presented to their physician earlier in the clinical course, while patients who had been ill for some time tended to have high IgG titers and lower IgM titers. Upon adequate antimicrobial therapy, the serum IgG titers decreased four- to eightfold over the subsequent 3 to 6 months. Subsequent increases in EIA IgG and IgA titers were seen in patients with relapsing disease. The persistence of high levels of IgG or a slower decline in titers following treatment in patients without relapse was associated with the presence of focal infection. Antibrucellar IgM and IgG may also be present during bacteremic periods.[985] In 1993, Goldbaum and coworkers in Argentina characterized an 18-kDa cytoplasmic protein that was present in all smooth and rough *Brucella* species

examined.[493]Sera from patients with active brucella infections reacted with this antigen in an EIA-based assay, while patients who did not have brucellosis or who had inactive disease were negative with this test. This EIA could also differentiate healthy vaccinated cattle from vaccinated cattle

527

that had been infected with a wild-type, disease-producing strain. This antigen has been purified by affinity chromatography, and the gene for the antigen has been cloned in *E. coli*, with retention of reactivity of the recombinant molecule with animal and human sera containing anti-*Brucella* antibodies. This molecule has been characterized as a lumazine synthase, an enzyme involved in riboflavin biosynthesis.[494] A commercially available EIA for detection of IgG and IgM (PANBIO, Windsor, Brisbane, Australia) was compared with standard SAT and Coombs' test for the diagnosis of brucellosis in Beirut, Lebanon. The sensitivities of the *Brucella* EIA IgM and IgG assays were 100% and 91%, respectively, while the specificity was 100% for both EIAs.[52] Recently, two lateral flow EIAs for detection of anti-*Brucella* IgM and IgG, respectively, have been evaluated for rapid diagnosis of brucellosis in endemic regions.[552,627]In one study, these lateral flow assays were positive in 91% and 97% of sera from adults and children with brucellosis, respectively, and the agreement of these assays with SAT was 92% using an SAT cutoff titer of ≥1:160.[627]

Al-Shamahy and Wright reported on an antigen-detection EIA assay for brucellosis.[23] The test used monoclonal antibodies against the *Brucella* LPS and was performed on serum specimens. As few as 100 *Brucella* organisms or 10^5 μg/mL LPS could be detected. This assay was challenged with 1,607 sera from random blood donors, 146 patients with brucellosis, 20 patients at risk for *Brucella* infection, and 264 sera from patients with infections other than brucellosis. The sensitivity of the assay was 100% compared with positive blood cultures; the specificity of the assay was 99.5% among random blood donors and 99.2% for patients. These data indicated that antigen detection using this assay was an acceptable alternative to blood culture for the diagnosis of *Brucella* infection. Rapid LA tests have also been designed for the serologic diagnosis of brucellosis. Abdoel and Smits developed and evaluated a LA assay using latex beads sensitized with *Brucella* LPS.[2] The test was evaluated with 45 serum specimens from patients with culture-confirmed brucellosis, 90 samples from culture-negative patients diagnosed with brucella infection, and 281 serum samples from patients with illnesses other than brucellosis. The sensitivity and specificity of the test for detection of anti-*Brucella* antibodies were 89.1% and 98.2%, respectively.

Isolation and Cultural Characteristics

Because of the risk of laboratory-acquired *Brucella* infections, all work with specimens suspected of harboring *Brucella* and all manipulations of *Brucella* cultures should be performed in a class II biologic safety cabinet using precautions for BSL-3 organisms. Procedures that generate aerosols (aspiration of liquid with syringes, using a "vortex" mixer, vigorous bulb pipetting, etc.) should be kept to a minimum. To comply with these guidelines, close communication among the laboratory director, the technologists, and the physicians caring for patients with "possible" brucellosis is necessary. The clinician should alert the clinical laboratory personnel when a diagnosis of brucellosis is being considered so that the laboratory staff can take the necessary safety precautions.

Since *Brucella* species infect the RES, the specimens of choice for recovery of organisms in suspected cases primarily include blood and bone marrow. In a study of 50 patients eventually diagnosed with brucellosis, cultures of blood and bone marrow were positive in 70% and 92% of the patients, respectively.[507] Conversely, a study of 106 cases of brucellosis in Amman, Jordan, found that blood cultures were positive in 44.4% of patients, while bone marrow culture was positive in only 27.7% of patients.[1179] Rates of positive cultures from these specimens are dependent on presentations and clinical conditions of individual patients (i.e., subacute, acute, or chronic disease) and previous antimicrobial chemotherapy. In a study performed in Turkey, blood and bone marrow cultures were collected from 102 patients: 61 had acute infection, 29 had subacute infection, and 12 presented with chronic disease.[628] Blood and bone marrow specimens were cultured using the BACTEC 9050 system. The overall rate of positive blood cultures was 48%, while the positivity rate for bone marrow cultures was 34%. The time to detection in the BACTEC system was 4.2 days for bone marrow specimens and 5.8 days for blood specimens. Among the patients with acute disease, blood and bone marrow cultures were positive in 66% and 46% of the patients, respectively. Among those 28 patients with acute disease and positive bone marrow cultures, 23 had positive blood cultures and 5 had negative blood cultures. Of the 29 patients presenting with subacute illness, blood and bone marrow cultures were positive in 31% and 21%, respectively. Interestingly, among the 12 patients with chronic brucellosis, none had positive blood cultures and only 1 patient had a positive bone marrow culture.[628] Another Turkish study reported that among 30 patients with acute brucellosis, 83.3% had positive bone marrow cultures and 66.6% had positive blood cultures. For 17 patients with subacute disease, bone marrow and blood cultures were positive in 52% and 23.5%, respectively; 1 of 3 patients with chronic disease had a positive bone marrow culture and none of 3 had positive blood cultures for *Brucella.*[993] *Brucella* can also be recovered from pus, tissue, CSF, pleural fluid, joint fluid, and ascites fluid specimens and should also be inoculated into blood culture bottles.[1386]

For isolation of *Brucella* species, blood and bone marrow specimens are inoculated

into aerobic and anaerobic bottles, and because of their slow growth rates, conventional blood cultures should be incubated at 35°C for 4 to 6 weeks with blind subcultures to chocolate and blood agar. Continuously monitored blood culture instruments usually detect positive blood/bone marrow cultures with *Brucella* species after 5 to 7 days of incubation. Yagupsky evaluated the ability of the BACTEC 9240 instrument to detect growth of *Brucella* species and found that 21 (78.8%) of 27 positive cultures were detected by the 9240 instrument within 7 days; the remainder were detected by blind subculture after 2 to 3 weeks of incubation.[1388] Ozturk et al.[995]evaluated the BACTEC 9240 system with blood and bone marrow cultures from 23 patients with brucellosis diagnosed by serology. Blood and bone marrow cultures were positive for 19 (82.6%) and 13 (81.2%) of the patients, respectively. All blood cultures were positive within 7 days, and bone marrow cultures were positive within 4 days.[995] An evaluation of the BACTEC 9120 continuously monitored system found that all of 20 *B. melitensis* were flagged with a mean detection time of 63.87 hours and that 13 (65%) of the 20 isolates were flagged as positive by the BACTEC 9120 within the first 72 hours.[380] Recovery of *Brucella* may also be influenced by the type of

blood culture media used. BACTEC MYCO/F LYTIC medium was formulated to enhance detection of intracellular bacteria by lysis of the blood cells in the bottle. In a side-by-side comparison of the BACTEC MYCO/F lytic medium and the regular BACTEC Peds Plus/F aerobic blood culture bottle, both media had similar sensitivity in detecting positive cultures, but the time to detection was significantly longer with the MYCO/F lytic medium (104 +/− 46.7 hours) than with the Peds Plus/F medium (65.5 +/− 19.9 hours).[1379] Using the BacT/ALERT continuously monitored blood culture system (bioMérieux, Inc., Durham, NC), Solomon and Jackson detected *B. melitensis* in the blood culture of a patient in 2.8 days, and these investigators used seeded blood cultures to show a mean detection time of 48 hours +/− 1 hour in bottles inoculated with 100 cfu of *B. melitensis* per mL.[1209] Ozturk et al.[993] evaluated the BacT/ALERT (bioMérieux, Inc., Durham, NC) continuously monitored blood culture instrument (using a 7-day incubation period) in comparison with conventional blood culture in *Brucella* broth for 4 weeks, with blind subculture every 48 hours. Of 59 positive cultures detected in 100 specimens (50 bone marrow specimens and 50 blood specimens), all 59 were detected with the *Brucella* broth culture, while the BacT/ALERT detected only 30 (50.8%). These investigators suggested that positive cultures were missed by the BacT/ALERT because of the low inoculum, the short (7-day) incubation period, possible toxicity of SPS, and the slow production of CO_2 by

the organism, which is the metabolic product detected by the BacT/ALERT system.[993] A side-by-side comparison of the BACTEC 9240 and the BacT/ALERT reported that all of 17 *Brucella* isolates were recovered with both blood culture systems; the mean time to detection was 2.5 days for the BacT/ALERT and 2.8 days for the BACTEC 9240.[100] The BacT/ALERT standard aerobic, BacT/ALERT FAN, and BacT/ALERT-enhanced aerobic bottles also support rapid growth of brucellae as evidenced by simulated blood culture studies.[1229]

Rapid recovery of *Brucella* species from blood cultures has also been accomplished with the Isolator lysis-centrifugation method.[839,1384,1387,1388] Recovery of *Brucella* using this method takes 2 to 4 days and yields a semiquantitative assessment of the level of bacteremia. The sensitivity of lysis-centrifugation exceeds 90% for acute disease and is about 70% for chronic disease.[380,939]

Continuously monitored blood culture systems have also been evaluated for detection of brucellae in other sterile body fluids. In a study of 1,072 synovial fluids from patients with arthritis, specimens were processed by the Isolator 1.5 Microbial Tube and inoculated into BACTEC 9240 blood culture media. Fifteen specimens were positive for *B. melitensis* by lysis-centrifugation, and 14 of these positives were also detected by the BACTEC 9240 within 3 to 7 days.[1386] The single positive culture missed by the BACTEC instrument had 1.3 cfu of organisms per mL as determined with the the Isolator 1.5 Microbial tube (Wampole Laboratories, Cranbury NJ). Akcam and colleagues compared conventional culture of various body fluid with inoculation of aerobic BACTEC blood culture bottles and recovered five isolates of *B. melitensis* from the BACTEC-processed specimens only.[8] Cetin and colleagues compared results obtained by conventional culture of sterile body fluids with inoculation of BACTEC Peds Plus bottles and recovered two isolates of *Brucella* species from synovial fluid and pleural fluid by the BACTEC method only.[225]

Identification of Brucella *Species*

A presumptive identification of a "possible *Brucella* species" can be made when a slow-growing, faintly staining, minute coccobacillus is recovered from blood or bone marrow cultures of a "compatible" patient, that is, one with a history of possible occupational exposure, travel to an endemic area, or ingestion of uncooked meats or unpasteurized dairy products. *Brucella* species grow slowly on blood and chocolate agars, forming visible colonies in 3 to 5 days (Image Plate 9-5D). *Brucella* species do not grow on MacConkey, EMB, or other "enteric" selective or differential media. Good growth will also be obtained on buffered charcoal yeast extract (BCYE) agar used for isolation of *Legionella* species.[1056]

All *Brucella* species are aerobic and require oxygen for recovery from clinical

specimens. Although production of acid from carbohydrates may be demonstrated under certain conditions, their metabolism is largely oxidative. Strains of *Brucella* are positive for both oxidase and catalase; most brucellae reduce nitrate to nitrite, and some may also reduce nitrite to nitrogen gas. All species are indole- and VP-negative. Conventional identification methods for *Brucella* species include the requirement of CO_2 for growth, production of urease and H_2S (at 4 days, using lead acetate strips), and sensitivity to the dyes basic fuchsin (1:50,000 and 1:100,000), thionin (1:25,000, 1:50,000, and 1:100,000), and thionin blue. Dye sensitivity is used not only to aid in identifying the species, but, in the case of *B. abortus* and *B. suis*, is also helpful for determining the biovar of the organism. *B. abortus* and *B. suis* are subdivided into biovars on the basis of biochemical and serologic differences, while the biovars (actually serovars) of *B. melitensis* are defined solely on the basis of serologic differences, since they are classically resistant to basic fuchsin, thionin, and thionin blue. The recognition of serologically confirmed strains of *B. melitensis* that are thionin sensitive suggests that the conventional identification scheme needs to be modified and that new, less cumbersome identification methods are needed.[305] *B. melitensis*, *B. suis*, and *B. abortus* produce urease; with a heavy inoculum, *B. suis* strains usually will be urease-positive on Christensen's urea medium within 5 minutes. Identification of *Brucella* species has also been accomplished by COA and colony dot-blot using a genus-specific monoclonal antibody that detects the A or M antigens of *B. melitensis*, *B. abortus*, and *B. suis*.[1306] Phenotypic characteristics that are useful for identification of *Brucella* species are shown in Table 9-12.

Brucella species are not included in the data bases of any of the commercially available kit systems for identifying gram-negative organisms except for the Vitek 2 Gram-Negative (GN) Identification card, which includes *B. melitensis* in the database. Inadvertent use of these kits may delay diagnosis and treatment. *Brucella* organisms have been misidentified as *Moraxella phenylpyruvica* by the API 20NE nonenteric identification system, as *Moraxella* species by the MicroScan Negative COMBO type 5 system (Siemens Healthcare, Deerfield IL), and as *Haemophilus influenzae* biotype IV by the HNID panel (Siemens Healthcare).[90,97] In one instance, the technologist who inoculated an API 20NE

strip with a *B. melitensis* isolate subsequently developed brucellosis.[97] The RapID NF Plus system (Remel, Lenexa, KS) for identification of nonfermentative gram-negative bacteria misidentified a gram-negative isolate from two sets of blood cultures of the same patient as *Ochrobactrum anthropi*.[608] On the third admission of this patient to the hospital for surgical repair of a femoral bone fracture, pus from the hip socket grew the same short gram-negative rod that was recovered from the previous blood cultures. The Vitek 2 GN Identification card identified the organisms as *B. melitensis*, with a 97% likelihood, and subsequent ribosomal RNA sequencing and serotyping at the CDC confirmed all the isolates as *B. suis*. A study performed in Macedonia reported recovery of 16 presumptive *Brucella* species from blood cultures that were identified as *B. melitensis* by the Vitek 2 card within 8 hours; differences in substrate profiles among the isolates suggested different strains.[208]

Other novel test systems have been evaluated for their ability to identify *Brucella* species. Preliminary studies on the identification of *Brucella* species with the Biolog carbon substrate utilization identification system indicated that all *Brucella* species oxidized three of the 95 substrates on the panel, and that *B. melitensis*, *B. abortus*, and *B. suis* could be differentiated from one another by differential oxidation of seven additional substrates.[1365] Using the results of seven tests on the biotype 100 (bioMérieux, Marcy-l'Étoile, France), a manually inoculated carbon substrate assimilation gallery, Lopez-Merino et al.[805] were able to identify 85.6% of 92 *Brucella* strains; specificity varied from 97.4% to 100%, depending on the species. These workers emphasized that the biotype 100 must be inoculated in a biologic safety cabinet. Al Dahouk and coworkers evaluated the Taxa Profile (Merlin Diagnostics, Bornheim-Hersel, Germany), a commercial biotyping system, for its potential use in identifying *Brucella* species.[14] This test utilizes three microtiter plates coated with

various substrates. Plate A detects utilization of 191 amines, amides, amino acids, organic acids, and heterocyclic aromatic compounds; Plate C contains 191 different mono-, di-, and tri-polysaccharides and sugars; and Plate E contains 188 substrates that detect various peptidases, proteases, glycosidases, and esterases. The plates were inoculated with 23 reference strains representing all *Brucella* species, and 60 field isolates. After analysis of results with the three plates (570 substrates), a battery of 96 tests were selected for *Brucella* identification and typing (Micronaut), and this single plate was challenged with 113 *Brucella* strains. These organisms showed characteristic profiles and allowed identification of isolates to the species level, although biovar determinations could not be resolved. Finally, Ferreira and colleagues evaluated MALDI-TOF (matrix-assisted laser desorption/ionization time-of-flight) mass spectrometry (Bruker Daltonics, Leipzig, Germany) for its ability to identify brucellae.[420] After creating MALDI Biotyper profiles using type strains of *Brucella* species, the system was challenged with 131 clinical isolates, and blood cultures seeded with these organisms were also tested. All strains, either from agar plates or seeded blood cultures, were identified to the genus level by MALDI-TOF, with lesser correlation for species-level identifications.

The isolation and identification of *Brucella* species are time-consuming, requires considerable microbiologic skill, and must be performed in BSL-3 facilities. Because of the economic impact of brucellosis on livestock and wildlife, several molecular methods have been developed for the identification and biotyping of *Brucella* species isolated from animals or animal products (e.g., milk), including conventional PCR methods, multiplex PCR assays, and "real-time" PCR approaches. Earlier molecular approaches were directed at the detection of these organisms in animals and animal products (e.g., milk specimens), and subsequently assays were developed for detection of organisms in clinical specimens. The challenge for molecular assays for the detection of the genus *Brucella* is that the various species have greater than 90% homology with one another. A variety of gene targets have been used to design primers and probes for genus-, species-, and biotype/biovar-level identifications. Targets for these assays include the16S rRNA, 16S-23S internal transcribed spacer (ITS) region, IS*711*, outer membrane protein genes (*omp2, omp2a*, *omp2b*, *omp31*), *bcsp31*, and *per* genes.[938,1067,1087,1106]

In 1994, Bricker and Halling at the U.S. Department of Agriculture developed a multiplex PCR that was able to identify and differentiate several *Brucella* species and biovars, including *B. abortus* biovars 1, 2, and 4, all three biovars of *B. melitensis*, *B. suis* biovar 1, and *B. ovis.*[177] This assay exploited the presence of IS*711,* an insertion sequence that is unique to *Brucella* species, and is found at species-specific and biovar-specific regions of the chromosome. The species and biovars identified by this assay constitute most of those seen in the United States in animals and in human infections. Conventional identification and typing of field isolates correlated 100% with

the results of the multiplex assay. These workers subsequently augmented their PCR assay with additional primers to allow rapid discrimination between pathogenic strains and the *B. abortus* vaccine strains (S19 and RB51) in previously vaccinated livestock and to detect additional livestock-related isolates.[176,178] This assay is called the AMOS PCR because it detects *Brucella* "**A**bortus, **M**elitensis, **O**vis, and **S**uis," respectively. Redkar and colleagues subsequently designed AMOS "real-time" PCR tests using upstream primers derived from the 3′ end of the IS*711* insertion element, and downstream primers and probes from unique sequences specific to individual *Brucella* species and biovars.[1067] The assay used two adjacent fluorescence resonance energy transfer (FRET) probes that hybridized to the amplicons as they were formed. The assay took 30 minutes and identified all biovars of *B. abortus*, *B. melitensis*, and *B. suis* biovar 1. Ewalt and Bricker described an abbreviated version of the *Brucella* AMOS PCR for more rapid screening in the field.[407] Conventional multiplex PCR assays have also been designed for identification of specific biovars of *Brucella abortus* (i.e., biovars 5, 6, 9, 3, and subgroup 3b) recovered from livestock in Spain and for identification and typing of isolates of *B. suis* causing porcine brucellosis in Spain.[419,965] Rees and colleagues described a single-tube PCR assay that used variable-number tandem repeat (VNTR) analysis for simultaneous identification and strain typing of *B. melitensis*, *B. abortus*, and "*Brucella* species" involved in epidemiologically linked infections in families who became infected in Mexico and subsequently developed disease in California.[1069] Mitka and colleagues evaluated four different PCR assays, each of which used different primer pairs and gene targets (including *bcsp31*, *omp2, omp28*, and *bp26)* using serum, buffy coat,

or whole blood specimens, and all four methods were greater than 95.5% sensitive and 100% specific.[899]

Several other multiplex PCR assays have been designed that identify all described *Brucella* species.[616,803,864] In 2008, a multiplex PCR identification typing system was designed and evaluated with isolates in seven international laboratories on five continents.[803] This test, called the Bruce-ladder, used primers selected to detect species- and/or strain-specific sequences. *Brucella* strains (n = 625) tested were from different geographic locations worldwide and included animal and human clinical isolates. Identification with Bruce-ladder was based on the numbers and sizes of seven PCR amplicons analyzed by electrophoresis in 1.5% agarose gels. Bruce-ladder identifications were species-specific, and all strains and biovars from the same *Brucella* species gave the same amplicon profile. The Bruce-ladder assay was also able to identify *B. abortus* S19,*B. abortus* RB51, and *B. melitensis* Rev. 1 vaccine

strains. The Bruce-ladder assay was also able to identify species and biovars not identified by AMOS PCR, including *B. canis*, *B. neotomae*, *B. pinnipedialis*, *B. ceti*, *B. abortus* biovars 3, 5, 6, 7, and 9, and *B. suis* biovars 2, 3, 4, and 5. The Bruce-ladder was specific for *Brucella* species and DNA from 30 other related strains failed to amplify with the primers for *Brucella*-specific sequences. This method was reproducible in all seven laboratories and could be performed with several different DNA extraction methods and commercial thermocyclers. The assay could be completed in less than 24 hours and performed with whole-cell bacterial lysates. In 2010, a similar multiplex PCR assay was described that used eight primer pairs previously incorporated in the multiplex assay, but added primers specific for *B. microti*.[864] *B. ceti* and B. *pinnipedialis* could be distinguished on gels by a size difference of a 794 base pair amplicon, and the assay also demonstrated a unique amplicon pattern for *B. inopinata*, which produced a polyacrylamide gel pattern similar to *B. abortus*, but with an additional 272 base pair fragment.

Some multiplex PCR assays for *Brucella* identification and typing make use of a technique called single nucleotide polymorphism or SNP analysis. This technique identifies single nucleotide differences between and/or among species. This technique has diverse applications in clinical microbiology, and has been used for identification and typing of *M. tuberculosis*, differentiation of *Burkholderia* species groups, and differentiation of vaccine- and wild-type strains of varicella zoster virus, among others. Scott and colleagues used this technology to develop a multiplex assay in which sequence polymorphisms were identified in *glk*, *trpE*, and *omp25* genes that were specific for the individual species or marine mammal species groups.[1164] Amplification and sequencing of amplicons containing discrete polymorphisms provided unambiguous identifications as one of the six classical *Brucella* species or as one of the marine mammal-associated species. Several other research groups subsequently used this technology to design real-time PCR assays based on SNP technology that enabled identification of *Brucella* species and biovar typing.[453,502] The real-time SNP assay reported by Koylass and colleagues was compared with the "Bruce-ladder" assay described above and found that the SNP assay was more accurate for differentiating *B. canis* and *B. suis* isolates than the "Bruce-ladder" assay.[733]

Several real-time PCR methods for identification of *Brucella* have been developed and published.[439,687,1053,1067] The principal advantages of these approaches include the rapidity of test results and the avoidance of amplicon contamination. FRET probe, hydrolysis probe (i.e., TaqMan), and SYBR Green I detection methods have been used, and amplification targets have included IS*711*, *bcsp31*, *omp*, and *per* genes, and the 16S-23S ITS region.[156,687,1053] Redkar and colleagues described three separate real-time assays specific for identification of *B. abortus* (7 biovars), *B. melitensis* (3 biovars), and *B. suis*. Forward primers for the assay were derived from the IS*711* insertion element, while the reverse primers and FRET probes were selected from

species-specific or biovar-specific chromosomal sequences.[1053] Winchell et al.[1356] designed a real-time PCR using seven different primer sets, including a primer (Bspp) that specifically identified organisms in the genus *Brucella*, and six primer sets that enabled detection of all *Brucella* species, with the exception of *B. inopinatus*. Following amplification, species identification was accomplished by high-resolution melt (HRM)-curve analysis, with each species having a different melting profile. Subsequent testing of strain BO1 (*B. inopinatus*) and BO2 confirmed that these isolates are *Brucella* species (i.e., positive with the Bspp primer), that they are distinct from other brucellae, and that BO2 may actually be a different species than *B. inopinatus* (BO1).

Real-time PCR assays have also been designed for detection of brucellae in a variety of human clinical specimens, including blood cultures, whole blood, and serum. Kattar and colleagues developed and evaluated three real-time PCR assays with LightCycler hybridization probe detection of the 16S-23S ITS, the *omp25* gene, or the *omp31* gene, respectively.[687] Each assay was 100% sensitive and specific, with the ITS target having the lowest limit of detection. The ITS assay was challenged with 340 whole blood specimens (24 from brucellosis patients, 31 with treated brucellosis, and 299 SAT-seronegative patients). Clinical sensitive and specificity and positive and negative predictive values were 66.7%, 99.7%, 94.1%, and 97.6%, respectively. A real-time assay using SYBR Green I and LightCycler (Roche Diagnostics, Mannheim, Germany) methodology was described by Quiepo-Ortuno and coworkers for detection of *Brucella* species in human serum samples.[1052,1053] This assay amplified a 223 base pair region of the *bcsp31* immunogenetic membrane protein, and specificity of the assay was determined by melting-curve analysis and sequencing to verify specificity of the PCR-derived products. After optimization of assay conditions, the test was challenged with 62 serum samples from patients with active brucellosis and 65 negative control sera. This assay was 91.9% sensitive and 95.4% specific for diagnosis of active brucellosis, was reproducible, and took less than 2 hours to perform. This assay was subsequently modified for quantitative detection of *Brucella* species in serum samples, and compared with blood culture results, SAT results, and BrucellaCapt results for 46 patients with brucellosis and 64 control patients (including 36 patients with a history of treated brucellosis, 17 asymptomatic patients at risk for brucellosis, and 11 patients with other conditions).[1052] Forty-four (95.7%) of patients with brucellosis were PCR-positive. Five control patients with positive PCRs included four who had just completed treatment for brucellosis and a fifth who was a veterinary surgeon working in a *Brucella* control/

eradication program. The sensitivity and specificity of the assay were 95.7% and

92.2%, respectively, and the predictive values of positive and negative PCR results were 89.8% and 96.7%, respectively. Corresponding values for blood cultures were 69.6%, 100%, 100%, and 78.8%, respectively.

Molecular methods can also be used not only for identification of of isolates, but also for strain typing of *Brucella* isolates. Since the entire genomes of *B. melitensis* and *B. abortus* have been sequenced, regions of DNA have been found that are useful as unique markers for strain typing. In the genomes of these organisms, regions of DNA have been found that possess a variable number of tandem sequence repeats (VNTRs) that range from 1 to 10 base pairs per repeat and from 1 to more than 30 repeats per locus. The locations and numbers of these VNTRs within the published genome sequences are known. One of the first studies using this technology identified an 8 base pair, tandem repeat sequence in nine loci of *B. abortus*, and these loci were hypervariable among various strains of *B. abortus*. Using PCR, the number of repeat sequences per locus generated strain-specific "fingerprints" that were able to identify *Brucella* species type strains and to differentiate unrelated *B. abortus* isolates recovered from cattle and other animals.[174] LeFlech and colleagues used the VNTR technology to establish a 15-marker, two-panel PCR assay for *Brucella* species.[774] The first panel used eight markers to establish a species identification along classical species lines, while the second panel used seven markers and was able to differentiate among isolates of the same biovar. Whatmore and associate used the same technology and identified 21 VNTRs, ranging from 5 to 40 base pairs in length. Six loci were sufficient to determine species identification, while the remaining 15 could discriminate among isolates of the same species/biovar isolated from different geographical locations.[1345] VNTR analysis was rapid, reproducible, and applicable for epidemiologic investigations involving *Brucella* transmission and for determining relationships between and among *Brucella* isolates from various parts of the world.

Treatment of Brucellosis

The treatment of human brucellosis is an evolving area because of the spectrum of disease, the possibility/likelihood of chronic infection, and the propensity for multiorgan system complications.[837,1206] Despite in vitro susceptibility to many antimicrobial agents, in vitro results do not necessarily translate to clinical efficacies and outcomes in patients. Successful treatment requires prolonged antimicrobial therapy, usually with a combination of agents, and in some cases, surgical intervention may also be indicated. The administration of agents that penetrate and have activity within phagocytic cells is prerequisites for therapy, since brucellae are facultative intracellular pathogens, and therapy needs to be prolonged. Short-course therapy is not effective since most patients will relapse.[1208] Current therapy is a combination of doxycycline (200 mg/day PO, for 6 weeks) plus gentamicin (5 mg/kg/day, IM for 7

days).[1115,1207] The treatment recommended by the WHO includes oral doxycycline (200 mg/day) plus rifampin (600 to 900 mg PO) for a minimum of 6 weeks. The regimen of oral tetracycline (2 g/day for 6 weeks) or doxycycline combined with streptomycin or gentamicin (1 g/day, IM for 2 to 3 weeks) is associated with fewer relapses than the WHO recommendations.[63,838] Treatment of brucellosis with cephalosporin monotherapy, such as ceftriaxone, has resulted in failures and cannot be recommended.[748] The fluoroquinolones generally show good activity against *Brucella* species in vitro, even though the MICs for these agents tend to be higher than for other gram-negative bacilli.[697] Studies indicate that these agents cannot be used for single-agent therapy and have been associated with therapeutic failure rates as high as 25%.[24] A randomized, prospective study evaluated the efficacy of ciprofloxacin versus rifampin plus doxycycline in the treatment of acute brucellosis. After treatment for 45 days, five of the six patients treated with ciprofloxacin relapsed, despite in vitro susceptibility and low MICs of the *B. melitensis* isolates.[749] In a Turkish study, the clinical efficacy of a combination of ofloxacin and rifampin for 6 weeks was comparable to that achieved with the doxycycline–rifampin combination.[12] Fluoroquinolone agents and the newer cephalosporins may show better clinical efficacy when incorporated in combination therapy with other agents. SXT, when used in combination with rifampin or an aminoglycoside, is useful for treatment of children less than 8 years old (tetracyclines are contraindicated).[1206] Older children can receive a modified doxycyline (4 mg/kg/day, PO)–rifampin (10 mg/kg/day, PO) regimen for 6 weeks. For severe pediatric infections, gentamicin (5 mg/kg/day, IM) may be added for the first 5 to 7 days of treatment. For *Brucella* endocarditis, a combination of antimicrobial therapy and surgery (i.e., valve replacement) is usually necessary, although some patients have been responded to antimicrobial chemotherapy alone.[40,543,835,838] Therapy for *Brucella* endocarditis, like that caused by other bacterial agents, requires that bactericidal levels of antimicrobial agents be administered. Doxycycline, rifampin, and SXT have been used successfully for endocarditis in conjunction with valve replacement. For CNS disease, aminoglycoside regimens are contraindicated because these agents do not reach therapeutic levels in the CSF. Combination therapies with two or three drugs (e.g., doxycycline, rifampin, and SXT) that penetrate the CNS and are active against the infecting isolate are recommended.[876] The treatment of multiorgan disease may require that triple-antibiotic therapy be more prolonged and certain types of complications (e.g., spondylitis) respond better to the doxycycline–gentamicin regimen than to the doxycycline–rifampin regimen.[62,1194] During and subsequent to the completion of therapy, patients should be monitored for evidence of relapsing/recurring disease by serology using either the 2-ME modification of the SAT test or by EIA.

Francisella Species

Epidemiology of Tularemia

Tularemia is the disease caused by the fastidious gram-negative coccobacillus *Francisella tularensis.*[393] Reservoirs of the bacterium in nature include rabbits, rodents, squirrels, muskrats, beavers, voles, deer, lemmings, and raccoons. Domesticated animals such as cattle, swine, and horses are fairly resistant to infection, while sheep are relatively susceptible. The organism is transmitted among animals by ticks and biting flies, such as deerflies.[1026] Transovarial transmission

533

of *F. tularensis* also occurs in the tick, thereby providing a renewing source of the organism in the environment. Infections in humans are most commonly acquired by bites from infected ticks, deerflies, and mosquitoes or by direct contact with blood or internal organs of infected animals.[1169]Contaminated water sources, aerosols, and animal bites are also sources of infection for humans. Among ticks, at least 13 different species are known to be naturally infected with *F. tularensis*, with the dog tick (*Dermacentor variabilis*), the wood tick (*Dermacentor andersoni*), and the Lone Star tick (*Amblyomma americanum*) being the most common in North America. Disease transmission from tick exposure occurs in the Rocky Mountain regions of the United States and eastwards. In California, Wyoming, and Nevada, biting flies are the principal vectors.[218] In contrast, mosquitoes constitute the main vector for disease transmission in the former Soviet Union, Scandinavia, and surrounding regions.[387] Among hunters, infections have occurred following skinning, dressing, and eating infected animals, including rabbits, hares, beavers, muskrats, birds, and squirrels. These activities may generate aerosols, resulting in airborne transmission of the bacteria. Contaminated water is also an important source of the organism in the environment, and infections in humans have occurred following ingestion of water from wells where infected animal carcasses have been found. A large 1999 to 2000 outbreak of tularemia in Kosovo was traced to contaminated food and water, with rodents being identified as the organism source.[1076] Infections acquired by the airborne route have occurred following inhalation of dust and hay containing rodent feces and carcasses. Recent outbreaks of tularemia in Martha's Vineyard have been associated with landscaping, yardwork, and lawn mowing, and animal infections in the area have been documented in skunks and raccoons.[857] Human infections have also been acquired from exposure to or bites from carnivores, including domestic cats. In these cases, contamination of the mouth or claws of the cat following killing and feeding on prey is the likely mode of organism acquisition, although cats may also

acquire systemic infections.[1283,1332] Human infections have also been traced to infected prairie dogs that were sold as pets.[216] *F. tularensis* is highly contagious—as few as 10 to 50 organisms administered intradermally or via the aerosol route are sufficient to cause infection, and the organism can easily penetrate minute, inapparent breaks in the skin.[393] Tularemia has also been acquired from laboratory accidents that have occurred during processing of infected specimens, isolation and identification of the organism, and manipulation of large numbers of organisms in research settings. Human-to-human transmission does not occur.

Prior to World War II, tularemia was relatively common in the United States, but the incidence has steadily declined during the 1950s, and since 2001, case rates of tularemia are less than 0.05 cases per 100,000 population.[221] Although the disease has been reported throughout the United States, the vast majority of cases now occur in the south and south central states (i.e., Missouri, Kansas, Arkansas, Oklahoma, and Texas). In 2006, over half of the cases reported in the United States occurred in Arkansas, Kansas, Missouri, Nebraska, and Massachusetts.[221] The areas with the largest numbers of cases have shifted slightly northward from the south central regions of the United States, possibly secondary to climate change.[931] Most cases occur during the summer months or midwinter, and correspond to peaks of vector-associated disease and hunting-associated disease, respectively.[634] Males are more commonly infected than females, which is related to the association of this infection with certain occupations (e.g., farmers, large-animal veterinarians, hunters, sheep shearers and herders, hunters and trappers). Incidence rates in the United States are highest in children aged 5 to 10 years and adults 75 years of age and older.

During the last decade, issues have been raised concerning the potential use of *F. tularensis* as an agent of biologic warfare and bioterrorism. Consequently, *F. tularensis* is classified as a category A bioterrorism agent by the CDC.[187,346,1093] In the United States, *F. tularensis* was investigated as a potential biologic warfare agent in the 50s and 60s, prior to the termination of the US offensive bioterrorist program, and it is likely that other countries have investigated this agent as well. At Fort Detrick, animals and both civilian and military human volunteers were exposed to aerosols containing *F. tularensis* to determine the infectivity of the agent delivered in this fashion and to assess the efficacy of vaccines, prophylactic therapies, and treatment modalities.[274]Working groups in the biodefense arena have concluded that organism dispersion via aerosol would be the most likely scenario for a bioterrorist event involving *F. tularensis*, as infection by inhalation would affect the largest population.[346] With this method of dispersion, pneumonic and typhoidal disease would be the most likely clinical presentations (see below). Kaufmann and colleagues at the CDC recently published a "best and worst" case scenario if *F. tularensis* organisms were released as an "aerosol cloud" as a part of a bioterrorist event.[690] If the infective

aerosol dose of *F. tularensis* is 50 to 100 organisms, and assuming an 82.5% attack rate, exposure of 100,000 people would result in 82,500 cases of pneumonic tularemia. With a 6.2% death rate, 6,188 deaths would be expected, with an economic impact of between $465 million and $562 million!

History and Taxonomy

Tularemia was first described in 1911 by McCoy as the cause of a plague-like disease in California ground squirrels during investigations of possible bubonic plague among rodent populations in the San Francisco Bay area following the 1906 earthquake. McCoy and Chapin subsequently isolated the causative agent and named it *Bacterium tularense* after Tulare County, California, the site of their laboratory.[870] From 1912 through 1925, Edward Francis was studying the human disease called "deerfly fever" and made the connection between this illness and the "plague-like disease" described by McCoy in rodents. He investigated the modes of transmission, studied the causative agent, and coined the name "tularemia." This name reflects that of Tulare County, where McCoy and Chapin isolated the organism, and the "bacteremia" that occurs as a manifestation of infection. For his pioneering work on the cultivation of the organism and methods for serologic diagnosis, the associated clinical syndromes, and the recognition of the principal reservoirs and vectors, Francis received the 1959 Nobel Prize in science, and the name of the organism was changed from *Bacterium tularense* to *Francisella tularensis* in his honor. Based on molecular taxonomic techniques, *F. tularensis* is classified in the order *Thiotrichales*,

family *Francisellaceae* in the γ-subdivision of the *Proteobacteria*.[472,1192] Sequencing of 16S genes and whole-genome sequence analysis of several strains of *F. tularensis* indicate that the closest relatives are endosymbionts such as *Wolbachia persica*.[693] The family *Francisellaceae* includes the genera *Francisella* and *Fangia*. Genus *Fangia* includes a single species, *F. hongkongensis*, a gram-negative coccobacillus isolated from seawater in Hong Kong.[761]

Members of the genus *Francisella* are gram-negative, nonmotile, strictly aerobic facultative intracellular coccobacilli. At the present time, the genus *Francisella* includes four species: *F. tularensis*, *F. philomiragia*, *F. noatunensis*, and *F. hispaniensis*. *F tularensis* is divided into four subspecies: *F. tularensis* subsp. *tularensis*, *F. tularensis* subsp. *holarctica*, *F. tularensis* subsp. *Mediasciatica*, and *F. tularensis* subsp. *novicida*.[615,752,988] The last subspecies was formerly a separate species (*F. novicida*), but was reclassified as a subspecies of *F. tularensis* in 2010.[615] *F. noatunensis* was formerly a subspecies of *F. philomiragia* (*F. philomiragia* subsp.

noatunensis), but was elevated to species status in 2009.[888,988] *F. noatunensis* includes two subspecies: *F. noatunensis* subsp. *noatunensis* and *F. noatunensis* subsp. *orientalis*.[988] The organism named *Francisella piscicida* is a later heterotypic synonym of *F. noatunesis* subsp. *noatunensis* and is no longer a valid species name.[988] The four subspecies of *F. tularensis* can all cause tularemia, although they differ in their virulence for humans and rabbits.[474,652] *F. tularensis* subsp. *tularensis* (also called *F. tularensis* subsp. *nearctica* or biovar type A) predominates in North America but is not commonly found in Europe (although this subspecies was recognized in Slovakia), is associated with ticks and rabbits, and is virulent in both rabbits and humans.[536,654] This biogroup is characterized phenotypically by acid production from glycerol and possession of citrulline ureidase.[843,1138] Type A strains have been divided into two genetically distinct subpopulations or clades, termed *A1* and *A2*, by a molecular technique called multiple-locus VNTR analysis (MLVA), and additional molecular typing methods have delineated subtypes within types A1 (i.e., A1a, A1b) and A2 (i.e., A2a and A2b).[653,693,736,1027] Disease due to A1 strains is clinically more severe and occurs primarily in the eastern half of the United States, while disease due to A2 strains is milder and occurs only in the western United States.[412,1025,1218] However, deerfly-associated infections due to both A1 and A2 clades have occurred in Utah.[1025] *F. tularensis* subsp. *holarctica* (formerly called *F. tularensis* subsp. *palaearctica* or biovar type B) has been isolated in Europe, Asia, Japan, and North America, is associated with waterborne infection in rodents, tick, and mosquito vectors, and is intermediate in virulence in humans and minimally virulent in rabbits.[34,634] Disease due to subspecies *holarctica* may be more common in the United States than previously thought.[1276] Subspecies *holarctica* strains are glycerol-negative and do not usually produce citrulline ureidase. *F. tularensis* subsp. *mediaasiatica* was suggested for strains isolated in the central Asian focus of the Soviet Union, and *F. tularensis* biogroup *palaearctica japonica* was suggested for isolates from Japan.[1138] Initially, all four were proposed as separate species by Soviet scientists, but this proposal has not been generally accepted. Central Asian and Japanese strains have been shown to have low virulence for rabbits (like biogroup *holarctica/palaearctica*), but are clearly more closely related to *F. tularensis* biogroup *tularensis* based on 16S rRNA analysis.[1138] Recent data using two insertion sequence elements to type strains by RFLPs revealed that Japanese strains of *F. tularensis* subsp. *holarctica* (*palaearctica*) may actually represent another subspecies.[1252] *F. novicida,* originally isolated from water sources in Utah in 1951, was previously classified as a *Pasteurella* species, and was renamed as *Francisella novicida* in 1959.[752] Genetic studies subsequently determined that *F. novicida* was not a separate species, but constituted another biogroup of *F. tularensis* (biogroup novicida), since

the degree of 16S rRNA similarity was 99.6%.[430,598] *F. tularensis* biogroup novicida was elevated to subspecies status (i.e., *F. tularensis* subsp. *novicida*) in 2010.[615] *F. tularensis* subsp. *novicida*, which is an organism of relatively low virulence, has been isolated from water containing dead muskrats and from humans. *Francisella*-like organisms have been recovered from fish and human infections in recent years, suggesting that the genus may undergo expansion in the future.[961,986,1347]

F. philomiragia includes bacterial strains formerly called "philomiragia bacteria" that were mistakenly included with the yersiniae as "*Y. philomiragia.*" These organisms show genetic and antigenic relatedness to *F. tularensis* subspecies and have similar cell wall fatty acid and ubiquinone constituents. Analysis of the 16S rRNA of these organisms has corroborated the genotypic relationship of *F. tularensis* and *F. philomiragia*.[430,431,598] *F. philomiragia* is considerably less virulent than *F. tularensis* and has been isolated mostly from animals (e.g., muskrats) and water. Unlike *F. tularensis*, *F. philomiragia* is an opportunistic agent, causing pneumonia and systemic infections in patients with chronic granulomatous disease, near-drowning victims, and patients with hematologic malignancies.[828,1187,1338] Over a 12-year period, 14 human isolates of *F. philomiragia* were submitted to the Special Bacteriology Branch of the CDC. Of these 14 isolates, five were from patients with chronic granulomatous disease, five were from individuals who nearly drowned in salt water, two were from unknown human sources, and single isolates were from a patient with Hodgkin's disease and a patient with myeloid metaplasia.[598,1165,1338] These cases have defined the clinical spectrum of *F. philomiragia* as a rare agent of necrotizing pneumonia, bacteremia, and meningitis.[1165,1338] A recent case of *F. philomiragia* adenitis and pulmonary nodules was reported in a 10-year-old boy with chronic granulomatous disease following a facial abrasion from a saltwater crab.[828]

F. noatunensis subsp. *noatunensis* and *F. noatunensis* subsp. *orientalis* are well-known pathogens of various fresh- and saltwater fish, including three-line grunt in Japan, tilapia in America and Asia, hybrid striped bass from America, Atlantic Salmon from Chile, and Atlantic cod from Norway.[888,987,988] In these various fish species, these bacteria cause chronic granulomatous infections of the heart, kidney, spleen, and liver. *F. noatunensis* subspecies are most closely related to *F. philomiragia*. The new species *F. hispaniensis* was a blood culture isolate from a patient with bacteremia secondary to acute obstructive pyelonephritis.[615] This isolate was initially thought to be a strain of *F. tularensis* subsp. *novicida*, but analysis of five housekeeping genes and two genes encoding membrane proteins revealed that it was distinct from recognized *Francisella* species and subspecies. In July of 2008, two isolates—one from CSF and one from blood—were recovered from two different patients.[737] The

first isolate was recovered from the CSF of a 15-month-old female with hemophagocytic syndrome and juvenile rheumatoid arthritis, and the second was isolated in a blood culture from an 85-year-old man with end-stage renal disease. When 16S rRNA sequences were analyzed, the two isolates showed 97% identity with *F. tularensis* subsp. *tularensis*, *F. tularensis* subsp. *holarctica*, *F. tularensis* subsp. *novicida,* and *F. philomiragia*, and were 98% similar to sequences found in soil isolates in the genus *Francisella*. All *F. tularensis*-specific tests (e.g., slide agglutination with specific antisera, fluorescent antibody (FA) tests, and PCR analysis) were negative. Investigators proposed that these two isolates, which were genotypically and phenotypically similar, may represent a new *Francisella* species.[737]

In 1997, another possible *Francisella* species was recognized as an endosymbiont in ovarian tissue of female *Dermacentor andersoni* ticks, but has not been detected in male ticks.[940] The relation of this organism, designated the "*D. andersoni* symbiont" (DAS), and *Francisella* species is based on the presence of a specific membrane antigen and 16S rRNA sequences that are similar to those of *F. tularensis*. These endosymbionts are termed FLEs or "*Francisella*-like endosymbionts." These FLEs have been identified in ticks belonging to the genera *Dermacentor*, *Amblyomma*, *Rhipicephalus*, and *Ornithodoros.*[1162,1230] Investigation of obligately endosymbiotic bacteria found in *Paramecium tetraurelia* found that one of these endosymbionts, *Caedibacter taeniospiralis*, formed a novel evolutionary lineage with the γ-*Proteobacteria* and shared 87% similarity in its 16S rRNA sequences with the family *Francisellaceae*.[103] In a study of FLEs from a variety of tick species, Machado-Ferreira and colleagues identified gene sequences of the *F. tularensis* pathogenicity island gene *iglC* and its regulatory gene *mglA* in FLEs.[819] The *iglC* gene encodes a protein in *F. tularensis* that is involved in bacterial escape from the phagolysosome and intracellular bacterial survival. At the present time, FLEs do not appear to be pathogenic in humans, but the recognition of gene sequences in FLEs that are similar to *F. tularensis* virulence-associated genes suggests a pathogenic potential for these unusual agents. Using primers and probes for various regions of the *lpnA* gene of *F. tularensis*, which encodes a lipoprotein, a 233 base pair fragment was identified that was able to discriminate among *F. tularensis* subspecies and FLEs.[406] This method would be useful in field studies of *Francisella* species in environments where FLEs are likely to be present. This molecular approach was useful not only for the detection and differentiation of *Francisella* subspecies and FLEs, but was also helpful for detection of atypical *Francisella* isolates associated with human disease, such as the unusual *F. tularensis* strain FnSp1, which is now *F. hispaniensis*.[615]

Clinical Spectrum of Tularemia

Clinical manifestations of tularemia depend on the mode of acquisition of the organism, the bacterial subspecies involved, the innate virulence of the infecting strain, the immunocompetence of the host, and the extent of organ system involvement.[580]After infection, there is an incubation period of a few hours to 3–5 days, but it may range as far as 3 weeks. The onset is acute, with fever, chills, malaise, headache, sore throat, and sometimes diarrhea. Fevers may wax and wane but usually remain elevated for 4 to 5 weeks in the absence of treatment. During this time, weight loss, lymphadenopathy, and chronic illness develop. Patients who are infected with less virulent strains may have a mild illness that resolves spontaneously, while others develop chronic, debilitating, multisystem infections.

Tularemia was clinically divided into six syndromes: ulceroglandular tularemia, glandular tularemia, oculoglandular tularemia, oropharyngeal tularemia, typhoidal tularemia, and pneumonic tularemia. This classification has been replaced by a binary disease classification recognizing ulceroglandular and typhoidal disease. The distinction between these two forms depends on the involvement of skin/mucous membranes and the location and severity of the associated lymphadenopathy. About 75% of patients present with the ulceroglandular form, while 25% present with the typhoidal form. Ulceroglandular tularemia, which is the most common clinical presentation, now encompasses ulceroglandular, glandular, and oculoglandular syndromes.[1099] The patient presents with a painful lesion at the site of organism entry that later ulcerates, forming a central, punched-out ulcer with a raised periphery. Vesicular ulcers resembling those of herpes simplex and varicella viruses that have been culture-positive for *F. tularensis* have also been described. The location of the lesion depends on whether the infection was obtained from an arthropod or a mammalian vector. In 2% to 12% of cases, the primary lesion is in the oropharynx and results from ingestion of contaminated food or water. Mucous membrane involvement presents as severe granulomatous conjunctivitis, loss in visual acuity, preauricular and submandibular lymphadenopathy, and, in some patients, nonexudative pharyngitis.[210,470] Some patients present with severe headache, tonsillitis, and exudative pharyngitis suggestive of streptococcal pharyngitis, diphtheria, or Vincent's disease. Pharyngeal involvement invariably has associated regional lymphadenopathy that can result in lymph node and retropharyngeal abscess formation. Otitis media and middle ear infections are rare complications.[535,816] Enlarged lymph nodes and abscesses may become fluctuant and suppurate through the overlying skin or become persistent.[276,576] In some case, lymphadenopathy and fever are present, but a skin lesion is not apparent.[815,969] In these cases, the lesion may have healed or may be innocuous and unnoticed. Typhoidal tularemia presents with an abrupt onset of fever, chills, headache, sore throat, vomiting, and abdominal pain and tenderness. No initial skin lesion or

lymphadenopathy is apparent, and the infection is probably acquired by ingestion of contaminated water or food. Typhoidal tularemia is the only form in which diarrhea is a prominent part of the clinical presentation. The diarrhea is usually loose and watery. Almost half of the patients with typhoidal tularemia develop secondary pleuropulmonary disease, with pulmonary infiltrates and pleural effusions. In this form, blood and sputum cultures may be culture-positive, and the mortality rate is usually high. Bloody stools may be seen, particularly in children. Pneumonia is seen in about 80% of patients with typhoidal tularemia and in about 30% of those with ulceroglandular tularemia and results from inhalation of aerosols containing the organism or from hematogenous dissemination.[106,415,416] Radiographic examinations may show involvement of one or more lobes, with pleural effusions, pneumonic infiltrates,

abscess formation, pulmonary nodules, and hilar lymphadenopathy.[487,937] Symptoms include fever, dry cough with minimal sputum production, and pleuritic chest pain. Clinically, pneumonic tularemia resembles tuberculosis, atypical pneumonias due to *Legionella*, *Chlamydophila pneumoniae*, *Chlamydophila psittaci*, *Coxiella burnetii*, and fungal pneumonia. Pneumonic tularemia tends to be more severe in patients with underlying conditions, such as malnourishment, alcoholism, renal disease, chronic granulomatous disease, and HIV infection.[842] Complications such as hepatosplenomegaly, renal failure, and rhabdomyolysis occur more frequently in these individuals. Pneumonic tularemia is usually seen in adults and is associated with certain occupations (e.g., sheep shearers, animal husbandry workers, laboratorians), farming activities (e.g., threshing), lawn mowing, and brush cutting. This association is likely due to the presence of rodent feces or infected animal remains in hay.[1235]

Clinical tularemia can display an array of presentations in individual patients. Plourde et al.[1036] reported a case of glandular tularemia with some features of typhoidal disease in a child who had sustained an insect bite on the left scapula. Inguinal lymphadenopathy rather than lymphadenopathy near the site of the insect bite was found, and the patient developed abdominal distention and severe, watery diarrhea, both of which are features of typhoidal disease. In another instance, a serologic diagnosis of tularemia was achieved on a 53-year-old woman with a large pericardial effusion who reported close contact with rabbits 2 weeks prior.[747] Chronic infection of a knee prosthesis was reported in a patient with degenerative joint disease 6 months after a tick bite.[304] Meningitis and brain abscess are a rare complication of *F. tularensis* infection.[471,595,1095] Patients with meningitis may or may not have significant nonmeningeal disease (glandular or typhoidal tularemia). CSF findings are

consistent with a bacterial meningitis (i.e., low glucose with high protein), and show a predominance of lymphocytes on Gram's stain of the CSF. A *F. tularensis* ventriculoperitoneal shunt infection was first reported in 1996 in a 5-year-old boy with myelomeningocoele.[1034] Signs and symptoms were limited to the CNS, with no other systemic involvement. Two weeks prior to presentation, the child had been with friends who were skinning a rabbit. Clinical and bacteriologic cure was achieved with intrathecal gentamicin and shunt replacement. LeDoux reported a case of presumptive *F. tularensis* CNS disease in a 61-year-old man whose clinical presentation was predominantly gait ataxia.[771] In 2000, Tancik and Dilliha reported the first published case report of *F. tularensis* native valve endocarditis in a 42-year-old man from Arkansas.[1244] The patient responded to a 4-week course of gentamicin. Severe disease is also associated with compromised host status, as evidenced by a rapidly fatal infection in a neutropenic bone marrow transplant recipient.[1145] *F. tularensis* subsp. *novicida* is a rare pathogen, and only a very few infections have been reported, including the recent description from Thailand of *F. tularensis* subsp. *novicida* bacteremia in a woman undergoing chemotherapy for ovarian cancer.[773]

Detection, Isolation, and Cultural Characteristics

Because this organism can penetrate through small breaks in the skin, it is potentially dangerous to handle specimens or cultures of *F. tularensis* in the laboratory. As with brucellosis, tularemia may not be suspected when a patient presents to the clinician; so considerable time may be spent handling specimens and cultures before this diagnosis is entertained. For laboratories working with clinical materials of human and animal origin, BSL-2 practices, containment equipment, and facilities are recommended, while BSL-3 and Animal BSL-3 practices are required for working with live cultures or performing experimental animal studies.[1279] In the routine clinical microbiology laboratory, all specimens and cultures should be processed in a class II biologic safety cabinet, gloves should be worn during all procedures, and any procedures that may generate aerosols should be avoided. With the threat of bioterrorism, screening tests for *F. tularensis* and other bioterrorism agents must be incorporated into laboratory bench procedures in order to permit rapid presumptive identification of an isolate so that it can be referred to level B laboratories for definitive identification.[1093] Persons with confirmed laboratory exposure should be treated prophylactically.

F. tularensis may be isolated from primary ulcers, lymph node aspirates and biopsies, sputum, bone marrow, and tissue biopsies (e.g., liver, spleen). Specimens should be kept at 4°C to 8°C until processing. Specimens may also be placed in Amies transport medium with charcoal or in Stuart medium at room temperature prior to processing. The organisms have also been isolated from peripheral blood specimens, usually in the setting of preexisting, underlying disease. Positive blood cultures have

been found in patients with typhoidal, pneumonic, and oropharyngeal tularemia, and in the single report of *F. tularensis* endocarditis.[593,951,1046,1276,1320] In case reports describing *F. tularensis* bacteremia, growth of the organism was found after 3 to 7 days' incubation using the BACTEC radiometric system. However, in one patient with endocarditis, *F. tularensis* was recovered after 9 days with the BACTEC system.[1244] *F. tularensis* was isolated after 12 days' incubation from a BACTEC nonradiometric aerobic blood culture bottle (BACTEC NR6A) that was inoculated with a 10 to 20 μL volume of an percutaneous fine needle aspirate of an inguinal lymph node.[179] If tularemia is suspected clinically, broth blood cultures should be incubated beyond the standard 5- to 7-day incubation period used in many laboratories. Blind subculture of blood culture bottles may be advantageous for detection.

F. tularensis is a small, pale-staining, gram-negative coccobacillus. Classically, the organism has a growth requirement for cysteine, cystine, or other sulfhydryl-containing compounds, and the preferred medium for isolation was glucose cysteine blood agar. However, *F. tularensis* will grow on commercially available chocolate agar and modified Thayer-Martin agar, since these hemin-containing medium are supplemented with a growth enrichment (e.g., IsoVitelex, BD Biocience) that contains cysteine, cystine, and other nutrients required by fastidious bacteria. Like the brucellae, this organism is also able to grow on BCYE agar, the medium used for isolation of *Legionella* species.[1340] *F. tularensis* has also been isolated from a biopsy of a cutaneous lesion by the centrifugation shell vial technique using human embryonic lung fibroblasts.[440] Although the organism failed to grow upon subculture on bacteriologic media, the identity of the organism was determined by PCR analysis of the organism

537

growing in the shell vial. Atypical strains may lack the cysteine requirement of "classical" *F. tularensis* strains, but they are usually weakly oxidase-positive, catalase-negative, agglutinate strongly in *Francisella* antiserum, and unreactive in other phenotypic tests, including those for biogroup determinations.[122] Cellular fatty acid analysis of these strains revealed the presence of long-chain (i.e., C_{18} to C_{26}) saturated and unsaturated fatty acids, and large amounts of 3-hydroxy-octadecanoate (3OH-$C_{18:O}$), a fatty acid that is unique to *F. tularensis*.[644] These unusual hydroxy fatty acids comprise part of the lipid A structure in the LPS of the organism. Consequently, these organisms may be identified readily by cellular fatty acid analysis using the Microbial Identification (MIDI) System and Library Generation System (LGS) software (MIDI, Newark, NJ). Clarridge and colleagues isolated two nonfastidious *F. tularensis* strains from blood culture of patients with pneumonia.[282] These isolates

grew on both chocolate and blood agar and were identified as *F. tularensis* by phenotypic characteristics, 16S rRNA gene sequencing, and rDNA probe hybridization. These strains also failed to agglutinate in commercial *F. tularensis* antisera. Strains of *F. tularensis* subsp. *novicida* and *F. philomiragia* do not demonstrate a requirement for cysteine.

F. tularensis is obligately aerobic; growth is stimulated by increased CO_2 and may require 2 to 5 days' incubation at 35°C to 37°C before colonies are visible on agar medium. Colonies on chocolate agar are gray, smooth, buttery, and about 2 mm in diameter after 3 days' incubation. *F. tularensis* subsp. *tularensis* grows more slowly than the other subspecies. Colonies of *F. philomiragia* are larger, whiter, and mucoid. *F. tularensis* subspecies are oxidase-negative, are weakly catalase-positive, grow poorly (if at all) on MacConkey agar, and are inert biochemically. *F. philomiragia* isolates are oxidase-positive. Species identification is usually confirmed by agglutination tests using specific rabbit polyclonal antisera. Cultures should be examined over a 10- to 14-day period. Phenotypic characteristics of *Francisella* species are presented in Table 9-13.

Studies using spiked blood cultures and experimentally infected mice initially suggested the utility of PCR as a method for detection and identification of *F. tularensis* in clinical specimens from humans.[362,667,801] These assays were able to detect both *tularensis* and *holarctica* subspecies at sensitivities equal to 1 colony-forming unit/mL of blood. Subsequently, a multiplex PCR assay targeting both the 16S rRNA gene and a 17-kDa lipoprotein gene was successfully developed for direct detection of *F. tularensis* in swabs from ulceroglandular tularemia lesions in Sweden.[654,1193] The lipoprotein gene is conserved among *F. tularensis* strains and does not show sequence similarities with other known prokaryotic sequences published in current gene banks.[654] PCR performed on wound specimens was able to provide a rapid diagnosis in patients with suspected ulceroglandular tularemia who were negative on culture and had not yet seroconverted.[654,682] Subsequent investigations of ulceroglandular

tularemia in Sweden have further confirmed the clinical and diagnostic utility of PCR.[389] PCR had also been applied to lymph node tissues and aspirates for the diagnosis of oropharyngeal tularemia. During an investigation of an outbreak of oropharyngeal tularemia in Turkey, PCR performed on lymph node aspirates of all seven patients was positive; these tests were positive even though all seven patients had been receiving antimicrobial chemotherapy for over 2 weeks when the tests were performed.[209] PCR has also been applied to the diagnosis of oculoglandular disease, with positive results being obtained from a conjunctival swab and a conjunctival nodule in two patients, respectively; both patients had positive *F. tularensis* PCR results from blood cultures.[679] Two additional patients in this study had positive PCR and cultures from lymph node tissue. In response to the need for epidemiologic tools for investigating outbreaks of tularemia, PCR approaches have also been developed to detect infection directly in experimental animals and in insect vectors, and to provide methods for typing and discrimination of strains.[338,411,474,586,1252] Real-time PCR assays have been developed that identify and distinguish the A1 and A2 clades of *F. tularensis* subsp. *tularensis*.[902]

Several other novel techniques for rapid detection/identification of *F. tularensis* have been developed as a direct result of concerns over the use of *F. tularensis* in

bioterrorism and biologic warfare. Grunow and colleagues developed a standard EIA and a handheld immunochromatographic assay that used monoclonal antibodies against LPS antigen as the capture antibody for detecting *F. tularensis* subsp. *tularensis* and *F. tularensis* subsp. *holarctica* directly in veterinary specimens.[520] Antigen-capture EIAs using time-resolved fluorometry have also been developed for detection of several bioterrorism-associated agents in both clinical and environmental samples.[1024] Emanuel and coworkers developed a fluorogenic PCR-based method for detection of *F. tularensis* in infected mice. This assay could be performed using a handheld thermocycler designed for field use; results were available within 4 hours.[396] Multiplex PCR platforms capable of detecting a number of agents have also been developed in response to the threat of bioterrorism. These real-time, bead- or DNA microarray-based amplification assays have been developed and optimized to detect *F. tularensis*, *Y. pestis*, *B. anthracis*, and *B. melitensis* in animals tissues (e.g., cow anthrax, hare tularemia), blood specimens (e.g., blood spiked with serial dilutions of pathogens), and environmental samples.[1195,1259,1355]

Because strains belonging to the different *F. tularensis* biogroups are antigenically homogenous, subspecies are differentiated from one another on the basis of phenotypic criteria or subspecies-specific probes for 16S rRNA.[430] Strains of *F. tularensis* subsp. *tularensis* produce acid in media containing glucose, maltose, or glycerol as a carbon source. These also hybridize with an oligonucleotide probe for subspecies *tularensis*-specific 16S rRNA sequences. Subspecies *holarctica* strains produce acid from glucose and maltose, but not from glycerol, and hybridize with a probe that is specific for subspecies *holarctica* 16S rRNA sequences. Both subspecies *mediaasiatica* and subspecies *palaearctica japonica* strains hybridize with the subspecies *tularensis*-specific probe; however, subspecies *mediaasiatica* strains produce acid from glycerol and sucrose, while subspecies *palaearctica japonica* strains acidify media containing either glucose or glycerol. Serologic methods can distinguish between subspecies *tularensis* and *novicida* strains, but not between subspecies *tularensis* and *holarctica* strains. Citrulline ureidase, an enzyme that correlates with virulence of *F. tularensis*, is found in virulent strains of subspecies *tularensis,* some *holarctica* strains, and *mediaasiatica* strains.[843,1138] The enzyme is not found in attenuated *tularensis* strains and in most subspecies *holarctica* strains with low virulence. Phenotypic testing of these organisms is problematic, since reactions are often delayed or variable.

Treatment of Tularemia

The drug of choice for treatment of tularemia is the aminoglycoside streptomycin, with gentamicin being an alternative agent. Doxycycline has also been used but is associated with higher relapse rates than aminoglycoside therapy, especially if administered early

in the clinical course. The initial clinical response to treatment with tetracyclines is dramatic (i.e., patients defervesce rapidly), but relapse rates after therapy are over 12%, which is twice the relapse rate seen with gentamicin therapy. Intramuscular or intravenous gentamicin and doxycycline are not useful for treatment of *F. tularensis* meningitis owing to poor penetration into the CNS, but patients have responded to intrathecal gentamicin or intrathecal combinations of streptomycin or gentamicin with doxycycline. Intravenous therapy with erythromycin has also been used successfully, but in vitro data suggest that the *F. tularensis* strains are not predictably susceptible. Scheel et al.[1146] found that 14 of 22 Scandinavian strains were resistant to erythromycin and clarithromycin in vitro, and resistance to erythromycin is substantial among strains recovered in Russia.[1281] Fluoroquinolones are also active against type A and type B *F. tularensis* isolates. However, clinical responses to fluoroquinolone therapy in patients with disease due to subspecies *tularensis* are suboptimal compared with infections caused by the less virulent *holarctica* subspecies. In the former cases, combination therapy with gentamicin and a fluoroquinolone may result in a better clinical response.[387,388]

Using the CLSI-recommended broth microdilution method, Urich and Petersen tested 92 *F. tularensis* subsp. *tularensis* (type A) isolates and 77 *F. tularensis* subsp *holarctica* (type B) isolates and found that all organisms tested were susceptible to those agents that are used for the treatment of tularemia, including streptomycin, gentamicin, tetracycline, doxycycline, ciprofloxacin, and levofloxacin.[1281] All strains were in the susceptible range for erythromycin, with type A strains having MICs two doubling dilutions lower than type B strains. Valade and investigators in France tested 71 *F. tularensis* subsp. *holarctica* stains and found that reproducible results could not be obtained for some agents using the broth microdilution method. Using agar dilution, all 71 subsp. *holactica* isolates were susceptible to streptomycin, gentamicin, doxycycline, ciprofloxacin, nalidixate, and chloramphenicol.[1282] While some in vitro studies using broth dilution methods have reported low MICs for β-lactams when tested against *F. tularensis*, other studies using agar dilution have concluded that *F. tularensis* is resistant to β-lactam antimicrobial agents.[83,1146] In a study of 22 animal and human *F. tularensis* isolates using the agar dilution

539

method with blood–cysteine–glucose agar, all strains were resistant not only to penicillin and cephalothin, but also to cefuroxime, ceftazidime, aztreonam, imipenem, and meropenem, with MIC of >32 μg/mL for all drugs. Ikaheimo and colleagues used Etest strips on cysteine heart agar plates for testing 20 human isolates and 18 isolates from dead animals. All strains were susceptible to the agents that have been used for

treatment (i.e., streptomycin, tetracycline), but were resistant to β-lactams and carbapenems, including ceftriaxone, ceftazidime, cefepime, imipenem, meropenem, and piperacillin–tazobactam.[621] Other studies have also determined that *Francisella tularensis* subspecies are generally resistant to penicillins and cephalosporins but susceptible to the mainstay drugs used for therapy.[860,1258] Clinical experience with third-generation cephalosporins for tularemia indicates that they are not effective. Cross and Jacobs reported on eight cases of documented failures with outpatient use of ceftriaxone in the treatment of tularemia.[315]

Isolates of *F. philomiragia* are usually susceptible to the aminoglycosides, the fluoroquinolones, and tetracycline, and variably susceptible to amoxicillin clavulanate, rifampin, and erythromycin. Most strains produce β-lactamase enzymes and are resistant to ampicillin, and some strains may be resistant to cefazolin, cefotaxime, and SXT.

Virulence of F. tularensis

The factors that are responsible for the virulence of *F. tularensis* are being studied intensively at this time because of funding increases in bioterrorism programs.[991,1013] The organism produces no identifiable exotoxins, and its virulence stems from its ability to grow to large numbers within host tissues, and to induce a significant inflammatory host response. Upon infection, the organism multiplies locally for 3 to 7 days, then spreads to the regional lymph nodes and disseminates via the lymphohematogenous route to involve multiple organs. An initial inflammatory response ensues, with the accumulation of neutrophils, fibrin, and macrophages. Lymphocytes and macrophages migrate into the infected tissues, engulf the organisms, and form granulomas in multiple sites (i.e., lymph nodes, bone marrow, spleen, liver, and lungs). Organisms remain viable within these macrophages by inhibition of phagosome–lysosome fusion and utilization of iron from host cells. The predominant antibody response in humans is to LPS. The LPS of the organism has a unique structure, induces less cellular toxicity, and does not bind to host molecules involved in triggering proinflammatory responses. Animal studies have demonstrated that immunization with LPS induces protection against *F. tularensis* strains of low virulence, but will not protect against more virulent strains.[299] Natural infection or immunization with the *F. tularensis* live vaccine strain (LVS) engenders long-lasting cell-mediated and humoral resistance to reinfection, with the cell-mediated immune response being the most important protective mechanism. Cell-mediated immunity appears 7 to 10 days after infection, with IgM, IgG, and IgA agglutinating antibodies appearing during the subsequent 2 weeks. Lysis of cells harboring organisms by immune effector cells in the liver and other organs releases organisms from intracellular compartments, thereby enabling them to infect other cells. If left

untreated, suppuration of involved lymph nodes in various tissues results in additional manifestations of systemic disease. Persistence of cell-mediated, protective immunity with a concomitant decline in humoral immunity has been demonstrated in individuals who were naturally infected 25 years earlier.[401] Studies performed with mutants of the LVS strain suggest that the principal virulence factor of *F. tularensis* is the ability to invade and multiply within macrophages, hepatocytes, and other cells of the RES. *F. tularensis* is able to enter host macrophages and, once inside, is able to destabilize the phagosome and escape into the cytosol of the cell, where it then multiplies to high numbers.[1140] Eventually, the bacteria are released by organism-induced apoptosis. *Francisella* organisms are also able to enter neutrophils without triggering an oxidative burst, and to multiply inside the neutrophils as well.[867] Acid phosphatases unique to *F. tularensis* play a key role in the escape of organisms from macrophages and neutrophils. *F. tularensis* contains a pathogenicity island comprising 19 genes that are essential for virulence, and the products of these genes are under current investigation.[935] Pili and secretion systems for virulence factors have also been detected.[544]

The LVS vaccine was developed in Russia via multiple in vivo and in vitro passages of a virulent *F. tularensis* subsp. *holarctica* strain and was sent as a gift to the United States in 1956. The vaccine was subsequently tested on volunteer populations by the US Army.[298,299] Although the vaccine is effective in protecting against low- and high-dose subcutaneous and low-dose aerosol challenge with a virulent type A strain, it does not adequately protect against high-dose aerosol administration of virulent *F. tularensis*. When administered by the aerosol route instead of scarification, greater protection was seen, but some volunteers developed disease from this attenuated strain. Because of the lack of adequate responses in volunteers and the questionable degree of attenuation observed in the volunteers subjected to aerosol inoculation, the vaccine did not achieve licensure in the United States. Investigations with subunit vaccines based on immunoreactive surface proteins and lipoproteins of the organism were disappointing, as the level of protective immune responses were less than that seen following administration of LVS.[497] In addition to attenuated and subunit vaccines developed from LVS and *F. tularensis* subsp. *holarctica*, mutants of *F. novicida* have also been investigated as surrogate organisms for live, attenuated tularemia vaccines. Investigated organisms have included *F. novicida* strains with mutations in the pathogenicity island genes, metabolic pathways genes, acid phosphatase genes, and in genes affecting LPS biosynthesis. Immunization of mice with these various mutants has led only to the demonstration of protective immunity against the homologous strain, and none have been able to confer protective immunity to mice on challenge with either *F. tularensis* type A or type B.[1048,1180] Live mutants of *F. novicida* that are unable to escape from the phagosome following infection do

not appear to function well as live vaccine candidates, suggesting that the vaccine needs to mimic actual infection more closely and replicate outside of the phagosome in order to stimulate humoral or cell-mediated immune responses. Mutants of the LVS strain (*F. tularensis* subsp. *holarctica*) confer immunity against the wild-type LVS strain and variable degrees of protection against heterologous type B and some type A strains.[1013] As with the wild-type LVS,

540

mutants of LVS do not appear to confer a high level of immunity when *F. tularensis* type A or B challenge strains are administered via the respiratory route. The use of attenuated strains or mutants of *F. tularensis* subsp. *tularensis* has also been investigated. Wu and colleagues showed that giving a sublethal dose of a virulent type A strain as a booster inoculation following vaccination with LVS provided augmented protection when compared with giving a booster dose of the LVS strain.[1372] In addition to investigations on which vaccine types (i.e., killed, live-attenuated, or subunits) engender the best immune response, vaccine researchers are also examining the routes of vaccine administration (scarification, parenteral, respiratory inhalation) to see which route affords the best protection against challenge with virulent type A and type B strains of *F. tularensis*.[1372]

Afipia Species, *Bosea* Species, and Other α-*Proteobacteria*

Afipia species are fastidious members of the class α-2 *Proteobacteria*, order *Rhizobiales*, family *Bradyrhizobiaceae*.[171,755] These organisms live within free-living amebae belonging to the genus *Acanthamoeba* and can be isolated from them by amebal enrichment and coculture methods. Amebal coculture is a technique in which axenic amebae are used as host systems for isolation of intracellular bacteria directly from clinical or environmental specimens. Bacteria from these specimens enter the amebae and multiply, subsequently leading to lysis of the amebae and the release of the intracellular organisms. Bacterial characterization is accomplished by differential stains, subcultures, and molecular methods (e.g., PCR, sequencing). Amebal enrichment techniques involve culture of environmental amebae on nonnutritive agar media seeded with enteric bacteria (e.g., *E. coli*) as a food source. Following incubation, the agar surface is screened for the presence of motile amebae, followed by subculture onto additional plates of seeded nonnutritive agar. Intracellular bacteria can then be isolated by amebal coculture, adapted to in vitro cultivation on agar media

such as BCYE agar, tested for phenotypic traits, and characterized by molecular approaches such as 16S rRNA sequencing. Amebal coculture and enrichment techniques have been specifically developed to identify bacterial agents in environmental samples and in specimens from patients.[746] Organisms in the genus *Afipia* were first isolated from lymph node aspirates of patients with cat scratch disease (CSD; *A. felis*); additional species were subsequently recovered from human clinical specimens (*A. clevelandensis*, *A. broomeae*, *Afipia* genospecies 1 and 2) and water (*Afipia* genospecies 3).[171] In 1999, LaScola and colleagues recovered *A. felis* from the water supply of a French hospital by amebal coculture, and a subsequent systematic cocultivation survey of water samples from the Timone Hospital Center in Marseilles yielded 68 α-*Proteobacteria* that were divisible into 7 clusters by 16S rRNA sequence comparisons.[753,759] Five clusters were composed of organisms closely related to *A. felis* and various *Afipia* genospecies; some of these subsequently were characterized as new *Afipia* species (i.e., *A. birgiae*, *A. masseliensis*, and *Afipia felis* genospecies A).[755] Another study performed on ICU water samples at four university hospitals in Marseille yielded 64 bacterial strains that were identified as *Afipia* species or close relatives within the *Rhizobiaceae*.[757] In this same study, a serosurvey of 85 ICU patients with hospital-acquired pneumonia at these hospitals was performed, and 11 patients were found to have elevated antibody titers to *Afipia* genospecies 1 (2 patients),*Mesorhizobium amorphae* (3 patients), and two unnamed bacteria (6 patients) that were genotypically related to *Rasbobacterium.* In vitro studies have also shown that *Afipia* species are able to grow within human cells, including HeLa, macrophages, and endothelial cells. Phenotypic characteristics for the identification of *Afipia* and related species are presented in Table 9-14.

The genus *Bosea* includes gram-negative, oxidase-positive, motile environmental bacilli composed of several species (*B. thiooxidans*, *B. minatitlanensi*, *B. massiliensis*, *B. vestrisii*, *B. eneae*, *B. sequanensis*, *B. lascolae*, *B. lupini*, *B. lathyri*, *B. robiniae*).[328,343,756,989,1253] *B. minatitlanensis* and *B. massiliensis* have been isolated from hospital water supplies by amebal cocultivation and characterized after adaptation to growth on BCYE and blood agar. Coculture methods, serology, and molecular techniques have suggested possible involvement of these *Proteobacteria* in ventilator-associated pneumonias. In a study from Sainte-Marguerite Hospital in Marseille, Berger and colleagues screened 210 ICU patients with pneumonia. Both ameba-associated and conventional agents were implicated in 15 patients and included *B. massiliensis*, *Mesorhizobium amorphae*, and several *Legionella*-like amebal pathogens (LLAPs).[113] In another study using amebal cocultivation, LaScola and colleagues tested water from ICU sites weekly for 6 months using amebal cocultivation, and the isolates that were obtained were adapted to growth on BCYE agar.[754] Organisms recovered from water samples included *Legionella anisa*, several

LLAPs, *A. broomeae*, *B. massiliensis*, and *Bradyrhizobium* species. At the same time, serum and BAL specimens for subsequent amebal coculture were obtained from 30 ICU patients. Amebal isolates from these specimens were adapted to growth on BCYE agar and characterized by molecular methods. Sera from patients were tested for antibodies against the ameba-associated bacteria obtained from ICU patients using indirect microimmunofluorescence. Twelve of 30 serum samples indicated host seroconversion to one or more ameba-associated bacteria from ICU water samples; most seroconversions occurred against *L. anisa* and *B. massiliensis*, which were the most common water isolates. The nucleic acids of *L. anisa* and *B. massiliensis* were each detected once (2 patients) in 66 BAL specimens obtained from the 30 patients. Seroconversion to *L. anisa* and *B. massiliensis* was observed 4 weeks and 2 weeks after the BAL specimen was PCR-positive for these organisms, respectively.[754]

*Mesorhizobiu*m and *Bradyrhizobium* species are α-*Proteobacteria* that are closely related to both *Afipia* and *Bosea* species, while *Rasbobacterium* forms a monophyletic subcluster related to *Afipia* and *Methylobacterium* species. *Mesorhizobium* and *Bradyrhizobium* species are found in water but have their specific ecologic niche in soil, where they establish symbiotic relationships with leguminous plants and fix atmospheric nitrogen in exchange for carbohydrates from the associated plants.*Rasbobacterium* was originally isolated in 1997 from a 33-year-old Swedish man with an

influenza-like illness, with subsequent development of persistent fevers, sepsis, and pericarditis.[139] The patient's fevers persisted for several months despite repeated courses of antimicrobial agents, and the patient experienced three relapses with similar symptoms over the subsequent 21 months. The organism was repeatedly isolated from blood and also from pericardial fluid. Of the three isolates recovered from the patient, two could be cultivated on cell-free media, while the third was isolated only by cocultivation in Vero cells. Phenotypically, *Rasbobacterium* is a motile gram-negative bacillus that grows optimally at 25°C to 30°C and is oxidase- and urease-positive.

Bartonella Species

Taxonomy

The genus *Bartonella* currently comprises at least 25 species and subspecies of fastidious gram-negative bacteria that are vector-transmitted and highly adapted to one

or more mammalian reservoir hosts. Older members of genus *Bartonella* were formerly classified in the genus *Rochalimaea* (*Bartonella quintana*, *Bartonella vinsonii*) and the genus *Grahamella* (*Bartonella talpae*, *Bartonella peromysci*, *Bartonella grahamii*, *Bartonella taylorii*, and *Bartonella doshiae*).[129,172] This genus also includes the agents of CSD, *Bartonella henselae* and *Bartonella clarridgeiae,* and several other species found in a variety of mammalian hosts. Genetic analyses by 16S rRNA sequencing and DNA hybridization techniques confirmed that *Bartonella* is the only genus in the family *Bartonellaceae*. This family resides in the order *Rhizobiales*, which is in the α-2 subgroup of the class α-*Proteobacteria*.

Epidemiology of Bartonella *Species*

The discovery of *B. henselae* and *B. quintana* as opportunistic human pathogens, the evidence for *B. henselae* as the agent of CSD and the likelihood of vector-borne transmission of these bacteria among animals and humans prompted extensive studies on the epidemiology of these novel organisms and their roles as emerging human and veterinary pathogens.[166,261,533] Using cultural, serologic, and molecular methods, several new *Bartonella* species have been discovered and described during the last several years. In 1993, a unique isolate named *B. elizabethae* was recovered from a patient with endocarditis.[324] In 1995, Clarridge and colleagues published a description of their laboratory approach for diagnosis of CSD and included presentations of two patients with CSD.[281] While *B. henselae* was recovered from both patients, a second *Bartonella* species was isolated from a kitten that belonged to one of the patients. This isolate was given the name *B. clarridgeiae* in honor of Dr. Jill Clarridge, and in 1997, the first patient with CSD caused by *B. clarridgeiae* was described.[721,764] During a survey to determine the prevalence of *B. henselae* in cats in the San Francisco Bay area, another new *Bartonella* species was isolated from two cats.[372] These two isolates were 97% to 100% related to one another by DNA sequencing, but only 68% to 92% related to the type strain of *B. henselae*. This new species was named *B. koehlerae*. In 2000, a fourth cat-associated species ("*B. weissii*") was isolated from felines in Utah and Illinois; this organism was identical to another species—"*B. bovis*"—which was subsequently found in beef cattle in North Carolina.[119,250,1072] During the period from 1993 to the present, several *Bartonella* species have been described in many vertebrate hosts that are transmitted by a wide range of confirmed or putative insect vectors. These species, their primary hosts, and known or putative vectors of transmission are listed in Box 9-9.

It is now well established that *Bartonella* species constitute a unique group of bacteria that are responsible for unusual infections in wild and domesticated animals and in humans. Infected animals may be asymptomatic or may develop significant disease, including chronic bacteremia. These animals serve as reservoirs and potential

sources of additional animal or human infections. In 1995, a novel *Bartonella* species was described by workers at the College of Veterinary Medicine at North Carolina State University as a cause of canine endocarditis. Phenotypic and genotypic characterization of this agent confirmed its relatedness to the "vole agent," *B. vinsonii*, and this organism was christened *B. vinsonii* subsp. *berkoffii*.[165,172,723] This subspecies represented a previously unrecognized cause of cardiac arrhythmias, endocarditis, myocarditis, syncope, and sudden death in dogs. In 2000, *B. vinsonii* subsp. *berkhoffii* was detected by PCR analysis in valvular tissue as the cause of human endocarditis in a 35-year-old man, who also had contact with several animals, including a dog.[1116] In 1999, another *B. vinsonii* subspecies, designated *B. vinsonii* subsp. *arupensis*, was isolated from blood cultures of a cattle rancher in Wyoming with an acute febrile illness that had a marked neurologic component.[1333]

Serosurveys and blood culture studies among small mammals, ruminants, and other wildlife have resulted in the descriptions of several *Bartonella* species. During a survey to determine potential reservoirs of *Bartonella* species in wild mammals, another new species, designated *B. alsatica*, was isolated from blood cultures of wild rabbits (*Oryctolagus cuniculus*) trapped in the Alsace region of France near the Rhine River.[574] This species was subsequently documented as a cause of endocarditis and axillary lymphadenitis in two humans, both of which had significant contacts with rabbits.[43,1064] The species *B. schoenbuchii*, *B. bovis*, *B. capreoli*, and *B. birtlesii* have been isolated from blood cultures of roe deer, dairy cattle, reindeer, and small mammals, respectively.[119,120,336] Isolation of bartonellae from rodents and other wild mammals has prompted searches for these bacteria in tick populations. Among DNA extracts from 109 *Ixodes ricinus* ticks collected from roe deer in the Netherland, 70% contained 16S rRNA gene sequences for *Bartonella* or species closely related to *Bartonella*.[1158] *Bartonella* gene sequences have also been detected in extracts prepared from *Ixodes* and *Dermacentor* ticks that were collected in California.[232] *Ixodes ricinus* ticks fed on ovine blood infected with cultured *B. henselae* were demonstrated to transmit the bacteria across larval developmental stages. *B. henselae* migrated to the salivary glands of the tick, multiplied, and were actively transmitted from the infected tick to blood, thereby providing experimental evidence that *I. ricinus* is a competent vector for *B. henselae*.[311]

Bartonella infection is widespread and highly prevalent in rodent populations in different localities. The species

Candidatus "*B. antechini*"	*Antechinus flavipes* (Mardos [small carnivorous marsupial])	Fleas (*Acanthopsylla jordani*), ticks (*Ixodes antechini*)	671
B. australis	*Macropus giganteus* (gray kangaroos)		443
B. birtlesii	*Apodemus* spp. (wood mice)	Fleas	120
B. bovis	*Bos taurus* (domestic cattle)	Ticks, biting flies	119
B. capreoli	*Capreolus capreolus* (roe deer)	Biting flies	119
B. chomelii	*Bos taurus* (domestic cattle)		827
B. coopersplainsensis			530
B. doshiae	*Microtus agrestis* (field voles)	Fleas	129
B. japonica	*Apodemus* spp. (wood mice)		625
B. peromysci	*Peromyscus* spp. (field mice)	Fleas	129
B. phoceensis	*Rattus norvegicus* (rats)	Fleas	529
B. queenslandensis			630
B. rattaustraliani			530
B. rattimassiliensis	*Rattus norvegicus* (rats)	Fleas	529
B. schoenbuchensis	*Capreolus capreolus* (roe deer)	Biting flies	336, 1101
B. silvatica	*Apodemus* spp. (wood mice)	Biting insects	625
B. talpae	*Talpa europaea* (moles)	Unknown	129
B. taylorii	*Apodemus* spp. (wood mice)	*Ctenocephalides nobilis* (fleas)	129
Candidatus "*B. thailandensis*"	*Rodents*		1129
B. tribecorum	*Rattus norvegicus* (rats)	Fleas	575
B. vinsonii subsp. *vinsonii*	*Microtus pennsylvanicus* (meadow voles)	Fleas	172, 723

B. tribecorum was isolated from the blood of two wild rats (*Rattus norvegicus*) that were trapped in the Alsace region of France.[575] A field study of 7 rodent species from 12 different geographic areas in the southeastern United States found *Bartonella* species in blood cultures of 42.2% of 279 rodents tested.[729] These isolates represented 14 phenotypic variants that clustered into 7 phylogenetic groups, 4 of which contained previously described *Bartonella* species. Genetic analyses of isolates from Peruvian rats and from rats (*R. norvegicus*) captured in Louisiana and Maryland revealed gene sequences identical with those of *B. elizabethae*, which has otherwise been recovered only from a patient with endocarditis.[324] A study conducted in Japan found that 26% of 546 small mammals imported into Japan as pets had *Bartonella* bloodstream infections.[626] These animals included Egyptian jerboas, gerbils, spiny mice, and sand rats. Ellis and coworkers suggested that *Rattus* species, and perhaps other rodents, are the reservoir for *B. elizabethae*, and that the presence of antibodies against *B. elizabethae* among inner-city intravenous drug users reflected infection with this or a related *Bartonella* species.[392] In a study of 200 sera from "street people" using a free clinic in downtown Los Angeles, the seroprevalence of antibodies to *B. elizabethae*, *B. quintana*, and *B. henselae* was 13.6%, 12.5%, and 9.5%, respectively.[1200]

The involvement of *B. henselae* and *B. clarridgeiae* in CSD prompted investigations into the prevalence and pathogenicity of these organisms in domestic cats, the reservoir for both organisms. Seroprevalence studies have documented high rates of *Bartonella* infection among cats in various parts of the world. These studies have involved detection of feline bloodstream infections and seroepidemiology. In a study conducted in San Francisco, 41% of blood specimens from 61 impounded or pet cats were culture-positive for *B. henselae.*[714] Among 205 cats living in Northern California, 39.5% had sustained *B. henselae* bacteremia and 81% tested positive for *B. henselae* antibodies, with bacteremic cats having higher antibody titers than nonbacteremic cats.[257] A study conducted in France on 94 stray cats from 10 different cat colonies reported that 53% of the animals were bacteremic with a *Bartonella* species.[573] Of the 50 isolates obtained, 35 were *B. henselae* or a *B. henselae* variant, and 15 were *B. clarridgeiae*. A second French study of 436 domestic cats found that 5 cats (1.1%) were co-infected with *B. henselae* and *B. clarridgeiae*, while 2 cats (0.5%) were co-infected with two variant *B. henselae* strains, showing differences in 16S rRNA gene sequences.[534] Seroprevalence studies conducted on large cat populations in Baltimore, Sweden, and Denmark reported *B. henselae* seroprevalences of 14.7%, 8.3%, and 45.5%, respectively.[254,259,490] Another Swedish study demonstrated that 25% of 292 cats had antibodies to *B. elizabethae*, with the highest

prevalence (46%) being found in cats living in Stockholm.[589] The authors pointed out that *B. elizabethae* was the most common agent found in human patients in the same geographicl region.

Bartonella species, particularly *B. henselae*, have also been sought in cat fleas (*Ctenocephalides felis*), the presumed vector responsible for transmission of bartonellae among cats. A survey of 113 cats from shelters in the Netherlands found that 50% were seropositive for *Bartonella* species and 22% of the cats had positive blood cultures.[115] Seven of 27 DNA extracts of cat fleas removed from these cats contained *Bartonella* DNA. Chomel and coworkers detected *B. henselae* DNA in 34% of 132 fleas removed from 47 cattery cats, 89% of whom were bacteremic with *B. henselae*.[262] Cat fleas removed from bacteremic cats were able to transmit *B. henselae* to specific pathogen-free cats. However, pathogen-free kittens housed together with bacteremic cats without fleas did not become infected with *B. henselae*. It has been shown that *B. henselae* can multiply to high numbers in the cat flea, and the organism can remain viable in flea feces for at least 3 days.[423]

In cats, bacteremia with *B. henselae* or *B. clarridegiae* is usually asymptomatic, and the presence of overt disease appears to be strain-dependent. Kordick and colleagues inoculated 18 specific pathogen-free cats with *B. henselae* or *B. clarridgeiae* and found that despite persistent bacteremia, clinical signs and symptoms were minimal.[720] *Bartonella* DNA could be detected by PCR in the blood, brain, lymph nodes, myocardium liver, and kidneys of infected animals. O'Reilly and coworkers inoculated 9 cats with a virulent *B. henselae* strain and found that all 9 became bacteremic within 14 days' postinfection; one animal remained bacteremic up to 18 weeks' postinfection.[980] All animals developed anti-*B. henselae* antibodies. In another study of 19 cats belonging to 14 patients with CSD, 17 of them had positive blood cultures and 13 cats remained culture-positive for *Bartonella* during the ensuing 12 months.[724] A study of three naturally infected cats over a 2-year period found relapsing bacteremias in all three cats, with intervals of 3 to 19 months between relapses.[668] Following bacteremic episodes, increases in *B. henselae*-specific antibody titers were noted. Serial blood isolates of *B. henselae* from individual bacteremic cats were shown to have different RFLPs over time. The emergence of genetically distinct organisms at various peaks of bacteremia in these animals may contribute to the establishment of persistent bacteremic infections.

The development of polyphasic cultural/molecular approaches for detection of bartonellae has revealed that these organisms have an impact on canine health that was not appreciated before. The involvement of *B. vinsonii* subsp. *berkhoffii* as a cause of endocarditis in dogs was established in the mid-1990s, and other *Bartonella* species have been detected in related species, such as coyotes and foxes.[234] The involvement of other *Bartonella* species, including *B. henselae*, in canine disease has now also

been established. During the last 10 years, at least eight *Bartonella* species, including *B. henselae*, *B. vinsonii* subsp. *berkhoffii*, *B. koehlerae*, *B. clarridgeiae*, *B. elizabethae*, *B. washoensis*, *B. quintana*, and *B. rochalimae*, have been implicated in canine infections and disease syndromes.[166,258,378,533] Although thought to infect only cats, *B. henselae* was isolated from a dog in Gabon in 2004.[528] Subsequently, *B. henselae* was detected in lymphoid and liver tissue specimens in canines with generalized granulomatous lymphadenitis, granulomatous hepatitis, and peliosis hepatis using cultural and molecular techniques.[377,378]

Bartonella species are associated with infections in the compromised host, particularly patients with HIV-1 infection. *Bartonella* infections now include several well-described conditions, including classical and urban trench fever, bacillary angiomatosis with cutaneous and/or systemic

involvement, peliosis hepatis, relapsing fever with bacteremia, endocarditis, and CSD.[1271] The type species of the genus *Bartonella*, *B. bacilliformis*, causes Oroya fever, a geographically restricted febrile illness. The unfolding epidemiology of *Bartonella* species, increasing knowledge regarding animal and human disease, and information concerning the variety of insect vectors responsible for zoonotic infection are largely due to elegant laboratory approaches based on both traditional culture methods and advanced molecular-based technologies.[166,673]

Human Infections Associated With Bartonella *Species*

Oroya Fever and Verruga Peruana. These two clinical entities are manifestations of infection with *Bartonella bacilliformis*. These infections are geographically restricted because of the limited habitats of the principal sandfly vectors *Lutzomyia verrucarum* and *Lutzomyia peruensis*. The reservoir of the organism is unknown, although humans with asymptomatic bacteremia may serve as the reservoir. Infections are seen in river valleys of the west Andes Mountains at altitudes between 500 and 3,200 meters above sea level in Peru, Ecuador, and Columbia.[614] This disease is emerging as a public health problem in Peru, and recent reports have documented human *B. bacilliformis* infections over larger geographic areas, including the Columbia, Ecuador, Andean highlands, and the Amazon region east of the Andes Mountains.[726,820,825] In recent years, the highest incidence of disease has occurred in pediatric age groups.[229] This infection is also known as Carrion's disease after Daniel Carrion, a Peruvian medical student who developed the disease after inoculating himself with material from an infectious lesion. Humans are the only known reservoir/host for *B. bacilliformis*. Following the bite of an infected female vector, symptoms of Oroya fever develop

from 3 weeks to 3 months, although asymptomatic infection may also occur. Disease onset may be abrupt or insidious. With an insidious onset, the patient presents with anorexia, headache, malaise, and a slight fever lasting 2 to 7 days or more. When the onset is abrupt, the patient presents with fever, severe headache, chills, abdominal pain, arthralgias, and nausea and vomiting. Pallor and severe anemia ensue because of destruction of red blood cells by the organisms. Jaundice, hepatosplenomegaly, and generalized lymphadenopathy appear, along with severe muscle and joint pain.[824] Common complications include neurologic involvement, meningeal signs (e.g., delirium, seizures, coma), and respiratory symptoms (i.e., dyspnea). About 30% of patients develop opportunistic infections or reactivation of latent infections (e.g., toxoplasmosis, salmonellosis, tuberculosis, histoplasmosis) because of cellular immune compromise. Noninfectious complications include anemia, intracranial hypertension, and multiorgan dysfunction. During this phase, the organisms may be isolated from the blood and can actually be seen on blood smears within red blood cells. Acute infection during pregnancy can result in abortion or maternal and fetal death. Untreated, the fatality rate of Oroya fever ranges from 45% to 90%; with treatment, fatalities are reduced to less than 10%. Most mortality is seen in pediatric age groups. This "critical" stage lasts from 2 to 4 weeks, at which time the organisms disappear from the circulation, the fever normalizes, and the anemia spontaneously resolves.

After resolution of fever, pain in the bones, joints, and muscles may persist to the eruptive stage of verruga development, which is characterized by the development of lesions on exposed parts of the body, on mucous membranes, or in internal organs.[614]These lesions develop over 1 to 2 months and may persist for months to years. Lesions that develop during the eruptive phase may be miliary (i.e., multiple, widely scattered, and small 2 to 3 mm lesions), nodular (i.e., few eruptions, 8 to 10 mm in diameter), single or diffuse, large, deep-seated lesions.[95] When large lesions are located near joints, they may impede mobility. Mucocutaneous lesions may also appear in the mouth, conjunctiva, and nasal passages. Symptoms associated with the eruptive phase include fever, headache, malaise, arthralgias, osteoarticular pain, and bleeding of the lesions.[825] Joint pain and fever usually subside after appearance of the skin lesions. Anemia is usually not present during this stage of the disease. Histopathology of the lesions show dermal dendrocytes interspersed with macrophages, lymphocytes, and plasma cells; these lesions have been confused with malignant neoplasms, lymphomas, or sarcomas.[56]

B. bacilliformis can be seen in the tissues both intra- and extracellularly with the Warthin–Starry or Giemsa stain and can be cultured from cutaneous lesions and from blood and bone marrow. On Giemsa-stained blood films, the organisms appear as blue-to-purple extraerythrocytic and intraerythrocytic bacilli and coccobacilli. Susceptibility testing of human isolates of *B. bacilliformis* has shown that these bacteria are susceptible to β-lactams, chloramphenicol, tetracyclines, macrolides,

rifampin, the aminoglycosides, and the fluoroquinolones.[1203] Oroya fever has been treated with a variety of agents, including penicillin, tetracycline, and streptomycin, but chloramphenicol is considered the drug of choice. During the last decade, however, resistance to chloramphenicol has emerged in some isolates of *B. bacilliformis*.[1203] Acute-phase infections should be treated with ciprofloxacin for 10 days, with dosages adjusted depending on age.[614] If complications develop, ciprofloxacin is given with ceftriaxone or ceftazidime for 10 days.[1100] Amoxicillin clavulanate has been used for uncomplicated Arroyo fever in pediatric patients with good results. Adjunctive therapies (e.g., packed red blood cell transfusions) may be needed in patients with severe anemia. Complicated infections in pregnant women are treated with chloramphenicol in conjunction with penicillin G for 14 days. For the eruptive phase of the disease, chloramphenicol and penicillins are not effective. Rifampin may be given to both children and adults for 7 to 14 days and should be given along with another active agent, as rifampin resistance may emerge rapidly. Ciprofloxacin, erythromycin, and azithromycin are effective oral agents and should be taken for 7 to 14 days.

"Classical" and "Urban" Trench Fever. *B. quintana* is the agent of trench fever, a louse-borne, debilitating febrile illness that affected almost 1 million people, including German and allied military personnel during World War I.

546

After the war, trench fever continued to occur in Spain, France, Italy, parts of Eastern Europe, North Africa, and China. *B. quintana* has also been detected in lice obtained from regions of Peru and South America where trench fever has not been documented previously. Serologic tests indicate the presence of the organism in Bolivia and Mexico as well. The organism is transmitted by the human body louse, *Pediculus humanus*, which has increased in prevalence worldwide during the last 10 to 15 years, particularly in resource-limited countries and in areas of great social, political, and economic turmoil, such as the former Soviet Union and regions of Eastern Europe. The bacterium infects the body louse when it bites an infected human, as humans are the only known reservoir of these agents. The body louse transmits the infection when it subsequently bites another human and sheds organism-laden feces that contaminate the bite wound.[95] After an incubation period of 5 to 20 days, the disease may have a long clinical course that may last 4 to 8 weeks, with relapsing fevers, malaise, shaking chills, drenching sweats, and severe neck, back, and leg pain. Conjunctivitis, retro-orbital pain, and tibial (i.e., shin-bone) pain are characteristic. Splenomegaly and macular rashes have been observed in some patients. Fevers may last 4 to 5 days during each relapsing cycle or may persist unabated for weeks. Macular or papular

rashes may also appear in crops on the truck and extremities. The disease is usually not severe and is self-limited. Patients have a rapid response to treatment with tetracyclines and/or chloramphenicol.

Persistent *B. quintana* bacteremia was a recognized symptom of classical trench fever and is a common manifestation of reemergent or "urban trench fever" among the homeless and alcoholic residents of urban envoironments.[186,1215] This infection is associated with fever, night sweats, prolonged or intermittent bacteremia, louse infestation, and high antibody titers against *B. quintana*. The appearance of *B. quintana* infection among homeless individuals in urban areas has prompted investigations of emergent trench fever and other louse-borne illnesses among indigent people in several cities. Fever and bacteremia caused by *B. quintana* was first documented in 10 homeless, inner-city patients in Seattle who were HIV antibody-negative but had chronic alcoholism as an underlying disease.[1215] All of these individuals presented with fever, two had splenomegaly, two reported a recent cat scratch, and one developed endocarditis (see below).[1214] Brouqui and colleagues documented *B. quintana* bacteremia in 10 (14%) of 71 homeless patients in France.[186] Five of these patients were chronically bacteremic as evidenced by multiple positive blood cultures over several weeks, and eight patients with bacteremia were afebrile. In addition, 30% of the patients had high titers of anti-*B. quintana* antibodies, and recent infections (i.e., bacteremia or seroconversion) were detected in 17 patients (24%). In this study, homeless patients with *B. quintana* bacteremia were more likely to have had exposure to lice, and to have headaches, leg pain, and thrombocytopenia (i.e., low platelet counts), compared with those who did not have bacteremia or were seronegative for *B. quintana* antibodies.[185,186] *B. quintana* DNA was detected by PCR in lice collected from 3 of 15 patients from whom they were collected. Two of these patients were bacteremic, and one was seropositive. Serologic studies have also demonstrated a high prevalence of *Bartonella* infections among inner-city IV drug users. Comer and colleagues reported that 37.5% of serum specimens collected from 630 IV drug users in Baltimore reacted with at least one *Bartonella* antigen (i.e., *B. henselae*, *B. quintana*, or *B. elizabethae*) by indirect FA (IFA).[297] The role of body lice in the transmission of urban trench fever has been confirmed by several epidemiologic and laboratory investigations. In one study, lice were collected from 268 persons at the Moscow Municipal Disinfection Center and subjected to PCR analysis for detection of the *B. quintana gltA* gene sequence. *B. quintana* DNA was detected in 12.3% of the lice samples studied.[1125] In a study of 139 homeless persons seen by San Francisco Project Homeless, 33 (23.9%) had body lice and 12 (8.7%) had head lice infestations. In this survey, 33.3% of those with body lice and 25% of those with head lice had lice pools infected with *B. quintana*.[149] These studies have confirmed the pivotal role of *P. humanus* in the epidemiology of reemergent, 21st century trench

fever.

Bacillary Angiomatosis. Bacillary angiomatosis (BA) is a bacterial infection caused by *B. henselae* and *B. quintana*, which results in an unusual widespread vascular proliferation; this is seen most commonly in patients with advanced HIV disease.[1031,1035,1142] BA has also been reported in immunosuppressed transplant patients, individuals receiving cancer chemotherapy, and patients undergoing long-term corticosteroid treatment; it may also develop in immunocompetent adults and children.[121,600,1412] Patients with AIDS and BA usually have CD4 counts of less than 200 cells/μL when lesions appear. The disease may manifest as cutaneous lesions or may occur as a disseminated infection. Cutaneous lesions manifest as maculopapular lesions, pedunculated lesions, hyperkeratotic or indurated plaques, and nodular lesions with or without subsequent ulceration.[1159,1412] Usually BA develops as discrete lesions that enlarge and coalesce to form larger nodules. Lesions of Kaposi's sarcoma (KS) are usually light pink to brown or black and are plaque like rather than nodular, although on some body surfaces, BA lesions may initially develop as flat, hyperpigmented, indurated plaques. BA formation in part is due to ability of bartonellae to induce angiogenesis and tumorous vasculoproliferative lesions.[1035] Lesions may be located deep in the subcutaneous tissues (e.g., liver, spleen) and may involve bone, forming large osteolytic lesions.[1109] Bone involvement with BA is painful, usually affects the radius, fibula, and tibia, and is associated primarily with *B. quintana* infection. Visceral involvement may occur as disseminated vascular lesions or as bacillary peliosis hepatis when the liver is involved. Extracutaneous BA has been documented in upper and lower respiratory and gastrointestinal tracts, the conjunctivae and orbit, the heart, diaphragm, biliary tract, muscles, liver, spleen, lymph nodes, the genital tract, and the CNS. Internal lesions may cause compression or obstruction of internal organs, with constitutional signs and symptoms of fever, anorexia, vomiting, and weight loss. Histopathologic diagnosis of BA requires punch or excisional biopsies for cutaneous and subcutaneous lesions. Excision is usually used

547

for deep-seated lesions. Biopsies may also be submitted for culture and analysis by electron microscopy and molecular methods.

Histologically, cutaneous BA lesions are composed of lobular proliferations of blood vessels composed of plump "epithelioid" endothelial cells within an edematous to fibrotic stroma. Usually, there is an abundant neutrophilic infiltration and aggregates of purplish granular material, representing clusters of bacteria. When biopsied tissue sections are stained with the Warthin–Starry silver stain, blue-black clumps and tangled masses of interstitial bacteria are seen.[475,911] Similar histologic patterns are seen in

other affected tissues, including mucocutaneous lesions, lymph nodes, liver, spleen, bone marrow, gastrointestinal tract, and peritoneum. The differential diagnosis of BA includes CSD, angiosarcoma, KS, pyogenic granuloma, hemangioma, glomangioma, angiokeratoma, and verruga peruana. BA lesions can be histologically differentiated from KS lesions in that there are no bizarre, jagged blood vessels as seen in KS and the inflammatory infiltrate consists of lymphocytes, histiocytes, and neutrophils as opposed to plasma cells.[1368] While BA and pyogenic granulomas are both vascular proliferations with endothelial cell swelling and stromal edema, the latter condition has less of a neutrophilic infiltrate and does not contain the amorphous aggregates of bacteria seen with the Warthin–Starry stain. KS differs histologically from BA in that KS displays slit-like and irregular vascular spaces and spindle-shaped endothelial cells that do not protrude into the lumen. Although there are morphologic characteristics useful in differentiating BA from KS, histochemical and immunohistochemical stains are commonly used to finalize the diagnosis. KS lesions will also stain positively for human herpes virus type 8 using immunoperoxidase staining and will be negative with Warthin–Starry staining. The infiltrating growth pattern, nuclear pleomorphism, and absence of Warthin–Starry bacillary staining help differentiate angiosarcoma from BA. *B. henselae* and, in some cases, *B. quintana* have been isolated from the blood, skin lesions, bone, visceral organs, and brains of patients with BA.[475,600] In a 1997 case–control study of 49 patients with BA in San Francisco, 53% were infected with *B. henselae* and 47% were infected with *B. quintana*. *B. henselae* infection was linked with exposure to cats and cat fleas, while infection with *B. quintana* was associated with low income, homelessness, and lice exposure.[716] BA may be a manifestation of CSD peculiar to the compromised host. *Bartonella* organisms are able to stimulate angiogenesis, the physiologic process that results in the formation of new blood vessels, and to affect the migration and proliferation of endothelial cells.

Cutaneous BA usually responds to treatment with erythromycin, but antimicrobial therapy must be continued for 4 to 12 weeks.[911,1100] Doxycycline may also be used in those who cannot tolerate erythromycin. Longer courses of antimicrobial agents may be necessary since lesions often recur after the cessation of therapy. BA lesions that are confined to the skin may be excised surgically. Good clinical responses to other antibiotics (ceftriaxone, ciprofloxacin, other macrolides, chloramphenicol, SXT, and ciprofloxacin with gentamicin) have also been reported, but relapse is common following cessation of therapy. Drugs that inhibit cell wall biosynthesis (e.g., penicillins and cephalosporins) are not useful in the treatment of BA.

Peliosis. Peliosis hepatis is characterized by the presence of cystic, blood-filled lesions that are scattered throughout the parenchyma of the liver.[1368] Cases of peliosis involving the liver and spleen (splenic peliosis) have been reported in association with HIV infection.[1022] Most patients with hepatic or splenic peliosis also have BA, and

bacteria similar to those seen on Warthin–Starry stained biopsies of BA are also seen within the blood-filled cysts that are present in the liver and spleen. Most patients with bacillary peliosis hepatis present with weight loss, abdominal pain, intractable nausea, anemia, diarrhea, fever, hepatosplenomegaly, and lymphadenopathy. Liver enzymes are usually elevated, with alkaline phosphatase levels being as high as 5- to 10-fold above the normal value. Parenchymal bacillary peliosis of other internal organs (i.e., heart, larynx, lungs, adrenals, cervix, ovaries, pineal gland, and choroid plexus) has been reported as well. Peliosis hepatis appears to be associated exclusively with *B. henselae* infection and is believed by some to be another manifestation of BA.

Fever and Bacteremia. *B. henselae* bacteremia has been described in HIV-infected individuals, patients with AIDS, pharmacologically immunosuppressed recipients of allogeneic transplants, and occasionally immunocompetent hosts with no known risk factors for immunosuppressive disease.[1071,1197,1335] Immunocompromised patients present with relapsing fevers, weight loss, malaise, and fatigue. *B. henselae* bacteremia has been detected in those with and without focal BA or peliosis. In HIV-infected patients, *B. henselae* may also present as a generalized, inflammatory disease of the RES; organisms may be detected histopathologically or by molecular techniques in necrotic, inflammatory lesions in the spleen, liver, heart, bone marrow, and lymph nodes.[1196] In immunocompetent, HIV-negative individuals, *B. henselae* bacteremia presents with an abrupt onset of fever with accompanying joint and muscle pain, and some patients may manifest signs and symptoms of CNS involvement (i.e., headache, photophobia, and meningismus). *B. henselae* has been documented serologically as the cause of "fever of unknown origin" in both children and adults.[635,823,1268] These patients present with fever, anorexia, headache, and other constitutional symptoms. Bacteremia with *B. henselae* and *B. vinsonii* subsp. *berkhoffii* has also been associated with neurologic and neurocognitive dysfunction and neurologic disease.[167,169]

As mentioned earlier persistent fevers and bacteremia are hallmarks of both classical and urban Trench fevers as well.

Immunocompetent patients usually have a rapid response to a short (10 days or less) course of therapy, and generally do not relapse; in some cases, infections may resolve without antimicrobial therapy. However, Lucey and colleagues reported on two immunocompetent patients who had relapsing illness with positive blood cultures for *B. henselae*.[810] Interestingly, both of these patients had experienced tick bites before becoming ill. These two cases were the first in

which transmission of *B. henselae* by insects was epidemiologically suggested.

Drancourt, Raoult, and others reported two patients with bacteremia and chronic granulomatous mediastinal adenopathy from whom *B. quintana* was recovered from blood and bone marrow cultures.[370,1062] These patients were middle-aged women who were seronegative for HIV, had underlying diseases (i.e., corticosteroid treatment, chronic renal failure requiring hemodialysis), had exposure to cats, kittens, and cat fleas, and were successfully treated with parenteral aminoglycosides. Interestingly, neither patient developed a detectable serologic response against *B. quintana*.

Endocarditis. *Bartonella* species, and *B. quintana* in particular, have been isolated from several patients with "culture-negative" endocarditis and myocarditis.[371,385,442,540, 639,905,1393] Endocarditis due to *B. quintana* was first reported in 1993 in a 50-year-old, HIV-1 infected homosexual man who presented with night sweats, weight loss, and fatigue.[1213] On physical examination, mild renal insufficiency, splenomegaly, anemia, and a holosystolic heart murmur were noted. Echocardiography revealed mitral and aortic valve vegetations. Subsequently, *B. quintana* was documented as a cause of bacteremia in 10 febrile, homeless, alcoholic patients in Seattle; one of these patients developed aortic valve endocarditis.[1214] *B. quintana* was also recovered as the cause of endocarditis in three homeless, alcoholic men in France.[369] All four of these patients required aortic and/or mitral valve replacement. In 1993, Hadfield and coworkers described the first case of endocarditis caused by *B. henselae* in a 59-year-old HIV-negative man with a history of alcohol abuse; another instance of *B. henselae* endocarditis was subsequently reported in 1995 in a previously healthy 41-year-old man.[542,599] Both of these patients required valve replacement surgery. Since then, *B. henselae* has been identified as the cause of both native and prosthetic valve endocarditis in immunocompromised and immunocompetent patients.[620,684,1393] *B. elizabethae* was first reported as a cause of endocarditis in an immunocompetent 31-year-old man.[324] This infection resolved with valve replacement and treatment with vancomycin and imipenem. In 1996, Raoult and colleagues reported on 22 additional French patients with *Bartonella* endocarditis who were diagnosed by serology, culture, and molecular techniques.[1063] Of the 22 patients, 11 were alcoholics, 9 were homeless, 13 had preexisting valvular injuries, and 4 had histories of cat exposure. Most patients had aortic valve vegetations, and many developed embolic complications, with all but two patients requiring valvular surgery. Implicated organisms included *B. quintana* (5 patients), *B. henselae* (4 patients), and an undetermined *Bartonella* species (13 patients). The last 13 patients were diagnosed by serologic tests that could not distinguish between *B. quintana* and *B. henselae*. In this study, *B. quintana* endocarditis was associated with homelessness and chronic alcoholism without previously existing valvular damage, while *B. henselae* endocarditis occurred mostly in patients with preexisting valvular pathology and a history of contact

with cats. *Bartonella* endocarditis has been successfully treated with combinations of parenteral amoxicillin and gentamicin, parenteral vancomycin with ofloxacin and netilmicin followed by oral ofloxacin, rifampin, and pristinamycin, and with parenteral ceftriaxone followed by a prolonged course of oral erythromycin.[369,1063,1214] Two patients with endocarditis caused by *B. vinsonii* subsp. *berkhoffii* have also been reported.[972,1116]

Bartonella species also cause endocarditis and other cardiac disease in dogs.[263] Breitschwerdt and colleagues in North Carolina described a case of endocarditis involving the aortic and mitral valves in a 3-year-old spayed Labrador retriever.[165] A fastidious gram-negative bacillus was isolated from the dog's blood using the lysis-centrifugation method, and DNA extracted from the involved heart valves was amplified by PCR and compared with other *Bartonella* species. DNA hybridization, 16S rRNA sequencing, cellular fatty acid analysis, and phenotypic testing of the isolate characterized the organism as a new *Bartonella* species that most closely resembled *B. vinsonii*. The name *B. vinsonii* subsp. *berkhoffii* was proposed for this new organism.[723] This agent represented a new veterinary pathogen causing cardiac arrhythmia, myocarditis, and endocarditis in dogs; it has also been reported as the agent of endocarditis in a human.[164,1116] *B. henselae*, *B. elizabethae*, and *B. clarridgeiae* have been detected by molecular techniques in blood specimens from dogs.[263] Wild and domesticated canines may be reservoirs for all of these agents.

Cat Scratch Disease. CSD is a common cause of lymphadenopathy, particularly in children and adolescents. Most infections occur between September and March in warm climates; the peak incidence in July and August. About 90% of patients have a history of exposure to cats, with a cat scratch or a cat bite having occurred in about 75% to 80% of these persons. Kittens seem to be more frequently implicated than adult cats, and transmission appears to be by direct contact, since the disease generally follows a bite, scratch, or lick from a young cat. About 3 to 10 days after the scratch or bite, a primary erythematous papule or pustule forms. This lesion persists for about 2 to 3 weeks. During this time, low-grade fever may be present in one-third of patients, with both malaise and fever being noted in about one-fourth of patients. About 10% will have headache and muscle aches with a sore throat and a faint rash that lasts for 1 to 2 weeks. Over 90% of patients develop regional lymphadenopathy, the location of which is dependent on the site of the cat bite or scratch. Since most lesions are on the upper extremities, the adenopathy usually develops in axillary, cervical, or submandibular lymph nodes. Noncontiguous or generalized lymphadenopathy and hepatosplenomegaly are uncommon, but when present may be confused with malignancy (i.e., lymphoma).[485,694] Affected lymph nodes usually exhibit granulomas, suppurative granulomas, stellate microabscesses, and follicular

hyperplasia. Clusters of bacillary organisms may be seen in lymph node biopsies stained with the Warthin–Starry silver impregnation stain. Enlarged lymph nodes usually regress spontaneously over several months, although up to 20% of patients may show lymphadenopathy for 12 to 24 months. Disease may be more severe, complicated, or disseminated in immunocompromised hosts; *Bartonella* infections have been transmitted by solid organ transplantation (e.g., liver transplantation).[146,1082,1163]

549

Patients with CSD may have atypical presentations and complications may develop; so clinical acumen and a thorough patient history are important. CSD was reported in a 32-year-old veterinarian who initially sought medical attention for fever of unknown origin and persistent back pain over a month duration. This began after an accidental needlestick injury. Infection was confirmed by serologic and molecular testing.[790] Some patients, particularly children, may require surgical drainage of abscesses and/or removal of infected lymph nodes.[917] Complications include oculoglandular syndrome of Parinaud, which presents as an ocular granuloma or conjunctivitis with preauricular lymphadenopathy, osteomyelitis, epitrochlear mass mimicking rhabdomyosarcoma, hepatic and splenic microabscesses, hepatitis, and granulomas.[59,510,1098,1290] The oculoglandular syndrome results from a cat scratch, lick, or bite on the eyelid or conjunctivae, although autoinoculation from a primary lesion into the eye may also occur. CSD encephalopathy and aseptic meningitis are rare complications that occur 1 to 6 weeks after regional lymphadenopathy becomes apparent; these may be characterized by encephalitis, seizures, myelitis, neuropathy, and retinitis.[483,949,1367] The patient may exhibit headache, mental status changes, seizures, convulsions, combative behavior, and/or coma. Neuroretinitis associated with CSD has also been reported, including a patient with *B. henselae* bacteremia that resulted in acute loss of vision.[318,800] Systemic CSD may cause multifocal osteomyelitis at sites remote from the initial scratch or bite. Pulmonary manifestations of CSD are extremely rare.[845]

CSD is usually a self-limited illness that does not generally respond to targeted antimicrobial therapy. Despite in vitro susceptibility of *B. henselae* to many agents, their use for treatment of CSD has not resulted in clear-cut benefits for the patient. Only the aminoglycosides, and gentamicin in particular, have demonstrated effectiveness in the treatment of suppurative complications of CSD.[924] Reports of successful treatment of CSD with azithromycin may be related not only to the susceptibility of *Bartonella* species to this agent, but also to penetration and intracellular accumulation of azithromycin within neutrophils and macrophages, resulting in ratios of 40:1 for intracellular:extracellular drug concentrations.[252,872]

Ciprofloxacin has also been used successfully for the treatment of CSD, again presumably because of its intracellular accumulation.[597]

Microbiologic and serologic studies conducted over the last several years have established that *B. henselae* is the principal bacterial agent responsible for CSD. In 1992, Regnery and colleagues isolated *B. henselae* from the blood of an asymptomatic cat on two occasions and demonstrated that 88% of patients with CSD had high antibody titers to *B. henselae* antigens by IFA.[1073,1074] Molecular techniques were used subsequently by several research groups to demonstrate the presence of *B. henselae* DNA in purulent material from the suppurative lymph nodes of patients with CSD.[36,38,503] Using IFA, Zangwill and his collaborators found that 84% of 45 patients with CSD had anti-*B. henselae* antibodies compared with 3% of 112 control patients.[1411] Furthermore, 81% of cats belonging to CSD patients were also seropositive compared with 38% of 29 control animals. This study also reported that the risk of CSD was greater for those individuals with kittens than for those with adult cats, that individuals with bites and scratches from kittens were at higher risk for CSD than those with wounds from adult cats, and that risk of CSD was also greater if the kitten had fleas. Bacilli observed in biopsies from suppurative lymph nodes have also been identified as *B. henselae* by immunocytochemical staining with antibodies against *B. henselae*.[892] The etiologic role of *B. henselae* in CSD has been further strengthened by the large number of epidemiologic studies on *B. henselae* infection in domestic cats.

In 1997, a second *Bartonella* species, *B. clarridgeiae*, was also described in association with a case of CSD.[721] In this case, a veterinarian developed CSD after a bite wound from a 6-week-old cat. Blood cultures collected from the patient and serologic tests (IFA) for *B. henselae*, *B. quintana*, and *B. elizabethae* antibodies were negative. However, the serum of the patient reacted in an IFA test with a *Bartonella* isolate recovered from blood cultures obtained from the cat. Serologic evidence for *B. clarridgeiae* infection was also obtained from a CSD patient with constitutional symptoms, a history of exposure to cats and cat scratches, and a large chest wall abscess.[845] While cultures from the patient remained negative, *B. clarridgeiae* was isolated from the blood of one of the patient's cats.

Miscellaneous Infections. Since the discovery of the association of *Bartonella* species with CSD, BA, and peliosis hepatis, several other manifestations of *B. henselae* infection have been reported in both immunocompromised and immunocompetent hosts. In most of these infections, an association with young cats has been documented, lending further credence to the possibility that uncommon clinical manifestations of *B. henselae* infection represent part of a continuum in the clinical presentation of CSD. These manifestations have included neuroretinitis without

the oculoglandular syndrome of Parinaud, isolated unilateral and diffuse lymphadenitis, severe myocarditis, and neurologic disease associated with rapidly progressive dementia.[871,1161,1367] Meininger and colleagues described a healthy man who developed chronic active myocarditis due to *B. henselae* that resulted in heart failure and the need for heart transplantation.[879] The association of *Bartonella* with AIDS-related dementia was examined by a serologic study conducted in Los Angeles by Schwartzman and colleagues in which both cat ownership and neuropsychological decline and dementia were associated significantly with the presence of IgM antibodies to *B. henselae*.[1160] Caniza and coworkers described a case of opportunistic pulmonary infection due to *B. henselae* in a 19-year-old woman who was a kidney transplant recipient.[197] Tissue from pulmonary nodules of this patient was negative on culture but contained 16S rRNA specific for *B. henselae* by PCR. All eight of the domestic cats that lived with the patient had positive blood cultures for *B. henselae*; PCR analysis of these isolates established that the feline isolates were identical to that found in the lung tissue of the patient. *B. henselae* infection has also been responsible for intraocular and retinal inflammation and optic disk edema resulting in substantial loss of visual acuity.[1309] Golnick et al. reported four patients who presented with vision loss resulting from intraocular inflammation, swelling of the optic nerve, and retinal detachment.[496] Patients had elevated titers against *B. henselae* and responded to treatment

550

with resulting improvements in vision. Neuroretinitis has also been diagnosed in a patient with serologic evidence of infection with *B. elizabethae*.[968] In an unusual presentation of infection, bilateral neuroretinitis accompanied by severe headache and behavioral changes was diagnosed in a 55-year-old infected woman, who also had insulin-dependent diabetes mellitus and hypothyroidism. PCR analysis of DNA extracted from intraocular fluids revealed the presence of a 16S rRNA gene sequence that showed 100% homology with *B. grahamii*, a species normally found in rodents in Europe and North America.[695] The patient owned a dog but had no history of exposure to cats, rodents, or other animals. The patient also had serologic evidence of *B. henselae* infection by EIA, which was likely due to cross-reactivity with *B. grahamii*. She responded to therapy with daily oral doxycycline and rifampin for 4 weeks. Intraorbital and retinal infections with *B. henselae* have also been diagnosed by detection of DNA in intraocular specimens.[496,1327] Renal microabscesses and vertebral osteomyelitis due to disseminated *B. henselae* infection have also been reported.[512,1132]

Emerging Pathogens in the Genus Bartonella

Bartonella species originally described in animals are increasingly being detected in humans, often in association with febrile illnesses. In 2006, Raoult and coworkers described a 74-year-old man who developed endocarditis. Excised valvular tissues and blood samples were inoculated into human endothelial shell vials, and growth of *Bartonella* species in the shell vials was demonstrated by immunofluorescence after 2 months. Extraction of DNA from the cultures, blood, and valve tissue, followed by amplification and sequencing, revealed that the isolate was *B. alsatica*, a species previously described in wild rabbits.[574,1064] In 2008, Angelakis and colleagues described a 79-year-old woman from France with a large axillary mass that developed 1 month after she had scratched her finger while butchering a wild rabbit. A fragment of her excised lymph node and some rabbit tissues was subjected to nucleic acid extraction, and the extracted DNA was used as a template in three PCR assays specific for the *B. alsatica* 16S-23S intergenic spacer region, the *ftsZ* gene, and 16S rDNA.[43] All results on the lymph node indicated infection with *B. alsatica.* In 2009, another patient in France was diagnosed with endocarditis due to *B. alsatica*.[645] *B. rochalimae*, an agent of infective endocarditis in dogs, has been isolated from rodents, gray foxes, and from humans.[399,579,791] *B. washowensis*, a species found in ground squirrels, was isolated from a 70-year-old man with fever and myocarditis; molecular studies documented that the source of the isolate was probably exposure to rodents or arthropod vectors carrying the agent.[728] *B. tamiae*, a relatively new species described in 2008, was isolated from blood cultures of three patients in Thailand.[727] Candidatus *B. melophagi*, a proposed but as yet unvalidated new *Bartonella* species that is associated with sheep, was isolated from blood cultures of two women, both of whom developed acute febrile illnesses.[107,822] The identification was confirmed by molecular analyses of 16S rRNA, the citrate synthase, and RNA polymerase gene sequences and assessment of the 16S-23S intergenic spacer region. Both women lived and worked with and around animals, but only one had any exposure to sheep. In 2010, a new *Bartonella* candidate species, candidatus *B. mayotomonensis,* was isolated from native aortic valve tissue of a 59-year-old male with endocarditis.[788] The unique identity of this isolate was determined by amplification and sequencing of the 16S rRNA, *ftsz*, *rpoB*, and *gltA* genes and assessment of the ITS region.

Detection, Isolation, and Identification of Bartonella *Species*

Specimen Types. Specimens that may be submitted for recovery of *Bartonella* species include blood, biopsy specimens of suspected cutaneous or systemic BA lesions, lymph node biopsies, and aspirates. Specimens collected early in the clinical course are preferable, particularly lymph node biopsy specimens from patients with

suspected CSD, and should be collected prior to the administration of antimicrobial agents. Late-stage, suppurative lymph nodes may not yield organisms because of the intense local cellular immune response. Lysis-centrifugation methods using the Isolator blood lysis method (Wampole, Cranbury, NJ) have been reported to enhance recovery of these fastidious bacteria from blood specimens. Blood may also be submitted in sterile plastic ethylenediaminetetraacetic acid (EDTA) or sodium citrate tubes. With EDTA blood specimens, freezing the blood and then thawing it at room temperature prior to direct plating may also enhance recovery. Tissue specimens should be homogenized prior to culture; the homogenate can be used for direct culture and for DNA extraction prior to molecular amplification/detection. Since the organisms produce little or no CO_2 during growth, detection of *Bartonella* species in automated blood culture systems (e.g., BACTEC; BacT/Alert, etc.) may be problematic. Isolates have been recovered from BACTEC high-volume aerobic resin PLUS 26 bottles, although the organisms did not register growth indices above the positive threshold. Therefore, staining smears prepared from inoculated bottles with the acridine orange fluorescent stain intermittently during incubation may be helpful for detection.[5]

Microscopic Examination of Clinical Specimens. The Warthin–Starry silver stain has been used to visualize bartonellae in tissue. This stain is nonspecific, and other microorganisms may also exhibit staining. Lymph node specimens from patients with suspected CSD may or may not exhibit positive staining if the biopsy is not submitted early in the clinical course. Biopsies from BA lesions will usually show large numbers of organisms in Warthin–Starry stained preparations.

Culture. *Bartonella* species may be isolated by inoculation of the appropriate agar media or by cocultivation in cell culture. Blood submitted in either Isolator or EDTA tubes and homogenized tissue specimens can be inoculated directly onto freshly prepared chocolate agar or brain–heart infusion (BHI) agar containing 5% fresh rabbit or horse blood. Blood-supplemented BHI, tryptic soy, and Columbia agars and enriched chocolate agar may also

551

support growth. Selective media are not available, and media containing antimicrobial agents should not be used. Inoculated plates are incubated in a humid atmosphere at 35°C to 37°C in 5% to 7% CO_2 for at least 28 days. Growth is usually noted within 5 to 15 days, although some *Bartonella* strains may require up to 45 days incubation before growth is apparent.[760,1269] Subcultures from slow-growing primary cultures may require 15 to 20 days' incubation before good growth is obtained. Most bartonellae do not grow under anaerobic conditions, at temperatures of 25°C or 42°C,

or in the absence of hemin and CO_2. *B. bacilliformis* is exceptional, in that this species favors a lower growth temperature (i.e., 25°C to 28°C) and does not require supplemental CO_2 for growth. Some *Bartonella* species (e.g., *B. koehlerae*) may not grow on fresh rabbit blood agar and requires the use of freshly prepared chocolate agar for optimal recovery.

Isolation of *Bartonella* species has also been accomplished using cell culture methods, which are performed with shell vials containing a human endothelial cell monolayer (e.g., ECV 304 cell line), the T24 bladder carcinoma cell line, or other cell types (e.g., Vero cells, HeLa cells, L292 cells).[42,44,369,715,1062,1413] Specimens processed by this technique have included biopsy specimens from cutaneous and osseus BA lesions and heparinized blood. Koehler and colleagues used a bovine endothelial cell line (i.e., CPA cells, ATTC cell line #207) to isolate both *B. henselae* and *B. quintana* from minced tissue biopsies of BA lesions. After 9 to 36 days of incubation, the turbid culture supernatants were subcultured to agar media for subsequent growth and identification.[715] Drancourt and colleagues used ECV 304 cells (a continuous human endothelial cell line) to recover *B. quintana* from blood specimens of homeless patients with endocarditis.[369] With this technique, organisms can be detected in the shell vial by immunofluorescence and identified by PCR or other molecular techniques.[42,44] Broth-enrichment recovery of *Bartonella* species has also been performed with a defined medium containing RPMI 1640 (a tissue culture-type liquid medium) supplemented with hemin, amino acids, and pyruvate.[1362] This medium was used to successfully recover *B. henselae* from human and cat blood and from lymph node biopsies of CSD patients.

One of the most helpful developments in the cultural diagnosis of *Bartonella* infections is the use of preenrichment for subsequent molecular and cultural organism detection as part of a three-specimen source polyphasic cultural/molecular approach. Preenrichment is performed in *Bartonella* α-*Proteobacteria* growth medium (BAPGM), an optimized insect cell culture-based growth medium that is able to support growth of seven *Bartonella* species.[166,821] BAPGM uses a basal medium formulated for growth of insect cells in culture.[1086] This basal medium is supplemented with NAD, ATP, pyruvate, and several amino acids. After adjustment to a pH of 7.4, the medium is filter-sterilized and supplemented with defibrinated sheep blood at a final concentration of 5%. The polyphasic approach involves DNA extraction of the patient specimen for direct detection by PCR (first sample), a second PCR after enrichment culture in BAPGM for 4 weeks (second sample), and another PCR performed on any visible growth resulting after 4 weeks from a blood agar subculture of BAPGM after the 4-week incubation period.[359] BAPGM is commercially available (Galaxy Diagnostics, http://www.galaxydx.com). This polyphasic approach has been used for detection of *Bartonella* species in several

veterinary specimens from dogs and cattle (i.e., blood, tissue biopsies, CSF, abdominal, pericardial, seroma, and aqueous fluids, joint fluid).[82,249,359,377,907] Polyphasic detection using BAPGM has resulted in the recovery of various *Bartonella* species (i.e., *B. henselae*, *B. vinsonii* subsp. *berkhoffii*, *B. bovis*, *B. koehlerae*, *B. volans*-like) from canines and the isolation of *B. tamiae* from febrile human patients in Thailand.[727,1019] Riess and colleagues described another enrichment growth medium that used Schneider's *Drosophila* powder medium (Serva, Heidelberg, Germany) supplemented with 10% fetal calf serum and glutamine.[1086] This medium grew *B. henselae* more efficiently than BAPGM. The Schneider's medium/fetal calf serum formulation does not contain whole blood or hemin; so the growth of *B. henselae* could be detected visually. The addition of 5% sucrose to this medium resulted in even faster growth of this fastidious organism, allowing these workers to actually calculate a generation time of about 5.6 hours for the *B. henselae* Marseille strain.[1086] Supplemented Schneider's medium also supported the growth of *B. quintana* and *B. vinsonii*. Lynch and colleagues compared several culture methods using strains of *B. henselae*, *B. quintana*, *B. elizabethae*, and *B. tamiae* and found that optimal growth of these organisms occurred using combined mammalian cell and insect cell culture medium with supplementation (i.e., 10% fetal calf serum, pyruvate, sucrose, HEPES buffer).[817] This combination medium also supported the growth of Vero E6 cells (primate kidney epithelial cells, ATCC CRL-1586). Although the cell-free medium supported adequate growth of laboratory-adapted *Bartonella* strains, coculture with Vero E6 cells may still be more sensitive for primary isolation of *Bartonella* species from clinical specimens of veterinary or human origin.

Gram's Stain and Colony Morphology. On primary isolation, *Bartonella* species appear initially as white, small adherent colonies that vary in size and shape. Some strains of *B. henselae*, *B. quintana*, and *B. elizabethae* may pit the agar surface during growth.[1269] Characteristically, *B. henselae* colonies are white or tan, dry, adherent, "cauliflower-like," embedded in the agar, and morphologically heterogeneous. Colonies of *B. quintana* are glistening, flat, smooth, and nonpitting on agar media. *B. elizabethae* colonies resemble *B. henselae* except that weak or partial hemolysis may be noted around colonies growing on heart infusion agar with 5% rabbit blood. Isolates of *B. clarridgeiae* form raised, white, adherent colonies on agar. With multiple passages, the colonies of most *Bartonella* species colonies become less dry, less adherent, and larger, and tend to grow faster. Colonies of *B. bacilliformis* differ from the others species in that they are initially small, smooth, and translucent and remain so upon serial subculture. On Gram's stain, *Bartonella* organisms appear as small, slightly curved, pleomorphic, gram-negative bacilli that measure about 1 µm to 2.5 µm in length by 0.5 µm to 0.6 µm. Strains of *B. henselae*, *B. quintana*, and several other species may show "twitching" motility when mounted in saline. Bartonellae may be

better visualized using the

552

Gimenez stain, since counterstaining using either safranin or carbol fuchsin may be weak.

Identification Methods. In general, *Bartonella* species are biochemically nonreactive in routine phenotypic biochemical identification tests, including oxidase, catalase, indole, urease, decarboxylase, and nitrate reduction tests. A general presumptive identification may be based on the slow growth (usually greater than 7 to 10 days), characteristic colony morphology on agar-based medium, and negative oxidase and catalase tests. This presumptive identification must also consider the specimen type and the clinical presentation of the patient. Presumptive identification of certain *Bartonella* species, including *B. henselae*, *B. quintana*, and *B. vinsonii*, may be determined with commercial identification systems that use chromogenic enzyme substrates to detect preformed bacterial enzymes (e.g., Microscan Rapid Anaerobe panel, RapID ANA II, Rapid ID32A).[1334] These systems produced biochemical reaction patterns that were unique within their own data bases, but only the reactions on the Microscan Rapid Anaerobe Panel were able to separate *B. henselae* and *B. quintana* at the species level. This panel distinguished all species tested, generating unique biotype codes for each species (i.e., code 10077640 for *B. henselae*, code 10073640 for *B. quintana*, and code 10077240 for *B. bacilliformis*) (Table 9-15).

Bartonella species may be identified by gas-liquid chromatographic analysis of cellular fatty acids by mass spectrometry.[1335] All *Bartonella* species contain greater than 50% C18:1, 16% to 25% C18:0, and 16% to 22% C16:0, with minor amounts of C13:1 and C17:03 fatty acids. *B. henselae* isolates lack cellular fatty acids C15:0 and C12:0, which are present in isolates of *B. vinsonii* and *B. bacilliformis*, respectively. *B. quintana* could be differentiated from most *B. henselae* isolates by the presence of less than 20% C18:0 in *B. quintana* and greater than 20% C18:0 in *B. henselae*. The cellular fatty acid composition of *B. elizabethae* is most similar to that of *B. vinsonii* and includes C15:0 (not found in *B. henselae* or *B. quintana*) and larger amounts (21%) of C17:0 than *B. henselae* (3%), *B. quintana* (1%), and *B. vinsonii* (9%). *B. elizabethae* also contains smaller amounts of cellular fatty acid C16:0 (13%) than the other species, which contain from 17% to 20% C16:0 cellular fatty acids. MALDI-TOF mass spectrometry has also been used to identify *Bartonella* species. Reference strains representing 17 recognized *Bartonella* species were analyzed, and the consensus spectrum obtained for each of the species was unique among the various spectra for 2,843 bacterial organisms included in the Brucker MALDI-TOF database, including 109 other α-*Proteobacteria*. In addition, 39 blinded *Bartonella* strains were

correctly identified to the species level.[441]

Definitive identification of *Bartonella* species is best accomplished by amplification-based molecular methods. These methods can be used for confirmation of isolates recovered in culture, or may be performed directly on tissue, pus, or biopsies. PCR amplification of various genes, including the citrate synthase gene (*gltA*), heat-shock proteins, riboflavin synthesis genes, cell division genes, or 16S-23S rRNA intergenic spacer regions, and restriction endonuclease analysis of the amplicons have been used successfully for this purpose.[76,650,848,851,1416] Matar and colleagues used PCR along with primers in the 16S rRNA and 23S rRNA genes to amplify the spacer region between the 16S rRNA gene and a part of the the 23S rRNA gene, followed by restriction enzyme cleavage.[851] This approach resulted in characteristic restriction profiles for *B. bacilliformis*, *B. vinsonii*, and *B. quintana* and two profiles for *B. henselae*, suggesting that this method may be useful both for identifying *Bartonella* species and for subtyping isolates of *B. henselae*. Jensen et al. described a single-step PCR-mediated amplification of the 16S-23S rRNA intergenic spacer region that resulted in amplicons of unique size for each *Bartonella* species.[648] Joblet and colleagues found that *gltA* gene amplification followed by digestion with two different restriction enzymes allowed differentiation of *Bartonella* species.[650] Sequence analysis of the 940 base pair fragment of the citrate synthase-encoding gene (*gtlA*) and the 60-kDa heat-shock protein gene (*groEL*) could also be used to construct phylogenetic trees for determining relationships between validly described *Bartonella* species and uncharacterized *Bartonella* strains.[130,848] Primer/probe oligonucleotides have been designed based on localized sequence differences within the riboflavin synthesis gene (*ribC*), and these sequences have been used to develop species-specific PCR assays for identification of *B. henselae*, *B. quintana*, *B. bacilliformis*, and *B. clarridgeiae*.[111] Rodriquez-Barradas and coworkers developed a similar "repetitive element" PCR identification method using primers derived from either repetitive extragenic or intergenic consensus sequences. Because these sequences already existed in multiple, discontinuous copies that result in multiple, discontinuous amplicons following PCR, treatment with restriction endonucleases prior to PAGE was not necessary.[1097] Handley and Regnery at the CDC reported a PCR-dependent identification method based on amplification of restriction endonuclease-cleaved segments. The enzymes used in this procedure resulted in large fragments that could be annealed with primers corresponding to base sequences adjacent to endonuclease restriction sites for subsequent PCR and resolution by PAGE.[554] Molecular approaches have also been used for direct detection of *Bartonella* species in clinical specimens. Matar and colleagues reported a PCR-RFLP method for simultaneous detection and identification of bartonellae directly in clinical specimens, including lymph node biopsies and aspirates, skin, subcutaneous nodules, and other tissues.[851]

This method involved the use of PCR primers from conserved regions of the 16S rDNA gene, followed by restriction endonuclease digestion and amplicon analysis. Sander and Penno used PCR to generate biotinylated amplicons of the 16S rRNA gene region and immobilized the amplicons in streptavidin-coated microtiter wells.[1136] Hybridization of these amplicons with species-specific digoxigenin-labeled 16S rDNA oligonucleotide probes and subsequent addition of antididigoxigenin peroxidase in a modified EIA format provided rapid identification of both *B. henselae* and *B. quintana*. This method could both detect and quantify *B. henselae* and *B. quintana* directly in clinical specimens in concentrations as low as 10^3 cfu/mL. Avidor and colleagues evaluated PCR-mediated 16S rRNA gene amplification followed by *B. henselae* probe hybridization with PCR-based amplification of either *gltA* or *htrA* (heat-shock

554

protein genes) followed by RFLP analysis of amplicons for direct detection of *B. henselae* in clinical specimens.[76] *B. henselae* DNA was detected in 100% of 32 pus and lymph node specimens by the 16S rRNA PCR/probe identification method, and in 94% and 69% by the *gltA*/RFLP and *htrA*/RFLP methods, respectively. These investigators suggested that direct testing by *gltA*/RFLP was preferable and easier since species-specific hybridization (via probe) was not necessary with this method.[76] The single-step PCR assay using the 16S-23S rRNA intergenic spacer region target developed by Jensen et al. was able to detect *B. henselae* DNA in blood specimens from infected cats.[648] DNA was amplified from 100% of infected cat blood specimens containing >50 cfu of *B. henselae* per mL and from 80% of blood specimens containing 10 to 30 cfu of *B. henselae* per mL of blood. More recent evidence indicates that some gene sequences found in bartonellae may not be as specific as once thought. For example, the citrate synthase gene (*gltA*) found in *Bartonella* species has homologies with gene sequences found in some host genomes, including mice, rats, humans, and other human pathogens.[291]

Real-time PCR assays have also been described for the direct detection and differentiation of *Bartonella* species and genotypes. Colborn et al. performed whole-genome scans on isolates of *B. henselae*, *B. quintana*, and *B. bacilliformis*, and compared nucleotide sequences with those for other *Bartonella* species published in Gene Bank.[291] They also searched for similar sequences in other bacteria capable of infecting human blood and tissues and in potential mammalian or arthropod vectors for bartonellae. Using this approach, a real-time PCR primer set flanking the NADH dehydrogenase gamma subunit (*nuoA*) gene was identified. Detection of the *nuoA* gene was compared with detection of the citrate synthase gene (*gltA*) and the *fitZ* gene using the requisite primer pairs. These three assays were compared for their ability to amplify reference DNAs from several *Bartonella* species. The *nuoG* primer set successfully amplified all 11 *Bartonella* species tested. When DNA from field-collected specimens, including specimens from rat livers and from ticks, was examined, the *nuoG* primer set demonstrated significantly higher sensitivity and specificity for *Bartonella* than the other primer sets by consistently yielding more sequence-confirmed PCR-positive results. For 61 ticks sampled, the *nuoG* primer set yielded 7 *Bartonella*-positive samples, compared to 1 and 0 for the *ftsZ* and *gltA* sets, respectively. Of 24 liver samples tested, 18 were found to be *Bartonella* positive by the *nuoG* primer set, compared to 10 and 2 for the *ftsZ* and *gltA* sets, respectively.[291] Diaz and colleagues developed a genus-specific real-time PCR assay targeting a 301 base pair region of the *ssrA* gene, which encodes an RNA species also known as transfer-messenger RNA (tmRNA).[355] This is a single copy molecule involved in processing of nascent peptides during translation. Unlike some targets used for detection and identification of *Bartonella* species (e.g., *gltA*), gene sequences that are

homologous with the *ssrA* target sequence have not been detected in any eucaryotic organisms to date.[291] Using this target gene sequence, over 30 unique species, subspecies, and strains within the genus *Bartonella* were detected in blood specimens from elk and cattle. Species identification was achieved by sequencing of the *ssrA* amplicon.

Real-time PCR methods are increasingly being used for direct diagnosis of *Bartonella*-associated diseases. A real-time RT-PCR assay specific for the *Bartonella* 16S-23S intergenic spacer region and the *pap31* gene of *B. henselae* has been used for direct detection of *B. henselae* in skin biopsy specimens, lymph nodes, and swab specimens from CSD patients.[42,44] Broad-range, real-time PCR for 16S and 18S rDNA has been used to detect *Bartonella* species in EDTA blood specimens and in valve specimens.[444]

Serologic Diagnosis

The laboratory diagnosis of CSD is mainly based on molecular methods and serologic testing by either indirect immunofluorescence (IFA) or EIA. IFA is the most widely used technique although it is much more time-consuming than EIA methods. Serologic methods for the diagnosis of *Bartonella* infections have been used in both clinical and veterinary settings. Evaluations of serologic tests report a range of sensitivity and specificity depending on the study population, case definitions of CSD, and materials and methods employed in the testing procedure. Variability in the sensitivity of *B. henselae* serology, particularly IgM testing, may also be due to regional variability in the distribution of different *B. henselae* genotypes (see below). For example, in the Netherlands, *B. henselae* genotype I (serotype Houston I) and genotype II (serotype Marseille) have been found in CSD patients. Some serologic tests include only genotype I *B. henselae*; so test sensitivity may be improved by inclusion of genotype II strains as antigen sources.[115,117]

IFA methods for detection of *Bartonella* antibodies are not highly standardized and vary principally in the source of the bacterial antigens that are fixed to the IFA slides.[1414] Some methods use bacteria grown on agar media, while others use *Bartonella* isolates cocultivated with tissue culture cells as the fixed antigen on the IFA slides. Bergmans and coworkers in the Netherlands evaluated the detection of anti-*B. henselae* IgM and IgG using both IFA and EIA and found significant variability depending on the source of the bacterial antigens for IFA slide preparation.[116] Sera from 21 patients with "possible CSD" (patients fulfilling only 1 of 4 clinical criteria) and 22 with "probable" CSD (patients fulfilling 2 of 4 clinical criteria) were examined. When *B. henselae* cells cocultivated in Vero cells were used as the IFA antigen, the sensitivity of IgG detection was only 31.8% for sera from patients with "probable CSD" and 33.3% for patients with "possible CSD." When *B. henselae* grown on agar

media was used as the IFA antigen, the corresponding sensitivities of the assay for the two patient groups were 40.9% and 14.3%, respectively. Sensitivities of less than 50% were also seen for IgM determinations made by IFA in both groups of patients, regardless of antigen source. Specificities of both the IgG and IgM assays were assessed using sera from healthy blood donors and ranged from 95% to 100%.[116] Vermeulen and colleagues evaluated an in-house IFA test that used agar-grown genotype I *B. henselae* as the antigen.[1302,1303] This assay was challenged with specimens from 61 patients with CSD, based on clinical data and a positive PCR assay for *B. henselae*, and 56 specimens from a group of patients with different clinical diagnoses and a negative *B. henselae* PCR assay. The sensitivity and specificity of the IFA for IgM

detection were 53% and 93%, respectively, while the sensitivity and specificity for IgG detection were 67% and 82%, respectively.

IFA assays have also been developed that use *Bartonella* species that have been cocultivated in Vero cells, ECV endothelial cells, or other cultured cell monolayers. In 1995, Dalton and colleagues at the CDC cocultured *B. henselae*, *B. quintana*, and *B. elizabethae* in Vero cell monolayers and used these organisms to prepare slides for IFA testing. Of 91 patients whose illness met a strict clinical definition of CSD, 95% had IFA titers of ≥64 to either *B. henselae* or *B. quintana*.[323] Since *B. quintana* has not been associated with CSD, it was believed that positive titers against *B. quintana* represented serologic cross-reactions between the two species. Cross-reactions between *B. elizabethae* and the other two *Bartonella* species were observed only with specimens having extremely high titers against *B. henselae* or *B. quintana*. Vero cell–cocultivated *B. bacilliformis* organisms were also used to develop an IFA procedure for diagnosis of bartonellosis in endemic regions of South America. The IFA was found to be 82% sensitive in detecting antibodies in acute-phase sera of 106 patients with slide-positive (i.e., organisms observed in erythrocytes on a Giemsa-stained thin smear), PCR-positive, or culture-confirmed bartonellosis.[228] Based on the high point prevalence of 45% observed prior and during the study period, the IFA test had a positive predictive value of 89%. In their report of *B. quintana* endocarditis in three homeless men, Drancourt and associates found that all three men had high IgG titers against *B. quintana* by a microimmunofluorescence technique.[369] Titers were higher when the *B. quintana* cells used for the procedure were cocultivated in the ECV endothelial cell line (titers of 6,400 to 12,800) than when the cells were from cultures grown on 5% sheep blood agar (titers of 400 to 800).

IFA slides prepared with either blood agar-derived or cell-associated *B. henselae* or *B. henselae/B. quintana* as the antigen are available commercially and include MRL-

BA and MRL-Vero (MRL Diagnostics, USA; Virion, Institut Virion, Switzerland),*Bartonella* IFA (BION Enterprises, USA), *Bartonella* IFA IgG (Focus Diagnostics, Cypress, CA), *B. henselae IgM/IgG*, *B. quintana IgM/IgG*, *B. henselae/B. quintana* IgM/IgG (EUROIMMUN Schweiz AG, Hirschmattstrasse, CH-6003 Luzern), and *B. henselae*/*B. quintana* IFA (Fuller Laboratories, Fullerton, CA). Zbinden and associates studied two commercial IFA kits that use blood agar-derived organisms (MRL-BA, MRL Diagnostics, USA; Virion, Institut Virion, Switzerland) and cell-associated organisms (MRL-Vero/*Bartonella* IgG Substrate slides, MRL Diagnostics, USA; *B. henselae* slides, Bios, Germany).[1413] These commercial slides were compared with their in-house IFA that used Vero cell–cocultivated *B. henselae* as the antigen. In general, kits that used agar-grown *B. henselae* antigen showed higher titers (less specificity) than kits using cell-associated organisms. The MRL-Vero *B. henselae* kit alone was then compared with the in-house system. Using a cutoff titer of 256 and sera from 26 patients with CSD and 240 controls, the MRL-Vero IFA kit showed a sensitivity of 84.5% and a specificity of 93.4%. Similar results were found in a second evaluation of the MRL IFA test.[862,1413,1414]

Focus Diagnostics (Cypress, CA) markets an IFA kit for detection of IgG against *B. henselae* and *B. quintana*. Each well of individual eight-well slides contains two antigen spots consisting of Vero cells infected with either *B. henselae* (Houston strain) or *B. quintana*. Sera are screened at a dilution of 1:64, and positive results at this dilution are titered further. According to the package insert, titers of <64 are considered negative for current infection. Titers of ≥64 and <256 are considered to be evidential of infection at an undetermined time, with the suggestion that a second specimen be drawn 10 to 21 days after the first specimen, and that the first and second specimens be tested together in order to detect a fourfold or greater increase in titer. IFA titers of ≥256 are considered as presumptive evidence of recent infection. This assay was evaluated with 154 sera from normal blood donors (58 from rural Switzerland and 96 from the United States) and with 60 sera from patients with a clinical diagnosis of CSD (including lymphadenopathy and cat exposure).[427] The overall specificity of the IFA test was 89.5% (75.4% for Swiss blood donors and 97.9% for US blood donors), while the test sensitivity was 96.7%. An evaluation using sera from 50 CSD patients and 55 controls without CSD showed an overall sensitivity of 98% and a specificity of 69% at the 1:64 cutoff recommended by the manufacturer.[1303] The Focus Diagnostics *Bartonella* IFA IgG test is for export only and is not for distribution in the United States. A similar IFA product is available from Fuller Laboratories (Fullerton, CA).

The BION Enterprises assay utilizes human larynx carcinoma cells that have been infected with *Bartonella henselae* Houston-1(ATCC 49882). In a study of this assay, 63% of 19 children with CSD had antibody titers (≥512) on hospital admission; titer increases in a second serum sample obtained 1 to 3 weeks later were detected in four

additional patients. Using this assay, 13% of 116 children without CSD had IgG titers of ≥64.[1135] EUROIMMUN markets three *Bartonella henselae* assays in Europe. Two are IgM IFAs that use either a mammalian cell–cocultivated *B. henselae* Houston strain or a cocultivated *B. henselae* Marseille strain. An IgG IFA assay is also available, which uses the cocultivated Houston strain. The IgM IFAs are screened at a cutoff of 1:100, while the IgG assay is screened at a cutoff of 1:320. In a study of 50 CSD patients and 55 controls without CSD, the Houston and Marseille strain assays showed sensitivities of 54% and 50%, respectively, while the corresponding specificities of the assays were 96% and 87%, respectively. Screening of the same patients with the Houston IgG assay showed a sensitivity of 88% and a specificity of 89%.[1303]

EIA has also been evaluated as a serologic method for diagnosis of CSD. As with IFA procedures, EIAs have also used agar-grown or cocultivated organisms as the antigen. Barka and colleagues at what was then Specialty Laboratories (Santa Monica, CA) developed an EIA for detection of specific IgG, IgM, and IgA using *B. henselae* cells grown on agar as the solid-phase antigen.[91] Of serum specimens from 40 confirmed cases of CSD (by clinical history, culture, and/or histopathology), 38 (95%) had elevated levels of antibodies against *B. henselae*. Although none of the 40 CSD patients in this study had *B. henselae*-specific IgM or IgA in the absence of IgG, the authors stated that they had observed *B. henselae*-specific IgM as the only marker in some patients and had also seen IgG seroconversion in the presence of IgM occur over a 2- to 3-week period. Positive EIA results were not observed in any of 92 specimens from patients with documented high antibody titers for other agents, including

Afipia felis, *Rickettsia typhi*, *Rickettsia rickettsii*, *Borrelia burgdorferi*, *Yersinia pestis*, *Chlamydia trachomatis*, rubella virus, and cytomegalovirus (CMV). Using the same EIA, Bergmans and colleagues compared serologic methods with PCR for diagnosis and found that test concordance for diagnosis was highest between the IgM EIA and PCR.[116] These workers suggested that the most appropriate strategy for diagnosis of CSD was to perform an IgM EIA first. If the IgM serology by EIA was positive, the patient had CSD. If the IgM EIA was negative, *Bartonella* PCR from pus or tissue should be performed.

In 2001, Giladi and colleagues described an EIA for IgG and IgM that used and an *N*-lauroyl-sarcosine-insoluble outer membrane antigens from agar-grown *B. henselae* as the antigen.[486] This assay was evaluated in a group of 84 patients with definite CSD by history and at least one confirmatory test (PCR, culture, or skin test). This group was compared with a control group of 34 patients without CSD. Anti-*B.*

henselae IgG was detected in 63 and IgM in 40 of the 84 patients with CSD. Both antibodies were found in 32 patients, IgG alone was found in 31 patients, and IgM alone was found in 8 patients. The sensitivity of the EIA was calculated to be 75% for IgG and 48% for IgM, respectively. When either or both results were used for diagnosis, sensitivity increased to 85%.[486] This same assay was subsequently evaluated with specimens from 98 patients with confirmed CSD.[885] Of these, 53% tested positive for anti-*B. henselae* IgM; 88% of these patients had an initial sample that tested positive, while the remaining 12% of patients seroconverted within 1 to 8 weeks after the first serum was collected. All patients with CSD and a high IgG titer experienced disease onset within the prior 12 months. Biopsy specimens for PCR analysis were obtained from 26 of the 98 patients, and of the 24 patients who were PCR-positive, 83% and 58% were IgG- and IgM-positive, respectively. In this study, IgM seropositivity lasted for approximately 3 months, with only 4% of the study population remaining positive for IgM for more than that time. These workers concluded that IgM seropositivity in a patient with CSD is indicative of acute disease. IgG titers decreased over a longer period of time. Vermeulen and coworkers also evaluated a laboratory-developed EIA for diagnosis of CSD using a whole-cell sonicate of *B. henselae* grown on Columbia sheep blood agar.[1303] This assay was compared with an IFA test using organisms grown in the same fashion, but without the sonication step. EIA for IgM detection had a sensitivity and specificity of 65% and 91%, respectively, compared to IFA, which had a sensitivity of 53% and a specificity of 93%. For detection of anti-*B. henselae* IgG, the sensitivities of IFA and EIA were only 67% and 28%, respectively. From these studies, it is clear that serologic tests for diagnosing CSD need to be improved and that no ideal serologic test has been described. Detection of IgM antibodies against *B. henselae* by either IFA or EIA is highly suggestive for diagnosis in patients suspected of having CSD, with positive predictive values of about 87%, and that tests for IgG appear to be of limited value.[1302,1303] These workers concluded that, given the low sensitivity of serologic assays, PCR analysis for *B. henselae* should be performed for patients with suspected CSD who have negative serologic tests.

Serologic cross-reactions have also been noted between *Bartonella* species and other organisms, including *Coxiella burnetii* (the causative agent of Q fever) and *Chlamydophila* species.[369,758,858] In patients with *B. quintana* endocarditis, titers of >256 were observed against *C. pneumoniae* and titers of >64 were observed against both *C. psittaci* and *C. trachomatis*.[369,370] While absorption of the serum specimens with *C. pneumoniae* did not reduce the titers against *B. quintana*, absorption with *B. quintana* successfully quenched reactivity with *C. pneumoniae*. In another study, more than 50% of patients with chronic Q fever had significant antibody titers to *B. henselae*. Cross-absorption and immunoblot studies established that reactivity with *B. henselae* resulted from cross-reactions with *C. burnetii* antibodies; absorption of

serum with *C. burnetii* removed reactivity with *B. henselae* antigen, while adsorption with *B. henselae* removed only the reactivity against *B. henselae*.[758] Absorption of sera with *C. pneumoniae* or *B. quintana* removed anti-*C. pneumoniae* antibodies, while adsorption with *C. pneumoniae* did not change titers against *B. quintana*.[858] In the case of *Bartonella* endocarditis, specific titers may be high, with the titers against these other agents being significantly lower, suggesting that misdiagnoses should not occur provided that antibodies against all of these agents are sought simultaneously. As mentioned, sera with high anti-*B. henselae* titers may cross-react with other *Bartonella* species as well. Conversely, patients with chronic Q fever endocarditis may develop an array of antibodies that cross-react with *B. henselae*, *B. quintana*, and several other agents, including *Rickettsia rickettsii*, *Ehrlichia chaffeensis*, *Legionella* species,*Chlamydia* species, and *Anaplasma phagocytophilum*.[509] Zbinden and coworkers reported significant *B. henselae* IgM IFA cross-reactivity in 20 patients infected with Epstein–Barr virus (EBV); 45% were seropositive with agar-derived *B. henselae* antigen, and 95% were seropositive with cocultivated *B. henselae* antigen by IFA.[1415] Cross-reactivity with *C. burnetii*, *C. pneumoniae*, EBV, CMV, and *T. gondii* has been reported for several of the commercially available IFA assays as well.[1303]

The ability of serology to provide a diagnosis of *Bartonella* infections is impacted by several factors, not all of which are clear at the present time. In HIV-infected patients with manifestations of *Bartonella* infection, a significant antibody response may not be observed because of HIV-related immunosuppression. Failure to mount an antibody response has also been observed in immunocompetent patients, as evidenced by the absence of an antibody response in a host with chronic lymphadenopathy and positive blood cultures for *B. quintana*.[1062] Failure to detect antibodies may also be due to antigenic heterogeneity of the organisms themselves. Antigenically different strains of *B. henselae* have been recovered from patients with endocarditis and from cats; these strains were not only serologically different, but were also noted to be different by protein profiles and 16S rDNA sequences.[117,369] Using recombinant DNA technology, a 17-kDa protein has been isolated from *B. henselae* that is specifically reactive with sera from patients with CSD and may have value as a diagnostic serologic reagent.[37] Using an immunoproteomic approach, along with immunoblotting and MALDI-TOF, several candidate proteins of *B. henselae* have been detected that may be useful for serodiagnosis of CSD and other *Bartonella* infections in the future.[1128] At the present time, IFA is the most frequently used serologic test for CSD. Using this technique, IgG antibodies in CSD

patients are usually high (e.g., ≥512), while lower IgG titers may be found in both

CSD patients and healthy controls. In specimens with low titers, a second serum sample collected 10 to 14 days later may help to confirm the diagnosis. Seroconversion, a single high titer, or a fourfold titer increase in a second serum specimen is highly suggestive of CSD.[1135]

Products for *Bartonella* serologic testing are available from commercial vendors, and many reference laboratories also offer testing for these agents. Focus Diagnostics (Cypress, CA) markets an IFA kit for detection of IgG against *B. henselae* and *B. quintana*. Each well of individual eight-well slides contains two antigen spots consisting of Vero cells infected with either *B. henselae* or *B. quintana*. Sera are screened at a dilution of 1:64, and positive results at this dilution are titered further. According to the package insert, titers of <64 are considered negative for current infection. Titers of ≥64 and <256 are considered to be evidential of infection at an undetermined time, with the suggestion that a second specimen be drawn 10 to 21 days after the first specimen, and that the first and second specimen be tested together in order to detect a fourfold or greater increase in titer. IFA titers of ≥256 are considered as presumptive evidence of recent infection. This assay was evaluated with 154 sera from normal blood donors (58 from rural Switzerland and 96 from the United States) and with 60 sera from patients with a clinical diagnosis of CSD (including lymphadenopathy and cat exposure).[427] The overall specificity of the IFA test was 89.5% (75.4% for Swiss blood donors and 97.9% for US blood donors), while the test sensitivity was 96.7%. The Focus Diagnostics *Bartonella* IFA IgG test is for export only and is not for distribution in the United States. A similar IFA product is available from Fuller Laboratories (Fullerton, CA).

IFA serology for detection of *B. henselae* and *B. quintana* IgG and IgM and molecular tests for detection of these agents in whole blood, serum, plasma, tissue, and CSF specimens are available from several commercial reference laboratories (Associated Regional University Pathologists [ARUP], Salt Lake City, UT; Quest Diagnostics, Santa Monica, CA; Microbiology Reference Laboratory [MRL], Cypress, CA).

In Vitro Antimicrobial Susceptibility

Using agar dilution, *B. henselae*, *B. quintana*, and *B. vinsonii* are susceptible to a variety of antimicrobial agents, including ampicillin, third-generation cephalosporins, tetracyclines, macrolides, rifampin, SXT, and aminoglycosides.[861] MICs for oxacillin, cephalothin, clindamycin, chloramphenicol, and the fluoroquinolones were near the maximum concentrations of drug available in the serum. A subsequent study used agar dilution with blood-supplemented Columbia agar to determine the in vitro susceptibilities of 9 *B. quintana*, 3 *B. henselae*, and single isolates of *B. elizabethae* and *B. bacilliformis*.[859] All isolates were susceptible to β-lactams, macrolides,

doxycycline, aminoglycosides, and rifampin. The isolates appeared less susceptible to the semisynthetic penicillins, first-generation cephalosporins, and clindamycin. Susceptibilities of these 14 isolates to the fluoroquinolones were variable. Antimicrobial susceptibility testing of *Bartonella* species has also been performed using Etest methods.[135,365,1017,1270] In general, MIC results with the Etest have correlated well with agar dilution results for all classes of agents tested. Tsuneoka and coworkers used Etest methodology to test 32 *B. henselae* isolates from cats and a single strain from a human.[1270] All isolates were susceptible to minocycline, the macrolides, and the β-lactams, with clarithromycin being the most active macrolide (MICs ≤0.023 μg/mL). Gentamicin was the least active agent against *B. henselae* in this study.

Other in vitro susceptibility studies on *Bartonella* species have focused on the ability of antimicrobial agents to inhibit organism growth in a cell culture environment. Ives et al. studied the susceptibility of *Bartonella* species to several macrolide antimicrobial agents using a Vero cell monolayer cocultivation method.[630,631] Organism inhibition by different concentrations of antimicrobial agents was assessed by visual enumeration of organisms as determined by specific immunofluorescence in comparison with cultures without antibiotics after 5 days' incubation. Using this method, individual isolates of *B. henselae*, *B. quintana*, and *B. elizabethae* were susceptible to erythromycin, clarithromycin, azithromycin, dirithromycin, and roxithromycin.[630,631] These workers also pointed out that both erythromycin and doxycycline are concentrated in phagocytic cells, reaching levels that exceed the achievable serum concentrations. While the growth of organisms phagocytized by neutrophils and macrophages would likely be inhibited due to the high drug levels attained in these cells, different species or strains of *Bartonella* may behave differently within endothelial cells or other types of cells. Kordick et al. found that all strains of *B. henselae* and *B. clarridgeiae* recovered from naturally and experimentally infected bacteremic cats were susceptible to doxycycline, enrofloxacin, and ciprofloxacin.[721,722] However, successful treatment (defined by failure to detect bacteremia by culture or by PCR) occurred in only 9 of 14 cats that received enrofloxacin and in 2 of 8 cats that were treated with doxycycline. These workers concluded that standard agar dilution susceptibility tests on *Bartonella* species do not provide any clear-cut information on the therapeutic efficacy of the agents, since there is very little information on the cellular tropisms of *B. henselae* and *B. clarridgeiae* in cats. It was postulated that feline cells infected with *Bartonella* may be functionally impaired to the extent that antimicrobials are not taken up or are compartmentalized away from the organisms themselves.[721]

Bordetella Species

Background and Taxonomy of Bordetella *Species*

The genus *Bordetella* contains nine species: *B. pertussis*, *B. parapertussis*, *B. bronchiseptica*, *B. avium*, *B. hinzii*, *B. holmesii*, *B. trematum, B. petrii*, and *B. ansorpii*.[518] Genetic studies have shown that these organisms are very closely related to each other. In fact, DNA hybridization techniques indicate that these organisms may not be sufficiently different from one another to justify the assignment of individual species, although definite genetic, phenotypic, and immunologic differences exist among them. Sequence analyses of 16S rRNA of the described *Bordetella* species have demonstrated

common phylogeny with the genus *Alcaligenes*, and the genus *Bordetella* now resides in the β-2 subdivision of the *Proteobacteria* in the family *Alcaligenaceae*, order *Burkholderiales,* along with the genera *Achromobacter*, *Alcaligenes*, *Pelistega*, *Sutterella*, *Oligella*, and *Taylorella*. The genetic relatedness of *Bordetella* species to the genus *Alcaligenes* is also supported by the finding that both *B. pertussis* and *B. bronchiseptica* produce a siderophore called alcaligin that is almost identical to that produced by *Alcaligenes denitrificans*.[906]Members of the genus *Bordetella* are small, gram-negative coccobacilli on primary isolation. On subculture, they tend to become more pleomorphic. They are obligately aerobic, grow optimally at 35°C to 37°C, do not utilize carbohydrates, and are inactive in most biochemical tests. *B. pertussis*, *B. parapertussis*, *B. holmesii*, and *B. petrii* are nonmotile, while *B. bronchiseptica*, *B. avium*, *B. hinzii*, and *B. ansorpii* are motile via peritrichous flagella. These organisms do not require hemin or NAD. However, primary isolation of *B. pertussis*, in particular, requires the addition of charcoal, ion exchange resins, or 15% to 25% blood to neutralize the growth-inhibiting effects of unsaturated fatty acids, sulfides, peroxides, and heavy metals. *B. parapertussis* is somewhat less exacting in its growth requirements, but isolation still requires the use of the same special media used for *B. pertussis*. The remaining species are less fastidious and will grow on routinely used agar media, including blood, chocolate, and MacConkey agars.

The genus *Bordetella* includes species isolated from both man and other animals. Humans are the only recognized host of *B. pertussis*. *B. parapertussis* was also thought to be restricted to human hosts, but in addition to humans it has also been isolated from the respiratory tracts of pneumonic lambs in Scotland and New Zealand.[1041] *B. parapertussis* is also able to cause a pertussis-like illness in humans. *B. bronchiseptica* is found in a variety of animals (e.g., nonhuman primates, dogs,

cats, rabbits, horses, turkeys, swine, foxes opossums) and is occasionally found in humans, primarily as an opportunistic agent.[1339] As the name suggests, *B. avium* is found in birds and causes rhinotracheitis in turkeys.[696] *B. hinzii* was formerly called "*B. avium*-like bacterium," turkey coryza bacterium type II, *Alcaligenes faecalis* type II, and *Alcaligenes* species strain C2T2; this organism was formally assigned to the genus *Bordetella* in 1995.[1288] *B. hinzii* was originally described as a commensal organism in poultry, and has since been isolated from a variety of human clinical specimens. *B. holmesii* was formerly called CDC nonoxidizer group 2 (NO-2).[1343] Characterization of these isolates by DNA–DNA hybridization, 16S rRNA sequencing, and cellular fatty acid/ubiquinone analysis established their relationship to genus *Bordetella*. Since 1995, *Bordetella trematum* has been described as a new species that is found in human wounds and ear infections, and novel "*Bordetella holmesii*-like" strains have been isolated from patients with bacteremia, endocarditis, and respiratory tract infections.[1245,1287] *B. petrii* was first described as an environmental organism that was initially isolated from an anaerobic bioreactor culture enriched from river sediment.[1307] Since its initial description, *B. petrii* has also been isolated from several human clinical sources, including blood and sputum. *B. ansorpii* was first described in 2005, when it was isolated from a purulent epidermal cyst on the neck of a patient with rhabdomyosarcoma.[711]

Epidemiology of Pertussis

Pertussis continues to be an endemic disease of worldwide importance and remains an important cause of death in children less than 1 year old worldwide, with an estimated 10 million cases and as many as 400,000 deaths annually. Humans are the only known host of *B. pertussis*, and transmission occurs via direct contact with aerosolized droplets from infected, coughing individuals. The attack rate is very high, with greater than 90% of susceptible individuals becoming infected after significant exposures. For unknown reasons, disease among children occurs more often in females than in males and tends to occur in epidemic cycles of 3 to 5 years. Prior to the availability of the whole-cell killed vaccine in 1947, about 200,000 cases of pertussis were reported in the United States each year.[1346] At that time, most cases of pertussis occurred among children from 1 to 5 years of age. After 1947, when the whole-cell DPT vaccine was licensed and recommended by the American Academy of Pediatrics, reported cases of pertussis began to decline until 1976, when only 1,010 cases were reported.[1346] Subsequently, the annual number of reported cases has increased steadily, and in 2004, the incidence reached 8.9 cases per 100,000, with nearly 19,000 cases being reported that year.[247] Despite sustained high coverage for childhood pertussis vaccination, a total of 16,858 cases of pertussis and 12 infant deaths were reported in

2009.[223] Increasing incidences of pertussis despite high vaccination coverage is also being seen in several other countries, including Canada, Italy, Japan, Switzerland, and the Netherlands.[1242] Because the whole-cell vaccine provides protection for a limited duration, fully immunized individuals were protected, but adults had little or no immunity for passive transfer to infants. Consequently, during the 1980s and throughout the 1990s, the highest incidence of pertussis during this era of vaccination has progressively shifted to younger and younger infants. In the United States, during the early 1990s, between 40% and 50% of reported pertussis cases occurred in children who were less than 1 year old.[213,214] Similar incidence rates have been reported in other countries that have maintained vaccination protocols. For example, during the 15-month period from July 1993 through October 1994, 65% of index cases of pertussis in a French medical center occurred in children less than 1 year of age.[96] In resource-rich (i.e., developed countries) with well-established immunization protocols, pertussis has now emerged as an infectious problem in two age groups: individuals greater than 10 years of age and those under the age of 5 months. In the United States, during the 1980s, the mean annual incidence of pertussis in infants under 4 months increased from 63.4 cases per 100,000 to 88.7 cases per 100,000 in the 1990s.[1243] For US data from 2001 through 2003, the highest incidence was in infants under 6 months of age (98.2 cases per 100,000) compared with 12.3 cases per 100,000 in infants aged 6 through 11 months.[219] The greatest amount of pertussis-related mortality also occurs primarily among infants; surveillance data collected from 1992 through 1993 showed that infants less than 1 year of age accounted for 42% of the reported cases and 87% of the reported deaths. In countries where vaccination is not commonly practiced, the 1- to 5-year age group remains at highest risk.[214]

559

Pertussis has also become a significant problem in older children, adolescents, and adults. In Europe, incidence rates between 1998 and 2002 increased 115% in children older than 14 years.[211] In the United States, incidence rates in adolescents aged 10 to 19 years increased from 5.5 cases per 100,000 in 2001 to 10.9 cases per 100,000 in 2003.[219] Several factors have contributed to the change in pertussis epidemiology, leading to increasing disease rates in infants less than 5 months of age and in children greater than 10 years. Waning immunity following childhood vaccination in the absence of booster immunizations is an important contributing factor. The duration of protection following immunization with whole-cell vaccines ranges from 4 to 14 years, while the duration following acellular vaccine administration is about 5 to 6 years.[1337] Adolescents who received childhood acellular pertussis vaccines and adults who receive the whole-cell vaccine are at risk for pertussis in the absence of booster

inoculations. Studies have also shown that at least two vaccine doses are required for complete protection, and according to most immunization schedules, 5-month-old infants are too young to have received 2 vaccine doses and continue to be at risk for pertussis.[973] In a large multinational study of infants hospitalized with pertussis, 75% had received either no vaccine or only one dose of pertussis vaccine.[732] Therefore, continued susceptibility due to incomplete immunization status is another factor contributing to increased rates of disease. Adults and adolescents who acquire the organism due to waning vaccine- or disease-induced immunity act as reservoirs that may transmit the infection to unvaccinated or partially vaccinated infants.[1242] Because of atypical presentations of pertussis in older individuals, the disease is often unrecognized and treatment is not given, is delayed, or is incomplete. These infected individuals are an important source for transmission of *B. pertussis* to others, but especially to infants and young children who are not adequately immunized. In many cases, older relatives, including parents and grandparents, healthcare workers, and classmates are the source of infections in infants and children.[390,1004,1323] Reduced vaccine-induced immunity may also be due to structural polymorphisms of virulence factors between circulating *B. pertussis* strains and vaccine components, including pertactin and pertussis toxins (PTs).[492,568] Finally, improved methods for diagnosis such as PCR have resulted in increased testing volumes and have also contributed to marked increases in detection and a better assessment of disease incidence.

Clinical Significance of Bordetella pertussis

B. pertussis causes the syndrome called pertussis or "whooping cough." The organism is acquired via droplet infection, and is highly contagious, with an attack rate of greater than 90% in nonimmunized individuals. Partial immunization of children against pertussis may alter the classical clinical presentation. Furthermore, the presentation and diagnosis of pertussis in young children (i.e., less than 1 year old) may be complicated by concomitant viral respiratory tract infections, including influenza and respiratory syncytial viruses in particular. Classically, clinical pertussis in unvaccinated children can be divided into three stages. After an incubation period of 7 to 10 days (range 5 to 21 days), the **prodromal** *or catarrhal stage* begins and is characterized by nonspecific "cold" or "flu" symptoms, such as rhinorrhea, conjunctival injection, low-grade fever, and malaise.[582,1263] The disease is highly communicable at this stage since large numbers of organisms are present in the upper respiratory tract, and cultures collected at this time have the greatest likelihood of being positive. A dry, nonproductive cough appears late in this stage and increases in persistence, severity, and frequency. This evolves into the **paroxysmal or spasmodic stage** after several days to a week. This stage is characterized by the "staccato cough," with the prolonged inspiratory "whoop" heard at the end of the coughing spell; this phase may

last for 2 to 6 weeks. Not all children with pertussis have the characteristic cough. During this stage, there is no fever or other systemic signs and symptoms. Inspiratory efforts are futile during the coughing paroxysm, and the "whoop" is caused by the inspiration of air through the swollen and narrowed glottis. The coughing spell is frequently followed by by cyanosis and vomiting. This stage may be so severe that intermittent ventilatory assistance may be required. Complications that may occur during the course of the disease include pneumonia secondary bacterial infections, otitis media, CNS symptoms (i.e., convulsions, high fever), encephalopathy, cerebellar ataxia, inguinal hernia, and rectal prolapse associated with the severe coughing. The pathophysiology of encephalopathy associated with complicated pertussis is not known because of the unavailability of a suitable animal model, but suggested mechanisms include anoxia secondary to the coughing paroxysms, hypoglycemia secondary to the toxic effects of PT, and intracerebral hemorrhage. The **convalescent stage** generally begins within 4 weeks of onset, and during this time, there is a decrease in the frequency and severity of the coughing spells. The virulence factors of *B. pertussis* are discussed in Box 9-10.

The clinical presentation of pertussis is markedly different in infants, adolescents, and adults. Pertussis in infants can have severe presentations, have high mortality, and requires rapid diagnosis and treatment. A 2007 report on infants with pertussis admitted to the intensive care unit of an Australian tertiary-care hospital over a 20-year period described 49 patients, aged 4 to 8 weeks.[933] None of the infants had received a full immunization series, and 94% had not received any pertussis immunizations. Reasons for admission included apnea with and without paroxysms (63%), pneumonia (18%), and seizures (10%). Infants presenting with apnea with or without severe cough survived, but all seven deaths occurred with infants admitted to the ICU with pneumonia. Premortem complications included cardiovascular compromise, severe encephalopathy, and multisystem organ failure.

Atypical pertussis seen in older children, adolescents, and adults is attributed to the fact that most adults were immunized as children and that waning immunologic recall results in a modified, less severe illness.[787] Older children and adults with symptomatic but unrecognized pertussis are often sources of the organism in pediatric cases. Studies of pertussis in adults have focused on individuals with persistent cough and have used culture/molecular methods and serology to demonstrate the presence of the organisms or significant titer increases against unique antigens of *B. pertussis*, respectively. In a 2006 study of children aged 5 to 16 years presenting to

BOX 9-10

Virulence Factors of *Bordetella pertussis*

Factor	Comments
Pertussis toxin	Pertussis toxin (PT) is a major virulence factor of *B. pertussis*. PT is a single protein of 105–117 kDa molecular weight that has a wide spectrum of biologic activity and is produced only by *B. pertussis*.[795,796] Biologic effects of PT include the sensitization of mice to histamine, the production of lymphocytosis, activation of pancreatic islet cells, and stimulation of immune responses. Antibody directed against PT is protective for mice when challenged by either intracerebral or respiratory tract inoculation. The genes for the PT peptides are arranged as an operon; this operon is present in *B. pertussis*, *B. parapertussis,* and *B. bronchiseptica*, but the genes are neither transcribed nor translated in the last two species.[58,1220] Antibody directed against PT is also protective in animal models of pertussis. PT is the only molecule that is represented in every acellular pertussis vaccine formulated thus far.
Filamentous hemagglutinin	Filamentous hemagglutinin (FHA) is a cell surface adhesin of 220-kDa molecular weight that has hemagglutinating activity and, along with PT, mediates adhesion of *B. pertussis* to eukaryotic cells in vitro and to ciliated cells of the upper respiratory tract. FHA also displays immunomodulatory activity in human peripheral blood mononuclear cells (PBMCs).[356,795] FHA has multiple binding activities that enable *B. pertussis* to adhere to and, in some cases, invade different cell types, including macrophages, at different stages of infection and in concert with other adhesins. Binding of FHA to macrophages leads to phagocytosis of the organisms without the oxidative burst associated with phagocytosis of other microorganisms. This unusual circumstance may be critical for intracellular survival of *B. pertussis*. Antibody against FHA provides some immunity against respiratory infections, but not intracerebral challenge in animals, presumably by inhibiting attachment of the organisms.
	Pertactin describes several surface-associated cell membrane proteins found in three *Bordetella* species. Pertactin P.69 of *B. pertussis* has a molecular weight of 69 kDa, and homologous proteins of slightly different molecular weights are found in *B. parapertussis* (pertactin P.70) and *B. bronchiseptica* (pertactin P.68).[795] Pertactins are encoded and produced as slightly larger

Pertactin	proteins that are proteolytically cleaved to yield the biologically active molecules. *B. pertussis* pertactin was originally called P69 or 69K protein; the true molecular weight has been determined to be about 60.5 kDa after it was found that pertactin was derived from post-translational processing of a larger precursor protein. The pertactin of *B.pertussis* functions along with FHA to mediate attachment of the bacterium to tissue culture cells by helping the FHA molecule achieve a conformation that maximizes bacterial cell binding.[57] Pertactin is also required for *Bordetella* species to resist neutrophil-mediated clearance.[624]Antibodies against pertactin P.69 protect mice against infection with *B. pertussis* administered by the aerosol route, but protection against intracerebral challenge requires antibodies against both P.69 and FHA.
Adenylate cyclase-hemolysin	*B. pertussis* produces an adenylate cyclase-hemolysin (AC-H), a bifunctional 177-kDa protein of that is secreted into the medium and possesses both adenylate cyclase and hemolytic activities.[198,795] The protein is able to bind to susceptible cells and is translocated into the cell intact. Inside the target cell, the molecule is proteolytically cleaved. Activation of the adenylate cyclase activity by the eucaryotic protein calmodulin results in intracellular accumulation of cyclic AMP. This accumulation may suppress expression of the local immune response by inhibiting neutrophil chemotaxis and phagocytosis.[581]
Tracheal cytotoxin	Tracheal cytotoxin (TCT) is a small molecule of about 921 Da that is composed of a disaccharide tetrapeptide derived from the cell wall peptidoglycan. The molecule contains glucosamine, muramic acid, alanine, glutamic acid, and diaminopimelic acid in a 1:1:2:1:1 ratio and is released into the culture supernatant during the logarithmic growth phase.[302] TCT specifically damages and kills the ciliated epithelial cells lining the airways where the organism attaches and may contribute to the characteristic cough of clinical pertussis. TCT has also been shown to adversely affect polymorphonuclear cell function at low concentrations, and is toxic to these cells at higher concentrations.[795]TCT also elicits IL-1 production and induces nitric oxide synthase, which is believed to mediate damage to the respiratory tract epithelium. TCT and other similar muramyl peptides have several other biologic activities, including pyrogenicity and adjuvanticity.
	B. pertussis also produces a heat-labile toxin (HLT or dermonecrotizing toxin) that is a single polypeptide of about 140

Heat-labile toxin (dermonecrotizing toxin)	kDa.[795] HLTs produced by *B. pertussis, B. parapertussis,* and *B. bronchiseptica* are similar in their biologic properties and are physicochemically and serologically indistinguishable, whereas HLT produced by *B. avium* is slightly different in these respects. HLT induces contraction of blood vessels due to specific constrictive effects on vascular smooth muscle tissue and causes hemorrhagic necrosis in mice and guinea pigs. Although its role in the pathogenesis of pertussis, if any, is not known, constrictive effects of HLT on the highly vascularized tissues of the respiratory tract could lead to local inflammation and may explain some of the respiratory tract pathology associated with pertussis.

561

Lipooligosaccharide	Like other gram-negative bacteria, *B. pertussis* possesses lipopolysaccharide (LPS or endotoxin) in its cell wall outer membrane. Like some other bacterial pathogens, the endotoxin of *B. pertussis* is actually a lipooligosaccharide (LOS). This LOS contains lipid A and an oligosaccharide core with 2-keto-3-deoxyoctulosonic acid, but lacks the long-chain polysaccharide "O" antigens found in LPS molecules. The role of LOS in the pathogenesis of pertussis is not known, although it has the usual properties associated with LOS of many organisms, including pyrogenicity, adjuvanticity, induction of interferon production, mitogenicity, and polyclonal activation of B cells. *B. pertussis* LOS may be at least partially responsible for the reactogenicity associated with the whole-cell pertussis vaccine.
Heat-labile "O" agglutinogens	*Bordetella* species also possess specific antigens termed "O" agglutinogens (AGGs) on the bacterial cell surface. Fourteen heat-labile AGGs have been described for *Bordetella* species. These agglutinogens are associated with fimbriae and apparently are also involved in the mediation of attachment to target cells. AGGs 1 through 6 are found in *B. pertussis*; AGG 1 is common to all *B. pertussis* strains, with AGGs 2 through 6 being present in various combinations in different strains.

clinicians with cough for more than 14 days, 37% had serologic evidence of pertussis.[558]A study of 130 university students reporting to the student health service with a cough of 6 days' duration or greater found that 26% had serologic evidence of recent *B. pertussis* infection.[894] A subsequent study with this population found that 15% of 319 students with cough of ≥5 days' duration had serologic evidence of *B. pertussis* infection; 17 of these individuals also had serologic evidence of coexisting viral, *Chlamydophila pneumoniae*, or *Mycoplasma pneumoniae* infections.[633] A study of US Marine Corps trainees who reported 7 or more days of cough found that 17% had acute *B. pertussis* infection.[643] A study of 51 healthcare workers who were evaluated annually from 1984 to 1989 for rises in antibody titers to four pertussis-specific antigens (PT, filamentous hemagglutinin [FHA], pertactin, and fimbriae) found that 90% had a significant increases in antibody titer to one or more pertussis antigens between two consecutive years during the 5 years of the study.[351] Among 246 German adults with a coughing illness of greater than 14 days' duration, evidence of *B. pertussis* infection was found in 64 (26%), 5 had positive nasopharyngeal cultures and 59 were diagnosed on the basis of serology and/or PCR.[1150] A study in Denmark of 201 patients with coughs persisting for a mean of 6.5 weeks found that 4 patients (2%) were culture-positive for *B. pertussis* and 11 (5.5%) were positive by PCR (including the 4 culture-positive patients).[128] Serologic evidence of pertussis infection was also demonstrated in 100 adults aged ≥65 years who were studied over a 3-year period. Between 3.3% and 8% of this population had pertussis infections each year, and between 37.5% and 50% were symptomatic as a result of the infection.[591] A study of 178 adults in Denmark with a duration of coughing between 2 weeks and 3 months reported that 3.4% to 12.4% were seropositive for pertussis, indicating recent infection.[322]

The clinical spectrum of pertussis in adults has been described in several studies and case reports. In a UCLA study, the two principal clinical diagnoses entertained for those individuals found to have pertussis were nonspecific upper respiratory tract infection (39%) and bronchitis (48%).[894,1039] In a study conducted in Germany on 64 adults with documented *B. pertussis* infection, only 39% were thought to have pertussis and 14% were thought not to have pertussis clinically; other diagnoses included upper respiratory tract infections, nasopharyngitis, pharyngitis, adenoiditis, and sinusitis. However, of the 64 patients, 70% had a paroxysmal cough, 38% had an inspiratory whoop, and 17% experienced post-tussive vomiting.[1150] Another German study of 84 adults with pertussis found persistent (>21 days) cough in 81%, spasmodic coughing in 65%, and choking in 56%.[1042] Eighteen patients had complications, including otitis media, pneumonia, urinary incontinence, cervical lymphadenopathy, acute hearing loss, rib fractures, and inguinal hernia. Pertussis-associated

encephalopathy has also been documented in adult pertussis.[548] Although uncommon, acute *B. pertussis* infections in adults have been described; in one case, acute pertussis was diagnosed in a 53-year-old man who acquired the organism from his son, who had been immunized, and had a mild case of whooping cough.[1201] *B. pertussis* has also been isolated from adults with underlying disease such as HIV infection. Ng and coworkers isolated *B. pertussis* from BAL and transbronchial biopsy specimens of three patients with AIDS.[945] These organisms were recovered on media for isolation of *Legionella*. Doebbeling et al. reported the isolation of *B. pertussis* from the upper respiratory tract of a 25-year-old HIV-positive patient with a 4-month history of paroxysmal cough; a similar case was also reported in a 60-year-old patient with AIDS in Belgium.[292,360] Despite these case reports, pertussis is believed to be relatively rare in HIV-infected individuals, with an estimated prevalence of nasopharyngeal carriage of less than 6.5 cases per 100,000 patients.[289] *B. pertussis* has also been isolated from blood cultures of immunocompromised hosts on at least three occasions. All three patients had underlying diseases, including Wegener's granulomatosis and multiple myeloma; in two patients the infection was fatal.[217,642,1266]

Pertussis Vaccines

The original whole-cell pertussis vaccine was administered along with diphtheria and tetanus toxoids and aluminum-coated adjuvants (DTwP). After licensure, widespread use of whole-cell vaccine resulted in declines in pertussis in countries employing mandatory immunization, and additional evidence of efficacy accrued as a result of diminished immunization programs in some countries. Diminished public acceptance of immunization in Great Britain beginning in

the mid-1970s resulted in pertussis reaching epidemic proportions among children less than 5 years of age in the late 70s. While experience suggested clinical efficacies of greater than 80%, variations in the performance of whole-cell vaccine preparations became more apparent during prospective clinical efficacy studies conducted with potential acellular pertussis vaccines. Publicity surrounding reports of encephalopathy and permanent neurologic sequelae that were temporally related to receipt of DTwP vaccine accelerated efforts to develop acellular or "subunit" vaccines. Acellular pertussis vaccines contain PT and FHA, and some also contain pertactin (69-kDa protein) or both fimbriae and pertactin.[308,526] Pertussis vaccines are combined with diphtheria and tetanus toxoids in the DTaP vaccine for children, and the Tdap for adolescents and adults (see below). In the United States, three DTaP vaccines are licensed:

- Infanrix (GlaxoSmithKline Pharmaceuticals): contains PT, FHA, and pertactin
- TriPedia (Sanofi Pasteur, Inc.): contains PT and FHA
- DAPTACEL (Sanofi Pasteur, Inc.): contains PT, FHA, pertactin, and fimbriae types 2 and 3

The immunization schedule consists of three doses of DTaP by intramuscular injection at 4- to 8-week intervals, typically at 2 months, 4 months, and 6 months of age, with a fourth dose at 15 to 18 months of age. A fifth dose is recommended at 4 to 6 years of age. In general, studies have demonstrated that multicomponent vaccines containing pertactin and fimbrial antigens in addition to PT and FHA elicit a more robust immune response than vaccines containing only PT and FHA.[1040] These vaccines also appear to be highly immunogenic when administered along with other childhood immunizations. DTap is also available in combinations with inactivated polio vaccine (KINRIX, GlaxoSmithKline Pharmaceuticals), *H. influenzae* type b vaccine (TriHIBit, Sanofi Pasteur), inactivated polio and hepatitis B vaccines (Pediarix, GlaxoSmithKline Pharmaceuticals), and inactivated polio and *H. influenzae* type b vaccines (Pentacel, Sanofi Pasteur, Inc.). KINRIX is only used for dose 5 of DTaP, which occurs at age 4 to 6 years, when the child is due for the inactivated polio vaccine booster. TriHIBit is licensed for the 15- to 18-month dose, which can be given after the first three DTaP and hepatitis B vaccine series.

Acellular pertussis vaccines have been investigated for immunogenicity in previously vaccinated or unvaccinated adults. Studies in adult populations have shown that these vaccines, given alone or combined with diphtheria and tetanus toxoid, produce minimal adverse effects and engender brisk antibody responses to PT, FHA, pertactin, and fimbrial antigens present in the vaccine with no interference with the responses to either of the toxoids. The combination "Tdap" vaccines are combinations of tetanus toxoid, diphtheria toxoid, and acellular components of *B. pertussis*, including PT, FHA, pertactin, and fimbrial antigens. As indicated by the lowercase "d," the concentration of diphtheria toxoid has been reduced in these "adult" formulations to prevent adverse effects, while the "a" in "aP" indicates that acellular pertussis components are present. Acellular pertussis booster vaccines formulated specifically for adolescents and adults have now been licensed for use in the United States and include Boostrix (GlaxoSmithKline Biologicals) and ADACEL (Sanofi Pasteur). Boostrix contains detoxified PT, FHA, and pertactin, while ADACEL contains PT, FHA, pertactin, and fimbriae types 2 and 3 as the acellular pertussis components. Boostrix is licensed for use in adolescents aged 10 to 64 years of age, while ADACEL is licensed for adolescents and adults aged 11 to 64 years.[783] The Advisory Committee on Immunization Practices (ACIP) has recommended that all adolescents scheduled for a diphtheria/tetanus booster (recommended every 10 years) and any adult receiving a tetanus toxoid booster receive Tdap instead.[181,735] Tdap can also be

administered as prophylaxis for tetanus wound management. Five years between doses of tetanus toxoid or doses of tetanus toxoid and Tdap is the current standard since frequent exposure to tetanus toxoid can cause local reactions. People who will be in contact with young infants are encouraged to get Tdap even if it has been less than 5 years since the last tetanus booster to reduce the risk of infants being exposed to pertussis. ACIP has also recommended that all healthcare workers receive Tdap.[783]

Clinical Significance of Other Bordetella *Species*

Bordetella parapertussis. *B. parapertussis* is associated with a pertussis-like illness in humans as well, but it is generally less severe in clinical presentation. Children with *B. parapertussis* infection had shorter durations of coughing, bronchospasm, whooping, vomiting, apnea, and cyanosis.[114,850] However, outbreaks of *B. parapertussis* have been reported where the illness has been quite severe and resulted in death, particularly in very young children. Wirsing von Konig and Finger compared the severity of disease in 33 children with *B. parapertussis* infection with 331 patients with *B. pertussis* infection and found that the frequency of whooping paroxysmal coughing, whooping, and vomiting were almost identical in both groups.[1358] Heininger and colleagues also compared *B. pertussis* infection in 76 patients with *B. parapertussis* infection in 38 patients matched by age and sex. They also found that the illness caused by *B. parapertussis* was typical of pertussis but much less severe, and that, unlike pertussis, lymphocytosis was not a characteristic of the infection, presumably due to the absence of the lymphocytosis-promoting activity of PT.[571] In a study conducted in Germany after introduction of the acellular pertussis vaccine, Liese and colleagues documented 180 *Bordetella* infections in small children.[787] Of these 180 cases, 116 (64%) were caused by *B. pertussis* and 64 (36%) by *B. parapertussis*. Paroxysmal cough, inspiratory whooping, and vomiting for ≥21 days were found in 53%, 22%, and 8% of all *B. pertussis* cases and in 22%, 5%, and 0% of all *B. parapertussis* cases, respectively. Of the 116 *B. pertussis* cases, 81 (70%) of the children had received at least one dose of acellular pertussis vaccine, and of the 64 cases of *B. parapertussis* infection, 56 (87.5%) had received at least one vaccine dose. Typical pertussis was present in 29 (83%) of 35 unvaccinated *B. pertussis* cases, in contrast to 33 (41%) of 81 vaccinated *B. parapertussis* cases.

Bordetella bronchiseptica. *B. bronchiseptica* causes respiratory tract infections in various animal species (e.g., infectious tracheobronchitis or "kennel cough" in dogs,

pneumonia in cats, atrophic rhinitis and bronchopneumonia in pigs and piglets,

pneumonia and otitis media in rabbits and guinea pigs) and may be isolated as a commensal from the human upper respiratory tract. Humans may acquire the organism from domesticated animals, and nosocomial transmission from patient to patient may also occur.[617,1066] *B. bronchiseptica* is an unusual cause of infections primarily in immunocompromised hosts, including patients with hematologic malignancies, solid organ transplants, human stem cell transplant recipients, cystic fibrosis, and COPD.[489,495,498,617,866,943,1339] Since 1991, several cases of *B. bronchiseptica* pneumonia, sinusitis, and pleural infections have been reported in patients with AIDS.[382,468,866,1304] Bacteremia, meningitis following head trauma, peritonitis, bronchitis, and pneumonia caused by *B. bronchiseptica* have been reported in patients with underlying liver disease, alcoholism, asplenia, hematologic malignancy, chronic renal failure, asthma, systemic lupus erythematosis, and severe hypertension.[105,1028,1338,1361] *B. bronchiseptica* may occasionally cause severe infections, such as pneumonia with shock, in immunocompetent patients.[1241] Rare reports of endocarditis caused by *B. bronchiseptica* have also appeared in the literature. In one such instance, the patient presented with fever and a dermatitis around a recent surgical incision.[1189] The patient's dog frequently nipped and licked the area of dermatitis surrounding the incision, suggesting a canine origin for the organism.

Bordetella avium. *B. avium* causes rhinotracheitis in turkeys and other avian species.[696] *B. avium* infections in humans have been described in patients with cystic fibrosis.[1216] This organism was also isolated from BAL fluid from a 68-year-old man with pneumonia and hemoptysis following a 10-day history of increasing shortness of breath and cough, and from a 61-year-old homeless man with COPD.[561] The isolate from the latter patient showed 11 base pair differences and 15 base pair differences compared with the type strain of *B. avium* and the type strain of *B. trematum*, respectively; so the isolate was termed *B. avium* like.

Bordetella hinzii. *B. hinzii* was proposed as a new species in 1995, although the organism had been described informally when it was isolated from sputum and multiple blood cultures collected from a 42-year-old patient with AIDS who did not have any respiratory tract symptoms.[303,1288] This *B. avium*-like organism has been isolated from the respiratory tract of chickens and turkeys in addition to respiratory tract specimens from humans. *B. hinzii* strains were isolated on eight occasions over a 3-year period from an adult patient with cystic fibrosis in association with acute exacerbations of his chronic pulmonary disease; the organism could not be eradicated from the respiratory tract of the patient despite appropriate chemotherapy.[462] In 2000, fatal *B. hinzii* bacteremia was reported in a 69-year-old man with cholestasis, and *B.*

hinzii was isolated along with *Nocardia asteroides* complex organisms from BAL fluid of a patient with AIDS.[466,686] Although avian exposure of the respiratory tract could be ruled out in the patient with AIDS, possible acquisition from avian exposure or gastrointestinal colonization was suggested as possible modes of pathogenesis in the bacteremic patient. *B. hinzii* has been isolated from biliary tract specimens collected from a liver transplant recipient with chronic cholangitis and from blood cultures obtained from a patient with myelodysplastic syndrome.[69,457] In 2008, sepsis with *B. hinzii* was documented in a 36-year-old woman with EBV viremia, human herpes virus type 6 viremia, and diffuse large B-cell lymphoma. In this case, *B. hinzii* was also isolated from sputum cultures.[612] Another as yet unnamed "*B. avium*-like" isolate was recovered in mixed culture from a patient with chronic otitis media. This isolate was distinct in its antimicrobial resistance pattern, protein and fatty acid composition, and both DNA:DNA and DNA:rRNA hybridizations.

Bordetella holmesii. *B. holmesii*, described originally as CDC nonoxidizer group 2 (NO-2), has been isolated from blood cultures of patients with acute febrile illnesses, endocarditis, sickle cell anemia complicated by arthritis, diabetes, prior splenectomies, Hodgkin's disease, and respiratory insufficiency.[1343] Of the 15 patients described in this report, underlying disease was present in seven cases, three occurred in asplenic patients, and one patient had been bitten by a dog. The strains described in this 1995 report had been isolated in Switzerland, Saudi Arabia, and the United States. In 1996, Lindquist and colleagues isolated *B. holmesii* from multiple blood cultures of a 12-year-old boy who presented with fever, headache, and a history significant for splenectomy 4 years earlier.[792] Although the normal habitat of *B. holmesii* is unknown, the patient had frequent and prolonged contact with hunting dogs and had recently suffered a fishhook injury to his thumb. Tang and others at the Mayo Clinic reported the isolation of *B. holmesii*-like organisms from three patients with septicemia, endocarditis, and respiratory failure.[1245] Risk factors in these three patients included underlying asplenia, Hodgkin's disease, and severe cardiomyopathy, respectively. *B. holmesii* was also isolated from a 10-month-old infant who presented to the emergency room with fever and irritability.[910] Originally diagnosed as having a viral syndrome, *B. holmesii* was recovered from a single aerobic blood culture within 36 hours. Follow-up found the infant to be afebrile and asymptomatic. *B. holmesii* has also been isolated from multiple blood cultures of a 24-year-old man who presented with dry cough and fever, and a history remarkable for neonatal-onset sickle cell anemia, hepatitis C, tibial osteomyelitis at age 6 years, and frequent abdominal crises requiring multiple transfusions until the age of 8 years.[948] *B. holmesii* was isolated from blood, pleural fluid, and lung biopsy specimens from a previously healthy 14-year-old girl with a 6-month history of weight loss and dyspnea.[1122] *B. holmesii*

bacteremia has also been documented as a cause of fever and bacteremia in patients with asplenia, sickle cell disease, and nephrotic syndrome.[364,868,998,1183] *B. holmesii* bacteremia may also occur as a complication of hemodialysis.[516] *B. holmesii* has also been isolated from respiratory tract specimens of patients suspected of having pertussis. Of 10,996 specimens submitted from January 1995 through December 1998 to the Massachusetts State Laboratory Institute in Boston for culture of *Bordetella* species, 32 specimens grew *B. holmesii*, while 740 and 96 specimens were positive for *B. pertussis* and *B. parapertussis*, respectively.[865,1399] A study conducted on French patients with suspected pertussis found *B. holmesii*

564

DNA by real-time PCR in 20.3% of patient specimens.[947] However, a 2006 survey of 2,804 nasopharyngeal swabs from Finnish patients and 8,515 swabs from Dutch patients with suspected pertussis using a specific, real-time PCR assay for *B. holmesii* failed to detect any specimens that were positive for this agent.[48]

Bordetella trematum. *B. trematum*, another recently described species, has been recovered from human wound specimens, diabetic leg ulcers, and patients with chronic otitis media.[332,1287] This species was found to be genetically and chemotaxonomically more closely related to type strain of genus *Bordetella* (*B. pertussis*) than to the type strain of the genus *Alcaligenes* (*A. faecalis*).[1287]

Bordetella petrii. *B. petrii* was first isolated in 2001 from an anaerobic dechlorinating bioreactor culture enriched with sediment from river water.[1307] Subsequently, two strains of *B. petrii* were isolated from a patient with mandibular osteomyelitis and from a patient with chronic suppurative mastoiditis.[458,1219] Similar strains have also been isolated from respiratory tract specimens from patients with COPD and bronchiectasis. In these patients, the organism may persist for years and be isolated from purulent sputum each time the patient had an exacerbation of symptoms.[770] The environmental origin of *B. petrii* is also supported by its recovery from marine sponges and grassroot microenvironments.

Bordetella ansorpii. *B. ansorpii* is a species that was first described in 2005. This novel species was isolated from the purulent exudate of an epidermal cyst on the neck of a 19-year-old female in Korea who was hospitalized for chemotherapy due to rhabdomyosarcoma.[711] This same organism was isolated in the United Kingdom in 2007 from two sets of blood cultures that had been collected through a Hickman catheter that had been placed 6 months prior.[459] The patient was an 88-year-old man

who was receiving chemotherapy for acute myeloid leukemia.

Culture and Isolation of Bordetella pertussis

Since *B. pertussis* preferentially attaches to the ciliated epithelium in the upper respiratory tract, the specimen of choice is a nasopharyngeal aspirate. Nasopharyngeal aspirates are optimally collected with an infant-size feeding tube connected to a mucus trap. The tip of the feeding tube is threaded into one nostril along the floor of the nasopharynx until it reaches the posterior pharynx. Once the tube is in place, gentle suction is applied. Following aspiration, saline (1 mL) is flushed through the tubing into the trap.[546] For swab specimens, a small-tipped, nasopharyngeal swab is passed posteriorly through each nostril until the swab tip reaches the posterior nasopharynx. Each swab is left in place for 30 seconds to one minute to allow organisms to adsorb onto the swab. Cotton-tipped swabs should not be used, because cotton material may be inhibitory to the organism. In addition, PCR-based assays for direct detection of *B. pertussis* may be inhibited by calcium alginate fibers and aluminum; specimens processed for detection of *B. pertussis* by PCR should be collected with Dacron swabs with plastic shafts.[1310] Nasopharyngeal swabs collected along with an aspirate may provide the highest yield of positive cultures. Regular throat cultures are not appropriate for isolation of *B. pertussis*. Specimens for bordetellae also require special transport media for optimal organism recovery. Regan–Lowe (RL) transport medium may be used for aspirates and swab specimens and has the advantage of serving as both a transport and an enrichment medium (see below).

Special medium is required for the isolation of *B. pertussis.* The classical medium used for this organism is Bordet–Gengou (BG) agar. This medium is prepared from potatoes to impart a high starch content to the medium. The starch neutralizes toxic materials that may be present in the agar or in the specimen itself. Peptones are omitted from the medium, since these proteins are also inhibitory. BG agar also contains glycerol as a stabilizing agent. Although "homemade" BG agar base is superior, dehydrated basal medium is commercially available (Remel Laboratories; BD Biosciences). The base is prepared ahead and stored under refrigeration. If a patient is suspected of having pertussis, the laboratory must be notified in advance of receiving the specimen, since the final medium must be freshly made. Although optimal, this is impractical for most laboratories. To prepare the medium for use, the potato/glycerol agar base is melted, and 30 mL of defibrinated sheep blood per 100 mL agar base medium (approximately 23% blood w/v) is added. Cephalexin (final concentration of 40 µg/mL) should be added to some of the medium to inhibit contaminating gram-positive organisms that may be present in the specimen; methicillin (2.5 µg/mL) or oxacillin (0.625 µg/mL) may be substituted for the cephalexin. Both nonselective and selective medium should be inoculated, since some *B. pertussis* strains may be slightly inhibited by cephalexin.

In 1977, Regan and Lowe described a medium containing charcoal and horse blood that has demonstrated superiority to BG agar in several studies (Image Plate 9-5G and 9-5H).[1070] Although originally described as a transport/enrichment medium, RL agar formulations are available both as a semisolid transport/enrichment medium and as a solid medium for organism isolation. The formula for RL medium is shown below (per liter distilled water):

Charcoal agar (Oxoid CM 119)	51 g
Horse blood, defibrinated	100 mL
Cephalexin	0.04 g
Amphotericin B (optional)	0.05 g
Final pH	7.4

The semisolid transport/enrichment medium is identical in formula to the isolation medium shown above, except that the charcoal agar is present in half strength (i.e., 25.5 g/L) and is dispensed into sterile screw-capped tubes rather than into 100 mm Petri dishes. It is also recommended that some of the medium be prepared without cephalexin so that both selective and nonselective media are available for recovery of the organisms. Optimally, media should be directly inoculated at the time of specimen collection onto both selective (methicillin- or cephalexin-containing) and nonselective media. If a transport system is used, the RL semisolid

565

medium is optimal, since Stuart and Amies transport medium formulations are not suitable for maintaining the viability of *B. pertussis*. Specimens transported in semisolid RL medium can be subcultured on receipt to RL isolation medium or BG medium with and without cephalexin (or methicillin). The transport medium is then incubated along with the primary plate and subcultured to RL agar after 48 hours' enrichment at 35°C in ambient atmospheric air. Contrary to widely held beliefs and practices, ambient air is superior to a CO_2-enriched incubation environment. Plates should be incubated for at least 7 to 10 days. In a study conducted in Canada, however, 7 (16%) of 44 *B. pertussis* isolates and 2 (50%) of 4 *B. parapertussis* isolates were obtained only after 12 days of incubation.[689] *Bordetella* species will also grow on BCYE agar used for the isolation of *Legionella* species.[945]

Although culture is considered the "gold standard," the availability of sensitive molecular assays has demonstrated that the diagnostic performance of culture methods is highly dependent on the stage of the disease when specimens are collected, previous

antimicrobial administration, vaccination status, the techniques used to collect the specimens, transport conditions, and the experience of the laboratory in handling pertussis specimens and cultures.[248] The earlier in the clinical course that specimens are obtained, the greater the yield obtained with culture. Under optimal conditions, the sensitivity of pertussis culture can be 80% to 90%, but in practice, sensitivity usually ranges from 30% to 60%.[1406] The yield of *B. pertussis* in culture declines after 2 or more weeks of cough illness, after antimicrobial treatment, or after previous pertussis vaccination.[1291] By the time patients have been symptomatic for 2 to 3 weeks, the sensitivity of culture falls to less than 5%.[248]Although *B. pertussis* can be isolated in culture as early as 72 hours after plate inoculation, cultures may require 10 days' to 2 weeks' incubation before they can be definitively called negative. However, culture is required to obtain isolates for antimicrobial susceptibility testing or molecular typing.

Direct FA Test

Direct FA (DFA) tests have been used to detect *B. pertussis* and *B. parapertussis* directly on smears prepared from nasopharyngeal specimens (Image Plate 9-5E). While DFA tests do provide rapid results, culture on appropriate media is more sensitive than DFA and far less sensitive than molecular methods (i.e., PCR). Depending on when in the clinical course the specimens are collected, the DFA test may not detect small numbers of organisms that may be detected by culture or by PCR. Historically, the sensitivities reported for DFA have ranged from 11% to 68%, with corresponding specificities of 99.6% to 100%.[797,1336] Halperin and associates found that only 6 of 20 patients who were positive by culture were DFA-positive, and that only 4 of the 12 DFA-positive, culture-negative cases were confirmed by serologic testing of acute and convalescent serum speciemens.[547] Tilley and colleagues evaluated culture, two PCR assays, and DFA for diagnosis of pertussis with 637 nasopharyngeal swabs and aspirates submitted for pertussis evaluation.[1257] DFA reagents included polyclonal antipertussis and antiparapertussis reagents (BD Difco FA Pertussis and BD Difco FA Parapertussis, BD Biosciences), fluorescein isothiocyanate-labeled monoclonal anti-LPS antibody, and "Accu-MAb Plus" *B. pertussis/B. parapertussis* monoclonal antibody reagents (Delta Biotech, Inc., British Columbia, Canada). The sensitivities of the polyclonal DFA reagent, the anti-LPS antibody reagent, and the commercial monoclonal antibody reagent were 11.4%, 5.2%, and 8.3%, respectively, while the corresponding specificities were 94.6%, 98.1%, and 98.4%, respectively. In contrast, the two PCR assays used in this study had sensitivities of 95.0% and 89.2%. DFA smears were often difficult to interpret due to the small size of the bacteria and the presence of artifacts. Owing to poor performance and the availability of superior diagnostic approaches, the DFA test for detection of *B. pertussis* should no longer be performed in clinical microbiology

laboratories.[1336]

Cultural Characteristics and Identification of Bordetella *Species*

On culture, colonies of *B. pertussis* may be observed after 2 to 4 days. Growth is usually apparent sooner on antibiotic-free medium, but this is not always the case. Plates should be examined under a dissecting microscope (10×) with oblique incident light to determine colony characteristics. Fresh clinical isolates of *B. pertussis* on BG agar appear as smooth, shiny colonies with a high, domed profile. Classically, the colonies are described as resembling small droplets of mercury. Colonies on BG agar may be slightly β-hemolytic, particularly in the more confluent areas of growth or after prolonged incubation. On RL agar medium, colonies are small, domed, and shiny, with a white mother-of-pearl opalescence. *B. parapertussis* colonies grow more rapidly, are more β-hemolytic on BG agar, and are gray or slightly brown in color. *B. bronchiseptica* colonies are apparent within 24 hours, are large, are flatter, and have a dull rather than a shiny appearance. The latter species resembles a nonfermentative gram-negative rod (like an *Alcaligenes* species) in the appearance of its colonies and the production of a distinct "nonfermenter" odor. Gram's stain morphology of these organisms also differs. *B. pertussis* appears as small, pale-staining coccobacilli, while *B. parapertussis* and *B. bronchiseptica* are more definitely rod-shaped (Image Plate 9-5F). Because of the pale staining of the organisms, the safranin counterstain should be left on the slide for at least 2 minutes.

Once isolated, *B. pertussis* can be identified by the FA test or slide agglutination, since the organism is quite inert in biochemical identification tests (Table 9-16). For the FA test, organisms from plates should be suspended in phosphate-buffered saline (PBS), and known cultures of both *B. pertussis* and *B. parapertussis* should be used as controls. For slide agglutination, an organism suspension equivalent to a McFarland no. 3 turbidity standard should be prepared in PBS, and positive and negative controls should be included. Serologic methods may be used to identify *B. parapertussis* as well, but biochemical methods may provide a presumptive identification. *B. pertussis*, *B. bronchiseptica*, *B. hinzii*, and *B. avium* are oxidase-positive with Kovac's oxidase reagent, while *B. parapertussis*, *B. holmesii*, and *B. trematum* are oxidase-negative. *B. parapertussis*, *B. bronchiseptica*, *B. hinzii*, and *B. holmesii* are catalase-positive, while *B. pertussis* is variable for catalase production. Both *B. parapertussis* and *B. bronchiseptica* are urease-positive, with the latter species producing a positive test in less than

4 hours. *B. bronchiseptica* can be misidentified as *Oligella ureolytica* or *Ralstonia paucula*, but *B. bronchiseptica* reduces nitrate to nitrite (*R. paucula* is negative), does not reduce nitrite to nitrogen gas, and is penicillin susceptible (*O. ureolytica* reduces nitrite to nitrogen gas and is penicillin-resistant). *B. hinzii* is variable for urease production, while *B. pertussis*, *B. holmesii*, *B. avium*, and *B. trematum* are urease-negative. Both *B. parapertussis* and *B. holmesii* produce a soluble brown pigment on agar media, while *B. pertussis*, *B. bronchiseptica*, *B. hinzii*, *B. trematum*, and *B. avium* do not. Other characteristics for the identification of *Bordetella* species are shown in Table 9-16.

Molecular Methods for Detection and Identification of Bordetella *Species*

With the genetic characterization of *B. pertussis* and other *Bordetella* species, molecular assays have been developed for direct detection of these organisms in nasopharyngeal specimens and for identification of organisms recovered in culture. PCR-based assays have, in fact, become the tests of choice for diagnosis of pertussis because of their exquisite sensitivity and specificity. Nucleic acid target sequences specific for *B. pertussis* and other species have been identified and sequenced, and primers and probes have been designed for detection of these targets by PCR. Targets identified for potential use in direct detection include the PT gene promoter region (*ptxA*), outer membrane porin (PO) genes, the adenylate cyclase gene, the *recA* gene, and sequences determined to be species-specific based on the entire *B pertussis* genome sequences.[1045,1305]

Most molecular techniques described for *Bordetella* species involve the detection of

insertion sequences such as IS*481*, IS*1001*, and IS*1002*. *B. pertussis* carries up to 80 to 100 copies of IS*481,* and this sequence is found in *B. pertussis, B. holmesii*, and occasionally *B. bronchiseptica.* IS*1001* is found in *B. parapertussis* and occasionally in *B. bronchiseptica* and *B. holmesii*. Reischl and colleagues designed a real-time PCR assay targeting IS*481* and found that specificity of the assay was compromised by the finding of similar IS*481* sequences in *B. holmesii*.[1077] Sloan and colleagues also designed a multiplex, real-time PCR assay for detecting IS*481* and IS*1001* of *B. pertussis* and *B. parapertussis*, respectively, and also noted that false-positive results may occur with *B. holmesii*.[1198] This approach was also used by other investigators, who also noted the presence of IS1001 in *B. holmesii*. Differentiation of *B. parapertussis* and *B. holmesii* was accomplished by sequencing of the amplification product. Poddar designed a LightCycler assay for *B. pertussis* and *B. holmsei* targeting IS*481*, and differentiation of the two species was accomplished by PCR probe-target melting profile analysis, which was able to detect the single nucleotide difference in the IS*481* sequences of the two organisms.[1037] Menard and colleague described a similar assay for *B. pertussis* and *B. parapertussis* based on amplification of the IS*481* and IS*1001* of *B. pertussis* and *B. parapertussis*, respectively, with species identification again confirmed by melting-curve analysis.[882] In this study, one specimen grew *B. bronchiseptica* while the PCR assay was positive for *B. pertussis*. The *B. bronchiseptica* strain harbored an IS*481* insertion sequence, which is found in less than 1% of *B. bronchiseptica* isolates. Rooda and colleagues designed a real-time PCR assay for detection and discrimination of all clinically relevant *Bordetella* species.[1107] This assay detected IS*481*, IS*1001*, and IS*1002*. Amplification of both IS*481* and IS*1002* confirmed detection of *B. pertussis*, amplification of both IS*1001* and IS*1002* confirmed detection of *B. parapertussis*, and amplification of IS*1001* only confirmed detection of *B. bronchiseptica*. Amplification of IS*481* only detected *B. holmesii* and the rare isolate of *B. bronchiseptica* harboring the IS*481* element. Knorr and colleagues devised two real-time LightCycle PCR assay for *B. pertussis* where specimens were tested for detection of IS*481* and, if positive, for the presence of IS*1001*.[710] Specimens positive for IS*481* and negative for IS*1001* were confirmed to be *B. pertussis*. No *B. holmesii* strains (where IS*481* and IS*1001* are both present) were detected in this study. Xu and coworkers designed a single-tube, "triplex" real-time PCR assay that used three targets for amplification: *ptxP* (PT promoter region) and IS*481* for *B. pertussis*, and the insertion sequence IS*1001* for *B. parapertussis*.[1377] The lower limits of detection in this assay were 1 to 5 cfu for *B. pertussis* and 1 cfu for *B. parapertussis*. Even though IS*1001* is also found in some *B. holmesii* strains, the primers and probes used in this triplex assay were specific for *B. parapertussis.* Specific detection of *B. holmseii* directly in clinical specimens has been accomplished by designing real-time PCR assays targeting a 50 base pair segment

of the housekeeping gene *recA* that is polymorphic among *B. holmesii* and all other *Bordetella* species.[538]

Serologic Tests for Diagnosis of Pertussis

Prior to the vaccine efficacy trials, serologic tests for pertussis were performed with inactivated whole cells, whole-cell sonicates, or crude acellular extracts of *B. pertussis* as antigens and interpretation of these tests was often difficult. For vaccine trials conducted with the WHO, pertussis serology was developed as a semistandardized EIA procedure using purified antigens and was included in the case definition of pertussis.[1359] These antibody assays used purified antigens (e.g., PT, FHA, pertactin, fimbrial antigens) in an EIA format. Antibody directed against PT is specific for *B. pertussis*, while anti-FHA antibodies are also produced following infection with *B. parapertussis*. Other organisms may also engender antibodies that cross-react with *B. pertussis* FHA (e.g., nontypeable *H. influenzae*). Following natural infection, antibodies usually appear 10 days to 2 weeks after the onset of symptoms, with anti-PT and anti-FHA IgG antibodies being detected in over 90% of patients and IgA antibodies being detected in 20% to 40% of infected individuals. Immune responses to other antigens (e.g., pertactin, fimbrial antigens) tend to be more variable and may be found in 20% to 60% of infected persons. Therefore, the most specific serologic assay is IgG to PT as it is unique to *B. pertussis* and the titer rapidly falls below cutoff values within 4 to 5 months' post infection and, in 82% of patients, with 1 year post infection.[85,316,1325]

The immune response to pertussis is also influenced by vaccination status and age of the host. In the case definition developed by WHO, serologic confirmation required paired sera (showing seroconversion from negative to positive, or a fourfold titer increase), along with clinical criteria

568

(i.e., a spasmodic cough for more than 21 days).[1359] Trollfors et al. performed pertussis serology on a group of unvaccinated Swedish children with clinical (i.e., cough ≥21 days and cough <21 days) and nonserologic evidence of *B. pertussis* infection (i.e., positive culture, PCR).[1265] Among those with cough for ≥21 days, levels of anti-PT and anti-FHA increased 400-fold and 68-fold, respectively. More than 90% of the children had significant titer increases to both antigens if the acute specimen was obtained within 14 days of disease onset. Serology may not be useful with very young acutely ill patients, as some culture-positive individuals, particularly infants less than 3 months of age, do not develop measurable antibodies.[248] The highest sensitivity and specificity for the serologic diagnosis of pertussis are the

demonstration of at least a twofold rise in titer against PT between an acute and a convalescent specimen.[856] In vaccinated children, the secondary immune response results in rapid increases in antibody titer; so a significant titer changes between sequential specimens may not be seen. Serologic testing on older, vaccinated populations may be diagnostically useful since a high titer from the secondary immune response in a single serum specimen may indicate a current infection.[856] This approach may be useful for diagnosing pertussis in adolescents and adults, since pertussis often is not included in the initial differential diagnosis of nonpediatric respiratory infections; consequently, attempts at culture or PCR are made late in the clinical course when these two assays may be negative.[248]

Treatment of Pertussis

Pertussis in children is generally treated with erythromycin (estolate form, 40 to 50 mg/kg/day) in four divided doses for 14 days to prevent relapse. For adults and adolescents, 2 g/day is administered for 14 days. Shorter courses (e.g., 7 to 10 days) may not eliminate the organism from the upper respiratory tract. Administration of antimicrobial therapy even during the paroxysmal stage shortens the severity and the duration of illness. Strains of *B. pertussis* are susceptible to erythromycin in vitro, having MICs ranging from 0.02 µg/mL to 0.12 µg/mL. Erythromycin resistance in *B. pertussis* was not seen until 1995, when the first case of pertussis caused by an erythromycin-resistant *B. pertussis* strain was reported in a 2-month-old child in Yuma, Arizona.[785] After the child failed to improve clinically on a 12-day course of erythromycin, disk testing of the isolate showed no zones of inhibition around the erythromycin, clarithromycin, and clindamycin disks. Agar dilution testing revealed an erythromycin MIC of >64 µg/mL. Erythromycin-resistant strains of *B. pertussis* remain relatively uncommon, but their prevalence may be underestimated. In a survey of 47 isolates from children collected in the intermountain west region of the United States from January 1985 through June 1997, only one strain was erythromycin-resistant (MIC = 32 µg/mL) on agar dilution testing.[725] Screening of 1,030 *B. pertussis* isolates at the CDC using a disk diffusion method revealed 5 strains that displayed a heterogenous resistance phenotype in which isolated colonies grew within the zones of inhibition around an erythromycin disk after 5 to 7 days' incubation.[1352] When these colonies were subcultured and retested, only the resistant phenotype grew, and erythromycin susceptibilities of these isolates were shown to be >256 µg/mL by Etest. Retesting of isolates demonstrating heterogenous susceptibility to erythromycin consistently produced resistant colonies after 5 to 7 days that were not apparent after incubation for 3 to 5 days. Erythromycin resistance in these strains is apparently due to a mutation that alters the erythromycin binding site in the 23S rRNA gene.[92] Other drugs have been used in open noncomparative studies and successfully eliminate the

organism from the respiratory tract. Azithromycin for 3 to 5 days or clarithromycin for 7 days is able to eliminate *B. pertussis* from the nasopharynx and does not have the attendant gastrointestinal side effects of erythromycin.[28] TMP-SMX administered for 7 days is able to eradicate *B. pertussis* from the nasopharynx and has been used to successfully treat patients with erythromycin-resistant isolates. While TMP-SMX may be a useful alternative to erythromycin, the dosage and duration of therapy have not been ascertained. Fluoroquinolones also have generally good activity against *B. pertussis*, but clinical trials have not been performed since fluoroquinolone use is contraindicated in children. These agents may be useful for treatment of adults with pertussis infection.[504]

Antimicrobial Susceptibility Testing of Bordetella *Species*

Although CLSI-approved, standardized procedures are not available, several methods have been evaluated for in vitro antimicrobial susceptibility testing of *Bordetella* species. Agar dilution susceptibility testing has been performed with a number of media, including Müeller–Hinton agar with 5% horse blood, BG agar with 5% or 20% horse blood, and RL agar without cephalexin.[587,605] Hoppe and Paulus evaluated BG agar with 5% horse blood, Oxoid charcoal agar with 5% horse blood, and Müeller–Hinton agar with 5% horse blood for in vitro agar dilution testing. They found that Müeller–Hinton with horse blood provided the most consistent results.[605] MICs determined on charcoal-containing media were one- to fivefold higher for clinical isolates, control strains, and *S. aureus* ATCC 29213, due to inactivation of some antimicrobial agents by charcoal. Using the agar dilution method, *B. pertussis* was susceptible to β-lactams (i.e., ampicillin/amoxicillin), macrolides (i.e., azithromycin, clarithromycin, erythromycin, roxithromycin), sulfonamides (i.e., SXT), rifampin, and fluoroquinolones (i.e., ciprofloxacin, ofloxacin, temafloxacin, trovafloxacin).[604,606,725] Among the fluoroquinolones, levofloxacin was more active against *B. pertussis* (MIC= 1 μg/mL) than against *B. parapertussis* strains (MICs >2 μg/mL).[606] Most *B. pertussis* strains were resistant to tetracycline. Hill et al. tested a disk diffusion procedure using RL agar with a standardized inoculum (0.5 McFarland standard) and found that this method accurately detected erythromycin resistance. Resistant strains (MIC >256 μg/mL) produced no zones around the standard erythromycin disk, while susceptible strains (MIC ≤0.06 μg/mL) produced zones of at least 42 mm.[587]

Etest strips (bioMérieux, Inc.) and modified disk diffusion methods have also been evaluated for antimicrobial susceptibility testing of *B. pertussis*. Korgenski and Daly found essential agreement between agar dilution MICs and Etest MICs for 89.1% of 46 isolates (i.e., the Etest MIC was within

+/− 1 doubling dilution of the agar dilution MIC, while the remaining 10.9% had Etest MICs that were more than 1 doubling dilution different than the agar dilution MIC).[725] Hill and colleagues also evaluated the Etest using both BG agar with 20% horse blood and RL agar and found that the Etest method produced similar results to those of their "reference" agar dilution procedure (using BG agar with 20% horse blood) for erythromycin, rifampin, and chloramphenicol; SXT MICs using Etest were lower than those obtained with agar dilution.[587] Etest was employed in a erythromycin susceptibility survey of 99 *B. pertussis* isolates collected from 1971 through 2006 in Australia.[1190] All *B. pertussis* isolates were susceptible to erythromycin, with MICs of <0.12 μg/mL. Galanakis and Englund used Etest and Müeller–Hinton agar with 5% sheep blood to test 100 *B. pertussis* isolates from a regional laboratory in Washington state for susceptibility to macrolides (erythromycin, azithromycin), β-lactams (amoxicillin, meropenem), fluoroquinolones (ciprofloxacin, moxifloxacin), clindamycin, SXT, and tigecycline.[467] All isolates were susceptible to all agents. Elevated MICs were seen for clindamycin (3 strains) and amoxicillin (1 strain); MICs for azithromycin were slightly lower than those for erythromycin. All other agents, including tigecycline, were very active against all strains tested. A study of 27 *B. pertussis* isolates in Taiwan also found that all strains were susceptible to macrolides and SXT using Etest with Müeller–Hinton agar with 5% horse blood.[1397]Using Etest with Müeller–Hinton agar containing 5% sheep blood, Gordon and colleagues in Iowa tested 45 *B. pertussis* isolates and found that all isolates were susceptible to all agents tested, including macrolides (i.e., erythromycin, azithromycin, clarithromycin), clindamycin, fluoroquinolones (ciprofloxacin, gatifloxacin, and trovafloxacin), and SXT.[504] Similar results were reported by Fry and colleagues using Etest and Müeller–Hinton agar with 5% horse blood for testing of 583 *B. pertussis* isolates collected from 2001 through 2009.[460] Standardization of susceptibility testing for these organisms is needed for investigation of new antimicrobial agents against the bordetellae, and it may gain additional clinical relevance if erythromycin resistance becomes more widespread.

The other *Bordetella* species tend to be more resistant to antimicrobial agents than *B. pertussis*. As a part of the Multicenter Pertussis Surveillance Project, agar dilution antimicrobial susceptibility data were collected on 46 *B. parapertussis* and 11 *B. bronchiseptica* isolates.[741] Although the *B. parapertussis* strains were susceptible to erythromycin, SXT, and ciprofloxacin, most were resistant to amoxicillin and all were resistant to rifampin and tetracycline. Levofloxacin, ciprofloxacin, and cefpirome, a broad-spectrum cephalosporin, were more active against *B. pertussis* than against *B. parapertussis*.[606] Among the macrolides, both erythromycin and azithromycin are active against *B. parapertussis*, with 90% of strains having MICs for erythromycin and azithromycin of 0.5 μg/mL and ≤0.06 μg/mL, respectively.[604] In the multicenter surveillance project, 82% of *B. bronchiseptica* isolates were susceptible to SXT, 27%

were susceptible to ciprofloxacin, and all *B. bronchiseptica* strains were resistant to amoxicillin, erythromycin, rifampin, and tetracycline.[741] *B. hinzii* isolates are resistant to ampicillin, ampicillin sulbactam, cefazolin, ceftriaxone, cefotaxime, cefuroxime, cefotetan, aztreonam, ciprofloxacin, and tobramycin, and are susceptible to cephalothin, ceftazidime, cefepime, imipenem, tetracycline, SXT, levofloxacin, gentamicin, and amikacin.[462,686] Isolates of *B. holmesii* are susceptible to amoxicillin, amoxicillin clavulanate, cephalosporins (i.e., cefazolin, cefotaxime, ceftazidime), aminoglycosides (gentamicin, tobramycin, amikacin), imipenem, tetracycline, erythromycin, rifampin, ciprofloxacin, and SXT, but are resistant to penicillin.[792,948,1245]

Introduction

During the summer of 1976, an explosive outbreak of pneumonia of unknown etiology occurred among persons who attended an American Legion convention in Philadelphia.[66] Individuals in whom the multisystem illness (which included pneumonia) developed were said to have Legionnaires' disease.[24] A total of 182 infected patients were documented, of whom 29 died. By early January 1977, the etiologic agent had been isolated by Dr. Joseph McDade of the Centers for Disease Control (CDC).[110] Thus, within 6 months, a major medical mystery was solved and a new family of bacteria, the *Legionellaceae,* was discovered. The history of *Legionella* and Legionnaires' disease has been thoroughly reviewed.[61,113,149,171] Information is also available through the CDC (http://www.cdc.gov/legionella/index.html) and other web sites.[11]

Taxonomy and Characteristics of the Genus *Legionella*

In 1979, Brenner, Steigerwalt, and McDade classified the bacterium that caused the Philadelphia outbreak of Legionnaires' disease as *Legionella pneumophila,* in the family *Legionellaceae.*[21] At present, 50 validly published species and subspecies and a total of 71 serologic types of *Legionella* have been isolated from either human specimens, environmental sources, or both (Table 10-1).[81,173] Several recently described species are obligate intracellular parasites of free-living amoebae and can be isolated only by cocultivation with amoebae.[2,37] These amoeba pathogens were initially recognized by Rowbotham,[134] who called them *Legionella*-like amoeba pathogens (LLAPs). The most frequent of these species appears to be *L. lytica* (formerly called *Sarcobium lyticum*).

Legionella species are non–spore-forming, narrow, gram-negative bacilli, 0.3 to 0.9 µm in width. In length the bacteria vary from short forms, 1.5 to 2 µm in length, to longer filamentous forms. They are usually short and thin or coccobacillary when seen in direct smears of clinical specimens, but are more variable in length after growth in suboptimal culture media, when forms longer than 20 µm are not unusual. Legionellae stain much more readily with the Diff-Quik, Giemsa, or Gram–Weigert stains than they do with the traditional Gram's stain in touch preparations of fresh tissue imprints, smears of bronchial alveolar lavage (BAL) fluid, or sputum. The addition of 0.05% basic fuchsin to the safranin counterstain in the Gram's procedure, however, yields

TABLE 10-1 Species of the Genus *Legionella* (Number of Serogroups)

Species Isolated From Humans and From the Environment	Species Isolated From the Environment Only
L. anisa	*L. adelaidensis*
L. bozemanii (2)	*L. beliardensis*
L. birminghamensis	*L. brunensis*
L. cincinnatiensis	*L. busanensis*

L. wadsworthii	*L. taurinensis*
	L. waltersii[a]
	L. worsleiensis

[a] The pathogenicity of this organism for humans is unclear.

far better staining of *Legionella* spp., as well as many other poorly staining gram-negative bacilli.

Except for three species that are nonmotile, *L. oakridgensis*, *L. nautarum,* and *L. londinensis*, the remainder of *Legionella* species are motile by means of one or more polar or subpolar flagella.[173] The *Legionellaceae* are aerobic and nutritionally fastidious. They require L-cysteine and iron salts for growth. R.E. Weaver first cultivated *L. pneumophila* on Müeller–Hinton agar supplemented with 1% IsoVitalex and 1% hemoglobin. Isolates may grow very slowly on the chocolate agar used for gonococcus isolation as well.[38] The optimal growth medium is a variation on the charcoal yeast extract agar developed by the late James Feeley.[58] The yeast extract in the medium supplies the necessary nutrients. Activated charcoal removes toxic oxygen radicals produced by exposure of many media to light.[80] *N*-(2-acetamido)-2-aminoethanesulfonic acid (ACES) buffer has a pK of 6.9, the optimum for growth of *Legionella* spp. Addition of ACES buffer and α-ketoglutarate yields buffered charcoal yeast extract (BCYE) agar.[41]

Growth on BCYE agar with no growth on blood agar is one of the most useful presumptive clues that an isolate could be a species of *Legionella.* Another gram-negative organism that also grows on BCYE but not on ordinary blood agar is *Francisella tularensis.* In contrast to *Francisella* spp., which produce acid from carbohydrates, *Legionella* spp. neither ferment nor oxidize carbohydrates. Certain thermophilic spore-forming bacilli and *Bordetella pertussis* are also capable of growing on BCYE agar; differences in morphology, serologic features, and cellular fatty acids aid in differentiating these organisms. *Legionella* spp. produce characteristic branched-chain fatty acids in their cell walls.[173] Most species are weakly catalase positive and peroxidase positive. The sodium hippurate hydrolysis test, which is positive for *L. pneumophila* and negative for the majority of other *Legionella* species isolated from clinical materials, provides a useful presumptive procedure for differentiation between *L. pneumophila* and the other *Legionella* species. Phenotypic characterization of *Legionella* isolates using biochemical tests is of only limited value for presumptive identification of isolates to the species level. Serotyping of isolates using immunofluorescent antibody (IFA) testing, however, is a practical way to differentiate isolates presumptively as species of *Legionella.* Definitive identification of *Legionella* species may require nucleic acid studies and other chemotaxonomic reference procedures.[49,147]

Clinical and Pathologic Spectrum of Legionellosis

Legionnaires' disease occurs both sporadically, in the form of community-acquired pneumonia, and in epidemics.[23,57,56] In addition to Legionnaires' disease, a mild form of illness called Pontiac fever occurs.[72] Illness may also involve anatomic regions of

the body outside the chest cavity. Thus, the term *legionellosis,* including Legionnaires' disease, Pontiac fever, and extrapulmonary involvement with *Legionella* species, is used in this chapter to refer to any infection caused by bacteria of the family *Legionellaceae.* Approximately 85% of documented patients with legionellosis have *L. pneumophila* as the causative factor. Serogroups 1 and 6 of *L. pneumophila* account for up to 75% of the legionellae reported to cause human illness.[127] In addition to *L. pneumophila,* many other species have been isolated from clinical specimens collected from humans (Table 10-1). An international survey of patients with culture-confirmed infections disclosed that the most frequent non-*pneumophila* species were *L. longbeachae* and *L. bozemanii.*[174] *L. micdadei*[92,36] and *L. dumoffii*[156,85] have also been responsible for sporadic and epidemic disease in certain locales. Multiple species and/or serogroups may be present in water systems, either environmental or potable, and the same patient may be infected with more than one serogroup or species simultaneously.[101]

598

TABLE 10-2 Clinical Manifestations in Two Types of Legionellosis

	Legionnaires' Disease	**Pontiac Fever**
Mortality	15%–30%	0%
Incubation period	2–10 days	1–2 days
Symptoms	Fever, chills, cough, myalgia, headache, chest pain, sputum, and diarrhea. Confusion or other mental status changes have occurred in some patients.	Similar to influenza: fever, chills, and myalgia. Cough, chest pain, and confusion have been reported in some patients.
Lung	Pneumonia and pleural effusion. Occasionally, pneumonic disease will progress to a lung abscess.	Pleuritic pain; no pneumonia, no lung abscess
Kidney	Renal failure (proteinuria, azotemia, and hematuria in some)	No renal manifestations
Liver	Modest liver-function abnormalities	No liver-function abnormalities
Gastrointestinal tract	Watery diarrhea, abdominal pain, and nausea and vomiting	No abnormalities

Central nervous system	Somnolence, delirium, disorientation, confusion, and obtundation. Rarely, seizure has been documented.	No central nervous system manifestations

Legionellosis has most commonly been recognized as a form of pneumonia. The earliest symptoms typically include fatigue, muscle aches, and a slight headache. During the first day, patients commonly experience a rapid onset of dry cough and elevated temperature (i.e., 102°F to 104°F or higher) with chills. Abdominal pain and gastrointestinal symptoms (i.e., nausea, vomiting, and diarrhea) occur in many patients. A summary of clinical manifestations is given in Table 10-2. Investigators have repeatedly demonstrated their inability to distinguish among the various etiologies of pneumonia based on clinical history, physical examination, or traditional laboratory tests.[131] However, the introduction of the *Legionella* urinary antigen test and nucleic acid amplification assays has improved our ability to definitively diagnose patients with legionellosis.

At onset, chest roentgenograms typically show patchy infiltrates, which may progress to five-lobe consolidation.[152,54,112] Figure 10-1 illustrates a chest roentgenogram of a patient with legionellosis. Infiltrates are bilateral in two-thirds of patients, and abscess cavities may be present, particularly in immunocompromised patients. Laboratory findings commonly include, in varying combinations, the following: a moderate leukocytosis with a left shift, proteinuria, hyponatremia, azotemia, elevated serum aspartate aminotransferase (AST), and a high erythrocyte sedimentation rate. As mentioned previously, legionellosis may also take the form of a mild, self-limited illness of short duration, known as Pontiac fever. This disease presents with elevated temperature, myalgia, malaise, and headache, but with few or no respiratory findings and no pneumonia.[59,63] Table 10-2 provides a comparison of the clinical aspects of Legionnaires' disease and Pontiac fever. Both pneumonic disease and nonpneumonic disease may result from exposure to the same environmental source.[71]

The clinical spectrum of legionellosis has expanded from that which was originally defined. The illness may involve essentially any organ system of the body, with or without pneumonia. Examples of selected manifestations of extrapulmonary involvement follow. Bacteremia has been reported, but data on its frequency are lacking.[43,98,130] Nearly half the patients with Legionnaires' disease show central nervous system manifestations such as headache, lethargy, confusion, stupor, and other less frequent manifestations, including ataxia, coma, and seizures.[84] A painful, nonpruritic, macular rash, limited to the pretibial surfaces of the legs, has been reported; however, dermal manifestations are uncommon.[78] *L. pneumophila*

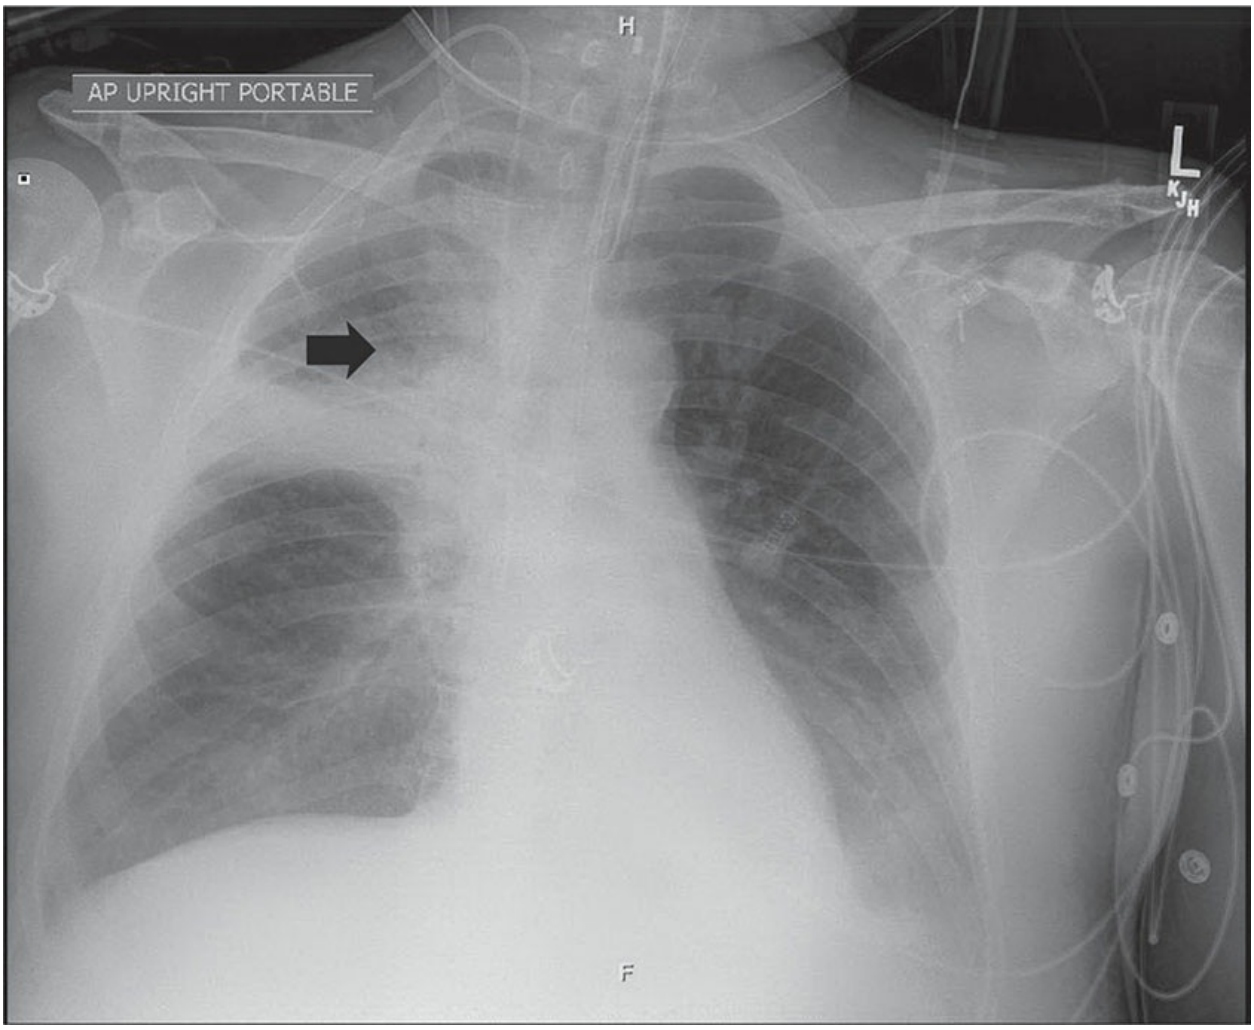
serogroup 1 has been demonstrated in lymph nodes, spleen, kidney, and bone marrow and has been documented in acute myocarditis,[166,172] prosthetic valve endocarditis,[109] pericarditis,[108] and hemodialysis fistula infections.[89] Arnow and associates[7] reported the isolation of *L. pneumophila* serogroup 3, mixed with multiple species of anaerobic bacteria, from a perirectal abscess. *L. pneumophila* serogroup 4 was shown by direct immunofluorescence in lesions of acute pyelonephritis in a patient who had both pneumonia and pyelonephritis associated with this organism.[35] Cutaneous legionellosis, caused by *L. pneumophila* serogroup 8, has been described in a 27-year-old woman who was immunosuppressed secondary to an allogeneic stem cell transplant.[122] In general, however, reports of extrapulmonary manifestations have been more commonly associated with *L. pneumophila* than with other species. For example, *L. micdadei* was the only organism isolated from a cutaneous leg abscess of a 62-year-old woman who had been receiving prednisone and cyclophosphamide for rapidly progressive glomerulonephritis.[4] This organism has also been described as causing a neck mass in a 9-year-old girl.[124] There are a number of excellent reviews of the manifestations of illness produced by *Legionella* species other than *L. pneumophila*, for those interested in further reading.[56,57,112–114]

The high seroprevalence of antibody to legionellae in some populations suggests that asymptomatic or subclinical infection may be common. This assumption is bolstered by the documentation of unrecognized infection (defined by seroconversion) that occurred in a group of patients who had undergone renal transplantation.

Predisposing Factors

Three factors are required or enhance the likelihood of symptomatic infection:

1. The presence of virulent legionellae in an environmental source.



■ **FIGURE 10-1** This chest roentgenogram was from a patient with legionellosis. It was interpreted as having a right upper lobe infiltrate *(arrow)*, as well as a small left-sided pleural effusion.

2. An efficient mechanism for dissemination of bacteria from the environment to human subjects.
3. Diminution of host defense mechanisms that are effective against this organism.

Persons who have Legionnaires' disease are usually middle-aged or older (mean age, about 55 years); however, the disease can occur in persons of any age, including children.

Legionellosis must be included in the differential diagnosis of immunosuppressed patients in whom fever and pulmonary infiltrates develop. It should be considered in patients in whom pneumonia is not responsive to penicillins, cephalosporins, or aminoglycosides; or in any patient with severe pneumonia, especially when there is no other readily apparent alternative diagnosis. In individuals receiving hemodialysis,

recipients of organ transplants, and other surgical patients, for example, Legionnaires' disease has been a major cause of morbidity and mortality.[123,96]

Other potential predisposing conditions include diabetes mellitus, alcoholism, chronic obstructive pulmonary disease, and cardiovascular disease. Cigarette smoking was suggested as a predisposing factor in the Philadelphia outbreak and in some subsequent outbreaks. A prerequisite is exposure to concentrated virulent *Legionella* organisms in the environment. Thus, legionellosis has occurred with higher frequencies among travelers to a site with an ongoing hyperendemic, which often is unrecognized.[12] Infections have also occurred on cruise ships, usually associated with the use of whirlpools or hot tubs.[83]

As a result of the prerequisites outlined above, sites where elderly or debilitated individuals congregate are most likely to be problem areas. Certainly healthcare facilities have been a major problem, partially thanks to the unwitting

collaboration of engineers who place cooling towers upwind from intake vents for fresh air.[34]

Pathology and Pathogenesis

Pathologic features of human infection with several species of *Legionella* other than *L. pneumophila* are similar to those found in *L. pneumophila* infections. A multifocal lobular pneumonia often becomes confluent and may assume a lobar appearance. Small abscesses are common; less frequently, large abscesses that can be visualized radiographically occur.

Histologically, neutrophils, macrophages, and large amounts of fibrin fill airspaces, and septic vasculitis of small blood vessels has been observed. Pulmonary fibrosis and decreased pulmonary function may occur as a long-term sequela.[27] Legionellae do not stain well with hematoxylin and eosin (H&E) in formalin-fixed paraffin sections but may be visualized if large numbers are present. A silver impregnation method, such as the Dieterle, Steiner, or Warthin–Starry method will stain the organisms reliably.[159] Silver impregnation techniques are nonspecific and stain virtually all microorganisms present in addition to *Legionella.* The Brown–Hopps tissue Gram's stain will also demonstrate the bacteria, but careful attention to detail and appropriate controls are essential.

Whenever possible, fresh imprints of lung biopsy material should be prepared, because visualization and analysis of all bacteria are easier in smears than in histologic sections. Legionellae can be demonstrated with Giemsa, Gram–Weigert, and Gram's procedures, especially if 0.05% basic fuchsin is added to the traditional safranin

counterstain in Gram's procedure (Image Plate 10-1) The organisms are facultative intracellular pathogens and may be found within macrophages and neutrophils or extracellularly.

A distinctive characteristic of *L. micdadei* is the presence of acid-fastness in clinical material, a property that is lost after cultivation on agar. Modified decolorization (i.e., a Fite stain), as used for *Nocardia* spp. may be necessary. Instances have been recorded in which *L. pneumophila* was isolated from a specimen in which acid-fast bacilli had been demonstrated.[13] It is difficult, however, to be certain that a co-infection with *L. micdadei* was not present, as this species is more difficult to isolate than is *L. pneumophila.*

Considerable progress has been made toward an understanding of the pathogenesis of legionellosis.[67,151,52,60,82] The bacteria are facultative intracellular pathogens and replicate predominantly within cells of the monocyte/macrophage system, including prominently pulmonary alveolar macrophages. In the natural environment, a variety of free-living amoebae support the growth of legionellae. These organisms are often phagocytized by polymorphonuclear neutrophils, but they do not appear to replicate in these cells. Within macrophages, legionellae inhibit phagolysosomal fusion and acidification of the phagosome; they continue multiplying until the host cell ruptures, releasing the organisms, which can then infect other phagocytic cells. The detailed pathogenesis is a subject of intensive ongoing investigation. Cell-mediated immunity rather than humoral immunity appears to play the central role in the host defense against legionellae.

Epidemiologic and Ecologic Aspects of Legionellosis

Legionella species are widespread in both natural and man-made environments. Legionnaires' disease and Pontiac fever may be contracted by exposure to a wide variety of environmental sources, but there is no convincing evidence of a carrier state in humans, or of person-to-person transmission. Thus, there is no evidence that patients who have or have had Legionnaires' disease are "contagious." Furthermore, *Legionella* spp., once isolated in the laboratory, have not proven to be any more hazardous to laboratory personnel than bacteria routinely isolated in the clinical microbiology laboratory. Inhalation of aerosolized organisms from environmental sources or possibly the aspiration of organisms present in water or in oropharyngeal contents are the most likely routes of spread. An early review by Broome remains relevant.[23]

Incidence

Legionellosis has been documented in countries around the world, but the morbidity and mortality associated with both the epidemic and sporadic cases of legionellosis are underreported in public health statistics. Most countries lack a disease-oriented surveillance system for tracking the disease. Additionally, clinicians and microbiology laboratories may overlook the infection because of lack of awareness on the part of clinicians and/or failure of laboratories to use proper diagnostic methods.[73]

In general, it has been estimated that less than 5% to 12% of cases of pneumonia are caused by *Legionella* species, a number which has increased with the introduction of improved diagnostic techniques.[39] In outbreaks of Legionnaires' disease (as opposed to Pontiac fever), attack rates for the exposed high-risk population are usually low, but have been reported to be as high as 30%.[6] In one review, *Legionella* species (6.7% of etiologic agents) ranked as the third most common etiologic agents (following *Streptococcus pneumoniae,* 15.3%, and *Haemophilus influenzae,* 10.9%) for community-acquired pneumonia among 359 patients admitted to university, community, and Veterans Affairs hospitals examined in a US multicenter study.[56] In other countries, the frequency of sporadic cases of community-acquired pneumonias caused by *Legionella* species varied from 2% in the United Kingdom to 3% to 4% in Germany and 10% in France.[135] The incidence of Pontiac fever in the general population is not known. Outside an outbreak setting, sporadic cases of Pontiac fever are probably almost always unrecognized. In any event, the definition of Pontiac fever is partially epidemiologic; differentiation of sporadic nonpneumonic cases of "Legionnaires' disease" and Pontiac fever is impossible clinically. Patients with pneumonic and nonpneumonic disease (i.e., Pontiac fever) have been reported from the same exposure to environmental bacteria, presumably reflecting differences in host defenses and/or number of bacteria inhaled.

When evaluating studies of incidence, it is important to recognize the inherent bias introduced by the methods chosen by the investigators, by the feasibility of diagnosing some causes of pneumonia, and probably also by the inherent interests of those collecting the data. In a comprehensive study of pneumonia acquired in the outpatient setting, *Legionella* spp.

601

were far down the list of etiologic agents.[17] In all studies, the most common etiologic agent has been "unknown."

Legionellaceae *in the Environment*

As mentioned earlier, species of the genus *Legionella* are present in diverse natural

and man-made habitats. Numerous studies have been focused on the ecology of *Legionella* species in man-made habitats, such as cooling towers that use evaporation of water and potable (drinking) water systems within buildings. Man-made habitats probably serve as "amplifiers" or disseminators of legionellae that originated in natural environments.

Natural Habitats. *Legionella* spp. have been found in natural waters from around the world, including ground water.[129] They are widespread in lakes, ponds, streams, and both cold and warm springs. They have been isolated from aquatic habitats with temperatures ranging from 5.7°C to 63°C[64] and in hot spring water used for hydrotherapy.[18] There appear to be higher concentrations of *Legionella* species in warmer waters (30°C to 45°C) than in water at cooler temperatures.[162] In Puerto Rico, legionellae were recovered from marine waters and from epiphytes in trees.[121]

Although soil (e.g., wind-blown dust from an excavation site) was implicated epidemiologically (but not studied microbiologically) as a source of *Legionella* in one of the early outbreaks of Legionnaires' disease, there have been few reports of attempts to isolate *Legionella* spp. from soil. *L. pneumophila* and *L. bozemanii* were isolated from samples of wet soil soon after recognition of the organism.[111] Steele et al.[146] isolated *L. pneumophila, L. longbeachae* serogroup 1, and *L. micdadei* from potting soils in Australia. *L. longbeachae* serogroup 1 was also isolated from natural soil and from pine sawdust. Epidemiologic and microbiologic studies from South Australia in association with an outbreak of legionellosis due to *L. longbeachae* serogroup 1 suggested that soil, and not water, could be the natural habitat of *L. longbeachae* serogroup 1 and that soil could be the source of this organism in human disease. In this study, gardening in soil, rather than exposure to water contaminated with *L. longbeachae,* appeared to be the major environmental risk factor associated with legionellosis.[145] Much more work on the ecology of *Legionella* spp. in natural aquatic and terrestrial habitats is needed.

Aquatic Habitats Made by Humans (Artificial). There have been numerous reports that associated the presence of *L. pneumophila* in institutional potable hot water with the occurrence of legionellosis. Legionellae appear to survive the usual chlorination procedures of municipal water treatment facilities, and thus, not unexpectedly, may be present in potable water supplied to homes, apartment buildings, hotels, hospitals, and other buildings.[3,150] Potable hot water, especially if it does not exceed 55°C, has contained high concentrations of *Legionella* in some instances. In addition to water temperature, the construction of the plumbing system also seems to play an important role; for example, the presence of certain kinds of resins in gaskets; the presence of dead ends or cul-de-sacs, where there is stasis, obstruction, or stagnation in water

flow; and the presence of biofilms or slime layers on the surface of pipes containing other commensal bacteria, protozoa, and algae may favor the presence of legionellae.[99,144] Many of these studies were performed before the importance of environmental protozoa was realized, and it is not clear whether some of the associations may have been fortuitous rather than causal. Some of the factors associated with enhanced replication of the bacteria in homes have been defined,[30] but addressing the problem at the residential level will be all but impossible. It is worth noting that apparently nosocomially acquired infection may, in actuality, have been acquired in the patient's home.[138]

In modern society, the mechanisms by which bacteria in water may be aerosolized and transmitted to unwitting respiratory tracts are legion. In 1990, the CDC reported an outbreak of community-acquired Legionnaires' disease involving 33 persons that was associated with a grocery store mist machine.[103] The mist machine continuously generated a tap water aerosol (presumably containing *L. pneumophila*) in respirable (2 to 5 μm) droplets over the produce display. The system used ultrasonic transducers located in the humidifier's tap water reservoir to create the mist.

Other public sources of infection have included ornamental fountains.[79] Whirlpool spas have been implicated frequently as the source of the organism for patients with legionellosis.[55,74] Dramatically, a large outbreak at a flower show in the Netherlands was traced to whirlpool spas used in the exhibits.[32] An isolate of *L. pneumophila* was also recovered from a sprinkler used in the exhibits, but the genotype of this strain was different from that of the two whirlpool spas and the infected patients. Such experiences emphasize the importance of bacterial culture and molecular analysis of clinical and environmental strains during the investigation of an epidemic.

Although legionellae have been isolated from shower heads and shower water on repeated occasions, the epidemiologic evidence that bathing or showering in such water leads to legionellosis has been rather weak.[65,114] Supportive evidence reported by Breiman and associates from an investigation of an outbreak of nosocomial Legionnaires' disease at a hospital in South Dakota strengthened the hypothesis that aerosolized shower water can serve as the vehicle for spread of *L. pneumophila* to patients.[20]Perhaps the most bizarre instance of water-associated Legionnaires' disease was a neonatal infection that was acquired during a home birthing in a domestic spa bath.[118]

Factors that promote the growth of legionellae in plumbing systems are poorly known in spite of a large accumulation of literature. Legionellae are fastidious organisms that require enriched media for growth in the laboratory, and it is unlikely that drinking water supplies all their nutritional requirements for growth and energy. Rowbotham was the first to report that *Legionella* species multiply in close association with free-living aquatic and soil amoebae of the genera *Acanthamoeba* and *Naegleria*

(see Chapter 22).[133] Others have confirmed and extended these observations, not only with *Acanthamoeba* and *Naegleria,* but also with other amoebae, such as *Hartmannella* and the ciliate *Tetrahymena.*[62,119,161] Thus, amoebae or ciliates phagocytize legionellae, as they do other bacteria in nature, and the legionellae then survive and multiply within nutritionally deficient habitats by living

parasitically within the protozoa. In addition, it has been suggested that the amoebae, which form cysts, might offer further protection to legionellae within the cysts against the effects of chlorine.[90,143] Scientists have taken advantage of this association to enhance recovery of legionellae from the environment, and one species, *L. lytica,* consists of strains that grow only intracellularly in amoebae.

Legionellosis in Travelers

Since the 1976 outbreak of Legionnaires' disease, which occurred among travelers to Philadelphia, travel-associated epidemics and sporadic instances of Legionnaires' disease have been recognized in many countries on all continents.[88,132] The true incidence of travel-associated disease is not clear. Infections are likely to be underreported not only because of underdiagnosis and lack of awareness of the epidemiologic significance, but also conceivably because of concerns about the effect of adverse publicity on tourism. Clusters and sporadic infections occur each year, associated especially with hotels and with hotel water systems contaminated with legionellae. Not surprisingly, the outbreaks may be recurrent and persistent until the nature of the problem is recognized and corrected. Clusters of infections have also been observed among travelers who have been on board cruise ships.

Sporadic disease and clusters of travel-associated *Legionella* infection should be reported to state and federal public health agencies and should lead to investigations of the source and magnitude of the outbreak to prevent further spread among the traveling public. As demonstrated first in the 1976 Philadelphia epidemic and confirmed repeatedly, it may only be the collection of multiple individual reports of disease by a central repository, such as a public health facility, that triggers the recognition of the problem.

Apparently sporadic disease that is not linked to travel may also be, in actuality, related to an unrecognized epidemic focus.[15] Bhopal has suggested approaches that may be useful for public health authorities to detect problems in their catchment areas.[14]

A recent twist to the theme of travel-associated infection has been the recognition that participants in holiday cruises are at risk of contracting this as well as other

infections.[26] As has been true for resorts on dry land, these infections have been traced to contaminated water systems, such as whirlpool spas.

Nosocomial Outbreaks of Legionellosis

Within hospitalized populations are patients who may be compromised and are very susceptible to infections in general. These patients are at risk of acquiring legionellosis should they be exposed to virulent organisms.

The usual source of *Legionella* in hospitalized patients is water[140] (mainly the hot water system), especially from showers or baths.[53] In addition, patients may be infected from cooling towers that are part of or adjacent to the healthcare complex.[1,70] Other documented sources have included nasogastric tubes (with microaspiration of legionellae in contaminated water), humidifiers, respiratory therapy equipment (e.g., masks and hand-held nebulizers washed with contaminated tap water), whirlpools, and other less common sources. Early diagnosis of legionellosis and epidemiologic surveillance of infections within the hospital are needed not only for prompt and effective therapy but to aid in instituting control measures to prevent subsequent infections. With the high mortality rate for nosocomial Legionnaires' disease (range, 30% to 50%), it would seem prudent that efforts be taken to prevent the spread of *Legionella* species from the hospital environment to patients who are likely to be most susceptible to infection.

Nosocomial Legionnaires' disease has also been specifically linked to the use of tap water to clean nebulizers used for delivery of medication and to other respiratory therapy equipment. In a report by Mastro et al.,[107] the use of tap water contaminated with *L. pneumophila* to wash medication nebulizers was a major factor that led to an outbreak of nosocomial Legionnaires' disease in patients with chronic obstructive pulmonary disease. In one particularly instructive cluster of infections, the disease was more common in patients who were both receiving corticosteroids and exposed to nebulizers or room humidifiers filled with tap water.[8]

Some instances of nosocomial Legionnaires' disease have been linked to microaspiration of water contaminated with *Legionella* species in patients with nasogastric tubes.[16,44,106,105] A different twist was documented at Stanford University Medical Center when wound infections caused by legionellae developed in postsurgical patients who had been bathed with tap water. The bacteria were clearly introduced directly into the wounds,[100] rather than into the respiratory tract with subsequent dissemination, a sequence of events that has also been documented.

Given all of these occurrences and the relative ease with which sterile water may be used in individuals at high risk, the continued use of tap water is difficult to justify or defend.[5]

Laboratory Diagnosis

The mainstay of diagnosis has traditionally been culture, which is absolutely specific and provides isolates for epidemiologic study and molecular typing. Detection of urinary antigen is a useful adjunctive technique, particularly in patients who do not produce adequate sputum for culture. It is highly sensitive, but urine specimens remain positive for an extended time following the resolution of disease. Detection of nucleic acids has not yet reached the stage of widespread commercial availability and practicality, but will probably be a major diagnostic resource in the future.[116] Traditionally, serologic diagnosis required seroconversion, which provided only retrospective information; it was particularly useful for investigation of epidemics. Advances in serologic testing afford the differentiation of *Legionella*-specific immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies, which is helpful in confirming the diagnosis of legionellosis. Although this does represent an advance, other tests, such as the *Legionella* urinary antigen, polymerase chain reaction (PCR), and culture, would be positive in acute disease prior to seroconversion. The limitations of select diagnostic tests have been reviewed.[164] The use of more recently introduced diagnostic tools, such as PCR and urinary antigen testing, has vastly improved the ability of the laboratorian

603

to meaningfully contribute to the diagnosis of legionellosis in particular and community-acquired pneumonia in general.[10,104]

Selection, Collection, and Transport of Clinical Specimens

The broad clinical spectrum and severe morbidity and mortality of Legionnaires' disease emphasize the need for rapid and accurate laboratory diagnosis. When legionellosis is suspected clinically, lower respiratory tract specimens should be collected for both culture and/or *Legionella* PCR. Although some still use direct fluorescent antibody (DFA) testing, this is inferior to PCR in both sensitivity and specificity. Appropriate specimens include expectorated sputum, materials collected using bronchoscopy (e.g., bronchial brush, biopsy, lavage, or washings), transtracheal aspirates, lung biopsies, fine-needle aspirates of lung, and pleural fluid. In most situations, it is appropriate to test specimens for *Legionella* spp. only upon specific request. It would be appropriate, however, to include legionellae in the spectrum of pathogens sought when culturing lung tissue, in those collected postmortem, if the cause of death remained undetermined. Such routine culture can serve as one part of the warning system that these water-associated pathogens are a problem in a particular

institution.

Primary isolation of *Legionella* species on solid media has been successful from closed- and open-lung biopsy material, pleural fluid, transtracheal aspirates, BAL samples, and sputum. A reasonably semi-effective selective medium is available for the primary isolation of *L. pneumophila* from sputum and contaminated bronchial materials.[40,42,167]

Specimens should be collected carefully to avoid aerosols and transported to the laboratory at ambient temperature in sterile, leak-proof containers, preferably within 2 hours after collection. Specimens to be sent to a reference laboratory should be refrigerated or packed on wet ice if a delay of less than 2 days is anticipated. Specimens that are to be stored for days or weeks should be maintained at 70°C or colder. These may be shipped on dry ice. Specimens that must be shipped to a reference laboratory should be packaged and mailed in accordance with federal regulations (see Chapter 1). If specimens are being submitted only for pathologic study and are to be fixed in buffered neutral formalin before shipment, they need not be refrigerated or frozen during transport. Specimens for PCR analysis should be handled in a manner similar to culture.

L. pneumophila has been isolated from blood cultures on a few occasions using conventional media supplemented with L-cysteine and ferric pyrophosphate, and in the distant past using BACTEC (Becton Dickinson Instrument Systems, Sparks, MD) radiometric aerobic and anaerobic media with no special supplements.[48] Blind subculture of the BACTEC aerobic and anaerobic bottles onto BCYE appears to be necessary for isolation of legionellae. As mentioned previously, legionellae may also be encountered, albeit rarely, in extrapulmonary sites. The practical value of seeking *Legionella* spp. in blood cultures or extrapulmonary sites on a routine basis is low. However, the ability to perform cultures from nonrespiratory sites should be retained in the event it is needed.

In addition to the above specimens, urine (preferably an early-morning sample) should be collected for detection of *Legionella* antigen and serum should be submitted for serologic studies. An acute-phase serum sample should be collected early as an adjunct to other tests that may enable a more rapid diagnosis. This should be tested for *Legionella*-specific IgM and IgG antibodies. The presence of *Legionella*-specific IgM with or without the presence of *Legionella*-specific IgG is supportive of acute disease. Antibodies may not be detectable very early in the course of disease, so a convalescent study should be performed if the cause of the infection was not determined. Serologic studies are particularly useful in patients who produce minimal sputum.[167] Unfortunately, the development of a diagnostic antibody titer can be slow and may occur in no more than 75% to 80% of patients who ultimately are shown to have Legionnaires' disease.[167] In addition, there are individuals who have seroconverted but have remained asymptomatic; these patients likely had a subclinical

infection.

Direct Examination of Clinical Specimens

Gross Examination. The gross examination of lung specimens may aid the pathologist in selecting the best areas for culture or histologic examination. Direct smears of exudates or touch preparations of fresh lung biopsy material should be prepared. Frozen sections of lung samples are also useful in diagnosis. Frozen sections and touch preparations should be placed in methanol for fixation if Gram's stain, H&E, Giemsa, Diff-Quik, or modified-Kinyoun acid-fast stains are desired. The Giemsa stain is useful for demonstrating legionellae and other bacteria in fresh touch preparations of lung or bronchoscopic materials. Gram's stain should also be performed, because of the differential information it provides.

Microscopic Examination. Various specimens (e.g., transtracheal aspirates, pleural fluids, aspirates from thoracic empyema, fine-needle aspirates of lung, and touch preparations of lungs) can be stained with Gram's stain. Methanol fixation is better than heat fixation, and the intensity of staining can be improved by increasing the time of safranin staining to 10 minutes or longer. Alternatively, 0.05% carbolfuchsin to the safranin improves the intensity of staining with the counterstain. The Gram–Weigert, Diff-Quik, or Giemsa stain may reveal more organisms than can be seen with routine Gram's staining. In formalin-fixed, paraffin-embedded histologic sections, *Legionella* organisms cannot be readily seen in the H&E, Gram, Brown–Brenn, Brown and Hopps, or MacCallum–Goodpasture stained preparations. The Gomori methenamine silver (GMS) stain and periodic acid–Schiff (PAS) stain are not useful for demonstrating legionellae. A modified acid-fast stain, as performed for *Nocardia* spp., is useful for demonstrating *L. micdadei*.[117] All of these stains may be done on either impression smears or tissue sections but are most satisfactory on thin smears. A very sensitive histochemical method for demonstrating bacteria of all types is one of the silver impregnation stains, developed originally for spirochetes. A modified Dieterle stain was originally used, wherein the organisms stain black to dark brown. Other silver impregnation techniques, such as

the Steiner and Warthin–Starry methods, will also work and stain the organisms similarly. These silver stains are usually performed on histologic sections. Although sensitive, the deposited silver grains in these stains obscure the bacterial morphology and, of course, the Gram reaction cannot be determined. The morphology of *L. pneumophila* is shown in Image Plate 10-1A, B, and D.

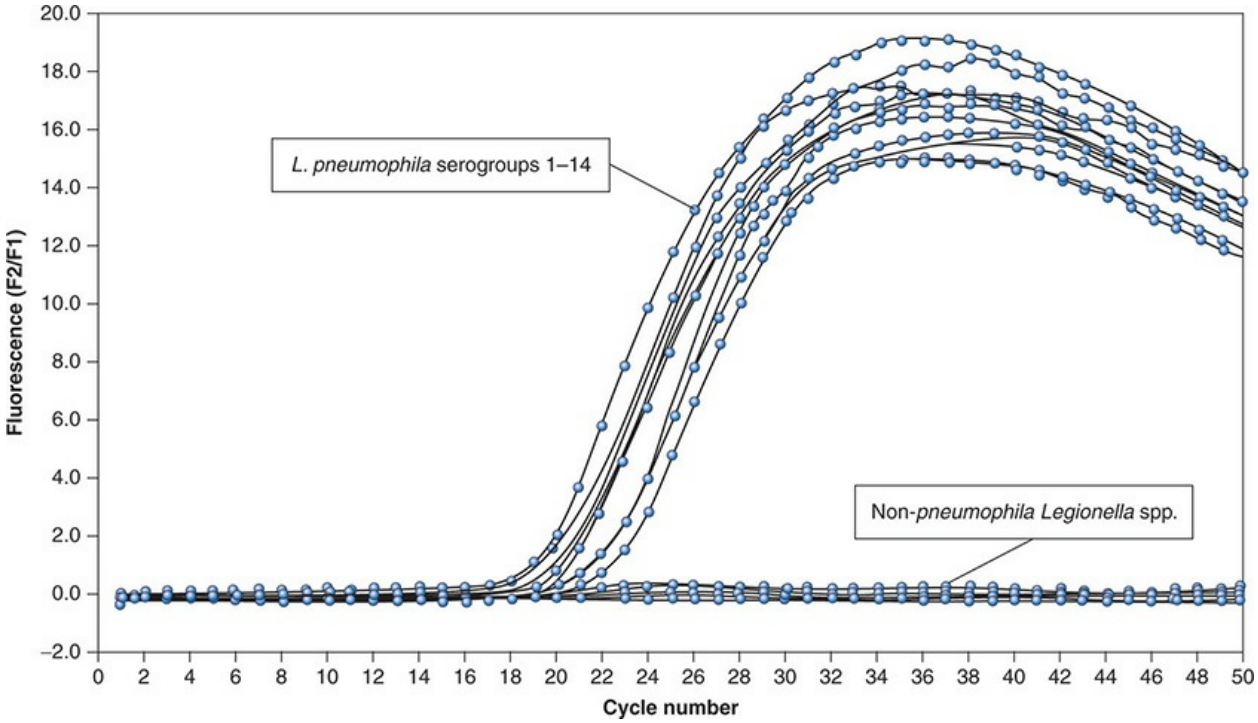
Legionella PCR and Other Molecular Methods

As with many other fastidious microorganisms, PCR or other nucleic acid amplification-based assays have proven more sensitive than culture for the detection of *Legionella.* Although there are some commercially available assays, many assays are laboratory developed tests.[76,125,128,158,165] Figure 10-2 demonstrates the amplification curves for an *L. pneumophila*-specific PCR. In addition, these assays are also available through high-quality reference laboratories.

Hayden et al.[76]studies archived BAL specimens from patients who were proven by culture to have legionellosis with both PCR and DFA. The sensitivity and specificity for PCR were each 100%, whereas for DFA these were 44% and 100%, respectively. We reviewed the 22,345 tests for *Legionella* performed at the Cleveland Clinic over a 4-year period. These included the results of an *L. pneumophila*-specific PCR, the *Legionella* urinary antigen test, and *Legionella* culture. There were 20 patients with laboratory-confirmed legionellosis during that time frame based on having at least two of these three tests positive. Of these, 50% (10/23) were positive by all tests, 45% were culture negative, but PCR and *Legionella* urinary antigen positive, and 5% (1/20) were positive only by PCR and culture.[28] In this setting, PCR was the most sensitive assay, followed closely by *Legionella* urinary antigen; culture disappointingly detected only 55% of the infected patients. There were no non-*pneumophila Legionella* species detected in this time frame.

Direct Fluorescent Antibody Testing. Direct immunofluorescence assays, originally developed by Cherry et al.[29] at the CDC, have been used for rapid detection of *Legionella* species in clinical specimens from the respiratory tract. Compared with culture and PCR, the DFA has a low sensitivity (25% to 70%).[173] The specificity has been high, but when there is a low prevalence of *Legionella* infection, false-positive results are unacceptably frequent. The DFA test for *L. pneumophila* has been positive in a few healthy individuals.[22] In addition to potential immunologic cross-reactions, contamination with environmental bacteria appears to have caused some false-positive results, even when scrupulous care is exercised when the test is performed. Use of immunofluorescence for diagnosis directly on patient specimens cannot, therefore, be recommended.

Immunofluorescence is a useful method, however, for identifying isolated bacteria. Several commercial suppliers market fluorescein isothiocyanate (FITC)-conjugated polyvalent antisera, as well as control sera and other reagents for *Legionella* DFA testing.[46] As a note of caution, some monoclonal DFA conjugates have failed to detect *L. pneumophila* in hot and cold storage tank water and in swab samples from showers and a water tap[160]; thus, these cannot be recommended for DFA studies of potable water or other samples



■ **FIGURE 10-2** This real-time PCR amplification curve for a *Legionella pneumophila*-specific PCR demonstrates that the 14 serotypes of *L. pneumophila* are detected, whereas non-*pneumophila Legionella* species are not detected in this assay.

from man-made water systems. PCR-based methods are superior for environmental testing.

In performing the DFA test, specific antibody in the form of FITC-labeled polyvalent antiserum (conjugate) directed against the antigen(s) to be detected is usually purchased commercially. The directions of the manufacturer of the kit should be followed. Antigen (present on or in *Legionella* organisms) is fixed on a slide, and then overlaid with FITC-labeled antibody. The antigen binds the FITC-labeled antibody, forming an antigen–antibody complex. This complex is not washed away when gently rinsed with buffer. When the antigen(s) of a *Legionella* species has reacted with FITC-conjugated antibody, exposure to ultraviolet light causes the FITC molecule to emit longer wavelengths of light in the yellow-green region of the color spectrum, and using a fluorescence microscope, the bacteria can be seen as brilliantly fluorescing yellow-green rods.

***Legionella* Antigen Detection.** Procedures for detecting *Legionella* antigens in urine, developed by Kohler and associates[95] at the Indiana University Medical Center, have included radioimmunoassay, enzyme-linked immunosorbent assay, and latex

agglutination. Commercially available immunoassays for detection of antigenuria caused by *L. pneumophila,* serogroup 1 have a very high specificity that approaches 100%. A number of high-quality assays are commercially available for the detection of antigen of *Legionella* in the urine. This test is very useful, especially for patients who do not produce adequate sputum for culture. It should be performed in conjunction with *Legionella* PCR and/or culture on all patients suspected to have legionellosis. The major limitations of the assay is that it is restricted to a single serogroup, albeit the most common human pathogen in the genus. Another potential limitation is the prolonged excretion of antigen in some patients, which may be up to 1 year. In particular, immunosuppressed patients with delayed resolution of fever are likely to excrete antigen for more than 60 days.[142] Detection of urinary antigen must, therefore, be carefully correlated with the clinical history and other laboratory and radiologic findings before ascribing the current infection to *Legionella.*[94] Occasional cross-reactions among serogroups of *L. pneumophila* have also been described.[93]

Detection of *Legionella* in Clinical Specimens

Isolation of Legionella *Species From Clinical Specimens*

Bacteriologic culture of *Legionella* is a method used in many laboratories to diagnose legionellosis.[176] Although culture is one and one-half to three times more sensitive than the DFA test, it is less sensitive than PCR-based methods and *Legionella* urinary antigen testing.

The cultivation of a *Legionella* species is usually of clinical significance, because these bacteria are not routinely isolated from the upper respiratory tract normal microbiota.

The recommended nonselective solid medium for isolation of legionellae is BCYE agar, which contains L-cysteine, ferric pyrophosphate, ACES buffer, α-ketoglutaric acid, and activated charcoal. The medium is available commercially from several manufacturers. In addition to BCYE, one should consider the use of one or more selective media to avoid overgrowth by normal microbiota. Antibiotics have been added to the BCYE base, resulting in reasonably effective selective media. One useful selective medium contains BCYE base supplemented with cefamandole, polymyxin B, and anisomycin; this is known as BMPA. Another option contains glycine, vancomycin, polymyxin B, and anisomycin; this medium is referred to as "modified Wadowsky–Yee" or MWY medium. The cefamandole in the former modification will inhibit *Legionella* species that do not produce β-lactamase, whereas the MWY medium is not as selective as BMPA. BCYE-based selective media are widely available commercially. Because the selective media may inhibit some legionellae, such

media should be used in conjunction with nonselective BCYE.

Tissue Specimens. To inoculate BCYE or BMPA media, the fresh lung tissue should be gently applied (i.e., dabbed) in the first quadrant and a sterile inoculating loop used to transfer this inoculum to the other quadrants for primary isolation. Alternatively, a sterile tissue grinder can be used to homogenize 1- to 2-mm pieces of minced tissue in 0.5 to 1 mL of a sterile broth, such as trypticase soy broth or enriched thioglycolate medium. After homogenization, the plating medium is inoculated with approximately 0.1 mL of the homogenate and streaked for isolation. In addition, slides for Gram's stain should be prepared from the same specimen.

Pleural Fluid and Transtracheal Aspirates. Pleural fluid and transtracheal aspirates are inoculated directly onto the selective and nonselective media as for tissue homogenates. The BCYE and BMPA plates are incubated in a 5% to 10% CO_2 incubator at 35°C and examined daily for 5 days; they may be examined further every 2 to 3 days for up to 2 weeks. Other media for lower respiratory tract specimens (e.g., sheep blood agar, chocolate agar, and MacConkey agar) are inoculated and incubated in the usual way. The same specimen used for culture is further processed by making smears for Gram's stain.

Acid-Wash Decontamination Procedure. The selective media currently available for primary isolation of legionellae are not completely selective, thus permitting breakthrough growth of other bacteria (e.g., *Bacillus* spp. or *Pseudomonas* spp.). In addition, growth of legionellae on BCYE may be inhibited by other bacteria in clinical specimens, even when antibiotics are incorporated into the selective media. The treatment of contaminated respiratory specimens such as sputum, bronchial washings, bronchial lavages, and tracheal aspirates with an acid-wash solution before inoculation of BCYE and BMPA plates has been reported to improve isolation of *Legionella.*[25] The protocol outlined in Chart 10-1may be used for processing specimens that contain normal microbiota. The use of acid-wash decontamination has not become commonplace in the clinical laboratory. It has, however, been shown to increase the yield of legionellae from environmental specimens when compared with direct

inoculation of selective or nonselective media with and without the inclusion of concentration methods.[97] Heat treatment of specimens produced only a marginal increase in the yield of *Legionella* isolates and was not recommended for routine use.[51]

Blood Cultures. Collection of blood for *Legionella* culture may occasionally be useful in certain clinical settings. Broth culture methods and lysis-centrifugation have both been used. Blind subculture or staining with a sensitive stain, such as acridine orange, of broth cultures must be performed, because legionellae do not regularly activate the indicators of growth in commercial systems. Patients with positive blood cultures had significantly higher concentrations of legionellae in respiratory specimens than those with negative blood cultures. The usefulness of routine blood cultures in less severely ill patients is not clear.

Identification of Legionella *Species*

Colonies of *Legionella* typically appear on BCYE after 2 to 3 days of incubation in areas that have been heavily inoculated. If only a few organisms are present and if the plates have been lightly inoculated, however, isolated colonies may take several more days to develop. The colonies are variable in size, ranging from punctate or up to 3 to 4 mm. They are glistening, convex, circular, slightly irregular, and have an entire margin (Image Plate 10-1C). When examined through a dissecting microscope (7× to 15×), *Legionella* colonies appear to have crystalline internal structures within the colonies or a speckled, opalescent appearance similar to that of *Fusobacterium nucleatum* (see Chapter 16, and Image Plates 10-1C and D). Some species show a blue-white fluorescence under long-wave (366 nm) ultraviolet light (Image Plate 10-1E); others exhibit a red fluorescence (Table 10-3). Colonies suspected of being *Legionella* should be subcultured onto an ordinary unsupplemented 5% sheep blood agar plate or BCYE lacking L-cysteine and onto BCYE medium that contains L-cysteine. Organisms that grow on 5% sheep blood, on BCYE that lacks L-cysteine, or on other routine media (such as MacConkey agar) are probably not *Legionella.* Occasional isolates of *Legionella* spp. may be recovered on enriched chocolate agar. Isolates of gram-negative bacilli with typical colonial characteristics of *Legionella* that grow on BCYE or BMPA medium after 48 hours or longer of incubation, but do not grow on BCYE that lacks L-cysteine or on sheep blood agar should be characterized. Most such isolates belong to *L. pneumophila* serogroup 1, but there is geographic variation in the species and serogroups recovered. The most convenient laboratory test for confirming a suspected *Legionella* isolate is the DFA test. Colonies can be tested with the fluorescent antibody conjugates mentioned previously to serogroup the isolate. Occasionally, organisms will be found that resemble *Legionella* but do not react with the serologic reagents used in the DFA test. Biochemical tests are unfortunately of limited use (Table 10-3); characterization of cellular fatty acids is useful if the laboratory has the capability of performing this analysis (Table 10-4). For most laboratories, however, the appropriate action will be submission of the isolate to a reference laboratory to determine if it represents a serogroup for which reagents were not available or even a previously unrecognized species or serogroup. It should

be noted that there are non-*Legionella* species that require L-cysteine, fail to grow on blood agar, and may resemble *Legionella* in colony and microscopic morphology.[173] Tests used in definitive characterization of *Legionella* species in some reference or research laboratories include serologic tests, gas-liquid chromatography of cellular fatty acids, and nucleic acid genetic studies. DNA sequencing of the *mip* gene may also be used to identify the *Legionella* to the species level.[47,147] Selected characteristics for laboratory recognition of *Legionella* species are shown in Image Plate 10-1.

Antimicrobial Susceptibility and Treatment

The mortality rate among patients with legionellosis caused by *L. pneumophila* has varied from 0% to 30%, depending on the clinical setting and patient population. Erythromycin has been effective in reducing the case-mortality rate and historically has been the drug of choice for legionellosis. Mortality from *Legionella* infection correlated both with delay in initiation of erythromycin therapy after admission to the hospital and with total delay in starting the antibiotic.[77] Other agents that achieve high intracellular concentrations, such as other macrolides, quinolones, tetracyclines, ketolides, and tetracyclines, are the other options. Although β-lactams and aminoglycosides demonstrate in vitro efficacy, these are not useful clinically. Although no randomized trials have been performed for the treatment of patients with legionellosis, the newer macrolides and quinolones are often selected for first-line therapy.

Because *Legionella* spp. are facultative intracellular pathogens, which replicate inside monocytes and macrophages, antimicrobial agents that are concentrated within these cells are most likely to be successful in treatment. The newer macrolide antimicrobial agents (e.g., azithromycin and clarithromycin), and the fluoroquinolones (e.g., ciprofloxacin and perfloxacin) are more active in vitro and in experimental models than erythromycin, although clinical experience with these agents is still limited. Rifampin is known to be very active in vitro[155] and could be given in addition to erythromycin or another macrolide to some patients who are seriously ill or fail to respond to macrolide therapy alone; rifampin, however, should not be given alone. Alternatively, doxycycline in combination with rifampin has been recommended for moderately or severely ill patients. Trimethoprim-sulfamethoxazole with or without rifampin is another potential option. The penicillins (e.g., penicillin, carbenicillin, oxacillin); first- (e.g., cephalothin, cefazolin), second- (e.g., cefamandole, cefoxitin), and the third-generation cephalosporins; aminoglycosides (e.g., gentamicin, tobramycin, amikacin); and vancomycin are not effective in treatment. In vitro antimicrobial susceptibility testing of *Legionella* isolates has not been standardized and does not correlate with the clinical response to antibiotic therapy in patients. Therefore, performance of in vitro antimicrobial susceptibility testing on *Legionella*

isolates in the hospital diagnostic laboratory is not recommended because the results are not readily interpretable by either the microbiologist or the clinician.

[a]All species are gram negative, show no growth on unsupplemented blood agar, and require L-cysteine (present in BCYE agar) for primary isolation; an exception to this exists for laboratory-adapted strains of *L. oakridgensis*, which lose the requirement for L-cysteine. These organisms are catalase positive or peroxidase positive. None reduce nitrate to nitrite, produce acid from D-glucose, or produce urease.
[b]One strain negative.
[c]Negative on initial isolation; may be positive after transfer on BCYE agar.
[d]Rare strains have been isolated from patients with modified acid-fast bacilli in clinical specimens.
[e]A few strains are negative.
+, positive; –, negative; +(w), weak reaction; w, weak; BW, bluish white autofluorescence.

L. wadsworthii	a-$C_1$5:0

[a] The major cellular fatty acids, as determined by gas-liquid chromatography, of select, pathogenic *Legionella* species are listed. These bacteria are unusual compared with the other gram-negative bacteria because of their relatively large amounts of cellular branched-chain acids. The most abundant acid of *L. pneumophila* and some strains of *L. longbeachae* is i-$C_1$6:0. However, strains of *L. longbeachae* may have either i-$C_1$6:0 or $C_1$6:1 as the major acid, or the two acids may be present in roughly equal amounts as the two most abundant acids. Conversely, the major fatty acid of *L. bozemanii, L. micdadei, L. dumoffii, L. gormanii, L. jordanis*, and certain other species is a saturated, branched-chain, 15-carbon acid (a-$C_1$5:0).

[b] The numbers before the colon represent the number of carbon atoms contained in each of the different fatty acids; the numbers after the colon are the number of double bonds; i indicates a methyl (-CH_3) branch at the iso carbon atom (i.e., the next to last carbon atom); a indicates a methyl branch at the anteiso carbon atom (i.e., the second from last carbon atom).

Serologic Studies for Legionella

The serum indirect IFA test is recommended as an adjunct for diagnosis of legionellosis, particularly for patients who do not or cannot provide adequate respiratory specimens (such as sputum) for culture. The sensitivity of the IFA test is 75% to 80%, and the specificity is 106%.[154,168,170] Clinicians must wait, however, 2 to 6 weeks for patients to develop a fourfold rise in antibody titer. Reagents for *Legionella* serodiagnostic tests should detect antibodies of IgG, IgM, and IgA classes. In some patients, a rise in IgM titer may occur without a detectable rise in IgG or IgA titers or may occur earlier in the course of illness than a rise in IgG titer.[175] IgM antibody may persist for as long as 1 year, so its presence cannot be used to diagnose a recent infection.

As documented by Wilkinson et al.,[168,170] the serum IFA test using *Legionella* antigens may cross-react with the serum of patients who have certain other infections. Sera of patients who had outbreak-associated *Mycoplasma pneumoniae* infections and patients with Q fever cross-reacted with *L. longbeachae* serogroup 2 and *L. jordanis.* Also, cross-reactions were noted between sera of patients who had outbreak-associated tularemia (*Francisella tularensis*) and *L. jordanis* antigen. In addition, false-positive cross-reactions have been observed in patients with *Bacteroides fragilis, Proteus vulgaris, Rickettsia* spp., and *Citrobacter* spp.[75] Some cross-reactions can be eliminated by absorption of antisera with *E. coli,* albeit with some diminution in the anti-*Legionella*titer.[169] Cross-reactions with *Campylobacter* spp. can be removed by absorption of sera with that bacterium.[19]

Seroconversions (fourfold increase in antibody titer) to reciprocal titers of 1:128 or greater are required for serodiagnosis of recent infection with *Legionella.* Single elevated reciprocal IFA titers of 256 or greater may be suggestive of *Legionella* infection during an outbreak. In sporadic cases of pneumonia, however, a 1:256 or higher titer does not necessarily indicate recent infection because such high titers can persist in healthy persons with no current clinical evidence of legionellosis. As a practical matter, it is unlikely that the follow-up required to demonstrate seroconversion will happen in most sporadic cases.

Environmental Microbiology Studies

Molecular Detection of Legionella *in Environmental Samples*

Given the inadequacy of traditional methods for the recovery of legionellae, it is not surprising that molecular methods have been widely employed. Amplification methods have been successfully used to detect legionellae in a variety of environmental samples. Lund et al.[102] have used both culture and quantitative PCR for the detection of *Legionella* in biologic waste water. Culture disclosed a 16% (21/130 cultures) positivity rate legionellae; overall 9% (12/130 culture) were *L. pneumophila.* Conversely, 99% (433/437 analyses) were positive for some type of legionellae; overall, 46% (218/470 analyses) disclosed *L. pneumophila.* Others have questioned the utility of molecular amplification methods, because conceivably the detection of nucleic acids from dead organisms is possible.[33]

Isolation and/or Detection of Legionella *in Environmental Samples*

The widespread presence of *Legionella* spp. in both natural and man-made waters, in the absence of patients with clinical illness, has been observed repeatedly and argues against routine microbiologic culture of water. Conversely, considerable evidence has accumulated that cites potable water as the source of the organism in many patients who have had infection with *L. pneumophila.* Institutional hot water has been implicated frequently in legionellosis; however, more studies

are needed on the magnitude of *Legionella* contamination in home potable water and hot water systems and the frequency of association with legionellosis.[45] For instance, factors that increase the likelihood that *Legionella* spp. will colonize home water systems were defined, but these factors did not appear to increase the incidence of legionellosis acquired in the community. Given the high probability that large numbers of healthy persons are frequently exposed to these organisms in nature, in homes, the workplace, and in private and public buildings of all sorts, it appears that many legionellae in natural and municipal waters are not highly virulent, that exposure to the organism is minimal in extent, or that most persons are not susceptible hosts, or perhaps all are true. Thus, microbiologic enumeration of *Legionella* species in potable or other waters (such as cooling towers) has no clinical or epidemiologic relevance to disease in humans, unless associated infections are documented clinically. Unfortunately, there are not sufficiently adequate markers of virulence to distinguish environmental isolates that are "pathogenic" from those that are unlikely to be pathogens, nor are there appropriate tests that predict in which human hosts legionellosis will develop versus who will be resistant when exposed to *Legionella* in the environment. Furthermore, the degree and extent of exposure to the organism cannot be measured accurately. Therefore, microbiologic surveillance of environmental waters is especially difficult to interpret in the absence of associated

infections, and is even difficult to interpret in the presence of documented infections. Conversely, the clinical and epidemiologic surveillance of patients (e.g., by hospital infection control nurses) is recommended as part of a program to prevent nosocomial legionellosis.

In outbreaks of nosocomial legionellosis, hyperchlorination of the hospital water to a level between 2 and 6 mg/L of free residual chlorine and raising the temperature of the hot water to more than 70°C or a combination of hyperchlorination and heat flushing are methods that have proven effective for suppressing the growth of *Legionella.*[115,141,143] To accomplish heat flushing or thermal eradication, the hot water is circulated throughout the building water system at a temperature of 70°C to 75°C. All shower heads and faucets are flushed with hot water with the objective to kill the *Legionella* in these sites. Protocols for hyperchlorination and thermal eradication have been published elsewhere.[115,141,143] Unfortunately, there is a risk of scalding from the hot water, and precautions should be taken to minimize this possibility (e.g., warning signs or heating the water for relatively short periods of time when most patients are asleep). This is complicated by regulations in some states that require the water temperature in hospitals to be less than 120°F (48.9°C) to prevent scalding of patients. Continuous chlorination (i.e., to achieve 1.5 parts per million free residual chlorine levels) may be unduly corrosive and destructive for some plumbing systems and equipment; there is also a potential risk of toxic exposure to trihalomethane. If the heat and/or chlorination treatments are not done continuously, treatment should be recurrent because recolonization of the water is highly predictable and tends to recur following cessation of either heat shock or chlorination. Other methods, including ultraviolet light sterilization, ozonation, addition of amebicidal agents, and addition of trace metal ions (e.g., silver, copper), are being investigated as alternative water system treatments.

If nosocomial infections with *Legionella* are documented, a highly focused microbiologic investigation of environmental samples may be undertaken to aid in determining the most likely source of the *Legionella*. Control measures such as heat and/or chlorination may be designed in an effort to eliminate or suppress the organism, and follow-up environmental cultures may help determine the effectiveness of these measures. For hospitals with an outbreak or a hyperendemic *Legionella* problem, periodic microbiologic surveillance of the environment, combined with ongoing or repetitive control measures, should be considered unless it can be shown that no new cases of legionellosis have occurred.

The methods outlined in the protocol of Barbaree and coworkers[9] are recommended for persons who wish to isolate and identify *Legionella* species from environmental water. In this protocol, water samples (1 to 2 L) are collected and concentrated using 0.2-mm (pore size) polycarbonate filters. Viable counts are performed with and without prior acid treatment on BCYE and medium that contains

BCYE base supplemented with glycine, polymyxin B, vancomycin, and anisomycin.

Typing of Legionella *Isolates*

Because of the widespread distribution of *L. pneumophila* serogroup 1 in the environment, serogrouping with the DFA reagents described previously has had only limited epidemiologic usefulness in investigating the source of different strains. A number of investigators have developed methods to type or subgroup strains of *L. pneumophila* serogroup 1. Analyses of subtypes within *L. pneumophila* serogroup 1 using panels of monoclonal antibodies,[87,86] genetic structural analysis of *L. pneumophila* using a multilocus enzyme electrophoresis technique,[50,139] and determination of plasmid contents[120] of different isolates from different sources have all been investigated. Other techniques have included electrophoresis of *L. pneumophila* outer membrane proteins[148] and a typing method based on the use of cloned biotinylated DNA probes for analysis of restriction-fragment-length polymorphisms (RFLPs).[137] One of the more promising typing methods is random amplified polymorphic DNA (RAPD) profiling of *L. pneumophila* by PCR; this method appears to be faster and less costly than RFLP typing. RAPD profiling has been reported to be more discriminatory than RFLP typing of some *Legionella* isolates, and is capable of detecting differences among isolates with identical RFLP types.[136] An investigation of an epidemic or analysis of apparently unrelated strains can be strengthened by comparison of the molecular pattern of isolates from patients and from the environment. Although sequencing of nucleic acid directly from specimens may prove feasible for epidemiologic studies eventually, at present isolated strains are required, emphasizing once again the importance of culture in the diagnosis of these infections. It is important to remember that demonstration of "indistinguishable" strains from patients and from an environmental site means that the environmental site is "in contention" as the source of the infections, but does not prove the association. Thorough epidemiologic analysis and consideration of all possibilities are essential. Unfortunately, some of those possible sources may not yet be apparent to anyone. The classic example of this phenomenon was

TABLE 10-5 Correlation of Monoclonal Antibody Patterns With Epidemiologic Analysis

Monoclonal Antibody Pattern	Clinical Strains	Environmental Strains

A	Epidemic-associated infections	Cooling tower
B	Sporadic nosocomial infections	Hospital potable water
C	Sporadic community	—

Adapted from reference 85.

the recognition that potable water was the source of infections at a Veterans Affairs hospital after initial assumptions that cooling towers were the source proved to be unfounded.

In general, characterization of nucleic acids is more discriminatory than analysis of antigenic structure using monoclonal antibodies. Interestingly, antigenic types and genomic variants are not always concordant.[31] The ultimate test for any typing technique is discriminating strains into groups that make sense epidemiologically. The patterns must show enough differences to separate strains into related groups, but not too many that the excessive discrimination (i.e., the demonstration of meaningless variation) occurs. On the one hand, apparently similar strains might appear different if another typing tool was used. On the other hand, consensus agreement may be necessary to decide how many of what kind of differences actually define real-world differences with a particular technique. Whenever possible, it is optimal to analyze strains with more than one technique.

At its best, molecular or antigenic typing can rationalize an epidemic or endemic problem. Analysis of a group of clinical and environmental strains from one location over a period of years produced three clusters of strains, as summarized in Table 10-5. These strains were characterized with a panel of monoclonal antibodies, relatively nondiscriminatory reagents. Amplified-fragment-length polymorphism analysis has been used successfully by a group of European investigators.[69] The polymorphism types of *L. pneumophila* serogroup 1 have been defined and validated by proficiency testing.[68] Another group used automated ribotyping, using reference strains, and concluded that the procedure was useful for genomic analysis, but not sufficiently discriminatory to be used for epidemic analysis. The brightest promise involves the so-called next-generation sequencing. This technology, which can be used to rapidly and efficiently either sequence the entire bacterial genome or simultaneously determine the sequence of multiple taxonomically important genes, has been used in a variety of outbreak investigations. The precise role this will play in the future remains to be determined, but it is fairly certain that this technology will play a role in this area.[153]

CHAPTER 11

Neisseria Species and *Moraxella catarrhalis*

thePoint For additional ancillary materials related to this chapter, please visit the point.

Introduction

Taxonomy of the Family *Neisseriaceae* and the Family *Moraxellaceae*

General Characteristics of the Genus *Neisseria*

Clinical Significance of *Neisseria* Species

Neisseria gonorrhoeae
- Epidemiology
- Infections Caused by *N. gonorrhoeae*

Neisseria meningitidis
- Meningococcal Epidemiology: Serogroups, Serotypes, and Serosubtypes
- Carriage of *N. meningitidis*
- Infections Caused by *N. meningitidis*
- Meningococcal Prophylaxis and Meningococcal Vaccines

Other *Neisseria* Species

Introduction

Gonorrhea was recognized at least as early as the time of Galen (2nd century AD), who named the disease after the Greek words *gonor* ("seed") and *rhoia* ("flow"), suggesting that the disease was related to the flow of semen. References to this infection are also found in the Old Testament and in written histories of several cultures. Although well recognized as a sexually transmitted infection by the 13th century, gonorrhea was not distinguished from syphilis until the mid-19th century. In 1897, *Neisseria gonorrhoeae*, the etiologic agent of gonorrhea, was first observed in purulent exudates from the genital tract and conjunctiva by Albert Neisser at the University of Breslau in Germany. Subsequent isolation of the organism, inoculation

into human volunteers, and reisolation of the organism by Bumm in 1885 proved the causal relationship between the organism and the disease (see Koch's postulates, Chapter 5).

Epidemic cerebrospinal meningitis was known early in the 19th century, but the etiologic agent was not described until 1884, when Marchiofava and Celli observed the organism in meningeal exudates. In 1887, Weichselbaum isolated the organism, now called *Neisseria meningitidis*, in pure culture and first described its characteristics and etiologic role in six patients with acute meningitis. Additional work by Kiefer in 1896 and Albrecht in 1901 established the existence of the meningococcal carrier state in healthy individuals. Over the period from 1929 through 1943, large outbreaks of meningococcal disease in Chile and US cities focused scientific attention on this organism. With subsequent outbreaks among military recruits in the United States and abroad, a better understanding of the epidemiology, pathogenesis, chemoprophylaxis, and prospects for vaccine development began to emerge. During the late 1930s, sulfonamide agents were found to eradicate the meningococcal carrier state, thereby providing a means for prevention of disease spread. During the early 1960s, resistance to sulfonamides began to emerge among meningococci, along with the appearance of epidemic disease at two military installations in California. These outbreaks stimulated the development of effective polysaccharide vaccines against both serogroups A and C meningococci. At present, epidemic serogroup A *N. meningitidis* meningitis remains a serious problem in regions of Africa, and meningococcal disease is still seen among semi-closed military populations.[482] In both the United States and Europe, serogroup C meningococcal disease has increased in the community and on college and university campuses, resulting in marked increases in disease incidence among adolescents and young adults. Molecular techniques have enabled researchers to examine possible meningococcal virulence factors and to understand the "molecular epidemiology" of meningococcal serogroups, serotypes, subserotypes, and clonal virulence.

N. gonorrhoeae and *N. meningitidis* continue to be formidable and versatile pathogens that provide a challenge for both clinicians and clinical laboratorians. Although methods for isolation and identification of *Neisseria* species from clinical specimens have not changed significantly, new nucleic acid probe- and nucleic acid amplification-based techniques for direct detection of *N. gonorrhoeae* have greatly modified laboratory approaches to the diagnosis of gonococcal disease. The development of resistance to antimicrobial agents continues to be a major concern in the new millennium, particularly with the appearance of fluoroquinolone resistance among gonococci and meningococci and the emergence of gonococcal strains with diminished susceptibility to ceftriaxone. Recognition, treatment, and management of meningococcal disease in a community require the cooperation of clinicians, clinical laboratories, and epidemiologists in order to formulate the most appropriate

interventions. On occasion, the recovery of "nonpathogenic" and newly recognized *Neisseria* species from immunocompromised patients must also be considered by the microbiologist in formulating an approach to the detection and identification of *Neisseria* species and "*Neisseria*-like" bacteria in clinical specimens.

Taxonomy of the Family *Neisseriaceae* and the Family *Moraxellaceae*

Members of the genus *Neisseria* are classified in the family *Neisseriaceae*, order *Neisseriales* in the β-subgroup of the phylum *Proteobacteria*. The β-*Proteobacteria* also includes several families of nonfermentative, gram-negative bacteria (i.e., families *Alcaligenaceae*,*Burkholderiaceae*, *Comamonadaceae*, and *Spirillaceae*). The family *Neisseriaceae* also includes the genera *Allysiella*, *Aquaspirillum*, *Chromobacterium*, *Eikenella*, *Kingella*, *Simonsiella*, and *Vitreoscilla*. *Moraxella catarrhalis* is a member of the genus *Moraxella*, which is classified in the family *Moraxellaceae*, order *Pseudomonadales* in the γ-subgroup of the phylum *Proteobacteria.* The genus *Moraxella* comprises more than 20 species, with *M. catarrhalis* being the most clinically significant species recovered from human specimens. *M. catarrhalis* has a gram-negative diplococcal morphology similar to most of the *Neisseria* species, but the other members of the genus *Moraxella* are coccobacillary gram-negative organisms. The other *Moraxella* species are discussed in Chapter 7.

General Characteristics of the Genus *Neisseria*

Members of the genus *Neisseria* are coccal or rod-shaped gram-negative organisms that frequently occur in pairs or short chains. Diplococcal species have adjacent sides that are flattened, giving them a "coffee bean" appearance. All species in the genus *Neisseria* inhabit mucous membrane surfaces of warm-blooded hosts. These organisms are nonmotile and do not form spores, and most species grow optimally at 35°C to 37°C. The organisms are capnophilic and grow best in a moist environment. *Neisseria* species produce acid from carbohydrates oxidatively, and acid production from various carbohydrates constitutes part of the reference identification of these species. Most *Neisseria* species grow as gram-negative diplococci, except for the three *N. elongata* subspecies and *N. weaveri*, which are medium-to-large, plump rods that sometimes occur in pairs or short chains, and

N. bacilliformis, *N. animaloris*, and *N. zoodegmatis*, which are short bacilli or coccobacilli.[26,293,309] All species in the genus are oxidase-positive and (except for *N. elongata* subspecies *elongata, N. elongata* subspecies *nitroreducens,* and some isolates of *N. bacilliformis*) are catalase-positive.[89,281] Members of the genus that are found in humans include *N. gonorrhoeae*, *N. meningitidis*, *N. lactamica*, *N. sicca*, *N. subflava* (including biovars *subflava*, *flava*, and *perflava*), *N. mucosa*, *N. flavescens*, *N. cinerea*, *N. polysaccharea*, *N. bacilliformis*, and *N. elongata* subspecies. Among animal species, *N. canis* and *N. weaveri* are found as part of the normal respiratory tract flora of dogs. *N. macacae*, *N. dentiae*, and *N. iguanae* are found in the mouths of rhesus monkeys, cows, and iguanid lizards, respectively.[26,56,309] *N. denitrificans* is present in the upper respiratory tract of guinea pigs and was reclassified in the genus *Bergeriella* as *Bergeriella denitrificans* in 2005.[710] *N. animaloris* and *N. zoodegmatis* were formerly called the Centers for Disease Control and Prevention (CDC) eugonic fermenter (EF)-4a and EF-4b, respectively.[660] These species are found in the mouths of dogs and have been isolated from dog bite wounds. *N. wadsworthii* and *N. shayeganii* are new species that were isolated from archived clinical reference specimens.[702]The clinical significance, cultural characteristics, and procedures for differentiating these organisms are discussed later in this chapter.

Most *Neisseria* species found in humans are normal inhabitants of the upper respiratory tract and are not considered as pathogens, although on occasion these organisms may be isolated from infectious processes, particularly in the settings of underlying disease and immunosuppression. *N. gonorrhoeae* is always considered a pathogen, regardless of the site of isolation. *N. meningitidis* also causes significant and oftentimes severe disease but may also colonize the human nasopharnyx without causing disease. Although most *Neisseria* species are not exacting in their nutritional requirements for growth, the pathogenic species, *N. gonorrhoeae* in particular, are more nutritionally demanding. *N. gonorrhoeae* will not grow in the absence of the amino acid cysteine and a usable energy source (i.e., glucose, pyruvate, or lactate). Some strains display requirements for amino acids, pyrimidines, and purines as a result of defective or altered biosynthetic pathways. The *Neisseriae* are aerobic, but will grow under anaerobic conditions if low concentrations of an alternative electron acceptor (e.g., nitrites) are present.[368,369] Although the saprophytic *Neisseria* species can utilize amino acids for growth, glucose or another energy source is required by the pathogenic *Neisseria* for metabolism via the Krebs cycle (see Chapter 5). The growth of *Neisseria* species is also stimulated by CO_2 and humidity. Atmospheric CO_2 shortens the lag phase by being rapidly assimilated for initial nucleic acid and protein biosynthesis. In the clinical laboratory, use of enriched media and incubation of cultures in 5% to 7% CO_2 fulfills the requirements for the recovery of these organisms from clinical specimens.

The pathogenic *Neisseria* species possess several factors and characteristics that contribute to virulence. *N. meningitidis* strains isolated from serious infections usually possess polysaccharide capsules external to the outer membrane on the surface of the bacterial cells; 13 different capsular serogroups have been described (see later discussion). The capsules render the organisms resistant to phagocytosis, particularly in the absence of opsonizing antibodies.[35] Various outer membrane protein (OMP) antigens found in both *N. gonorrhoeae* and *N. meningitidis* also have functions associated with virulence. Both gonococci and meningococci also produce an immunoglobulin A (IgA_1) protease capable of splitting humoral and secretory IgA_1 into Fab and Fc fragments, potentially neutralizing the effects of secretory IgA and abrogating mucosal resistance to infection.[468] Nutritional and atmospheric conditions also contribute to the virulence of both gonococci and meningococci. Colonization and subsequent infection of mucosal surfaces by these organisms require iron, and both of these organisms have genetically regulated enzymatic methods for releasing iron from transferrin and lactoferrin, making free iron available for bacterial metabolism. Requirements for individual amino acids or other trace nutrients may also restrict the abilities of different gonococcal and meningococcal strains to cause certain clinical syndromes. Since *N. gonorrhoeae* strains are able to grow anaerobically in the presence of nitrite as an electron acceptor, this property may contribute to gonococcal virulence by allowing the organism to proliferate in anaerobic milieus, such as the endocervix, rectum, genital tract, and the pharynx, and would explain the pivotal role of this organism in pelvic inflammatory disease, in which the organism may be recovered in culture along with obligately anaerobic bacteria.[369]

Clinical Significance of *Neisseria* Species

Neisseria gonorrhoeae

Epidemiology. *N. gonorrhoeae* is the causative agent of gonorrhea, a bacterial infection of great public health significance. In the United States, the incidence of gonorrhea steadily increased during the 1960s and early 1970s, with the highest incidence—over 460 cases per 100,000 population—occurring in 1975.[132] The "gonorrhea epidemic" that occurred during that time was attributable to several factors, including an increasing at-risk population of young adults, importation of less susceptible gonococcal strains along with the return of servicemen from the Vietnam conflict, increasing use of nonbarrier contraceptive methods (i.e., the birth control pill and intrauterine devices), and improved screening, outreach, and contact tracing. Since the early 1980s and into the 1990s, the incidence of gonorrhea has steadily declined. This decline was largely due to changes in sexual behaviors, particularly among men

who have sex with men (MSM), in response to AIDS, and to more effective case-finding and contact tracing among women. Incidence rates during the mid-1990s and into the new millennium continued to decline, with 128 cases per 100,000 reported from 1998 through 2006, and 119 cases per 100,000 reported in 2007.[135] However, gonorrhea remains the second most common reportable disease in the United States.[138] The incidence of gonorrhea is still high among sexually active teenagers (ages 10 through 19 years) and young adults (ages 20 through 24 years) of all races, with the highest attack rates being among 15- to 19-year-old women.[132] Disproportionately high rates of gonococcal and chlamydial

infections are found among urban-dwelling African Americans, particularly women in this 15- to 19-year age group.[485] Over the past several years, the incidence of gonorrhea has dramatically increased among MSM in the United States and abroad. The reasons for this include behavioral responses related to the availability of highly active antiretroviral therapy (HAART) and the management of HIV infection as a chronic illness.[606] A study in Seattle demonstrated that the incidence of gonococcal infection in MSM more than tripled from 1995 to 2003, while the incidence in the Seattle population at large changed minimally.[355]Among heterosexuals, gonococcal infection is disproportionately seen among African Americans and reflects other social dynamics beyond socioeconomic status, including stability of partner relationships, participation in high-risk sexual behaviors, drug and alcohol use, social disenfranchisement, and incarceration.[235] Both social (i.e., urban residence, lack of education, access to health care, unmarried status, race/ethnicity, male homosexuality, prostitution, histories of other sexually transmitted diseases) and behavioral risk factors (i.e., unprotected intercourse, multiple partners, other high-risk partners, drug use) have been identified for targeting by outreach/intervention and STD control programs. Transmission of gonorrhea and maintenance of the infection in a population are related to a social subset of “core” or “high-frequency transmitters” who serve as reservoirs of infection. These individuals have frequent, unprotected sexual contacts with multiple partners during incubation periods subsequent to organism acquisition and prior to recognition of infection and treatment, thereby maintaining a pool of infection and transmission within a population.[100,593] On a worldwide basis, the highest incidence of gonorrhea and its complications is found in resource-limited countries, such as those in Africa and Latin America.

The risk of acquiring gonorrhea is multifactorial and is related to the frequency and sites of exposure. For heterosexual males, the risk of acquiring urethral infection from an infected female is about 20% for a single exposure and up to 80% for four

exposures.[313] Owing to anatomical considerations, the risk of infection of the female genital tract from a single exposure to an infected male is much higher, being on the order of 50% to 70% per exposure.[408] Transmission of rectal infection is also quite efficient, and studies among MSM have demonstrated that urethral infection following fellatio from an infected partner may account for as much as 26% of urethral infections diagnosed in this population.[385] Among women, use of hormonal contraceptive methods is associated with an increased risk of gonococcal infection, while barrier methods such as condoms and diaphragms used with spermicidal foams and gels (i.e., non–oxynol-9) exert a protective effect against infection.[418,419]

Infections Caused by *N. gonorrhoeae*. In males, *N. gonorrhoeae* causes an acute urethritis with dysuria and urethral discharge (Fig. 11-1).[435,454] The incubation period between acquisition of the organism and onset of symptoms ranges from 1 to 14 days or longer, with an average of 2 to 7 days. Infections in men are asymptomatic during the prodromal stages of infection, and conversely, 95% to 99% of men with urethral gonococcal infection will experience a discharge at some time. The discharge is purulent in 75% of cases, cloudy in 20%, and mucoid in about 5%; the consistency of the discharge at presentation is affected by the length of time that the infection has been incubating and whether the patient has recently urinated. About 2.5% of men presenting to sexually transmitted disease clinics are truly asymptomatic, and it is estimated that the prevalence of asymptomatic urogenital gonorrhea in men in the general population may be as high as 5%. This pattern of disease is often associated with infection by certain Por IA gonococcal serovars and with the arginine–hypoxanthine–uracil (AHU) strains and certain other auxotypes of *N. gonorrhoeae* (see below).[102,370,373,464] If left untreated, most cases of gonorrhea in men resolve spontaneously, but in less than 10% of cases, ascending infection may result in gonococcal epididymitis, epididymo-orchitis, prostatitis, periurethral abscess, and urethral stricture.[641] These complications are rarely seen in clinical practice in the United States.

■ **FIGURE 11-1** Male with purulent urethral discharge characteristic of *Neisseria gonorrhoeae* infection.

In females, the primary gonococcal infection is present in the endocervix, with concomitant urethral infection occurring in 70% to 90% of cases. After an incubation period of 8 to 10 days, patients may present with cervicovaginal discharge, abnormal or intermenstrual bleeding, and abdominal or pelvic pain; the latter suggests the presence of upper genital tract disease. The presence of dysuria indicates significant urethral involvement.[101] Gonococcal infection of the vaginal squamous epithelium of postpubertal women is uncommon, and in women with hysterectomies, the urethra is the most common primary site of infection. Although it has often been stated that most women with genital gonococcal infection are asymptomatic, this is probably not

true. This assertion was based on the detection of infected women during widespread screening in locales such as family planning clinics, and did not account for those women who presented to physicians or emergency rooms with a spectrum of symptoms referable to the genital tract (e.g., vaginal discharge, dyspareunia, menorrhagia) or the lower abdomen.[435]

618

Symptoms of uncomplicated endocervical infection often resemble those of other conditions, such as cystitis or vaginal infections, and the symptomatology of gonococcal endocervicitis is often clouded by co-infection with *Chlamydia trachomatis*, *Trichomonas vaginalis*, and/or *Candida albicans*. While the genital tract may appear normal, careful endocervical examination often reveals areas of friable cervical mucosa that bleed on swabbing.[101] Only 10% to 20% of infected women, however, will present with an obvious mucopurulent endocervical discharge. Infection of the Bartholin's and Skene's glands may be seen in about one-third of women with genital tract infection. Careful manipulation of these areas can sometimes provide purulent material for direct examination and culture. Endocervical gonorrhea may also complicate pregnancy and is a recognized cofactor for spontaneous abortion, chorioamnionitis, premature rupture of membranes, and premature delivery.[341,435] Infants born to women with genital tract infection are at risk for developing gonococcal conjunctivitis ("ophthalmia neonatorum") or pharyngeal gonococcal infection.

Ascending gonococcal infection may occur in 10% to 20% of infected women and can result in acute pelvic inflammatory disease (PID) that is manifested as salpingitis (infection of the Fallopian tubes), endometritis, and tubo-ovarian abscess, all of which can lead to scarring of the Fallopian tubes, ectopic pregnancies, sterility, and chronic pelvic pain.[341,389,435]Symptoms of gonococcal PID include bilateral lower abdominal pain, abnormal cervical discharge and bleeding, pain on motion, fever, and peripheral leukocytosis. PID caused by *N. gonorrhoeae* generally occurs early, rather than late, in infection and often during or shortly after the onset of menstruation. Fever, leukocytosis, elevated erythrocyte sedimentation rates, and C-reactive protein (CRP) are seen in about two-thirds of patients, while chills, nausea, and vomiting are variable features of PID. Women with salpingitis may also develop a perihepatitis called the Fitz–Hugh–Curtis syndrome, which is characterized by direct extension of the organisms from the Fallopian tube to the liver and peritoneum, resulting in right upper quadrant pain and the finding of adhesions between the liver and the anterior abdominal wall on laparoscopy. The development of PID is influenced by many factors, including diagnosis and treatment for other genital tract infections (e.g., *C. trachomatis* infection, bacterial vaginosis), prior PID, the use of oral contraceptives,

intrauterine devices, vaginal douching, characteristics of infecting strains, and the immune competence of the host.[477,478] Obstruction of the Fallopian tubes, leading to infertility, occurs in 10% to 20% of women following a single episode of acute gonococcal PID and in 50% to 80% after three or more episodes.[693] Among women with ectopic pregnancies, up to 80% have a history of prior PID.[211] In pregnant women, gonococcal infection is associated with an increased risk of complications, including premature labor, premature rupture of the fetal membranes, spontaneous abortion, and infant mortality. Complications due to gonococcal infections are uncommon after the first trimester.

N. gonorrhoeae may also cause pharyngeal and anorectal infections.[596] Oropharyngeal gonococcal infection is seen in MSM and women who acquire the infection by engaging in orogenital sexual contact with an infected partner. Pharyngeal gonorrhea may also be seen occasionally in heterosexual men resulting from performing cunnilingus with an infected partner. The prevalence of oropharyngeal gonococcal infection is particularly high among MSM, patients seen at STD clinics, and HIV-positive individuals.[335,385,513] Patients with oropharyngeal gonococcal infection often have gonococcal infection at genital and/or rectal sites as well.[265,431] Among MSM, in particular, the oropharynx may be the source of transmission to sexual contacts.[385] Over 90% of oropharyngeal gonococcal infections are asymptomatic and are diagnosed by culture of the organism from the throat.[54,501] In many cases, pharyngeal gonococcal infections resolve without antimicrobial therapy. Anorectal infections are seen primarily in MSM who practice unprotected receptive anal intercourse. Kent and colleagues examined 174 rectal specimens from MSM seeking HIV testing and found a prevalence of rectal gonorrhea of 2.9%.[354] A second study conducted in Seattle found a prevalence of rectal gonococcal infection of 2.2% among 500 MSM.[412] Rectal gonococcal infection is frequently associated with HIV infection. In a study of 564 MSM, the prevalence of rectal gonorrhea was 7.1%. In this study, the prevalence of rectal gonorrhea among HIV-positive MSM was 15.2%, 3.5 times the prevalence observed in HIV-negative MSM.[361]Among MSM, gonococcal infection of the rectum may be the only infected anatomic site.[288]Women may also acquire rectal infections by receptive anal intercourse, but most rectal infections in women are due to perianal contamination with infected cervicovaginal secretions. Rectal gonococcal infections are often asymptomatic, but some individuals may experience symptoms ranging from mild pruritis to acute proctitis with anorectal pain and itching, a mucopurulent discharge, bleeding, tenesmus, and constipation 5 to 7 days following infection.[365,541] Anoscopic examination of the anal canal usually reveals an edematous and erythematous rectal mucosa and a purulent discharge associated with the anal crypts.[700]*Chlamydia* infection, herpes simplex virus infection,

and other sexually transmitted infections are included in the differential diagnosis of anorectal gonococcal infection.

In a small percentage (approximately 0.5% to 3%) of infected individuals, gonococci may invade the bloodstream, resulting in disseminated gonococcal infection (DGI).[167,450,596] This infection is characterized by low-grade fever (rarely above 39°C), hemorrhagic skin lesions, tenosynovitis, migratory polyarthralgias, and septic arthritis. Blood cultures are intermittently positive, so at least three blood culture sets should be obtained when a diagnosis of DGI is suspected. Women appear to be at a greater risk for developing DGI, particularly during menstruation and during the second and third trimesters of pregnancy. The skin lesions are exquisitely painful and initially appear as a papule that evolves into a necrotic pustule on an erythematous base (Fig. 11-2, Image Plate 11-1B). There may be as few as 5 or up to 30 lesions present, and the majority of them are on the extremities (i.e., toes, fingers).[168,450] Cultures of skin lesions and synovial fluids from patients with DGI are often negative, suggesting that immune processes (e.g., antigen/antibody complex deposition) contribute to the signs, symptoms, and pathogenesis of DGI. On occasion, patients may develop extensive macular, papular, or petechial rashes and vasculitis.[334,427] In 30% to 40% of cases, organisms localize in one or more joints to cause a purulent and destructive

619

■ **FIGURE 11-2** Skin lesion of DGI on the index finger of the left hand. Skin lesions associated with DGI are usually located on the extremities.

gonococcal arthritis.[530] Joint involvement is usually asymmetric and most commonly involves the knee, elbow, wrist, fingers, or ankle joints.[530] Infected synovial fluid frequently contains 40,000 to 60,000 cells/mm^3, with greater than 80% being polymorphonuclear neutrophils.[258,530] Gram's stain and culture of joint aspirates are positive in only 10% to 30% of cases. Molecular methods (i.e., polymerase chain reaction [PCR], strand displacement amplification) have also been successfully applied to the detection of gonococci in synovial fluid and swab specimens obtained from skin

lesions.[362,525]

Complications of DGI include permanent joint damage, endocarditis, and rarely, meningitis. Gonococcal endocarditis develops in 1% to 2% of patients with disseminated infection and follows a rapid and destructive course.[577] The aortic valve is involved in 50% of cases and mitral valve involvement is present in 30% of cases; four cases of gonococcal tricuspid valve infection have also been reported.[11] Thompson and Brantley reported on gonococcal endocarditis in a 23-year-old man that required prosthetic valve placement due to severe aortic insufficiency and a prolapsed aortic cusp.[633] In 1997, the first case of gonococcal endocarditis associated with systemic lupus erythematosus (SLE) was diagnosed in a 24-year-old woman who presented with nonspecific symptoms of cough, chest pain, fever, and malaise without signs or symptoms of DGI.[637] Transthoracic and transesophageal echocardiograms showed a large vegetation on the pulmonary valve, and blood cultures were positive for *N. gonorrhoeae*. Nielsen and colleagues used the Gen-Probe APTIMA transcription-mediated amplification (TMA) test on surgically excised valvular tissue to successfully diagnose gonococcal endocarditis in a 45-year-old male.[484] Pericarditis and pericardial effusions are also complications of DGI, and adult respiratory distress syndrome, septic shock, and multisystem organ failure have been reported in association with gonococcal bacteremia.[386] Gonococcal meningitis is a rare complication of DGI that has features typical of meningitides caused by other organisms.[442] Other features associated with DGI (e.g., arthritis, tenosynovitis, and skin lesions) are also seen in these patients. Molecular approaches have been helpful in diagnosing gonococcal meningitis, as cerebrospinal fluid (CSF) cultures may be negative due to the fastidious nature of the organism.[104,106,442] Clinical entities that resemble DGI include Reiter's syndrome, pyogenic and crystal-induced arthritis, syphilitic and tuberculous arthritis, rheumatoid arthritis, Lyme disease, and rheumatic fever. Repeated bouts of DGI have been observed in individuals with certain complement deficiencies.[222] Disseminated disease may develop following infection at genital or extragenital sites. Studies of isolates recovered from cases of DGI have shown that these more invasive strains have unusual characteristics, including unique nutritional requirements (e.g., requirements for arginine, hypoxanthine, and uracil for growth [AHU strains]), defined PorIA serovar classification, and resistance to bactericidal activity of normal human serum.[218,464] With the decline in the prevalence of AHU/Por IA serovars over many years, increasing numbers of DGI infections have been associated with other auxotype/serovar classes.[628]

Ocular gonococcal infections, once seen primarily among neonates who acquired the organism during passage through an infected birth canal ("ophthalmia neonatorum"), occur in adults who become infected by autoinoculation from genital

secretions.[22,242] Laboratory personnel working with cultures may also become accidently infected if care is not taken to protect the eyes.[429] Conjunctival infection with *N. gonorrhoeae* is usually painful, with the presence of photophobia, markedly decreased visual acuity, eyelid edema, periorbital cellulitis, and a profuse purulent conjunctival discharge.[523] This infection may be uni- or bilateral and may be complicated by epithelial or stromal keratitis, ulcerative keratitis, corneal perforation, prolapse of the iris, and endophthalmitis.[173] Prompt antimicrobial therapy is required in these cases. The presence of underlying disease (e.g., HIV infection, SLE, hepatitis B infection with cirrhosis) can be associated with atypical presentations of gonococcal infection (e.g., endophthalmitis, bacteremia).[233,524,703] Gonococcal scalp abscesses have been reported in neonates as a complication of intrauterine fetal monitoring.[674] Periurethral and cutaneous gonococcal abscesses have been reported in both HIV-positive and HIV-negative individuals.[352,595]

Historically, gonococcal infections in children included only ophthalmia neonatorum, which is described above. Almost all cases of gonorrhea in children during the newborn period are the result of ocular contamination, although more serious infections with gonococci in newborns have been reported.[226] Transmission of gonorrhea from adults to children by fomites (e.g., shared towels) was proposed as a mode of transmission in older children. However, it is now recognized that gonococcal infections, including conjunctivitis, and other sexually transmitted diseases in children beyond the immediate neonatal period (defined as beginning at birth up through the first month of life) are indicators of sexual abuse.[58,292,423] With a careful, multidisciplinary approach, histories of sexual contacts can usually be obtained from older children. When a child with gonorrhea is

identified, investigation of both adult caretakers and other siblings frequently reveals infected adults and other infected children. Gonococcal infections in children resemble those in adults, with some notable differences. *N. gonorrhoeae* causes a vaginitis with a vaginal discharge, rather than a cervicitis, in prepubertal girls. The epithelium of the prepubertal vagina is composed of columnar epithelial cells, which are the cell types that *N. gonorrhoeae* preferentially infects. With the onset of puberty, these cells are replaced by a stratified squamous epithelium that is not susceptible to gonococcal infection. Urethral infection in male children, if present, resembles that seen in adults. Pharyngeal and rectal gonococcal infections, as in adults, are usually asymptomatic in children.

Neisseria meningitidis

Meningococcal Epidemiology: Serogroups, Serotypes, and Serosubtypes. *N. meningitidis* is a primary pathogen that causes an array of infectious processes, ranging from occult sepsis with rapid recovery to fulminant overwhelming fatal disease.[35,707] Some patients may manifest limited aspects of this clinical spectrum, while others may progress across this spectrum with alarming rapidity. A major virulence factor of all disease-associated isolates of *N. meningitidis* is the polysaccharide capsule. Thirteen meningococcal capsular polysaccharide serogroups (A, B, C, D, H, I, K, L, X, Y, Z, W135, and 29E) have been described, but most infections worldwide are caused by organisms belonging to serogroups A, B, C, X, Y, and W135. Serogroup B *N. meningitidis* strains cause a substantial proportion of endemic disease in many parts of the world, including the United States. Serogroup C and serogroup Y strains have been associated with outbreaks of disease in both the United States and other countries. Serogroup A strains occur primarily in the "meningitis belt" of sub-Saharan Africa and have been responsible for the largest meningococcal epidemics, with serogroups C, X, and W-135 also responsible for some disease in regional areas of Africa (e.g., Kenya, Togo, Niger), China, Argentina, and in Hajj pilgrims.[217,536,544,615,616,632,698,699,722] Because of the availability and widespread use of polysaccharide and conjugate vaccines against *N. meningitidis* serogroups A, C, Y, and W-135, serogroup B is now responsible for up to 90% of disease in some countries, particularly in Europe (Box 11-1).[643] Some data suggests that serogroup C may be associated with more hypervirulent clones and tends

BOX 11-1

Global Epidemiology of *N. meningitidis* and Meningococcal Disease: An Overview

Among the countries of Latin American, little data is available due to recognized underreporting, but a 2008 survey of almost 7,000 isolates collected from 2000 through 2005 from 19 Latin American countries (especially Brazil and Chile) reported that 69% of meningococcal isolated belonged to serogroup B, 26% were serogroup C, and serogroups Y and W-135 each comprised about 2% of isolates.[255]Brazil experienced epidemics of serogroup A disease in the 1920s through the 1940s, with subsequent overlapping serogroup A and serogroup C meningococcal epidemics occurring during the early 1970s.[185]During the late 1990s and into 2002, the annual incidence of meningococcal disease in Sao Paolo was 6 cases per 100,000 and the involved serogroups were serogroup B (59%) and serogroup C (36%).[183]During 2003 to 2005, annual disease incidence in Sao Paolo was 3.9 cases per 100,000, with almost two-thirds of isolates belonging to serogroup C. In southern

Brazil, similar incidence rates have been observed throughout the late 1990s and into the mid-2000s; however, the serogroup distribution in the southern regions of Brazil included a preponderance of serogroup B isolates (78.9%), along with serogroup C (14.1%) and serogroup W-135 (6.2%).[48]The prevalence of isolates belonging to serogroup W-135 in southern Brazil now exceeds 17%, with all isolates belonging to the ST-11 complex.[691]In Chile, incidence rates of meningococcal disease have remained stable for many years at 0.6 per 100,000, with isolates belonging to serogroups B (71%), C (12%), and Y (10%). Argentina reported decreases in the rates of meningococcal disease during the period from 1993 through 2005, with serogroup B and C isolates predominating.[152]During 2008, disease due to serogroup W-135 began to emerge, with this serogroup being identified in 28% of disease cases.[217]Cuba experienced a national outbreak of serogroup B meningococcal disease during the early 1980s, but disease incidence has continued to decline since that time to 0.6–0.7 cases per 100,000 from 1998 through 2000, with a further decline to 0.3 cases per 100,000 in 2003.[193] In Columbia, disease incidence data are not available, but a study of 434 isolates collected in Columbia from 1994 through 2006 showed that serogroup B isolates predominated (78%), followed by serogroup C (10%), serogroup Y (9%), and serogroup W-135 (2%); serogroup Y isolates comprised none of the isolates from 1994 and 50% of isolates collected in 2006.[324]

In certain regions of sub-Saharan Africa that are referred to as the "meningitis belt," meningococcal disease caused primarily by serogroup A strains occurs annually, with incidences as high as 1,000 cases/100,000 population.[536,632]This region extends from Senegal in the west to Ethiopia in the east. Epidemics of meningococcal disease occur in cycles of 5–12 years, beginning during the dry seasons in the region and ending with the onset of the rainy season. During the dry season, temperatures fall below 10°C at night, causing populations to congregate in enclosed areas and leading to efficient person-to-person

transmission of the organisms. In addition, the drying effects of strong winds from the Sahara Desert on the oropharyngeal mucosa further increase the risk of invasive meningococcal disease.[457]The last major epidemic caused by serogroup A *N. meningitidis* occurred in 1996 through 1997, causing over 250,000 clinical cases and over 25,000 deaths. This serogroup A strain belonged to the ST-5 complex and caused epidemics of disease in Ethiopia, the Sudan, Kenya, Tanzania, and Chad from 1988 until 1998. In 1995, a new serogroup A clone (ST-7) appeared in Algeria and subsequently spread throughout the meningitis belt, causing an outbreak of meningococcal disease in the Sudan in 1999.[483]Extension of the meningitis belt into the southern regions of Africa was heralded by outbreaks of ST-7 disease in refugee camps in Rwanda, Burundi, and the Republic of Tanzania. Until about 2000, other

meningococcal serogroups were uncommon agents of disease in Africa, with rare outbreaks due to serogroup C strains and small epidemics due to serogroup X isolates in Chad, Niger, Ghana, and Kenya.[120,202]Since 2002, serogroup W-135 strains have emerged in the region that were originally linked to strains infecting individuals participating in the 2000 Hajj pilgrimage to Mecca, Saudi Arabia.[517,615,616]These individuals had been vaccinated with serogroup A and C polysaccharide vaccines, setting the stage for the emergence of the serogroup W-135 strain belonging to the ST-11 complex. This strain apparently arose due to a capsular switch from serogroup C to serogroup W-135. In 2002, over 200 cases of disease due to this strain occurred in Burkina Faso, and isolates belonging to this clone were isolated from individuals within and outside of the meningitis belt.[32]Administration of a trivalent serogroup A/C/W-135 vaccine caused an abrupt decline in disease due to this strain and the emergence of a new serogroup A strain belonging to the ST-2859 complex in 2003.

In the Middle East, most meningococcal disease involvement has been associated with the Hajj pilgrimage to Mecca, Saudi Arabia. During the 1987 pilgrimage, an outbreak of serogroup A meningococcal disease occurred, and travelers returning to the United States from Saudi Arabia demonstrated high rates of group A meningococcal nasopharyngeal carriage.[462]After the 1987 pilgrimage, meningococcal A and C polysaccharide vaccination was made mandatory in order for pilgrimage participants to enter Saudi Arabia.[120]This resulted in virtual disappearance of this serogroup A strain. Beginning in 2000, serogroup W-135 strains emerged during the Hajj pilgrimage, causing over 400 cases of meningococcal disease.[615]When Hajj participants returned to their countries of origin, cases caused by the same serogroup W-135 clone were reported in England, France, Israel, the United States, and other countries.[697,698]The disease strain belonged to ST-11 and had a unique serotype/serosubtype that was similar to strains seen in the England in previous years, only the UK strains belonged to serogroup C and not W-135. It was postulated that mandatory immunization of Hajj participants with serogroup C vaccine had exerted selective pressure for the same ST-11 clone to undergo a capsular switch to serogroup W-135, with serotype and serosubtype markers remaining unchanged.[8,445]Subsequent introduction of the quadrivalent meningococcal vaccine into Saudi Arabia as a visa requirement for Hajj participants has eliminated outbreaks of meningococcal disease in the region.[697]

In Europe, meningococcal disease is associated with serogroup B and C isolates, and incidence rates have declined from 1.67 cases per 100,000 in 1999 to 1.01 per 100,000 in 2006.[229] As in the United States, the highest incidence of disease has been among children less than 1 year of age and teenagers 15 to 19 years of age. During the late 1990s and early 2000s, several countries, including the United Kingdom, Ireland, Spain, Belgium, Portugal, and the Netherlands, experienced increases in disease due to a hypervirulent serogroup C strain belonging to the ST-11 clonal complex. Intensive meningococcal serogroup C vaccination programs in these countries were

implemented from 1999 to 2006 and were highly successful in controlling the spread of this strain, which had been responsible for up to 40% of cases in the United Kingdom alone.[426,643]At the same time as the reduction in serogroup C infections, the proportion of laboratory-confirmed disease due to serogroup B strains increased to 87% in 2007 and 2008 from between 46% and 69% in previous years. These serogroup B strains belong to ST-40 and ST-44 clonal complexes and these strains are now responsible for most meningococcal disease in Europe and the United Kingdom.[93]A second serogroup B clone (ST-269) that was first described in the Netherlands during the 1970s emerged as a cause of invasive disease in the United Kingdom and Scotland in the late 1990s; this same serogroup B clone has also been identified in Quebec, Canada.[196,393]Isolates belonging to serogroup W-135 emerged in France in 2000 and these strains are now the third most common meningococcal serogroup in both France and the United Kingdom.[698]The influx of W-135 strains into these regions at that time reflected the return of pilgrims from the Hajj to their home countries subsequent to the outbreak of W-135 disease in Saudi Arabia.[283]Because of the contribution of W-135 strains to the emergence of disease in areas to which Hajj pilgrims were returning, the United Kingdom made an official recommendation that pilgrims attending Hajj receive the tetravalent meningococcal polysaccharide vaccine for serogroups A, C, Y, and W-135. Visa requirements established in 2002 made receipt of the quadrivalent vaccine compulsory.

During the 20th century, most meningococcal disease in China was due to serogroup A strains, with four epidemics occurring in 1959, 1967, 1977, and 1984. During these epidemics, disease incidence was as

622

high as 500 cases per 100,000.[722]All of these epidemics were due to the ST-5 clone, which has existed in the region for over 60 years, although the serotypes and serosubtypes of these serogroup A ST-5 clonal isolates varied. During the epidemic periods, this clonal group spread from China to Russia, Scandinavia, Nepal, and Saudi Arabia. Institution of a national immunization effort with monovalent serogroup A or bivalent serogroup A and C polysaccharide vaccines in the early 1980s reduced the disease incidence in the region to 0.2–1.0 cases per 100,000 population.[722]The last epidemic in China associated with ST-5 began in 1993, with subsequent spread to Moscow and Mongolia by 1996.[632]Beginning in 2000, *N. meningitidis* strains belonging to serogroups B and C caused sporadic outbreaks of disease China, and 2003 saw the emergence of another hyperinvasive serogroup C strain belonging to the ST-4821 complex.[574]Serogroup A strains remain important causes of outbreaks in India and the Philippines.[471,707]Meningococcal disease is fairly rare in Japan, with

fewer than 30 cases being reported each year, with most disease being due to the ST-32 clone of serogroup B *N. meningitidis*.[314]Severe meningococcal disease appears to be rare in the Far East (i.e., Taiwan, Malaysia, Thailand), with a disease incidence of less than 0.2 per 100,000 population.[153,508,522]

to cause more severe disease than other serogroups.[196,691] This increased virulence manifests as more severe residual effects (e.g., cutaneous lesions with scarring, limb loss, renal failure) and a higher case-fatality ratio than with other serogroups.[227,543,587] In France, a serogroup C clone (ST-11) had a case-fatality ratio of 22% compared with 15% for other French serogroup C isolates. In 2007, this clone caused 5 of 9 disease clusters, with increased virulence as evidenced by extensive hemorrhagic rashes in infected patients.[177]

Meningococcal isolates can be further characterized by OMPs that are expressed on the cell surface termed PorA and PorB. PorB (formerly class 2 and class 3 OMPs) are immunogenic proteins that determine the meningococcal serotype, while PorA proteins (formerly class 1 OMPs) determine the serosubtype.[253,448,657] PorB genotyping can be performed by sequencing of the *porB* gene, while PorA genotyping is performed by sequencing of two variable regions (VR1 and VR2) of the *porA* gene. *porA* genotyping has largely replaced serologic methods for PorA subserotyping because the gene may be variably expressed and single point mutations in *porA* may have a significant impact on virulence. *N. meningitidis* isolates can be further divided into 1 of 13 immunotypes based on lipo-oligosaccharide (LOS) antigenic determinants.[644]Although these methods are helpful in determining the relatedness of strains locally and in defined clinical settings, none of them are able to discriminate and define genetic relatedness of meningococcal strains for global epidemiologic purposes. *N. meningitidis* is able to undergo antigenic variation via horizontal gene transfer with other meningococci or saprophytic neisseriae, by autologous recombination within its own genome, and by variable gene expression due to the presence/absence of insertion sequences, tandem nucleotide repeats, and frame-shifts in nucleic acid transcription.[31,411,562] Horizontal gene transfers may result in **capsular switching**, where a strain changes from one capsular serogroup to another. Isolates that have undergone this process will have the same genetic serosubtype and immunotype, but will express different capsular serogroups. Meningococcal serogroup antigen gene sequencing by sialytransferase gene PCR can be used to confirm serologic grouping methods and to determine the genetic grouping of serologically "nongroupable" strains containing capsular genes that are "switched off."[83,239,305] Capsular switching permits "immunologic escape" from immunity to the original serogroup expressed by a given strain, thereby enabling

outbreaks of meningococcal disease to be initiated and sustained over considerable periods of time.[610] Capsular switching often results in strains that express the serogroup C capsular antigen. In a study of 1,160 invasive isolates collected from 2000 to 2005 in the United States, serogroup C isolates were the results of 12.9% of the switching events, compared with 1.5% resulting in serogroup B and 0.9% resulting in serogroup Y isolates. When sequence types (STs, see below) of these serogroup C strains were determined, 97.2% were STs usually associated with serogroup B, suggesting that these strains had undergone a "B" to "C" capsular switch.[183,299] Serogroup C-to-B and capsular C-to-W-135 capsular switches have been documented in isolates from Portugal and New Zealand, respectively.[59,581] Due to the high frequency of antigenic variation in OMPs and the phenomenon of capsular switching, other methods have been developed to genetically define, identify, and track pathogenic *N. meningitidis* strains globally.[238,610] Techniques such as multilocus enzyme electrophoresis (MLEE) have been used for strain characterization, but this method has been largely replaced by multilocus sequence typing (MLST). MLST is performed by sequencing of portions of seven housekeeping genes and determines the genetic lineage of meningococcal isolates in the community.[239,428] A clonal complex is comprised of a group of STs that share at least 4 of the 7 loci in common with an "ancestral genotype."[657] MLST, when used in conjunction with *porA* and *porB* genotyping and LOS immunotyping, has helped scientists and epidemiologists identify a number of genetically-defined clonal groups that are responsible for both epidemic and sporadic, endemic meningococcal disease.[120] Although MLST has replaced MLEE as a principal method for strain characterization, meningococcal isolates in the epidemiology literature are often referred to by both their enzyme type (ET designation) and their sequence type (ST designation). Other molecular genetic methods (e.g., DNA fingerprinting, restriction fragment length polymorphisms, pulsed-field gel electrophoresis, ribotyping, repetitive element-based PCR analysis, random-amplified PCR,*porA* gene sequencing, and PCR-amplicon endonuclease analysis) have also been developed for monitoring the epidemiology of pathogenic

623

N. meningitidis strains on a worldwide basis, but are not as widely used as MLST.

Clonal analysis of *N. meningitidis* has revealed many interesting characteristics related to virulence and disease. Virulent clones are distinguished by having high transmission rates and causing high rates of disease upon introduction into a susceptible population. Avirulent clones are found in asymptomatic carriers and rarely cause disease, even when transmitted at rates similar to those of virulent clones.[300] The presence of virulent clones coupled with high transmission rates, a susceptible

population, certain host factors (e.g., smoking, mucosal immunity, viral co-infections, congenital/acquired complement deficiencies), and environmental/behavioral factors (crowding, close contact, smoke exposure) leads to high carriage rates and the often explosive appearance of disease.[120,243,716] Eventually, circulating virulent clonal groups undergo genetic diversification via transformation and various selective environmental pressures; these clones may then disappear and/or reemerge at a later time.[120] Invasive clones within an ST complex may express different serogroups. For example, the ST-11 sequence type that expresses serogroup C is responsible for outbreaks of meningococcal disease in the United States, Europe, and Canada, while the same ST-11 clonal complex expressing the serogroup W-135 capsular antigen has caused disease in Africa and Saudi Arabia.[8,93,483,457] Mayer et al.[445] showed that an outbreak of W-135 was due to the clonal expansion of a strain, rather than the emergence of a new strain. Conversely, Shao et al.[574]reported a new serogroup C clone in the Anhui province in China.

Worldwide, various pathogenic clones of *N. meningitidis* composed of different serogroups, serotypes, serosubtypes, and immunotypes are responsible for both endemic and epidemic disease.[185,193,299] Endemic meningococcal disease occurs at rates of 1 to 3 cases per 100,000 persons in the United States, and in 10 to 25 cases per 100,000 persons in developing countries. In the United States, the annual incidence of meningococcal disease peaked in the 1990s with an incidence of 1.7 per100,000 population and, subsequently declined to 0.35 per 100,000 in 2007, due to decreases in all three of the most common serogroups in the United States (serogroups B, C, and Y).[299] Attack rates are highest among children aged 3 months to 1 year and among older teenagers and young adults. Major changes in meningococcal epidemiology during the 1990s included an increase in incidence of community-acquired serogroup C infections, and an increase in disease among teenagers and young adults of both high school and college age.[124,300,426,543] During the 1990s, outbreaks of invasive meningococcal disease occurred on college campuses and were associated with patronage of bars, drinking, cigarette smoking, and dormitory residence.[164,322,323] Substantial amounts of disease have also been seen among non–first-year college students and among students living in off-campus housing.[296,298] During the mid-1990s through 2002, 76 outbreaks of meningococcal disease were identified in the United States; these occurred in colleges, primary and secondary schools, nursing homes, and the community.[246,327] As mentioned above, most of these outbreaks were caused by serogroup C strains, but serogroup Y *N. meningitidis* belonging to the ST-23 complex emerged during the early 1990s, and by the mid-1990s accounted for more than 25% of meningococcal disease, with infants, the elderly, and the immunocompromised being at greatest risk. In Oregon, outbreaks of meningococcal disease occurred in the mid-1990s due to serogroup B strains belonging

to the ST-32 clonal complex.[195] At the present time, serogroup C and serogroup Y strains account for about 31% and 35% of isolates, respectively, followed by serogroup B (23%), and serogroup W-135 (11%).[301] In Canada, the current incidence of meningococcal disease is 0.56 to 1.2 per 100,000, with serogroups C and Y accounting for 25.1% and 21.9% of isolates, respectively.[300]Recently, serogroup B strains belonging to the ST-269 complex emerged in Canada, with serogroup B strains now accounting for over 43% of isolates.[393] The epidemiology of the outbreak of meningococcal disease in and around New Dehli, India, has been reviewed.[471] Box 11-1 contains a brief discussion of the global epidemiology of *N. meningitidis* and meningococcal disease.

Carriage of *N. meningitidis*. *N. meningitidis* may be asymptomatically carried in the oropharynx and nasopharynx of a variable percentage of individuals, and the rate of carriage is related to several factors, such as age, socioeconomic class, and the presence of actual disease in a community.[35,711] In general, carriage rates tend to be less than 3% in children less than 4 years and increase to 24% to 38% in the 15-year- to 24-year-old age group.[121,155] The duration of carriage may also vary with the individual and the serogroup of the colonizing strain, and carriage of meningococci in the nasopharnyx may be transient, intermittent, or persistent.[12] During periods when disease is present in a community, the carriage rates may not be very different from observed rates when no clinical disease is being reported, but the proportion of individuals carrying the more virulent strain has been noted to increase.[35] The carriage prevalence among household contacts of patients with meningococcal disease is usually higher than in the population at large and at least half of the household carriers will be colonized with the same strain as the household's patient.[109,579] Contrary to what has been promulgated for years, the rate of meningococcal carriage does not appear to be seasonal, although most meningococcal disease in developed countries tends to occur during late winter and early spring. Crowded living conditions facilitate respiratory spread of meningococci, and this crowding affects both the transmission of the organism and the occurrence of overt disease. This has been amply demonstrated by the large outbreaks that have occurred on military bases over the years, where large numbers of young, susceptible adults live together in close quarters for prolonged periods. In addition, among university students, meningococcal carriage rises rapidly during the first few weeks of the academic year, largely due to residence in close quarters and socialization in classrooms and gathering places.[474] In addition, persons with bacterial or viral respiratory tract infections also tend to have higher meningococcal carriage rates.[604]Other factors that are associated with increased meningococcal carriage include male gender, cigarette smoking or exposure to

secondary smoke, and low socioeconomic status.[122] Carriage strains may be encapsulated (groupable) or nonencapsulated (nongroupable). Meningococcal colonization of the upper respiratory tract results in a humoral immune response, with formation of serogroup-specific and broadly cross-reactive

bactericidal antibodies against several other outer membrane antigens within 7 to 10 days.[35,711] Even individuals who are colonized with nongroupable strains develop high titers of antibodies against groupable strains, probably owing to the presence of shared antigenic determinants. In one study of 38 individuals who carried nongroupable strains in the nasopharynx, 2% to 52% of the men developed group-specific antibodies, depending on the serogroup examined.[527] This response does not eliminate the carriage state, but it may protect the host from overt disease. The best culture-based method of detection of meningococcal carriage is accomplished by swabbing the posterior wall of the oropharynx, followed by immediate inoculation and incubation of selective medium (e.g., modified Thayer–Martin [MTM] medium).[535]

Infections Caused by *N. meningitidis*. In some individuals, the meningococcal strain that becomes established in the upper respiratory tract goes on to enter the bloodstream and initiate systemic disease. A low level of serum bactericidal antibodies is a principal host factor associated with increased risk of infection, and it appears that invasive *N. meningitidis* disease occurs in those persons who are newly infected with a strain against which the individual lacks bactericidal meningococcal serogroup-specific antibodies.[229] In a study among military personnel, Edwards and coworkers[216] found that 86% of 31 patients had negative nasopharyngeal cultures during the 2 weeks before becoming ill, and that four patients were culture-negative the day before disease onset.[216] However, another case report documented a 7-week interval between nasopharyngeal acquisition of the organism and onset of meningeal disease.[475] Concurrent viral or mycoplasmal infection of the upper respiratory tract may also facilitate systemic invasion by the organism because both sporadic and epidemic outbreaks of meningococcal disease have been associated with outbreaks of viral and mycoplasmal respiratory tract infections.[463] Low socioeconomic status and minority status are associated with an increased risk of meningococcal disease, and the risk of meningococcal disease is also higher among those carriers with deficiencies in the terminal complement components (e.g., C5, C6, C7, C8, and C9) or the properdin system.[244,538] Other underlying conditions, such as hepatic failure, SLE, multiple myeloma, HIV infection, and asplenia may also predispose to serious meningococcal disease.[35,223] Newer behavioral risk factors associated with organism acquisition and

emergent meningococcal disease were brought into focus with college-based disease outbreaks include smoking (both active and passive), kissing, dormitory residence in colleges/universities, patronage of drinking establishments (bars, nightclubs), and sharing of drinking glasses/bottles.[164,249,322,323,424]

The pathogenesis of meningococcal disease is poorly understood and, although much has been reported on the descriptive epidemiology of the organism and its disease states, very little is known about the dynamics of disease production.[508,605,648] Humans are the only natural host for *N. meningitidis* and the organism is spread by respiratory droplets. Meningococci colonize the upper respiratory mucosa and may subsequently invade the bloodstream. Initial attachment to the nasopharyngeal mucosa is apparently mediated via interaction of cell surface adhesins with the I-domain of integrin-α chains or membrane cofactor protein (CD46).[344] A variety of cell surface adhesins are found in meningococci and include pilus proteins (PilC, PilQ), OMPs (Opa, Opc, PorA, PorB), and LOS.[451] Antigenic variation at the adhesin and pilus levels regulates the avoidance of nonspecific host factors during initial adherence to the epithelial mucosa. Environmental factors such as smoking and concomitant viral upper respiratory tract infections increase the risk of colonization due to alterations in the mucosa or abrogation of local immunity.[600] Initially, the polysaccharide capsule blocks the adhesins other than pili, but, subsequently, OMPs bind to the C46 receptor and Opa proteins bind the heparin sulfate proteoglycan receptors, respectively, on endothelial and phagocytic cells. This stimulates the release of cytokines by these cells, with subsequent endocytosis of the organisms by the epithelial cells.[210,605,648] PorB proteins subsequently become inserted into the membrane of the phagosome, preventing fusion with lysosomes.[453] In this way, meningococci can avoid humoral immune mechanisms and survive in mononuclear leukocytes. Meningococcal intracellular survival is determined by many factors, including IgA_1 protease, which degrades lysosome-associated membrane proteins, preventing phagosomal maturation and stimulating upregulation of capsule expression. In addition, intracellular replication is augmented by the capacity of meningococci to acquire iron through specialized iron transport systems (e.g., hemoglobin-binding receptor [HmbR], transferring-binding protein [TbpAB], lactoferrin-binding protein [LbpAB]).[511] The principal meningococcal virulence factor associated with bloodstream invasion is the polysaccharide capsule. Resistance to complement-mediated bacteriolysis and phagocytosis is determined by the expression of the capsule and the LOS present in the outer membrane.[343] In addition, certain class 1 OMPs of *N. meningitidis* are able to downregulate the expression of various complement receptors on neutrophils, thereby inhibiting ingestion of the organisms.[73] Bloodstream invasion by meningococci also correlates with the systemic release of a variety of inflammatory cytokines (e.g., interleukin-1, interleukin-6, tumor necrosis factor-α) that contribute to the

pathogenesis of meningococcemia and meningococcal septic shock.[665] Some of these cytokines may increase the permeability of the blood–brain barrier and allow entry of meningococci into the CSF. In addition, meningococcal invasion of endothelial cells with resulting edema and induction of apoptosis may also release organisms into the CSF and other closed spaces.

At the present time, *N. meningitidis* is the second leading cause of community-acquired meningitis in the United States, largely due to the availability and widespread use of highly efficacious *H. influenzae* and *S. pneumoniae* conjugate vaccines.[115,215] *N. meningitidis* is the most frequent cause of meningitis and sepsis in young adults the world over.[283,605] Clinical presentations of disease may be quite varied and include meningoencephalitis, meningitis with or without meningococcemia, meningococcemia without meningitis, and bacteremia without septic complications.[35,115] Initial symptoms are usually nonspecific and severe disease may supervene within 6 to 8 hours, so recognition of meningococcal syndromes by the clinician is key to successful patient management. The onset of acute meningococcal meningitis

625

is sudden, with fever and chills, myalgias, and arthralgias.[115] The classical signs of meningitis, such as confusion, headache, fever, and nuchal rigidity, may be seen in only about 27% to 50% of patients ultimately diagnosed with meningococcal meningitis.[35,301] Nausea and vomiting may also be a part of the clinical presentation, particularly in children. Meningococcemia and widespread dissemination of the organism are heralded by the rapid development of a rash, which is seen in about 50% to 60% of patients. This rash starts as a pink, maculopapular eruption and then becomes petechial. Initially, these petechiae appear on the mucous membranes (e.g., conjunctivae, hard palate), and then spread to the trunk and the lower extremities. Lesions on the truck may be clustered near the beltline where pressure is applied to the body. Skin lesions are indicators of bleeding complications and coagulopathies that are caused by the organism. Fulminant, rapidly progressive disease may result in formation of additional macules and papules that progress to purpuric or ecchymotic areas of cutaneous hemorrhage and necrosis. About 10% of patients with meningococcemia develop purpura fulminans, resulting in extensive areas of tissue destruction secondary to coagulopathy; aggressive monitoring of coagulation parameters and replacement of coagulation factors (e.g., fresh frozen plasma, platelet transfusions) may benefit some of these patients.[4] Progression of these lesions may lead to peripheral gangrene of the digits that sometimes require amputation. Diffuse neurologic involvement, rather than focal signs and symptoms, and cardiac involvement occur more frequently with meningococcal meningitis than with other

types of bacterial meningitides. Cardiac abnormalities, particularly myocarditis and myocardial dysfunction, are seen in more than half of patients who succumb to meningococcal infection. Clinically, these abnormalities are manifested by congestive heart failure, pulmonary edema, and high central venous pressure.[35]Purulent pericardial effusion with and without cardiac tamponade are complications of meningococcal disease that are seen in both adults and children and usually develop during convalescence.[57,190,290,295,318,720] In one case report, sepsis with a group B meningococcus triggered an acute myocardial infarction in a 42-year-old man with normal coronary arteries.[245]

Fulminant meningococcal shock often dominates the clinical picture of meningococcal meningitis and acute meningococcal sepsis.[35] The patient becomes unresponsive, with absence of superficial and deep tendon reflexes and a depressed sensorium. The presence of shock, a low white blood cell count, a rash, and altered mental status on presentation are associated with a poor clinical outcome in these patients. Mortality from meningococcal septic shock is also associated with low serum potassium and a negative base excess, reflecting generalized metabolic abnormalities. Low platelet and serum CRP levels, which are associated with durations of petechiae and purpura, are predictive of impending disseminated intravascular coagulation (DIC).[380] In fatal cases, autopsies reveal terminal myocarditis and/or lesions of DIC, with microthrombi and thromboses observed in many organs. Avascular necrosis of bone due to thrombosis in intraosseus blood vessels secondary to DIC has also been documented in severe meningococcal disease in both children and adults.[107,571]The classic finding of acute hemorrhagic necrosis of the adrenal glands represents the anatomic hallmark of the Waterhouse–Friderichsen syndrome.[6,585] Despite the availability of excellent therapeutic agents, meningitis with sepsis caused by *N. meningitidis* still may have a mortality rate of up to 30%. Among survivors of infection, up to about 23.9% may develop some degree of sensorineural deafness.[383]

N. meningitidis may also cause bloodstream infection (meningococcemia) without meningitis.[35] This presentation occurs in 5% to 20% of patients with meningococcal disease. Patients with meningococcal bacteremia usually present with a fever, headache, malaise, hypotension, and peripheral leukocytosis. Symptoms of a respiratory tract infection may also be present, but meningeal signs and symptoms are not. Some patients may present with cutaneous lesions, including purpura.[314,358] Meningococci are recovered from blood cultures, but the patient may be clinically well by this time, and no therapy or a short course of therapy is administered. With chronic meningococcemia, the patient is generally symptomatic, with a low-grade fever, rash or purpura, and occasionally arthritis. This presentation is clinically very similar to the gonococcal arthritis–dermatitis syndrome.[542] This form of meningococcal disease, with or without meningitis, has been noted to recur in some patients who have

inherited underlying deficiencies in C3, properdin, C5, C8, and other late complement components.[244] Individuals with underlying conditions that are associated with hypocomplementeric states, such as SLE, are at risk for serious meningococcal disease, and chronic meningococcemia has also been documented in HIV-infected patients.[7,41,240]

N. meningitidis may also cause other infections, some of which result from hematogenous dissemination. Blood-borne spread of the organism may seed other internal organs, leading to complications such as septic arthritis, osteomyelitis, cellulitis, endophthalmitis, and spontaneous bacterial peritonitis.[264,396,430] Septic arthritis may occur along with meningitis or meningococcemia, but primary septic arthritis, with isolation of the organism from joint fluid, may occur without evidence of meningitis or meningococcemia.[34,79,446,449,680] Arthritis usually affects the knees and ankles, but any joint may be affected. Some articular symptoms may also be immune-mediated and both septic and immune-mediated arthritis may occur in the same patient.[70] Osteomyelitis is a rare manifestation of meningococcal infection, with only eight cases reported in the medical literature.[103] In these cases, bone invasion was first detected by radiographic studies and most often involved the long bones (e.g., femur, humerus, tibia). In cases of meningococcal osteomyelitis, blood cultures are usually positive. Soft tissue cellulitis is also a rare clinical presentation of hematogenous meningococcal dissemination and may be observed in otherwise normal hosts or patients with underlying diseases, including diabetes, obesity, pulmonary hypertension, congestive heart failure, and poor lower-extremity circulation.[289,353,518] This complication often involves the periorbital region, but may also involve the neck and the extremities. Involved areas are erythematous, swollen, warm, and tender, and blood cultures are usually positive. Patients with this clinical manifestation have ranged in age from 4 months to 83 years.[145,518] Endogenous endophalmitis is also a rare complication of meningococcal meningitis and meningococcemia.[51,143,713]Patients initially present with blurred vision or loss of visual

acuity and may or may not have systemic signs of sepsis when they present with vision problems. Vitreous specimens are often culture-positive, as are blood and/or CSF cultures, and intravitreal and systemic therapy with third-generation cephalosporins are indicated. Complications may include anterior uveitis and retinal detachment.[5,151] Occasionally, *N. meningitidis* may be isolated from distant body sites without other clinical evidence of meningitis, meningococcemia, or other foci of meningococcal infection. Meningococcal endocarditis is rare, with only 12 cases reported since 1960. Patients usually are elderly and have underlying disease (e.g.,

diabetes, complement deficiencies), and have preexisting valvular disease or prostheses, although endocarditis has been described in a healthy 13-year-old male with no cardiac abnormalities.[19,38,62] Lastly, *N. meningitidis* is one of the long list of organisms that have been recovered from patients with peritonitis and bacteremia complicating continuous ambulatory peritoneal dialysis.[162]

Acute meningococcal conjunctivitis has also been recognized as a distinct clinical entity. This infection may arise as a primary or exogenous infection, or as a secondary endogenous infection.[30, 225,297] Primary infection may be invasive or noninvasive. In invasive primary infection, the conjunctival infection occurs first, followed by the development of systemic disease. In primary, noninvasive disease, only conjunctival infection develops. Secondary endogenous infection occurs as a subsequent complication of systemic meningococcal disease.[28,515] Most cases of meningococcal conjunctivitis occur as a part of systemic infection with *N. meningitidis*, and systemic meningococcal disease associated with conjunctival infection develops in 10% to 18% of patients.[55,221] Primary conjunctivitis caused by *N. meningitidis* has been reported in neonates, older children, and adults.[248,494] In two-thirds of cases, the infection is limited to only one eye. In a review of 84 cases of primary meningococcal conjunctivitis, systemic meningococcal disease (i.e., meningitis or meningococcemia) developed in 17.8%; among these patients the mortality was 13.3%.[55] Systemic infection occurred more frequently among patients who received topical, rather than systemic, antimicrobial therapy; in fact, the risk of developing systemic disease was almost 20-fold greater for patients receiving topical therapy versus systemic therapy. Complications of the infection that were limited to the eye included corneal ulcers, hypopyon, keratitis, subconjunctival hemorrhage, and iritis.[713] In a report of three cases of primary meningococcal conjunctivitis in the United Kingdom, a younger sibling of the index case developed meningococcal meningitis, prompting the authors of this report to suggest that prophylaxis for close contacts of cases of primary meningococcal conjunctivitis is warranted.[599] Saperstein and colleagues also reported a case of exogenous meningococcal endophthalmitis, in which the organism entered the eye via a leaky filtering bleb following cataract surgery instead of via bloodstream dissemination.[558] In the reported cases of meningococcal endophthalmitis, this localized infection often presents without signs or symptoms of meningitis.[356,717]

Meningococcal pneumonia is infrequently seen, but presents primarily as a community-acquired pneumonia that is indistinguishable clinically from other acute bacterial pneumonias.[35,270,701] The pathogenesis of pneumonia may involve hematogenous dissemination or aspiration followed by direct invasion of the lung parenchyma. This infection occurs primarily in middle-aged to older persons with preexisting illnesses, including viral respiratory tract infections, chronic obstructive

pulmonary disease, coronary artery disease, diabetes, HIV infection, and SLE.[526,680,701] Patients usually present with classical signs and symptoms, including fever, dyspnea, cough, and consistent radiographic findings.[701] In a study of 68 military recruits with meningococcal pneumonia proven by culture of transtracheal aspirates, fever, rales, and lobar infiltrates were common findings.[379]The patients were moderately ill, but there were no fatalities. In a review of 58 cases of community-acquired meningococcal pneumonia over the last 25 years, blood cultures were found to be positive in 79.3%, although symptoms and sequelae associated with meningococcemia failed to develop in these patients.[701] Sputum cultures were positive in 15 (83.3%) of 18 cases in which sputum specimens were collected, and 5 of the 58 patients died from their infection. The diagnosis of meningococcal pneumonia is complicated by the presence of the organism in the nasopharynx, resulting in oropharyngeal contamination of expectorated sputum specimens. In addition to pneumonia, fulminant bacteremic supraglottitis has been reported in association with serogroup B, C, and Y meningococcal infections.[382,476,532,568,586] These infections were characterized by sore throat, dysphagia, swollen suproglottic tissues, and cervical cellulitis. Five of the six patients described with this condition required intubation or emergency tracheostomy, indicating that meningococcal supraglottitis is a fulminant, potentially life-threatening infection.

N. meningitidis may occasionally be isolated from the male urethra, the female genital tract, and the anal canal. In these sites, it may cause infections that are clinically indistinguishable from gonococcal infections, such as acute purulent urethritis, cervicitis, salpingitis, and proctitis.[147,348,417,495,540] Orogenital, anogenital, and oroanal sexual practices are believed to be responsible for the presence of meningococci in these anogenital sites.[655] Primary neonatal conjunctivitis due to *N. meningitidis* was described in a newborn delivered to a mother with endocervical meningococcal infection.[248] The meningococcal isolates obtained from the conjunctival culture of the baby, an endocervical culture from the mother, and an oropharyngeal isolate from the father of the baby were identical by pulsed-field electrophoretic analysis.

Meningococcal Prophylaxis and Meningococcal Vaccines. The risk of secondary meningococcal disease in close household contacts of a primary case of meningitis or meningococcemia is 500- to 800-fold greater than that of the general population. Close contacts include members of the same household, child care center contacts, and any person directly exposed to the patient's oropharyngeal secretions through kissing, mouth-to-mouth resuscitation, or endotracheal tube placement and management. Close contacts may also include individuals who frequently sleep and/or eat in the same dwelling with an index case. Individuals with intimate contacts within closed

populations, such as college dormitories, military barracks, and long-term-care facilities, are also candidates for meningococcal chemoprophylaxis. It is the standard of practice to provide

627

chemoprophylactic antimicrobial therapy to these contacts as soon after exposure as possible. Ideally, antimicrobial prophylaxis should be administered within less than 24 hours after identification of the index case. Secondary cases of meningococcal disease among close contacts to an index case usually occur within 10 days of exposure. Prophylaxis administered 2 weeks or more after exposure is not effective in preventing secondary cases. During the 1940s and 1950s, sulfonamides were effective in eradicating the meningococcal carrier state and in preventing disease. However, during the 1960s, resistance to the sulfonamides developed in *N. meningitidis* strains. High doses of penicillin transiently eliminate meningococci from the nasopharynx, but the organisms rapidly reestablish themselves after treatment is discontinued. Currently, oral rifampin (adults, 600 mg q12h for 2 days; children less than 1 month of age, 5 mg/kg for 2 days; children older than 1 month of age, 10 mg/kg for 2 days) is administered to eradicate carriage, although this drug may fail to eradicate the organisms in 10% to 20% of carriers. Rapid emergence of rifampin resistance among meningococci has also been noted, even during the time of drug administration. Ceftriaxone, administered as a single intramuscular dose (children, 125 mg; adults, 250 mg) will also eradicate meningococcal carriage for about 2 weeks.[578]Azithromycin (500 mg single dose) has also been shown to eradicate meningococcal carriage in adults, but is not one of the agents recommended for chemoprophylaxis at this time.[268] Ciprofloxacin (adults, 500 mg single dose) and ofloxacin (400 mg single dose) have also been shown to be 95% effective in eliminating nasopharyngeal meningococcal carriage for anywhere from 2 to 5 weeks.[260,266,521] In 2008, three cases of meningococcal disease due to ciprofloxacin-resistant serogroup B strains were reported among residents of North Dakota and Minnesota during 2007 and 2008.[136,708] The first case was epidemiologically linked to a case that occurred in the same region in 2006, except that the particular strain lacked the *gyrA* mutation that confers resistance to fluoroquinolones. Consequently, ciprofloxacin should not be used for meningococcal chemoprophylaxis in regions of the United States where resistant isolates have been isolated and identified, and alternative agents should be used for chemoprophylaxis. A case of meningitis due to a ciprofloxacin-resistant serogroup A strain was also documented in a traveler from Italy who acquired the infection in New Delhi, India.[388]

Because the virulence of *N. meningitidis* is closely associated with the group-specific capsular polysaccharides of the organism, it has been possible to develop

vaccines to protect against meningococcal disease. Univalent group A and group C polysaccharide vaccines and a tetravalent vaccine incorporating group A, C, Y, and W135 capsular polysaccharide material are available. The latter tetravalent polysaccharide vaccine is called MPSV4 (Menomune-A, C, Y, W-135, meningococcal polysaccharide vaccine, 4 serogroups, Sanofi Pasteur, Inc., Swiftwater, PA).[273,398] The polysaccharides in MPSV4 are T-cell-independent antigens, meaning that they stimulate mature B-lymphocytes and not T-lymphocytes. Because of this, serogroup A and C polysaccharides and MPSV4 do not elicit an immunologic memory, so the immune response is not long lasting and does not engender an anamnestic response on subsequent challenge with the same polysaccharide antigen. The monovalent polysaccharide vaccines and MPSV4 elicit immune responses in older children and adults, but are poorly immunogenic in children less than 2 to 3 years of age. While the serogroup A polysaccharide induces a modest immune response in children as young as 3 years, the serogroup C polysaccharide is poorly immunogenic, particularly in children less than 2 years of age.[274,279]Polysaccharides of serogroups Y and W-135 are immunogenic in children over 2 years old and in adults.[284] In addition to the variability of the immune response, the duration of the response to these native polysaccharide vaccines is short-lived and antibody titers fall rapidly over time following immunization.[398] Among infants less than 12 months of age vaccinated with the group A polysaccharide, a detectable antibody response was maintained for only 12 months and, among children immunized at ages 12 to 17 months, titers were detectable for 2 years.[349] In a 1998 study from Montana, only 18% of 1-year-olds, 32% of 2-year-olds, and 50% to 60% of children aged 4 and 5 years produced bactericidal antibody titers in response to the serogroup C polysaccharide vaccine.[443] In addition, native serogroup A and C polysaccharide vaccines may induce immunologic hyporesponsiveness (tolerance) in both children and adults when two doses are given during the first 6 months of life.[86,278,425] MPSV4, in particular, has been widely used in vaccination programs, is safe and well-tolerated, and adverse reactions are relatively uncommon.

In January of 2005, MCV4, a tetravalent meningococcal polysaccharide conjugate vaccine, was licensed for use in the United States (Menactra, Sanofi Pasteur, Inc.), and, in January of 2010, a second MCV4 vaccine was licensed (Menveo, Novartis).[176,514] Both vaccines consist of serogroup A, C, Y, and W135 meningococcal capsular polysaccharides conjugated to diphtheria toxoid. Conjugation to this protein carrier enables the antigen to engender a T-cell-dependent instead of a T-cell-independent immune response. Consequently, the initial immune response to the antigen is more substantial and a strong anamnestic "immunologic memory" response occurs on reexposure to the antigen. In January 2005, the Advisory Committee on Immunization Practices (ACIP) licensed MCV4 for use in persons 11 to 55 years of

age, and, in May of 2005 recommended routine immunization with one dose of MCV4 for persons 11 to 12 years old and those entering high school (i.e., 15-year-olds) if not previously vaccinated.[131] The ACIP recommendations were revised again in June of 2007 to include routine vaccination of all individuals aged 11 to 18 years with a single dose of MCV4, with persons aged 11 to 12 years being vaccinated as recommended previously.[134] ACIP, along with the American Medical Association (AMA), the American Academy of Family Physicians, and the Society for Adolescent Medicine stressed that the ideal time for vaccine receipt for adolescents would be during the healthcare visit recommended for children aged 11 to 12 years. Vaccination was also recommended for persons aged 19 to 55 years who are at increased risk for meningococcal disease, including college freshmen living in dormitories, microbiologists working in clinical laboratories, military recruits, travelers to or residents of countries with endemic meningococcal disease, and those individuals with anatomic/functional asplenia or terminal complement component deficiencies. College

freshmen should be vaccinated with MCV4 before college entry if they have not been vaccinated previously.[131] The feasibility of targeting vaccinations on college campuses has led some schools to recommend that all incoming freshmen be vaccinated. CDC published another update in September of 2009, recommending that persons previously vaccinated with either MSPV4 or MCV4 who are at risk for disease should be re-vaccinated with MCV4.[137] If vaccinated at or after the age of 7 years, revaccination should occur 5 years later, and, if vaccinated at ages 2 to 6 years, revaccination should occur after 3 years. After review of data on vaccine immunogenicity in high-risk groups, persistence of bactericidal antibody following immunization, vaccine efficacy, and cost-effectiveness of various vaccination strategies, the ACIP published another update in 2010 recommending routine vaccination of adolescents at age 11 or 12 years, plus a booster dose at age 16 years.[141] This update also recommended a two-dose primary series of MCV4 administered 2 months apart for those persons aged 2 years through 55 years who have complement component deficiencies, functional/anatomic asplenia, and adolescents with HIV infection.

With the availability of effective conjugate vaccines for meningococcal serogroups A, C, Y, and W135, and the conjugate vaccine against *H. influenzae* type b, serogroup B *N. meningitidis* has become the major cause of bacterial meningitis worldwide. The meningococcal serogroup B polysaccharide capsule is comprised of a linear polymer of α2-8 *N*-acetylneuraminic acid (sialic acid).[622] This unique chemical structure and antigenic properties render it poorly immunogenic in humans. This lack of antibody

response has been attributed to the homologies of the group B polysaccharide to the polysialated form of the neural cell adhesion molecules found in fetal brain tissue.[247] Polysaccharide vaccines prepared from group B strains are poorly immunogenic in both children and adults. Efforts to develop group B vaccines have focused on the organism's OMP antigens. Immunity to group B OMPs is type-specific rather than group-specific, so any potential vaccine would have to include the OMPs of several group B serotypes and serosubtypes involved in disease production. Another approach that has been investigated is modification of the polysaccharide structure by replacing the *N*-acetyl groups of the sialic acid residues with *N*-propionyl groups and then conjugating this molecule to tetanus toxoid.[336] A short clinical trial evaluating the safety and immunogenicity of this candidate vaccine found that both immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies specific for the *N*-propionylated capsular B polysaccharide were produced and no antibodies that were reactive with sialic acid were detected.[97] However, the antibodies appeared to lack functionality (e.g., opsonic activity) in bactericidal assays. A similar approach that has been used in other studies is the synthesis of peptides that mimic hyper-immunogenic epitopes that are unique to the meningococcal serogroup B polysaccharide. Removal of *N*-acetyl groups from the sialic acid residues of the capsular polysaccharides resulted in molecules that still contained immunodominant epitopes of the serogroup B polysaccharide, and antibodies against this material did not cross-react with glycoproteins in cultured cell lines.[278,456] With all of these approaches, the concern remains that the similarities between the native serogroup B molecule and neuraminic acid residues in the central nervous system (CNS) may engender autoimmunity or interfere with fetal neural development.[247]

Much of the serogroup B vaccine work has concentrated on the use of outer membrane vesicle (OMV) preparations. OMVs are prepared from blebs of meningococcal outer membrane that are released during growth. The OMV are extracted with detergents to release LOS and endotoxicity. OMV preparations prepared from wild type, circulating meningococcal strains have been used for the control of epidemics in localized outbreaks involving specific serogroup B meningococcal clones.[257,310,311,351] These OMVs generally produced brisk antibody responses, particularly if the vaccine and disease strains were similar antigenically. The immune response to meningococcal OMV preparations is predominantly against the PorA cell wall outer membrane antigen that are known to be highly variable. In order to broaden the protection afforded by OMV vaccines, more than one serogroup B strain may be included or OMPs prepared from mutant strains that express more than one PorA antigen may be used for OMV preparation.[114,156,555] Characterization of these antigens by the Netherlands Vaccine Institute resulted in recombinant OMV formulations of various PorA preparations and the production of 8-valent ("Hexa-

Men") and 9-valent ("Nona-Men") group B meningococcal vaccines.[155,310,661] These vaccines were estimated to engender the production of anti-PorA antibodies for more than 70% of circulating serogroup B meningococcal strains. However, the principal drawback with the use of the PorA antigens from *N. meningitidis* is the hypervariability of this antigen over time. OMVs have also been prepared from of *N. lactamica* for possible use in meningococcal serogroup B vaccines.[276,277]*N. lactamica* strains lack the PorA protein but have a number of antigens in common with *N. meningitidis.* The safety and immunogenicity of an *N. lactamica* OMV vaccine was evaluated in a phase 1 placebo-controlled double-blind clinical trial.[278] This OMV vaccine was immunogenic, and produced rises in titers of IgG against the vaccine *N. lactamica* strains. A modest cross-reactive response to the vaccine was also elicited against six diverse serogroup B *N. meningitidis* strains. This IgG reacted with meningococcal OMVs, produced serum bactericidal antibodies, and elicited opsonophagocytic activity. Genetic manipulation of *N. meningitidis* by insertion of genes for candidate vaccine molecules into the organism has also been investigated. Inserted genes are hyper-expressed in the meningococcal strain, and OMV vaccines are prepared from the modified meningococcal strain expressing the selected antigen(s). Koeberling and colleague inserted the gene for the lipoprotein, cofactor H binding protein, into a meningococcal strain, and OVS preparations containing the expressed protein produced a functional immune response in animals, whereas the purified, recombinant antigen did not.[377] Several serogroup B meningococcal antigens have been investigated as vaccine candidates and, generally, most of them have shown disappointing results. In most cases, the antigens are not highly immunogenic and the antibodies that are produced do not function well in bactericidal assays. Assessment of vaccine efficacy is hampered by the lack of an animal model for human meningococcal disease. While measurement of in vitro correlates of antibody protection (e.g., the serum bactericidal activity assay) are used as surrogates for protective immunity, a number of

individual protective mechanisms are involved in the immune response to meningococcal infection and the development of overt meningococcal disease.

Other Neisseria *Species*

Neisseria lactamica is an organism that is of special concern because it is able to grow on selective media for gonococci and meningococci and must be differentiated from them. *N. lactamica* is found more frequently in the oropharynges of children than in adults.[49,116]This organism may be isolated from throat cultures of children in the

course of investigations of alleged sexual abuse, and *N. lactamica* must be differentiated from *N. gonorrhoeae* by the clinical laboratory. *N. lactamica* has been isolated as a rare cause of meningitis and sepsis in both adults and children; the adult case was associated with a fracture of the cribriform plate.[186,390] This organism has been associated with recurrent otitis media and with septicemia in a 7-year-old child during immunosuppressive therapy for acute lymphocytic leukemia.[493,565] *N. lactamica* also has been recovered from the female genital tract in association with a persistent vaginal discharge.[631] Recent case reports have described *N. lactamica* as a cause of cavitary lung disease in an organ transplant recipient, septicemia and arthritis in a patient with myeloma on immunosuppressive therapy, and bacteremic pneumonia in a patient with cirrhosis.[231,688,719] In the latter case, the isolate had reduced susceptibilities to penicillin (minimal inhibitory concentration [MIC] 0.75 μg/mL) and ciprofloxacin (MIC ≥ 0.5 μg/mL).*N. lactamica* may act as a natural immunogen against *N. meningitidis* due to the presence of antigens that cross-react with meningococcal strains. Anti-meningococcal bactericidal antibody titers increase steadily in infants despite low rates of meningococcal carriage in the same population.[116] This has provided indirect support for the idea that childhood carriage of *N. lactamica* may subsequently confer some protection against meningococcal disease. *N. lactamica* may be useful for inducing protective antibodies against meningococcal infection by whole-cell kill vaccines, OMV vaccines, or purified OMP vaccines.[64]

Neisseria subflava (biovars *flava*, *subflava*, and *perflava*), *N. mucosa*, *N. sicca*, *N. polysaccharea*, and *N. flavescens* have been reported most frequently as uncommon causes of native and prosthetic valve endocarditis.[21,29,302,407,415,582] With native valve endocarditis, cardiac structural abnormalities caused by past infections (e.g., rheumatic fever) or prior surgery are frequently present. In some reports, the use of intravenous (IV) drugs was a significant risk factor for endocarditis, because oral secretions may be used to dissolve drugs or to clean the skin before injection. Native valve endocarditis due to *N. mucosa* was described in a healthy 20-year-old woman after having her tongue pierced 1 month prior to the onset of symptoms.[642] In addition to endocarditis, these normally saprophytic organisms have been isolated from other significant infections. *N. subflava* has been isolated from joint fluid of a child with septic arthritis, and as a cause of bacteremia, meningitis, discitis, and vertebral osteomyelitis.[14,42,52,342,486,685] At the University of Illinois, a *N. subflava* bv. *perflava* strain was repeatedly recovered from urine cultures of a 10-year-old boy with congenital structural abnormalities of the urinary bladder.[331] *N. subflava* bv. *perflava* peritonitis has also been reported as a complication of chronic ambulatory peritoneal dialysis (CAPD).[678] *N. mucosa* has been isolated as an unusual cause of meningitis, pulmonary abscesses, ocular infections, septic arthritis/bursitis, crepitant cellulitis, dialysis-related bacteremia, and continuous ambulatory peritoneal dialysis-associated

peritonitis.[113,267,320,410,575,576,607] *N. sicca* has been isolated as a rare cause of pneumonia, bronchiectasis, meningitis in compromised hosts, CSF shunt infection, sinusitis, osteomyelitis, septic arthritis, Bartholin's gland abscess, endocarditis, and peritonitis in patients maintained on long-term peritoneal dialysis.[66,220,263,285,315,461,479,559,659] *N. subflava* bv. *perflava* and *N. sicca* have also been isolated from blood cultures of patients with end-stage HIV disease.[465] *Neisseria polysaccharea* is found in the upper respiratory tract of about 0.5% of individuals and has not been described as part of a pathologic process.[88,533] These saprophytic *Neisseria* species may present therapeutic dilemmas because some isolates may be penicillin resistant due to the presence of altered penicillin-binding proteins.[254] In these cases, the isolates must be identified to species, and antimicrobial susceptibility tests should be performed. Furthermore, intergenic recombination between the *penA* genes of these commensal *Neisseria* species and *N. gonorrhoeae* may be responsible for the emergence of mosaic *penA* genes in *N. gonorrhoeae* that encode altered penicillin-binding protein 2 (PBP 2). Gonococcal strains with altered PBP 2 have decreased susceptibility to intramuscular (IM) and orally administered (PO) cephalosporins used for treatment (see below).

Neisseria cinerea is a saprophytic species of the upper respiratory tract that is of particular interest because of its cultural resemblance to *N. gonorrhoeae*, its occasional recovery from genital sites, and its association with syndromes similar to those caused by gonococci, such as purulent conjunctivitis and proctitis.[91,207,209,371,374] *N cinerea* has also been recovered as the cause of nosocomial pneumonia in a patient with AIDS and cavitary lung disease in a renal transplant patient.[92,346] *N. cinerea* bacteremia has been documented in a child with pneumonia and otitis media, in an alcoholic male with intra-abdominal disease, in a patient receiving hemodialysis, and in a 17-year-old male following a fist fight in which he suffered significant facial trauma.[339,363,591] In the latter case, the organism was also recovered from the CSF. *N. cinerea* was described as the cause of tricuspid valve endocarditis in an IV-drug user and peritonitis associated with CAPD.[63,613]

The rod-shaped members of the genus *Neisseria* include the three subspecies of *N. elongata* (subsp. *elongata*, subsp. *glycolytica*, and subsp. *nitroreducens*), *N. weaveri*, and *N. bacilliformis*.[26,27,89,281,293,309] Up until 1990, *N. elongata* included only two subspecies, *N. elongata* subsp. *elongata* and *N. elongata* subsp. *glycolytica*. These organisms are normally found in the human upper respiratory tract. Neither of these subspecies had been implicated in human infections until 1995, when *N. elongata* subsp. *glycolytica* was isolated from wound specimens of three patients and from blood cultures of a 57-year-old man with subacute bacterial endocarditis and aortic insufficiency.[27] Hombrouck-Alet and colleagues used 16S rDNA sequencing to identify *N. elongata* subsp. *glycolytica* bacteremia in a neutropenic patient with

squamous cell carcinoma.[312] In 1996, Nawaz and colleagues reported endocarditis caused by *N. elongata* subsp. *elongata* that was

630

complicated by a ruptured mycotic aneurysm of the right brachial artery, and this organism was subsequently documented as a cause of endocarditis in a 65-year-old female with type II diabetes.[36,473] *N. elongata* subsp. *nitroreducens* was formerly called CDC group M-6.[281] This "*Moraxella*-like" bacterium was shown to be related to the *Neisseria* species, in general, and to *N. elongata* subspecies, in particular, on the basis of genetic studies, cellular fatty acid composition, and phenotypic properties. *N. elongata* subsp. *nitroreducens* is found normally in the oropharynx of humans and has been reported as an opportunistic agent of bacteremia, native and prosthetic valve endocarditis, and as a cause of osteomyelitis following oral surgery.[208,230,307,316,317,452,704] This organism has also been isolated from urine and appendiceal tissue.[281] *Neisseria weaveri*, a rod-shaped organism that was formerly called CDC group M-5, is part of the upper respiratory tract flora of dogs and cats and may be isolated from human wounds and blood cultures associated with animal bites.[26,111,309] In 2002, *N. weaveri* was isolated from bronchial washings and sputum of a 60-year-old male with bronchiectasis and from a wound infection in a 7-year-old girl following a tiger bite.[108,507] In 2010, *N. weaveri* was identified as a cause of peritoneal dialysis-associated peritonitis.[376] *N. bacilliformis* was first described in 2006.[293] This species has been isolated from a submandibular wound in a patient undergoing a mandibulectomy, sputum specimens from two patients with brain lymphoma and lung cancer, respectively, and a lung abscess in a patient with lymphoma. *N. bacilliformis* was subsequently isolated from blood cultures of a 47-year-old male with bicuspid aortic valve endocarditis.[444]

N. animaloris and *N. zoodegmatis* are the new species designations for the former CDC group EF-4a and EF-4b, respectively.[660] These organisms are found in the oral cavities of dogs and cats and are rare isolates from bite wounds associated with these animals. *N. canis*, *N iguanae*, and *N. dentiae* are animal strains isolated from the oral cavity and upper respiratory tracts of cats, guinea pigs, iguanae, and cows, respectively.[56,589] *N. canis* has been recovered from human wounds resulting from cat bites.[287,552] *N. wadsworthii* and *N. shayeganii* are new species that were isolated from archived human clinical specimens.[702]These organisms are most closely related to *N. bacilliformis*, *N. canis*, and *N. dentiae*.

Clinical Significance of *Moraxella catarrhalis*

M. catarrhalis has received much attention as an emerging human pathogen over the last two decades.[347] For many years, *M. catarrhalis* was believed to be part of the normal human upper respiratory tract flora, but studies by Vaneechouette and colleagues and Knapp and Hook showed that this organism is found in the upper respiratory tracts of only 1.5% to 5.4% of healthy adults and is more common in the respiratory tracts of healthy children (50.8%) and elderly adults (26.5%).[370,670] A Danish study also found that *M. catarrhalis* was not a significant member of the nasopharyngeal flora of adults and was rarely present in children less than 1 month of age.[219] However, 36% of children aged 1 to 48 months had *M. catarrhalis* as a part of their respiratory tract flora, and, in this same age group, the prevalence of *M. catarrhalis* in children with respiratory tract infections was 68%. A study of nasopharyngeal colonization with *M. catarrhalis* during the first 2 years of life showed that 66% of 120 serially cultured children became colonized during the first year and that 77.5% were colonized by the end of the second year.[232] A study conducted among newborns and infants in Gambia, West Africa, found a 70% prevalence of *M. catarrhalis* carriage; carriage was about 57% during the first week of life and gradually increased to above 80% by 21 weeks of age.[384]Among healthy adults, the colonization rate of *M. catarrhalis* is about 4%, which correlates with the lower infection rates seen in adults compared with children. When isolated from adults with respiratory tract disease, the organism is more frequently found in specimens that represent lower respiratory tract secretions than in specimens with oropharyngeal contamination. Increased rates of respiratory tract colonization in adults are associated with chronic bronchitis, bronchiectasis, and chronic obstructive pulmonary disease.[469] Among adults with chronic airway disease who were followed over a 27-month period, Klingman and colleagues found that 42.9% were colonized with *M. catarrhalis* and that each patient was colonized with one to four different strains, each strain persisting for about 2 to 3 months.[367]The more frequent recovery of this organism from the respiratory tracts of children and elderly patients with chronic respiratory disease supports its role in certain childhood infections and in lower respiratory tract infections in older individuals.

Infections of the respiratory tract and adjacent anatomic areas account for the majority of clinical conditions involving *M. catarrhalis* as the etiologic agent. These infections include otitis media, sinusitis, bronchitis, and pneumonia.[347,469,672] Although otitis media caused by this organism may occur in any age group, most studies have centered on this organism's role in pediatric infection. *M. catarrhalis* causes about 15% to 20% of acute otitis media, based on cultural and molecular studies of carefully collected middle ear fluid specimens.[360,547] In a study by Van Hare and coworkers, *M.*

catarrhalis was the only bacterial pathogen isolated from middle ear fluid of 40 (11%) of 355 children with acute otitis media and was co-isolated with either *Haemophilus influenzae* or *Streptococcus pneumoniae* in 21 (6%) of the patients. In otitis-prone children with otitis media with effusion (presence of fluid in the middle ear without clinical signs of acute otitis media), *M. catarrhalis* has been detected by culture and molecular techniques in up to 6% of aspirated middle ear effusion specimens.[303,304] Serial cultural studies of otitis-prone children over the first 2 years of life have also shown that these children have consistently higher rates of colonization with *M. catarrhalis* than other children. The bacteriologic findings with acute otitis media are mirrored in studies of acute sinusitis in the same age groups. In carefully collected maxillary sinus aspirates from children with acute sinusitis, *M. catarrhalis* may be isolated in either pure or mixed cultures from 2% to 16% of patients.[94] Acute sinus infections in adults have also been associated with this organism but with less frequency than in children. Despite its involvement in otitis media and sinusitis in children, *M. catarrhalis* is an uncommon cause of community-acquired lower respiratory tract infection in this age group.[611] In children with pneumonia, *M. catarrhalis* may behave as a

primary pathogen or as a secondary pathogen superimposed on an antecedent viral infection (e.g., respiratory syncytial virus). *M. catarrhalis* pneumonia has been reported in immunocompromised children and those with chronic underlying lung disease.[381] On rare occasions, *M. catarrhalis* may cause fulminant tracheitis and lower respiratory tract disease in apparently healthy children.[580]

Lower respiratory tract infections due to *M. catarrhalis* in adults occur predominantly in elderly and immunocompromised patients, particularly individuals with chronic obstructive pulmonary disease (COPD), bronchiectasis, congestive heart failure, and predisposition to aspiration.[447,469] Immunologic abnormalities related to underlying diseases (e.g., diabetes, alcoholism, HIV infection, transplantation) are also important contributory factors.[13,432,570]Exacerbations of COPD due to *M. catarrhalis* are associated with dyspnea, increased production of purulent sputum, constitutional symptoms, and fever. The role of *M. catarrhalis* in these exacerbations is supported by the presence of *M. catarrhalis* in cultures of the distal airways (i.e., bronchoscopy, tracheal aspiration) and demonstration of new *M. catarrhalis* strain acquisition coincident with the acute increase in respiratory symptoms.[460,573,590] These patients also develop an antibody response against the newly acquired *M. catarrhalis* strain in the lower airways and will have elevated markers of airway inflammation associated with acquisition of the new strain.[50] In pediatric patients, *M. catarrhalis* bacteremia

can occur secondary to otitis media, sinusitis, or pneumonia and usually is seen in those infants with sickle cell disease, leukopenia, and HIV infection.[3,611,635] In a review of 17 children with *M. catarrhalis* bacteremia, most of the children were less than 2 years old, 82.3% of the children had no underlying disease, and 76.5% had concomitant lower respiratory tract infections.[9] In children, *M. catarrhalis* bacteremia may also result from periorbital and preseptal cellulitis, a presentation long associated with *H. influenzae* type b sepsis.[635] In adult patients, *M. catarrhalis* bacteremia usually occurs as a complication of respiratory tract infection in those who are immunocompromised due to acute lymphoblastic and myeloid leukemia, lymphoma, AIDS, hypogammaglobulinemia, sickle cell disease, and congenital neurologic abnormalities.[78,325,447,609,635] *M. catarrhalis* bacteremia associated with infection of a prosthetic vascular graft was reported in 2010 in a 53-year-old man diagnosed with aortic dissection and hypertension.[556] In a review of 53 cases of *M. catarrhalis* bacteremia, neutropenia and/or malignancy was present in 30.2% of patients and 24.5% had underlying respiratory tract disease.[325] However, 28.3% of the cases occurred in immunocompetent individuals. Bacteremia in adults may result from a primary focus, such as sinusitis or pneumonia, but in immunocompromised patients, the portal of entry may not be apparent.[635] Nosocomially-acquired pneumonia due to *M. catarrhalis* may occur in hospital respiratory units and pediatric intensive care units.[531]

M. catarrhalis has been involved in several other types of infections, including endocarditis, meningitis, ocular infections, urogenital tract infections, wound infections, septic arthritis, and continuous ambulatory peritoneal dialysis-associated peritonitis. Cases of endocarditis due to *M. catarrhalis* are rare, with only five cases reported through 2000. Endocarditis has been documented in individuals with and without prior valvular disease and has occurred as a complication of invasive procedures (e.g., balloon angioplasty).[557,603] Rare cases of *M. catarrhalis* meningitis and ventriculitis have occurred spontaneously in previously well patients, following surgical procedures involving the head and neck, or secondary to infected ventriculoperitoneal shunts or external ventricular drains.[337,472,546] Viagappan and colleagues reported an unusual case of *M. catarrhalis* brain abscess in a 36-year-old male following a penetrating orbital injury with a pool cue and fatal neonatal meningitis was described in a 26-day-old infant 2 weeks after undergoing abdominal surgery.[171,679] Conjunctival infections caused by *M. catarrhalis* have been documented during the neonatal period and later in childhood, and endophthalmitis secondary to cataract or glaucoma filtering surgery and periorbital cellulitis with sepsis have also been described in patients.[67,225,640] Ophthalmia neonatorum caused by *M. catarrhalis* results either from acquisition of the organism at birth from the mother's

colonized genital tract or from respiratory tract secretions of the child's caretakers. Recovery of this organism from the male or female genital tract is rare, but *M. catarrhalis* has been reported as a cause of a gonorrhea-like urethritis following oral–genital sexual contacts in a few cases.[2] Septic arthritis of both native and prosthetic joints caused by *M. catarrhalis* has been reported in patients with rheumatoid arthritis being treated with immunosuppressive therapies, including injected and oral steroids, methotrexate, and infliximab.[397,492] Peritonitis due to *M. catarrhalis* has also been described in patients who are undergoing continuous ambulatory peritoneal dialysis.[163,677]

Isolation of *Neisseria* Species

Neisseria gonorrhoeae

Direct Gram-Stained Smears. In sexually transmitted disease clinics, the diagnosis of gonococcal urethritis in adult males is frequently made by the observation of gram-negative diplococci within or closely associated with polymorphonuclear leukocytes (PMNs) on a smear prepared from the urethral discharge (see Image Plate 11-1A). When properly performed, the Gram stain has a sensitivity of 90% to 95% and a specificity of 95% to 100% for diagnosing genital gonorrhea in symptomatic men.[366] In females, Gram stains of endocervical specimens collected under direct visualization of the cervix (i.e., with a speculum in place) may also be very helpful in diagnosis (see section on specimen collection). Gram-stained smears of such specimens have a sensitivity of 50% to 70%, depending on the adequacy of the specimen and the patient population. An endocervical smear showing gram-negative intracellular diplococci, particularly from a woman with other signs and symptoms of gonococcal infection, is highly predictive. In asymptomatic women, however, the predictive value of the Gram stain is much lower. In patients with symptomatic proctitis, smears collected under direct visualization through an anoscope may provide a diagnosis in 70% to 80% of such patients, as opposed to blind collection, where Gram-stained smears have a sensitivity of only 40% to 60%.[700] Because of the presence of other gram-negative coccobacilli and bipolar staining bacilli

632

in rectal and endocervical specimens contaminated with vaginal secretions, care must be taken not to overinterpret smears obtained from these sites. Gram-stained smears have no value in the diagnosis of pharyngeal gonococcal infection. Gram-stained smears should not be relied upon for diagnosis of gonorrhea and should be used

adjunctively along with more specific tests.

Direct smears for Gram's stain should be prepared from urethral and endocervical sites and should be collected with a separate swab. For smear preparation, the swab is rolled gently over the surface of a glass slide in one direction only. This technique minimizes distortion and breakage of PMNs and preserves the characteristic appearance of the microorganisms (Image Plate 11-1A). Smears prepared from specimens submitted in transport media may be more difficult to interpret due to distortion of the PMNs or to interfering substances (e.g., charcoal). Smears from normally sterile or minimally contaminated sites (e.g., joint fluid, skin lesions) should also be prepared.

Specimen Collection and Transport. As with other pathogenic microorganisms, successful isolation depends on the collection of proper specimens, and this is particularly important for the recovery of *N. gonorrhoeae*. Because this organism can cause infection at a variety of body sites, collection of appropriate specimens for culture and diagnosis is dependent on the sex and sexual practices of the patient and on the clinical presentation. In all cases, specimens from genital sites (male urethra, female endocervix) should be collected. If the patient has a history of orogenital or anogenital sexual contacts, collection of oropharyngeal or anal canal specimens is also appropriate. In suspected cases of DGI, blood cultures and specimens from genital and extragenital sites should be obtained. Appropriate sites for culture are summarized in Box 11-2.

Specimens should be collected with Dacron or Rayon swabs. The calcium alginate used to prepare some swab lots may be toxic to gonococci.[391] Cotton swabs may also be used; however, some brands of cotton contain fatty acids that may be inhibitory for gonococci. Therefore, calcium alginate and cotton swabs should be used only if the specimens are inoculated directly onto growth media or are transported in nonnutritive transport media. Some transport medium formulations contain charcoal to inactivate toxic materials present in the swab material or in the specimen itself. Instruments used to aid in the proper collection of specimens (e.g., vaginal specula) should be lubricated with warm water or saline because various water- and oil-based lubricants may also inhibit organism growth. Box 11-3 describes collection procedures for the recovery of *N. gonorrhoeae* from different anatomic sites.

The role of the clinical microbiology laboratory in diagnosing gonococcal infections in children is crucial and involves the proper handling of appropriately collected specimens and the accurate identification of isolated organisms.[58,291,292,423] Culture is the recommended method for detecting *N. gonorrhoeae* in urogenital, pharyngeal, or rectal swab specimens. Nonculture tests (e.g., probe-based direct detection methods, nucleic acid amplification tests) have not been recommended for testing either victims or alleged assailants implicated in sexual assaults.[126,128] In the case of prepubertal

females, specimens should be obtained from the vagina, the oropharynx, and the rectum and inoculated onto media as described below. Cervical specimens are not recommended for prepubertal girls. Vaginal specimens are collected by swabbing the vaginal wall for 10 to 15 seconds to absorb any secretions, or, if the hymen is intact, the specimen is collected from the vaginal orifice. For boys with a urethral discharge, a meatal discharge specimen is an adequate substitute for an intraurethral swab specimen. Specimens for diagnosis of rectal, urethral, or oropharyngeal gonococcal infections in children are collected as for adults. Because of the legal implications of a diagnosis of *N. gonorrhoeae* infection in a child, only standard culture procedures should be performed.[140] Gram's stains are inadequate to evaluate prepubertal children for gonorrhea and should not be used to diagnose or exclude gonorrhea. Specimens from the vagina, urethra, pharynx, or rectum should be inoculated onto selective media for isolation of *N. gonorrhoeae* as described below.

Although maximal recovery of gonococci is obtained when specimens are plated directly onto growth medium after collection, this technique might not always be possible or practical, particularly in busy clinics or hospital emergency rooms.[414] For these situations, various transport systems are available:

Nonnutritive Swab Transport Systems. Stuart's or Amie's buffered semisolid transport media are used for transport of swab specimens for *N. gonorrhoeae*. Some swab transport systems use sponges soaked with transport medium, while others use a semisolid medium with or without activated charcoal. Semisolid transport media are superior to devices that use medium-soaked sponges. Sponge material in some swab transport systems may contain substances (e.g., sulfur or quaternary ammonium compounds) that can inhibit or injure fastidious organisms such as gonococci. Some swab transport systems, such as the Copan Diagnostics M40

BOX 11-2

Body Sites to Culture for *Neisseria gonorrhoeae*

Patient	Primary Site(s)	Secondary Site(s)
Female	Endocervix	Rectum, urethra, pharynx
Male, heterosexual	Urethra	Pharynx
Male, homosexual/bisexual	Urethra, rectum, pharynx	
Female, disseminated infection	Blood, endocervix, rectum	Pharynx, skin lesions,[a] joint fluid[b]
		Pharynx, rectum, skin

lesions,[a] joint fluid[b]

BOX 11-3

Specimen Collection Procedures for Diagnosis of Gonococcal Infections

Specimen	Collection Procedure
Male urethra	Purulent discharge may be expressed by stripping the penis anteriorly and collecting the material on a swab. Specimens from asymptomatic males are obtained by inserting a calcium alginate nasopharyngeal swab 2–4 cm into the urethra. The swab is gently rotated as it is withdrawn. For nonculture specimens, the swab supplied or specified by the manufacturer should be used.
Endocervix	After the speculum is in place, a sponge, swab, or gauze should be used to remove any cervical mucus or discharge. Insert the swab 1–2 cm into the cervical canal and rotated against the wall of the endocervical canal two or more times, with a gentle side-to-side motion. Allow time for the organisms to adsorb onto the swab surface. Sample any cervical discharge that may be present. The swab should be withdrawn without touching any vaginal surfaces and placed in the appropriate transport medium. Nonculture specimens should be obtained as directed by the test manufacturer in the package insert.
Rectum	Insert the swab 4–5 cm into the anal canal and gently move it from side to side to sample the anal crypts. Allow a few seconds for the organisms to adsorb onto the swab, and gently rotate the swab during withdrawal. If heavy fecal contamination is observed on the swab, collect another specimen with a fresh swab.
Oropharynx	With the aid of a tongue depressor, firmly swab the tonsillar areas and the posterior pharynx.
	After venipuncture, inoculate suitable blood culture media (tryptic soy broth,

Blood	After venipuncture, inoculate suitable blood culture media (tryptic soy broth, Columbia broth) containing SPS. If SPS Vacutainer tubes are used for blood collection, transfer the blood specimen from the tube into blood culture medium as soon as possible, because exposure to high concentrations of SPS may be inhibitory to gonococci.
Joint fluid	Joint fluid should be aspirated with a needle and syringe and inoculated into an aerobic blood culture bottle.
Skin lesions	Punch biopsy specimens are collected and placed in a sterile container with a small amount of broth or sterile saline and hand-carried to the laboratory.
Conjunctivae	Collect conjunctival discharge from the inner aspect of the lower eyelid with a small nasopharyngeal swab. Prepare smears for Gram's stain as described in the text.

Transystem, have consistently outperformed other swab transport systems (e.g., Medical Wire and Starplex Scientific) in studies addressing survival of gonococci over time.[212,282] Studies with these newer swab collection devices (Copan Transystems, Copan Diagnostics, Inc., Corona, CA; now marketed as BBL CultureSwab Plus, BD Diagnostics) suggest that semisolid Amie's transport medium with or without charcoal may preserve the viability of gonococci for as long as 48 hours, although the viability of many gonococcal isolates may decrease noticeably after 24 hours. The new Copan Eswab system with liquid Amie's transport medium (Copan Diagnostics, Inc., Corona, CA) has been shown to have equivalent or superior performance to other swab transport systems (e.g., CultureSwab MaxV [Becton–Dickinson], Remel BactiSwab [Remel]) in maintaining survival of *N. gonorrhoeae* during transport. These nylon-flocked Eswabs provide acceptable recovery of *N. gonorrhoeae* after 24 hours of storage at room temperature and they fulfill the acceptance criteria as described in the Clinical Laboratory Standards Institute (CLSI) M40-A quantitative elution method for validation.[158,673] The Eswab transport system has also been demonstrated to enhance detection of *N. gonorrhoeae* and *C. trachomatis* by nucleic acid amplification assays.[148] While some studies have shown that gonococci may survive refrigeration in some swab transport systems up to 48 hours, other studies have demonstrated that refrigeration beyond 6 hours may result in significant reductions in viable organisms, regardless of the transport system used.[37,212,319] In order to prevent loss of organism viability, swab specimens submitted in transport medium should not be refrigerated and should be inoculated onto growth medium within 6 hours after collection.

Culture Media Transport Systems. Transport of specimens on culture media presents certain advantages and several systems for this purpose are commercially

plates containing various formulations of selective media (Remel; BD Diagnostic Systems, Sparks, MD), the Gono-Pak system (BD Diagnostic Systems), and the InTray GC system (BioMed Diagnostics, Inc., White City, OR).[24,69,191,441] The JEMBEC and Gono-Pak systems are available with either MTM or Martin–Lewis (ML) selective medium from both BD Diagnostic Systems and Remel Laboratories. While the Gono-Pak and JEMBEC systems require refrigerated storage prior to use, the sealed InTray system permits storage of the medium at room temperature for up to 1 year. With these systems, media are inoculated with the specimen and placed in an impermeable plastic bag with a bicarbonate–citric acid pellet. Contact of the pellet with moisture (via evaporation from the medium [JEMBEC] or via crushing an ampoule of water adjacent to the pellet [Gono-Pak]) generates a CO_2-enriched environment within the bag. Incubation for at least 18 to 24 hours at 35°C prior to transport to a reference laboratory allows initial outgrowth of the organisms and minimizes the loss of viability that may be encountered with swab transport systems.

Selective Culture Media: Inoculation and Incubation. A variety of enriched selective media for culture of *N. gonorrhoeae* are available and include MTM medium, ML medium, GC–Lect medium (BD Diagnostic Systems), and New York City (NYC) medium. MTM, ML, and GC–Lect are chocolate agar-based media that are supplemented with

TABLE 11-1 Antimicrobial Agents in Selective *Neisseria* Media

Antimicrobial Agent	Media Formulation (μg/mL)			
	MTM	ML	NYC	GC–LECT

Trimethoprim	5	5	5	5

growth factors for fastidious microorganisms, whereas NYC medium is a clear peptone–corn starch agar-based medium containing yeast dialysate, citrated horse plasma, and lysed horse erythrocytes.[237] These media contain antimicrobial agents that inhibit other microorganisms and allow the selective recovery of *N. gonorrhoeae*, *N. meningitidis*, and *N. lactamica* (Table 11-1). Vancomycin and colistin, antimicrobials present in all four formulations, inhibit gram-positive and gram-negative bacteria (including saprophytic *Neisseria* species), respectively. GC–Lect agar (BD Diagnostic Systems) also contains lincomycin. Trimethoprim is added to inhibit the swarming of *Proteus* species present in rectal and, occasionally, in cervicovaginal specimens. Nystatin, amphotericin B, or anisomycin is added to inhibit yeasts and molds. These media allow selective recovery of *N. gonorrhoeae* from body sites harboring a large endogenous bacterial flora. NYC medium will also support the growth of genital mycoplasmas and ureaplasmas. These media are commercially available in either petri dishes or JEMBEC plates. The formulas for these media are available in general media references.

Commercially available selective media vary in their ability to support the growth of pathogenic *Neisseria* species and to inhibit growth of nonpathogenic *Neisseriae* and other contaminants. Failure of these various selective media to support gonococcal growth may also be due to the susceptibility of some *N. gonorrhoeae* strains to vancomycin. These strains account for a variable percentage of isolates depending on the geographic area. Because of this, it is prudent to inoculate male and female genital specimens onto both selective (e.g., MTM) and nonselective (chocolate agar) media. Inoculation of nonselective media enables the recovery of other possible genital tract

jars are used, candles should be made of white wax or bees' wax; scented or colored candles release volatile products during burning and extinction that may inhibit the growth of the organisms. Plates are inspected at 24, 48, and 72 hours before a final report of "no growth" is issued. Suspect colonies are subcultured to chocolate agar, incubated, and used as inoculum for identification procedures.

Neisseria meningitidis

Specimen Collection and Transport. Specimens helpful in the diagnosis of meningococcal disease include CSF, blood, aspirates and biopsy specimens, and nasopharyngeal and oropharyngeal swabs.[491] Occasionally, meningococci may be sought in sputum and tracheal aspirates. Procedures for collection and processing of specimens that may yield *N. meningitidis* are presented in Box 11-3. Genital, rectal, and oropharyngeal isolates of *N. meningitidis* may be recovered using the collection and inoculation procedures described for *N. gonorrhoeae* in Box 11-2. Incubation conditions for media inoculated with specimens are the same as those described for *N. gonorrhoeae* above. Meningococci grow well on all selective media for the pathogenic *Neisseriae* and vancomycin-susceptible strains have not been described. Contrary to widely held beliefs, most strains of *N. gonorrhoeae* will grow on commercially available sheep blood agar, albeit not as well as on chocolate agar. Recovery of both gonococci and meningococci from blood cultures may be adversely affected by the anticoagulant sodium polyanethol sulfonate (SPS) that is present in blood culture media.[224]This effect may be neutralized by addition of sterile gelatin (1% final concentration) to the media or by processing the blood specimen by lysis-centrifugation (i.e., Isolator).[502,569] Joint fluids from patients with suspected meningococcal arthritis should be inoculated into aerobic blood culture bottles and, if sufficient volume is obtained, an aliquot of joint fluid should be cytocentrifuged and examined by Gram stain.[491]

Laboratory Safety. Using postings on selected e-mail clinical microbiology discussion groups, Sejvar and colleagues obtained data regarding reports of laboratory-acquired meningococcal infections from 1985 through 2001 and identified 16 cases (9 cases due to serogroup B and 7 due to serogroup C *N. meningitidis*).[572] Based on these data, an attack rate of 13 cases per 100,000 microbiologists was calculated, as compared to an attack rate of 0.3 case per 100,000 in the general population. This represents more than a 40-fold increased risk of disease among clinical microbiology personnel.*N. meningitidis* is classified as a biosafety level 2 organism, which means that a biologic safety cabinet must be used for the manipulation of specimens that

meningococcal arthritis should be inoculated into aerobic blood culture bottles and, if sufficient volume is obtained, an aliquot of joint fluid should be cytocentrifuged and examined by Gram stain.[491]

635

have a substantial risk for the generation of aerosols (e.g., grinding, centrifuging, vortex mixing).[653] Such manipulations include the preparation of heavy organism suspensions for inoculation of identification systems and for serogrouping of meningococcal isolates by slide agglutination.[25] Reports of laboratory-acquired meningococcal infections suggest that manipulation of cultures, rather than specimens, increases the risk of infection for microbiology laboratory technologists and technicians.[44,359,583] The use of a biologic safety cabinet when manipulating cultures for these purposes would ensure protection of the laboratorian from aerosolized organisms. Alternative measures for protection (e.g., safety glasses, splash guards, masks) may afford added protection. Education and adherence to established laboratory safety precautions should minimize the risk of meningococcal infections for clinical microbiology laboratory personnel. Laboratory policies should also be developed for situations that may require administration of prophylaxis to employees who are exposed to meningococci. Laboratory administrators currently offer the quadrivalent meningococcal vaccine to microbiology laboratory staff as this measure would decrease but not eliminate the potential risk of laboratory-acquired meningococcal infections.[127,131,141]

Direct Gram-Stained Smears and Direct Capsular Antigen Tests. A rapid presumptive diagnosis of meningococcal meningitis can be made by direct examination of CSF using the Gram stain. If sufficient (i.e., more than 1 to 2 mL) CSF is received, the specimen should be centrifuged to obtain a pellet of material for examination and culture. Cytocentrifugation of CSF specimens enhances the detection of small numbers of organisms and increases the sensitivity of the Gram stain in comparison

coagglutination tests, MLK Diagnostics AB, Sollentuna, Sweden). A negative test does not rule out meningitis caused by any of the organisms that commonly occur. In addition, false-positive latex agglutination tests may also occur, particularly with urine specimens, resulting in unnecessary treatment and prolonged hospitalization. These tests should always be performed in conjunction with a cytocentrifuged Gram's stain and culture on enriched agar media. Due to the enhanced sensitivity of the Gram's stain provided by specimen cytocentrifugation and the problems with the specificity of the antigen detection assays, most laboratories in the United States no longer perform these tests routinely and they are not recommended.

Isolation and Incubation. For recovery of *N. meningitidis,* CSF specimens should be cultured on nonselective chocolate agar and sheep blood agar as described in Box 11-4, whereas specimens that may harbor other organisms (e.g., oropharyngeal and nasopharyngeal swab specimens) should be inoculated onto both selective (e.g., MTM, ML, NYC, or GC–Lect agar) and nonselective media. Plates are incubated in 5% to 7% CO_2 at 35°C (CO_2 incubator or candle extinction jar) and inspected after 24, 48, and 72 hours before a final report of "no growth" is issued. Suspicious colonies are subcultured to blood and chocolate agar for further identification.

Identification of *Neisseria* Species

Colony Morphology

Gonococci produce several colony types in culture. In Kellogg's scheme, these types are termed T1 through T5 and are described in terms of colony size and other colonial characteristics (coloration, topography of the colonies, reflection of light, and so forth). On the individual cellular level, organisms comprising colony types P^+ and P^{++} (formerly T1 and T2, respectively) possess pili on the cell surface, whereas cells in colony type P^- (T3, T4, and T5) lack pili. Isolates obtained on primary cultures are predominantly of the P^+ and P^{++}colony types. These colonies tend to be small, glistening, and raised (Image Plate 11-1C and 11-1D). With subculture of individual piliated colonies, the culture can be maintained in this colonial type. Organism suspensions prepared from 18- to 24-hour cultures containing primarily P^+ and P^{++} colony types tend to be smooth and homogeneous. With nonselective subculture (i.e., a "sweep" of growth), the other colony types will become more evident, with all colonies eventually becoming the nonpiliated varieties. These types are larger, flatter, and do not have the characteristic glistening highlights of the piliated colony types. Cultures containing predominantly the large-colony types frequently do not form smooth suspensions, as the colonies become gummy owing to autolysis and release of

are termed T1 through T5 and are described in terms of colony size and other colonial characteristics (coloration, topography of the colonies, reflection of light, and so forth). On the individual cellular level, organisms comprising colony types P^{+} and P^{++} (formerly T1 and T2, respectively) possess pili on the cell surface, whereas cells in colony type P^{-} (T3, T4, and T5) lack pili. Isolates obtained on primary cultures are predominantly of the P^{+} and P^{++}colony types. These colonies tend to be small, glistening, and raised (Image Plate 11-1C and 11-1D). With subculture of individual piliated colonies, the culture can be maintained in this colonial type. Organism suspensions prepared from 18- to 24-hour cultures containing primarily P^{+} and P^{++} colony types tend to be smooth and homogeneous. With nonselective subculture (i.e., a "sweep" of growth), the other colony types will become more evident, with all colonies eventually becoming the nonpiliated varieties. These types are larger, flatter, and do not have the characteristic glistening highlights of the piliated colony types. Cultures containing predominantly the large-colony types frequently do not form smooth suspensions, as the colonies become gummy owing to autolysis and release of cellular DNA. The presence of all of these colony types on a subculture from a primary plate may frequently give the appearance of a mixed culture. Careful scrutiny and subculture with the use of a dissecting microscope (10×) enables one to become familiar with these colony types. Variation in colony type is invariably seen with fresh isolates of *N. gonorrhoeae*. Atypical gonococci (i.e., those with multiple nutritional requirements such as the AHU-requiring strains) also produce various colony types, but these develop more slowly and require the use of a dissecting microscope for detection and colony type characterization.

636

BOX 11-4

Specimen Collection Procedures for Isolation of *Neisseria meningitidis*

Specimen	Collection Procedure
Cerebrospinal fluid	In cases of suspected meningococcal meningitis, as much spinal fluid as possible (at least 1 mL) should be sent to the laboratory for culture, because small numbers of organisms may be present. The CSF specimen should be hand-carried to the laboratory after collection and must not be refrigerated. An aliquot of the CSF should be cytocentrifuged for the Gram's stain. If sufficient CSF is available, the

Nasopharyngeal swabs	Nasopharyngeal swabs are particularly important for detecting colonization of individuals who are close contacts to cases of meningococcal disease and for carrier surveys. For these specimens, a fine swab on a flexible metal wire (e.g., a calcium alginate nasopharyngeal swab) is passed through to oropharynx and behind the uvula, where the nasopharynx is sampled. Usually, carefully collected throat swabs will provide the same information. These specimens are inoculated onto a selective medium such as MTM.
Biopsies	Biopsy specimens should be hand-carried to the laboratory in sterile containers. Specimens should be moistened with sterile saline or broth and should not be refrigerated. In the laboratory, the specimens should be aseptically teased apart and cultured on chocolate and blood agar.
Aspirates	Aspirates from closed spaces are collected with a needle and syringe. In the laboratory, these specimens are inoculated onto blood and chocolate agar media.

Colonies of *N. meningitidis* are larger than gonococcal colonies, usually attaining a diameter of about 1 mm or more after 18 to 24 hours' incubation. Colonies are low and convex, with a smooth, moist entire edge and a glistening surface. On sheep blood agar, colonies are usually gray, and heavily encapsulated strains may be mucoid (Image Plate 11-1F) The medium beneath and adjacent to the colonies may exhibit a gray-green cast, particularly in areas of confluent growth. Young cultures have a smooth consistency, while older cultures become gummy due to autolysis.

Gram Stain and Oxidase Test

Primary plates for isolation of *N. gonorrhoeae* should be examined after 24, 48, and 72 hours' incubation using a hand lens or, preferably, a dissecting microscope. Smears prepared from suspicious colonies should be examined with the Gram's stain, and an oxidase test should be performed. The Gram's stain of the colony should show uniform, characteristic gram-negative diplococci. Some of the organisms may appear as tetrads, particularly on smears prepared from young colonies. Organisms on smears prepared from older cultures may appear swollen and display a wide variation in counterstaining intensity. Smears prepared from partially autolyzed colonies may be uninterpretable. Examination by Gram's stain is essential for presumptive identification because other organisms may occasionally grow on selective media, particularly from oropharyngeal specimens (discussed later).

Oxidase test results are obtained with the tetramethyl derivative of the oxidase reagent (*N*,*N*,*N*,*N*-tetramethyl-1,4-phenylenediamine, 1% aqueous solution). This

smooth consistency, while older cultures become gummy due to autolysis.

Gram Stain and Oxidase Test

Primary plates for isolation of *N. gonorrhoeae* should be examined after 24, 48, and 72 hours' incubation using a hand lens or, preferably, a dissecting microscope. Smears prepared from suspicious colonies should be examined with the Gram's stain, and an oxidase test should be performed. The Gram's stain of the colony should show uniform, characteristic gram-negative diplococci. Some of the organisms may appear as tetrads, particularly on smears prepared from young colonies. Organisms on smears prepared from older cultures may appear swollen and display a wide variation in counterstaining intensity. Smears prepared from partially autolyzed colonies may be uninterpretable. Examination by Gram's stain is essential for presumptive identification because other organisms may occasionally grow on selective media, particularly from oropharyngeal specimens (discussed later).

Oxidase test results are obtained with the tetramethyl derivative of the oxidase reagent (*N*,*N*,*N*,*N*-tetramethyl-1,4-phenylenediamine, 1% aqueous solution). This solution is placed on a piece of filter paper and a portion of the colonial growth is rubbed onto the reagent with a platinum loop, a cotton swab, or a wooden applicator stick. With fresh cultures, a dark purple color will appear within 10 seconds. Excellent results are obtained with the oxidase reagents that are packaged in crushable glass ampoules (e.g., BACTIDROP Oxidase, Remel Laboratories).

Superoxol Test

Superoxol is another helpful test for the rapid presumptive identification of *N. gonorrhoeae*.[553]Superoxol is 30% hydrogen peroxide (not the 3% solution routinely used for the catalase test).*N. gonorrhoeae* strains produce immediate, brisk bubbling when some of the colony material is emulsified with the reagent on a glass slide. Both *N. meningitidis* and *N. lactamica*, the other species that grow on selective media, produce weak, delayed bubbling. In a study using this test on organisms recovered on selective media, all 201 gonococci tested produced immediate, vigorous bubbling in superoxol, whereas 241 of 242 meningococci and 1 of 2 *N. lactamica* strains produced negative or delayed, weak positive reactions.[553] When testing isolates grown on MTM medium, Perez and colleagues found that the positive and negative predictive values of the superoxol tests for the identification of *N. gonorrhoeae* were 96.7% and 100%, respectively.[509]

637

Differentiation of Other Organisms on Selective Media

appear swollen. Coccobacillary *Moraxella* species will form long filaments or spindle-shaped cells under the influence of subinhibitory concentrations of penicillin. *Acinetobacter* species can be differentiated by their negative oxidase reaction. *Capnocytophaga* species appear as pale-staining, gram-negative, slightly curved, fusiform bacteria and are both oxidase negative and catalase negative. On prolonged incubation (i.e., longer than 48 hours), these organisms tend to spread owing to their gliding motility and may impede recovery of gonococci from oropharyngeal specimens.

Presumptive Criteria for Identification of N. gonorrhoeae

All isolates of oxidase-positive, gram-negative diplococci that are recovered from urogenital sites and that grow on selective media may be presumptively identified as *N. gonorrhoeae*. The superoxol test described previously provides an additional presumptive test for identifying these isolates. However, confirmatory identification tests are recommended for all isolates and are required for identification of isolates from extragenital sites (i.e., throat, rectum, blood, joint fluid, CSF) should be identified definitively by at least two tests. Furthermore, presumptive isolates of *N. gonorrhoeae* recovered from children should also be confirmed by at least two tests that involve different principles. These may include carbohydrate utilization tests, immunologic methods (e.g., monoclonal antibody coagglutination tests), enzymatic procedures (e.g., chromogenic detection of specific enzyme activities) or the DNA probe culture confirmation test.[404] Isolates should be preserved to enable additional or repeated testing.[128,140,392,696] This is extremely important because certain social and medical–legal issues are raised following release of the results. At the present time, nucleic acid amplification tests are not recommended for testing of specimens from children (see below).

Identification Tests for Neisseria Species

Confirmatory tests for *gonococci, meningococci*, and other *Neisseria* species include carbohydrate utilization tests, chromogenic enzyme substrate tests, immunologic tests (e.g., coagglutination, other tests), multitest identification systems, and DNA probe tests. Carbohydrate utilization tests and the multitest identification systems can be used to identify *N. gonorrhoeae, N. meningitidis*, and the other *Neisseria* species. Chromogenic substrate identification procedures are limited to identifying those isolates that are able to grow on selective media (i.e., *N. gonorrhoeae, N. meningitidis, N. lactamica*, and some strains of *M. catarrhalis*). Coagglutination, other immunologic tests, and the DNA probe culture confirmation test are available for identification of *N. gonorrhoeae* only. The newer nucleic acid hybridization and nucleic acid amplification procedures are approved for direct detection of *N.*

legal issues are raised following release of the results. At the present time, nucleic acid amplification tests are not recommended for testing of specimens from children (see below).

Identification Tests for Neisseria Species

Confirmatory tests for *gonococci, meningococci*, and other *Neisseria* species include carbohydrate utilization tests, chromogenic enzyme substrate tests, immunologic tests (e.g., coagglutination, other tests), multitest identification systems, and DNA probe tests. Carbohydrate utilization tests and the multitest identification systems can be used to identify *N. gonorrhoeae, N. meningitidis*, and the other *Neisseria* species. Chromogenic substrate identification procedures are limited to identifying those isolates that are able to grow on selective media (i.e., *N. gonorrhoeae, N. meningitidis, N. lactamica*, and some strains of *M. catarrhalis*). Coagglutination, other immunologic tests, and the DNA probe culture confirmation test are available for identification of *N. gonorrhoeae* only. The newer nucleic acid hybridization and nucleic acid amplification procedures are approved for direct detection of *N. gonorrhoeae* in genital tract and urine specimens only. Table 11-2 shows the phenotypic characteristics for reference identification of *Neisseria* species and *M. catarrhalis*.

Carbohydrate Utilization Tests

Conventional CTA Carbohydrates. The conventional technique for the identification of *Neisseria* species employs cystine-tryptic digest semisolid agar base (CTA) medium containing 1% carbohydrate and a phenol red pH indicator (Image Plate 11-1E). The usual test battery includes CTA-glucose, -maltose, -sucrose, and -lactose, plus a carbohydrate-free CTA control. The lactose structural analog, *o*-nitrophenyl-β-D-galactopyranoside (ONPG), may be substituted for the lactose tube, and the addition of fructose to the test battery is helpful for identifying the various *N. subflava* biovars. Some commercial CTA formulations may be supplemented with ascitic fluid to support the growth of more fastidious organisms. CTA media are inoculated with a dense suspension of the organism to be identified from a pure 18- to 24-hour culture on chocolate agar. The inoculum is either prepared in 0.5 mL of saline and divided among the tubes, or each tube is individually inoculated with a loopful of the organism. The inoculum is restricted to the top 1/2 inch of the agar-deep tubes. The tubes are incubated in a non-CO_2incubator at 35°C with the caps tightened firmly. With a heavy inoculum, most isolates produce a detectable change in the color of the phenol red indicator within 24 hours. If the inoculum is heavy enough, many strains will change the indicator within 4 hours. However, some fastidious gonococcal strains may require 24 to 72 hours to produce sufficient acid to change the indicator. Because CTA media

volumes of a balanced salts solution (BSS; pH 7.0) with phenol red indicator are dispensed in nonsterile tubes to which single drops of 20% filter-sterilized carbohydrates are added (Image Plates 11-1G). A dense suspension of the organism is prepared in the BSS with a bacteriologic loop; this suspension may be mixed on a vortex mixer to disperse clumps. One drop of this suspension is added to each of the carbohydrate-containing tubes. The tubes are incubated for 4 hours at 35°C in a non-CO_2 incubator or a water bath. This method is very economical, the reagents are easy to prepare and inoculate, and the results are clear-cut. Details for this method are presented in Chart 11-1. The key to this technique is the use of "reagent grade" carbohydrates. Maltose obtained from some bacteriologic media companies may produce positive or equivocal results for *N. gonorrhoeae* in the rapid carbohydrate

This method is very economical, the reagents are easy to prepare and inoculate, and the results are clear-cut. Details for this method are presented in Chart 11-1. The key to this technique is the use of "reagent grade" carbohydrates. Maltose obtained from some bacteriologic media companies may produce positive or equivocal results for *N. gonorrhoeae* in the rapid carbohydrate degradation test, presumably owing to the presence of contaminant glucose. Inocula for this procedure may be obtained from the primary culture if sufficient colonies are present and if the growth is less than 24 hours old. Because bacterial growth does not occur in the test medium, small numbers of contaminants that may be present do not interfere with results. However, incubation cannot be continued overnight.

CarboFerm *Neisseria* Test. The CarboFerm Neisseria kit (Hardy Diagnostics, Santa Maria, CA) consists of an 8-well reagent cuvette that comes packaged as 12 strips snapped into a plastic frame (Image Plate 11-1H). The frame is labeled with row designations A through H. The wells of the cuvette are sealed with a plastic-cap strip, which is removed prior to inoculation. The wells in row A contain dehydrated peptone medium base with phenol red indicator and no added carbohydrates (control wells). The wells in rows C, D, E, and F contain the same medium base with added carbohydrates; these wells contain glucose (wells in row C), maltose (wells in row D), lactose (wells in row E), and sucrose (wells in row F) along with the dehydrated peptone medium and phenol red indicator. The wells in row H contain bromo-chloro-indoyl butyrate (butyrate esterase substrate) impregnated on a filter paper disk at the bottom of the well. The wells in rows B and G are empty. The kit also includes screw-capped test tubes containing inoculation fluid. The kit is designed to identify the gram-negative, oxidase-positive diplococci belonging to the genus *Neisseria* and *Moraxella catarrhalis*.

To inoculate the CarboFerm *Neisseria*, an organism suspension equal to or exceeding the turbidity of a No. 4 McFarland standard is prepared in the inoculation buffer. This inoculum is prepared from an 18- to 24-hour culture of the organism on chocolate, blood, or selective media (e.g., MTM medium). Four to five drops of the inoculum are placed in wells A (control), C (glucose), D (maltose), E (lactose), F (sucrose), and H (butyrate esterase substrate). The cuvette is placed in an ambient air incubator at 35°C. After 15 minutes, well H (the butyrate esterase substrate) is examined for the presence of a blue color. If the filter paper disk is teal-blue in color, the organism is identified as *M. catarrhalis*, and testing is completed. If the disk in

Other Carbohydrate Utilization Methods. *Neisseria*-Kwik test kit (Micro-Biologics, St. Cloud, MN), and the Gonobio Test (I.A.F. Production, Inc., Laval, Quebec, Canada) are also commercial modifications of the rapid carbohydrate test procedure. The *Neisseria*-Kwik uses a tray containing dehydrated carbohydrates in separate wells. Each well is inoculated with a heavy suspension of the organism prepared in buffer, and results are read after 3 to 4 hours by noting changes in the colors of indicators. The Gonobio Test is a 2-hour method that requires heavy inoculation of microtubes containing carbohydrate substrates. Both of these systems have been evaluated and compare well with conventional methods.[198]

Chromogenic Enzyme Substrate Tests

The enzymatic identification systems use specific biochemical substrates that, after hydrolysis by bacterial enzymes, yield a colored end product that is detected directly (e.g., a yellow nitrophenol or nitroaniline product) or after the addition of a diazo dye-coupling reagent (i.e., cinnamaldehyde reagent for detection of free β-naphthylamide). The use of these systems is restricted to those species that are able to grow on selective media—*N. gonorrhoeae*, *N. meningitidis*, and *N. lactamica*. Because some strains of *M. catarrhalis* grow on selective media, these systems will also provide a presumptive identification of this organism. Chromogenic substrate identification tests should not be used to identify suspected meningococci recovered on blood and chocolate agars without prior subculture of the isolate to selective media. The enzymatic activities that are detected in these systems include β-galactosidase (BGAL), γ-glutamyl transpeptidase (GGT) aminopeptidase, and prolyliminopeptidase (PIP) (Table 11-3). β-galactosidase and γ-glutamylaminopeptidase are specific for *N. lactamica* and *N. meningitidis*, respectively. Occasional isolates of *N. meningitidis* may lack γ-glutamyl aminopeptidase activity; a meningococcal strain that was isolated from a carrier was found to lack this enzyme because of the presence of an insertion sequence disruption in the *ggt* gene.[619]Reexamination of the GGT activity of 245 *N meningitidis* isolates identified the presence of two other GGT-defective isolates.[618] Absence of GGT and presence of PIP identifies an organism as *N. gonorrhoeae. M. catarrhalis* lacks all three of these enzymatic activities. The commercial systems that use this approach are the Gonochek II, the BactiCard Neisseria, and the Neisstrip.

641

TABLE 11-3 Enzymatic Activities Used for Identification of the Pathogenic *Neisseria* Species

Absence of GGT and presence of PIP identifies an organism as *N. gonorrhoeae. M. catarrhalis* lacks all three of these enzymatic activities. The commercial systems that use this approach are the Gonochek II, the BactiCard Neisseria, and the Neisstrip.

N. gonorrhoeae	–	–	+	–
M. catarrhalis	–	–	–	+

+, positive reaction; –, negative reaction; V, variable reaction.

The utility of preformed enzyme tests for identification of *N. gonorrhoeae* may be limited in the future due to the recognition and spread of gonococcal strains that lack PIP activity. This enzyme is encoded by the *pip* gene, and translation of this gene results in the functional 310-amino-acid PIP protein. Failure to produce functional PIP was determined to result from either 1 of 2 mutations in the *pip* gene—a thymidine deletion mutation resulting in a frame-shift in the codon sequence and a nonfunctional 123-amino acid truncated protein—or a thymidine insertion resulting in a truncated, nonfunctional protein 55 amino acids in length.[75] From 2000 through 2002, a clone of *N. gonorrhoeae* that lacked this enzyme activity became widely disseminated throughout the United Kingdom.[505] This strain typed as serovar IB-4 by coagglutination serology. Phenotypic and genotypic characterization of gonococcal isolates in Denmark during 2002 and 2003 identified the same PIP-negative gonococcal clone in that country.[250] In both the United Kingdom and Denmark, these isolates were recovered primarily from MSM. Subsequent studies by Alexander and colleagues determined that the overall prevalence of PIP-negative *N. gonorrhoeae* strains in England and Wales was 4.33%, and variation in the prevalence of these strains in various clinics in London reflected a higher frequency of these isolates among MSM.[17,18] A 2006 study conducted in Sydney, Australia documented the appearance, spread, and subsequent decrease in subtypes of PIP-negative gonococci among 3,926 strains collected from July 2002 to September 2005.[43] During the third quarter of 2002, PIP-negative *N. gonorrhoeae* comprised only 3% of isolates and, by the third quarter of 2003, these strains comprised 22% of all isolates. These strains subsequently decreased in prevalence and by the third quarter of 2005, 6% of referred

2007, one PIP-negative strain was detected among 250 isolates at the Quebec Public Health Laboratory.[96] A subsequent study in Canada surveyed 5,675 gonococcal isolates submitted to the public health laboratories revealed 19 PIP-negative strains distributed among several Canadian provinces, including British Columbia, Saskatchewan, Manitoba, Quebec, and Prince Edward Island.[438] Another study conducted in Spain found 10 (6.9%) PIP-negative, serovar IB-4 *N. gonorrhoeae* among 143 isolates received by the Regional Laboratory for Gonococci in Oviedo, Spain from 2003 through 2006.[500]

Because of the increasing prevalence of these PIP-negative isolates throughout the world, the performance of test systems (i.e., BactiCard *Neisseria*, Gonochek II, RapID NH; *Neisseria* PET, and API NH) that rely on this enzyme activity to help identify gonococcal isolates and to differentiate them from other neisseriae may be compromised. PIP-negative *N. gonorrhoeae* isolates may generate ambiguous identifications, including "doubtful *N. gonorrhoeae*" and "presumptive *Kingella kingae*," and these types of spurious identification should prompt the performance of additional identification approaches.[17] PIP is a hydrolase enzyme that selectively removes the *N*-terminal proline residue from peptides, and the name of the enzyme varies depending upon the manufacturer of the kit system being used (e.g., PIP, proline aminopeptidase, hydroxyproline aminopeptidase, prolyl arylamidase). Manufacturers of these commercial systems need to standardize the format and names of these tests to avoid confusion for the end users and include warnings in the package inserts concerning proper use and interpretation of the tests in light of the increasing prevalence of PIP-negative strains. Emergence of these gonococcal strains has made it necessary and imperative to use at least two different identification methods based on different criteria (i.e., biochemical, immunologic, or molecular) for confirmation of *N. gonorrhoeae*.[438,652]

Gonochek II. The Gonochek II (EY Laboratories, San Mateo, CA) is a single tube that contains the three dehydrated chromogenic substrates (Image Plate 11-2A). After rehydration with four drops of phosphate-buffered saline (pH 7.4), 5 to 10 colonies of oxidase-positive, gram-negative diplococci from a pure culture growing on selective medium, or a suitable subculture, are emulsified in the tube with a wooden applicator stick. The tube is capped with the stopper and incubated at 35°C for 30 minutes. Specific color reactions in the bacterial suspension confirm the isolate as

N. meningitidis (hydrolysis of γ-glutamyl-*p*-nitroanilide; yellow) or *N. lactamica* (hydrolysis of 5-bromo-4-chloro-3-indoyl-β-D-galactopyranoside; blue). If the suspension is colorless at the end of the incubation period, the stopper is split apart

medium, or a suitable subculture, are emulsified in the tube with a wooden applicator stick. The tube is capped with the stopper and incubated at 35°C for 30 minutes. Specific color reactions in the bacterial suspension confirm the isolate as

642

N. meningitidis (hydrolysis of γ-glutamyl-*p*-nitroanilide; yellow) or *N. lactamica* (hydrolysis of 5-bromo-4-chloro-3-indoyl-β-D-galactopyranoside; blue). If the suspension is colorless at the end of the incubation period, the stopper is split apart and the top part of the stopper is inserted into the tube. The tube is inverted so that the bacterial suspension comes in contact with the diazo dye-coupler (o-aminoazotoluene diazonium salt [Fast Garnet]) present on the stopper. The detection of β-naphthylamine released by bacterial hydroxyprolyl aminopeptidase activity (red) identifies the isolate as *N. gonorrhoeae*. The absence of a colored product at the completion of the testing and reading steps provides a presumptive identification of *M. catarrhalis*. In a large evaluation of this system, the Gonochek II identified 99% of 176 gonococci, 97% of 173 meningococci, and 100% of 48 *N. lactamica* and 10 *M. catarrhalis*, respectively.[332] Other investigators have also evaluated Gonochek II and have found it reliable for identifying these organisms.[198] Isolates that lack the PIP or GGT enzymes will not be correctly identified by Gonochek II.[17]

BactiCard *Neisseria*. The BactiCard *Neisseria* (Remel Laboratories, Lenexa, KA) uses four chromogenic substrates that are impregnated on four individual test circles within a cardboard holder (Image Plate 11-2B). After moistening each of the four circles with a single drop of rehydrating fluid, several colonies of the organism taken from selective media (or from a subculture from selective media) are rubbed onto each of the four test areas. After incubation on the bench top for 2 minutes, the indoxyl butyrate esterase substrate circle (IB; 5-bromo-4-chloro-3-indolyl butyrate) is inspected for the appearance of a blue to blue–green color. If this test is positive, the organism can be identified as *M. catarrhalis*, and no further testing is necessary. If the IB test is negative, the card is incubated on the bench for an additional 13 minutes (total test time: 15 minutes). After this time, the β-galactosidase substrate circle (BGAL; 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside) is inspected for the presence of a blue–green color. If this test is positive, the organism can be identified as *N. lactamica,* and no further testing is necessary. If the BGAL test is negative, a single drop of color developer reagent is placed on the PIP (PRO; l-proline-β-naphthylamide) and the GGT (GLUT; γ-glutamyl-β-naphthylamide) test circles. These two tests are read as positive if a definite pink or red color develops within 30 seconds of reagent addition. A positive PRO reaction identifies the isolate as *N. gonorrhoeae,* whereas a positive GLUT reaction identifies the organism as *N. meningitidis*. The PRO reaction

Immunologic Methods for Culture Confirmation of N. gonorrhoeae

Coagglutination Test. Coagglutination tests make use of the ability of protein A on *Staphylococcus aureus* cells to bind IgG molecules by their Fc region. Binding of antigonococcal antibody to killed *S. aureus* cells, and subsequent mixture with a suspension of gonococci causes visible agglutination of the suspension.[25] Two coagglutination tests for the identification of *N. gonorrhoeae* are currently available—the Phadebact Monoclonal GC Test and the GonoGen I test. The Phadebact monoclonal GC coagglutination test (MKL Diagnostics AB, Sollentuna, Sweden; Remel [USA distributor]) employs monoclonal antibodies to gonococcal Por (protein I). Unlike the GC OMNI test previously marketed by Phadebact, the monoclonal GC test contains one reagent that reacts with serogroup WI *N. gonorrhoeae* strains, and a second reagent that reacts with serogroup WII/WIII strains. Because a negative control reagent is not included, gonococcal isolates will react with either the WI or the WII/WIII reagent, depending on the Por antigen composition of the individual isolate. Failure to agglutinate in either reagent constitutes a negative test. To perform the test, a suspension (0.5 McFarland turbidity standard) is prepared in buffered saline (pH 7.2 to 7.4) and is boiled for 5 minutes. After cooling, the suspension is mixed with test and control reagents on a cardboard slide. Agglutination within 1 minute is a positive test. A blue dye is incorporated in the reagents to help visualize agglutination against the white background of the card. Careful attention to procedural details is necessary in order to prevent false-positive and false-negative results. Evaluations of the previously available GC OMNI test reported sensitivities of 98% to 100% and specificities of 99% to 100%.[198,206,332]Organism suspensions heavier than the specified McFarland density, however, may yield false-positive results. In addition, the use of saline with a pH less than or greater than 7.4 has also been reported to produce false-positive results with some strains of *N. lactamica*, *N. cinerea*, and *M. catarrhalis*.[332,333] The GonoGen I coagglutination culture confirmation test for *N. gonorrhoeae* (New Horizons Diagnostics, Columbia, MD) is no longer commercially available.[350,394] In addition the direct fluorescent antibody culture confirmation test, as previously described,[588,687,692] originally marketed by Syva and subsequently by several other commercial vendors (lastly by Trinity Biotech, Wicklow, Ireland) has also been discontinued.

GonoGen II Test. The GonoGen II (New Horizons Diagnostics, Columbia, MD) uses anti-Por monoclonal antibodies that are conjugated to colloidal gold as the detection reagent. A suspension (McFarland no. 1) is prepared in 0.5 mL of an organism lysing solution, and 1 drop of the antibody reagent is added. After 5 minutes, 2 drops of the suspension are passed through a membrane filter that retains antigen-antibody complexes. Retention and concentration of the complex on the filter turns the filter

described,[588,687,692] originally marketed by Syva and subsequently by several other commercial vendors (lastly by Trinity Biotech, Wicklow, Ireland) has also been discontinued.

GonoGen II Test. The GonoGen II (New Horizons Diagnostics, Columbia, MD) uses anti-Por monoclonal antibodies that are conjugated to colloidal gold as the detection reagent. A suspension (McFarland no. 1) is prepared in 0.5 mL of an organism lysing solution, and 1 drop of the antibody reagent is added. After 5 minutes, 2 drops of the suspension are passed through a membrane filter that retains antigen-antibody complexes. Retention and concentration of the complex on the filter turns the filter red, identifying the organism as *N. gonorrhoeae*. Nongonococcal isolates result in the filter remaining white or pale pink. Janda and associates[333] found that the GonoGen II identified 91.8% of 194 *N. gonorrhoeae* strains; 5 strains were negative and 11 strains produced equivocal color reactions on the membrane. In addition, a meningococcal strain and two

643

N. lactamica isolates repeatedly produced false-positive test results. Kellogg and Orwig found that the GonoGen II identified 99.6% of 248 gonococcal strains, but 7 of 22 *N. meningitidis* strains produced false-positive test results, leading these investigators to suggest that positive GonoGen II test results need to be confirmed by another method.[350]

Multitest Identification Systems

Five kit systems are available that can be used not only for identifying *Neisseria* species but also for identifying other fastidious gram-negative organisms. These systems are the RapID NH (*Neisseria-Haemophilus*) system (Remel Laboratories, Image Plate 11-2C), the *Haemophilus-Neisseria* identification (HNID) panel (Dade/American Microscan, Sacramento, CA; Image Plate 11-2D), the API NH system (bioMerieux, Inc., La Balme-les-Grottes, France;Image Plate 11-2E, 11-2F, 11-2H), the BD Crystal *Neisseria-Haemophilus* ID kit (BD Diagnostic Systems, Sparks, MD) and the Vitek 2 *Neisseria-Haemophilus* (NH) identification card (bioMerieux, Inc., Hazelwood, MO).[53,206,328,529,658] All of these systems use modified conventional tests (e.g., acid production from carbohydrates, urease, indole, ornithine decarboxylase) and chromogenic substrates to provide either 2- to 6-hour identifications of *Neisseria*, *Haemophilus*, and other fastidious gram-negative bacteria encountered in clinical specimens. The MicroScan HNID panel does not include *N. cinerea* in its database, and these organisms are misidentified as either *N. gonorrhoeae*

identification.[53] The Crystal *Neisseria-Haemophilus* ID kit uses fluorescent substrates along with rapid conventional test to identify *Neisseria* and other organisms. The Vitek 2 NH card provides automated identification of *Haemophilus* and *Neisseria* species, along with several other fastidious gram-negative bacteria. Evaluations have shown that the NH card is able to identify the pathogenic *Neisseria* species and *M. catarrhalis* within 6 hours.[529,658]

DNA Probe Test for Culture Confirmation of N. gonorrhoeae

The Accuprobe *Neisseria gonorrhoeae* Culture Confirmation Test (Gen-Probe) identifies the *N. gonorrhoeae* by the detection of species-specific rRNA sequences. In the test, organisms from growth on agar media are lysed and mixed with a chemiluminescent-labeled single-stranded DNA probe that is specifically complementary to gonococcal rRNA. After hybridization occurs, the DNA probe/rRNA double-stranded complex is selected by a chemical process, and the presence of the probe in the double-stranded material is detected by addition of detection reagents that hydrolyze the chemiluminescent tag on the probe, thereby releasing light energy. This energy is detected in a chemiluminometer instrument, and the result is reported as positive or negative. In an evaluation conducted at the University of Illinois examining monoclonal antibody coagglutination procedures, the direct fluorescent antibody test, and the AccuProbe for *N. gonorrhoeae* identification, the latter test was the only procedure that was 100% accurate in identifying *N. gonorrhoeae*.[333] Similar results for the AccuProbe test have been reported by others.[715] This test may be particularly useful for confirming those isolates that may not be easily identified by other confirmatory test procedures.

Nucleic Acid Hybridization Tests for N. gonorrhoeae

Probe hybridization technology is also used in the currently available tests for direct detection of *N. gonorrhoeae* in urogenital specimens. One of the two direct hybridization assays, the PACE 2 (Hologics, San Diego, CA), has been discontinued. The remaining nucleic acid hybridization assay for direct use on clinical specimens is the Digene Hybrid Capture 2 CT/GC assay (Qiagen Gaithersburg, MD).

The Digene Hybrid Capture 2 assay uses signal amplification instead of target amplification to increase its sensitivity of detection. In this assay, target DNA becomes hybridized to sequence-specific RNA probes provided with the assay. Hybrid products are transferred to wells of a microtiter tray, where they become immobilized by antibodies in a microtiter well. A detection reagent, consisting of an antibody conjugate that is specific for RNA/DNA hybrids, is then added to each microwell. Multiple enzymes are conjugated to each of these antibody molecules, and many antibody molecules bind to each RNA/DNA hybrid, resulting in marked signal amplification

The Digene Hybrid Capture 2 assay uses signal amplification instead of target amplification to increase its sensitivity of detection. In this assay, target DNA becomes hybridized to sequence-specific RNA probes provided with the assay. Hybrid products are transferred to wells of a microtiter tray, where they become immobilized by antibodies in a microtiter well. A detection reagent, consisting of an antibody conjugate that is specific for RNA/DNA hybrids, is then added to each microwell. Multiple enzymes are conjugated to each of these antibody molecules, and many antibody molecules bind to each RNA/DNA hybrid, resulting in marked signal amplification upon addition of the chemiluminescent enzyme substrate. In a study performed with endocervical swab specimens from 1,370 women, the Digene assay demonstrated a sensitivity of 92.6% and a specificity of 98.5% compared with culture.[563] In an examination of 669 endocervical specimens, the Digene test performed with 92.2% sensitivity and greater than 99% specificity for detection of *N. gonorrhoeae* when compared with culture.[172] Van Der Pol and colleagues found that the Digene assay performed with a sensitivity of 100% and a specificity of 99% for detection of *N. gonorrhoeae* in endocervical swab specimens.[664]

Nucleic Acid Amplification Tests for N. gonorrhoeae

Several nucleic acid amplification assays (NAATs) are available for the direct detection of *N. gonorrhoeae* in clinical specimens (Box 11-5).[695] FDA-cleared tests employ various amplification approaches, including PCR (AMPLICOR *Neisseria gonorrhoeae* PCR, COBAS AMPLICOR *Neisseria gonorrhoeae* PCR, COBAS 4800 CT/NG test, Roche Molecular Diagnostics, Indianapolis, IN), strand displacement amplification (SDA) (BD ProbeTecET, BD Diagnostics, Sparks, MD) and TMA (APTIMA Combo 2, Gen-Probe, San Diego, CA), and real-time PCR (Abbott RealTime CT/NG,

Abbott Molecular Diagnostics, DesPlaines, IL). All of these NAATs detect both *N. gonorrhoeae* and *C. trachomatis*. None of the currently available NAATs are FDA-cleared for use with extragenital (i.e., oropharyngeal, rectal), pediatric, or ocular specimens, although studies have been performed addressing some of these specimen types (see below).

The AMPLICOR *N. gonorrhoeae* PCR assay and the automated COBAS AMPLICOR systems use conventional PCR-based amplification. For both AMPLICOR assays, the amplification target sequence in *N. gonorrhoeae* is a 201 base pair fragment of the cytosine DNA methyltransferase gene. The original nonautomated assay uses the Perkin–Elmer 9600 thermal cycler with subsequent amplicon detection by EIA using microwell plates that are coated with an oligonucleotide to capture the biotinylated amplicon products. The COBAS AMPLICOR is a benchtop automated system in which target DNA is amplified by a conventional PCR reaction using built-in thermal cyclers. Biotinylated amplification products are captured with magnetic particles that are coated with amplicon-specific oligonucleotide probes, and the products are detected colorimetrically using an avidin–

horseradish peroxidase conjugate.

Several studies have examined the performance of the AMPLICOR gonorrhea assay and most studies have documented sensitivities in excess of 90%.[144,399] While this assay has demonstrated greater than 90% sensitivity for the detection of *N. gonorrhoeae* in endocervical specimens, the clinical trial data showed that the test was less sensitive with urine specimens from females (i.e., 64.8%).[504] This has been seen in other evaluations of this system as well.[144,666] In a study of 344 urine and urethral swab specimens from males and 192 urine and endocervical swab specimens from females, Crotchfeldt and colleagues found that the sensitivity of the AMPLICOR PCR assay was 94.4% for male urine specimens and 97.3% for male urethral swab specimens, while the sensitivities of the assay for urine and endocervical swab specimens from women were 90% and 100%, respectively.[168] Assay specificities generally range from 95.9% to 98.5% for urine specimens and from 97.0% to 99.4% for swab specimens. A large multicenter evaluation of both the semiautomated AMPLICOR microwell assay and automated COBAS AMPLICOR assay examined 2,192 matched endocervical swab and urine specimens from women and matched urine and urethral swab specimens from 1,981 men.[437] The AMPLICOR microwell assay and the COBAS AMPLICOR yielded concordant results on 98.8% of the specimens and exhibited virtually identical sensitivities of 99.5% and 99.8% for endocervical swab and urine specimens from women, respectively, and 98.9% and 99.9% for male urethral swab and urine specimens, respectively. This assay has been reported to have false positives caused by nonpathogenic *Neisseria* species.[504] In a study examining the specificity of

the AMPLICOR microwell assay, Farrell found that 6 of 15 *N. subflava* strains produced positive results, including one strain that was isolated from a vaginal specimen.[236] Other studies, as well as the manufacturer, have also acknowledged that saprophytic neisseriae (e.g., *N. cinerea*, *N. subflava/sicca*, and *N. flavescens*) may produce positive, cross-reactive results in the AMPLICOR *N. gonorrhoeae* PCR assay.[504,538,663] This cross-reactivity may contribute to lower positive predictive values for this assay with urogenital specimens from certain populations. Because of these specificity problems, the CDC issued guidelines suggesting that additional testing for gonococcal infection be performed in situations where the positive predictive value of a test was expected to be lower than 90%.[128] Confirmatory testing with a more specific method such as 16S rRNA PCR should be considered in low-prevalence populations.[194]

Roche Molecular Systems markets the COBAS 4800 CT/NG test. This is an

automated multiplex PCR assay that detects plasmids of *Chlamydia trachomatis* and the DR-9 direct repeat sequence that is specific to *N. gonorrhoeae.* A randomized internal target sequence of nucleic acid is added to each specimen as an internal control to minimize false-negative results due to amplification inhibition. An evaluation performed in Australia tested 419 specimens (318 urine and 180 swab specimens) on the COBAS 4800 system and compared the results with those obtained with the Roche AMPLICOR PCR assay.[539]Specimens that were positive for *N. gonorrhoeae* were confirmed with an in-house real-time PCR assay. For urine specimen, the sensitivity, specificity, and negative and positive predictive values for *N. gonorrhoeae* were 92.9%, 100%, 99.7%, and 100%, respectively. For swab specimens, the corresponding values were 100%, 99.4%, 100%, and 90%, respectively. An assessment of test specificity was performed using a panel of 223 other *Neisseria* isolates, and no nongonococcal *Neisseria* strains were positive with the 4800 assay. A second study evaluating the specificity of NAATs tests also found no false-positive reactions with other *Neisseria* species for the COBAS 4800 assay.[612]

The BD ProbeTec ET system uses SDA rather than PCR for amplification, so all testing is performed isothermally without the need for a thermal cycler.[413] The system has a higher throughput than other amplification methods, with a capacity to perform 300 assays in an 8-hour shift. The system also has options for test performance and interpretation both with and without an amplification control, and uses reagents that can be stored at room temperature. In this assay, the amplification target is in the chromosomal pilin gene-inverting homologue, which is already present in multiple copies in the gonococcal cell.[112] The ProbeTec ET is approved for the detection of *Neisseria gonorrhoeae* in female endocervical, male urethral, and female and male urine specimens. Studies have documented sensitivities of greater than 96% for endocervical, male urethral, and male urine specimens, but lower sensitivity for urine specimens from females. Van Der Pol and associates[662] evaluated the ProbeTec ET with both swab and urine specimens from men and women. For swab and urine specimens from women, the sensitivities of the ProbeTec ET system were 96.6% and 84.9%, respectively. For swab and urine specimens from men, the sensitivities of the ProbeTec ET were 98.5% and 97.9%, respectively. Specificities ranged from 94.4% to 100% for urine specimens and from 94.8% to 99.6% for swab specimens. In another evaluation of the ProbeTec ET with 733 endocervical swab specimens from commercial sex workers in Belgium, the SDA procedure performed with a sensitivity of 90% and a specificity of 100% compared with culture.[667] In a study of 3,544 urine specimens submitted for *N. gonorrhoeae* testing, Akduman and colleagues found that the sensitivity and specificity of the ProbeTec ET were 99.2% and 99.3%, respectively, in a population with a prevalence of 3.6% by culture.[10]Another evaluation performed in Canada with urine specimens from 825 males and 399

females compared the ProbeTec ET with the Roche COBAS AMPLICOR PCR and found that the SDA procedure was 100% sensitive and 99.7% specific, while the PCR assay was 96.7% sensitive and 98.9% specific.[144] Like the AMPLICOR assays for *N. gonorrhoeae*, the BD ProbeTec ET also can yield false-positive reactions with several nongonococcal *Neisseria* species.[504] Subsequently, BD Diagnostics marketed the BD Viper System, which automates previously manual and semiautomated steps of the BD ProbeTec ET assays for *N. gonorrhoeae* and *C. trachomatis* testing.[516,630] With this automated approach, incubations, amplification, and detection all occur on the BD Viper System, with repetitive pipetting labor relegated to a robotics system.

The APTIMA Combo 2 assay uses isothermic TMA for detection of gonococci and chlamydiae in female endocervical and male urethral swab specimens and first-voided male and female urine specimens. This NAAT amplifies gonococcal 16S rRNA, and uses a chemiluminescent single-stranded DNA probe for detection of the amplified product. This test is perhaps the most sensitive NAAT for detection of *N. gonorrhoeae,* with sensitivities above 97% for endocervical specimens, male urethral specimens and urine specimens from males, and above 91% for urine specimens from females. Gaydos and colleagues evaluated this assay system with both endocervical swabs and urine specimens submitted for detection of *N. gonorrhoeae*.[262] The sensitivity and specificity of the APTIMA system were 99.2% and 98.7%, respectively, for endocervical swab specimens, and 91.3% and 99.3%, respectively, for first-collected urine specimens. This assay has undergone several evaluations, including the use of physician- and self-collected vaginal swabs for organism detection.[149,150] The APTIMA test also appears to be less susceptible than other amplification assays to inhibitors of amplification that are usually found in urine specimens. In addition, false-positive reactions with saprophytic *Neisseria* species have not been observed with the APTIMA assay.[275] Gen-Probe also markets a *N. gonorrhoeae* stand-alone NAAT (Gen-Probe AG) that detects a slightly different gene target of the 16S rRNA subunit; this assay can be used to confirm positive gonorrhea results obtained with the combo assay.[275] The AG assay has demonstrated a sensitivity of 99.4% to 100% for urethral swab specimens from both symptomatic and asymptomatic males, with corresponding specificities of 97.1% to 97.5%. Sensitivities and specificities for the AG assay with first-voided urine specimens were 90.9% to 99.4% and 99.0% to 99.5%, respectively.[150]

The Abbott RealTime CT/GC assay is a PCR assay for direct qualitative detection of the opacity (*opa*) gene of *N. gonorrhoeae* and plasmid DNA of *C. trachomatis.* The Abbott CT/NG uses an automated sample preparation platform (m2000sp) that enables magnetic microparticle DNA

capture/extraction. An internal control is added to each sample, and postextraction, the template DNA and master mix is dispensed into an optical reaction plate. This plate is transferred to a real-time PCR instrument (m2000rt) for amplification. The test is approved for female endocervical swab, clinician-collected vaginal swab, and self-collected vaginal swab specimens, male urethral swab specimens, and male and female urine specimens from symptomatic patients. This test has also been cleared for testing clinician-collected and patient-collected vaginal swab specimens and female and male urine specimens from asymptomatic patients. In a side-by side evaluation of the Abbott RealTime PCR, Gen-Probe TMA, and BD ProbeTec ET SDA assays on 500 first-void urine specimens, the sensitivity of the RealTime assay was 96.9%, compared with 99% for TMA and 98% for SDA. RealTime PCR and TMA demonstrated 100% specificity while SDA showed a specificity of 99.5%.[400] In a large, multicenter study, real-time PCR was evaluated and compared to TMA, SDA, and culture as reference assays to determine the infection status of the patient.[261] The evaluation included all approved specimens types. The overall sensitivity and specificity of the Abbott RealTime PCR assay for *N. gonorrhoeae* were 96.9% and 99.7%, respectively. In comparison, the sensitivity and specificity for the TMA assay were 96.1% and 99.5%, respectively, while those for the SDA assay were 92% and 97.3%, respectively. Comparison of this real-time system with an in-house real-time *porA* pseudogene assay showed 100% concordance for male urine specimens with corresponding urethral swab specimens and some male rectal specimens as well.[686] Cheng and colleagues compared the Abbott RealTime assay with the Roche COBAS AMPLICOR PCR assay with endocervical and male urethral swab specimens and male and female urine specimens from 1,384 patients.[146] In this study all positive AMPLICOR PCR assays were confirmed by an in-house real-time PCR assay for the *por* A pseudogene. After resolution of results obtained with the Roche test there was complete agreement between the positive and negative test results. These workers also pointed out an enhanced ability of the RealTime CT/NG assay to detect dual infections. Specificity studies on the Abbott RealTime assay showed low-level cross-reactivity with single strains of *N. meningitidis* and *N. mucosa.*[612]

One of the newest NAAT for *N. gonorrhoeae* and *C. trachomatis* detection is the Versant CT/GC DNA 1.0 assay (Siemens Healthcare Diagnostics, Berkeley, CA). This is a "kinetic PCR" system that consists of a sample preparation module for automated specimen preparation and processing, and a real-time PCR amplification/detection module. The assay is performed on the Versant kPCR system. This assay was compared to the APTIMA Combo 2 TMA assay using 1,129 patient specimens (589 urine and 540 swab specimens).[357] For detection of *N. gonorrhoeae*, the agreement between the Versant assay and TMA was 100% for the positive urine and swab specimens, and the agreement for negative specimen was 99.6% for urine specimens and 99.0% for swab specimens. The Versant assay did not demonstrate any cross-

reactivity with nongonococcal *Neisseria* species, other bacteria, or yeasts. This assay is not yet FDA-cleared for use in the United States.

Even though NAATs are not currently FDA-cleared for diagnosis of gonorrhea and *Chlamydia* infections at extragenital body sites, several studies evaluating the utility of NAATs in the diagnosis of rectal and pharyngeal gonococcal infections have been done, particularly in populations of MSM.[54,528] In many studies, NAATs were compared to culture and were found to be equivalent to or far more sensitive than culture methods. Some studies performed culture plus all three commercially available NAAT systems (i.e., PCR, SDA, and TMA) and defined a "true positive" using a rotating standard where 3 of 4 comparator tests were positive. Bachmann and colleagues evaluated culture and NAATs for diagnosis of oropharyngeal gonorrhea with 961 evaluable specimens from patients with a history of oral–genital sex in the previous two months.[46] Using the defined standard described above, the sensitivity of culture, PCR, SDA, and TMA were 65.4%, 91.9%, 97.1%, and 100%, respectively. The specificity of culture was 99%, and the specificities of SDA and TMA were 94.2% and 96.2%, respectively. The specificity of the AMPLICOR PCR was only 71.8%, which may be related to the detection of saprophytic *Neisseria* species in the oropharynx described previously for the AMPLICOR assay. Bachmann and coworkers[47] also evaluated NAATs for the diagnosis of rectal gonococcal infection and used the same rotating standard to evaluate the results. For rectal (n = 441) specimens, the sensitivity of culture, PCR, SDA, and TMA were 71.9%, 95.8%, 100%, and 100%, respectively. The specificity of culture was 99.7% and ranged from 95.5% to 96% for the three NAATs. These workers concluded that the currently available NAATs were more sensitive for the detection of gonococcal infections than culture at rectal and oropharyngeal sites, that PCR, TMA, or SDA could be valuable for diagnosis of rectal gonococcal infections, and that TMA and SDA but not PCR could reliably detect oropharyngeal gonococcal infections. Other studies have found similar results.[399,499,501] Because of high specificity, TMA appears particularly useful for detection of gonococcal oropharyngeal and rectal infections. PCR, on the other hand, appears to have a lower sensitivity than either TMA or SDA for detection of extragenital gonococcal infections. Because these test systems are not FDA-cleared for testing oropharyngeal or rectal specimens, this use is considered "off-label" and CLIA verification of NAAT performance is required prior to their use for diagnosis of gonococcal infections at extragenital sites. Many workers in the STD field feel that NAATs may play an important role in the diagnosis of extragenital gonococcal infections that may be missed by traditional methods and that these tests may be critical for effective public health intervention in sexually active populations.[455,528,564]

The use of nucleic acid-based methods for detection of *N. gonorrhoeae* in clinical specimens has both advantages and disadvantages. The advantages include the demonstrated superior sensitivity of these methods compared with culture, the ability

to test easily collected specimens (i.e., urine, self-collected vaginal swabs), and more rapid turnaround times. While gonococcal culture ranges from 85% to 95% in sensitivity, the increased sensitivity of NAAT approaches make them highly suitable for patient screening.[259]Testing of urine in place of endocervical or urethral swab specimens makes collection easy and does not require special collection equipment or entailed collection instructions. Lastly, organisms do not need to be viable in order to detect the nucleic acid, so less stringent collection and transport conditions can be used in comparison with culture-based testing. Disadvantages

647

include the cost of the assays (including equipment and expendables), the need for separate, dedicated space for specimen processing/test performance and modifications of laboratory workflow to prevent amplicon contamination of the instrumentation and the environment. A very real "down side" to the widespread use of these non–culture-based assays is the unavailability of gonococcal isolates for surveillance of emergent resistance to antimicrobial agents. Lastly, different gonococcal strains may have altered target gene sequences, or nongonococcal *Neisseria* species may have genes that are also present in certain gonococcal strains, leading to both false-negative and false-positive results. Despite the high specificities of these assays, their performance in low-prevalence populations requires additional study. As mentioned previously, the CDC has suggested that positive NAAT results should be confirmed in populations where the test has a positive predictive value of less than 90%.[128] Confirmation may involve repeating the original NAAT on the same specimen, repeating the original test on the original specimen with quenching by a competitive probe, testing the original specimen with an NAAT that detects a different gonococcal gene target, or testing a second specimen with a second NAAT that is different from the initial NAAT and that detects a different gonococcal gene sequence.[128] Some workers have recommended confirmatory testing with more specific molecular methods targeting gonococcal 16S rRNA or genes that are "specific" for *N. gonorrhoeae* (e.g., the *cppB* gene, the *porA* pseudogene, multicopy *opa* genes) for positive amplified test results obtained in populations with a low prevalence of gonorrhea.[194,271,306] However, even some of these gene targets, such as the *cppB* gene, show considerable differences in prevalence in gonococcal strains in different parts of the world.[98,422] Dual-target molecular assays targeting more than a single gonococcal gene (e.g., the *porA* pseudogene and conserved multicopy *opa* genes) may decrease the potential for sequence-related, false-negative results and may provide greater confirmatory power.[271,306,433] An evaluation of the CDC confirmatory approaches conducted in San Francisco found that 89% to 96% of samples positive by SDA, PCR, and TMA were confirmed by

repeat testing of the same specimen and that 85% to 98% of SDA, PCR, and TMA results were confirmed by using different NAATs on the original specimen. For first-void urine specimens from men, any NAAT could be used for confirmation, but for other specimen types some NAATs could not be used to confirm positive results with other NAATs.[459] Other workers have also found that some NAATs cannot be used to confirms the results of other NAATs due to different specimen extraction steps and other procedural details.[16,294] Because of specificity problems with NAATs in low-prevalence populations, none of these assays can be used to document gonococcal or chlamydial infections in children, since a false-positive result for a sexually transmitted infection can lead to erroneous reports of sexual abuse, with far-reaching legal consequences.[291,292] However, a 2009 multicenter study found that NAAT testing of urine specimens from prepubertal children undergoing evaluation for sexual abuse had high sensitivity and specificity, and that a positive NAAT confirmed with an alternate gene target NAAT may be the best method and approach for detection of *N. gonorrhoeae* in children suspected of being sexually abused.[74]

MALDI-TOF for Identification of Neisseria Species

Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry is an emerging method for the identification of bacterial agents and has been applied to a wide variety of organisms, including *Neisseria* species.[470] Ilina and colleagues examined 29 *N. gonorrhoeae*, 13 *N. meningitidis*, and 15 saprophytic *Neisseria* species isolates using MALDI-TOF.[321] Mass spectra profiles of *N. gonorrhoeae* and *N. meningitidis* showed limited intra-species variability and comparisons of the spectra between species revealed numerous significant differences. Alignment of the main spectra clearly separated isolates of *N. gonorrhoeae*, *N. meningitidis*, and the nonpathogenic species that were tested (*N. lactamica*,*N. mucosa*, *N. subflava* biovars, *N. elongata*, *N. polysaccharea*, and *N. sicca*). MALDI-TOF has also been used to characterize and differentiate meningococcal isolates belonging to specific enzyme (ET) and ST complexes.[420] MALDI-TOF shows promise as a rapid, inexpensive method for identification of *Neisseria* species.

Sexual Abuse/Assault and N. gonorrhoeae

Because of the medical–legal issues that are raised after isolating *N. gonorrhoeae* from a child, and the recovery of gonococci from both genital and nongenital body sites, proper identification of isolates is imperative. Whittington and associates[696] reported on 40 bacterial isolates from children younger than 15 years of age that had been identified as *N. gonorrhoeae* and that were referred to the CDC for confirmation. Fourteen (35%) of these strains had been misidentified by the originating laboratory,

including 4 *N. cinerea*, 3 *N.lactamica*, 2 *N. meningitidis*, 3 *M. catarrhalis*, 1 *K. denitrificans*, and an unidentified nongonococcal *Neisseria* species. In 10 of the 14 cases, the organisms were isolated from children for whom there was no supporting evidence of sexual abuse. In many instances, the laboratories reporting these isolates were using the commercial kits described earlier for identification of *N. gonorrhoeae*. As mentioned previously, some commercial carbohydrate utilization test systems may produce false-positive glucose reactions for *N. cinerea*, which could lead to the misidentification of this species as *N. gonorrhoeae*.[91] Coagglutination tests, although generally quite reliable, may produce false-negative results with some gonococcal strains and may also show false-positive results with some isolates of other *Neisseria* or related species, including *N. lactamica*, *N. cinerea*, and *M. catarrhalis*. Procedural details for these tests differ among manufacturers, and package insert instructions must be followed closely. Enzymatic tests for detection of gonococcal prolyl iminopeptidase (PIP) must be used only for those neisserial isolates that are able to grow well on selective media. Some *N. cinerea* strains and occasional isolates of *N. subflava* bv. *perflava* may be recovered on selective media and may also be positive for prolyl -iminopeptidase in commercial systems.[329] Isolates recovered from oropharyngeal sites may be particularly troublesome. *N. lactamica*, a species that grows well on selective media and that may be misidentified as *N. gonorrhoeae*, colonizes the oropharynges of almost 60% of children between the ages of 1 and 4 years.[272]

648

As mentioned previously, the CDC recommends that presumptive isolates of *N. gonorrhoeae* recovered from children, regardless of the site of isolation, should be confirmed by at least two tests that involve different principles. These may include carbohydrate utilization tests, immunologic methods (e.g., monoclonal antibody coagglutination tests), enzymatic procedures (e.g., chromogenic detection of specific enzyme activities), or the DNA probe culture confirmation test (AccuProbe *Neisseria gonorrhoeae*, Gen-Probe). Nonculture techniques, such as nucleic acid hybridization and NAATs, are investigational tests in children, so positive results with these assays must be confirmed with a culture. If a laboratory is unable to establish a definitive identification, the isolate should be sent to a reference laboratory for further testing. If possible, the isolate should also be saved in the event additional testing is needed. This can be accomplished by removing the growth from a few chocolate agar plates, suspending the growth in 1 to 2 mL of decomplemented horse serum:brain–heart infusion broth (1:1), and storing at −70°C.

Typing Methods for N. gonorrhoeae

Although the identification systems discussed in the previous section of this chapter and the biochemical characteristics in Table 11-2 are reliable for the routine identification of *N. gonorrhoeae* in the clinical laboratory, other techniques have contributed greatly to our understanding of the biology and epidemiology of the gonococcus. One of the first methods used for typing of gonococcal strains was auxotyping. Auxotyping of *N. gonorrhoeae* is based on the requirements of different *N. gonorrhoeae* strains for various nutritional requirements such as amino acids, purines, pyrimidines, and vitamins.[110,118] This method uses a completely chemically defined medium. Comparison of growth on the complete medium compared with media having individual deletions of these growth constituents define the auxotype. For example, if a strain failed to grow on the defined medium without proline, that strain was defined as a proline-requiring auxotype. Auxotyping was still being regularly used when serovar typing methods were described. Serovar typing is based on the antigenic differences of the PorB (also called PorI) OMPs encoded by the *porB* gene of *N. gonorrhoeae*.[373,656]Serovars are determined by coagglutination using a panel of monoclonal antibodies. With the serovar typing system used at the CDC *Neisseria* Reference Laboratory, two coagglutination reagents initially divided all gonococcal strains into two groups that expressed either the PorIA or the PorIB epitope. Strains that expressed PorIA were subdivided into 18 serovars, while strains that expressed PorIB were subdivided into 28 serovars.[373] Serovar determinations by coagglutination have higher discriminatory power than auxotyping and both methods were often used together (i.e., A/S, auxotype/serovar typing) to augment the auxotyping data and provide even more discriminatory power. Serovar typing was fast and easy to do, but reproducibility, subjectivity of reading coagglutination reactions, and the increasing prevalence of nontypeable strains due to changes in PorB proteins over time were distinct disadvantages of serovar typing. In addition, reagents for serovar typing are now either unavailable or too expensive. Both auxotyping and serotyping have been largely supplanted by molecular-based typing approaches.

Molecular typing methods for *N. gonorrhoeae* are generally more reproducible and provide better discrimination between and among gonococcal strains than auxotyping or serotyping. Adaptation of several gel analysis-based methods used to characterize other organisms have been applied to typing of gonococcal isolates These techniques included plasmid content analysis, and restriction fragment length polymorphism (RFLP) fingerprinting using pulsed-field gel electrophoresis (PFGE), ribotyping, and Opa typing. Plasmid analysis initially defined the characterization of some strains and included molecular weight determinations, and plasmid sequence analysis. This technique resulted in the discovery of cryptic plasmids, plasmids carrying genes for β-lactamase production and tetracycline resistance, and gonococcal plasmids that contained genetic information enabling gene transfer between strains (i.e., conjugative plasmids).[199,200,467] However, the ability of this method to differentiate gonococcal

strains was insufficient due to acquisition and loss of plasmids over time. RFLP/PFGE methods involve digestion of cellular DNA with rare-cutting restriction enzymes and subsequent separation of DNA fragment by gel electrophoresis. This method is highly discriminatory and can be used to define populations of gonococci, identify clusters in defined geographical areas, and in forensic evaluations.[184,649,709] The disadvantages of RFLP/PFGE approaches include cost, long turnaround times for results, and the need for considerable expertise in performing and interpreting the results. Ribotyping is a typing technique in which rRNA nucleic acid probes are used to detect ribosomal DNA sequences in gonococcal chromosomal DNA following restriction endonuclease digestion and DNA fragment separation by RFLP. This method has its greatest utility when coupled with other typing methods, but it is expensive and labor intensive to perform.[405,480] Opa typing involves amplification of the eleven *Opa* genes followed by restriction endonuclease digestion and gel elecrophoresis.[496] This method, like RFLP/PFGE methods is labor intensive, has a long turnaround time, and is not highly standardized. Nevertheless, *Opa* typing has been used to define gonococcal populations and clusters, to trace organism transmission, and to discriminate reinfection from treatment failures.[378,503] Opa typing may provide greater discriminatory ability when coupled with other sequence-based typing methods.[466,682] Typing of the *lip* gene has been used similarly to *Opa* typing.[639] This method involves amplification and sequencing of the *lip* genes, which encode an outer membrane lipoprotein of 18- to 30-kDa molecular weight that is found in all gonococci. Three *lip* genes have been identified and sequenced. The nucleotide sequences of these genes predict peptides that consist of an amino acid pentamer that is repeated 13 to 19 times. Variations in the numbers of lip repeats in a sequence, and the nature of the sequences themselves, can be used along with auxotype, serovar, antimicrobial susceptibilities, and other characteristics, to construct a highly discriminatory system for typing of individual isolates. Lip typing has been used along with PFGE in investigations of sexual abuse of children.[184]

Several gonococcal typing methods are based on sequence analysis of specific genes, and include *porB* sequencing, NG-MAST, and MLST. Full or partial sequence analysis of the *porB* gene provides a reproducible and highly discriminatory method for strain typing. *porB* sequencing has been used

to define regional gonococcal strains, identify disease contacts, and for study of gonococcal population genetics.[409,651] Sequencing of the *porB* gene can be accomplished by a variety of methods, including automated DNA sequencing instrumentation and pyrosequencing. The *porB* ST, based on sequencing of a specific

490 base pair region of the *porB* gene, is also a part of another typing method called *N. gonorrhoeae* multiantigen sequence typing (NG-MAST).[440] The NG-MAST approach uses sequence analysis of the variable internal fragments of the *porB* gene (490 base-pairs) and the *thpB* gene (390 base-pairs), which encodes the B-subunit of the transferrin-binding protein. NG-MAST is reproducible and provides robust discrimination between and among gonococcal strains, thereby providing unambiguous data that can be standardized for global comparisons of gonococcal strains. Because of the reproducibility of this method and the ease of performance, an online database of numbered STs is available to researchers (http://www.ng-mast.net). Strains with identical ST or NG-MAST types can be further differentiated by any of the methods already described (e.g., Opa typing, PFGE, etc.).[406,466] NG-MAST has been used for definition and identification of populations and clusters of *N. gonorrhoeae*, contact tracing, investigation of treatment failures, and forensic investigations.[72,182,406] MLST involves sequencing of seven or more conserved housekeeping genes.[510,681] MLST is a reproducible typing method, although the use of more than seven genetic loci may be necessary to provide greater discriminatory power when examining large numbers of strains. MLST has also been used to study the evolution of the gonococcus as a species over time.[65]

Molecular Methods for Detection of N. meningitidis

Molecular methods for direct detection of *N. meningitidis* in clinical specimens have also been described, but none are commercially available.[197] Lansac and colleagues described genus- and species-specific PCR identification assays using primer pairs derived from the aspartate β-semialdehyde gene (*asd*) of *Neisseria* species and a conserved OMP gene (*ctrA*) of *N. meningitidis*, respectively.[387] The first assay was 100% specific for identification of 321 of 322 strains representing 13 *Neisseria* species, while the second assay amplified DNA from 256 *N. meningitidis* isolates belonging to nine different serogroups. It is important that molecular assays detect the known serotypes as these are not predictable by location, as evidenced by Ibarz-Pavón and the SIREVA working group, which denoted that serogroup distribution is highly variable among Latin American and Caribbean countries.[255] Several PCR assays have also been described for direct detection of meningococci in clinical specimens. During an ongoing epidemic of serogroup B disease that began in Chile in 1987, Saunders and his research group developed a nested PCR assay that amplified the *porA* gene encoding the subserotype-specific protein.[561] Use of this assay on CSF specimens during the epidemic resulted in a test sensitivity of 96.7% with a specificity of 100%.[560] Molecular assays have been designed that detect the meningococcal insertion element IS*1106*, but, due to the mobility of these sequences and the

possibility of transfer to other neiserriae, molecular detection of IS*1106* may result in false-positive tests.[85] PCR methods that amplify multiple capsular polysaccharide genes (e.g., *ctrA* PCR assay) or that amplify serogroup-specific genes (e.g., the *siaD* PCR assay) have also been described.[83,84,401,402,519] Taha described a PCR assay performed directly on CSF for simultaneous meningococcal detection and serogrouping. The detection assay amplified a conserved gene involved in the regulation of meningococcal adherence to target cells (*crgA*), while a simultaneous multiplex PCR assay was performed with oligonucleotides in the *siaD* genes for serogroup B, C, Y, and W135 detection and in the *orf-2* gene cassette required for serogroup A capsular biosynthesis for serogroup A detection.[614]Orvelid and colleagues described a PCR-based method for detection of serogroup A meningococci in CSFs.[497] This assay used primers and probes specific for the gene cassette encoding the (α1-6)-linked *N*-acetyl-D-mannosamine comprising the serogroup A capsular polysaccharide. LightCycler-based PCR assays also have been described that are able to detect, identify, and perform *porA* gene serosubtyping of *N. meningitidis* directly from clinical specimens.[458]

Serogrouping and Typing of N. meningitidis

Identification procedures for meningococci (and gonococci as well) produce the best results when inoculated from fresh 18- to 24-hour subcultures on chocolate or blood agar. In carbohydrate utilization confirmatory tests, the acidic reaction in the maltose tube will frequently be stronger than that in the glucose tube because maltose is degraded by the organism to two glucose molecules, which are then metabolized. Glucose-negative, maltose-negative, and asaccharolytic *N. meningitidis* strains may also be occasionally isolated. An unusual maltose-positive, glucose-negative strain of *N. meningitidis* has also been recovered from a patient with septicemia.[690] If such biochemically aberrant strains are recovered, chromogenic substrate confirmatory tests or serogrouping of the isolates should be performed.

Slide agglutination is the most commonly used technique for serogrouping meningococci. A dense suspension of the organism is prepared in 0.5 to 1.0 mL of phosphate-buffered saline (PBS), pH 7.2, from a 12- to 18-hour subculture on trypticase–soy blood agar. One drop of this suspension is mixed with one drop of meningococcal antisera on a sectored slide, and the slide is rotated for 2 to 4 minutes. Groupable strains will generally agglutinate strongly within this time. Although isolates from systemic infections will usually agglutinate rapidly, those from carriers may fail to agglutinate (nongroupable strains) or may autoagglutinate in PBS. Use of younger cultures from blood agar (6 to 8 hours) or use of a serum-enriched media, such as trypticase–soy agar containing 10% decomplemented horse serum, may resolve these problems. Antisera for the major meningococcal serogroups are available from BD

Diagnostic Systems. Some of these nongroupable strains may actually be *N. polysaccharea*; testing for production of polysaccharide from sucrose will help identify this species (see later discussion).[88] Rare strains of *N. meningitidis* may also produce polysaccharide from sucrose due to acquisition of the gene for amylopectin production from *N. polysaccharea* by horizontal gene exchange.[723]

650

In addition to serogroup determinations, *N. meningitidis* isolates may also be serotyped and serosubtyped on the basis of their OMP and LOS antigens. These techniques are used mainly for investigations of epidemics and sporadic outbreaks of disease and are not amenable for use in routine clinical microbiology laboratories. In addition to serologic techniques, several molecular techniques have been applied to investigations of meningococcal disease and to the epidemiology of *N. meningitidis* strains. These techniques were described in an earlier section of this chapter (see **Meningococcal Epidemiology: Serogroups, Serotypes, and Serosubtypes**).

Cultural Characteristics of Other *Neisseria* Species

The following sections present helpful features for the laboratory identification and characterization of the gram-negative cocci. Suggestions for the performance of differential and confirmatory tests described in detail in the previous section plus additional test procedures are also outlined. Characteristics for identification of *Neisseria* species and *M. catarrhalis* are shown in Table 11-2.

N. lactamica

N. lactamica resides in the upper respiratory tract and is found more frequently in children and adolescents than in adults.[49] *N. lactamica* grows on selective media and produces acid from glucose, maltose, and lactose. ONPG is also hydrolyzed and can be used as a substitute for lactose in the test battery. Some strains of this organism have been reported to cause false-positive reactions with some commercial coagglutination tests.[334,335] Penicillin-resistant strains of *N. lactamica* contain an altered PBP 2 that is similar to the PBP 2 found in relatively penicillin-resistant strains of *N. meningitidis*, suggesting that commensal species like *N. lactamica* (and *N. polysaccharea*) are the source of genetic resistance determinants currently being found in meningococci and gonococci.[421,551] A 2002 study of 286 *N. lactamica* isolates

found that all strains were considered to have intermediate susceptibility to penicillin (MIC 0.25 μg/mL), that 1.7% were resistant to ampicillin, and that 2.1% had decreased susceptibility to ciprofloxacin.[39] All isolates were susceptible to cefotaxime and ceftriaxone.

N. cinerea

Colonies of *N. cinerea* resemble the large-colony types of *N. gonorrhoeae* and may yield results consistent with *N. gonorrhoeae* in some kit identification systems.[91] *N. cinerea* grows on both blood and chocolate agar. On chocolate agar after 24 hours' incubation, colonies are about 1 mm in diameter and are smooth with entire edges. The organism does not produce acid from carbohydrates in either CTA-based media or the rapid carbohydrate degradation test. Weak positive reactions with glucose after overnight incubation have been reported in some identification systems and the positive hydroxyprolyl aminopeptidase reaction may also result in misidentifications of *N. cinerea* as *N. gonorrhoeae*. Most *N. cinerea* isolates, however, do not grow well on MTM or other selective media, which precludes testing of this organism on chromogenic substrate tests such as the Gonochek and the BactiCard *Neisseria*. *N. cinerea* can be differentiated from the asaccharolytic species *N. flavescens* by its inability to produce polysaccharide from sucrose (see later discussion) and the lack of a discernible yellow pigment. This species can also be separated from *M. catarrhalis*, another asaccharolytic species, by its negative reactions for nitrate reduction, DNase, and tributyrin hydrolysis (Table 11-2). A helpful test for differentiating *N. cinerea* from *N. gonorrhoeae* is the **colistin susceptibility test**. A suspension of the organism (0.5 McFarland turbidity standard) is prepared in broth and is swabbed onto a chocolate or blood agar plate as for a disk diffusion susceptibility test. A 10-mg colistin disk is placed on the inoculum, and the plate is incubated in CO_2 for 18 to 24 hours. N. cinerea is colistin-susceptible and will have a zone that is larger than or equal to 10 mm around the disk. Generally, *N. gonorrhoeae* will grow up to the edge of the disk.

Neisseria subflava *biovars*, N. mucosa, *and* N. sicca

Identification of the "nonpathogenic" *Neisseria* species is not generally necessary unless the organism is determined to be clinically significant, or if the organism is isolated from a systemic site (e.g., blood, CSF) or in pure culture. Identification is based on colony morphology, growth on simple nutrient medium, inability to grow on selective media, acid production from carbohydrates, reduction of nitrate and nitrite, and synthesis of a starch-like, iodine-staining polysaccharide from sucrose. **Nitrate reduction** and **nitrite reduction** are determined in medium (tryptic soy or heart infusion broth) containing 0.1% (w/v) KNO_3 and 0.01% (w/v) KNO_2, respectively. **Polysaccharide synthesis** is determined by inoculating the organism onto brain–heart

infusion agar containing 5% sucrose. Medium lacking sucrose is inoculated as a negative control. After incubation at 35°C for 48 hours, the plates are flooded with Gram's or Lugol's iodine (1:4 dilution). A positive test is indicated by the development of a deep blue color in and around the colonies synthesizing the polysaccharide. We have also obtained excellent results by adding regular Gram's iodine (1 to 2 drops) to the sucrose-containing tube in the rapid carbohydrate degradation technique after 4 hours incubation. If positive, a deep blue color appears in the tube. This is compared with the tan color seen in the other carbohydrate tubes (e.g., the maltose tube) after addition of Gram's iodine.

Strains of *N. subflava* can be subdivided into three biovars (*subflava*, *flava*, and *perflava*) on the basis of acid production from fructose and sucrose and synthesis of iodine-positive polysaccharide from sucrose (Table 11-2). All three biovars reduce nitrite, but not nitrate. *N. mucosa* has a carbohydrate utilization pattern similar to *N. subflava* bv. *perflava* and also produces the iodine-positive polysaccharide, but *N. mucosa* is able to reduce both nitrate and nitrite to nitrogen ($N_{2)}$ gas. All of these organisms also display varying degrees of yellow pigmentation. The *N. sicca* strains are biochemically identical with *N. subflava* bv. *perflava*, but they characteristically form dry (desiccated), adherent, leathery colonies on agar media that cannot be emulsified readily.

651

N. polysaccharea

N. polysaccharea is found in the human oropharynx. This organism is an oxidase-positive, catalase-positive, gram-negative diplococcus that forms smooth yellow colonies.[520] In the original description of this organism, the ability to grow on selective media (e.g., MTM agar) was a key characteristic. Subsequent studies indicate, however, that growth on selective media for the pathogenic *Neisseria* is a variable characteristic of *N. polysaccharea* because of the colistin susceptibility of some strains.[23] Strains that are able to grow on selective media have colistin MICs of 64 µg/mL or greater, whereas strains that are inhibited have colistin MICs of 1 µg/mL or less. After 24 hours growth, *N. polysaccharea* forms colonies of about 2 mm in diameter on chocolate or blood agar. Acid is produced from glucose and maltose but not from fructose or lactose. Acid production from sucrose is variable and appears to depend on the types of media used to determine this characteristic. *N. polysaccharea* also possesses an amylosucrase that synthesizes an acidic extracellular polysaccharide from sucrose.[105,520] The polymer is composed mainly of α1,4-linked D-glucopyranosyl residues along with about 6% O-substituted α4,6 D-glucopyranosyl branch points.[539] Production of various amounts of the material by different strains

may explain the variable nature of the sucrose reaction.[533,534] Nitrate is not reduced, whereas nitrite frequently is reduced. *N. polysaccharea* can be differentiated from *N. meningitidis* by polysaccharide synthesis and the γ-glutamylaminopeptidase tests. *N. polysaccharea* produces iodine-positive polysaccharide from sucrose and is γ-glutamylaminopeptidase-negative, whereas *N. meningitidis* does not produce iodine-positive polysaccharide from sucrose and is γ-glutamyl aminopeptidase-positive.[23,88] Like *N. gonorrhoeae*, *N. lactamica*, and some *N. meningitidis* strains, *N. polysaccharea* is prolyl aminopeptidase-positive. The organism requires cysteine for growth and does not grow on nutrient agar or on chocolate agar at 22°C.

N. flavescens

N. flavescens is found in the respiratory tract and is rarely associated with infectious processes. This organism grows as smooth, yellowish colonies on both blood and chocolate agar. In addition to growth on nutrient agar at 35°C, most strains will also grow at room temperature on chocolate or blood agar. This organism is able to synthesize iodine-positive polysaccharides from sucrose (see later discussion) and can be differentiated from *M. catarrhalis* by its inability to reduce nitrate and its negative DNase and tributyrin hydrolysis reactions.

N. elongata Subspecies

N. elongata subspecies *elongata, glycolytica*, and *nitroreducens* are rod-shaped members of the genus *Neisseria*.[89,282,704] All subspecies are members of the human upper respiratory tract flora and all have been isolated from infectious processes.[473,704] These subspecies can be differentiated on the basis of catalase reactivity, acid production from glucose, and reduction of nitrate (Table 11-2).

N. weaveri

N. weaveri is an oxidase- and catalase-positive rod that is found in the oral cavity of dogs. It does not produce acid from carbohydrates and does not reduce nitrate, but does reduce nitrite to nitrogen gas. DNase is not produced and tributyrin hydrolysis is negative.

N. bacilliformis

N. bacilliformis is a rod-shaped *Neisseria* species that is oxidase-positive and catalase-variable.[293] The organism grows on blood and chocolate agar, forming light-yellow pigmented, smooth colonies. No growth is seen on selective media such as MTM medium. *N. bacilliformis* is assacharolytic in carbohydrate utilization tests, and is both nitrate reductase- and tributyrin hydrolysis-variable. This organism may be

misidentified as a *Moraxella* species with the API 20NE system.

N. animaloris *and* N. zoodegmatis

N. animaloris and *N. zoodegmatis* were formerly called CDC EF-4a and EF-4b, respectively.[660]These gram-negative coccobacilli are found in the mouths of dogs and have been isolated from dog bite wounds. Both of these organisms are gram-negative coccobacilli that are weakly hemolytic on blood agar, are oxidase- and catalase-positive, and produce acid from glucose only. Both species grow on MacConkey agar and neither produce indole, acetoin (VP test), urease, ornithine decarboxylase, lysine decarboxylase, or β-galactosidase. Both species reduce nitrate to nitrite, but only *N. animaloris* reduces nitrite to nitrogen gas. In addition, *N. animaloris* is arginine dihydrolase (ADH)-positive, while *N. zoodegmatis* is ADH-negative. Genotypically, these species are most closely related to *N. canis* and *N. dentiae*.

N. wadsworthii

This species was described in 2011 and is based on two isolates that were recovered from a hand wound and a peritoneal fluid specimen in 2005 in New York.[702] This organism is gram-negative, coccoid, is oxidase- and catalase-positive, and reduces nitrate to nitrite. On Gram's staining, pairs and short chains may be seen. Colonies are small, are nonhemolytic, and have a yellow-to-orange pigment. On the API NH system, *N. wadsworthii* produces acid from glucose, but not from fructose, maltose, or sucrose. Reactions for ornithine decarboxylase, urease, alkaline-phosphatase, indole, lipase, and β-galactosidase are negative. On this identification system, the proline arylamidase (prolyl iminopeptidase) is positive and γ-glutamyl aminopeptidase is variable.

N. shayeganii

This species is based on two isolates recovered from a sputum specimen and an arm wound.[702] This rod-shaped organism forms small, nonhemolytic, yellow-to-gray colonies on agar media. Like *N. wadsworthii*, the organism is oxidase- and catalase-positive and reduces nitrate to nitrite. On the API NH, this organism produces acid from glucose and is γ-glutamyl aminopeptidase-positive. No acid is produced from maltose, fructose, or sucrose, and reactions for urease,

ornithine decarboxylase, β-galactosidase, alkaline-phosphatase, lipase, and indole production are negative. The prolyl iminopeptidase reaction is variable and strain-dependent.

Cultural Characteristics and Identification of *Moraxella catarrhalis*

M. catarrhalis grows well on both blood and chocolate agars, and some strains will also grow well on MTM and other selective media. Colonies are generally gray-to-white, opaque, and smooth. The organism is asaccharolytic in carbohydrate degradation tests and may actually turn peptone-based identification media alkaline. Most strains reduce nitrate and nitrite and produce DNase. The DNase activity is detected by heavily spot-inoculating a plate of DNase test medium containing toluidine blue O on an area the size of a dime. After overnight incubation, hydrolysis of the DNA is detected by a change in the color of the media around and under the inoculum from blue to pink. *S. aureus* and *S. epidermidis* strains are also inoculated onto the plate as positive and negative test controls, respectively.

M. catarrhalis may also be distinguished from *Neisseria* species by its ability to hydrolyze ester-linked butyrate groups (butyrate esterase).[594] This enzyme activity is detected with a substrate called tributyrin. A rapid fluorescent tributyrin hydrolysis test that uses 4-methylumbelliferyl butyrate as a substrate was reported by Vaneechoutte and coworkers.[669] In this study, all 62 *M. catarrhalis* strains were positive with this test within 5 minutes, whereas all other *Neisseria* species tested were negative. A very rapid (2.5 minute) and reliable indoxyl butyrate hydrolysis spot test has also been described and is commercially available (Remel Laboratories; Carr-Scarborough, Stone Mountain, GA; Image Plate 11-2G).[174,416] This same test is also included on the BactiCard *Neisseria* along with the three other chromogenic substrates for *Neisseria* identification (see Image Plate 11-2B).[329] The RapID NH system also contains a fatty acid ester hydrolysis test to assist in the identification of *M. catarrhalis* (see Image Plate 11-2C). Indoxyl acetate, which is used for the identification of *Campylobacter* species, can also be used as a substrate for the esterase enzyme of *M. catarrhalis*.[329,594] In addition, Most clinically significant *M. catarrhalis* strains also produce an inducible, cell-associated β-lactamase (see below).[205] Because of its inducible nature, rapid acidometric β-lactamase tests (i.e., those that rely on conversion of hydrolysis of penicillin to penicilloic acid) may yield false-negative results. Best results are obtained with the iodometric method or with the chromogenic cephalosporin test.

Antimicrobial Susceptibility of *Neisseria* Species

N. gonorrhoeae

Prior to the mid-1970s, penicillin was the drug of choice for the treatment of gonococcal infections, with tetracycline and macrolides being used for treatment of patients with penicillin allergy.[403,706] Incremental increases in the MICs of penicillin for *N. gonorrhoeae* isolates lead to several modifications of the US Public Health Service treatment schedules over the years. In 1976, strains of *N. gonorrhoeae* with high-level resistance to penicillin were imported into the United States from West Africa, and the Far East. These isolates contained plasmids that carried genes for a β-lactamase enzyme and were given the moniker "PPNG" for penicillinase-producing *N. gonorrhoeae*. During the mid- to late 1970s and into the 1980s, the number of cases of gonorrhea caused by PPNG strains increased 15-fold, with large outbreaks occurring in NYC, Los Angeles, and Miami, and these strains became endemic in several metropolitan areas of the United States. Plasmid-mediated resistance to tetracycline also appeared during this time.[706] At that time, spectinomycin was recommended for the treatment of these infections. By 1981, however, several spectinomycin-resistant *N. gonorrhoeae* isolates had been reported, and subsequently, spectinomycin-resistant PPNG isolates also appeared.[40,721] At the same time, strains of *N. gonorrhoeae* that were penicillin-resistant but β-lactamase-negative were also documented. Because of the increasing resistance of *N. gonorrhoeae* to previously recommended antimicrobial agents and based on several controlled clinical efficacy trials, the US Public Health Service recommended that all patients with uncomplicated gonococcal infection receive 1 of 5 single-dose treatment regimens.[126] These include ceftriaxone (125 mg IM), cefixime (400 mg PO), ciprofloxacin (500 mg PO), ofloxacin (400 mg PO), or levofloxacin (250 mg PO). Each of these therapies also included azithromycin (1 g PO) or doxycycline (100 mg PO, twice a day for 7 days) for treatment of co-infecting *Chlamydia trachomatis*.

In Europe, fluoroquinolone agents were being used for the treatment of gonococcal infections in the mid-1980s, and, beginning in 1986, treatment failures with enoxacin and ciprofloxacin were being reported from the Netherlands and the United Kingdom.[280,684] In Japan, treatment failures with the fluoroquinolones were first reported in 1994, and by the late 1990s, more than 80% of gonococcal isolates in Japan were resistant or intermediately susceptible to fluoroquinolones.[181] Subsequently, other treatment failures were documented in patients treated with fluoroquinolones in the Far East, Canada, and Australia.[178,345,625,627] In the United States, fluoroquinolone resistance was first noted in Hawaii among *N. gonorrhoeae* strains from heterosexuals, likely due to importation from Asia. During the next few years, fluoroquinolone-resistant *N. gonorrhoeae* strains appeared in California among MSM, necessitating revision of treatment recommendations for MSM populations.[123,125,129,130,372]Gonococcal strains that have decreased susceptibility or

that are resistant to the fluoroquinolones have been now been documented worldwide.[157,375,620,627] Fluoroquinolone-resistant *N. gonorrhoeae* strains were also resistant to penicillin and many were resistant to tetracycline as well; all strains were susceptible to ceftriaxone and cefixime.[180]Fluoroquinolone-resistant isolates have gene mutations that result in amino acid substitutions in the A and B subunits (*GyrA* and *GyrB*, respectively) of DNA gyrase, and in the topoisomerase IV *parC*-encoded subunit.[61,179] In the United States, the prevalence of fluoroquinolone-resistant gonococci was less

653

than 1% prior to 2001, but increased to 2.2% in 2002, 4.1% in 2003, 6.8% in 2004, and 9.4% in 2005.[132] In a collection of over 3,000 strains isolated between January and June, 2006, 13.35% were resistant to the fluoroquinolones. Consequently, in 2007, the CDC discontinued recommending fluoroquinolone regimens for the treatment of gonorrhea.[133] In the 2010 CDC guidelines, treatment for uncomplicated gonococcal infection of the genital tract includes ceftriaxone (250 mg single dose, IM), cefixime (400 mg single dose, PO), or a single-dose injectable cephalosporin, plus either azithromycin (1 g single dose, PO) or doxycycline (100 mg, bid, 7 days).[140] DGI due to a ciprofloxacin-resistant gonococcal strain has also been reported.[170] The isolate in this case was susceptible to ceftriaxone (MIC 0.002 μg/mL), but resistant to penicillin (MIC > 32 μg/mL) and tetracycline (MIC 24 μg/mL).[170]

During 2000 through 2010, the Gonococcal Isolates Surveillance Project (GISP) documented the emergence of gonococcal strains with elevated MICs to both ceftriaxone (MIC ≥ 0.125 μg/mL) and cefixime (MIC ≥ 0.25 μg/mL). Strains with elevated MICs for ceftriaxone comprised only 0.1% of isolates in 2000 and 0.3% of isolates in 2010. For cefixime, such strains comprised only 0.2% of isolates in 2000 and 1.4% of isolates in 2010.[142] During the same 2000 to 2010 time period, the emergence of similar strains occurred in Canada.[439]As a corollary to increasing in vitro resistance to these agents, gonococcal treatment failures were documented in patients treated with either cefixime or ceftriaxone in Asia, Norway, and Japan.[489,624,626,650] Initially, reports from Japan described treatment failures in several men who were treated with cefixime, an oral cephalosporin.[181,714] Isolates from these patients had elevated MICs to cefixime (0.5 to 1.0 μg/mL) and ceftriaxone (0.125 to 0.5 μg/mL) by Etest methods. In Japan the proportion of gonococcal isolates with elevated MICs to cefixime (≥0.5 μg/mL) increased from 0% in 1999/2000 to 30% by 2002.[326] In China, the proportion of *N. gonorrhoeae* strains with elevated MICs of ceftriaxone was 18% in 1999 and doubled to 38% by 2006.[608] In Australia, such strains

comprised about 2% of the isolates recovered in 2008.[45] Increases in MICs to the cephalosporins have not been as dramatic in Europe as in other places. In the Netherlands, about 6% of isolates obtained from STD clinic patients between 2006 and 2008 had elevated cefotaxime MICs (0.125 to <0.5 μg/mL) by Etest.[192] These investigators also found that MSM were more likely to be infected with gonococcal strains having elevated MICs to the cephalosporins than heterosexual males. Confirmed cefixime treatment failures have been documented in both heterosexuals and MSM in Norway.[650] These cases were the first confirmed oral cephalosporin treatment failures reported outside of Japan. Multidrug-resistant gonococcal isolates with decreased susceptibilities to cefixime were isolated in 2001 from three patients in Hawaii.[689] According to data from GISP, US isolates with elevated MICs to ceftriaxone (MIC ≥ 0.06 μg/mL) increased from 0.6% in 2006 to 2% in 2008.[139] At the present time, CLSI defines decreased susceptibility to cefixime and ceftriaxone as those isolates with MICs ≥ 0.5 μg/mL.[140]

Strains of *N. gonorrhoeae* that have reduced susceptibility to the cephalosporins generally have mutations in the *penA* gene that affect PBP 2. Mutations of the *penA* gene are termed "mosaic" mutations because multiple mutations occurring at this genetic site incrementally affect the binding of cephalosporin molecules. Isolates of *N. gonorrhoeae* that have mutations of *penA* with mosaic arrangements display decreased susceptibility to both parenteral and oral cephalosporins.[20,364,487,498] Mutations in other chromosomal genes (e.g., the *ponA* gene encoding PBP 1, the *mtr* gene encoding a gonococcal efflux pump, and *penB*, which encodes proteins in the PorB1b outer membrane porin) may also result in or can contribute significantly to reduced cephalosporin susceptibility.[395,409,621,694] Mutations in the *ponA* gene results in decreased cephalosporin binding by PBP 1, while mutations in the *mtrR* gene decrease intracellular antimicrobial concentrations via increased expression and activity of antimicrobial efflux mechanisms. Mutations in *penB* result in an altered PorB1b porin structure and reduced permeability of the cells to antimicrobial agents, including cephalosporins. Isolates with mosaic *penA* mutations may display a range of cephalosporin susceptibilities, with mutations in the other genes incrementally resulting in higher MICs.[490]The *penA* genes that express mosaic mutations are also found in certain commensal *Neisseria* species that are found in the oropharynx, including *N. cinerea*, *N. subflava* bv *perflava*, *N. polysaccharea*, and some strains of *N. meningitidis*. Resistance determinants found in *N. gonorrhoeae* may have been acquired from these commensal species by genetic transformation.

In January of 2009, the first high-level ceftriaxone-resistant gonococcal strain was isolated from the pharynx of a female commercial sex worker in Kyoto, Japan.[488,489] This isolate had a ceftriaxone MIC of 2 μg/mL. Prior to this time, only one isolate with a ceftriaxone MIC of 0.5 μg/mL had been reported previously.[621] Further

examination of this isolate revealed resistance to all β-lactam antimicrobial agents (except for the carbapenems [meropenem, ertapenem] and piperacillin-tazobactam, which are not recommended treatments) and was negative for β-lactamase.[488] The MICs of ceftriaxone were 2 to 4 μg/mL (by Etest, CLSI, and WHO methods), and the MIC of cefixime was 8 μg/mL. This resistant strain possessed a unique resistance determinant ($penA_{H041}$ for strain H041) along with several previously described resistance mutations. The $penA_{H041}$ locus was similar in sequence to loci of cefixime-resistant isolates recovered in Japan from cefixime treatment failures that had only modest increases in the MIC of ceftriaxone (i.e., 0.064 to 0.125 μg/mL).[488,489] Transformation tests confirmed that transfer of this unique allele resulted in the transfer of high-level resistance to ceftriaxone and other extended-spectrum cephalosporins to previously susceptible isolates. The presence of the additional resistance determinants provided sufficient alterations of penicillin-binding proteins to boost the MICs of ceftriaxone by 16-fold to 500-fold. This strain was also resistant to tetracycline, the macrolides, the fluoroquinolones, trimethoprim–sulfamethoxazole, and chloramphenicol and was susceptible to spectinomycin and rifampin.[488] The potential for the development of resistance to these agents is of great concern, since no other well-studied and effective antimicrobial treatment options or combination therapies are available at this time. CDC and PHS have stated that clinicians seeing patients with gonococcal infections must be vigilant for possible treatment failures among their patients who are being treated with the CDC/PHS-recommended regimens. Clinical specimens from these patients must be

cultured and gonococcal isolates recovered from these specimens should be forwarded to a reference laboratory so that antimicrobial susceptibility testing can be performed. The continued emergence of *N. gonorrhoeae* strains that are resistant to the last remaining chemotherapeutic agents is an incredible challenge to the healthcare community and the world.[403] New, multifaceted strategies are needed for gonorrhea prevention and control that include surveillance for antimicrobial resistance, enhanced primary (e.g., sexually active women, MSM, culture of genital/nongenital sites) and secondary (e.g., routine testing among high-risk groups, expedited partner notification/therapy) screening, and development of new approaches/agents for treatment (e.g., combination therapies, provider/public/private partnerships and collaborations, legislative/regulatory industry incentives for drug development).[403,623,624,626,706]

Azithromycin is also effective for the treatment of uncomplicated gonococcal infections, but emergent resistance to macrolides in *N. gonorrhoeae* is a real

concern.[71,406,629] In the past, a 2-g oral dose of azithromycin has been used to treat gonococcal infections, and a 1-g oral dose is currently given to treat chlamydial infections following treatment for gonorrhea. Clinical treatment failures using a 1-g single-dose azithromycin treatment regimen have been documented in patients infected with gonococcal strains with azithromycin MICs of 0.125 to 0.5 μg/mL.[634] Such strains with decreased susceptibility to azithromycin have been documented in the United States and other countries since the mid-1990s.[706] According to the 2007 GISP data, 0.4% of isolates collected in the United States had azithromycin MICs of≥2 μg/mL, and 30% of isolates had azithromycin MICs of ≥0.5 μg/mL.[135] In Japan, over 60% of *N. gonorrhoeae* strains isolated in 2007 to 2008 had azithromycin MIC of ≥0.5 μg/mL. In 2004, gonococcal strains with high-level azithromycin resistance (MIC ≥ 256 μg/mL) were isolated in Scotland and, over the next 3 to 4 years, the same strains appeared in England, Wales, and Italy.[154,506,601] In Scotland, the percentage of isolates with high-level azithromycin resistance increased from 0.3% in 2004 to 3.9% in 2007. Given the increasing prevalence of gonococci with elevated azithromycin MICs and the emergence of strains with high-level resistance to this agent, it is doubtful that a single 2-g dose of azithromycin will be effective for treatment of gonococcal infections caused by these particular isolates, and widespread use of azithromycin may lead to the further development of resistance.[706] Strains with decreased susceptibility to azithromycin and other macrolides usually have mutations, deletions, or insertions in genes encoding efflux pump mechanisms, mutations in one or more of the 23S rRNA methylase *erm* genes, or ribosomal mutations in 23S rRNA.[481,537,718] CLSI has not established breakpoints for susceptibility testing of *N. gonorrhoeae*, although GISP places isolates with azithromycin MICs of ≥2 μg/mL as having decreased susceptibility to this agent.[135]

The CLSI currently recommends either agar dilution or disk diffusion for antimicrobial susceptibility testing of *N. gonorrhoeae*.[160] The recommended medium is GC agar base plus 1% defined growth supplements (e.g., Isovitalex). Cysteine-free growth medium must be used for testing the carbapenems or drugs containing clavulanate. The inoculum, equivalent to a 0.5 McFarland turbidity standard, is prepared in Müeller–Hinton broth or 0.9% PBS, pH 7.0, from a direct colony suspension using growth from a 20- to 24-hour chocolate agar plate incubated in 5% CO_2. The agar dilution plates are incubated at 36°C ± 1°C in 5% CO_2 for 20 to 24 hours. The disk diffusion procedure uses GC agar base with 1% defined growth supplements (cysteine-free medium is not required for testing carbapenems and clavulanate-containing drugs by the disk diffusion method). Breakpoints are available for interpretation of both agar dilution and disk diffusion procedures. Gonococcal isolates with ceftriaxone MICs of ≤0.25 μg/mL are considered susceptible. In addition to CLSI procedures for disk diffusion and agar dilution, Etest (bioMérieux, Inc.)

methods for antimicrobial susceptibility testing of *N. gonorrhoeae* have also been published.[668,712]

N. meningitidis

Despite the occasional recovery of *N. meningitidis* strains with decreased susceptibility to penicillin, penicillin G remains the drug of choice in the United States for treatment of meningococcal meningitis because the vast majority of strains are susceptible to penicillin and ampicillin. For treatment of serious meningococcal infections, parenteral penicillin G (300,000 units/kg/day) is administered for 10 to 14 days. Chloramphenicol (100/mg/kg/day up to 4 g/day) is an alternative in penicillin-allergic patients. The third-generation cephalosporins (ceftriaxone, cefotaxime, and ceftazidime) achieve levels in CSF several orders of magnitude greater than the susceptibility of the meningococcus to these agents. The duration of antibiotic therapy may vary somewhat with the manifestation of the disease and with the response of the patient. At present, when the meningococcus is sensitive to the agents just mentioned, 10 to 14 days of therapy is usually sufficient. Ceftriaxone is currently the third-generation cephalosporin of choice for the treatment of meningococcal disease. For children, ceftriaxone is given at a dosage of 25 mg/kg every 12 hours, IV, up to 1 g. For adults, 1 g ceftriaxone is administered IV every 12 hours. In addition to antimicrobial therapy, patients with serious meningococcal disease require intensive supportive care, including management of the shock state, and careful monitoring of vital signs for detection of complications (e.g., ARDS, neurologic sequelae, pericarditis) and disease progression (e.g., coagulation studies for DIC).[665] New adjunctive therapies, such as recombinant human bactericidal/permeability-increasing protein show promise in the prevention of multiorgan system failure due to endotoxemia.[269] Other biologic agents, such as monoclonal antibodies directed against endotoxin or against cytokines involved in meningococcal septic shock (e.g., IL-1, IL-6, TNF-α), may also play a role as adjunctive therapeutic interventions.[187,665,683]

Despite the fact that the vast majority of strains, particularly in the United States, remain susceptible to penicillin, evidence is accumulating that the antimicrobial susceptibility profiles of *N. meningitidis* strains are evolving. Historically, penicillin-susceptible strains of *N. meningitidis* have penicillin MICs of ≤0.06 μg/mL. In 1983, Dillon and associates[199] in Canada isolated the first β-lactamase-producing meningococcal strain from a urogenital specimen. This isolate harbored the gonococcal 4.5 Mdal β-lactamase plasmid and the 24.5 MDa conjugative plasmid. Subsequently, only three additional β-lactamase-producing *N. meningitidis* isolates

have been reported in the literature: two strains were isolated in 1988 from two patients with meningitis in South Africa, and the fourth isolate was recovered in 1989 from a patient in Spain.[87,252] β-Lactamase-positive strains have penicillin MICs of >256 μg/mL. In 1987, an *N. meningitidis* isolate was recovered in Spain that had diminished susceptibility to penicillin (MIC > 0.06 μg/mL) but was β-lactamase-negative.[549] These strains are referred to as relatively resistant, moderately susceptible, or as having diminished susceptibility to penicillin. Most of the relatively resistant meningococci that have been reported have belonged to either serogroup B or C. Since that time, additional isolates with similar characteristics have been reported in Canada, the United Kingdom, Europe, Greece, South Africa, Belgium, and the United States.[68,76,95,99,214,647,654,671,705] In 1997, active surveillance by the CDC accumulated 90 isolates from 121 cases of reported meningococcal disease. Of these, 3 isolates (<3%) were moderately susceptible to penicillin, with MICs of 0.12 μg/mL.[545] Of the remaining 87 penicillin-susceptible strains, 49 had MICs of 0.06 μg/mL. While penicillin-susceptible strains have MICs of ≤0.06 μg/mL, strains with decreased susceptibility have penicillin MICs ranging from 0.10 μg/mL to 1.0 μg/mL.[545,550] In studies that have examined the prevalence of these strains, decreased susceptibility to penicillin has been defined as those strains with penicillin MICs of ≥0.125 μg/mL. *N. meningitidis* with decreased susceptibility to penicillin are now found worldwide.

Diminished susceptibility to penicillin in moderately resistant *N. meningitidis* strains is apparently due to decreased binding of penicillin by altered meningococcal cell wall PBP 2, which is encoded by the meningococcal *penA* gene.[33,364,617,636] Similar low-affinity forms of PBP 2 are found in penicillin-resistant strains of other *Neisseria* species, including *N. lactamica*, *N. flavescens*, *N. polysaccharea*, and *N. gonorrhoeae*. The altered, low-affinity forms of PBP 2 in *N. meningitidis* strains apparently arose from recombinational events that resulted in the replacement of sequences in the native meningococcal *penA* gene with corresponding genetic material from the commensal *Neisseria* species.[90,551,598] These sequence alterations in the native meningococcal *penA* gene result in *penA* genes with mosaic structures containing commensal *Neisseria* gene sequences. Only a few amino acid changes in the *penA* gene are necessary to decrease the affinity of PBP 2 for penicillin.[597] The clinical significance of diminished penicillin susceptibility in *N. meningitidis* is unclear at present. Although both treatment failures and higher rates of complications have been observed in patients infected with relatively resistant strains, the administration of higher doses of penicillin has been clinically effective.[646] Third-generation cephalosporins (i.e., ceftriaxone, cefotaxime) are active against both penicillin-susceptible and moderately penicillin-resistant *N. meningitidis* strains, but the MICs of some agents for moderately susceptible strains—particularly cefuroxime, aztreonam,

and imipenem—may be significantly higher than those of susceptible strains. In 2001, a serogroup B strain with a penicillin MIC of 2 μg/mL was reported from Poland, and in 2005, a serogroup C meningococcal isolate with a penicillin MIC of 1.5 μg/mL by Etest was isolated from a case of meningitis in Belgium.[234,286] With the increasing prevalence of *N. meningitidis* strains with decreased susceptibility to penicillin and the appearance of resistant strains with high penicillin MICs, the role of penicillin in the treatment of meningococcal disease will most definitely undergo dramatic changes in the next several years.

Recently, reports have appeared documenting fluoroquinolone resistance among *N. meningitidis* isolates. In 2000, an *N. meningitidis* strain with decreased susceptibility to ciprofloxacin (MIC of 0.25 μg/mL) was isolated from a 19-year-old female with invasive meningococcal disease in Australia.[567] Susceptible strains usually have ciprofloxacin MICs of ≤0.03 μg/mL. PCR amplification and sequencing of the *gyrA* gene of this isolate revealed a three-nucleotide difference from wild type, ciprofloxacin-susceptible strains. Decreased susceptibility to fluoroquinolones, particularly ciprofloxacin, has been reported in serogroup B *N. meningitidis* in France and Spain, serogroup C meningococci from Australia, serogroup Y strains from Argentina, and serogroup A meningococci from India.[15,152,166,324,567,584] A case of meningitis due to a ciprofloxacin-resistant serogroup A strain was also documented in a traveler from Italy who acquired the infection in New Delhi, India.[388] As mentioned previously, three cases of meningococcal disease due to ciprofloxacin-resistant serogroup B strains were reported among residents of North Dakota and Minnesota during 2007 and 2008.[136,708] The first case was epidemiologically linked to a case that occurred in the same region in 2006, except that the particular strain lacked the *gyrA* mutation that confers resistance to fluoroquinolones. Mutations in *gyrA* appear to be the genetic events that result in fluoroquinolone resistance, as efflux pump mechanisms in these strains appear to be intact.[117] Consequently, ciprofloxacin is no longer recommended for meningococcal chemoprophylaxis in regions of the United States where resistant strains have been isolated.*N. meningitidis* strains have also demonstrated resistance to other antimicrobial agents. High-level chloramphenicol resistance has been reported in isolates from France and Vietnam.[256]Fear of the spread of chloramphenicol resistance is justified since the drug is a mainstay of therapy for meningitis in sub-Saharan Africa.[592] High-level resistance to sulfonamides, the drug formerly used for prophylaxis, is now widespread and may be found commonly among certain epidemic clones of serogroup A *N. meningitidis*.[592] In a study conducted in Spain, 43.6% of 55 strains from both cases and carriers were resistant to trimethoprim–sulfamethoxazole.[251] The emergence of rifampin resistance has also been observed even during the administration of rifampin prophylaxis.[165] Rifampin resistance emerges either due to alterations in cell membrane permeability or to

mutations in the *rpoB* gene that codes for the β-subunit of the meningococcal RNA polymerase.[1,602] Tetracycline resistance among meningococci is due to acquisition of the *tetM* tetracycline resistance determinant.[645]

The CLSI has published microbroth dilution, agar dilution, and disk diffusion procedures for standardized antimicrobial susceptibility testing of *N. meningitidis*.[161,675] The microbroth dilution method uses cation-supplemented Müeller–Hinton broth with lysed horse blood (2.5% to 5%, v/v), while both agar dilution and disk diffusion methods use Müeller–Hinton agar supplemented with 5% sheep's blood. The inoculum for all three procedures is prepared from a direct colony suspension adjusted to a 0.5 McFarland turbidity standard from a chocolate agar subculture incubated at 35°C

656

in 5% CO_2. The tests are incubated for 20 to 24 hours at 35°C ± 2°C in a 5% CO_2 atmosphere. MIC breakpoints and MIC correlates for the disk diffusion procedure are available for penicillin and ampicillin, cefotaxime, ceftriaxone, meropenem, azithromycin, minocycline, fluoroquinolones (i.e., levofloxacin, ciprofloxacin), trimethoprim–sulfamethoxazole, sulfisoxazole, chloramphenicol, and rifampin. The Etest may also prove valuable in determining the antimicrobial susceptibility of individual meningococcal isolates.[169,436,676]

Antimicrobial Susceptibility of *Moraxella catarrhalis*

The appearance and spread of resistance to antimicrobial agents among the pathogenic *Neisseria* are also reflected in the antimicrobial susceptibility of *M. catarrhalis* isolates. Prior to the mid-1970s, this organism was broadly susceptible to antimicrobial agents. β-Lactamase-positive *M. catarrhalis* were first isolated in 1976; by the end of the decade, about 75% of strains produced β-lactamase enzymes. Worldwide, the percent of β-lactamase-positive *M. catarrhalis* strains ranges from 80% to 100%.[60] A study by Doern and Tubert demonstrated that the chromogenic cephalosporin (nitrocefin) disk and tube tests had superior sensitivity for detection of β-lactamase and the nitrocefin disk chromogenic cephalosporin test was adopted by many laboratories.[205] Studies of *M. catarrhalis* β-lactamase enzymes have shown that three types of enzymes are found in strains of this organism. These enzymes are called BRO-1 (or Ravisio-type) and BRO-2 (or 1908-type), and BRO-3.[81,228,566]BRO-3 is a

membrane-bound precursor of the other two BRO enzymes. The "BRO" moniker is a contraction of "*BR*anhamella" and "*mOraxella*," since similar β-lactamases are found in rod-shaped moraxellae as well. Strains of *M. catarrhalis* produce either BRO-1 or BRO-2, and these enzymes can be differentiated by isoelectric focusing. Strains that produce BRO-1 enzymes account for about 90% of the β-lactamase-producing *M. catarrhalis* isolated from clinical specimens, while BRO-2-producing strains account for the remaining 10%.[213]Molecular analysis of β-lactamase production indicates that the BRO-1 enzyme is encoded by a single chromosomal gene (*bla*) that encodes a 314-amino acid polypeptide.[82] Sequence analysis of the *bla* genes from BRO-1- and BRO-2-producing isolates differ by five nucleotide bases that result in only a single amino acid residue difference in the amino acid sequences of the BRO-1 and BRO-2 enzymes. However, a 21 base pair deletion was found in the promoter region of the BRO-2 gene. Differences in MICs of BRO-1- and BRO-2-producing *M. catarrhalis* strains may be explained by lower levels of BRO-2 production due to the deletion in the promoter region, while the structure and enzymatic activities of the two enzymes are similar.[82] Patients who have been infected with BRO-2 β-lactamase-producing *M. catarrhalis* strains have also responded clinically to ampicillin and penicillin. The BRO-1 has a molecular weight of about 32.5 kDa. Variations in the reported molecular weight of this enzyme, which range from 28 kDa to 41 kDa, are explained by the presence of free and lipid-associated forms of BRO-1.[80] The *bla* gene may be transposon-associated and transferable by either transformational or conjugative mechanism.[80] In vitro studies indicate that the *M. catarrhalis* β-lactamases may indirectly function in virulence by inactivating penicillin or ampicillin given for other respiratory tract infections, such as pneumococcal pneumonia.[308]

Studies published during the early 1990s on isolates from the United States and abroad indicated that *M. catarrhalis* strains are generally resistant to penicillin, ampicillin, and amoxicillin, and susceptible to amoxicillin-clavulanate, second- and third-generation parenteral and oral cephalosporins (i.e., cefixime and cefaclor), macrolides, tetracyclines, and rifampin.[77,204,241,554,634] This susceptibility pattern has remained stable as demonstrated in more recent studies of *M. catarrhalis* from the US Sentry Antimicrobial Surveillance Program and other countries (e.g., Italy, Turkey).[189,228,340,434] While most isolates are susceptible to the fluoroquinolones, resistance has emerged in isolates recovered from patients who were on long-term therapy with such agents.[188,201] Other than variations in β-lactamase production, no notable differences in the antimicrobial susceptibilities of *M. catarrhalis* strains isolated from several countries have been noted.[188,189,228] Rare strains of *M. catarrhalis* may be resistant to tetracyclines, macrolides, or trimethoprim–sulfamethoxazole.[227]

In 2010, the CLSI published guidelines for antimicrobial susceptibility testing of *M.*

catarrhalis.[159] Microbroth dilution testing is performed with cation-adjusted Müeller–Hinton broth with a direct colony suspension inoculum that is equivalent to a 0.5 McFarland turbidity standard. The tests are incubated at 35°C in ambient air for 20 to 24 hours. Breakpoints are available for amoxicillin-clavulanate, parenteral (i.e., cefuroxime, cefotaxime, ceftazidime, ceftriaxone) and oral (i.e., cefaclor) third-generation cephalosporins, macrolides (i.e., azithromycin, clarithromycin, erythromycin), quinolones (i.e., ciprofloxacin, levofloxacin), tetracycline, clindamycin, trimethoprim–sulfamethoxazole, chloramphenicol, and rifampin. The absence of resistant strains of *M. catarrhalis* to several of the agents precludes defining any results categories other than "susceptible." Prior to having a standardized method for antimicrobial susceptibility testing of this organism, it had been noted that broth dilution tests for ampicillin, penicillin G, cephalothin, cefamandole, cefuroxime, and cefaclor were highly inoculum-dependent due to the production of varying amounts of β-lactamases.

More detailed information on antimicrobial susceptibility testing of these organisms is presented in Chapter 17.

671

With the exception of the *Enterobacteriaceae*, gram-positive bacteria, particularly the cocci, are the microorganisms most frequently isolated from clinical specimens. These bacteria are widespread in nature and can be recovered from the environment or as commensal inhabitants of the skin, mucous membranes, and other body sites in humans and animals. The ubiquity of these gram-positive bacteria in nature makes the interpretation of their recovery from patient specimens occasionally difficult unless clinical manifestations of an infectious disease process are apparent. Recovery of these organisms from specimens should always be correlated with the clinical condition of the patient before their role in an infectious process can be established.

Although gram-positive bacteria may cause infection by multiplication both locally and systemically, some organisms may multiply at a localized site and exert their pathogenic effects by producing exotoxins or enzymes that act at distant sites. Staphylococcal toxins are responsible for food poisoning, scalded skin syndrome, and toxic shock syndrome.[303,304] Streptococcal toxic shock syndrome (see Chapter 13) is a clinical entity where signs and symptoms of infection and pathologic features of disease are largely due to the effects of exotoxins. Gram-negative bacteria, on the other hand, possess endotoxin, which is the lipid portion of the outer membrane lipopolysaccharide. Systemic infections with gram-negative bacteria may lead to endotoxic shock, which is characterized by hypotension, vascular collapse, and sometimes death. This occurs most frequently when gram-negative organisms gain entry to the bloodstream.

With the increasing numbers of staphylococcal species being recognized in human infections and the finding of resistance to multiple antimicrobial agents in both the common and the uncommon isolates, it is imperative that the clinical microbiologist be

familiar with current methods for characterizing these organisms. In this chapter, the clinical significance and laboratory procedures for isolation and identification of the staphylococci and related organisms will be presented. In Chapter 13, the streptococci and *streptococcus*-like bacteria will be discussed. Antimicrobial susceptibility testing of these bacterial groups will be addressed in Chapter 17.

Taxonomy of Staphylococci and Related Gram-Positive Cocci

The taxonomy of staphylococci and related gram-positive cocci has undergone significant modifications with the application of molecular and chemotaxonomic methods, which have documented the diversity of organisms in the genera *Staphylococcus*,*Micrococcus*, *Macrococcus*, and *Rothia*. In volume 3 of the revised *Bergey's Manual of Systematic Microbiology*, the genera *Staphylococcus* and *Macrococcus* are classified in the family *Staphylococcaceae*, order *Bacillales*, in the phylum *Firmicutes*, while the genera *Micrococcus, Rothia*, and related cocci are distributed between the family *Dermacoccaceae* and family *Micrococcaceae* in the phylum *Actinobacteria* (Box 12-1). All of the former members of genus *Stomatococcus* are now placed in the genus *Rothia*.[47,109]

The genus *Micrococcus* has undergone extensive taxonomic dissection based on 16S ribosomal DNA sequence analysis.[512] Genus *Micrococcus* originally included nine species: *M. luteus*, *M. lylae*, *M. varians*, *M. roseus*, *M. agilis*, *M. kristinae*, *M.nishinomyaensis*, *M. sedentarius*, and *M. halobius*. In 1995, *M. roseus*, *M. varians*, and *M. kristinae* were transferred into the genus *Kocuria* as *K. rosea*, *K. varians*, and *K. kristinae*, respectively, while *M. halobius*, *M. nishinomiyaensis,* and *M. sedentarius*were placed into three separate genera as *Nesterenkonia halobia*, *Kytococcus sedentarius*, and *Dermacoccus nishinomiyaensis*, respectively. *M. agilis* was reclassified in the genus *Arthrobacter* as *A. agilis*. Since the dissection of genus *Micrococcus* into these genera began in 1995, several additional species in the genus *Micrococcus*, *Dermacoccus*, *Kocuria*, *Kytococcus*, and *Nesterekonia* have been described. Most species belonging to these genera have been isolated from air, soil, various extreme environments (e.g., marine sediment, deep sea mud, activated sludge), and food (usually fermented seafood). The various genera were initially delineated from each other based on chemotaxonomic (i.e., menaquinone analysis, fatty acid analysis, polar lipid characterization, peptidoglycan composition) and phylogenetic (i.e., 16S ribosomal DNA sequencing) data. Species within genera have been characterized further by additional genotypic analyses and phenotypic test results (i.e., carbohydrate assimilation and acidification tests, urease, acetoin production,

enzymatic activities, etc.). In general, these "*Micrococcus*-like" bacteria are cocci in various cellular arrangements or short rods. Micrococci and related species are gram-positive cocci that are slightly larger than staphylococcal cells. Micrococci are 1 to 1.8 µm in diameter, while staphylococci are 0.5 to 1.5 µm in diameter. The cells are arranged mostly as pairs, tetrads, and irregular clusters. In the rest of this chapter, these organisms will be referred to as micrococci and related species. Colonies of most species are pigmented, and all are catalase-positive; results for the oxidase test vary among the species.

Rothia mucilaginosa, a former member of genus *Stomatococcus*, is an encapsulated gram-positive coccus that is a part of the normal human respiratory microbial flora.[47] Based on 16S rDNA sequencing and chemotaxonomic data, this organism is most closely related to organisms in the genus *Rothia,* which also includes *R. dentocariosa, R. nasimurium* (an organism found in the nares of mice), *R. aeria*, *R. amarae*, and *R. terrae*.[109] While *R. mucilaginosa* and *R. nasimurium* are gram-positive cocci, the other *Rothia* species are gram-positive coryneform bacilli that sometimes show rudimentary branching. Because of their coccal morphology, *R. mucilaginosa* will be described in this chapter, whereas the other *Rothia* species will be discussed in Chapter 14.

Members of the genus *Macrococcus* are animal isolates that appear as large, gram-positive cocci, with individual cells measuring 1.0 to 2.5 µm in diameter. The macrococci have fewer 16S rRNA sequences in common with the staphylococci, have a greater G+C content in their DNA, lack cell wall teichoic acids, and generate unique ribotyping patterns. Members of the genus *Macrococcus* are related to the "*S. sciuri* group" of staphylococci, which are the only staphylococcal species that are oxidase-positive. The genus *Macrococcus* includes seven animal species: *M. equipercicus* and *M. caroselicus* (horses), *M. bovicus* (cattle), *M. caseolyticus*

BOX 12-1

Classification of the Staphylococci and *Staphylococcus*-Like Bacteria

Class	Order	Suborder	Family	Genera
"Bacilli"	*Bacillales*		*Staphylococcaceae*	*Gemella, Jeotgalicoccus, Macrococcus, Nosocomicoccus, Salinicoccus, Staphylococcus*
Actinobacteria	*Actinomycetales*	*Micrococcineae*	*Dermacoccaceae*	*Demetria, Dermacoccus, Kytococcus, Yamilla*
			Micrococcaceae	*Arthrobacter, Kocuria, Micrococcus, Nesterenkonia, Renibacterium, Rothia* (includes former *Stomatococcus* species)

(formerly *Staphylococcus caseolyticus,* dairy products, meats, pilot whales), and *M. brunensis*, *M. hajekii*, and *M. lamae* (skin of llamas).[281,344] These organisms have not been implicated in human infections.

Clinical Significance of Staphylococci and Related Gram-Positive Cocci

The genus *Staphylococcus* is currently composed of several species, many of which may be encountered in human clinical specimens (Box 12-2). Staphylococci are nonmotile, non–spore-forming, catalase-positive, gram-positive cocci. These organisms are arranged as single cells, pairs, tetrads, and short chains, but appear predominantly in grapelike clusters. Most species are facultative anaerobes except for *S. aureus* subsp. *anaerobius* and *S. saccharolyticus*. These two species grow anaerobically and, unlike the facultative species, are often catalase-negative. Staphylococci are generally found on the skin and mucous membranes of humans and other animals. In some cases, this association is highly specific. For example, *S. capitis* subsp. *capitis* is a part of the normal microbiome of human skin and sebaceous glands of the scalp, forehead, and neck, while *S. auricularis* is found primarily in the external auditory canal.[285,286] Some species are found only in animals and are recognized as veterinary pathogens. For example, *S. hyicus* causes an infectious dermatitis in swine, and *S. intermedius* has been isolated from several types of infections in dogs, including cutaneous infections, mastitis, wounds, and reproductive tract infections.[134,204,205] The latter species has also been isolated from dog bite wounds in humans.[529] *S. delphini, S. felis, S. schleiferi* subsp. *coagulans,* and *S. lutrae* cause infectious processes in dolphins, domesticated cats, dogs, and sea otters, respectively.[162,241,242,569] Humans may become colonized or infected with these organisms by frequent or close contact with animals (e.g., veterinarians, zoo workers, farmers). Some of the pathogenic staphylococci in both humans and animals produce an enzyme called coagulase, and detection of this enzyme is used in the

laboratory to identify these organisms.[204,569] Among the staphylococci, the coagulase-positive species, *S. aureus*, and two coagulase-negative species, *S. epidermidis* and *S. saprophyticus*, are seen frequently in human infections.

Staphylococcus aureus *subsp.* aureus

S. aureus is by far the most important human pathogen among the staphylococci. It is found in the external environment and in the anterior nares of 20% to 40% of adults. Other sites of colonization include intertriginous skin folds, the perineum, the axillae, and the vagina. Although this organism is frequently a part of the normal human microflora, it can cause significant opportunistic infections under the appropriate conditions. Factors which may predispose an individual to serious *S. aureus*infections include the following:

- Defects in leucocyte chemotaxis, either congenital (e.g., Wiskott–Aldrich syndrome, Down's syndrome, Job's syndrome, and Chediak–Higashi syndrome) or acquired (e.g., diabetes mellitus, rheumatoid arthritis);
- Defects in opsonization by antibodies secondary to congenital or acquired hypogammaglobulinemias or complement component (especially C3 and C5) deficiencies and/or defects;
- Defects in intracellular killing of bacteria following phagocytosis due to inability to activate the membrane-bound oxidase system, resulting in the absence of peroxides and superoxide from phagocytic vacuoles (e.g., chronic granulomatous disease, lymphoblastic leukemia, and both acute and chronic myelogenous leukemia);
- Skin injuries (e.g., burns, surgical incisions, eczema);
- Presence of foreign bodies (e.g., sutures, intravenous lines, prosthetic devices)[393];
- Infection with other agents, particularly viruses (e.g., influenza);
- Chronic underlying diseases such as malignancy, alcoholism, and heart disease;
- Therapeutic or prophylactic antimicrobial administration.

Under these circumstances, *S. aureus* may cause a variety of infectious processes ranging from relatively benign skin infections to life-threatening systemic illnesses (Box 12-3). Skin infections include simple folliculitis and impetigo, as well as cellulitis, furuncles and carbuncles involving subcutaneous tissues and causing systemic symptoms, such as fever (Image Plate 12-1A and 12-1B). *S. aureus* is frequently isolated from postsurgical wound infections, which may serve as a nidus for the development of systemic infections. Community-acquired staphylococcal bronchopneumonia is usually seen in elderly individuals and has been associated with viral pneumonia as a

BOX 12-2

Human, Animal, and Environmental *Staphylococcus* Species

Species	Comments
Staphylococci Found in Humans and Nonhuman Primates	
S. aureus	See text
S. epidermidis	See text
S. saprophyticus	See text
S. auricularis[286]	This species is found in the human external auditory canal and is rarely implicated in infections. *S. capitis* has been isolated from blood cultures during an episode of sepsis in a low-birth-weight infant and from peritoneal fluid of a patient on peritoneal dialysis.[233,322]
S. capitis[285]	*S. capitis* is part of the normal human flora and is found surrounding the sebaceous glands on the scalp and forehead. In 1991, this species was divided into two subspecies, *S. capitis* subsp. *capitis* and *S. capitis* subsp. *ureolyticus*. *S. capitis* subsp. *ureolyticus* can be differentiated from subsp. *capitis* by its positive urease activity, the ability to produce acid from maltose under aerobic conditions, and cellular fatty acid profiles. This species has been reported as a cause of native valve and prosthetic valve endocarditis, endocarditis associated with upper endoscopy, and pacemaker implantation.[110,127,258,379,384,528] *S. capitis* has been documented as a cause of sepsis in critically ill premature infants, including one case of meningitis.[442,589] In 2010, a case of community-acquired meningitis caused by *S. capitis* was reported in a 65-year-old woman.[402] In these cases, all of the isolates were resistant to oxacillin, erythromycin, and clindamycin. Strains of *S. capitis* have also displayed heteroresistance to vancomycin.[140] An outbreak of *S. capitis* colonization and infection in an intensive care unit was traced to almond oil used for neonatal skin care.[196]
S. caprae[135,265]	*S. caprae* was originally thought to be solely an animal species isolated from goats and goats' milk. In 1991, *S. caprae* was cultured from an exudate from a patient with dermatitis and from the urine of a second patient.[259] In a study of the distribution of *Staphylococcus* species among human clinical specimens, *S. caprae* comprised 10.7% of the 1,230 strains examined.[265] *S. caprae* was the cause of an outbreak of bacteremia in a neonatal intensive care unit, where it was recovered from the nares of 6 of 32 neonates during an MRSA surveillance study.[460] In this outbreak, all *S. caprae* isolates were methicillin-resistant and positive for the *mecA* gene. *S. caprae* was reported isolated from an intra-articular empyema following arthroscopic knee surgery and as a cause of iatrogenic osteomyelitis following surgical implantation of orthopedic materials.[7,151,494] *S. caprae* has been implicated in cases of endocarditis, catheter-related bacteremia, urinary tract infection, sepsis in a neonate with congenital heart disease, and iatrogenic meningitis.[42,262,280,509] *S. caprae* is most closely related to *S. epidermidis* and *S. capitis* subspecies.[177]
S. cohnii[288,480]	*S. cohnii* was first described in 1975, and in 1991, was divided into two subspecies: *S. cohnii* subsp. *cohnii* and *S. cohnii* subsp. *urealyticum*.[288] Subspecies *cohnii* has only been isolated from humans, while the latter urease-positive subspecies has been isolated from both human and nonhuman primates. Both are normal flora on the skin. *S. cohnii* is an emergent opportunistic agent, having been reported as a cause of community-acquired pneumonia, primary septic arthritis, infection of spinal fixation materials, brain abscesses, and catheter-related sepsis in immunocompromised patients.[33,152,160,352,353,612] Chorioamnionitis and neonatal sepsis with meningitis due to *S. cohnii* have also been reported.[266,506] Linezolid resistance has been described in this species, and methicillin-resistant strains of *S. cohnii* appear similar to MRSA isolates on certain brands of chromogenic agar for detection of MRSA.[420,428,578]
S. haemolyticus[480]	*S. haemolyticus* is part of the human normal skin microflora and is also found in nonhuman primates. This organism has been documented as a cause of primary and nosocomial bacteremia, wound/soft tissue infections, central venous catheter-associated septic pulmonary emboli, peritonitis, endocarditis, urinary tract infections, and nosocomial neonatal/pediatric infections.[45,154,156,200,297,422,473,527] Strains of *S. haemolyticus* that have relatively high MICs (i.e., from 2 to $\geq$8 μg/mL) for vancomycin have been reported in clinical settings of prolonged vancomycin administration, suggesting selection of resistant clones over time.[228,484,572] In this regard, strains of *S. haemolyticus* that are resistant to both glycopeptides (i.e., vancomycin and teicoplanin) and/or that are susceptible to vancomycin and resistant to teicoplanin have been described.[52,98,297] Glycopeptide resistance in *S. haemolyticus* and other coagulase-negative staphylococci is usually expressed heterogeneously, with both susceptible and resistant subpopulations existing within a single culture.[52] The emergence of glycopeptide resistance in *S. haemolyticus* has underscored the importance of correct identification and susceptibility testing of these isolates and monitoring their spread within the hospital environment. The causes of glycopeptides resistance are multifactorial and relate principally to alterations in the cross-linkages within the cell wall peptidoglycan and, therefore, with the successful interaction of the

	antibiotic with its target.[54] Vancomycin-resistant strains of *S. haemolyticus* demonstrate a reduced growth rate, reduced peptidoglycan hydrolase activities, and possess thicker cell walls than vancomycin-susceptible strains.[277] Methicillin-, fluoroquinolone-, and linezolid-resistant isolates of *S. haemolyticus* have also been reported.[30,355,453,527,615] The presence of multi-antibiotic-resistant *S. haemolyticus* in the hospital environment and transmission of resistant clones via hands of healthcare workers has been documented using several chemotaxonomic and molecular methods (e.g., immunoblotting of staphylococcal polypeptides, plasmid analysis, restriction-length polymorphisms of chromosomal DNA, PFGE of total DNA).[527]
S. hominis[283,285]	*S. hominis* is found on the skin of humans and has been isolated from infections as a low-grade pathogen causing catheter-related sepsis in immunocompromised hosts. *S. hominis* has also been reported as a cause of endocarditis and endophthalmitis.[247,274,523] In 1998, the species was divided into two subspecies: *S. hominis* subsp. *hominis*, and *S. hominis* subsp. *novobiosepticus*.[283] *S. hominis* subsp. *hominis* is predominantly skin-associated is an infrequent isolate from infections, while *S. hominis* subsp. *novobiosepticus* is recovered more frequently from blood cultures and *bona fide* infections.[94,123,406] Subspecies *novobiosepticus* is novobiocin-resistant and does not produce acid from D-trehalose or *N*-acetyl-D-glucosamine, while the subspecies *hominis* is novobiocin-susceptible and produces acid aerobically from both of these carbohydrates. 2010, an intensive care unit isolate of *S. hominis* subsp. *hominis* was shown to possess mutations resulting in elevated MICs for both teicoplanin and linezolid.[507]
S. lugdunensis[170]	This species, first described in 1988, has rapidly established itself as a significant human pathogen.[167] *S. lugdunensis* colonizes the human inguinal area as established by inguinal fold culture sampling and the predominance of *S. lugdunensis* isolates obtained from abscesses in the pelvic girdle region.[39,560] In recent years, several reports have described *S. lugdunensis* as an important cause of native valve- , prosthetic valve-, and pacemaker-associated endocarditis. These infections have been complicated by the development of embolisms and myxomas.[51,91,105,327,405] CNS infections have included meningitis, brain abscess, and ventriculoperitoneal shunt infections.[148,183,256,472] *S. lugdunensis* osteoarticular infections include infected hip prostheses, osteomyelitis, vertebral discitis, and septic arthritis following arthroscopic surgical procedures.[72,296,359,361,487] Bacteremia, vascular line infections, urinary tract infections, skin and soft tissue infections, endophthalmitis, and peritonitis may also involve this pathogen.[23,99,101,203,289,410,417,481,619] A septic shock presentation similar to that seen with gram-negative bacteria has also been associated with *S. lugdunensis* bacteremia.[81] Oxacillin-resistant strains of *S. lugdunensis* carrying the *mecA* gene have also been characterized.[538] According to the CLSI, *S. lugdunensis* antimicrobial susceptibilities are interpreted using the *S. aureus* breakpoints rather than those used for other coagulase-negative staphylococci.[107] *S. lugdunensis* and *S. pseudolugdunensis* are ornithine decarboxylase- and PYR-positive.
S. massiliensis[8]	This species, described in 2010, was isolated from a brain abscess in a 52-year-old man.[8] Newer information indicates that *S. massiliensis* is probably part of the normal flora of human skin.[620]
S. pasteuri[96]	*S. pasteuri* is a newly described species that is found in human and animal clinical specimens and in food. *S. pasteuri* has been isolated from blood cultures of a patient with leukemia and from contaminated apheresis platelet units.[474,475]
S. petrasii[409]	This new species, described in 2013, was isolated from blood, wound pus, nasal swabs, and several ear swabs from patients with acute otitis externa. This coagulase-negative species was distinct from known *Staphylococcus* species by 16S rRNA, *hsp60, rpoB, dnaj, tuf*, and *gap* gene sequencing. The two subspecies—*petrasii* and *croceilyticus*—can be differentiated by phenotypic and genotypic techniques.[409]
S. pettenkoferi[547,548]	*S. pettenkoferi* is a new human staphylococcal species that has been isolated from bloodstream infections, wound infections, and a case of osteomyelitis in a diabetic foot infection.[13,329,505,547,548] This species has also demonstrated resistance to linezolid.[365]
S. pseudolugdunensis[532]	This new PYR- and ornithine decarboxylase-positive species has been isolated from blood cultures, where it has been misidentified as *S. lugdunensis*.[532] This species was not recognized by a *S. lugdunensis*-specific primer/probe set targeting the *tuf* gene (for elongation factor Tu) and cannot be differentiated from other commonly isolated staphylococci based on phenotypic reactions.
S. saccharolyticus[276]	This anaerobic species was previously called *Peptococcus saccharolyticus* and was transferred to the genus *Staphylococcus* based on DNA sequence analysis of 16S ribosomal RNA. The organism is found on human mucous membranes. Two cases of endocarditis (one involving a native heart valve, and the other a prosthetic heart valve), a case of spondylodiscitis, and one patient with fatal pneumonia caused by *S. saccharolyticus* have been reported.[189,299,599,610] Over a 6-month period, *S. saccharolyticus* was isolated from blood cultures of 16 different patients in 12 different wards in a hospital in Germany. Despite intensive investigations, no common links among the patients or no "outbreak" source could be identified.[517]

S. schleiferi[170]	*S. schleiferi* was first described in 1988 and has been isolated from several human infections, including brain empyema, wound infections, bacteremia complicating vertebral osteitis, infection of a hip prosthesis, indwelling catheter infection, nosocomial urinary tract infections, prosthetic valve endocarditis, osteomyelitis, and pacemaker infections.[71,82,227,290,301,403,542] In 1990, the species was divided into two subspecies; human and canine isolates (associated with pyoderma) have been designated *S. schleiferi* subsp. *schleiferi,* and isolates causing external otitis in dogs have been designated *S. schleiferi* subsp. *coagulans.*[243,354] When the subspecies were first described, it was thought that subspecies *schleiferi* isolates were clumping factor-positive and tube coagulase-negative, while subspecies *coagulans* isolates were clumping factor-negative and tube coagulase-positive.[243] Vandenesch and colleagues[556] subsequently isolated three strains of *S. schleiferi* subsp. *schleiferi* that were both clumping factor- and tube coagulase-positive.
S. simulans[285]	*S. simulans* is found on the skin and in the urethras of healthy women. *S. simulans* has been isolated as a cause of septicemia, osteomyelitis, native valve endocarditis, septic arthritis following open reduction of a fractured fibula, vertebral osteomyelitis, and prosthetic joint infection.[133,339,343,445,554] As with certain other coagulase-negative staphylococci (i.e., *S. epidermidis*, *S. haemolyticus*, and *S. hominis*), methicillin-resistant strains of *S. simulans* possesses an additional PBP2a (PBP2') that exhibits a low affinity for methicillin, cephalothin, and cefamandole and has amino acid sequences analogous to the PBP2a (PBP2') found in MRSA isolates.[431]
S. warneri[285]	This species represents about 1% of the staphylococci normally found on human skin. *S. warneri* is now a well-recognized cause of catheter-related bacteremia, native valve and prosthetic valve endocarditis, hematogenous vertebral osteomyelitis and discitis, and ventriculoperitoneal shunt-associated meningitis.[18,26,66,70,279,350,520] Incani and colleagues[244] described a patient with meningitis caused by *S. warneri*; the patient also had lymphoma and *S. sterccoralis* hyperinfection syndrome. Isolates recovered from humans are now called *S. warneri* subsp. 1, while isolates from nonhuman primates are called *S. warneri* subsp. 2.
S. xylosus[480]	*S. xylosus* is found in both human and nonhuman primates and has been reported as a cause of upper and lower urinary tract infections, septicemia, and endocarditis associated with intravenous drug use.[113] This organism was isolated from a pancreatic pseudocyst in an HIV-infected patient, from a otogenic brain abscess in an adolescent female, and from a root canal infection.[5,351,497] *S. xylosus* has also been isolated from goats' milk and cheese.[363]
Staphylococci Found in Other Animals	
S. agnetis[536]	This newly described species was isolated from milk samples from cows with subclinical and mild clinical mastitis.
S. arlettae[479]	This species is found on mammals and birds and is of undetermined clinical significance and taxonomic status.
S. chromogenes[134,205]	This species, formerly a subspecies of *S. hyicus*, causes cutaneous infections in cattle, swine, and goats.[15]
S. delphini[569]	This coagulase-positive species causes purulent skin lesions in dolphins.
S. devriesei[524]	This new species has been isolated from the teats milk of dairy cows.
S. equorum[479]	*S. equorum* is a rare species of undetermined pathogenic significance. *S. equorum* has been recovered primarily from horses as well as from goat milk and cheese, and has also been isolated from human clinical specimens.[363,391] *S. equorum* subsp. *linens* serves as a starter culture component for various surface-ripened cheeses.[434]
S. felis[241,242]	*S. felis* is the most commonly isolated *Staphylococcus* species in cats, causing otitis, cystitis, abscesses, wounds, and other cutaneous infections.
S. gallinarum[135]	This species is found in poultry and is nonpathogenic.
S. hyicus[134]	*S. hyicus* is found in cattle and cows' milk and is associated with exudative epidermitis ("greasy pig syndrome"), an acute disease of suckling and weaned pigs. Strains of *S. hyicus* causing this skin infection produce three types of exfoliative toxins and a calcium-dependent extracellular lipase/phospholipase enzyme that contribute to the pathology of this syndrome.[14,459] Although not considered a pathogen of humans, a case of human wound infection caused by *S. sciuri* following a donkey bite was reported in 1997.[399]
S. intermedius[204]	*S. intermedius* is part of the flora of dogs, minks, horses, and cats and may cause cutaneous, urinary tract, bone, and central nervous system infections in several animal species. *S. intermedius* is the predominant coagulase-positive *Staphylococcus* recovered from normal and infected canine skin and from serious canine infections.[187] Human carriage of *S. intermedius* is rare even among individuals with frequent exposure to animals.[336] This organism has been isolated from humans with infected dog bite wounds and has also been

	recovered from individuals with non–canine-inflicted injuries, including infections of varicose vein ulcers and suture incisions.[529,530] Minor infections (e.g., otitis externa) with this organism may also occur as a consequence of close, nontraumatic contact with the family canine.[534] *S. intermedius* catheter-related sepsis in a 63-year-old cancer patient and *S. intermedius* pneumonia following coronary artery bypass surgery have also been reported.[180,555] *S. intermedius* may also cause cutaneous infections in persons with no exposure to dogs or other animals.[270] *S. intermedius* is characterized by being tube coagulase-positive, but clumping factor-variable.
S. kloosii[479]	This species is found in mammals and is of uncertain clinical significance and taxonomic status. In 2011, *S. kloosii* was isolated from several blood cultures from a 60-year-old patient following a intracranial bleed.[420]
S. lentus[478]	*S. lentus*, formerly a subspecies of *S. sciuri* (i.e., *S. sciuri* subsp. *lentus)* is part of the normal skin flora of sheep and goats.
S. lutrae[162]	This species, described in 1997, was isolated during postmortem examinations of three sea otters (*Lutra lutra*) from the Inner Hebrides Islands. Isolates were obtained from liver tissue and spleen tissues and from a mammary gland and supramammary lymph node. *S. lutrae* is free coagulase-positive and clumping factor-negative, and is most closely related to *S. delphini*, *S. felis*, *S. intermedius*, *S. schleiferi*, and *S. muscae*.
S. microti[389]	This species, described in 2010, was isolated from the viscera of common voles.[389]
S. muscae[206]	This species is found as a transient part of the body surface flora of flies that inhabit cow barns, but not found on flies inhabiting human dwellings.[206]
S. nepalensis[511]	This recently described species was isolated from nares swabs and lung tissue of goats with respiratory tract symptoms in areas of Nepal.[511] This species has also been isolated from rectal swabs of healthy South American squirrel monkeys, a urine specimen from a human with cystitis, pig skin, and the environment.[390]
S. pseudintermedius[136]	This coagulase-positive species was isolated from clinical and necropsy specimens obtained from a cat, a dog, a horse, and a parrot and was found to constitute a distinct taxon related to *S. intermedius* and *S. delphini*.[136] This organism has been isolated from infections in dogs, including necrotizing fasciitis and infection after joint prosthesis implantation.[364,594] *S. pseudintermedius* has also been isolated from nares specimens of humans with frequent exposure to dogs and cats (e.g., dog and cat owners, veterinary staff).[503,561]
S. rostri[450]	This relatively newly described species was isolated from nares specimens of pigs in Switzerland.[450,516]
S. sciuri[287]	*S. sciuri* is widely distributed in nature and has been isolated from foods, farm animals, rodents, marsupials, marine mammals, and occasionally from humans and their pets. Three subspecies are currently recognized.[282,346] *S. sciuri* subsp. *sciuri* is part of the transient skin flora in various mammalian and avian species; it is seldom found on humans and nonhuman primates. *S. sciuri* subsp. *carnaticus* is found mainly on bovine hosts and beef products. *S. sciuri* subsp. *rodentium* is found mainly on rodents. Human isolates have been recovered from wounds, skin, and soft tissue infections, and, in 1998, a case of *S. sciuri* endocarditis was reported.[218,346,519] *S. sciuri* has also been isolated as a cause of peritonitis in a dialysis patient. An examination of 30 human clinical isolates of *S. sciuri* found that 70% were subsp. *sciuri*, 23% were subsp. *rodentium*, and 7% were subsp. *carnaticus*. All subspecies of *S. sciuri* have been found to harbor a homolog of the *S. aureus* methicillin resistance gene *mecA* that is found in MRSA strains.[114,608] These two *mecA* homologs have about 80% base-pair similarities. *S. sciuri* strains that carry their native *mecA* homolog express borderline resistance to methicillin, while those strains that carry the MRSA *mecA* gene express heterogenous resistance to methicillin.
S. simiae[408]	This species was isolated from rectal swab specimens obtained from squirrel monkeys.
S. stepanovicii[216]	*S. stepanovicii* is a novobiocin-resistant staphylococcal species that was isolated from the skin, fur, and intestinal tracts of wild, small mammals, including rodents, voles, field mice, and shrews.
S. vitulinus[593]	This species was described in 1994 and is found as a part of the flora of horses, voles, and pilot whales. It has also been isolated from meat products, including lamb, chicken, ground beef, and veal. DNA hybridization studies show that this species is most closely related to *S. lentus* and *S. sciuri*.
Other Staphylococci (Mostly Environmental)	
S. carnosus[477]	This species is used as a starter culture in the processing of meats such as salami and sausage. At present, two subspecies are recognized: *S. carnosus* subsp. *carnosus* and *S. carnosus* subsp. *utilis*.[438]
S. condimenti[438]	This species is found in soy sauce mash (as is *S. piscifermentans*) and is closely related to *S. carnosus* subspecies.

S. fleurettii[577]	This species has been isolated from cheeses prepared from goats' milk.
S. piscifermentans[531]	This species is found in fish, fermented fish products, and soy mash and is closely related to *S. carnosus* and *S. condomenti*.[407]
S. succinus[310]	This species, first described in 1998, was isolated from a fragment of 25- to 35-million-year-old Dominican amber.[310] This species phenotypically resembles *S. xylosus* and is closely related to *S. xylosus*, *S. saprophyticus*, *S. equorum*, and other novobiocin-resistant staphylococci. A subspecies of *S. succinus*, *S. succinus* subsp. *casei*, has been proposed for isolates from Swiss surface-ripened cheese.[434] In 2006, several isolates from human clinical specimens were identified as *S. succinus*.[391]

BOX 12-3

Infections Associated With *Staphylococcus* aureus

Infection	Comments
Folliculitis	Folliculitis is a benign infection of the superficial dermis that is restricted to the ostia of the hair follicles and is characterized by the presence of small, reddish, painful lesions and the absence of systemic symptoms.
Impetigo	Impetigo is a superficial staphylococcal infection of the dermis that is seen mostly in children and usually presents on exposed areas, especially the face. Impetigo occurs in two forms: nonbullous and bullous.[179] Nonbullous impetigo begins as a single red macule or papule that quickly becomes a vesicle. The vesicle ruptures to form an erosion, and the lesion and its contents dry to form characteristic honey-colored crusts with erythematous margins that may be pruritic. Impetigo may be spread to surrounding areas by autoinoculation. Bullous impetigo is a localized form of staphylococcal scalded skin syndrome that most commonly affects neonates but also can occur in older children and adults. Superficial vesicles progress to enlarging bullae with sharp margins and no surrounding erythema. When the bullae rupture, yellow crusts with oozing result. Bullous impetigo is usually found in moist, intertriginous areas (i.e., the diaper area, axillae, neck folds). Systemic symptoms are not common but may include fever and sometimes gastroenteritis. Most cases are self-limited and resolve without scarring in several weeks. *S. aureus* accounts for 80%–90% of cases of impetigo, with the remaining being associated with group A β-hemolytic streptococci. Impetigo caused by these two organisms are indistinguishable clinically.
Furuncles and carbuncles	Furuncles are deeper-seated infections of the hair follicles in which suppuration extends through the dermis into the subcutaneous tissues. These lesions present as painful, firm, raised lesions with necrotic centers containing purulent material. Generalized systemic symptoms are usually absent. Carbuncles refer to even more deep-seated lesions that involve the subcutaneous tissues and several adjacent hair follicles. Several lesions may be present and may coalesce via the formation of subcutaneous sinus tracts. Carbuncles tend to occur on the back of the neck and are often associated with systemic signs of chills and fever. Carbuncles require prompt surgical drainage and management includes parenteral antimicrobial therapy.
Hidradinitis supperativa	Hidradenitis suppurativa is a chronic or relapsing inflammatory disease of the skin, involving the apocrine gland-bearing areas including axillae, groin, perineal and perianal regions This condition is characterized by the presence of multiple furuncle-like lesions associated with blocked and infected apocrine sweat glands. While local pain, swelling, and erythema are present, systemic symptoms such as fever are usually absent.
Mastitis	Mastitis refers to breast infections associated with childbirth and lactation and is characterized by edema, swelling, firmness and, occasionally, erythema of the breast tissues. Superficial abscesses may be drained by needle aspiration, while deeper, persistent lesions require incision and drainage for cure, often along with antibiotic therapy.
Wound infection	Most staphylococcal wound infections occur in the postsurgical setting and are recognized by redness, swelling, and pain around the surgical site, and the presence of cloudy, serosanguinous drainage. The approach to wound care in patients with staphylococcal wound infection is dependent on the depth of the infection, the condition of the host, the presence and/or severity of clinical signs and symptoms, and the presence/absence of foreign bodies within the wound. These factors determine the extent of debridement necessary and the requirement for parenteral antimicrobial chemotherapy. These infections are often caused by the same strain of *S. aureus* carried in the anterior nares of the infected patient.[579]
Cellulitis and complicated soft tissue infections	Cellulitis refers to rapidly spreading inflammation and infection of the soft subcutaneous tissues and may go on to involve the superficial fascia and the subcutaneous fat. While group A β-hemolytic streptococci are the most frequent causes of this infection, *S. aureus* is occasionally responsible, especially in the presence of an abscess

or cutaneous ulcer. Cellulitis may involve *S. aureus*, other gram-positive organisms, and gram-negative bacteria as well, so specimen collection should include aspirates from the leading edge of the spreading cellulitis and collection of blood cultures, and broad-spectrum empiric therapy should be initiated. **Erysipelas** is a type of cellulitis with a well-demarcated raised border that is usually caused by group A β-hemolytic streptococci but is occasionally caused by *S. aureus*. This infection is painful and lymphatic involvement is prominent. As with cellulitis, collection of localized specimens and blood cultures are helpful, and antimicrobial coverage should be broad-spectrum and promptly administered. Necrotizing fasciitis can result from localized spread of staphylococcal infection or may arise hematogenously. This infection evolves rapidly so prompt diagnosis, surgical debridement, and fasciotomy are absolutely necessary for good clinical outcomes. Necrotizing fasciitis may involve *S. aureus*, β-hemolytic streptococci, and gram-negative bacteria (e.g., *P. aeruginosa*), so high-dose broad-spectrum antimicrobial therapy is warranted.

Bloodstream infections

S. aureus is responsible for between 20 and 30 episodes of bloodstream infection per 100,000 persons per year worldwide and is associated with a mortality rate of 20%–30%.[43,454] Operationally, bloodstream infections are hospital-acquired or community-acquired. The former usually occur 2 or more days after hospitalization, while community-acquired infections arise 2 or more days before hospitalization. Community-acquired (CA) bacteremia may be associated with previous or ongoing healthcare institution exposure or outpatient encounters; consequently, CA-bloodstream infections are more accurately termed either healthcare-associated (HCA)-community onset or CA-community onset bloodstream infections.[440] HCA-bloodstream infections that arise in the community generally occur in patients with indwelling catheters and other access devices and in patients on dialysis or undergoing outpatient treatment protocols. Community-onset CA-bloodstream infections arise in previously healthy persons and develop from localized infection elsewhere (e.g., skin and soft tissue infections, abscesses, ulcers, bone infection, burns). HCA-bloodstream infections arising in the hospital or in the community usually involve more resistant *S. aureus* strains than infections with onset occurring outside the healthcare inpatient/outpatient settings. Patients with staphylococcal bacteremia usually present with chills, rigors, and fever. Small hemorrhagic skin lesions may be present and those on the skin may evolve to form larger, necrotic ulcers. Endocarditis following *S. aureus* bacteremia occurs in about 10% of patients and may present in a subtle manner, or with multiple signs and symptoms.[86] With infection of the heart valves, more subtle hemorrhagic manifestations (e.g., Janeway lesions, Roth spot, splinter hemorrhages) may be apparent. Heart murmurs, pericardial friction rubs, and pericardial effusions may be present and, depending on the type of murmur, often suggest the likely location(s) of bacterial involvement and valvular insufficiency. Transthoracic and transesophageal echocardiography aid in delineating the extent of cardiac involvement and help to determine the need for and immediacy of surgical interventions. Thrombocytopenia is frequently present, and disseminated intravascular coagulation represents a rare but fatal complication occurring early in the clinical course. Metastatic foci of infection may develop in multiple organ systems, and hematogenous seeding of the kidney can result in mild-to-severe renal insufficiency, abscesses and pyelonephritis. If bloodstream infection is associated with infected access devices, the removal of these materials is essential for organism clearance from the bloodstream.[111] During and following removal, an 8- to 10-day course of parenteral antimicrobial therapy is recommended with follow-up including collection of additional blood cultures and exclusion of infective endocarditis. Other complications of *S. aureus* bloodstream infection may require longer antibiotic courses ranging from 10 to 14 days following cutaneous infections to 4- to 6-week regimens involving deep-seated infections (e.g., abscesses, bone infections).[111] Prior to the availability of antimicrobial susceptibility information, initial therapeutic coverage is directed against MRSA.

Endocarditis

S. aureus is a cause of native valve endocarditis and is also a leading cause of prosthetic valve endocarditis.[161,381,378,586] *S. aureus* infective endocarditis usually presents as an acute septic syndrome with fever, nonspecific symptoms (i.e., arthralgias, myalgias, pleuritic pain), and the appearance of a new cardiac murmur. Petechial skin lesions and Janeway lesions may be present; these indicate the development of septic emboli. Large vegetations may form on the valves, break off, and embolize to the coronary and peripheral arteries and to various organ systems. Septic emboli and mycotic aneurysms may be carried to the central nervous system where they can cause cerebral infarcts, abscesses, and intracerebral or subarachnoid hemorrhages. Diagnosis is aided by echocardiography, with transesophageal approaches being the most useful for detection of mycotic aneurysms. Right-sided endocarditis is seen primarily in injection drug users. For native valve endocarditis due to MSSA, a penicillinase-resistant penicillin (e.g., oxacillin, nafcilllin) or a first-generation cephalosporin (e.g., cefazolin) with or without an aminoglycoside is generally used.[440] Vancomycin is recommended for those with allergy to β-lactam antibiotics and in those with endocarditis due to MRSA. Therapy must be continued for 4–6 weeks. For prosthetic valve endocarditis due to MSSA, a penicillinase-resistant penicillin is administered along with rifampin and gentamicin. Vancomycin with rifampin and gentamicin is recommended for those with β-lactam allergy and in those with endocarditis due to MRSA. Treatment of prosthetic valve endocarditis must be continued for at least 6 weeks.

Meningitis	Meningitis due to *S. aureus* may occur as a complication of bacteremia or local trauma due to neurosurgical interventions, placement of shunts, surgery or injury (e.g., severe head trauma).[44,432] Meningitis complicating *S. aureus* bacteremia usually occurs in compromised individuals with a focus of infection elsewhere (i.e., abscess, osteomyelitis, pneumonia).[419] Although the signs and symptoms are similar to other meningeal infections, comorbidities (e.g., immunodeficiency, underlying disease) are present more frequently. Meningitis due to *S. aureus* is rare (2%–8% of all meningitides), but the mortality rate is high.
Pericarditis	Pericarditis (infection of the membranes surrounding the heart) due to *S. aureus* may arise hematogenously or secondary to local infection from penetrating chest trauma, surgery, or septic emboli.[463] Pericarditis may also occur as a complication of staphylococcal endocarditis. Patients present with chest pain, friction rubs, generalized heart failure and/or mediastinitis.
