housed in a provisional hematology unit. The authors conclude that, despite the inability to recover *S. proliferans* from the patients' rooms or adjacent corridors, circumstantial evidence indicated a nosocomial outbreak. Two similar related infections have been reported by Simarro et al.[257] Both patients were admitted to the hematologic ward in nearby rooms during building work in the hospital. After a previous episode of bacterial sepsis in the neutropenic phase, which improved with antibiotic treatment, the respiratory status in both patients deteriorated, presenting acute dyspnea, with a lung infiltrate in one of them. A few hours later both patients died. Blood cultures were positive for *S. prolificans*. De Battle et al.[64] described a patient with leukemia who developed a disseminated *S. prolificans* infection during a period of chemotherapy-induced neutropenia. *S. prolificans* was recovered from four blood cultures. At autopsy, disseminated fungal infection was found, with multiple intravascular mycotic thromboses in the lungs, liver, spleen, and other organs. The authors make the plea that every effort be made to protect patients with leukemia from the invasion of saprophytic fungi during periods of therapy-induced neutropenia.

A variety of other hyaline molds may cause disease in the susceptible host. Chan et al.[40] report peritoneal dialysis-related peritonitis caused by *Paecilomyces variotii* in two patients. Each of these patients had received multiple antibiotics as a treatment for bacterial peritonitis, possibly contributing to the emergence of the opportunistic *Paecilomyces* infection.

1359

Paecilomyces species–related infections have also been reported by Chan-Tack et al.[41] (fungemia in an adult bone marrow transplant recipient), Gucalp et al.[104] (amphotericin B-refractory sinusitis in an immunocompromised adult), Okhravi et al.[204](endophthalmitis following penetrating keratoplasty), and Westenfeld et al.[288] (a patient with subcutaneous infection with prepatellar bursitis). Castro et al.[37] reported a case of deep subcutaneous infection of the left forearm with *Purpureocillium lilacinum* (formerly *Paecilomyces lilacinus*) in a kidney-transplant recipient, which responded to oral griseofulvin therapy. These authors reviewed 42 instances of human mycoses due to *Paecilomyces* species, usually in conjunction with prosthesis implants or immunosuppression. The differentiation of these microscopically-similar fungi is important as most strains of *P. lilacinus* are resistant to amphotericin B, whereas most strains of *P. variotii* are susceptible.

Scopulariopsis spp. have been reported to cause infections of nails, subcutaneous tissue, and the lungs.[274] Phillips et al.[224] report several patients with *S. brevicaulis* mycosis involving the toenail in an allogeneic bone marrow transplant recipient. Other infections cited were hypersensitivity pneumonitis, fungus ball formation in the lung, and deep subcutaneous infections in immunocompromised hosts. Miscellaneous *Scopulariopsis* infections include invasive fungal sinusitis reported by Ellison et

al.[79]and by Jabor et al.,[135] the latter involving invasive nasal destruction in a nonimmunocompromised host; a fatal case of *S. brevicaulis* prosthetic-valve endocarditis reported by Migrino et al.[186]; and a patient with a recurrent subcutaneous infection, occurring in a patient 6 years after liver transplantation, reported by Sellier et al.[251]

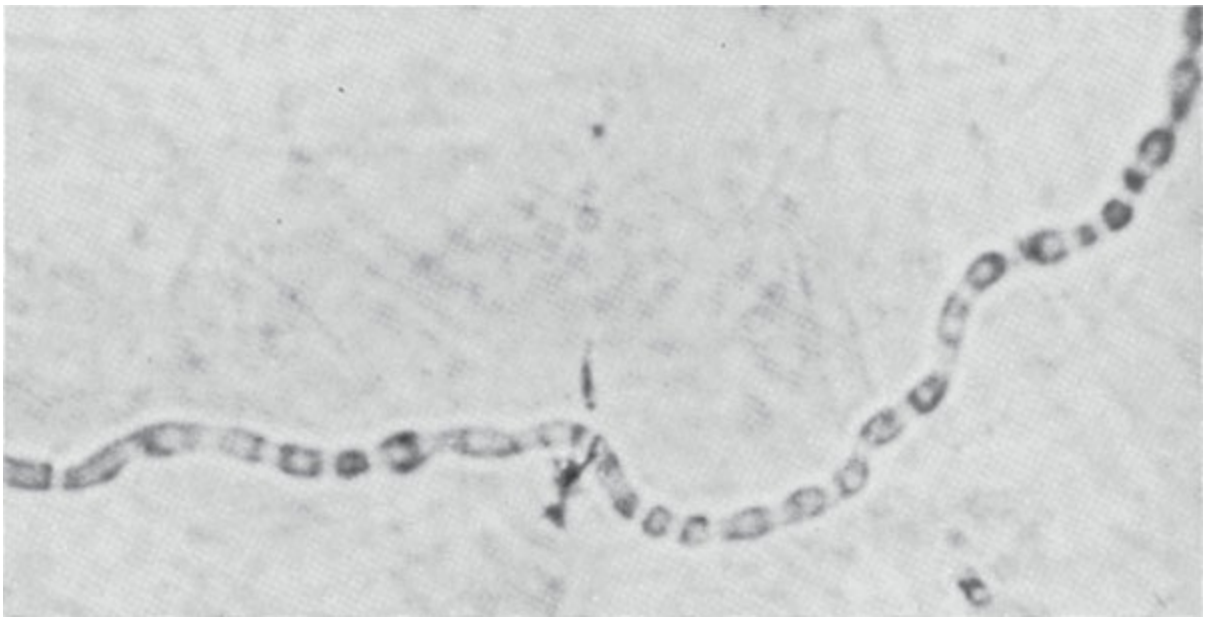
Schell and Perfect[247] report a patient with neutropenia who developed a disseminated infection caused by *Acremonium strictum*. In this patient, the organism was recovered from blood cultures after previous recovery from fecal specimens suggests the gastrointestinal tract as the primary source of infection.

Identification of the Dermatophytes

The dermatophytes are a distinct group of fungi that infect the skin, hair, and nails of humans and animals, producing a variety of cutaneous infections, colloquially known as "ringworm." Any mold recovered in culture from specimens labeled skin, nail, or hair should be assessed to determine whether it is a dermatophyte. One must be alert, however, that other pathogenic fungi, including the dimorphic molds, can also involve the skin and may have features, such as delicate, narrow diameter hyphae and resistance to cycloheximide, which are similar to the dermatophytes. In addition, many saprophytic environmental molds may be recovered, especially from nails. Determining the pathogenic nature of these fungi is challenging as they could represent either a contaminant or the cause of infection. Repeated isolation of such fungi, the exclusion of the presence of a dermatophyte, and the demonstration of invasive fungal form by histopathology would provide supportive evidence that the onychomycosis was caused by the fungus.

The direct examination using the KOH/calcofluor white preparation is useful for the direct detection of dermatophytes. Observing typical hyphal segments in direct skin scales (Fig. 21-44) or either ectothrix or endothrix invasion of infected hairs are helpful preliminary findings (Fig. 21-45).

The colonies of the various strains of dermatophytes vary considerably in rates of growth, morphology, and pigment production, sometimes even within the same species. Therefore, the genus and species designation depends on observing microscopic features. In some instances, the species-level identification, particularly for the species of *Trichophyton*, is not possible without supplemental biochemical/biophysical testing. Species-level identification, although of epidemiologic interest, is not necessary for treatment. There are, however, a few colony characteristics, which may be helpful



■ **FIGURE 21-44** Photomicrograph of a KOH mount of skin scraping, illustrating a hyphal segment of one of the dermatophytic fungi. Note that the hyphal fragment is breaking up into tiny arthroconidia (1,000×, oil immersion).

from a patient with dermatophytosis. Note the endothrix invasion with septate hyphae centrally and conidia at the periphery (GMS stain, 400×).

1360

in the identification of a given species; these are discussed below, where appropriate. Representative dermatophyte colonies are illustrated in Image Plate 21-4. The species of medical importance more commonly encountered in clinical laboratories are *Microsporum canis*, *Microsporum gypseum*, *Trichophyton mentagrophytes*, *Trichophyton rubrum*, *Trichophyton tonsurans*, *Trichophyton verrucosum*, and *Epidermophyton floccosum.*

In a survey of dermatophyte infections in the United States conducted by Weitzman,[286] *Trichophyton tonsurans* was the dermatophyte species most frequently recovered (44.5% of cases), and *Trichophyton rubrum* (41.3%) was next in frequency, followed less commonly by *Trichophyton mentagrophytes* (8.5%), *Microsporum canis* (3.5%), and *Epidermophyton floccosum* (1.1%).

The dermatophytes are separated into three genera, *Microsporum*, *Trichophyton,* and *Epidermophyton*, based primarily on differences in the microscopic morphology and modes of sporulation. An approach to the identification of the genera and species of the dermatophytes is presented in Display 21-3.

The genus ***Microsporum*** is characterized by the production of many macroconidia, and few or no microconidia. The macroconidia are multicelled and thick-walled, and have a thick, echinulate, or verrucose cell wall. The species identifications are based on differences in morphology of the macroconidia. The microconidia, if present, are small, hyaline, and tear-drop or elliptical in shape and attach directly to the sides of the hyphae.

The genus ***Trichophyton*** is characterized by the production of many microconidia, and few or no macroconidia. The macroconidia, when formed, in contrast to those of *Microsporum* spp. are thin-walled and smooth. The size and arrangement of the microconidia are important in making a species-level identification. The production of pigment, urease activity, hair penetration capabilities, and the differential growth patterns on culture media with and without thiamine and niacin (*Trichophyton* differential agars) are also used to achieve a species-level identification.

The genus ***Epidermophyton*** is characterized by the production of clavate, smooth-walled, two- to four-celled macroconidia that are borne either singly from the hyphae or, more characteristically, in clusters of two or three. The absence of microconidia is of prime importance in making the identification of *Epidermophyton.*

Identification of Microsporum Species

Microsporum canis. *Microsporum canis* is a zoophilic dermatophyte. Infection is often contracted from the family pet. Growth is rapid, within 3 to 5 days. The colonies are initially white and silky, later developing a lemon-yellow pigment at the colony peripheral apron (Image Plate 21-4A). The reverse of the colony becomes yellow-brown as the colony matures.

Microscopically, both macroconidia and microconidia may be observed, with the former predominating. The production of spindle-shaped (fusiform), multicelled macroconidia that are pointed, and may be slightly turned to one side at the tip, is characteristic of *Microsporum canis* (Fig. 21-46). Scattered microconidia may be seen borne laterally directly from the hyphae. In hair infections, mosaic clusters of microconidia develop on the outside of the shaft (**ectothrix**).

■ **FIGURE 21-46** Photomicrograph and sketch of a multicelled macroconidium of *Microsporum canis,* illustrating the spindle shape, thick echinulate wall, cross septations and tapered tip.

Microsporum gypseum. *Microsporum gypseum* is a geophilic dermatophyte, and infection is usually contracted from contact with soil. Growth is rapid, within 3 to 5 days. The colonies are flat, initially white but turning fawn-brown to reddish-brown on maturity (Image Plate 21-4B). The surface becomes sugary or granular as conidia are produced.

The macroconidia of *M. gypseum* generally are more numerous than found with *M. canis*, are less fusiform and have rounded tips (Fig. 21-47). A history of exposure to soil and possibly infected animals, and the colony morphology may be helpful in making the differential identification.

Microsporum nanum. *Microsporum nanum* is a zoophilic dermatophyte that is associated with pigs and is a relatively rare cause of dermatophytosis.[236] The colonies of *M. nanum* grow rapidly, within 3 to 5 days. The surface is cottony, initially white, and later buff-colored, turning to brownish-red on the reverse side. Tufts may appear on the surface with maturity.

1361

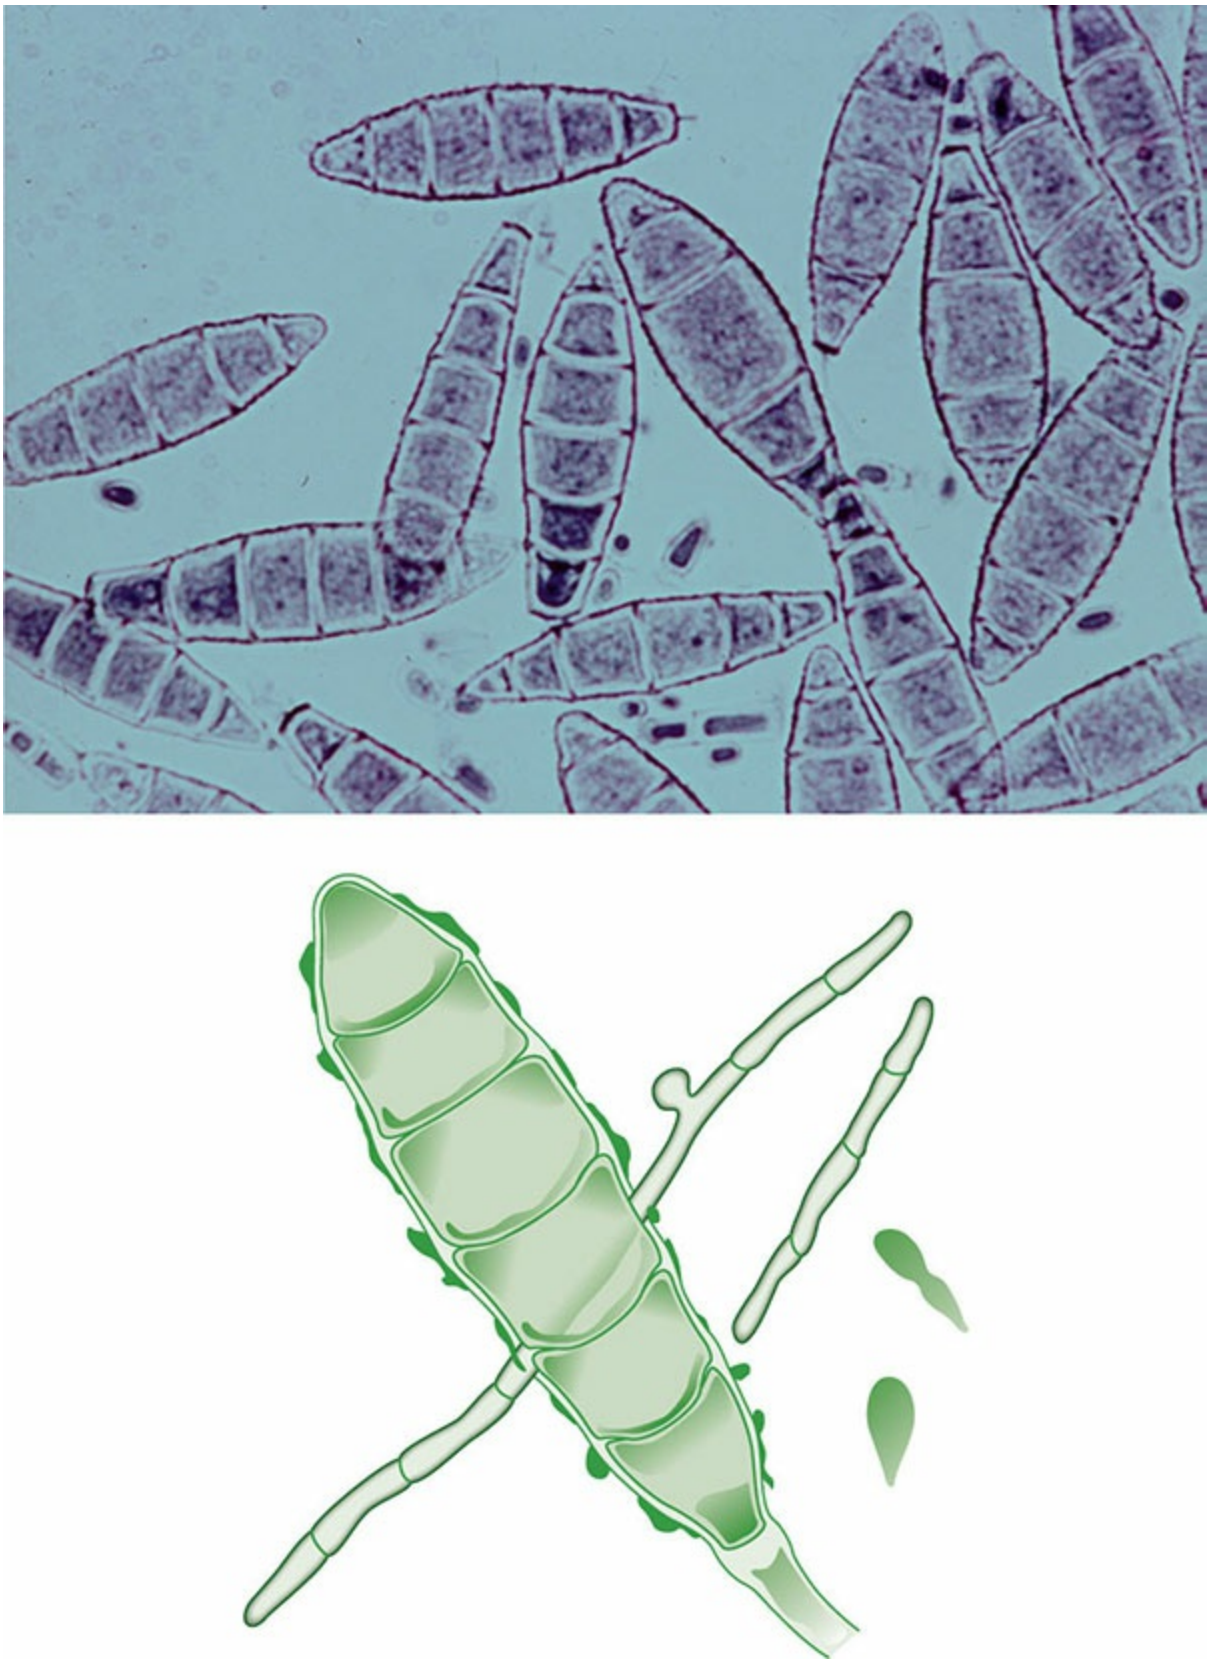

FIGURE 21-47 Photomicrograph and sketch of a multicelled macroconidium of

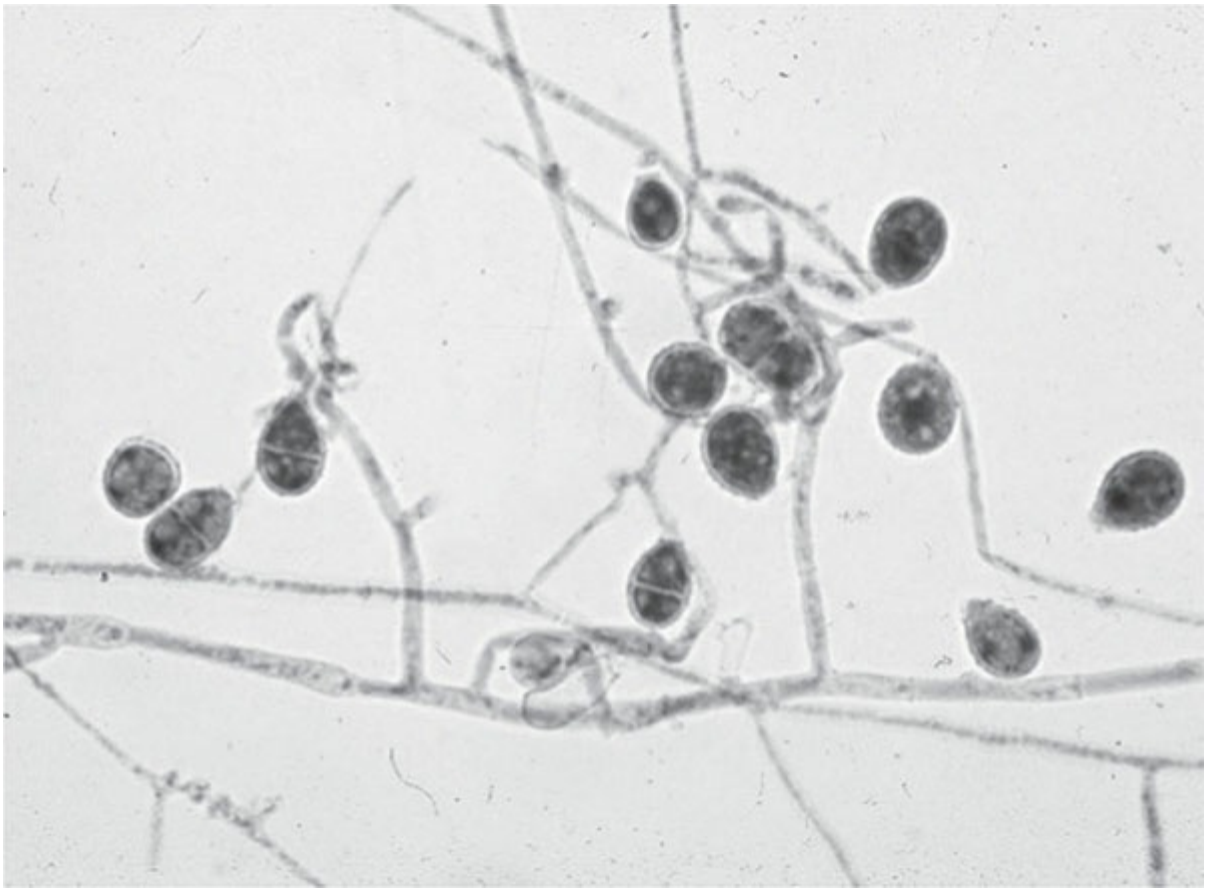
Microsporum gypseum, revealing a thick, echinulate wall, cross septations and a rounded terminal cell.



■ **FIGURE 21-48** Photomicrograph of the macroconidia of *Microsporum nanum*. They differ from those of *E. floccosum* by being two-celled and having a thick, echinulate wall.

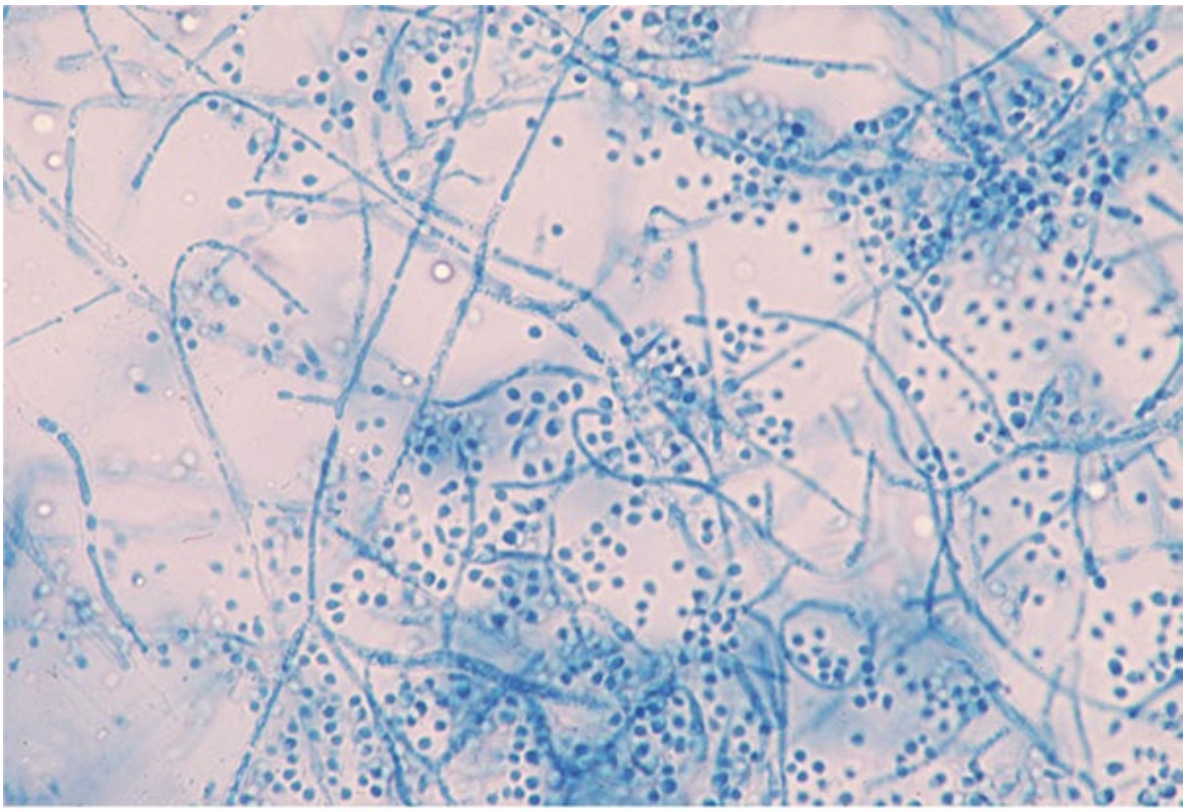
Microscopically, two- to three-celled, oval to clavate macroconidia are characteristically seen. At cursory evaluation, the macroconidia produced may resemble those of *Epidermophyton floccosum*. The cell walls are finely verrucose (Fig. 21-48) in contrast to the conidia of *E. floccosum,* which have smooth walls. Small 3 to 5 mm clavate to cylindrical microconidia are derived from the sides of the hyphae, an additional important observation in differentiating *M. nanum* from *E. floccosum*.

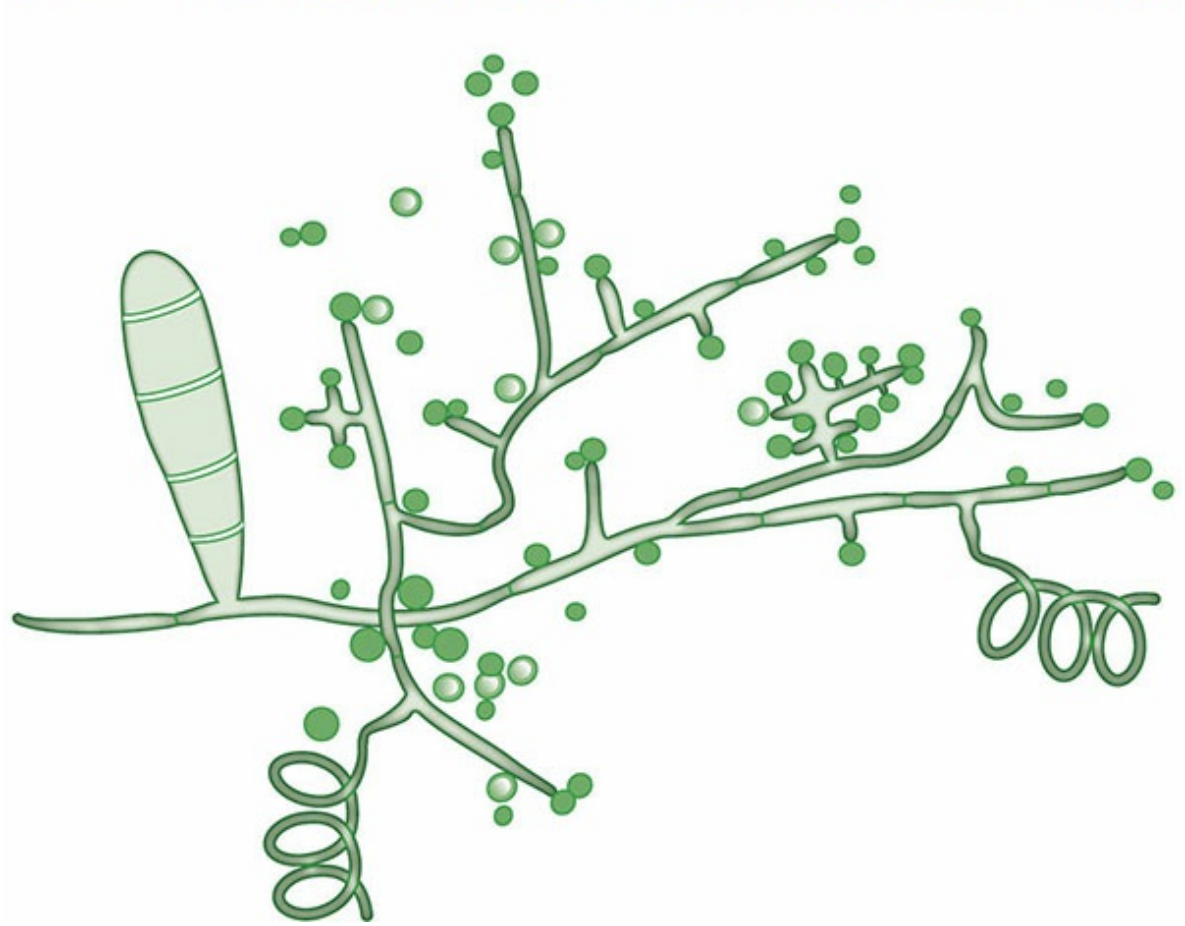
Identification of Trichophyton Species

Trichophyton mentagrophytes. *Trichophyton mentagrophytes* is a zoophilic dermatophyte, and infection may be contracted from a wide variety of animals.

Growth is relatively rapid, with maturation in 3 to 5 days. One of two colony types may be observed: cottony or granular. The cottony variants are initially white, but may become cream to tan with maturity. A central raised central area of cobweblike sterile hyphae often develops. The periphery and reverse of the colony may be rose to tan (Image Plate 21-4D). The granular variants produce flat and spreading colonies with a fine to coarse granular surface. The colonies are initially white or off-yellow, but later become tan to brown. A red pigment similar to that seen with *T. rubrum* may be observed; however, the pigmentation is never as intense as with *T. mentagrophytes*, particularly when colonies in parallel are grown on cornmeal agar or PDA (Image Plate 21-4F).

The microconidia tend to form in loose grapelike clusters (*en grappe*) (Fig. 21-49). Macroconidia are typically absent



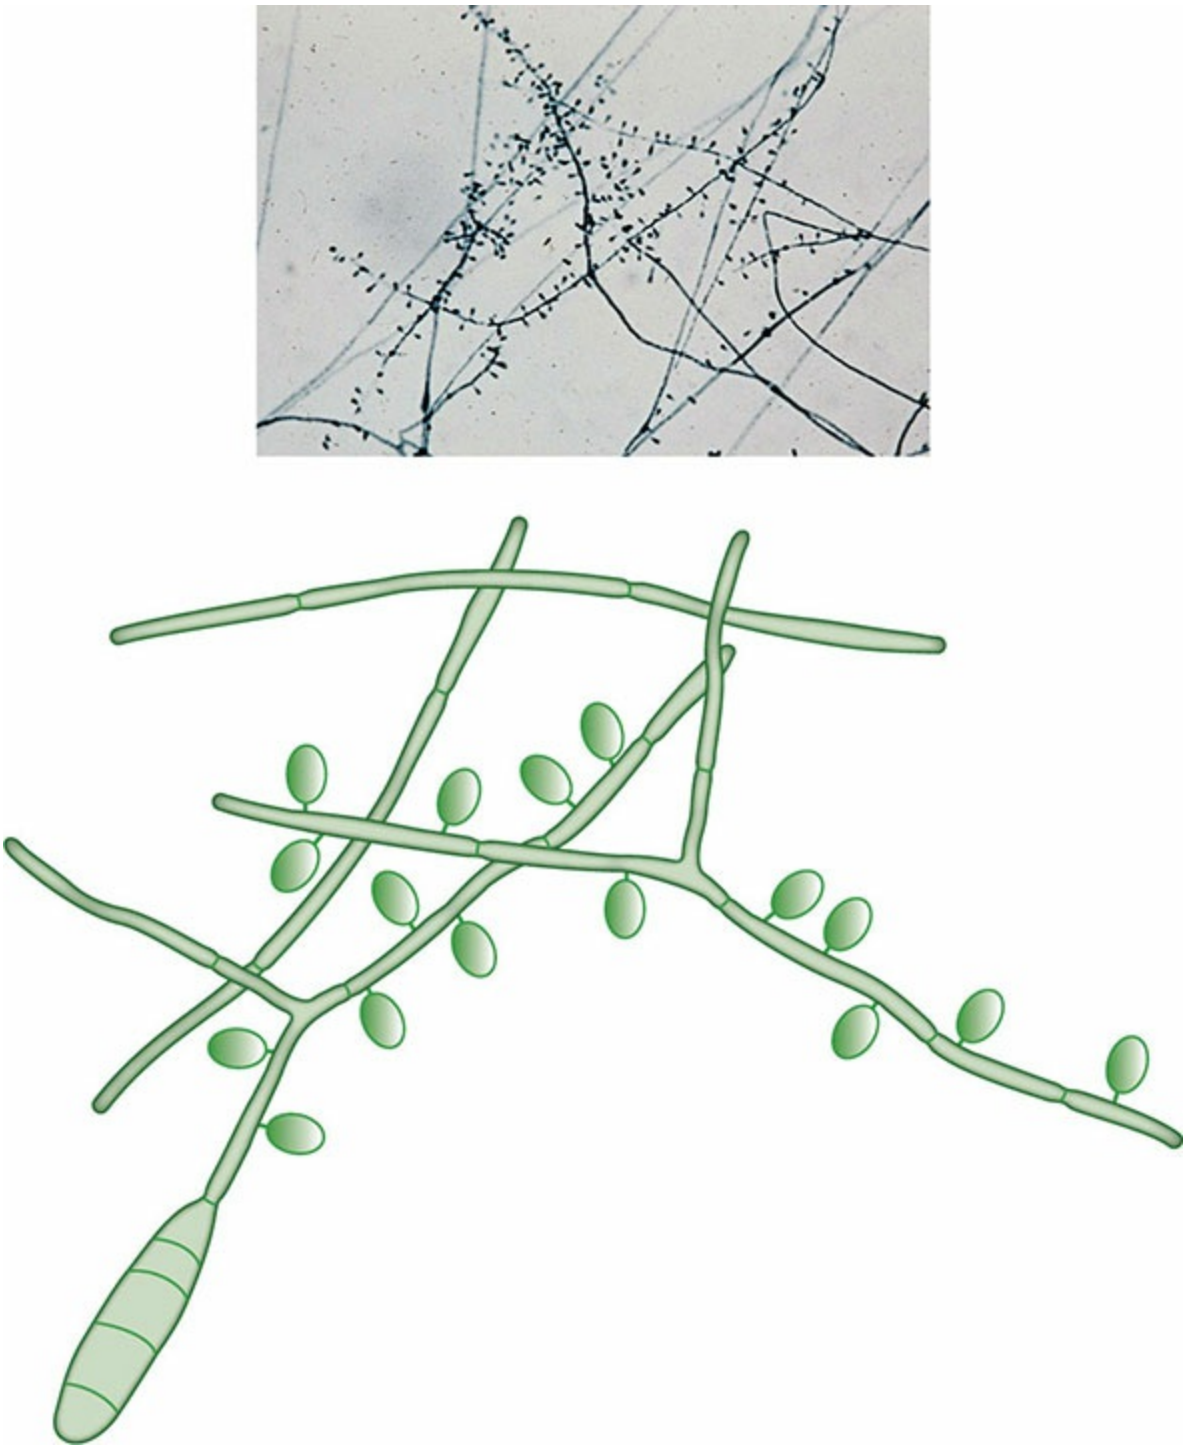


■ **FIGURE 21-49** Photomicrograph and sketch of the microscopic forms of *Trichophyton mentagrophytes,* illustrating tiny, spherical conidia arranged in loose clusters.

or present in small numbers; they are more common in granular cultures. If present, they are long, multicelled, cigar-shaped and have thin, smooth walls. Spiral hyphae and chlamydospores are often seen in the vegetative hyphae. Most strains are urease-positive, and in hair infections the hyphae invade the shafts (**endothrix**). There is equal growth on the *Trichophyton* differential agars.

Trichophyton rubrum. *Trichophyton rubrum* is an anthropophilic dermatophyte that commonly infects the skin and nails. Growth on SDA is relatively slow, requiring 4 to 7 days until maturity. The colony surface is initially white, and the consistency may be cottony, velvety, or granular, depending on the strain, the culture medium being used, and the magnitude of sporulation. As the species name indicates, a key observation is the production of a water-soluble, wine-red pigment on the reverse of the colony that diffuses into the agar (Image Plate 21-4E and F). Pigment production is more intense with colonies grown on cornmeal agar or PDA than on SDA.

Microscopically, the microconidia of *T. rubrum* tend to be teardrop-shaped (pyriform) and are usually distributed on either side of the hyphal strands, producing a "birds on a fence" appearance, rather than the loose clustering seen with *T. mentagrophytes* (Fig. 21-50). Multicelled macroconidia may rarely be observed; if present, they are elongated and cigar-shaped, with smooth, thin walls, similar to those produced by *T. mentagrophytes*. Urease is not produced by this species, and the hair shaft is not invaded in the hair-baiting or hair penetration test. There is equal growth on the *Trichophyton* differential agars.

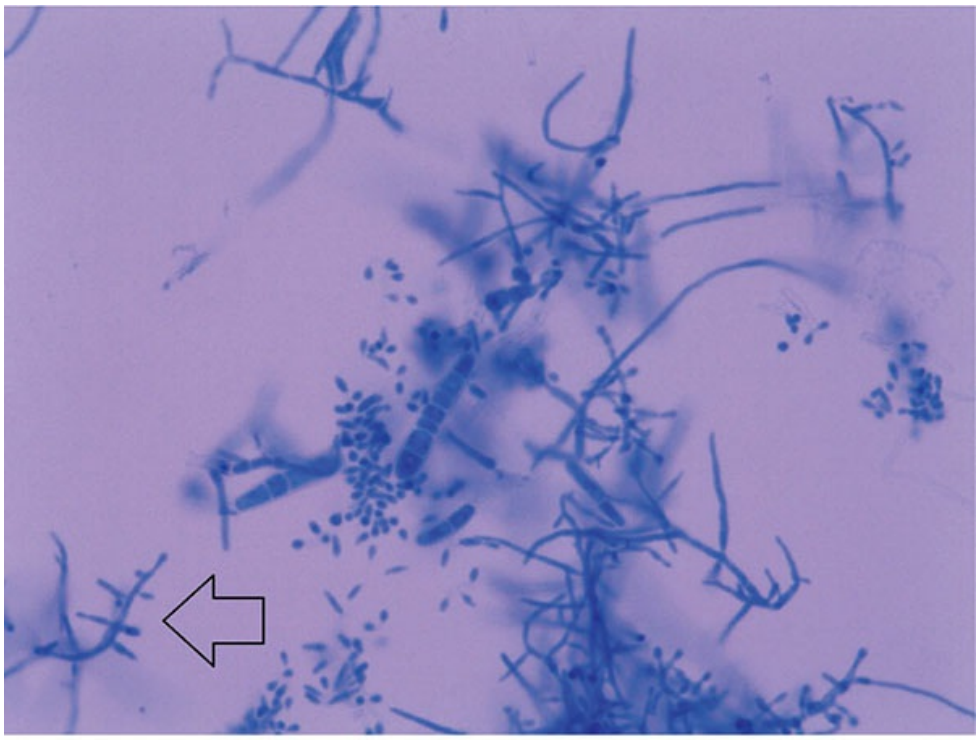


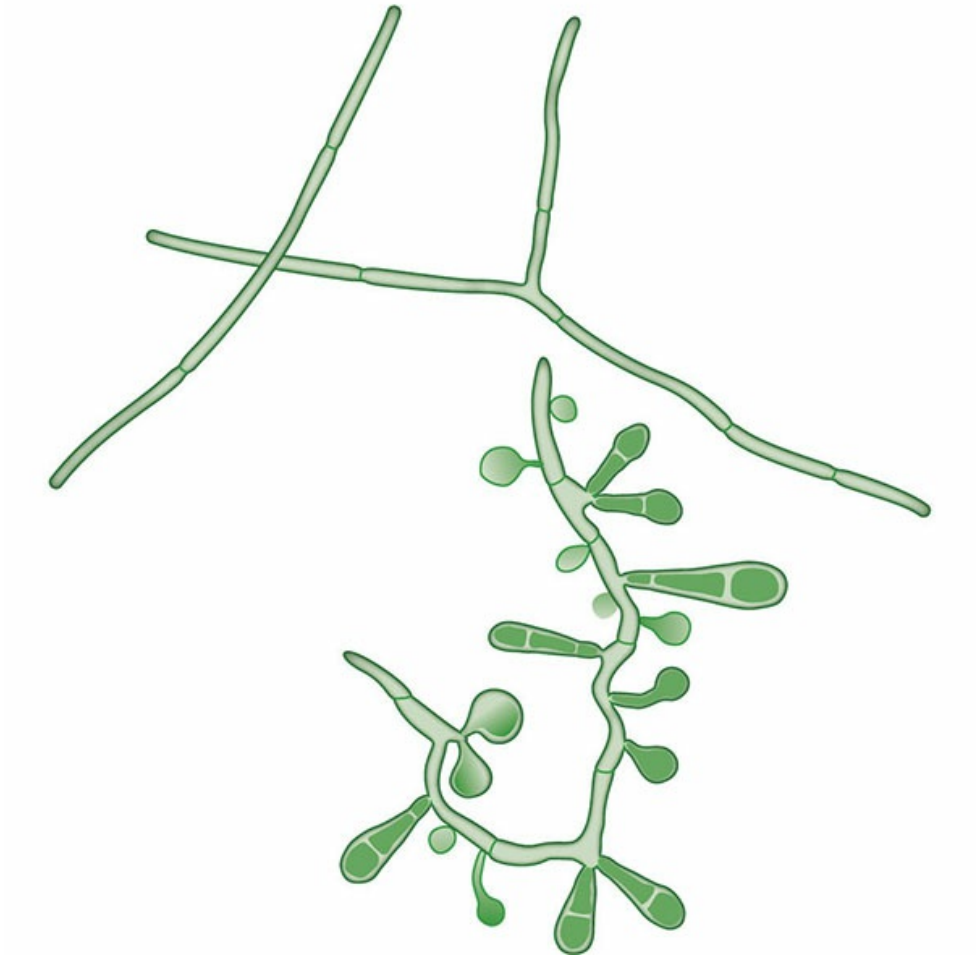
■ **FIGURE 21-50** Photomicrograph and sketch of the microscopic forms of *Trichophyton rubrum,* illustrating the production of tiny conidia from the sides of the hyphae in a "birds on a fence" arrangement.

Trichophyton tonsurans. *Trichophyton tonsurans* is an anthropomorphic

dermatophyte that causes infections of the nails, skin, and scalp. Growth is slow, requiring 7 to 10 days to maturity. The colonies have a characteristic granular, buff surface, with the development of deep radial rugae on maturation (Image Plate 21-4G). The identification can be confirmed by demonstrating poor growth on *Trichophyton* agar 1, which is deficient in thiamine; thiamine is an absolute growth requirement for *T. tonsurans*. There is good growth on *Trichophyton* agar 4, which contains thiamine.

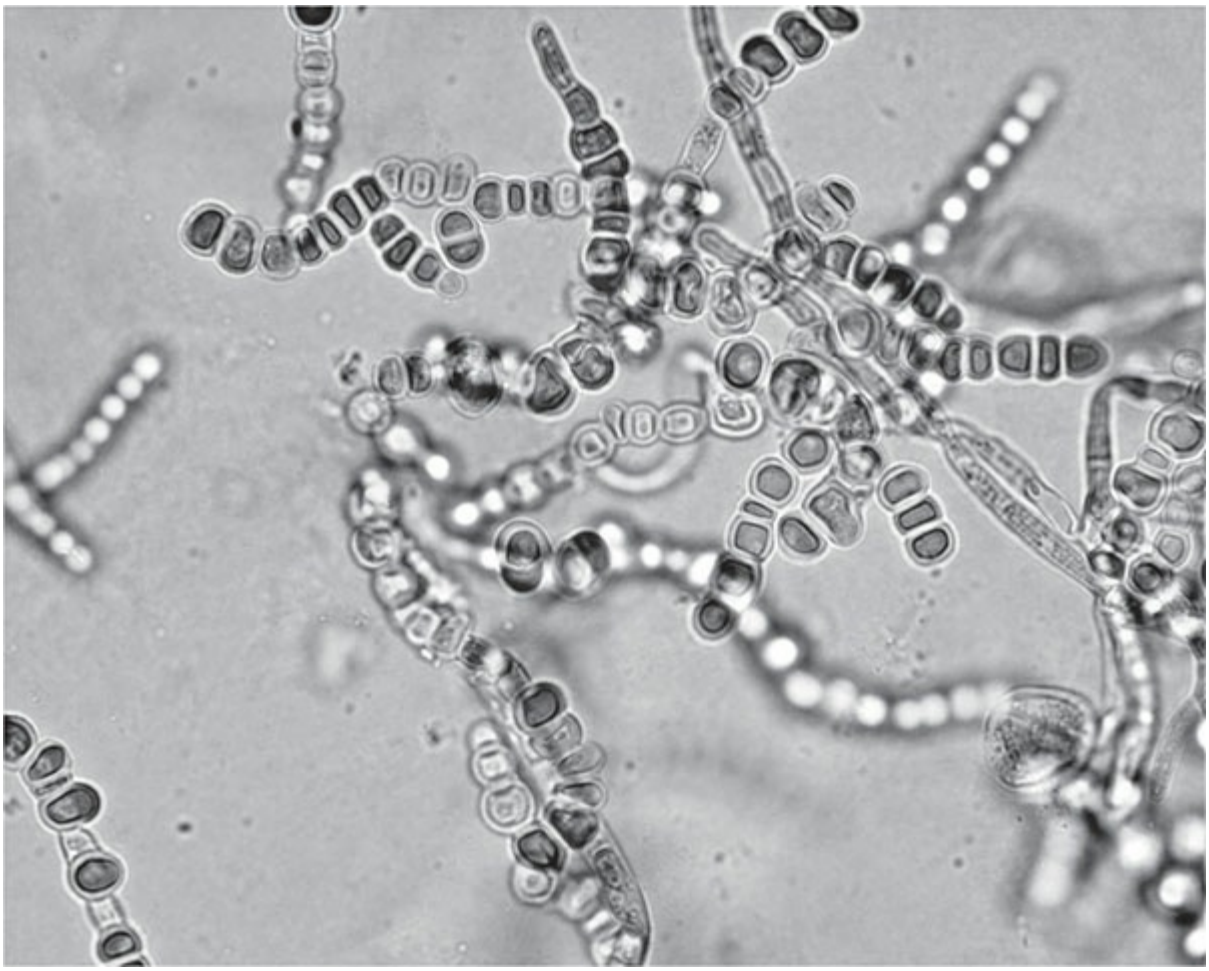
Microscopically, the microconidia are usually distinctive. They vary considerably in size, and range from elongated, club-shaped, or large and balloon-shaped forms may be admixed with smaller oval or teardrop-shaped microconidia (Fig. 21-51). Macroconidia are rarely observed in laboratory isolates.





■ **FIGURE 21-51** Photograph and sketch of the club-shaped and spherical microconidia of *T. tonsurans* free and borne laterally from the delicate hyphae *(arrow)*. Additionally, several smooth and thin-walled macroconidia are present in this preparation.

1363



■ **FIGURE 21-52** Photomicrograph of the microscopic appearance of chains of chlamydospores, characteristic of *Trichophyton verrucosum.*

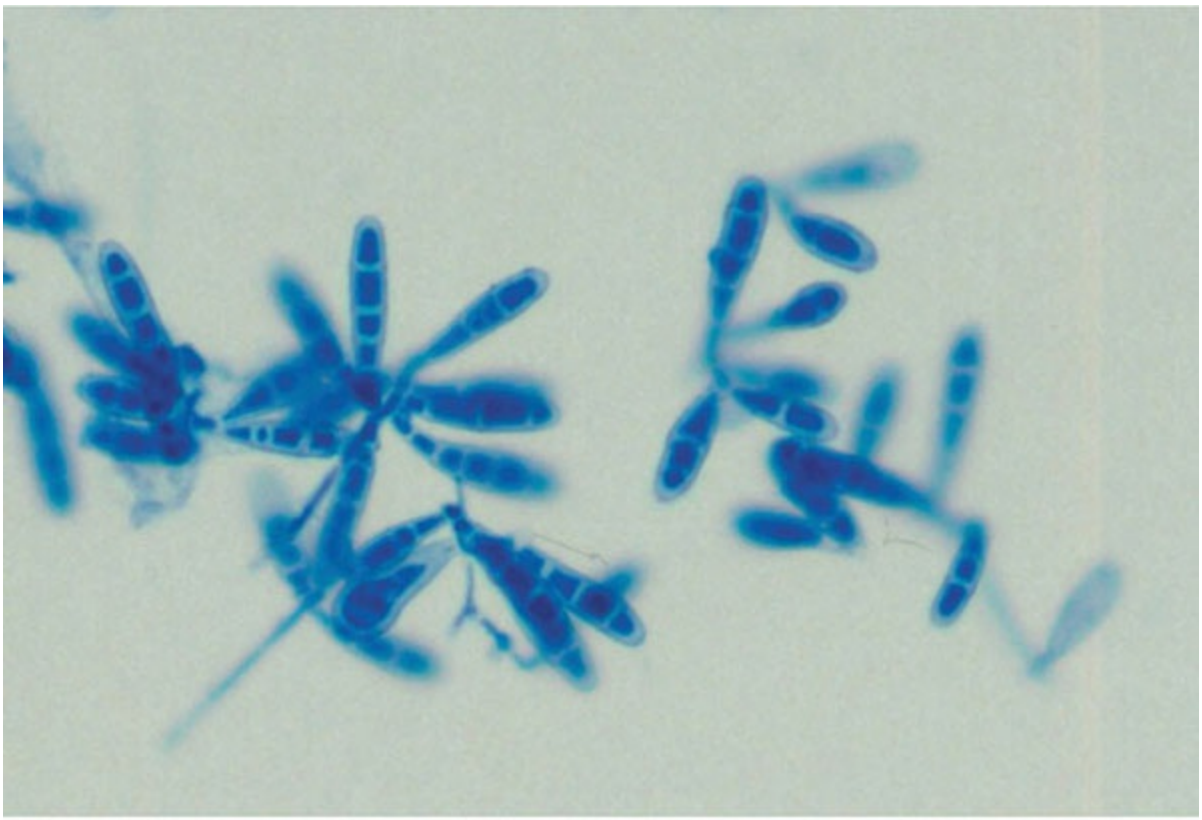
Trichophyton verrucosum. *Trichophyton verrucosum* is a zoophilic fungus that causes infections in cattle. Although it is transmitted by direct contact, it also may be transmitted by fomites. It may infect the skin, hair, and skin. Growth is slow, requiring 7 to 14 days to maturity. Growth is poor in *Trichophyton* agar 1, which is deficient in thiamine and inositol. Growth, however, will be observed on *Trichophyton* agars 2, 3, and 4, all of which contain either thiamine, inositol, or both. Colonies are small,

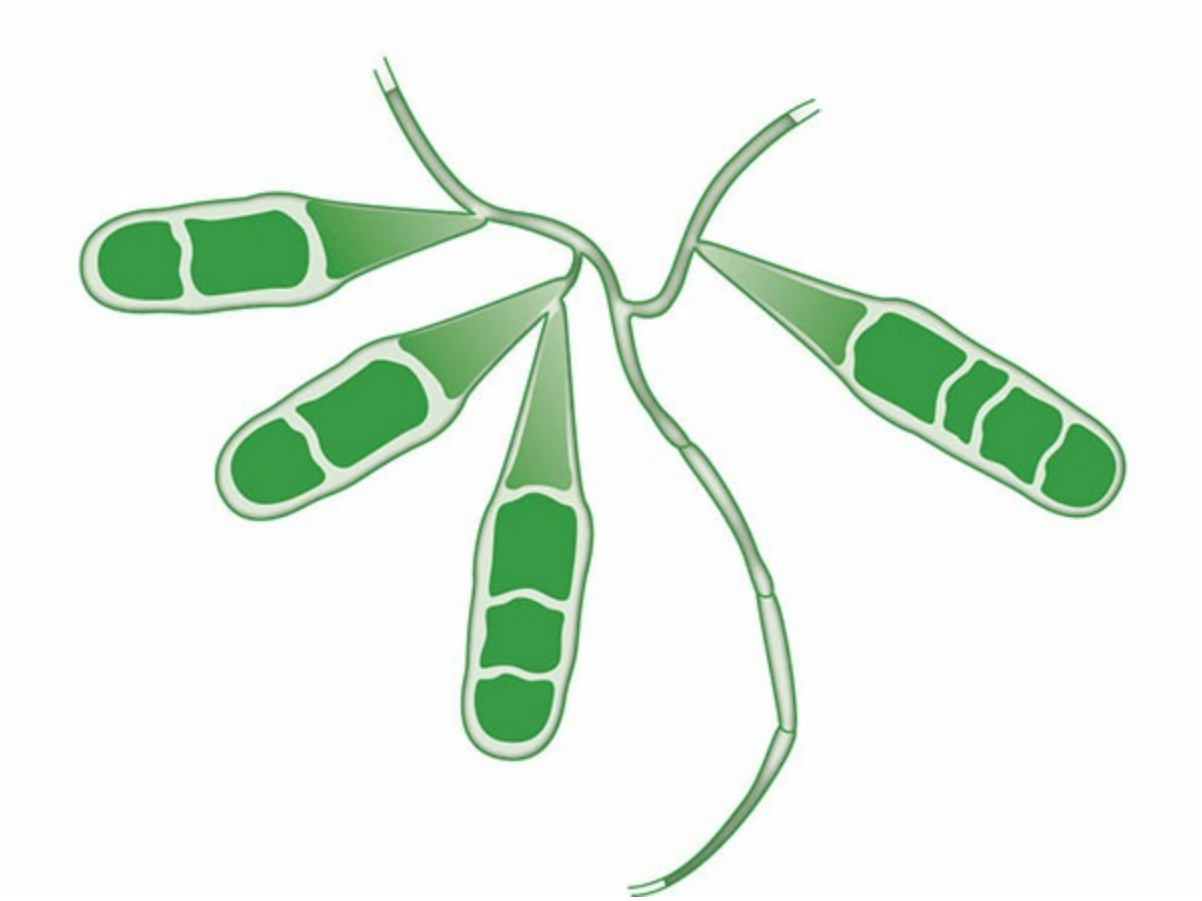
circular, flat, glabrous initially or downy later, and white to off-yellow. The reverse of the colony remains nonpigmented.

Microscopically, sporulation is usually poor. Antler-type hyphae may be observed and also typical are the production of numerous chlamydospores typically arranged in chains (Fig. 21-52). Macroconidia are rare, but are distinctive when present. They are multicelled, have thin, smooth walls, and are thin with a paddle, "string bean," or "rat tail" configuration. Microconidia, when present, are small, pyriform, and borne directly along the sides of the hyphae.

Epidermophyton floccosum. *Epidermophyton floccosum* is an anthropophilic dermatophyte that is an important cause for tinea cruris (jock itch) and tinea pedis (athlete's foot). The colonies grow rapidly, within 3 to 5 days; initially they are gray-white and then develop a distinct, characteristic khaki-green pigment when mature. Yellow-white streamers of hyphae may be seen radiating from the center of the colony to the periphery (Image Plate 21-4H). The surface becomes granular on further maturity as conidia are produced.

Microconidia are never produced—a key observation. Thus, if microconidia are observed in an unknown culture of a dermatophyte, *E. floccosum* can be eliminated from consideration. **Macroconidia** are usually abundantly produced, are typically club-shaped, and have three to five cells and thin, smooth walls (Fig. 21-53). The macroconidia often cluster in groups of three or four. Chlamydoconidia are typically present, particularly in older cultures.





■ **FIGURE 21-53** Photomicrograph and sketch of a cluster of elongated, cylindrical-shaped macroconidia of *Epidermophyton floccosum* with smooth walls and transverse septa. Microconidia are not produced by this fungus.

Diagnosis Using Nonculture Techniques

Molecular diagnostic assays have been described that detect dermatophytes, but these have not been widely employed and are not commonly used. Therefore, this section is limited in scope. Liu et al.[167] have used arbitrarily primed polymerase chain reaction and were able to identify up to 20 of the 25 dermatophyte species or subspecies under investigation. Although the use of such technology may be rarely required, reference is provided here for those instances when more exacting definition is needed.

The clinical manifestations of the various dermatophyte infections are in Clinical Correlation Box 21-4.

The Dimorphic Fungi

A subset of the hyaline molds, the dimorphic fungi, is usually considered separately because they have unique characteristics. First, they are dimorphic; that is, they exist in the mold form in the environment ("room temperature incubation"), whereas yeasts or yeast-like forms are produced during infection (i.e., in situ in the human body). All of these, except,

CLINICAL CORRELATION BOX 21-4 The Dermatophytes

Tinea capitis, Tinea corpora, Tinea pedis, and *Tinea cruris* are the names given to the various forms of dermatophyte infections. Onychomycosis refers to infections of the nails. With the advent of more effective oral antifungal therapy, the laboratory identification of the dermatophytes is now less frequently required. In most clinical practices, a KOH or KOH/calcofluor white mounts of skin scales, nail scrapings, or hairs are observed for the detection of typical hyphae that tend to break up into arthroconidia. Therapy is commonly instituted without obtaining a culture, if the direct examination demonstrates fungal elements and the examination is performed in the physician's office (i.e., provider performed microscopy). Although the vast majority of infections are superficial, there have been reports of locally invasive

disease, which is more likely in an individual with a compromised immune system.[250]

The term "tinea," dating back to the Middle Ages, refers to the circular holes in garments produced by the clothes moth, an appearance similar to the ringlike lesions of the skin produced by dermatophytic fungi. The term is now used to describe the various clinical syndromes caused by the dermatophytes. Tinea infections are also common in dogs, cats, horses, cattle, and other animals, providing a source for human zoophilic infections. The following is a brief summary of the several clinical types of tinea infections.

Tinea capitis—Ringworm of the Scalp
Several types of infection may be observed:

1. Gray-patch ringworm, a communicable ectothrix infection of children caused by *Microsporum audouinii* or *M. canis*;
2. Inflammatory ectothrix infection with *T. mentagrophytes*, of animal origin;
3. Black-dot ringworm, an endothrix infection in which infected, degenerate hairs break off at the skin surface producing what appears to be a black dot, caused by *T. tonsurans*; and
4. Fungating exophytic masses (kerions) produced by *T. tonsurans*, or favus infections caused by *T. schoenleinii* (in Scandinavia and northern Europe) and by *T. violaceum* (in southern Mediterranean Europe).

During the past 50 years, *T. tonsurans* has replaced *T. audouinii* as the predominant etiologic agent of *tinea capitis* in the United States and Western Europe.[76,107,299] *T. tonsurans* infections are contagious, as evidenced by an outbreak of *tinea corporis* infections among four healthcare workers in an inpatient rehabilitation ward who contracted the disease from an infected patient.[166] The contagious spread of *T. tonsurans* has become a nuisance among young competitive wrestlers. As the lesions appear somewhat different in a subset of youth wrestlers compared with the pediatric population as a whole, the term "*tinea gladiatorum*" has been applied to this form of infection.[152] *Tinea capitis* is most frequently obtained either from direct contact with an infected person or with a variety of fomites; an asymptomatic adult carrier state may contribute to persistence of infection in a given setting.[19] In a study of dermatophyte infection in 202 children residing in Kuwait, al-Fouzan et al.[7] found that *tinea capitis* was the most common infection and *M. canis* was the most prevalent species (96% of patients in this series). Although in the great majority of infected patients the infection remains confined to the superficial skin, reports have indicated that the fungus can invade deeper tissues in immunocompromised hosts. King et al.[148] report a subcutaneous papular infection in a kidney-transplant recipient wherein invasive fungal elements were seen in a deep biopsy of the skin. Similarly, deep subcutaneous penetration of erythematous nodules of the scalp and face has been seen in a patient with AIDS.

Tinea corporis—Ringworm of the Body
Typical annular lesions on the skin of the smooth parts of the body that have a spreading, hemorrhagic border are caused most commonly by *T. rubrum*, *T. mentagrophytes*, and *T. tonsurans*. *T. tonsurans* is being recovered with increasing frequency as the cause of *tinea corporis* in the United States. *T. rubrum* in particular is well suited to survive on the surface of the skin, leading to chronic infection, often enduring for the lifetime of the patient.[58] The mannans of *T. rubrum* appear to be better able to suppress cell-mediated immune reactions than are mannans from other fungi, thus modulating host response and permitting survival. *T. rubrum* also can survive off the human body as spores in desquamated skin scales, promoting person-to-person transmission in various human habitats. Zoophilic *M. canis* and geophilic *T. gypseum* infections are also occasionally encountered in clinical practice.

Tinea barbae—Ringworm of the Bearded Area
This zoophilic infection has most commonly been found in farm and dairy workers. *T. mentagrophytes* is the most common agent recovered from human infections, and the lesions tend to be inflammatory. *Trichophyton verrucosum* is also commonly associated with *tinea barbae*, acquired from the hide of dairy cattle. Sabota et al.[239] have reported *T. verrucosum* infection in five patients, three of whom had severe pustular *tinea barbae* and two of whom had eruptions of the forearms. All five patients were dairy farmers. A KOH preparation showed hyphae, and cultures yielded *T. verrucosum* in all three instances. *T. verrucosum* can cause pustular *tinea barbae*

in farmers that may be mistaken for a *Staphylococcus aureus* infection by clinicians, including infectious disease experts. The answer to the simple question "Are you a dairy farmer?" may suggest the possibility of *T. verrucosum* in the proper clinical setting.

Tinea cruris—Ringworm of the Groin
The lesions tend to be circinate and serpiginous, with inflammatory, vesicular, enlarging margins, most commonly caused by *Epidermophyton floccosum*. This infection may reach epidemic proportions in athletes, soldiers, and ship's crews, among whom towels, linen, and clothing may be shared.

Tinea pedis—Ringworm of the Feet (Athlete's Foot)
This is the most common fungal infection in humans, typically manifesting as itching, scaling, or seeping skin lesions on the soles of the feet and/or between the toes. Infections are most common during the warm, humid months. *T. mentagrophytes, T. rubrum*, and *E. floccosum* are the dermatophyte species most commonly recovered. The increased amount of keratin on the soles of the feet and the palms of the hands

makes these two sites selectively vulnerable to infection with *T. mentagrophytes* and other dermatophytes. The capability of *T. rubrum* to survive as spores in desquamated skin scales makes these hyperkeratotic areas particularly vulnerable to contracting infections from contaminated bath towels, locker room floors, and other human habitats.

Tinea unguium—Ringworm of the Nails
Tinea unguium is the term used to describe involvement of the nails by dermatophyte fungi, to be differentiated from onychomycosis, which refers to nail infections caused by a wide variety of fungi, including non-dermatophytic fungi, such as *Scopulariopsis,* among a variety of others. *Tinea unguium* infections begin at the lateral or distal edge of the nail plate and results in paronychial inflammation. As the lesion progresses, the nail becomes thickened and brittle, with accumulation of subungual keratinized debris. The dermatophytes most commonly involved are *T. rubrum* and *T. mentagrophytes*.

Lugo-Somolinos and Sanchez,[174] in a study of 100 consecutive patients with diabetes, found no greater incidence of dermatophyte infections compared with a control population. Dermatophyte infections of one type or another were found in 31% of the patients with diabetes mellitus and in 33% of the control group. Thus, contrary to popular notion, diabetes mellitus apparently does not predispose to dermatophytosis.

Coccidioides species are thermally dimorphic (i.e., produce the yeast or yeast-like form when incubated at 35°C to 37°C. The mold form is produced in the environmental niche of the fungus and produces the infective conidia. Humans and animals become infected predominantly through inhalation of airborne conidia for all dimorphic fungal pathogens, except *Sporothrix schenckii* which predominantly causes infection through direct traumatic implantation. Once in the body (i.e., at a temperature of 35°C to 37°C) the conidia transform into a yeast form, or spherule if the infecting pathogen is a *Coccidioides* spp. Apart from *Sporothrix schenckii,* the dimorphic fungal pathogens are important causes of "deep-seated" infections in humans. The severity of the infection is largely determined by the infecting organism, site of infection and burden of disease, immunologic status of the host, and availability and promptness of antifungal therapy.

The species of medical importance that are reviewed here include the following:

Blastomyces dermatitidis
Coccidioides immitis/C. posadasii
Histoplasma capsulatum
Sporothrix schenckii complex

The colonies from these fungi, with the exception of *Coccidioides* species, typically grow slowly (10 to 30 days) when recovered in primary culture from clinical specimens. In instances wherein the load of fungal organisms in a clinical specimen is high, then growth may be observed within 4 to 7 days. The growth of *Coccidioides* is sufficiently rapid that a fine delicate growth may be observed within 24 to 72 hours on routine blood agar plates incubated at 35°C. This represents a hazard to bacteriologists; therefore, all plates that contain a mold should be handled within a biological safety cabinet. At 30°C, the usual temperature of laboratory incubation, the colonies appear as a mold with a delicate, silky, hairlike, or cobweblike mycelium. In some cases, focal areas may appear yeast-like, particularly during the early phases of growth or if recovered on blood-containing media (Image Plate 21-5A). The colonies typically are gray-white or buff, although a few strains may show light pastel yellow shading into pink pigmentation. Colonies of *S. schenckii* may have a darkened appearance, which increases with extended incubation. The dimorphic fungi as a group also have the capability of growing in culture media containing cycloheximide, a valuable property in separating these fungi from the saprophytic filamentous molds, including their environmental mimics, which grow poorly or not at all.

If mold-to-yeast conversion is attempted (i.e., the temperature of incubation is increased to 35°C to 37°C), a prickly stage of transformation may be observed before the typical yeast-like colonies develop (Image Plate 21-5C). When yeast conversion is complete, the colonies have a pasty, yeast-like appearance, are glabrous, are usually entire, and have an off-white-to-yellow pigmentation (Image Plate 21-5E). Although demonstrable, yeast conversion of mold cultures is rarely attempted in most laboratories; confirmation of suspect

1366

isolates is usually achieved using commercially available nucleic acid probes or other molecular techniques.

Even prior to the production of conidia, one of the dimorphic molds may be suspected microscopically if very delicate hyaline, septate hyphae is observed and there is growth on cycloheximide-containing media. Commonly, the hyphae line up in parallel bundles. The next step in species-level identifications is made from the microscopic examination of colonies recovered in culture, based on the size, shape, position, and derivation of conidia. Confirmation is usually achieved by the use of a specific nucleic acid probe or another molecule technology (e.g., DNA sequencing). It is also possible to make an identification based on the morphology of the yeast or yeast-like forms as seen in stained tissue sections. The criteria for identification of the individual dimorphic molds will be presented in the paragraphs that follow.

Blastomyces dermatitidis *and Blastomycosis*

Blastomyces dermatitidis is a mold found in the soil and decaying vegetation. It is endemic in the states adjacent to the Mississippi and Ohio River valleys (Kentucky, Arkansas, Mississippi, North Carolina, Tennessee, Louisiana, Illinois, and Wisconsin).[21,150] In contrast to histoplasmosis, in which the extent of the endemic zone has been clearly mapped based on positive skin tests, the regions of infection with blastomycosis are determined only on the basis of individual case findings because of the lack of a sensitive skin test.[62] Humans are presumed to become infected from inhalation of airborne conidia, possibly secondary to the mechanical disruption of the mold form. One patient contracted blastomycosis after spreading mulch, which presumably harbored the mold. Blastomycosis is also a disease of animals, with a high incidence of infection in dogs.

Laboratory Presentation. The colonies typically grow slowly in primary culture (10 to 30 days), except in cases of heavy infections, wherein growth may be seen within 1 week. At 30°C, the colonies appear as a gray-white to light-buff-colored mold with a delicate, silky, or hairlike mycelium (Image Plate 21-5B). Growth occurs on cycloheximide-containing media, which is an important differentiating feature for molds that may be morphologic mimics for *Blastomyces*. In conversion to the yeast form, a prickly stage may be seen during transformation before the typical yeast-like colonies develop. The colonies become smooth and more yeast-like, except, in some instances, for the aerial protrusion of delicate spikes (Image Plate 21-5C).

Microscopically, in the mold form, the hyphae are delicate (approximately 2 µm in diameter), hyaline, and septate. Spherical to oval conidia measuring 1 to 4 µm in diameter are borne singly at the tips of long or short conidiophores (some believe these resemble "lollipops") (Fig. 21-54). The conidia of the soil saprobe, *Chrysosporium* spp., have a similar appearance microscopically. It is important to recognize that the microscopic examination of very young colonies of *Blastomyces* may contain remnants of the yeast forms that have not completely converted to the mold phase.

The yeast conversion colonies grown at 35°C on enriched agar are small, entire, slightly convex, smooth, and may have an off-yellow or buff pigmentation. Microscopically, the yeast forms are large (10 to 15 µm), and characteristically have a single bud attached by a broad base (Fig. 21-55). These broad-based budding yeast forms may also be observed in tissue sections often associated with a pyogranulomatous inflammatory response (Fig. 21-56, left). These forms may be confused in tissue sections with the endospores and immature spherules of *Coccidioides immitis* that may be lying adjacent to one another. However, the development of endospores within the spherules provides for the true identification of *C. immitis* (Fig. 21-56, right).

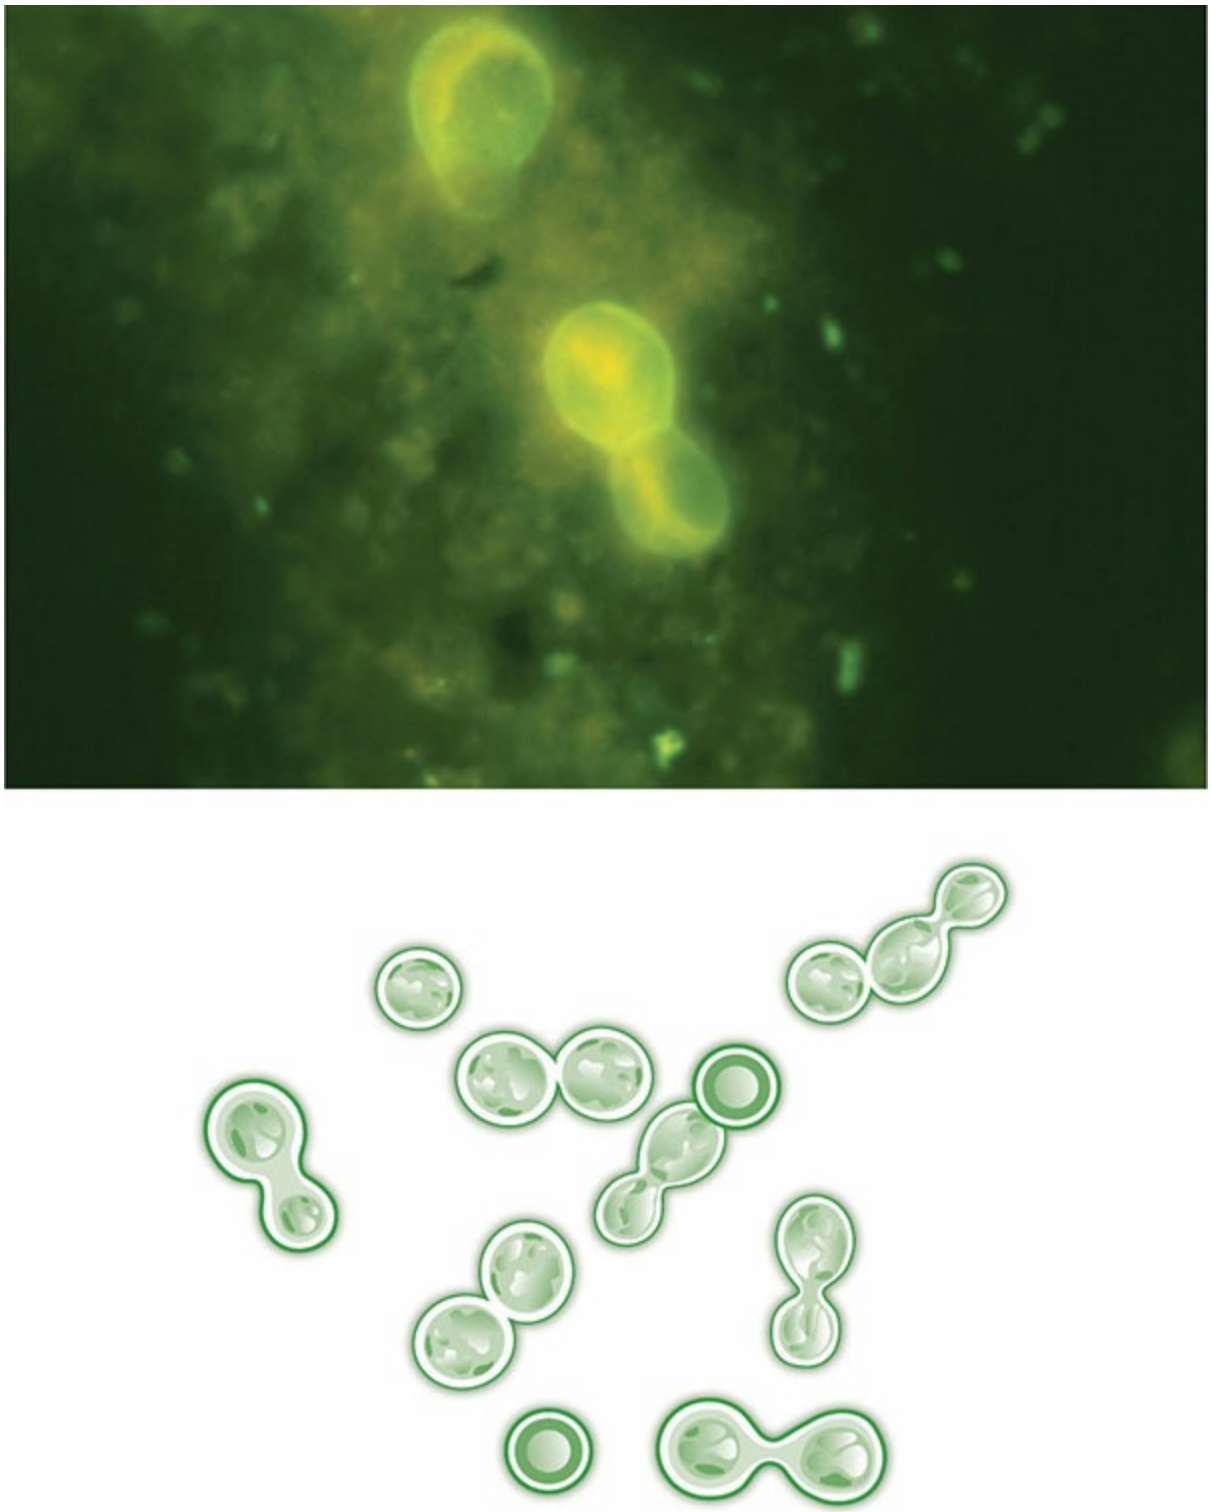
Diagnosis Using Nonculture Techniques. Serologic tests for antibody detection alone are generally considered to be inadequate for use in diagnosis of blastomycosis. However, a positive test is useful in a patient wherein blastomycosis is in the differential diagnosis. The immunodiffusion and complement fixation assays are positive in only approximately 25% of known cases. Enzyme immunoassays (EIAs) are more sensitive than immunodiffusion (ID), but less specific. A large common-source outbreak is cited in which the sensitivity of EIA (77%) was higher than that of ID



■ **FIGURE 21-56** **A.** Photomicrograph of a GMS-stained tissue section illustrating loose clusters of black-staining yeast cells of *Blastomyces dermatitidis*, some with a characteristic broad-based bud *(arrow)*. **B.** Photomicrograph of an H&E-stained tissue section, illustrating small empty immature spherules of *Coccidioides immitis*, along with

(28%) or complement fixation (CF) (9%), but its specificity was lower, 92%, compared with 100% for ID and CF.[73]

Blastomyces urinary antigen may be used as an ancillary diagnostic test. In one study, it detected antigenuria in 92.9% of patients with blastomycosis, including 89.3% of disseminated and 100% of pulmonary forms of disease.[74] Other body fluids also may be suitable for antigen testing. Antigen has been detected in serum, cerebrospinal fluid (CSF), and bronchoalveolar lavage fluid (BAL). Detection of antigen in BAL may improve the sensitivity for diagnosis in patients with pulmonary disease, particularly in milder cases. Antigen detection in CSF may be helpful in establishing a diagnosis of *Blastomyces* meningitis, as yeast cells are not seen in direct examinations and cultures are negative in approximately 50% of patients. Failure of antigen to clear during a course of therapy may herald treatment failure; a recurrence of illness may be detected if antigen levels rise by two- or threefold.[74] Although Connolly et al.[55] found the assay to have high sensitivity and specificity, they also reported that the *Blastomyces* urinary antigen tests demonstrated cross-reactivity in 95.6% of patients with histoplasmosis. The clinical manifestations of blastomycosis are presented in text in Clinical Correlation Box 21-5.

Coccidioides immitis, Coccidioides posadasii, *and Coccidioidomycosis*

Coccidioides species are endemic in arid and semi-arid areas, such as deserts. There are now two recognized species in the genus *Coccidioides*, *C. immitis*, and *C. posadasii*. *C. immitis* is the species that is endemic in California (e.g., in the San Joaquin Valley), whereas *C. posadasii* is the species found elsewhere (e.g., southern portions of Arizona, and parts of Mexico). These species are morphologically indistinguishable and can be differentiated only using advanced molecular methods. *Coccidioides* is a dimorphic fungus, but it is the one dimorphic pathogen wherein the dimorphism is not due solely to temperature differences (i.e., it is not thermally dimorphic). The mycelial form grows in the hot deserts, in which the elevated subsurface temperatures are ideal for propagation. The hyphae are branched, and fragment into individual arthroconidia when the soil is disturbed. These arthroconidia are tiny, light, and easily windborne in clouds of blowing sand and dust. On inhalation, these arthroconidia escape the mechanical defenses of the upper respiratory tract and reach deeper portions of the bronchial tree. Within the alveoli, the arthroconidia transform into thick-walled spherules, which, on maturity, are filled with endospores. Endospore-containing spherules are the diagnostic forms seen in stained tissue

sections.

1367

CLINICAL CORRELATION BOX 21-5 Blastomycosis

1368

The clinical presentations of blastomycosis have been categorized by Davies and Sarosi[62,63] as follows:

1. Asymptomatic, usually discovered only in outbreak situations;
2. Flu-like illness of brief duration, resembling other upper respiratory infections;
3. Illness resembling bacterial pneumonia, with acute onset of high fever, lobar infiltrates, and productive cough;
4. Subacute or chronic respiratory illness with a symptom complex simulating tuberculosis or lung cancer, with radiographic presentation of fibronodular infiltrates or mass-like lesions; and
5. Fulminant infectious adult respiratory distress syndrome (ARDS) with high fever, diffuse infiltrates, and progressive respiratory failure.

In clinical settings, blastomycosis almost always begins in the lungs as the primary pulmonary form of the disease, with pneumonia being the most common initial

clinical manifestation.[30] The pneumonia may be short-term, mimicking bacterial pneumonia, or may become more indolent; occasionally, it may be progressive and severe. Most commonly, symptoms resolve spontaneously after a brief flu-like syndrome. Dry cough, low-grade fever, weight loss, night sweats, pleuritic chest pain, and myalgias may be presenting symptoms early in acute infections. Persistent localized chest pain, weight loss, night sweats, and malaise may indicate progression to a chronic form of disease.

Mississippi has been noted to have a high prevalence of blastomycosis.[163] Even in this endemic area of physician awareness, the diagnosis of blastomycosis was difficult to recognize. Blastomycosis was correctly suspected on initial examination in only 18% of 123 patients being evaluated at the University of Mississippi Medical Center in Jackson.[164] Nonspecific pneumonia (40%), malignant tumors (16%), and tuberculosis (14%) were the most frequent misdiagnoses. Only in the presence of cutaneous involvement was the initial suspicion raised to 64%. These misdiagnoses often led to unnecessary surgeries, delays in treatment, or the administration of ineffective antibiotic therapy for months. Immunosuppression (25% of patients) and diabetes mellitus (22% of patients) were the more frequent predisposing conditions.

Rarely pregnant women will contract blastomycosis.[165] Fetal risk exceeded maternal risk in this review. Of 20 babies born from mothers with blastomycosis, only 2 (10%) had transplacental infection and both died. Not only did none of the 18 affected mothers die of the disease, there was no progression with 14 complete cures and considerable postpartum regressions of lesions in the other four women.

Bone is a common site for extrapulmonary infection. From the older literature, a patient with temporal bone osteomyelitis secondary to *B. dermatitidis* manifesting as serous otitis media was reported by Farr et al.[85] In a study of 17 patients by MacDonald et al.,[176] the metaphyses of long bones and small bones were most frequently involved. The metaphyseal lesions tend to be eccentric, well circumscribed, and lytic. More recently, Hadjupavlou et al.[109] reported a patient with blastomycosis of the lumbar spine that caused severe and crippling deformity. The authors emphasize the importance of early, aggressive treatment to prevent deformity and disability.

The genitourinary tract, particularly the prostate gland, epididymis, and kidney; the brain, with local abscess formation; lymph nodes; and the adrenal gland are other extrapulmonary sites of involvement culled by Kwon-Chung and Bennett[160] from the earlier literature. The clinical manifestations commonly are those of nonspecific epididymitis and prostatitis, and the diagnosis must be made by demonstrating organisms in biopsy material, and may be missed in the absence of a high degree of suspicion.

Blastomyces may disseminate to the skin and other sites with squamous epithelium. A report by Hanson et al.[120] of two patients with laryngeal blastomycosis that was misdiagnosed as squamous cell carcinoma is concerning. In one of these patients, this

misdiagnosis led to radiotherapy and laryngectomy. In the second patient, although a clinical diagnosis of glottic squamous cell carcinoma was rendered, the budding yeast forms of blastomycosis were identified in a biopsy specimen. Review of the English-language literature demonstrates that blastomycosis may be misdiagnosed clinically and microscopically as squamous cell carcinoma.

Reder et al.[229] reviewed a large series of blastomycosis diagnosed at the Mayo Clinic. Involvement of the skin and mucous membranes (including the larynx) was quite common, often with clinical and histologic features resembling well-differentiated squamous cell carcinoma. Skin or mucous membrane involvement usually indicates systemic disease, and in many instances these may be the presenting lesions. The diagnosis of blastomycosis should be considered in the differential diagnosis of any patient with nonhealing skin lesions associated with risk factors such as living in an endemic area and having an occupation or vocation involving frequent contact with soil.[16] Single or multiple ulcerating papules or pustules of the skin, usually involving the face, hands, or lower legs, may slowly progress into an ulcerated verrucous granuloma with an advancing serpiginous border. Primary cutaneous lesions occurring at the site of penetrating injuries of the skin do not spread systemically.

Blastomycosis is not considered as one of the AIDS-defining infections; nevertheless, in some practice settings, a distinct increase in incidence and in severity of disease occurring in immunocompromised hosts has been observed.[289] Disease is particularly progressive in patients with AIDS, particularly when the CD4 count drops below 200/mL.[213] Fraser et al.[92] studied in parallel two friends, one with AIDS, who were infected with the

1369

same strain of *B. dermatitidis* (proven by restriction endonuclease analysis). In the patient with AIDS, severe, progressive fatal pulmonary blastomycosis developed despite aggressive treatment with fluconazole and amphotericin B; his HIV-negative friend responded completely to the same course of therapy. The authors concluded that cellular immunity plays a critical role in the progression of disease in patients with blastomycosis.

Of interest is the review of 123 charts of patients with the diagnosis of blastomycosis at the University of Mississippi Medical Center to determine the role of wet preparation, cytology, histology, and culture in diagnosing this fungal disease.[164] The etiologic agent was detected by cytology in 56.1% of all cases, and in 71.8% of pulmonary cases. Wet preparation was second in sensitivity to detect the fungus (37.4%); histology was the third (32.5%). Cultures were positive in 64.2% of all patients but provided the initial diagnosis in only 3.2% of all patients. There was pulmonary involvement in 87% of patients, cutaneous involvement in 20%, osseous involvement in 15%, and central nervous involvement in 3%. Dissemination with intraocular disease has also been reported.[172]

Rarely, hyphal forms may be found in tissue sections, particularly if the affected site has been exposed to air. Hagman et al.[110] reported five cases of coccidioidomycosis in which hyphae were found in brain tissue or spinal fluid. They theorized that the presence of foreign material in the central nervous system of these patients was associated with morphologic reversion to the saprophytic form.

The incidence of coccidioidomycosis in endemic areas has varied in part based on weather conditions; there were increases in the incidence of disease in 1991 and 1992 during alternating periods wherein heavy rainfall was followed by drought.[38] The disruption of the soil has also been associated with an increase in disease; there was a marked increase in incidence, which also occurred in the decade following the Simi Valley earthquake.[211] Kirkland and Fierer[149] have estimated that this outbreak cost more than $66 million in direct medical expenses and from time lost from work in Kern County, California, alone. In endemic areas, particular attention should be paid to ranchers, farmers, construction workers, and others engaged in outdoor activities requiring intimate exposure to dust and soil. Archeologists participating in excavations in endemic areas are at particularly high risk for infection.

Coccidioidomycosis remains a growing problem in the southwestern United States.[12] Related is the parallel increase in individuals with depressed cellular immunity, particularly those with HIV infection, those who have undergone allogeneic transplantation, and others on immunosuppressive medications.[276] Logan et al.[169] report that coccidioidomycosis remains the most common endemic mycosis in North America, largely related to the increase in solid organ transplants. They cite underlying renal and liver disease, T-lymphocyte suppression from antirejection medication, and activation of immunomodulating viruses, such as cytomegalovirus, among these patients, as factors increasing the risk for coccidioidomycosis. Interestingly, half of all patients that developed coccidioidiomycosis during the first year after transplantation were thought to represent the reactivation of previously acquired coccidioidal infection, rather than the acquisition of a new infection.

Dark-skinned individuals, pregnant women, and individuals of Filipino descent are at higher risk for disseminated disease, in addition to those with compromised immune systems. Individuals who travel to endemic regions are also at risk for infection, which may present after their return to non-endemic regions.[86] Therefore, travel history remains an important part of the clinical history. Patients with acute coccidioidomycosis who come to medical attention are likely to present with pulmonary manifestations, including pneumonia, cavities, and nodules. An old, inactive coccidioma may be detected on routine chest roentgenogram and be excised to exclude malignancy. Thus, coccidioidomycosis is of nationwide importance.

Physicians everywhere must maintain a heightened awareness of this disease and obtain a careful travel history of patients presenting with pulmonary signs and symptoms to avert delays in diagnosis and treatment.

Laboratory Presentation. The colonies of *C. immitis* vary in morphology but usually appear as delicate cobweblike, gray-white mycelium. When grown on blood-containing agar, the colonies may appear dark green-black in areas where hemoglobin pigments have been adsorbed (Image Plate 21-5F). Extreme care should be exercised when examining cultures suspicious for this fungus, since the arthroconidia are readily airborne. It is particularly important that bacteriologists initially examine their plates with the lid in place to assure that a mold is not present, since this fungus grows sufficiently rapidly to be recovered on routine bacteriologic media within the few days these plates are examined.

Microscopically, in the mold form grown at 30°C, the hyphae are delicate and every other cell in the vegetative hyphae becomes a barrel-shaped arthroconidium. The cells between the arthroconidia, dysjunctor cells, are vegetative cells that have died. These appear as empty spaces between the arthroconidia. The alternating pattern of arthroconidium, dysjunctor cell, arthroconidium, etcetera imparts and alternate staining pattern (Fig. 21-57). *Malbranchia* species and *Gymnoascus* species are saprophytic fungi that may appear morphologically similar to *Coccidioides*; these, however, are inhibited by cycloheximide, unlike *Coccidioides*. *Coccidioides* is not thermally dimorphic, so confirmation of the identity of the fungus is usually achieved by genetic probe analysis or another molecular method.

A true yeast form does not exist for *C. immitis*. As mentioned above, the diagnostic forms observed in tissue sections are spherules that range from 20 to 200 µm in diameter and, when mature, are filled with endospores that are 2 to 4 µm in diameterFig. 21-58).

1370

The clinical manifestations of coccidioidomycosis are presented in Clinical Correlation Box 21-6.

Histoplasma capsulatum and Histoplasmosis

Histoplasmosis, caused by the dimorphic fungus, *Histoplasma capsulatum*, is a common cause of systemic fungal disease in the United States. It is also the most common fungal infection in patients with AIDS and is an AIDS-defining illness.[188] The major endemic areas of histoplasmosis in North America are the drainage basins of the St. Lawrence, Ohio, Mississippi and Missouri River valleys, where a high percentage of the population is skin-test-positive, indicating past infection.

Histoplasmosis is also found in Central America.

Isolated indigenous cases have been reported from Europe—in Germany, Belgium, Holland, Australia, Italy, and Denmark.[34,54,207] *H. capsulatum* is the dimorphic fungus with the widest geographic distribution.

CLINICAL CORRELATION BOX 21-6 Coccidioidomycosis

Following exposure to *Coccidioides* arthroconidia, an influenza-like syndrome known as "valley fever" develops in the majority of individuals; in most instances, it is confined to the lung and self-limited, resolving over a period of weeks or months without therapy.[96] Sixty percent of infected individuals are asymptomatic; many skin-test-positive individuals do not recall having symptoms. Those who are symptomatic experience an acute, short-term, lower respiratory tract infection with varying degrees of cough, sputum production, chest pain, fever, and arthralgia. A bacterial-pneumonia-type syndrome is unusual, although two such instances have been reported.[171] Chronic pulmonary disease with sequelae ultimately develops in only 2%–5% of infected individuals. Solitary "coin lesions" or granulomas, solid or cavitary, usually located peripherally within the lung parenchyma, are common residual findings.

Based on original work by Fish et al.[89] and later refined by Minamoto and Rosenberg,[188] there are six categories of disease, based on the primary clinical presentation:

Group 1, Focal pulmonary disease—localized alveolar infiltrates; discrete lung nodules, solid or cavitary; hilar adenopathy.

Group 2, Diffuse pulmonary disease—a clinical syndrome simulating *Pneumocystis jirovecii* infection

Group 3, Cutaneous coccidioidomycosis—usually concomitant with pulmonary disease, with papules, pustules, nodules, subcutaneous abscesses, ulcers, and/or verrucous granulomas

Group 4, Meningitis—CSF pleocytosis, chiefly lymphocytes but possibly with increased eosinophils, lowered glucose and elevated protein concentrations.

Group 5, Disseminated disease—extrathoracic lymph node (most commonly inguinal) or liver involvement; distant spread reported most commonly in kidneys, thyroid gland, heart, pituitary gland, esophagus, and pancreas.

Group 6, Positive coccidioidal serology without a clinical focus of infection.

In endemic areas, infection with HIV is also a risk factor for more severe coccidioidomycosis.[12] In a study by Singh et al.[260] of 91 patients coinfected with HIV and *C. immitis*, fever, chills, weight loss, and night sweats were the most common symptoms. The mortality rate in this group was 60%, with diffuse pulmonary disease and a CD4 lymphocyte count of <510/μL, which were independent predictors of death. Coccidioidal serum serology titers were positive in only two thirds (68%) of these patients, with negative results found in 23%. The highest percentage of false-negative serology reactions were in the group of patients with progressive, invasive pulmonary disease.

Antoniskis et al.[15] found that two of eight patients in their study with coccidioidomycosis and HIV infection were repeatedly seronegative, concluding that histopathology and culture remain the most reliable methods for establishing the diagnosis in patients with AIDS. Conversely, Arguinchona et al.[17] found that asymptomatic individuals with positive CF serum serology titers went on to have active coccidioidomycosis. In reference to the accuracy of tissue biopsies, of 54 patients with coccidioidomycosis reported by diTomasso et al.,[68] transbronchial biopsy was 100% sensitive in yielding a rapid diagnosis, in contrast to cytologic examination of bronchial fluid or bronchoalveolar lavage, which provided a diagnosis in only 34% of patients.

The association of increased risk for disseminated coccidioidomycosis during pregnancy remains controversial. Wack et al.,[282] refuting many previous studies in which coccidioidomycosis during pregnancy was considered a devastating disease with high mortality, found only 10 patients among 47,120 pregnancies among women living in Tucson, Arizona. The infection resolved in seven of the women in whom coccidioidomycosis was diagnosed during the first or second trimester; progressive disease developed in two of three women who were diagnosed in the third trimester. Improvement in medical care and the introduction of antifungal therapy relatively early in the course of coccidioidomycosis may account for the lower mortality rate among pregnant women compared with that reported in the past.

Although coccidioidomycosis is primarily a pulmonary disease, Arnold et al.[18] report that disseminated disease affecting skin, subcutaneous tissue, bone, joints, and meninges develops in approximately 0.5%–1.0% of infected individuals. In a review of 47 patients from the medical literature, these authors found that virtually all head and neck manifestations in patients with disseminated coccidioidomycosis involved the skin, with a predilection for the central face. The lesions often tended to be multiple, including life-threatening airway lesions. A report of coccidioidal prostatitis by Truett and Crum[275] serve as a reminder that fungal agents must be included in the differential diagnosis of conditions in which they might be least expected. Persistent sterile pyuria, prostatitis, and granulomatous disease of the prostate were the presenting signs and symptoms in the patients reported.

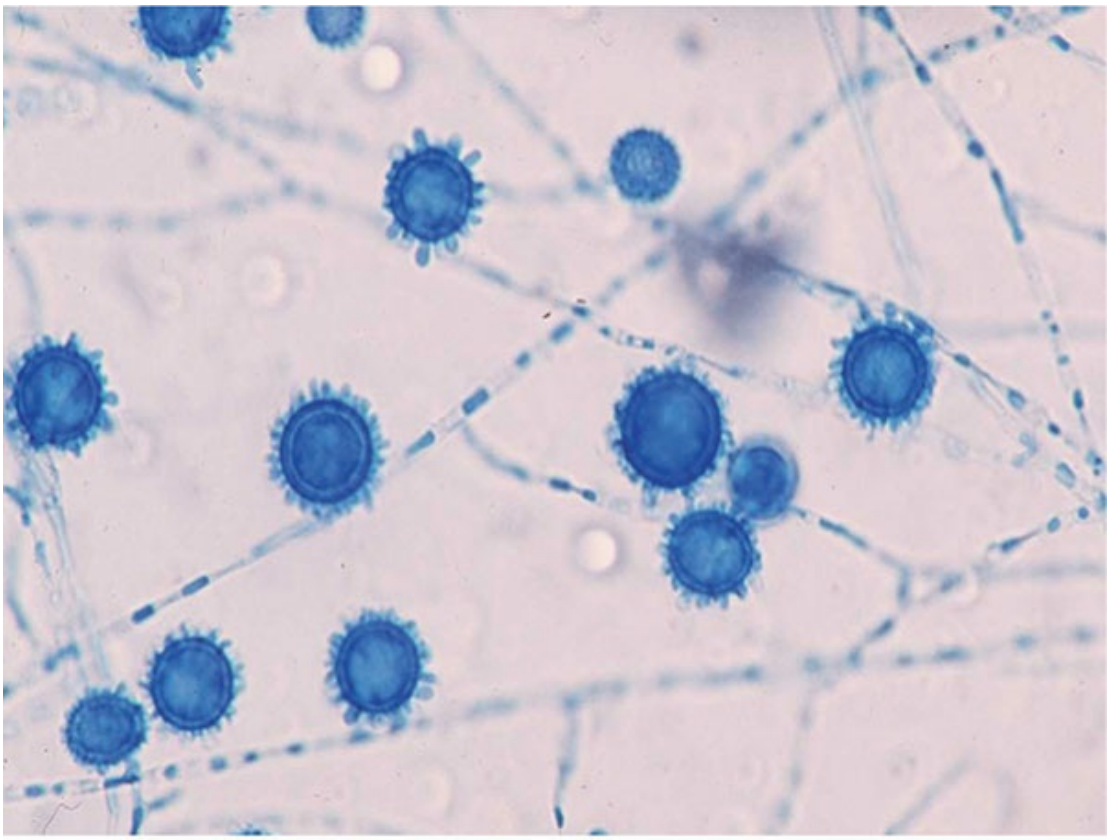
The mycelial form of *H. capsulatum* is present in warm, moist soil rich in nitrogen and other organic contents, such as that produced by heavy accumulation of bird or bat excreta. Bird roosts, chicken houses, caves, or old buildings frequented by bats are areas that have been associated with infection. Patients with advanced HIV infection (i.e., AIDS) or those who are otherwise severely immunocompromised are counseled to avoid frequenting these areas as much as possible. Disruption of these areas by bulldozing or cleanup efforts may expose humans to large numbers of airborne conidia. Three large outbreaks of histoplasmosis in the Indianapolis, Indiana, and metropolitan area have been cited in 1978 in conjunction with the demolition of an amusement park, in 1980 related to the building of a swimming pool and in 1988 to 1993 during the time of the construction of a large tennis complex.[298]

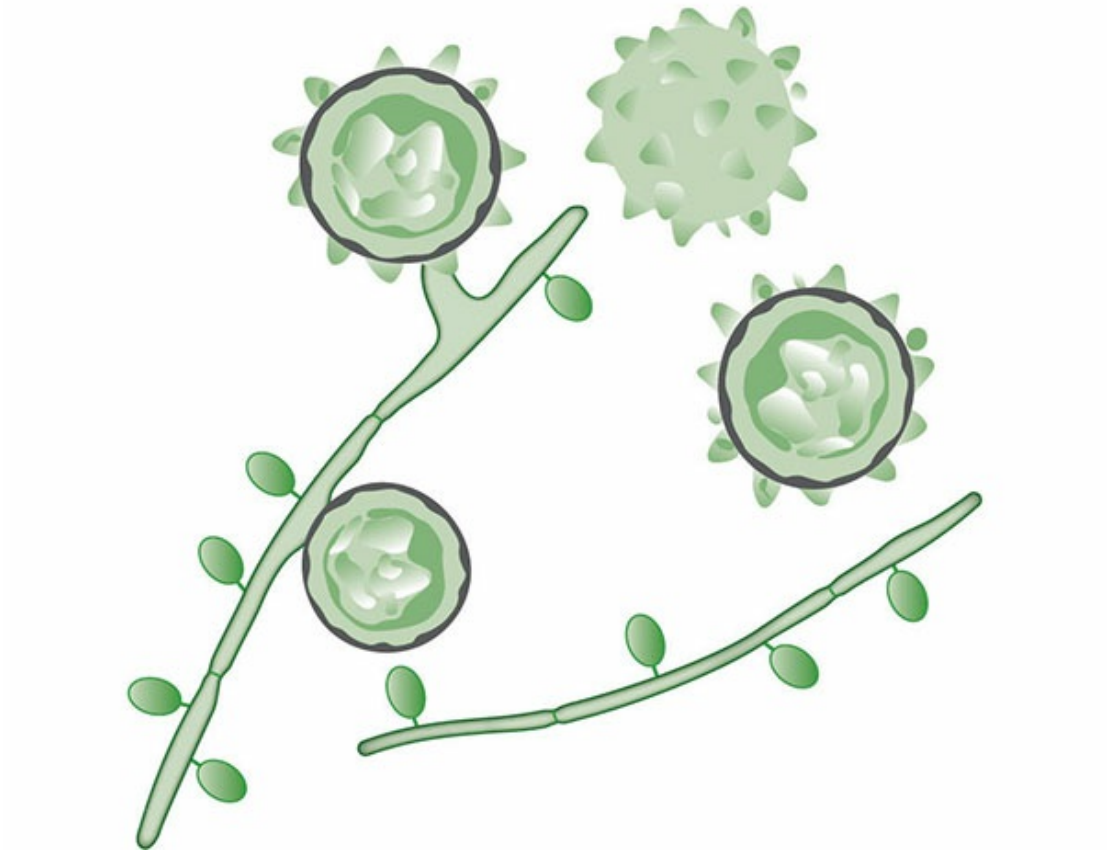
During one of these outbreaks, Williams et al.[298] detected antigen in 92%, 21%, and 39% of patients with the disseminated, chronic pulmonary, and self-limited forms, respectively. The authors conclude that tests for serum antigen are most useful in patients with clinical findings of disseminated infection or during the first month of illness in cases of severe pulmonary involvement when serologic tests for antibodies may be negative.

Laboratory Presentation. The mold form of *H. capsulatum* is typically the slowest growing of the dimorphic molds taking usually between 10 and 30 days to grow. Rarely, cultures from specimens with a very heavy concentration of organisms may demonstrate growth as early as 5 days of incubation. The colonies are cottony and may develop a delicate cobweblike or hairlike aerial mycelium; these are initially white, but may turn gray or gray-brown with age (Image Plate 21-5D).

Microscopically, the diagnostic structures seen in the mold form are large, roughened/spiked (i.e., tuberculate) macroconidia measuring 10 to 20 µm in diameter

1372



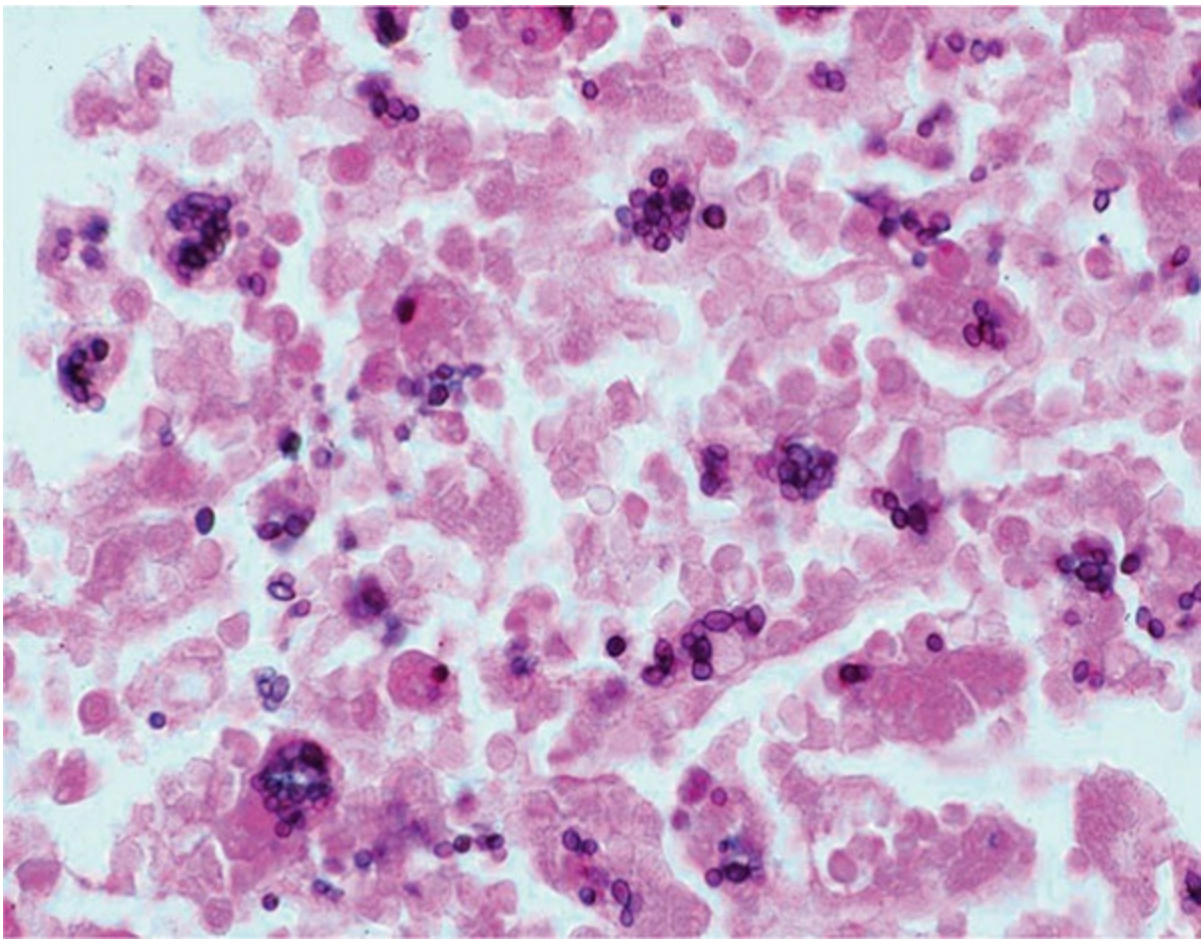


■ **FIGURE 21-59** Illustrated in the photomicrograph and sketch is the mold form of *Histoplasma capsulatum* forming large, spherical tuberculate (i.e., spiked) macroconidia.

(Fig. 21-59). In earlier cultures, small oval microconidia may be seen borne on small conidiophores that simulate those of *B. dermatitidis*. The microscopic features of *Sepedonium* species appear similar, but this species is inhibited by cycloheximide and would be negative in the genetic probe analysis for *H. capsulatum*.

The yeast colonies of *H. capsulatum*, whether grown from primary cultures incubated at 37°C or after conversion from the mold form, are typically smooth, yellow-white, and somewhat glistening, with a pasty consistency (Image Plate 21-5E).

Microscopically, the yeast cells of *H. capsulatum* are small, 2 to 4 μm in diameter, and may show a single unipolar bud. In histologic sections, the yeast cells often appear clustered either within a macrophage or remaining in this configuration after the macrophage has died. In some instances, the yeasts are surrounded by a clear space, which appears to be a capsule (Fig. 21-60). This, in fact, is not a capsule, but rather a retraction artifact due to tissue processing, but is responsible for the species name of this organism. The background inflammatory reaction is granulomatous in the immunocompetent. The granulomas may be necrotizing or non-necrotizing. Cavitation may occur with progressive disease that clinically and radiologically simulates tuberculosis. Patients with profound immunosuppression, particularly T-cell-related immunosuppression, may not be able to generate a granulomatous response. In these patients, the yeasts of *H. capsulatum* appear in histiocytes and macrophages throughout the reticuloendothelial system.



■ **FIGURE 21-60** Photomicrograph of a tissue section revealing macrophages containing loose clusters of intracytoplasmic 2–3 μm diameter, black-staining pseudoencapsulated yeasts forms of *Histoplasma capsulatum* (GMS stain, 400×).

The mold form of *H. capsulatum* is often difficult to convert to the yeast form in culture. For this reason, the nucleic acid probe test or other molecular methods are recommended to confirm the final identification. The nucleic acid probe test is relatively easy to perform and requires minimal growth mass (i.e., it may be accurately within 1 day after the appearance of initial growth in culture). The cultures need not be mature or have developed conidia for probe testing to be performed. Huffnagle and Gander[132] evaluated 95 mold-phase fungi, including 41 isolates of *H. capsulatum*, and demonstrated 100% specificity and sensitivity. Padhye et al.[209] correctly identified 103 of 105 *H. capsulatum* cultures using a chemiluminescent, acridinium ester-labeled, single-stranded DNA probe complementary to the rRNA of *H. capsulatum* mold forms (AccuProbe; Gene Probe, San Diego, CA). Similarly, Hall et al.[114] correctly identified 53 of 54 isolates of *H. capsulatum* and Stockman et al.[264] demonstrated 100% sensitivity and specificity in the study of 86 strains of *H. capsulatum* and 154 other

nontarget fungi also using the AccuProbe assay. The age of the culture, medium for isolation, and morphologic state did not affect the results, which indicates that an identification can be made before characteristic spores are produced.

The diagnosis of histoplasmosis may be made or supported by identifying the small, intracellular budding yeast cells in tissue sections or stained smears. Blumenfeld et al.[25] were able to identify intracytoplasmic organisms in both Diff-Quik and Papanicolaou-stained smears of bronchoalveolar lavage fluid. Follow-up studies of tissue sections stained with methenamine silver revealed budding yeasts in an intracellular location, confirming that they were *H. capsulatum.* Caution, however, is recommended as other yeasts,

1373

such as *C. glabrata,* have the same morphologic appearance. In such instances, the type of inflammatory response present is useful in suggesting the most likely pathogen. *C. glabrata* elicits a neutrophilic response, whereas *Histoplasma* elicits granulomas in the immunocompetent and will be present in histiocytes in the profoundly immunocompromised.

Diagnosis Using Nonculture Techniques. Molecular methods, particularly commercially available nucleic acid probes, remain a common method for the confirmation of isolates as *H. capsulatum.*[294] Some have used the probes on all suspect isolates prior to sporulation, in an effort to reduce the time to identification. Broad-range fungal PCR with DNA sequencing and species-specific rapid cycle PCR are alternate molecular methods that may be used for the confirmation of suspect isolates. These have also been used successfully for the detection of *Histoplasma* directly in clinical specimens. Serologic tests for anti- *Histoplasma* antibodies are useful studies in patients with suspected histoplasmosis. Serologic studies are positive in over 90% of patients with cavitary or disseminated forms of histoplasmosis. These serologic tests, however, are less sensitive in immunosuppressed patients (50% to 80%), many of whom cannot produce antibodies. Tests for antibody also have the disadvantage of a 4- to 6-week delay before a sufficiently high titer of antibody is achieved to afford detected. *Histoplasma* antibodies may also be elevated in patients with blastomycosis, coccidioidomycosis, and paracoccidioidomycosis.[293]

The CF test using yeast and mycelial antigens is more sensitive than the ID test. In acute pulmonary histoplasmosis, the CF test is positive at titers of at least 1:8 in 90% of patients, whereas in the immunodiffusion test, M bands are present in about 76%, and H bands in 23% of patients.[73] Titers in the range of 1:8 to 1:16 may be residual from past infection. A single titer of 1:32 or higher or a fourfold increase in titer is diagnostic of active histoplasmosis. Immunodiffusion is sufficiently insensitive that

other serologic tests are recommended.

Radioimmunoassay and enzyme immunoassay also cannot be recommended, although antibodies may be detected sooner and in a higher proportion of patients. These assays are poorly standardized and difficult to quantitate and interpret. Specificity is also low, with relatively high rates of false positivity in persons with other fungal or mycobacterial infections.[293]

Antigen detection provides a useful test in the diagnosis of histoplasmosis, particularly disseminated histoplasmosis in immunocompromised patients. The assessment for this antigen in the urine of patients with histoplasmosis has better sensitivity compared with the assessment of a serum. Therefore, urine is the preferred specimen for testing. In a study of 226 patients 18 years old or younger in whom *H. capsulatum* antigen was detected in urine specimens by radioimmunoassay, Fojtasek et al.[90]found that 85% had disseminated disease and 15% had self-limited pulmonary disease, when at least one other corroborating standard test was positive. The use of this test on other specimen types, such as bronchoalveolar lavage specimens has also been studied. *H. capsulatum* antigen was detected in bronchoalveolar lavage fluid in 19 of 27 cases (70.3%) of pulmonary histoplasmosis studied by Wheat et al.[291] *Histoplasma* urinary antigen testing is now commonly used in patients suspected to have histoplasmosis. The several clinical manifestations of histoplasmosis are presented in Clinical Correlation Box 21-7.

CLINICAL CORRELATION BOX 21-7 Histoplasmosis

Most patients with histoplasmosis resolve after an acute pulmonary illness of varying degrees of severity, characterized by fever, headache, chills, cough, and chest pain. In most instances, patients have an influenza-like illness that resolves without therapy. Progression to pneumonia and enlargement of the mediastinal lymph nodes may occur. In less than 1% of patients, a chronic pulmonary form may develop, characterized by persistent cough, low-grade fever, and occasional episodes of hemoptysis. Cavitary lesions may develop in adults, or one or more thick, laminated, calcified "histoplasmomas" may be seen by chest roentgenogram examination. Mediastinal granuloma formation followed by fibrosing mediastinitis has been reported, but the etiologic nature of *H. capsulatum* in this disease remains in contention.[181] Dyspnea, hemoptysis, post-obstructive pneumonia, and superior vena cava obstruction are associated complications. The intense fibrosis found in these cases renders surgery difficult. A rare complication of pleural effusion and pericardial fibrosis has been reported by Kilburn and McKinsey.[147] Constrictive pericarditis later developed in the reported patient, confirmed at autopsy. Because *H. capsulatum* is an obligate intracellular organism residing in macrophages of the

reticuloendothelial system, varying degrees of hepatomegaly, splenomegaly, and lymphadenopathy may be seen in cases of acute and chronic disseminated disease, which usually occurs in immunosuppressed hosts.

Progressive Disseminated Histoplasmosis

Progressive disseminated histoplasmosis is an AIDS-defining illness, being the first manifestation in 50%–75% of AIDS patients with histoplasmosis.[245,292] The clinical manifestations are fever, fatigue, and weight loss, the latter often presenting as a wasting disease.[112] Nightingale et al.[199] found a 4% prevalence of histoplasmosis among 980 patients with AIDS seen in Dallas, Texas; examination of the peripheral smear and bone marrow established the diagnosis in 88% of these patients. Currently, the histoplasma urinary antigen test would be used and has a very high sensitivity in this setting (i.e., disseminated disease). In addition, Huang et al.[131] report five patients with disseminated histoplasmosis in patients with AIDS; all had fungemia, and three died within 4 weeks after the diagnosis was established. The use of the Isolator lysis-centrifugation system is recommended for blood cultures for patients with suspected *H. capsulatum* fungemia.

1374

The presence of AIDS typically renders histoplasmosis refractory to therapy. Kurtin et al.[158] reviewed bone marrow and peripheral blood specimens in 13 patients with AIDS and disseminated histoplasmosis. Anemia, leukopenia, and thrombocytopenia were found in 12, 10, and 7 patients, respectively. Circulating organisms in blood smears or buffy-coat preparations were seen in five patients, usually associated with the presence of circulating normoblasts and severe absolute monocytopenia. The marrow specimens revealed one of four morphologic patterns: (1) no morphologic evidence of infection; (2) discrete granulomas; (3) lymphohistiocytic aggregates; or (4) diffuse macrophage infiltrates.

Lysis centrifugation for recovery of organism from blood cultures and cultures for bone marrow aspirates or respiratory specimens, in conjunction with morphologic examination of the bone marrow, peripheral blood smear, and respiratory secretions usually confirm the diagnosis.[194]

Other organ systems involved with histoplasmosis in patients with AIDS include the central nervous system, which may take the form of chronic meningitis, cerebral or spinal cord mass lesions simulating neoplasms, or encephalitis and an unusual instance of sinusitis reported by Butt and Carreon.[13,33,290]

Wheat et al.[290] found CNS manifestations in 10%–20% of patients with disseminated histoplasmosis, and that the organism may be the cause of chronic meningitis with no other evidence of dissemination in select patients. Cerebral or spinal cord mass lesions resembling neoplasms or abscesses and encephalitis were the most common forms of presentation in this series.

Gastrointestinal Tract

Histoplasmosis of the gastrointestinal tract, usually of the small bowel, may present as ulcers or as a mass, often mimicking inflammatory bowel disease or carcinoma.[42] The gastrointestinal tract is secondarily involved in 70%–90% of cases of disseminated histoplasmosis, although primary involvement of the gastrointestinal tract is infrequently encountered.[266] Jain et al.[136] report a 67-year-old man who presented with chronic diarrhea that did not respond to the conventional treatment. He was found to have isolated colonic histoplasmosis infection, which was treated with itraconazole.

Patients with histoplasmosis of the oropharynx have also been reported, in which lesions may be mistaken for carcinoma on initial presentation,[126] particularly when the vocal cords are involved. Sataloff et al.,[246] in a review of the literature, found fewer than 100 cases of histoplasmosis presenting as laryngeal carcinoma, since the first case was reported in 1952. Perhaps of more significance, Economopoulou et al.[75] reviewed 20 case reports from the literature of oral histoplasmosis in HIV-infected patients, in many instances, the oral lesions appeared to be the primary or only manifestation of disease.

Although disseminated histoplasmosis came to the attention of the medical community early in the HIV epidemic, prior to the use of highly active antiretroviral therapy (HAART), it is less commonly seen in resource-rich countries that can provide the necessary therapy for patients with HIV. The new risk for disseminated histoplasmosis is secondary to the approved and widespread use of immunomodulating agents (i.e., so-called "biologics). These agents, which are used in patients with rheumatoid arthritis, inflammatory bowel disease, and psoriasis, include etanercept, adalimumab, and infliximab. The modulation of the immune system in these patients, in addition to aiding in the control of their underlying disease, increases their risk for disseminated fungal infections and tuberculosis.[276]

Cutaneous Histoplasmosis

Cutaneous lesions may be the initial presentation for histoplasmosis in about 10% of patients with disseminated disease. Erythematous or hyperpigmented papules, pustules, folliculitis, eczematous changes, erythema multiforme, and rosacea-like rashes are the more common skin manifestations.[289] Chalub et al.[39] reported four patients with disseminated histoplasmosis in patients with AIDS. Multiple small (up to 3 mm in diameter) erythematous maculopapules on the extremities, face, and trunk, often centered around hair follicles were observed. These appear similar to the lesions caused by molluscum contagiosum. Histologically, perivascular infiltrates with conspicuous leukocytoclasis, the lack of a macrophage response, and absence of granulomas and organisms free in the dermis, intraneurally and in skin appendages, were seen.

Genitourinary Histoplasmosis

Although genitourinary tract fungal infections are more commonly seen in blastomycosis, genitourinary involvement in histoplasmosis has been reported. Kahn and Thommes[139] reported a patient with massive granulomatous orchitis and epididymitis with caseous necrosis. Two additional patients have been reported by Friskel et al.[93]

Ocular Histoplasmosis

The ocular histoplasmosis syndrome has been reviewed by Ciulla et al.[46] The classic clinical triad includes discrete atrophic choroidal scars in the macula or mid-periphery known as histo spots, peripapillary atrophy, and choroidal neovascularization. Severe loss of central vision is a major complication.

1375

Septicemia

Although septicemia with fungal agents is uncommon, the opportunity to establish an early diagnosis may be missed if the blood culture techniques being used are inadequate. Paya et al.[215] found that the use of the lysis centrifuged blood culture tubes was the optimal technique for recovering *H. capsulatum* yeast forms from the blood in suspected cases of disseminated disease, significantly increasing the yield of positive cultures and shortening the time of recovery. The superiority of this system is also supported by the observations of Murray,[194] who in a study of 182 fungal isolates of all types, found that *H. capsulatum* was recovered only in the lysis-centrifugation system. Early diagnosis is important, as dissemination can be rapidly progressive and fatal in immunocompromised patients.

Sporothrix schenckii Complex and Sporotrichosis

Nucleic acid sequence analysis has demonstrated that the fungi traditionally considered as *Sporothrix schenckii* is actually a group of fungi that are morphologically similar.[179] The differentiation of these organisms is not necessary for the treatment of disease, so the use of the term "complex" is acceptable, until a time it is demonstrated that differentiation is needed. Members of the *Sporothrix schenckii* complex (hereafter simply *S. schenckii*) are fungi that are found worldwide in soil and in vegetative matter, particularly sphagnum moss, wood splinters, and rosebush thorns. These fungi, when they find their way into a subcutaneous location, usually through traumatic inoculation, are the causative agent of sporotrichosis, a chronic infection of humans, and wild and domestic animals. Humans become infected when the organism penetrates the skin of individuals handling contaminated substances. The infection is characterized by the development of nodular lesions of the cutaneous and subcutaneous tissues, and if untreated, the development of lymphatic involvement (lymphocutaneous disease). Draining sinuses from foci on subcutaneous infection may form in chronic infections. Dissemination is rare, but may occur in immunocompromised patients, with systemic spread to the bone, muscle, central nervous system, and lungs. Also rare is solitary pulmonary involvement, but this has occurred after inhalation of conidia from highly contaminated substances.

Certain occupations place workers at increased risk for infection. Hajjeh et al.[113] reported an outbreak of sporotrichosis in workers at a tree nursery in Florida. Lymphocutaneous sporotrichosis developed in 9 of 65 (14%) of workers involved in the production of sphagnum moss topiaries. The risk was directly related to the duration of working with sphagnum moss, in particular with the task of filling topiaries, and in individuals with less gardening experience. Those wearing gloves were protected.

An interesting outbreak was reported by Dooley et al.[71] Within a 5-week period, five patients living in Oklahoma presented with cutaneous sporotrichosis, four of whom had maintained hay bales in a Halloween haunted house. A fifth patient apparently contracted the disease while visiting the house. Thus, contact with hay may represent yet another risk factor.

A high area of endemicity for sporotrichosis has been reported by Pappas et al.[212] In a remote area of the south central highlands of Peru, 238 patients with culture-proven sporotrichosis were observed in a period of 3 years. The incidence of sporotrichosis in this region was calculated at between 48 and 60 cases per 100,000 persons, with the highest incidence among children aged 7 to 14 years. The skin of the face was the most commonly affected site. The disease was clinically confined to the skin and subcutaneous tissue in all patients.

Laboratory Presentation. The growth of *Sporothrix schenckii* in culture is usually within 3 to 5 days at 30°C, although smooth, yeast-like colonies may develop as early as at 36 to 48 hours on 5% sheep blood agar incubated at 35°C. In some instances, the initial growth that occurs at 30°C may appear yeast-like, as full yeast-to-mycelial conversion has not yet occurred. These yeast cells may be elongated with somewhat pointed end, resembling the corn smut *Ustilago.* The colonial morphology varies depending on the media used and the presence or absence of blood in the media. Colonies are usually smooth and may become tough and wrinkled or folded. A delicate, dark, fuzzy, aerial mycelium develops when the colonies mature. The color is initially gray-white, but may turn buff, brown or brown-black as the colony matures (Image Plate 21-5G). The colonies become distinctly yeast-like when incubated at 35°C to 37°C, and may turn dark brown or black on maturity (Image Plate 21-5H).

The identification can be made microscopically by observing in the mold form delicate, septate hyphae from which are borne oval, smooth conidia measuring 2 to 4 µm in diameter. The hyphae and conidia are often hyaline, but some variants may increase the pigmentation with time. The conidia are attached by a delicate, hairlike structure (i.e., a denticle) to the conidiophore. By exacting focus of the microscope and using an oil immersion objective, it is possible to observe the characteristic hairlike attachments between the conidia and the conidiophore (from which the species name is derived). The publication by Sigler et al.[255] includes excellent photomicrographs illustrating this microscopic feature. Conidia of *S. schenckii* are arranged either laterally along the side of the hyphae or in daisylike clusters from the tip of a straight, delicate conidiophore (i.e., a fleurette morphology) (Fig. 21-61).

The yeast forms of *S. schenckii* are 2 to 4 µm in diameter and may be spherical, oval, or elliptical, often with a single bud (Fig. 21-62). These may be observed in the histologic assessment of a skin biopsy, the direct examination (i.e., KOH/calcofluor white) or following mycelial-to-yeast thermal conversion. Most helpful in making the microscopic identification of *S. schenckii* yeast forms is the observation of elongated oval forms (i.e., cigar-bodies) that measure 3 × 10 µm. These yeast forms may be difficult to detect in routine H&E-stained sections of human tissue, so if infection is suspected based on the inflammatory response present, then a methenamine silver stain should be ordered. This will demonstrate a mixture of spherical yeast with the more characteristic elliptical yeast cells (Fig. 21-63).

Diagnosis Using Nonculture Techniques. Nonculture techniques are not routinely employed for the diagnosis of sporotrichosis. Although molecular assays have been developed, they are not used on a routine basis. The application of serologic techniques has proven to be of minimal benefit in the diagnosis of sporotrichosis. Latex agglutination tests have been used in the past with limited success, particularly in the diagnosis of primary skin infections, in which results are usually negative. Agglutination titers of 1:80 or higher have been helpful in the diagnosis of active, extracutaneous infections.[61]

The clinical manifestations of sporotrichosis are presented in Clinical Correlation Box 21-8.

■ **FIGURE 21-63** Photomicrograph of a cutaneous biopsy from a patient with sporotrichosis revealing numerous spherical to oval yeast cells of *Sporothrix schenckii*, some of which show elongated, two-celled cigar-shaped buds (high-power, methenamine silver stain).

1377

CLINICAL CORRELATION BOX 21-8 Sporotrichosis

In the United States, subcutaneous fungal infections are most commonly caused by a member of the *Sporothrix schenckii* complex.[11] DNA sequencing studies have revealed that a number of morphologically similar species make up what has been termed *"Sporothrix schenckii."*[188] Although differentiation of these is possible, the term "complex" is preferred, since they all produce a similar disease and there is no

difference in treatment.

The most common form of sporotrichosis is lymphocutaneous. The appearance of a small, red, painless pustule on an extremity, together with the appearance of multiple, linearly placed secondary pustular or ulcerating lesions along the proximal lymphatics is sufficient to suspect the diagnosis. The primary pustule may slowly enlarge, ulcerate, and discharge a small amount of serosanguineous exudate. Varying degrees of cellulitis with swelling and redness of the surrounding subcutaneous tissue may be observed. The secondary satellite lesions present initially as verrucous, erythematoid plaques, or scaly patches, often developing into ulcers that also exude purulent material. Diagnosis is often delayed because associated secondary bacterial colonization may be mistaken for the primary infectious agent. Bacterial superinfections may also confuse the gross appearance.

In patients with progressive disease, the infection may spread to joints, tendon sheaths, bursae, bone, and muscle.[302] Purvis et al.[228] report a patient with bilateral polyarticular arthritis of the wrists and elbows. Although arthritis is an uncommon manifestation of sporotrichosis, this report points to the broadened spectrum of disease that may be caused by this fungus.[43]

Sporotrichal arthritis is an uncommon disease. Howell and Toohey[129] report the findings of 13 patients with sporotrichal arthritis who had been treated in Wichita-area hospitals. The typical presentation was of an afebrile patient with a mildly swollen warm joint without erythema. Seventeen joints were involved, including 10 knees, 3 interphalangeal joints, 1 elbow, 1 midtarsal, 1 intercarpal, and 1 metatarsophalangeal joint. Most of the patients were middle-aged men, and significant alcohol intake was noted in 77% of the patients. Wang et al.[284] report a patient with a prepatellar bursa infected with *Sporothrix schenckii*. The infection persisted despite itraconazole therapy, and cure was achieved only after surgical excision of the bursa.

Primary pulmonary sporotrichosis is rare. However, England and Hochholzer[80] reported primary pulmonary sporotrichosis in eight patients following inhalation of airborne conidia, an otherwise rare occurrence. Cough, sputum production, and low-grade fever are the usual presenting symptoms.

In immunosuppressed patients, sporotrichosis may have atypical presentations, with the disease tending to become widespread and disseminated. Cutaneous disease beginning as localized lesions may disseminate to other skin sites, with dissemination to the meninges in one reported patient, which is a presentation this author has also seen.[70] Diagnosis may be difficult when sporotrichosis initially presents as fungemia and disseminated disease.[9] Although localized sporotrichosis is an innocuous disorder that responds well to therapy, these authors found in immunocompromised hosts that the disease is potentially life-threatening and often is difficult to treat, requiring prolonged therapy with potentially toxic medications such as amphotericin B. Reversal of immunosuppression in conjunction with antifungal therapy is the proscribed treatment.

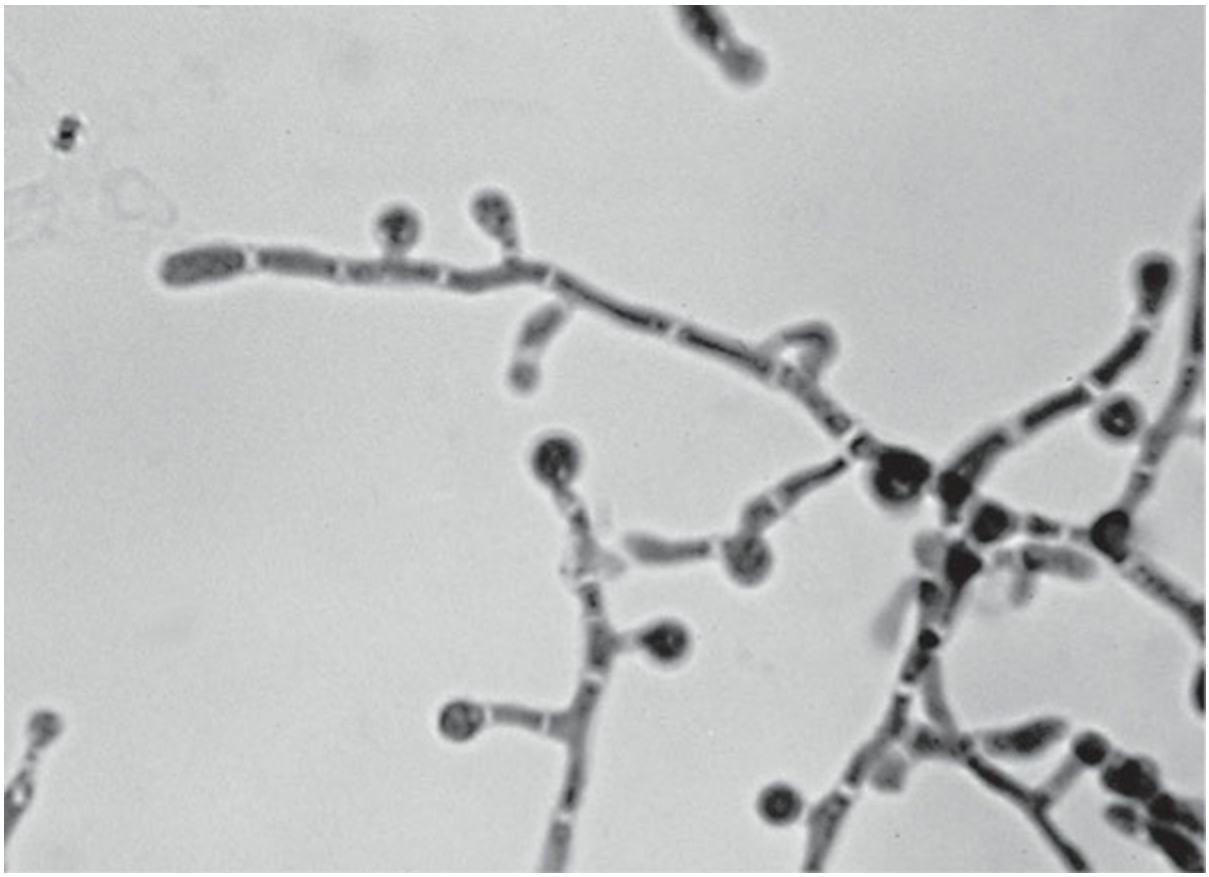
Paracoccidioides brasiliensis and Paracoccidioidomycosis

Paracoccidioidomycosis is a progressive subacute to chronic systemic granulomatous fungal infection caused by the thermally dimorphic fungus, *Paracoccidioides brasiliensis*. The mycelial form of this fungus resides in the soil, and pulmonary infection develops in humans by inhalation of the small (4 μm diameter) conidia. Skin and mucocutaneous infections occur by direct inoculation of spore-contaminated material. In South America, 80% of infections have been reported from Brazil; followed in order of incidence by case reports from Colombia and Venezuela; endemic areas also exist in southern Mexico and in all countries in Central America except Belize and Nicaragua.[32]

The overall prevalence rate of paracoccidioidomycosis is difficult to derive, since infections often occur in resource poor countries with a limited public health infrastructure. Although estimates of a million or more infected patients have been made, many patients either are not reported or remain undiagnosed. Botteon et al.[28] studied two groups of blood donors. One group consisted of donors living in a rural area where paracoccidioidomycosis is endemic, whereas the other from a group of urban residents residing in Sao Paulo. Serologic studies showed that 21% of 700 patients from the endemic rural areas had evidence of current or remote disease, whereas only 0.9% of 350 urban patients were serologically positive. Thus, with a population of approximately 169 million, even if the lower urban prevalence rate of paracoccidioidomycosis is used, well over 1.5 million residents of Brazil alone have been infected.

Countries in the Caribbean islands, the Guyanas, and Chile have been free of reported disease. In endemic areas, most infections occur in and around humid forested regions. The disease most frequently involves adults over 30 years of age, is rare in children, and occurs in males more often than in females, with an overall ratio of 15:1. Although the majority of patients are agriculturists, infections have been reported in individuals with rare direct exposure to soil and vegetation as indicated by the report cited above. Whites are more prone to infections than Native Americans; more severe infections tend to develop in immigrants coming to endemic areas.[32]

1378



■ **FIGURE 21-64** Photomicrograph of the mold form of *Paracoccidioides brasiliensis,* illustrating the small, smooth, spherical conidia borne laterally and terminally from short conidiophores derived from septate hyphae.

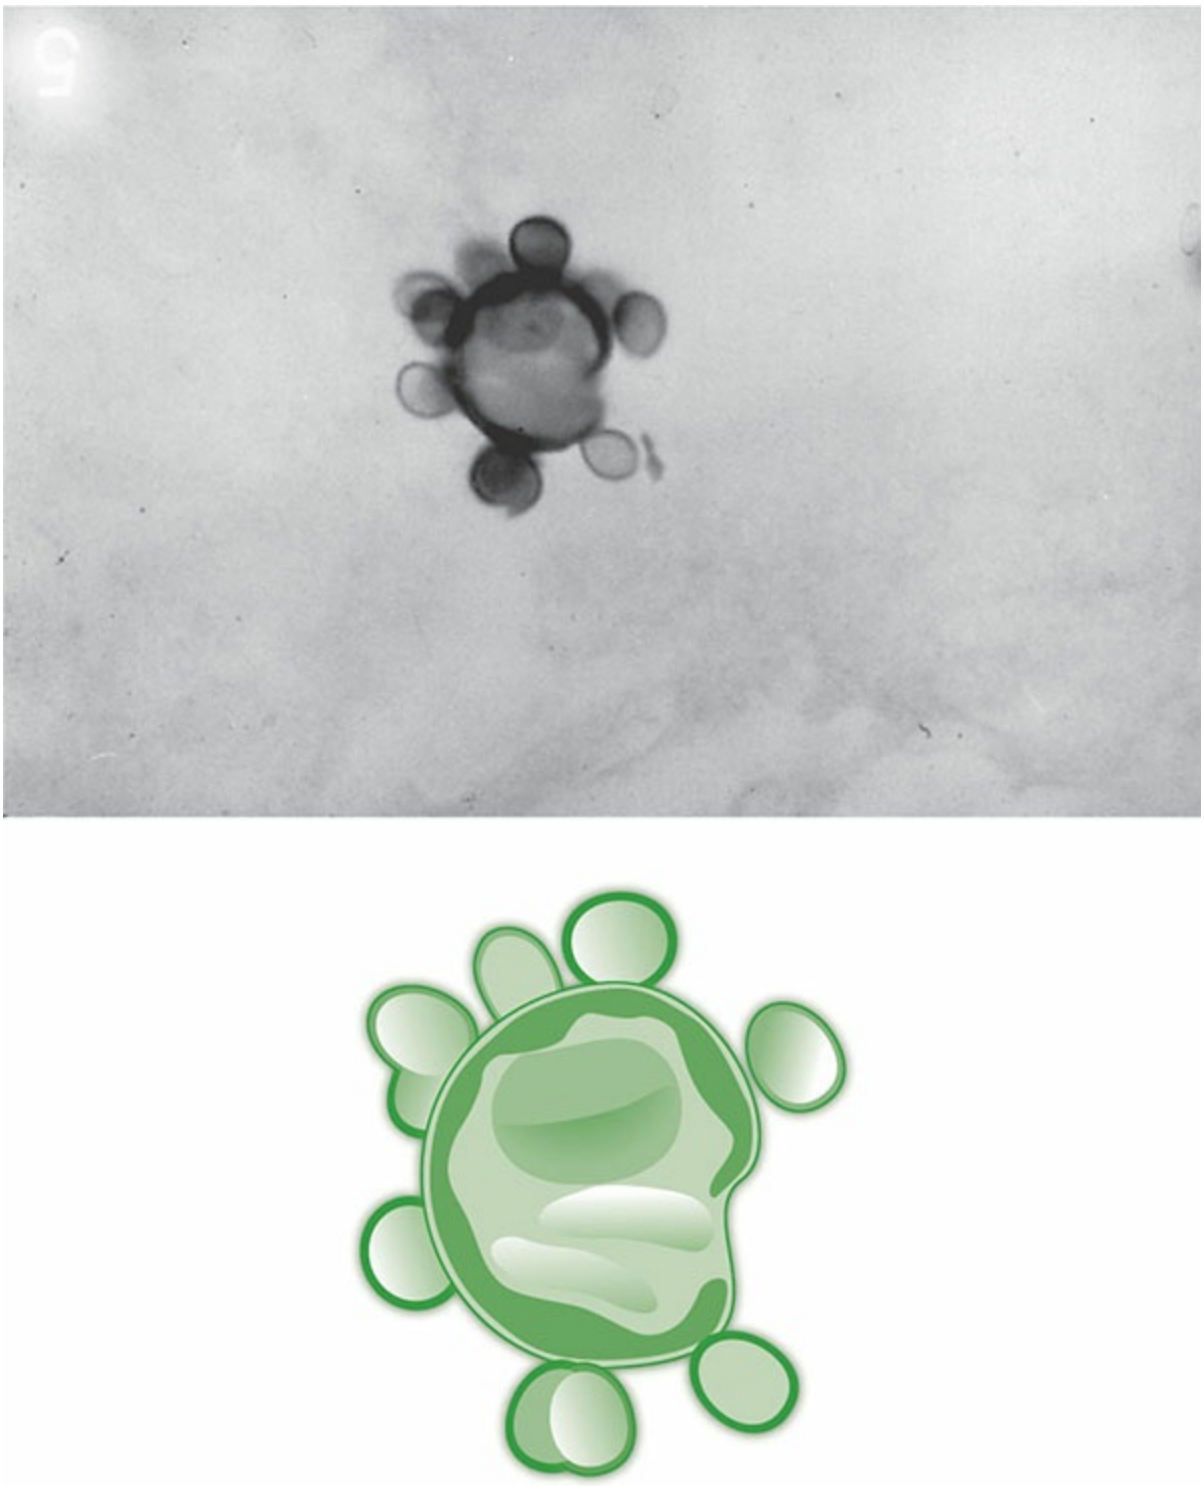
Laboratory Presentation. The colonies are similar in appearance to those of *Blastomyces dermatitidis*. They are slow-growing at 30°C, requiring 10 to 20 days to mature, are gray-white, and have a delicate silky or hairlike mycelium.

When incubated at 25°C to 30°C, *P. brasiliensis* grows very slowly over 10 to 30 days as a silky, white to gray-tan mold. The identification and differentiation from other similar appearing molds can be made by microscopically observing the delicate, hyaline septate hyphae that make up the background mycelium. Oval, nonpigmented, 2 to 4 µm conidia are borne singly from short, slender conidiophores directly from the hyphae, in a "lollipop" fashion, similar in appearance to those produced by *Blastomyces dermatitidis* (Fig. 21-64).

The identification can be confirmed by converting the mold to the yeast form, which is accomplished by inoculating a small portion of the mold colony to enriched brain-heart infusion agar. Conversion to the yeast form, however, is slow. The mother yeast cells of *P. brasiliensis* observed in culture are usually 6 to 15 µm in diameter, but may grow larger. These are differentiated from the similarly-sized *B. dermatitidis*,

by the presence of multiple narrow-necked buds (i.e., in contrast to the single, broad-based budding forms of *B. dermatitidis*). Although a genetic probe is not commercially available for *P. brasiliensis*, the commercially available probe for *B. dermatitidis* cross-reacts with *P. brasiliensis*, and can be used in conjunction with other findings to secure the identification.

The same yeast form is present in the tissues of infected patients. Therefore, the diagnosis of paracoccidioidomycosis can be most quickly established by demonstrating directly in clinical materials the characteristic 10 to 30 μm spherical, thick-walled yeast cells, with multiple daughter buds, each attached by a narrow-necked bud, which has been likened to a "mariner's wheel" (Fig. 21-65). These yeast forms may be best observed in KOH/calcofluor white preparations. In some cases, the budding daughter cells may form short chains. In tissue sections, the background inflammation is usually granulomatous-to-pyogranulomatous (i.e., granulomatous inflammation that is admixed with varying concentrations of polymorphonuclear leukocytes). The yeast forms are best seen in PAS- or GMS-stained sections.



■ **FIGURE 21-65** Photomicrograph and sketch of the yeast form of *Paracoccidioides brasiliensis,* illustrating the large central yeast cell that is giving rise to multiple buds, forming a "mariner's wheel."

Diagnosis Using Nonculture Techniques. The exoantigen test, refined by Camargo et al.,[35] is a means for confirming the culture identification of unknown isolates. Indirect immunofluorescence techniques, immunoenzymatic assays, and molecular methods have been used by investigators to establish the diagnosis of paracoccidioidomycosis. The immunodiagnostic approaches to the diagnosis of paracoccidioidomycosis have been reviewed by Brummer et al. and de Camargo.[32,65] Serum IgG levels remain elevated for at least 1 year after infection.

Mendes-Giannini et al.[184] demonstrated IgG, IgA, and IgM-specific antibodies to a 43-kDa antigen of *Paracoccidioides brasiliensis* in patients with paracoccidioidomycosis, and further demonstrated that a lowering of the titers during a course of treatment was correlated with an improvement in symptoms. Gomez et al.,[102] using a monoclonal antibody directed against the yeast form of *Paracoccidioides brasiliensis*, were able to develop an inhibition ELISA test capable of detecting small quantities of circulating antigen in the serum of patients with active disease. Of 46 patients with paracoccidioidomycosis, 37 tested positive (80.4%).

Antigen-detection assays are being used for the diagnosis of paracoccidioidomycosis. The detection of the gp43 and gp70 antigens of *Paracoccidioides* is the target of these assays.[65] In addition to detecting these in blood, they have been

assessed in cerebrospinal fluid and bronchoalveolar lavage fluid. The quantitative or semiquantitative nature of these assays allows for trend analysis of antigen levels; antigen decline and clearance should occur with successful therapy.

Molecular methods have also been employed to diagnose paracoccidioidomycosis. Sandu et al.[242] have developed a 14-base DNA probe specific for the 5′ terminus of fungal 28S ribosomal gene sequences of *P. brasiliensis*. Applying a uniform diagnostic protocol, consisting of common cell lysis and DNA purification procedures followed by PCR amplification, these authors demonstrated selective identification of *P. brasiliensis* from 47 other species of fungi representing 25 genera. PCR and other molecular methods provide alternate means to establish the diagnosis of paracoccidioidomycosis.

The clinical manifestations of paracoccidioidomycosis are presented in Clinical Correlation Box 21-9.

CLINICAL CORRELATION BOX 21-9 Paracoccidioidomycosis

Upon inhalation of spore-contaminated dust, the small (4 μm diameter) conidia reach the distal portion of the pulmonary parenchyma, where they develop into yeast cells that may be confined locally, or where they may propagate and disseminate to distal organs in patients with progressive disseminated disease. In an immunocompetent host, local growth is retarded and the infection may end without development of a lesion. When symptomatic, Brummer et al.[32]have divided paracoccidioidomycosis into two general categories: (1) juvenile form, acute or subacute, and (2) chronic form, adult-type.

Juvenile Form, Acute or Subacute

The juvenile form of disease includes only 3%–5% of all infections, primarily involving children or young adults, the majority of whom are immunosuppressed. The course of disease is relatively rapid (weeks to months), marked by diffuse involvement of the reticuloendothelial system. Hepatosplenomegaly, lymphadenopathy, and bone marrow hyperplasia are common clinical presentations. Dysfunction of the bone marrow may be so severe as to simulate a lymphoproliferative disorder.[170] Biopsies of the involved organs or tissues often reveal a large number of actively proliferating yeast cells, in the absence of granuloma formation. In this form of the disease, the lungs are seldom involved, although organisms may be detected in respiratory secretions. Mesenteric lymph nodes may on occasion become so enlarged as to cause bowel obstruction. Prognosis of the juvenile form of the disease is poor.

Chronic Form, Adult-Type

Approximately 90% of patients have this form of disease, which occurs most commonly in adult men. Interestingly, the high level of estrogen in pre-menopausal women acts to inhibit the mycelial-to-yeast conversion that is necessary for infection; this, in part, explains the differences noted in the incidence of infection between men and women. The disease is slowly progressive, tends to remain confined primarily to the lungs, and may take months or years to become fully established. The lungs are involved in over 90% of infected patients, and in many instances the lungs are the sole site of infection. The pulmonary lesions as seen on chest roentgenogram may be nodular, infiltrative, fibrotic, or cavitary and are preferentially localized to the lower lobes of the lungs.[170] Cough, expectoration of sputum, and shortness of breath are the common symptoms, often accompanied by low-grade intermittent fever, weight loss, and anorexia. The clinical and radiologic findings often mimic tuberculosis. The chronic disease may be mild, moderate, or severe, depending on the patient's general condition and immune status; severe fibrosis leading to chronic obstructive pulmonary disease and *cor pulmonale* are the fatal sequelae.

Brummer et al.[32] cite several examples of extrapulmonary involvement, including the infection of the eyes, the central nervous system, bone, and the genital tract. Sant' Anna et al.[243] review the findings from seven patients with laryngeal disease. All these

patients were middle-aged males, predominantly farm workers. Dysphonia, dysphagia, dyspnea, and cough were the main presenting symptoms. The first diagnostic impression was carcinoma in each of these patients.

These and other dimorphic fungal infections may also involve the mouth.[8,100] Almeida et al.[8] report that oral fungal infections (mycoses) have come into particular prominence since the advent of HIV infections, as well as the phenomenal increase in world travel, with increased exposure to infections endemic in the tropics. Almeida et al. further report on 21 Argentinian patients living in the province of Corrientes who presented with oral manifestations of *Paracoccidioides brasiliensis*. All patients except one had detectable pulmonary involvement. The long-term administration of itraconazole provided cures for these patients. The authors emphasize the need for early diagnosis and adequate therapy to prevent extensive tissue destruction. Long-term follow-up also is mandatory, as the recurrence rate is high.

The clinical manifestation encountered among the 27 patients with AIDS reported by Goldani and Sugar[101] ranged from indolent infection to a rapidly progressive course. Disseminated disease was the most common form, with lung, skin, and lymph nodes being the most common sites of infection. Prolonged fever, lymphadenopathy, hepatosplenomegaly, and cutaneous lesions were most commonly encountered. The diagnosis is best made by direct examination and culture of sputum specimens, skin biopsies, and lymph node aspirates. As

mentioned before, PCR assays of these specimens promises to greatly enhance the ability to make a diagnosis. About half of the patients in this series died despite aggressive antifungal therapy.

Severo et al.[252] report involvement of the male genital tract in a native of Brazil, and review of 18 additional patients gathered from the Brazilian literature. Manns et al.[177] discuss a 59-year-old man who presented with paracoccidioidomycosis more than 15 years after leaving South America. Practitioners throughout the world must keep this infection in mind when evaluating a patient with appropriate travel history who has pulmonary, mucosal, or cutaneous manifestations suggestive of this disease, along with weight loss and other constitutional symptoms.

Dematiaceous Fungi

Agents of Phaeohyphomycosis

In contrast to the hyaline group of fungi that have nonpigmented cells walls, there is a second large and genetically heterogeneous group of saprophytic molds that produce

melanin and melanin-like pigments in their cell walls. This results in the production of darkly pigmented hyphae. Both the reverse and the surface of the colonies are visibly dark, appearing gray, brown, or black. The examination of the reverse of the colony gives the best indication of the hyaline or dematiaceous nature of a mold, since some hyaline molds, such as *Aspergillus niger,* produce black spores yet are hyaline molds.

The term phaeohyphomyces (Greek *phaeo* = dusky, gray) has been applied to fungal infections caused by this dematiaceous group of fungi. The concept of "phaeohyphomycosis" was first proposed by Ajello et al.[6] in 1986 to "cover all infections of a cutaneous, subcutaneous and systemic nature caused by hyphomycetous fungi that develop in the host tissues in the form of dark-walled, dematiaceous septate mycelial elements." Thus, as originally described, *phaeohyphomycosis* was a term used to describe a histopathologic entity rather than representing any particular clinical disease or fungal species as identified in laboratory cultures.[66,234] It has come to be used as the dematiaceous equivalent of hyalohyphomycosis (i.e., a generic term for an invasive fungal infection caused by a dematiaceous mold). Chromoblastomycosis and mycetoma are distinctive clinical entities different from phaeohyphomycosis. Chromoblastomycosis is caused by select dematiaceous fungi, whereas mycetomas may be caused by bacteria, hyaline molds, or dematiaceous molds. Select etiologic agents of phaeohyphomycosis, chromoblastomycosis, and mycetoma will be covered here.

Laboratory Presentation. This dematiaceous fungus, in the broadest terms, produces either dark gray, brown, or black wooly colonies or colonies that have a velvety surface. As denoted above, the reverse of the colony is darkly pigmented, as this represents the dematiaceous hyphal mat. Although the colony morphology is not distinctive among this group of fungi and microscopic examination is necessary to make a genus/species identification, the type of colony (i.e., wooly vs. velvety) provides a clue to the likely possibilities. For example, *Alternaria*, *Bipolaris*, and *Curvularia* produce wooly colonies, whereas *Fonsecaea, Phialophora*, and *Cladosporium/Cladophialophora* produce velvety colonies. Representative colonies of the more rapidly growing, dematiaceous molds are shown in Image Plate 21-3A–D. In general, the agents of chromoblastomycosis and mycetoma are usually slower-growing, small, and velvety colonies.

Microscopically, the dematiaceous molds have a dark brown mycelium composed of uniform hyphae with parallel walls and distinct septations. Pigment may not be obvious in some species in the earliest phases of growth, but will be developed with further incubation. The following genera of fungi are rapidly growing molds (i.e., wooly colonies) that produce darkly staining, multicellular macroconidia: *Alternaria*, *Ulocladium*, *Stemphylium*, *Epicoccum*, *Bipolaris*, *Drechslera*, *Curvularia*, and *Exserohilum*.

The identification of these fungi can be simplified by first separating these into one of two categories based on the morphology of the conidia: 1. Macroconidia (i.e., multicelled conidia) that have septations that are both longitudinal and perpendicular (i.e., transverse septa) with respect to the longitudinal axis of the conidium. These conidia often also have oblique septations and are commonly referred to as muriform. 2. Macroconidia that contain only perpendicular (i.e., transverse) septations with respect to the longitudinal axis of the conidium.

Macroconidia with Transverse and Longitudinal Septa (Muriform)

The genera of fungi of medical importance included in this group are:

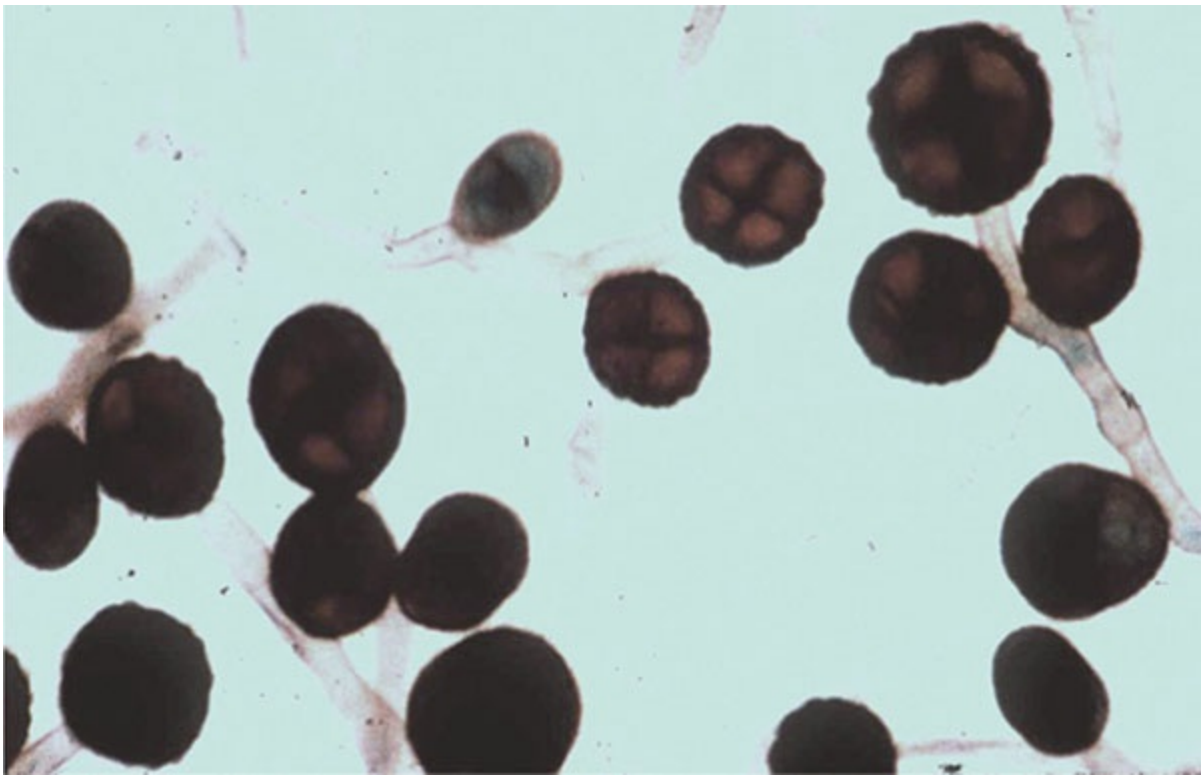
- *Alternaria* species
- *Ulocladium* species
- *Stemphylium* species
- *Epicoccum* species

***Alternaria* Species.** The formation of short chains of large, smooth-walled, multicelled, macroconidia separated by both cross and longitudinal septa (muriform) are characteristic of *Alternaria* spp. The macroconidia are shaped like drumsticks, with the elongated beak of one conidium butting against the rounded, blunt end of the next (Fig. 21-66). The fungi are most commonly contaminants and only rarely cause human infections. In fact, they are so infrequently the causes of disease that the assurance of corresponding histopathologic evidence of infection is strongly recommend prior to considering the initiation of therapy.

***Ulocladium* Species.** *Ulocladium* spp. also produce muriform macroconidia; however, the conidia from these fungi are more spherical than those of *Alternaria* spp. They do not form in chains, but rather are borne from short, twisted "bent knee," or **geniculate,** conidiophores (Fig. 21-67). These conidiophores are formed circumferentially (i.e., around), which is a **sympodial derivation**. This sympodial, geniculate conidiation is a type of conidiogenesis that will be encountered in other dematiaceous fungi.

1381

■ **FIGURE 21-66** Photomicrograph of a short chain of dark-staining, muriform macroconidia characteristic of *Alternaria* species.



■ **FIGURE 21-67** Photomicrograph of dark-staining, muriform macroconidia derived from geniculate conidiophores, characteristic of *Ulocladium* species.

***Stemphylium* Species.** The muriform macroconidia produced by *Stemphylium* species is superficially similar to that of *Ulocladium* spp. Closer inspection, however, will disclose that they are slightly constricted in the mid-aspect of the conidium, which gives the conidium a "Figure 8" appearance. In addition, these are borne singly at the apex of a short, straight conidiophore (i.e., the sympodial geniculate conidiation of *Ulocladium* is absent). The terminal aspect of the conidiophore is swollen and is often more darkly pigmented than the rest of the conidiophore (Fig. 21-68).

***Epicoccum* Species.** The hyphae of *Epicoccum* typically form focal repeated branching and rebranching in the foci of conidiation, forming masses known as **sporodochia**. Short, club-shaped conidiophores arise from these masses, bearing multicelled, muriform, spherical to slightly club-shaped macroconidia, which may be roughened on the surface, giving a blackish wartlike appearance (Fig. 21-69). An important colonial characteristic is the production of a yellow pigment that diffuses into the agar.

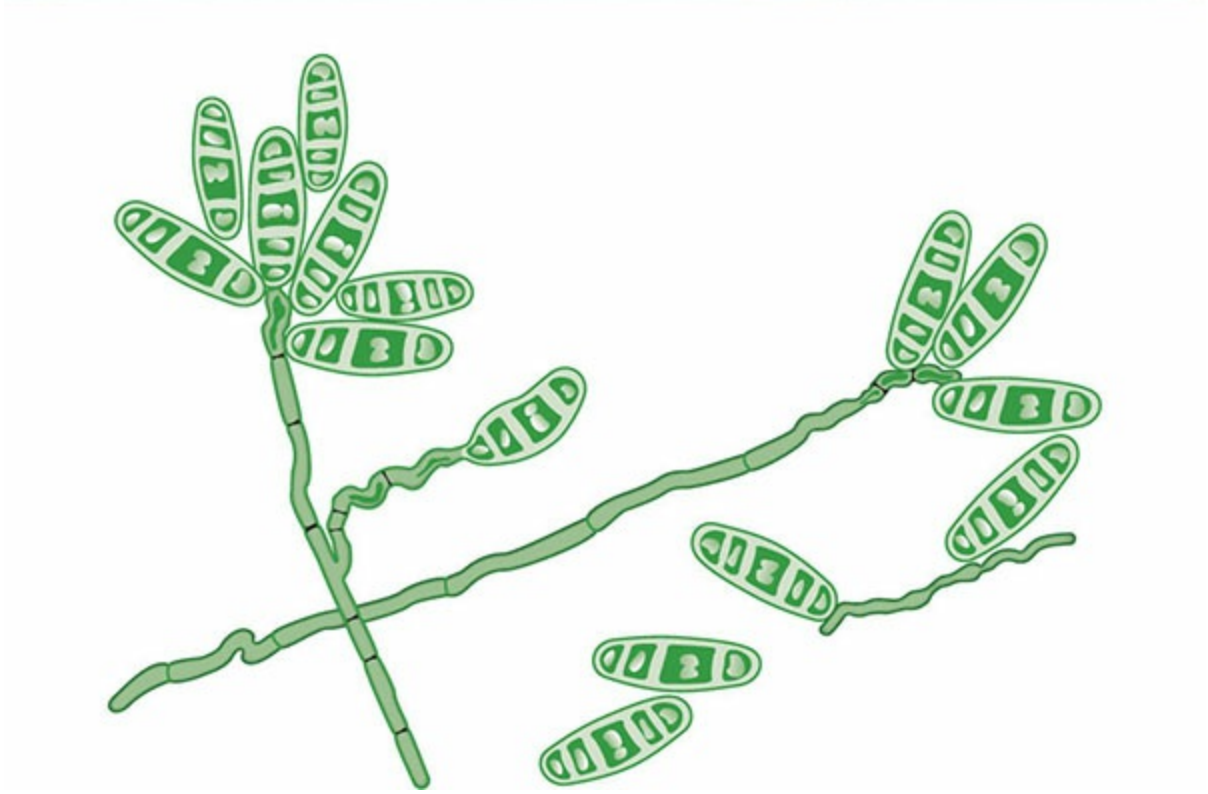
1382



■ **FIGURE 21-70** Photomicrograph and sketch of cylindrical, smooth-walled, multicelled macroconidia characteristic of *Bipolaris* species.

Macroconidia with Transverse Septa

***Bipolaris* Species.** The distinguishing feature of *Bipolaris* spp. is the production of multicelled, elliptical to oval, thick-walled macroconidia with smooth surfaces; these are produced by sympodial, geniculate conidiation, as described above (Fig. 21-70). Close inspection of these conidia in preparations using a stain, such as lactophenol cotton blue, will disclose that the septations between the cells of the conidium are incomplete. These are termed distoseptae and when present, one can often visualized the continuity of cytoplasm from one cell in the conidium to the adjacent cell. The designation *Bipolaris* is derived from the property of producing germ tubes that **arise from both (i.e., bi) end (i.e., polar) cells of the macroconidia**, which grow in parallel with the long axis of the cell. These can be demonstrated when examined in direct water or saline mounts of the conidia that have been incubated at 25°C for 8 to 24 hours.

Bipolaris species are important causes of fungal keratitis following an eye injury and may cause phaeohyphomycosis in the immunocompromised host.

***Dreshslera* Species.** *Drechslera* spp. also produce cylindrical, multicelled macroconidia from sympodial geniculate conidiation that are indistinguishable from those of *Bipolaris* spp. The conidia have non-protruding, rounded contours at the base cell. The germ tube test is used to differentiate this fungus from *Bipolaris*. In saline mounts, a germ tube may be produced by any of the cells of the multicellular conidium. A microscopic search of the germinating conidia will demonstrate some wherein the germ tube is arising from an internal cell, rather than only from the terminal cells. These germ tubes are readily recognized, since they extend **at right angles to the longitudinal axis** of the conidium.

Drechslera spp. are very infrequent in clinical practice. *Drechslera* is not an important cause of human disease and is presented here because of the morphological similarities of the conidia to *Bipolaris*. The vast majority of fungal isolates that produce conidia that are morphologically consistent with *Bipolaris* or *Drechslera* are determined to belong to the genus *Bipolaris*.

***Curvularia* Species.** The macroconidia of *Curvularia* spp. are easy to recognize, having four to five cells separated by transverse septa, borne through sympodial geniculate conidiation. The second cell from the terminal end (i.e., non-hilar end) of the conidium continues to grow after the others have stopped, which imparts a curved shape to the conidium, which some believes resembles a boomerang (Fig. 21-71). *Curvularia* is an important caused of phaeohyphomycosis and may cause allergic

fungal sinusitis.

***Exserohilum* Species.** The conidia of *Exserohilum* spp. are similar to those of *Bipolaris* spp., except that they are longer, have more cells/conidium and characteristically have an **extended, prominent protruding hilum** from the hilar cell (Fig. 21-72). Although *Exserohilum* is an infrequent cause of human disease, in 2014 there was significant contamination of an injectable methylprednisolone with environmentally-derived *Exserohilum*. This product was nationally distributed and was the source of infection in many patients.[154]

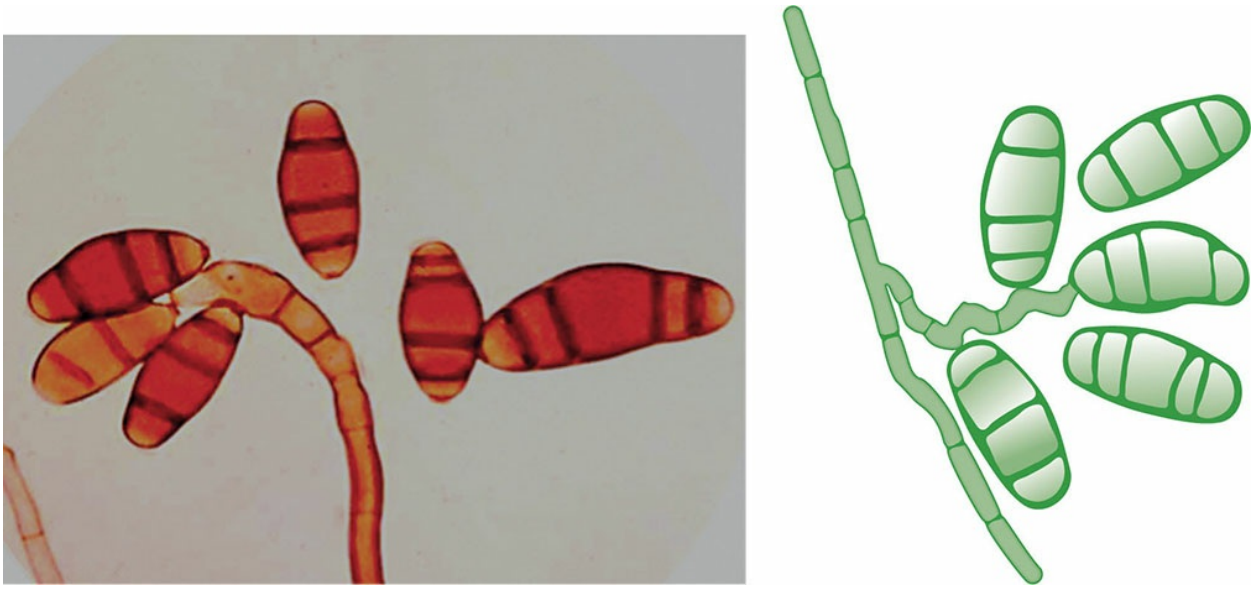
Miscellaneous Moderately to Rapidly Growing Dematiaceous Molds

There are three genera of the molds fungi that will be considered here largely because they are not well categorized elsewhere. These are *Nigrospora* species, *Phoma* species, and *Chaetomium* species. The latter two fungi may be confused with one another, so careful attention to differentiating characteristics is important.

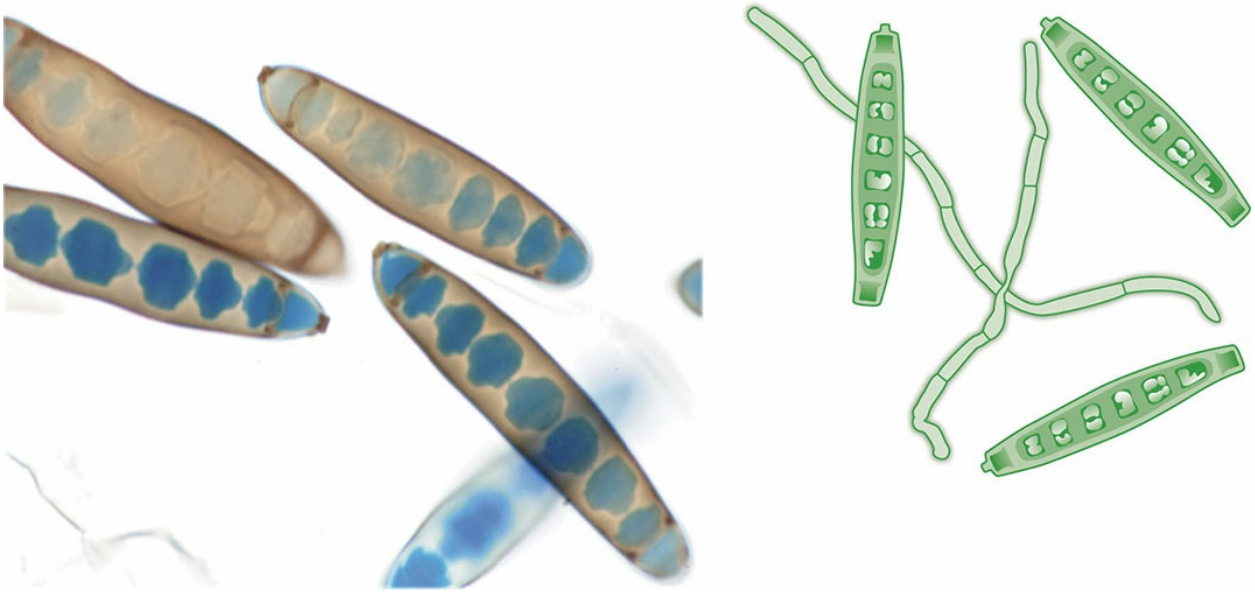
***Nigrospora* Species.** The colonies of *Nigrospora* spp. are rapidly growing and cottony; initially they are dirty white, but turn gray with maturity as the vegetative hyphae become pigmented. The reverse of the colony also becomes darkly pigmented. Microscopically, the conidia are solitary, large, subglobose, smooth, and jet black and are borne from the tips of inflated, urn-shaped conidiophores (Fig. 21-73). The conidia of *Nigrospora,* to some, resemble a jet-black rugby ball or North American Football.

***Phoma* Species.** The colonies of *Phoma* spp. are buff to dark brown, spreading over the surface with an indistinct outer margin. The consistency is more glabrous than cottony because aerial hyphae develop poorly. Microscopically, large dark brown to black, smooth-walled, leathery, saclike structures called **pycnidia** are characteristically seen (Fig. 21-74).

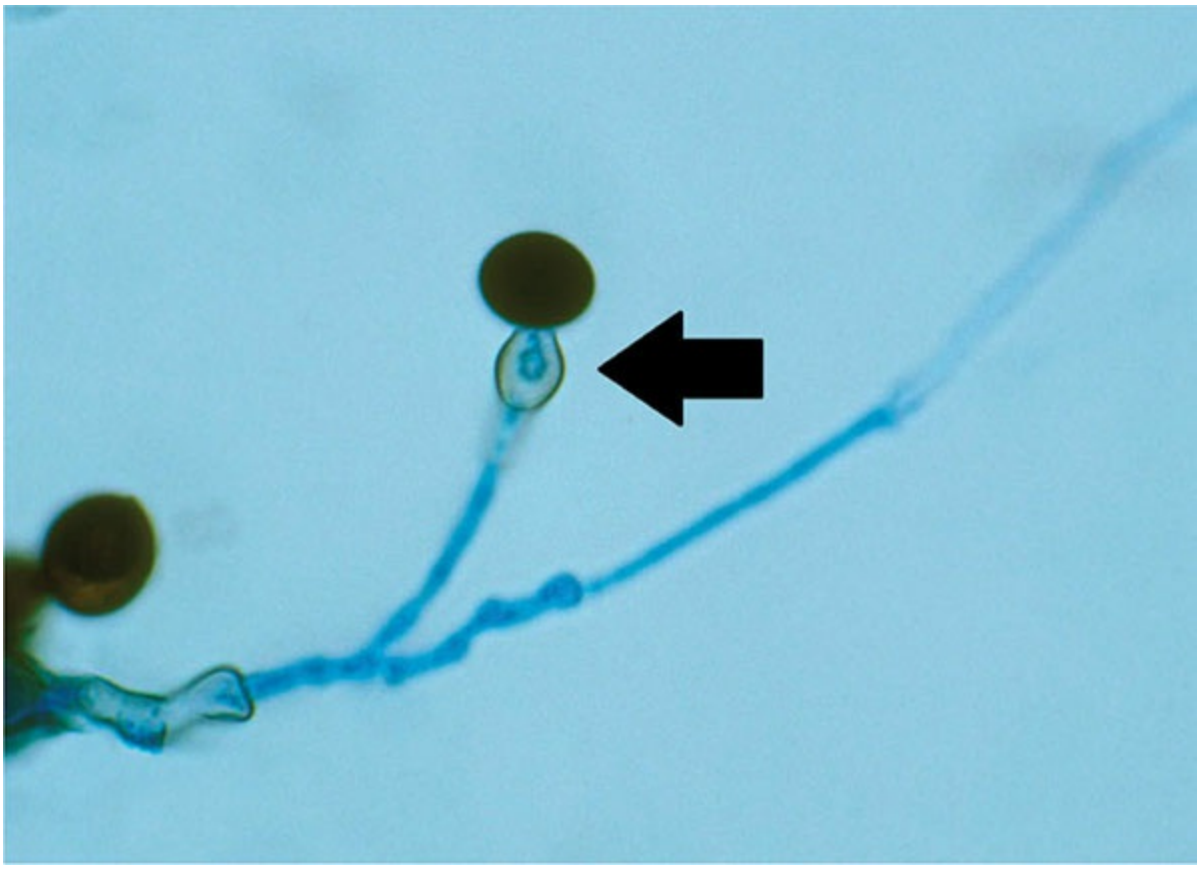
1383



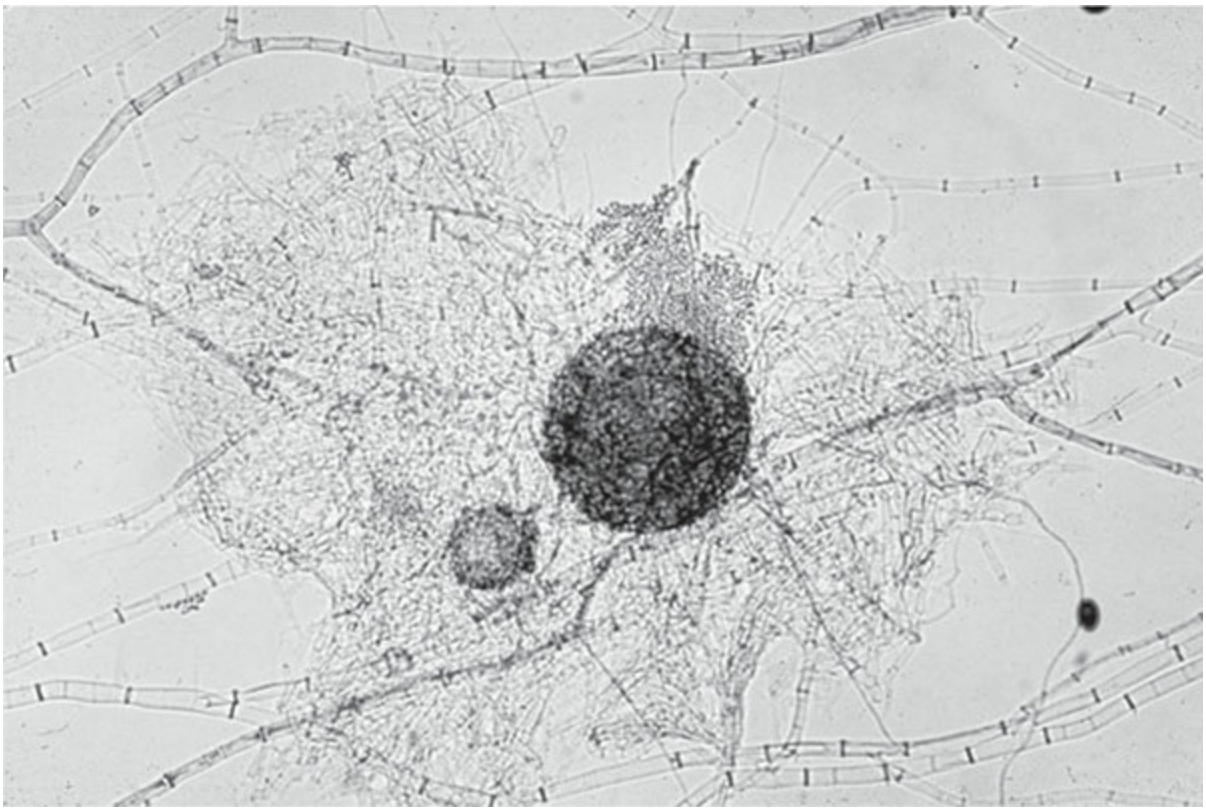
■ **FIGURE 21-71** Photomicrograph and sketch of dark-staining, multicelled macroconidia divided by transverse septa and bent due to overgrowth of next-to-terminal cell, characteristic of *Curvularia* species.



■ **FIGURE 21-72** Photomicrograph and sketch of long, pencil-shaped macroconidia of *Exserohilum* species, characterized by a terminal protrusion from the hilar cell.



■ **FIGURE 21-73** This photomicrograph of *Nigrospora* demonstrates a jet-black conidium supported by a bulbous conidiophore.



■ **FIGURE 21-74** Photomicrograph of a large saclike pycnidium of a *Phoma* species, with scattered tiny, hyaline conidia observed in the background.

1384

Within the pycnidia are borne myriad cylindrical, spindle-shaped or spherical, hyaline, one-celled conidia, which are asexually derived and released through a hole or ostiole. Because pycnidia may appear similar to the cleistothecia produced by *Aspergillus* spp., *Chaetomium* spp., and other telomorphic fungi, one must determine whether the spores contained are conidia, as is the case with *Phoma* spp., or are the larger, darker-staining ascospores characteristic of the ascosporogenous fungi. This differentiation can be made in cellophane tape mounts by gently pressing the surface of the tape with the tip of a pencil over the unknown baglike structure, while visualizing it under the scanning objective of a microscope until it ruptures. The release of the one-celled hyaline conidia as described above confirms the identification of *Phoma* spp.

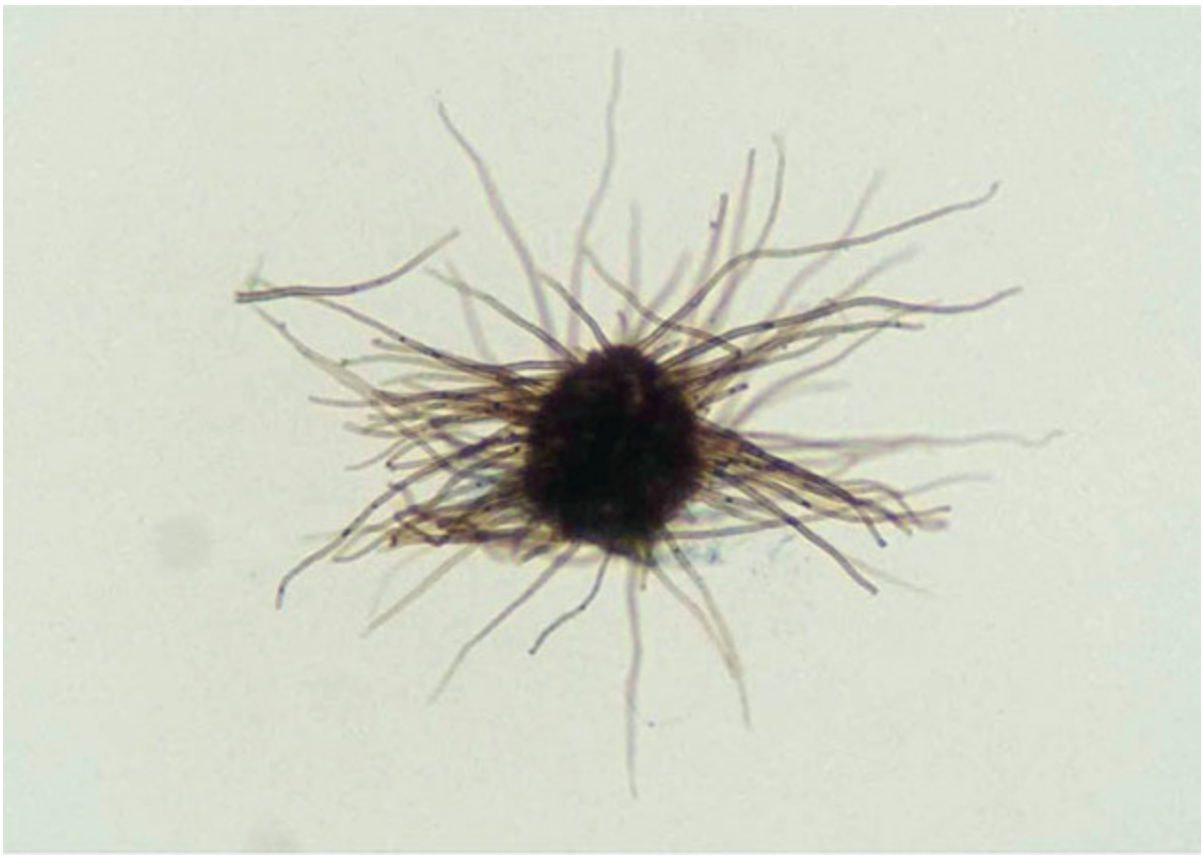
***Chaetomium* Species.** The colonies of *Chaetomium* spp. are initially white, but may become yellow, yellow-green, or copper-colored on maturity. Dark dots appear with the formation of cleistothecia. Microscopically, septate hyphae are formed, in addition to large, setae (i.e., spiked hyphae-like elements) may be observed extending from the wall of saclike cleistothecia. The word "setae" is derived from the Latin term for

bristle; these structures may be straight, coiled, or curved. Some believe the combination of these structures simulates the extending legs of a spider (Fig. 21-75).

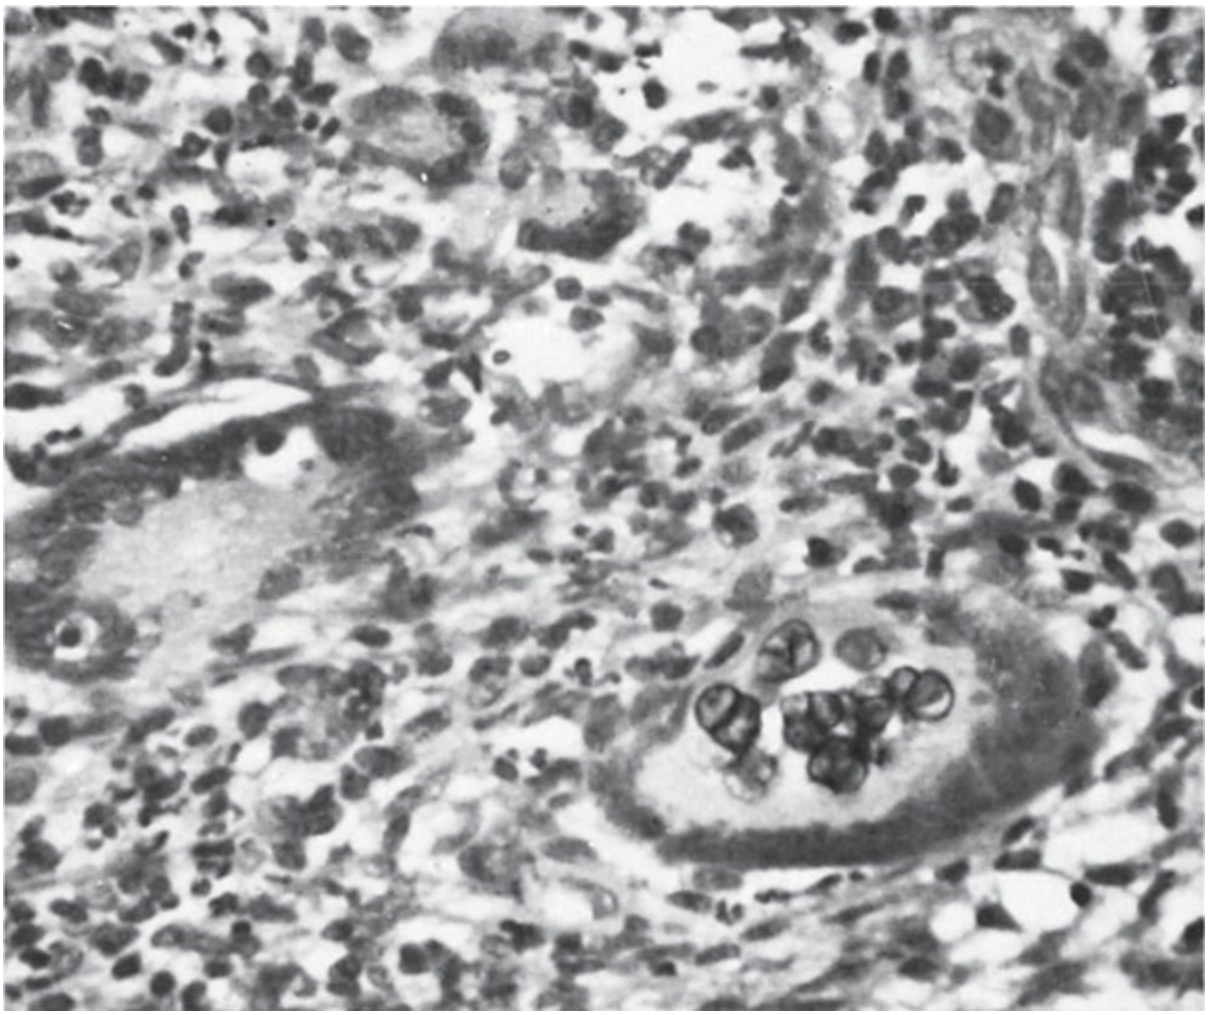
Slowly Growing Dematiaceous Fungi

The slowly growing dematiaceous molds are responsible for a variety of types of infections, including phaeohyphomycosis, chromoblastomycosis, and mycetoma. Phaeohyphomycosis has been described above, so a brief review of chromoblastomycosis and mycetoma will be given.

Chromoblastomycosis is an infection of the skin and subcutis. This is clinically characterized by the formation of elevated, roughened multicolored verrucous vegetations, most commonly spreading over the dorsal surfaces of the feet and lower leg. These agents gain entrance to the skin through traumatic wounds and penetrating injuries. The diagnostic forms are muriform, light-yellow-to-brown oval-to-spherical bodies that are grouped in clusters. Internal septations are seen in some of these yeast-like forms; however, budding does not occur. These are termed sclerotic bodies or more colloquial as copper pennies (Fig. 21-76). Microabscesses and granulomatous nodules (i.e., a pyogranulomatous response), extreme acanthosis, and pseudoepitheliomatous hyperplasia with varying degrees of fibrosis and scarring are the common histologic changes.



■ **FIGURE 21-75** Photomicrograph of the spiderlike pycnidium of a *Chaetomium* species.



■ **FIGURE 21-76** Photomicrograph of a tissue section from a patient with subcutaneous chromoblastomycosis. Note the inclusion of several spherical sclerotic bodies within the giant cell located in the lower right quadrant in the field of view (H&E, 400×).

Chromoblastomycosis is caused by a group of slow-growing, dematiaceous fungi belonging to the genera *Cladophialophora/Cladosporium*, *Phialophora*, and *Fonseceae*.[77] Mycetoma is an infection that is located primarily in the subcutaneous tissue, forming an abscess or granulomatous mass with the formation of sinus tracts that reach the surface of the skin. A mycetoma is a tumifactive mass that damages tissues through erosion and pressure, rather than invasion. Mycetomas may be caused by bacteria (i.e., eubacterial mycetoma) or fungi (i.e., eumycotic mycetoma). Purulent material containing grains or granules of microbial elements are often discharged from these sinus tracts, and are also observed in direct examinations and histologic sections. The grains are white if the eumycotic mycetoma is caused by a hyaline mold, whereas the grains are brown or black if the eumycotic mycetoma is caused by a dematiaceous mold.

The following species of slow-growing dematiaceous fungi are the most common causes of chromoblastomycosis, mycetoma, and other deep-seated mycotic infections:

- *Cladophialophora (Cladosporium) carrionii*
- *Cladophialophora (Xylohypha) bantiana*
- *Phialophora verrucosa*
- *Pleurostomophora (Phialophora) richardsiae*
- *Fonsecaea pedrosoi*
- *Exophiala* species

The differentiation between each of the species listed above depends on the observation of key differences in the mode of conidiation, the structure of the conidiophores and phialides or annellides, and the morphology and arrangement of the conidia.

1385

The causative agents of chromoblastomycosis include *Cladophialophora*, which reproduces with typical *Cladosporium*-type conidiation, which may be complemented by the production of phialides. In the *Cladosporium*-type sporulation, elliptical, dark-staining conidia are produced in long, branching chains, each separated by a delicate scar known as a dysjunctor (Fig. 21-77). *Phialophora verrucosa* is another cause of chromoblastomycosis and reproduces with *Phialophora*-type sporulation. This is characterized by the production of single phialides that are either urn-shaped or long and tapered. Phialides, which range in length from 4 to 7 μm in length, are borne directly from the sides of the hyphae. The terminal portion of the phialide is characteristically elongated, simulating the top of a soda bottle. Spherical to oval-shaped, yellow-pigmented conidia are produced from within each phialide, and aggregate in ball-like clusters at the terminal opening. These conidia may dislodge and aggregate along the sides of the phialides and along the adjacent supporting hyphae (Fig. 21-78). In the acrotheca-type sporulation, sympodial branches of conidiophores are produced from the sides of the hyphae, simulating the prongs of a coat rack. Short chains of conidia are borne from these clusters (Fig. 21-79). Although *Rhinocladiella* species are not a cause of chromoblastomycosis, the *Rhinocladiella*-type sporulation may be produced by *Fonsecaea* species. This is a variant of acrotheca-type sporulation in which the conidia are produced singly, directly, and laterally from the sides of the hyphae (Fig. 21-80). It is important to note that in addition to the typical *Fonsecaea*-type sporulation, that *Fonsecaea* species may also produce *Cladosporium*-type, *Phialophora*- type, and *Rhinocladiella*- type sporulation. These have been termed polymorphic fungi, because they produce a variety of morphologic forms. The conidia in a related, less commonly encountered species, *Fonsecaea compacta*, are

arranged in tight clusters.

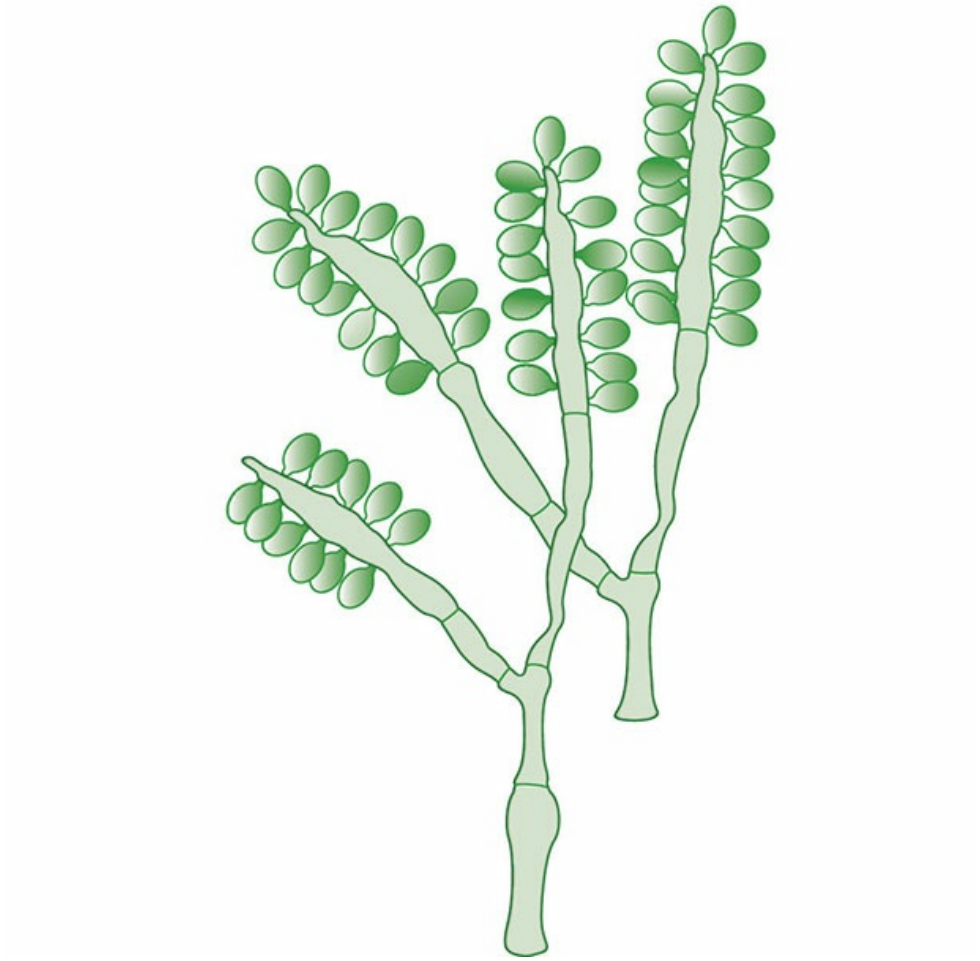
1386



■ **FIGURE 21-80** Photomicrograph and sketch of rhinocladiella-type sporulation in which elliptical conidia are borne directly and laterally in compact rows from the sides of the conidiophore.

***Cladophialophora/Cladosporium* Species.** There are a variety of *Cladosporium* and *Cladophialophora* species. The two most common or of the most medical importance will be highlighted. *Cladosporium carrionii* produces freely branching hyphae that give rise to long chains of dark-staining, elliptical conidia. The so-called "shield cells" are the points wherein branching occurs. The conidia and shield cells often show scars or dysjunctors that are more darkly pigmented that the rest of the hyphae or conidia and represent the points of previous attachment (Fig. 21-77).

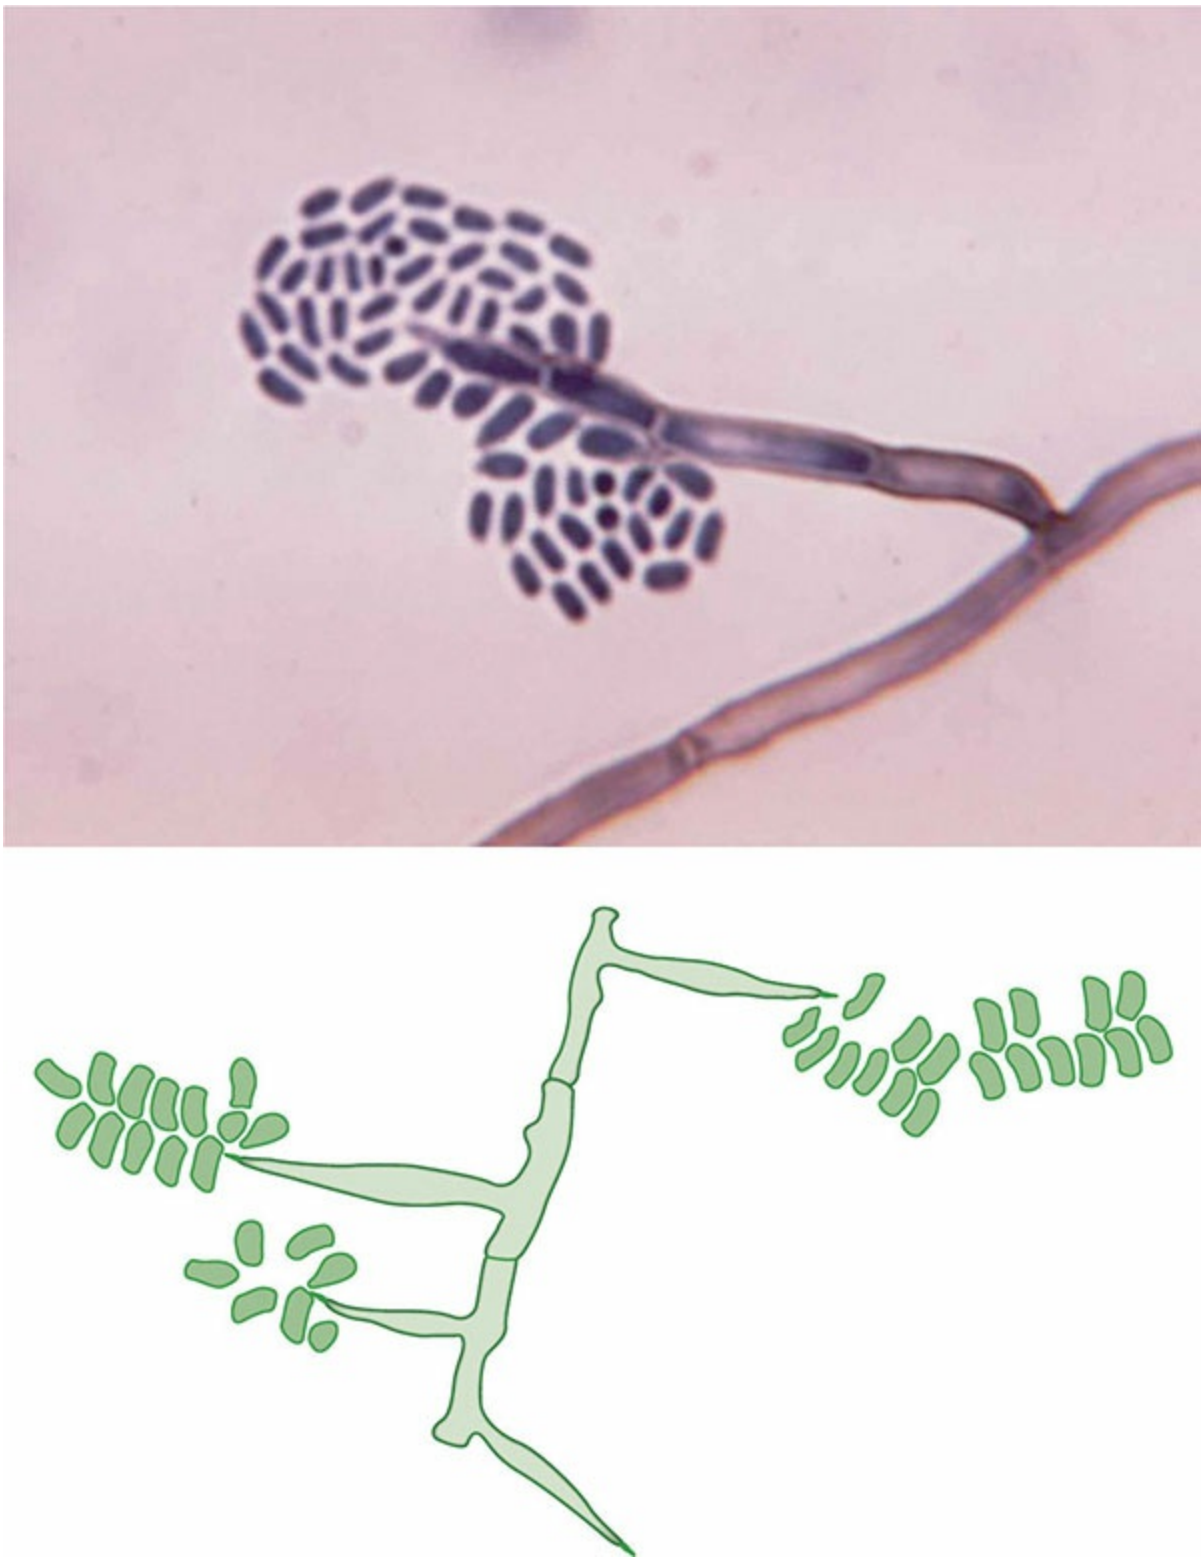
***Cladophialophora bantiana* (formerly *Xylohypha* or *Phialophora bantianum*).** This is a closely related species that also produces conidia of the *Cladosporium*-type; however, the chains of conidia are very long, with as many as 30 cells each and producing nonpigmented conidia without dysjunctors. *Cladophialophora bantiana* grows at 42°C and does not liquefy gelatin, which are two additional characteristics by which it can be differentiated from *Cladophialophora carrionii,* which does not possess these properties.

■ **FIGURE 21-81** Photomicrograph of the long conidiophores of *Pleurostomophora richardsiae*, illustrating the characteristic flat saucerlike terminal ending of the phialide.

Pleurostomophora (Phialophora) richardsiae. In contrast to the narrow bottlelike phialides of *Phialophora verrucosum*, those of *Pleurostomophora richardsiae* are flat and saucer-shaped (Fig. 21-81). *Pleurostomophora richardsiae* is a common agent recovered from phaeohyphomycotic cysts and may cause invasive phaeohyphomycosis. Spherical to elliptical, hyaline conidia are borne in tight clusters at the tips of these phialides, held together by a mucinous material. These conidia may also dislodge and aggregate along the sides of the phialides.

Scedosporium prolificans. *Scedosporium prolificans (inflatum)* is a rarely encountered, but important cause of phaeohyphomycosis in humans, particularly those with immunocompromising conditions. Microscopically, this may be mistaken for members of the *P. boydii* complex. The colony morphology of this organism is more distinctly dematiaceous with a surface that is often an olive-drab green, in distinct contrast to the house-mouse gray of the *P. boydii* complex (Image Plate 21-2G).

***Exophiala* Species.** There are a number of *Exophiala* species. Many of these have phenotypic characteristics of *E. jeanselmei,* so will be included in the *E. jeanselmei* complex. The other *Exophiala* species, which is morphologically identical but may be differentiated by biophysical characteristics, is *E. dermatitidis,* formerly known as *Wangiella dermatitidis.* Both of these species often produce wet-to-mucoid, yeast-like colonies upon initial isolation. Cursory microscopic examination discloses yeast-like cells. However, upon closer examination it is apparent that true budding is absent and instead these are single-celled forms that are reproducing through annelloconidiation (i.e., annellides rather than phialides are produced). The colonies transform from wet and yeast-like to a velvety mold with extended incubation. Long, tapered conidiophores are produced that extend from the hyphae in right or obtuse angles. The tips of the conidiophores appear to be sharply pointed from the production of progressive annellide formation (Fig. 21-82). Rings or annellides may be



■ **FIGURE 21-82** Photomicrograph and sketch of *Exophiala* species, illustrating the long, tapered conidiophores from the tips of which are released elongated annelloconidia that arrange in loose clusters.

observed beneath the tapered tip of the phialide with exacting focusing of the microscope and diminution of the condenser light.[160] The clinical manifestations of phaeohyphomycosis, chromoblastomycosis, and mycetoma are presented in Clinical Correlation Box 21-10.

The Laboratory Identification of Yeasts

The monomorphic yeast species of medical importance that are most commonly encountered in clinical microbiology laboratories include:

- *C. albicans* and other *Candida* species
- *Trichosporon* species
- *Rhodotorula* species
- *Saccharomyces* species
- *Wickerhamomyces (Hansenula/Pichia) anomalus*
- *Malassezia furfur*

Candida Species and Candidiasis

Candida species are the yeasts most commonly isolated from clinical specimens. From data obtained from 180 U.S. hospitals participating in the National Nosocomial Infections Surveillance (NNIS) system, 27,200 fungal isolates associated with nosocomial infections were reported in the United States between January 1980 and April 1990. Of these, *Candida* spp. accounted for 19,621 (72.1%).[137] Factors predisposing to this high frequency of yeast infections include:

CLINICAL CORRELATION BOX 21-10 Phaeohyphomycosis, Chromoblastomycosis, and Eumycotic Mycetoma

Brandt and Warnock[31] from the CDC have published a review covering the epidemiology, clinical manifestations, and therapy for infections caused by these dematiaceous fungi. They list *Alternaria* species, *Bipolaris* species, *Cladophialophora bantiana*, *Curvularia* species, *Exophiala* species, *Fonsecaea pedrosoi*, *Madurella* species, *Phialophora* species, *Scedosporium prolificans*, *Scytalidium dimidiatum*, and *Exophiala dermatitidis* as the more important human pathogens within this group. They describe these fungi as being widespread in the environment, and found in soil, wood, and decomposing plant debris. The cutaneous,

subcutaneous, and corneal infections associated with these dematiaceous fungi occur worldwide, but are more common in tropical and subtropical climates. Infection most commonly results from traumatic implantation into the skin or other tissue. Most progressive cases occur in immunocompetent individuals. They also cite the dematiaceous molds as being important causes of invasive sinusitis and allergic fungal sinusitis, most commonly following inhalation of infective conidia.

Phaeohyphomycosis

An invasive fungal infection caused by a phaeoid or dematiaceous mold is a phaeohyphomycosis. Although cerebral infection is the most important form of systemic phaeohyphomycosis, other localized deep forms of the disease, such as arthritis, and endocarditis, have been reported. Disseminated infection is uncommon, but the incidence is higher among immunocompromised individuals. *Scedosporium prolificans* is an important cause of disseminated infection in the immunocompromised and is difficult to eradicate, as it is multidrug resistant. Literally hundreds of isolated cases of fungal infections caused by the rapidly growing, saprophytic species of dematiaceous molds have been reported in the recent medical literature. Space here allows for only a few examples. The three more common clinical manifestations of phaeohyphomycosis caused by the saprophytic fungi are keratitis, sinusitis, and onychomycosis.

1388

As an example of keratitis, Wilhelmus and Jones[297] reported their laboratory experience with the isolation and identification of *Curvularia* species as a cause of keratitis over a 30-year period. The records for 32 individuals were available for analysis. It was determined that trauma, usually with plants or dirt, was the risk factor in half the cases. The majority of patients (69%) were infected during the hot, humid summer months along the U.S. Gulf Coast. Presenting signs varied from superficial, feathery infiltrates of the central cornea to suppurative ulceration of the peripheral cornea.

Sinusitis is also a common site of infection with dematiaceous fungi. From the older literature, Adam et al.[2] reported nine patients with sinusitis presenting as allergic rhinitis or nasal polyposis, caused by *Bipolaris* and *Exserohilum* species. Fernandez et al.[87] reported on the findings derived from a search of the literature for pediatric *Curvularia* infections, and of the 16 cases identified, 13 had allergic sinusitis, a unique form of sinusitis in which a history of asthma or nasal polyps were predisposing conditions. The patients in this review were usually immunocompetent teenagers who had a prolonged duration of symptoms, usually >3weeks.

Onychomycosis caused by *Alternaria* species is being reported with increasing frequency, particularly in patients with immunodeficiency. Romano et al.[237] reported nine cases of onychomycosis caused by *Alternaria alternata* observed in Tuscany,

Italy. Diagnosis was made on the basis of repeated direct microscopic mycologic examination and culture. In most of the patients, dystrophy and distal subungual hyperkeratosis of one or two nails of the feet or hands were the primary clinical manifestations. Seven cases were treated with oral itraconazole; this treatment was successful in six cases. Importantly, chronic nail infections may serve as the nidus for dissemination non-dermatophytic fungi in immunocompromised patients.

A number of dematiaceous fungi are neurotropic, including *Cladophialophora bantiana*, *Ramichloridium* (*Rhinocladiella*) *mackenziei*, *Ochroconis gallopava*, and *Exophiala dermatitidis*. Although infections have occurred in immunocompromised persons, cerebral phaeohyphomycosis is most common in immunocompetent individuals who may or may not have obvious risk factors.[69] Revankar et al.[230] reviewed 101 cases of culture-proven primary central nervous system phaeohyphomycosis reported in the English-language literature from 1966 to 2002. They found that the most frequently isolated species was *Cladophialophora bantiana*. The mortality rates were high among these reported cases, regardless of immune status. Therapy has not been standardized, although the combination of amphotericin B and the new triazoles, such as posaconazole, along with an aggressive medical and surgical approach may improve survival rates.

Chromoblastomycosis

Chromoblastomycosis is widespread in tropical South America, occurring most commonly in male farm and plantation workers. Silva et al.[256] reviewed 325 cases reported in the Amazon river drainage region of Brazil. The data obtained revealed a mean age range of affected individuals between 41 and 70 years, 93.2% of whom were males. Agricultural workers comprised 86.1% of the total. Lesions on the lower limbs (feet and legs) were found in 80.7%. In 24% of patients (78 cases), the etiologic agent was isolated and identified through culture. *Fonsecaea pedrosoi* was present in 77 patients and *Phialophora verrucosa* in only one case. Similar results were reported by Minotto et al.[189] in a study of 100 patients residing in Rio Grande do Sul, Brazil. Again, male patients predominated (4:1); the majority were white farmers ranging in age from 50 to 59 years. Most commonly, severe verrucous lesions appeared on their lower limbs, with the average time between the appearance of the disease and medical diagnosis being 14 years. Thorn wounds were associated with the disease in 16% of the cases. Statistical analysis showed recrudescence of the disease in 43% of cases despite the treatment used. *Fonsecaea pedrosoi* was recovered from 96% of the cases; *Phialophora verrucosa* in 4%.

As noted, these fungi most commonly gain entry through traumatic inoculation. For example, Wortman[304] reported a patient with chromoblastomycosis caused concurrently by *Fonsecaea pedrosoi* and *Nocardia brasiliensis*, complicating a traumatic penetrating injury.

Mycetoma

Mycetoma refers to a subcutaneous infection in which the tissue is markedly swollen with the formation of deeply penetrating sinus tracts that erode through the superficial skin and discharge purulent material. The feet (Madura foot) and hands are most commonly involved, becoming markedly swollen and deformed in serious infections. Mycetomas have two primary causes—bacteria belonging to the family Actinomycetales (*Actinomyces*, *Nocardia*, and *Streptomyces* species), and the true fungi (eumycotic mycetomas), primarily the dematiaceous fungus *Exophiala jeanselmei* and the hyaline mold *Pseudallescheria boydii* in sporadic cases encountered in the United States.

Mycetoma is more commonly seen in other parts of the world, particularly western and eastern Africa. A history of prior injury is common. The lower extremities tend to be involved in the majority of cases, with the upper extremities and other sites such as the gluteal region, the lumbar area, submandibular area, and face less commonly.

The description many years ago of the presentation of a mycetoma by Thammayya et al.[273] of a patient who also lived in India remains classic for the condition: "The right lower leg and foot were irregularly swollen, firm,

1389

painless, and nontender and had many small nodules and sinuses all over the swelling. The lower end of the tibia and bones of the foot were affected.

The discharge from the sinuses and nodules contained black-brown, soft, vermicular, crescent-shaped to irregular granules, measuring 0.5–2.00 mm and composed mostly of swollen spherical cells, 4–8 μm diameter, and a few hyphae, 2.5–3.0 μm diameter."

A relatively high incidence has also been encountered in Japan. Murayama et al.[191] report a 34-year-old woman with SLE who developed a mycetoma involving the lower leg. In an accompanying literature review of *Exophiala jeanselmei* infections in Japan, these authors found reference to 54 cases (24 in men and 30 in women). Fifty of these infections (21 men and 29 women, an interesting shift in the male:female ratio) were caused by dematiaceous fungi. About half of these patients had underlying diseases, and the sites of the lesions were mainly on the extremities.

- Immunosuppressive conditions associated with chemotherapy, and stem cell and solid organ transplantations
- Prolonged hospitalization
- Vascular catheterizations
- Prolonged administration of broad-spectrum antibacterial agents

Wright and Wenzel,[305] in a review of patients with nosocomial candidiasis, cite burns,

artificial respiratory assistance, colonization with *Candida* species, and repeated transfusions as additional risk factors. These authors cite a 1996 nationwide study of participating hospitals, conducted under the Surveillance and Control of Pathogens of Epidemiologic Importance (SCOPE) program that *Candida* species has been established behind *Staphylococcus* species as the most frequent cause of septicemia in hospitalized patients.

Patients with cancer, particularly those with leukemia lymphoproliferative disorders, in whom the peripheral white blood count is depressed, are also at increased risk. Kalin and Petrini[141] cite an increase in mortality in patients with leukemia caused by fungal infections from a low frequency of 5% prior to the antibiotic era, to a current frequency of 40%. *Candida* species were recovered most frequently as the primary agents. Advanced age, although not directly related to yeast infections, nonetheless contributes to increased morbidity and mortality. For example, mucocutaneous candidiasis in the aged, including thrush and denture stomatitis, was commonly associated with local mechanical irritation of the oral mucosa.[124]

At the opposite end of the age spectrum, critically ill newborn babies also are at high risk for acquiring nosocomial yeast infections, with particular involvement of the central nervous system. Other conditions predisposing to yeast infections include altered host defenses due to compromised protein stores or antibody production, suppression of the normal bacterial flora, pregnancy, and diabetes mellitus or other chronic metabolic diseases.

Candida species are identified by a variety of methods that include germ tube testing, the use of chromogenic media, biochemical/assimilation testing, cornmeal agar morphology and increasingly by molecular methods and mass spectrometry.

In vitro antifungal susceptibility testing has been standardized through the efforts of the CLSI. This has made it possible to determine the degree of resistance of yeast isolates.[220,231] Applications of the E test have also made available to clinical laboratories the ability to determine select antifungal susceptibility profiles.[221,222] Key clinical manifestations of candidiasis are presented in Clinical Correlation Box 21-11 (*C. albicans*) and Clinical Correlation Box 21-12 (*Candida* spp., non- *albicans*).

CLINICAL CORRELATION BOX 21-11 Candidiasis (*Candida albicans*)

Human candidiasis is most commonly caused by *Candida albicans*. The rapid germination in tissues after seeding from the bloodstream; the production of proteases, adhesins to extracellular matrix proteins, and complement-binding

receptors; and phenotypic switching are the most important virulence factors contributing to its increased infectivity.[57,202] The history, taxonomy, epidemiology, and virulence factors for *Candida albicans* have been reviewed by McCullough[182] and by Pfaller.[219] The clinical manifestations of *Candida albicans* are primarily of three types: mucocutaneous, cutaneous, and systemic.

Mucocutaneous Candidiasis

Candidiasis of the mucous membranes most commonly involves the oral cavity and the vaginal canal. Oral candidiasis, a condition known as thrush (a term derived from the Scandinavian word trosk), is one of the most common clinical manifestation of candidiasis in humans. The infection is manifested as white patches or plaques on the buccal mucosa and tongue,[20] which, in more serious infections, may coalesce into a membrane. These adhere firmly to the epithelium, revealing a reddened, edematous base when removed. The diagnosis can be made by observing microscopically the characteristic pseudohyphae and blastoconidia in Gram-stained preparations of

smears prepared from some of the exudate (Fig. 21-89). Alteration of the normal flora after prolonged antibiotic therapy, low pH of the salivary secretions in newborns, hypertrophy of the papillae of the tongue ("black hairy tongue"), and chronic glossitis are predisposing causes.[25] Oral candidiasis is now recognized as an AIDS-defining condition, seen in virtually 100% of patients with AIDS.[270]

Although classically caused by *Candida albicans*, the closely related species, *Candida dubliniensis*, may also cause thrush.[180,203,267] The mucous membranes of the trachea and bronchi, and virtually any part of the alimentary canal may harbor *Candida* infections, most commonly representing extensions of oropharyngeal disease. Cases of esophagitis, gastritis, enteritis, and perianal disease have been reported. The gastroesophageal junction in particular is a common site for *Candida* infections. A low-pH environment may explain this predisposition, particularly in patients with hematologic malignancy. Dysphagia, retrosternal pain, upper gastrointestinal bleeding, and nausea are associated symptoms. Esophageal candidiasis may also occur as an extension of oropharyngeal thrush, particularly in newborns.

Cutaneous Candidiasis

Infections of the skin commonly involve the moist, intertriginous areas, such as in the webs of the fingers and toes, beneath the female breasts, in the armpits, and in the folds of the groin. Infection of the nails proper is known as onychomycosis, or paronychia if the folds of skin encasing the nails are involved. Diaper rash infection of neonates is also a common manifestation. Chronic mucocutaneous candidiasis is an opportunistic infection of skin and mucous membranes associated with several genetic defects involving compromised leukocyte function, or of the endocrine

system. Thymic dysplasia with and without hypogammaglobulinemia, hypoparathyroidism, and chronic granulomatous disease, the latter involving a myeloperoxidase defect of phagocytes precluding post-phagocytic killing of yeast forms, are among the predisposing conditions.[235]

Disseminated Candidiasis

Systemic candidiasis is a relatively rare condition, occurring primarily as a terminal event in patients with debilitating, neoplastic (e.g., blast crisis of leukemia), immunosuppressive diseases and following organ transplantation, particularly during an acute rejection syndrome. The conditions underlying hematogenous candidiasis is reviewed by Abi-Said.[1]

Candidiasis of the Urinary Tract

This presentation is relatively rare, manifesting as cystitis (more commonly caused by *Candida glabrata*) and pyelonephritis, either ascending from a bladder infection or from hematogenous spread from a distant primary site of infection.

Aggregates of pseudohyphae and blastoconidia may be seen histologically in glomeruli, presumably in a microenvironment conducive to growth because of the lowered pH from Na^+ and H^+ ion exchanges. Currently, *Candida glabrata* ranks second or third as the causative agent of superficial (oral, esophageal, vaginal, or urinary) or systemic *Candida* infections, as reported by Fidel et al.[88] The emergence of *C. glabrata* as a nosocomial pathogen may be related to partial or complete resistance to fluconazole, which has been effectively used in the treatment of other yeast infections. Zmierczak et al.[310] report a patient with chronic, recurrent *C. glabrata* arthritis initially involving the right ankle. One year after successful treatment, the infection recurred in the left knee; this was thought to represent hematogenous dissemination.

Fungemia and Endocarditis

Candida albicans is the most common cause of fungemia, accounting for usually somewhere between 50% and 60% of isolates. The remainders are predominant non-*albicans Candida* species, with the most frequent among these being *C. glabrata.* Most instances of fungemia are associated with an intravascular access device. *Candida* endocarditis is most often seen in people with preexisting valvular disease, particularly following episodes of septicemia associated with the use of indwelling catheters, prolonged intravenous infusions, and IV drug abuse. Hogevik and Alestig[128] present a review of seven patients with endocarditis occurring in western Sweden. In four patients, the infections were associated with prosthetic-valve placements; in three patients the native valves were involved. Because of high mortality, the authors stress the need for early diagnosis, immediate antifungal therapy, and emergency surgery if sonography reveals a lack of response.

Most strains of *C. albicans* can be recovered from blood cultures in most

commercially available blood culture bottles, Marcelis et al.[178] report that culture media containing resin (specifically, BACTEC PLUS high-blood-volume resin was used in their study) may enhance recovery, particularly in patients receiving antifungal agents.

Candida Meningitis

This rare condition is secondary to dissemination from sites of infection in the gastrointestinal or respiratory tracts, from septic emboli released from infected heart valves, from trauma, or as a complication of neurosurgery. In a retrospective review of 21 patients with *Candida* species isolated from cerebrospinal fluid following neurosurgery, Geers and Gordon[97] found that 86% of these patients had indwelling cerebrospinal devices (shunts). Gelfand et al.[98]reported instances of superinfection following acute bacterial meningitis in adults who

incurred trauma to the central nervous system or surgical intervention. They counsel that any patient with bacterial meningitis who does not improve with antimicrobial chemotherapy should be examined for *Candida* superinfection, particularly patients with indwelling catheters.

CLINICAL CORRELATION BOX 21-12 Infections with *Candida* Species, Non- *albicans*

Species of *Candida* other than *C. albicans* are also normal microbiota of cutaneous and mucocutaneous surfaces. Wingard[301] found in a review of 1,591 *Candida* infections published in 37 reports showed that non- *Candida albicans* species were the causative agents in 46% of systemic infections. *Candida tropicalis* accounted for 25% of the infections, *C. glabrata* for 8%, *C. parapsilosis* for 7%, and *C. krusei* for 4%. From these reports, patients with leukemia were more likely to be infected with *C. albicans* or *C. tropicalis*, whereas bone marrow transplant recipients were more likely to be infected with *C. krusei* or *C. lusitaniae*.

In a similar study, Wright and Wenzel[305] found that *Candida albicans* was recovered from 58% of nosocomial infections, *C. tropicalis* in 25%, *C. parapsilosis* in 15%, *C. glabrata* in 6%, and *C. lusitaniae* in 2%. *C. tropicalis* and *C. krusei* were more frequently recovered from patients with neutropenia who had lymphoma or leukemia, *C. parapsilosis* from neonates receiving hyperalimentation fluids, and *C.*

glabrata in postsurgical patients who had solid tumors removed. The non- *albicans Candida* species are commonly encountered, so it is important that laboratories maintain competency in the ability to accurately identify these isolates.[52]

In an extensive review of new and emerging yeast pathogens, Hazen evaluated what at the time were considered 30 emerging yeast pathogens with 168 references.[123] Although among the non- *C. albicans* species, *C. parapsilosis*, *C. glabrata* (particularly isolates in blood cultures), *C. krusei*, *C. guilliermondii*, *C. lipolytica*, and *C. kefyr* (formerly *C. pseudotropicalis*) were on the increase, Hazen also mentions the emergence and significant increase in incidence of *Malassezia*, *Rhodotorula*, *Wickerhamomyces (Hansenula/Pichia) anomalus,* and *Trichosporon* species as non- *Candida* species isolates from clinical materials, with several citations to specific case reports of infections caused by these agents.

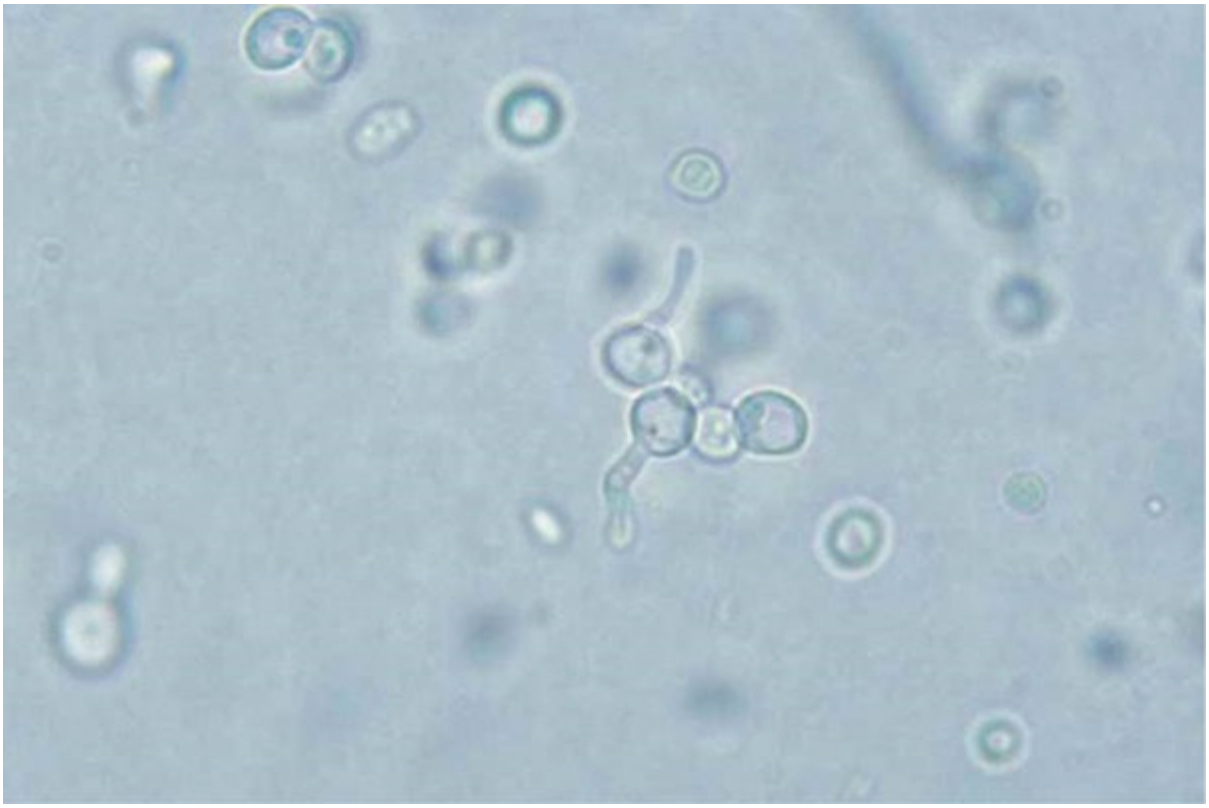
Several causes have been proposed for the sudden emergence of species of yeasts as agents of invasive infections. Included are the use of broad-spectrum antibiotics and antineoplastic agents, the widespread administration of vancomycin, intravenous catheterization, and the increased number of patients with neutropenia and immunosuppression. The widespread use of fluconazole may account for the relative decrease in recovery of *C. albicans* from blood cultures relative to other *Candida* species.

Cross-contamination by hospital personnel may also account for increases in yeast infections in certain environments. For example, a survey of hospital personnel by Strausbaugh et al.[265] revealed that 70% of nurses and non-nursing hospital personnel carried yeasts on their hands, with *Rhodotorula* spp. and *C. parapsilosis* being the most frequently recovered. In this regard, newborn infants, who are intimately handled by nursing personnel, represent another population that is susceptible to candidiasis.[145] See Weems for a full review of the clinical pathology of *C. parapsilosis*.[285]

Display 21-7 provides a guide to the laboratory identification of these yeasts. Most clinically significant yeast isolates grow within 36 to 72 hours in culture on sheep blood agar, potato dextrose, and most other nonselective primary isolation media. The colonies are typically white or yellow-white with a smooth or pasty consistency (Image Plate 21-6A). When an isolate presents with colonies consistent with one of the monomorphic yeasts, traditionally the first step is to determine whether the isolate has the ability to produce a germ tube. If a germ tube is produced in the germ tube test, then a presumptive identification of *C. albicans* can be reported, and further workup is usually not necessary. It is acknowledged that *C. dubliniensis* can also produce a germ tube. If one desires to distinguish between *C. albicans* and *C. dubliniensis*, then additional testing is necessary, but in most instances germ tube producing isolates are simply reported as *C. albicans.*

Germ Tube. A germ tube is defined as a filamentous extension from a yeast cell that is about half the width and three to four times the length of the parent cell (Fig. 21-83). The true germ tube produced by *C. albicans* has no constriction at the neck (i.e., the base wherein the hyphal extension connects with the parent cell). The germ tube is the initial phase of true hyphal production and does not have the constriction at the base characteristic of pseudohyphae. *C. tropicalis* is known to produce a pseudogerm tube, which can be mistaken for a germ tube, if attention is not given to base of the hyphal extension. A description of the germ tube procedure is included in Box 21-6. As mentioned before, a presumptive identification of *C. albicans* can be made if germ tubes are produced. Not all strains of *C. albicans* produce germ tubes; therefore, if a germ tube is not produced, then the culture should be submitted for biochemical testing and inoculated to a cornmeal agar plate. At the end of the incubation period, the cornmeal preparation is observed microscopically for the presence of chlamydospores and regularly spaced blastoconidia, which, if present, also allow for the presumptive identification of *C. albicans* (Fig. 21-84).

1392

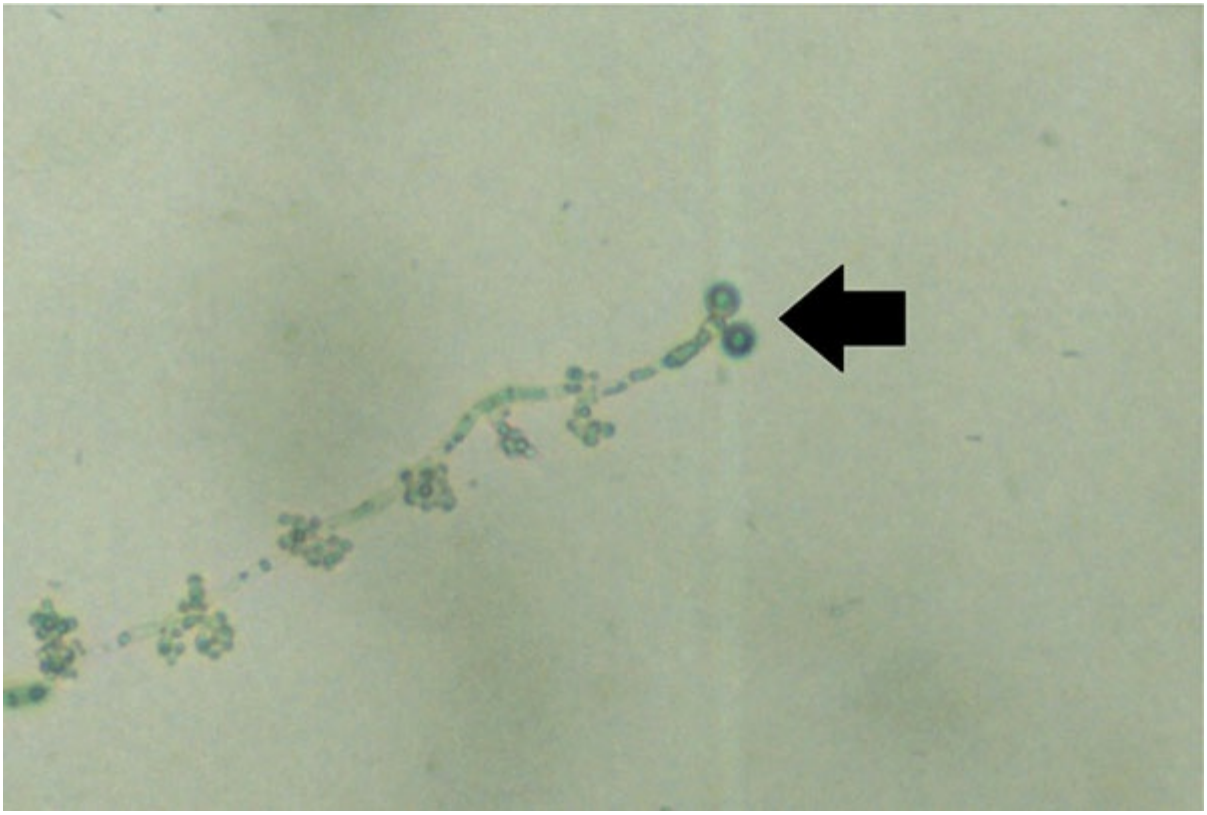


■ **FIGURE 21-83** Photomicrograph of a germ tube, characteristic of *Candida albicans* (oil immersion).

BOX 21-6

Procedure: Germ Tube Test

1. A small portion of an isolate colony of the yeast to be tested is suspended in a test tube containing 0.5 mL of rabbit or human plasma or serum.
2. The test tube is inoculated at 35°C for no longer than 2 hours.
3. A drop of the yeast-serum suspension is placed on a microscope slide, overlaid with a coverslip, and examined microscopically for the presence of germ tubes (Fig. 21-83).
4. The test is not valid if examined after 2 hours.



■ **FIGURE 21-84** This cornmeal preparation of *C. albicans* demonstrates chlamydospores *(arrow)* and regular clustering of blastoconidia.

Cornmeal Agar Preparations. The preparation of the cornmeal agar mount is described in Box 21-7.

Again follow Display 21-7. If pseudohyphae and blastoconidia are present, a

presumptive identification of *Candida* species can be made. The different patterns of growth in the cornmeal agar preparations are often sufficiently distinctive to establish presumptive species identification.

BOX 21-7

Procedure for Inoculation of Cornmeal-Tween 80 Agar

1. Make three parallel streaks 1/4 in., or 1 cm, apart into the surface of cornmeal agar, holding the inoculating wire at about a 45-degree angle.
2. Lay a coverslip on the surface of the agar, covering a portion of the inoculated streaks.
3. Incubate the inoculated plates at 30°C for 24–48 hours in a closed, moisturized chamber. At the end of the incubation period, examine microscopically through the coverslip and observe the pattern of growth.

Growth Patterns of Yeasts on Cornmeal Agar. When observing the growth in a cornmeal agar preparation, determine at the onset whether pseudohyphae are present. The observation of pseudohyphae and blastoconidia put an unknown isolate into the genus *Candida*. Most human infections are caused by *C. albicans*. However, with the increase in immunosuppression related to organ transplantation and other related conditions, and the emergence of opportunistic fungal pathogens, the recovery of non-*albicans Candida* species in pure or predominant culture from blood or other sterile body sites cannot be ignored. A careful clinical correlation is necessary to determine whether further workup is necessary. The patterns of growth on cornmeal agar are helpful in making a presumptive identification and in serving as a quality-control check on species identifications provided by the biocodes indicated by automated and kit systems. Because none of the cornmeal agar patterns are diagnostic (with the exception of the chlamydospore production by *C. albicans*), carbohydrate assimilation studies or the results derived from one of the commercial yeast identification systems are necessary before a definitive identification can be reported.

If a presumptive identification cannot be made from the observation of the cornmeal agar preparation, tests for nitrate reduction, urease activity, inositol assimilation, nitrate reduction, and the production of caffeic acid (using a niger seed agar plate or performing a filter paper strip test), in addition to carbohydrate assimilation studies, are helpful in separating these various species. Although these studies can be accomplished by conventional techniques, packaged yeast identification kits or automated systems are currently used in most laboratories. In those rare

instances in which referral to carbohydrate assimilation profiles are required, the reader is referred to Tables 19-8, 19-9, and 19-10 on pages 1045, 1050, and 1054 in the 5th edition of this textbook.

Chromagar. CHROMagar, a chromogenic differential culture medium, is being used in many laboratories to facilitate the isolation and presumptive identification of certain clinically important yeast species, particularly

1393

C. albicans. Observation of colony morphology and distinctive patterns of color are used to separate yeast species, particularly when observed in mixed cultures. *C. albicans* forms distinctive yellow-green to blue-green colonies.

Ainscough and Kibbler[3] evaluated the cost-effectiveness and time advantage of CHROMagar in comparison with SDA. An overall sensitivity of 95.2% was observed in the study of 21 yeast isolates recovered from 298 clinical samples from patients with neutropenia and those with AIDS. CHROMagar was found in this study to be 100% sensitive and 100% specific for *C. albicans*. It provided the most economical and least time-consuming approach to the initial culture and presumptive identification of yeast isolates. The authors also recommend the direct inoculation for blood cultures when yeast cells are seen on microscopy.

Candida albicans. Two patterns of growth on cornmeal agar are helpful in identifying *C. albicans*: (1) the production of chlamydospores and/or (2) blastoconidia that arrange in dense clusters evenly distributed along the pseudohyphae (Fig. 21-84). A review for these cornmeal agar patterns is particularly helpful in making an identification for strains that are germ tube–negative.

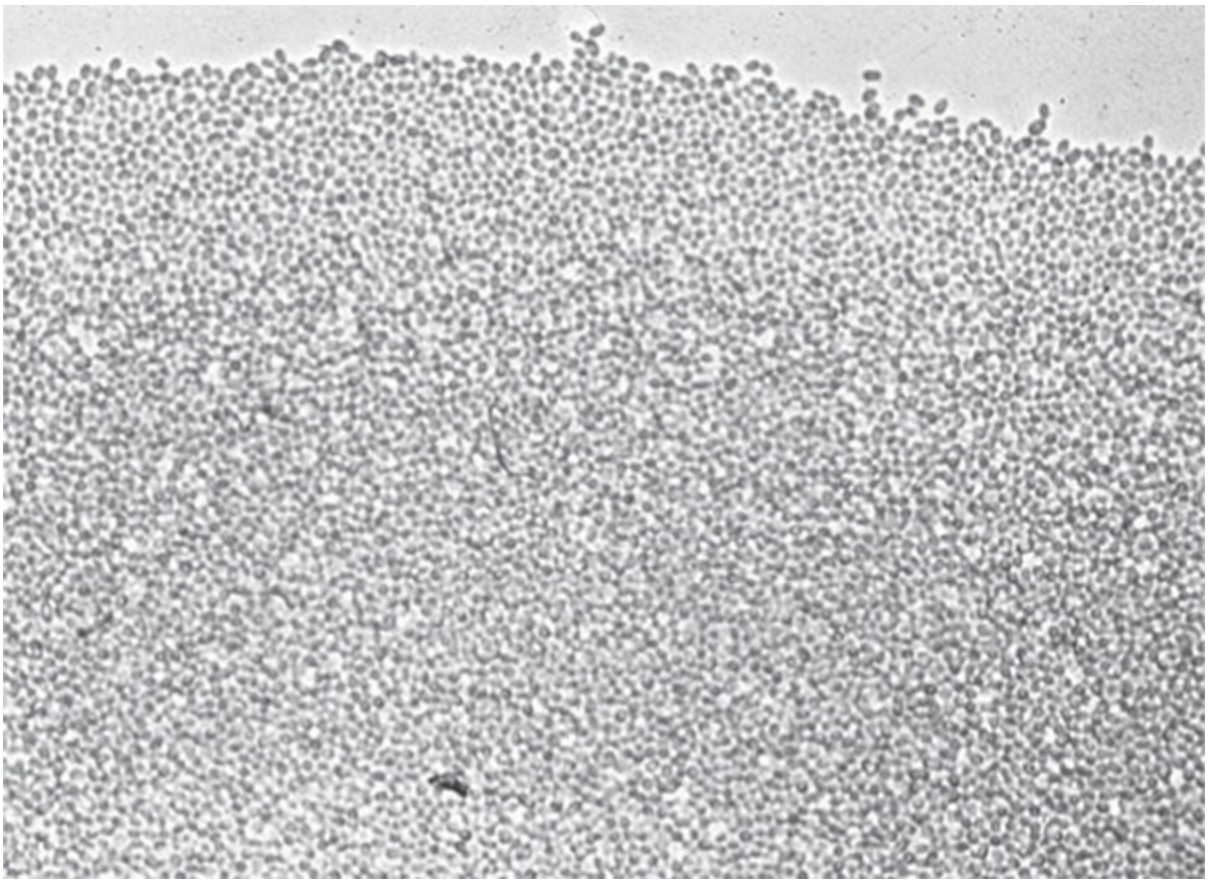
The colony growth of *C. albicans* may also lead to a presumptive identification. The edges of the colonies often present radiating starburst spicules in older cultures (Image Plate 21-6B).

If the germ tube test is negative and chlamydospores are not observed in the cornmeal agar mount, a yeast cell other than *C. albicans* has probably been isolated. Although approximately 5% of *C. albicans* may not produce germ tubes, it would be quite rare to have a strain that also fails to produce chlamydospores. In keeping with Display 21-7, the next step is to observe the patterns of growth on cornmeal agar to presumptively identify other *Candida* spp. To reiterate, it is important to review the patterns of growth on cornmeal agar as a quality-control check on the species identifications provided by automated and kit systems, as they are not always correct. To this end, the classic patterns for these more commonly encountered non- *albicans* *Candida* species are discussed below.

Candida glabrata. *Candida glabrata* is the currently accepted name for this organism. It is an agent of urinary tract infections, comprising about 20% of all yeast isolates from urine specimens.[94] Cases of endocarditis[36] and disseminated infection[125] caused by *C. glabrata* have been reported. *C. glabrata* assimilates both glucose and trehalose, an assimilation pattern that is helpful in making the laboratory identification.

Colonies of *C. glabrata* grow more slowly than other yeasts, often requiring 48 to 72 hours to evolve. Thus, if a slower-growing yeast is recovered on blood agar from a clinical specimen (particularly from the urine), that grows as small, entire, convex, glossy, smooth colonies (Image Plate 21-6 *E*) and that microscopically appears as 2 to 3 mm in diameter, single-budding, regular-sized yeast cells, without the formation of pseudohyphae, *Candida (Torulopsis) glabrata* should be considered. On cornmeal agar preparations, the cells of *C. glabrata* arrange in relatively tight clusters, without the separation or size variation, as seen with *Cryptococcus* spp. (Fig. 21-85).

Candida tropicalis. *Candida tropicalis* produces pseudohyphae with blastoconidia either borne singly or in small irregular clusters along the pseudohyphae at points of constriction (Fig. 21-86). Because this pattern is not specific, carbohydrate assimilation studies or identification through the use of one of the yeast identification systems is necessary.

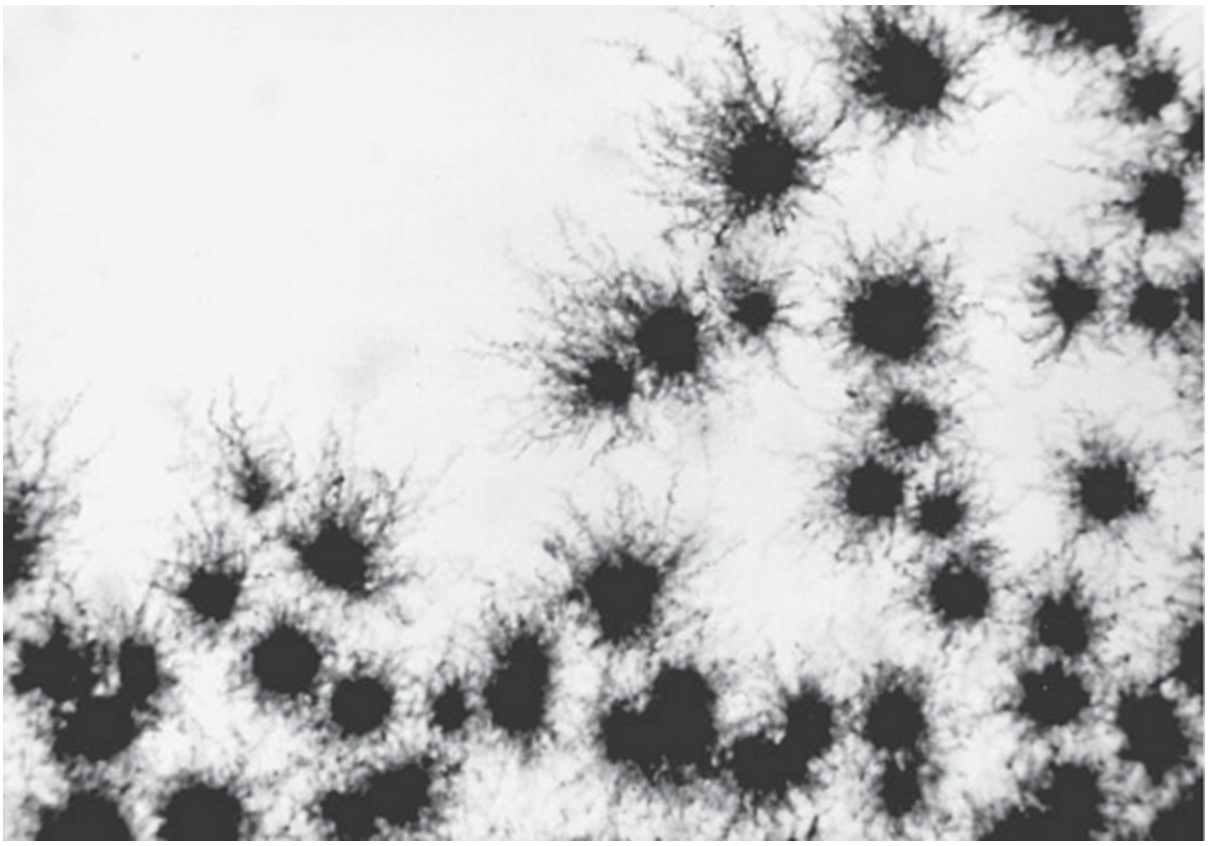


■ **FIGURE 21-85** Photomicrograph of a cornmeal agar preparation of *Candida glabrata,* illustrating tight clusters of tiny, uniform yeast cells not separated by capsular material.

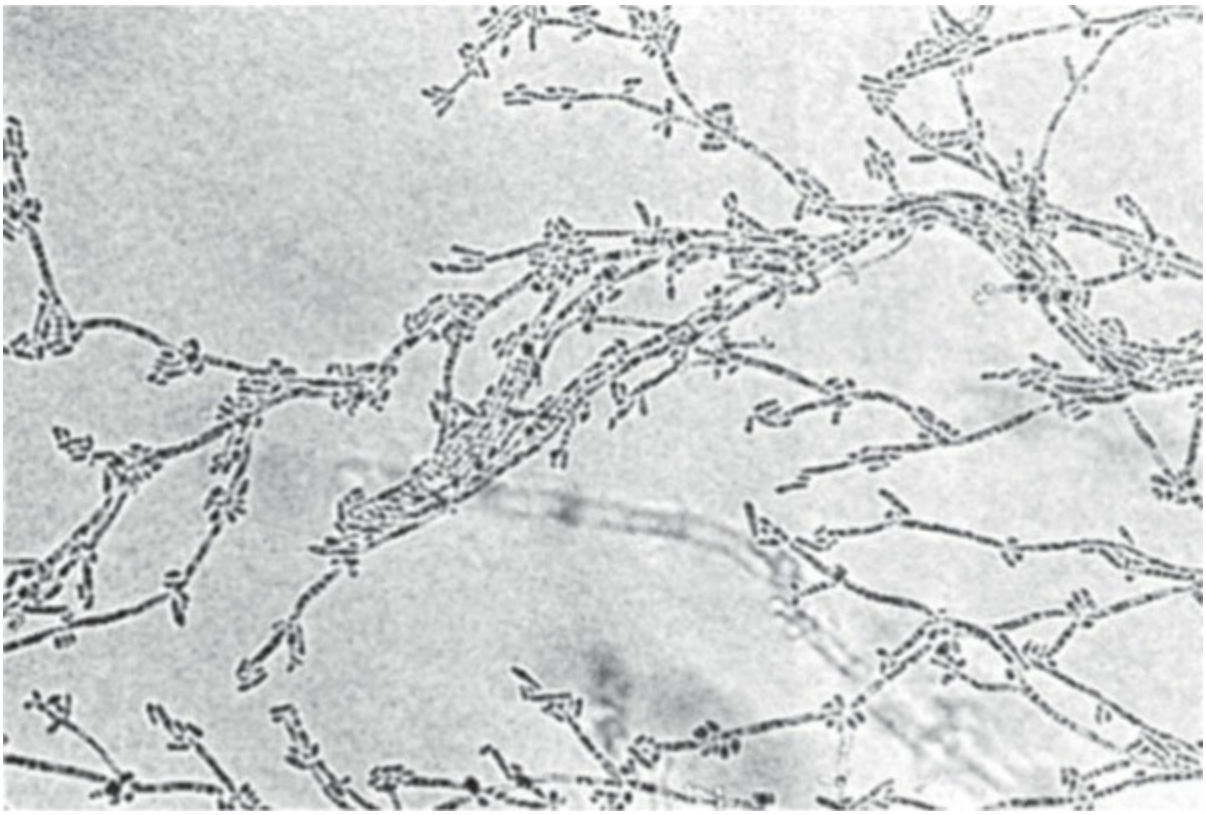
■ **FIGURE 21-86** Photomicrograph of a cornmeal agar preparation of *Candida tropicalis,* illustrating light production of conidia irregularly along the hyphae.

Candida parapsilosis. Key to the presumptive identification of *C. parapsilosis* in cornmeal agar preparations is the observation of multiple focal areas of satellite growth adjacent to the streak lines, forming what has been colloquially referred to as a "sagebrush" pattern (Fig. 21-87). Once observed, this pattern will consistently match the identification codes obtained from commercial systems.

Candida kefyr. Key here is the observation of the abundant production of elongated to rectangular blastoconidia that form distinct loose, criss-cross clusters, likened to the arrangement of "logs in a stream" (Fig. 21-88). *C. krusei* also produces a similar pattern, except that the points of derivation are sequentially clustered more as branches from a tree. Carbohydrate assimilation studies may be required to differentiate these two species.



■ **FIGURE 21-87** Photomicrograph of a cornmeal agar preparation of *Candida parapsilosis,* illustrating the characteristic formation of satelliting "spider or sagebrush colonies" along the streak line.



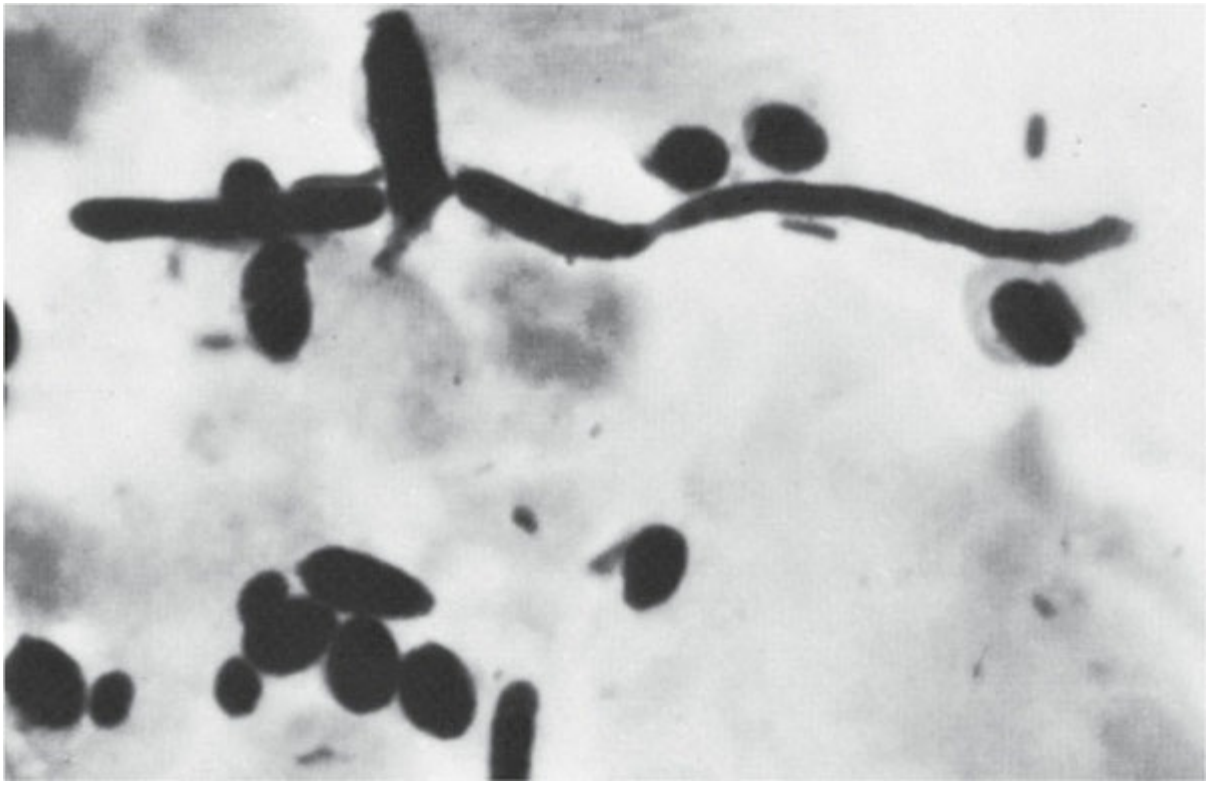
■ **FIGURE 21-88** Photomicrograph of a cornmeal agar preparation illustrating the "log-in-stream" arrangement of elongated blastoconidia characteristic of *Candida kefyr*.

Other Emerging Pathogenic *Candida* Species. The definitive identification of non- *albicans Candida* species is important to detect emerging pathogenic strains, particularly those that have acquired resistance to antifungal drugs.[202] *Candida krusei* has known resistance to fluconazole.[301] *Candida dubliniensis*, phenotypically closely related to *C. albicans*, particularly those strains recovered from patients with oropharyngeal thrush, may have acquired induced resistance to fluconazole.[180] It is unclear if these mechanisms of resistance are acquired because selective pressures or innate, because when large numbers of *C. dubliniensis* isolates have been tested, the resistance profile is similar to that of *C. albicans*. The following characteristics aid in distinguishing *C. dubliniensis* from *C. albicans*.

- The inability to grow at 45°C
- The more abundant production of chlamydospores (see Fig. 21-89).
- Growth characteristics on specialized media.
- Carbohydrate assimilation profile
- DNA sequence or MALDI-TOF pattern
- Germ tube positive, but negative result using the *Candida albicans* PNA FISH

tests.

Sporadic amphotericin B resistance has evolved in certain lineages of *Candida lusitaniae* through a mechanism of switching from previously susceptible colonies.[306] Again, it is unclear if this resistance is acquired or inducible, since most *C. lusitaniae* isolates test susceptible to amphotericin B.



■ **FIGURE 21-89** Photomicrograph of Gram-stained sputum, showing pseudohyphae and budding blastoconidia characteristic of *Candida* species (Gram's stain, 1,000×).

Species That Fail to Produce True Hyphae

Isolates that fail to form hyphae on cornmeal agar include *Cryptococcus* spp., *Candida glabrata, Rhodotorula* spp., and *Saccharomyces* spp. The yeast cells of *Cryptococcus* spp. are spherical, vary in size, and are widely separated by capsular material. The yeast cells of *Candida glabrata* are smaller, regular in size, and tend to arrange in compact clusters. The genus characteristics will be discussed in more detail below, along with the differentiating features of other less commonly encountered genera, such as *Rhodotorula*, *Saccharomyces*, *"Wickerhamomyces* (*Hansenula/Pichia*) *anomalus*, and *Malassezia*. Occasional strains of *Candida* spp. may produce only rudimentary pseudohyphae or none at all; therefore, cornmeal agar

preparations should be set up for any colony that is suspicious for *Candida* spp.

***Cryptococcus neoformans* and Cryptococcosis.** The recovery of *Cryptococcus neoformans* from clinical specimens must always be considered significant until proven otherwise. Until the onset of the AIDS epidemic early in the 1980s, the incidence of cryptococcosis in the United States was low (about 300 cases per year). Most of these early cases occurred in patients with cellular immunodeficiencies, particularly in individuals with Hodgkin's disease.[156] Currently, *C. neoformans* is one of a select group of microorganisms causing infection in patients with AIDS, occurring in 6% to 13% of cases, depending on the place of residence.[190] The incidence of cryptococcosis in patients with AIDS is as high as 15% or greater in some locales in Sub-Saharan Africa.[188]

Of the cryptococci, *Cryptococcus neoformans* is responsible for most human infections. This species is an encapsulated yeast with its natural habitat in the soil. Soil contaminated with pigeon, chicken, or turkey droppings, in which the pH is alkaline and the nitrogen concentration is increased, in particular promotes organism replication. Yeast

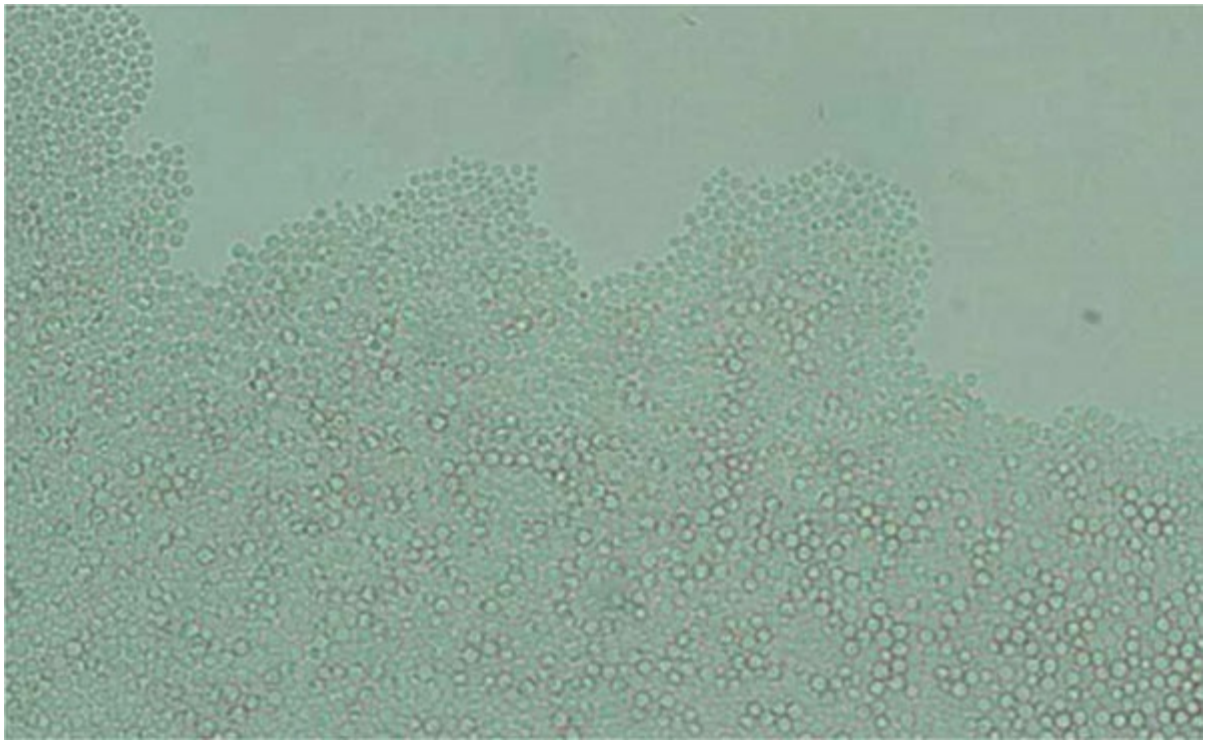
cells may become airborne in clouds of dust created during sweeping, cleaning, and excavating projects. Therefore, poultry farm workers, groundskeepers of city parks frequented by starlings and other birds, and spelunkers, who may explore bat-infested caves, are particularly at risk for acquiring infection. Persons who are immunosuppressed, particularly those with AIDS, are advised not to participate in these activities. In cases in which an immediate exposure is not evident, the onset of acute cryptococcosis may represent unmasking of latent infections.

Capsule synthesis is a major virulence determinant, providing a mechanism for adherence to mucosal linings and protection from phagocytosis, both during transit through the bloodstream and at the sites of infection.[119] *Cryptococcus neoformans* has a particular tropism for the central nervous system, and many cases initially manifest clinically as meningitis. The production of melanin pigment also is a virulence determinant, protecting the yeast against oxidant-induced damage. The production of proteinases, mannoproteins, and release of polyol metabolites account for the invasion and cell destruction observed at the sites of infection.

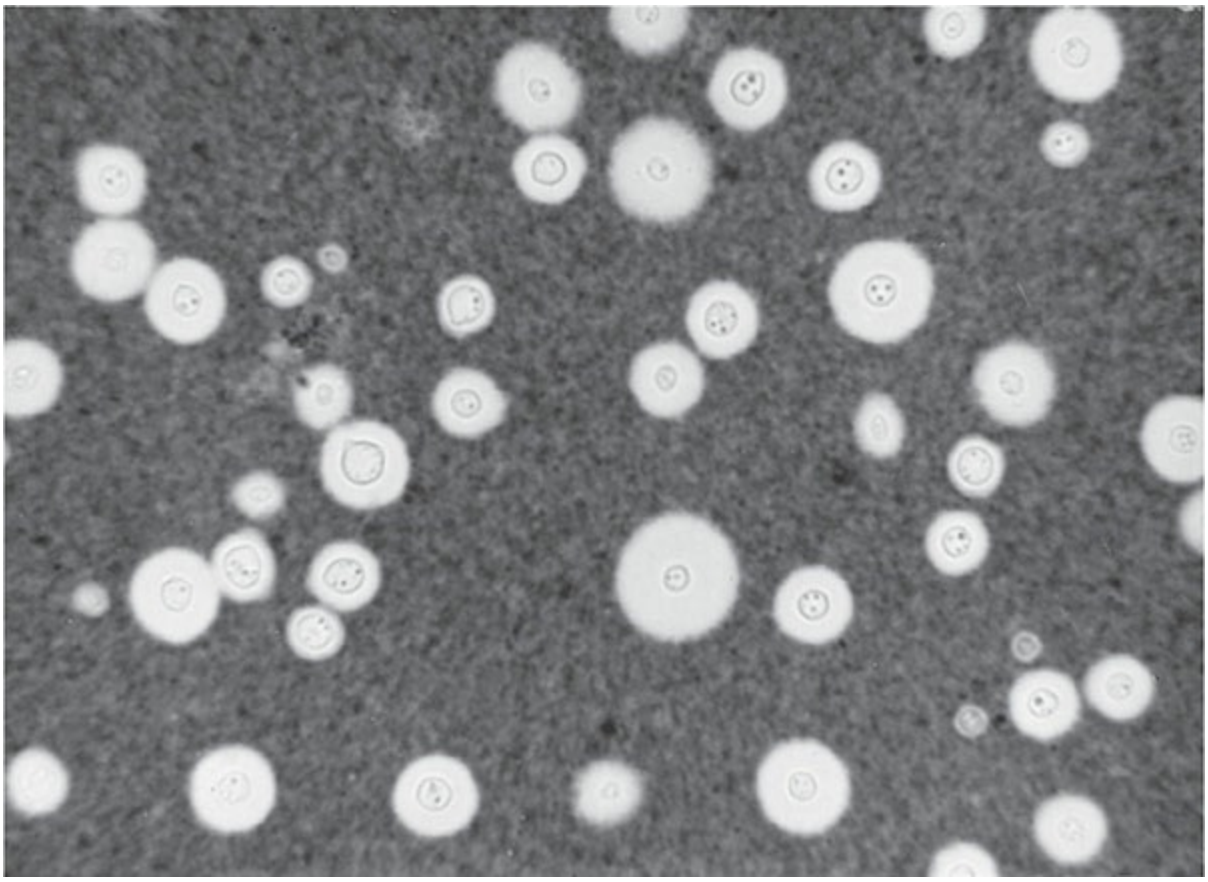
Cryptococcus neoformans can be suspected if a yeast produces colonies that are distinctly mucoid. It should be mentioned, however, that not all strains may produce obvious capsules. Strains with obvious capsules often elicit a more pronounced granulomatous reaction, as observed in tissue sections, in contrast to the liquefaction necrosis that is more commonly associated with invasion by poorly encapsulated

strains. Growth is usually observed within 36 to 72 hours on 5% sheep blood agar and most other primary isolation media (Image Plate 21-6).

Microscopically, the identification of *Cryptococcus* species can be made by demonstrating irregularly sized (4 to 10 µm), spherical yeast cells surrounded by a thick polysaccharide capsule (cells may be as much as 20 µm or more in diameter if the capsule is included in the measurement). In cornmeal agar preparations, pseudohyphae are not produced; irregular-sized, spherical yeast cells are separated one from the other by spaces produced by the capsular material (Fig. 21-90). Encapsulated yeast cells, often with a single bud attached by a hairlike strand, may also be seen in India ink preparations (Fig. 21-91). Because of its insensitivity, the India ink procedure is being performed less commonly on cerebrospinal fluid specimens submitted to clinical laboratories, giving way to the more sensitive cryptococcal antigen-detection tests.



■ **FIGURE 21-90** Photomicrograph of a cornmeal agar preparation of *Cryptococcus neoformans,* illustrating the irregular-sized, spherical yeast cells separated by polysaccharide material. Some mycologists feel that these resemble "glass beads."



■ **FIGURE 21-91** Photomicrograph of an India ink preparation, illustrating the irregular-sized, encapsulated, spherical yeast cells of *Cryptococcus neoformans*.

An isolate suspicious for *C. neoformans* can be confirmed by demonstrating the production of caffeic acid, either through the production of a maroon-red pigment on "bird seed" agar (Image Plate 21-6 *D*) or directly by inoculating a reagent-impregnated filter paper strip with a portion of the unknown colony and observing for the development of a black pigment.

Although other *Cryptococcus* spp. may be recovered from humans, their role as causative agents for infection is uncommon. The clinical presentations of such cases range from skin lesions to fungemia. Most cases of non- *neoformans* fungemia are nosocomially acquired, usually in patients with neutropenia, associated with indwelling intravascular catheters.[138] These authors also report two cases of fungemia caused by *Cryptococcus laurentii*, and warn that most non- *neoformans* cryptococci are more resistant to fluconazole and flucytosine than most *C. neoformans* isolates, thereby requiring a species identification in clinically relevant cases.

Diagnosis by Nonculture Methods. Antigen-detection assays on cerebrospinal fluid specimens are most commonly used to establish the diagnosis of cryptococcal meningitis, largely replacing the time-honored but less sensitive India ink technique.

The capsular material serves as the reactant, resulting in the agglutination reaction for the reagents used in these assays.[91] The latex agglutination assays currently available from several manufacturers are reliable, easy to perform, and sufficiently sensitive and specific to be implemented widely in most clinical mycology laboratories. Special equipment is not required, and the test procedure is easy to master. False-positive reactions can occur secondary to the use of inappropriate specimen transport containers and contaminating disinfectants or soaps.[23] Syneresis fluid from agar plates may contaminate inoculating needles during colony sampling, leading to false-positive results, so the use of these assays for the identification of isolates is not recommended. Additional clinical information on cryptococcosis is presented in Clinical Correlation Box 21-13.

***Rhodotorula* Species.** *Rhodotorula* spp. are environmental fungi that may become part of the human microbiota and have been recovered from the urine and feces. Recovery from respiratory secretions is usually of little significance.

CLINICAL CORRELATION BOX 21-13 Cryptococcosis

Cryptococcosis occurs in both immunocompetent and immunocompromised patients. Most immunocompetent patients may never know they have been infected, unless the nodular cryptococcoma is discovered on chest X-ray. Immunocompromised patients cannot mount the granulomatous response to contain the infection and dissemination via the blood to the central nervous system occurs causing meningitis or meningoencephalitis.[138] Following are the several clinical manifestations of cryptococcosis. Cryptococcosis is an AIDS-defining illness, and HIV testing should be considered whenever *C. neoformans* has been recovered from clinical specimens or when antigen-detection tests are positive.

Although rare, non- *neoformans Cryptococcus* species may also serve as agents of fungemia and disseminated disease.[138] More recently, *Cryptococcus gattii* has emerged as a cause of cryptococcal meningitis in immunocompetent hosts.

Central Nervous System

Central nervous system disease may occur with or without evidence of disease elsewhere. The onset of symptoms may be insidious, with mild headaches, memory lapses, or personality changes being the only clues. Low-grade fever may also be present. As the disease progresses, signs and symptoms suggestive of meningitis slowly develop—namely, nuchal rigidity, tenderness of the neck, and positive knee

and leg flexion tests (Brudzinki's and Kernig's signs). In cases of localized cryptococcal granulomas, signs and symptoms such as paralysis, hemiparesis, and Jacksonian seizures may be evident. Blurring of vision, diplopia, ophthalmoplegia, slurred speech, double vision, and unsteadiness of gait are usually manifestations of an expanding lesion (cryptococcoma). Papilledema is generally a sign of increased intracranial pressure. Weight loss, malaise, persistence of fever, nausea, vomiting, and dizziness may be experienced as the disease progresses. In progressive fulminant or fatal cases, mental changes may be marked (agitation, irritability, confusion, hallucinations, psychosis), developing into delirium, coma, and finally death. Cerebrospinal fluid examination may reveal an increase in lymphocytes, low glucose levels, and elevated protein. Spontaneous onset of CNS cryptococcosis is an AIDS-defining illness. Paradoxically, because of the immunosuppression induced by the HIV in patients with AIDS, there may be a very large number of yeasts in the CSF, but relatively minimal signs and symptoms. This is because the inflammatory response is largely responsible for the signs and symptoms.

Pulmonary Cryptococcosis

Cryptococcus is thought to gain entry into the body via the lungs, although cryptococcal pneumonia is quite rare compared with cryptococcal meningitis. Nevertheless, localized or generalized pneumonia may be seen. Sweeney et al.[268] report the findings of a 10-year-old boy with a malignant fibrous histiocytoma of bone and pulmonary nodule that was found to be secondary to *C. neoformans* infection. This diagnosis was suggested by the appearance of a pulmonary lesion on a computerized tomographic study. Cryptococcal pulmonary disease is often recognized as a result of imaging done for other reasons. Zhu et al.[308] also report four cases of pulmonary cryptococcosis in non-HIV-infected patients, associated with cryptococcal meningitis. Again, all four patients had no apparent symptoms of pulmonary disease.

The natural history, clinical presentation, diagnosis, and therapy of primary pulmonary cryptococcosis have been elucidated in a review of 41 patients by Kerking et al.[143] This group was able to establish the diagnosis when an abnormal chest roentgenogram was associated with the isolation of *C. neoformans* from respiratory secretions and/or the observation of mucicarmine-positive, typical-appearing organisms in sections of lung tissue. The majority of the patients in their series had underlying conditions predisposing to cryptococcal infection: immunosuppressive therapy (28/41), diabetes mellitus (20/41), hematologic or lymphoreticular malignancies (12/41), recent renal transplantation (10/41), and connective tissue diseases or other underlying illness (5/41). Seven of the patients had no detectable underlying abnormalities. Constitutional symptoms, such as fever and malaise, occurred in over half the patients. Chest pain, dyspnea, weight loss, and night sweats in varying combinations were observed in from one fourth to one third of the patients. Only seven of the patients reported cough. Seven patients were asymptomatic and

studied only because of abnormal roentgenograms. The abnormalities observed on chest X-ray examination included circumscribed mass lesions, alveolar or interstitial infiltrates, abscesses with air–fluid levels or cavitary lesions (7/41), solitary coin lesions, and multiple small rounded opacities.

The majority of patients with pulmonary exposure to *Cryptococcus* will develop a subclinical infection that results in a cryptococcoma. This is evidenced by the fact that the incidence of cryptococcomas is far greater than the incidence of cryptococcal pneumonia that comes to medical attention. The cryptococcoma may be discovered years after the primary infection in radiologic studies that are done for other reasons. Aspiration or excision of the "coin lesion" is necessary to exclude malignancy. Other infectious causes in this clinical and radiological differential diagnosis include a histoplasmoma, coccidioma, and tuberculosis.

1397

Cutaneous Cryptococcosis

Primary cryptococcal infection of the skin is rare; usually cutaneous disease is a manifestation of systemic infection.[111] Murakawa et al.[190] found that in their institution 5.9% of patients treated with cryptococcal infection and AIDS also had skin lesions. The authors describe a variety of appearances of these lesions—umbilicated papules, nodules, and violaceous plaques, with the former resembling molluscum contagiosum and the latter more reminiscent of Kaposi's sarcoma. In this review, lesions were most commonly seen on the head and neck. A comparison of the clinical manifestations of cutaneous cryptococcosis in the pre-AIDS and AIDS era has been presented by Pema et al.[216] As mentioned, although rare primary skin disease may occur. Hamann et al.[117] reported a 75-year-old man from Australia with cryptococcal cellulitis of the right arm. In retrospect, one wonders if this may have been *C. gattii*, which is a *Cryptococcus* species that is morphologically and biochemically similar to *C. neoformans* and causes disease in immunocompetent hosts.

Disseminated Cryptococcosis

C. neoformans produces capsular material that aids the fungus in surviving phagocytosis by segmented neutrophils and mononuclear phagocytes. These fungi may be distributed widely in the human host. In patients with disseminated disease, virtually any viscera or organ system may be involved. The neurotropic nature of this fungus dictates that there is usually a meningeal component, and as mentioned before, dissemination to the skin is common in such patients. Minamoto and Rosenberg[188] report that cryptococcal prostatitis persists after apparently successful therapy in 29% of men with disseminated disease and serves as a reservoir for relapse. Liu[168] culled from the literature 40 cases of cryptococcal osteomyelitis, which 75% of the time was limited to a single bone. The vertebrae were the most common site.

Sarcoidosis, tuberculosis, and previous steroid therapy were the main predisposing causes of cryptococcosis in these patients. Cryptococcal myositis is only rarely reported, most commonly occurring in patients with HIV infection, but may occur in individuals with immunosuppression from other causes. For example, O'Neill et al.[206] reported myositis in a heart-transplant recipient undergoing immunosuppressive therapy. Primary liver disease may predispose to cryptococcal peritonitis, although infection of the peritoneum is a rare event.[263] Cryptococcal infections of the urinary tract are also uncommon.[261] When *C. neoformans* is recovered from the urinary tract, a search for disseminated disease should be made.

Rhodotorula spp. have been recovered from shower curtains, bathtub grout, and toothbrushes. In the past, infections have been rare; however, currently, *Rhodotorula mucilaginosa* (formerly *R. rubra*) and *R. glutinis* are noted as opportunistic pathogens. Fungemia is most often associated with colonized catheters or contaminated intravenous solutions.[44,146] Septicemia related to indwelling catheters, meningitis, and peritonitis in patients receiving continuous peritoneal dialysis are among the uncommon infections caused by this organism.

The observation of a yeast-like colony with a red or orange-red pigmentation (Image Plate 21-6F) is most likely *Rhodotorula* spp. The microscopic morphology is nondiagnostic. Pseudohyphae are not formed; rather, oval budding yeast cells in irregular, loose clusters are observed. Most strains are rapidly urease-positive. Assimilation studies are most commonly used for species-level differentiation.

***Saccharomyces* Species.** The colonies, appearing within 36 to 48 hours, are gray-white and pasty in appearance, with irregular rugae. The appearance is nonspecific, and carbohydrate assimilation study is the most common method used to confirm the identification. Failure to assimilate cellobiose and xylose is helpful in separating *Saccharomyces* spp. from other biochemically related species.

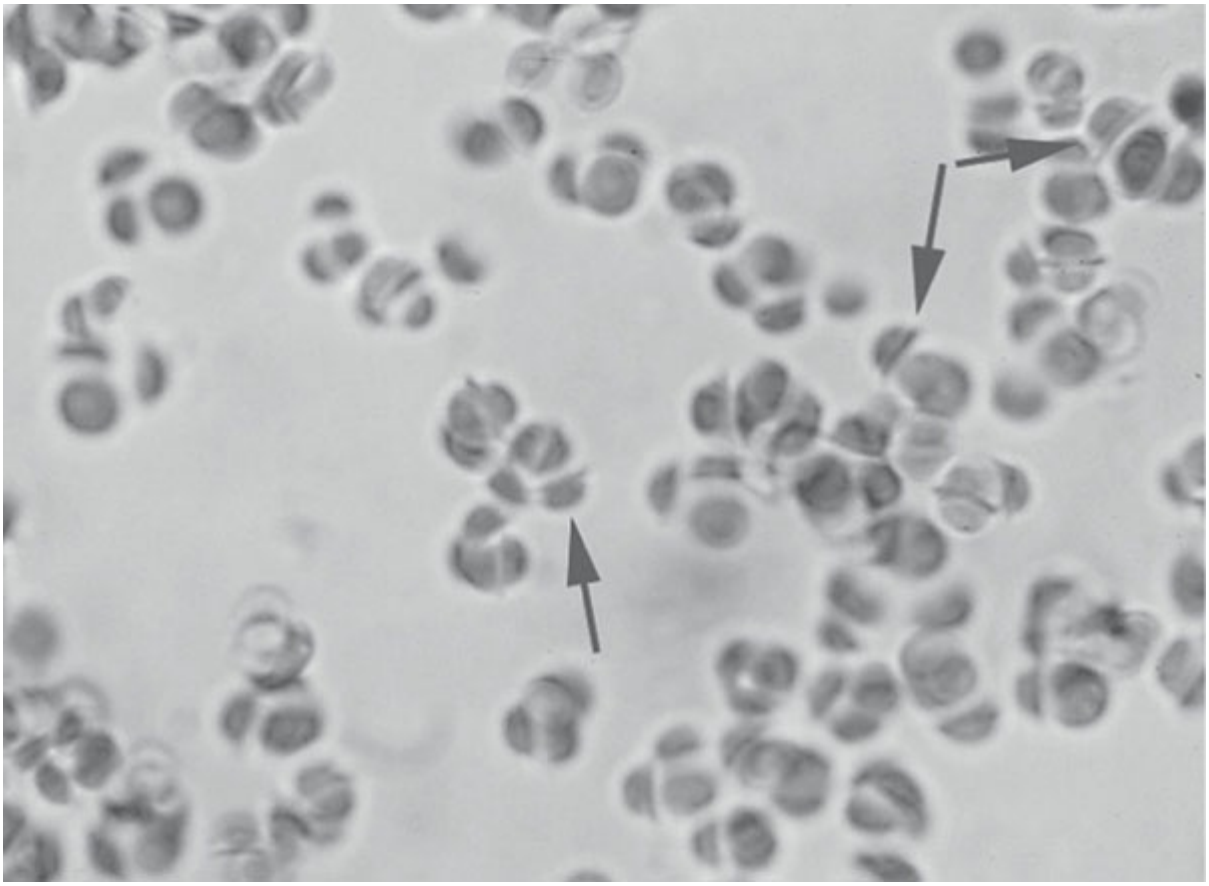
The microscopic morphology is also not specific. Loose clusters of large, oval, budding yeast forms are observed in cornmeal preparations. When colonies are grown on nutritionally poor ascospore agar, which contains potassium acetate, yeast extract, glucose, water, and distilled water, the identification can be confirmed by observing ascospores. After incubation of an inoculated plate for 7 to 10 days, a smear can be prepared from one of the isolated colonies and stained with an acid-fast stain. Observe for ascospores, which appear as large, thick-walled, spherical cells with a distinct red pigment in an acid-fast preparation (Image Plate 21-6H).

Saccharomyces cerevisiae, the common "baker's" or "brewer's" yeast, usually colonizes the mucous membranes of humans but is not commonly considered pathogenic. Occasional instances of fungemia in immunosuppressed patients have

been reported in the older literature.[45,83,198,272] Oliver et al.[205] describe three bone marrow transplant recipients on a hematology unit in whom invasive *S. cerevisiae* infection developed. Two of the patients died. Genotyping of the invasive and carriage strains demonstrated an indistinguishable strain from patients who had been on the unit at the same time, suggesting cross-infection.

***Wickerhamomyces anomalus* (Formerly *Hansenula anomala*).** A rare isolate in clinical laboratories, *Wickerhamomyces anomalus*, is included here because, in addition to *Saccharomyces* spp., it also produces acid-fast ascospores when observed in an acid-fast smear. The ascospores of *Wickerhamomyces* differ from those of *Saccharomyces* by being flattened on one side rather than spherical, with a distinct outer rim or lip at the flat base, simulating the derby hat of an English bobby (Fig. 21-92). Some of the automated identification instruments will identify this fungus by the anamorphic name *Candida pelliculosa.* Isolated infections have been reported in immunosuppressed patients, commonly associated with

1398



■ **FIGURE 21-92** Photomicrograph of an acid-fast stained preparation, revealing acid-fast yeast cells on *Wickerhamomyces anomalus anomala* (i.e., *Candida pelliculosa*), characteristically shaped like an English bobby hat, complete with brim (*arrows*).

indwelling catheters. Murphy and Buchanan[192] report 52 neonates who were colonized with then called *Hansenula anomala*, some of whom had evidence of systemic infection. Ma et al.[175] report a premature infant with staphylococcal osteomyelitis who was found to have *Wickerhamomyces anomalus* fungemia just before the initiation of the antimicrobial therapy with teicoplanin. The infant was cured after 10 days of antifungal therapy. Kalenic et al.[140]report a recent outbreak of *Wickerhamomyces anomalus* infection in eight adult patients treated at a surgical intensive care unit. The source of the infections and route of transmission were not identified. When searching the medical literature for this or any other fungus for which there have been nomenclature changes, it is important to remember to search under the former and current name, as well as any anamorphic name, such as with this fungus.

***Malassezia* Species.** Recovery in culture of some of these organisms may be difficult because there is a subset of *Malassezia* species that require long-chain fatty acids for growth. When recovery of the organism is anticipated based on the clinical history, a few drops of virgin olive oil should be added to the surface of a sheep blood agar plate immediately after inoculation. In some mycology laboratories, it has been the practice to overlay the agar plates prepared from all blood cultures received from the neonatal intensive care ward because newborns receiving total parenteral nutrition are at high risk for *Malassezia* septicemia.[59] The organisms grow well as small yeast colonies underneath the oil droplets (Image Plate 21-6G). Microscopically, the organism from the plate appears as small budding yeast cells lying singly and in loose clusters. The budding yeast often has a "bowling pin" morphology, and in many instances a "collarette" is discernible at the base of the bud.

In the past, if the *Malassezia* isolate was lipophilic, it was called *M. furfur,* whereas it was called *M. pachydermatis* if it was not lipophilic. However, with the advent of DNA sequencing, it was discovered that there were actually a number of species within each of these groups. For simplicity and for clinical identification purposes, since there are no differences in therapy based on the precise species, the lipid-dependent species are referred to as the *M. furfur "* complex," whereas the lipid-independent species are referred to as the *M. pachydermatis* "complex."

Members of the *Malassezia furfur* complex are lipophilic yeasts that are a common commensal of the skin. This organism causes a superficial cutaneous infection, tinea versicolor. Tinea versicolor presents as scaling lesions of the skin, primarily of the thorax and back, and at times extending to the neck, face, and arms. The lesions are

flat, irregular in outline, and may have a tan or brown pigmentation, but often appear as white blotches of discoloration, particularly in skin exposed to sunlight. The fungal elements in these lesions produce a brick-red fluorescence when examined with long-wavelength ultraviolet light (Wood's lamp). Direct examination of skin scrapings reveal hyphal elements, and 3 to 5 μm diameter, spherical budding yeast cells (colloquially referred to as "spaghetti and meatballs"), with the formation of a distinct collarette at the margin between the mother and daughter cell. Note, the morphology from the lesion is different from that seen from the plate (see above), wherein there is no hyphal element production.

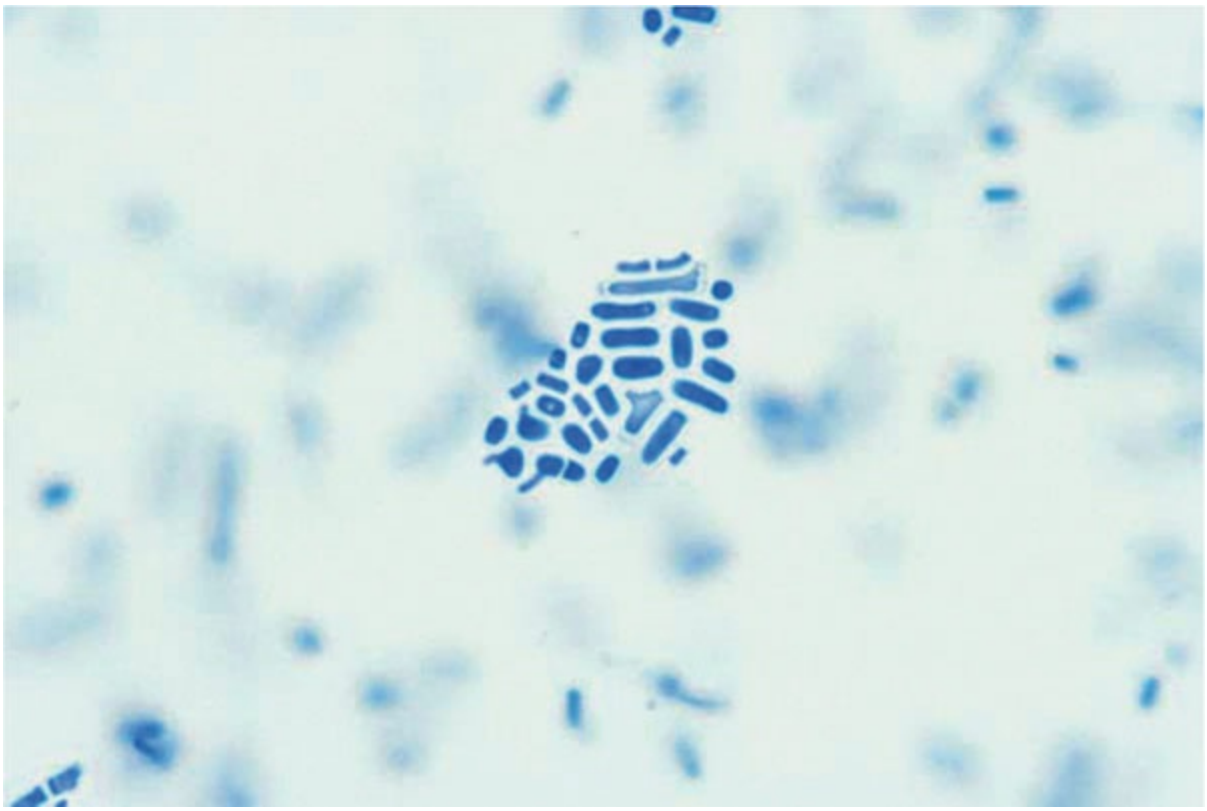
Systemic infections and septicemia have also been reported, most commonly associated with deep-line vascular catheters, particularly in patients receiving long-term hyperalimentation therapy that contains a lipid supplementation. Rosales et al.[238]reported a very-low-birth-weight infant receiving total parenteral nutrition and intralipid fluid infusion into the subarachnoid space, which developed *Malassezia furfur* meningitis. Many of the hyperalimentation emulsions are rich in long-chain fatty acids. This is an ideal microenvironment to support the growth of the endogenous lipophilic organisms that are present on the skin surface. The catheter provides a barrier break in the skin through which the proliferating organisms can enter the bloodstream.

Species That Produce True Hyphae

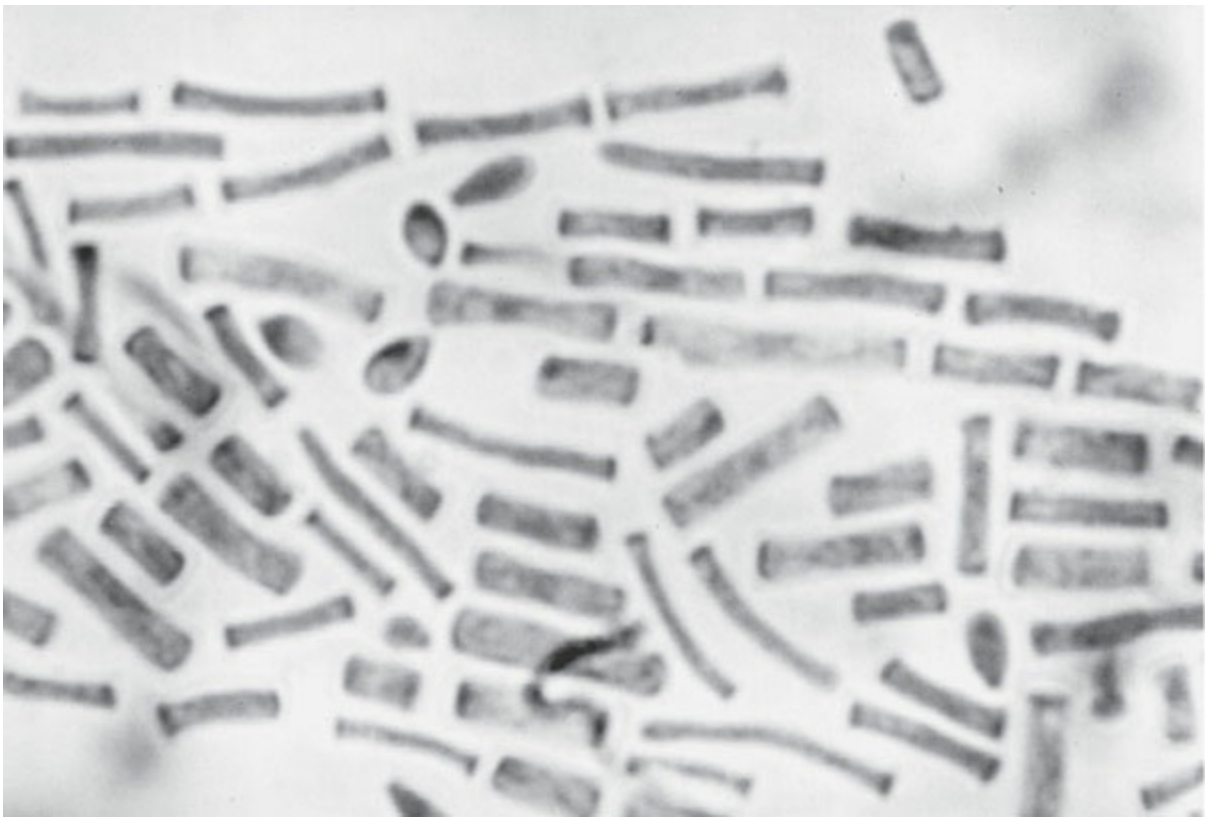
There are three organisms that are often considered together because of morphologic similarities and difficulties in differentiating. They are *Geotrichum candidum, Trichosporon* spp., and *Blastoschizomyces capitatus.* The colonies of these fungi are white-to-cream and initially yeast-like. Soon after isolation, however, they develop a delicate, silk-like surface as true hyphae and arthroconidia on maturity. Morphologic and biochemical features are used for differentiation.

In cornmeal agar mounts, yeasts, pseudohyphae, and true hyphae are produced. The true hyphae become transformed into arthroconidia in some areas. Morphologically, *Geotrichum candidum* often produces a single germ tube from one corner of the arthroconidium, simulating a hockey stick (Fig. 21-93). In contrast, *Trichosporon* spp. typically form blastoconidia from both corners of an arthroconidium, simulating "rabbit ears" (Fig. 21-94). *Blastoschizomyces capitatus* produces clusters of annelloconidia, which are flattened at the point of connection.

Biochemically, *Trichosporon* spp. are urease-positive and often is cycloheximide-resistant, but there is strain variability for the latter test. *Geotrichum candidum* is urease-negative and susceptible to cycloheximide. *Blastoschizomyces capitatus* is resistant to cycloheximide and does not produce urease.



■ **FIGURE 21-93** Photomicrograph of *Geotrichum candidum,* illustrating arthroconidia, a few of which present the characteristic germ-tube-like extension from one corner, simulating a "hockey stick."



■ **FIGURE 21-94** Photomicrograph of a *Trichosporon* species, illustrating arthroconidia, one of which presents the characteristic budding blastoconidia from two corners, simulating "rabbit ears."

The clinical manifestations of infections by these organisms are presented in Clinical Correlation Box 21-14.

Laboratory Identification of Fungi with Both Hyaline and Dematiaceous Components

***Aureobasidium pullulans* and *Hormonema dematioides*.** Both *Aureobasidium* and *Hormonema* grow as smooth, moist colonies tan colonies upon early isolation, which become darker and more mold-like with extended incubation. Microscopically, these produce large, dark, dematiaceous hyphae that often appear as arthroconidia; hyaline septate hyphae are also produced. Myriad small, elliptical, single-celled, hyaline conidia are produced from buds from the centers of individual hyphal segments (Fig. 21-95). Occasional cases of cutaneous phaeohyphomycoses secondary to *Aureobasidium pullulans* have been reported in humans.[240] Rare cases of disseminated nosocomial fungal infection due to *Aureobasidium pullulans* var. *melanigenum* in a severely traumatized patient has been reported by Bolignano and

Criseo.[27] A 50-year-old patient with an infected corneal ulcer by this organism was reported by Gupta and Elewski.[108] In this patient, scleritis developed 5 days after surgery, and the patient became asymptomatic after antifungal therapy, surgical debridement, and cryotherapy. It is acceptable to finalize an isolate as *Aureobasidium/Hormonema* complex, if it becomes difficult to determine a definitive identification, as these are usually contaminants. Differentiation is achieved by denoting synchronous versus asynchronous conidiation, and, more easily determined, if the conidia are produced by the hyaline cells only or by both the hyaline and dematiaceous cells. *Aureobasidium* undergoes synchronous conidiation and the conidia arise only from hyaline cells. In contrast,

CLINICAL CORRELATION BOX 21-14 Arthroconidia-Producing Yeasts and Yeast-Like Fungi

Trichosporonosis

The *Trichosporon* species have undergone significant reclassification based on DNA sequencing. *Trichosporon beigelii* is no longer recognized as a species, but it is important to remember this previous nomenclature when searching the medical literature. There are now many recognized *Trichosporon* species, with *T. asahii, T. mucoides, T. cutaneum, T. inkin,* and *T. ovoides* being the most clinically relevant. The latter three species are important causes of white piedra. This fungus may be carried on the skin, particularly around the anus. White piedra is an infection involving the hair of the scalp, body, or pubic hairs, presenting as small, circumscribed nodules or concretions on the hair shafts. Each nodule contains twisted fungal hyphae, which can be readily observed in direct KOH/calcofluor white preparations, and from which the organism can be readily recovered. The infection can often be eradicated simply by shaving; only rarely is the use of topical or systemic azoles necessary to eradicate the infection.

Disseminated disease, most likely endogenous in origin, representing extensions from colonized cutaneous or gastrointestinal sites, may develop in persons who are immunosuppressed, and become life-threatening in some cases.[82] Hoy et al.[130]reviewed 19 patients with disseminated *Trichosporon* (called *T. beigelii,* but likely represented *T. asahii*) infections in patients with a variety of neoplastic diseases being treated at M.D. Anderson Hospital in Houston over a 10-year period. A nonspecific febrile illness or pneumonia was the most common clinical

manifestation among this group of patients. Three fourths of these patients died; in relation to the discussion elsewhere, the diagnosis was not suspected prior to death in 25% of the autopsied cases. Other *Trichosporon* species, may cause invasive infection, particularly in patients with hematologic malignancy.[142]

The report by Sweet and Reed[269] indicates that neonates are not immune to disseminated disease. Yoss et al.[307] found that low-birth-weight infants in particular were susceptible, a situation of great concern because most infections in this group have been fatal.

Unfortunately, in many instances the diagnosis is often delayed either because the condition may not be recognized or because the organism is not quickly identified in the laboratory. It is important that microbiologists recognize the characteristic arthroconidia in cornmeal mounts as the initial clue to the identification and perform appropriate confirmatory tests.

Trichosporon asahii is rapidly urease-positive and quite saccharolytic, producing acid from most carbohydrates. As a precautionary note, *Trichosporon* spp. share antigenic determinants with *Cryptococcus neoformans*; therefore, serum and cerebrospinal fluid from patients with disseminated disease may give a false-positive reaction with the cryptococcal latex agglutination test.

Geotrichosis

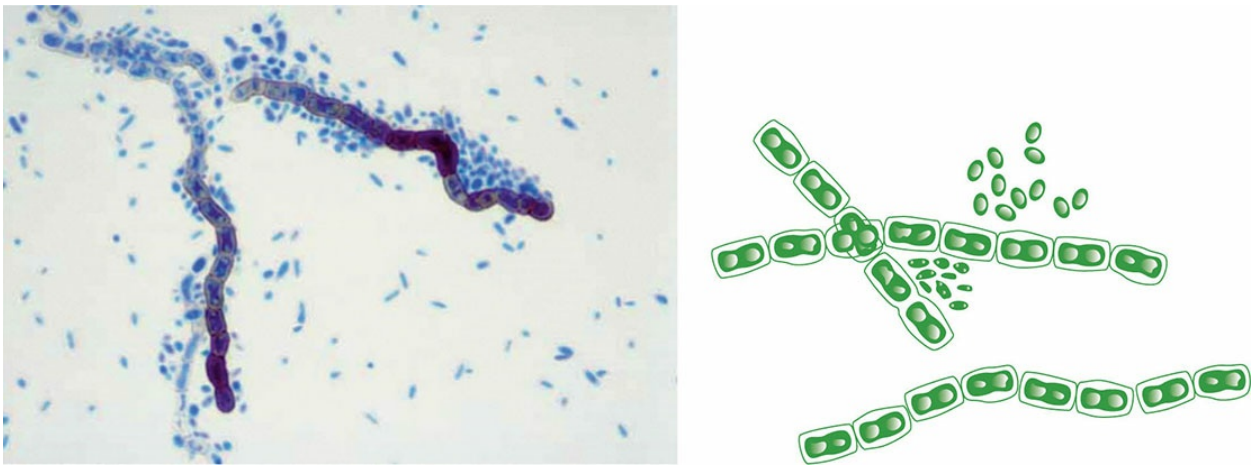
Disseminated infections with *Geotrichum candidum* are less commonly encountered. Isolated patients with disseminated *Geotrichum candidum* infection have been reported, and two in patients with acute leukemia.[248] In one of these patients, renal failure developed 3 days before death. The glomeruli were blocked with hyphal segments of *Geotrichum candidum*. The other patient, reported by Andre et al.,[14] was a young girl being treated for hepatoblastoma. After complications with secondary bacterial infections, this patient survived following a 5-week course of intravenous amphotericin B followed by 6 months of oral itraconazole. Although treatment regimens in patients with disseminated *Geotrichum* infection have not been established, the use of high doses of itraconazole and liposomal amphotericin B is recommended.[248]

Although patients with pneumonitis secondary to Geotrichum species have been reported, the recovery of this organism from respiratory secretions usually represents either contamination or commensal habitation, and other causes of disease should be ruled out. *G. candidum* assimilates only glucose, galactose, and xylose, which, except for the xylose utilization, is a pattern similar to that of *T. capitatus*. Most strains of *Geotrichum* are urease-negative, which is useful in differentiating this organism from *Trichosporon* species.

Blastoschizomycosis

Infections by *Blastoschizomyces capitatus* are rare. These usually occur in patients with significant underlying disease and are more commonly seen in the

immunocompromised host. Birrenbach et al.[22] report their experience with five patients infected by *B. capitatus*. Three were immunosuppressed because of chemotherapy for leukemia, whereas two were immunosuppressed secondary to renal transplantation. Three of the patients had fungemia, whereas the yeast was isolated from peritoneal fluid in one and the urine in another. All three of the patients with fungemia had pulmonary involvement, one had additional involvement of the brain, whereas the third also had involvement of the liver, spleen, skin, and brain. The three patients with fungemia died, which is not uncommon, as there is a high mortality associated with *B. capitatus* infections.



■ **FIGURE 21-95** Photomicrograph and sketch of the microscopic appearance of *Aureobasidium pullulans*, illustrating chains of large, dark-staining arthroconidia-like cells with small, hyaline conidia in the background.

1401

Hormonema undergoes asynchronous conidiation and the conidia arise from both the hyaline and the dematiaceous cells.

Laboratory Identification of "Black Yeasts"

Hortaea (Phaeoannellomyces) werneckii. The genus "*Phaeoannellomyces*" was created in 1985, by McGinnis et al.[183] "to accommodate those black yeasts that are characterized by the development of yeast cells that function as annellides" (*phaeo* = dark; *annello* = annellides; *myces* = fungus). Unfortunately, this beautifully named fungus has been taxonomically reclassified into the genus *Hortaea.*

Hortaea werneckii microscopically produces two-celled yeast cells. The daughter

cell is produced from an extension from the mother cell, which then contracts to form a scar (annellide), appearing as a deep-staining septum that separates the two cells (Fig. 21-96). Engleberg et al.[81] have reported a patient with a phaeohyphomycotic cyst caused by this or a related organism. More commonly, this fungus is known of as the cause of tinea nigra, a fungal infection of the palms of the hands. The yeast-like cells with this species are unicellular and may develop thick dark walls and pseudohyphae on maturity.

Controversy still exists with this group of organisms,[160] which are morphologically similar to the black yeast-like forms seen in early cultures of *Exophiala* species (covered above).

■ **FIGURE 21-96** Photomicrograph and sketch of the yeast forms of *Hortaea werneckii*, revealing elongated double yeast cells separated by a distinct deeply staining transverse bar

(annellide).

Commercially Available Yeast Identification Systems

Several packaged kits for identifying yeasts have been introduced by commercial companies.[281] These change over time, with the development of newer and improved products. Most recently has been the introduction of MALDI-TOF mass spectrometry for which there are two, excellent FDA-approved applications for yeasts. Although the initial capital costs are somewhat higher for mass spectrometry than for other identification systems, the cost is recovered quite quickly due to savings in reagent costs. Another advantage of the MALDI-TOF is the more rapid time to identification, which potentially could have a clinical impact.

The use of any of these systems requires technical skills and sufficient familiarity with each test performed to enable accurate interpretations. In each instance, the manufacturer's instructions must be closely followed. Each laboratory director or supervisor must weigh factors such as cost, availability and supply, shelf life and stability of reagents, adaptability to workflow, and the specific needs of the clinical services before a decision can be made to implement these systems in the home laboratory.

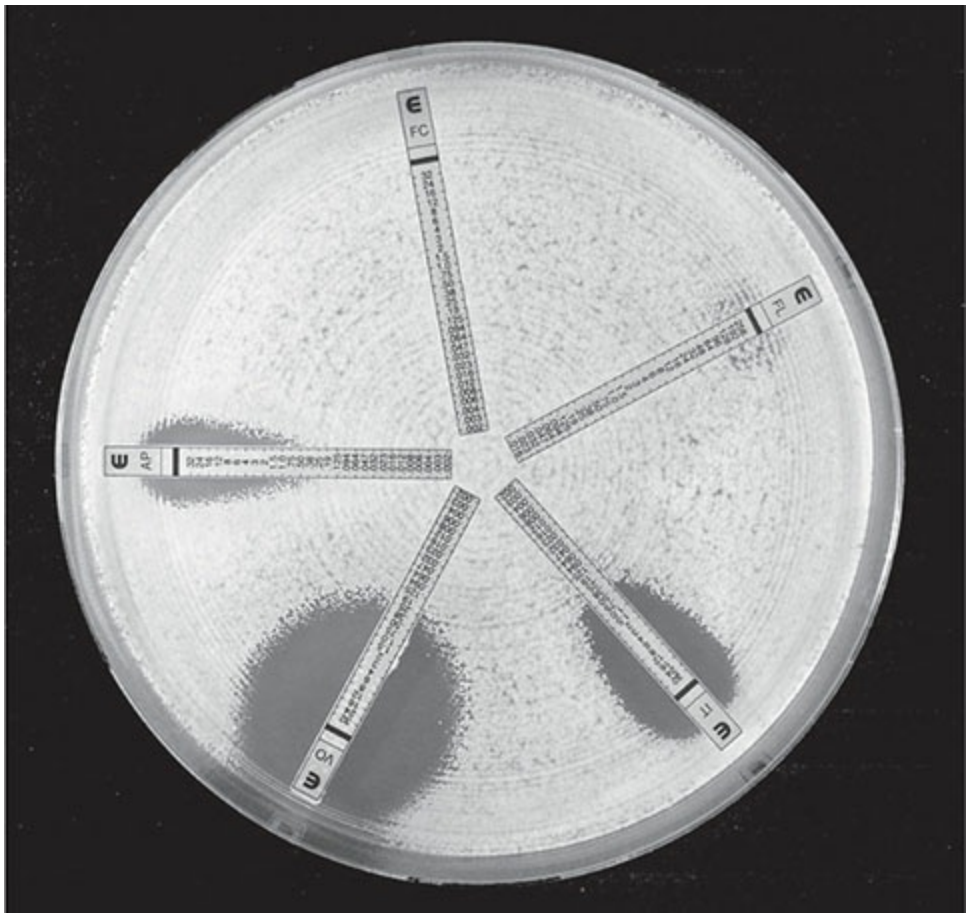
Antifungal Susceptibility Testing

The CLSI Subcommittee on Antifungal Susceptibility Testing has established standardized and reproducible methods for the antifungal susceptibility testing of yeasts.[196,223,220,231] Establishing these laboratory standards, particularly for the yeasts, has provided valuable guidelines for antifungal therapy with improved correlation with clinical outcomes.[99] There are established standards for broth dilution susceptibility testing for yeasts (M27-A2), disk diffusion susceptibility testing for yeasts (M44-A), and the broth dilution standards for filamentous fungi (M38-A).[48–51,55]

Sewell and coworkers,[253] in a comparative study of susceptibility tests for fluconazole, have shown that the Epsilometer "Etest" (bioMerieux) compares favorably with the reference methods, with an overall 84% agreement, reaching as high as 90% for most *Candida* species, except for *C. tropicalis* (56%). *Candida* (*Torulopsis*) *glabrata* also had low comparison values in this study (34%).

The Etest uses a plastic strip containing a defined continuous gradient of antimicrobial drug, which is placed on the surface of an agar plate after it has been

evenly plated with an inoculum containing a standardized concentration of the yeast organisms to be tested (Fig. 21-97). The plastic strip releases the antifungal agent into the surrounding agar, producing a logarithmic increase in the concentration of antibiotic from as low as 0.002 µg/mL to as high as 256 µg/mL, depending on the antifungal agent being tested. The details for performing the Etest, including the recommended test medium, the preparation of the standard inoculum, the steps of the procedure, and the readout can be found in the publication by Colombo et al.[53] This report also included the results for the Etest against 200 yeast isolates, compared with the standard methods for several individual drugs. The essential agreements between the two methods within a ±1 dilution were 71% for ketoconazole, 80% for fluconazole, and 84% for itraconazole. Since the publication of this paper, the use of



■ **FIGURE 21-97** Photograph of the surface of an agar plate demonstrating an Etest. Several gradient diffusion strips have been placed on a lawn of growth of *Candida kruzei*. The MIC interpretations of the strips reading clockwise beginning with fluconazole in the 11-o'clock position are: FL (fluconazole), >256 µg/mL; FL (flucytosine) >32 µg/mL; IT

(itraconazole), 0.38μg/mL; VO (voriconazole) 0.38 μg/mL, AP (amphotericin B), 2 μg/mL.

a standardized medium (RMPI 1640), a final reading at 48 hours, and other adjustments have raised the essential agreement percentage sufficient to establish the Etest as an alternative method for the fungal susceptibility testing of most yeast species. As mentioned before, because the Etest is less labor intensive and easy to perform, in-house antifungal susceptibility testing is now within the reach of many clinical microbiology laboratories. Some have employed the Etest for molds.

Pfaller et al.[221] in a multi-institutional study demonstrated a high level of reproducibility of the Etest minimal inhibitory concentration (MIC) method between four participating institutions. Each participating laboratory received subcultures of two American Type Culture Collection (ATCC) QC *Candida* strains (*C. parapsilosis*, ATCC 22019 and *C. krusei*, ATCC 6258), Etest strips, and sufficient RPMI agar plates to perform 20 replicate tests with each of five drugs—amphotericin B, fluconazole, flucytosine, itraconazole, and ketoconazole. In almost all of the drug/bug combinations tested, a very tight distribution was observed, ranging between 98% and 100% of the MICs, falling within a three-dilution range. The selective discrepancies of results between the Etest and the standard method for flucytosine and fluconazole against *C. krusei* was related to uneven growth between the glucose-enriched Etest agar and the unsupplemented broth used in the reference macrobroth test.

The Etest detected a resistant subpopulation of strains not detected by the reference method. After analyzing all the data, the authors concluded that the study established excellent interlaboratory and intralaboratory levels of agreement between the two methods, providing further documentation of the utility of the Etest in determining antifungal susceptibility profiles. This standardization of the test methods, the establishment of interpretive breakpoints for certain drug–yeast combinations, and reproducibility of results both within and between clinical laboratories will provide the basis on which clinical outcomes can be measured.[84]

The motivation to implement in vitro antifungal susceptibility tests in clinical laboratories goes beyond establishing the resistance profiles of a given isolate. The emergence of antifungal resistance is becoming an issue of increasing concern. For example, with the more widespread use of fluconazole, reports of fluconazole resistance in *Candida* species and *Cryptococcus neoformans* have increased.[279] Peyron et al.[218] have found that the Etest provides the optimal means for discrimination between *C. lusitaniae* isolates that are amphotericin B–resistant and amphotericin B–susceptible. Decreased susceptibility to itraconazole has been observed against select *Aspergillus fumigatus* isolates. Azole resistance has also been noted in *C. albicans* isolates from patients with AIDS, presumably resulting from the extended use of this drug in the treatment of oropharyngeal candidiasis (thrush). The

intrinsic resistance of *Candida krusei* to the imidazoles and emerging resistance of *Candida glabrata* to this group of antifungal agents are also problematic. White et al.[295] have published a review of the clinical, cellular, and molecular factors that underlie the development of resistant strains, particularly of *C. albicans*. This work serves as a primer for those who would like more information. More recently, the CLSI has provided species-specific breakpoints for the commonly encountered yeasts for which there were adequate data, as well as epidemiologic cutoff values, the latter of which reflect the wild-type susceptibility distribution to a particular drug. Both of these represent advances in our ability to provide more tailored therapy for patients. In summary, it is becoming imperative that clinical microbiology laboratories provide in vitro antifungal susceptibility data in order to guide the most appropriate use of the newer antifungal agents, as well as to detect these emerging patterns of resistance.

Unusual Fungi

Pneumocystis jirovecii

Pneumocystis jirovecii, as the genus name implies was originally thought to be a parasite. However, based on DNA sequence analysis, *Pneumocystis jirovecii* has been shown to be more genetically more closely aligned with the fungi, and thus has been reclassified as an ascosporogenous fungus. Additionally, it has been demonstrated that the species that infects humans, *P. jirovecii,* is distinct from that which infects rats, *P. carinii,* which is the reason for the change in nomenclature. Criteria note by Hadley and Ng[121] regarding the reclassification of this organism include the following:

- There are ultrastructural similarities between the cell walls of the cyst of *P. jirovecii* and those of other fungi.
- The cristae in the mitochondria of *P. jirovecii* are lamellar, whereas protozoans have tubular cristae.
- The cyst forms containing intracystic bodies resemble those of ascospores formed by the Ascomycetes.
- A high homology of the more conserved domains of the rDNA gene compared with that of Ascomycetes.
- The β-tubulin gene is 89% to 91% homologous with that of some of the filamentous fungi.
- *P. jirovecii* possesses separate proteins for thymidylate synthase and dihydrofolate reductase activities, whereas protozoa produce a single bifunctional protein.

- NADH dehydrogenase subunits 1, 2, 3, and 6; cytochrome oxidase subunit II; and a small subunit of rRNA have an average similarity of 60% with fungi, but only 20% with protozoa.

Pneumocystosis was recognized early in the HIV epidemic as a rapidly progressive, bilateral pneumonia that often contributed to the death of the patient. Although infections with this organism had been recognized prior to the HIV epidemic, infections were rare. There unusual infections were reported as comorbid conditions in patients with cancer and severe malnutrition. This disease is now recognized in patients with other immunocompromising conditions secondary to receiving chemotherapy or immunosuppression to control transplantation rejection or autoimmunity. In patients with more profound immunosuppression, frothy material fills the terminal alveoli of the lungs, which appears as "ground glass infiltrates" on chest roentgenogram. In patients with a lesser degree of immunosuppression or reconstitution of their immune system, the organisms appear within granulomas; in this presentation, the pathologist must be careful not to mistake the cyst forms of *Pneumocystis* with the morphologically similar yeasts of *H. capsulatum.*

Until recently, the morphologic assessment of respiratory specimen has been the mainstay of diagnosis and is still commonly used in most laboratories. Nonspecific staining options include the Diff-Quik stain, calcofluor white, toluidine blue, and the GMS stain. All of these, except for the Diff-Quik, rely on the detection of the cyst form of the organism, some of which will disclose the characteristic parentheses-shaped, intracystic bodies. Immunofluorescent stains are also an option. Although these stains are useful, studies at the Cleveland Clinic have demonstrated that they are significantly less sensitive than PCR, which may emerge as the new diagnostic standard.

Microsporidia

The tiny organisms of phylum *Microsporidia* do not stain well with most stains. The Weber stain[284a] and the Ryan stain[238a] have been used with success in clinical laboratories. The chromotrope R stain has been developed at the Centers for Disease Control and Prevention (CDC) to stain this group of organisms. In this stain, the concentration of the chromotrope 2R component has been increased by 10 times to facilitate the penetration of dye into the minute fungal forms. It is important to prepare a thin smear using approximately 10 μL of 10% formalin-fixed unconcentrated stool suspension on a glass slide (formalin concentrates may also be used, but the number of organisms, which do not concentrate well, per field of view is not substantially increased). The quick hot-Gram-chromotrope procedure is an alternative stain that is fast, reliable, and simple to perform.[194] Using this technique, a routine Gram stain is first performed on the thin smear, but instead of safranin, the slide is placed in a

warmed (50°C to 55°C) chromotrope stain for at least 1 minute. The microsporidia spores appear as dark-staining violet ovoid structures against a pale green background. A control slide that contains microsporidia spores from a 10% formalin-preserved specimen should be included for each staining run. This control provides a point of reference to distinguish true spores from similarly appearing objects. These stains are described in more detail below.

The microsporidia are obligate intracellular parasites that are sufficiently unique to be classified into a separate phylum, *Microsporidia*.[169] The unique feature of the *Microsporidia* is the production of spores that contain a complex tubular extrusion mechanism (i.e., the polar tubule or polar filament) by which the infective material, "sporoplasm," is injected into host cells. This occurs when an appropriate host cell stimulates the microsporidian spore (e.g., changes in pH and in ionic concentration of the intestinal contents for intestinal microsporidia). Upon appropriate stimulus, the coiled tubule is everted and penetrates the host cell. Within the host cell, asexual replication occurs either in a parasitophorous vacuole or within the cytoplasm, depending on the species. Eventually, the microsporidia are released from the cell fully functional and ready to infect the next host cell.

Over 140 genera and 1,200 species are included in this collective group called *Microsporidia*. This single-celled, minute parasites cause disease in a variety of nonhuman hosts, including insects, fish, laboratory rodents, rabbits, fur-bearing animals, and primates.[24] They are true eukaryotes (perhaps arising as a very early branch of the eukaryotes), having a nucleus, a nuclear envelope, and an array of intracytoplasmic membranes. Within the phylum, 15 genera have been shown to cause human diseases. Among these, the most important are species within *Encephalitozoon, Nosema, Pleistophora*, and *Enterocytozoon*. A former genus of medical importance, *Septata,* has been reclassified within the *Encephalitozoon*. Species differentiation is virtually impossible by light microscopy. Differentiation has classically been achieved using ultrastructural morphology achieved by transmission electron microscopy. Molecular studies are also important for definitive characterization.

Laboratory Identification. The diagnosis of microsporidiosis can be made by identifying microsporidia spores in the stool, as noted above, or in formalin-fixed, paraffin-embedded tissues. Although clusters of intracellular microsporidia may be seen in H&E-stained sections, they are better seen in tissue Gram stain preparations. They may also be seen in PAS, silver (GMS), acid-fast, or Giemsa-stained sections. The spores appear within intestinal enterocytes, characteristically located between the cell nucleus and the lumen of the intestine. In PAS-stained preparations, a PAS-positive granule may be observed at the anterior end of each spore. These appear as dark-staining dots when stained with Giemsa. Several photomicrographs demonstrating these spores can be found in Garcia.[102]

Electron microscopy continues to serve as the morphologic gold standard. The identification of spores with a polar tube is characteristic of all genera. Members of the genus *Encephalitozoon* are enclosed in a host-produced, phagosome-like, limiting vesicle (i.e., the parasitophorous vacuole). Both *Enterocytozoon* species and *Nosema* species develop in direct contact with host-cell cytoplasm without a limiting vesicle; *Nosema* species are distinguished by having paired, abutted nuclei.[24]

The laboratory diagnosis is most commonly made in the clinical parasitology section by demonstrating spores in stained preparations of fecal specimens.

Microsporidia have the following characteristics:

- The spores are tiny, ranging from 1.5 to 2.5 × 2.5 to 4.0 μm.
- They are oval to cylindrical in shape and possess thick walls that render them environmentally resistant and difficult to stain.

1404

- A transverse pink-staining band midway in the cells is a key identifying feature (Image Plate 22-4H).
- The spores stain poorly with H&E, but can be better visualized with Gram, acid-fast, PAS, Giemsa and a modified trichrome stain.
- They are gram-positive and some are acid-fast; in PAS stains an anterior PAS-positive granule is observed.
- The stain devised by Weber et al.[280] can be highly recommended for the detection of microsporidia spores in duodenal aspirates and in fecal material (Box 21-8).

DeGirolami et al.[65a] found that both Weber's modified trichrome stain and the fluorochrome Uvitex 2B stains were equally and highly sensitive compared with duodenal biopsies in detecting microsporidia spores in smears of duodenal aspirates biopsy material from 43 patients. Ryan et al.[238a] describe a modified stain in which the phosphotungstic acid is decreased in concentration to 0.25 g/dL and aniline blue instead of fast green was used as the counterstain. Each staining procedure requires 90 minutes, and selection between the Weber and the Ryan stain is one of personal preference. Kokoskin et al.[152a] found that performing the stain at a temperature of 50°C and decreasing the time of staining to 10 minutes produced a deeper, easier-to-interpret stain. Because the microsporidia spores are very small and may resemble bacteria or very small yeast cells, staining of positive control material is always necessary when performing either of these stains.

Although all species of microsporidia may cause disseminated infections, and organisms may be found in several organs, including liver, kidney, and brain,

Enterocytozoon bieneusi is the species that tends to preferentially infect enterocytes in the small bowel mucosa, particularly in patients with AIDS.[91] However, several case reports, as reviewed by Pol et al.,[225a] indicate that *E. bieneusi* may colonize the bile-duct epithelium leading to cholangitis. The estimated prevalence of microsporidium intestinal infection in AIDS patients may be as high as 12%,[163] or even higher if special techniques including cytocentrifugation, fluorescent antibody detection, and serology are used. *Encephalitozoon cuniculi* is most commonly associated with disseminated infection, with a predilection for infecting the brain and kidneys. *Nosema corneum* has been found in several cases of keratoconjunctivitis[32]; however, *Encephalitozoon cuniculi* and *Encephalitozoon hellem* have also been recovered from the cornea and conjunctiva in patients with AIDS with keratoconjunctivitis.[73] Conjunctivitis, scleritis, sensation of foreign body, and blurred vision are common presenting symptoms. Interestingly, infections of the cornea are often devoid of significant inflammation, even though abundant organisms are present, even in immunocompetent hosts.

Those with experience may be able to identify the characteristic, tiny (2 μm in diameter) intracytoplasmic spores in stained tissue sections of intestinal biopsies. Spores are best demonstrated using Brown-Brenn or Brown-Hopps tissue Gram stains or Giemsa-stained touch preparations. Organisms may also be seen in semithin plastic sections stained with methylene blue-azure II with basic fuchsin or toluidine blue counterstains.[24] Positive control slides should always be prepared in parallel when using any of these stains. Spores have also been demonstrated in CSF and urine by the use of immunofluorescence light microscopy. The infrequency of recognized infection caused by these organisms, particularly in resource-rich countries with effective HIV therapy, makes diagnosis a challenge.

Aldras et al.[6a] demonstrated the superiority of detecting microsporidia spores in the stools of patients with AIDS with indirect immunofluorescence antibody stains, using polyclonal antisera to *E. cuniculi* and *E. hellem* and monoclonal antibodies raised against *E. hellem*. Similarly, Zierdt et al.[309] used a variety of polyclonal mouse and rabbit antisera raised against *E. cuniculi* and *Encephalitozoon hellem* spores in an indirect fluorescent antibody assay to successfully identify microsporidial spores in 11 of 12 fecal samples, in addition to detection of antigen in colon and duodenal fluids and in duodenal biopsy touch preparations. Franzen et al.[91a] successfully used microsporidian DNA amplification by PCR on six known positive duodenal biopsy specimens to

Weber Stain for the Detection of Microsporidia Spores in Stool Specimens[284a]

1. Prepare slides for light-microscopic examination of stool taking a 10-µL aliquot of unconcentrated liquid stool concentrate in 10% formalin (12:3 ratio), spread thinly over an area 45× 25 mm^2.
2. Fix smears in methanol for 5 minutes.
3. Stain for 90 minutes in the Weber chromotrope-based stain. To prepare the stain, mix:
   - Chromotrope 2R (Harleco, Gibbstown, NJ), 6.00 g
   - Fast green (Allied Chemical & Dye, New York), 0.15 g
   - Phosphotungstic acid, 0.70 g
   - Allow these ingredients to stand for 30 minutes in 3 mL of glacial acetic acid. Then mix with 100 mL of distilled water.
4. After staining, rinse slides in acid alcohol (4.5 mL of acetic acid and 995.5 mL of 90% ethyl alcohol) for 10 seconds and then rinse briefly in 95% alcohol.
5. Successively dehydrate smears in
   - 95% alcohol for 5 minutes
   - 100% alcohol for 10 minutes
   - Hemo-De (xylene substitute, Fisher Scientific) for 10 minutes
6. Examine 100 oil immersion fields per slide, a reading time of approximately 10 minutes. Look for the small, 1–4 µm, cylindrical spores that stain bright pink-red.

detect a 353-bp DNA fragment specific for *Enterocytozoon bieneusi*. They suggest that PCR may be a useful approach to diagnosing microsporidiosis in HIV-infected patients. In fact, molecular diagnosis with species-specific PCR primers is likely the gold standard for the detection and identification of microsporidian species.[59] A challenge for the molecular diagnostic approach for microsporidia is that PCR-based assays are species-specific (i.e., a "broad-range" assay that detects all microsporidia species has not been developed). An approach is to test for the most common species, with the recognition that negative results due not exclude microsporidiosis caused by a species not covered by the assay.

BOX 21-8

Effective therapy for microsporidiosis is limited. Treatment of intestinal infections due to *Enterocytozoon bieneusi* with pyrimethamine, metronidazole, or trimethoprim–sulfamethoxazole (SXT) may be effective. De Groote et al.[65b] report successful treatment of a patient with AIDS using albendazole, a situation wherein PCR was used

to provide an early diagnosis. For a comprehensive review of human microsporidial infections, including over 250 references, see Weber et al.,[284b] who introduce several diagnostic options that will facilitate future studies on the incidence, risk factors, origins of infection, modes of transmission, clinical manifestations, pathogenesis, and treatment of this emerging pathogen.

Serologic Diagnosis of Fungal Diseases

Fungal serology is usually performed in reference laboratories. The time-honored procedures, including tube precipitin, immunodiffusion, latex agglutination, and CF tests are giving way to newer, more sensitive technologies. Among these, CF and immunodiffusion are still commonly used. EIA techniques that use species-specific monoclonal antibodies are being more widely used in clinical mycology laboratories.[118]

As a general rule, single species-specific serologic reactions in titers of 1:32 or greater indicate disease; however, demonstrating a rising titer fourfold or greater in samples drawn 3 weeks apart may be of greater significance.[61] Titers less than 1:32 or that do not show a fourfold increase between the paired samples usually indicate the presence of either early infection or nonspecific cross-reactivity with other antigens. The results from all serologic studies, nonetheless, must be considered presumptive, and correlated with the clinical and microbiologic findings.

Antibodies of the IgM class are commonly detectable about 2 weeks after the disease is acquired, and indicate recent infection. Usually IgM antibodies are no longer detectable after 6 months. IgG antibodies appear shortly after the rise in IgM titer, do not peak until about 6 to 12 weeks, and may remain elevated for many months after infection. Thus, a single elevated IgG antibody titer cannot be used to distinguish between recent and remote infections. The use of IgM and IgG assays is becoming more widespread and can help with distinguishing acute from remote infection.

The nonculture serologic and molecular techniques pertinent to the various types of fungal infections have been reviewed in the respective sections. Much attention is now shifting to sensitive assays being developed for the direct detection of fungal antigens in clinical specimens and in biologic fluids, often leading to same-day results. The continuous advances made in molecular diagnostics make it mandatory for the directors and supervisors of clinical mycology laboratories to peruse the current medical literature to determine which of these techniques may be applicable to specific clinical settings.[151] The following are proposed or confirmed taxonomic name changes of medically-important fungi. The traditional nomenclature has been predominantly retained throughout this chapter, but readers should be aware of these changes (Table 21-8).

TABLE 21-8 Taxonomic Name Changes of Medically-Important Fungi

Former Name	New Name
Bipolaris australiensis	*Curvularia tsudae*
Bipolaris hawaiiensis	*Curvularia hawaiiensis*
Bipolaris spicifera	*Curvularia spicifera*
Blastoschizomyces capitatus	*Saprochaete capitata*
Cunninghamella bertholletiae	*Cunninghamella elegans*
Geotrichum candidum	*Dipodascus geotrichum*
Madurella grisea	*Trematosphaeria grisea*
Ochroconis constricta	*Scolecobasidium constrictum*
Ochroconis gallopava	*Verruconis gallopava*
Paecilomyces lilacinus	*Purpureocillium lilacinum*
Paecilomyces variotii	*Paecilomyces divaricatus*
Penicillium marneffei	*Talaromyces marneffei*
Rhizopus oryzae	*Rhizopus arrhizus*
Scedosporium prolificans	*Lomentospora prolificans*

1406

Preliminary Observations Suggestive of the Zygomycetes

- Colonies rapidly growing with a poorly defined margin, filling the Petri dish in 48–72 hours
- Colony surface is wooly in consistency, and may become speckled as sporagnia are produced
- The hyphae are irregular in diameter, broad and ribbon-like, and aseptate-to-pauciseptate
- Sporangiospores are borne within spherical or cylindrical, sack-like sporangia, supported at the tips of sporangiophores

Root-Like Rhizoids are Formed

Yes / No

Sporangiophores borne nodally	Sporangiophores borne internodally. Prominent flare-like apophysis	Spherical conidia borne from the surface of a globose sporangium.	Sporangia borne in cylindirical sporangia radiating in daisy-head fashion from the surface of a spherical columella.	Sporangiophores broadly curved back on themselves	Sporangiophores often branched, with no swelling where sporangiophore and sporangium merge.
***Rhizopus* species**	***Lichtheimia* species**	***Cunninghamella* species**	***Syncephalastrum* species**	***Circinella* species**	***Mucor* species**

■ **DISPLAY 21-1** Algorithm showing genus identification of the *Zygomycetes*.

Preliminary Observations Suggestive of a Hyaline Mold

- Colonies rapidly growing, entire, cottony to granular, white or with varying pastel colors
- Hyphae are narrow, septate, hyaline, and have parallel walls

Conidia in Chains / **Conidia in Clusters** / **Conidia Borne Singly**

Colonies green and granular; phialides branching and blunt; conidia 2-3 µm, spherical.	Colonies green to yellow-tan or light purple; phialides tapered; conidia 2-3 µm elliptical, irregular in size and staining.	Colonies buff, granular, and radially rugose; 4-6 µm, circular, rough-walled annelloconidia with truncated bases.	Colonies gray-white to salmon-colored, glabrous; elliptical conidia arranged in clusters at the tip of the phialide.	Colonies fluffy, intense rose or purple pigment surface and reverse; large, multi-celled, sickle-form macroconidia.	Colonies spreading as green lawn without a border; balls of spherical conidia supported by tapered, finger-like phialides.	Colonies spreading as green or yellow lawn without a border; balls of spherical conidia borne laterally at tips of tapered phialides.	Colonies house-mouse gray and cottony; elliptical conidia, turning dark with age, borne from tips of delicate conidiophores.	Colonies gray-white and cottony; elliptical non-pigmented conidia borne from tips of delicate conidiophores, resembling *Blastomyces dermatitidis*.	Colonies gray-white and cottony; large, spherical, rough-walled macroconidia resembling *Histoplasma capsulatum*.	Colonies gray-white and cottony;small elliptical conidia in loose clusters, each attached by a delicate denticle to a geniculate conidiophore.
***Penicillium* species**	***Paecilomyces or Pleurostomophora* species**	***Scopulariopsis brevicaulis***	***Acremonium* species**	***Fusarium* species**	***Gliocladium* species**	***Trichoderma* species**	***Pseudallescheria boydi* complex**	***Chrysosporium* species**	***Sepedonium* species**	***Beauveria* species**

Genus *Aspergillus*

Sporulation from Top Half of Vesicle / **Phialides Circumferentially Placed** / **Cleistothecia Seen**

Phialides uniseriate	Philides biseriate Compact aleuroconidia produced.	Phialides biseriate Loose penicillus-like structures produced.	Conidia smooth and clear or buff. Roughened. Conidiophores may be biseriate or uniseriate.	Conidia rough and black. Condiophores are very long.	Colonies white and smooth. Conidiophores are short and pigmented brown.	Colonies variegated, green, yellow, white.
Colonies blue-green, granular and often rugose	Colonies cinnamon, granular and radially rugose	Colonies gray-green to tan with yellow patches	Colonies yellow/green, cottony or granular	Colony surface peppery black;		
Aspergillus fumigatus	***Aspergillus terreus***	***Aspergillus versicolor***	***Aspergillus flavus***	***Aspergillus niger***	***Aspergillus nidulans.***	***Aspergillus glaucus***

■ **DISPLAY 21-2** Algorithm showing laboratory identification of the rapidly growing hyaline molds.

1407

Preliminary Observations Suggestive of the Dermatophytes

- Colonies grow in 3-5 days with distinct margins
- Colony surface is cottony to granular in consistency. Surface pigmentation ranging from gray white to yellow-buff
- Hyphae are narrow, septate, and hyaline
- Combinations of microconidia and/or macroconidia are produced, the size, shape, and arrangement of which provide for genus/species identifications

MICROSCOPIC EXAMINATION

Macroaleureospores large, club-shaped, walls thin and smooth, multi-celled, walls thin and smooth.	Macroaleureospores multi-celled, walls thick and rough. Microconida few or absent.		Microconidia abundant; macro-aleureospores few or absent, walls thin and smooth			Aleureospores usuall not present; hyphae only observed.
No microconidia produced.	Macroaleureospores are spindle-shaped, pointed, curved tip.	Macroaleureospores are broad club-shape with rounded tip.	Microconidia spherical, uniform in loose clusters.	Microconidia tear-shaped, borne laterally from hyphae.	Microconidia irregular in size, balloon forms seen.	Antler hyphae and chlamydospores in chains observed.
Colony khaki-colored	Reverse of colony lemon-yellow	Colony cinnamon-colored		Wine-red pigment in agar	No growth on Trichophyton #1 agar	Slow-growing. Colony smooth on surface, heaped and partially submerged.
Epidermophyton flocossum	*Micrsporum canis*	*Microsporum gypseum*	*Trichophyton mentagrophytes*	*Trichophyton rubrum*	*Trichophyhton tonsurans*	*Trichophyton verrucosum*

■ **DISPLAY 21-3** Algorithm showing genus identification of the commonly encountered dermatophytes.

Preliminary Observations Suggestive of a Dimorphic Fungus

- Colonies grow slowly usually 7–14 days required for primary isolation
- Colony surface is gray-white and cob-web in consistency.
- Hyphae are delicate, septate, and hyaline. Arrangement in parallel bundles may be seen
- Species identification are made based on the size, shape, morphology, and arrangement of conidia

MICROSCOPIC EXAMINATION

Conidia, spherical, with thin-smooth walls, borne at the tips of short, straight conidiophores. (lollipops)	Hyphae segment into barrel-shaped arthroconidia, separated by non-staining cells. (alternate staining)	Tiny, microconidia produced early. Later, large, spiked spherical macroconida are important for identification.	Small, club-shaped conidia produced radially at the tip of a straight conidiophore, in a daisy head and/or sleeve arrangement.	Small, thin-walled conidia borne at the tips of long, straight conidiophores, when produced.
Blastomyces dermatitidis	*Coccidioides species*	*Histoplasma capsulatum*	*Sporothrix schenckii complex*	*Paracoccidioides brasiliensis*
CONFIRM SPECIES IDENTIFICATION BY YEAST CONVERSION (OR NUCLEIC ACID PROBE)				
Spherical yeast cells, 10–15 µm in diameter, with a single broad-based bud.	Large spherules, 75–200µm in diameter, containing 3-5µm endospores observed in stained tissue sections.	Tiny, spherical, hyaline, smooth-walled conidia arranged in clusters. Seen intra-cellularly in stained tissue sections.	Elongated, 2–8 µm in length, single-budding yeast, often referred to as cigar bodies.	Large, spherical, smooth, thick-walled mother cell with multiple buds, mariners wheel.

■ **DISPLAY 21-4** Algorithm showing genus identification of the dimorphic fungi.

1408

Preliminary Observations Suggestive of a Dematiaceous Mold

- Colonies grow in 3-5 days, are cottony or wooly, gray-brown or brown black; reverse jet black
- Hyphae are narrow, septate, brown-pigmented, and have parallel walls

Muriform Macroconidia				Transverse Macroconidia			Pycnidia or Conidia Single			
Multi-celled, muriform, macroconidia, beak or drumstick-shaped, borne in simple or branched chains, with the blunt end of one abutting the tapered end of the next.	Multi-celled muriform macroconidia borne singly from the tips of geniculate conidiophores, in a sympodial derivation.	Multi-celled muriform macroconidia, each borne singly from the tips of short conidiophores, simulating a bale of cotton on a stick.	Multi-celled muriform macroconidia, mature and immature, borne singly, aggregating in loose clusters.	3-4 -celled macroconidia divided by transverse septa only. The subterminal cells grow more rapidly, become enlarged, resulting in a boomerang appearance.	Conidiophores dark, simple or branched, geniculate, bearing cylindrical conidia in a sympodial pattern. Conidia with multiple cells, encased in thickened septal walls. Germ tubes from each end of germinating conidia.	Conidiophores and conidia similar in appearance to those of *Bipolaris* species. A single germ-tube is observed emanating at right angles from the germinating conidia. Any cell may germinate in the germ tube test, not just the terminal cells.	Conidiophores dark, erect, and geniculate. Multiseptate, elongated pencil-shaped conidia borne singly in a sympodial pattern. Each conidium has a dark, prominently protruding knob from the hilar cell.	Large, jet-black-spherical to oblong conidia borne singly from the tips of short, broad, conidiophores, each with a cup-like concavity within which the conidia rests.	Small, hyaline, spherical to elliptical conidia borne within sack-like, globose to subglobose pycnidia, scattered amid brown-staining septate hyphae with parallel walls.	Large perithecia, dark-brown to black, globose to flask-shaped, formed in the sub-stratum amid brown-staining, septate hyphae. Distinctive elongate, hairlike-hyphae protrude from the inside, simulating the legs of a spider
***Alternaria* species**	***Ulocladium* species**	***Stemphilium* species**	***Epicoccum* species**	***Curvularia* species**	***Bipolaris* species**	***Drechslera* species**	***Exserohilum* species**	***Nigrospora* species**	***Phoma* species**	***Chaetomium* species**

■ **DISPLAY 21-5** Algorithm showing laboratory identification of the rapidly growing dematiaceous molds.

1409

Preliminary Observations Suggestive of the Agents of Phaeohyphomycosis/Chromomycosis/Mycetoma

- Colonies grow in 3–5 days with distinct margins
- Colony surface is cottony to granular in consistency. Surface pigmentation gray-white to brown black; reverse jet black
- Hyphae are relatively broad, have parallel walls, are distinctly septate, and are dark yellow to brown in color
- Conidia are borne in chains, clusters, or singly from the tips or sides of phialides distinctive for each genus

MICROSCOPIC EXAMINATION

Conidia Borne in Chains			Conidia Borne in Clusters			Conidia Borne Singly		
Short branching chains of elliptical conidia with dysjunctor scars	Long chains (35+ cells) of elliptical conidia without dysjunctor scars	Colonies rapidly growing; no growth at 42°C. *Cladosporium* type sporulation	Phialides short, urn-shaped		Phialide long and tapered	Sympodial phialides bearing elliptical conidia (acrotheca-type sporulation)		Conidia borne laterally from the hyphae (rhinocladiella-type sporulation)
			Tip of phialide bottle-shaped	Tip of phialide saucer-shaped		Conidia arranged loosely	Conidia arranged tightly	
Cladophialophora carrionii	***Cladophialophora bantiana***	***Cladosporium* species**	***Phialophora verrucosa***	***Pleurostomophora richardsiae***	***Exophiala* species**	***Fonsecaea* pedrosoi***	***Fonsecaea compacta***	***Rhinocladiella* species**

*Different *Fonsecaea* species may show several combinations of cladosporium,-phialphora, acrotheca, and cladosporium-types of sporulation.

■ **DISPLAY 21-6** Algorithm showing genus identification of the agents of chromoblastomycosis, phaeohyphomycosis, and mycetoma.

1410

Preliminary Observations Suggestive of Yeasts

- Colonies grow in 24–72 hours
- Colony surface is smooth to mucoid; may develop feet or low aerial mycelium. Surface pigmentation ranging from white to yellow to rose red to black
- True hyphae may be present or absent.
- Pseudohyphae may or may not be present
- Blastoconidia are produced, the size, shape, and arrangement of which provide for genus/species identifications

MICROSCOPIC EXAMINATION

Pseudohyphae and Blastoconidia Produced		True Hyphae and Arthroconidia Produced		Hyphae Absent			Black Yeasts	
Germ Tube Test		Urease Test		Urease Test			Annelloconidia	
Pos	Neg	Pos	Neg	Pos	Pos	Neg	No	Yes
Chlamydospores on cornmeal Agar	No chlamydospores on cornmeal Agar			Caffeic Acid Test	Orange to red colonies		Dark-staining hyphae producing hyaline blastoconidia	Two-celled yeast cells with dividing cross septa (annellide)
				Pos / Neg				
Candida albicans	***Candida* species**	***Trichosporon* sp.**	***Geotrichum* sp.**	***Cryptococcus neoformans*** / ***Cryptococcus* species**	***Rhodotorula* species**	***Saccharomyces* sp. *Wickerhamomyce* sp. *Malassezia* sp. *Blastoschizomyces* sp.**	***Aureobasidium pullulans***	***Exophiala* spp.**
	Make presumptive ID based on patterns of growth on cornmeal agar.	Look for blastoconidia on corners of arthroconidia--rabbit ears on cornmeal agar	Look for right angle germ tubes from corners of arthroconidia (hockey sticks) on cornmeal agar	Look for irregular-sized yeast cells surrounded by capsular material	Inositol Neg			May produce hyphae and phialides when mature

CHAPTER 22

Parasitology

thePoint For additional ancillary materials related to this chapter, please visit the point.

Introduction

Risk and Prevention of Parasitic Infections

Clinical Manifestations of Parasitic Disease

Collection, Transport, and Specimen Processing

- Fecal Specimens
  - Preservation of Clinical Stool Specimens
  - Visual Examination
  - Processing Fresh Stool Specimens for Ova and Parasite Examination
- Examination of Intestinal Specimens Other Than Stool
- Examination of Extraintestinal Specimens
  - Sputum and Other Respiratory Tract Specimens
  - Urine and Body Fluids
  - Tissue Biopsies and Aspirates
  - Corneal Scrapings or Biopsy
  - Muscle Biopsy

Blood

Identification and Differentiation of Parasites

Life Cycles of Human Parasites
Direct Versus Indirect Lifecycles of Nematodes

Intestinal Protozoa

The Intestinal Amoebae
Amebiasis and *Entamoeba histolytica*
Entamoeba histolytica Versus *Entamoeba coli*
Serologic Diagnosis of Amebiasis
Nonpathogenic *Entamoeba histolytica*: *Entamoeba dispar*
Other Intestinal Amoebae
Other Protozoa *Blastocystis hominis*

Intestinal Flagellates
Giardia intestinalis (Formerly *Giardia duodenalis*)
Other Intestinal Flagellates

Ciliates: *Balantidium coli*

Coccidia
Cryptosporidium Species
Cyclospora cayetanensis
Cystoisospora belli
Sarcocystis Species

Nematodes

Ascariasis and *Ascaris lumbricoides*
Laboratory Identification

Trichuriasis and *Trichuris trichiura* (Whipworm)
Laboratory Identification

Enterobius vermicularis
Laboratory Identification

Hookworms
Laboratory Diagnosis

Strongyloidiasis and *Strongyloides stercoralis*
Laboratory Identification

Trichostrongylus Species

Capillaria philippinensis
Laboratory Identification

Cestodes

Taenia solium and *Taenia saginata*
Laboratory Identification
Diphyllobothrium latum: The Giant Fish Tapeworm

Serologic and Molecular Diagnosis of Parasitic Infections

Drugs Commonly Used in the Treatment of Parasitic Diseases

Introduction

Knowledge of common parasites dates back to antiquity. Worms fitting the description of *Enterobius vermicularis*, *Ascaris lumbricoides*, and the tapeworms have been mentioned in the ancient writings from many countries; additionally, certain symptoms known to be caused by these worms have also been described.[124] Ectoparasites, such as lice, fleas, and ticks, could not have been overlooked. Ruffer[217] reported the observation of calcified *Schistosoma haematobium* eggs in the remains of two mummies of the 20th dynasty in Egypt (1200 to 1090 BC), proving the existence of this infection in ancient Egypt. Chinese settlers in ancient times living in infected areas were familiar with the clinical picture of severe hookworm infection, which was called "lazy yellow disease."

Imaginary parasites have played an important role in medicine from ancient times. The pain of toothache was attributed to the work of a special boring "tooth-worm." Similarly, pus exuding from the ear and the eye resulted from the action of earworms and eye worms, respectively. Heartworms were responsible for sudden death; echo worms, possibly related to *Ascaris* balls in the intestine, were described, with the advice to those taking medication to remain silent during treatment for fear that the worm would be listening and not be removed.[124]

For centuries, spontaneous generation was thought to account for the origin of parasites, among other small creatures. It was commonly believed that out of a certain combination of the elements, parasites as well as other living organisms can be created. Tapeworms were known to be associated with the ingestion of raw meat; therefore, they were thought to take their origin in the stomach from macerated food, before being passed out in the stool. Since Roman times, tapeworms were thought to

be transformed strips of intestinal mucosa; according to many, *Ascaris* worms originated in phlegm. According to ancient theorists, something imperceptible or invisible is endowed with all potentialities—then through the action of a metaphysical principle, or of a primordial force, visible living beings can be created.[24]

An understanding of the protozoan parasites developed closely with improvements in the compound microscope. van Leeuwenhoek is credited with making the first observation of protozoa, a "motile animalcule" in the gut of a horsefly, shortly thereafter found to be present in his own feces. The current opinion is that he was looking at *Giardia duodenalis*, but this remains speculative. After these observations, however, over a century passed before progress in the study of the protozoans was made. With the widespread use of the compound microscope, by the turn of the 20th century, the morphology and life cycles of virtually all human parasites afflicting humans were well defined. The chronology of these advances is well presented in Foster's historical account for those who desire further reading on the subject.[76]

Despite the implementation of preventive measures to minimize the prevalence of parasitic diseases in most of the resource-limited countries, human parasites still account for inestimable loss of life, widespread morbidity, and the slowing of economic development. To quote from a report of the distribution of human parasites in China, "prevalence rates (of parasitic diseases) are of such staggering magnitude that the mind has difficulty in conceiving the descriptive statistics."[275] As further stated in this report, "the total number of protozoan and helminthic infections currently existing worldwide far outnumbers the total world population since multiple infections is the rule rather than the exception." Box 22-1 lists the estimated worldwide prevalence of human parasitic diseases, based on statistics published by the World Health Organization and from other sources.

In the United States, certain parasite species are encountered more frequently than others, and expertise in their identification must remain foremost. From a Centers for Disease Control and Prevention (CDC) intestinal parasite surveillance program, parasitic forms were found in 64,901 (15.6%) of the over 400,000 stool samples examined.[26] *Giardia intestinalis* (previously *G. duodenalis*) was found in 3.8% of all stool specimens, *Trichuris trichiura* ova in 2.7%, *Ascaris lumbricoides* ova in 2.3%,*Enterobius vermicularis* ova in 1.6% (not a true reflection of the incidence of this disease, since stool specimen examination is not the most sensitive method for establishing a diagnosis), and *Entamoeba histolytica* in 0.6% of all stool specimens. Diphyllobothriasis, sparganosis, and anisakiasis are also seen with increased frequency as ingestion of fresh fish becomes more in vogue. Private practitioners and public health officials must be on the alert for a possible increase in *Taenia* infections, including cysticercosis and other parasitic diseases, with the advent of more frequent travel and a more free exchange of foodstuff between North America and other countries.[223]

Bruckner and associates[21] reported a summary of the parasites found in a 6-month survey of stool specimen examinations on outpatients treated at Olive View Medical Center and Harbor General Hospital in Los Angeles (Box 22-2). In this study, other protozoa were identified in about 3% of all stool specimens; other nematodes were identified in 3% and cestodes in 0.5% of specimens. Similarly, Amin,[6] in a study conducted through the Parasitology Center in Tempe, Arizona, reported that one-third of 5,792 fecal specimens that were surveyed from 2,896 patients in 48 states and the District of Columbia during the year 2000 tested positive for intestinal parasites. Multiple infections with

BOX 22-1

Estimated Worldwide Prevalence of Parasitic Diseases[a]

Parasitic Disease	Global Prevalence (Millions of People)
Amebiases	500
Giardiasis	200
Ascariasis	800
Trichuriasis (whipworm)	800
Hookworm	900
Strongyloidiasis	50–100
Enterobius (pinworm)	42 (resource-rich countries)
Taenia (including cysticercosis)	1% of population in endemic countries
Diphyllobothriasis	5–10
Schistosomiasis	200
Fascioliasis	1–2
Clonorchiasis	20 (Asia)
Paragonimiasis	4–5
Malaria	100–270

Leishmaniasis	12
Trypanosomiasis (African)	20,000 new cases/year
Trypanosomiasis	15 (Chagas' disease)
Onchocerciasis	20
Filariasis	90
Echinococcus disease	1/100,000–150/100,000

[a]The incidence figures recorded here are rough estimates, intended only to illustrate the huge magnitude of infections. There are variations in numbers published in different sources, which probably reflect incomplete access to information or to differences in extrapolation of known data to the population at large.

BOX 22-2

Incidence of Parasites in Stool Specimens[21]

Organism	Olive View (1,350 Samples)	Harbor General (493 Samples)
	%	%
Giardia intestinalis	14.5	8.7
Endolimax nana	13.0	8.5
Entamoeba coli	10.5	7.7
Entamoeba histolytica	4.5	5.3
Ascaris lumbricoides	3.9	2.0
Hymenolepis nana	3.3	1.4
Dientamoeba fragilis	2.1	2.8

two to four parasitic species constituted 10% of 916 infected cases. *Blastocystis hominis* was found in 662 patients (72% of the 916 cases). Eighteen other species of intestinal parasites were identified—*Cryptosporidium parvum* and *Entamoeba histolytica/E. dispar* ranked second and third in prevalence, respectively. Prevalence

of infection was lowest (22% to 27%) in winter, gradually increased during the spring, and reached peak at 36% to 43% between July and October; then, prevalence gradually decreased to 32% in December. These studies provide examples of the types of parasites most likely to be encountered. The types of parasites present in a community are dependent on a number of variables, such as immigration and travel among the local populous.

Malaria is uncommon in the United States, usually found in individuals who have traveled into endemic areas. The CDC received reports of 1,687 cases of malaria with onset of symptoms during 2012 among persons in the United States or one of its territories.[268] Although this was a 12% decrease from the 1,925 cases reported in 2011, there has been an overall steady increase in the trend of the total number of cases. On average, there has been an increase of 28.6 cases per year since this surveillance began in 1973. *P. falciparum, P. vivax, P. malariae*, and *P. ovale* were identified in 54.4%, 16.6%, 3.2%, and 3.5% of cases, respectively. The remainders were either mixed or the species was not determined. The infections were acquired in Africa (n = 1,200), Asia (n = 200), Central America and the Caribbean (n = 68), South America (n = 48), or elsewhere or the location of the acquisition was unknown.

Because of expanded international travel and expanded military presence abroad, students and technologists working in diagnostic laboratories must maintain competence in the recognition of the agents of all parasitic diseases. Trade agreements between countries, some known to be endemic for parasitic diseases, also open up borders to the influx of goods, particularly foodstuffs that potentially are contaminated with animal parasites. Travelers from the United States to foreign lands must also remember that a variety of parasitic diseases are endemic in most resource-limited countries and that appropriate precautions must be taken to avoid infection. Unfortunately, accurate numbers of parasitic diseases and the prevalence of specific parasites are not readily available in many countries because of the lack of mandatory system of reporting for certain diseases. Parasitic diseases are often overlooked or misdiagnosed since symptoms are frequently nonspecific and have similarities with other diseases.

The frequent occurrence of certain parasitic infections in immunocompromised patients has spurred a new interest in laboratory parasitology among laboratory workers in nonendemic areas. Although this began with the introduction of HIV, the increasing number of transplant recipients and individuals receiving immunomodulating therapeutics for a variety of diseases contributes significantly to the cohort of immunocompromised patients in our communities.[253] For example, *Cryptosporidium* species were rarely recognized in humans before 1983, but in 1984, comprised 13.8% of all pathogenic protozoa. In a survey conducted at the New York Columbia-Presbyterian Medical Center of 41,958 stool specimens submitted for examination during the period 1971 to 1984, *Strongyloides stercoralis* was approaching the

incidence of *Trichuris trichiura* as the most frequently identified

1420

nematode. Harms and Feldmeier[111] postulate that HIV and parasitic infections may interact and mutually affect one another. For example, it is known that individuals with other sexually transmitted diseases, such as trichomoniasis, are at increased risk for contracting HIV, likely through alterations in mucous membranes.[170]

Risk and Prevention of Parasitic Infections

The risk factors for acquiring parasitic infections during travel to infested areas of the world and prophylactic measures have been reviewed by Warren and Mahmoud.[257] At lowest risk is the businessman who stays in first-class hotels in large cities for short periods. At the opposite end of the spectrum are volunteers and missionaries who live in tents or native dwellings in rural settings.

Most parasitic diseases are contracted either through ingestion of contaminated food or water or through the bite of an arthropod vector.[264] Drinking untreated water or brushing teeth with contaminated water can be particularly hazardous. Because most intestinal parasites withstand freezing, contaminated ice water is equally unsafe. This is a factor often forgotten by the traveler. They consider themselves safe by drinking soda, but forget the ice made with local, possibly contaminated water. Hot tap water is relatively safe because the infective forms of most intestinal parasites are heat-sensitive; however, tap water may not consistently exceed the critical temperature of 43°C (110°F); thus, its safety cannot be guaranteed. The ingestion of fresh, unpasteurized milk should also be avoided in endemic areas for a variety of reasons. Bottled, pasteurized milk and carbonated beverages are usually safe.

The ingestion of undercooked meats or raw/smoked fish can lead to infection with flukes, tapeworms, nematodes such as *Trichinella spiralis,* and protozoa such as *Toxoplasma gondii*. Raw vegetables are relatively safe if peeled before eating; however, lettuce and other leafy vegetables are particularly difficult to rid of infective parasitic eggs and cysts.

Precautions should be taken to avoid insect bites in tropical regions. The use of screens, bug bombs, insect repellents, and long-sleeved protective clothing is highly recommended. It is recommended by the CDC and other experts that insect repellents should contain ≥20% DEET (i.e., *N, N*-diethyl-*m*-toluamide or *N, N*-diethyl-3-methyl-benzamide), which is present in many commercially available products. Travelers to foreign countries, particularly to resource-limited countries in the tropical or subtropical climates, should consult the CDC Yellow Book, which is available online

(e.g., http://wwwnc.cdc.gov/travel/page/yellowbook-home-2014), concerning appropriate immunization programs and other notices to travelers.

Travelers to tropical regions should also be warned against swimming in natural freshwater estuaries. The infective cercariae of *Schistosoma* species abound in many freshwater rivers, lakes, and canals and can easily penetrate the unbroken skin of an unsuspecting wader. Chlorine in the concentration used in swimming pools may not make the water safe. Schistosomal cercariae that infest humans are not found in seawater; however, swimmer's itch may occur after wading in brackish water following penetration of the skin by cercariae of species that infect animals.

Examining physicians should make an effort to obtain a history of recent travel into regions where parasitic diseases are endemic and question patients carefully about the conditions under which they lived. The laboratory should be informed if a physician suspects a parasitic disease so that relevant specimens can be collected and the proper procedures performed for optimal parasite recovery. Serologic studies to screen for subclinical infections with *S. stercoralis* should be performed prior to initiating immunosuppressive drugs; a stool examination, albeit less sensitive, may also be considered.

Clinical Manifestations of Parasitic Disease

The most common symptom of intestinal parasitic infection is diarrhea that may be watery, bloody, and/or purulent. Cramping abdominal pain may be a prominent feature in diseases in which the bowel mucosa or wall is invaded by the parasite, such as in infections with hookworms, schistosomes, or intestinal flukes. Heavy infections with *Ascaris lumbricoides* can result in small bowel obstruction. Patients with tapeworms may be asymptomatic, except for weight loss despite an increased appetite and food intake. Bloating, belching, and steatorrhea may be seen in patients with giardiasis.[238,272]

Peripheral blood eosinophilia (15% to 50% or higher) is one of the more important markers for certain parasitic infestation. Eosinophilia may also be seen in various body secretions, such as sputum, diarrheal stools, suppurative exudates, or fluids from pseudocysts or various body cavities. However, the lack of eosinophils in either the blood or body fluids does not preclude the possibility of a parasitic disease, since eosinophilia is not a common manifestation for some diseases or the load of parasites may be minimal. Infections by helminthic parasites commonly generate an eosinophilic inflammatory response, whereas most protozoal infections do not. *Cystoisospora*, however, may be an exception to this rule. A generalized urticarial skin rash, thought to be a hypersensitivity reaction secondary to metabolic or lytic products of dead organisms that are absorbed into the circulation, may also suggest parasitic infection.

Although nonspecific, elevation in serum immunoglobulin levels, particularly IgE, may add support to the presence of a parasitic disease, particularly if coupled with eosinophilia.

Hepatosplenomegaly is a common manifestation of leishmaniasis (kala-azar) and liver fluke infection.[179] Portal hypertension, in particular, can be caused by *Schistosoma mansoni* and *S. japonicum*, with jaundice being a common presenting sign. Space-occupying cystic lesions of the liver, brain, and other organs can be found in amebiasis, echinococcosis, and cysticercus (i.e., infection by the larval stage of *Taenia solium*) infections.

Suprapubic pain, frequent urination, and hematuria are highly suggestive of *Schistosoma haematobium* infection. The presence of *Salmonella* serogroup Typhi in the urine is

evidence of an infection with *S. haematobium,* as it is thought that this bacterium colonizes the eggs of the parasite that are imbedded in the bladder wall and act as a nidus. Transient pneumonitis (i.e., Loeffler's pneumonia) may be experienced during the larval migratory phases of *Ascaris,* hookworm, or *Strongyloides* infections. This condition can be suspected if large numbers of eosinophils are observed in the sputum. When more severe cough, chest pain, and hemoptysis occur with the formation of parabronchial cysts, then the lung fluke infection should be suspected (i.e., paragonimiasis). Low-grade fever, weight loss, facial edema, and skeletal muscle pain indicate possible infection with *Trichinella spiralis*. Focal itching of the skin may occur at the sites of penetration of hookworm larvae or the cercariae of *Schistosoma* species.

Generalized constitutional symptoms are more commonly experienced after infections with blood parasites. Fever, chills, night sweats, lassitude, myalgias, and weight loss are common manifestations of malaria, leishmaniasis, and trypanosomiasis. Varying degrees of hepatosplenomegaly and lymphadenopathy are also seen with these diseases. Neurologic signs and symptoms secondary to encephalitis, meningitis, or localizing neuropathies may be seen in a variety of parasitic diseases. Central nervous system (CNS) involvement is commonly diffuse in African trypanosomiasis (i.e., sleeping sickness) and falciparum malaria, while space-occupying abscesses or cysts are more commonly seen with *Entamoeba histolytica*, *T. solium* (cysticercosis), and *Echinococcus granulosus* infections. Primary infections with *Toxoplasma gondii* present with lymphadenopathy and constitutional symptoms resembling acute mononucleosis, whereas reactivation disease in the CNS of the immunocompromised patient presents radiologically as a "ring-enhancing lesion" and often clinically as encephalitis/meningoencephalitis.[144] Cardiac myopathy is one of the most serious

complications of South American trypanosomiasis (*Trypanosoma cruzi*), of toxoplasmosis, and of several larval migratory infections.[165] Huge swellings of the legs, arms, and scrotum (elephantiasis) are common symptoms of filariases, because the adult worms block the lymphatic vessels, resulting in extensive chronic inflammation and fibrosis. Localized subcutaneous nodules or serpiginous inflammatory areas in the skin may be seen in diseases such as onchocerciasis, dracunculiasis, or cutaneous larva migrans, representing the larval migratory forms of hookworms of dogs and other animals.

A succinct overview of the clinical and laboratory aspects of several common and uncommon parasitic diseases has been published by Tan.[243]

Collection, Transport, and Specimen Processing

Appropriate specimens must be collected from the patient and transported to the laboratory sufficiently preserved to allow for the detection and identification of any parasites or parasite eggs. The diagnosis of parasitic infections relies in large part on macroscopic or microscopic examination of feces, urine, blood, sputum, and tissues. The implementation of reliable laboratory processing techniques is an integral step. It is not possible to review more than a few of the commonly used laboratory procedures that can aid in the recovery and identification of parasitic forms in clinical specimens. For a succinct, current, and practical overview of these procedures, the reader is referred to the section "Diagnostic Procedures" found in the current edition of the classic text by Garcia.[87]

Fecal Specimens

Stool specimens should be collected in a clean, widemouthed container with a tightly fit lid. Specimens that are mixed with water (i.e., contamination from the toilet bowel or bed pan) or urine are unsuitable because trophozoites may lose their motility or undergo lysis. Medications containing mineral oil, bismuth, antibiotics, antimalarials, or other chemical substances may compromise the detection of intestinal protozoa. Thus, examination of specimens must be delayed for one or more weeks after diagnostic procedures (barium enema) or therapy is stopped. Patients who have received a barium enema may not excrete organisms in their stools for at least one week following the enema. The container lid should be tightly affixed immediately after collection of the sample to maintain adequate moisture. Every specimen container must be properly labeled, as outlined in Chapter 1 of this text.

In obtaining fecal specimens for the examination of parasites, cathartics with an oil base should be avoided, since oils retard the motility of trophozoites and distort the

morphology of other forms. Specimens should also be collected before the administration of certain drugs and compounds that may compromise examination, or collection should be delayed until after the effects of such agents have passed. Such substances include antacids, kaolin, mineral oil and other oily materials, nonabsorbable antidiarrheal preparations, barium or bismuth (7 to 10 days needed for clearance of effects), antimicrobial agents (2 to 3 weeks needed for clearance), and dyes used for the visualization of the gallbladder (3 weeks needed for clearance).

The collection of three fecal specimens usually suffices to establish the diagnosis of intestinal parasitic diseases—two obtained on successive days during normal bowel movement and a third after a Fleet's phosphosoda or magnesium sulfate purge is recommended. No more than one fecal sample per day should be accepted. Some advocate that only a single specimen is required to diagnose most intestinal parasitic infections, unless there is a very high clinical suspicion of a parasitic infection. This approach depends on the experience of the microscopist and the parasitic load in the specimen, or it may be implemented if the patient becomes asymptomatic between sample collections.[87] Hiatt et al.[121] found that, with additional examinations, the yield of *Entamoeba histolytica* increased by 22.7%, of *Giardia duodenalis* by 11.3%, and of *Dientamoeba fragilis* by 31.1%. In contrast, Morris et al. evaluated results of the yield of 2,015 stool examinations to determine the yield of specimens obtained from patients who had been hospitalized >3 days.[178] They conclude that parasitic infections are unlikely in this patient population. Others have corroborated this finding, but exceptions exist for the elderly and patients with an immunocompromising condition. Posttherapy specimens should be examined 3 to 4 weeks after treatment of patients with protozoan infections and 5 to 6 weeks after therapy for *Taenia* infections.

1422

If a polymerase chain reaction (PCR)-based assay is requested on a stool specimen, implementation of the specimen transport protocol recommended by the manufacturer should be followed. The following suggestions are made for laboratory-developed tests:

1. Collect the specimen in the absence of typical preservatives used for the microscopic examination of stool (e.g., formalin and polyvinyl alcohol [PVA]).
2. Store and ship the specimen either refrigerated (4°C) or frozen (shipped with dry ice).
3. Alternatively, mix stool specimens in potassium dichromate (1:1 dilution with 5% w/v) or in absolute ethanol (1:1 dilution) and ship the specimen refrigerated.

Details of the extraction procedure and steps to follow in the DNA amplification have

been published.[113]

Preservation of Clinical Stool Specimens. Many stool specimens for examination of ova and parasites are collected at home, in a physician's office, or in a clinic some distance from the laboratory that performs the examination. Because trophozoites disintegrate rapidly after defecation and do not encyst, liquid stool specimens should be examined within 30 minutes after collection (not 30 minutes after receipt in the laboratory), and semiformed stools within 60 minutes, in order to detect motile trophozoites, particularly in suspected infections with *E. histolytica*. Formed stools, in which trophozoites are not expected, may be examined up to 24 hours after passage for the presence of helminth eggs. Stool specimens should never be frozen and thawed or placed in an incubator because parasitic forms may deteriorate rapidly.

Several preservatives are available for permanent fixation of stool specimens that are held for future teaching purposes or that must be sent to reference laboratories for analysis Chart 22-6. Box 22-3 presents the formulation and preparation of several currently used preservatives. The advantages and disadvantages are summarized below.

Formalin and Polyvinyl Alcohol. Stool specimens submitted in two vials, one containing formalin and the other PVA, had been the standard method used for the preservation of stool specimens for the morphologic examination for eggs, larvae, and protozoal parasites. These remain excellent preservatives, but as noted below acceptable alternatives exist. As noted in previous editions of this text, the eggs of *Trichuris trichiura* and the cysts of *Giardia* do not concentrate as well from PVA as from formalin-fixed material; similarly, the morphology of larval forms of *Strongyloides stercoralis* is poor in PVA-fixed stools and the oocysts of *Cystoisospora* (*Isospora*) *belli* may be undetectable.

Alternative Fixatives. Concerns over the toxicity of formalin and the difficulty of disposal of preservatives containing mercuric chloride have led several commercial companies to market alternatives to the gold standard, low-viscosity PVA (LV-PVA) reagent. In a study of 68 fresh stool specimens, collectively containing 31 parasitic forms, Jensen and colleagues[135] concluded that Proto-Fix (Alpha-Tec Systems, Vancouver, WA) and EcoFix (Meridian Diagnostics, Cincinnati, OH) were environmentally safe substitutes for PVA, resulting in the least parasite distortion. Pietrzak-Johnston et al.[203] also concluded that EcoFix is comparable to traditional LV-PVA for the visualization of protozoa in permanent-stained smears in a study of 20 positive stool specimens containing one or more parasites with stages consisting of eggs, larvae, and cysts; these findings confirmed the earlier findings of Garcia and Shimizu.[85] In each of these studies, the parasitic forms had well-defined nuclear detail, with certain parasites even easier to identify in the EcoFix-preserved specimens than in the traditional PVA-fixed samples.

When properly stained by standard techniques, the organisms have a blue-green to purple cytoplasm and red to purple-red chromatin against a green-staining background. Helminth eggs and larvae have a red or purple appearance.

More recently, several one-vial fixatives have been marketed. These have a number of advantages and relatively few limitations. Both the permanent smear and the concentrate can be made from a single vial. These fixatives are free of mercuric chloride, which makes disposal simpler and less expensive. Fortunately, most stool immunoassays are compatible with these fixatives. In some instances, these may be slightly more expensive than traditional fixatives. There are some color differences compared the staining of stool specimens with traditional stains, but this can be learned. Overall, these are an acceptable, environmental-friendly option to the traditional formalin/PVA fixatives. Several commercially available fecal concentration devices exist, including the FPC JUMBO tube and the FPC HYBRID connector systems (Evergreen Scientific, Los Angeles, CA), the PARA-SED concentration system (Medical Chemical, Torrance, CA), and the MACRO-CON concentration system (Meridian Diagnostics, Cincinnati, OH), in addition to an automated countertop workstation for the microscopic analysis of fecal concentrates (DiaSys, Waterbury, CT), as presented by Garcia.[84] Each of these products, in current use in clinical laboratories, can be recommended.

Visual Examination. Freshly passed stool specimens submitted for the detection of parasites should be visually examined for the presence of barium, oils, or other materials that may render them unacceptable for further processing. Patches of blood or mucin should be specifically selected for microscopic study because they may be derived directly from ulcers or purulent abscesses, where the concentration of amoebae or other parasites (e.g., *Balantidium*) may be highest. Visual examination can also be used to determine the appropriate procedures to perform. Formed stools are unlikely to contain trophozoites; thus, wet mounts are usually unnecessary and only concentrates need to be prepared. Helminth eggs, larvae, and protozoan cysts can be seen in the sediment of concentrates. The preparation of direct mounts should be limited to liquid to semiformed stools, and stained smears should be prepared to better demonstrate the internal structures of any parasitic forms observed. These approaches are described in more detail in the sections to follow.

Processing Fresh Stool Specimens for Ova and Parasite Examination. If fresh stool specimens are to be examined, which is uncommon, then liquid stool specimens should be examined within 30 minutes of passage (not within 30 minutes of arrival in the laboratory) in order to maximize the chance for observing motile trophozoites. Soft specimens, which may contain either trophozoites and/or cysts, should be examined within 1 hour of passage. In instances wherein there will be delays in examination (e.g., due to prolonged specimen transport), then the specimen should be preserved as

previously discussed to avoid possible disintegration of trophozoites. Formed stool specimens should be similarly preserved or can be kept for up to 1 day with refrigeration; it will not contain protozoal parasites, but may contain the eggs of helminths. Three types of preparation should be made for fresh liquid and soft stool specimens that have been submitted for parasitic examinations: (1) direct wet mounts, (2) concentrates, and (3) permanent-stained smears. Only concentrates and permanent-stained smears need to be prepared on stool specimens received in preservative.

1423

BOX 22-3

Common Fecal Specimen Fixatives: Formulations and Preparation

10% Formalin-Saline

In an appropriate storage container with a tightly fitting lid, add 100 mL of formaldehyde in 900 mL of 0.85% sodium chloride.

Advantages

- It is readily available, is easy to prepare, and serves as an all-purpose fixative.
- The prepared reagent has a long shelf life.
- The morphology of helminth eggs, larvae, protozoan cysts, and coccidial forms is well preserved.
- Formalin-preserved specimens are suitable for concentration procedures, epifluorescence microscopy, and performance of acid-fast, safranin, and chromotrope stains, and compatible with immunoassay kits.

Disadvantages

- Formalin-preserved specimens are not suitable for the preparation of trichrome-stained smears.
- Preservation is inadequate to maintain the morphology of protozoan trophozoites.
- Formalin levels must be monitored per current regulations, although these are usually very low and within established safe levels.

  Some parasitologists prefer a formula containing 5% formalin, which is purported to be less damaging to protozoa and emits less formalin vapor into the laboratory environment.

LV-PVA

Formulation

PVA, 10.0 g
95% ethyl alcohol, 62.5 mL
Mercuric chloride, saturated aqueous, 125.0 mL
Glycerin, 3.0 mL

Preparation

The liquid ingredients are mixed in a 500-mL beaker and the PVA powder added without mixing. Cover the beaker with paper or foil and allow the PVA to soak overnight. Slowly heat the mixture to 75°C and gently swirl for about 30 seconds until a light milky suspension is achieved.

Advantages

- The morphology of protozoan trophozoites and cysts is well preserved.
- Permanent smears stained with trichrome are easily prepared.
- Parasite forms are both preserved and adhere to the slide.
- Preserved samples remain stable for several months.

Disadvantages

- The morphology of helminth eggs and larvae, coccidian, and microsporidia is inadequately preserved.
- Mercuric chloride is the main ingredient, making it difficult and expensive to dispose of the fixative.
- The reagent is difficult to prepare in the laboratory.
- Cannot be used for concentration procedures or immunoassay kits.
- Unsuitable for acid-fast, safranin, and chromotrope stains.

MIF

Formulation

The two solutions must be prepared and stored separately and mixed together only immediately before use.

Solution I

Tincture of merthiolate, 1:1,000, 40 mL
Formaldehyde, 10% aqueous (USP), 5 mL
Glycerol, 1 mL
Distilled water, 50 mL

Solution II

Potassium iodide crystals (KI), 10 g
Iodine crystals (add after KI dissolves), 5 g of distilled water, 100 mL

Preparation

The shelf life of each solution is many months if stored at room temperature in a brown bottle. In a small vial, combine 9.4 mL of solution I with 0.6 mL of solution II just before use. Add the equivalent of about 1/4 teaspoon of fresh feces, and thoroughly mix with an applicator stick. Allow the suspension to settle

for 24 hours; then, with a pipette, remove a small portion of the pale orange middle layer and the deeper-staining lower layer for preparation of smears.

Advantages

- The reagent components both fix and stain the parasitic forms.
- Preparation is easy and shelf life is long.
- Suitable for concentration procedures.

Disadvantages

- As with formalin preservative, it is not suitable for preparation of permanent trichrome smears.
- The morphology of protozoan trophozoites is poorly preserved.
- The iodine component may interfere with other stains and fluorescence and may cause distortion of protozoa.

Sodium (SAF)

Formulation

Formaldehyde (37%–40% solution), 0.6 mL
Glacial acetic acid, 0.3 mL
Sodium acetate, 225.0 mg
Distilled water, 13.88 mL

Preparation

Dissolve the sodium acetate in the distilled water, slowly add the glacial acetic acid and formalin solutions, mix, and store. The shelf life is several months.

Advantages

- Easy to prepare and reagent has long shelf life.
- Suitable for acid-fast, safranin, and chromotrope stains.
- No interference with immunoassay kit assays.
- Free of the toxic chemical mercuric chloride.

Disadvantages

- Albumin-glycerin or similar additive must be used for adhesion of specimen to slides.
- Permanent stains are inferior to those obtained with PVA or Schaudinn's fixative.

Schaudinn's Fixative

Formulation

Mercuric chloride, saturated aqueous solution ($HgCl_2$), 110 g
Distilled water, 1,000 mL

Preparation

Into a beaker in a water bath placed in a hood, boil the mercuric chloride until dissolved, and let stand for several hours until crystals form.

Schaudinn's Fixative (Stock)

Mercuric chloride, saturated aqueous solution, 600 mL

Ethyl alcohol, 95%, 300 mL

Add 5 mL of glacial acetic acid per 100 mL of stock solution just before use.

Advantages

- Protozoan trophozoites and cysts are well preserved.
- Permanent-stained smears are easily prepared.

Disadvantages

- Mercuric chloride is the main ingredient, making it difficult and expensive to dispose the fixative.
- The morphology of helminth eggs and larvae, coccidian, and microsporidia is poorly preserved.
- Albumin-glycerin or a similar additive must be used for adhesion of the specimen to slides.
- Less suitable than other preservatives for concentration procedures.

Modified PVA (Copper or Zinc)

Advantages

- Suitable for making permanent trichrome-stained smears.
- No mercuric chloride.

Disadvantages

- Inconsistent staining.
- Organism morphology poor, particularly with the Copper modifications.

1425

Single Vial Fixatives

(Includes EcoFix, Unifix, Proto-fix, STF, and Parasafe)

Advantages

- Both the concentrate and the permanent smear can be made from a single vial.
- No mercuric chloride.
- Many immunoassays can be performed with this fixative.

Disadvantages

- There are some limitations regarding which stains can be used with which fixatives.
- May be more expensive.
- Some staining differences and possible staining inconsistencies.

Direct saline mounts are valuable for the detection of motile trophozoites. Helminth eggs and larvae and protozoan cysts may also be observed in direct saline mounts; the addition of a drop of iodine may aid visualization of these forms. For fecal specimens that are watery or liquid, centrifugation of the specimen alone may suffice because trophozoites do not concentrate well from liquid stools, and cysts that may be present will be seen in the sediment. The direct examination may be omitted for the processing of semiformed stools since any parasitic forms present will still be detected in the concentrated preparation.

Final identifications of parasites should not be made from examination of direct mounts alone; rather, permanent-stained smears should be prepared and examined to confirm the characteristic morphologic features. Permanent stains should be prepared on any specimens for which a delay in transport is anticipated (see below).

Preparation of Direct Wet Mounts. The wet mount procedure is useful for the identification of protozoan trophozoites, cysts, oocysts, and both helminth eggs and larvae. The saline mount is prepared by emulsifying a small portion of fecal material in a drop of physiologic saline on a microscope slide, then overlaying the mixture with a coverslip. Ideally, two mounts can be prepared on the same slide, the second one using iodine. Mounts should be just thick enough that newspaper print can be read through the slide. If the mounts are too thick, particularly iodine preparations, parasitic forms often stain poorly and may be difficult to differentiate from background debris. If the smear is too thin, parasitic forms in low numbers may be diluted out and missed during routine microscopic examination. Saline mounts are also prepared to observe the motility of trophozoites. Protozoan cysts also appear more refractile in saline than in iodine preparations. The internal structures of trophozoites or protozoan cysts are often poorly delineated in saline preparations, making definitive identification difficult. Permanent-stained smears should always be prepared, particularly if *Giardia* is suspected.

The oocysts of *Cyclospora* species may be observed microscopically in wet preparations using UV fluorescence microscopy, on which they appear intensely blue (UV excitation filter set at 330 to 365 nm). The use of both brightfield and fluorescence microscopy provides an efficient and reliable approach to secure this diagnosis. Additional smears should also be prepared in the event that an identification is not made from the original preparations.

Iodine is used as a stain to highlight the internal structures of intestinal parasites. One percent solutions of iodine (e.g., D'Antoni's iodine, prepared by adding 1.0 g of potassium iodide and 1.5 g of powdered iodine crystals to 100 mL of distilled water) should be used. Lugol's iodine, used for Gram's stains, in full strength is too strong to stain protozoan forms but can be used if a freshly prepared solution is diluted 1:5 with

distilled water. Examination of iodine mounts alone, however, may not be satisfactory because trophozoites are no longer motile. Both saline and iodine mounts can be prepared on a single microscope slide, making it easy to compare any suspect forms.

If desired, the coverslip(s) may be sealed. A preparation of molten petroleum jelly and paraffin in a 1:1 ratio can be applied to the margins of the coverslip using the tip of a cotton-tipped swab. The paraffin and petroleum jelly must be heated to approximately 70°C to mix both just before use. The seal is made by first securing the four corners by placing a drop of hot sealant to anchor the coverslip. A thin layer of the mixture is then spread around the edges. Sealing the coverslip keeps organisms from moving when using oil immersion objectives and prevents the preparation from drying out. Other suitable sealing preparations can be used, if desired (e.g., clear nail polish).

The entire coverslip area should be systematically scanned with an overlapping back and forth motion, using the 10× objective. If a suspect form is observed, a higher magnification may be necessary to study internal details.

Fecal Concentration Methods. Eggs, cysts, and trophozoites are often in such low numbers in fecal material that they are difficult to detect in direct smears or mounts;

therefore, concentration procedures should always be performed. The two most commonly used are (1) flotation and (2) sedimentation. Both are designed to separate intestinal protozoa and helminth eggs from excess fecal debris. The details for these procedures are found in Chart 22-1.

Flotation techniques. Flotation techniques are less commonly used in clinical laboratories than the sedimentation procedure. The flotation method uses solutions that have higher specific gravity than the organisms to be floated so that certain parasitic forms rise to the top, while fecal debris sinks to the bottom. Most commonly, zinc sulfate with a specific gravity of 1.18 is used. In comparison, the specific gravity of protozoa and many of the helminth eggs is lower. For example, the specific gravity of a hookworm egg is 1.055, an *Ascaris* egg 1.110, a *Trichiura* egg 1.150, and *Giardia* cysts 1.060.

The chief advantage of the flotation technique is that it produces a cleaner material in which parasitic forms are easy to distinguish. The major disadvantages are that the walls of eggs and cysts will often collapse, thus hindering identification; also, some parasite eggs do not float. Also, the operculated trematode and cestode eggs may not be detected because the high concentration of the zinc sulfate suspension causes the opercula to open and the egg to fill with fluid and sink to the bottom of the tube. For this reason, both the top filtrate and the bottom sediment should be examined microscopically.

Bartlett and associates[13] have described a modified zinc sulfate flotation technique that may be adapted for use with specimens that have been formalin-fixed. The formalin fixation not only prevents operculated eggs from opening so that they can be detected in flotation eluates, but it also prevents the distortion of morphology caused by salt solutions of high specific gravity.

Sedimentation techniques. Solutions of a specific gravity lower than the parasitic organisms are used, thus concentrating the eggs, cysts, and other forms in the sediment. Sedimentation techniques are recommended for general diagnostic laboratories because they are easier to perform and less prone to technical errors.

The concentration of intestinal parasites by either gravity or centrifugation leads to the efficient recovery of protozoa, eggs, and larvae, although they may be more difficult to detect in microscopic mounts and in stained smears because of the comparatively large amount of background debris. Ethyl acetate has been substituted for diethyl ether in the formalin concentration procedure used in most laboratories. Young and associates[284] have demonstrated that ethyl acetate is less flammable and less hazardous to use than diethyl ether and that the capability to concentrate cysts and eggs is not compromised. Care must be taken during the washing steps in the procedure to decant the supernatant carefully; otherwise, a significant number of parasitic forms can be lost. Neimeister et al.[185] have demonstrated that Hemo-De, available from commercial distributors, is an effective replacement for ethyl acetate. Hemo-De is a solvent with a specific gravity and solubility similar to that of ethyl acetate; it is nonflammable, nontoxic, and biodegradable (classified as GRAS [generally regarded as safe]) by the US Food and Drug Administration).

Permanent-Stained Smears. Although temporary wet mounts of fecal material for direct microscopic examination facilitate the rapid detection of intestinal parasites in fecal specimens, smaller protozoan organisms may be missed. Therefore, Garcia[87]and others recommend that permanent stains be prepared as part of the examination of every stool specimen submitted for parasitologic examination. The detection and identification of *Entamoeba histolytica, Giardia duodenalis,* also known of as *G. lamblia* and *G. intestinalis* and other protozoan infections can be greatly enhanced through the examination of permanent smears.[231] The morphology of cysts and trophozoites is better visualized in stained smears. Permanent mounts may also be prepared from stained smears, for future use in teaching collections, and for future consultation with experts when unusual forms are observed.

Two types of permanent stains are commonly used to visualize intestinal protozoa in fecal smears: (1) the iron hematoxylin stain and (2) the modified (Wheatley's) Gomori's trichrome stains. The iron hematoxylin stain is the time-honored technique used for the most exacting definition of the morphology of intestinal parasites. The staining procedure is somewhat difficult to control and is best performed by an experienced person to achieve optimum results. Therefore, the trichrome stain is

widely used in diagnostic laboratories. It is easy to perform, and good results are obtained with both fresh and PVA-preserved fecal material. The trichrome staining procedure is reviewed in detail in Chart 22-2.

There are parasitic diseases caused by protozoa that are not detectable or not readily detected in the iron hematoxylin or modified trichrome stain. These include cryptosporidiosis, which most commonly occurs in immunocompromised patients and cyclosporidiosis, which is usually food-borne.[267] Infections by the microsporidia, which were initially thought to be parasites but are now known to be fungi, are covered in the chapter dedicated to mycology.

New causes of diarrhea were discovered early in the HIV epidemic, which are now known to infect a wider range of individuals. Foremost among these were *Cryptosporidium* species. *Cystoisospora belli*, formerly known of as *Isospora belli*, is also known to infect similarly immunocompromised populations. Finally, *Cyclospora*, a parasite usually associated with food-borne disease, was described, and may infect immunocompetent and immunocompromised hosts alike. These organisms all stain well with the modified acid-fast stain, in which 1% sulfuric acid is used as the decolorizer. Additionally, a fluorescent antibody method is also available for the visual detection of *Cryptosporidium* species. In many products, this is available in combination with a monoclonal antibody directed against *Giardia duodenalis* cysts (discussed in detail later in this chapter). Either fresh or formalin-fixed material must be used to perform the acid-fast and/or the monoclonal antibody techniques; PVA-preserved specimens cannot be used.[84]

Examination of Intestinal Specimens Other Than Stool

Parasites such as *Giardia duodenalis* and *Strongyloides stercoralis* commonly inhabit the duodenum and jejunum. Specimens of duodenal contents may be required to demonstrate these organisms. A saline wet mount can be prepared from the aspirated material and examined microscopically. If motile organisms are seen, examination of a second iodine preparation may be helpful to highlight the internal structures so

that a definitive identification can be made. Again, the examination of fresh duodenal or jejunal aspirates is infrequently performed. More commonly, a small intestinal biopsy will be performed and evaluated by the surgical pathologist.

Duodenal contents were more commonly examined in the past by the string test.[137] The implement used is a weighted gelatin capsule containing a coiled length of nylon string (commercially available as Enterotest). One end of the string protrudes from the capsule, which is taped to the face of the patient. The capsule is swallowed, and peristalsis carries the weighted string into the duodenum. After 4 to 6 hours, the string

is removed and any bile-stained mucous adhering to the distal end is used to prepare direct mounts and stained smears for microscopic study. The examination of duodenal contents should be performed only on patients with signs and symptoms suggestive of giardiasis. McHenry et al.[172] obtained duodenal aspirates from 144 patients who were undergoing endoscopy for other reasons. *Giardia duodenalis* was recovered in only one patient (0.7%).

Enterobius vermicularis infects the large intestine, but the female migrates and deposits eggs in a perianal location. This infection is best detected using cellulose tape or similar, now commercially available products. In brief, the adhesive surface of a 3- or 4-inch strip of clear cellulose tape is applied to the perianal folds of a patient in whom pinworm infection is suspected Chart 22-5. Specimens collected in the early morning, soon after the patient arises and before bathing, are optimal for detecting ova. A tongue blade can be used to provide a firm backing for the tape. The tape is then placed adhesive side down on a glass microscope slide and examined for the characteristic ova of *E. vermicularis*. A commercially available "paddle" with a flat, sticky surface (BD Falcon SWUBE Pinworm Paddle) can be used to obtain the specimen. The microscopic appearance of a positive preparation is illustrated in Figure 22-1.

Examination of Extraintestinal Specimens

Sputum and Other Respiratory Tract Specimens. On rare occasions, the larval stages of hookworm, *Ascaris lumbricoides* or *Strongyloides stercoralis*, or the eggs of *P. westermani* may be seen in sputum or other respiratory tract specimens. The preparation of a direct saline mount is usually sufficient. If the sputum is unusually thick or mucoid, an equal quantity of 3% *N*-acetyl-L-cysteine can be added to liquefy the specimen, which is then mixed for 2 or 3 minutes and centrifuged. After centrifugation, a wet mount of the sediment is prepared for microscopic examination. If examination of the sputum specimen is delayed for any reason, 10% formalin should be added to preserve helminth eggs or larvae. The organisms present in the respiratory tract may also be identified by the cytopathologist.

■ **FIGURE 22-1** Photomicrograph of a positive cellulose tape preparation from a patient with suspected pinworm infection, illustrating several oval, thin-walled eggs of *Enterobius vermicularis*.

Urine and Body Fluids. Samples of large volume should be allowed to settle for 1 or 2 hours. About 50 mL can then be taken from the bottom sediment for centrifugation. The highly concentrated sediment can then be examined by preparing a direct wet mount. If objects suggestive of parasites are seen, examination of an iodine mount or a stained preparation may be helpful in highlighting the diagnostic internal structures.

Tissue Biopsies and Aspirates. Cutaneous ulcers (as seen in leishmaniasis), skin nodules (seen in onchocerciasis and in *Mansonella streptocerca* infections), and lymph nodes may be either aspirated with a fine needle or biopsied. In suspected cases of cutaneous leishmaniasis, material should be aspirated with a needle and syringe from beneath the ulcer bed. A "skin snip" can be obtained to diagnose subcutaneous leishmanial disease by grasping a small portion of skin with a forceps or elevating it with the tip of a needle. The tip of the small "cone" of skin is then sliced with a scalpel. The snip should be sufficiently deep to include the dermal papillae; however, it should not be so deep as to produce extensive bleeding.

All biopsy tissue must be submitted to the laboratory without the addition of formalin fixative. If a delay in processing cannot be prevented, the specimens should

be placed in PVA fixative. If the specimen is soft, a small portion should be scraped free and placed in a drop of saline for wet mount examination. Impression smears should also be prepared, performed by pressing a freshly cut surface of the tissue against the surface of a glass slide and placing the slide immediately into a fixative, such as Schaudinn's solution. Trichrome and other stains can be applied.

The remaining portion of the biopsy material should be submitted in 10% buffered formalin for histologic examination. As denoted above, the histologic examination of intestinal biopsies may reveal a wide variety of infections. The eggs of *Schistosoma, Cryptosporidium, Giardia, Entamoeba histolytica*, and in some instances cross sections of *E. vermicularis* may be seen in biopsied materials, among others. Other examples include the evaluation of excised or biopsied pulmonary specimens which may disclose the larvae of *Strongyloides,* the eggs and/or worms of *Paragonimus,* or the degenerate nematode *Dirofilaria immitis.* The infectious disease pathologist is a partner with the microbiologist in securing the cause of infectious diseases. Collaborative communication translates into the best patient care possible.

Corneal Scrapings or Biopsy. Corneal scrapings are helpful in making the diagnosis in suspected cases of *Acanthamoeba* keratitis. The corneal scrapings, obtained by

a physician, are placed on a slide and fixed in methyl alcohol for 3 to 5 minutes. Garcia[87] suggests that staining should be done using calcofluor white, a commercially available textile whitener. A solution of 0.1% calcofluor white and 0.1% Evans blue are dissolved in distilled water. A few drops of this solution are placed on the methanol-fixed smear for 5 minutes. The slide is then tipped and the fluid drained into an absorbent paper towel; a coverslip is added and examined for characteristic amebic cysts (trophozoites do not stain), which will have an apple-green or blue-white fluorescence depending on the exciter light/filter combination used.

Muscle Biopsy. The characteristic spiral larval forms of *Trichinella spiralis* are best demonstrated in a tease mount made from a skeletal muscle biopsy (Image Plate 22-11G). Garcia[87] suggests that the biopsy material be treated with a digestion fluid before examination. The digestion fluid is prepared by adding 5 g of pepsin to a mixture of 1,000 mL of distilled water and 7 mL of concentrated HCl. The tissue is placed in a widemouthed Erlenmeyer flask, and digestion fluid is added in a ratio of 1 part tissue to 20 parts fluid. The digestion mixture is held at 37°C for 12 to 24 hours. After digestion, examine a few drops of the eluate under the microscope for the presence of larvae. If none are seen, centrifuge a 15-mL aliquot of the mixture and examine the sediment.

Blood. Although the examination of fresh blood is rarely performed, it can be done for the evaluation of motile parasites. A drop of anticoagulated blood can be placed on a microscope slide, a coverslip put in place, and the specimen microscopically examined for large, often motile, extra-erythrocytic forms, such as trypanosomes and microfilariae. The presence of microfilariae in the circulating blood exhibits a marked periodicity depending on the species involved; therefore, the time of specimen collection is critical. If a filarial infection is suspected, the optimal collection times for demonstrating microfilariae are *Loa loa*—midday (10 AM to 2 PM); *Brugia or Wuchereria*—at night, after 8 PM; *Mansonella*—any time; *Onchocerca*—any time. There is no advantage for the direct evaluation of blood over the standard evaluation of thick and thin blood films. Additionally, such an evaluation exposes one unnecessarily to blood-borne pathogens. Therefore it is not recommended.

When first examining a stained blood film, screen the smear under low-power magnification (×250 or less) in search for these larger parasitic forms that may be missed if only oil immersion is used. The morphology of intraerythrocytic parasites (i.e.,*Plasmodium* and *Babesia*) is best observed in Wright- or Giemsa-stained peripheral blood films.

Blood smears prepared for the detection of blood parasites should be collected specifically for that purpose. Smears should be prepared on anticoagulated blood specimens as soon after collection as possible since the long exposure to the anticoagulant may distort the morphology of mature schizonts and gametocytes. Also, exflagellation may occur and sexual stages may develop during storage of the blood sample in a laboratory environment, which is cooler than body temperature. Exflagellated gametocytes may be confused microscopically with *Borrelia* species. Merozoites, particularly those of *Plasmodium vivax,* may be released from mature schizonts and reinvade erythrocytes, where they may appear similar to the small "accolade" ring forms of *Plasmodium falciparum*. These are the reasons that the collection of capillary blood samples with the immediate preparation of thick and thin blood films is preferable. This is commonly performed in field studies, but rarely in the hospital environment.

Both thick and thin blood films should be prepared. The thick film is the sensitivity portion of this assay and is usually simply used to detect the presence of a blood parasite. In contrast, the thin film is the specificity arm of the assay and is used to identify the etiologic agent, often to the species level.

Thick smears consist of a thick layer of dehemoglobinized (lysed) erythrocytes. A thick smear of proper density is one that allows one to barely read the words of newsprint through the film. Thick blood smears contain a 30× concentration of parasitic elements compared with an equal area of a thin smear. Thus, the preparation of thick smears is particularly useful in detecting malarial parasites in light infections; however, the morphology of trophozoites is often compromised, making it difficult to make a species identification. If elements suspicious for malarial parasites are

observed, a thin smear should be prepared to make a species identification.

The thick smear is prepared by placing two or three drops of blood on the surface of a glass microscope slide to cover an area the size of a dime. If capillary blood is obtained from a fingerstick, it should flow freely; "milking" of the finger should be avoided. Stir the drop, if uncoagulated blood is used, for about 30 seconds to prevent formation of fibrin clots. If anticoagulated blood is used, which currently is almost the universal practice, stirring is not necessary because fibrin strands do not form. Potassium ethylenediaminetetraacetic acid (EDTA) is the anticoagulant of choice.

Lay the slides flat on the tabletop and allow the smears to dry thoroughly, as any residual moisture may cause the film to detach. The time to drying will take at least 30 minutes, but may take much longer in a humid climate. The drying time can be shortened by ventilating the smear with a fan or hair dryer set on "cool." The chance for detachment is increased with smears made from anticoagulated blood. Once the film is dry, the blood should be laked by placing the slide in water or a buffer solution immediately before staining.

The thin blood smear is used primarily for the definitive genus- and species-level identification of the blood parasite present. It is prepared exactly as a peripheral smear is prepared for a differential blood count. At least two smears per patient should be prepared. Thin smears consist of blood spread in a layer such that the thickness decreases progressively toward the feathered edge, where the erythrocytes do not overlap. The thin-feathered edge should be 1.5 to 2.0 cm long. Care must be taken in preparing the thin film to see that the feathered edge is evenly spread and free of holes, streaks, or other artifacts. The preparation of thin and thick blood smears is described in Chart 22-3. At least three specimens should be taken on successive days if initial samples are negative for parasites.

Garcia (personal communication) has described a technique by which both a thick and thin smear can be accomplished on the same slide. Two or three drops of anticoagulated blood are placed at one end of a glass slide, then with an applicator stick, smear the drop over the surface of the remainder of the slide using a continuous rolling motion.

1429

Both thick and thin areas will develop where the concentric circles intersect. Both thin and thick smears should be stained as soon as possible after preparation, always within 48 hours, with Giemsa or Wright's stain. The pH of both the stain and the buffer must be carefully controlled and should be between 7.0 and 7.2. The stains used in the routine hematology laboratory are closer to pH 6.8, eliminating any possibility of observing Schuffner's dots or Jame's stippling. The use of automated staining instruments is to be avoided. Thick smears may require a slightly longer exposure to the stain than the time used for the thin smear preparations.

It is recommended that at least 300 oil fields be microscopically examined at 1,000× magnification on the thin film and approximately 100 fields on the thick film. The number of organisms may be very few in patients in relapse, in those who have an early infection, or in those who have received inadequate treatment or partial prophylaxis. In these instances, the number of fields examined should be doubled. Proper interpretation of the thick smear requires considerable experience, and positive controls for comparison should be made available.

Identification and Differentiation of Parasites

Although certain clinical signs and symptoms may suggest the possibility of a parasitic disease, the final diagnosis is made by demonstrating the causative organism in properly collected specimens. Because many artifacts resemble parasitic forms, the final identification must always be made based on well-established morphologic criteria. Microscopic interpretations, in particular, cannot be left to guesswork, and a laboratory diagnosis of a parasitic disease should not be rendered until adequate identifying features can be clearly and objectively demonstrated. Select artifacts that have features suggesting true parasites are illustrated in Image Plate 22-1.

Traditionally parasites are separated into various morphologic and/or taxonomic groups (e.g., protozoa, nematodes, cestodes, trematodes, etc.). One should recognize that even closely related or taxonomically grouped parasites may have very different modes of infection and mechanisms of transmission. For example, even though hookworms and pinworms are taxonomically included with the nematodes, there are considerable differences in their life cycles, modes of infection, and the seriousness of the diseases they cause. In fact, each species of parasite should be considered unique unto itself, as attempts to group them by whatever criteria will meet with some degree of failure.

The microscope will be the tool most commonly used to identify parasites. Therefore, it should have an eyepiece fit with an accurately calibrated ocular micrometer. The procedure for calibrating an ocular micrometer is presented in Chart 22-4. The ability to measure exactly the size of parasitic forms encountered in clinical specimens is often critical for the correct identification of the parasites. In the discussions that follow, emphasis is placed on the size ranges of various diagnostic parasite forms that are reviewed.

Life Cycles of Human Parasites

Many of the life cycles of human parasites are included in the sections on the laboratory identification that follow. It is not intended that students memorize every phase of every life cycle; rather, these descriptions are helpful in pinpointing the

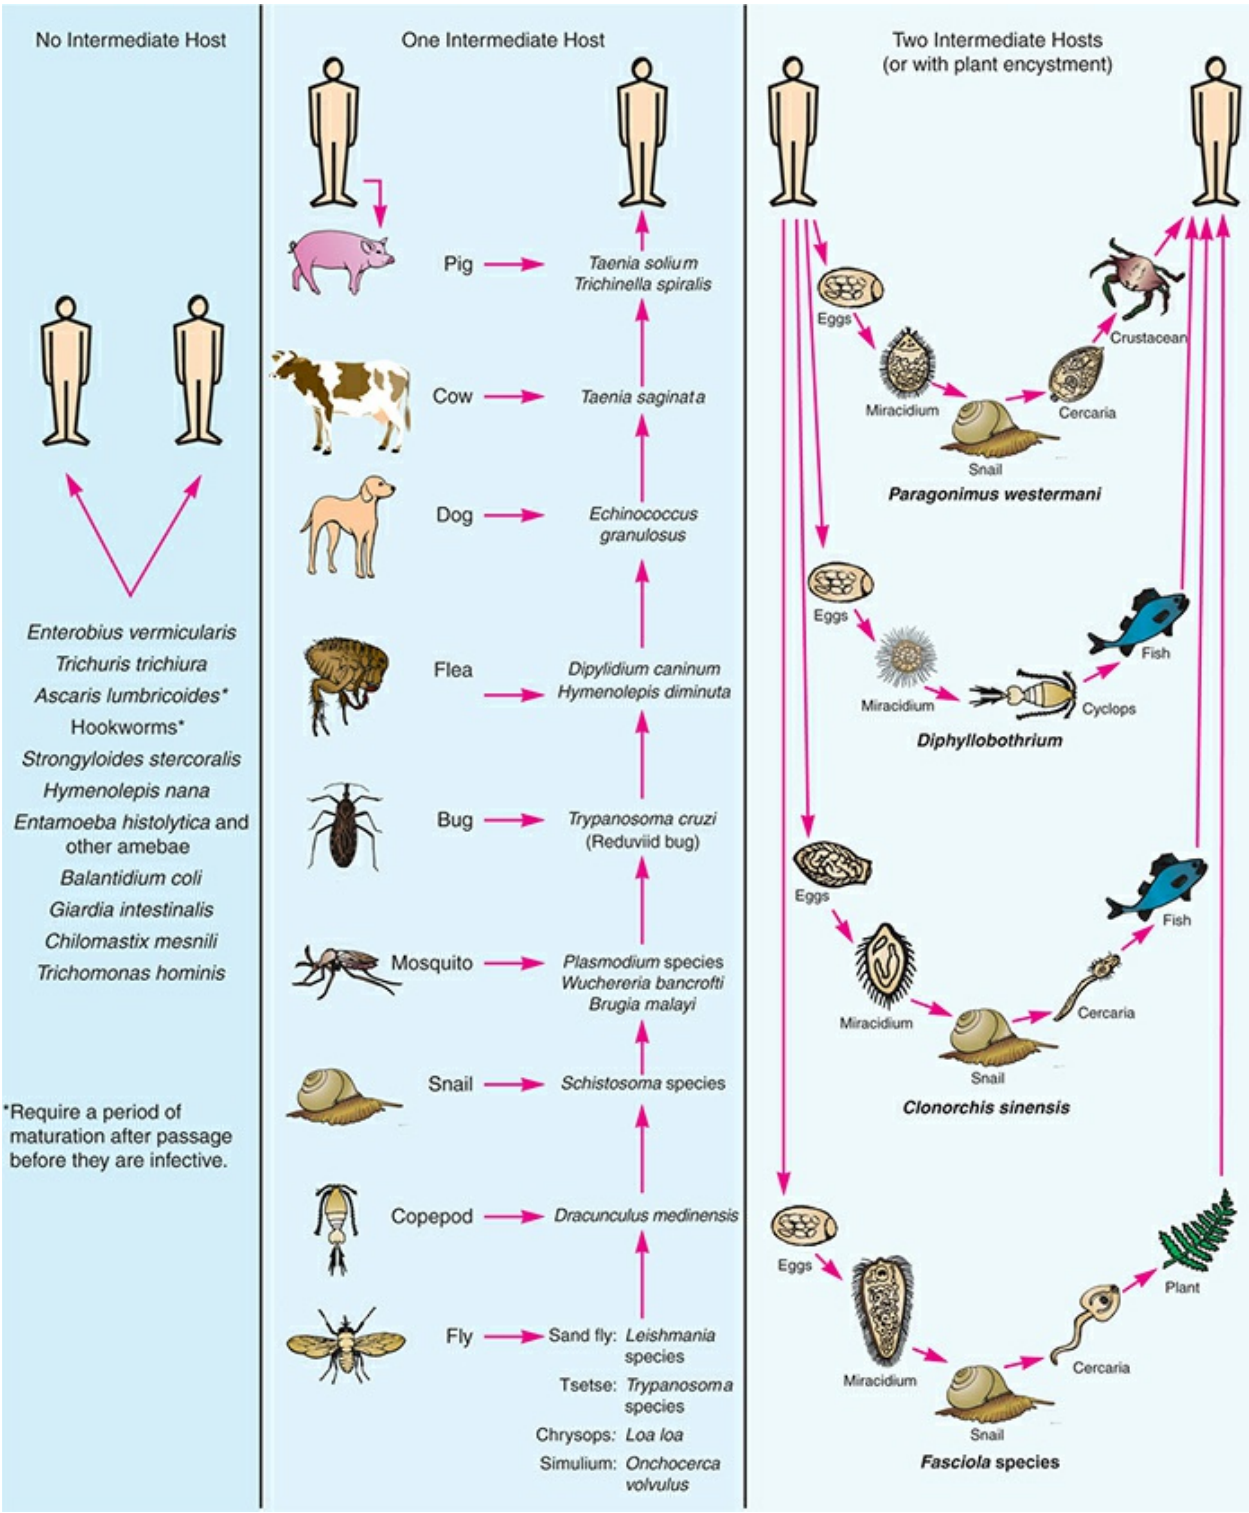
infective, invasive, and diagnostic forms of each parasite, an awareness of which is necessary to make a diagnosis. DPDx is an excellent resource for students and practitioners alike. This site (http://www.cdc.gov/dpdx/) is maintained by the Division of Parasitic Diseases and Malaria of the CDC. It contains up-to-date information, color images, and illustrated life cycles of the most common, and some less common, parasites.

Figure 22-2 has been designed to provide an overall orientation to the life cycles of parasites of importance to humans. Parasites can be divided into three major groups on the basis of their life cycles: (1) those having no intermediate hosts, (2) those using one intermediate host, and (3) those for which two intermediate hosts are necessary.

Parasites that have no intermediate host are transmitted directly between humans, or animal to animal, through fecally contaminated food or water. This is true for most of the intestinal protozoal parasites and for some nematodes such as *Enterobius vermicularis* and *Trichuris trichiura*. Human-to-human transmission occurs through the transfer of cysts or ova that can survive external environmental conditions and contaminate food and water supplies. The eggs of *Ascaris lumbricoides*, *Trichuris trichiura*, and the hookworms require a period of maturation after the stool is passed into the environment before they become infective.

Direct Versus Indirect Lifecycles of Nematodes. *Enterobius vermicularis* and *Trichuris trichiura* are the two common human parasites with a direct lifecycle. This means that once the egg is ingested and the internal larva has emerged, it develops within the intestinal tract into the adult form. In contrast, in indirect life cycles, the immature larvae migrate to and through the lungs after which it is swallowed and then develops into an adult form in the intestinal tract. This may occur with parasites transmitted through the fecal–oral route, such as the eggs of *Ascaris lumbricoides*, or with larval parasites that are able to penetrate through intact human skin, such as the hookworms and *Strongyloides stercoralis.*

Parasites requiring one intermediate host commonly involve a large mammal, rodent, crustacean, or insect vector within which they complete their life cycle. This process may be either simple or complex. For example, humans serve as the definitive host for *Taenia* spp., which reside in the intestinal tract. The definitive host is the host in which sexual reproduction occurs. The pig and cow, for *T. solium* and *T. saginata,* respectively, are intermediate hosts for these tapeworms. They are present as encysted larvae and reside in skeletal muscle of the animal. The parasitic cycle is completed when humans ingest the encysted parasitic form in raw or undercooked meat. The released larvae ultimately find their way to the intestine to mature into adult worms. A caveat to *T. solium* infections is that humans may also act as the intermediate host for the parasite, if they ingest a viable egg. When the larval form of this tapeworm is present



■ **FIGURE 22-2** An overview of the life cycles of some parasites of human importance.

The parasite species are divided by their need for zero, one, or two intermediate hosts. Sketches of the common intermediate hosts are also included.

1431

in humans, the disease is called cysticercosis.[259] Echinococcosis is another example of cystic larval disease in humans. In echinococcosis, canines are the definitive or primary host, harboring the adult echinococcal tapeworm in its intestine. In the normal life cycle of echinococcosis, sheep normally serve as the secondary or intermediate host, in which, following ingestion of infective eggs, the cystic lesions develop primarily in the liver. The life cycle of the parasite is completed when dogs and other carnivores ingest the larval-infected offal of dead sheep. Humans become accidentally infected when they ingest the eggs found in the feces of the dog.

Parasites involving insects usually go through a complex series of developmental stages before the infective form is released. In malaria, for example, the plasmodia undergo sexual recombination with ookinete production within the mosquito before infective sporozoites are formed in the salivary glands of the mosquito. These sporozoites are then injected into a human host during a blood meal. There are similarities in the life cycles in diseases such as trypanosomiasis, leishmaniasis, and filariasis.

Parasites that require two intermediate hosts (*Diphyllobothrium latum* and most trematodes) follow similar life cycles. Eggs that are passed from the adult parasite within the definitive host hatch in a suitable aqueous environment and release ciliated, free-swimming forms called miracidia. The miracidia are highly motile and move very rapidly (2 mm/sec). Through the action of photoreceptors, touch receptors, and chemoreceptors, miracidia are attracted to their complementary snail host. Attachment must take place within a few hours because their life span is very short. They possess anteriorly placed glands that secrete proteolytic enzymes to penetrate into the snail's integument. Penetration into the snail takes about 30 minutes, during which time the miracidium loses its cilia. Once in the snail, each transforms into the sporocyst stage, in which asexual replication occurs to produce the next form, the rediae. Thereafter, numerous free-swimming, infective cercariae are formed.

The cercariae occur in a variety of shapes depending on the species. Upon release from the snail, the cercariae seek out and invade the flesh of crustaceans or fish (i.e., the second intermediate host), through the action of enzymes produced by several paraoral penetration glands. The definitive host becomes infected by ingesting the metacercaria contained in raw or inadequately cooked crustacean or fish meat. There are some exceptions to this general life cycle among the trematodes. For example, in the life cycle of *Fasciola* and *Fasciolopsis* species, the cercariae become attached to water plants as inactive, encapsulated metacercaria, rather than infecting a second

intermediate host. Humans are infected by these parasites by ingesting raw or poorly cooked water plants on which these metacercariae are attached.

Intestinal Protozoa

Four broad groups of intestinal protozoa are currently recognized, as listed below: (1) the amoebae, (2) the flagellates, (3) the ciliates, and (4) the coccidia. The task of learning the differential features of these protozoa is somewhat lessened when one realizes that only a few species are of medical importance within each of these major groups. Following the classification proposed by Levine et al.,[152] the following are the intestinal protozoa that will be presented here:

Ameba
- *Entamoeba histolytica/Entamoeba dispar/Entamoeba hartmanni*
- *Entamoeba dispar*
- *Entamoeba coli*
- *Entamoeba polecki*
- *Iodamoeba bütschlii*
- *Endolimax nana*

Flagellates
- *Giardia intestinalis* (formerly *G. duodenalis*)
- *Chilomastix mesnili*
- *Dientamoeba fragilis*
- *Pentatrichomonas hominis*

Ciliates
- *Balantidium coli*

Coccidia
- *Cryptosporidium* species
- *Cystoisospora (Isospora) belli*
- *Sarcocystis* species
- *Cyclospora* species

The Intestinal Amoebae

Three genera of amoebae may inhabit the intestinal tract of humans: *Entamoeba*, *Iodamoeba,* and *Endolimax*. Some of these, such as *Entamoeba coli,* are considered nonpathogenic. It is important that these are objectively identified in stool specimens and not be confused with other protozoa that may cause disease. Additionally, it is usually evident that the patient has been exposed to unclean food or water. Of the amoebae, *Entamoeba histolytica* is the principal pathogen for humans. At the onset of

training, students must develop an approach by which they can consistently identify this parasite when seen in stool specimens. The *Entamoeba histolytica* "look-alikes," *E. hartmanni*, and the newly designated species *Entamoeba dispar*, to be described in more detail later, have been found to be nonpathogenic and of little clinical significance when observed in stool specimens.[59]

Amebiasis and *Entamoeba histolytica*. Amebic dysentery is caused by pathogenic strains of *E. histolytica*.[210] The organism is transmitted via the direct fecal–oral route through contaminated water or food supplies, either directly from the excreta of infected persons or indirectly by cockroaches or flies that can act as mechanical vectors. Improvements in sanitation, socioeconomic conditions, and alterations in specific practices such as hand washing, fly control, improved water quality, and sanitary facilities are necessary to control parasite transmission. An estimated, 5% to 50% of individuals in endemic areas are intestinal carriers of *Entamoeba histolytica*. Ten percent of these individuals will develop invasive, dysenteric bowel disease, whereas 0.5% will develop extraintestinal disease, most commonly liver abscesses. Of those with liver abscesses, 2% to 10% die. The death rate can reach as high as 70% in patients with fulminant colitis. The clinical syndromes associated with *E. histolytica* infections are presented in Clinical Correlation Box 22-1.

1432

CLINICAL CORRELATION BOX 22-1 Amebiasis

The disease syndromes resulting from infection with *E. histolytica* have been outlined by Guerrant.[105] The majority of humans infected with *E. histolytica* (80%–99%) are asymptomatic, as determined by observing for excreted cysts in fecal screening examinations or from the data of serologic surveys. A majority of those with symptoms have disease limited to the gastrointestinal tract, following an average incubation period of 1–4 weeks after infection. The typical large bowel lesions are called "buttonhole" ulcers because the trophozoites that penetrate through the mucosa are incapable of digesting the musculature of the bowel wall, and therefore extend laterally along the submucosa. (Image Plate 22-2D illustrates several trophozoites in the submucosa.) Lower abdominal pain, low-grade fever, and bloody diarrhea with or without tenesmus are the usual presenting symptoms. Pregnancy, malnutrition, underlying metabolic diseases, and corticosteroid therapy predispose to more serious disease. Complications are relatively uncommon, developing in 1%–4% of cases, and include bowel perforation and peritonitis. Paracecal amebomas, at times forming an annular inflammatory mass simulating colonic carcinoma, have been reported.

Extraintestinal amebiasis occurs with varying frequency in different geographical areas. In Mexico, invasive disease develops in about one in every five infected individuals, compared with only one in 100–1,000 in the United States. The onset of symptoms may be within days after the acute bout of dysentery, or it may be delayed by months or even years. The liver is the most common organ of extraintestinal involvement. Adams and McLeod[3] report that in up to 50% of cases of amebic liver abscesses, a history of intestinal amebiasis is lacking and trophozoites or cysts cannot be detected in stool specimens. Symptoms include weight loss, low-grade fever, weakness, and vague right upper quadrant discomfort and elicitation of pain between the ribs on palpation. Anemia, leukocytosis, and an elevated alkaline phosphatase are other supporting findings. The diagnosis is usually made by observing the characteristic single, large defect in the right lobe with a liver scan. Direct extension into the pleura or pericardium or metastatic foci in the brain, lung, and kidney is an uncommon event.

The life cycle of *E. histolytica*, as a prototype for all intestinal ameba, is shown in Figure 22-3.

Laboratory Identification. The cysts and trophozoites of the intestinal amoebae must be differentiated from a variety of confusing background artifacts that may be present in microscopic mounts and smears of fecal material.[96] Welsh[265] denotes that the correct identification of amoebae is dependent on the accurate observations of skilled laboratory workers, which laments the high frequency of both overidentification and underidentification of amoebae in stool specimens. This is evidenced often by the poor performance of national proficiency testing surveys. Several studies were cited, indicating that in up to one-third of laboratories in the United States and other countries, *E. histolytica* was not correctly identified; furthermore, several outbreaks of presumed amebiasis investigated by the CDC were false alarms because of laboratory misidentification errors. Pollen grains, incompletely digested vegetable elements, and host-derived somatic cells are among artifacts that can be confusing. Several commonly encountered artifacts are illustrated in Image Plate 22-1.

In particular, amebic cysts must be differentiated from active polymorphonuclear leukocytes that may have two or more lobes to their nuclei. The cytoplasm of leukocytes, however, is coarse, the nucleus is without evidence of a distinct karyosome, and the nuclear membrane is thick with no evidence of attached chromatin (Image Plate 22-2A). Microscopists can minimize the chances of error by making sure that parasitic structures are objectively identified before making a positive identification. If there is any doubt, one should search for more convincing forms in the same preparation, examine additional mounts from the same specimen, consult with a more experienced person, or request that additional stool specimens be obtained.

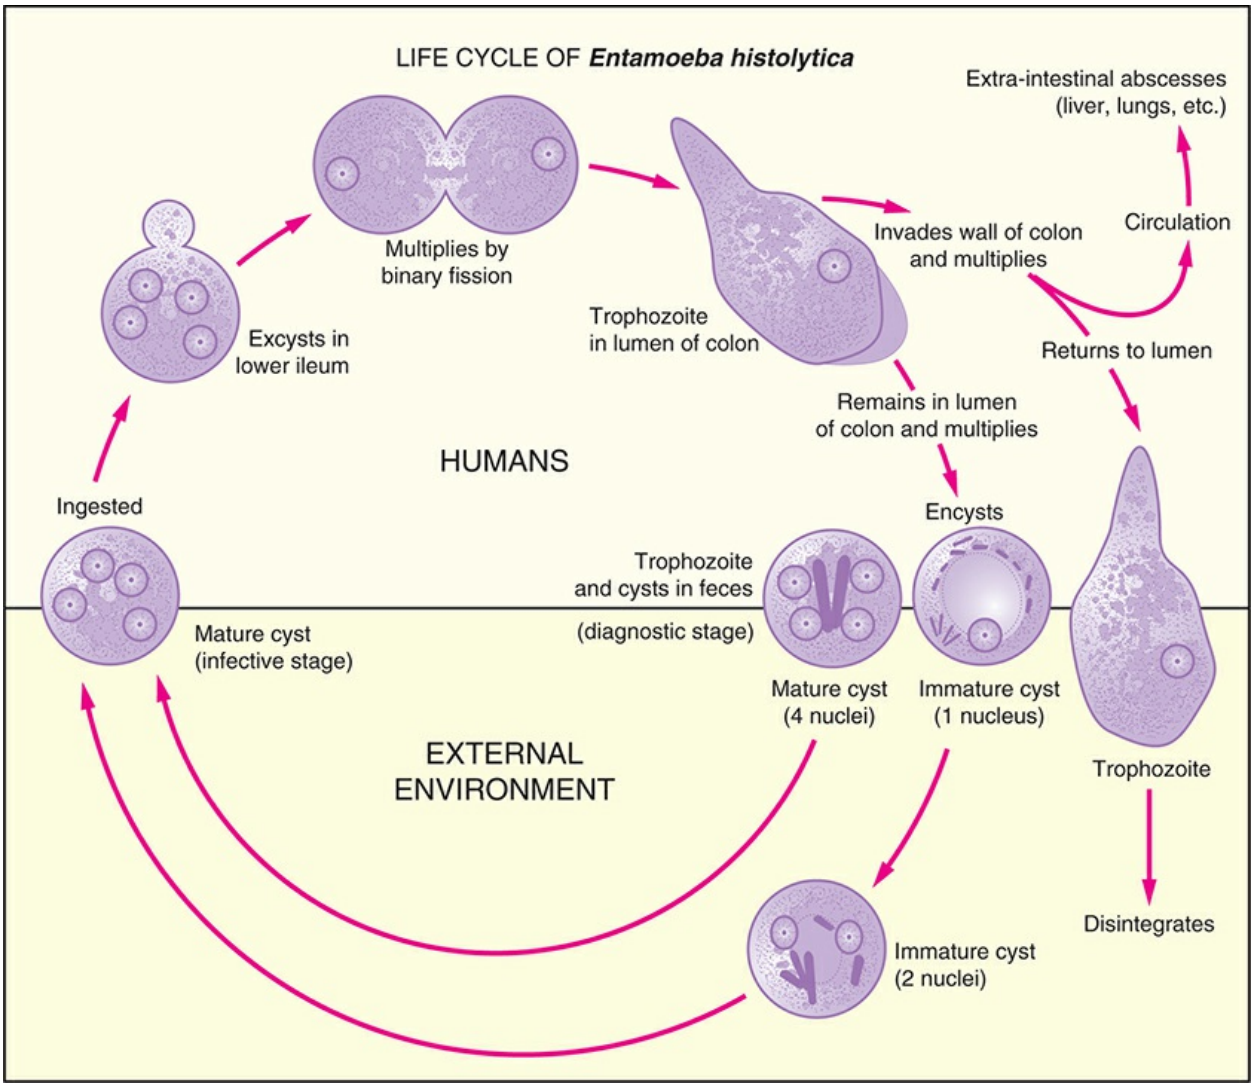
Once it is determined that a form observed in a stool specimen is indeed an ameba, either a trophozoite or a cyst, a detailed examination of the nucleus should be undertaken to determine whether chromatin has been deposited on the nuclear membrane, giving the appearance of a densely stained ring (Image Plate 22-2B). This ring of chromatin is characteristic of an "*Entamoeba*"-type nucleus. The nuclei of amoebae belonging to the other genera, *Iodamoeba* and *Endolimax*, are devoid of this peripheral placement of chromatin and appear more as a "ball in socket," with a large karyosome in a nucleus devoid of the thickened peripheral chromatin (Image Plate 22-2I, J, and K).

Entamoeba histolytica Versus *Entamoeba coli*

Definitive Microscopic Criteria for Differentiation

- The trophozoites of *E. histolytica* have a unidirectional motility; that is, they extend pseudopods along only one plane when observed in a microscopic mount. Conversely, the trophozoites of *Entamoeba coli* extend pseudopods in multiple planes. These features can only be observed in fresh stool preparations, which are not commonly available.
- The trophozoites of *E. histolytica* also have the unique capability of ingesting erythrocytes; it is extremely rare that ingested red cells will be seen in *Entamoeba coli* trophozoites. Gonzalez-Ruiz et al.[95] found that erythrophagocytic strains of *E. histolytica* always demonstrate a pathogenic zymodeme pattern. They concluded that erythrocyte phagocytosis is virtually 100% specific for *Entamoeba histolytica* and when observed in fecal mounts is predictive of infection with an invasive strain.

1433



■ **FIGURE 22-3** The life cycle of *Entamoeba histolytica* is simple, with no intermediate hosts required. Resistant cyst forms are found in the external environment, which, when ingested by a human in contaminated food or water, excyst in the intestine and develop into free-living, motile, feeding trophozoite forms. These trophozoites may invade the intestinal mucosa, and potentially can reach the circulation and cause extraintestinal abscesses in various organs, particularly the liver.

- An *Entamoeba*-type cyst that possesses more than four nuclei rules out *E. histolytica* (Image Plate 22-2F).

Secondary Microscopic Criteria for Differentiating *E. histolytica* From *E. coli.* All other identifying characteristics between these two amoebae are secondary, may be inconsistent, and can lead only to a presumptive identification when observed.

- The trophozoites and the cysts of *Entamoeba* coli (15 to 50 µm [usual range: 20 to 30 µm] and 10 to 35 µm [usual range: 15 to 20 µm], respectively) on the average are larger than those of *Entamoeba histolytica* (12 to 40 µm [usual: 10 to 20 µm] and 10 to 20 µm [usual: 12 to 14 µm], respectively); however, there is sufficient overlap in size to reduce the significance of this observation.
- The intranuclear karyosomes of *E. histolytica*, whether observed in trophozoites or in cysts, tend to be tiny and more centrally placed (Image Plate 22-2B), in contrast to the relatively larger and more eccentrically positioned karyosomes of *Entamoeba coli* (Image Plate 22-2E).
- The ring of nuclear chromatin of *E. histolytica* is evenly dispersed and beadlike (Image Plate 22-2B), whereas it is more blotchy (i.e., chunky) in distribution in *Entamoeba coli* (Image Plate 22-2E).
- The cytoplasm of *E. histolytica* trophozoites tends to be smooth or finely granular (Image Plate 22-2B), whereas cytoplasm of *Entamoeba coli* trophozoites is more filled with debris and phagocytosed bacteria or yeasts (Image Plate 22-2E).
- Although chromatoid bars are seen in only about 10% to 15% of cysts, when present, those of *E. histolytica*

1434

(and *E. hartmanni*) have smooth, rounded ends (Image Plate 22-2H), whereas those seen in the cysts of *Entamoeba coli* are fragmented and frayed in appearance, possibly with pointed ends (Image Plate 22-2F).

By combining two or more of these features when observing several amebic forms in a given microscopic mount, a highly presumptive if not definitive identification can usually be rendered.

The critical observation of an endameba-type nucleus of an amebic form in a microscopic mount may also be useful in two other situations. The precysts of both *E. histolytica* and *Entamoeba coli* can form prominent intracytoplasmic vacuoles, closely simulating the glycogen mass characteristic of *Iodamoeba bütschlii* (Image Plate 22-2I). *Entamoeba hartmanni* develops both trophozoites and cysts that are on the average smaller, within the 5 to 15 µm, range that is the same size range as *Endolimax nana*. Again, differentiating the endameba-type nuclei characteristic of the "ball-in-socket" nucleus present in both *Endolimax and Iodamoeba* will minimize confusion between these two species (In Image Plate 22-2, compare Frames B and K).

Entamoeba polecki is another member of the *Entamoeba* genus that may rarely be found in human stool specimens, particularly in individuals who may have close association with pigs. Considerable experience is necessary before the microscopic forms of this organism can be objectively identified in stool specimens. The

trophozoite resembles *Entamoeba coli* in size, sharing the sluggish pattern of motility, the eccentric location of the nuclear karyosome, and the "dirty" appearance of the cytoplasm. The cysts typically have only one nucleus (never more than two) with a small, eccentric karyosome and fine, even distribution of chromatin along the nuclear membrane. Small, multiple, iodine-positive glycogen masses may be seen in the cytoplasm. A human infection caused by this parasite has been reported in a Japanese refugee.

Serologic Diagnosis of Amebiasis. Sensitive and specific serodiagnosis of invasive amebiasis has been demonstrated by Lotter et al.,[160] who used immunoblotting and enzyme-linked immunosorbent assay (ELISA) techniques to detect a specific recombinant surface protein of pathogenic *E. histolytica*. Cummins et al.[48] did pioneering work to use rapid latex agglutination test to detect patients with extraluminal amebiasis. More recently, van Doorn and colleagues assessed three assays, a rapid dipstick test, a latex agglutination test, and an ELISA, on well-characterized patients with extraintestinal amebiasis, intestinal amebiasis, and cyst passage. All assays had a sensitivity of 93.3%, with specificities that varied from 98.1%, 99.5%, and 97.1%, respectively.[249] A number of enzyme immunoassays (EIAs) are commercially available for the serologic detection of patients with *E. histolytica.* These have replaced more cumbersome serologic assays used previously. These assays are most useful for patients with extraintestinal disease, who do not have detectable parasites present in the stool. The CDC reports that these EIAs detect approximately 95% of patients with extraintestinal disease. The sensitivity decreases to 70% for patients with active intestinal disease and 10% for asymptomatic carriers, but performs well (95%) in the patient population wherein the diagnosis may be most challenging because of the absence of parasites in the stool.

There are at least two assays that detect the antigens of *E. histolytica.* These assays unfortunately cannot be performed on preserved stool specimens and require either fresh or frozen stool. Although Haque and associates[108] reported these assays to be useful for the diagnosis of patients with amebic liver abscess, this case is not corroborated by Zeehaida and colleagues, who found it positive in only 8.6% of patients with liver abscess. This latter finding is not surprising, since many of these patients may no longer have detectable parasites in the stool. Far better sensitivities have been demonstrated when antigen detection was compared with stool microscopy. Further guidance regarding parasitic serology and antigen testing is available through the CDC (http://www.cdc.gov/dpdx/diagnosticProcedures/serum/tests.html) and additional publications.[109]

Nonpathogenic *Entamoeba histolytica: Entamoeba dispar*. As early as 1925, Brumpt first recognized that severe dysentery or amebic liver abscess develops in only

about 10% of individuals infected with *E. histolytica*, while 90% of intestinal carriers remain asymptomatic. This prompted the hypothesis that amebic infections are caused by two species with the same morphology but with different pathogenicities.[22] Thus, the presence of *E. histolytica* cysts in stool specimens does not necessarily indicate active infection; it indicates that only certain strains are capable of tissue invasion.[234]

In 1978, Sargeaunt and Williams[219] used starch gel electrophoresis to demonstrate that extracts obtained from amoebae grown in axenic cultures had different isoenzyme patterns. Specifically, the reactivity of four enzymes, glucose phosphate isomerase, phosphoglucomutase, malate dehydrogenase, and hexokinase, resulted in 18 so-called zymodeme patterns. This group of investigators later found that only *E. histolytica* strains demonstrating certain zymodeme patterns were associated with human infections. Furthermore, only nonpathogenic zymodeme patterns were found in the 20% of homosexual men attending sexually transmitted disease clinics who harbored intestinal *E. histolytica*.[5] The further demonstration by Weinke et al.[262] that only *E. histolytica* isolates with pathogenic zymodemes were recovered from five travelers returning from the tropics, in contrast with a group of 320 male homosexuals who had neither pathogenic zymodemes nor symptoms of amebiasis, led to the realization that methods must be developed by which these pathogenic and nonpathogenic strains could be differentiated.[220]

During the late 1980s and early 1990s, many questions remained unanswered concerning the pathogenicity of certain strains of *E. histolytica.* The indigenous bacterial microbiota and the ability of *E. histolytica* to modulate its virulence depending on culture conditions were thought to play a role.[173] Geurrant[105] and Ravdin[209] discuss other virulence mechanisms characteristic of *E. histolytica* to produce disease. These included (1) chemically defined adherence factors (galactose-specific adhesin) that determine whether the organism can attach to the bowel mucosa, (2) the secretion of cytotoxins, including hyaluronidase, trypsin, pepsin, gelatinase, and hydrolytic enzymes for casein, fibrin, and hemoglobin, and (3) the production of proteolytic enzymes.

The host uses several defenses to protect against invasion by parasites.[200] Pancreatic proteases, bile salts, and bacterial

glycosidases may destroy the galactose-specific adhesin on the ameba surface and block adherence. Colonic mucins, produced in response to contact of the epithelial cells by amoebae, can also effectively block adherence by binding the carbohydrate recognition domain of the galactose adhesin. Humans who have debilitating disease, are malnourished, or have defective immune responses are particularly prone to both

intestinal and extraintestinal disease.

The issue of the underlying mechanism for pathogenicity of *E. histolytica* was finally brought to conclusion by Clark and Diamond,[39] who used molecular methods based on analysis of stable DNA polymorphisms to identify the DNA patterns unique to different strains of *E. histolytica*. It was through these studies based on molecular biology, coupled with those of Orozco and colleagues,[191] who cloned, sequenced, and characterized various *E. histolytica* clones and strains, that the differences in pathogenic and nonpathogenic strains of *E. histolytica*, and the expression of their various differences in zymodeme patterns, were found to be based on encoded genetic differences. Clark and Diamond[39] have officially retained the name of the classic, pathogenic strain as *Entamoeba histolytica*, and given the nonpathogenic strain the designation *Entamoeba dispar*.[22]

Efficient techniques have been developed to differentiate between these two species. Antigen-detection and PCR-based methods based on amplification of rRNA genes are most commonly used. Antigen-detection tests are relatively simple to perform, provide for rapid results, and are best suited for use in most diagnostic parasitology laboratories, and for use in the field. Enzyme immunoassay (EIA) kits are commercially available for detection of fecal antigens for the diagnosis of intestinal amebiasis. These assays use monoclonal antibodies that detect the galactose-inhibitable adherence protein in the pathogenic *E. histolytica*. The primary drawback of these assays is the requirement for fresh, unpreserved stool specimens. Several EIA kits for antigen detection of the *E. histolytica*/*E. dispar* group are available in the United States; when assessing these for use, it is important to determine whether the assay is specific for *E. histolytica* or whether it detects both *E. histolytica* and *E. dispar*.

Yau et al.[281] developed monoclonal antibodies against a recombinant 170-kDa subunit of the Gal or GalNAc lectin of *Entamoeba histolytica* that specifically recognizes *E. histolytica* but not *Entamoeba dispar* in preserved stool samples. These antibodies were found not to cross-react with other bowel protozoa, including *Entamoeba coli, Giardia duodenalis*, and *Dientamoeba fragilis.* Haque and colleagues[109] demonstrated that the performance of the antigen-detection kit, TechLab (Blacksburg, VA) *E. histolytica* test, designed to specifically identify *E. histolytica* and differentiate it from *E. dispar* in stool specimens, was comparable in sensitivity to a nested PCR procedure run in parallel.

Other workers have found that PCR-based tests were more sensitive than antigen-detection procedures in the detection of *E. histolytica/E. dispar.* Katzwinkel-Wladarsch et al.,[138] using a simple DNA extraction method and PCR amplification, were able to detect the gene that encoded for an *E. histolytica*-specific antigen directly in stool specimens containing as few as one trophozoite per milligram of feces. Acuna-Soto et al.[2] demonstrated that PCR techniques could also be used to detect *E.*

histolytica in formalin-fixed stool specimens. Blessmann et al.[18] using a real-time PCR technique were able to detect as little as 0.1 parasites per gram of feces. Of note, the sensitivity of this PCR procedure indicated that both microscopic examination of stool specimens and culture underestimate the presence of *E. histolytica* infections. The disadvantages of PCR procedures are the amount of time consumed in performing the test, its relative complexity, the cumbersomeness of performance, the requirement for special equipment, and the relatively high expense. Newer, commercially available multiplex assays for enteric pathogens, some of which are parasite pathogens, are easier to use, more cost-competitive, and likely to be widely used.

Given that a high percentage of persons in whom morphologic forms resembling *E. histolytica/E. dispar* are observed in stool specimens may not require treatment, follow-up *E. histolytica*-specific antigen-detection or PCR-based procedures should be performed in the future to correctly identify the nonpathogenic *E. dispar* subgroup. The reagent kits currently available for transport of specimens to a reference laboratory require the processing of a fresh stool specimen for antigen detection. If therapy is not prescribed in patients in whom *E. histolytica/E. dispar* organisms are identified in stool specimens, the patients should at least be informed that they are carrying potentially virulent organisms requiring that they practice preventive measures accordingly. Metronidazole (Flagyl) is the treatment of choice when indicated.

Other Intestinal Amoebae. Two other commonly encountered intestinal protozoa, *Iodamoeba bütschlii* and *Endolimax nana*, warrant further consideration. The CDC still characterizes these as among the ameba that are generally not considered pathogenic. It is important from the laboratory perspective that these organisms are correctly identified in stool specimens, and not be confused with other protozoa that may cause disease. Therefore, the identifying criteria for each are as follows.

Iodamoeba bütschlii

- The trophozoite, which ranges from 6 to 25 μm, possesses a "ball-in-socket"-type nucleus. The smaller forms are difficult to distinguish from *Endolimax nana,* and a search for the more distinctive cysts should be made (Image Plate 22-2I).
- The cyst, which ranges from 6 to 15 μm, in addition to the "ball-in-socket" nucleus, possesses a unique, large, iodine-positive staining glycogen vacuole (the structure from which the genus name is derived) (Image Plate 22-2J).
- *Note:* Early precysts of *Entamoeba coli* and, less frequently, of *E. histolytica* may also have a cytoplasmic inclusion that appears similar (Image Plate 22-2G). However, more than one nucleus may be observed, each with a ring of chromatin on the nuclear membrane, characteristic of the so-called *Entamoeba*-type nucleus.

Endolimax nana

- Relatively small size, ranging from 5 to 8 μm.
- Observing trophozoites with a single nucleus devoid of peripheral chromatin, and a large "ball-in-socket" karyosome (Image Plate 22-2K).

- The cysts are also small (5 to 14 μm), and have up to four nuclei, each of which has a relatively large, blot-like karyosome (Image Plate 22-2L).
- *Entamoeba hartmanni*, although in the same size range as *E. nana*, can be distinguished primarily because both the trophozoite and the cysts possess an *Entamoeba*-type nucleus, in contrast to the "ball-in-socket" nucleus of *E. nana*.
- The cysts of *Entamoeba hartmanni* typically contain one or more chromatoid bars, with smooth, rounded end margins (Image Plate 22-2H).

Other Protozoa *Blastocystis hominis*. *Blastocystis hominis*, once thought to be a yeast, has been classified as a belonging to the phylum *Bigyra*. There is some debate regarding whether this phylum best resides in the kingdom *Protista* or in *Chromista*, which contains certain algae. Zierdt[286] considered this organism to have the following characteristics:

- Has no cell wall.
- Grows only in the presence of bacteria and not on fungal media.
- Has a preference for alkaline pH and a mildly hypotonic environment.
- Reproduces by binary fission and not by budding.
- Extends and retracts pseudopods and ingests bacteria.
- Is optimally active at 37°C, does not grow at 25°C, and is killed at 4°C.

Yet, Stenzel and Boreham[240] point out that little is known of the basic biology of the organism, and controversy surrounds its taxonomy and pathogenicity. Three morphologic forms (vacuolar, granular, and ameboid) have been described, although additional forms (cyst, avacuolar, and multivacuolar) have also been observed. Little is known about the biochemistry of the organism, and organelles and structures of unknown function and composition are present in the cells. Several life cycles have been proposed, but none have been experimentally validated, and the form involved in transmission has not been defined.

Morphologically, the forms of *B. hominis* present in human specimens have the following features:

- Appear as irregularly sized spherical cells ranging from 5 to 15 μm in diameter, although smaller forms may occasionally be found (Image Plate 22-2M).

- Possess a homogeneous staining (i.e., green in trichrome stains) central body that occupies[3] 70% of the cell.
- Have nuclear material either scattered in undefined fragments between the central body and the outer membrane, or
- Appear as one or two elongated masses in a bipolar distribution.

MacPherson and MacQueen[162] denote the morphologic variability in size, shape, nuclear detail, and central body characteristics between cells, which may account to some extent for the differences in the incidence of detection of *B. hominis* in various reported studies.

Early studies by Zierdt[286] and additional studies in the mid-1980s[81,150,251] were offered as evidence that *B. hominis* may be a cause of gastrointestinal disease. The potential pathogenic nature of *B. hominis* is supported by the instances of recurrent diarrhea associated with this organism as reported by Vannatta[251] and Lebar.[150] In the latter study, numerous *B. hominis* (i.e., 5 per high-power field) forms were seen in stool specimens in patients in whom cultures for bacterial pathogens and tests for rotavirus particles were negative. The symptoms subsided when these patients received antiprotozoal therapy. Recurrent diarrhea without fever, episodes of vomiting, and cramping abdominal pain have been the chief symptoms.

Blastocystis hominis may be a pathogen when no other agent is found, or when the parasite burden is high.[270] Garcia and associates,[82] in a review of more than 6,000 stool specimens, found that 289 (4.8%) were positive for *B. hominis.* This organism was the only parasite found in two-thirds of the patients. Within this group, gastrointestinal symptoms were noted in 24 patients, the majority of whom had underlying debilitating disease or were immunosuppressed. The clinical picture shows that patients with *B. hominis* consist of nonspecific abdominal pain, watery diarrhea, anorexia, vomiting, and weight loss. Rarely, a more invasive form of the disease with rectal bleeding can occur. Antonelli et al.[8] describe a 10-year-old girl who was hospitalized for diarrhea, abdominal pain, and fever. Many *B. hominis* forms were demonstrated in her stools, and she responded favorably to treatment with metronidazole. The authors, therefore, cite this incident as another in recognition of the fact that *B. hominis* should be considered a human pathogen.

In rebuttal, Markell and Udkow,[166] in a study of 32 persons with *B. hominis* detected in the stool in whom at least six stool examinations were performed, found that 27 had other recognized pathogens—*E. histolytica*, *Giardia*, or *Dientamoeba fragilis*. In all of these patients, symptoms subsided with therapy. In the five remaining patients in whom only *B. hominis* was found, treatment with iodoquinol eradicated the organisms, but symptoms more consistent with irritable bowel syndrome persisted. Nagler et al.,[180] in a study of 12 patients with exacerbated

inflammatory bowel disease in whom stool specimens were positive for *B. hominis*, also concluded that this organism is not a significant pathogen for this entity. All of their patients improved on medical therapy, three on treatment with corticosteroids alone and one on bowel rest without medication. Five patients failed to improve on metronidazole, but four responded to subsequent courses of corticosteroids. Keystone and Kozarsky,[142] applying antigen, isoenzyme, and DNA analyses, indicate that *Blastocystis hominis* may be more than one organism, with both virulent and avirulent strains identified. Such findings may account for the differences in apparent virulence as reported by various workers, similar to that which was discovered for *E. histolytica* and *E. dispar*.

Until the issue of pathogenicity is settled, clinical laboratory parasitologists should still indicate the detection of *B. hominis* in stool specimens in the final report. Some form of quantitation should be made (e.g., rare, few, moderate, many); specifically, the presence of five or more *B. hominis* forms per high-power field is considered in the moderate to many category, and is reported by most laboratories. The clinician must evaluate whether such reports have clinical significance and decide whether to treat based on the clinical presentation.

1437

Intestinal Flagellates

All of the organisms in this group are motile by the means of one or more flagella. Other structures also serve as an integral part of the locomotor organelle, namely, the kinetoplast to which the flagella are attached and the axostyle and parabasal bodies. Therefore, when any of these structures are identified in a parasitic form, the parasite can be tentatively grouped with the flagellates. Unlike the amoebae, which assume variable shapes, the flagellates are more rigid and tend to retain distinctive shapes, a feature often helpful in their identification. *Giardia intestinalis*, *Chilomastix mesnili*, *Pentatrichomonas hominis*, and *Dientamoeba fragilis* are the species of flagellates most commonly seen in human stool specimens submitted for examination.

***Giardia intestinalis* (Formerly *Giardia duodenalis*)**. By the late 1980s, *Giardia intestinalis* had become the most frequent cause of parasitic gastrointestinal disease in the United States,[202] and has become a major worldwide public health challenge.[70,127,149,228] In a past surveillance study, *Giardia* was found in 3.8% of 414,820 stool specimens submitted to state health laboratories.[27] There have been numerous outbreaks of giardiasis, with addition outbreaks reported each year.[77,100,176] In 2010, there were 19,927 cases of giardiasis reported, which is significantly less than the 27,778 cases reported in 1996; there has been a steady downward trend in the

incidence of disease year over year.[80,283] A number of outbreaks of giardiasis in children in day care settings have also been reported.[239,274] The high prevalence of giardiasis is worldwide, with endemic areas reported in England, Russia, several countries in Eastern Europe, and many coastal areas of the Mediterranean.[228] *Giardia intestinalis* was found in 10% of children residing in the Ain-Shams and El-Mowassa orphanages in Cairo[222]; it was the most common parasitic disease (11.63%) found among Muslims coming for the annual "Hajj and Omra" pilgrimages to Mecca.

The life cycle of *Giardia intestinalis*, representative of the intestinal flagellates, is shown in Figure 22-4. The clinical syndromes associated with *Giardia* infections are presented in Clinical Correlation Box 22-2.

Giardia intestinalis is readily identified in microscopic mounts of fecal specimens. The key identifying features are as follows:

Trophozoite

- The size ranges between 9 and 21 μm long by 5 to 15 μm wide, is bilaterally symmetrical, and has two nuclei, one on either side of a central axostyle (giving the appearance of a "face") (Image Plate 22-2O).
- Cytoplasm is finely granular. Two median parabasal bodies, simulating a "mustache," are located on either side of the axostyle. Sucking disks occupy half of the ventral surface.
- Organisms attach to the surface of epithelial cells, a feature important for the pathologist (Image Plate 22-2N).
- In wet preparations, has a graceful "falling leaf" motility is seen, albeit this is not frequently performed. If ever needed, this feature is useful in distinguishing it from *C. mesnili*, which has a slower, stiff motion, and from *T. hominis*, the movement of which is quick, jerky, and darting.

Cyst

- Cysts measure from 8 to 12 μm, is oval in outline, and may be lightly bile-stained.
- When mature, the cysts possess four nuclei, with a small karyosome that is eccentrically placed.
- There is no peripheral chromatin on the nuclear membrane.
- There is a clear space beneath the thin cyst wall, producing an easy-to-recognize "halo" effect (Image Plate 22-2P).
- Ill-defined longitudinal fibrils and four median bodies are present.

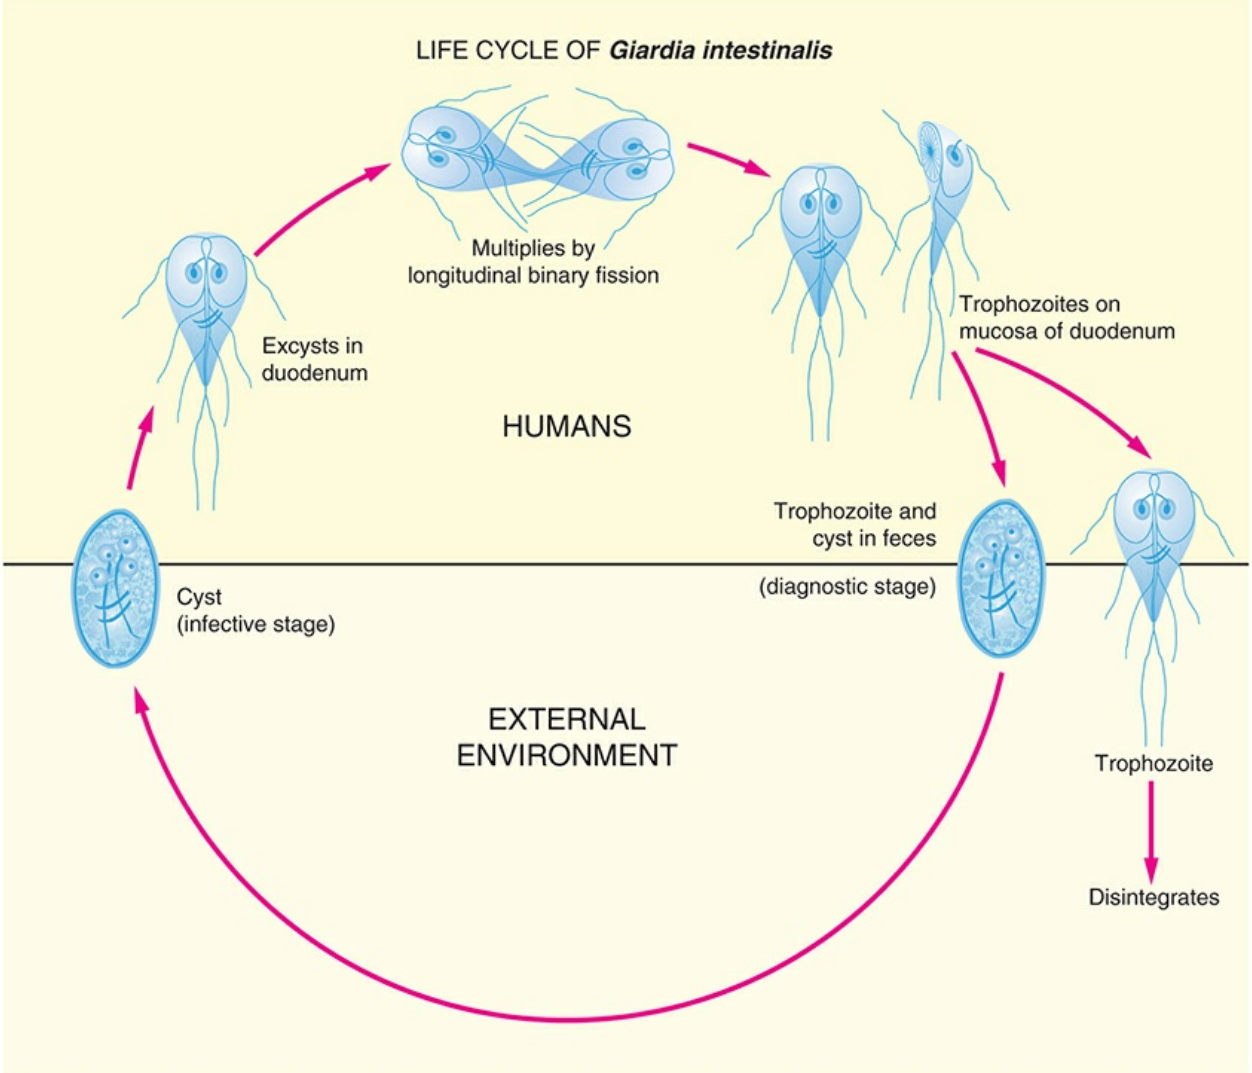
Because of irregular shedding of organisms in the feces, several specimens should be obtained on nonsuccessive days and may be required to establish a diagnosis in suspected cases, particularly in chronic disease. In a study reported by Heymans et

al.,[120] 53% of the patients had symptoms referable to giardiasis that existed for 6 months or more. The yield can be improved by preparing stained smears from concentrated fecal specimens, as organisms may often be missed if only saline mount procedures are performed.[86,231] Heymans and associates[120] also found that the examination of three stool specimens on nonconsecutive days had a sensitivity of 95.7% in detecting organisms in patients known to have giardiasis. Organisms were found in only three of 109 duodenal biopsies in patients whose stool examinations were negative (false-negative rate of 2.8%). Similarly, McHenry et al.[172] found only one positive aspirate in 144 duodenal aspirates in patients with nonspecific gastrointestinal symptoms. The conclusion can be drawn, therefore, that extraordinary procedures need not be performed to establish the diagnosis of giardiasis if there have been negative stool examinations.

The string test is an alternative to duodenal aspiration or biopsy procedures for patients highly suspected to have giardiasis in whom a diagnosis has not been established.[137] This procedure is described above, but is rarely used in practice.

Immunofluorescent Detection. Garcia et al.[84] reported 100% sensitivity and specificity in the detection of *Giardia duodenalis* cysts and *Cryptosporidium* oocysts in fecal specimens, using the MERIFLUOR (Meridian Diagnostics) direct immunofluorescence detection system. *Giardia* cysts appeared as oval, apple-green fluorescing forms measuring 11 to 14 μm in diameter, whereas the *Cryptosporidium* oocysts measured 4 to 6 μm in diameter and displayed the same fluorescence.[260] An advantage of this technology is the ability to screen smears under low-power magnification and the ability to detect forms in low concentration as major advantages of the direct fluorescence system.[80] It is not uncommon to find organisms by the fluorescence procedure that are not observed by routine ova and parasite examination.

Antigen Detection. The detection of antigens on the surface of organisms or shed from organisms in stool specimens is the current test of choice for diagnosis of giardiasis.[133] It provides increased sensitivity over more common microscopy techniques. There are multiple commercial products to choose from for the immunodiagnosis of giardiasis. These are either plate-based colorimetric immunoassays or lateral flow immunoassays. Most can be used on fresh or frozen stool samples, and those preserved in formalin, merthiolate-iodine-formaldehyde (MIF), and sodium acetate-acetic acid-formalin (SAF) fixatives, but not in PVA. The sensitivity and specificity of these kits approach 100% when compared with microscopy.



■ **FIGURE 22-4** The life cycle of *Giardia intestinalis* is also simply completed by a fecal–oral route of transmission, with the cysts providing for a long-term survival in the external environment under adverse environmental conditions. Cysts commonly find their way into streams and wells from inadequately controlled sewer systems, and mountain streams downriver from residential areas are commonly contaminated. Some animals also harbor *Giardia*. Humans become infected by ingesting fecally contaminated water or poorly washed fresh foods. In the human intestine, trophozoite multiplication occurs via binary fission. Trophozoites and cysts are passed in the feces to complete the life cycle.

CLINICAL CORRELATION BOX 22-2 Giardiasis[272]

Symptoms

Giardia intestinalis, also known of as *Giardia duodenalis,* is a known cause of acute

diarrhea, abdominal pain, and in some cases, constitutional symptoms such as weight loss and lassitude. In patients with chronic infections, malabsorption and steatorrhea simulating sprue may be experienced. The exact mechanism by which *Giardia* causes disease is not known. Physical occlusion of the mucosa, bile salt deconjugation, enterotoxin excretion, prostaglandin release, and injury to the mucosal epithelial cell brush border are several hypotheses reviewed by Smith and Wolfe.[238] The drugs of choice in the treatment of giardiasis when clinically indicated are metronidazole (Flagyl) or tinidazole.

1439

Epidemiology
Most infections are sporadic, contracted after exposure to contaminated food or water under a variety of circumstances. Waterborne outbreaks have been cited by Smith and Wolfe[238] in locales as diverse as Colorado, Russia, and New York and among campers in the western United States. In a follow-up on the Aspen/Snowmass outbreak, Lapham and associates[149] found only two cases of giardiasis among 225 visitors, a rate far lower than that reported during the previously cited outbreak. Giardiasis has been reported among individuals drinking water from an unfiltered municipal water supply in Dunedin, New Zealand[77]; in a chlorinated community water supply in Penticton, British Columbia[176]; among preschool children drinking from school water supplies in Lesotho[70]; and from use of a new hotel water slide that had been cleansed by both Bromide and sand filtration.[100] Although Holtan[127] and others have cited campers as a high-risk group for contracting giardiasis, Welch[264] found such risk as minimal at best, based on a review of 104 manuscripts relative to backcountry water as a potential source for acquiring infection. The author placed greater emphasis on observing careful hand washing techniques over water purification to decrease the risk for infection. There is a zoonotic potential that giardiasis is also carried by domestic animals such as calves and lambs (and perhaps wild rodents as well), which may serve as a reservoir of infection. Children attending day care centers have in the past also been placed in a high-risk group for contracting giardiasis, as evidenced by three reported past outbreaks in Wisconsin,[239] with attack rates of 47%, 17%, and 37%, respectively; and in Southern Ontario, Canada,[274] where almost 10% of children between the ages 2 and 5 years old were found to harbor *Giardia cysts*.

Several of these rapid immunochromatographic (ICT) assays are available in a combined format that includes the detection of either *Cryptosporidium* or *Giardia.* At least one product also offers the detection of *Cryptosporidium parvum*,

Giardiaduodenalis, and *Entamoeba histolytica,* but this assay requires fresh stool. These offer the advantage of short test time and multiple results in one reaction device with excellent sensitivity and specificity.

Since the early 1990s, the diagnosis of giardiasis had been established from the use of immunologic methods designed to directly detect *Giardia duodenalis* antigen in fecal specimens.[147] EIAs using antibodies prepared against a variety of *Giardia* antigens developed as the technology most often used.[241] Knisley and colleagues,[147] using rabbit and goat antisera following immunization with *Giardia* trophozoites, reported sensitivities of 92% and 87% and specificities of 87% and 91%, respectively. Carlson and coworkers[26] reported a 97% correlation between enzyme immunoassay and direct microscopic examination on 353 specimens from human subjects in the United States. Stibbs,[241] using a monoclonal antibody-based antigen-capture enzyme immunoassay for the detection of *Giardia duodenalis* antigen in human stool specimens, also found a 97% correlation with microscopic examinations, including formalin-fixed specimens.

Rostoff and associates[216] have evaluated a commercially available enzyme immunoassay (ProSpecT/Giardia; Alexon, Mountain View, CA) that detects *Giardia*-specific antigen 65 (GAS 65). All of 93 specimens obtained from symptomatic patients who had a positive microscopic stool examination for *Giardia* gave strongly positive visual and spectrophotometric results. Of 232 randomly collected specimens, only six with a negative microscopic stool examination had positive EIA results. A review of the clinical evidence strongly suggested that these six patients in fact had giardiasis. With these results taken into account, the EIA test was performed with a sensitivity of 96% and a specificity of 100%. Similarly, Scheffler and Van Etta[224] also demonstrated that antigen detection is also highly sensitive and specific when testing formalin-preserved stool samples. The ProSpecT/*Giardia* kit had a sensitivity of 95%, a specificity of 100%, positive predictive value of 99.5%, and a negative predictive value of 100%relative to conventional microscopy in the study of 223 formalin-preserved stool specimens. In summary, the EIAs for *Giardia* are simple to use and reliable methods for the rapid assessment of stool specimens for the more prevalent intestinal parasite in North America.

Other Intestinal Flagellates

Chilomastix mesnili. *Chilomastix mesnili* is a flagellate of cosmopolitan distribution, more commonly found in persons living in warm climates. It is considered to be a nonpathogen, and treatment is not required when forms are found in fecal specimens. Infections are acquired through ingestion of feces-contaminated food and water; improved personal hygiene and sanitation are paramount to reduce the incidence of colonization with this organism.

The key features for identification are as follows:

Trophozoites

- These are pear-shaped (i.e., pyriform) in outline, measuring 6 to 24 µm in length and 4 to 8 µm in width (Image Plate 22-3A).
- There is a single large nucleus immediately beneath the outer membrane.
- A prominent cytosome is adjacent to the nucleus.
- There are three anterior flagella immediately adjacent to the nucleus, which are often difficult to visualize, but possibly seen by reducing the amount of condenser light and sharpening the focus.

Cysts

- These are pear- to lemon-shaped and range from 6 to 10 µm long, by 4 to 6 µm wide (Image Plate 22-3B).
- There is a distinctive hyaline knob on one side (Image Plate 22-3C).

- These possess a single nucleus with a small central karyosome.
- Characteristically there is curved cytostome, appearing as a "shepherd's crook," which is diagnostic when observed.

Dientamoeba fragilis. *Dientamoeba fragilis* is a flagellate,[279] even though flagella are not observed with the light microscope. In practice, this organism may appear as an amebic trophozoite, rather than as flagellate in microscopic mounts. It is pathogenic, producing a syndrome characterized by persistent diarrhea, abdominal pain, loss of appetite, weight loss, flatulence, and anal pruritus.[269] Microbiologists in clinical laboratories should be aware that *D. fragilis* is being recovered from stool specimens with increasing frequency. It has been reported in 1.4% to 19% of specimens submitted for routine examination and in up to 47% of defined populations, such as patients in mental health facilities.[279] In some settings, identification of *D. fragilis* in stool specimens is as frequent as *Giardia duodenalis;* in fact, in laboratories where *G. duodenalis* is being identified to the exclusion of *D. fragilis*, a review of collection and diagnostic methods may be in order. Because the organisms are fragile and a cyst is not produced, *Dientamoeba fragilis* may be difficult to identify in wet mounts and concentrates. A thorough review of the permanently stained preparation is virtually mandatory for detection of this parasite.

Grendon et al.[101] warn that failure to use recommended stool fixation and permanent staining techniques virtually precludes identification of *D. fragilis*. To increase probability, they strongly recommend that all stools submitted for examination should be fixed in PVA, SAF, or Schaudinn's fixatives, and that all specimens, regardless of consistency, should be permanently stained prior to microscopic

examination. Chan et al.[30] successfully used an indirect fluorescence antibody assay to improve screening of preserved fecal specimens for *D. fragilis*, and further suggested that the development of ELISAs to detect *D. fragilis* antigens in fecal specimens would improve detection.

The identification of *D. fragilis* is made in fecal preparations by observing the trophozoite. A cyst stage has not convincingly been identified. There has been a claim that a cyst form has been discovered, but this has not been independently corroborated. Regardless, cysts are not readily seen in clinical specimen, so even if they are rarely produced, they are not of diagnostic value. The diagnostic morphologic features of *D. fragilis* are as follows:

- The appearance of an asymmetrical "ameboid" form, measuring 5 to 12 μm in dimension.
- The presence of two nuclei (Image Plate 22-3D). Approximately 20% of forms may possess only a single nucleus, and these forms are difficult to differentiate from the trophozoites of *Endolimax nana*. Scanning of the smear will usually reveal the more diagnostic, double-nucleated forms.
- Prominent karyosomes that are fragmented into four to eight granules may be seen and when present are diagnostically useful.
- Relatively broad-lobed, clear pseudopods that provide purposeful motility when observed in wet mounts; this is of limited utility, given the rarity of performing direct wet mounts on fresh stool.

Because *D. fragilis* does not have an identified or well-characterized cyst state, direct food-borne or waterborne transfer from host to host is less likely. The nine times higher incidence of *D. fragilis* in patients with pinworm infection suggests that the *Enterobius vermicularis* eggs may be infected with the flagellate and/or serve as the vector for transfer between humans. This possibility may also explain why almost 50% of reported cases of dientamoebiasis occur in patients under 20 years of age. The treatments of symptomatic patients have included tetracycline and metronidazole, among others.

Pentatrichomonas hominis. *Pentatrichomonas* (formerly *Trichomonas*) *hominis* has been encountered in all parts of the world. Although recovered from diarrheal stool specimens, it is not thought to be pathogenic. It may be somewhat more difficult to definitively identify this organism in stained fecal preparations because the trophozoites are fragile and do not stain well. There is no cyst stage.

Identification is made by detecting trophozoites, which possess the following features:

- Measure 7 to 15 μm long by 4 to 7 μm wide, are teardrop-shaped, and possess a single anterior-placed nucleus, which is slightly displaced from the outer

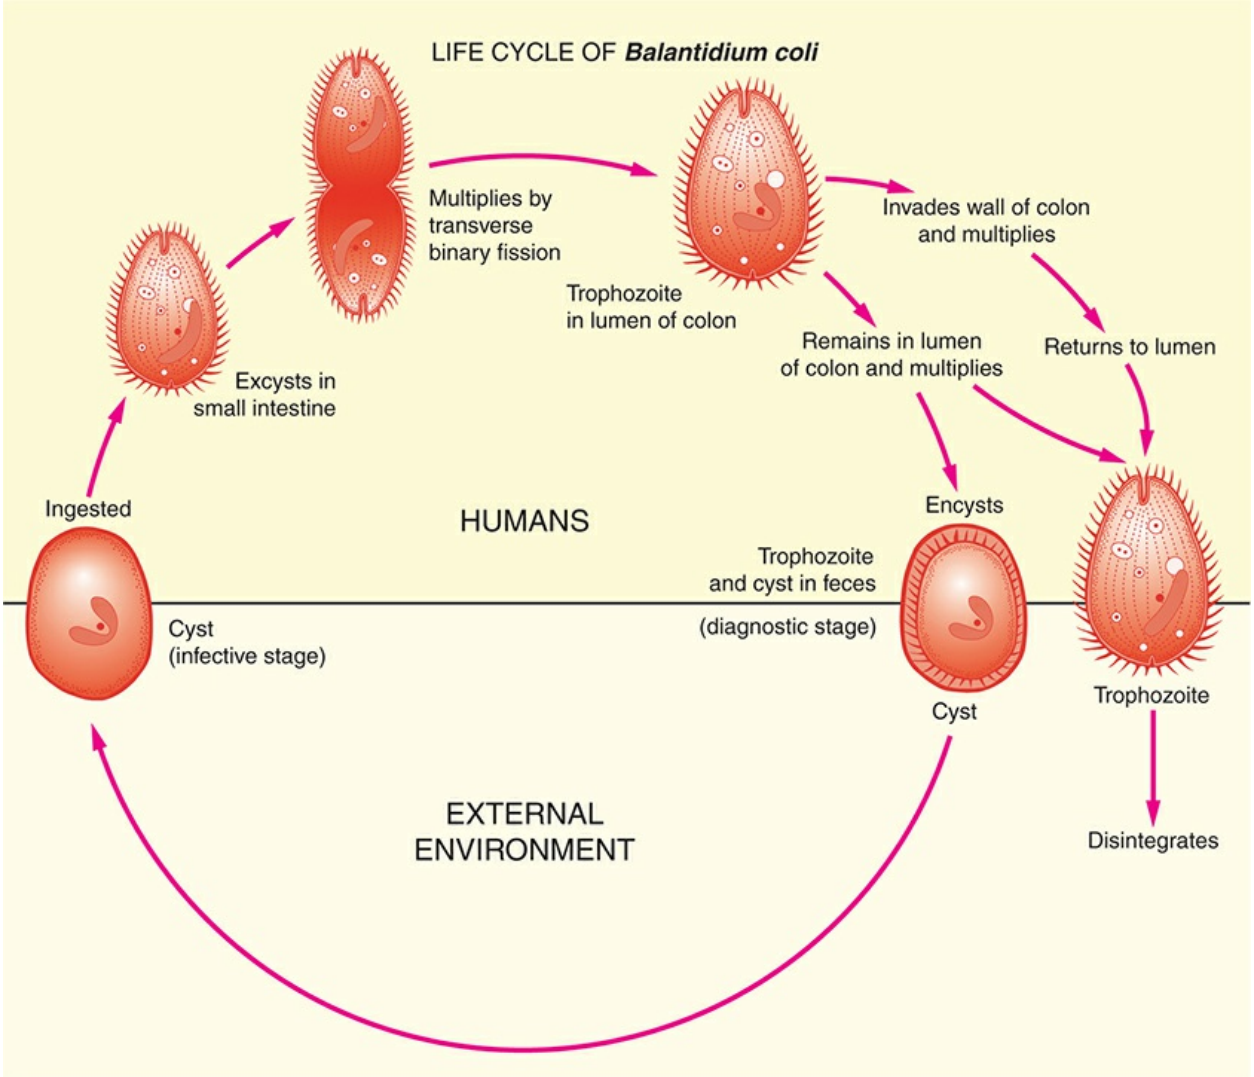
membrane, helping to distinguish it from *Chilomastix mesnili* (Image Plate 22-3E).

- These possess an undulating membrane that extends the full length of the organism. This is helpful in differentiating this organism from *Trichomonas vaginalis*, the undulating membrane of which extends only half or slightly more than half the distance of the body. In practice, this is not particularly useful, as the undulating membranes are not seen in regular trichrome-stained smears; rather, mounts of anoxic cultures are needed to demonstrate this feature.
- In wet mounts, which again are not common, have a somewhat stiff, rotary motility, from the action of a single flagellum that is located along an undulating membrane that extends the full length of the body.
- Typical forms when observed in stool specimens are most likely *T. hominis*. It is important not to mistake *T. hominis* for *T. vaginalis*, as the latter is a sexually transmitted disease.

Ciliates: Balantidium coli

Balantidium coli is the only member of the ciliates known to infect humans. The mode of transmission from humans to humans is via a simple fecal to oral route, and an intermediate host is not required for completion of the life cycle. The life cycle of *Balantidium coli* is shown in Figure 22-5. Although *Balantidium coli* is found primarily in swine and less commonly in other animals, it has a worldwide distribution. Human balantidiosis is most prevalent where pigs are raised and slaughtered.[86] Reports of infection are uncommon, with most coming from Latin America, the Far East, and New Guinea. Infestation in humans is generally noninvasive, asymptomatic, and self-limited. In debilitated patents carrying a heavy load of trophozoites, bloody dysentery, severe dehydration, or, in rare instances, death may result. These form "flask-shaped ulcers" similar to those produced by *Entamoeba histolytica.* Image Plate 22-3F demonstrates several *B. coli* trophozoites invading the submucosa of the bowel. This photomicrograph was prepared from a rare fatal case of *Balantidium* infection. Intestinal ulcers, mesenteric lymphadenitis, and rare extraintestinal extension to liver, lung, and other organs have been reported in isolated patients.[146] Tetracycline, metronidazole, and iodoquinol have all been used effectively.

1441



■ **FIGURE 22-5** The life cycle of *Balantidium coli* is simple, requiring no intermediate host. Cysts pass in feces into the external environment. On ingestion of cyst-contaminated food or water, excystation takes place in the small intestine. Then, there is multiplication by binary fission and trophozoites occupy the colon. On encystations, cysts are again passed in the feces to complete the life cycle.

Balantidium coli is readily recognized in stool specimens because of its large size (100 µm or greater in diameter). Additional diagnostic features include the following:

Trophozoite

- The cell membrane is covered throughout the circumference with short, delicate cilia.
- There is a large, kidney-shaped macronucleus. This is most visible in direct iodine-stained mounts (Image Plate 22-3G).

- A small, spherical micronucleus is present adjacent to the macronucleus. This may not always be readily apparent in every organism.
- A rotary, boring motility when observed in wet mounts.

Cyst

- Cysts are spherical to ellipsoid in shape, measuring 50 µm to 65 µm.
- A single kidney-shaped macronucleus, often with a small, spherical micronucleus (Image Plate 22-3H).
- Small vacuoles persist in the cytoplasm.
- Cilia are retracted within a thick, tough cyst wall.

Coccidia

The organisms that are commonly called coccidia are members of the phylum *Apicomplexa*, class *Coccidia*, and order *Eimeriida*. These are obligate tissue parasites with sexual and asexual stages in their life cycles. Included in this group are the malarial parasites (i.e., *Plasmodium* species), the tissue

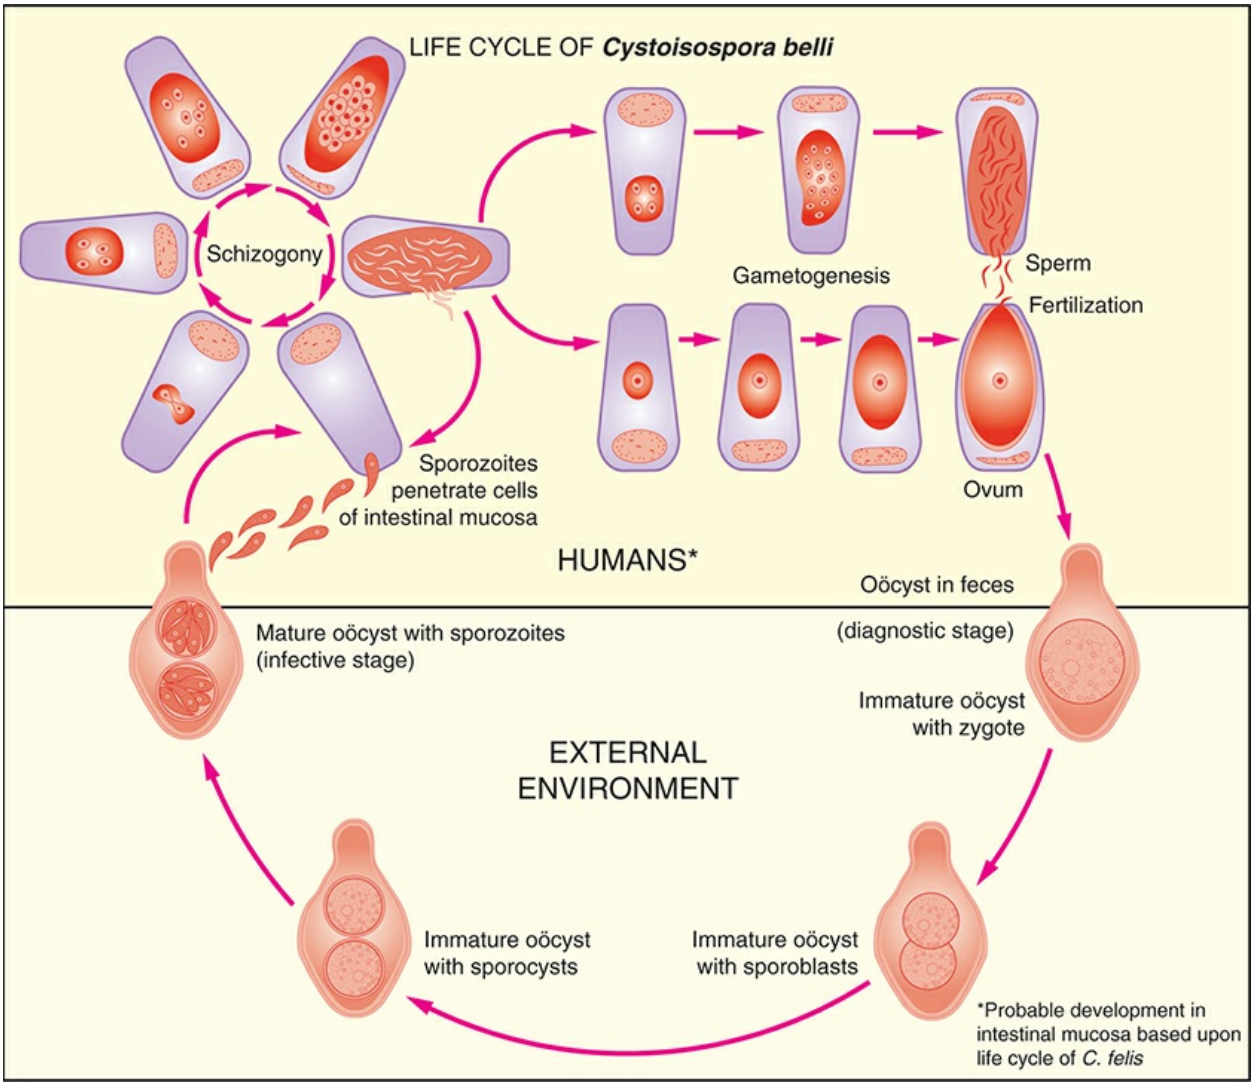
protozoan *Toxoplasma gondii*, and the intestinal coccidia—*Cystoisospora* (*Isospora*) *belli, Cryptosporidium* species, *Cyclospora* species, and *Sarcocystis* species.

The life cycle of most coccidia requires an external intermediate host, such as a cat, calf, human, or other animal, in which sporogenesis and oocyst formation takes place. The life cycle of *Cystoisospora belli* differs only in that both the sexual and asexual stages of gametogenesis occur in the same host without the need for a second host. The life cycle of *Cystoisospora belli*, as representative of the coccidia, is shown in Figure 22-6.

***Cryptosporidium* Species.** Cryptosporidia are minute coccidian protozoa that have been known to be associated with enterocolitis in a variety of domestic animals, including calves, pigs, and chickens.[7] Cryptosporidiosis came to the forefront of human medicine as an opportunistic infection seen in patients with AIDS through the 1980s.[248] At that time, it was appropriately characterized as an emerging infection.[49,184] It continues to cause significant morbidity and mortality in this patient population in resource-poor parts of the world wherein there is not access to highly active antiretroviral therapy. The detection of *Cryptosporidium* or *Cystoisospora belli*, which also infects HIV patients, should prompt testing for HIV infection and, if negative, for another immunocompromising condition.

Humans become infected either from direct contact with infected animals or from ingestion of fecally contaminated food or water. Curtailing the waterborne transmission

of



■ **FIGURE 22-6** Life cycle of *Cystoisospora belli*. Immature oocysts containing one sporocyst are released in the feces into the external environment. Under ideal environmental conditions, the oocyst matures and develops two sporozoites that serve as the infective form. On ingestion of infective oocysts in contaminated food or water by a human host, excystation takes place in the intestine. The released sporocysts invade the mucosal epithelial cells in which schizogony takes place. Mature sporozoites are released from the intestinal cells. In the process of gametogenesis, male and female gametocytes are formed. After fertilization, an oocyst with a thick cell wall develops. Release of these immature oocysts into the external environment completes the life cycle.

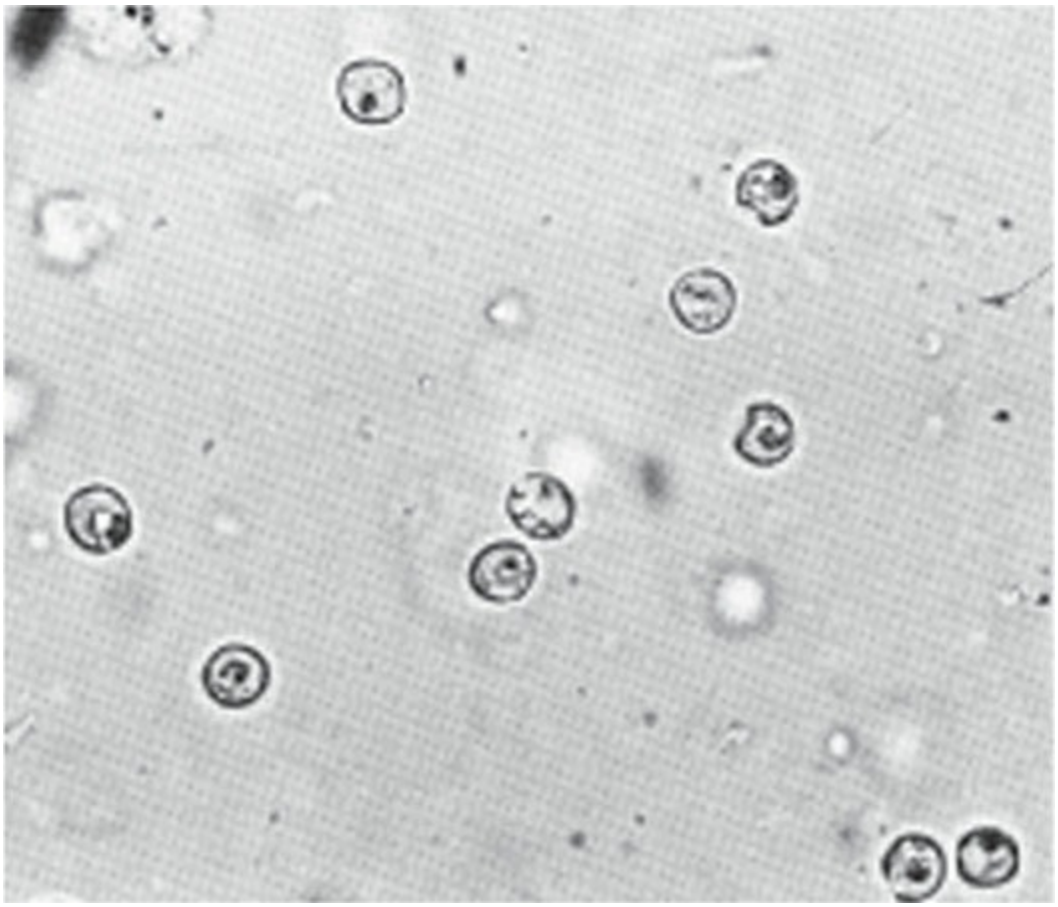
1443

Cryptosporidium is particularly challenging, since the oocysts are resistant to chlorination and may persist in posttreatment water supplies.[237] Two major outbreaks of gastroenteritis and diarrheal disease have been reported in immunocompetent individuals, one in Milwaukee,[161] involving over 300,000 people, and the other in Carroll County, Georgia,[114] with an estimated 90,000 documented people contracting acute cryptosporidiosis. The only collective risk factor determined in each of these outbreaks was exposure to the public water supply, which was filtered and chlorinated in compliance with Environmental Protection Agency guidelines.

The organism during all stages of development is confined to the microvilli of intestinal epithelial cells. Thus, the diagnosis can be made in hematoxylin and eosin (H&E)–stained sections of small bowel by observing the tiny oocysts, often in huge numbers, attached to the surface of the epithelial cells lining the villi (Image Plate 22-4A). Oocysts have a propensity to adhere to the brush border of the epithelial cells with loss or degeneration of the microvilli at the attachment zone.[184] The loss of microvilli may result in impaired digestion, malabsorption, and diarrhea that make up the clinical syndrome. Substantial volumes of diarrhea that occur in the immunocompromised host with a severe infection cause electrolyte abnormalities and may be life threatening. The clinical manifestations of cryptosporidiosis are presented in Clinical Correlation Box 22-3.

The diagnosis is commonly made by identifying oocysts in fecal specimens.[136] These are extremely difficult to identify in the standard iodine wet mounts and modified trichrome-stained permanent smears. Effective detection relies upon the use of EIAs/immunofluorescent assays or the use of modified acid-fast staining. Cryptosporidia have the following characteristics:

- Cryptosporidia measure 5 to 6 μm in diameter, are ovoid to spherical, and appear highly refractile when observed in flotation preparations (Fig. 22-7).[156]
- Small granules may be observed internally, or, with phase contrast microscopy, up to four slender, bow-shaped sporozoites may be seen in each oocyst.[49,184] This is not commonly observed in standard preparations.



■ **FIGURE 22-7** Oocysts of *Cryptosporidium* as observed in a fecal flotation preparation (original magnification ×1,280). (Courtesy of Bruce C. Anderson.)

- These organisms appear as homogeneous, red-staining spherical oocysts, 4 to 6 µm in diameter, when observed in acid-fast–stained stool preparations (Image Plate 22-4B).

With heavy infections, the concentration techniques routinely used for the recovery of eggs and parasites in most laboratories are adequate for the recovery of *Cryptosporidium* oocysts. With light infections, Sheather's sugar flotation method may be performed as described by Garza[89] (Box 22-4), although this is rarely used in current practice. A modified formalin-ethyl acetate (FEA) stool concentration technique to detect *Cryptosporidium* oocysts in stool specimens is in common use. Following the usual FEA procedure, the sediment was layered and floated over a hypertonic saline solution to separate parasites from stool debris. This technique showed the most significant improvement in the recovery of oocysts from stool specimens that were formed and not fatty.

CLINICAL CORRELATION BOX 22-3 Cryptosporidiosis

The clinical syndrome of cryptosporidiosis includes a cholera-like, watery or mucous diarrhea, persistent gastroenteritis with varying degrees of vomiting and abdominal cramping, malabsorption, and low-grade fever. In immunocompetent patients, the syndrome is self-limited, with symptoms diminishing over 7–14 days. Cryptosporidiosis in patients with AIDS or other profoundly immunocompromising conditions, however, often is particularly troublesome because of the prolonged and progressively severe watery diarrhea that may last for months. In these patients, treatment must be aggressive, particularly if the CD4 count is below 200 per cubic millimeter.

Following infection, oocyst-positive stools occur between 7 and 28 days of infection, with a mean incubation period of 7.2 days. Conversely, Shepherd and coworkers,[229] in a study of 49 patients, found that most patients stopped shedding oocysts by 20 days, with symptoms related to shedding in 25 of the 49 patients. Thus, duration of diarrhea and the onset and length of time of oocyst shedding is patient-dependent.[136] Therapeutic regimens have largely been unsuccessful in severely immunocompromised patients, possibly because of the unique parasitophorous vacuole that is formed within the host cell, sheltering the parasite from antimicrobial drugs.

Currently, treatment with azithromycin,[267] nitazoxanide, and paromomycin[73] is partially active, but reversal of immunosuppression, if at all possible, is important to achieve parasite clearance.[40] Excellent reviews of the clinical, epidemiologic, and parasitic aspects of cryptosporidiosis have been published.[184,267]

BOX 22-4

Sheather's Flotation Technique for Recovery of *Cryptosporidium* Oocysts in Fecal Specimens

1. A heavy suspension of feces is made in physiologic saline solution and strained through gauze into a centrifuge tube to one-half full.
2. Add an equal volume of Sheather's sugar solution (500 g of sucrose, 320 mL of distilled water, and 615 g of melted phenol) to bring the surface of the liquid

slightly above the top of the tube. Gently mix the suspension with an applicator stick.

3. Place an 18 mm^2 or 22 mm^2 coverslip on the surface of the suspension, and let stand undisturbed for 45 minutes.
4. Gently remove the coverslip, and mount it on a glass slide. Observe under phase contrast microscopy for the spherical, highly refractile 5μm diameter oocysts.[87]

A modified acid-fast stain is commonly used to detect *Cryptosporidium* oocysts in air-dried, methanol-fixed smears prepared directly from a fecal sample.[89] The carbol fuchsin stain is applied to the smear in the same manner as the routine acid-fast stain; however, 1% H_2SO_4 is used as the decolorizer instead of acid alcohol. The oocysts appear pink-red against the light green background of the counterstain.

Several immunoassay kits are commercially available for the detection of *Cryptosporidium* oocysts in fecal specimens.[88] In a comparative study, Garcia and Shimizu[85] found a sensitivity of 98% to 99% and a specificity of 100% for the detection of *Cryptosporidium* oocysts using the ProSpecT (Alexon), the Meridian Premier *Cryptosporidium*, and the Meridian MERIFLUOR *Cryptosporidium/Giardia* EIA kits (Meridian Diagnostics). This affirms similar results previously reported by Kehl et al.,[140]who found that the Color Vue *Cryptosporidium* assay (Seardyn, Indianapolis, IN), the ProSpecT *Cryptosporidium* microtiter assay, and the MERIFLUOR *Cryptosporidium* kit, previously mentioned, were equally sensitive and specific for the detection of *Cryptosporidium*, although in their experience, the immunofluorescence procedure was considered easiest to read and required the least hands-on technologist time.

The extreme sensitivity and specificity make PCR-based methods for *Cryptosporidium* oocyst detection quite attractive, particularly in the analysis of drinking water. These PCR assays may detect as few as one oocyst in a sample, making them the most sensitive methods available.[79,177] The PCR detection of oocysts may also be affected by numerous substances found in stool specimens, for which special nucleic acid extraction techniques have been developed.[52,285] This has necessitated the optimization of methods to avoid amplification inhibition. More recently, several multiplex assays have been released, which take a syndromic approach to the diagnosis of infectious gastroenteritis. These are FDA-approved or pending approval, easy to use, and detect a wide variety of pathogens, such as the most common causes of bacterial, viral, and parasitic gastroenteritis, including *Cryptosporidium.* Clark has reviewed the biology, diagnosis, procedures for laboratory identification, and treatment of cryptosporidiosis for those who desire further

reading.[40]

Cyclospora cayetanensis. The organisms now included in the genus *Cyclospora* were originally thought to be cyanobacteria or blue-green algae-like organisms.[155,187,192,236] *Cyclospora* species have morphologic characteristics similar to *Cystoisospora* and *Cryptosporidium,* except that they have two sporocysts per oocyst and two sporozoites per sporocyst (*Cystoisospora belli* has two sporocysts per oocyst and four sporozoites per sporocyst; *Cryptosporidium* species have four nonencysted sporozoites per oocyst.)[75] The species name, *Cyclospora cayetanensis,* honors the Universidad Peruana Cayetano Heredia in Lima, Peru, the institution where much of the original epidemiologic and taxonomic research was performed.

In unstained, unconcentrated stool specimens, the oocysts of *Cyclospora* species appear as nonrefractile, spherical to oval, and slightly wrinkled bodies, measuring 8 to 10 μm in diameter. This is almost twice the size of the oocysts of *Cryptosporidium* species and an important differentiating feature. There is an internal cluster of membrane-bound globules within the cell.[16] These parasites are acid-fast and stain with a faint pink or pink-red color with darker staining internal structures (Image Plate 22-4C). Older cells may fail to stain. Therefore, the presence of both staining forms and non-staining forms is common, and is also a useful differentiating feature. The oocysts stain orange-red with safranin. They do not stain with iron hematoxylin, Grocott-Gomori methenamine silver, iodine, or periodic acid–Schiff (PAS).[155] The oocysts autofluoresce strong green (450 to 490 DM excitation filter), or intense blue (365 DM excitation filter) under epifluorescence. Directors and supervisors of microbiology laboratories must decide whether stool specimens are to be routinely examined for the presence of *Cryptosporidium* and *Cyclospora* organisms. In many settings, the performance of an acid-fast stain on a stool specimen requires a separate order. This additional stain could readily be added to the routine stool studies in outbreak situations. One of the recently released FDA-approved multiplex assays includes reagents that target *Cyclospora*.

The life cycle of *Cyclospora*, which is also a member of the apicomplexan, is similar to that of *Cryptosporidium* species. Sporozoites excyst from oocysts in the digestive tract soon after ingestion in contaminated food or water. The sporozoites enter the epithelial cells in the small intestine. The mechanism by which diarrhea is produced is not known; endoscopy reveals moderate to marked erythema of the distal duodenum. Duodenal and jejunal biopsies reveal blunting of jejunal villi, villous atrophy, and crypt hyperplasia of varying degrees. The absence of fecal leukocytes and erythrocytes indicates that the process is not invasive; impaired D-xylose absorption implies a malabsorption-type syndrome.

Illness usually follows ingestion of contaminated food or water and occurs primarily in the warm summer months. There are numerous outbreaks that have been reported, a review of which is instructive. Only a few will be mentioned here. Powdered milk diluted with water before consumption has been implicated.[277] In a Chicago outbreak at Cook County Hospital, diarrhea developed in house staff and employees in a dormitory following failure of the dormitory's water pump.[276] *Cyclospora*-linked disease often occurs as traveler's diarrhea, with several literature citations of diarrhea occurring in travelers returning from Haiti, Mexico, Guatemala, Puerto Rico, Morocco, Cambodia, Pakistan, India, the Solomon Islands, and particularly Nepal.[125,205]Specifically, outbreaks in the United States and Canada during the spring months of 1996 and 1997 were related to the ingestion of raspberries imported from Guatemala.[117] There have been 27 reported outbreaks of cyclosporiasis in the United States from 2000 to 2013. Although raspberries were suspected in at least four of these outbreaks, other implicated foods included basil, blackberries, snap peas, snow peas, and bagged salad mix (http://www.cdc.gov/parasites/cyclosporiasis/outbreaks/foodborneoutbreaks.html). Sifuentesosornio et al.[232] reviewed and compared cyclosporidiosis in patients with and without AIDS. The incubation period is 2 to 7 days. The onset of diarrhea may be abrupt (68% of cases) or gradual (32%).[225] Watery diarrhea, which is self-limited in immunocompetent patients (rarely lasting more than 12 days), may be accompanied by mild nausea, abdominal cramping, fatigue, and malaise.[229] In immunocompromised patients, the diarrhea may be prolonged, lasting 4 to 6 weeks, may simulate tropical sprue, and may be associated with biliary disease. The voluminous diarrhea that may occur in these patients leads to life-threatening dehydration and electrolyte abnormalities. In a review of stool specimens from 450 patients with AIDS, Pappe et al.[192] found *Cryptosporidium* species in the stool specimens of 135 (30%), *Cystoisospora belli* in 12%, *Cyclospora* in 11%, *Giardia* in 3%, and *Entamoeba histolytica* in 1%.

Specific pharmacotherapy has proven to have limited effectiveness. Oral trimethoprim–sulfamethoxazole has been effective in the treatment of some patients; metronidazole, norfloxacin, quinacrine, nalidixic acid, and diloxanide furoate have been used with varying success in others.[126,192] In profoundly immunocompromised patients, treatment is often limited to supportive care with hydration and nutritional supplements, although Pappe et al.[192] found trimethoprim–sulfamethoxazole effective in some patients, particularly when increased doses were prescribed. In a study conducted in Nepal, the shedding of oocysts and disappearance of symptoms occurred after 7 days of therapy.[125] All efforts should be made in reverse the immunosuppression, if possible, as the restored immune system will assist in the elimination of the infection.

Cystoisospora belli. Cystoisosporiasis, an illness characterized by diarrhea and malabsorption, was formerly only rarely encountered and was considered to be of limited clinical significance. Severe disease may be experienced in immunocompromised hosts, in which heavy concentrations of organisms may be seen in the intestine. Fever, headache, steatorrhea, and weight loss may occur in protracted cases; deaths due to dehydration and electrolyte imbalance have been reported in overwhelming infections. The disease may persist for months in these patients. It is recovered with increased frequency in patients with AIDS, and the detection of this organisms should prompt questioning regarding high-risk behaviors, HIV testing or other immunocompromising conditions. Garcia[87] reports several patients with AIDS who had debilitating intestinal and extraintestinal disease caused by this organism. It is further recommended that patients with HIV who plan to travel to Central and South America or resource-limited countries be advised of the waterborne and food-borne transmission of *C. belli,* and consider chemoprophylaxis. Although immunocompromised individuals are at risk for severe disease, cystoisosporiasis, immunocompetent individuals may also be infected.[199] The drug of choice is trimethoprim–sulfamethoxazole; pyrimethamine is an effective alternative.

Human *C. belli* infections differ from those of other coccidians in that both the sexual and asexual forms inhabit the human intestine. Therefore, a second host is not required to complete the life cycle. Human-to-human transmission can occur after ingesting infective oocysts in fecally contaminated food and water; thus, the disease is not a zoonosis.

The oocysts are the diagnostic forms observed in human fecal specimens. They measure 25 to 30 µm in diameter, have a thin, smooth wall, and are nonmotile in fresh stool. Immature oocysts contain a single sporocyst (Image Plate 22-4E); more typically, the mature oocysts that contain two sporocysts are observed in fecal specimens (Image Plate 22-4F).

***Sarcocystis* Species.** *Sarcocystis* species use two mammals for the sexual and asexual phases of their life cycles. Humans may serve as either the intermediate or the definitive host. As the definitive host, humans become infected by ingesting poorly cooked infected beef or pork; the sexual cycle of the organism develops in the subepithelial portion of the small bowel mucosa. Intestinal infections are associated with *S. hominis* or *S. suihominis,* are often asymptomatic, but may on occasion result in a diarrheal syndrome similar to that produced by *Cystoisospora belli*. The diagnostic forms in stool specimens are broadly oval oocysts measuring between 10 and 20 µm. They contain two sporocysts, appearing similar to those of *C. belli*. Single sporocysts measuring 13 to 17 µm may also be seen.

Acting as intermediate host, which occurs when humans inadvertently ingest oocysts from other animal stool sources, sarcocysts develop in the skeletal

musculature and may be observed in biopsies of skeletal muscle, or have been seen in skeletal muscle at autopsy.[14] The sarcocysts in skeletal muscle measure approximately 100 × 300 µm in dimension (Image Plate 22-4G). This form is usually asymptomatic, although a history of polymyositis and eosinophilia has been reported in rare instances. Arness et al.[9] reported an outbreak of acute eosinophilic myositis among a 15-man US military team working in rural Malaysia. Varying degrees of fever, myalgia, bronchospasm, fleeting pruritic rashes, transient lymphadenopathy, and subcutaneous nodules developed in seven soldiers; all of these symptoms are common for sarcocystosis. Laboratory abnormalities included eosinophilia, elevated erythrocyte sedimentation rates, and elevated levels of creatine kinase in muscle. *Sarcocystis* spp. were recovered from a

skeletal muscle biopsy specimen obtained from the patient who was identified as the index case. Symptoms persisted in some soldiers for as long as 5 years. In such prolonged cases, chronic myositis, fasciitis, and myonecrosis with calcification may be seen histologically.

Nematodes

The nematodes are helminth roundworms; the adults of which are characterized by a tapered, cylindrical body with longitudinally oriented muscles and a triradiate esophagus. The species of intestinal nematodes (roundworms) that most commonly infect humans include the following:

Ascaris lumbricoides
Trichuris trichiura
Hookworms: *Necator americanus* and *Ancylostoma duodenale*
Strongyloides stercoralis
Enterobius vermicularis

It has been estimated that the number of people worldwide infected with intestinal nematodes is in the billions, and this number increases as the world population grows, particularly in resource-poor areas.[20,24,31] The magnitude of these figures translates into considerable human morbidity and mortality from the effects of this parasite, from a variety of mechanisms, such as blood loss, malnutrition, and intestinal blockage. Therefore, it is highly likely that clinical laboratories will detect the eggs, larvae, or even an adult of one of these parasites.

The life cycles of this group of helminths vary in complexity and modes of infection. None of these nematodes, however, utilize an intermediate host in their life cycle (Fig. 22-8). However, most require a stage outside the human host for the ova to develop into an infective form.

The egg or ovum is a mature gamete produced by adult females residing in the intestine and passed with the feces. This form is the latent stage, serving as the infective form in most instances. It is also the form that will be seen in the microscopic examination of the stool and will be used to make the definitive diagnosis. The ova of most nematode species require intermediate stages of development in the external environment to develop into a viable larvae. This development is dependent on the temperature, moisture, and nature of the soil into which they are passed. Life cycle drawings with legends are included for several of the nematode species to be presented in this chapter.

Ascariasis and Ascaris lumbricoides

It has been estimated that *Ascaris lumbricoides* alone affects approximately 25% of the world's population, which is 1.7 a billion people.[24] The highest prevalence of disease occurs in often malnourished people residing in resource-poor countries. Areas with modern water and waste treatment have a low incidence of disease. *Ascaris lumbricoides* undertakes what has been termed an *indirect* life cycle. Following the ingestion of a fertilized egg and excystation, the larva penetrates the bowel wall and begins a migration to the lungs. It penetrates the lungs, enters the bronchioles, and is eventually swallowed. The second exposure to the gastrointestinal tract triggers the development of the adult form. These nematodes are highly adapted to their human host, and so minimal tissue damage occurs with migration. The transient eosinophilic pneumonia or pneumonitis that occurs is termed Löeffler's pneumonia. The migration of numerous worms from exposure to multiple eggs would be associated with more extensive tissue damage. This indirect life cycle will become very medically important for another nematode discussed below, *Strongyloides stercoralis.* Although infections with few worms may go medically unnoticed, mechanical obstruction of the intestine may occur with massive infections.[12] A life cycle drawing of *Ascaris lumbricoides* is found in Figure 22-8.

The clinical manifestations of ascariasis[245] are presented in Clinical Correlation Box 22-4.

Laboratory Identification. The laboratory diagnosis of ascariasis is made either by observing the adult worms as they protrude or are passed from body orifices or by visualizing in situ in the intestine or in contiguous duct systems such as the biliary or pancreatic ducts at endoscopy, surgery, or autopsy.[107,163] In some instances, these may be detected radiologically. Most commonly, the identification is made by detecting

the characteristic ova in stool specimens. The key identifying characteristics of *Ascaris lumbricoides* are as follows:

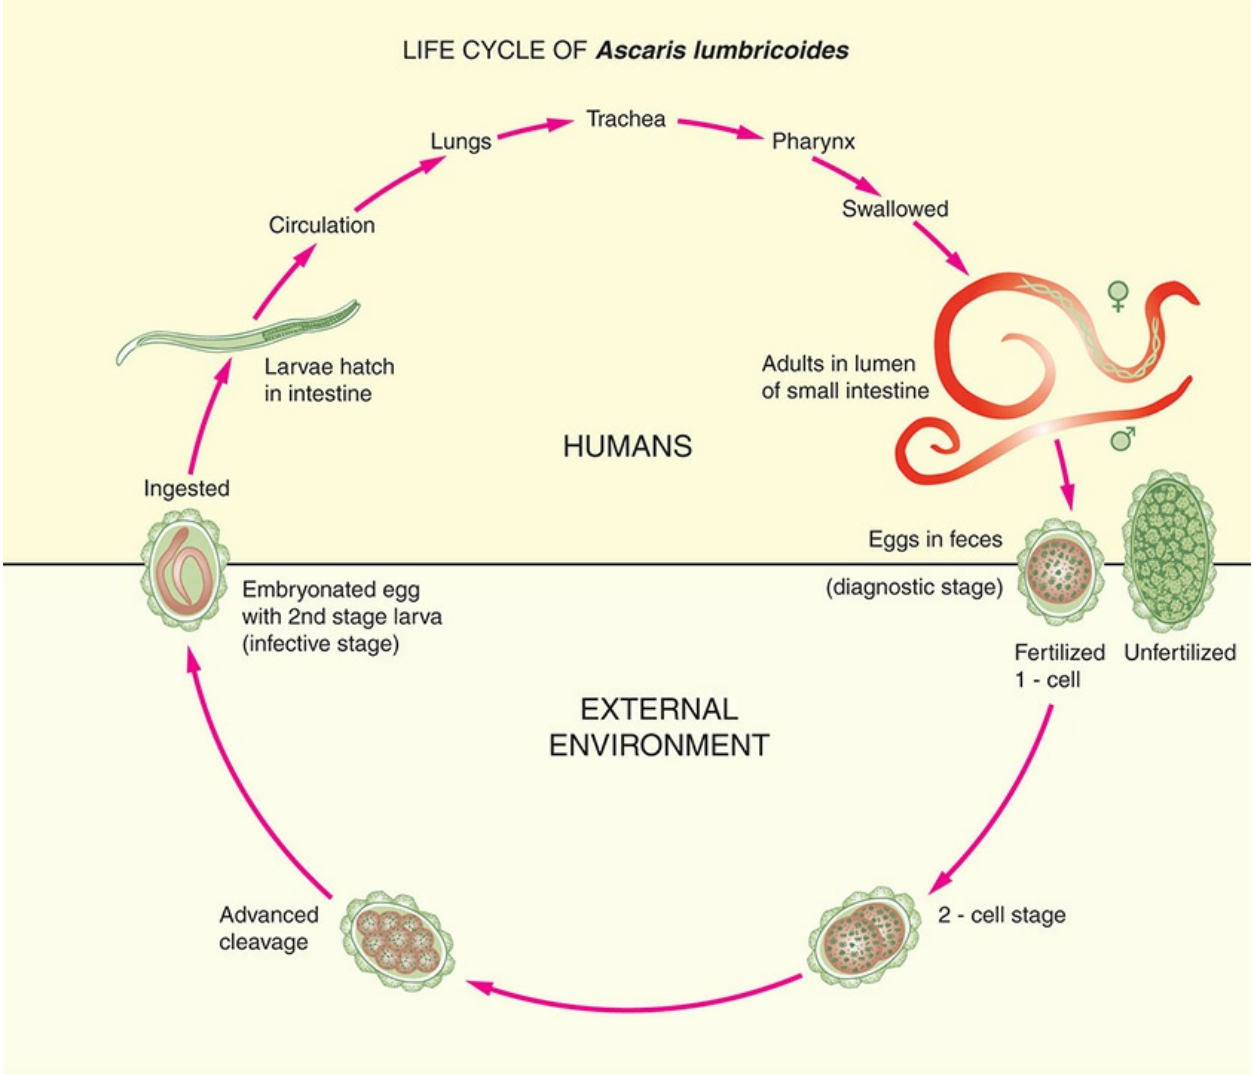
Adult Worms

- The adult worms measure between 15 and 35 cm in length.
- Male worms are smaller, and can be identified by their curved tail (Image Plate 22-5A).
- The cuticle is smooth and lacks the annular muscular striations characteristic of earth worms. It is important that parasitologists are aware of the morphology of earth worms, as occasionally these are submitted to the laboratory for identification.

Ova

- Fertilized eggs measure between 45 and 60 µm; unfertilized eggs average 90 × 40 µm.
- They are yellow-brown (bile-stained), oval, or spherical, and characteristically have a thick, transparent, hyaline shell covered by an albuminous coat (Image Plate 22-5B).
- Eggs that have had prolonged exposure to pancreatic secretions may be devoid of the albuminous coat (decorticoid).
- Fertilized eggs can be recognized by the cleavage of the internal yolk. Conversely, internal organization is lacking in unfertilized ova. Embryonated eggs in later stages of development may contain the larva (Image Plate 22-5C).
- Unfertilized, decorticate ova may resemble vegetable cells and can be extremely difficult to recognize in stool specimens (Image Plate 22-5D). In most instances, examination of additional fields will usually reveal the characteristic thick, outer mammillated albuminoid eggs.

Unfertilized *Ascaris lumbricoides* eggs are too heavy to float in the zinc sulfate flotation procedure and may be



■ **FIGURE 22-8** Life cycle of *Ascaris lumbricoides*. The life cycle does not involve an external intermediate host. It is somewhat complex, requiring a period for egg maturation in the external environment and a transpulmonary larval migratory phase in humans, which may result in transient asthma-like symptoms in heavy infections. Fertilized eggs passed into the soil require 2 to 3 weeks under ideal conditions of moisture and temperature to develop from the initial two-cell stage to advanced cleavage and the final infective embryonated stage. Upon ingestion of food or water contaminated with infective eggs by a human host, the larval forms hatch in the intestine and enter the circulation. After passage through the lung capillaries, the larvae break out into the pulmonary alveoli, then are coughed up and swallowed. In the intestine, they mature into male or female adult worms, where they may remain confined to the lumen or migrate to various ducts or orifices. Gravid females lay a large number of eggs that are passed with the feces to complete the life cycle.

CLINICAL CORRELATION BOX 22-4 Ascariasis

Patients with light infections may be asymptomatic. In heavy intestinal infections, abdominal pain, discomfort, and diarrhea are common findings. In contrast to hookworms, for which a heavy worm load is prerequisite to the presence of disease, a human intestinal infestation with only one *A. lumbricoides* worm, because of its large size, may be important. Ascarid adults have the propensity to migrate and wander into the bile ducts, pancreatic duct, or lumen of the appendix, or may rarely penetrate the bowel. Maddern et al.[163] reported a fatality caused by acute pancreatitis wherein a single *Ascaris lumbricoides* worm was found impacted within the ampulla of Vater. Appendicitis, pancreatitis, biliary obstruction, and hepatic abscess formation are all potential complications, even in light infections.[107]

1448

This propensity for ascarids to wander from the lumen of the intestine, particularly during drug therapy, is one reason why inadequate or incomplete courses of treatment can be particularly dangerous. In heavy infections, adult worms may protrude from the rectum or be coughed up. Intestinal obstruction, intussusception, volvulus, and bowel perforation are other potential complications of heavy infection. Intestinal obstruction occurs in approximately two of every 1,000 individuals infected, resulting in a fatality rate of six per 100,000 children.[245] Baird et al.[12] report an ascariasis hyperinfection in a 2-year-old South African girl from whom 796 *Ascaris lumbricoides* worms, weighing an aggregate of 550 g, were removed at autopsy. Torsion and gangrene of the heavily worm-infested ileum was the cause of death. Worms were also recovered from the stomach, esophagus, intrahepatic and extrahepatic bile ducts, and the gallbladder.

Treatment is with albendazole, which is also effective against *Trichuris trichiura*, a commonly found coinfecting organism. Mebendazole is an alternative treatment. Side effects include abdominal pain and diarrhea, particularly if infection is heavy and many worms are expelled. Use of the drug is contraindicated during pregnancy, wherein pyrantel pamoate is the alternative. There also is little evidence that drugs are helpful during the larval migratory stage of infection, so additional therapy may be needed.[87]

missed if the sediment is not also examined. The presence of only unfertilized ova in stool specimens may indicate infection with a single female worm. One adult female *Ascaris lumbricoides* can produce about 200,000 ova per day; therefore, the

enumeration of ova in fecal specimens using egg counts, a valuable procedure in evaluating the magnitude of hookworm infections, does not necessarily reflect the worm load in ascariasis.

Trichuriasis and Trichuris trichiura *(Whipworm)*

The overall incidence of *Trichuris trichiura* infections is not known, although a 90% prevalence has been cited in certain populations in Cameroon, Malaysia, and Caribbean countries. Vermud et al.[253] found that *T. trichiura* was the most common nematode recovered from 41,958 stool specimens submitted to the Columbia-Presbyterian Medical Center in New York.

The life cycle of *Trichuris trichiura* follows a simple fecal–oral route of transmission without an intermediate phase in an external host. This parasite has a so-called "direct" life cycle, since following ingestion of the egg the adult eventually develops in the intestinal tract without transpulmonary migration. The life cycle is illustrated in Figure 22-9. The clinical manifestations of trichuriasis are presented in Clinical Correlation Box 22-5.

Laboratory Identification. The laboratory diagnosis of trichuriasis is most commonly made by observing characteristic barrel-shaped ova in fecal specimens. The adults measure 30 to 50 mm in length, with the males on the average being slightly smaller. The males can be recognized by their long, thin tapering morphology that forms a 360-degree coil, from which the colloquial term *whipworm* is derived. In intestinal infections, the head is buried in the mucosa of the large bowel; therefore, adults are rarely seen in stool specimens. A magnified photograph of an adult worm is shown in Image Plate 22-5G, left.

Ova

- The eggs measure in the range of 54 × 22 μm.
- They are among the more readily recognized nematode eggs in microscopic preparations by their distinct barrel shape and the refractile, convex, hyaline polar plugs at either end (Image Plate 22-5F).
- These eggs may be confused only with the eggs of *Capillaria philippinensis.* However, the polar plugs of *C. philippinensis* are less prominent, are flat, and the shell is thicker and pitted (Image Plate 22-5P).

Enterobius vermicularis

"Pinworm" infections have been known since ancient times, and possibly represent the most common of all nematode infections. A well-known phrase is, "you may have had an infection as a child, or, if not, may likely get it when you have children." The life cycle of *Enterobius vermicularis,* like *Trichuris trichiura,* is a direct life cycle.

The eggs are spread by a fecal–oral route. Importantly, the eggs are infectious when they are deposited in the perianal area, meaning that direct human-to-human transmission occurs, similar to that of the intestinal amoebae.

Laboratory Identification. The diagnosis of pinworm infection may be made by observing adult worms either visually on the anal opening or microscopically in transparency (tape) mounts. These mounts are prepared by pressing the sticky side of a short segment of tape on the perianal folds or perineal skin, then sticking the tape to the surface of a glass slide for microscopic study (Image Plate 22-4F). The characteristic eggs are uncommonly seen in stool specimens (i.e., the diagnosis is not achieved using an O&P examination). Specimens collected from children early in the morning when worm migration is maximal have the greatest yield. The clinical manifestations of enterobiasis are illustrated in Clinical Correlation Box 22-6. The identifying characteristics are as follows:

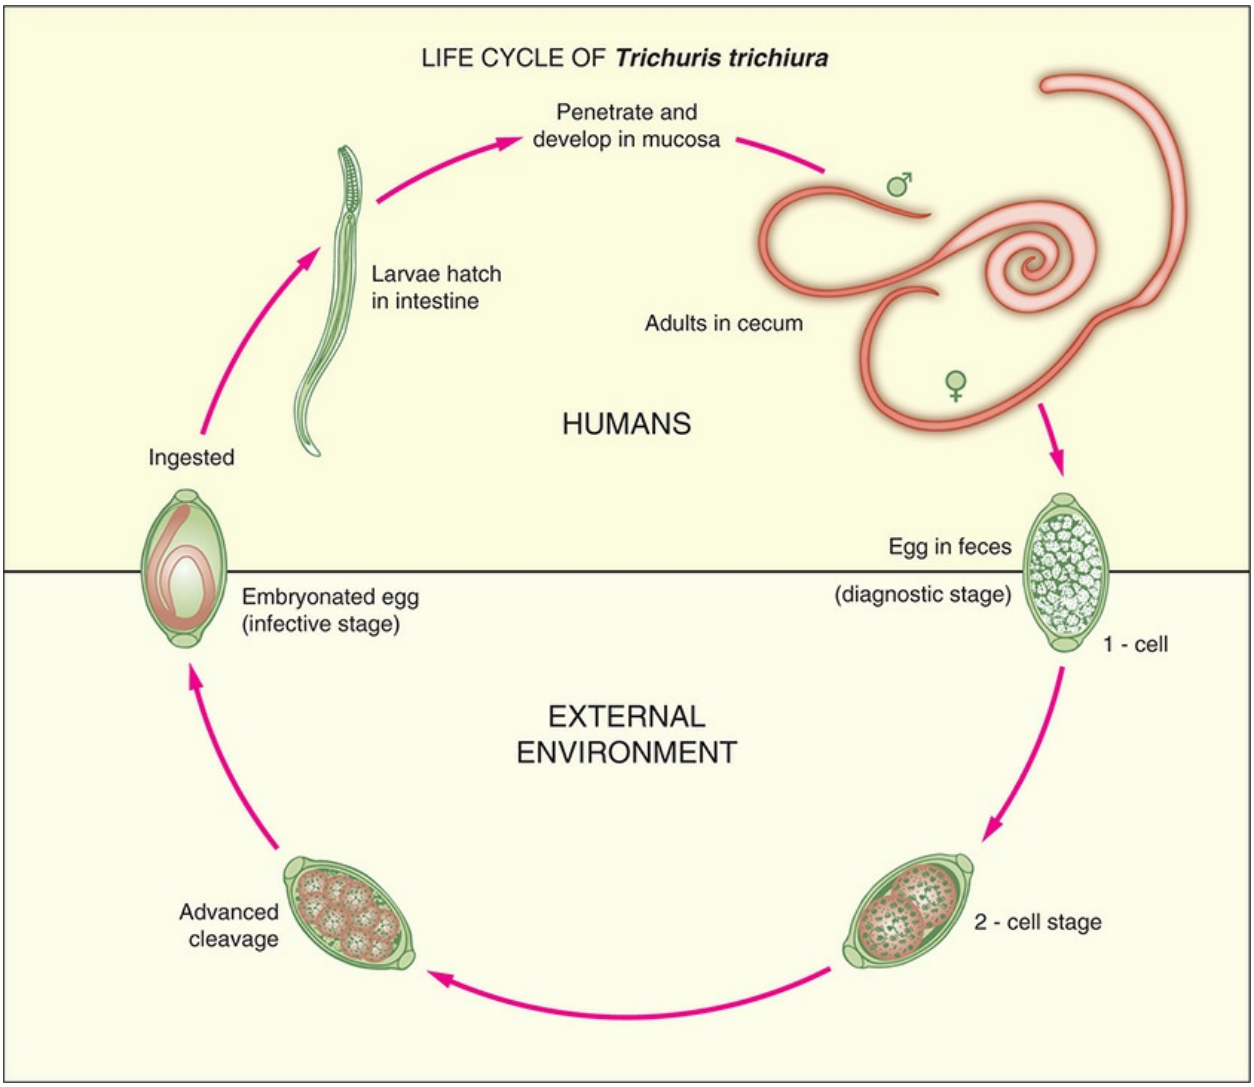
Adult Worms

- The adult female worm measures approximately 8 to 13 mm long × 0.4 mm in diameter.
- It can be recognized by the cuticular, winglike alar expansion at the anterior end (Image Plate 22-5E) and the long pointed tail, which makes the organism resemble a "pin."

Ova

- Measure approximately 30 × 50 µm in size.
- Have a thin, smooth, transparent shell.

1449



■ **FIGURE 22-9** The life cycle of *Trichuris trichiura* is what has been termed a direct life cycle, since after ingestion development occurs directly in the intestinal tract, without transpulmonary migration. The eggs, after passage into the external environment, also require a period of about 21 days under favorable conditions before they become infective. Upon ingestion of embryonated eggs by a human host, larvae hatch in the intestine. However, in contrast to the ascarids, these larvae penetrate into the mucosa of the intestine, primarily in the cecum, where they become anchored and develop into adult male and female worms. Gravid females pass eggs into the feces to complete the life cycle.

CLINICAL CORRELATION BOX 22-5 Trichuriasis

In light infections, patients are generally asymptomatic. The adult worms inhabit the large intestine. In heavy infections, diarrhea, dysentery, and abdominal discomfort,

resulting largely from mechanical damage to the intestinal mucosa, may be experienced. Anemia, growth retardation, and intestinal leakiness have been identified as predictable consequences of heavy infection and may serve as an indication of the intensity of infestation.[41] Varying degrees of malabsorption may also be observed, and because the diarrhea tends to be watery, sodium and potassium electrolyte imbalances may be a problem. Rectal prolapse in children is one of the complications of heavy infection with *Trichuris*.[254] Because the tiny adult worms are visible with the naked eye, the term *coconut cake* prolapse has been used to describe this condition.

Mebendazole is the drug of choice, but more than one dose may be necessary to effect a cure. Albendazole is an less effective alternative.

1450

CLINICAL CORRELATION BOX 22-6 Enterobiasis

The adult worms reside in the cecum and rectum. The diagnosis on occasion is made by observing worms in stained histologic preparations of the appendix or other portions of bowel. Symptoms occur when the gravid female deposits eggs in the folds of the perianal skin during the night. Nocturnal *pruritus ani* is the usual presenting symptom due to the irritation caused by the deposited eggs. Infections occur most commonly in children, and females are more prone to infection than males. In heavy infections, vaginitis with a mucoid discharge and/or urethritis may occur in young females.[87] Nervousness, insomnia, and nightmares are other presenting symptoms.

Pyrantel pamoate or mebendazole is effective, but more than one dose may be necessary as immature forms may be less susceptible to the drug. As infections may recur, repeat treatment after 1 or 2 weeks may be necessary if symptoms recur.

- Are oval in outline and asymmetrical, with one side flattened. Sometimes a groove is visible in the egg on the flattened side (Image Plate 22-5F).
- Each egg usually contains a well-developed larva (Image Plate 22-5E, right).

Hookworms

Ancylostoma duodenale is the Old World hookworm, and *Necator americanus* is the New World species, as defined by the predominant areas of endemic disease. Because the life cycles of these two species are essentially the same and cannot be differentiated by the appearance of their eggs, the general term *hookworm* is

commonly used for both species. An estimated 700 million to 900 million people worldwide are infected with hookworm (mostly *Ancylostoma duodenale*), 0.2% of whom suffer from severe anemia.

Unlike *Ascaris,* which gains entry to the host by the ingestion of eggs, the hookworm is one of the few parasites that has the ability to penetrate intact human skin. Following penetration, an indirect life cycle ensues, which results in an adult worm. This worm attaches to the intestine and feeds on the blood from the capillary-rich lamina propria of the bowel.[41] The life cycle is illustrated in Figure 22-10. The clinical manifestations of hookworm disease are presented in Clinical Correlation Box 22-7.

Laboratory Diagnosis. The laboratory diagnosis is made most commonly by observing the characteristic eggs in stool specimens, although may rarely be made by observing adult worms in the intestine as they are anchored to the mucosal lining of the intestine. It is important that the eggs of the hookworms are identified in stool specimens, and perhaps quantitative counts be made, because potentially severe disease may be associated with this nematode in heavy infections. Even light infections have been linked to serious sequelae, secondary to chronic anemia. The ova of both *A. duodenale* and *N. americanus* are identical; they also cannot be distinguished from the eggs of *Strongyloides stercoralis*, which usually are not seen in the stool, as this organism passes larvae rather than eggs.

Adult Worms

- Measure up to 1.5 cm in length, and reside in the upper intestine, where they are firmly attached to the mucosa by the biting action of cutting mouth parts.
- Observation of the mouth parts can be used to distinguish between the two species.
- *Ancylostoma duodenale* has two pairs of chitinous teeth (Image Plate 22-5I).
- *Necator americanus* is fit with a pair of cutting plates (Image Plate 22-5J).
- The male worms are distinguished by their frayed, posterior bursa.

Ova

- Eggs measure approximately 60 × 40 μm, and are distinctly oval.
- The shells are thin, smooth, transparent and nonpigmented.
- The yolk cells retract, leaving a clear space beneath the shell (Image Plate 22-5K).

Rhabditiform Larvae

- Rhabditiform larvae are rarely seen in the stool, since eggs are passed in hookworm infections. Nevertheless, it is important to be able to differentiate these from the larvae of *Strongyloides,* which are superficially similar.

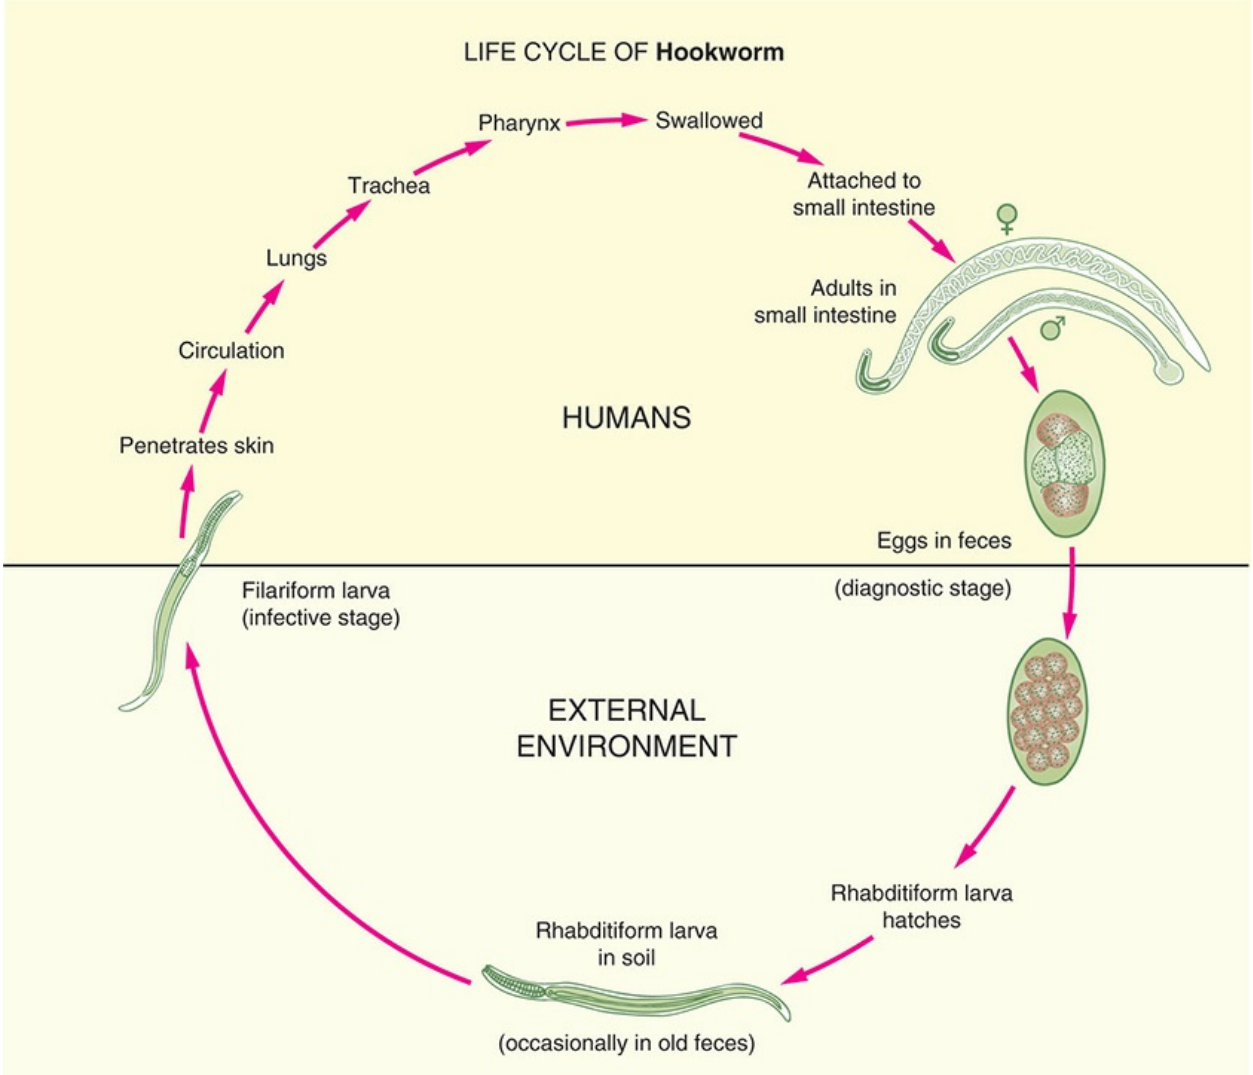
- The rhabditiform larvae of the hookworms possess a long buccal cavity (Image Plate 22-5L, left), which distinguishes it from *Strongyloides stercoralis,* which has a short buccal cavity (Image Plate 22-5L, right).
- The rhabditiform larvae of the hookworms lack a genital primordium, which is present in the rhabditiform larvae of *Strongyloides stercoralis*.

Strongyloidiasis and Strongyloides stercoralis

Peculiarities in the life cycle set infections with *Strongyloides stercoralis* apart from those of other nematodes. Most important among these is that the laboratory diagnosis of strongyloidiasis is usually made by observing the rhabditiform larvae rather than eggs in stool specimens (Image Plate 22-5M). As with the hookworms, *Strongyloides* is able to penetrate intact human skin whereafter it undergoes an indirect life cycle, as described. The life cycle is illustrated in Figure 22-11. Interestingly, *Strongyloides* also survives in the environment in a nonparasitic cycle; ergo, parasitosis is not necessary for the propagation of *Strongyloides.*

Worldwide, the magnitude of strongyloidiasis is similar to that of the prevalence of hookworm infections, with upward of an estimated 800 million people being infected, involving up to 10% of the population in some locales.[129] The incidence of infection in any given region is variable as the filariform larvae require considerable moisture and survive best where

1451



■ **FIGURE 22-10** Life cycle of hookworm. Hookworm eggs are usually passed in early stages of cleavage into the feces from gravid female worms. In approximately 24 hours in soil of ideal temperature and moisture content, the eggs hatch into the first larval stage, the free-feeding rhabditiform larva. About 5 to 7 days later, the rhabditiform larva transforms into the third-stage filariform larva, the infective form for humans. Depending on the temperature and moisture content of the soil, filariform larva can remain infective for up to 6 weeks. Humans become infected by penetration of the filariform larva on skin contact, either of the hands when digging into larva-infested soil or walking barefoot in soil contaminated with human feces. Similar to the ascarids, the hookworm larvae also penetrate the intestinal mucosa, enter the circulation, break out into the pulmonary alveoli, are coughed up, and swallowed. The larvae again burrow into the intestinal mucosa, where they develop into adult male and female worms. These adult worms remain firmly attached to the mucosa and access the blood supply of the host by cutting either plates or pairs of teeth depending on the species. Female worms lay large numbers of eggs that pass in the feces to complete the life cycle.

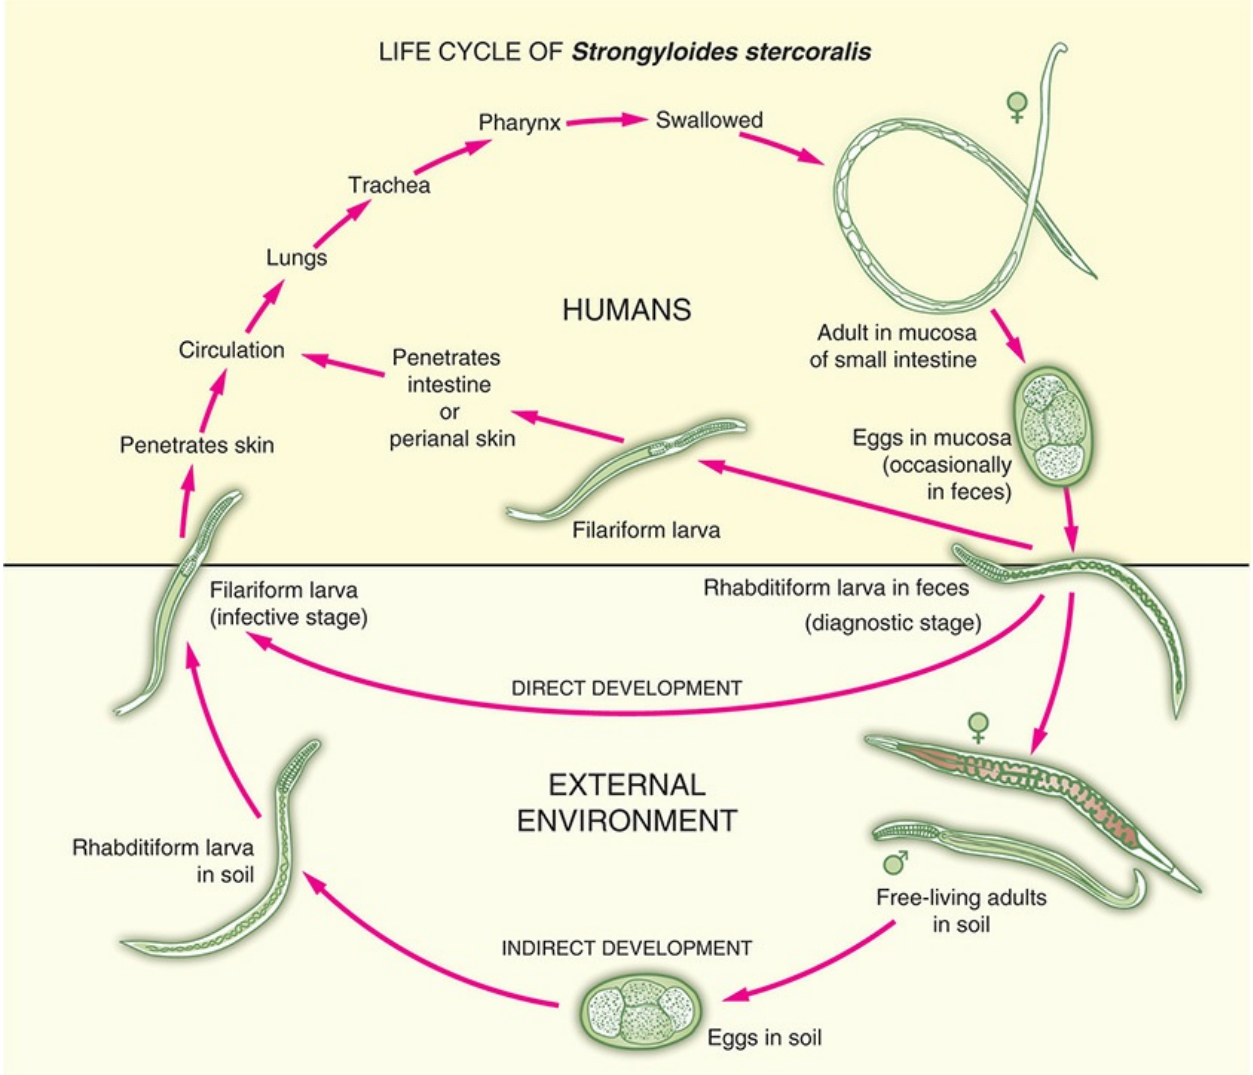
CLINICAL CORRELATION BOX 22-7 Hookworm Infections

Symptoms may occur relative to various stages of the life cycle. Skin infections may be experienced at the penetration sites of filariform larvae, particularly when humans are infected with nonhuman hookworm species ("ground itch").[254] Loeffler's syndrome in lungs and eosinophilia may be seen during the pulmonary larval migratory stage. Adult female hookworms produce only about 2,500–5,000 eggs per day; thus, the fecal egg counts may reflect the number of adult hookworms and, in turn, indicate the severity of infection. The presence of more than 2,000 hookworm eggs per milliliter of feces in women and children, and more than 5,000 per milliliter in males, is usually associated with anemia. Egg counting techniques are described by Garcia.[87]

1452

In heavy infections of 500 or more worms, the host could lose the equivalent of 1/2–1 pint of blood per week, resulting in severe hypochromic, iron deficiency anemia, and marked erythroid hyperplasia of the bone marrow, which in turn may lead to osteoporosis and the formation of bone cysts. Weakness, fatigue, growth retardation, peripheral edema, and congestive heart failure may be complications in severe infections. Of major concern worldwide is the lack of mental development from anemia-associated hypoxia in millions of children infected with hookworms. Diarrhea, abdominal pain, and nausea are manifestations of the intestinal phase of infection. Kelley et al.[141] reported that hookworm infections developed in 35 of 684 soldiers who took part in the Grenada military operations; they were most commonly associated with ground exposure near homes where sanitation practices were minimal.

Albendazole and other benzimidazoles are effective therapy; iron replacement should be given to patients with iron deficiency anemia.



■ **FIGURE 22-11** Life cycle of *Strongyloides stercoralis*. The life cycle of *Strongyloides stercoralis* is similar to that of the hookworms, except that the majority of eggs hatch into rhabditiform larvae while still in the intestinal lumen. Some of the rhabditiform larvae may transform into filariform larvae while still within the intestinal lumen. These can directly invade the mucosa or perianal skin, resulting in a cycle of chronic reinfection.151 This occurs unbeknownst to the immunocompentent host and occurs at a relatively low level (i.e., the reinfection cycle is not eliminated, but rather kept at a low steady-state by the immune system). However, once the host becomes immunocompromised, the rate of reinfection increases, resulting in what might be a fatal hyperinfection syndrome.[132,145] In cases of diarrheal disease, eggs, indistinguishable from those of hookworm, may occasionally be observed in the feces. Under ideal conditions of moisture and temperature in the external environment, rhabditiform larvae hatch, and quickly transform into infective filariform larvae. Humans become infected by direct penetration of filariform larvae into the skin on direct contact. The migration of these invasive larvae into the circulation is similar to that of hookworms, ultimately resulting in

the development of adult worms in the intestine.

1453

the water table is high. There have been outbreaks among military personnel stationed in endemic areas.[141] In the United States, strongyloidiasis is endemic in the rural south and southeast, with 3% to 5% of people being infected in some locales.[254] Infections also have high prevalence among patients in mental institutions, inmates in prisons, and in immigrants who formerly resided in endemic tropical regions.

Unlike other nematodes, *Strongyloides* commonly reinfects the same host, establishing a chronic parasitic infection. This is due to the fact that some of the larvae that are passed in the stool may penetrate either the bowel wall or the perianal skin. Chronic infections are usually unapparent, unless the host becomes immunocompromised.[97,110] This may occur through age or therapeutics (e.g., immunosuppressives given to control transplant rejection).[53] In such an instance, *Strongyloides* hyperinfection syndrome ensues, which is often fatal.[36,100,207] Less commonly, complications such as perforation and hemorrhage have been seen.[17] The clinical manifestations of strongyloidiasis are presented in Clinical Correlation Box 22-8.[112]

CLINICAL CORRELATION BOX 22-8 Strongyloidiasis

Skin irritation and pruritus in the form of low-grade chronic dermatitis may be seen at the portal of entry.[34] The full-blown ground itch characteristic for cutaneous infections from nonhuman hookworm infections usually does not occur. Leighton and MacSween,[151] however, reported a 74-year-old woman with a 65-year history of urticarial-like eruptions since childhood. These symptoms were finally correlated with chronic or long-term strongyloidiasis. The case for making a diagnosis of disseminated strongyloidiasis through recognition of filariform larva in skin biopsies was also made by Gordon et al.[97]

The intestinal manifestations of *Strongyloides* infections vary from few to no symptoms in light infections to severe necrotizing bowel disease in heavy infections. Symptoms may suggest peptic ulcer disease in some patients; in others, involvement of the small intestine may radiographically mimic Crohn's disease. A massive upper gastrointestinal hemorrhage involving a 29-year-old black immigrant from Africa caused by a heavy infection of the duodenum with *S. stercoralis* has been reported.[17]

With a heavy infective dose, pulmonary disease suggestive of Loeffler's

pneumonia, manifested as wheezing and eosinophilia, may occur; or in cases of hyperinfection syndrome to be described later in this chapter, full-blown pneumonia, cough, and shortness of breath may develop. Harris and associates[112] report two patients with disseminated strongyloidiasis in which the diagnosis was first made by observing larva in the sputum. They suggest that immunosuppressed patients in whom nonbacterial pneumonia develops, particularly in the presence of eosinophilia, should have both stool and sputum samples checked for infection with *S. stercoralis*.

Long-term corticosteroid therapy may also predispose to disseminated *Strongyloides* infections. Chu et al.[36] describe a 65-year-old man with steroid-dependent chronic obstructive pulmonary disease who developed pneumonia secondary to *Strongyloides*. The diagnosis was made based on larvae that were detected in an expectorated sputum specimen. In general, the pneumonitis caused by nematode larvae is transient and characterized by cough and fever; in more severe cases, it is characterized by chest pain, dyspnea, and hemoptysis.

Immunosuppressed hosts are particularly vulnerable to disseminated *Strongyloides* infections. The propensity for *S. stercoralis* eggs to hatch quickly and to produce intraintestinal filariform larvae (Image Plate 22-5N) makes patients vulnerable to autoinfection, producing a condition known as hyperinfection syndrome.[132] Purtilo and associates,[207] after observing the absence of granulomatous tissue response to larvae in several autopsy cases of fatal strongyloidiasis, concluded that an intact cell-mediated immune system is necessary to keep the organism in check. Once immunity is compromised or abrogated, hyperinfection from direct invasion of the intestinal mucosa (Image Plate 22-5O) with dissemination of larvae to many organs and tissues is liable to occur in patients harboring the parasite. Genta[90] offers the alternative argument that corticosteroids, rather than working through suppression of immunity, may in fact act directly on the worm as "molting hormones" that directly promote organism proliferation, making disseminated disease a more likely possibility. Although *Strongyloides* hyperinfection syndrome has not been specifically associated with HIV positivity and AIDS, a few instances have been reported.[110]

Because *S. stercoralis* can be harbored by humans as a subclinical infestation for many years following initial contact, patients in whom disseminated strongyloidiasis develops need not have had a recent exposure. Klein and associates[145] reiterate the need to screen stool specimens for strongyloidiasis before treating patients living in endemic areas with a course of immunosuppressive therapy. Recipients of organ transplants represent another high-risk group. This group should have serologic screening prior to beginning immunosuppressive therapy. Some have advocated a stool examination, which may be performed but is an insensitive method of detection.[53] Hyperinfection syndrome is further complicated because of the increased risk of gram-negative sepsis developing, presumably because intestinal bacteria accompany the penetrating *Strongyloides* larvae.

Thiabendazole and ivermectin are commonly used antihelminthics for strongyloidiasis, and are superior to albendazole. Ivermectin is usually used in

patients with hyperinfection syndrome.

1454

Laboratory Identification

Rhabditiform Larvae

- The rhabditiform larva of *S. stercoralis* has a buccal cavity which is short (Image Plate 22-5L, right), in contrast to the hookworms which have a long buccal cavity (Image Plate 22-5L, left).
- *Strongyloides stercoralis* rhabditiform larvae also have a prominent, oval genital primordium about one-third the distance from the tail.
- Often chronic infections are associated with very few parasites, making an objective diagnosis difficult. Examination of several stool specimens on successive days may be required, or the concentration procedure of Baermann may be indicated. In this procedure, active larvae are induced to migrate out of a fecal mass into a water reservoir through a wire screen covered with a pad of gauze, as described by Garcia.[87] DeKaminsky,[57] in a study of 427 stool samples, found that an additional 33 patients were diagnosed using a modified Baermann technique, and 28 additional patients were diagnosed using the agar plate culture method.

Trichostrongylus *Species*

Uncommonly detected in the United States, *Trichostrongylus* species are small adult nematodes similar to the hookworms that reside with heads buried in small intestinal epithelium. Adult worms typically inhabit the gastrointestinal tracts of sheep, cattle, goats, and other herbivores. Infection occurs through the ingestion of third-stage larvae that lie on grass and other vegetation. These parasites do not possess the special mouthparts characteristic of hookworms, and so the leaching of blood does not occur. Heavy infections may produce abdominal pain, diarrhea, and mild eosinophilia, but for the most part symptoms are minimal. The eggs of *Trichostrongylus* resemble the eggs of hookworms, but are longer (78 to 98 μm × 40 to 50 μm), with more pointed ends. It is important to recognize these subtle differences in egg morphology so that an incorrect diagnosis of hookworm infection is not made. Pyrantel pamoate is commonly used for treatment, with albendazole and mebendazole as alternatives.

Capillaria philippinensis

Capillaria philippinensis is an extremely small nematode; the adults measure 1.5 to 3.9 mm in length, and their width ranges from 5 mm at the filamentous head to 30

mm in midbody. After considerable research to find the reservoir hosts, it is now believed that fish-eating birds are natural hosts within a fish–bird life cycle.[44] Humans become infected when they eat poorly cooked fish commonly consumed by birds.

The disease is endemic in the Philippines, Thailand, and regions adjacent to the South China Sea. Local eating habits include ingestion of raw animal organs and the use of intestinal juices from animals to season rice and other foodstuffs. Additionally, eating uncooked crabs and small freshwater fish is considered a delicacy in many indigenous populations. Infection with *C. philippinensis* always causes illness and may lead to death if untreated. From 1967 to 1990, 1,884 confirmed cases of intestinal capillariasis were documented, from which 110 people died.[44]

The gradual onset of abdominal pain, borborygmus (i.e., stomach gurgling), and intermittent diarrhea over a 4- to 8-week period is the common presenting clinical picture. Severe protein-losing enteropathy, malabsorption of fats and sugars, and low xylose excretion are commonly seen. Fluid loss and electrolyte imbalances characterized by low plasma levels of potassium, sodium, and calcium are seen. Increased IgE levels and depressed IgG, IgM, and IgA levels occur. Postmortem examinations of patients who have died of this disease disclosed heavy infection in the jejunum, with focal mucosal atrophy at sites of organism invasion.[44]

Laboratory Identification

- The eggs of *C. philippinensis* may be confused with the eggs of *Trichuris trichiura* because of a similar morphology.
- In contrast to *T. trichiura,* the eggs of *C. philippinensis* have less conspicuous polar plugs and a thick, striated, or pitted eggshell (Image Plate 22-5P).
- A misidentification could lead to serious sequelae, unnecessary morbidity, or even the death of patients infected with *C. philippinensis*, if this infection proceeds untreated.

Cestodes

The cestodes are a subclass of helminths comprising true tapeworms, which have a scolex and a series of hermaphroditic, egg-producing body segments called proglottids. The cestodes of human importance to be presented are as follows:

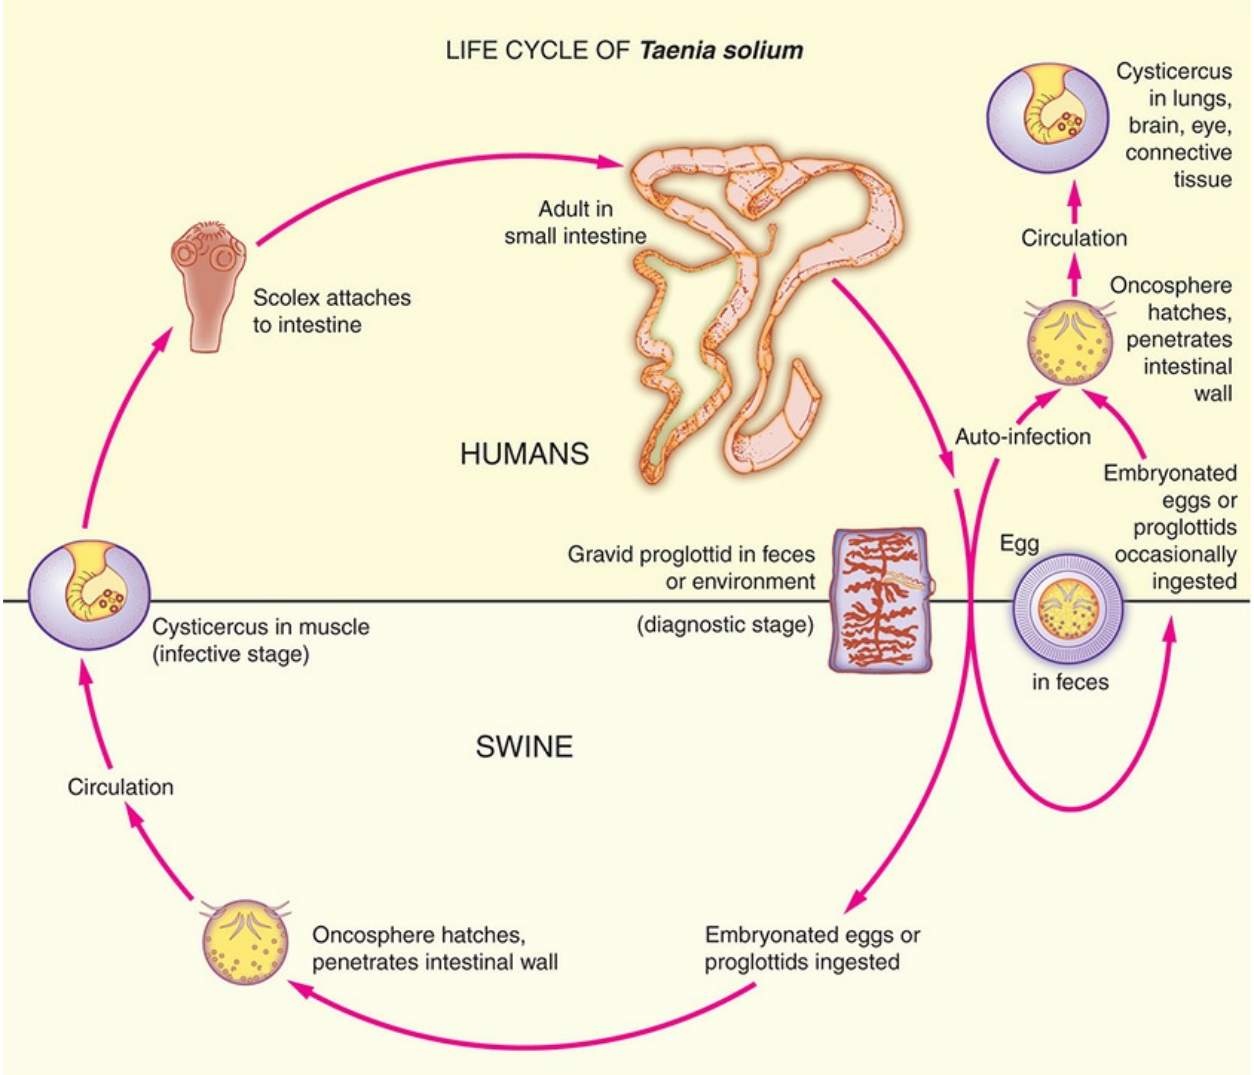
Taenia saginata
Taenia solium
Diphyllobothrium latum
Hymenolepis nana
Hymenolepis diminuta

Dipylidium caninum

The body of an adult cestode or tapeworm, called the strobila, consists of two parts, a scolex and the proglottid (Image Plate 22-6A). The scolex is the anterior portion with hooklets and/or suckers by which the worm attaches and anchors to the intestinal mucosa. The crown of the scolex, called the rostellum, may be fit with hooklets (i.e., armed) (Image Plate 22-6B) or may be devoid of hooklets and smooth (i.e., unarmed). These morphologic differences are helpful in establishing a species-level identification.

The major portion of the body of a tapeworm consists of a long series of segments called proglottides. Each proglottid possesses male and female reproductive organs; the uterine branches of which are packed with eggs when mature (Image Plate 22-6C). The eggs or proglottides filled with eggs are passed in the feces. Subtle differences in the size, shape, and internal structures of proglottides serve as aids in establishing a species-level identification. The evaluation of stool in microscopic mounts for the detection of eggs is the most common means of establishing a laboratory diagnosis.

With the exception of *Hymenolepis nana*, in which human-to-human transmission of infections may occur through ingestion of fecally contaminated food or water that



■ **FIGURE 22-12** Life cycle of *Taenia solium*. A human infected with an intestinal tapeworm passes proglottids and/or mature eggs into the external environment, where soil, water, and vegetative matter become contaminated with fecal matter. In the case of *Taenia solium*, the embryonated eggs are ingested by a pig, within the intestine of which an oncosphere hatches and penetrates the mucosa. The released larvae enter the circulation and migrate to the skeletal muscle to encyst in the form of a bladderlike cyst called a cysticercus. On ingestion of such cysticercus-infested pork by an unsuspecting human, the scolex evaginates in the intestine and the scolex attaches to the intestinal mucosa. In time, the tapeworm grows through the proliferation of hundreds of proglottids, until a length of several meters is reached. Eggs and proglottids are again released into the intestinal lumen and passed with the feces to complete the life cycle. The right side of the figure demonstrates that humans may also act as an intermediate host for this parasite, if an egg is ingested. This disease is cysticercosis.

contains infective eggs, the life cycles of the cestodes require one or more intermediate

hosts to support larval development. The life cycle of *Taenia solium,* as a representative of cestodes, is illustrated in Figure 22-12.

Taenia solium *and* Taenia saginata

Taenia infections have been known since biblical times, primitive knowledge of which may be related to the Judaic prohibition against the ingestion of pork. Humans acquire the intestinal infections with an adult *Taenia* tapeworm through the ingestion of encysted larval in poorly cooked pork (*T. solium*) or beef (*T. saginata*) (Image Plate 22-6D). The intestinal infections with the adult tapeworms of these two species produce similar symptoms in humans, as discussed below. Of greater medical importance is the fact that humans may also serve as an intermediate host for *T. solium.* This would occur if a human ingested the egg of *T. solium*. In this type of infection, called cysticercosis, the larvae travel widely throughout the body and may encyst in any tissue, but have a propensity to encyst in the brain[266] (Image Plate 22-6E). Laboratory workers must be careful when handling the ova-packed proglottides of *T. solium* to avoid inadvertent hand-to-mouth transmission. Human cysticercosis does not

occur with *T. saginata*; however, as the true identity of the infecting organisms may not be immediately known, care must be taken when handling any proglottides.

Cysticercosis has high prevalence in Mexico and Latin America, where an estimated 350,000 persons are infected. The disease has been found in 2% to 3% of individuals autopsied in Mexico City, accounting for 25% of all intracranial masses found by computed tomography scans.[204] In the past, neurocysticercosis had been uncommon in the United States, with only a few hundred cases recorded since surveillance began in 1957. However, more recently, there has been a marked increase in disease, which has, in part, paralleled the increase of immigration of people from endemic areas.[42] In 1989, cysticercosis became a reportable disease in California.[68] During the first year, 134 cases were reported, nearly all (117) from people of Hispanic background and most of whom had immigrated from countries where *T. solium* is endemic. In addition to the higher incidence of disease in California, several sporadic infections have also been reported from various areas in the United States, including Texas, Colorado, Pennsylvania, and Missouri.[171] Perhaps because of this experience, Roman et al.[213] propose that neurocysticercosis be declared an international reportable disease. Several publications reflect high rates of incidence of symptomatic cysticercosis in many regions throughout the world, as exemplified by endemic areas in Andean communities and in Burundi, as reported by Cruz et al.[45] and by Newell et al.,[186] respectively. The clinical manifestations of taeniasis and cysticercus infections are presented in Clinical

Correlation Box 22-9.

Laboratory Identification. The laboratory diagnosis of *Taenia* tapeworm infections (i.e., taeniasis) is usually made by observing the characteristic eggs in microscopic mounts of fecal material; the adult worms or portions thereof are required to make a species-level identification, since the eggs for the two species are morphologically indistinguishable.

The identifying characteristics of *Taenia* species are as follows:

Ova

- Spherical in shape, measuring approximately 30 by 45 µm in diameter.
- Characteristic smooth, thick shell with radial striations (Image Plate 22-6H). A photograph of these eggs in situ within the uterus of a gravid female worm is illustrated in Image Plate 22-6G.
- Three pairs of hooklets may be observed internally, in a structure called an oncosphere.

Adult Worms

The features by which *T. saginata* and *T. solium* can be differentiated are as follows:

	Taenia saginata	***Taenia solium***
Strobila:	4–10 m long Up to 2,000 proglottids	2–4 m long 800–1,000 proglottids
Scolex:	Four suckers Unarmed rostellum	Four suckers Armed rostellum (Image Plate 22-6B)
Proglottides:	More than 13 lateral uterine branches	Less than 13 lateral uterine branches (Image Plate 22-6C)

CLINICAL CORRELATION BOX 22-9 Taeniasis and Cysticercosis

Taeniasis

Intestinal symptoms are usually insignificant. Passage of proglottides in stool may be the first indication of disease. Epigastric pain, vague abdominal discomfort, nervousness, and increase in appetite may be experienced. Weight loss is minimal. Eosinophilia is usually moderate.

Cysticercosis

Cysticercosis refers to the development of extraintestinal encysted larval forms of *T. solium* in various organs following the ingestion of gravid eggs in fecally contaminated food or water. Although most human infections are caused by *T. solium*, other species of animal tapeworms can on rare occasions also produce morphologically similar cysticerci (e.g., coenurosis). The CNS is involved in 60%–96% of patients, a condition known as neurocysticercosis (Image Plate 22-6E). The majority of patients with neurocysticercosis have more than one cyst, with as many as 200 found in one autopsy case.[171]

Symptoms vary considerably from patient to patient and are dependent on the anatomic location of the cysticercus. Lesions in the cerebral cortex may result in seizures or localizing neurologic deficits. Cranial nerve palsies, in particular involving the fifth and seventh nerves, and abnormal reflexes are commonly found. Cysticercosis is the most frequently identified cause of epilepsy in young adults living in endemic areas, and it is the sole manifestation in up to one-third of patients.[221] Focal seizures occur in up to three-fourths of those infected. Intraventricular brain cysts may obstruct the flow of cerebrospinal fluid, leading to symptoms of acute intracranial hypertension (headache, vertigo, nausea, vomiting, papilledema, and visual disturbances); changes in personality and mental status are present in 40% of patients.[171]

The invasive larvae (onchospheres) are susceptible to circulating antibody and complement in the human host[266]; however, significant titers develop only after the larvae have transformed into the antibody-resistant metacestodes. In fact, antibody may bind via Fc receptors to the worm, which may use it as a source of protein.

1457

Taeniaestatin and other parasite molecules may interfere with lymphocyte proliferation and macrophage function, thus paralyzing the cellular immune response.

Praziquantel and albendazole have been extensively tested and successfully used for the treatment of neurocysticercosis, usually in combination with corticosteroids.[259] There is debate concerning the treatment of extensive neurocysticercosis because dying cysticerci provoke an enhanced inflammatory response, which may lead to cerebral edema, herniation, and death. Corticosteroid use may also be needed. In some instances, surgery is necessary.

A mass effort to treat cysticercosis in a rural community in Mexico was undertaken giving all participating citizens a single dose of praziquantel of 5 mg/kg; human taeniasis was reduced by 56%, and late-onset seizures by 70% over a 42-month period.[221] In this same study, anticysticercus antibody levels were reduced in humans by 75%, and by 55% in treated pigs. Vaccines, using recombinant antigens, have been developed and found in experimental studies to induce over 90% protection for challenge infections for hydatid disease in sheep, providing encouragement for

potential vaccine use in humans as well.[154]

Chapman et al.[32] have developed a species-specific DNA probe that differentiates *T. solium* eggs from those of *T. saginata*. The authors describe the isolation and characterization of recombinant clones that contain repetitive DNA sequences (a 158-bp sequence) for *T. solium* and an unrelated *T. saginata* sequence that encodes a portion of the mitochondrial *cytochrome c oxidase I* gene, each specifically hybridizing with genomic DNA from respective species. In the absence of such probes, it is not possible to differentiate *T. solium* from *T. saginata,* based on egg morphology alone. This should be clearly conveyed to the clinician who ordered the stool examination, since individuals, particularly children, in the home of a patient shedding *T. solium* eggs are at elevated risk for neurocysticercosis. Sloan et al.[235] examined the use of an enzyme immunoassay for the serologic diagnosis of cysticercosis. An immunoblot assay is available at the CDC for confirming the diagnosis of cysticercosis; acceptable specimen types include serum and cerebrospinal fluid (CSF).

Diphyllobothrium latum: *The Giant Fish Tapeworm*

D. latum, the human giant fish tapeworm, uses two intermediate hosts in the development of its larval forms. Endemic areas include the cold clear lake regions of Scandinavia, northern Europe, northern Japan, the upper Midwest of the United States, Canada, and Alaska. Figure 22-13 is an illustration of the life cycle of *D. latum*. The clinical manifestations of diphyllobothriasis are presented in Clinical Correlation Box 22-10.

Laboratory Identification

Adult Worm

Although the proglottides are rarely passed in the stool, but when found they are distinctive.

- An intact strobila measures 3 to 10 m in length and has over 3,000 proglottides.
  - Only a part of the strobila is recovered in most instances.
- Individual segments (i.e., proglottids) are characteristically broader than they are long (*latum* is Latin for *broad*) (Image Plate 22-6I).
- The scolex is rarely recovered from stool specimens. If recovered the features include the following:
  - It is almond-shaped and measures 2 to 3 × 1 mm.
  - It is distinctive for two deep dorsoventral suctorial grooves (*bothria* = pit), demarcated by lateral lip-like folds (*phyllon* = leaves) (Image Plate 22-6J).

- Each proglottid includes a nondescript coiled uterus in the form of a compact rosette (Image Plate 22-6K).

Ova

The laboratory diagnosis of human *D. latum* infection is commonly made by identifying the characteristic operculated eggs in stool specimens. This is the only operculated egg that is from a cestode; all other operculate eggs that will be covered are from trematodes.

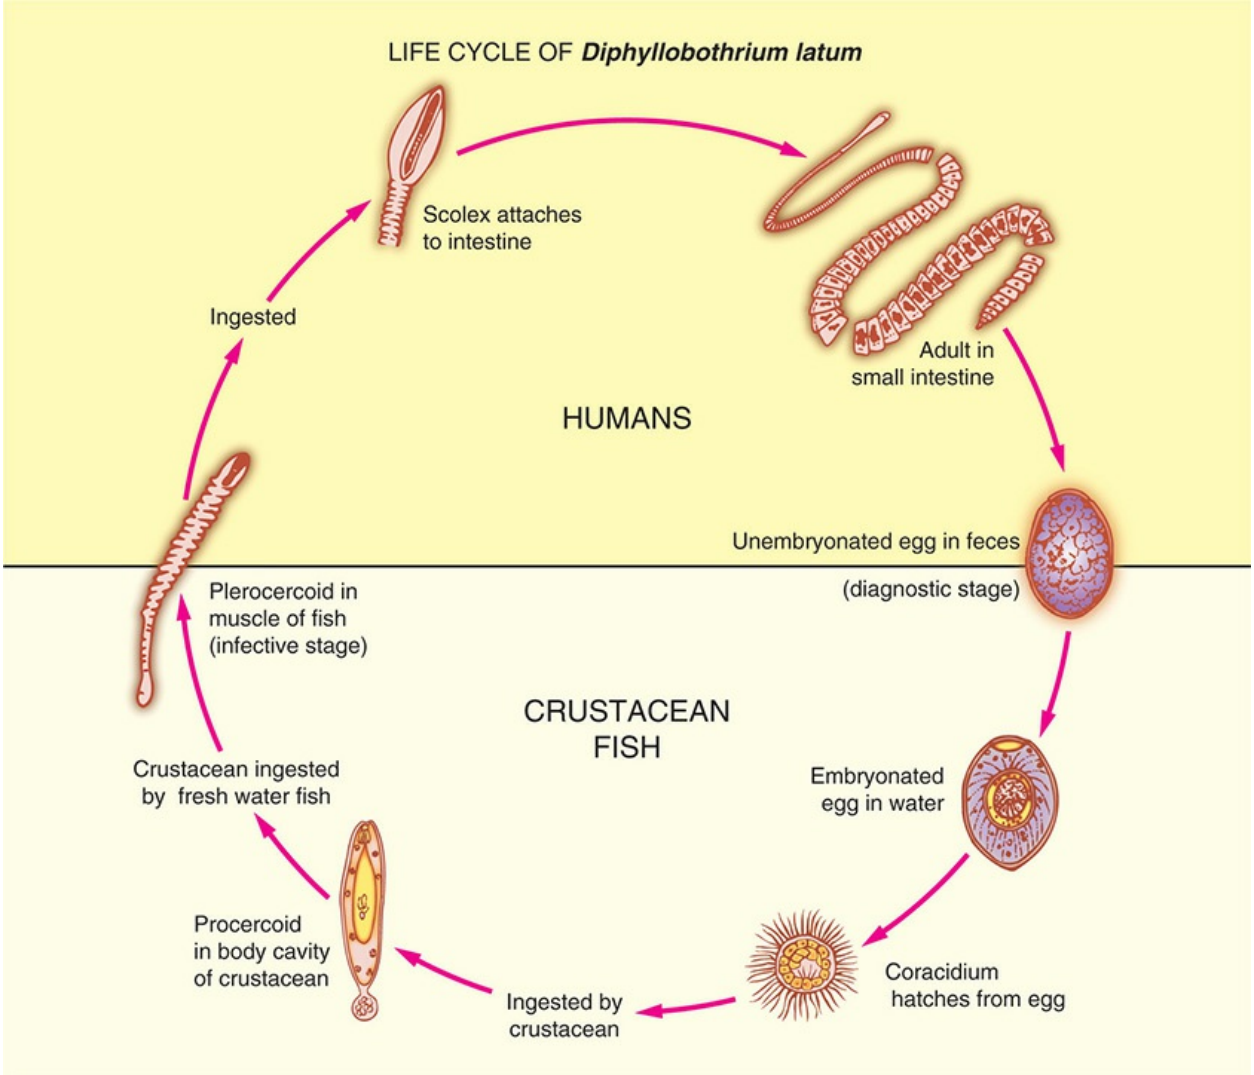
The eggs of *D. latum*:

- Measure approximately 55 to 75 × 40 to 55 μm and are elongated.
- Have a smooth shell with an inconspicuous non-shouldered operculum at one end and a knoblike thickening at the other end (i.e., the abopercular end) (Image Plate 22-6L).
- These are differentiated from the operculate eggs of *Paragonimus westermani* (discussed later) by the lack of a distinctly shouldered operculum and lack of an abopercular knob (Image Plate 22-7P).

Hymenolepis *Species*

Hymenolepis nana, known as the dwarf tapeworm, has a worldwide distribution and is one of the more common causes of cestode infections in humans, particularly in children. In contrast, *Hymenolepis diminuta* is primarily a parasite of rats and mice, and is uncommonly found in humans. Various species of arthropod (e.g., "meal beetles"), which harbor the infective larval forms, serve as intermediate hosts. A photograph of an *Hymenolepis* cysticercus as it may appear within the insect is illustrated inImage Plate 22-6F. Humans become infected through the ingestion of these larval-infected insects. Such an intermediate host is not obligatory for human-to-human transmission of *Hymenolepis nana*. Most commonly, humans become infected through the ingestion of food or water contaminated with *Hymenolepis* eggs.

1458



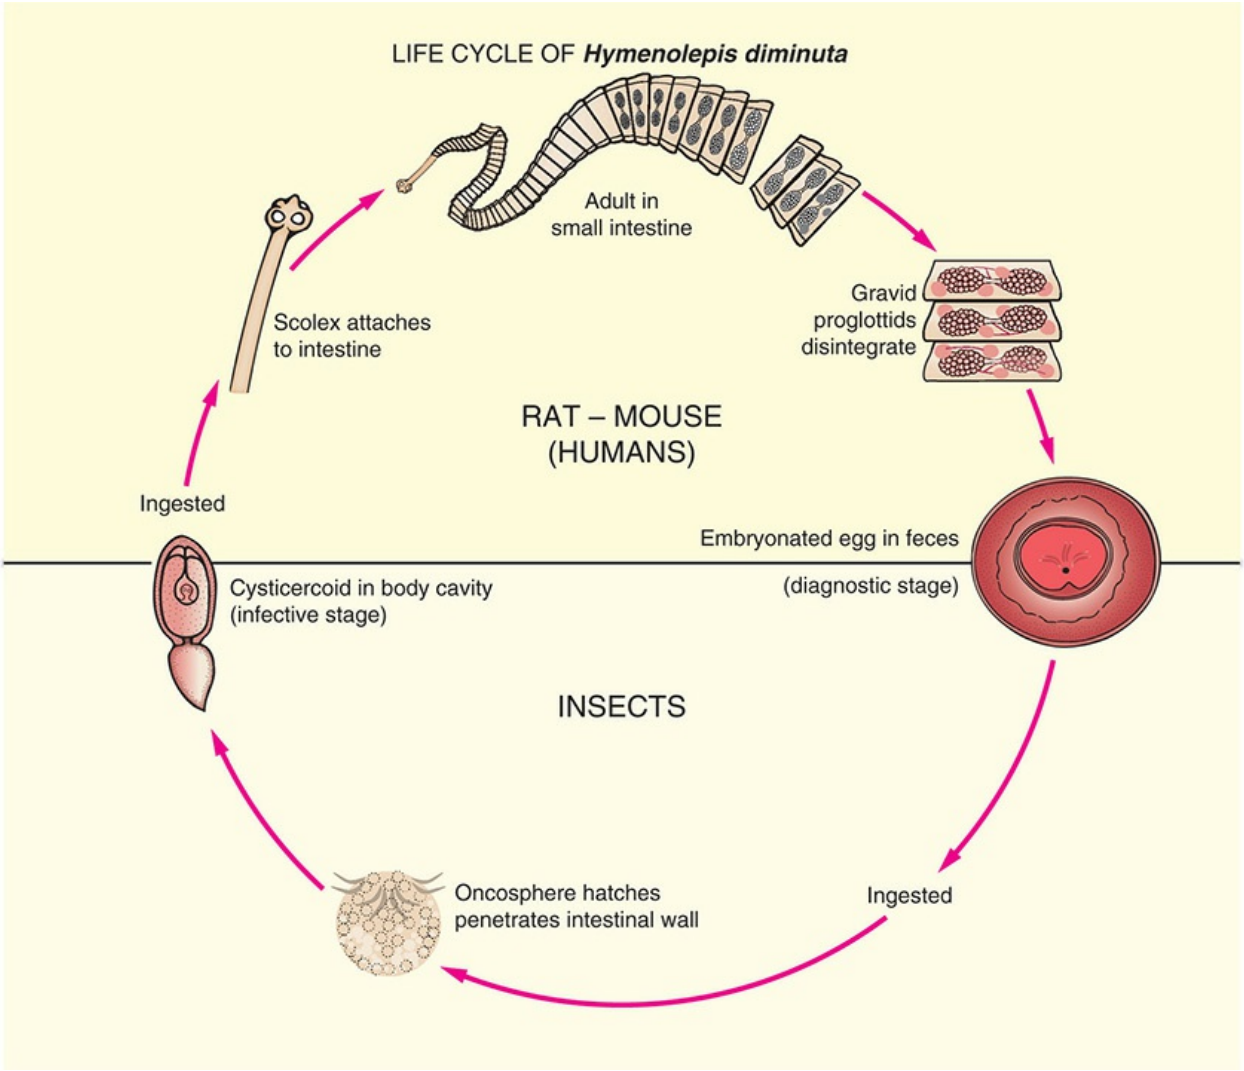
■ **FIGURE 22-13** The life cycle of *Diphyllobothrium latum* involves two intermediate hosts. Unembryonated eggs, passed with the fecal material from an infected human into a freshwater estuary, undergo embryonation during a period of several days and hatch, releasing a free-swimming coracidium. These coracidia in turn are ingested by a crustacean (copepods or cyclops), within the body cavity of which develop procercoid larvae. Copepods serve as one of the major food sources for a variety of freshwater fish in North America. Following ingestion of the copepod by the fish, the plerocercoid larvae of the parasite (spargana) develop within the flesh of the fish. Humans ingest these plerocercoid larvae in raw or poorly cooked fish, where they develop into adult worms in the intestine. On maturation, the adult worm passes eggs into the feces, to complete the life cycle.

CLINICAL CORRELATION BOX 22-10 Diphyllobothriasis

Patients may harbor an adult worm for up to 20 years. Intestinal symptoms are minimal. Large adult worms may cause mechanical bowel obstruction, accompanied by abdominal pain and diarrhea. In a minority of patients infected with *D. latum*, particularly in northern Europe and specifically in Finland, megaloblastic anemia secondary to vitamin B_{12} deficiency occurs, secondary to the selective competition of the parasite for this essential vitamin. Praziquantel is an effective therapy, with niclosamide as an alternative.

Humans may also become infected with the larval plerocercoids of diphyllobothroid tapeworms closely related to *D. latum*, causing an infection known as sparganosis. Adult worms are found in dogs and cats; the larval form develops in humans following ingestion of larval-infected Copepoda or the raw flesh of amphibians and reptiles. The plerocercoid larvae (sparganum) develop into pruritic nodules in the subcutaneous tissues over a period of months. Peripheral blood eosinophilia is a nonspecific clue to the possibility of sparganosis; however, the characteristic larvae must be demonstrated in subcutaneous nodules before a definitive diagnosis can be made.

1459



■ **FIGURE 22-14** Life cycle of *Hymenolepis diminuta*. Embryonated eggs, passed into soil or water from an infected human via the feces, in turn are ingested by an insect. An oncosphere hatches in the intestine of the insect and penetrates the intestinal wall. An infective cysticercoid then develops in the body cavity. On the accidental ingestion of the infected insect by a human, larvae are released and penetrate the villi of the upper part of the small intestine. The scolex attaches to the intestinal mucosa, where they develop into adult worms. On maturity, embryonated eggs are released from gravid proglottids and passed in the feces, to complete the life cycle.

Figure 22-14 is an illustrated life cycle of *Hymenolepis diminuta.* Infections with *Hymenolepis* are largely subclinical. The clinical manifestations of hymenolepiasis are presented in Clinical Correlation Box 22-11.

Laboratory Identification. The laboratory diagnosis of *Hymenolepis* infections is usually made by detecting the characteristic parasite eggs microscopically in mounts of

fecal specimens.

Ova

- The eggs are morphologically distinctive between *H. nana* and *H. diminuta*. Each has a smooth outer shell and an inner membrane, containing a hexacanth (six hooklets) embryo.
- The eggs of *H. nana* are oval, small (47 × 57 µm), and possess a characteristic pair of polar filaments that arise from thickenings on either side of the hexacanth membrane (Image Plate 22-6M).
- *H. diminuta* eggs are spherical, larger (58 × 86 µm) than those of *H. nana*, and are devoid of polar filaments (Image Plate 22-6N).

Adult Worms

- The adult worms of *H. nana* are small, measuring no longer than 1.5 inches when mature.
- They often simulate mucous threads; thus, they are not commonly seen in stool specimens.
- The tiny scolex has a protruding, armed rostellum with a row of 20 to 30 hooklets.

1460

CLINICAL CORRELATION BOX 22-11 Hymenolepiasis

In contrast to infections with *Taenia* and *Diphyllobothrium* species, in which only one worm most commonly inhabits the intestine, up to 1,000 *H. nana* worms may be present in a patient. Symptoms in light infections may be absent or limited to mild, diffuse lower abdominal pain and loose stools. Anorexia, abdominal pain, diarrhea, headache, nervousness, and pruritus ani may be seen in heavy infections. Peripheral eosinophilia is mild to moderate (4%–16%). Autoinfection, in which ova hatch in the intestine and reinfect via the normal life cycle described in the text, may result in a huge worm burden that can cause severe complications, particularly in immunosuppressed patients. The treatment options include praziquantel, niclosamide, and nitazoxanide.

Dipylidium caninum

The life cycle of *Dipylidium caninum* is similar to that of *Hymenolepis diminuta*.

Humans serve as an accidental host, and become infected following ingestion of dog or cat fleas that are infected with the cysticercoid form of the cestode. The adult tapeworm resides in the intestine of dogs or cats. The eggs, discharged in the feces, are ingested by several species of dog fleas or lice; the infective cysticercoids develop within the body cavity of the insect. Upon ingestion of a dog flea by a human, the cysticercoid larva penetrates the small intestinal mucosa and develops in situ into adult worms. Human infections most commonly occur in children, who have more intimate contact with household pets and, when very young, are likely to eat undesirable objects from the floor. Symptoms are usually minimal or absent. In heavy infections, varying degrees of indigestion, appetite loss, and vague abdominal discomfort may be experienced.

Praziquantel is the treatment of choice; niclosamide is also effective. Human infection is preventable by keeping pet dogs and cats free of tapeworms and fleas.

Laboratory Identification. The adult worms are not commonly seen. The laboratory-based identification is usually accomplished through the detection of characteristic egg packets in the stool.

Adult Worm

- The strobila ranges from 15 to 70 cm in length and possesses 60 to 175 proglottides.
- The scolex is rhomboidal in shape, possessing a retractile, conical armed rostellum.
- The proglottides measure 12 × 2.7 mm, and are distinctive for possessing a double genital pore (*Dipylos* means two gates) (Image Plate 22-6P).
- Proglottides may detach from the strobila and migrate singly or as short chains from the anus of cats and dogs, appearing as tiny grains of rice when deposited on the carpet or floor.

Ova

The laboratory diagnosis in human infections is usually made by observing the characteristic egg packets microscopically, each of which:

- Contain 15 to 25 globular eggs (Image Plate 22-6P).
- Each egg measures 35 to 60 µm in diameter.
- Each egg also contains an oncosphere with six hooklets.

Trematodes

The trematodes are also known of as flukes, several of which are parasites for humans. Flukes are leaf-shaped (i.e., there is dorsoventral flattening). All that are

human parasites are hermaphroditic, except for the schistosomes. These parasites possess two suckers—one oral sucker, through which the digestive tract opens, and the other is ventral for attachment. The trematodes of human importance to be presented in this chapter are as follows:

The Schistosomes: *S. mansoni*, *S. haematobium*, *S. japonicum*
Liver Flukes: *Fasciola hepatica* and *Clonorchis sinensis*
Giant Intestinal Fluke: *Fasciolopsis buski*
The Lung Fluke: *Paragonimus* species, most commonly *P. westermani*

The initial stages in the life cycles of trematode parasites are virtually identical, with free-swimming miracidia released from gravid eggs discharged into appropriate water estuaries in the feces from an infected human. All flukes include snails as an intermediate host. Many trematodes also require a second intermediate host. The type animal utilized as an intermediate host is dependent on the species of trematode. The developmental stages of the trematode species included in this chapter are depicted in the life cycles presented.

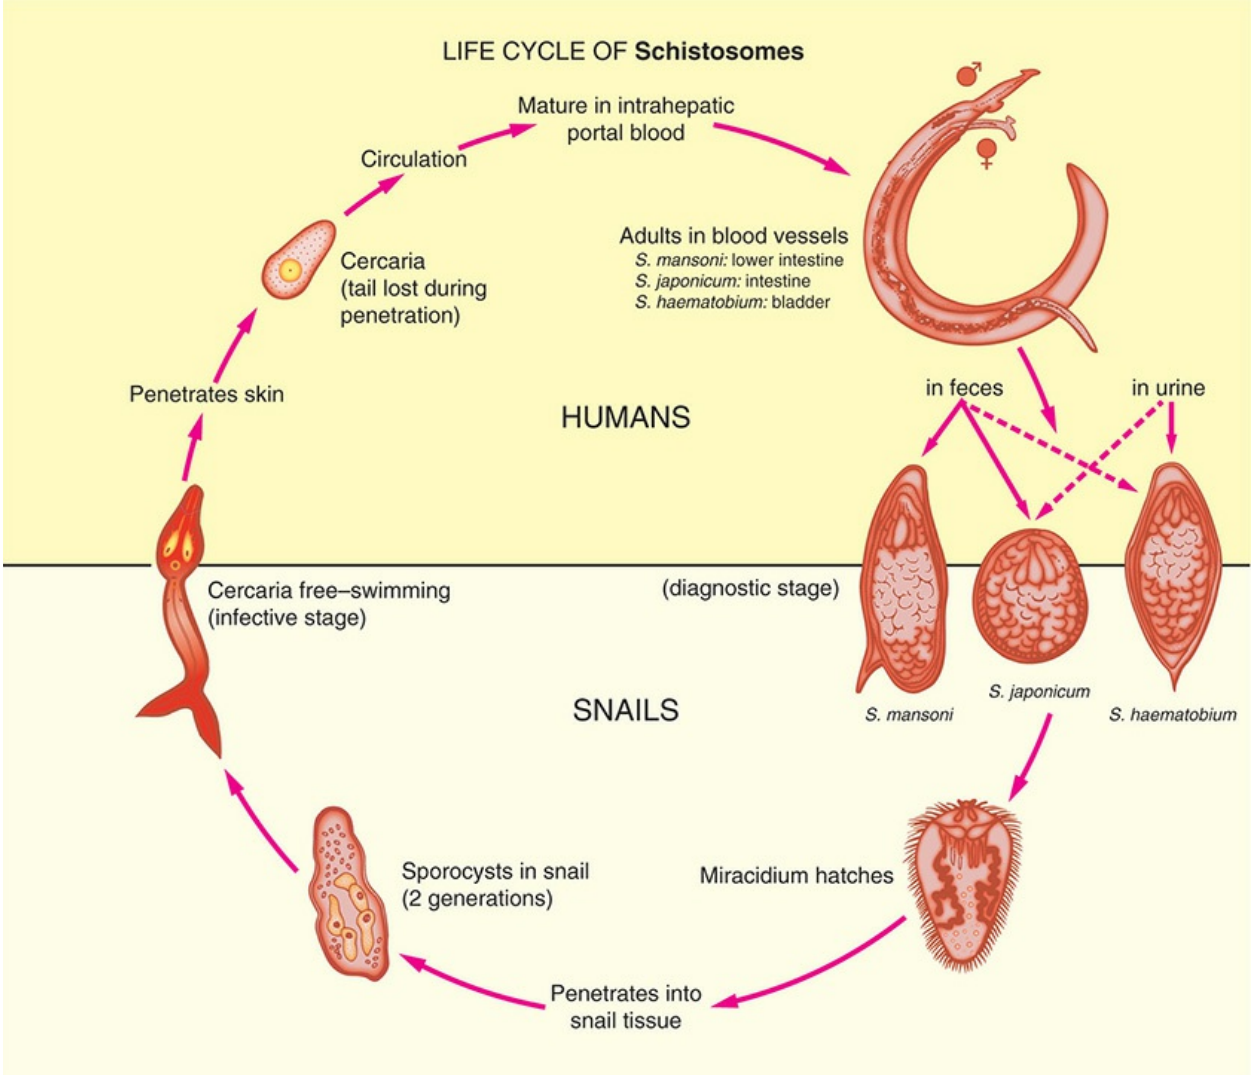
Schistosomes

The name schistosome is derived from the appearance of the adult male, the body of which has a longitudinal genital groove, or canal, serving as a receptacle for the female during copulation (Image Plate 22-7A). Three *Schistosoma* species, *S. mansoni*, *S. haematobium*, and *S. japonicum*, cause the majority of human infections. *S. mekongi* is a human parasite that is endemic along the Mekong river; the eggs of this are morphologically indistinguishable from *S. japonicum*. *S. intercalatum* is another less commonly encountered human pathogen. The egg of this parasite resembles those of *S. haematobium,* but it causes disease that clinically mimics that caused by *S. mansoni*. *S. intercalatum* is endemic in Central and West Africa.[242] The life cycle of the schistosomes is similar to that of other flukes except that a second intermediate host is not required to transmit disease.[54] The *Schistosoma* life cycle is illustrated in Figure 22-15.

Depending on the species, the schistosome adults are located in various parts of the portal vein system: (1) in the portal veins of the large intestine for *S. mansoni* and *S. intercalatum*, (2) in the small and large intestine for *S. japonicum* and *S. mekongi*, and (3) in the veins of the urinary bladder for *S. haematobium*. Adult worms, which measure about 2.5 to 3 cm in length and 0.5 mm in diameter when mature. Heavy infections cause portal vein obstruction at the sites where they reside, heavy infections lead to portal hypertension. Extensive tissue damage also results from the deposition of the myriad of eggs that are produced daily by the female.[242] The cutaneous manifestations of schistosomiasis have also been described.[55] A presentation of the

clinical manifestations of schistosomiasis is found in Clinical Correlation Box 22-12.

1461



■ **FIGURE 22-15** Life cycle of the schistosomes. Eggs, passed in the feces into freshwater lakes, canals, and the like, hatch under suitable conditions, releasing a free-swimming miracidium. The miracidium penetrates the tissues of an appropriate species-specific snail, within which it undergoes maturation division to form hundreds of cercariae. The free-swimming cercaria, released from infected snails, have the capability to directly penetrate the water-softened skin of unsuspecting swimmers and waders in freshwater estuaries. Once in the subcutaneous tissues, the heads of the cercariae enter the circulation and migrate to the portal venous system, where they develop into adult male and female flukes. The females, occupying the gynecophoral canal of the male, produce a myriad of eggs that are released into an appropriate aquatic estuary to complete the life cycle.

Laboratory Identification. The laboratory diagnosis is made by detecting the characteristic eggs in stool or urine, depending on the species.

Ova

- The eggs are very large. Following are the range of dimensions for each of three commonly encountered human species:
- *Schistosoma mansoni*: 116 to 180 × 45 to 58 µm.
- *Schistosoma haematobium*: 112 to 180 × 40 to 70 µm.
- *Schistosoma japonicum*: 75 to 90 × 60 to 68 µm.
- The eggs of *S. mansoni* and *S. haematobium* are distinctly oval.
- The eggs of *S. mansoni* possess a prominent lateral spine (Image Plate 22-7B).
- The eggs of *S. haematobium* possess a terminal spine (Image Plate 22-7C).

1462

CLINICAL CORRELATION BOX 22-12 Schistosomiasis

Davis[54] has divided the clinical manifestations of schistosomiasis into four distinct stages, manifesting as symptoms that often overlap, particularly in individuals who are constantly reexposed to infection.

Stage 1: "Swimmer's Itch." Cercarial invasion early on produces a prickling sensation or itching of the involved skin. In nonimmune individuals, skin reactions ranging from minute petechiae to urticaria or a pruritic papular eruption may be seen. The signs and symptoms of these eruptions are generally more severe in reaction to cercariae of nonhuman (bird) schistosomes. Davis-Reed and Theis[55] have reported a patient with cutaneous *Schistosoma haematobium* infection wherein this appeared as the sole clinical manifestation 3 years after exposure. This is a quite unusual presentation, as most commonly symptoms appear relatively soon after exposure. These authors counsel that dermatologists should be reminded of schistosomiasis in patients who present with unusual skin lesions, particularly with a history of travel in endemic areas.

Stage 2: Katayama Syndrome. During the second, or maturation, stage, during which the schistosomes are migrating to their preferred anatomic sites and pairing preparatory to egg laying, symptoms may be minimal or develop into what has been referred to as the Katayama syndrome or Katayama Fever, characterized by varying degrees and combinations of fever, malaise, backache, arthralgia, anorexia, cough, headache, and toxemia. Mild hepatosplenomegaly may be detected, and peripheral

blood eosinophilia may be significant. Because at this stage eggs are often not yet excreted, the diagnosis may be dependent on eliciting a history of exposure, the presence of typical dermatitis, and one or more of the symptoms listed above.

Stage 3: Granulomatous Inflammation. The third stage involves the inflammatory reaction secondary to the deposition and migration of ova in the tissues. Egg deposition is approximately 300 per day for female *S. haematobium* and *S. mansoni* worms, and 3,000 per day for *S. japonicum*. After invading the wall of the veins in which the adult female resides, the eggs have a propensity to penetrate into the adjacent viscera, eliciting a severe suppurative and granulomatous inflammation, ultimately resulting in fibrosis and scarring. Marked thickening of the walls of the intestine or urinary bladder, with loss of function, results. Bloody diarrhea, vague abdominal pain, and in severe cases, bowel obstruction may be observed with *S. mansoni*, *S. japonicum*, and *S. mekongi* infections. *S. haematobium* produces inflammation of the urinary bladder, resulting in intermittent hematuria, lower abdominal pain, and ultimately, contraction.

Stage 4: Chronic Inflammation. In the fourth, or chronic, stage of disease, marked progressive fibrosis around the areas of granuloma occurs, with a marked decrease in the number of excreted eggs. Patients with chronic *S. haematobium* infection have persistent urinary frequency and dysuria as the bladder continues to contract, and are also at high risk for squamous cell carcinoma of the urinary bladder. In late-stage *S. mansoni* infections, hepatosplenomegaly, cirrhosis, and ascites are common complications, as the eggs are swept upstream in the portal veins and lodge in the liver. Intestinal polyposis and inflammatory masses in the colon simulating carcinoma of the bowel may also be observed. *S. japonicum* may produce similar symptoms; however, because of its greater egg-laying capacity, morbidity may be much greater.

Praziquantel is the recommended treatment. Corticosteroids may be needed in acute infection (i.e., Katayama syndrome) or with CNS involvement.

- The eggs of the less commonly encountered species, *S. intercalatum,* also possess a terminal spine.
- The eggs of *S. japonicum* are broadly oval to semispherical; a small, rudimentary, lateral, knoblike spine may be seen if the plane of focus is correct (Image Plate 22-7D).
- The eggs of *S. mekongi* are morphologically indistinguishable from *S. japonicum.*

A photomicrograph of a forked-tail cercaria, the infective form in the life cycle of *Schistosoma* species, is illustrated in Image Plate 22-7E.

Several immunologic techniques, including immunofluorescent antibody procedures, ELISAs, radioimmunoassays, and complement fixation, are used in reference

laboratories to help establish a diagnosis. Using a monoclonal antibody raised against a 15-kDa tegumental antigen of *S. mansoni* adult worms, Da Silva et al.[51] have developed a competitive ELISA that they report as 94% sensitive in the detection of *S. mansoni* antigen in infected patients. Considerable work has been done by De Jonge et al.[56]and others to improve the serodiagnosis of schistosomiasis. van Etten et al.[250] report 95.5% sensitivity and 96.7% specificity in the detection of schistosomal cathodic antigen in the urine of patients infected with *S. mansoni*, using a monoclonal antibody-coated nitrocellulose/polyvinyl reagent strip. Such a strip is purported to be of value in the qualitative diagnosis of *S. mansoni* infections in control programs.

Fasciola hepatica *and* Fasciolopsis buski

Fascioliasis is primarily a cause of zoonotic parasitic liver disease in sheep. Flukes may remain in the bile ducts for many years, and can cause much damage from mechanical irritation at sites of local invasion, and the production of toxic by-products. Conversely, the adults of *Fasciolopsis buski* remain in the intestine, where they attach to the mucosa of the duodenum and jejunum. Other herbivores, such as deer, rabbits, cattle, goats, pigs, and horses, among others, may also be infected. *Fasciola hepatica* and *Fasciolopsis buski* are morphologically similar in many ways. The life cycles of both these parasites are the same, both of which require two intermediate hosts.

1463

The life cycle of *Fasciola hepatica* is illustrated in Figure 22-16. The clinical manifestations of fascioliasis and fasciolopsiasis are presented in Clinical Correlation Box 22-13.

Laboratory Identification

Adult Fluke

The adult flukes are seen only through endoscopy or if removed at surgery. They can be recognized by the following:

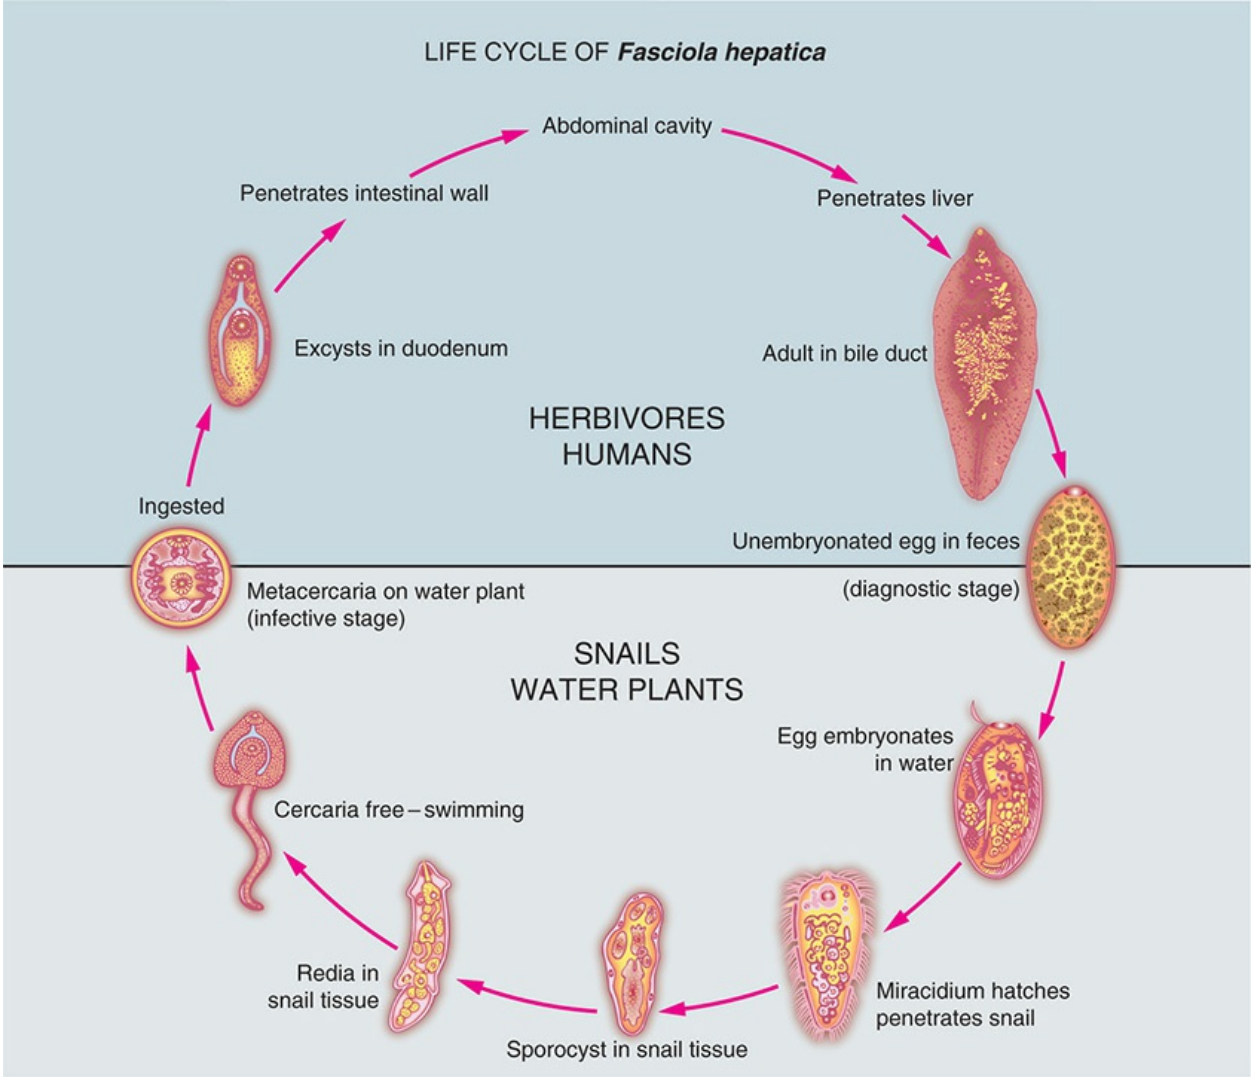
- The *F. hepatica* adults, which measure 20 to 30 × 8 to 13 mm, are flattened and leaflike in appearance, having a cone-shaped anterior protrusion (Image Plate 22-7F); the adult flukes of *F. buski* have a rounded cephalic end (Image Plate 22-7G).
- Each adult fluke has an anterior and a ventral sucker and are hermaphroditic, with a convoluted uterus seen anteriorly.

Ova

The laboratory diagnosis is most commonly made by detecting eggs in fecal preparations. The eggs can be recognized by their:

- Very large size (150 × 80 μm), ovoid shape, and yellow-brown staining.
- Thin, smooth shell, with an indistinct operculum (Image Plate 22-7H).
- The material within the egg is poorly organized and extends to the shell margin without leaving a clear space.

Because parasite eggs may be shed only after 8 weeks or more after infection or intermittently thereafter, serologic tests have been used in reference laboratories for the diagnosis of fascioliasis. Espino and Finlay[69] developed a mouse monoclonal antibody raised against *F. hepatica* excretory–secretory antigens, and a rabbit polyclonal antibody peroxidase



■ **FIGURE 22-16** Life cycle of *Fasciola hepatica*. On discharge of mature eggs via the stool into freshwater, embryonated eggs hatch and release free-swimming miracidia. After burrowing into the flesh of an appropriate snail, sporocysts are formed in the tissue. Within the snail, maturation/multiplication takes place in the redia, ultimately leading to the release of hundreds of free-swimming, straight-tailed cercaria. The cercariae attach to water plants and encyst as infective metacercaria. Humans become infected by ingesting raw or undercooked, metacercaria-infested water plants. Upon ingestion, the metacercariae excyst in the human duodenum with the release of larval forms. These penetrate into the intestinal wall, transmigrate the abdominal cavity, and enter the liver, where mature flukes develop in the bile ducts. These flukes are hermaphroditic and release eggs into the lumen of the bile ducts. The eggs in turn are carried into the intestinal tract, where they are discharged in the feces, completing the life cycle.

1464

CLINICAL CORRELATION BOX 22-13 Fascioliasis and Fasciolopsiasis

Upon ingestion of raw sheep or goat liver infected with adolescent worms, the flukes can attach to the pharyngeal mucosa and cause local laryngopharyngitis, called halzoun. Human fascioliasis is manifested by headache, chills, fever, and right upper quadrant pain. Hepatomegaly, jaundice, diarrhea, and anemia may occur in severe infections; hepatic biliary cirrhosis is a late complication. Bithionol is the most effective agent, but must be released from the CDC for treatment. A new therapeutic, triclabendazole, holds promise. Praziquantel, a formerly recommended drug, may have limited efficacy.

F. buski, a fluke similar to *F. hepatica* except that it is somewhat larger (20–75 × 8–20 mm) and has a rounded instead of a conical anterior portion (Image Plate 22-7G). These flukes reside in the intestine and by means of a small oral sucker, which they use to attach to the intestinal mucosa. Local mucosal ulcers produce varying degrees of epigastric pain, nausea, and diarrhea, especially in the morning. Ascites and intestinal obstruction may be seen in heavy infections. Laboratory diagnosis is made by identifying the large eggs in the feces, which are identical in appearance to those of *F. hepatica*.

conjugate detector to identify *Fasciola* ES antigen in stool specimens. The authors indicated that their antigen-detection test had the advantage over several other antibody-detection methods because serum titers may remain elevated even after cure. They also cite the advantages of detecting antigen in stool specimens over serum as (1) avoiding the problem of immune complex formation that decreases the potential rate of detection, (2) circumventing venipuncture in many regions of the world where the procedure is objectionable, and (3) having a test readily available for cure.

Bithionol is the most effective agent, and a newer agent, triclabendazole, holds promise. However, these are only available by release through the CDC. Praziquantel, a formerly recommended drug, may have limited efficacy, and should only be used if bithionol or triclabendazole is unavailable.

Clonorchis sinensis

Clonorchis sinensis, the Chinese liver fluke, is a relatively small fluke that varies in size (12 to 20 × 3 to 5 mm). When mature, it resides within the biliary ducts or in the

gallbladder of humans. The life cycle is similar to that of *Fasciola hepatica*, except that a freshwater fish rather than water plants are used as the second intermediate host. Humans become infected with *C. sinensis* by ingesting the raw or poorly cooked flesh of several species of freshwater fish. Figure 22-17 is an illustration of the life cycle.

The genus name (from the Greek *clon,* to divide, and *orchis*, testis) is derived from the freely branching testicular organ in the adult hermaphroditic fluke. The disease is most common in a wide area of Asia, particularly in Indochina, Japan, Korea, and Southern China. Importantly, this organism is the cause of cholangiocarcinoma.[226,230] The clinical manifestations of clonorchiasis are presented in Clinical Correlation Box 22-14.

Laboratory Identification. Adult flukes are rarely encountered. The laboratory-based diagnosis is usually achieved by the identification of the characteristic small, urn-shaped eggs in stool preparations.

Adult Fluke

- The adult fluke is flat and flabby, ranging in size from 12 to 20 × 3 to 5 mm.
- A bottle-shaped, protruding head is seen at the cephalic end (Image Plate 22-7I).
- An anterior sucker leads to an esophagus that branches into blind ceca that extend laterally to the posterior end (Image Plate 22-7J).
- A ventral sucker is located just anterior to a loosely coiled uterus (Image Plate 22-7K).
- Immediately posterior to the uterus is the ovary connected to delicate vitelline ducts (Image Plate 22-7L).
- A highly branched testes, from which the genus name is derived, extend into the posterior part of the body (Image Plate 22-7M). The blind termination of the ceca and an ill-defined excretory bladder are also seen in this photomicrograph.

Ova

- The typical egg is relatively small, urn-shaped, and measures 27 to 35 × 14 to 16 µm.
- A light yellow-brown pigmentation is evident from bile staining.
- A prominent convex, shouldered operculum is an identifying feature (Image Plate 22-7O).
- A small knob may be microscopically observed posteriorly when in the correct plane of focus.
- Note: This egg is morphologically similar to those of *Heterophyes heterophyes, Opisthorchis viverrini*, and *Metagonimus yokogawai*, three

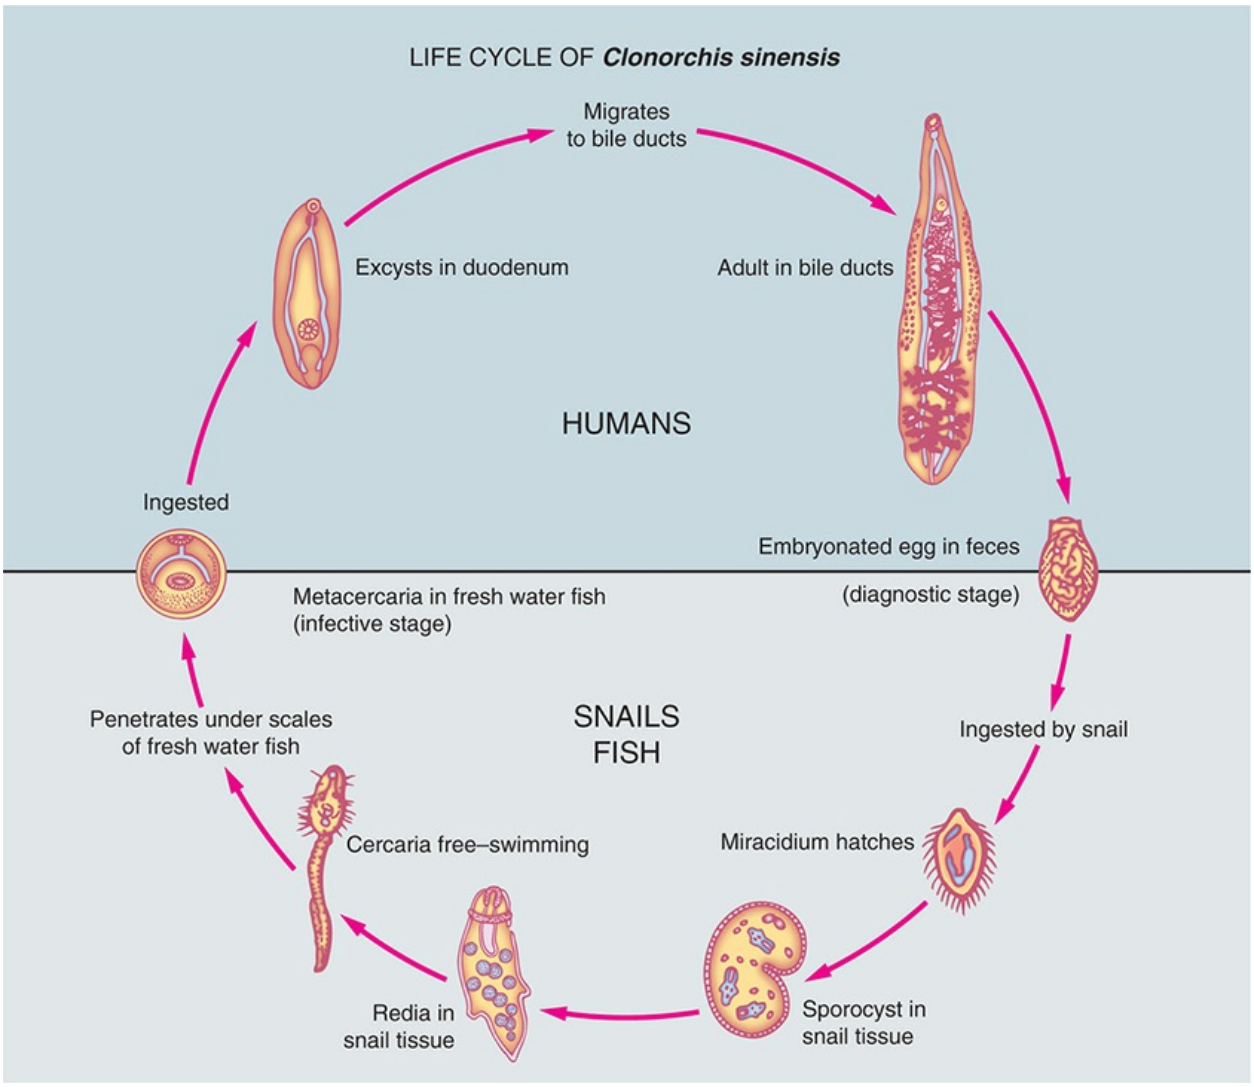
small intestinal flukes that are also prevalent in Asia and infect humans who ingest raw or pickled fish.

Paragonimus *Species, Most Commonly* P. westermani

Paragonimus species are present on all continents except Australia and Antarctica, with *Paragonimus westermani* being the most commonly encountered species. The adult worms measure in the range of 8 to 16 × 4 to 8 mm and are spoon-shaped, with one end contracted and the other elongated. The anterior and ventral suckers are of equal size.

The life cycle of these flukes begins when eggs from an infected host are passed into the environment. The miracidium infects the snail, which is the first intermediate host. Subsequent forms infect and develop within freshwater crabs or crayfish, which are the second intermediate host. Humans become infected following the ingestion of raw or poorly cooked crabmeat or crayfish, the flesh of which contains encysted metacercaria. Following ingestion, the metacercariae

hatch in the duodenum, releasing larvae that attach to the duodenal mucosa. The larvae penetrate the bowel wall, enter the abdominal cavity, and transmigrate the diaphragm to enter the pleural space. The larvae then invade the lung tissue, where maturation takes place. Figure 22-18 is an illustration of the life cycle. The clinical manifestations of paragonimiasis are presented in Clinical Correlation Box 22-15.



■ **FIGURE 22-17** Life cycle of *Clonorchis sinensis*. Upon discharge of mature eggs into freshwater, embryonated eggs hatch and release free-swimming miracidia. The miracidia are ingested by an appropriate snail, within which it hatches and forms a sporocyst in the snail tissue. The sporocyst in turn matures into redia, within which maturation/multiplication takes place, leading to the release of hundreds of free-swimming, straight-tailed cercaria. The cercariae attach to and penetrate under the scales of several freshwater fish species, forming metacercaria. Humans become infected by ingesting raw or undercooked, metacercaria-infested fish flesh. Upon ingestion, the metacercariae excyst in the human duodenum, with the release of larval forms that migrate into the bile ducts. These flukes are hermaphroditic and release eggs into the lumen of the bile ducts. The eggs in turn are carried into the intestinal tract, where they are discharged in the feces, completing the life cycle.

CLINICAL CORRELATION BOX 22-14 Clonorchiasis

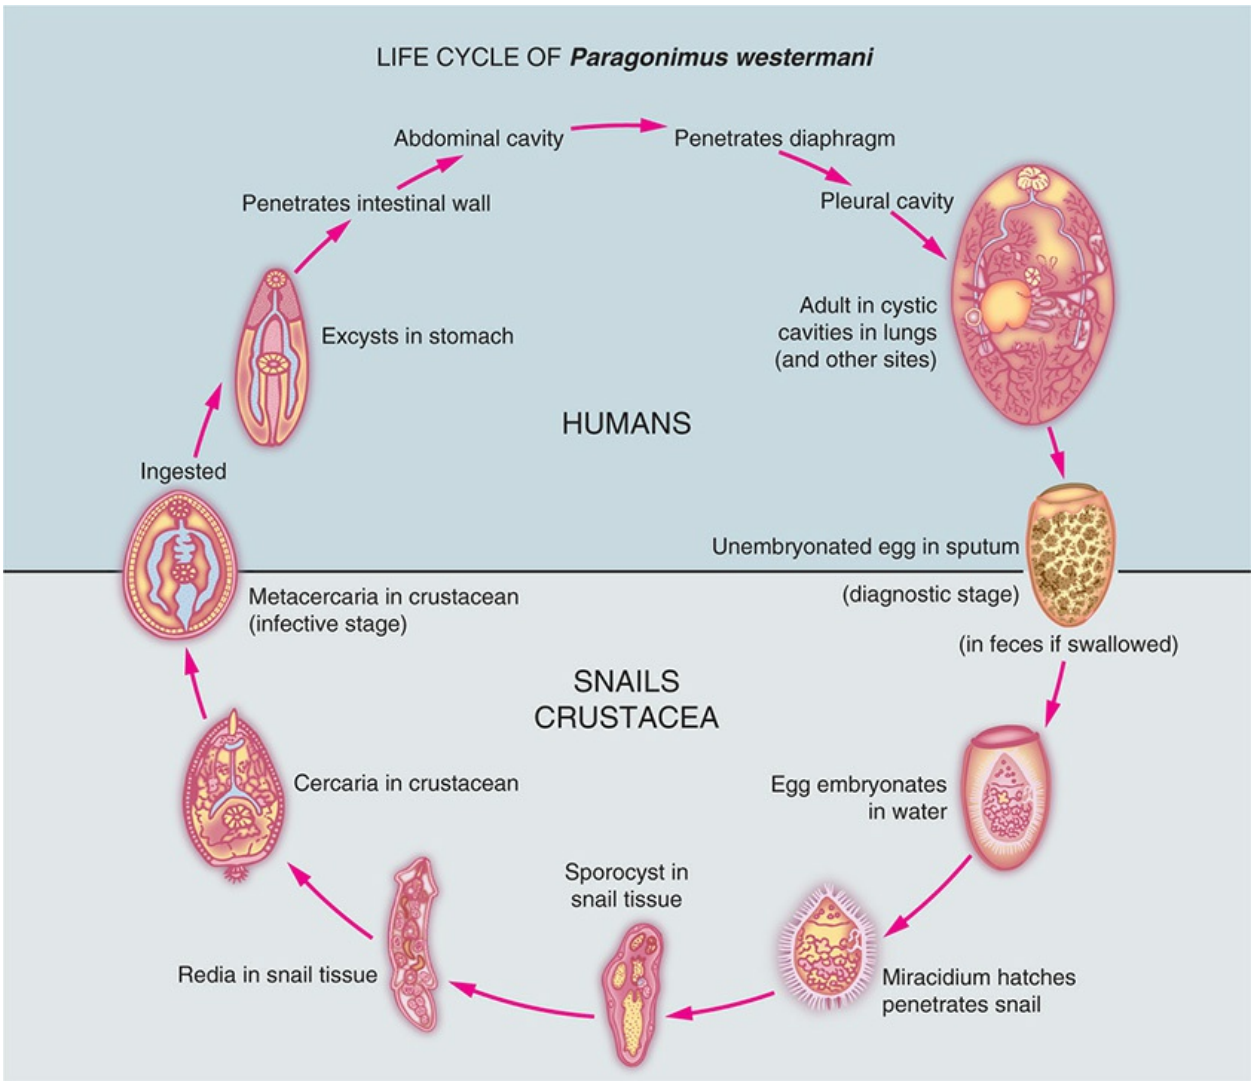
In light infections, the damage to the liver is minimal, and cirrhosis does not occur. Slight leukocytosis and eosinophilia may be observed early in infections. Although the bile ducts in human infections may become thickened and dilated, particularly at the points where the flukes are attached to the inner lining, biliary obstruction and jaundice are rare except in extremely heavy infections (Image Plate 22-7N). In most infections, the disease tends to remain low-grade and chronic, with organisms persisting for four or five decades, producing only minor symptoms of abdominal distress, intermittent diarrhea, and abdominal pain or tenderness. Of concern is the potential development of cholangiocarcinoma in association with chronic *Clonorchis* infections.[226,230]

Laboratory Identification. The laboratory diagnosis is most commonly made by detecting the characteristics ova microscopically in stool preparations or respiratory specimens.

Ova

- The eggs range in size from 80 to 120 × 48 to 60 µm.

1466



■ **FIGURE 22-18** Life cycle of *Paragonimus westermani*. Nonembryonated eggs are discharged either in the sputum or in the feces into a water environment. These eggs then embryonate in the water, releasing a free-swimming miracidium that penetrates the tissues of a species-specific snail. Sporocysts and redia develop in the snail, within which cercaria replicate. When mature, free-swimming cercaria break out of the snail and penetrate the gills, muscles, or viscera of a freshwater crustacean, within which they encyst as dormant metacercaria. Humans become infected following ingestion of raw or poorly cooked metacercaria-infested crabmeat or crayfish. Following ingestion, the metacercariae hatch in the duodenum, releasing larvae that penetrate the full thickness of the bowel wall, enter the peritoneal cavity, transmigrate the diaphragm, and enter the pleural space. The larvae then bore into the peripheral lung tissue, where they mature into adult flukes that reside within parabronchial cysts. Eggs are released into the sputum, where they are either expectorated or swallowed to ultimately pass in the feces, to complete the life cycle.

CLINICAL CORRELATION BOX 22-15 Paragonimiasis

Chills, fever, and marked eosinophilia may be seen during the migratory phase of the worm. In time, the adult fluke comes to reside within a small pseudocyst in the lung. The cyst enlarges as the adult fluke grows and may break into an adjacent bronchiole. When a pseudocyst ruptures into a bronchus, coughing and hemoptysis are common symptoms. Eggs produced by mature flukes are discharged into the bronchi and are ultimately swallowed by the patient from secretions coughed into the oropharynx. The disease tends to become chronic, leading to varying degrees of pulmonary fibrosis and scarring. Intermittent episodes of chest pain, fever, and chills may be late manifestations. Occasionally, ectopic migrations may occur. The worm may come to reside in the CNS. Unfortunately, this ectopic migration occurs more frequently in children. Praziquantel is the recommended treatment.

1467

- They are dark yellow-brown in color and have a thick, smooth shell with a prominent "shouldered" operculum.
- The shoulders serve to distinguish the *Paragonimus* ova from those of *Diphyllobothrium latum*, the opercula of which are smooth and devoid of shoulders (Image Plate 22-7P).
- *P. westermani* eggs also do not possess an antiopercular, knoblike protrusion characteristic of *Diphyllobothrium* eggs.

Blood and Tissue Parasites

Parasites found in the blood or in other organs are usually discussed separately from those inhabiting the gastrointestinal tract. The blood and tissue parasites covered here include protozoa, nematodes, and cestodes. Various parts of their life cycles are morphologically similar to their intestinal counterparts. For example, *Toxoplasma gondii* is a tissue coccidia, with many similarities to the coccidia covered above. Similarly, visceral and cutaneous larval migrans are caused by the larval forms of dog or cat nematodes. Echinococcosis is the larval form of a dog cestode that occurs in humans.

In general, the life cycles of the blood and tissue parasites are more complex than those of their intestinal counterparts, involving both sexual and asexual stages. Most of

the blood parasites are transmitted to humans by an arthropod vector within which the sexual phase of the life cycle develops. Alternatively some of these parasites use insects simply as a site for the development of the intermediate stages (i.e., molting) and as vectors (i.e., neither sexual or asexual replication occurs within the vector, simply development and transport).

Tissue parasites may be either intracellular or extracellular, depending on the species and the phase of the parasitic cycle. An outline of human blood and tissue parasites that will also serve as a guide to the discussion for the remainder of this chapter is as follows:

Blood and Tissue Protozoa	
Malaria	*Plasmodium falciparum* *Plasmodium vivax* *Plasmodium malariae* *Plasmodium ovale*
Babesiosis	*Babesia microti* and other species
Leishmaniasis	*Leishmania donovani* *Leishmania tropica* *Leishmania brasiliensis* *Leishmania mexicana*
Trypanosomiasis	*Trypanosoma brucei gambiense* *Trypanosoma brucei rhodesiense* *Trypanosoma cruzi* *Trypanosoma rangeli*
Toxoplasmosis	*Toxoplasma gondii*
Blood and Tissue Helminths	
Filarial Nematodes and Filariasis	*Wuchereria bancrofti* *Brugia malayi* *Loa loa* *Mansonella ozzardi* *Mansonella perstans* *Onchocerca volvulus* *Dirofilaria immitis*
Tissue Nematodes: Nonfilarial Worms	*Trichinella spiralis* *Toxocara canis* (visceral larva migrans) *Ancylostoma braziliensis* or *A. caninum* (cutaneous larva migrans) *Dracunculus medinensis* *Anisakis* species *Gnathostoma* species

Tissue Cestodes	*Echinococcus granulosus* *Echinococcus multilocularis* *Taenia multiceps* and *T. serialis* (coenurosis) *Spirometra mansonoides* (sparganosis)

Malaria

In the United States, the vast majority of patients with malaria are travelers, foreign-born students, or immigrants who have been exposed to mosquitos in endemic areas. In 2011, 1,925 cases of malaria were reported to the CDC, an increase from the previous years (i.e., 1,691 in 2010; 1,484 in 2009; and 1,298 in 2008).[47] These numbers are substantial increases over the 165 cases reported in 1988.[28] Although the vast majority of patients with newly diagnosed malaria in the United States have been foreign-born or recent returnees from endemic regions, anopheline vectors are found in many locales. For example, cryptic cases of malaria have been reported from San Diego County in California, and from Bay County in Florida.[91] None of the affected individuals gave a history of recent foreign travel, recent blood transfusions, or use of intravenous drugs. In some instances, infected patients had camped in mosquito-infested areas adjacent to encampments of migrant workers. Epidemiologic studies revealed that none of the migrant workers had a clinical history suggestive of malaria; however, the competent mosquito vector, *Anopheles hermsi*, was found along the San Luis Rey River in California. Similarly, two cases of indigenous malaria were reported from Suffolk County, New York, in persons who had no history of travel outside the United States.[29] Additionally, there have been reports of individuals contracting malaria who live in close proximity to international airports (i.e., airport malaria). The supposition is that infected mosquitos may occasionally be transported in incoming aircraft. Therefore, malaria should be included in the differential diagnosis of any patient with acute onset of cyclic fever, even if there is no history of recent foreign travel.

The worldwide incidence of malaria is astounding with infections estimated by the World Health Organization at 207 million infections in 2010, resulting in 627,000 deaths. It is estimated that 91% of the deaths were in Africa. Clinicians must, therefore, remain alert to the possibility of malaria in certain population groups. Although great progress in the elimination of malaria from certain locales has been made, malaria remains a worldwide challenge, with reemergence occurring in areas of previous control, particularly when control efforts are not maintained. Martens and Hall[167] attribute this resurgence in malaria to the relocation of poor people, often more likely to be infected with malaria, from endemic areas to malaria-free locales in search of a better life. The clinical manifestations of malaria are dependent on the infecting species, with infections caused by *P. falciparum* most likely to cause death. Clinical

manifestations are presented in Clinical Correlation Box 22-16.

CLINICAL CORRELATION BOX 22-16 Malaria

Fever is the constant presenting symptom of infections with all *Plasmodium* species. Temperature spikes commence 7–10 days following the bite of an infected *Anopheles* mosquito during a period when the organisms are undergoing preerythrocyte multiplication in the cells of the liver. Prodromal symptoms of headache, myalgia, malaise, and fatigue suggestive of a flu-like syndrome may be experienced during this period. However, once a brood of merozoites leaves the hepatic cells and invades the erythrocytes, the regularly spaced fever cycles begin in many instances. The least synchronous of the *Plasmodium* species is *P. falciparum.* The periodicity of each episode of high fever is related to the rupture of erythrocytes as merozoites are released into the circulation. The designations of this fever cycle "tertian" malaria, for *P. vivax, P. ovale,* and *P. falciparum* malaria, and "quartan" malaria for *Plasmodium malariae* malaria are somewhat confusing. The fever spikes for tertian malaria occur on an every-other-day schedule; however, because any given fever episode is counted as day 1, the next spike will not occur until the third day (thus, tertian). Similarly, the fever spikes of quartan malaria occur on an every three-day cycle; however, counting the first episode as day 1, the next spike will occur on the fourth day. Such classic fever patterns, however, may often be irregular and cannot be relied on exclusively to make a presumptive diagnosis.

Each fever episode is characterized by a short "cold" period lasting for approximately 1 hour, when the skin is cold and the lips and nail beds appear cyanotic because of peripheral vasoconstriction. This short period is followed by the sudden onset of the "hot period," when the skin feels warm and dry and fever spikes up to 105°F–106°F are experienced, lasting 3–6 hours. Headaches, chest and back pain, tachycardia, cough, vomiting, and delirium of varying degrees of severity accompany the fever spikes. Fatigue and sleep follow each febrile episode. Patients are essentially asymptomatic between febrile episodes.

Hemolytic anemia, splenomegaly, and tender hepatomegaly are found to varying degrees. Patients are highly susceptible to rupture of the spleen, and deep palpation of the left upper abdomen and flank should be avoided during physical examination. Lymphadenopathy is absent and always points to some other condition if lymph nodes are enlarged. Of greatest concern are the CNS complications that may occur secondary to *P. falciparum* infections. The erythrocytes infected with *P. falciparum* trophozoites undergo membrane changes in which "knobs" appear on the surface, causing them to become "sticky" and adhere to specific receptors on the endothelial

cell lining of capillaries.[37] The microcirculation of the brain is particularly vulnerable to blockage with *P. falciparum*-infected erythrocytes, resulting in small areas of cerebral infarction and hemorrhage.[4] Disturbances in consciousness ranging from somnolence to coma, behavioral changes, hallucinations, motor seizures, and occasionally tremors, focal muscle paralysis, and other localizing signs may be present. A rapidly progressive downhill course leading to death may occur in fulminant cases.

The life cycle of the *Plasmodium* parasite has two phases: a sexual cycle, known as sporogony, which takes place within the intestinal tract of the mosquito; and an asexual cycle, known as schizogony, occurring in the human host. The life cycle of *Plasmodium malariae*, as a prototype of all species of malaria, is shown in Figure 22-19.

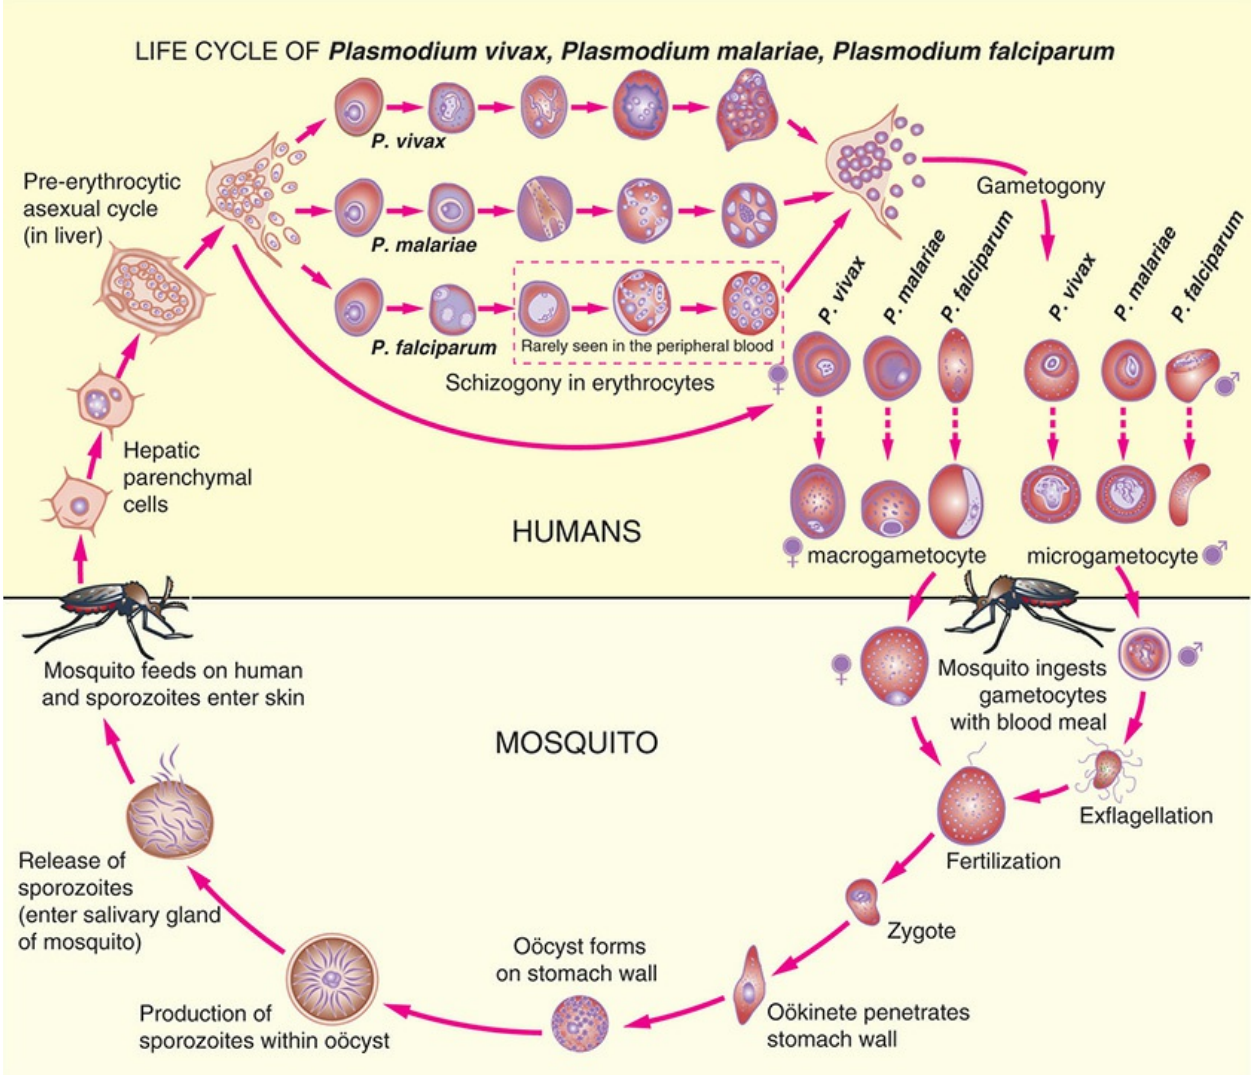
Laboratory Identification. Laboratory identification of the malarial parasites in humans, as previously described, is made by analysis of thick and thin peripheral blood smears. More than one assessment of blood is necessary to exclude the diagnosis. Smears should be obtained at different times of the day from patients with suspected infections because parasitemia may be intermittent, and the number of circulating parasites may vary depending on the phase of the parasitic cycle.

There are now five species of *Plasmodium* shown to cause human disease. The three species of *Plasmodium* most commonly causing human malaria are *P. vivax*, *P. falciparum*, and *P. malariae*. A fourth species, *P. ovale*, is rare in much of the world but relatively common in western Africa. The most recently described species, *P. knowlesi,* is endemic in only certain parts of Asia; this parasite is so rarely encountered that it is not covered further here. The differential features of the three common species are outlined below. The microscopic morphology of the intraerythrocytic forms is illustrated in Image Plate 22-8.

The laboratory identification of the various *Plasmodium* species is not difficult if an orderly approach based on the observation of a few key morphologic structures is followed. Foremost, the detection of the presence of a blood parasite is paramount, which is achieved most effectively through the analysis of the thick blood film. Once a parasite is detected, the thin blood film is used to achieve species-level identification. It is quite important that infections with *P. falciparum* be recognized as early as possible because the disease can be particularly severe, rapidly progressing to a fatal outcome. The most important feature in the differentiation of *Plasmodium* species is the size of the infected erythrocytes compared with uninfected erythrocytes. The comparison should be concluded after the comparison of many infected and uninfected cells. If the infected erythrocytes are the same size as uninfected erythrocytes (i.e., normocytic),

then the infecting species is either *P. falciparum* or *P. malariae.* If the infected erythrocytes are enlarged compared with the uninfected erythrocytes, then the infecting species is either *P. vivax* or *P. ovale.* A suggested laboratory approach to the identification of *Plasmodium* species is as follows:

1469



■ **FIGURE 22-19** Life cycles of *Plasmodium vivax, P. malariae,* and *P. falciparum* are illustrated. After several erythrocyte cycles have taken place, certain of the merozoites transform into sexual macrogametocytes (female) and microgametocytes (male). When a *Plasmodium*-free mosquito bites a human infected with malaria, these gametocytes are ingested along with the trophozoite-infected erythrocytes as part of the blood meal. In the stomach of the mosquito, the male microgametocytes develop six to eight flagella. The

microgametocytes penetrate the female macrogametocytes and produce fertilized zygotes. These zygotes then enter the wall of the mosquito stomach, where sporozoites eventually break out into the body cavity and migrate to the salivary glands. When the mosquito bites a new host, sporozoites are expelled from the salivary glands and injected through the proboscis.

Saliva containing infective sporozoites is injected into the bloodstream of humans through the mosquito proboscis. After circulating in the peripheral blood for 20 to 30 minutes, the sporozoites enter the parenchymal cells of the liver, where they begin to multiply (the exoerythrocytic cycle). In about 10 days, multiple small forms, called merozoites, are released from the liver cells into the circulation, where they infect erythrocytes. Within the erythrocytes (erythrocytic cycle), a series of developmental stages occur (Image Plate 22-8). These organisms develop into a "ring form" known as the trophozoite, which enlarges into an ameboid trophozoite. This subsequently divides into a segmented state known as the schizont. The individual segments of the schizonts are merozoites. When mature, the schizonts rupture the erythrocytes and merozoites are released into the circulation. These merozoites then seek out uninfected erythrocytes, and the erythrocytic cycle continues.

1. **First, rule out *Plasmodium falciparum*.** As mentioned above, this species is potentially the most dangerous, and infections should be diagnosed as early as possible. In the peripheral blood smear, look for the following:
   - The infected erythrocytes are normocytic compared to uninfected erythrocytes.
   - Tiny ring forms occupy less than one-third the diameter of the erythrocyte (Image Plate 22-8A).
   - Often, multiple forms are seen within one erythrocytes.
   - Often, two nuclei in the same ring.
   - Infections may be heavy, involving 20% or more of the erythrocytes, indicating a fulminant infection (i.e., hyperparasitemia).

   - The tiny rings often are plastered on the erythrocyte cell membrane, known as an "appliqué" form (Image Plate 22-8B).
   - Advanced forms (i.e., amoeboid trophozoites and schizonts) are rarely observed in stained peripheral blood smears. The only forms usually seen, except in terminal, fulminant infections, are early ring forms and gametocytes.
   - The presence of banana or crescent-shaped gametocytes is diagnostic (Image Plate 22-8C). Unfortunately, these may be absent in early stages of infection and usually begin to appear only after 7 to 10 days after onset of fever. Therefore, it is imperative that the parasitologist be able to identify *P.*

falciparum in the absence of these forms.

2. **Next, consider *Plasmodium vivax*.** Look for the following features in the peripheral smear:
   - Infected erythrocytes that are macrocytic compared with uninfected erythrocytes.
   - The infected erythrocytes may contain small, regular, punctate pink-red-staining granules in the erythrocyte membranes, called Schüffner's dots (Image Plate 22-8D).
     - Note: These dots are dependent on the pH of the stain and are not always present. The Wright's stain used in hematology, for example, is not pH balanced, and so Schüffner's dots will not be present. It should also be noted that *P. falciparum* very rarely contains larger, "comma-shaped" red dots called Maurer's clefts, so the presence of dots should not be the sole criteria for identification. It must be used in conjunction with the other morphology features present.
   - Ring forms in all stages of development may be present.
   - Young rings measure greater than one-third the diameter of the infected erythrocyte.
   - As the trophozoites mature, they transform from the ring trophozoite into the ameboid trophozoite.
   - Ameboid trophozoites undergo consecutive rounds of mitosis to form a cluster of merozoites called a schizont. The schizonts of *P. vivax* consist of 12 to 14 or more merozoites (Image Plate 22-8E).
   - Gametocytes are large and circular.
     - Note: Any single-celled nucleus occupying the majority of the cell diameter is likely a gametocyte.
   - Ameboid trophozoites can always be distinguished from gametocytes, because by the time an ameboid trophozoite reaches the size of half the diameter of the cell, it will undergo cellular division to form the schizont. Conversely, the gametocyte will continue to grow, occupying more than half of the cytoplasm, yet still remaining one nucleus; abundant hemozoin pigment is also often present (Image Plate 22-8F).
   - Malarial pigment in the form of finely granular, brownish pigment may be abundant in both the gametocyte and the schizont.
3. **Consider the identification of *P. malariae or P. ovale*.** The identification of these *Plasmodium* species is often by exclusion after the characteristics of *P. falciparum* and *P. vivax*, as above described, have been excluded. Look for the following features by which an objective identification can be made:

P. malariae

- Infected erythrocytes are normocytic compared with uninfected erythrocytes.

- The presence of ameboid trophozoites that form a "Band" across the infected erythrocytes (Image Plate 22-8G).
- There are no "dots" (e.g., Schüffner's Dots) ever present.
- Schizonts consist of 6 to 12 merozoites, which often form a "Rosette" (Image Plate 22-8H).
- Gametocytes are round and contained within normal-sized erythrocytes.

P. ovale

- The infected erythrocytes are macrocytic compared with the uninfected erythrocytes.
- Infected cells that are oval and have a fimbriated edge may be seen.
- The ameboid trophozoite is more compact than that of *P. vivax,* usually occupying only one-third of the cytoplasm of the infected cell.
- James' stippling, which are dots indistinguishable from Schüffner's dots, may be seen, but are also pH dependent.
- Schizonts contain 6 to 12 merozoites.
- The gametocytes are round, rather than crescent-shaped, which does not help differentiate them from *P. vivax and P. malariae,* but does differentiate them from *P. falciparum.*

The identification of *Plasmodium* species is usually not difficult if the principles described above are applied. Problems arise, however, in the interpretation of peripheral blood smears in patients who have been partially or inadequately treated when normal maturation of the parasites may be interrupted and only atypical forms are observed. The peripheral blood film interpretation may also be confusing if a given individual is infected with more than one *Plasmodium* species. Much progress has been made over the past decade in the molecular aspects of malarial infection. These advances, including an elucidation of the various genes encoding *Plasmodium falciparum* erythrocyte membrane protein 1, and those encoding the rosettin and rifin proteins on the surface of infected red blood cells, are reviewed in a publication by Chen et al.[35]

Individuals planning to travel to parts of the world endemic for malaria should consult the CDC Yellow Book (http://wwwnc.cdc.gov/travel/page/yellowbook) for complete advice on travel protection and prophylaxis. The type of prophylaxis recommended will be based on the prevalence of chloroquine-resistant malaria, previous reactions to antimalarial drugs, and the availability of medical care in the region to be visited.

Chloroquine prophylaxis should begin 1 to 2 weeks prior to anticipated travel and extend for 4 weeks after return. Chloroquine-resistant strains of *P. falciparum* have been found in all regions endemic for malaria. There are a variety of other prophylactic and therapeutic options for malaria, the scope of which is beyond this

text.[43]

1471

Babesiosis

Babesiosis in North America, which is the focus of this section, is caused by *Babesia microti*.[197] *B. divergens* causes a more severe disease in patients in Europe. *Babesia* is transmitted by the bite of a tick vector; *B. microti* is transmitted by the *Ixodes* tick, which is the same vector for *Borrelia burgdorferi*, the spirochete that causes Lyme disease. It has been shown that up to 40% of infected ticks are coinfected with both parasites. Perhaps this is not surprising, as both agents have the white-footed mouse,*Peromyscus leucopus*, as the main reservoir host. Most outbreaks have occurred in the northeastern regions of the United States, particularly in Connecticut, Nantucket Island, Long Island, and Cape Cod. The much lower incidence of babesiosis relative to Lyme disease in humans living in endemic areas may reflect the tendency of *B. microti* to produce subclinical infections. Serologic studies indicate that 10% of *B. burgdorferi*-seropositive Connecticut natives also have antibodies against *B. microti*, indicating that infections are far more frequent than previously suspected. Babesiosis may also be contracted through transfusion with contaminated blood or intravenous drug abuse via the sharing of contaminated needles. Transfusion-related infections have also been reported; specifically, a cluster of six transfusion-associated cases of babesiosis in New York State traced to a single asymptomatic donor.[62] It has been established that *B. microti* can remain infective at 4°C for 30 days, the normal storage time for donor blood.[67] A case of transfusion-related infection with the WA1 strain has also been recently reported from the state of Washington.[119] *Babesia*-like organisms have also been reported in Northern California.[198] Although many infections with *Babesia* are subclinical, severe-to-life-threatening disease occurs in patients without a spleen. In rare instances, exchange transfusion has been required.[64] The clinical manifestations of babesiosis are presented in Clinical Correlation Box 22-17.

The diagnostic intraerythrocytic forms described above are scarce during the early stages of infection and may be missed, even by experienced microscopists. Mattia et al.[168] used a buffy coat technique to improve the detection of parasitemia in patients with babesiosis. Garcia[87] has published a precautionary note warning of potential diagnostic problems with results derived from differential instruments. The number of fields routinely examined on instrument-read smears is quite small, and these instruments are not designed to detect intracellular parasites. Therefore, unless thick and thin blood film reviews are requested, patients with both babesiosis and malaria

may be missed.

Laboratory Identification. The laboratory diagnosis is most commonly made by detecting the intraerythrocytic parasitic inclusions in stained peripheral blood smears. They have the following identifying characteristics:

- The ring forms are tiny, ranging between 1.0 and 3.0 μm, resembling the early trophozoites of *P. falciparum* (Image Plate 22-9A).
- The nuclei are very small with usually only a single chromatin dot.
- Mature forms may appear as doublets, simulating rabbit ears; or, in tetrads resembling a Maltese cross.

CLINICAL CORRELATION BOX 22-17 Babesiosis

The symptoms in early babesiosis may be minimal: Malaise, anorexia, and fatigue are nonspecific symptoms that are easily confused with other infectious diseases.[197] Although the symptoms of infections incurred in the northeastern United States tend to be relatively mild, recent reports from case studies in California and other parts of the world indicate that fulminant, febrile, hemolytic disease presentations may be encountered.[198] Genetic studies reveal that these more severe infections may be caused by a strain more closely related to a known canine pathogen, *B. gibsoni*, or to *Theileria* species, rather than *B. microti*.[197] This strain, designated WA1 (Washington 1), and other such agents have been described. Dorman et al.[64] reported a 58-year-old man infected through a tick bite, in whom severe hemolytic anemia developed, followed by disseminated intravascular coagulation and acute renal and respiratory failure. Rapid clinical improvement was noted after treatment with clindamycin, 300 mg four times a day (started 2 days before admission), quinine (650 mg three times a day) on hospitalization, and an exchange transfusion, in which the proportion of parasitized red cells was reduced from 13.8% to 4.2%.

- The erythrocytes are not enlarged (i.e., are normocytic) and do not develop stippling.
- Extracellular forms may be seen, which is a distinctly distinguishing feature from *Plasmodium* species.
- Gametocytes and hemozoin pigment (i.e., malaria pigment) are not produced.

Hemoflagellates: Leishmania *Species and* Trypanosoma *Species*

The protozoan order *Trypanosomatida* includes members from the genera *Leishmania* and *Trypanosoma*, which are flagellates that inhabit the blood and tissues of humans. Three species/subspecies of *Trypanosoma* are associated with human disease;*Trypanosoma brucei* subspecies *gambiense* and *Trypanosoma brucei* subspecies *rhodesiense* cause African sleeping sickness, whereas *Trypanosoma cruzi* is responsible for South American trypanosomiasis. *Leishmania donovani*, the cause of visceral kala-azar in humans, and *Leishmania tropica* complex, the agents of cutaneous tropical sores, are the leishmanial species most commonly associated with human diseases.[195]

Four stages of development of the parasites may be observed. The leptomonas and crithidial stages of development are harbored within the insect vector, the latter representing the infective form for humans. The adult, or trypanosomal, forms have an elongated body with a posterior flagellum attached by a delicate undulating membrane that runs the

1472

length of the body. The tissue form of these protozoa is called an amastigote. It is devoid of flagella and is found as intracellular parasites. The amastigotes of *Trypanosoma* species infect somatic cells, whereas those of *Leishmania* infect cells in the reticuloendothelial system (i.e., monocytes and macrophages).

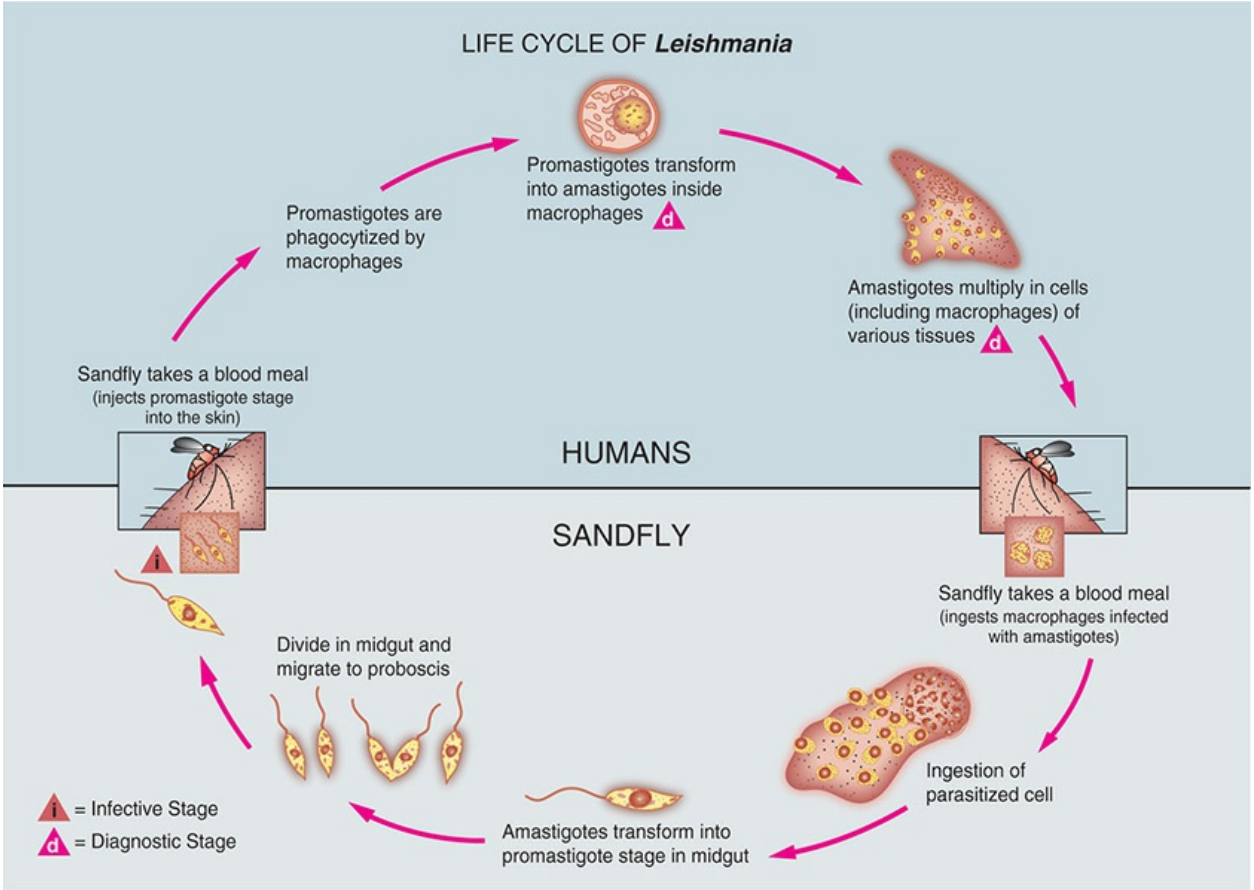
Leishmaniasis and *Leishmania* Species. Human leishmaniasis may take three forms, a disseminated disease, kala-azar, involving the liver, spleen, and other parts of the reticuloendothelial system, a primary cutaneous form, clinically manifesting as ulcers of the skin, and a mucocutaneous form (Image Plate 22-9B). Humans become infected through the regurgitation of the promastigotic infective forms of the parasite into the subcutaneous tissue as the *Phlebotomus* sandflies take a blood meal. Figure 22-20 depicts the life cycle of *Leishmania* species.

Although certain species are more likely to cause certain types of leishmaniasis, there is overlap. *Leishmania* is traditionally categorized into complexes and individual species. *Leishmania donovani* complex contains *L. donovani* and *L. infantum*, which is also known of as *L. chagasi*. *L. donovani* is an important cause of visceral leishmaniasis.[214] Important causes of leishmaniasis include the *L. mexicana* complex, *L. tropica, L. major,* and *L. braziliensis,* among others.

When the flagellates gain access to humans, they first invade inflammatory monocytes in the subcutaneous tissue at the site of the bite. When these inflammatory cells rupture, they release free parasites that in turn invade other monocytes and macrophages, within which they are disseminated throughout the reticuloendothelial system. The incubation period is in the range of 3 to 8 months. Disease progression or

cure is the result of the complex host/parasite interaction. The clinical manifestations of leishmaniasis are presented in Clinical Correlation Box 22-18.

Laboratory Identification. The laboratory-based diagnosis of leishmaniasis is made by demonstrating amastigotes in stained smears, in imprints, or in biopsies of infected tissues. This may be from a splenic aspirate in patients with visceral leishmaniasis. For cutaneous and mucocutaneous



■ **FIGURE 22-20** Life cycle of *Leishmania* species. A small skin papule develops at the site of the sandfly bite, but rarely progresses to an ulcer. The promastigotes transform into amastigotes, which proliferate locally in the subcutaneous tissue into amastigotic forms that disseminate throughout the reticuloendothelial system to involve the spleen, liver, bone marrow, and lymph nodes where the organisms are found as obligate intracellular parasites (Image Plate 22-9C). The simple life cycle is then completed when amastigotes are again taken up by a sandfly during a subsequent blood meal. The amastigotes transform into infective promastigotes in the midgut of the fly.

CLINICAL CORRELATION BOX 22-18 Leishmaniasis

Disseminated Leishmaniasis: Kala-Azar

Symptoms may be mild and self-limited. Conversely, there may be a sudden onset of symptoms, including spiking fevers (a pattern of two or three peaks per day), anorexia, malaise, and a feeling of ill health simulating typhoid fever or malaria. If the disease progresses and becomes chronic, low-grade fever, vague abdominal pain, enlargement of the abdomen from hepatomegaly and splenomegaly (which can become enormous), generalized lymphadenopathy, anemia, and leukopenia may persist. Recently, kala-azar has been recognized as an AIDS-related opportunistic infection.[179]

Primary Cutaneous Leishmaniasis

Disease is traditionally classified into Old World and New World forms. Old World disease, formerly called Oriental sore, is caused most commonly by members of the *L. tropica* complex (including *L. tropica, L. major*, and *L. aethiopica*). This form of disease is endemic in the tropical and subtropical regions of Asia Minor, China, the Southern Mediterranean, India, and Africa. At the site of insect bites on exposed parts of the body, the promastigotes injected into the skin are taken up by the reticuloendothelial cells, where they develop into the amastigotes. The species causing cutaneous leishmaniasis do not circulate except in very rare instances. An intensely pruritic papule develops at the site of the bite, which in the course of several weeks or months progresses to a chronic well-circumscribed ulcer with a raised, erythematous margin and a shallow bed (Image Plate 22-9B). The ulcers produced range from moist and multiple to drier with a tendency to crust over. Most lesions are benign and self-healing, and permanent immunity develops. The cutaneous lesions of *L. aethiopica* may not ulcerate but often result in deep, spreading subcutaneous infections, and this species also has the predilection for causing disseminated disease indistinguishable from *L. donovani* infections.[195]

New World cutaneous leishmaniasis is caused by the *L. braziliensis*, which is endemic in almost all countries in South America and in several regions in Latin America, and by the *Leishmania mexicana* complex, including several separate species endemic in various regions in Mexico, Guatemala, Venezuela, and in the Amazon basin of Brazil. *L. braziliensis* is the cause of aggressive, chronic cutaneous ulcers, with mucous membrane (oral, nasal, pharyngeal) spread, a clinical picture called espundia. Organisms of the *L. mexicana* complex are more likely to produce self-limiting cutaneous ulcers (60% of lesions occur on the ear lobes[87] producing what are known as "Chiclero ulcers"). The mucous membranes are less commonly involved, although *L. peruviana* is likely to produce a more diffuse cutaneous disease known as "uta" in Peru.

Stibogluconate sodium is the treatment of choice; treatment should be

individualized based on the available therapies, condition of the patient, and the extent of disease.

lesion, impression smears or tissue sections should be prepared from active lesions. Biopsies should be obtained from the elevated, inflamed margin of the lesion; aspirates should be obtained by extending the tip of the needle deep beneath the ulcer bed. The parasites at this stage have the following characteristics:

- The organisms are oval in shape, intracellular, and very small, averaging 2 to 4 µm in size.
- They simulate the yeast cells of *Histoplasma capsulatum* in many stained preparations, such as the H&E and Wright's stains.
  - Note: These parasites do not stain with the GMS stain, which is useful for differentiation.
- The *Leishmania* amastigotes possess a bar-like kinetoplast adjacent to the nucleus.
  - Note: This structure is helpful in distinguishing these organisms from the yeast forms of *H. capsulatum* (Image Plate 22-9C, D, and E).
- These parasites are largely within macrophages, which differentiates them from the amastigotes of *Trypanosoma*, with infected somatic cells.
  - Note: This difference is important, since the amastigotes of *Trypanosoma* also have a kinetoplast.

Culture methods, used primarily in laboratories serving practices in endemic areas, are described in detail by Garcia.[87] Lopez-Valdez et al.[159] also describe a culture method using buffy coat samples from peripheral blood that was successful in diagnosing leishmaniasis in patients with AIDS who presented with atypical clinical findings. Animal inoculation techniques are also used in these laboratories for diagnosing infections when parasite concentrations are low.

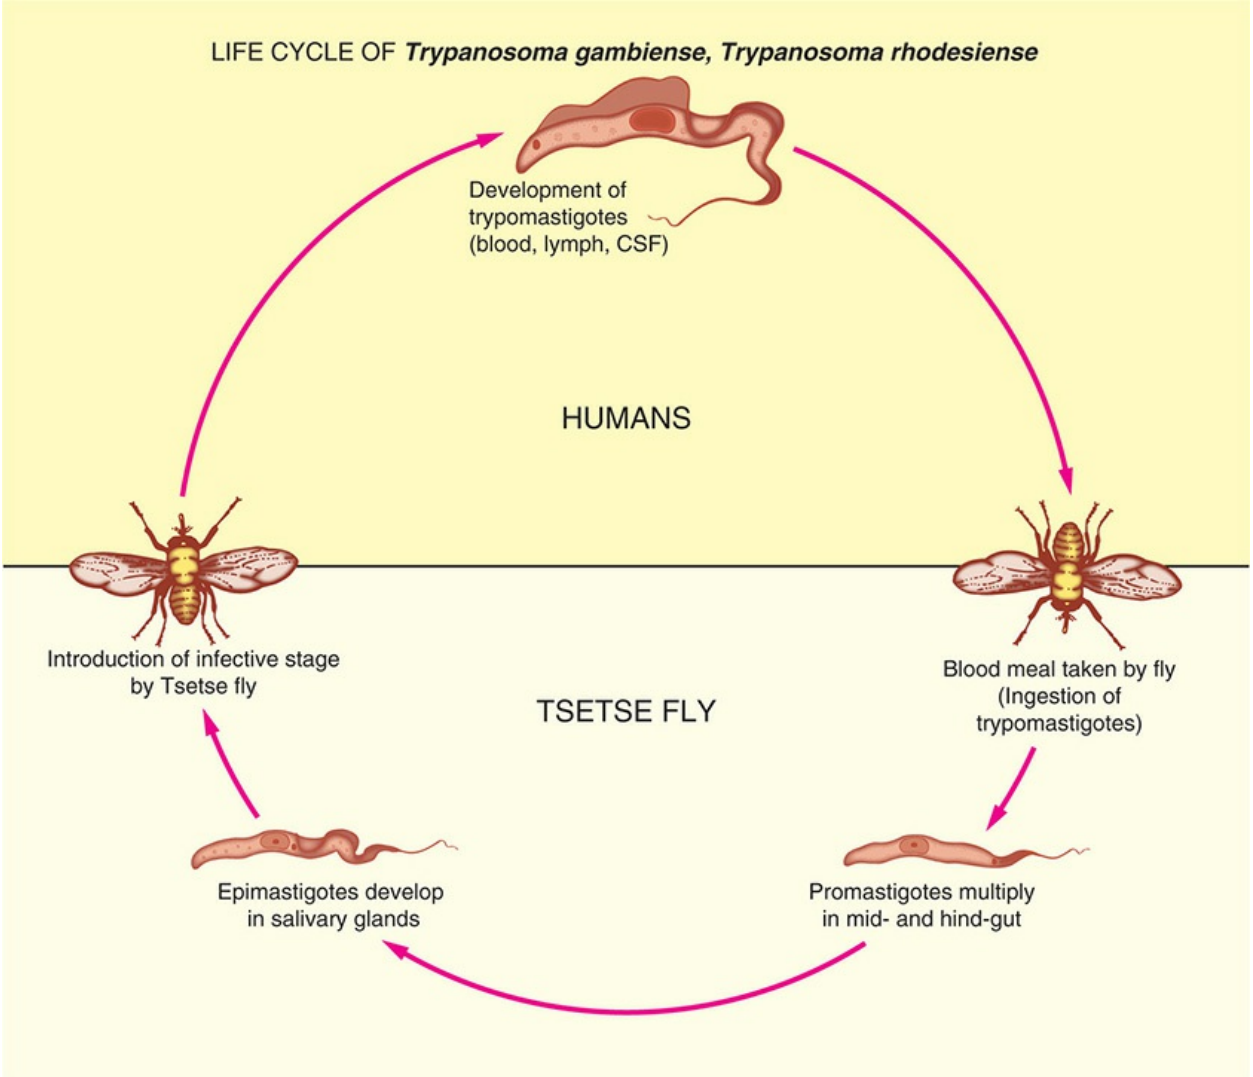
ELISA techniques, using species-specific monoclonal antibodies, immunohistochemistry, and nucleic acid amplification techniques, have been used successfully in the direct detection of *Leishmania* in extracts of tissue samples in laboratories where reagents are available. For example, Piarroux et al.[201] used a PCR assay amplifying a repeated sequence from the *Leishmania infantum* genome in a study of 73 patients with a working clinical diagnosis of visceral leishmaniasis; they demonstrated superior sensitivity of the method (82%) in making the diagnosis compared to examination of bone marrow aspirates (55%) and myeloculture (55%). They conclude that PCR may serve as an aid in diagnosing visceral leishmaniasis in immunocompromised patients. Rodriguez et al.,[212] using a PCR-hybridization technique, employing oligonucleotides directed against conserved regions of kinetoplast DNA, were able to detect the presence of *Leishmania*

cells in 98% of patients clinically diagnosed as having cutaneous leishmaniasis by a positive Montenegro skin test. They further believe that the technique is epidemiologically valuable in making the taxonomic discrimination between species.

Trypanosomiasis and *Trypanosoma* Species

African Trypanosomiasis: African Sleeping Sickness. Human trypanosomiasis is caused by a flagellate protozoan that inhabits the blood and tissues. The trypomastigote form, which measures 15 to 30 µm × 1.5 to 3.5 µm, has an elongated body with a posterior flagellum and a delicate undulating membrane that runs the length of the body. In Africa, wild game animals serve as the reservoir host. A central nucleus and a posterior kinetoplast are usually easily seen. These diagnostic forms can be seen in stained smears of peripheral blood (Image Plate 22-9F) and in the spinal fluid in certain stages of the infection. However, in chronic or light infections, Bailey and Smith,[11] in a study of blood samples obtained from 134 patients with *Trypanosoma brucei* subsp. *gambiense* infection, found the quantitative buffy coat test developed for malaria diagnosis to be the most sensitive diagnostic test for the detection of trypanosomal forms.

The life cycle involves animals and humans as the hosts, in which the mature trypanosomes circulate and divide in the peripheral blood and ultimately invade the CNS; an intermediate host and vector, the tsetse fly, is also involved. The immature forms develop in the salivary gland of the fly, ultimately forming infective metacyclic trypanomastigotes. The life cycle is illustrated in Figure 22-21.



■ **FIGURE 22-21** Life cycle of *Trypanosoma brucei* subsp. *gambiense* and subsp. *rhodesiense*. The life cycle shown here involves humans, and an insect, the tsetse fly, but in nature existed between the tsetse fly and animal hosts. On ingestion of trypomastigotes from an infected human through a blood meal, promastigotes are released in the stomach of the fly, and multiply in the midgut and hindgut, finally migrating to the salivary glands as epimastigotes. Humans are infected in turn through the bite of an epimastigote-infected fly. A chancre develops at the site of the insect bite, within which over a period of several weeks, the trypanosomes undergo multiplication and maturation. Ultimately, they invade the lymphatics and bloodstream, widely disseminating to lymph nodes and ultimately to the CNS. Organism multiplication continues to occur in the bloodstream despite humoral immunity of the infected host, a fundamental difference from infections caused by *T. cruzi*.

There has been substantial progress in controlling African trypanosomiasis. In a World Health Organization report issued in 1986, there were approximately 20,000 new cases diagnosed each year.[275] In 2009, the "10,000" threshold was broken (i.e., 9,878 cases were reported) due to sustained control efforts. In 2012, 7,216 cases were reported to the WHO. In the African form of trypanosomiasis, humans become infected through the bites of infected *Glossina* tsetse flies that harbor the infective procyclic trypanomastigotes in their salivary glands. Tsetse flies are found only in Africa. The capacity of these organisms to remain viable in a population of chronically infected people is due to the unique property of the organisms to periodically change the antigenic structure of the glycoproteins within their surface membranes, thus bypassing the effects of host antibodies.[63] The clinical manifestations of African trypanosomiasis are presented in Clinical Correlation Box 22-19.

Antigen-detection methods have been developed to diagnose African trypanosomiasis.[182,183] In a field trial in Zaire, Nantulya et al.[183] effectively used an antigen ELISA in evaluating 77 parasitologically proven cases of Gambian trypanosomiasis. Of these patients, 69 (89.6%) had antigens in serum and 35 (45.5%) had antigens in the CSF. Of the latter, 34 (97.1%) had elevated CSF white-cell counts, 29 (82.9%) had elevated protein levels, and 23 (65.7%) had trypanosomes microscopically identified in the CSF. The authors indicate that their ELISA test may be useful in staging disease and in follow-up to treatment. Kyambadde et al.[148] found that PCR demonstrated infection in 20 of 35 (57%) blood samples obtained from patients with suspected trypanosomiasis in Uganda, and in 21 of 34 CSF samples (61%). Of 21 blood samples negative for circulating diagnostic forms, 6 were positive by PCR (28.6%), and 8 of 21 CSF samples (38.0%) that were negative by double centrifugation were positive by PCR.

The particular subspecies causing the infection and the stage of disease are important when considering treatment. Pentamidine is useful for treating patients in the first stages of infections caused by *T. b. gambiense.* Other therapeutics, such as suramin, melarsoprol nifurtimox, etc., are available only through CDC.

South American Trypanosomiasis: Chagas' Disease. South American trypanosomiasis, also known as Chagas' disease, is caused by *Trypanosoma cruzi*. This parasite is found from the southern United States through Central and South America to Argentina. An estimated 10 to 12 million people are infected, approximately half of whom live in Brazil.[60] Although *T. cruzi* has been found in dogs, wild mammals, and insect vectors in the southern part of the United States, autochthonous human cases have been reported only very rarely.[106,244] The diagnosis may be made by observing circulating trypomastigotes in the peripheral blood, although the period of circulation is shorter than that observed in African trypanosomiasis. The trypomastigotes are similar in appearance to those of their African counterparts, except there is a distinct tendency for them to curl upon

themselves forming a letter "C" shape (Image Plate 22-9G).

An autochthonous infection reported in the United States was in rural Tennessee, when a mother found a triatomine bug in the crib of her 18-month-old boy.[118] The gut content of the bug was found to be infected with *Trypanosoma cruzi* both by light microscopy and PCR. A buffy coat prepared from a blood sample from the child was negative for organisms; however, it was positive by PCR, indicating low-level parasitemia. Thus, this autochthonous *T. cruzi* infection in the United States would have been missed without the mother's attentiveness and the highly sensitive PCR technique.

The life cycle of *T. cruzi* differs from the African species in that the triatomid (reduviid) bug serves as the arthropod vector. Both rodents and domestic animals, including dogs, cats, and pigs, serve as reservoir hosts for *T. cruzi*, and so eradication from endemic areas is not feasible. In the United States, opossums and raccoons have been found to be infected. In the incident reported above, three raccoons in the vicinity of the infected child had positive hemocultures for *T. cruzi*. Houses built of adobe, mud, or vegetative material, in which there are numerous cracks in the walls, provide the

CLINICAL CORRELATION BOX 22-19 African Trypanosomiasis

African trypanosomiasis, also known as African sleeping sickness, is caused by one of two subspecies of *Trypanosoma brucei*. Subspecies *rhodesiense* is endemic in the savannah and woodland regions of central and east Africa, whereas *Trypanosoma brucei* subsp. *gambiense* is endemic in the tropical rain forests of Central and Western Africa. The clinical disease caused by *T. brucei rhodesiense* tends to be of more rapid onset with a greater tendency to become rapidly progressive, even leading to death. Gambian trypanosomiasis is more chronic, characterized by neurologic deterioration, culminating in "sleeping sickness."

Patients infected with *T. brucei gambiense* first experience intermittent recurring fever associated with lymphadenopathy. Lymph nodes in the posterior cervical region of the neck are frequently involved, producing a lesion known as Winterbottom's sign. Ormerod[190] has demonstrated experimental evidence of a physiologic connection between cervical lymph glands and the ventricles of the brain, suggesting that Winterbottom's sign may be a marker for cerebral infection.

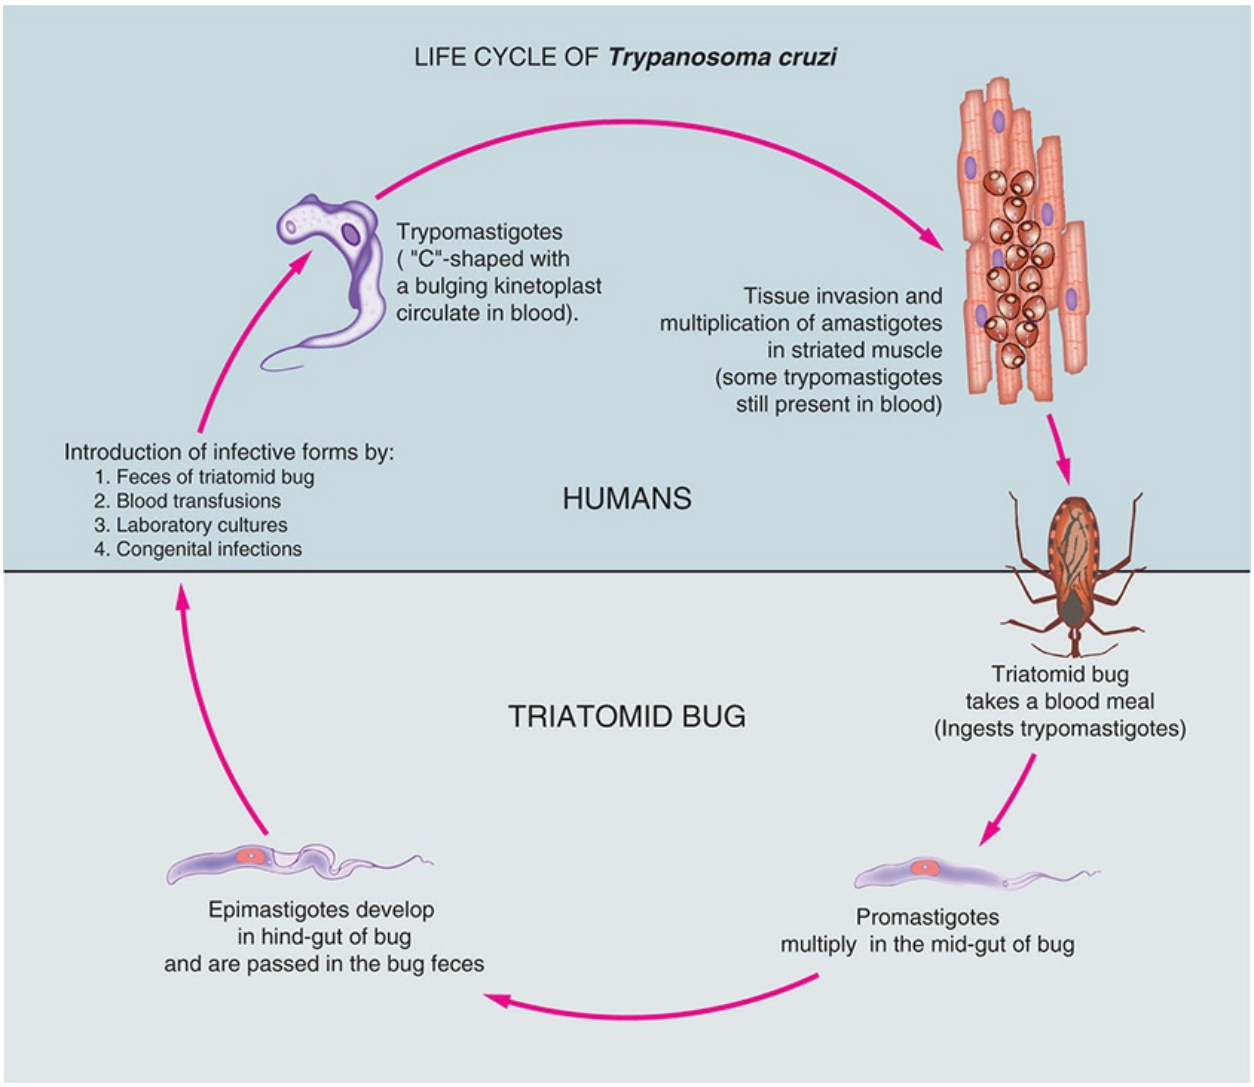
Hepatosplenomegaly may also be evident during this early stage of infection. As the disease becomes chronic, organism invasion of the CNS produces the sleeping sickness stage of the disease, characterized initially by behavioral and personality changes, leading to apathy, fatigue, confusion, and somnolence—signs of progressive meningoencephalitis. Emaciation and profound coma ultimately lead to death.

optimal breeding places for the reduviid bugs in endemic areas (Image Plate 22-9H). These insects are nocturnal and feed on sleeping victims. Prevention of the disease is largely aimed at improving housing conditions and decreasing the insect breeding environment. The life cycle of *T. cruzi* is illustrated in Figure 22-22.

Primary infection ranges from asymptomatic to fever, lymphadenopathy, and unilateral facial swelling. The great danger from South American trypanosomiasis is that visceral organs may be infected with the amastigotes of the parasite. This results in serious disease that may be fatal. The clinical presentations of South American trypanosomiasis are found in Clinical Correlation Box 22-20.

Trypanosoma rangeli is another trypanosomal organism transmitted to humans by reduviid bugs. Infections of humans and animals are asymptomatic. The trypanomastigotes can be identified in thick and thin smears of peripheral blood and morphologically resemble those seen in African trypanosomiasis. However, unless a careful clinical history is obtained, a misdiagnosis of *T. cruzi* infection may be made. Serologic testing may be of value in differentiating *T. rangeli* infections from Chagas' disease; however, duel infections may occur producing confusing results.

Serologic methods have been developed to detect *T. cruzi* serum antibodies to aid in the diagnosis of Chagas' disease.[93] Godsel et al.[92] identified in the serum of patients with Chagas'



■ **FIGURE 22-22** Life cycle of *Trypanosoma cruzi*. Humans become infected when the trypanosomal-infected fecal matter is discharged into the wound when the bug feeds. The bite is quite painful, and the infected feces are rubbed into the wound. In the human host, the C-shaped trypanosomes, with an enlarged kinetoplast compared with *T. brucei*, circulate in the bloodstream during the early acute phase of the disease (Image Plate 22-9G), and intermittent febrile episodes are experienced. The cycle is completed when a reduviid bug (Image Plate 22-9H) again bites an infected host.

1477

CLINICAL CORRELATION BOX 22-20 South American

Trypanosomiasis – Chaga's Disease

The etiologic agent of South American Trypanosomiasis or Chaga's Disease is *Trypanosoma cruzi*. Humans are infected through the bite of a triatomid bug (i.e. the reduviid bug) that is colloquially called a kissing bug. The bite of this insect vector does not transmit the parasite, but rather these are present in the feces of the insect. Patient who scratch at the bite site inadvertently inoculate the contaminated feces into the bite site. Acute infection is most commonly asymptomatic or produces only mild symptoms, but occasionally more severe reactions occur. Fever and swelling at the bite site are common in symptomatic patients. Unilateral periorbital swelling (Romaña's sign)occurs if the contaminated feces are rubbed into the eye. Trypomastigotes may be seen in the blood of the patient during the acute phase of disease.

The infection then may become chronic, with amastigotes replicating within somatic cells, such as the myocytes of the heart. In many instances, patients may never know that they have been infected, particularly if the acute infection was asymptomatic or produced subclinical disease with non-specific signs and symptoms. The damage done to the somatic cells of the patients continues for years, until organ systems fail. Infection of the heart may result in dysrhythmias or in dilated cardiomyopathy and congestive heart failure. Other common manifestations are the "mega-syndromes," which includes mega-esophagus and mega-colon, wherein these tubular organs are massively dilated and have lost the ability to effective produce peristalsis. These end-stage diseases can really only be effectively addressed through surgery, including cardiac transplantation.

disease a new recombinant antigen called FCaBP, a 24-kDa flagellar calcium-binding protein. This protein may be used as a component of a multiple-recombinant antigen preparation effective in screening for *T. cruzi* in donor blood supplies. Tantowitz et al.,[244] in a comprehensive review, discuss the importance of screening donor blood for Chagas' disease. The issue affects not only individuals living in countries with endemic disease, but also is of concern in the United States, where upward of 50,000 immigrants from endemic countries may be infected. Avila et al.[10] suggested a sensitive screening test for diagnosing chronic Chagas' disease in blood bank donors. They demonstrated 100% sensitivity compared with serologic tests in the detection of PCR-amplified products of *T. cruzi* kinetoplast minicircle DNA in 114 blood samples obtained from chronic patients with and without Chagas' disease, using a specific digoxigenin-labeled oligonucleotide probe. As mentioned, a chronic infection by *T. cruzi* may remain dormant for years. The organ damage that occurs throughout this silent period is irreversible and profound, often necessitating extensive surgery or even

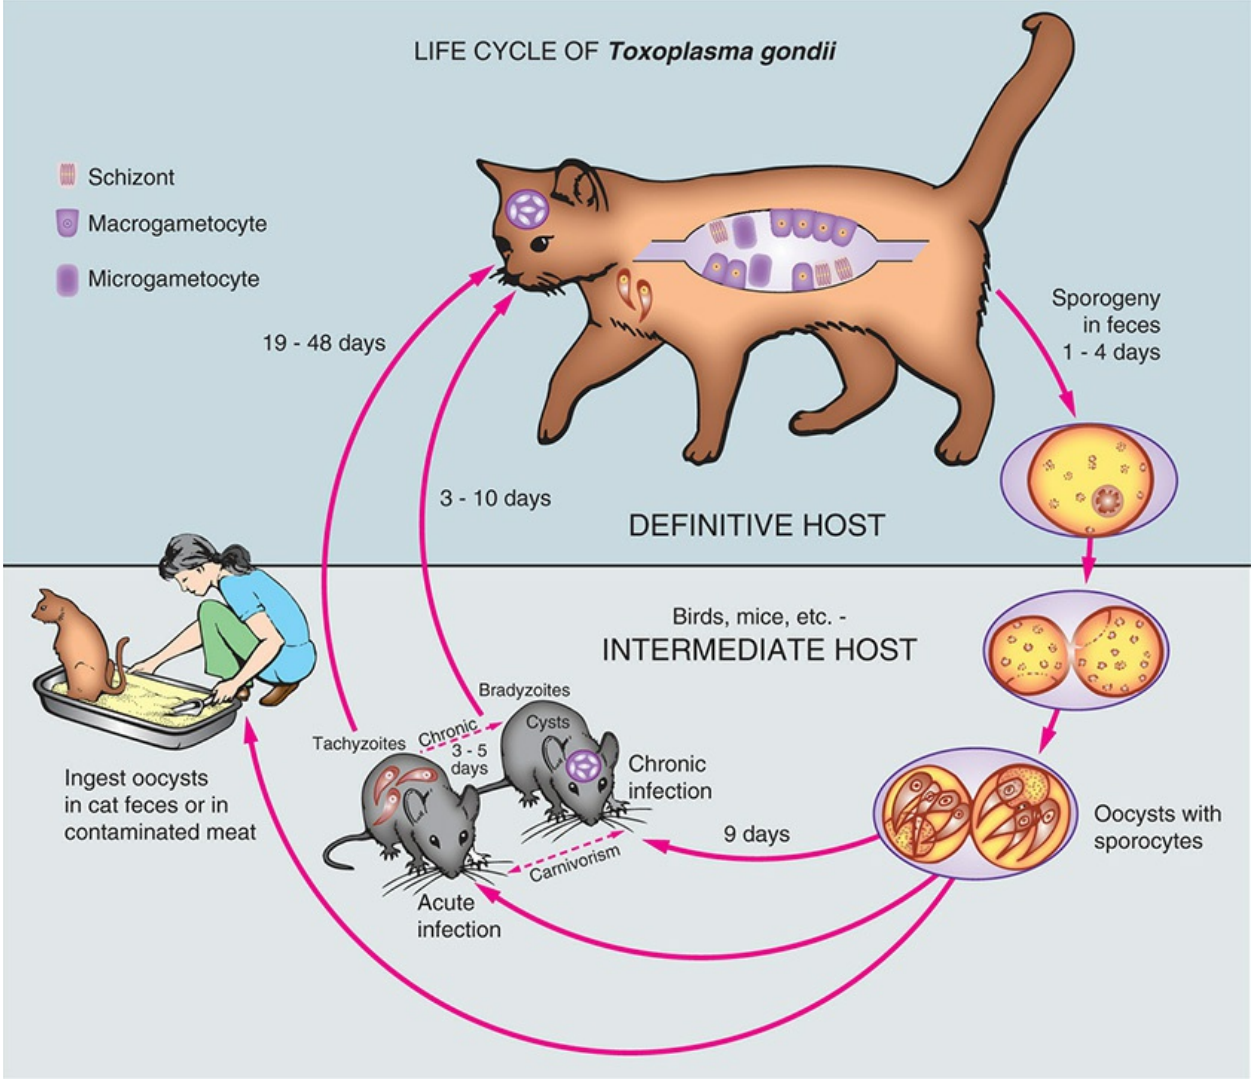
cardiac transplantation. Therefore, although there are few individuals in the United States with Chagas' disease, it has become the standard of practice to screen donated blood for evidence of infection.

Because the number of circulating trypomastigotes is very low in chronic Chagas' disease, PCR-based detection of *T. cruzi* kinetoplast DNA provides a highly sensitive method for establishing a diagnosis. Many studies have shown a high degree of sensitivity, comparable to xenodiagnosis, capable of detecting as few as one circulating trypomastigote in 20 mL of blood.[19,94] This method has also been found useful as a test for cure in the monitoring of patients who are undergoing therapy.

Toxoplasmosis and *Toxoplasma gondii*. *Toxoplasma gondii* is a protozoan parasite of felines, and infections of humans are largely accidental (i.e., in most instances, the human infection is a dead end without further propagation of the parasite in a feline, definitive host. The life cycle of *Toxoplasma gondii* is illustrated in Figure 22-23. Human infections are important because of a particular predilection for infection to involve CNS of the unborn child.

Three modes of transmission lead to most human infections: (1) directly from ingestion of infective oocysts in food (e.g., unwashed leafy vegetables) or water contaminated with cat feces; (2) indirectly, from ingestion of the raw or undercooked meat of animals that had ingested oocysts (it is estimated that 25% of lamb and pork meat sold at supermarkets contain viable tissue cysts); and (3) transplacental transfer to the fetus from a mother infected during pregnancy. Maternal infection rates during the reproductive years are estimated to be between 3% and 5%, but vary depending on the prevalence of disease.[78] Pregnant women should be strongly advised to avoid the handling of cats, cat feces (i.e., changing the litter box), and the ingestion of undercooked meat. Clinical symptoms may be minimal or absent in the acute stages of infection, and infants may not show some of the cardinal signs of infection—chorioretinitis, cerebral calcification,[215] hydrocephalus, or microcephaly—for several months or even years. Acquired infections in adults usually manifest as an acute mononucleosis-like illness, which includes lymphadenitis and lymphadenopathy. Most acute infections result in encystment of the organisms if the host is immunocompetent.

Two parasitic stages may be involved in human infections. After ingestion of oocysts or the encysted infective forms in uncooked meat, tachyzoites (Fig. 22-24 and Image Plate 22-10F) are released in the small intestine and first invade the mucosal epithelial cells, from which they enter the circulation, and then are widely distributed throughout the body. Considerable tissue damage may occur as the tachyzoites destroy the cells they parasitize; however, as the immune response develops, the tachyzoites become less active and ultimately aggregate within a membrane-enclosed cyst (Fig. 22-25, Image Plate 22-10G and H). Although inactive, the bradyzoites within these cysts may remain viable for weeks or for years. Most commonly, they ultimately



■ **FIGURE 22-23** Life cycle of *Toxoplasma gondii*. The life cycle of *T. gondii* has both sexual and asexual stages. The sexual stage occurs in the intestine of cats, where infective oocysts, measuring 10 to 12 μm in diameter, replicate within the intestinal mucosal epithelial cells and are excreted in the feces. The asexual stage commonly occurs in a variety of herbivorous and carnivorous animals that ingest the infective oocysts when foraging through contaminated soil and vegetative matter. Humans may also become infected by ingesting food or water contaminated with oocysts. Cockroaches, earthworms, snails, and slugs may also serve as transport hosts for oocysts.

disintegrate and become enmeshed in a hyaline scar and/or undergo calcification. The detection of intracerebral calcification in skull roentgenograms is one method for

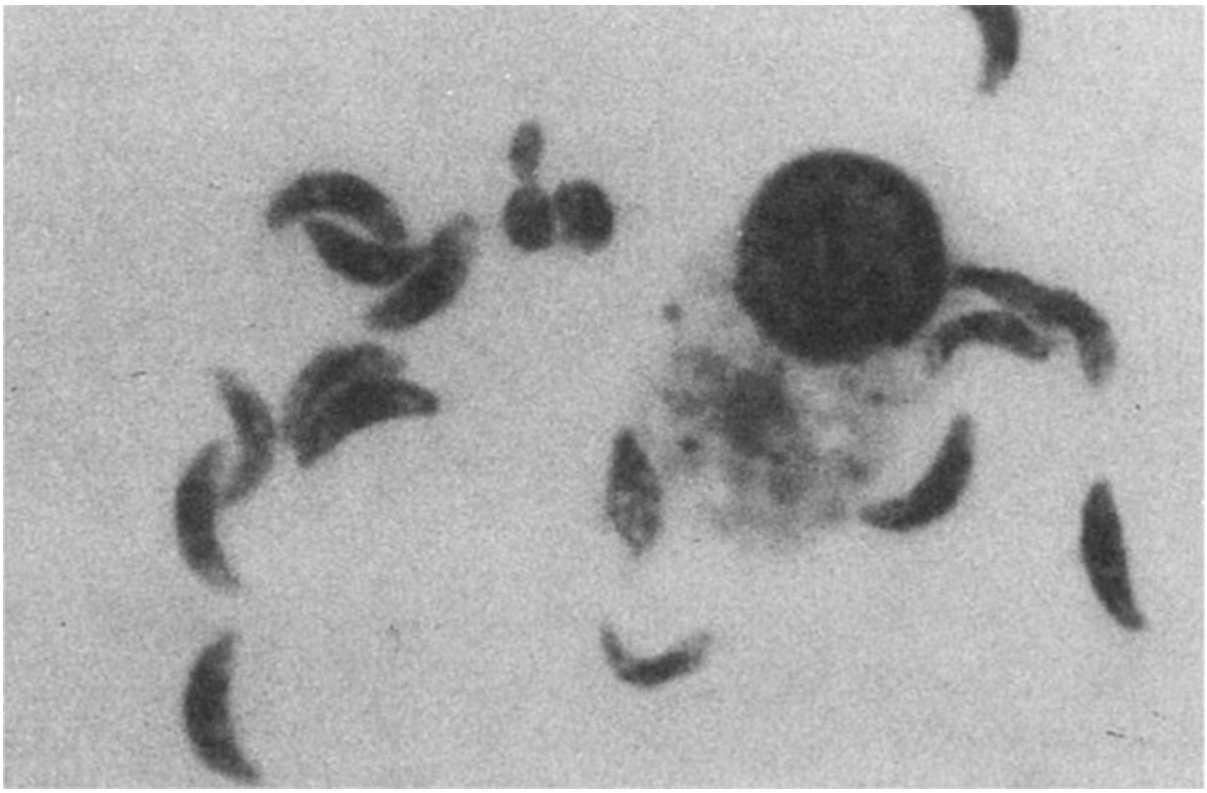
establishing previous infection.

If the host is immunocompromised or becomes immunocompromised even years after the primary infection, the parasite may excyst; bradyzoites transform into tachyzoites and begin replicating causing a variety of diseases, including myocarditis, meningoencephalitis, atypical pneumonia, and rhinochoroiditis.

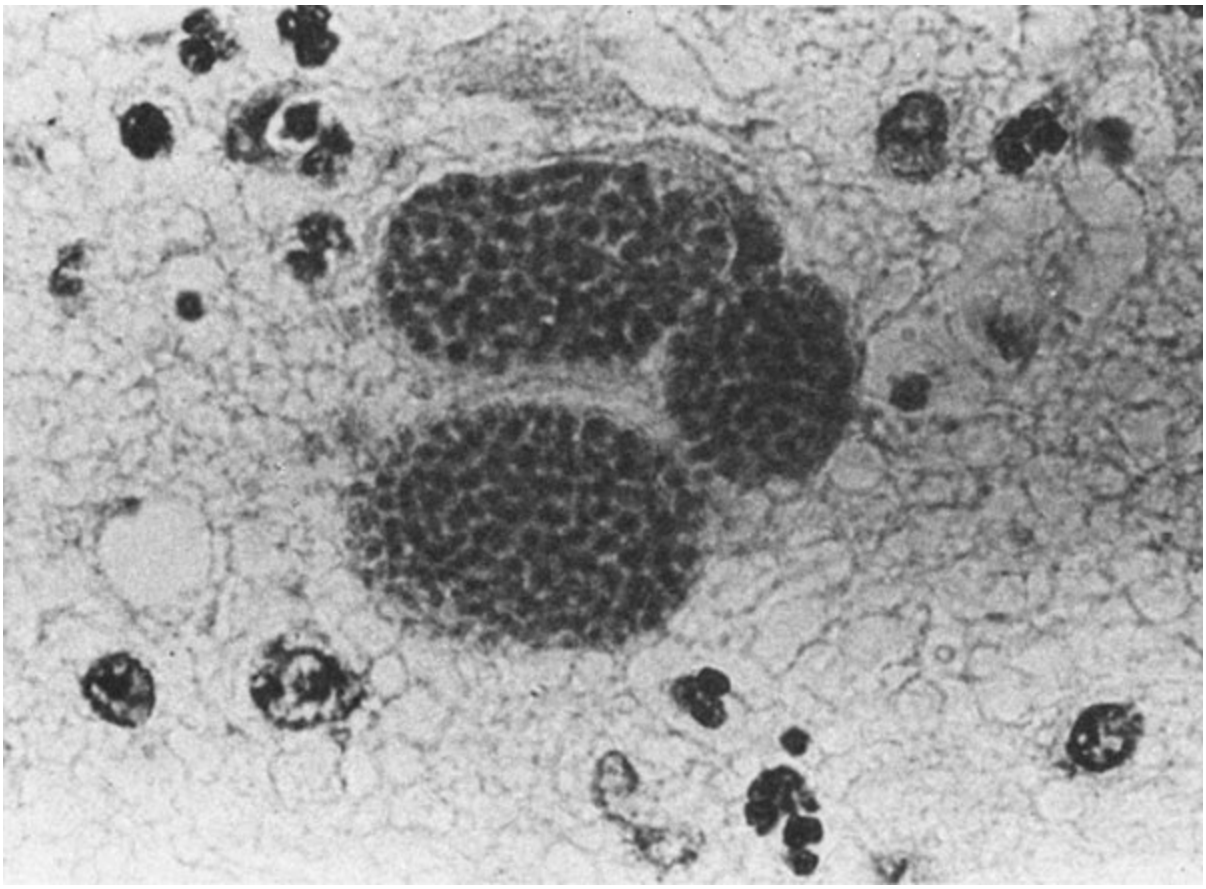
Laboratory Identification. The diagnosis of acute toxoplasmosis in an immunocompetent individual is usually made by serologic methods. In the immunocompromised with progressive disease, it can be made by demonstrating clusters of tachyzoites in stained smears using the PAS, Giemsa, and/or H & E stains. Fluorescent antibody staining and peroxidase–antiperoxidase techniques have been used to better demonstrate organisms in formalin-fixed and paraffin-embedded tissues. Tachyzoites are perhaps best seen in needle aspirates or impression smears stained with Wright–Giemsa.

- The tachyzoites are typically crescent-shaped, measure 3 to 4 × 6 to 7 μm, and have a dark-staining central nucleus (Fig. 22-26 and Image Plate 22-10F).
- One or more cysts, when observed in tissue sections of patients, usually indicate a chronic and usually inactive stage of infection, but serve as an important source of acute reactivation toxoplasmosis.

1479



■ **FIGURE 22-24** High-power view of Giemsa-stained impression smear demonstrating *Toxoplasma* tachyzoites. Note characteristic bow-shaped or crescent-shaped, with central dark-staining nucleus (×1,000).



■ **FIGURE 22-25** High-power view of the toxoplasmal bradyzoite cysts. Each pseudocyst contains several scores of trophozoites. These bradyzoite cysts are most commonly seen in patients with latent disease. Note the absence of an inflammatory reaction adjacent to these pseudocysts (H & E ×1,000).

- Cysts measure up to 200 μm in diameter and contain several hundred bradyzoites 2 to 3 μm in diameter (Fig. 22-27 and Image Plate 22-10G and H).

The serologic diagnosis of toxoplasmosis is complex, and a full account is beyond the scope of this presentation. Pioneering work has been done by McCabe and Remington,[169] a summary of which is included in Box 22-5. Because of the high prevalence of increased titers of *Toxoplasma* antibody in the general population, test results must be carefully interpreted before a definitive diagnosis can be established. The time-honored Sabin–Feldman dye test, based on the principle that live *Toxoplasma gondii* tachyzoites lose their affinity for methylene blue dye in the presence of immune

BOX 22-5

Interpretation of Serologic Results in Clinical Syndromes of Toxoplasmosis[169]

A. Acute acquired toxoplasmosis: immunocompetent patient
   The diagnosis can be highly suspected if:
   1. Seroconversion from negative to positive is demonstrated.
   2. A twofold increase in titer between a baseline sample and a repeated test 3 weeks later.
   3. A high IgM titer with a single high IgG titer (>1:1,000).
   4. A low IgM titer indicates that the infection was acquired 4 months or more before. The IgM titer usually reverts to normal within 9 months.
      Note: A negative dye or immunofluorescence assay result in an immunocompetent person virtually precludes the diagnosis of acute toxoplasmosis.

B. Acute acquired toxoplasmosis: immunosuppressed patient
   The criteria cited for immunocompetent patients apply to immunoincompetent individuals as well. However, IgM antibody or twofold rises in IgG antibody often are not detected; therefore, a negative test does not rule out acute toxoplasmosis. Organisms must be demonstrated in tissue biopsies or impression smears of aspirates before a secure diagnosis can be made in this group of patients or by PCR.

C. Ocular toxoplasmosis
   The diagnosis can be suspected if:
   1. Low titers of IgG antibody in the presence of a typical retinal lesion.
   2. "C" is equal to or greater than 8 using the following formula when testing aqueous humor fluid:

      (Antibody titer in fluid×concentration of γ-globulin in serum)/(Antibody titer in serum×concentration of γ-globulin in body fluid)

D. Congenital toxoplasmosis
   The diagnosis of *Toxoplasma* infection in the neonate can be established if:
   1. There is a persistent or rising titer in serologic studies.
   2. A positive IgM test at any titer after birth in the absence of a placental leak, or the organism is demonstrated in tissue biopsies or impression smears of aspirates or by PCR.

1480

serum, being both sensitive and specific, may be used as the reference method, but is not used in clinical practice. Newer, sometimes automated, techniques are used in

most reference laboratories, which bypasses the necessity of having to work with live organisms. Current assays assess for both IgM and IgG, so that an assessment of the phase of infection (i.e., acute vs. remote) may be determined in many instances with a single serologic study, rather than having to compare acute and convalescent titers. A number of methods have been explored for the serologic diagnosis of toxoplasmosis.[46,153,273]

Nucleic acid amplification techniques for the detection of *Toxoplasma* have also improved significantly over the past decade, particularly with the introduction of real-time PCR technology. Several reports describe the *T. gondii* B1 gene as a valuable target for PCR.[71,123,143,193] The B1 gene-amplification procedure is sufficiently sensitive to detect a single isolated parasite and as few as 10 parasites in a background of 100,000 leukocytes.[193] Nucleic acid amplification techniques are more sensitive and have virtually replaced cell culture as the method of choice in diagnosing acute or active *Toxoplasma* parasitemia, particularly in the immunocompromised host.[123] This has been used to detect *Toxoplasma* parasitemia in patients with AIDS and unexplained fever or CNS abnormalities.[71] Examination of blood by PCR may also be useful in diagnosing extracerebral toxoplasmosis from the local reactivation of latent brain cysts.[66] Dupon et al.[65] also found the PCR examination of CSF and/or blood to be a valuable adjunct in detecting reactivation of latent cerebral toxoplasmosis. In addition to detecting the *T. gondii* B1 nucleic acid sequences, they cite other studies successfully using p30, TGR1 genes, and the 18S rDNA as targets. PCR of the CSF for *Toxoplasma* has largely replaced the need for brain biopsy to achieve the diagnosis, just as PCR for the herpes simplex virus (HSV) and JC virus has largely replaced brain biopsy for the diagnosis of HSV-associated meningoencephalitis and JC virus-associated progressive multifocal leukoencephalopathy. PCR when applied to amniotic fluid has also proven useful for the diagnosis of congenital toxoplasmosis.[104]

Trichomoniasis and *Trichomonas vaginalis*. Trichomoniasis, caused by *T. vaginalis*, is one of the most common sexually transmitted diseases, and importantly, it is curable. It has been estimated that 3.7 million individuals in the United States are infected, but only approximately 30% are symptomatic. Therefore, it is important to test individuals who have had unprotected sex.

Symptomatic trichomoniasis most commonly occurs in women, wherein there is a green frothy discharge, odor, and vaginal discomfort, such as itching and pain upon urination. Although surprisingly infections in men are often asymptomatic, if symptoms occur, they may include a urethral discharge and pain upon urination and ejaculation. *Trichomonas* does not disseminate. However, the treatment of infected patients is important, since infection with this parasite increases the likelihood of contracting another sexually transmitted disease, most importantly HIV.

Traditionally, trichomoniasis has been diagnosed using a "wet prep" often performed in the physician's office. The identification of *Trichomonas* is quite simple when the vaginal fluid from symptomatic women is examined microscopically, since the trichomonads are motile. Although this test is highly specific in this setting, the sensitivity of a microscopic examination diminishes in infected but asymptomatic patients. One study demonstrated that the direct examination was only 58% sensitive compared with culture. The sensitivity of the microscopic examination is also diminished if the specimen is not examined immediately, but rather transported to a distant laboratory. Nonmicroscopic assays for the detection of *Trichomonas* have become favored secondary to increased regulation of physician-performed microscopy and laboratory consolidation.

Laboratory Identification. The morphologic evaluation of *T. vaginalis* is usually straightforward when fluids from an infected, symptomatic woman are examined and motile trichomonads are seen. However, it is important that the parasitologists have the ability to differentiate *T. vaginalis,* which is sexually transmitted, from *Pentatrichomonas hominis,* which is part of the normal microbiota of the intestinal tract. The morphologic criteria used to identify *Trichomonas vaginalis* include the following:

- Trichomonads are pyriform, measuring 10 to 12 μm, with a single oval nucleus.
- There is no cyst form.
- A basal body is present at one end from which numerous flagella arise.
- There is an axostyle, which extends the length of the organism and extends from the distal end.
- An undulating membrane is present that extends from the basal body.
  - *Trichomonas vaginalis*: The undulating membrane 1/2 to 3/4 of the length of the organism.
  - *Pentatrichomonas hominis*: The undulating membrane runs the full length of the organism.

Trichomonas culture has been used to preserve the viability of the trichomonads using Diamond's medium. Although culture for *Trichomonas* is feasible, it requires a longer time to result and has not become the standard of practice. The OSOM *Trichomonas* Rapid Test is a CLIA-waived, lateral flow ICT assay that detects the antigens of *T. vaginalis.* These have a 95% agreement, according to the package insert, with the wet preparation, which represents a waived alternative for physician's offices for the assessment of symptomatic patients.

The BD Affirm VPIII system is a probe-based technology designed to detect the most common agents of vaginitis and includes *Trichomonas vaginalis.* According to the package insert, the sensitivity and specificity of this assay were 93% and 99.9%compared to direct examination and 90% and 99.9% compared to culture. This

product represents an option to assess for multiple causes of vaginitis simultaneously.

Nucleic acid amplifications are emerging as the gold standard for the detection of *T. vaginalis*. Importantly, this highly sensitive technology affords the opportunity to detect individuals who are infected, but who are not symptomatic. This assay utilizes transcription-mediated amplification, which has been used successfully for many years for the detection of *N. gonorrhoeae* and *C. trachomatis*. The APTIMA *Trichomonas vaginalis* is currently the only FDA-approved nucleic acid amplification assay. Chapin and Andrea found this assay

1481

to have a clinical sensitivity of 95% and a specificity of 98%.[33] Importantly, this technology affords detection in men, which is a cohort that has largely gone undetected and represent an important reservoir.[227]

Metronidazole is the most commonly used therapy. Tinidazole is an FDA-approved alternative that is equally effective.

Blood and Tissue Helminths

Filarial Nematodes and Filariasis

The filarial parasites discussed here are threadlike nematode worms.[194] The adults inhabit primarily the circulatory and lymphatic channels, but may also be found in muscles, connective tissues, and serous cavities. Some species form a subcutaneous nodule. Three important species of filariae worms that commonly cause disease in humans, *Wuchereria bancrofti*, *Brugia malayi*, and *Loa loa,* will be covered here.

There have been substantial efforts to combat filariasis in the past decades. Regardless, the WHO estimates that 120 million people are currently infected, with 40 million who are disfigured or will be incapacitated by the disease; although, similar numbers were reported in 1989 and 1999, this still represents progress, given the growing population in affected areas.[139] Ninety percent of patients have bancroftian filariasis, whereas brugian filariasis accounts for most of the remainder.[181] Bancroftian filariasis is seen primarily in urban areas due to poor sanitation and intense breeding of *Culex* mosquitos. Brugian filariasis is mainly a rural disease transmitted by *Anopheles* and *Aedes* mosquitos. The number of infected persons varies based on economic conditions associated with increased exposure to the insect vector and the formation of favorable mosquito breeding sites.[256]

Humans acquire the disease following a bite from an infected mosquito (*W. bancrofti* and *B. malayi*) or tabanid flies for *Loa loa*. Biting midges serve to transmit

the nonsheathed species, *M. perstans* and *M. ozzardi*. The life cycle of *Wuchereria bancrofti* as a prototype for the filarial worms is illustrated in Figure 22-26.

Laboratory Identification. The laboratory diagnosis is made by observing circulating microfilaria in stained peripheral blood smears.[102] Microfilariae circulate in the peripheral blood with a regular periodicity that is dependent on the species of worm. Those of *W. bancrofti* and *B. malayi* are nocturnal, whereas those of *Loa loa* are diurnal.[208] Therefore, to diagnose bancroftian filariasis, optimally blood should be obtained between midnight and 2:00 AM In patients with light infections or when samples are collected at suboptimal times, membrane filtration, centrifugation, sedimentation (Knott's concentration), and preparation of thick smears are techniques that may help to detect low numbers of circulating microfilaria.[211] The use of polycarbonate filters (Nuclepore) to trap microfilaria on a filter after the red blood cells have been lysed is an alternative concentration technique.[58] Because the 3 to 5 μm pore size filters are transparent when wet, they can be directly examined for the presence of microfilaria on a microscope slide.

Long et al.[157] describe an interesting approach to the laboratory diagnosis of filariasis using an acridine orange/microhematocrit tube technique. A microhematocrit tube incorporating heparin, EDTA, and acridine orange serves as the basis for this test. On centrifugation, parasites become concentrated in the buffy coat and can be visualized through the clear glass wall of the tube. The acridine orange stains the DNA of the parasites, and the morphologic characteristics, including the nuclear patterns in the tail sections, can be examined by fluorescence microscopy to achieve a species-level identification.

Mature female worms produce myriad larvae known of as microfilaria that circulate in the blood and serve as the mode of transmission when the mosquito vector takes a blood meal. An identification can be made by observing key characteristics unique to each filarial species.

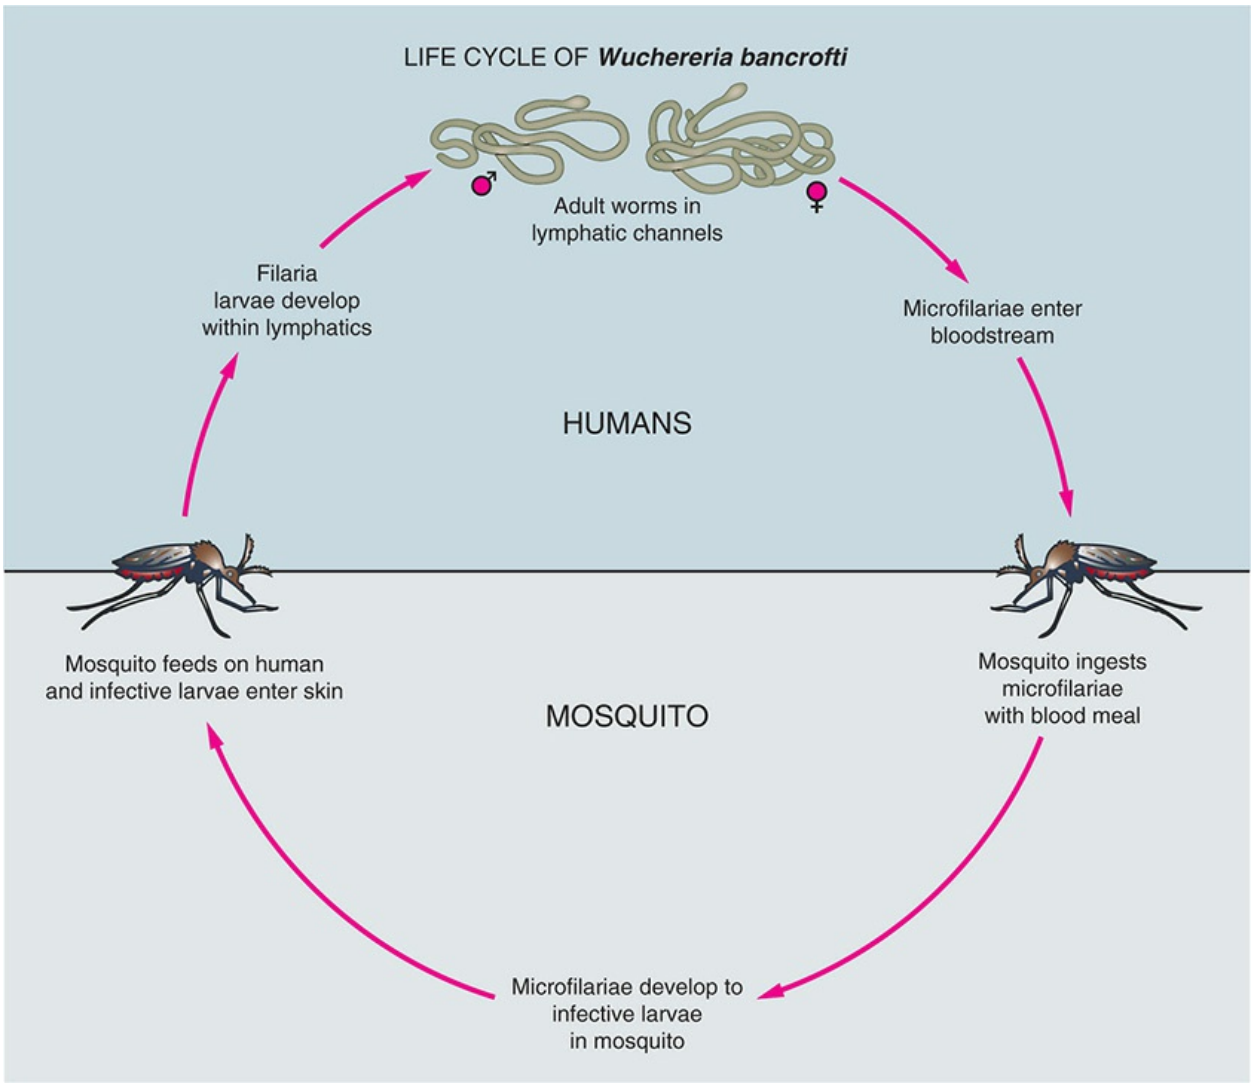
Microfilaria:

- Measure between 240–300 × 7–10 μm.
- Are ribbonlike and can be seen in microscopic mounts of anticoagulated blood by their undulating motion, displacing the red blood cells from side to side as they move.
  - Note: This is rarely done. In most instances, they are observed in the thick and thin blood film preparations. As several of the species cause cyclic fevers, they are in the differential diagnosis with *Plasmodium* species. Therefore, the examination of every thick and thin blood film should begin with a low-power (i.e., 100× magnification; use the 10× objective) to search the film for the presence of microfilaria.

- A prominent sheath surrounds the microfilaria of the species discussed here. It is obvious in stained peripheral blood smears for some species, but for others appears as a nonstaining area around the microfilaria. The sheath extends beyond the tail section. The sheath is a close-fitting membrane that envelops the microfilaria of these filarial worms, representing the remnants of the ovum membrane from which it was derived.
- Species of sheathed microfilaria can be differentiated by observing the size and the pattern of extension of nuclei into the tail sections:
  - *W. bancrofti:* the nuclei do not extend to the tip of the tail (Image Plate 22-10A).
  - *B. malayi:* two nuclei extend into the tail, spaced about 10 μm apart (Image Plate 22-10B).
  - *Loa loa:* an uninterrupted column of nuclei extend into and to the tip of the tail (Image Plate 22-10C). Importantly, the sheath of *Loa loa* does not stain well, or even at all, with the common Giemsa's stain; it often appears as an unstained area around the microfilariae.

The microfilaria of two other microfilaria species, *Mansonella perstans* and *Mansonella ozzardi*, may also be seen in the peripheral blood; however, patients with these infections are often asymptomatic. Occasionally, eosinophilia, lymphadenitis, low-grade fever, maculopapular rash, and urticaria have been observed in infected individuals. The microfilariae of these species are much smaller than those discussed above and are devoid of a sheath.

1482



■ **FIGURE 22-26** Life cycle of *Wuchereria bancrofti*. Humans acquire the disease following a bite from an infected mosquito (*W. bancrofti* and *B. malayi*) or tabanid flies (*Loa loa*). Biting midges serve as the intermediate hosts for the nonsheathed species, *M. perstans* and *M. ozzardi*. When the vector bites an infected human host, the infective microfilariae are ingested and penetrate the stomach wall of the insect. An infective third larval stage develops in the stomach, which in turn migrates to the thoracic muscles of the insect and then to the proboscis. When the insect bites a new human host, these infective larvae move down the proboscis and are injected into the cutaneous wound while the mosquito takes a blood meal. These infective larvae reproduce locally in the subcutaneous tissue and ultimately enter the peripheral lymphatics, where they find their way to lymph nodes and lymphatic channels in various parts of the body. Over a period of several weeks, the larvae develop into white, threadlike adult worms. The lymphatics of the lower extremities and the epitrochlear and femoral lymph nodes are the sites most commonly involved. Mature female worms release microfilariae that circulate in the blood, and are ingested by the appropriate insect during the next blood meal, to complete the life cycle.

Because the detection of circulating microfilaria by direct examination of blood is relatively insensitive in establishing a diagnosis of filariasis, and is dependent on the collection of specimens at specific times in the day, several antigen-detection procedures have been introduced. Weil et al.[261] demonstrated filarial antigen in the sera of 56 of 57 patients with bancroftian microfilaremia living in an endemic area in South India. Antigen shedding may be irregular, particularly during times when circulating microfilaria may not be detected; thus, even these approaches lack sensitivity. Simonson and Dunyo[233] have also found that three recently introduced approaches for antigen detection also hold much promise—the ICT card test and the TropBio ELISA for serum specimens, and the TropBio ELISA for filter paper specimens.

The advent of PCR assays is proving to be useful not only in establishing a diagnosis in cases of light or amicrofilaremic infections, but also for use in monitoring therapy and

in discriminating between past and present infection.[72] Of much current interest is the application of PCR technology in the diagnosis of bancroftian filariasis by examining diurnally collected sputum specimens.[1] Preliminary data from this initial study are quite encouraging and portend great potential in the future.

Onchocerciasis and *Onchocerca volvulus*. Onchocerciasis is a filarial worm disease that involves primarily the subcutaneous portion of the skin wherein dense, fibrous nodules are formed that range in diameter from 5 to 25 mm.[189] These occur at the sites of bites of the vector, the *Simulium* black or buffalo fly. The nodules are more likely to be distributed in the trunk, thighs, and arms in African subjects, but more likely are localized in the neck and shoulders in inhabitants of Central America. Lesions of the skin and eyes occur secondary to the dead and dying microfilariae produced by the female worm in the subcutaneous nodule.[15] It is estimated that 25 million people worldwide are infected with *Onchocerca volvulus*, of whom 300,000 are blind and another 800,000 have visual impairment. Onchocerciasis is a leading cause of blindness in the world.[115] Although these numbers are staggering, substantial progress has been made. Two previously endemic countries have been declared onchocerciasis free—Colombia in 2013 and Ecuador in 2014. These successes are secondary to large-scale community-based treatment of the populations at risk with ivermectin (www.who.int).

The *Simulium* fly has its main habitat in the underbrush lining the banks of fast-moving streams. African onchocerciasis occurs mainly in the Congo basin, Zaire,

Angola, and the Sudan; in the Americas, it is found in the highlands of Guatemala, the states of Oaxaca and Chiapas in Mexico, in Colombia, and in northeastern Venezuela. The life cycle of *Onchocerca volvulus* is illustrated in Figure 22-27.

The diagnosis is clinically suspected when a patient from an endemic area presents with pruritic subcutaneous nodules with associated dermatitis, loss of elasticity, and hyperpigmentation. Pruritus is a major symptom in some patients, resulting in fatigue, weakness, and inability to sleep to the point of being physically and socially debilitating. Affected areas of skin may become hot and edematous, discolored, and prematurely wrinkled, a condition known as mal morado in Central America. In Africa, involvement of the hip region, particularly around the inguinal lymph nodes, results in a condition known as "hanging groin," often leading to femoral and inguinal hernias. Several excellent photographs illustrating these clinical presentations have been published by Garcia.[87]

Image Plate 22-10D is an H & E–stained section through a nodule, including the cross section of a gravid worm that contains many microfilariae. Although the microfilariae may remain localized to the site of infection, they may wander through the adjacent skin and reach other tissues, including the eye. Ocular involvement is the most serious complication, often leading to varying degrees of loss of sight, known as "river blindness." The eye serves as a trap for wandering microfilaria, which may be found either dead or alive in the anterior chamber, cornea, choroid, and vitreous humor. The mechanical action and/or effects from secretory toxins released by the adult worm in a hypersensitive patient and/or the inflammatory response to the microfilariae are thought to account for the development of bilateral blindness. The severity of blindness in various endemic regions is dependent on the *O. volvulus* strain involved, as determined by DNA sequence analyses.[188]

Zimmerman et al.[287] successfully used PCR to detect microfilariae in skin snips, providing significantly increased sensitivity in detecting active infection than that achieved by routine microscopic examination or serologic assays. Enzyme immunoassays have also been used to help establish the diagnosis in patients presenting primarily with river blindness. Ogunrinade et al.[188] evaluated an enzyme immunoassay using recombinant *Onchocerca volvulus* antigens OC 3.6 and OC 9.3 as an aid in diagnosing patients with suspected onchocerciasis. Forty of 42 (95%) serum samples they tested from patients with known onchocerciasis were reactive with the OC 3.6 antigen, while 81% were positive for the OC 9.3 antigen. Additional studies revealed that the OC 3.6 antigen was most helpful in detecting prepatent infections in humans; the OC 9.3 antigen was more sensitive in patients with mature, patent infections.

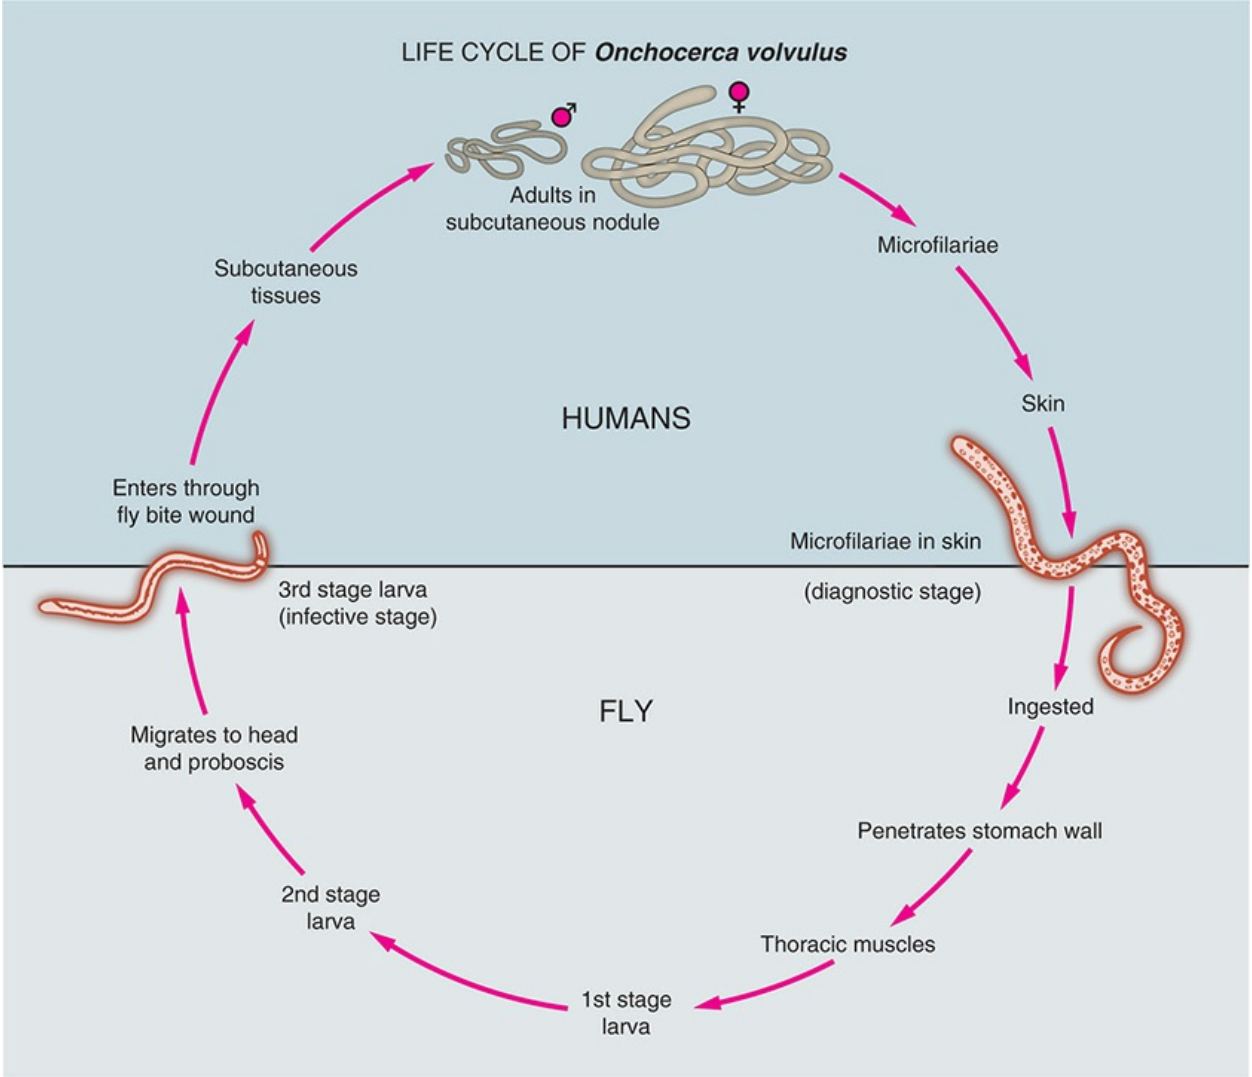
Treatment consists of the surgical removal of detectable nodules when possible. Ivermectin is currently considered the drug of choice in the treatment of onchocerciasis when surgical removal of lesions is not possible. This drug reduces the

numbers of microfilariae by blocking their release from the female worm. The drug is well tolerated, and side effects such as pruritus, arthralgia, and skin edema are usually minor. Diethylcarbamazine, beginning with small doses, plus suramin are alternative drugs that have been used successfully, although side effects from death of the microfilaria may require the addition of anti-inflammatory drugs. The administration of mebendazole or flubendazole (benzimidazole derivatives) has also been successful, with few side effects.

Dracunculiasis and *Dracunculus medinensis.* *Dracunculus medinensis* is a tissue roundworm that is taxonomically unique from other nematodes. It has been suggested that *D. medinensis,* also known of as the guinea worm, possibly represents the "fiery serpent" of biblical lore.[124] There has been an international campaign to eradicate *D. medinensis* with substantial success. There has been a steady reduction in dracunculiasis due to systematic intervention and eradication efforts. Dracunculiasis is now confined to only four countries in Africa, Chad, Ethiopia, Mali and South Sudan. Infections have diminished from an astounding 3.2 million in 1986 to 78,557 cases in 1998 (97% decrease), 148 cases in 2013, and 126 cases for 2014.[128] One important setback in the eradication efforts has been the discovery that this parasite, which was thought only to infect humans, also infects dogs, which can serve as a reservoir.

Humans acquire the infection through ingestion of infected Copepoda present in drinking water. The larvae develop into adult worms in the serous cavities and then the gravid females migrate to the subcutaneous tissue. These female worms can measure as long as 100 cm and cause a burning sensation and ulceration of the skin. The life cycle of the parasite is complete when the larvae produced by the female escape from the skin blister and are discharged into water in which the Copepoda live.

1484



■ **FIGURE 22-27** Life cycle of *Onchocerca volvulus*. In the life cycle, humans become infected by bites from a *Simulium* fly, the mouth parts of which possess the infective third-stage larval forms of the parasite. The adult worms develop in tangled masses within nodules beneath the skin, and the females produce microfilariae (Image Plate 22-9D). The microfilariae remain localized to the infection sites and do not circulate in the peripheral blood except in rare instances. The life cycle is completed when a black fly again bites a diseased human at one of the infection sites, picking up the microfilaria in the mouth parts. The microfilariae then develop in the fly by penetrating the stomach wall, entering the thoracic muscles, and transforming through first- and second-stage larvae. They mature into the infective third-stage larval forms to complete the life cycle.

Interruption of this life cycle in endemic area, through both the treatment of infected persons and production of clean drinking water, promises to eventually eradicate dracunculiasis.

Traditionally, these have been from the subcutaneous tissue by winding them slowly on a stick. Modifications of this technique are still used, with an emphasis on sanitary condition and the prevention of secondary infections.

Dirofilariasis and *Dirofilaria* Species. *Dirofilaria* species are filarial parasites of animals that accidentally infect humans through the bite of the mosquito vector. In the definitive host, the infective larval forms injected into the subcutaneous tissue from the proboscis of the mosquito enter into the circulation and ultimately find their way to the heart, where they develop into adults (heart worms) (Image Plate 22-10E). The most well known of these is *D. immitis,* the dog heart worm, but there are other *Dirofilaria* species that infect other animals (e.g., *D. tenuis* and *D. repens*). The diagnosis is made in infected dogs by observing circulating microfilaria in the peripheral blood. However, when humans are bitten by infected mosquitos, the larvae, because they

are in the wrong host, are incapable of completing their life cycle. Rather, they lodge in and obstruct pulmonary arterioles, where they cause infarction and develop into local granulomatous nodules that may, on occasion, reach sufficient size to be diagnosed as "coin lesions" on chest roentgenogram examination. Microfilariae are never produced and circulate in human blood. The diagnosis is made by histologic observation of immature filarial larvae within the pulmonary granulomatous nodules. Flieder and Moran[74] recently reviewed 39 cases of histologically proven dirofilarial pulmonary infection. Approximately half of this group were asymptomatic, with only a pulmonary nodule detected on radiologic studies obtained for routine physical examinations; the remaining half presented with respiratory symptoms. Only 10%presented with peripheral blood eosinophilia.

Tissue Nematodes: Nonfilarial Worms

Humans may be inadvertent accidental hosts for several nematodes and cestodes that have life cycles in other animals. The adults of these species normally reside in the intestinal tract or select tissues of the definitive hosts; humans become infected either by ingesting the larvae in poorly cooked meat, through cutaneous penetration or by the ingesting fertile eggs. Of particular concern in the United States is the potential increased exposure to a variety of helminthic parasites through the ingestion of uncooked seafood in the form of dishes such as sushi, sashimi, lomi-lomi salmon, and pickled herring, among others. A brief discussion of some of these types of parasitic diseases will follow.

Trichinosis and *Trichinella spiralis*. Trichinosis is a disease of carnivores caused predominantly by infection with the nematode *Trichinella spiralis*. It results from the ingestion of raw or poorly cooked meat. Humans are accidental hosts and are most commonly infected through ingestion of pork or pork products that contain encysted larvae.[99] Infections have also been reported after ingestion of poorly cooked bear and walrus meat.[38] Smoking, salting, or drying the meat does not destroy the infective larval forms; however, prolonged freezing (20 days at −15°C) decontaminates the meat. The disease has a worldwide distribution. In resource-rich countries, the disease prevalence decreases with improved animal husbandry practices. For example, in the United States, 4% of human cadavers were found to be infected in 1968, but by 1985, less than 50 new cases were being reported each year in the United States,[38] a tribute to the meat inspection program and the stringent laws concerning improved animal husbandry (e.g., against feeding uncooked garbage to pigs). The life cycle is illustrated in Figure 22-28. The clinical manifestations of trichinosis are presented in Clinical Correlation Box 22-21.

Laboratory Identification. The laboratory diagnosis of trichinosis is most commonly made by detecting the spiral larvae in muscle tissue (Image Plate 22-11G and H). The deltoid muscle of the upper arm or the gastrocnemius muscle of the calf are usually selected for biopsy. The specimen may be examined microscopically by first digesting the muscle fibers with trypsin and then mounting some of the digested tissue on a microscope slide. Alternatively, a tease preparation may be prepared by squeezing a small fragment of muscle in a drop of saline solution between two glass slides, in each case looking microscopically for the coiled larval forms. Linear or spiral larval forms may also be observed in stained tissue sections, although their morphology is often not as well delineated.

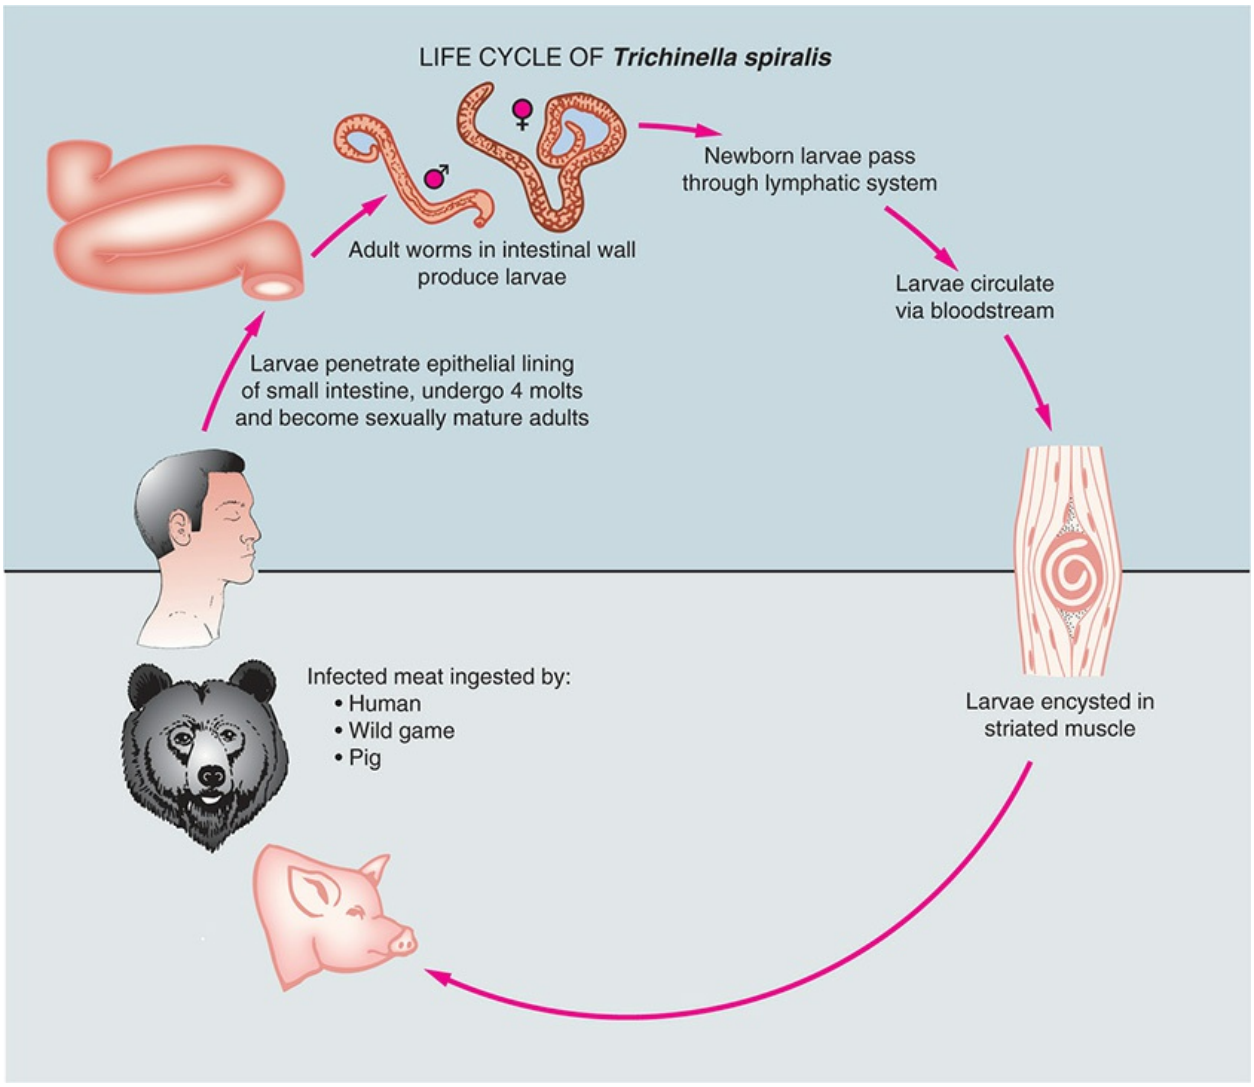
Serologic tests are also helpful in establishing a diagnosis. Mahannop et al.,[164] using crude antigens obtained from the infective-stage larvae of *Trichinella spiralis* in an ELISA system for detecting serum IgG antibodies to *T. spiralis*, reported a 100%sensitivity in a group of patients with confirmed trichinelliasis. They found cross-reactions in sera collected from patients with capillariasis, gnathostomiasis, opisthorchiasis, and strongyloidiasis. Serologic tests for *Trichinella* are commercially available in reference laboratories.

Visceral Larva Migrans and *Toxocara* Species. *Toxocara canis* and *T. cati* are the intestinal roundworms of dogs and cats, respectively. These have a life cycle similar to

CLINICAL CORRELATION BOX 22-21 Trichinosis

Symptoms in most patients are mild, as the number of larvae is commonly small. Many individuals have flu-like symptoms. The minimal number of ingested larvae required to produce symptoms is about 100, and a fatal dose is estimated to be 300,000.[99] Upon ingestion of contaminated meat, gastrointestinal symptoms are the first to appear, including nausea, diarrhea, and abdominal cramps, suggesting acute food poisoning. These symptoms may persist with varying degrees of severity for as long as 10 weeks. Pain, swelling, and weakness of involved muscles develop during the larval invasion stage, accompanied by fever. Peripheral blood eosinophilia, with differential counts reaching as high as 50%, is seen during the muscle invasion stage. Periorbital edema is a diagnostic sign, as extraocular muscles are commonly involved. Damage to muscles may result in irregularities in chewing, swallowing, and breathing, depending on the muscles involved and the degree of involvement. In about 10%–20% of patients, the CNS may be involved to varying degrees, with symptoms suggesting polyneuritis, myasthenia gravis, or paresis of localized muscle groups. Acute myocarditis is the most serious complication, which may result in death in infections with heavy worm loads. A review of antiparasitic drugs effective for trichinosis myositis has been reviewed by Watt et al.[258] Mebendazole and albendazole are effective in killing the adult worms, but do not kill the encysted larvae.

1486



■ **FIGURE 22-28** Life cycle of *Trichinella spiralis*. When humans ingest trichinosis-contaminated meat, the encysted larvae are released in the intestine and burrow into the villi. The larvae mature and mate, and develop into adult male and female worms, measuring from 2 to 4 mm in length. The average life span of the adults in the human intestine is about 1 month. During this time, each female releases as many as 3,000 larval offspring. These larvae pass through the lymphatic system and enter the circulation and are deposited throughout the tissues of the body. Most of these larvae are killed; however, many of those that reach the skeletal muscle become encysted and survive. The heaviest period of muscle invasion is around day 10 after infection. By days 17 to 20 postinfection, these larval forms differentiate and become encapsulated, forming a coil two-and-a-half times on themselves, surrounded initially by an acute and later a chronic granulomatous inflammatory reaction (Image Plate 22-11 *G* and *H*). The adjacent muscle fibers undergo degeneration, leaving a cyst that measures about 0.25 to 0.50 mm. In approximately 3 months, the worms die and the cystic lesions undergo a process of calcification, which is completed in 6–12 months.

that of human roundworm, *Ascaris lumbricoides.* These are the most common causes of human larva migrans.

Visceral larva migrans is a condition in which the larvae of nematode parasites of lower animals infect humans, and since the parasite is in an inappropriate host, it migrates through the tissues without further development.

The infection begins in humans, an accidental host, through the ingestion of embryonated eggs in the soil. The disease is most common in children because of their inadvertent ingestion of soil and their close association with dogs. The embryonated eggs hatch in the intestine of the human host, liberating the larvae, which, in turn, penetrate the bowel wall and enter the circulation. However, because humans are abnormal hosts, the pulmonary cycle is not completed; rather, the larvae wander in various organs, chiefly the liver. Involvement of the eyes and CNS may also occur. The migrating larvae cause local tissue reactions or granulomas. In most instances, the larvae eventually die out with no sequelae. The infection may be suspected in a child with hepatomegaly, nonspecific pulmonary disease,

1487

and a high peripheral blood eosinophilia, reaching as high as 50% to 90%.

Although a definitive diagnosis is confirmed only by the identification of larvae in autopsy or biopsy specimens, serologic testing is recommended to direct management and therapy. Detecting elevated titers in ocular fluid specimens is confirmatory of eye involvement (i.e., ocular larval migrans).

Buijs et al.[23] report that the seroprevalence of *Toxocara* among young schoolchildren in the Netherlands as of 1994 was 11% in the Hague and 6% in Rotterdam. They found a significant correlation of recurrent asthma and bronchitis in *Toxocara*-seropositive children. They speculate that elevated allergen-specific IgE in these patients may account for the asthma. Jacquier et al.[134] evaluated a commercial ELISA kit marketed by Biokema-Affinity Products (Crissier-Lausanne, Switzerland), which is based on detection of excretory/secretory antigen derived from second-stage *T. canis* larvae. In a study of 1,000 serum samples randomly collected from healthy blood donors and children in Switzerland, the seroprevalence of toxocariasis was 2.7%. Of the positive samples, the Biokema kit had an overall diagnostic sensitivity of 91% and a specificity of 86%. The lower specificity was due to cross reactivity of serum from patients with filariasis, strongyloidiasis, and trichinosis. In the interpretation of serologic results, one must recall that a small percentage of the US population, estimated at 2%, may have residual low titers from previous infection. The CDC currently offers an enzyme immunoassay for *Toxocara canis*; acceptable specimens include serum and vitreous fluid.

Cutaneous Larva Migrans—Infections by Animal Hookworms. The filariform larvae of dog or cat hookworms, commonly of the species *Ancylostoma braziliense* and *A. caninum*, are capable of penetrating the exposed skin of humans, producing a pruritic, papular condition known as "creeping eruption." The larvae penetrate deeply into the subcutaneous tissue and produce linear tracts that extend for several millimeters each day. Impetigo, vesicular allergic reactions and intense pruritus are the major local clinical manifestations of cutaneous infections, which persist for long periods.[34] Deep tissue migration (visceral larva migrans) may occur, but is less common than with *Toxocara* species, as described above. The diagnosis is made by a history of exposure and the presence of subcutaneous linear tracts. Tremblay and associates[247] described an outbreak of cutaneous larva migrans in a group of 140 vacationers in Barbados. Risk factors were younger age, infrequent use of protective footwear, and walking barefoot to the beach.

Biopsies of suspicious lesions are often of little use in establishing a diagnosis, showing only necrosis and an eosinophilic cellular infiltrate. Yamasaki et al.[278] have developed a recombinant *Toxocara canis* antigen that was found to be highly specific for toxocariasis, providing for a reliable diagnostic approach in practice settings where this test is available. Camous[25] reports success in treating this condition with a single 400-mg oral dose of albendazole (cure rate, 46% to 100%), or a single 12-mg dose of ivermectin (cure rate, 81% to 100%). Mebendazole and albendazole are currently recommended therapies.

Anisakiasis and *Anisakis* and Related Species. Anisakiasis is a zoonotic disease in which humans, through the ingestion of raw, pickled, smoked, or poorly cooked seafood such as sushi, sashimi, and smoked or pickled fish, become an accidental host for the larval nematodes. The predominant causes are *Anisakis simplex* and *Pseudoterranova decipiens*. The number of infections in the United States has increased as raw fish such as lomi-lomi salmon, sushi, and sashimi have become popular. Deardorff and Kent[61] report that only wild-caught salmon were infected; those pen-reared were free of infection. Thus, knowing the origin of fresh fish may help in avoiding infections.

Upon entering the stomach, the larvae penetrate into the intestinal wall, forming small tunnels and burrows amid a dense granulomatous inflammatory reaction. In some instances, mucosal ulcers can be identified. Nausea and vomiting may be experienced within 24 hours after ingesting contaminated fish. Later manifestations include sharp, periodic, upper abdominal pain and diarrhea, at times simulating gastritis, duodenal ulcer, or on occasion, acute appendicitis. Daschner et al.[50] report hypersensitivity allergic manifestations in a series of 40 patients with anisakiasis. Urticaria, angioedema, erythema, bronchospasm, and varying degrees of anaphylaxis

were the common presenting symptoms. Lopez-Serrano et al.[158] report an additional 22 patients with gastroallergic anisakiasis. Two or more worms were detected by gastroscopy in three of these patients. Moneo et al.[174] demonstrated that these allergic reactions are in response to a potent allergen (Ani S 1) produced in the excretory gland of the *Anisakis simplex* adult worm. Because these symptoms are often delayed, the diagnosis of anisakiasis may be difficult, but must be considered, particularly if there is a clinical history of ingestion of raw or undercooked fish. Anisakis larvae may on occasion migrate beyond the stomach, producing metastatic infections in the omentum, liver, pancreas, and lungs.[218] Ikeda et al.[131] report on the successful treatment of nine patients with gastric anisakiasis by removing the causative larval worms through an endoscope, which immediately alleviated the acute abdominal pain. Surgical removal of the worm granuloma and/or albendazole therapy is recommended.

Yaquihashi et al.[280] report on the successful diagnosis of anisakiasis using a microenzyme-linked immunosorbent assay, with a monoclonal antibody directed against a specific *A. simplex* larvae. However, this approach is limited to a few research or reference laboratories, as commercial reagents are not currently available.

Gnathostomiasis and *Gnathostoma spinigerum*. *Gnathostoma spinigerum* is a nematode that normally infects the intestinal tract of cats and dogs; however, humans may become accidental hosts by ingesting poorly cooked or pickled seafoods containing immature larval forms. The disease is endemic in cats and dogs in Asia. After ingestion of contaminated fish by a dog or cat, the released larvae develop in the stomach or intestinal wall into adults that become encased in granulomatous inflammatory nodules. In humans, however, the larvae do not mature; rather, they penetrate the gastric wall and migrate throughout the tissues. Deep cutaneous or subcutaneous tunnels may develop, simulating cutaneous larva migrans, or hard, nonpitting

painful swellings may occur. Hira et al.[122] reported a Thai resident living in Kuwait, who contracted gnathostomiasis and presented with acute pain in the right iliac fossa. A mass of the terminal ileum and cecum was removed, revealing an immature male *G. spinigerum* worm. Grobusch and associates[103] reported the removal of this parasite from a cutaneous granuloma of the arm in a woman from Bangladesh living in Germany. Marked eosinophilia and a grossly elevated IgE were also observed in this patient. The diagnosis was made by demonstrating *Gnathostoma*-specific serum antibodies using an enzyme immunoassay.

Parastrongyliasis (Angiostrongyliasis) and *Parastrongylus* Species. Human

parastrongyliasis, previously and often still referred to as angiostrongyliasis, is caused by the larvae of nematodes, the adults of which live in rats as the definitive host. The disease presents in humans in two clinical forms, depending on the species: *P. cantonensis*, endemic in Thailand, Tahiti, and Taiwan, among other South Pacific locales, causes a syndrome of meningitis, eosinophilic pleocytosis in the CSF, and peripheral blood eosinophilia (known as eosinophilic meningitis). *P. costaricensis*, the rat lungworm, endemic primarily in Costa Rica, with infections also reported in Mexico and in Central and South America, causes abdominal disease primarily of the distal small intestine and ascending colon, the sites of penetration by the developing larvae.

The adult female produces eggs at the site of infection in the rat lung, which are then swallowed and passed in the feces. Slugs, land snails, and other mollusks (less commonly, also freshwater prawns, land crabs, and frogs) ingest these eggs and serve as an intermediate host within which the infective third-stage larvae develop. Humans acquire the infection by ingesting foods, usually leafy vegetables, contaminated with infected snails and slugs or the slime layer they produce. After ingestion by humans, the larvae of *P. cantonensis* migrate to the brain, causing eosinophilic meningitis. Symptoms vary from mild headache, stiff neck, and weakness to more severe symptoms, including nausea, vomiting, pruritic skin rash, and a variety of neurologic symptoms, including paresthesias, fourth and sixth cranial nerve palsies, and in heavy infections, coma and death.

Witoonpanich et al.[271] report two instances of fatal infections that occurred among three infected members of family. Two days after ingestion of Pila snails, a generalized itchy maculopapular rash developed in all three patients, followed by myalgia, marked paresthesia, fever, and headache. Weakness of the extremities, urinary retention, and cloudiness of consciousness progressing to coma were experienced by the two patients with a fatal outcome. Autopsy revealed multiple tracks and cavities with the presence of *P. cantonensis* in the brain and various levels of the spinal cord.

In the normal host, the rat, *P. costaricensis* adults occupy arteries and arterioles in the ileocecal part of the intestine. Eggs deposited in the rat tissue hatch and escape in the feces. Slugs also serve as intermediate hosts, and humans become infected by ingesting slug-contaminated foods. The larvae penetrate the tissues in the ileocecal portion of the human intestine, including the appendix, where a combination of the adult worms and the deposited eggs cause a severe granulomatous inflammatory reaction, resulting in the formation of a tumorlike mass. Hulbert et al.[130] have reported on the infection of two children who acquired *P. costaricensis* infections within the United States. One patient presented with symptoms suggestive of acute appendicitis, whereas the other was thought to possibly have a Meckel's diverticulum.

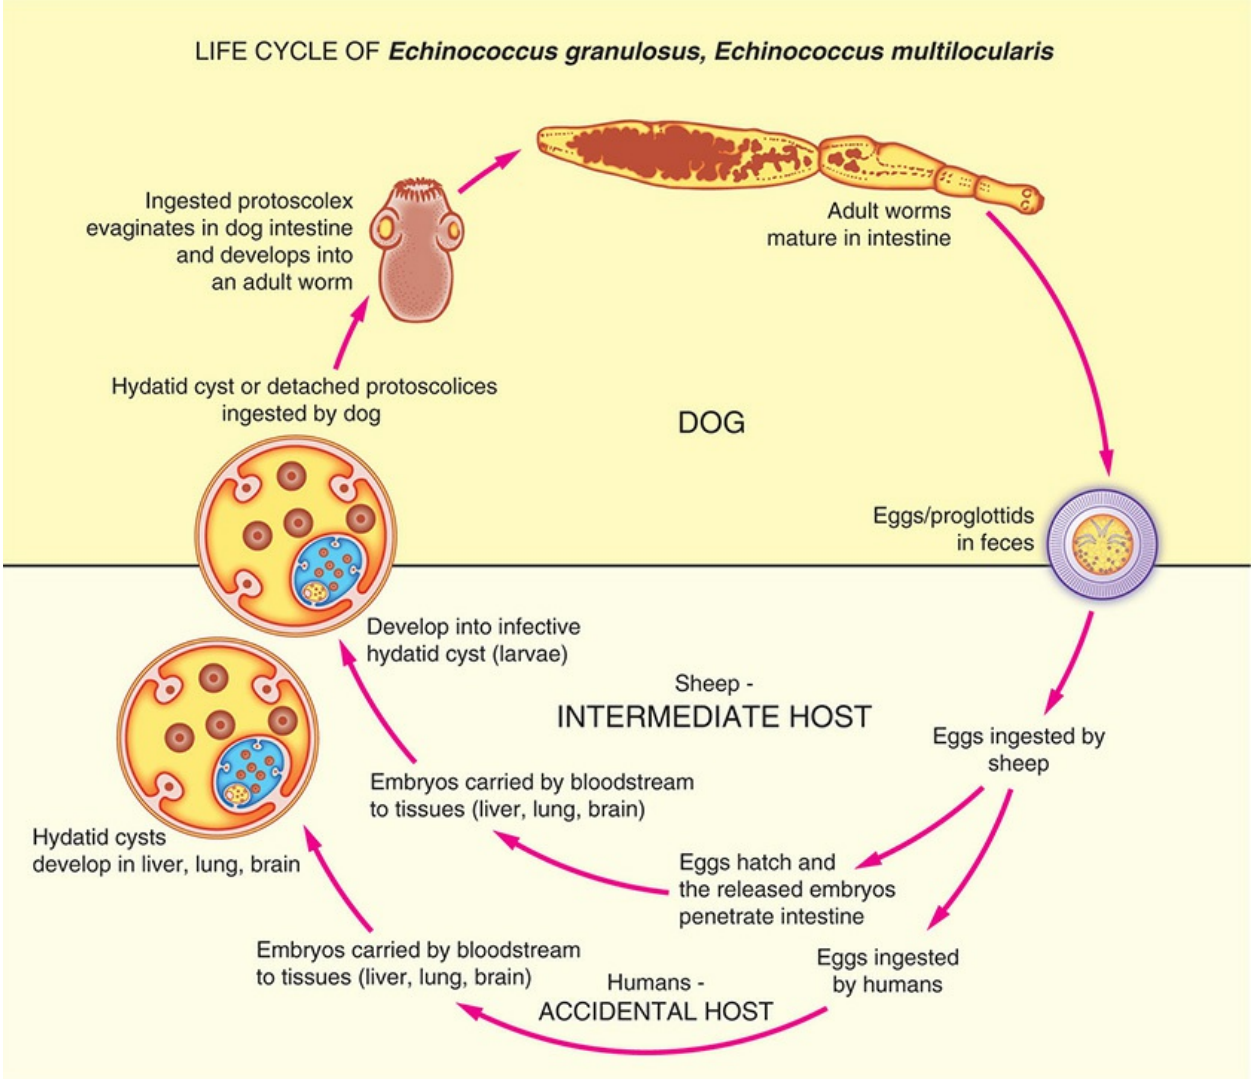
The diagnosis is usually made in patients in endemic areas on the basis of the symptoms described together with increased eosinophils in the spinal fluid and in the

peripheral blood. Larvae or young adult worms may be recovered in the CSF. A positive serologic ELISA titer, particularly when found in both serum and in the CSF, can also aid in the diagnosis.[258,260]

Echinococcosis (Hydatid Disease) and *Echinococcus* Species. Echinococcosis, or hydatid disease, is possibly one of the more difficult parasitic diseases to understand because of the peculiar cystic lesions that form when the larval stages of the parasite invade the viscera.[246] There are two main species that may infect humans, and these have a somewhat different morphology and patterns of behavior. These are *Echinococcus granulosus* and *Echinococcus multilocularis*. Humans are accidental hosts for both species. The normal life cycle of *E. granulosus* involves dogs or foxes as the definitive hosts, within the intestines of which the adult tapeworms reside. These tapeworms are very small, measuring only about 3 to 6 mm in length; they possess three proglottids and a scolex armed with a double row of hooklets (Image Plate 22-11F). Sheep, cattle, or swine serve as the intermediate hosts in which cystic larval disease develops, to be described below. *Echinococcus multilocularis* differs slightly in this regard as the definitive hosts are dogs, foxes, wolves, and cats, while the intermediate hosts are small rodents, including squirrels, field mice, and voles. If humans are infected, they are also intermediate hosts in whom the larval form of the parasite is harbored. The life cycle of *Echinococcus* is illustrated in Figure 22-29.

The cysts of *E. granulosus* grow slowly and usually remain quiescent for many years. Only rarely do cysts rupture, at times into the biliary tract and at other times through the liver capsule into the peritoneal cavity. If the cyst should rupture, either spontaneously in the body or during surgery, the danger from death from anaphylactic shock is high. Metastatic cystic lesions can also develop in virtually any of the visceral organs following the rupture of the primary cyst into the peritoneal cavity. If cyst material seeds the peritoneal lining, massive proliferation can occur with vascular invasion and spread to other organs. Brain cysts may also occasionally be found. The cysts of *E. multilocularis* grow more rapidly, with invasion of hepatic parenchyma simulating a carcinoma. Examples of hydatid cysts are illustrated in Image Plate 22-11B and C.

Laboratory Identification. The laboratory diagnosis may be made by demonstrating the daughter cysts or brood capsules with protoscolices in surgically removed tissue. The inner lining of the cyst is a germinal membrane from which numerous daughter embryos develop. These form as tiny polypoid structures (brood capsules) that line the inner reproductive membrane from which large numbers of daughter cysts are produced (Image Plate 22-11D). When the immature forms (protoscoleces) break free from the membrane and float in the fluid within the cyst, they are known as



■ **FIGURE 22-29** Life cycle of *Echinococcus granulosus*. Hexacanth eggs, either singly or within proglottids, closely resembling those of *Taenia* species, are passed in dog feces, and become embryonated in the soil. Under normal circumstances, these eggs are ingested by the natural intermediate hosts—sheep, cattle, or swine—or by the small rodents mentioned earlier in the case of *E. multilocularis*. The larvae are released from the eggs in the intestines of the intermediate hosts and, by means of their hooklets, penetrate the bowel wall and enter the circulation.

The circulating embryos are filtered out in the capillaries of various organs, usually the liver because it is the first organ to drain the mesenteric blood. *Echinococcus granulosus* produces a single multilayered cyst from which small cysts called bladder worms may form (Image Plate 22-11B). The cysts of *E. multilocularis*, as the species name implies, have multiple locules. Multiple cysts up to 5 cm in diameter, resembling what Aristotle called

hailstones, may be seen in some cases (Image Plate 22-11C). The life cycle is complete when infected viscera of the definitive host are eaten by a dog, fox, or other related carnivore. Humans may also become the intermediate host by ingesting the *Echinococcus* eggs, the larvae of which also may migrate to various organs, particularly the liver and lungs.

hydatid sand (Image Plate 22-11E). If examined under a microscope, each "grain of sand" is, in fact, a tiny embryonic beginning of a new tapeworm complete with an inverted scolex and a rostellum armed with hooklets (Image Plate 22-11E).

Several immunodiagnostic techniques are available by which a clinical diagnosis may be confirmed. Gottstein[98] provides a comprehensive review of the molecular and immunologic approaches to the diagnosis of hydatid disease. Most immunodiagnostic techniques involve the detection of *Echinococcus*-specific antibody in the serum of suspected patients, using a variety of crude antigens. The problem with methods using crude antigens is the serologic cross reactivity of echinococcal antibody tests with other parasite diseases, liver cirrhosis, and collagen diseases. Problems with cross reactivity have been substantially improved with the development of a selected antigen called arc-5. In a study conducted by Schantz

and McAuley,[223] a high percentage of the arc-5-positive persons subsequently were shown to harbor hydatid cysts. Cross reactivity of the arc-5 antigen has been demonstrated in the sera of patients with cysticercosis; however, the differential diagnosis should be possible clinically in such cases.

Verastegui et al.[252] offer an enzyme-linked immunoelectrotransfer blot assay for the diagnosis of hydatid disease that circumvents the cross reactivity in patients with cysticercosis. The antigen, prepared from lyophilized bovine hydatid fluid, was found to contain three 8-, 16-, and 21-kDa bands, that cross-reacted in only 12%, 4%, and 4%, respectively, of sera from patients with cysticercosis, a significant reduction from most ELISA assays. Newer EIAs provide greater than 90% sensitivity and specificity in detecting *Echinococcus*-specific antibodies. Using an ELISA procedure, Poretti et al.[206] demonstrated 91% sensitivity and 82% specificity for detecting *E. granulosus*-specific antigen in direct assay of cyst fluids, providing a 99% discrimination between seropositive cystic hydatid cases and noncestode parasitic infections or malignancies. Helbig et al.[116] were able to differentiate between cystic and alveolar disease with an assay using recombinant larval antigens, the results of which proved to be more specific than radiologic imaging studies. The CDC currently offers EIA and blot assays on serum to assist with the diagnosis of echinococcosis.

Although nucleic acid amplification tests have been devised for the detection of

Echinococcus, they have not come into practice. Namely, because if the cyst is aspirated or excised, the diagnosis is usually morphologically evident, and if the cyst is intact, serologic studies are superior.[98]

Coenurosis and *Taenia multiceps* and *T.* serialis. Coenurosis is another human disease related to tapeworms of dogs and foxes, *Taenia multiceps* and *T. serialis.* The normal intermediate hosts are rabbits, sheep, cattle, horses, and other herbivorous animals. Humans become infected by ingesting food or water contaminated with dog feces containing the eggs of these *Taenia* species. The disease in humans primarily involves the CNS, where the migrating metacestode larvae (i.e., a coenurus) develop into cysticercus-like cyst. These cysts differ from echinococcal cysts by having multiple protoscoleces, but these are without hooklets. No brood capsules or daughter cysts are seen. Symptoms are often those produced by a space-occupying lesion, including headache, vomiting, and localizing neurologic symptoms such as hemiplegia, paraplegia, aphasia, and seizures. Basal arachnoiditis leading to the posterior fossa syndrome and internal hydrocephalus is also a presenting symptom. The diagnosis is usually made following surgical removal of the cyst and the histologic recognition of the coenurus.

Sparganosis and *Spirometra* and *Sparganum* Species. Dogs and cats serve as the definitive host for several species of diphyllobothroid tapeworms belonging to the genus *Spirometra*. *Spirometra* eggs are passed in dog or cat feces into freshwater hatch and are ingested by minute *Cyclops* crustaceans, within which they develop into procercoid larvae. These larvae in turn develop into plerocercoid larvae, individually known as sparganum, in the flesh of a second intermediate host (fish, snakes, frogs) that feed on the *Cyclops.* Humans become infected by ingesting an infected *Cyclops,* by eating the raw, infected flesh of the second intermediate host, or from the practice in certain cultures of applying raw flesh of an intermediate host to the skin, eyes, or vagina as a poultice. On ingestion, sparganum larvae penetrate the bowel wall and enter the circulation, or penetrate through the mucous membranes.

Most lesions in humans are subcutaneous, where slow-growing, painful, red, edematous nodules develop. The definitive diagnosis is made only after surgical removal of a sparganum and identifying the slender, delicate white worm that measures 60 to 80 × 1 to 2 mm wide. Aberrant spargana have been observed in the external eye, where edematous swelling of the eyelid simulating Romaña's sign of Chagas' disease has been reported, in lymph channels producing elephantiasis-like swellings, and in the brain in the form of cerebral abscesses.

Serologic and Molecular Diagnosis of Parasitic

Infections

The serologic approach to the evaluation of parasitic diseases is most applicable when invasive techniques other than the routine examination of blood, feces, or other body fluids are required to establish a diagnosis. For example, the infective parasitic forms in toxoplasmosis, extraintestinal amebiasis, trichinosis, and cysticercosis are often lodged deep within tissues and organs, and either deep needle or open surgical biopsies are needed to confirm the diagnosis. In such cases, serologic diagnosis may be possible if several potential problems as outlined by Garcia[87] are considered:

1. Certain parasites that pass through several developmental phases may not provide sufficiently constant or continuous antigenic stimuli to elicit antibody formation.
2. Antibody responses in specific individuals may be lacking, either because of a limited antigenic stimulus, the individual is too immunocompromised to generate an antibody response, or because a relevant antigen is not present in the test system.
3. The antigens used in assays are a poorly defined heterogeneous mixtures or extracts of parasitic forms. Such antigen preparations may show cross reactivity that affects specificity, making interpretation difficult.
4. Patients living in endemic areas may have higher baseline antibody titers than those in nonendemic areas; thus, if possible, changes in titer must be ascertained. Serologic tests are usually more valuable in travelers to endemic areas. These individuals would not be expected to have any preexisting antibodies, and so a serologic response would be strong evidence of a newly acquired infection.
5. Reliable test kits for general diagnostic use often are not available from commercial sources. Even when

available, the incidence of parasitic disease is usually so low in most nonendemic locales. The low prevalence of disease has a negative influence on the positive predictive value of any test.

Several of the applications of antibody and antigen detection provided in Garcia's review are reflected in short sections included within the discussion of each animal parasite in this textbook. We have elected to include such discussions within each section rather than having a stand-alone presentation here. Many of the details of the various methods currently being used in research laboratories are beyond the scope of

this book. In a practical sense, the volume of parasitic diseases encountered in most practice settings in the United States is low, making serologic testing impractical in most diagnostic microbiology laboratories. In most instances, specimens from patients suspected of having a particular parasitic disease are referred to local and regional reference laboratories, including the various state public health laboratories. Each reference laboratory will have in operation a mixture of time-honored and newer technologies that is unique to that laboratory, and consultation is necessary to learn which application and the types of specimens required may be most applicable. Figure 22-30 is the list of serologic tests performed at the CDC for various parasitic diseases, along with the titers considered to be diagnostically significant, as originally published by Walls and Smith.[255]

Most of the advances in diagnostic clinical parasitology over the past 5 years involve the introduction of new molecular techniques for the detection of the nucleic acids of select parasites. Two FDA-approved commercially available molecular diagnostic products are available. These take a syndromic approach to the diagnosis of infectious gastroenteritis and include a panel of bacterial, viral, and parasitic pathogens. *Cryptosporidium, Entamoeba histolytica,* and *Giardia* are included in the Luminex Gastrointestinal Panel. The FilmArray includes *Cyclospora cayetanensis* in addition to the three parasites included in the Luminex panel. There are similar products in development by other companies.

Serum/Plasma Specimens

Antibody Detection Tests Offered at CDC

Disease	Organism	Test	Acceptable Specimens
Amebiasis	*Entamoeba histolytica*	Enzyme immunoassay (EIA)	Serum
Babesiosis	*Babesia microti* *Babesia* sp. WA1	Immunofluorescence (IFA)	Serum
Baylisascaris	*Baylisascaris procyonis*	Immunoblot	Serum or CSF
Chagas disease	*Trypanosoma cruzi*	IFA	Serum
Cyticercosis	Larval *Taenia solium*	Immunoblot (Blot)	Serum, CSF
Echinococcosis	*Echinococcus granulous*	EIA, Blot	Serum
Filariasis	*Wuchereria bancrofti* and *Brugia malayi*	EIA	Serum
Leishmaniasis	*Leishmania braziliensis* *L. donovani* *L. tropica*	IFA	Serum
Malaria	*Plasmodium falciparum* *P. malariae* *P. ovale* *P. vivax*	IFA	Serum
Paragonimiasis	*Paragonimus westermani*	Blot	Serum
Schistosomiasis	*Schistosoma sp.* *S. mansoni* *S. haematobium* *S. japonicum*	FAST-ELISA Blot	Serum
Strongyloidiasis	*Strongyloides stercoralis*	EIA	Serum
Toxocariasis	*Toxocara canis*	EIA	Serum, vitreous fluid
Trichinellosis (Trichinosis)	*Trichinella spiralis*	EIA	Serum

■ **FIGURE 22-30** Serologic assays available from the CDC.

1492

Application of molecular techniques has finally penetrated into diagnostic parasitology. It is hopeful that these very sensitive methods will afford the increased detection of patients with parasitic diseases.[196,263]

Drugs Commonly Used in the Treatment of Parasitic Diseases

Drug therapy of parasitic diseases is directed to interrupting the invasive capabilities of

parasites. Infections that occur primarily within the gastrointestinal tract are best treated with compounds that are poorly absorbed, resulting in high concentrations of active drug within the intestinal lumen. Agents that are well absorbed and achieve high serum and tissue levels are required for the treatment of invasive parasitic diseases, particularly the larval forms. In patients with intestinal and extraintestinal amebiasis, a combination of an absorbable and nonabsorbable drug to treat residual organisms in the intestine may be required. Many parasites exist in a cyst form, which may be poorly penetrated by many of the drugs, leading to potential reactivation of infection at a later date. For example, the inactive, encysted forms of *Toxoplasma gondii* are drug-resistant and may reactivate when immunity is lost.

Table 22-1 summarizes the mode of action and other attributes of select commonly used antiparasitic drugs. For a full review of all current drugs, including recommended drugs and dosages to be used for most human parasitic diseases, we refer the reader to select publications and infectious disease texts.[87,175]

TABLE 22-1 Drugs Commonly Used in the Treatment of Parasitic Infections

Drug	Type of Agent	Mode of Action	Comments
Amphotericin B	Polyene macrolide	Increases cell membrane permeability, leading to a loss by leakage, first of ions and then of other cellular contents. Binding is effected by sterols in membrane.	Mammalian cells may also be affected with severe side effects. Used in treatment of infections with *Acanthamoeba* species and in advanced cases of mucocutaneous leishmaniasis.
Chloroquine	4 aminoquinoline (quinine)	The concentration of drug achieved in malarial parasitized erythrocytes is several hundred times greater than in normal erythrocytes. The drug binds to ferriprotoporphyrin IX (FP), a degradation product of the hemoglobin present in the parasite food vacuole. The complex of chloroquine FP is lytic for the parasite.	Mainstay of malarial therapy for over two decades. *P. falciparum* drug resistance occurs in strains that can somehow sequester FP so that it does not bind to chloroquine. Chloroquine is not curative for *P. vivax*, because of the presence of hepatic hypnozoites.
Emetine	Alkaloid (cycloheximide)	Directly lethal to trophozoites of *E. histolytica* by causing degenerative changes in the trophozoites. The drug causes interruption of cell division by irreversibly inhibiting protein synthesis by preventing movement of mRNA along the 60s ribosomal subunit.	Used in the therapy for severe intestinal amebiasis or amebic liver abscess as an alternative to metronidazole. Mammalian cells are also affected, resulting in severe side effects and limiting its therapeutic use.
Diethylcarbamazine	Piperazine derivative (two nitrogens in benzene ring)	The drug is thought to alter surface properties and mobilization of microfilariae, causing them to leave the circulation through a specific neuromuscular effect. The microfilariae become trapped in the liver and are subject to phagocytosis.	Used primarily in the treatment of filarial infections. The drug is well absorbed, reaching peak serum concentrations within 3 hours, and is widely distributed throughout the body.
Ivermectin	A 22,23 dihydro derivative of avermectin B, a complex macrocyclic lactone produced by *Streptomyces avermitilis*	The drug acts on γ-aminobutyric acid (GABA) receptors on the parasite musculature. Inhibitory neurons that cause release of GABA from presynaptic terminals are stimulated, in essence blocking signal transmission from interneurons to excitatory neurons. The effect is the loss of locomotor activity by the parasite, making normally motile parasites highly susceptible to various host defenses.	The drug has a broad spectrum of antinematodal activity but has no effects on flukes and tapeworms. It has been effectively used in onchocerciasis, cutaneous visceral larval migrans, *Angiostrongylus meningitis*, and various gastrointestinal nematode infections.

1493

Mebendazole	Benzimidazole—benzine + five ring structure, including three carbon and two nitrogen molecules	Selective inhibition of glucose uptake in nematodes and cestodes, leading to increased utilization of parasite glycogen; parasites are thereby deprived of their main energy sources. Under action of the drug, the parasite is immobilized and in vitro larval development is interrupted.	Mebendazole is active against nematodes and used primarily in the treatment of trichuriasis, ascariasis, hookworm, and *Strongyloides* infections. The drug is minimally absorbed from the gastrointestinal tract, thus being most effective in the treatment of intraintestinal worms.
Melarsoprol	Arsenical (a dimercaprol derivative of melarsen oxide)	Arsenoxides attach to trypanosomes by covalent bonding—sulfur groups in arsenoxide exert lethal effect by blocking essential biologically active glycolytic enzymatic groups. Arsenicals react with sulfhydryl groups, leading to inactivation of various enzymes synthesized by the parasite for glycolysis.	Used in the treatment of trypanosomiasis. The drug enters parasite cells more rapidly than human cells, and thus is more toxic to the parasite. The drug crosses the blood–brain barrier and enters the cerebrospinal fluid, making it highly effective in the treatment of CNS infection.
Metronidazole (Flagyl)	5-nitroimidazole	Metronidazole is metabolized into derivatives, including superoxide radicals, that interfere with DNA metabolism in parasites, causing extensive breaks in the DNA strands and interrupting the helical structure. Protein synthesis in the parasite is thus disrupted.	Used in the treatment of invasive amebiasis and also for infections with *Trichomonas vaginalis* and *Giardia intestinalis*. Because only 10% of the drug is bound to serum proteins, it reaches high concentrations in the tissues, including lung, bile, bone, liver, and brain, exceeding levels required to inhibit the organisms against which it is active.
Niclosamide	Heterocyclic pyrazinoisoquinoline derivative	The oxidative phosphorylation of mitochondria of cestodes is interrupted. The effect on mature adult worms is lethal, inducing complete muscular paralysis in certain species. The drug induces the scoleces to detach and the worms to disintegrate before they are eliminated in the feces.	Niclosamide is an alternative drug for the treatment of tapeworms. Treatment for *Hymenolepis* worms is increased to 5 days because onchospheres develop in the jejunal villi, and cysticercoids emerge into the intestinal lumen about 4 days later.
Praziquantel: (pyrazinoquinoline)	8-aminoquinoline derivative	The drug acts by increasing the membrane permeability to calcium, causing contractions and paralysis of the musculature of worms. Neuromuscular effects lead to increased motility and spastic paralysis, causing the worms to detach and disintegrate in the intestine.	Used for the treatment of schistosomiasis, cysticercosis, tapeworm infections, and liver, lung, and intestinal flukes. The drug achieves excellent therapeutic levels in the liver, bile, and muscle tissue, and crosses the blood–brain barrier to reach the brain and spinal fluid as well.
Primaquine	Tetrahydropyrimidine	The drug is gametocidal and sporonticidal for all species of human malaria. Its mechanism of action is unknown, although inhibition of DNA synthesis is most likely.	Primaquine is a poor blood schizonticide but is effective against exoerythrocytic hypnozoites. Therefore, it is effective in preventing relapses due to *P. vivax* and *P. ovale*. Radical cure of malaria can be effected by a combination of chloroquine and primaquine therapy.
Pyrantel pamoate	Naphthylamine sulfonic acid, a polyanion dye	Pyrantel (and its analogs) acts as a cholinergic antagonist, causing the depolarization of muscle cells within the parasite, leading to irreversible contractures.	Used primarily in the treatment of infections with ascariasis, hookworms, pinworms, and *Trichostrongylus*. The drug is insoluble in water and poorly absorbed from the gastrointestinal tract, leading to little toxicity.

1494

Suramin		The drug inhibits glycerol 3-phosphate oxidase and glycerol 3-phosphate dehydrogenase, preventing reoxidation of nicotinamide adenine dinucleotide and decreasing adenosine triphosphate synthesis. This interruption in metabolism is lethal to the parasite.	The drug is widely distributed in the body but, because of avid protein binding in the serum, does not pass the blood–brain barrier. The drug is used in the treatment of early trypanosomiasis; however, as it does not penetrate into the CNS, it is not effective in the treatment of progressive CNS disease.
Thiabendazole	Benzimidazole	The precise mechanism of action of thiabendazole is unknown, but it is thought that is likely inhibits the fumarate reductase of the helminth. Inhibition of fumarate reductase interrupts the citric acid cycle and subsequently energy production.	The drug is well suited for the treatment of disseminated *Strongyloides* infection and any larval forms causing visceral and cutaneous larval migrans. The bulk of absorbed drug is metabolized in the liver and excreted as metabolites in the urine.
Stibogluconate sodium	An antimony-containing compound	The drug is thought to act on sulfhydryl-containing enzymes within the parasite, decreasing the flow of glucose into the tricarboxylic acid cycle, resulting in the accumulation of glycolytic byproducts that are toxic to the developing amastigotes.	Used primarily in the treatment of leishmaniasis. After intramuscular or intravenous administration, a serum peak is achieved in 2 hours, and over 90% of the drug is excreted within 8 hours. However, the drug does gradually accumulate in the tissues, explaining why long courses of therapy are necessary.

Introduction

Diagnostic virology has evolved rapidly in recent years from a predominantly cell culture–based service to one that is dominated by molecular diagnostics. In this transition period, we have chosen to retain descriptions of the traditional techniques, as some of these are still used in laboratories without molecular capabilities. The emphasis, however, will be on the new molecular diagnostic assays that have transformed the clinical virology laboratory in a way that provides clinicians with the rapid and accurate detection of viral pathogens in a timely manner.

Historical Review

The first stage of historical interest spanned the years during which the existence of infection by submicroscopic particles was established. For many decades after Carlos Finlay hypothesized that yellow fever was transmitted by the bite of a mosquito, the only means available for isolation of viral agents was the inoculation of animals or embryonated eggs. Agents of disease continue to be uncovered by the traditional use of subhuman primates (e.g., kuru and Creutzfeldt–Jakob viruses),[158] electron microscopy (e.g., severe acute respiratory syndrome [SARS]),[178] and even human volunteers (e.g., Norwalk agent of infectious gastroenteritis).[259] The next phase utilized cell cultures as a means to propagate viruses. Today, these previously used methods are complemented by sophisticated molecular diagnostic methods, including

next-generation sequencing (NGS).[19]

Evolution of Cell Culture Techniques

One of the major historic breakthroughs in diagnostic virology was achieved by Enders and colleagues,[129] who demonstrated that the virus that caused poliomyelitis could be isolated in nonneural cells in vitro. In the 1950s and 1960s, there was a rapid expansion of knowledge about clinical features, epidemiology, and diagnosis of common viral infections, largely provided by the expanding use of cell culture. Diagnostic efforts, which were an integral part of the clinical studies, were incorporated into university and government research laboratories. The high cost of the definitive identification of isolates, the absence of effective antiviral chemotherapy, and the paucity of cell culture facilities all combined to limit the importation of these tests into the diagnostic microbiology laboratory. A more detailed review of the historical development of virology is provided by Levine.[292]

Evolution of Diagnostic Virology Services

The first step was the incorporation of diagnostic services into clinical microbiology laboratories, many of which had previously limited their scope to bacteriology (including mycobacteriology), mycology, and parasitology. Box 23-1 lists some of the factors that facilitated and encouraged the transfer of technology and techniques from the research laboratory setting to a clinical diagnostic laboratory, usually in a pathology or microbiology department. A more detailed discussion of this transition can be found in previous editions of this book.

The complexity and sophistication of traditional viral diagnosis limited the introduction of these methods to clinical laboratories located in large medical centers, many of which were associated with academic centers. In the previous decade, the pace of technologic development, particularly in the field of molecular diagnostics, has accelerated so that some viral diagnostic testing for multiple pathogens (e.g., respiratory viral panel) can be introduced into community hospitals.

In addition to the scientific issues, an important determinant was the promulgation and enforcement of the CLIA ‘88 (Clinical Laboratory Improvement Amendments, 1988), the first major development in oversight of laboratories since the Clinical Laboratory Improvement Act of 1967 (CLIA ‘67). The numerous requirements for personnel and performance of tests were familiar to most clinical laboratories, but foreign (and extremely unwelcome) to most research laboratories, and essentially out of the reach of physician office laboratories. Although many of the molecular assays that target viruses are Food and Drug Administration (FDA)-approved, there are still many laboratory-developed tests (LDTs) in use throughout the country. The FDA has cited oversight for these assays, but the form of the oversight remains undetermined.

Many of these assays, for which there are not currently available FDA-approved options (e.g., quantitative Epstein–Barr virus PCR), are critical for patient care. It is a concern that if the oversight rules imposed by the FDA are too stringent, then local testing for these pathogens, which provides superior turnaround time, may be discontinued.

1502

BOX 23-1

Some Factors That Facilitate the Transfer From a Research Laboratory to a Diagnostic Laboratory

Factors That Encouraged Transfer of Testing to the Clinical Laboratory

- Appearance of clinical scenarios in which viral diagnosis is essential; e.g., herpes simplex in pregnant women.
- Development of antiviral chemotherapy.
- Availability of reliable commercial sources of mammalian cells for culture.
- Application of monoclonal antibody technology to diagnosis, with commercial availability of reliable reagents.
- Facilitation of more rapid diagnosis by application of molecular assays that target viruses of clinical relevance.
- Application of enzyme immunoassays to direct diagnosis.
- Application of more simple-to-use molecular diagnostic methods.
- Support for public health epidemiology of transmissible disease.

Developments in Diagnostic Virology

- Increasing frequency of clinical scenarios that depend on viral diagnosis; e.g., monitoring of viral loads in transplant recipients and the increased sensitivity of HPV assays.
- Increased number of diseases for which antiviral chemotherapy, including combination therapy, is possible.
- Commercial sources of cell culture materials are available, which include cells on coverslips for shell vial cultures, the development of mixed cell lines (e.g., R-Mix) and the availability of genetically modified to enhance detection (e.g., ELVIS system).
- Commercial availability of high-quality immunofluorescent reagents; some of these are pooled (e.g., respiratory viruses) or improve the efficiency of screening.
- Movement of nucleic acid amplification technology from the research laboratory into the clinic in the form of laboratory-developed tests (LDTs); commercial availability of systems or validated reagents for multiplex, monoplex, and

quantitative assays, many of which are FDA-approved, and available on simple-to-use platforms.
- Although most immunoassays are quick and inexpensive, they suffer from poor sensitivity; improved immunoassays have been developed to increase the sensitivity, which employ reader devices. These assays are being threatened by waived, point-of-care molecular assays.
- Support for outbreak investigation and tracking; some of the newer immunoassay devices have wireless capability to report influenza results to public health laboratories in an HIPPA-compliant manner.

Levels of Service

Each laboratory director or supervisor must determine the level of service that is appropriate for local clinical needs. This should be done after consultation with medical staff. It is far better to limit the scope of effort to the tests that can be performed with high proficiency than to attempt broad coverage when resources are insufficient and proficiency may be lost owing to infrequent performance. Several likely levels of service are listed in Box 23-2.

Most small hospital laboratories will probably fit into level 1 or 2,[428] whereas larger community hospital and university laboratories may offer services at level 3, 4, or 5. These hospitals are most likely to serve the patients who need comprehensive virology services. It is feasible to use such laboratories as regional diagnostic resources. The service levels that are possible have changed dramatically in recent years with the introduction of simple-to-use molecular diagnostic tests, some of which are CLIA-waived.

Taxonomy and Nomenclature

Taxonomy is the science of systematic classification using general rules and principles; the term is most commonly used for the study of living things. Nomenclature is the activity of ascribing names to the taxonomic subjects.

Many viral infections, such as influenza, chickenpox, measles, and hepatitis, were well characterized clinically long before the etiologic agent was recognized. Once isolated, the virus was given the name of the corresponding clinical condition. In an attempt to bring order to the scheme of classification, taxonomists have used modern knowledge of viral structure and antigenic composition to construct a systematic classification.[93] Orders, families, and genera have Latin stems, but the concept of species has been more difficult for virologists.[48,463] Often, the classical vernacular

names are used as species designations.

The International Committee on Taxonomy of Viruses (ICTV) has proposed the ICTV Universal System of Virus Taxonomy. A summary of the conventions of viral nomenclature is provided in Box 23-3. The hierarchical names are italicized and may be preceded by the taxon, which is not italicized. In the case of the species names, we are left with the peculiar situation that the same words may be italicized or not, depending on whether they are part of a taxonomic designation or are being used as the vernacular name. The taxonomic designation needs to be used only once in a scientific publication. For instance, a discussion might refer to measles virus (*Measles virus*, genus *Morbillivirus*, family *Paramyxoviridae*). At the moment, this approach to taxonomy and nomenclature appears to have preference, but the subject has not been settled definitively.

1503

BOX 23-2

Levels of Diagnostic Service

Level 1: No virology services performed. Specimens are collected for transfer to a reference laboratory.
Level 2: Limited virology procedures performed. Such laboratories may or may not also have the capability to detect viral antigens in body secretions and fluids. These laboratories also may or may not have the capability to inoculate specimens to tissue culture for transfer to reference laboratories. These laboratories may use fully automated (i.e., specimen-to-result) platforms for molecular testing.
Level 3: These laboratories are able to recover selected viral groups that grow in commonly used cell cultures. They may also perform limited identification of selected agents for which transportation, cell isolation, and simple immunologic confirmation systems are commercially available, with referral of other isolates to reference laboratories. These laboratories may use more complex, FDA-approved molecular diagnostic tests in an unmodified manner.
Level 4: These laboratories are expected to have personnel with a high degree of expertise in virology who are able to isolate all of the common viral groups and to perform clinically relevant identifications. These laboratories are able to perform complex laboratory-developed tests (LDTs), in addition to FDA-approved assays, and possibly traditional DNA sequencing.
Level 5: In addition to a high degree of expertise in virology, these laboratories may perform antiviral susceptibility testing. In addition to LDTs, these laboratories perform next-generation sequencing.

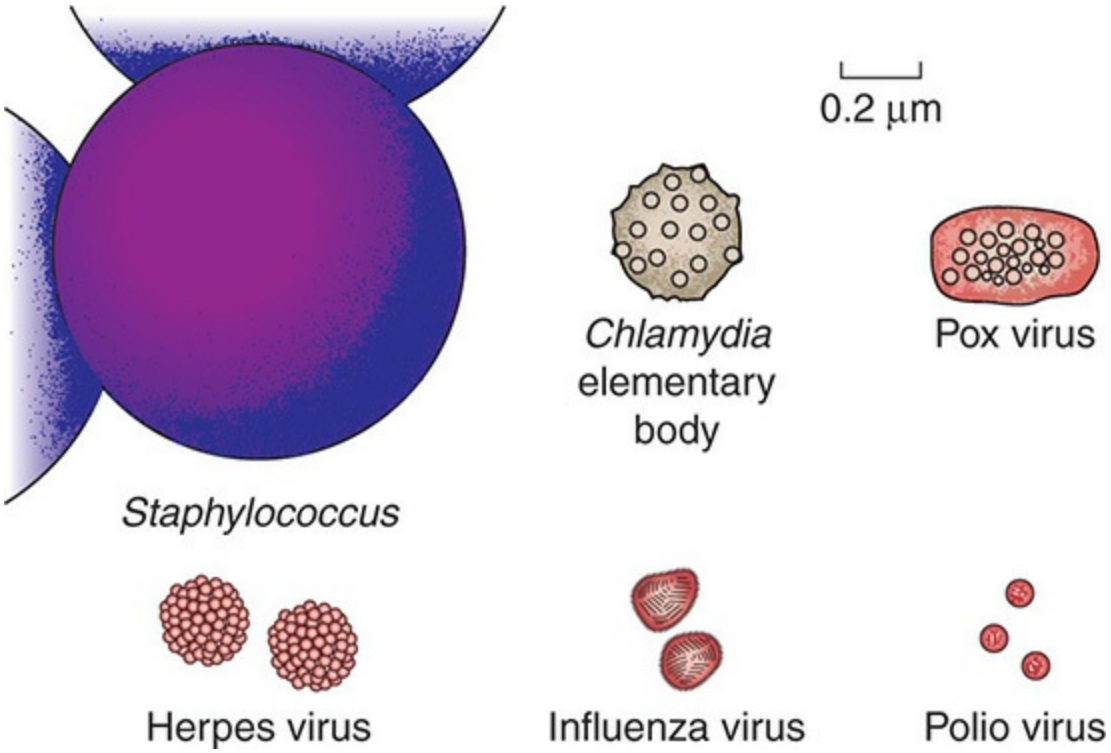
BOX 23-3

Conventions for Naming Viruses

Taxonomic Hierarchy	Ending	Example
Order	-virales	Mononegavirales
Family	-viridae	Paramyxoviridae
Subfamily	-virinae	Pneumovirinae
Genus	-virus	*Pneumovirus*
Species	None	*Human respiratory syncytial virus*

Much of traditional viral taxonomy derives from detailed knowledge of viral structure, but is now supplemented by nucleic acid studies. Viruses are among the smallest of infectious agents (Fig. 23-1). The poxviruses, which are the largest members of the virus family and similar in size to the smallest bacteria, are close to the resolution of the light microscope; an electron microscope is necessary to visualize all other viruses.

Almost without exception, viruses contain either DNA or RNA, but not both. Most of the medically important DNA viruses are double-stranded, an exception being parvovirus; most of the medically important RNA viruses are single-stranded, an exception being rotavirus (i.e., reoviruses). The center of any viral particle, the ribonucleoprotein core, contains coiled nucleic acid and protein.[204] Around the core is a protective shell composed of repeating protein units called capsomeres, which, in the aggregate, make up the capsid shell. With the nucleoprotein core, the nucleocapsid unit is complete. The architecture of most viruses has a symmetry that is either helical, similar to nucleic acid, or icosahedral, the architecture of a geodesic dome. These two symmetries, illustrated in Figure 23-2, provide the most efficient means for assembling the structural shells, an economy that is essential for these very small particles with limited genetic resources.

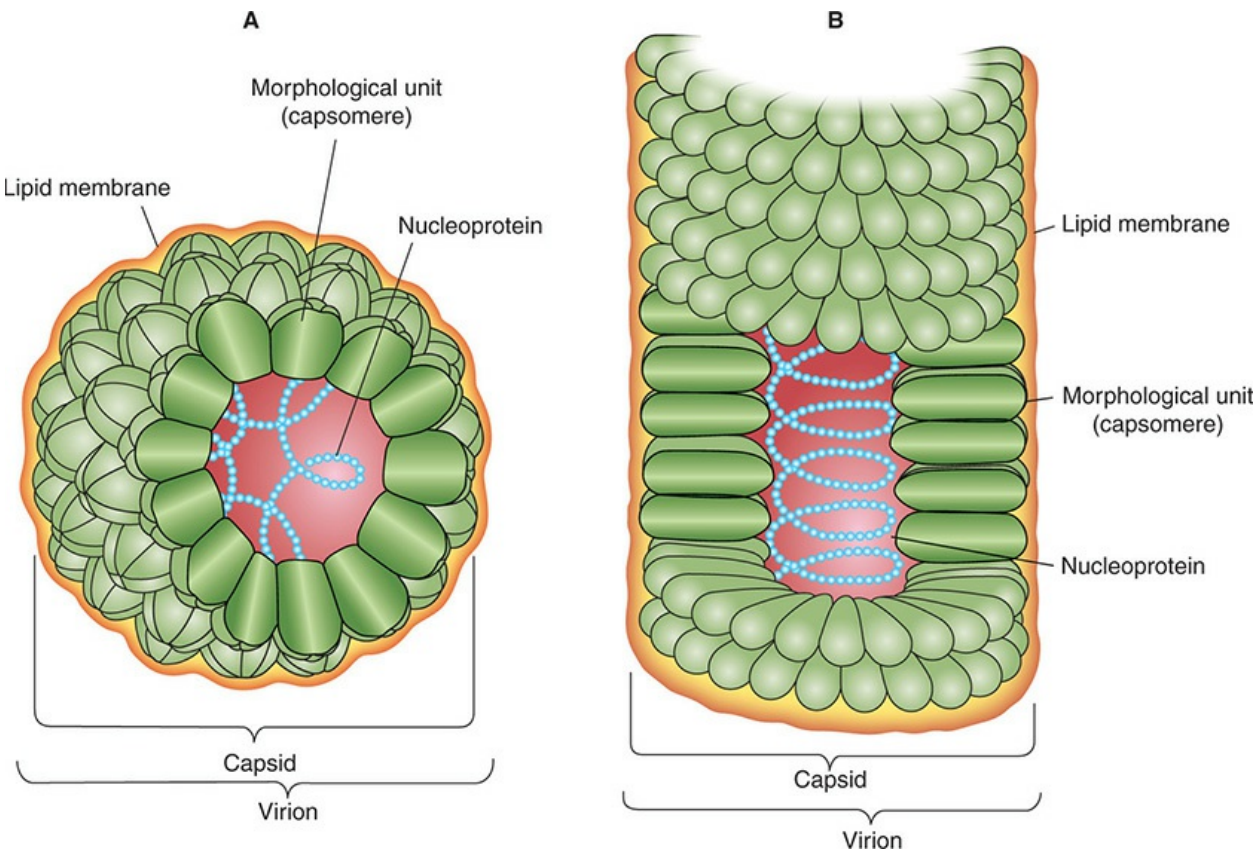


■ **FIGURE 23-1** Viruses are the smallest of infectious agents. The relative size of a bacterium, *Staphylococcus*, is compared with *Chlamydia*, with the largest virus group (poxvirus), and with one of the smallest viruses (poliovirus, a member of the enterovirus group).

As a general rule, DNA viruses replicate and are assembled in the nucleus; RNA viruses are assembled in the cytoplasm. The major exceptions to the site of replication are influenza viruses (RNA), which begin replication in the nucleus, and poxviruses (DNA), which replicate in the cytoplasm. The complex events that occur after a virus infects a cell are reflected only incompletely in the morphologic cellular changes. In some instances, however, one can see clearly how the virus has appropriated the genetic resources of the cell (Fig. 23-3). The final assembly of some viruses occurs at the nuclear or cytoplasmic membrane. The formation of the "envelope," for enveloped viruses, occurs as the virion moves from the nucleus to the cytoplasm or passes from the cytoplasm to the extracellular space; it is during these transitions that an external lipid-containing envelope is added to the nucleocapsid (Figs. 23-2 and 23-3 A-F). Lipid solvents and detergents readily inactivate such enveloped viruses, whereas their nonenveloped counterparts are not affected. The replication of some viruses results in death of the cell, often through cell lysis, with release of the assembled nucleocapsids. The enveloped viruses that mature at the cytoplasmic membrane are released from the cell by "budding" through the membrane (Figs. 23-3F and 23-4). In this process, the envelope accumulates portions of the lipid membrane from the cell,

as well as virus-specific glycoproteins that have been inserted into that membrane.

1504



■ **FIGURE 23-2** Virus morphology. Viruses are constructed with great economy. A central nucleoprotein core is surrounded by a protein capsid, which is made up of individual capsomeres. Some viruses also have a host-derived lipoprotein membrane around the nucleocapsid. The two most common organizational patterns of symmetry are icosahedral **(A)** and helical **(B)**. Ultrastructurally, the icosahedral viruses appear round, although the facets may occasionally be visualized (see the illustration of adenovirus in Table 23-2).

The major groups of viruses are summarized in Tables 23-1 and 23-2. Illustrative electron micrographs of negatively stained viral particles (provided by Frederick A. Murphy) are juxtaposed with a brief description of the families and genera. The list is not exhaustive, but includes the most important human pathogens. The taxonomic characteristics are summarized in the tables, but the vernacular names are used subsequently in the text.

Structural and biochemical features that are used for classification include the

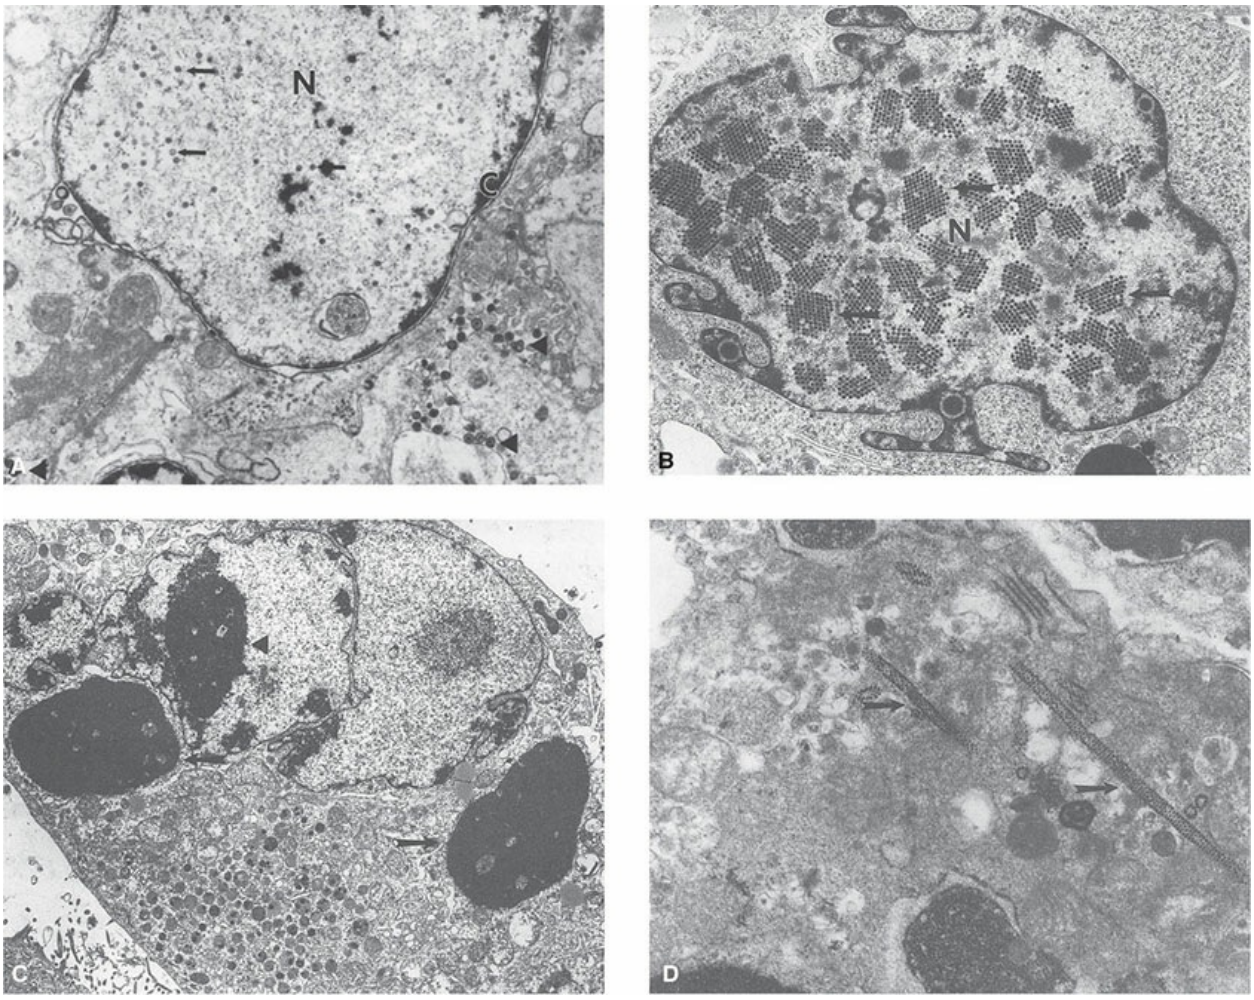
characteristics of the nucleic acid, the configuration or symmetry of the nucleocapsid (helical, icosahedral, or complex), the presence or absence of a lipid envelope, the size of the virion, the number of capsomeres, the stability of the virion to chemical treatment, and the antigenic composition.

The polarity of RNA viruses is considered positive if it can function as mRNA (i.e., proteins needed for construction of the virion can be synthesized directly from the viral nucleic acid once it is released into the cell by disruption of the virion capsid). An RNA virus with negative polarity must use an RNA-dependent RNA polymerase (i.e., an enzyme that must be packaged with the nucleic acid in the infecting virion) to make a complementary RNA molecule (i.e., an RNA molecule with a positive polarity), after which the necessary proteins can be synthesized. The genome of most RNA viruses is contained in one linear segment, but some viruses have a segmented genome. The segmented genome allows enhanced potential for genetic reassortments when two strains infect the same cell. One of the explanations for the amazing ability of influenza viruses to change dramatically (i.e., the cause of antigenic shift) and adapt is its segmented genome that facilitates recombination of segments when two different virions infect the same cell.

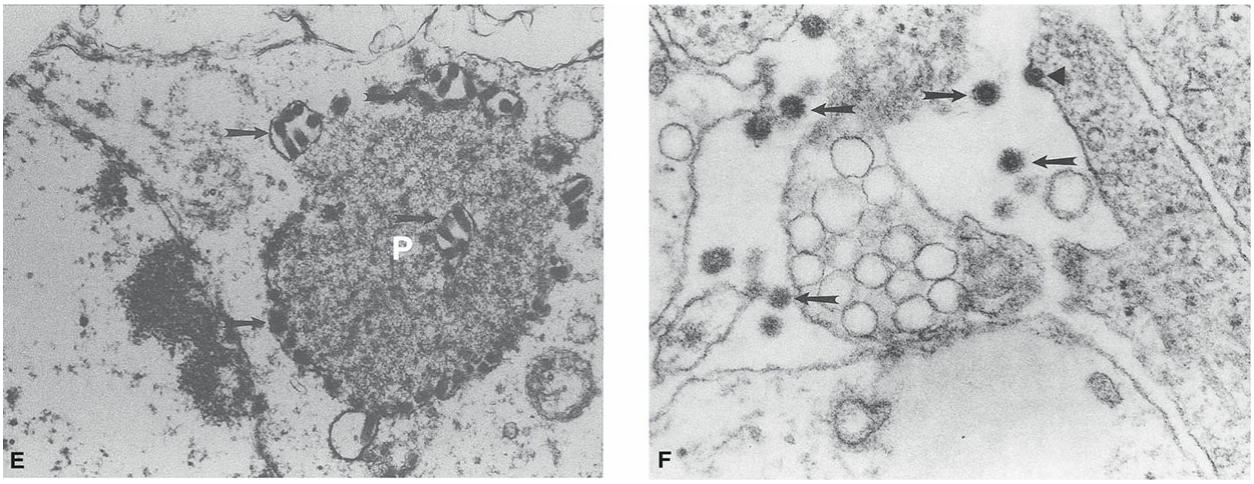
Clinical Manifestations of Viral Infections

The clinical manifestations of viral infections are legion. General symptoms include fever with or without chills, malaise, and myalgias. Specific symptoms derive primarily from the propensity of the virus to infect various cells and tissues (tropism), but may also depend on the route of infection, the virulence of the strain, the immunologic status of the patient,

1505

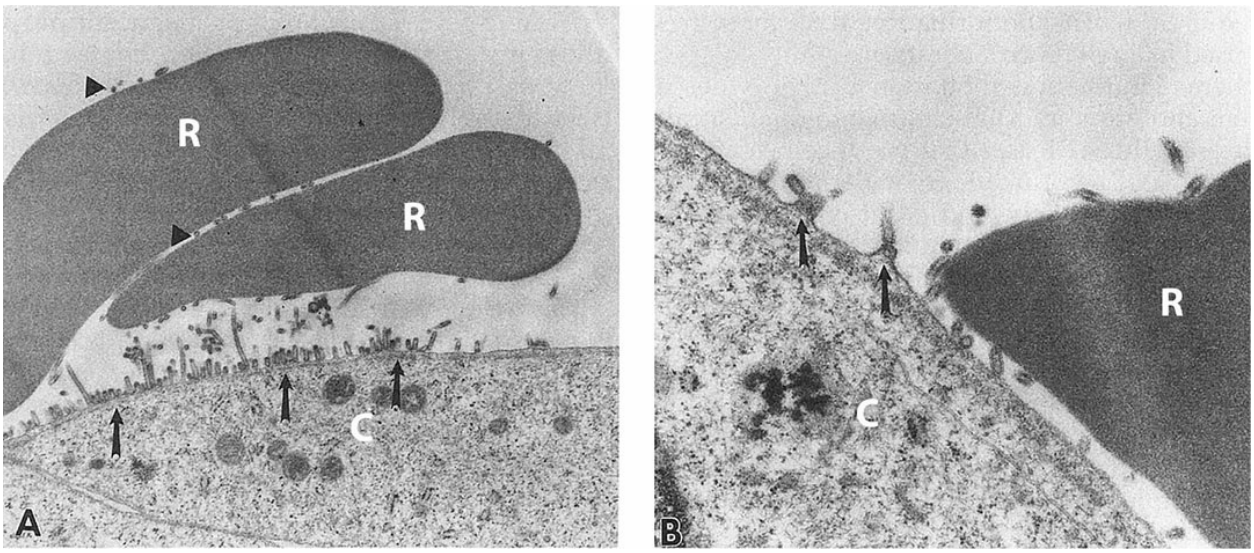


1506



■ **FIGURE 23-3** Ultrastructure of viruses. **A.** Herpes simplex virus. The herpesviruses are assembled in the nucleus of the cell (N). The cellular chromatin (C) is pushed to the edge

of the nucleus by the viral deoxyribonucleoprotein, which stains lightly in the micrograph. This material corresponds to the eosinophilic intranuclear inclusion seen with the light microscope (Image Plate 23-1). Nonenveloped virions (arrows) are assembled in the nucleus. Outside the nucleus, some mature virions that have acquired a lipid envelope from the host cell (arrowheads) are visible (MRC-5 cells, infected with herpes simplex virus, type 1, ×22,400). **B.** Adenoviruses are assembled in the nucleus (N). They have icosahedral symmetry and are not enveloped. They are often closely packed in paracrystalline arrays (arrows). As the viruses accumulate, the whole nucleus may become filled with virions, producing the inclusions seen with the light microscope (Image Plate 23-1E) (Infected HEp-2 cells ×22,400). **C.** Respiratory syncytial virus is assembled in the cytoplasm and matures at the cell membrane. Inclusions may be seen in the cytoplasm of infected cells, both in vivo and in vitro (Image Plate 23-1G). The inclusions (arrow) are intracytoplasmic and are composed of fibrillar ribonucleoprotein. Contrast the density of the nucleolus (arrowhead) with that of the inclusions (Infected HEp-2 cells, ×3,150). **D**. Coxsackievirus B. The enteroviruses are small RNA-containing viruses that have icosahedral symmetry and are often packed in a paracrystalline array (arrows). They are assembled in the cytoplasm. Inclusions are not seen with the light microscope (Infected rhesus monkey kidney cells, ×56,000). **E.** Rabies virus. This bullet-shaped rhabdovirus is assembled in the cytoplasm. The fibrillar nucleoprotein (P) and the elongated viruses (arrows) are found together. The mass of viral material corresponds to the Negri body, which is seen with the light microscope (Image Plate 23-1H). The internal structure that may be seen in classical Negri bodies comes from the incorporation of cytoplasmic material into the body of the inclusion (Infected human brain, ×25,000). **F.** Eastern equine encephalitis virus. This togavirus illustrates the maturation of virus particles at the surface of the cell. Mature virions (arrows) are present in the extracellular space. A maturing (budding) virion is denoted by the dense nucleoprotein core and a condensation of the cellular membrane where the envelope is forming (arrowhead). Some viruses, such as the myxoviruses, insert their hemagglutinins into the membrane at this stage; in classical virology, this afforded their detection by the adherence of red blood cells to the viral hemagglutinin in the cell membrane (hemadsorption) (Infected mouse brain, ×60,000). (E, courtesy of Daniel Perl; F, courtesy of Frederick Murphy).



■ **FIGURE 23-4** Electron microscopy of hemadsorption and hemagglutination of influenza A virus. A. Two red cells (R) have adhered to a monolayer of rhesus monkey kidney cells (C). The red cell-to-red cell adherence is caused by the large number of influenza virions that are "budding" from the surface of the kidney cells (arrows) or adhering to the red blood cells (arrowheads) (×35,000). B. At higher magnification, the bulges in the cell membrane at the point of budding can be seen clearly (arrows). The hemagglutinin and neuraminidase spikes on the virus particles appear as a "fringe" (×80,000).

and other predisposing factors such as underlying pulmonary or cardiac disease. The reader is referred to several excellent textbooks for additional details.[285,395]

Orthomyxoviruses

The orthomyxoviruses, which include influenza A, B, and C viruses, produce a wide variety of respiratory infections.[50,368] The influenza or "flu" syndrome begins with the abrupt onset of headache, fever, chills, and dry cough; later, high fever, myalgias, malaise, and anorexia appear. In young children, gastrointestinal symptoms may be prominent. Almost all influenza infections occur during the winter. Influenza A and B viruses account for most epidemic respiratory diseases in which there is excess mortality. They are rarely isolated in the absence of infection. Influenza A virus infects a variety of mammalian and avian species. Transmission of swine and avian influenza from pigs/chickens to humans has been described occasionally.[481] Influenza C virus is an uncommon cause of human infection, but may produce bronchitis and pneumonia.[335] Influenza viruses may directly produce serious lower respiratory tract disease or, more commonly, may set up the patient for a secondary bacterial

infection.[510] A fortunately uncommon twist to the secondary infection scenario has been the production of toxic-shock syndrome by the invading *Staphylococcus aureus*.[300] More commonly, *S. aureus* would cause a necrotizing pneumonia in the postinfluenza setting. Other complications of influenza include myocarditis[130] and encephalopathy,[222,443] although the virus is not usually detected in these situations.

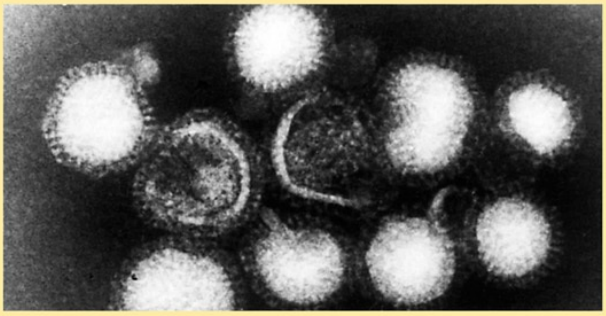
The structure and function of influenza virus are intimately related both to pathogenesis and to laboratory diagnosis.[279] The nucleoprotein antigen in the viral core defines the type of virus; for example, influenza A or B. This antigen is stable and is recognized by many of the diagnostic antisera, which are able to detect all circulating strains of a particular type. Two glycoprotein antigens on the surface of the influenza virion are important for pathogenesis, epidemiology,

TABLE 23-1 Classification of RNA Viruses (Selected Genera and Species That Infect Humans)

Family: *Orthomyxoviridae*
Species: *Influenza A virus*
Species: *Influenza B virus*
Species: *Influenza C virus*

Size: 80–120 nm, spherical or pleomorphic
Nucleic acid: Segmented, negative polarity, single-stranded RNA
Symmetry: Helical
Lipid envelope: Present
Antigens: Hemagglutinin and neuraminidase
Natural habitat: Humans and animals
Distribution: Worldwide

Mode of transmission: Aerosol droplet spread from person to person; rarely animal to person
Route of infection: Respiratory
Diseases: Respiratory infections, including coryza (common cold), tracheobronchitis, and pneumonia. Extrapulmonary symptoms are prominent in the influenza syndrome; rarely, extra-pulmonary disease such as myocarditis may be present.



Influenza A virus. The particles are roughly spherical but irregular. The internal helical structure is difficult to appreciate, but the fringe-like projections of hemagglutinin and neuraminidase are shown well. × 135,000.

Family: *Paramyxoviridae*
Subfamily: *Paramyxovirinae*
Genus: *Respirovirus*
Species: *Human parainfluenza virus 1*
Species: *Human parainfluenza virus 3*
Genus: *Rubulavirus*
Species: *Human parainfluenza virus 2*
Species: *Human parainfluenza virus 4*
Species: *Mumps virus*
Genus: *Morbillivirus*
Species: *Measles virus*
Subfamily: *Pneumovirinae*
Genus: *Pneumovirus*
Species: *Human respiratory syncytial virus*
Genus: *Metapneumovirus*
Species: *Human metapneumovirus*

Size: 150–300 nm, pleomorphic
Nucleic acid: Nonsegmented, negative polarity, single-stranded RNA
Symmetry: Helical
Lipid envelope: Present
Antigens: Hemagglutinin, neuraminidase, fusion protein, nucleocapsid (depending on virus)
Natural habitat: Humans and animals
Distribution: Worldwide

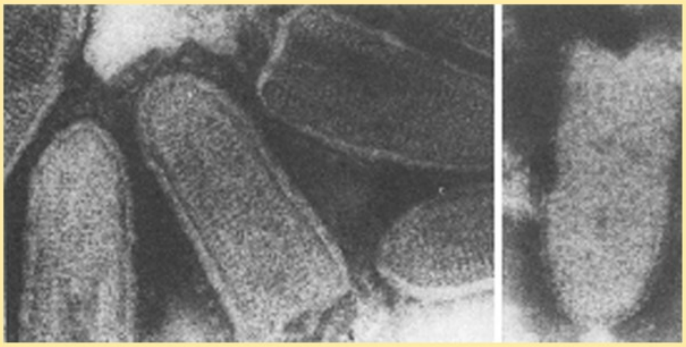
Mode of transmission: Droplet aerosol or direct inoculation
Route of infection: Respiratory
Diseases: Common cold, tracheobronchitis, rarely pneumonia (parainfluenza); tracheobronchitis, bronchiolitis, and pneumonia (respiratory syncytial virus); parotitis, pancreatitis, orchitis, meningitis (mumps); rash, pneumonia, encephalitis, subacute sclerosing panencephalitis (measles)

Human parainfluenza virus 1. The irregular virion has been disrupted, releasing a long strand of uncoiled RNA. The hemagglutinin fringes on the virion are evident.× 72,000

Family: *Rhabdoviridae*
Genus: *Lyssavirus*
Species: *Rabies virus*

Size: 50–95 nm by 130–389 nm, bullet shaped
Nucleic acid: Nonsegmented, negative polarity, single-stranded RNA
Symmetry: Helical
Lipid envelope: Present
Natural habitat: Wild and domestic animals
Distribution: Worldwide

Mode of transmission: Infected secretions, rabies usually transmitted by bites
Route of transmission: Cutaneous or respiratory
Disease: Encephalitis (rabies)

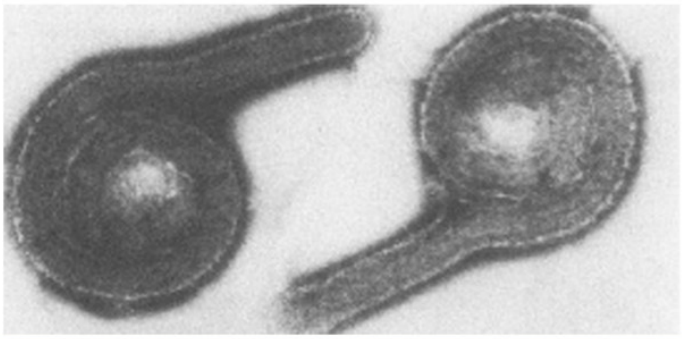


Vesicular stomatitis virus. The bullet shape of the virion is evident. The coiled helical nature of the internal ribonucleoprotein is reflected in the striations.× 216,000

Family: *Filoviridae*
Genus: *Marburgvirus*
Species: *Marburg marburgvirus*
Genus: *Ebolavirus*
Species: *Zaire ebolavirus*
Species: *Bundibugyo ebolavirus*
Species: *Tai Forest ebolavirus*
Species: *Sudan ebolavirus*

Size: 80 nm by 800–1,000 nm, filamentous
Nucleic acid: Nonsegmented, negative polarity, single-stranded RNA
Symmetry: Helical
Lipid envelope: Present
Natural habitat: Nonhuman primates
Distribution: Africa, Philippines

Mode of transmission: Unknown, but close contact required
Diseases: Hemorrhagic fever with fatality rates as high as 90%

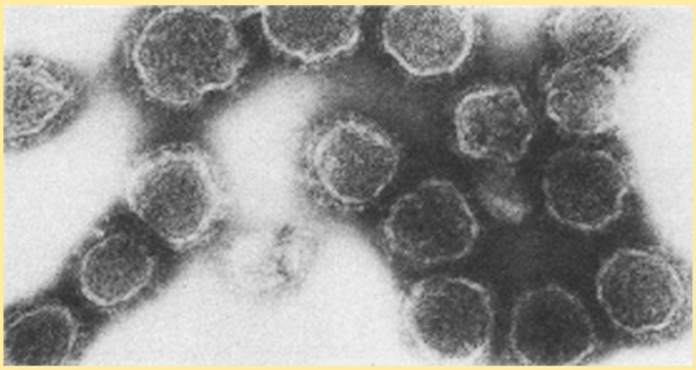


Ebola virus. Long, filamentous form has assumed a "crook" shape. × 59,000

Family: *Bunyaviridae*
Genus: *Orthobunyavirus*
Species: *California encephalitis virus*
Species: *La Crosse virus*
Genus: *Hantavirus*
Species: *Hantaan virus*
Species: *Sin Nombre virus*
Genus: *Nairovirus*
Species: *Crimean Congo hemorrhagic fever virus*
Species: *Rift Valley fever virus*
Species: *Sandfly fever Naples virus*

Size: 80–120 nm
Nucleic acid: Segmented, single-stranded RNA. May be negative polarity (*Bunyavirus, Hantavirus,* and *Nairovirus*) or contain examples of each polarity (*Phlebovirus*)
Symmetry: Helical
Lipid envelope: Present
Antigens: Surface hemagglutinin
Natural habitat: Small animals

Distribution: Worldwide
Mode of transmission: Bite of infected mosquitoes (*Bunyavirus, Nairovirus, Phlebovirus*); exposure to rodent excreta (*Hantavirus*)
Diseases: Febrile illness, aseptic meningitis (*Bunyavirus*); febrile illness, hemorrhagic fever, respiratory failure (*Hantavirus*); febrile illness, hemorrhagic fever (*Nairovirus*); febrile illness, encephalitis, hemorrhagic fever (*Phlebovirus*)

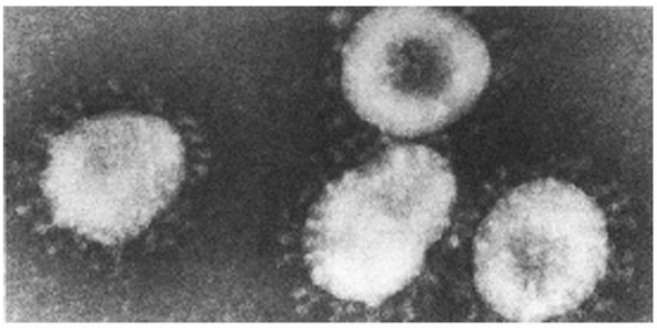


LaCrosse virus. Irregular virus particles; the lipid envelope and surface projections are evident.× 117,000

Family: *Coronaviridae*
Genus: *Alphacoronavirus*
Species: *Human coronavirus 229E*
Species: *Human coronavirus OC43*
Genus: *Betacoronavirus*
Species: *Severe acute respiratory syndrome-related virus*

Size: 120–160 nm
Nucleic acid: Nonsegmented, positive polarity, single-stranded RNA
Symmetry: Helical
Lipid envelope: Present
Natural habitat: Humans or animals (Coronaviruses)

Distribution: Worldwide
Transmission: Person to person, presumably by aerosol
Route of infection: Respiratory
Diseases: Common cold; rarely lower respiratory disease; severe acute respiratory syndrome

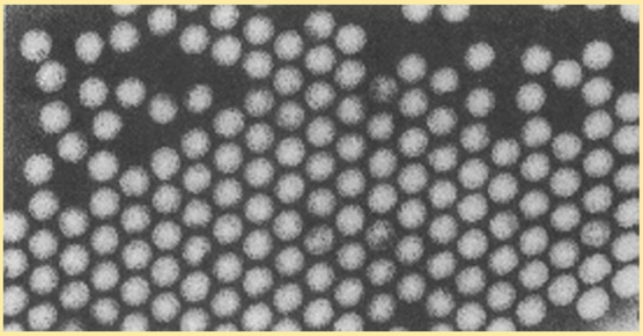


Human coronavirus OC43. The club-shaped projections are the most distinctive features of these pleomorphic particles. × 180,000

Family: *Picornaviridae*
Genus: *Enterovirus*
Species: *Enterovirus C (human poliovirus 1–3)*
Species: *Enterovirus A (human coxsackievirus A2)*
Species: *Enterovirus B (human echovirus)*
Species: *Rhinovirus A-C*
Genus: *Hepatovirus*
Species: *Hepatitis A virus*
Genus: *Parechovirus (Rhinovirus)*
Species: *Human parechovirus*

Size: 22–30 nm
Nucleic acid: Nonsegmented, positive polarity, single-stranded RNA
Symmetry: Icosahedral
Lipid envelope: Absent
Natural habitat: Human gastrointestinal tract; survives in environment (*Enterovirus, Hepatovirus, Parechovirus*); human upper respiratory tract (*Rhinovirus*)

Distribution: Worldwide
Transmission: Fecal–oral from human to human or contaminated water (*Enterovirus, Hepatovirus, Parechovirus*); human respiratory tract by aerosol or on hands (*Rhinovirus*)
Route of infection: Gastrointestinal (*Enterovirus, Hepatovirus, Parechovirus*); respiratory (*Rhinovirus*)
Diseases: Febrile illness, meningitis, encephalitis, myocarditis (*Enterovirus, Parechovirus*); hepatitis (*Hepatovirus*); common cold (*Rhinovirus*)

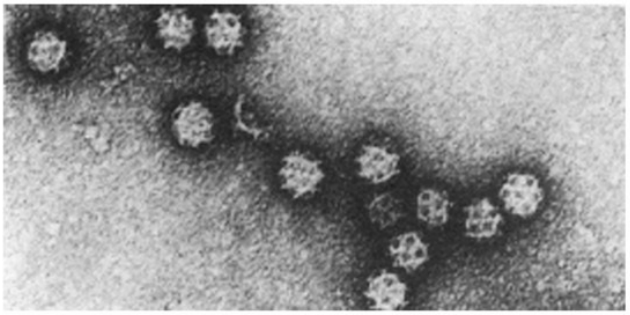


Poliovirus 1. The particles are small, regular, and nonenveloped. × 180,000

Family: *Caliciviridae*
Genus: *Norovirus*
Species: *Norwalk virus*
Genus: *Sapovirus*
Species: *Sapporo virus*

Size: 35–40 nm
Nucleic acid: Nonsegmented, positive polarity, single-stranded RNA
Symmetry: Icosahedral
Lipid envelope: Absent
Natural habitat: Human gastrointestinal tract

Distribution: Worldwide
Transmission: Fecal–oral; contaminated water
Portal of entry: Gastrointestinal
Diseases: Gastroenteritis

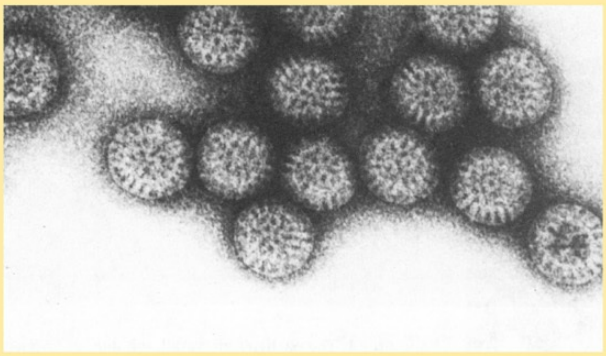


Swine exanthemata virus. Very small, regular particles with prominent cuplike depressions. The surface depressions of the human Norwalk-like viruses are not as pronounced.

Family: *Reoviridae*
Genus: *Orthoreovirus*
Species: *Mammalian orthoreovirus*
Genus: *Rotavirus*
Species: *Rotavirus A-C*
Genus: *Coltivirus*
Species: *Colorado tick fever virus*

Size: 60–85 nm, variable morphology
Nucleic acid: Segmented, double-stranded RNA
Symmetry: Icosahedral
Lipid envelope: Absent
Natural habitat: Gastrointestinal tract of humans (*Rotavirus*) and animals (*Rotavirus*)

Distribution: Worldwide
Transmission: Fecal–oral by direct contact; animal to human
Portal of entry: Gastrointestinal tract
Diseases: Gastroenteritis (*Rotavirus*); None (*Rotavirus*)



Rotavirus. The distinctive feature of the *Reoviridae* is the presence of a double shell, each with icosahedral symmetry. × 135,000

Family: *Astroviridae*
Genus: *Mamastrovirus*
Species: *Mamastrovirus 1, 6, 8, and 9*

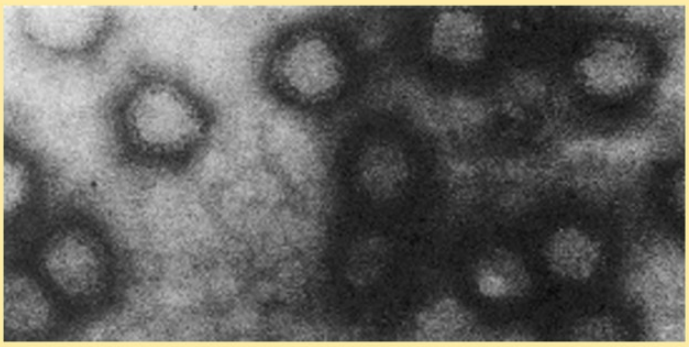
Size: 28–30 nm
Nucleic acid: Nonsegmented, positive polarity, single-stranded RNA
Symmetry: Icosahedral
Lipid envelope: Absent
Natural habitat: Gastrointestinal tract of human

Distribution: Worldwide
Transmission: Fecal–oral; contaminated water
Portal of entry: Gastrointestinal tract
Diseases: Gastroenteritis

Family: *Togaviridae*
Genus: *Alphavirus*
Species: *Eastern equine encephalitis virus*
Species: *Venezuelan equine encephalitis virus*
(Other arthropod-borne species)
Species: *Chikungunya virus*
Genus: *Rubivirus*
Species: *Rubella virus*

Size: 60–70 nm
Nucleic acid: Nonsegmented, positive polarity, single-stranded RNA
Symmetry: Icosahedral
Lipid envelope: Present
Natural habitat: Small mammals and insects (*Alphavirus*); humans (*Rubivirus*)

Distribution: Worldwide
Transmission: By mosquito bites (*Alphavirus*); aerosols or transplacental (*Rubivirus*)
Portal of entry: Cutaneous (*Alphavirus*); respiratory or vascular (*Rubivirus*)
Diseases: Hepatitis, meningitis, encephalitis, arthritis, febrile illness (*Alphavirus*); rash illness, congenital infection (*Rubivirus*)



Rubella virus. The spherical virions have a lipid membrane and surface hemagglutinin projections.× 135,000

Family: *Flaviviridae*
Genus: *Flavivirus*
Species: *Yellow fever virus*
Species: *St. Louis encephalitis virus*
Species: *Japanese encephalitis virus*
Species: *West Nile virus*
Species: *Dengue virus*

Size: 40–60 nm
Nucleic acid: Nonsegmented, positive polarity, single-stranded RNA
Symmetry: Icosahedral
Lipid envelope: Present
Natural habitat: Small mammals and insects (*Flavivirus*); humans (*Hepacivirus*)

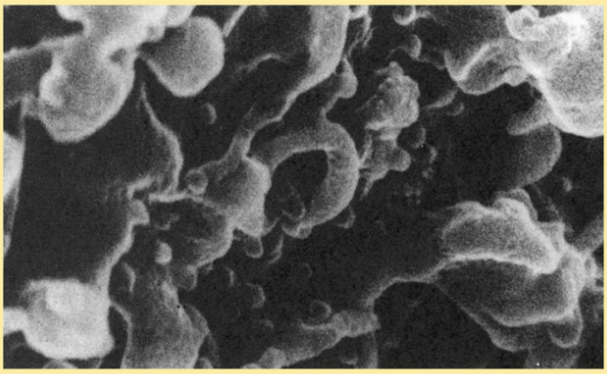
Distribution: Worldwide
Transmission: By bite of mosquito or tick (*Flavivirus*); by blood (*Hepacivirus*)
Portal of entry: Cutaneous (*Flavivirus*); vascular; sexual (*Hepacivirus*)
Diseases: Hepatitis, meningitis, encephalitis febrile illness, hemorrhagic fever (*Flavivirus*); hepatitis, cirrhosis, hepatocellular carcinoma (*Hepacivirus*)

(Numerous other species, many arthropod-borne)
Genus: *Hepacivirus*
Species: *Hepatitis C virus*
Genus: *Hepevirus*
Species: *Hepatitis E virus*

Family: *Retroviridae*
Genus: *Deltaretrovirus*
Species: *Primate T-cell lymphotropic virus,* Types 1 and 2 (HTLV)
Genus: *Lentivirus*
Species: *Human immunodeficiency virus,* Types 1 and 2 (HIV)

Size 80–100 nm
Nucleic acid: Nonsegmented, positive polarity, single-stranded RNA dimer (packaged with RNA-dependent DNA polymerase)
Symmetry: Variable
Lipid envelope: Present
Natural habitat: Humans

Distribution: Worldwide
Transmission: Sexual, contaminated needles, transfusions, maternal-fetal/neonate
Portal of entry: Mucous membranes, vascular
Diseases: T-cell leukemia and lymphoma (HTLV); acquired immunodeficiency syndrome (HIV)

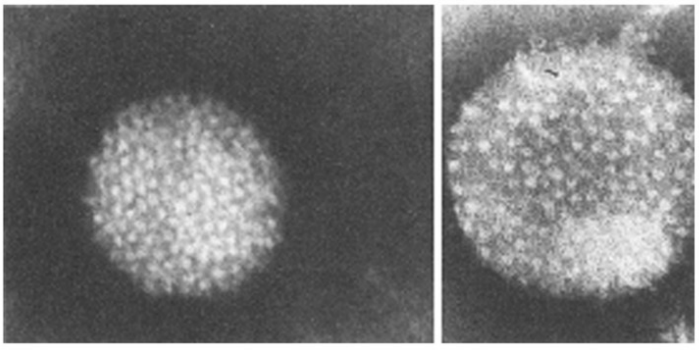


Human immunodeficiency virus. Scanning electron micrograph of human T lymphocyte with virus particles budding from surface

Family: *Arenaviridae*
Genus: *Arenavirus*
Old World Group
Species: *Lymphocytic choriomeningitis virus (LCM)*
Species: *Lassa virus*
New World Group
Species: *Junin virus*
Species: *Machupo virus*
Species: *Sabia virus*
Species: *Guanarito virus*

Size: 50–300 nm
Nucleic acid: Bisegmented, ambipolarity, single-stranded
Symmetry: Pleomorphic
Lipid envelope: Present
Naturally habitat: Rodents

Distribution: Worldwide (LCM); South America (Junin, Machupo, Sabia, Guanarito); Africa (Lassa)
Transmission: Contact with rodent or human secretions
Portal of entry: Respiratory, cutaneous (lacerations)
Diseases: Febrile illness, meningitis (LCM); hemorrhagic fever (Lassa, Junin, Machupo, Sabia, Guanarito viruses)

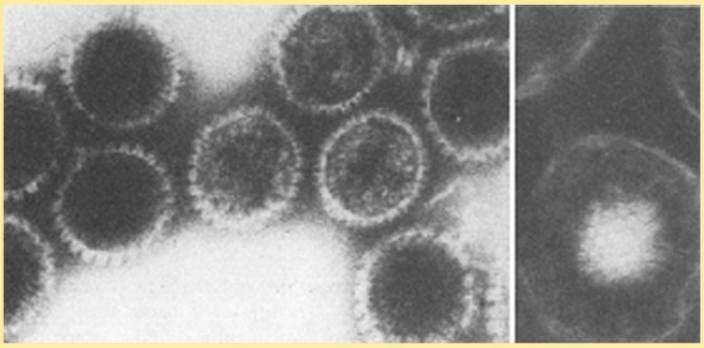


Lymphocytic choriomeningitis virus. The spherical virus has large surface projections. The name is derived from the Latin word *arenosus* (sandy), which was suggested by the internal ribosome-like particles that are seen by transmission electron microscopy. × 225,000

TABLE 23-2 Classification of DNA Viruses (Selected Genera and Species That Infect Humans)

Family: *Herpesviridae*
Subfamily: *Alphaherpesvirinae*
Genus: *Simplexvirus*
Species: *Human herpesvirus 1*
(Herpes Simplex virus Type 1; HSV1)
Species: *Human herpesvirus 2*
(Herpes Simplex virus Type 2; HSV2)
Genus: *Varicellovirus*
Species: *Human herpesvirus 3* (Varicella-Zoster virus; VZV)
Subfamily: *Betaherpesvirinae*
Genus: *Cytomegalovirus*
Species: *Human herpesvirus 5* (Cytomegalovirus; CMV)
Genus: *Roseolovirus*
Species: *Human herpesvirus 6A* (HHV6A)
Species: *Human herpesvirus 6B* (HHV6B)
Species: *Human herpesvirus 7* (HHV7)
Subfamily: *Gammaherpesvirinae*
Genus: *Lymphocryptovirus*
Species: *Human herpesvirus 4* (Epstein–Barr virus; EBV)
Genus: *Rhadinovirus*
Species: *Human herpesvirus 8* (Kaposi's sarcoma-associated herpesvirus; HHV8)

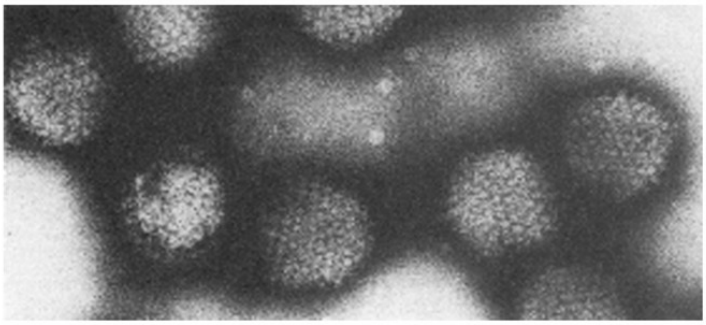
Size: 120–300 nm
Nucleic acid: Double-stranded DNA, nonsegmented
Symmetry: Icosahedral
Lipid envelope: Present
Natural habitat: Humans
Distribution: Worldwide
Transmission: By infected oral or genital secretions, by blood, or transplacentally
Portal of entry: Respiratory, cutaneous, intravascular, transplacental
Diseases: Pharyngitis, cervicitis, local skin lesions, pneumonia, esophagitis, encephalitis, disseminated infection (HSV1), skin lesions, meningitis, neonatal sepsis (HSV2); congenital infection, hepatitis, mononucleosis, pneumonia (CMV), chickenpox, disseminated infection, zoster/shingles (VZV), pharyngitis, mononucleosis, hepatitis (EBV); exanthema subitum (HHV6, HHV7), Kaposi's sarcoma, lymphoma (HHV8)



Herpes simplex virus. (Left) Naked nucleocapsids demonstrate the regular structure of the virion. Clearly defined structural units appear to have a central depression. (Right) Enveloped particle has, in addition, a lipid membrane derived from the infected cell. ×189,000.

Family: *Adenoviridae*
Genus: *Mastadenovirus*
Species: *Human mastadenovirus A-G*

Size: 70–90 nm
Nucleic acid: Double-stranded DNA, nonsegmented
Distribution: Worldwide
Symmetry: Icosahedral
Transmission: Fecal–oral, possibly aerosol droplet
Lipid envelope: Absent
Portal of entry: Respiratory, Gastrointestinal
Natural habitat: Humans
Diseases: Conjunctivitis, keratitis, pharyngitis, tracheobronchitis, pneumonia, cystitis; gastroenteritis (types 40 and 41)



Adenovirus, type 5. The regular arrangement of the structural units of the virion is clearly evident. ×234,000.

1513

Family: *Papillomaviridae*
Genus: *Alphapapillomavirus*
Species: *Alphapapillomavirus 1 (Human papillomavirus 32; HPV)*
Genus: *Betapapillomavirus*
Species: *Betapapillomavirus 1 (Human papillomavirus 5; HPV)*

Size: 55 nm
Nucleic acid: Double-stranded DNA, nonsegmented.
Lipid envelope: Absent
Symmetry: Icosahedral
Distribution: Worldwide
Transmission: Contact with infected secretions, sexual; the virus remains dormant in tissues and/or integrates into the host genome
Portal of entry: Cutaneous, mucocutaneous (oral and/or genital), respiratory
Diseases: Cutaneous, genital and respiratory papillomas (i.e., warts), and epithelial neoplasia, predominantly squamous cell carcinoma of the uterine cervix and of the head and neck

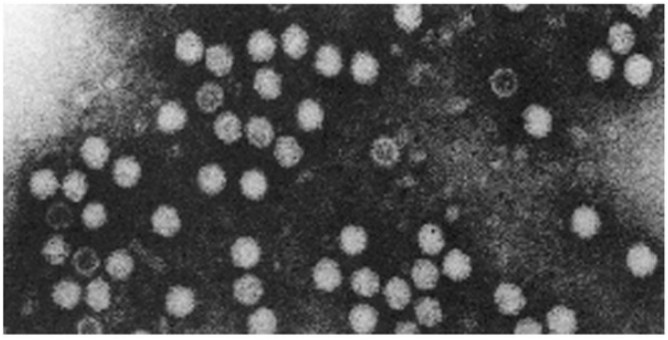
Human papillomavirus. These viruses have never been propagated successfully in cell cultures. The diseases have been associated by demonstration of virions, viral antigens, or nucleic acid in lesions. ×135,000.

Family: *Polyomaviridae*
Genus: *Polyomavirus*
Species: *BK polyomavirus*
Species: *JC polyomavirus*

Size: 40–45 nm
Nucleic acid: Double-stranded DNA, nonsegmented.
Lipid envelope: Absent
Symmetry: Icosahedral
Distribution: Worldwide
Transmission: Unknown; respiratory and urine/oral mechanisms are postulated. Virus remains latent and may reactivate in the presence of a suppressed immune system.
Portal for entry: Likely respiratory or oral.
Diseases: Hemorrhagic cystitis and renal transplant nephropathy (BK virus); progressive multifocal leukoencephalopathy (JC virus).

Family: *Parvoviridae*
Subfamily: *Parvovirinae*
Genus: *Erythroparvovirus*
Species: *Primate erythroparvovirus* (Human parvovirus B19)

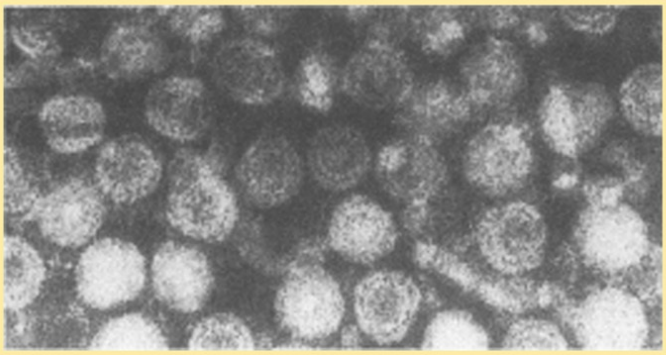
Size: 21–26 nm
Distribution: Worldwide
Nucleic acid: Single-stranded DNA; nonsegmented
Symmetry: Icosahedral
Lipid envelope: Absent
Natural habitat: Humans
Transmission: Person-to-person (route unknown); transfusion
Portal of entry: unknown; vascular
Diseases: Erythema infectiosum (fifth disease), hemolytic disease of newborn, anemia



H-1 virus. The virions are very small and regular in size and shape. Parvoviruses are unusual in that they contain single-stranded DNA.

Family: *Hepadnaviridae*
Genus: *Orthohepadnavirus*
Species: *Hepatitis B virus*

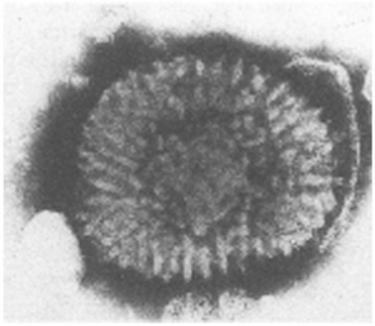
Size: 42–50 nm
Distribution: Worldwide
Nucleic acid: Double-stranded, circular DNA; nonsegmented
Transmission: Infected secretions and blood, sexual, transfusion
Symmetry: Complex
Portal of entry: Skin, vascular, genital
Lipid envelope: Present
Diseases: Hepatitis, cirrhosis, hepatocellular, carcinoma
Natural habitat: Humans
Antigens:
Surface antigen (HBsAg)
Core antigen (HBcAg)
Early antigen (HBeAg)



Hepatitis B virus. These 42-nm particles, which are the infectious agent, were originally known as Dane particles. ×225,000.

Family: *Poxviridae*
Subfamily: *Chordopoxvirinae*
Genus: *Orthopoxvirus*
Species: *Variola virus* (smallpox)
Species: *Vaccinia virus*
Species: *Cowpox virus*
Species: *Monkeypox virus*
Genus: *Parapoxvirus*
Species: *Orf virus*
Genus: *Molluscipoxvirus*
Species: *Molluscum contagiosum virus*
Genus: *Yatapoxvirus*
Species: *Yaba monkey tumor virus*

Size: 140–260 × 220–450 nm
Nucleic acid: Double-stranded DNA; nonsegmented
Symmetry: Complex
Lipid envelope: Usually present
Natural habitat: Humans and animals
Distribution: Worldwide; variola "eradicated"
Transmission: Respiratory, cutaneous
Portal of entry: Respiratory, cutaneous
Diseases: Cutaneous ulcerative lesions, disseminated disease (*Orthopoxvirus*), cutaneous ulcerative lesions (*parapoxvirus*, *Yatapoxvirus*), molluscum contagiosum (*Molluscipoxvirus*)



Vaccinia virus. The convoluted outer coat of these large, brick-shaped particles is evident. When smallpox existed, negative stain electron microscopy was a useful tool for differentiation of the small pox virus from those of varicella. ×49,500.

and therapy. The dominant antigen is the hemagglutinin, which is responsible for attachment to respiratory epithelial cells and is therefore an important target for influenza vaccines. The surface neuraminidase enzyme participates in entry of the virus into the cell. These surface antigens are constantly changing, so that they are a moving target for therapeutic and diagnostic antibodies. It is the constant, incremental change (antigenic drift) and periodic, quantum change (antigenic shift) that allow

recurring epidemics and pandemics, respectively, of influenza.

The viruses are named by their structure and geography. For instance, an isolate might be characterized influenza A/Leningrad/360/86 (H3N2). The name means that this strain was the 360th isolate of influenza A in Leningrad in 1986, and it contains the third antigenic type of hemagglutinin and the second type of neuraminidase. The hemagglutinin and

1515

neuraminidase are not useful antigens for diagnostic purposes, but they are essential for the epidemiologist to study so that the next year's vaccine can contain antibodies to currently circulating antigens. Although it has not yet been accomplished, attempts continue to predict the future drift of influenza A virus strains, so that the vaccine for the next flu season can be formulated more rationally.[44]

To date, a number of different hemagglutinin types have been recognized. The initial antigen (H1) was hypothesized to be a constituent of the strain that caused pandemic influenza in 1918, based on serologic analysis. Independent evidence to this end has been developed using modern molecular techniques on tissue from influenza victims.[390] Two samples came from formalin-fixed lung tissue in England, but the sample that yielded the most complete sequence was taken from the body of an Inuit woman who had been buried in Alaskan permafrost. There was a remarkable homogeneity among the three samples from diverse geographic locations.

Subsequent major epidemics have been associated with major shifts in the hemagglutinin: H2 during the Asian influenza epidemic in 1957 and H3 during the Hong Kong influenza epidemic of 1968. Subsequently, strains with either the H1 or H3 hemagglutinin circulated until a new strain of avian influenza (H5 hemagglutinin) killed 6 of 18 individuals infected in Hong Kong. This virus, which was spread directly from chickens to humans without another intermediary, had particularly virulent characteristics.[205] Fortunately, spread from human to human appeared limited. Subsequently, another strain (H9 hemagglutinin) appeared in Hong Kong with similar epidemiologic characteristics, but fortunately less mortality. H5 virus has reappeared in Southeast Asia, once again with high mortality rates in patients who were exposed to poultry, but without significant person-to-person transmission.[214,269]

Outbreaks of, what has been termed, Highly Pathogenic Asian Avian Influenza A (HPAI) (i.e., H5N1) have occurred in 15 countries, with documented infections in more than 700 people. The majority of infections have occurred in Indonesia, Vietnam, and Egypt, but there have been infected individuals who have traveled to Europe and Canada. Most of the infected patients have an epidemiologic exposure to infected poultry. Most infections have occurred in adults <40 years old and in children. This strain may cause pneumonia, respiratory failure, and death, but in some,

particulary children, milder disease has been reported.[72] Most importantly, the HPAI Asian H5N1 virus is not efficiently transmitted from person to person.

The fact that avian influenza viruses have crossed the species barrier to infect humans is cause for vigilant monitoring. Devastating pandemic disease awaits only the emergence of a strain with the combination of high virulence and efficient human-to-human transmission.

The most recent influenza pandemic was the H1N1 pandemic of 2009.[71] This particular strain, which was epidemiologically linked with swine, was highly contagious, but, fortunately, no more virulent than the influenza A strains typically encountered each year. Disease, therefore, ranged from mild to severe. The new virus originated in Mexico, but quickly spread to California. This virus, fortunately, was initially susceptible to oseltamivir, which was widely used for treatment. There were two interesting observations from the pandemic and the years that followed. First, the pandemic H1N1 strain did not disappear, but rather became an endemic strain of influenza (i.e., very similar to the current endemicity of West Nile virus in North America). The other interesting finding was the speed at which this virus developed resistance to oseltamivir.

Paramyxoviruses

The paramyxoviruses are a varied group that include parainfluenza viruses, mumps virus, measles virus, respiratory syncytial virus (RSV), and human metapneumovirus (hMPV).

Parainfluenza Viruses. The parainfluenza viruses, of which there are four serotypes, are important causes of respiratory disease, which is usually mild in adults but may be severe in young children or immunocompromised patients.[208]Parainfluenza viruses 1 and 2 cause croup (laryngotracheobronchitis) in children between the ages of 2 and 6 during the winter respiratory virus season in the Northern Hemisphere. Parainfluenza virus 3 is an important cause of bronchiolitis in children less than 2 years of age; infections occur throughout the year, with peaks in the fall and spring. Parainfluenza virus 4 causes less severe infections, which is likely the reason that it is less commonly recovered in the clinical virology laboratory (i.e., patients with subclinical disease do not present for testing). Many assays, including direct fluorescent antibody (DFA) reagents and molecular diagnostic tests, do not test for the presence of parainfluenza virus 4.

Mumps Virus. Mumps virus produces infectious parotitis. It also causes aseptic meningitis, which is usually mild, and may also affect the pancreas, the gonads, and more rarely the joints. The introduction of an effective vaccine has greatly reduced the incidence of mumps virus infection, although the vaccine is not 100% effective.

Interestingly, after the introduction of mumps vaccine, the circulating strains, which had been homogeneous, became more diverse.[247] There are small outbreaks of mumps every year. These often occur in the fall or winter, when there is crowding, or among individuals with close associations, such as sport teams. According to the Centers for Disease Control and Prevention (CDC), there were 1,151 individuals who contracted mumps in 2014 (http://www.cdc.gov/mumps/outbreaks.html).

Measles Virus. Measles virus (rubeola virus) is unlikely to be encountered in the clinical laboratory,[427] but unfortunately, this virus continues to cause focal outbreaks, the most recent of which was in California. Laxity in monitoring and enforcing immunization practices has led to explosive outbreaks in both young and adults, who may have waning immunity. Other at-risk populations include children, especially in inner-city areas where levels of immunization are low, and individuals who decline vaccination for a variety of reasons.[54] Molecular analysis suggests the existence of multiple imported strains, rather than a single endemic strain.[400]

The public health implications of exposure in our mobile society were illustrated by a classical epidemic of 247 individuals that began in a ski area in Breckenridge, Colorado.[58] After dispersal of infected individuals, patients with measles were detected in 10 states.

Three factors minimize the likelihood of isolating measles virus: the diagnosis is usually made on clinical grounds, and specimens are often not submitted to the laboratory.

1516

In addition, virus is isolated from respiratory secretions and urine only early in the course of the infection. Finally, many laboratories are moving from cell culture, which would support the growth of the virus, to specific molecular diagnostic assays. Therefore, the measles virus would not be detected by routinely used molecular respiratory virus assays, unless specifically sought (i.e., a specific reverse transcription polymerase chain reaction [RT-PCR] assay directed to the measles virus would need to be ordered).

The diagnostic rash is produced by complexes of viral antigen and antibody. Thus, at the time the diagnosis is made by a physician, the virus is being neutralized and cultures are likely to be negative. Atypical clinical symptoms were seen formerly in patients who had received early inactivated measles vaccines,[10] but this phenomenon is no longer prevalent. Pneumonia and encephalitis are the most serious complications of measles.[128,253] In addition, the measles virus rarely produces a chronic encephalitis known as subacute sclerosing panencephalitis.[365]

Respiratory Syncytial Virus. RSV causes recurrent respiratory infections from infancy through adult life. Epidemics are common and may be hospital-associated. There are two distinct serologic groups of RSV (A and B). A single group predominates in most epidemics,[343] but the viral type does not correlate with severity of infection.[313] Disease is concentrated in the winter months, although summertime infections may occur in warm climates.[478]

Infection is spread by large particle droplets and by fomites (e.g., contaminated environmental particles, such as dust), rather than by small particle aerosols. This viral infection is a major cause of nosocomial infection; careful attention to the principles of infection control is essential.[177] Good laboratory diagnostic support, which is most effectively accomplished using rapid molecular diagnostics, is needed not only for treating the individual patient, but also for limiting nosocomial spread of the infection.

RSV may produce croup, bronchitis, bronchiolitis, or interstitial pneumonia.[196] It is the most common cause of respiratory disease in hospitalized infants less than 1 year of age, rivaled only by the hMPV (see below). RSV infections are often severe in young children. If congenital heart disease or immunologic deficiency is present, the disease may be especially lethal. In one study, 8 (73%) of 11 infants with congenital heart disease and pulmonary hypertension died of the infection.[301] Many previously normal children, especially infants, are sufficiently ill that ventilatory support is required. Apnea is a prominent part of the syndrome.

Immunity to RSV is short-lived and incomplete. RSV was long thought to be a disease of infants and young children, but adult infection, including serious disease, is now recognized to be an important clinical problem.[138,197] Epidemics in nursing homes have been reported.[139]

The serious nature of RSV infection in immunocompromised adults has been recognized.[314] Serious RSV infection occurs also in adults with chronic diseases, such as diabetes, cirrhosis, and chronic obstructive pulmonary disease.[193]

Other Paramyxoviruses. Several other paramyxoviruses have been recognized as important causes of human infections. Most notable among these is the hMPV. This virus was initially recognized in Hong Kong, but has now been documented worldwide. It is a member of the subfamily *Pneumovirinae*, which includes RSV[325]; the human virus is closely related to two avian viruses. The disease produced by hMPV resembles RSV both clinically and epidemiologically.[31] It has been isolated using LLC-MK2 cells (i.e., a continuous rhesus monkey kidney cell line), a method not commonly used in diagnostic laboratories. The virus was recognized by cytopathic effect, but currently identification is most effectively made using molecular techniques. There are now molecular assays commercially available for the detection of hMPV, but widespread use is not commonplace.

Two other more recently recognized paramyxoviruses have been associated with severe neurologic disease, as well as respiratory infection. Both of these viruses are transmitted to humans from animals (i.e., zoonotic infections). Nipah virus has caused encephalitis in pig farmers in Malaysia and Singapore.[176] The *Pteropus* (i.e., large fruit) bats are the natural reservoir for the Nipah virus. Disease produced by this virus ranges from asymptomatic disease to fatal respiratory infections or encephalitis. The Nipah virus is closely related to Hendra virus, which shares the same natural reservoir. The Hendra virus produces disease in horses and a few human infections have occurred in Australia. The range of clinical presentations is like that of the Nipah virus described above. Laboratory-acquired infections have also been noted.

Picornaviruses

The picornaviruses, which include the rhinoviruses and the enteroviruses, constitute the other large and important group of RNA viruses. The rhinoviruses are frequent causes of the common cold. They are acid-labile and do not infect the gastrointestinal tract. Transmission of rhinoviruses occurs by generation of respiratory aerosols[96] and through contact with contaminated inanimate surfaces (i.e., fomites).

There are so many rhinovirus serotypes that immunologic diagnosis is impractical, as well as not being of clinical value. In the past, culture has only infrequently been requested because rhinovirus infections are uncomfortable, but almost never life-threatening, and there is no treatment. Some of the newer multiplex respiratory viral assays include rhinovirus or a combined rhinovirus/enterovirus combination result. These may be useful in immunocompromised hosts, wherein infections with even the usual "nuisance" viruses could contribute to increased overall morbidity.

The classical enteroviruses are polioviruses 1 through 3, coxsackieviruses A and B, and echoviruses.[359] The Coxsackie group received its name from a small town in Upstate New York where the first isolates were recovered. "Echo" stands for *e*nteric *c*ytopathic *h*uman *o*rphan, a name applied before the pathogenic potential of the viruses was appreciated. Subsequently, other members of the genus have been recognized and designated enteroviruses 68 through 71. A thorough molecular assessment, however, has changed this taxonomy.[290] The enteroviruses are now separated into four species, Enterovirus A through D, each of which contains numerous serotypes. This group taxonomically also contains the rhinoviruses. Enteroviruses can be isolated from 40% to 80% of patients with "aseptic" meningitis.[84]

1517

Many more instances of sporadic and epidemic aseptic meningitis are probably caused

by enteroviruses, based on the finding that the epidemic curve for all cases of aseptic meningitis parallels exactly the curve for cases from which enteroviruses have been isolated. This is becoming clearer, as molecular diagnostic methods are more commonly being employed. The peak incidence of disease is in the summer and early fall.

The enteroviruses, especially coxsackievirus B, also produce myocarditis, pericarditis, and epidemic pleurodynia. An association of these viruses with cardiomyopathy, a noninflammatory disorder of cardiac muscle, also exists.[456] Coxsackievirus A causes herpangina and hand-foot-and-mouth disease. The enteroviruses also produce febrile disease with rash, which is usually maculopapular but rarely can be vesicular. Enterovirus 70 causes epidemic hemorrhagic conjunctivitis and enterovirus 71 produces central nervous system (CNS) infection, including a polio-like paralysis. Most recently, Enterovirus D68 caused significant epidemics in the 2014 to 15 respiratory viral season. This virus produces respiratory infections that range from mild to severe and life-threatening (www.cdc.gov/non-polio-enterovirus/about/ev-d68.html).

Enteroviral infection is most common in infants and young children. Paradoxically, paralytic poliovirus disease is most prevalent in young adults. The spread of enteroviruses is facilitated by poor hygiene and sanitation, and by crowding. In populations among which virus spreads actively (e.g., low socioeconomic groups), infection occurs at an early age and paralytic disease is infrequent. Persons in high socioeconomic groups escape infection as infants and are more likely to experience paralysis after infection as a teenager. A similar phenomenon has been documented with varicella-zoster virus, Epstein–Barr virus (EBV), and rubella virus. Fortunately, paralytic disease was almost entirely caused by virulent poliovirus serotypes and has been virtually eliminated by immunization in most countries. Wild-type poliovirus has now been eradicated from much of the world; the World Health Organization (WHO) reports that the world has never been better positioned to eradicate polio.[65,497] Key areas wherein diseases transmission remains include Nigeria, Central Africa, and the Horn of Africa, wherein the outbreaks have occurred, as well as Pakistan and Afghanistan. Paralytic disease may be caused by traditional coxsackieviruses and enteroviruses, but only very rarely. The production of paralytic disease by enterovirus 71 has been noted.

The pathogenesis of most enterovirus infections includes primary infection of the respiratory or gastrointestinal tracts followed by viremia and infection of a distant target organ, such as skin, heart, or meninges. The inactivated (Salk) poliovirus vaccine elicits neutralizing serum antibodies, but not mucosal immunity. The vaccine works because the serum antibodies block the viremic spread to the meninges. The inability of the Salk vaccine to prevent mild gastrointestinal infection is not a serious problem for the individual patient, although it does allow continued circulation of the

virulent strain.

In recent years, most infections of paralytic poliomyelitis in developed countries have been caused by the attenuated (Sabin) vaccine strains. Consequently, inactivated (Salk) poliovirus vaccines are once again recommended for use in the United States. Up-to-date information concerning polio vaccination can be found on the CDC website (http://www.cdc.gov/vaccines/vpd-vac/polio/vacc-in-short.htm).

The symptoms of most enterovirus infections are produced by direct viral cytopathic effect on the target organ. Meningoencephalitis is accompanied by productive infection of the CNS by the actively replicating virus. In contrast, the clinical syndrome of myocarditis is caused by an immunologic reaction to enterovirus-infected cardiac tissue. By the time the patient becomes symptomatic, the virus has usually been eliminated from the heart.

It is clear from the pathogenesis of enteroviral infection that the culture or molecular detection of virus from patients with aseptic meningitis (i.e., productive infection) makes sense, but the similar testing of patients with myocarditis (immunopathologic disease) is unlikely to yield a viral isolate or positive result.

The human *parechovirus* is another member of the *Picornaviridae* that has been discovered and the pathogenicity of which continues to be described.[441] This virus has been associated with diarrhea, sepsis, hepatitis, and most importantly meningitis/encephalitis, which is similar to that caused by enteroviruses.[30,142] Molecular methods, which are necessary to detect this virus in a timely manner, are available from major reference laboratories.

Rhabdoviruses

Many other important RNA viruses have been described, some of which cause highly lethal infections. These viruses are primarily tropical and are therefore less likely to be encountered by clinical laboratories than are the picornaviruses and the myxoviruses. Among these are the rhabdoviruses, including the agent of rabies, which is important worldwide.

The diagnosis of rabies is made by detection of viral antigen or viral nucleic acids in clinical specimens from animals or humans. The culture of rabies virus is infrequently performed because of the simplicity, accuracy, and speed of direct immunofluorescence. This historical scourge is endemic in wild animals in the United States but is extremely uncommon in humans. Human exposure continues, however, from hunting dogs exposed to infected wild animals, from infected bats, and from domestic animals.[353] Although bats may be insectivorous and the contact may be only casual, these animals remain an important reservoir for the virus. In some instances, the only recognized contact was finding a bat in a bedroom in the absence of a recognized bite. In other instances, it may be impossible to identify any source for human rabies. Not uncommonly, the diagnosis is not suspected until autopsy.

Great anxiety is caused by possible exposures because of the lethality of the infection. The cost of preventing human disease can be enormous, as was shown in New Hampshire when a large number of individuals were potentially exposed to a rabid kitten in a pet store.[59] The estimated cost for epidemiologic investigation and prophylaxis was $1.5 million. Ongoing epizootic disease in raccoons in the eastern United States is of particular concern because of the frequency with which these aggressive animals invade human habitations. The molecular structure of rabies strains reflects their animal host. It is now possible to identify the likely source of a viral isolate from the nucleic acid composition of the virus.

1518

Unfortunately, rabies has been added to the list of transplant-transmitted infections.[438,439] In 2004, encephalitis, which was eventually determined to be caused by the rabies virus, occurred in three organ recipients (i.e., one liver and two kidney recipients). The donor, who died of complications from a subarachnoid hemorrhage, was not suspected of having an infectious disease, and rabies is not among the viruses for which routine screening is performed prior to organ donation. It was only during the subsequent investigation that friends of the donor recalled that he had been bitten by a bat. The subsequent investigation and an autopsy review revealed a fourth patient, also a recipient of the infected liver tissue, who also died of the disease. In addition to this unfortunate incident, there was also a case of inadvertent surgical transmission of rabies as a result of a corneal transplantation reported.[234]

Arenaviruses

The arenaviruses are a family of RNA viruses that share fascinating biologic characteristics.[42] Their natural host is a variety of rodents, which are persistently infected without an effective host response or symptomatic disease. Infectious virus is excreted in the urine, which is the source of human infection. Those at risk of infection are, therefore, individuals who come in contact with infected rodent excreta, either in their homes or at work in the fields. Person-to-person transmission occurs regularly only with Lassa virus, usually in healthcare workers who have been exposed to infected body fluids, especially at autopsy. Several of the hemorrhagic fever viruses appear to have been transmitted to sexual partners by convalescent men. The infected patient does not pose a significant risk to individuals with casual contact. Laboratory infections have been uncommon, but may occur (e.g., a laboratory worker was infected with Sabia virus).[56] The sources of infection have been aerosolization of culture fluids and probably rodent urine. Epidemics of lymphocytic choriomeningitis (LCM) virus have occurred among laboratory workers who worked with hamsters and

among individuals who owned hamsters as pets.[186] The major human pathogens, the geographic distribution, rodent reservoir, clinical disease, and date of discovery are summarized in Table 23-3.

LCM virus was discovered during investigation of the St. Louis encephalitis virus epidemic in 1933. It was soon recognized that the virus caused aseptic meningitis in humans. The frequency of infection is probably underestimated because clinicians do not suspect the infection and diagnostic tools are not readily available. Investigators found antibody to LCM virus in 5.1% of healthy women in Birmingham, Alabama.[445] Junin virus was the first recognized arenavirus cause of hemorrhagic fever, Argentinian hemorrhagic fever, in the pampas region. The mysteries of the epidemiology were unraveled a few years later by Karl Johnson et al. during investigation of an outbreak of Bolivian hemorrhagic fever in the Beni province, caused by Machupo virus.[249] Further notoriety for the viruses followed the recognition of severe hemorrhagic disease in several West African countries, caused by Lassa virus. Other additions to this group come from South America: Guanarito virus in Venezuela and Sabia virus in Brazil. The old viruses remain an important cause of disease, as demonstrated by the outbreak of Bolivian hemorrhagic fever in 1994 in the provinces of El Beni and Santa Cruz.[57]

The arenaviruses have a distinctive morphology (Table 23-1) that led to the recognition of the group.[345] They are roughly spherical, enveloped particles with prominent ribosome-like structures in the center. The name of the group derives from the Latin word *arenosus* (sandy), which was suggested by the internal particles. The original proposal, arenoviruses, was subsequently modified to arenaviruses to avoid confusion with adenoviruses.

Filoviruses

For many years, the only known member of this group was Marburg virus, which caused a mysterious, fatal illness among monkey handlers in a laboratory in Marburg, Germany in 1967.[405] The source of the virus was African green monkeys, but attempts to identify the agent in freshly caught monkeys

TABLE 23-3 Characteristics of Arenaviruses Pathogenic for Humans

Virus	Geographic Distribution	Rodent Host	Human Disease	Fatality Rate	Year of Discovery
Lymphocytic choromeningitis virus (LCM)	Europe, North and South America	*Mus domesticus; Mus musculus*	Aseptic meningitis	<1%	1939
Junin virus	Argentina	*Calomys musculinus*	Hemorrhagic fever	15%–30%	1958
Machupo virus	Bolivia	*Calomys callosus*	Hemorrhagic fever	25%	1963
Lassa virus	West Africa	*Mastomys* spp.	Hemorrhagic fever	15%	1969
Guanarito virus	Venezuela	*Zygodontomys brevicauda; Sigmodon alsoni*	Hemorrhagic fever	25%	1990
Sabia virus	Brazil	Unknown	Hemorrhagic fever	Too few cases to determine	1990
White water arroyo virus	Southwestern United States	*Neotoma albicula*	Hemorrhagic Fever	Several cases presumptively identified	1999
Lujo virus	Southern Africa	Unknown	Hemorrhagic Fever	80%	2008

1519

in Africa were unsuccessful. Over the next decade, there were few isolations of the virus, which remained a curiosity, albeit a lethal one. In 1977, a new virus, designated Ebola virus, was isolated from simultaneous outbreaks of disease in Zaire and Sudan. The outbreaks shared epidemiologic and clinical characteristics, and the viruses were found to be closely related, although antigenically distinct. The disease was characterized by high fever, shock, involvement of multiple organ systems, and diffuse hemorrhage. The mortality rate for Marburg virus was 25%; for Ebola–Sudan, 50%, and for Ebola–Zaire, 90%. As with Marburg, the source of the infection was unknown, but transmission was clearly associated with exposure to blood and body fluids of infected patients. The medical staffs of some of the small mission hospitals were decimated by the mysterious disease.

The two epidemics in remote areas of Sudan and Zaire caused alarm in public health and infectious disease circles, but did not make an impact on the general public. That situation changed dramatically when a large outbreak occurred in 1995 in Kikwit, Nigeria. More than 300 cases occurred over a short period, approximately one-third of which were in healthcare workers, and the fatality rate was approximately 80%. The epidemic was eventually controlled by introducing strict barrier precautions to prevent families and healthcare workers from having contact with secretions of infected patients. The source of this extensive epidemic was not clear.

A third strain of Ebola virus was identified in the Ivory Coast in 1994. Conjecture about the source in nature of Ebola virus had focused on monkeys because of the simian origins of Marburg virus, but no hard evidence had been found to support the hypothesis. A strain of Ebola virus most closely related to the Zaire type was isolated from the blood of a researcher, who probably acquired the infection while performing a necropsy on an infected chimpanzee. The highly lethal epidemic among chimpanzees was the first demonstration of natural infection in wild animals. Grooming and other

close contact was not a risk factor for acquiring infection by a chimpanzee, but consumption of meat was a risk.[150] The high mortality rate among the chimpanzees makes it unlikely that these primates are the natural reservoir of infection.

Additional evidence for a simian source of Ebola virus comes from an epidemic of lethal infection among cynomolgus monkeys in two animal holding facilities—the first in Reston, Virginia, and the second in Texas. In both instances, the animals had been imported from the Philippines; the virus was antigenically distinct from the strains isolated in Zaire, Sudan, and the Ivory Coast. Only five cases of human infection with the Reston strain of Ebola virus have been documented, all of which were asymptomatic. There was evidence of transmission of infection from animal to animal by aerosols, a terrifying epidemiologic characteristic that has fortunately been missing from the human epidemics. Data indicating epidemic disease among captive cynomolgus monkeys in the Philippines before export have also been reported. The fatality rate among infected monkeys was 82%, and infection was more likely to develop in monkeys held in a group cage than those held in individual cages.

The Ebola epidemic of 2014 to 2016 continues to rage in West Africa at the time of writing of this chapter, but fortunately due to extensive control measures and heroic efforts by many appears to be coming under control. As of June 09, 2015, 27,273 cases of Ebola virus disease were documented, with 11,173 deaths.[70] This equates to a death rate of 41%. This epidemic has been centered in the West African countries of Sierra Leone, Guinea, and Liberia. Transmission to countries outside the endemic areas has occurred largely via air travel; infected patients have been reported from the United States, the United Kingdom, Mali, and Italy.[70]

The filoviruses are RNA viruses with a characteristic ultrastructure (Table 23-1) and a distinctive filamentous morphology that gives the family its name. The two viruses, Marburg and Ebola, can be distinguished by ultrastructural morphology, and the types of Ebola virus are antigenically distinct.

These Biosafety Level 4 agents are unlikely to be encountered by clinical diagnostic laboratories. However, infection and specimen control measures have undergone review, given the importation of a few patients infected with or exposed to the Ebola virus in the current epidemic.[70] Interested readers can consult several excellent reviews of the biology of these fascinating viruses and the diseases they produce.[369,405]

Togaviruses and Flaviviruses

The *Togaviridae* and *Flaviviridae* now include many of the viruses that were previously known as arboviruses (arthropod-borne viruses), as well as some other, non–arthropod-borne viruses.[70] These groups are single-stranded RNA viruses with a lipid envelope.[411,413] The togaviruses were named for their lipid "toga" that surrounds

the virus. These biologically diverse agents have a complex ecology. They usually infect small mammals or birds and are transmitted from animal to animal by tick or mosquito vectors. Many of these viruses are also maintained within the arthropod lineage by transovarial passage from the gravid female to the larva. Humans are accidental hosts when they are inadvertently infected instead of the usual animal reservoirs.

Three members of these groups do not fit the traditional profile and will be discussed in their traditional context. These are the rubella virus, a togavirus, and hepatitis C and hepatitis E virus, which are flaviviruses.

The other division within the *Togaviridae*, the alphaviruses, contains the agents of eastern equine encephalitis, western equine encephalitis, and Venezuelan encephalitis, as well as the chikungunya virus, which is an emerging pathogen. The flaviviruses include the agents of St. Louis encephalitis, dengue (breakbone fever), yellow fever, and West Nile fever.

Small numbers of human infections with eastern equine encephalitis and western equine encephalitis infections occur each year. Human disease may be presaged by an increased incidence of illness in horses. Epidemics of St. Louis encephalitis occur approximately every 10 years in the southern part of the United States, especially in Texas, in the Gulf Coast states, and in Florida. The reservoir for St. Louis encephalitis virus is birds, and the mosquito vectors vary with the geographic location. Disease is most severe in the elderly, and infections tend to be concentrated in heavily wooded neighborhoods with poor screening of homes.

Dengue fever is prevalent in the Caribbean and in Southeast Asia. Imported cases are seen in the United States with

increasing frequency, and indigenous transmission of the virus in the continental United States has been reported occasionally, most commonly in Texas. A most unusual route of entry into the United States was uncovered when infected mosquitoes were found in stagnant water that had accumulated in tires imported from Southeast Asia. Uncomplicated dengue infection is an undifferentiated febrile disease, sometimes accompanied by a rash and arthralgias or arthritis. The differential diagnosis includes other viral infections, such as rubella. There are four distinct serotypes of dengue virus. As hypothesized by Halstead, serial infections with different serotypes trigger immunopathologic mechanisms that produce the dengue hemorrhagic fever syndrome.[199,308] Formerly limited to Southeast Asia, the lethal hemorrhagic form of the disease has occurred in the Caribbean with increasing frequency and is currently on the rise.

The West Nile virus produces a spectrum of neurologic diseases, including

encephalitis, meningitis, and a poliomyelitis-like syndrome.[417] Until 1999, it had produced localized infections in Africa, the Middle East, and Eastern Europe. In that year, it was discovered in New York City and has subsequently spread throughout the United States. The first patient with encephalitis was thought to have the disease caused by St. Louis encephalitis virus, which is closely related immunologically to the West Nile virus. These two viruses share other characteristics, including having birds as a frequent host (i.e., a characteristic that may be related to the rapid spread of the virus). The importation and spread of the West Nile virus demonstrates how quickly an infectious agent can go from exotic trivia to everyday relevance.[371]

The Zika virus is a flavivirus that is thought to be responsible for the wide-spread epidemic of microcephaly in Brazil and other tropical locales.

Chikungunya virus may accurately be described as an emerging pathogen, which is an often overused term. This is justified by the emergence of a genetic variant which increases the replicative capacity of the virus within the mosquito, as well as other characteristics. Chikungunya virus, as noted above, is a togavirus. Disease is transmitted by the *Aedes aegypti* and *Aedes albopictus* mosquitoes, both of which also transmit the dengue virus. Chikungunya causes high fevers, similar to that produced in dengue, but is more likely to cause severe polyarthralgias. The incubation is usually 3 to 7 days, but may be as short as 1 day or as long as 12 days. The acute infection usually resolves within 10 days; occasionally, complications such as nephritis, meningoencephalitis, and Guillain–Barré syndrome may occur. There is no specific treatment, but supportive care may be needed. Establishing a definitive diagnosis is important as symptoms overlap with dengue, and nonsteroidal anti-inflammatory agents, which may be of use in patients with chikungunya, should not be used in patients with dengue. This and additional information concerning the chikungunya virus is available through the CDC (www.cdc.gov/chikungunya/).

Bunyaviruses

The *Bunyaviridae* are a large and diverse group of viruses that are transmitted to humans by arthropod vectors, principally ticks and mosquitoes, as well as from the excreta of infected rodents. There are four medically important genera: (1) Bunyavirus, including the California encephalitis virus group; (2) Nairovirus, including Congo-Crimean hemorrhagic fever virus; (3) Phlebovirus, including Rift Valley fever virus and sandfly fever virus; and (4) Hantavirus, including the agents of Korean hemorrhagic fever, nephropathia epidemica, and hantavirus pulmonary syndrome.[70,352]

California Encephalitis Viruses. One of the most important of the bunyavirus groups in the United States is the California encephalitis group of viruses. Despite the name "California," these viruses produce disease most commonly in the midwestern and

north central states. The California encephalitis virus group commonly produces aseptic meningitis, a disease that occurs in the summer and is clinically indistinguishable from enteroviral disease.[47,352] Infections by the California encephalitis virus itself are uncommon; the LaCrosse virus is the most common human pathogen in the group. Most patients recover uneventfully from their infection.

Hantaviruses. The hantaviruses have expanded from exotic infectious agents to endemic threats in the United States.[413] The uniform characteristics of the group include asymptomatic, persistent infection of a rodent host, transmission to humans through infected rodent urine and excreta, and infection of the vascular endothelium. The status of the viruses, their rodent hosts, and associated clinical diseases are summarized in Table 23-4.

Severe hemorrhagic fever was recognized among American soldiers during the Korean War. Shock and renal failure, which were prominent symptoms, provided the descriptive name hemorrhagic fever with renal symptoms (HFRS). Fever, thrombocytopenia, and renal failure comprise the classical clinical picture of this disease. In the clinical setting, the return of platelets presages restoration of normal renal function. Shock and multiorgan failure, simulating bacterial sepsis, characterize the most severe cases. Less common manifestations include retroperitoneal hemorrhage and pulmonary edema. Some patients experience undifferentiated febrile illness with normal renal function. A clinical syndrome of severe hepatic disease has been described in Greece, where the prevalent strains resemble the virus associated with infections in Korea.

Subsequent to the documentation of the disease in Korea, it was recognized that this severe clinical syndrome occurred in the eastern Soviet Union and Manchuria. The etiologic agent was not isolated until 1982, when Hantaan virus, which was named after a Korean river where epidemic disease had occurred, was isolated. This virus produces asymptomatic, persistent infection in its rodent host, *Apodemus agrarius*. Subsequently, a second, related agent, Seoul virus, which produces less severe infection, was isolated. The rodent hosts of Seoul virus are urban rats, *Rattus norvegicus* and *Rattus rattus*. Seoul virus has been found in laboratory rats and has produced infection in laboratory workers. There are no documented cases of Hantaan virus infection in the United States, but cases of Seoul virus-induced HFRS have been documented serologically in Baltimore. The rat-associated hantaviruses in the United States have been associated with hypertensive renal disease, but not with other chronic renal diseases.[171] Although hypertensive renal disease is not usually associated with infectious agents, the lesson of *Helicobacter pylori* and gastritis should caution us against dismissing the association out of hand.

TABLE 23-4 Selected Hantaviruses: Hosts and Clinical Diseases

Virus	Geographic Distribution	Rodent Host	Clinical Disease
Hantaan	Far East	*Apodemus agrarius* (Eastern form)	Hemorrhagic fever with renal syndrome (HFRS)
Seoul	Worldwide	*Rattus rattus; Rattus norvegicus* (urban rats)	Mild HFRS
Dobrava	Balkans	*Apodemus flavicollis*	HFRS
Puumala	Scandinavia; Europe	*Clethrionomys glariolus* (vole)	Nephropathia endemica
Sin nombre	Southwestern United States	*Peromyscus maniculatus* (deer mouse)	Hantavirus pulmonary syndrome (HPS)
Bayou	Louisiana	*Oligoryzomys palustris* (rice rat)	HPS
Black Creek Canal	Florida	*Sigmodon hispidus* (cotton rat)	Unknown
New York	Northeastern United States	*Peromyscus leucopus* (white-footed mouse)	HPS
Monongahela	Eastern United States	*Peromyscus maniculatus nubiterrae* (forest form of deer mouse)	HPS
Andes	South and Central America	*Oligoryzomys longicaudatus*	HPS

For information on other viruses, consult reference 441.

A milder version of this infection, known as nephropathia epidemica, is produced by Puumala virus and occurs in Scandinavia (Table 23-4).[413] The virus produces asymptomatic infections in voles; in humans, it is an acute febrile disease with lower back pain and polyuria but with mild or no hemorrhagic manifestations and without shock. Patients recover without sequelae. The symptoms are frequently nonspecific, and the clinical diagnosis was correct in only 28% of cases in one Finnish study.

In 1993, the spotlight focused on hantaviruses when an outbreak of severe respiratory disease occurred in the Four Corners area of the southwestern United States.[370,413] The patients had a prodromal syndrome of fever, myalgia, cough or dyspnea, gastrointestinal symptoms, and headache, which progressed rapidly to irreversible pulmonary edema. With amazing rapidity, the causative agent was recognized as a new member of the hantavirus genus, named Sin Nombre virus (initially named Four Corners virus). The rodent host of Sin Nombre virus is the deer mouse, *Peromyscus maniculatus*. It is hypothesized that heavy rains increased food sources during that or the prior year, causing a great increase in the number of rodents, increasing the frequency of contact between humans and mice, and altering the epidemiology from sporadic, endemic disease to epidemic infection. There is no evidence of human-to-human transmission of hantavirus pulmonary syndrome. Retrospective diagnosis of cases of infection with Sin Nombre or a related virus dating back as far as 1978 has been made by immunoperoxidase staining of archived paraffin-embedded tissue.[505] All of the 12 infections identified retrospectively had occurred west of the Mississippi River, most in the far West of the United States.

Subsequent to the discovery of Sin Nombre virus, other related hantaviruses have been identified in the United States, including Louisiana, Florida, and the eastern United States (Table 23-4). The frequency of hantavirus infection outside of the

endemic areas is unknown.

The lung is the target organ pathologically as well as clinically.[370] Edema and fibrin deposition with the deposition of hyaline membranes in the airspaces are accompanied by an interstitial mononuclear exudate. Large immunoblastic cells infiltrate many organs. The hematologic findings include left-shifted neutrophilic leukocytosis, thrombocytopenia, circulating immunoblasts, and in severe cases, hemoconcentration. Viral antigen deposition is concentrated in endothelial cells, particularly in the pulmonary vasculature, and virus particles may be seen in those cells.[504] Hanta viral antigens are also found in follicular dendritic cells, macrophages, and lymphocytes.

Human Gastroenteritis Viruses

Viral gastroenteritis is second only to viral respiratory disease as a cause of virus-associated morbidity in the United States. The incidence of viral gastroenteritis has been estimated at approximately 11% per year.[114] Mortality is rare. Much has been learned about the etiologic agents of disease, but still only approximately 50% of infectious gastroenteritis can be assigned an etiology. Most of these agents have been identified initially by immunoelectron microscopy, but more commonly now by advanced molecular techniques, including NGS. In immunoelectron microscopy, immune serum is mixed with a virus suspension or a stool specimen. Clumping of the submicroscopic viral particles can be observed when negatively stained preparations are examined with the electron microscope. Most of these agents cannot be cultivated easily. Therefore, details of their composition are either not known or are being described; for convenience, they will be discussed with the most common pathogen, the rotaviruses.

The agents of viral gastroenteritis can be divided into four groups. The classification is fluid because of emerging evidence about some of the agents:

Rotaviruses
Caliciviruses
    Norwalk virus (i.e., Norovirus)
    Sapporo virus
Astroviruses
Enteric adenoviruses

1522

The frequency of these viruses is summarized in Table 23-5.[195] The data come from a study of fecal specimens submitted to a health maintenance organization in Georgia. The detection of the viruses in this study was entirely by molecular methods

and was performed at the CDC.

Many aspects of these viral gastrointestinal infections are similar. They cause acute vomiting or diarrhea, which is usually mild, self-limited, and noninflammatory. Bloody diarrhea does not occur. Microscopic analysis of biopsies from human volunteers who have ingested these infectious agents show blunting of intestinal villi and mild inflammatory changes in the submucosa, changes that are indicative of small-bowel malabsorption. Damaged cells at the tips of the villi are replaced by cells from the bases of the crypts over 5 to 10 days following the injury. Diarrhea that lasts more than 7 to 10 days is unlikely to be viral. Treatment is by replacement of lost fluid and electrolytes, usually caused by vomiting. Unfortunately immunity appears to be only partial.[114]

Of note is the absence of conventional intestinal viruses from the list of pathogens. There is little evidence that enteroviruses or respiratory adenoviruses cause gastrointestinal disease.

Rotaviruses. Rotaviruses are the most important human pathogens in the *Reoviridae*. The reoviruses themselves are not associated with human disease, but they have been useful in the study of molecular mechanisms of viral pathogenesis. "Reo" stands for *r*espiratory-*e*nteric *o*rphan, from the source of virus isolates and the lack of association with clinical disease. Rotavirus got its name from the wheel-like appearance of the virion in electron micrographs (Table 23-1).

The rotaviruses contain both human and animal pathogens, but animal rotaviruses do not infect humans. Human rotaviruses have been classified serologically, with most pathogenic human strains in the United States and Europe falling into group A. Human rotavirus is a common cause of gastroenteritis in infants and young children.[258] The clinical presentation is varied, but vomiting and dehydration are prominent features in comparison to gastroenteritis produced by other viruses. The combination of vomiting and a seasonal occurrence in the winter months has led investigators to name the condition "winter vomiting disease." The frequency and specificity of respiratory symptoms in rotavirus infection are controversial. It is possible that the prevalence of vomiting in rotavirus infection reflects the age of the patient rather than a property of the virus, because Norwalk virus produces significantly more vomiting in infants than in adults. Uhnoo and Svensson studied the comparative features of group A, subgroups 1 and 2 in Swedish infants.[459] Patients with subgroup 1 strains developed fever up to 39°C significantly more often than those with subgroup 2, but infants who had subgroup 2 infections were sicker, hospitalized more frequently, and more likely to have respiratory symptoms. The frequency of diarrhea and vomiting in the two groups was similar.

TABLE 23-5 Estimated Burden (Percentage) of Acute Gastroenteritis Caused by

Viruses in the Community

Any Virus	26.80%
Norovirus	15.90%
Astrovirus	4.40%
Rotavirus	2.1%[a]
Sapovirus	2.20%
Adenovirus	2.40%
Bacteria	4.10%
Parasites	1.00%
Unidentified	68.30%

[a] Incidence varies by age. The numbers given are for all age groups. In the referenced study, rotavirus was more common than norovirus in the 5- to 15-year age group.
Adapted from reference 195.

Chronic rotavirus infection may occur in immunosuppressed children. In adults, rotavirus infection is usually asymptomatic. These viruses are notorious causes of nosocomial infection, including epidemics, in children.

Caliciviruses. These viruses were originally identified by electron microscopy and characterized descriptively as small, round-structured viruses.[201] There are two major groups of viruses within the *Caliciviridae*: the Norovirus for which the species is the Norwalk virus and the Sapovirus for which the species is the Sapporo virus.

Norwalk Virus. This agent, originally termed the Norwalk agent of gastroenteritis, was recognized as a 27-nm particle in stool specimens from an outbreak of community gastroenteritis in Norwalk, Ohio. Subsequently, similar RNA viruses were isolated from other epidemics. Molecular analysis has revealed that there are two main clusters.[9] These agents are also referred to as noroviruses.[261]

Norwalk viruses have frequently produced epidemics of disease and also cause sporadic infection.[201] These viruses produce infection and active disease in persons of all ages, in contrast to most of the other viral agents, which produce symptomatic disease predominantly in infants and young children. They are the predominant cause of infectious gastroenteritis in adults. The Norwalk-like agents have been associated

with contaminated food and water and are one of the possibilities to consider when a patient has recently ingested shellfish and develops gastroenteritis. Epidemic disease has been described in venues that vary from football games to cruise ships or nursing homes.

Sapporo Virus. These agents resemble the Norwalk viruses morphologically, but differ immunologically and genetically. This virus, like the Norwalk virus, is named for the location of its discovery, Sapporo, Japan, where in 1977 it was discovered as the cause of gastroenteritis in infants. It may cause outbreaks of infantile gastroenteritis; although some food-borne transmission has occurred, this is not the usual route of spread.[81]

Astroviruses. The astroviruses also contain RNA and have been difficult to cultivate in vitro, although a few strains have been successfully grown.[320] They derive their name from their star-shaped ultrastructural appearance. Astroviruses,

1523

first identified in 1975 as a cause of diarrhea in children, are thought by some to be second only to rotavirus as a cause of gastroenteritis in children.[105] These viruses are also an important cause of infection in a wide variety of animals.[105] They have produced epidemic disease in young children, on pediatric wards, in day care centers, and in nursing homes. Concurrent infection with astroviruses and caliciviruses has been described.

Enteric Adenoviruses. A causative association of the classical adenovirus serotypes with diarrheal disease could not be established, but "noncultivable" serotypes were demonstrated by immunoelectron microscopy. Adenovirus types 40 and 41, which do not grow well in the usual tissue culture cells, are intestinal pathogens.[245] These enteric adenoviruses are the second most common cause of viral gastroenteritis in infants and have been associated with intussusception.[191] They produce sporadic infection, although epidemics have been described. Most patients are less than 2 years of age.

Coronaviruses

The classical coronaviruses are causes of the common cold.[225] Most require use of organ culture for reliable isolation and are unlikely to be encountered in the clinical laboratory.

A dramatic addition to the genus was recognized in 2003 when a novel coronavirus was identified as the cause of a mysterious new respiratory illness in China. This virus

is thought to have been possibly contracted initially from Himalayan masked palm civet cats, but it has also been isolated from other animals, such as Chinese ferret badgers, among others.[190] This infection was called SARS. In contrast to previously recognized coronavirus infections, SARS is characterized by lower respiratory infection that often required admission to an intensive care unit and may be fatal.[33,82]

The incubation period for SARS ranges from 2 to 10 days, with the average between 4 and 6 days.[425] There is no convincing evidence of transmission prior to the development of symptoms or after 10 days following the resolution of fever. There may be an influenza-like prodromal illness that includes fever, myalgias, and headache. As radiologic evidence of pneumonia develops and the patient's condition worsens, additional symptoms, such as chills, dyspnea, and cough, develop. Both leucopenia and lymphopenia are seen. Patients appear most infectious at about day 10 of the illness. Interestingly, watery diarrhea has also been described as a prominent symptom of patients with SARS.[495] Transmission is predominantly via respiratory droplets, but the fomites and the aerosolization of other body fluids or stool can transmit the disease. If the patient survives, then the disease will begin to resolve around the third week of illness. Between 6% and 20% of surviving patients had some type of pulmonary impairment. The virus, curiously, only infrequently infected children, and those infected had mild disease.

Another troubling characteristic of this infection is the propensity for infection of hospital personnel, particularly those who have close patient contact.[219] More that 40% of the infections in Canada and Singapore were nosocomially acquired, which demonstrates the need for strict adherence to respiratory infection prevention precautions for patients with respiratory tract infections.[498] With amazing rapidity and with the collaboration of scientists worldwide using electron microscopy and advanced molecular techniques, the cause of the infection was identified as a novel coronavirus. The significance of an hMPV that was isolated from some patients is unclear, but it likely represented only a coinfecting pathogen.[75] It is of interest that a conventional coronavirus, OC243, recently produced an outbreak of respiratory infections that included pneumonia.

There were 8,096 documented cases of SARS from 26 different countries by the cessation of the epidemic.[425] There was a case fatality rate of 10% during this first pandemic of the 21st century.

Although the severe acute respiratory syndrome coronavirus (SARS-CoV) has retreated into its zoologic niche, another coronavirus, the Middle East respiratory syndrome coronavirus (MERS-CoV), has emerged and is currently (i.e., at the time of this writing) causing infections that are of concern throughout the world.[387] This novel coronavirus, which is zoologically associated with camels, was first described in Saudi Arabia in 2012.[394] It is endemic to the countries around the Arabian Peninsula. A total

of 1,026 infections have been documented as of February 2015, with a 36.7% death rate (i.e., 376 deaths). This infection, like SARS, has spread to distant parts of the world secondary to the ease of air travel. The MERS-CoV has spread to 19 countries and there is an ongoing epidemic in South Korea at the time of this writing.[394]

Currently, there has been a slight male preponderance and the median age of infected individuals is 50 years. These numbers may change, if more asymptomatic or subclinical infections are discovered. There is a high likelihood of transmission of the virus to healthcare providers, unless respiratory precautions are strictly followed. Eighteen percent of infections have been in healthcare workers to date.[496]

Fever, cough, and dyspnea characterize MERS, but patients may also have chills, myalgia, nausea, vomiting, abdominal pain, and diarrhea. As with SARS, patients may develop leukopenia and lymphopenia.[394] Both thrombocytopenia and thrombocytosis have been described, as well as elevated liver enzymes.[394]

Coltiviruses

This group includes the virus of Colorado tick fever, an undifferentiated febrile illness that is usually mild and self-limited, but may on occasion be severe or even fatal.[401] It is transmitted by the bite of ticks. Previously, this virus was included in the Orbivirus group, which is composed of animal pathogens. The orbiviruses are members of the family *Reoviridae*, along with rotaviruses.

Retroviruses

The retroviruses are RNA viruses; they were so named because they contain an enzyme that transcribes RNA into DNA, a reversal of the normal sequence in which DNA is transcribed into RNA (i.e., retro). For many years, these viruses were known to cause tumors in animals. In the 1970s, two viruses that caused T-cell lymphocytic lymphomas in humans were recognized and classified as human T-cell lymphoma virus (HTLV-I and HTLV-II). This discovery

was extremely important biologically, but the tumors are uncommon.[175]

The retrovirus group assumed sudden prominence and increased notoriety in 1983 when a third human retrovirus was identified as the cause of the acquired immunodeficiency syndrome (AIDS).[165] AIDS had been recognized clinically several years earlier when opportunistic infections were detected in young men who were homosexual, bisexual, or drug addicts, but did not have conventional risk factors for *Pneumocystis* pneumonia or candidiasis.

Similar viruses were isolated in several laboratories and named variously HTLV-III, lymphadenopathy-associated virus (LAV), and AIDS-related virus (ARV). An expert panel settled on the name human immunodeficiency virus (HIV). Although HIV was first isolated in 1983, retrospective analysis of frozen serum and tissue suggested that a similar virus had infected a sexually active teenage boy in St. Louis in 1968.[163] Subsequently, a serologically related virus was isolated and named HIV-2. The distribution of HIV-1 is worldwide, whereas HIV-2 is found predominantly in West Africa, where it also causes AIDS. Patients with HIV-2 infection have been reported in the United States, but most patients have had some connection with West Africa. There are immunologic cross-reactions between HIV-1 and HIV-2, but advanced assays have been designed for resolution. These specific immunoassays must be performed both to distinguish between the two infections and also to detect the type-specific antigens with maximum sensitivity. To complicate matters further, at least one patient had been identified who was infected with both viruses. HIV is a member of the lentivirus (*lenti* = slow) subfamily of the *Retroviridae*. Other viruses in this group produce chronic infections with long periods of clinical latency. Some animal retroviruses also produce immunodeficiency, such as the simian immunodeficiency virus and feline leukemia virus. Infection across species has not been demonstrated.

TABLE 23-6 Key Facts: Global HIV Epidemic

- HIV continues to be a major global public health issue.
- HIV has claimed more than 39 million lives to date.
- Approximately 1.5 million people died from HIV-related causes in 2013.
- There were approximately 35 million people living with HIV at the end of 2013.
- There were approximately 2.1 million new HIV infections in 2013.
- Sub-Saharan Africa remains the most affected region, with 24.7 million people living with HIV in 2013.
- Almost 70% of new infections occur in sub-Saharan Africa.
- Approximately 12.9 million people living with HIV were receiving antiretroviral therapy (ART) globally in 2013.
  - Of these, 11.7 million people were receiving ART in low- and middle-income countries.
  - The 11.7 million people on ART represent 36% of the 32.6 million people living with HIV in low- and middle-income countries.
- The treatment of HIV in children is still poor in low- and middle-income countries.
  - Less than 1 in 4 children living with HIV had access to ART in 2013, compared to over 1 in 3 adults.

In contrast to the other lentiviruses HIV is genetically extremely heterogeneous, to the extent that virtually each isolate is unique (termed a quasi-species). There are, however, genetically related groups, which are in turn divided into clusters or clades. Group M (major) comprises 95% of global isolates and is divided into at least eight clades (A, B, C, D, F, G, H, and J). All clades are represented in Africa; in the United States and Europe, Clade B is the dominant subtype. (It should be noted that genetic clades do not map to distinct viral serotypes.)

Group O (Other) strains, which are found predominantly in West Africa, share less than 50% homology with Group M strains. Group N (non-M or O) viruses are found in Cameroon.

To complicate matters even further, all retroviruses have a propensity for recombination when multiple strains are juxtaposed. It was assumed that patients infected with HIV virus would be resistant to infection with a second strain. Unfortunately, the absence of complete immunity and the frequency of multiple exposures to virus have resulted in infection with several strains, a situation in which recombination can occur.[27]

There is no question that HIV is the most devastating plague of recent epidemics. It has changed our society (i.e., a resource-rich country) and continues to wreak havoc in resource-poor countries, despite international efforts. The advent of effective combination antiretroviral chemotherapy (i.e., highly active antiretroviral therapy) has transformed this infection in many ways into a chronic disease in resource-rich countries that can afford the drugs. Nevertheless, the epidemic continues to spread and in resource-poor countries has enhanced the spread of other infectious diseases, such as tuberculosis. Key facts regarding the global HIV epidemic are summarized in Table 23-6.

The discussion below is a brief attempt to capture some of the most salient features of this multifaceted virus and the diseases it produces. It is a tribute to modern science that an infectious agent was described only 3 years after the first reports of the clinical

syndrome. Without the modern armamentarium of molecular biology and virology, we would still be defenseless against this scourge.

The HIV-1 virion is icosahedral and contains 72 external spikes.[152] It is considerably more complex than HTLV-I and HTLV-II, consonant with its more complicated natural history. The gene products can be divided into three groups. The viral proteins that represent the most important diagnostic antigens are summarized in Table 23-7.

1525

The gp120 envelope protein facilitates entry of HIV-1 virus into the cell.[152] This protein has a remarkable affinity for a complex of receptors on the surface of cells throughout the body. The primary component of the complex, the CD4 receptor, is found on T-helper lymphocytes, macrophages, and Langerhans cells in the skin. The second part of the receptor complex is a chemokine receptor. Viral strains that interact with the CXCR4 receptor are most likely to infect T lymphocytes in vitro; strains that interact with the CCR5 receptor (R5 virus) are associated with macrophage cell lines in vitro. Some viruses which interact with both chemokine co-receptors can infect both lymphocytes and macrophages.

The enhanced susceptibility to HIV infection in patients with genital ulcers or other sexually transmitted diseases may result from the accessibility of CD4+ macrophages and lymphocytes in the inflamed bases of the ulcers and/or other alterations in mucosal immunity.[418]

The most important cells targeted by the virus, however, are the CD4+ T lymphocytes.[103] These "helper" lymphocytes assist in the organization of many cell-mediated inflammatory responses, such as the production of granulomas. Without them, the body is at increased risk for many opportunistic infections. In addition to the T-cell abnormality, defective response of B cells to T-cell-independent antigens has also been documented. Macrophages are very important, because they provide a place for virus to be sequestered even after infected T cells have been destroyed and/or most virus have been killed by antiretroviral therapy.

The initial encounter with HIV-1 virus produces a transient febrile disease, which may be accompanied by lymphadenopathy, pharyngitis, or a diffuse rash.[90] During the earliest phases of acute illness, high levels of circulating virus are present in the absence of specific antibody. It is at this phase that the diagnosis is established through the detection of the p24 antigen or of viral nucleic acids. Antibody develops within several weeks to several months in the natural course of the infection. The detection of these antibodies is the mainstay of diagnosis, as most patients do not present in the very early stages of the disease (i.e., prior to the production of antibodies).

The ensuing subclinical phase of the disease is accompanied by antibody production, circulating p24 antigen, immune complexes, and low levels of circulating

virus. Testing blood products for virus, using molecular amplification technology, has substantially reduced the risk of transfusing infected blood products. During the chronic viremia, repetitive mutations in the viral genome thwart the attempts of the host immune system to eliminate the infection. The onset of clinical illness is associated with an increase in the quantity of virus, both within peripheral-blood mononuclear cells and in plasma.

A wide spectrum of clinical conditions may result after HIV-1 infection. The CDC classification of HIV disease and associated conditions are summarized in Tables 23-8 and 23-9.[56] Certain diseases (Category C in Table 23-9) are highly associated and are termed AIDS-defining conditions.

The infectious complications of HIV infection include a variety of viral, fungal, mycobacterial, bacterial, and parasitic infections. The practice of infectious disease and clinical microbiology has been irrevocably altered by HIV. Numerous previously uncommon or exotic infections have become commonplace in centers that have large numbers of HIV-infected patients. Old rules concerning the seeking of a single pathogen as the cause of a disease must be disregarded when the patient is as severely immunosuppressed as are patients with AIDS or patients with leukemia and/or stem cell transplants. A wide variety of infections are possible, when the host inflammatory response is significantly diminished or absent. What would be "shotgun" microbiology in a normal patient becomes good practice in this group of patients. Integration of clinical, epidemiologic, and laboratory data is needed to decide which laboratory resources must be utilized for an individual patient.

The most common opportunistic infections that afflict patients infected with HIV are among the AIDS-defining conditions that are listed in Table 23-9. Some of the infections are characteristic of a particular phase of the disease. For instance, oral candidiasis is often a presenting feature of the disease. *Pneumocystis jirovecii* pneumonia first occurs when lymphocyte counts are relatively high early in the disease process. *Mycobacterium avium* complex infections tend to occur late in the disease, when the CD4+ lymphocyte count is low. Although infections with cell-associated pathogens (i.e., facultative intracellular organisms) are most closely associated with defects in cellular immunity, bacterial infections for which humoral immunity is an important host defense are also more common in HIV-infected patients. The search for the cause of an opportunistic infection should not

TABLE 23-8 CDC Classification System for HIV-Infected Adults and Adolescents

CD4 Cell Count Categories	*Clinical Categories*		
	A **Asymptomatic, Acute HIV, or PGL**	**B** **Symptomatic Conditions, not A or C**	**C** **AIDS-Indicator Conditions**
≥500 cell/μL	A1	B1	C1
200–499 cells/μL	A2	B2	C2
<20 cells/μL	A3	B3	C3

PGL, persistent generalized lymphadenopathy.
See Table 23-9 for categorical descriptions.
From reference 56.

TABLE 23-9 Symptomatic Conditions (Category B) and AIDS-Indicator Conditions (Category C) Included in the CDC Classification System for HIV-Infected Adults and Adolescents

Category B (Symptomatic Conditions)

These are symptomatic conditions occurring in an HIV-infected person that are (1) attributed to the HIV infection or indicate a defect in cell-mediated immunity, or (2) are considered to have a clinical course or management that is complicated by the HIV infection.

Examples include:

- Bacillary angiomatosis
- Candidiasis, oropharyngeal (thrush)
- Candidiasis, vulvovaginal; persistent, frequent, or poorly responsive to therapy
- Cervical dysplasia (moderate or severe)/carcinoma in situ
- Constitutional symptoms, such as fever (>38.5°C) or diarrhea lasting >1 month
- Hairy leukoplakia, oral
- Herpes zoster (shingles), involving at least two distinct episodes or more than one dermatome
- Idiopathic thrombocytopenic purpura
- Peripheral neuropathy

Category C (AIDS-Indicator Conditions)

Bacterial pneumonia, recurrent (two or more episodes in 1 year)
Candidiasis of bronchi, trachea, or lungs
Candidiasis, esophageal
Cervical cancer, invasive
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month duration)
Cytomegalovirus disease (except liver, spleen, lymph nodes)
Encephalopathy, HIV-related
Herpes simplex: chronic ulcers (>1 month duration); or bronchitis, pneumonitis, or esophagitis
Histoplasmosis, disseminated or extrapulmonary
Cystoisosporiasis, chronic intestinal (>1 month duration)

Kaposi's sarcoma
Lymphoma, Burkitt's, immunoblastic or primary central nervous system
Mycobacterium avium complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
Mycobacterium tuberculosis, pulmonary or extrapulmonary
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis jirovecii pneumonia
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of brain
Wasting syndrome due to HIV

From reference 56.

stop when the first agent is identified because many patients with AIDS have coinfections.

Not all HIV-related diseases are caused by opportunistic infections. HIV itself is cytopathic and produces clinical disease such as encephalitis and AIDS-related dementia. Collapse of the cellular immune system and its surveillance mechanisms leads to neoplastic complications, some of which may be virus-induced. Lymphomas are frequently encountered.[330] A previously unusual neoplasm, Kaposi's sarcoma, is well described in patients with AIDS, often as an early manifestation of the disease. Other manifestations of the disease may have an immunopathologic mechanism, or the mechanisms are unknown. Some infections that might have been predicted to afflict AIDS patients, such as legionellosis and aspergillosis, are relatively uncommon. The cellular immune system undoubtedly contributes to the control of invasive aspergillosis and legionellosis, but other mechanisms, not destroyed by HIV-1, must also be important.

As therapy for HIV infection and for infectious complications of the immunodeficiency has improved, the pattern of infections encountered has changed. An analysis of autopsies from Los Angeles during the period 1982 to 1993 documented a decrease in the number of fatal infections caused by *Pneumocystis jirovecii*, bacterial sepsis, cytomegalovirus (CMV), *Mycobacterium avium* complex, and *Toxoplasma gondii* from 1989 to 1993 compared with 1982 to 1988.[268] This trend has continued in the United States. Over time, institution of prophylaxis for AIDS-related infections and of more effective therapy has significantly diminished the number of deaths in resource-rich countries due to AIDS.[297] Although AIDS-defining conditions remain important, other chronic diseases and complications of antiretroviral therapy have become just as important.

Guidelines for children are included in the standard, whereas recommendations for screening of pregnant women have been published separately[68] (www.cdc.gov/hiv/risk/gender/pregnantwomen/facts/). HIV-1 is excreted in saliva,

milk, semen, and other body fluids. Breast-feeding is not advisable for women with HIV and those taking antiretroviral therapy according to the CDC (www.cdc.gov/breastfeeding/disease).

The most important groups at risk for HIV infection are those who have shared contaminated needles (drug addicts), those who have had sexual intercourse with an infected individual, and neonates of an infected mother. In resource-rich countries, the transmission of the virus through the therapeutic administration of blood products has been largely mitigated by improved donor screening techniques.

At the outset of the epidemic, most of the sexually transmitted infections in the United States and Europe were between homosexual or bisexual men (i.e., presently described as men who have sex with men [MSM]), but heterosexual transmission was soon documented. Heterosexual transmission of HIV-1 virus has been the dominant form of transmission in Africa from the beginning of the epidemic. The risk of transmission of HIV infection from mother to infant and the severity of disease in the infant are directly related to the severity of infection in the mother at the time of delivery.

Therapy for HIV infection has represented a constant battle between the virus and the pharmaceutical industry, resulting in alternating exhilaration and despair among patients and healthcare workers. By 1996, therapeutic efforts had concentrated on combination chemotherapy, using an inhibitor of RNA-dependent DNA polymerase (i.e., reverse transcriptase) along with an inhibitor of the viral protease.[125] The inhibitor of reverse transcriptase can be either nucleoside/nucleotide (NRTI) or nonnucleoside (NNRTI) in nature. Treating patients with these powerful drugs in combination, known as highly active antiretroviral therapy (HAART), has become a subspecialty of infectious diseases. The virus, of course, has also been resilient, developing resistance to the major classes of antiviral drugs,[87] particularly if therapy is incomplete or inadequate. In such instances, HIV genotyping (i.e., sequencing of the nucleic acid targets that encode for the proteins targeted by the antiretroviral agent) is an important means to determine the predominant and resistant quasi-species. One of the useful applications of NGS is the ability to determine the genotype of both the major and the minor quasi-species present. This affords the determination of which combination of antiretroviral drugs will be active against the predominant quasi-species, as well as those drug-resistance encoding mutations that are present in the mixture of minor quasi-species.

Although no therapy has yet proved capable of eradicating HIV infection, the sentence of death that a diagnosis of HIV infection once connoted has been reversed by HAART in societies that can afford the expensive drugs. When combined with better education of high-risk groups, HAART resulted in a stable or decreasing incidence of new infections for the first time. The ongoing challenge is to find resources to offer the new therapies to countries with meager financial reserves, and much has been undertaken in this regard by philanthropic individuals, societies, and governments. However, without continued vigilance, the epidemic curve may begin to turn upward secondary to a variety of causes, including continuing appearance of drug resistance, difficulty in reaching users of intravenous drugs, and a resurgence in unprotected sexual activity once it is (incorrectly) perceived that the death sentence has been lifted.[66]

The risk of transmitting HIV in blood transfusions has been dramatically reduced by screening all units of blood for antibody and asking members of high-risk groups not to donate blood. The result has been a substantial decrease in the incidence of transfusion-related HIV infection as the sensitivity of the tests used for screening blood products before transfusion has increased. The introduction of highly sensitive nucleic acid amplification assays for screening all units of blood administered in the United States has probably reduced the risk of transfusion to an absolute minimum.

Occupational exposure to infectious agents is a fact of life for medical personnel. Blood-borne pathogens are a major part of the problem, because of the frequency of the pathogens and of exposure to blood. Sharp objects (e.g., needles and surgical instruments) are the most frequent vehicles for transmission. Viral agents represent the most serious occupational risks. Recommendations for management, preferably by prevention, of occupational exposures have been formulated by the CDC.[60–63] A summary of the general recommendations is provided in Box 23-4.

BOX 23-4

Management of Occupational Blood Exposures[a]

Provide immediate care to the exposure site

- Wash wounds and skin with soap and water
- Flush mucous membranes with water

Determine risk associated with exposure by

- Type of fluid (e.g., blood, visibly bloody fluid, other potentially infectious fluid or tissue, or concentrated virus), and

Type of exposure (i.e., percutaneous injury, mucous membrane or non–intact skin exposure, or bites resulting in blood exposure)

Evaluate exposure source

Assess the risk of infection using available information

Test known sources for HBsAg, anti-HCV, and HIV antibody (consider using rapid testing)

For unknown sources, assess risk of exposure to HBV, HCV, or HIV infection

Do not test discarded needles or syringes for virus contamination

Evaluate the exposed person

Assess immune status for HBV infection (i.e., by history of hepatitis B vaccination and vaccine response)

Give postexposure prophylaxis for exposures posing risk of infection, according to current recommendations

Perform follow-up testing and provide counseling

[a]Hepatitis B (HBV), hepatitis C (HCV), and human immunodeficiency virus (HIV).

TABLE 23-10 Laboratory Support for Diagnosing and Treating HIV-Infected Patients

Parameter	Primary Approach	Secondary/Confirmatory Approach
Initial diagnosis	Fourth-generation HIV 1/2 Immunoassay	Multi-Spot assay with or without nucleic acid amplification
Prognosis and initiating therapy	Quantitative plasma viral concentration (viral load) and baseline HIV genotyping	
Initiating therapy and prophylaxis for opportunistic infections	Quantitation of CD4 lymphocytes	

Monitoring therapy	Quantitative plasma viral concentration (viral load)	
Evaluating clinical or virologic relapse	HIV genotyping	Rarely, HIV phenotyping

Treatment of patients with HIV infection is complicated and requires support from many areas of the laboratory. In some ways, the expansion of diagnostic possibilities has simplified the approach, as summarized in Table 23-10.

Herpesviruses

Viruses of the human herpesvirus group are among the most frequent isolates in general laboratories. The group consists of the following:

Herpes simplex virus (HSV), type 1
Herpes simplex virus, type 2
Human cytomegalovirus (CMV)
Epstein–Barr virus (EBV)
Varicella-zoster virus (VZV)
Human herpesvirus-6 (HHV-6)
Human herpesvirus-7 (HHV-7)
Human herpesvirus-8 (HHV-8)

Some members of the herpesvirus group can integrate their DNA with that of the host cell. These viruses produce a latent infection in lymphoid cells or ganglia of the CNS and subsequently reactivate to cause recurrent disease. In general, the primary infections are more severe than are recurrences. The primary infections produced by several viruses of this group are more severe when they occur during adolescence or adulthood, rather than childhood (e.g., VZV). The viruses circulate more freely and earlier in life among low socioeconomic groups and not until adolescence in more affluent society. The infections in high socioeconomic groups, therefore, tend to be more severe.

Herpes Simplex Virus. HSV causes a wide variety of infections.[486] Two serotypes of the virus infect humans. Shared antigens between types 1 and 2 complicate the early serologic differentiation of antigens and antibodies, but reliable reagents are now commercially available. In healthy persons, infections of the oral cavity and genital tract predominate. Type 1 infections are most common in the upper body, whereas type 2 infections produce genital lesions; but there are frequent exceptions to the rule. For example, as many as one-third of isolates from the genital tract represent type 1

strains.

The typing of herpes isolates from genital sites is not necessary for treatment, but does provide valuable prognostic information because genital infections caused by type 1 HSV are less likely to recur than are those caused by type 2 virus.[277] In a group of 457 women who had a primary genital infection (defined by absence of antibody to type 2 virus and a positive culture of genital lesions), 89% had a recurrence after a median of 391 days.[23] There were at least 6 recurrences during the first year in 38% of patients, and 20% of individuals had more than 10 recurrences. A sequential study of patients with recurrent infection demonstrated that the patient was asymptomatic and lacked visible lesions during one-third of the period during ongoing viral shedding.[469] Genital infections with either viral type are more likely to recur than oral infections with the same type.[277] In addition, the mechanism of infection may be different for the two serotypes. Exposure to type 1 virus begins in childhood, with antibody having developed in 25% to 50% of college students. Acquisition of antibody to type 2 virus does not begin until the teens and continues throughout the period of sexual activity. Isolation of type 2 virus from a genital site implies sexual transmission, whereas the route of transmission for type 1 virus may be by autoinoculation with oral secretions.

Herpesvirus is passed from person to person by infected secretions or lesions. Infection is usually sporadic, but an epidemic of cutaneous infection at a wrestling camp (*Herpes gladiatorum*) has been described.[21]

The most serious HSV infections are encephalitis, which most commonly affects the temporal lobe and the orbital aspect of the frontal lobe in adults, and disseminated infection in newborn infants, which may be acquired either during or after birth. HSV causes sporadic encephalitis. In the neonatal period, the infecting strains are usually type 2, reflecting their origin in the maternal genital tract. Type 1 strains are overwhelmingly predominant in older children and adults. The diagnosis is made by brain biopsy and culture. Culture of the cerebrospinal fluid (CSF) is too insensitive to be diagnostically useful. HSV is infrequently isolated from CSF. In the national collaborative study, an isolate was recovered from CSF in only 2 of 45 (4%) biopsy-proven cases herpes encephalitis.[371] Serologic diagnosis is too insensitive, nonspecific, and slow to be of use in therapeutic decisions. The widespread availability of HSV PCR on CSF specimen has significantly reduced the need for brain biopsy, which is now rarely performed for this reason. However, in the presence of a negative CSF PCR for HSV, a brain biopsy may still be necessary to establish this diagnosis or to detect other treatable causes of the disease.[487] The advent of sophisticated imaging techniques has also revolutionized the diagnostic approach.

1529

Magnetic resonance imaging (MRI) is more sensitive than computed tomography. Herpesvirus encephalitis occurs very rarely, if ever, in the presence of a normal MRI study. Lesions are not limited, however, to unilateral temporal lobe lesions. The abnormalities by MRI may be multifocal or diffuse.[412] At the beginning of the illness, the only abnormalities may be in the electroencephalogram.[399]

Herpesvirus remains latent in spinal ganglia after the initial infection. Type 1 virus is most commonly recovered from thoracic ganglia, whereas type 2 is more commonly recovered from sacral ganglia. Herpetic aseptic meningitis does occur uncommonly, usually caused by type 2 virus. Viral meningitis is characteristically associated with a normal level of glucose in the CSF, in contrast to the markedly diminished levels of glucose in bacterial meningitis. The cerebrospinal glucose level in herpes meningitis, however, may be very low, and the cell count may be in the thousands.[337] Early in the course of any viral meningitis, neutrophils may predominate, which confuses the clinical picture and suggests the possibility of a bacterial process. HSV, usually type 2, also causes recurrent lymphocytic meningitis (Mollaret's meningitis); the culture is almost uniformly negative, but the viral genome can be demonstrated in the CSF by PCR.[451]

Neonatal herpes infection is estimated to occur in 1:2,000 to 1:5,000 deliveries. It is almost always symptomatic and is frequently fatal. In a collaborative study, the mortality rate was 50% to 60% in infants with disseminated infection who were treated with acyclovir or vidarabine.[485] In contrast, no fatalities occurred among infants with disease limited to the nose, eyes, or mouth. The diagnosis is suggested by the development of vesicular skin lesions, but these may be absent in 20% of patients. Poor prognostic factors include disseminated disease, comatose state at admission to the hospital, disseminated intravascular coagulation, or prematurity.

The high morbidity and mortality rates of infant disease have prompted great efforts to diagnose maternal infection. Most cases of neonatal HSV infection are contracted during vaginal delivery and can be prevented by cesarean section. Complex protocols for screening pregnant women have been developed but unfortunately have not worked well. Asymptomatic maternal infection at the time of delivery occurs regularly, although the risk for infants appears to be low if the infection is recrudescent and maternal antibody to type 2 virus is present. Many women do not recognize their primary genital infection. In one study, specific antibody to type 2 HSV was detected in 439 of 1,355 pregnant women who had no clinical history of genital herpes (32%).[154] Asymptomatic shedding of virus in late pregnancy and at delivery was detected in 5 of 1,160 cultures (0.43%). During the pregnancy, 43 of the women who had antibody to type 2 virus recognized their first symptomatic genital infection.

Efforts to prevent neonatal infection have shifted to assessment of antibody status in pregnant women and careful examination for active clinical disease at the time of delivery. The commercial availability of reliable assays for type-specific antibody

facilitates identification of women who are at risk for primary infection.[338]

Persons with compromised defense mechanisms are predisposed to herpes simplex esophagitis, tracheobronchitis, or pneumonia and disseminated infection, including hepatitis. Herpes simplex infections may be necrotizing and may suggest a bacterial etiology if the characteristic inclusions are not recognized or viral cultures are not done.[350] Immunosuppression is not a prerequisite for lower respiratory tract infection or esophagitis. The risk factors for lower respiratory tract infection include intubation, suggesting that the pathogenesis may be similar to that of bacterial pneumonia—aspiration of contaminated oropharyngeal secretions.[384] Patients with extensive burns are at risk for infection both of the denuded skin and of the lower respiratory tract.[146]

Infection of the eye includes conjunctivitis, which may be accompanied by fever, photophobia, and regional lymphadenopathy. Herpetic keratitis, which has a branching or dendritic appearance, is the second most common cause of corneal blindness (after trauma) in the United States.

HSV is one of the viral causes of pharyngitis and tonsillitis, usually as a primary infection. The mucosa may be ulcerated, and lesions may be limited to the posterior pharynx.[174] Necrotizing tonsillitis may mimic bacterial peritonsillar abscess. Hemorrhagic cystitis has been reported as a part of disseminated infection,[108] and herpetic proctitis may occur in homosexual men.[179]

Cytomegalovirus. CMV is one of a family of related viruses that are specific for a particular species.[331] Mouse CMV, for example, does not infect humans, and vice versa. CMV was first isolated from mice by Margaret Smith, who subsequently isolated the human virus from the salivary gland tissues of an infected infant. She recognized the species specificity of the virus, although the reviewers of her manuscript, which was initially rejected, did not.[479]Isolation of the human virus was reported concurrently by Smith, Weller, and Rowe. With the generosity of a gentleman, who also happens to be a Nobel Prize winner, Dr. Weller gives Dr. Smith the credit for the primacy of her discovery. CMV is an opportunistic pathogen that may produce persistent, even lifelong, infections.[361] It was recognized many decades ago as a human pathogen by the peculiar cytopathology it produces (Image Plate 23-1D). Initially, investigators considered CMV as a protozoan invader of human tissue.[246]

This virus is associated with leukocytes and may be transmitted with a blood transfusion or transplanted organ. This is the reason for the movement toward leukoreduced blood products. When detected by monoclonal antibodies or genetic probes, CMV is concentrated in the neutrophil fraction of the buffy coat, rather than in the mononuclear fraction. This fact formed the basis for the CMV antigenemia assays that were widely used prior to being supplanted by viral load assays. Multiple

genetic variants of CMV have been found in a single infected patient.[85] Virus is also excreted in saliva and in semen. Venereal transmission has been strongly suggested by epidemiologically related clusters of infections. CMV may be passed from mother to offspring through the placenta, in cervical secretions during delivery, or in breast milk.

The variety of infectious diseases produced by this pathogen is great, and includes congenital infection, neonatal infection, heterophil-negative infectious mononucleosis, hepatitis, pneumonia in immunosuppressed patients, and disseminated infection in immunosuppressed patients.[361] In the past, it was difficult to determine whether an individual patient had CMV-induced disease or was only persistently infected, because replicating virus may be found

in normally sterile organs and body fluids in the absence of clinical disease. The use of quantitative PCR for CMV has largely changed this wherein higher viral loads correlate with histopathologically-proven disease.

It is relatively easy to document infection by culturing the virus or demonstrating the presence of specific antibody. In contrast to documentation of CMV infection, proof that a particular disease process is caused by CMV often requires biopsy and histologic examination, which is the most definitive. Even then, the assessment is not always easy. For example, occasionally, cells with CMV inclusions may be seen in the base of a colonic ulcer. It is not clear if this is ulceration secondary to CMV or local reactivation of virus in an ulcer bed that is due to another cause. In such instances, correlation with the plasma CMV viral load is essential. Similarly, the simple recovery of CMV from bronchoalveolar lavage correlates poorly with CMV pneumonia,[402] but the predictive value is increased if a high CMV viral load is demonstrated in the bronchoalveolar lavage fluid.

Detection of serum antibody is the most sensitive method for determining if the patient has ever been infected by CMV. The presence of serum immunoglobulin M (IgM) antibody is useful for determining recent infection. This is useful for patients with a heterophil-negative mononucleosis-like syndrome, which may be a primary CMV infection, and for screening for primary infections during pregnancy. A latent virus or one that is clinically silent may reactivate to produce disease. An individual patient may experience CMV disease after reactivation of a latent infection or after a primary exposure to the virus. The distinction is prognostically important, because primary infections are clinically more severe and more likely to cause symptomatic disease in a neonate.

Transplant donors and recipients should be serologically screened, so that seronegative patients do not receive blood or an organ from a seropositive donor.

As mentioned above, the primary CMV infection of previously healthy persons

usually manifests as a self-limited mononucleosis syndrome. As in EBV infection, there is evidence for CMV mononucleosis that the symptoms are produced by cytotoxic lymphocytes, which attempt to eliminate the CMV-infected cells.

The spectrum of disease is considerably broader in patients who are immunosuppressed, depending on the extent and type of immunocompromise. In patients who are moderately immunocompromised, such as kidney-transplant recipients, CMV pneumonia is a common manifestation. When immunosuppression is more extreme, extensive, overwhelming infection may result. Recipients of heart, liver, or bone marrow transplants or patients with AIDS may experience hepatitis, or previously unheard of complications such as perforation through an infected intestinal wall.

Most congenitally and neonatally acquired infections are asymptomatic, but subtle symptoms may develop in some infants who appear normal at birth. At the other extreme is disseminated infection with multiorgan disease and severe congenital abnormalities, such as microcephaly. The frequency of intrauterine transmission of CMV during a primary maternal infection has been estimated at 20% to 40%, and the risk of an adverse outcome is increased during the first half of the gestation.

Epstein–Barr Virus. EBV is the primary cause of infectious mononucleosis.[396] This versatile virus produces disease that ranges from acute self-limited infection to malignant neoplasms. The mononucleosis syndrome consists of fever, malaise, exudative pharyngitis, lymphadenopathy, and atypical lymphocytes circulating in the peripheral blood. Splenomegaly is common, and rupture of the spleen is a serious complication, but fortunately not frequently encountered. Acute hepatitis may also be a part of the syndrome.

The virus was originally recognized during studies of Burkitt's lymphoma in Africa and only later associated with mononucleosis.[396] The virus gains entry to the body by infecting the pharyngeal epithelium. Its primary cellular target, however, is the circulating B lymphocyte, which it infects and then immortalizes. The activated B lymphoblast, along with its passenger EBV, matures into a long-lived memory lymphocyte in the germinal center of the lymph node.[455] The result of this interaction is a polyclonal stimulation of the humoral immune system, which produces an array of antibodies to many antigens. At the same time, the cellular immune system is triggered to fight the EBV infection. It is the activated T lymphocytes that are seen in the peripheral-blood smear as atypical lymphocytes. The circle is completed when virus is excreted through the oral mucosa into the saliva. Young children usually have an asymptomatic or minimally symptomatic infection, and the diagnostic heterophil antibody test is often negative.

If integration of the EBV genome into certain types of cells occurs, a neoplasm may result instead of an acute infection. The unregulated growth of EBV in patients with

HIV infection, who have lost the regulatory control of cellular immunity, may lead to increased EBV-related tumors. Most of these tumors are of B-lymphocyte lineage, such as Burkitt's lymphoma and primary lymphoma of the brain, but nasopharyngeal carcinoma is also EBV-associated. A subset of gastric and colonic carcinomas has also been ascribed to infection with EBV. A variety of other processes include lymphocytic interstitial pneumonia and hemophagocytic syndrome. Establishing association of a latent or persistent virus such as EBV is not enough to prove a causal relationship, which can come only from repetitive association and careful molecular analysis, which often employs in situ hybridization studies. The relationship between EBV and lymphoma appears to be particularly complex.[455]

In the mid-1980s, it was suggested that a poorly defined syndrome of chronic fatigue might represent chronic EBV infection. Chronic EBV infection does exist and may be troublesome, but the nonspecific syndrome of chronic fatigue does not appear to be EBV-related.[102]

The cells that best support viral replication with shedding of infectious particles are epithelial cells of the oropharynx. Saliva from acutely ill or chronically infected patients contains viable virus, which can be demonstrated by co-cultivation with normal peripheral-blood lymphocytes. Alternatively, peripheral-blood lymphocytes of infected individuals can be cultured in the presence of an agent that depletes T lymphocytes, such as cyclosporine. The diagnosis of neoplastic manifestations must be by molecular demonstration that the virus has been integrated into the genome of the malignant cells. Cells from EBV-induced tumors can often be cultured as immortalized cell lines in vitro.

1531

HIV-associated lymphomas are less commonly encountered in resource-rich countries where HAART is readily available. In these situations, the populations at increased risk for EBV driven lymphomas are transplant recipients. The disease, adequately named "posttransplant lymphoproliferative disorder," ranges from poorly characterized lymphoid proliferations to definitive lymphomas. Early detection becomes imperative, as these are EBV driven and reversible or treatable if detected prior to the development of an outright lymphoma. Therefore, quantitative EBV viral load testing has become established as a means to monitor transplant recipients for increasing EBV levels and impending or developing posttransplant lymphoproliferative disease (PTLD).

Varicella-Zoster Virus. VZV causes chickenpox as a primary infection.[11] The virus may remain latent in the sensory ganglia of the spinal cord for many years before reactivating and producing disease for a second time. The lesions of reactivated

disease resemble chickenpox but are limited to the dermatome that is innervated by the infected nerve. The reactivation disease is known as shingles. The dermatome of most concern is the ophthalmic branch of the trigeminal nerve because destructive corneal infection may occur as part of the reactivation disease. Reactivation of the virus in nerves of the head and neck is also associated with subsequent VZV meningitis/meningoencephalitis. Before reactivation was understood, the virus of chickenpox was called varicella virus and that of shingles was called herpes zoster, which explains the curious nomenclature.

VZV produces considerable discomfort in healthy persons and may produce pneumonia, but in immunosuppressed individuals the disease can become a life-threatening disseminated infection. Pregnant women are at increased risk for severe varicella, and neonates who are born within 4 days of their mother's infection are at great risk because maternal antibodies have not yet developed. The risk of embryopathy in the fetus after maternal VZV infection in the first 20 weeks of pregnancy is approximately 2%.

Conventional wisdom states that immunity to varicella is lifelong and that all subsequent disease is recrudescent. Reinfection has been suggested, however, by careful serologic study of immune persons in a house that had an individual with chickenpox.[12] Housemates who had preexisting antibody remained well but developed increased antibody titers, indicating subclinical infection.

There is great concern in hospitals for the safety of immunosuppressed patients who come in contact with an infected person. Exposure may occur unwittingly because patients with VZV are infectious just before the onset of the characteristic rash. Measures to reduce risk include use of immune healthcare personnel for immunosuppressed patients and limitation of visitors. Prompt administration of zoster immune globulin after inadvertent exposure has a protective effect.

Human Herpesviruses-6 and -7. The human herpesvirus-6 virus (HHV-6) was first isolated from patients with lymphoproliferative disorders and named human B-lymphotropic virus.[367] The virus has the morphologic structure of a herpesvirus but is genetically unrelated to the five previously identified herpesviruses. Thus, it was named human herpesvirus-6. There are two currently recognized subtypes, designated A and B; subtype B is predominant. This virus shares with EBV the ability to grow in human lymphocytes. In contrast to EBV, which infects lymphocytes in a latent stage and does not actively grow in the cells, HHV-6 appears to produce only productive infection in human lymphocytes (i.e., mature infectious viral particles are produced in the infected cells).

In 1990, a new herpesvirus was isolated from $CD4^+$ T lymphocytes of a healthy individual, using techniques that cause activation of T cells. The virus, which was named human herpesvirus-7 (HHV-7), is distinct from but closely related to HHV-6.

The two viruses do not produce cross-immunity.

HHV-6 and HHV-7 produce a common childhood disease called exanthem subitum (also known as roseola infantum, roseola subitum, Duke disease, or fourth disease). Exanthem subitum occurs in children between 6 months and 3 years of age. Almost all children over the age of 13 months have antibody to HHV-6. Antibody to HHV-7 appears at a slightly older age.

Exanthem subitum begins with an abrupt fever, which is followed by a rash as the fever subsides on the third or fourth day. Febrile convulsions occur in approximately 8% of acutely infected patients. This infection is very unlikely in an afebrile child. The illness usually resolves without sequelae, but serious disease may result on rare occasions. In immunosuppressed adults HHV-6 has produced serious disease after transplantation of bone marrow and solid organs and in patients who are infected with HIV. These viruses have been suggested as etiologic agents in chronic fatigue syndrome, multiple sclerosis and neoplastic disease, but substantial supportive data has not emerged. The frequent reactivation of herpesviruses during the course of other diseases complicates definitive establishment of an etiologic role.

Human Herpesvirus-8. The next addition to the group of lymphotropic herpesviruses is the Kaposi's-sarcoma-associated herpesvirus, which has been named human herpesvirus-8 (HHV-8). As implied by the name, the virus was first detected in tissue from Kaposi's sarcoma in patients with HIV infection, using molecular techniques.[333] Subsequent investigation demonstrated that the viral gene sequences were present in several clinical types of Kaposi's sarcoma: that occurring in patients with AIDS, classical Kaposi's sarcoma unrelated to HIV infection, and Kaposi's sarcoma in homosexual men who are not infected with HIV. The sequences have been identified in AIDS-related body cavity–based lymphomas, which also contained genetic sequences from EBV. This type of HHV-8-associated lymphoma has been classified as "primary effusion lymphoma." Finally, HHV-8 is associated with a subset of patients with multicentric Castleman's disease, an atypical lymphoid hyperplasia, which may progress to lymphoma. The sequences are also found in nonneoplastic tissue of HIV-infected patients with Kaposi's sarcoma.

B Virus. In the 1930s, a virus of the herpes group was isolated from a patient in whom a fatal neurologic disease developed after being bitten by a monkey. About the same time, Sabin isolated a virus from another patient in whom

transverse myelitis developed after a monkey bite. He named the isolate B virus after the afflicted patient. It has also been called herpesvirus simiae, which is something of a misnomer because a variety of herpesviruses are found in monkeys. The actual

taxonomic name is *cercopithecine herpesvirus 1*, but "B virus" is more commonly used. In one review of herpes B virus infections 16 of the 25 infections were fatal.[488]

The B virus is unusual because it causes infections across species lines. It is indigenous to Old World monkeys, such as rhesus and cynomolgus, in which it establishes latency. Localized human infections have been reported, but most are severe and systemic. An animal bite is the usual means of transmission, but infection after a needlestick injury has been reported. A vesicular eruption often develops around the bite and is followed by regional lymphadenopathy and fever. Encephalitis, transverse myelitis or visceral necrosis accompanies systemic spread.

Of concern was the first documented episode of human-to-human transmission, which occurred as part of a cluster of infections at a research facility. Another concern in the past was the discovery that monkey kidney cells that had been commercially supplied for diagnostic laboratories were contaminated with B virus. Fortunately, no human infections resulted, but the cells were recalled.[482] The ability of B virus to replicate in monkey kidney monolayers has been known for years. In fact, the stress of processing the kidneys may stimulate activation of latent B virus. Cytopathic effect of the virus consists of cell enlargement and fusion, which may spread through the monolayer. Cowdry type A inclusions identical to those of HSV or VZV will be seen in stained cell preparations. Subculture to other monkey kidney cells or to rabbit kidney cells, which are used for isolation of HSV, will transmit the virus.

Adenoviruses

Adenoviruses were originally recognized when spontaneous degeneration occurred in adenoidal tissue cultures. They were called adenoid degeneration (AD), adenoid–pharyngeal–conjunctival (APC) or acute respiratory disease (ARD) agents.[423] These viruses can be present in the pharynx and in the feces without causing discernible disease. Designation of an infectious agent as the etiologic agent must be done carefully so that one is not misled by a fortuitous association. For instance, at one time adenoviruses were considered causes of the pertussis syndrome because they were isolated in the absence of the common bacterial cause, *Bordetella pertussis*. The role of adenovirus in a pertussis syndrome is controversial. It has been suggested that being fastidious, *B. pertussis* may not have been recovered in many cases of whooping cough while the adenoviruses represented incidental isolates or coinfecting pathogens.[233]

Adenovirus disease may be sporadic or may occur in epidemics. These viruses produce approximately 5% of the ARD in children less than 5 years of age and may be responsible for 10% of childhood pneumonia. They produce an exudative pharyngitis that can mimic group A β-hemolytic streptococcal disease. Adenoviruses may cause otitis, pharyngitis and gastroenteritis. Certain serotypes are associated with acute

conjunctivitis, with or without pharyngitis. Adenovirus infections of the gastrointestinal tract were discussed earlier with the other viral causes of gastroenteritis. The major adenoviral infections and their associated serotypes are summarized in Table 23-11.

Poxviruses

The poxviruses are a diverse group.[155] Most are animal pathogens, but some can also infect humans. The most well-known of the poxvirus group was the variola virus, the etiologic agent of smallpox and the sole member of the group that infects humans only. It has now passed from endangered species status, hopefully, into extinction.[132] After the last natural infection was recorded, stocks of viruses were restricted to the United States and Soviet Union; with the dissolution of Soviet Union, however, the possibility of dispersal of viral stocks beyond Moscow has been a concern. The genome of variola and five other pox viruses has been sequenced.[341]

The recognition that variola poses a major threat as an agent of bioterrorism has stimulated renewed interest. The population of the world is now largely susceptible or only partially immune, and physicians are unfamiliar with the

TABLE 23-11 Adenovirus Infections

Syndrome	Age Group	Serotypes
Acute febrile pharyngitis	Young children	1, 2, 3, 5, 6, 7
Pharyngoconjunctival fever	Young children and adolescents	3, 7, 14
Acute respiratory disease	Military recruits	3, 4, 7, 14, 21
Pneumonia	Young children Military recruits	1, 2, 3, 7 4, 7
Epidemic keratoconjunctivitis	All	8, 11, 19, 37
Acute hemorrhagic cystitis	Young children	11, 21
Gastroenteritis	Young children	39, 40
Meningoencephalitis	Children and immunocompromised patients	1, 2, 5
Hepatitis	Children and immunocompromised patients	1, 2, 5

clinical presentation and diagnosis of smallpox. The records of historical outbreaks, including an epidemic in Boston early in the 20th century, have been reexamined to refresh faded memories.[3,36] Immunization with vaccinia virus, one of the milestone achievements of modern medicine, was abandoned in the 1970s, because of well-characterized side effects of the vaccine.[38] The balance between cost and benefit of vaccination has clearly been affected by the altered circumstances,[156,157] but the proper course is disputed.[39,302] Residual antibody has been demonstrated in previously immunized individuals, but the efficacy of these antibodies is unclear.[160]

Orthopoxviruses of animals, such as cowpox and monkeypox viruses, can occasionally infect humans. These infections resemble smallpox clinically. A new dimension to the risk of monkeypox was added by the recognition of human infection that was acquired from pet prairie dogs.[389] The pets may have been infected by imported African rodents that are known to be susceptible to monkeypox virus. The differential diagnosis of all poxvirus infections includes VZV.[326] Laboratory support is, therefore, essential whenever the possibility of variola is raised.

The origin of vaccinia virus is unclear. It has many characteristics of a distinct species, but may have been derived from one of several candidate viruses (including cowpox virus) by mutation or recombination.

Members of two other genera, *Parapoxvirus* and *Yatapoxvirus*, are animal pathogens, but can infect humans. Tanapox virus causes human infection in parts of Africa, but it has produced disease in travelers after they have returned from an endemic area.[111]

Molluscum contagiosum virus, the sole member of the Genus *Molluscipoxvirus*, causes a distinctive cutaneous lesion; like variola it infects only humans.[132]

The parapoxviruses include agents causing diseases in sheep (orf or contagious pustular dermatitis virus) and in cows (milker's node or pseudocowpox virus). They may also produce localized infections in humans who are occupationally exposed to the viruses. The poxviruses are unlikely to be isolated in the clinical laboratory.

Papillomaviruses

The human papilloma viruses (HPVs) cause common warts, sexually transmitted venereal warts, and tumors of the respiratory, intestinal, and genital tracts. The viral nature of warts was known early in the 20th century, when they were transferred with cell-free filtrates, and Shope defined the rabbit papillomavirus as the cause of

papillomas in 1933.[298] The extensive and thorough study of HPV was impeded until molecular techniques sufficient for the task were developed in the 1970s.

More than 60 genetic types of HPV have been described. There are strong associations between certain genotypes and clinical lesions (Table 23-12). The common wart is the most common lesion, but most attention has been focused on the genital infections, including the association with neoplasia. Sexual partners of patients who are infected with HPV are also frequently infected with the same genotype.

The causative nature of HPV with cervical neoplasia has been constructed from many studies. Although HPV provides the major risk, additional factors appear to be necessary for the development of cancer. Rather than a dramatic shift from normal to neoplastic epithelium in the cervix, there is a continuous spectrum, recognized as increasingly severe grades of cervical intraepithelial neoplasia. The final stage in the process is the development of overt malignancy, invasive carcinoma, which may be either glandular or more commonly squamous. Likewise, there is a continuum in the expression of HPV genes and antigens. In the normal epithelium the cells of the basal layer progressively differentiate to form nonkeratinized squamous epithelium at the surface. As the cervical epithelial changes progress from mildly dysplastic to severely dysplastic, the following changes occur: (1) the cells become less differentiated throughout the epithelium, (2) the chromosomal content of the nuclei becomes increasingly abnormal, (3) the expression of HPV gene products (antigens) becomes less intense, and (4) the expression of HPV genes is increasingly difficult to demonstrate. A characteristic of the HPV-infected cell is koilocytosis, a perinuclear clearing in the squamous epithelium accompanied by nuclear atypia, although this appearance is not present in all infected cells. The appearance of koilocytic atypia in exfoliated cervical cells is shown in Figure 23-5.

The cellular biology of HPV supports a primary role in the development of neoplasia.[316] The viral types most closely associated with cervical cancer, particularly HPV-16 and 18, are capable of transforming cells in culture so that they lose their normal growth control mechanisms. The DNA from these types integrates into host DNA. The viral integration may cause chromosomal rearrangement and lead to abnormal cellular differentiation in vitro. Zur Hausen has put forth the hypothesis that cervical neoplasia is the result of failure of a primal cellular surveillance mechanism that was designed to control persisting viral genomes.[510]

Papillomavirus DNA has been demonstrated in normal cervical epithelium adjacent to genital warts and cancer. Failure to remove all the infected tissue may lead to recurrences. HPV DNA can also be demonstrated in 5% to 10% of women with normal cervical smears or biopsies. The infection may be transient; the association of even high-risk genotypes with cervical neoplasia is most dramatic when HPV DNA is persistently present.

National consensus recommendations for treatment of patients at risk for cervical

neoplasia, which evolve continually, include morphologic parameters (cervical exfoliative cytology) and viral determinants (detection of HPV). The molecular assessment for the presence of HPV is now part of the standard for screening women for cervical cancer and the precursors thereof. The current approach to classifying endocervical cytology is the Bethesda System.[434] Table 23-13 summarizes the cervical cancer screening guidelines of the American College of Obstetricians and Gynecologists (ACOG).

The role of the laboratory in the management of endocervical disease has many aspects.[101] Recommendations for management of HPV disease continue to evolve. The ACOG now includes the use of an HPV test in conjunction with a Pap test every 5 years, as an alternative to a Pap test alone every 3 years. The molecular methods designed to detect the presence of HPV are more sensitive than cytology, whereas cytology, and in some instances biopsy, provides the

TABLE 23-12 Association of Selected Human Papillomaviruses (HPV) with Clinical Disease

Viral Type	Clinical Disease	Neoplastic Potential
HPV-1	Deep plantar wart	Not described
HPV-2	Common wart Mosaic wart Lip lesions	Not described
HPV-3	Flat wart	Not described
HPV-4	Common wart	Not described
HPV-5	Plaques in epidermodysplasia verruciformis	Squamous carcinoma may develop in sun-exposed areas
HPV-6	Genital: exophytic condyloma; flat condyloma; giant condyloma Respiratory papillomas Conjunctival papillomas	Weak association, especially in vulva
HPV-7	Common butcher's warts	Not described
HPV-11	See HPV-6	See HPV-6
	Focal epithelial hyperplasia of oral	

HPV-13	cavity	Not described
HPV-16	Anogenital: Bowenoid papulosis; flat condyloma	High association in cervix Moderate association in vagina, vulva, anus, and penis Also found in respiratory tract, including larynx, tonsils, and oral cavity associated with head and neck squamous cell carcinoma.
HPV-18	Genital: flat condylomas	High association in cervix; infrequently found in precursor lesions. Associated with head and neck squamous cell carcinoma.
HPV-31	Genital: flat condyloma	High association with cervical cancer
HPV-32	Focal epithelial hyperplasia in oral cavity	Not described
HPV-33, -35, -39, -51, -52, -56, -58, -59, -68	Genital	Moderate association with cervical cancer
HPV-45	Genital	High association with cervical cancer

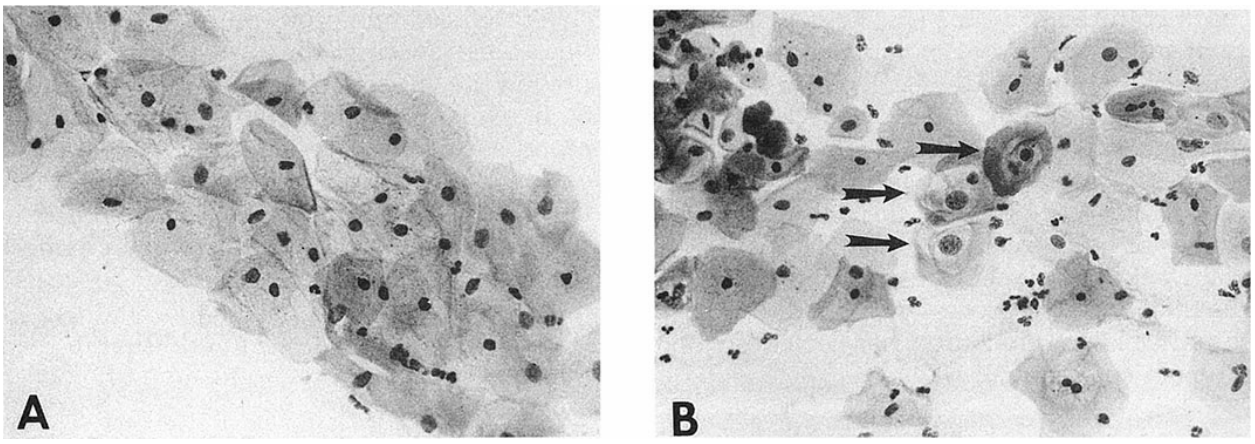

FIGURE 23-5 Cervical cytology. **A.** Normal exfoliated cervical squamous epithelial

cells. The nucleus is small and compact, and the cytoplasm is abundant in these mature, keratinized epithelial cells. **B.** Koilocytic atypia. The nuclei in some of these superficial cells are enlarged with coarse, clumped chromatin, and there is a pallor or clearing in the cytoplasm around the nucleus (perinuclear halo) (arrows) (Papanicolaou stain ×250).

1535

TABLE 23-13 The Cervical Cancer Screening Guidelines of the American College of Obstetricians and Gynecologists

- Cervical cancer screening should start at 21 years of age.
- Women 21–29 years old should have a Pap test every 3 years.
- Women 30–65 years old should have a Pap test and an HPV test every 5 years. As alternative option is the Pap test alone every 3 years.
- Women without a history of moderate or severe dysplasia or cancer should stop cervical screening after age 65, if they have had either three consecutive negative Pap tests or two negative HPV tests, with the most recent test performed within the past 5 years.

Note: Women with a history of cervical cancer, those with HIV, and those exposed to diethylstilbestrol (DES) before birth should not follow these routine guidelines.
Modified from http://www.acog.org/-/media/For-Patients/pfs004.pdf?dmc=1&ts=20150618T1250230513

specificity needed to accurately characterize the type and extent of disease present. The importance of a team approach to achieve optimal benefits for the patient is evident in this area of medical practice.

Polyomaviruses

There are a wide variety of polyoma viruses, but only a few that are of medical importance to humans. These are small, double-stranded DNA viruses that infect most individuals at some time during their life and usually cause subclinical disease. Discernible disease is caused by the reactivation of these viruses in immunocompromised hosts.

The JC and BK viruses, both named after the initials of the patients from which they were initially isolated, are the most common polyoma viruses encountered in human medicine. The JC virus produces a destructive demyelinating disease termed progressive multifocal leukoencephalopathy in immunocompromised patients.[304] The BK virus causes hemorrhagic cystitis, often in stem cell transplant recipients during

periods of profound neutropenia. It also causes nephropathy of the transplanted kidney in renal transplant recipients. The detection of both the BK and JC viruses relies predominantly on quantitative PCR, although other methods are available.

The Merkel Cell carcinoma virus is a more recently described polyoma virus, and as the name implies is associated with the rarely encountered Merkel Cell carcinoma. This neuroendocrine carcinoma occurs most commonly in immunocompromised individuals, particularly transplant recipients.

Parvoviruses

As the name implies, the parvoviruses are very small; they are unusual in that they contain single-stranded DNA. The only human parvovirus, known as B19, has been demonstrated to cause a common childhood febrile illness with rash. Erythema infectiosum is also known as fifth disease (the fifth childhood disease after rubeola, rubella, varicella, and roseola).[28,503] It is characterized by fever and a characteristic "slapped-cheek" rash in young children. Most persons are immune by the time they reach adulthood, but susceptible persons may experience arthritis or arthralgias. This pattern of mild rash illness in childhood and severe arthritis in adults resembles that of rubella virus. The rash in erythema infectiosum is maculopapular, but a vesiculopustular lesion has been reported in an adult.

Parvovirus B19 has an affinity for erythroblasts (i.e., immature red blood cell precursors). The receptor on human erythrocytes for parvovirus B19 is the P antigen; individuals who lack that antigen are naturally resistant to infection. Unfortunately, very few individuals lack the P erythrocyte antigen. Parvovirus B19 can produce transient anemia in normal persons and severe chronic anemia or aplastic crisis in patients with malignancies, hemoglobinopathies or immunodeficiency. If pregnant women contract a primary parvovirus infection, fatal erythroblastosis fetalis with hydrops may result. In this case the virus produces severe chronic anemia, whereas in immunologic erythroblastosis (Rh disease) antibodies to the fetal red cells do the damage. A viral hemophagocytic syndrome in children and adults has been associated with human parvovirus. Transmission of parvovirus infection from heavily infected patients to susceptible healthcare workers has been documented.

The clinical manifestations of human parvovirus infection during an epidemic in Cadiz, Spain, included hematologic manifestations in 13.9% of 43 patients, dermatologic lesions in 53.4%, arthralgias or arthritis in 20.9% and infection in pregnancy in 7.0% patients (two of these women suffered abortions). Fever and lymphadenopathy were presenting symptoms in 37% of the patients.[162]

Hepatitis Viruses

Many viruses can cause infectious damage to the liver. EBV and CMV occasionally

cause symptomatic hepatitis as part of the mononucleosis syndrome. The primary hepatitis viruses are a diverse group. The "alphabet soup" of hepatitis is summarized inTable 23-14. Several other viruses that have been described as agents of hepatitis are covered more extensively in specialized texts. For example, the hepatitis G virus, also known of as the GB virus, is a member of the family *Flaviviridae* and is an infrequent cause of hepatitis.[295,375,489] Similarly, agents such as the transfusion transmitted virus (TT virus) and SEN virus, both members of the family *Circoviridae*, are more appropriately covered elsewhere. The following sections concentrate on the most important hepatotrophic viruses.

Hepatitis A Virus. Hepatitis A virus produces sporadic and epidemic infectious hepatitis. The disease has been known since antiquity, but the virus was not identified until the 1970s. Hepatitis A virus was first classified as enterovirus 72 based on biochemical and physical features. Subsequently, it was recognized that there were considerable differences from classical enteroviruses. It has now been transferred into a new genus, *Hepatovirus*, within the family *Picornaviridae*.[223] There are seven genotypes of hepatitis A virus; most strains belong to genotype I.

Hepatitis A virus produces acute self-limited hepatitis that may be fulminant. The incubation period between exposure and clinical disease is short (<1 month). For 7 to 10 days before clinical illness, there is noncytopathic viral replication

TABLE 23-14 Primary Viral Causes of Hepatitis

Virus	Taxonomy	Transmission	Chronicity	Neoplasia
Hepatitis A	*Picornaviridae* *Hepatovirus*	Enteric: water, food, shellfish	No	No
Hepatitis B	*Hepadnaviridae* *Orthohepadnavirus*	Parental: blood, sexual, needles, enteric	Yes	Yes
Hepatitis C	*Flaviviridae* *Hapacivirus*	Parenteral: blood; less frequently sexual contact	Yes	Yes
Hepatitis D	*Deltavirus*	Parenteral: blood; requires Hepatitis B virus	Yes	Yes
Hepatitis E	*Hepeviridae* *Hepevirus*	Enteric	No	No

in hepatocytes, viremia, and fecal shedding of infectious virus. A period of viral replication with hepatocyte damage, including classical "ballooning" degeneration of liver cells, follows. At this point the communicable period is almost complete. Hepatitis A virus infection is rarely transmitted by blood transfusions because little virus is present in the blood and the duration of viremia is limited. Transmission of infection to patients with hemophilia in clotting factor concentrate, which contains samples from

many donors, has been described in Europe and the United States. Massive hepatic necrosis and postinfectious cirrhosis are rare. Chronic hepatitis and neoplasia are not complications.

Hepatitis A is transmitted by contaminated food and water. Bivalve shellfish from contaminated waters have produced numerous outbreaks because they are often eaten raw or steamed to a temperature that does not inactivate the virus.[272] In one outbreak in Shanghai more than 300,000 individuals were infected after eating raw clams taken from contaminated water.[223] Sexual transmission also occurs.[255]

The transmission of hepatitis A virus, like EBV and poliovirus, is determined by sanitation and socioeconomic condition. The virus circulates freely under conditions of poor sanitation and infects humans at an early age, when the infection is usually asymptomatic. More affluent citizens escape infection until later in life, when symptomatic hepatitis results[223] (see text on "Poliovirus" and "Epstein–Barr virus").

Hepatitis B Virus. Hepatitis B virus is a DNA hepatovirus. It produces acute and chronic hepatitis and is an etiologic agent of hepatocellular carcinoma.[161] Hepatitis B virus has a long incubation period (45 to 120 days) and is transmitted primarily by parenteral means.[224] Until routine screening of blood products for this virus was commonplace, hepatitis B was the most common cause of transfusion-associated hepatitis. Other parenteral routes have included acupuncture and tattooing. Hepatitis B antigen has been demonstrated in mosquitoes, but transmission of infection by arthropods has not been authenticated. This virus can be transmitted by sexual contact and has produced epidemic disease in male homosexuals, prostitutes, and abusers of intravenous drugs. Perinatal infection occurs, but breast milk does not appear to play a role in transmission. Hepatitis B virus may produce fulminant fatal acute hepatitis, called massive hepatic necrosis. It has been suggested that a mutation in the virus may cause this severe manifestation.

The array of mechanisms for transmission of hepatitis B virus infection recalls HIV. The concentration of hepatitis B virus in blood and body fluids is much greater than HIV, however, and nosocomial infection is consequently a greater problem. Hepatitis B has been an important cause of occupational infections in medical personnel, but the frequency has been greatly reduced by the widespread use of immunization in healthcare workers.

Hepatitis B virus is a 47-nm spherical virus that possesses several antigens of importance for diagnosis and pathogenesis. Several genotypes of hepatitis B virus have distinct clinical implications. Classically, genotype A produces longer survival and less severe disease; genotype B is found more commonly in infections that result in hepatocellular carcinoma; genotype C produces severe disease; genotype D occurs in fulminant hepatitis.[224]

There are three envelope polypeptides of particular importance: HBsAg (hepatitis B

surface antigen), HBcAg (hepatitis B core antigen) and HBeAg (hepatitis B e-antigen). This virus has not been cultured in vitro, but the variety of antigens and corresponding antibodies provide ample tools for documenting clinical disease. Although not absolute, the presence of e-antigen correlates well with the presence of DNA, DNA polymerase and with viral infectivity. The fascinating story of the discovery of Australia antigen (now known as HBsAg) and its relationship to hepatitis has been reviewed by Blumberg.[29] It serves as a reminder that no one can predict where basic research will have its clinical impact. Who would have predicted that a research group interested in genetic polymorphisms of blood proteins would discover the key to an important cause of human hepatitis?

For reasons that are unclear, in some persons who are infected with hepatitis B virus antibody develops and the virus is cleared from their system, whereas other patients continue to have circulating viral antigens. Chronic liver disease develops in a subgroup of these chronic carriers. Another serious complication of this infection is the integration of viral DNA into the genome of the liver cells and the development of hepatocellular carcinoma.

Hepatitis C Virus. After diagnostic reagents for hepatitis A and B viruses became available, it was obvious that there

were other causes of transfusion-associated hepatitis.[305] The unknown virus or viruses were dubbed non-A, non-B hepatitis. Thanks to the sophisticated technology of molecular biology we now recognize hepatitis C as the cause of most cases of transfusion-associated non-A, non-B hepatitis that occurred at that time. The virus, which could not be cultivated, was eventually characterized by molecular techniques, one of the early triumphs of molecular biology. Surprisingly, the newly characterized agent was found to be most closely related to a group of viruses that are transmitted by arthropods; it is now a genus (*Hepacivirus*) in the family *Flaviviridae*. Concepts of genetic relationships among hepatitis C virus strains are evolving. There are six genotypes, 1 to 6, with subtype 1a and 1b in group 1, numerous subtypes within groups 2 to 4, and only one type each of genotype 5 and 6. Patients who are infected with strains of clades 1a and 1b (corresponding to genotypes 1a and 1b) respond less well to interferon treatment and progress more rapidly to chronic liver disease than do individuals who have been infected with other strains. However, newer therapeutics promise to soon make genotypic subtyping unimportant. Otherwise, there appear to be few phenotypic differences among genetically dissimilar strains.

The epidemiology of hepatitis C infections has many similarities to that of hepatitis B, but some significant differences are apparent. The most common route of spread in

the past has been through blood products, including immune globulin. Transmission through blood exposure still may accidentally occur during surgery, and intravenous-drug abusers remain at elevated risk for disease. The screening of blood products for hepatitis C virus has substantially reduced the risk of transmission by this route. Sexual transmission is another means of transmission, but the frequency is much less than in hepatitis B infection. The prevalence of antibody to hepatitis C among healthcare workers in Baltimore was similar to that in the general population, suggesting that workers are exposed to low levels of virus or that the transmissibility is not great.[453]

Acute hepatitis C virus infection is often less severe than that of hepatitis B, but the frequency of chronic hepatitis C disease is high. The subject has been reviewed by Iwarson and colleagues.[244]

The long-term mortality of patients who are infected with hepatitis C virus is similar to that of controls, although infected patients have a slightly increased risk of dying from liver disease. New therapies, recently introduced at the time of this writing, are expected to effect cures in most patients infected with hepatitis C virus. Once a patient has a documented chronic infection, however, the outlook is much worse. Cirrhosis is a significant complication of chronic infection. Hepatitis C infection is an independent risk factor for hepatocellular carcinoma after the development of cirrhosis. Extrahepatic immunologic manifestations, such as cryoglobulinemia and rheumatoid factors, are a prominent part of hepatitis C infection, as they are for hepatitis B.

Hepatitis D Virus. Hepatitis D virus, also known as the delta agent, is a 35-nm double-shelled RNA virus that is incapable of multiplication without the surface antigen of hepatitis B.[169] The maturing delta virus covers itself in the HBsAg coat before infecting other cells. Thus, the biology of hepatitis D is inextricably tied to that of hepatitis B. Hepatitis D can produce infection and disease only in patients who are concurrently infected with hepatitis B or who are producing HBsAg from a previous infection. Not surprisingly, hepatitis D virus infection is concentrated in pockets of populations with hepatitis B virus infection, such as drug addicts and homosexual men.

When coinfection occurs, the clinical disease is similar to that of hepatitis B and is usually self-limited. When hepatitis D infects a patient who is a chronic carrier of hepatitis B, the clinical disease is much more severe, disease becomes chronic in as many as 80% of cases, and fatality rates may be dramatically increased to as high as 12%.

Hepatitis E Virus. Hepatitis E, one of the more recent additions to the hepatitis viruses, is a 27-nm labile RNA virus.[382] Hepatitis E virus produces an enterically transmitted acute hepatitis that most closely resembles that of hepatitis A. The viral genome has been cloned by techniques similar to those used to identify hepatitis C. The taxonomic status of this virus is not yet clear. It has similarities to the

caliciviruses, but its closest genetic relative is rubella virus, currently classified as a togavirus. Large waterborne epidemics of disease are produced under conditions of poor sanitation, but the infection has not yet been recognized as a cause of indigenous disease in the United States. Travelers to endemic areas, however, have returned to the United States with the infection.

Prion Diseases (Transmissible Spongiform Encephalopathies)

The transmissible spongiform encephalopathies are a fascinating group of CNS infections. They are defined by a distinctive cellular pathology, characterized by a vacuolated appearance of the cerebral white matter. The infections and their natural hosts are summarized in Table 23-15. A molecular and clinical classification of prion diseases has been proposed.[466]

For decades it has been recognized that the scrapie agent was novel—an apparently transmissible agent that contained no evidence of either type of nucleic acid. The responsible pathogen was originally considered a "slow virus," but the agent was more resistant to inactivation by X-rays, ultraviolet light, and harsh chemical treatment, including immersion in 10% formalin, than any other known infectious particle. In the 1960s, Pattison proposed that the agent was a basic protein and Griffith suggested several hypothetical mechanisms, one of which proved to be on target.[380] The nature of the infectious particles was painstakingly elucidated by Prusiner. He persisted in his battle to win over skeptical colleagues, and eventually won the Nobel Prize for his efforts. The unique infectious agent, which was named a prion, turned out to be a normal cellular protein (PrP^c) that was modified by a conformational change. The PrP^c protein is converted into the abnormal protein (PrP^{sc}) by refolding of a portion of its α-helical coil structure into a β-sheet.[379,380] Although the infectious-protein hypothesis has been generally accepted, agreement as to the nature of the infectious agent is not universal.[80]

The diseases produced by prions are referred to as transmissible spongiform encephalopathies (TSEs).[252,380,381] They were of veterinary interest until the first human TSE was

TABLE 23-15 Transmissible Spongiform Encephalopathies (Prion Diseases)

Agent	Natural Host	Human Infection
Scrapie	Sheep	No

Transmissible mink encephalopathy	Mink	No
Chronic wasting disease	Deer and elk	No
Kuru	Humans	Yes
Creutzfeldt–Jakob disease (CJD) (familial, sporadic, and iatrogenic forms)	Humans	Yes
Gerstmann–Straussler–Scheinker syndrome (GSS)	Humans	Yes
Fatal insomnia (familial and sporadic forms)	Humans	Yes
Bovine spongiform encephalopathy (BSE)	Cattle	Yes

recognized. Kuru occurred among a remote, isolated tribe of aborigines in the New Guinea highlands.[158] Gajdusek won a Nobel Prize for unraveling the mysterious disease that began with cerebellar ataxia and a shivering-like tremor, progressed to complete loss of motor and speech function, and resulted in death within a year. The agent was transmitted through the practice of ritual cannibalism as part of the mourning ritual for the dead. Transmission of the infection was stopped when the tribe was convinced to alter its practices. Subsequently, it was recognized that two rare human dementias—Creutzfeldt–Jakob disease (CJD) and a variant, Gerstmann–Sträussler–Scheinker syndrome (GSS)—were caused by a similar agent. These degenerative diseases, which occur in familial and sporadic forms, produce the rapid onset of dementia. Memory loss and behavioral problems ensue at some point in most patients. Death occurs within months to a year after onset.

Bovine spongiform encephalopathy (BSE) appeared in southern England in 1986, and approximately 100,000 cases had been documented by the end of 1993.[39] Scrapie has been passed from sheep to cattle experimentally,[170] and it has been conjectured that the disease was transmitted to cattle through sheep brains included in feed as a protein supplement.[37] Alternatively, BSE may have arisen by a chance mutation, as occurs in sporadic human CJD. Whatever the origin of the first case, the inclusion of animal products in animal feed allowed the widespread dissemination of the infection in cattle.[255]

What was an economic disaster turned into political and scientific catastrophes in 1996 when it was announced that some patients with “atypical Creutzfeldt–Jakob disease” in England may have been contracted by eating meat from cows with BSE. The British government underreacted, the European governments overreacted, and a crisis with more politics than science ensued. Soon it became clear that variant

Creutzfeldt–Jakob disease (vCJD) was real. Several authors believe that it resulted from eating contaminated meat,[91,255,466] although Prusiner has been more circumspect in his analysis.[379–381] vCJD differs from the classical form in several ways, including onset at a young age. The epidemic of BSE and apparently of vCJD in Britain was eventually brought under control by widespread slaughter of cattle and prohibition of animal products in animal feeds. The long incubation periods of TSE make caution in declaring victory a wise policy.[243]

The BSE and vCJD saga shattered the previously held and comforting theory that prion diseases were species-specific. Although TSE had been recognized for many years, there had never before been transmission across species lines. It was devastating to realize that the species barrier may not be absolute and that humans may not be immune to risk. Additional concern was raised by the recognition that at least one victim of CJD had participated in wild game feasts.[64] It is not known whether the wild game animals were afflicted with chronic wasting disease, which afflicts herds of elk and deer in the Western and North Central United States. The potential for additional risks to humans is, however, all too obvious. Another comforting illusion was destroyed when BSE was identified in both Canada and the United States.[67,115]

To date, all transmissions of prion disease have been through neural tissue, including transmission of CJD by hormones derived from human pituitary tissue, by transplantation of dura mater and corneas, and through contaminated electroencephalographic electrodes.[381] Infections have become clinically apparent more than 14 years after the putative exposure. Definitive evidence of transmission by extraneural tissue has not been forthcoming,[252] but prions have been documented outside the CNS in classical CJD[172] and in vCJD.[466]

When TSE is suspected clinically, elaborate precautions must be taken in the autopsy room and histology laboratory because the agents of these infections survive formalin fixation and are even demonstrable after tissue is embedded in paraffin blocks.

Clinical Classification of Viral Infections

Although virologic taxonomy is important scientifically, clinical schemes of classification have practical validity when considering an individual patient. The clinical syndromes and associated viruses that are most commonly encountered are summarized in Table 23-16. It is important to recognize that viruses from varying taxonomic groups may produce the same symptoms.

TABLE 23-16 Clinical Syndromes Associated with Viral Infections

Clinical System	Syndrome	More Likely Agents	Less Likely Agents
Respiratory	Coryza (common cold)	Rhinovirus Coronavirus Adenovirus Parainfluenza 3	Influenza A and B Parainfluenza 1 and 2 RSV Enterovirus
	Pharyngitis	Adenovirus Herpes simplex 1 Enterovirus EBV	Influenza A and B RSV Parainfluenza 1 and 2 Rhinovirus Coronavirus
	Croup	Parainfluenza 1 Parainfluenza 2 Parainfluenza 3	Influenza A RSV Measles Coronavirus
	Bronchiolitis	Parainfluenza 3 RSV hMPV	Adenovirus Parainfluenza 1 and 2 Influenza A and B Rhinovirus
	Pneumonia	Influenza A RSV Parainfluenza 3 Adenovirus CMV (immunosuppressed hosts)	Parainfluenza 1 and 2 Rhinovirus EBV Influenza B SARS coronavirus hMPV
	Pleurodynia	Coxsackievirus B	Coxsackievirus A Echovirus
Central nervous system	Aseptic meningitis	Echovirus Coxsackievirus A Coxsackievirus B	Mumps virus LCM Herpes simplex 2 VZV Adenovirus Bunyaviruses Parainfluenza 3 Polio virus (vaccine strains)
	Encephalitis	Herpes simplex 1	Togavirus Flavivirus Bunyavirus EBV Enterovirus Rabies CMV VZV
Gastrointestinal	Diarrhea (infants)	Rotavirus Adenoviruses 40 and 41 Astrovirus	Calicivirus (Norwalk)
	Diarrhea (adults)	Calicivirus	Rotavirus Adenoviruses 40 and 41 Astrovirus
Liver	Hepatitis	Hepatitis A Hepatitis B Hepatitis C	EBV CMV Hepatitis D Hepatitis E
Parotid gland	Parotitis	Mumps virus	Parainfluenza
Cutaneous	Vesicular rash	Herpes simplex 1 and 2 VZV	Echovirus Coxsackievirus A Vaccinia

	Maculopapular rash	Echovirus Coxsackievirus Human herpesvirus 6 and 7	Adenovirus EBV Dengue Measles Rubella
	Petechial rash	None frequent	Adenovirus Echovirus Coxsackievirus Hemorrhagic fever viruses
Urogenital	Hemorrhagic cystitis	BK virus (immunosuppressed host)	Adenovirus Herpes simplex 1
Cardiac	Myocarditis/pericarditis	Coxsackievirus A, B Echovirus	Adenovirus Herpes simplex 1 Influenza A Mumps
Ocular	Keratitis/conjunctivitis	Herpes simplex 1 VZV Adenovirus	Vaccinia Measles

Diagnosis of Viral Infections

The primary diagnostic technique for most viral infections has changed over the past decade from the isolation of the virus in cell culture to detection of the nucleic acids of the viruses by a variety of molecular methods, most of which involve nucleic acid amplification. Serologic techniques remain useful in a number of settings. These include determining the immunologic status of donors and recipients prior to transplantation and in the diagnosis of diseases wherein the viremia may have been transient (e.g., West Nile virus infection). The direct detection of viral antigen in body fluids or tissues has also been effective for some viruses, but there are limitations to this approach that are detailed below. The precise role that antigen detection will play a role remains uncertain, as molecular diagnostic assays become ever more user-friendly, some of which are even available as "waived" point-of-care tests. In Table 23-17, the methods most commonly used in hospital laboratories to diagnose viral infections are summarized. The advantages and disadvantages of each of these approaches are compared and contrasted in Table 23-18. Interested readers should consult excellent general references for more detailed discussions.[249,436]

Collection of Specimens for Diagnosis

In general, an attempt should be made to obtain material from the organ or organs that are infected. For the most common viral infections of the skin, the scrapings or aspirates of cutaneous lesions are the best specimens for testing, which depending on the laboratory may be direct immunofluorescence assay DFA and culture, or solely

molecular diagnostics. For diagnosis of infections of the respiratory and gastrointestinal tracts, secretions from those regions should be submitted. As molecular methods were developed at a time when DFA and culture were the standard of care, many of the transport media used for viral culture have been validated for molecular testing. This is not only convenient, but stabilizes the virus, should culture ever be needed for antiviral susceptibility testing or epidemiologic studies. Most viruses enter the body through the respiratory or gastrointestinal tracts. Although the most obvious clinical manifestations of disease may occur in a distant organ, it is often appropriate to collect a specimen from the point of entry. Sampling of multiple sites is particularly useful if it is difficult to obtain a specimen from an internal organ or if the virus is difficult to isolate from the target organ. For example, the skin is most dramatically involved in measles infection, but measles virus may be isolated from the respiratory tract or from the urine. Similarly, the cardiac and CNSs are commonly affected in serious enteroviral infection, but the virus may be isolated from the upper airways or from the gastrointestinal tract.

If the virus is rarely isolated from these nonsterile sites (as is the case with measles), recovery of a virus establishes an etiologic diagnosis. If the virus is recovered from sites where it may be found in the absence of disease (e.g., the enteroviruses in throat or stool specimens), the recovery of a potentially pathogenic virus provides at best a presumptive diagnosis.

Viruses colonize mucosal surfaces less frequently than do bacteria, but may be present more commonly during the months when increased circulation of viruses occurs—the winter for respiratory viruses and the summer for enteroviruses. The frequency with which enteroviruses colonize the gastrointestinal tract is greatest in infants and least in adults. In a study performed in Cincinnati, the carrier rate for echoviruses was 5.2% among 1- to 4-year-old children, 2.6% in 5- to 9-year-old children, and only 0.2% in 10- to 14-year-old children.[404] HSV and CMV may produce chronic infections and be shed intermittently into secretions and fluids.[361,486]

1541

TABLE 23-17 Methods for Diagnosis of Viral Infections

Virus	Primary Method	Expedited Method	Ancillary Method	Comments
Adenovirus, Non-Enteric	CA-NAAT LDT	FA CA-NAAT LDT	Culture Histology with IHC	
Adenovirus, Enteric	CA-NAAT LDT	FA, EIA	IEM	
Alphaviruses	LDT Culture	LDT	Serology	
Arenaviruses	LDT Culture	LDT EIA	Serology	Tests performed only in BSL-4 laboratories.
Astroviruses	CA-NAAT LDT	CA-NAAT LDT	EIA, IEM, and Serology	
Bunyaviruses	LDT	LDT	Serology	Both serology and molecular tests are recommended for hantavirus.
Calicivirus	CA-NAAT LDT	CA-NAAT LDT	EIA, IEM, and Serology	
Coronaviruses	CA-NAAT LDT	CA-NAAT LDT	Serology	Some of the common coronaviruses are now part of commercially available multiplex respiratory viral panels. Testing for the SARS or MERS coronaviruses is predominantly done in public health facilities.
Cytomegalovirus	CA-NAAT LDT Culture	CA-NAAT LDT	Serology Histology, possibly with IHC.	Serology is to determine immune status associated with transplantation. Quantitative PCR is used to monitor CMV viral loads for patients at risk for CMV disease.
Enteroviruses	CA-NAAT LDT Culture	CA-NAAT LDT	Serology	The large number of serotypes make serology challenging.
Epstein–Barr virus	Serology EIA CA-NAAT LDT	EIA CA-NAAT LDT	Histology with in situ hybridization	The method is dependent on the need. EIA and serology are predominantly used for the assessment of primary infection. Quantitative PCR is used to determine EBV viral loads in an effort to avoid the development of a posttransplant lymphoproliferative disorder.
Filoviruses	CA-NAAT LDT	CA-NAAT LDT	Culture Serology	Tests performed only in BSL-4 laboratories.
Flaviviruses	LDT	LDT	Serology Culture	
Hepatitis A virus	IgM serology		LDT	
Hepatitis B virus	Serology	CA-NAAT	CA-NAAT	Serology is used both for diagnosis and to monitor patients, wherein CA-NAAT testing is used to monitor patients.
Hepatitis C virus	Serology CA-NAAT	CA-NAAT	Genotyping Histology with IHC	Serology with reflex CA-NAAT is used for diagnosis; then CA-NAAT is used for monitoring. The availability of new drugs may make the need for genotyping obsolete.
Hepatitis D virus	Serology		LDT	
Hepatitis E virus	Serology		LDT	
Herpes simplex viruses	CA-NAAT Culture LDT	FA CA-NAAT LDT	Histology, possibly with IHC Serology, type specific	Variations of culture, such as shell vial assay and modified cell lines (e.g., enzyme-linked virus-inducible system [ELVIS]) should also be considered.
Human herpes virus 6 and 7	LDT	LDT	Serology	

Human herpes virus 8	LDT	LDT	Histology with IHC Serology	
HIV	Serology CA-NAAT	EIA	Genotyping	Serology with reflex, as needed, to CA-NAAT for diagnosis. Quantitative RT-PCR is used to monitor the viral load. Genotyping is used to determine the presence of resistance-associated mutations.
Influenza	CA-NAAT	CA-NAAT FA EIA	Culture	Culture-based methods are largely being replaced by CA-NAATs. New, waived, and simple-to-use point-of-care amplification may replace the insensitive EIAs.
Measles	Serology LDT		Culture	
Metapneumovirus	CA-NAAT LDT	CA-NAAT LDT FA	Culture	
Mumps	Culture LDT	LDT	Serology	
Papillomavirus	SA CA-NAAT		Pap test Histology	
Parainfluenza virus	CA-NAAT	FA CA-NAAT	Culture	
Parvovirus B19	LDT		Histology Serology	
Polyomaviruses	LDT Histology, with IHC or *in situ* hybridization.		Serology Cytology	Quantitative PCR is used for the detection and monitoring of the polyoma viruses in patients at risk or suspected of having associated disease.
Poxviruses	LDT Histology Culture		Serology	Serology is performed for determination of immune status; culture is performed in BSL-4 laboratories if smallpox threat is suggested.
Rabies	Culture FA LDT	FA LDT		Tests performed predominantly in public health facilities.
Respiratory syncytial virus	CA-NAAT	CA-NAAT FA EIA	Culture	
Rotavirus	EIA CA-NAAT	EIA CA-NAAT	IEM	
Rubella	Serology	LDT	Culture	
Varicella-zoster virus	LDT FA	LDT FA	Culture	Culture for VZV has poor sensitivity.

CA-NAAT, commercially available nucleic acid amplification test; LDT, laboratory-developed test, which is usually PCR-based; FA, direct or indirect immunofluorescence; EIA, enzyme immunoassay; IEM, immune electron microscopy; IHC, immunohistochemistry; SA, signal amplification.

The association of a clinical illness with a virus that has been recovered from a nonsterile site may be strengthened by demonstration of a serologic response to the isolated virus, although this inconvenient tack is rarely used.

The optimal specimens for viral diagnostics are aspirates of fluids, exudates, or secretions; tissues; washings of the upper airways; stool specimens; and plasma or whole blood. Swab specimens, which are convenient and more acceptable to patients than washings or aspirates, are acceptable in most situations. Swabs and nasopharyngeal washings are generally equivalent for recovery of respiratory viruses. The newer flock swabs are recommended, as these deliver a greater quantity of

clinical specimen compared with more traditional swabs. Some investigators have found that RSV is more reliably recovered from nasopharyngeal aspirates than from swabs,[212] but that experience has not been universal.[429] Virtually any material may be used for the swab tip, with the notable exception of calcium alginate (at least for HSV).[429]

1543

TABLE 23-18 Comparison of Diagnostic Methods

Method	Time	Advantages	Disadvantages
Culture	Days to weeks	Specificity maximum; sensitivity usually adequate, but depends on the virus; isolate available for characterization	Cell culture facilities needed; time for diagnosis may be long, but may be shortened by spin amplification.
Antigen detection	Hours to 1 day	Speed of diagnosis; used for viruses difficult to culture	False negatives due to limited sensitivity are an issue with non-DFA antigen detection methods (e.g., lateral flow EIA); hard to batch tests.
Molecular diagnostics	Hours to 1 day	Excellent sensitivity and specificity; speed of diagnosis; have become the method of choice for detecting most viruses	Some, but not all, require molecular facilities; potential for cross-contamination exists for some assays
Serology	Within a week	Assessment of immunity; used for viruses that are difficult to culture	Potential cross-reactions; sensitivity and specificity varies between manufacturers.

Viremia occurs frequently during viral infections but is not often detected. HIV, HBV, HCV, and the transplant-associated viruses (CMV, EBV, and BK) cause viremia and can be quantitatively detected by several methods, most commonly PCR-based methods. Blood may also be a useful specimen for diagnosis of enteroviral infection in young children and infants.[376]

To culture vesicular skin lesions, the skin should be cleansed with an alcohol swab and allowed to dry for at least 1 minute. The vesicle should then be unroofed with a sterile scalpel and a sterile swab touched several times to the base. The swab should be placed in a viral transport medium, as described below. Alternatively, the contents of the vesicle may be aspirated with a tuberculin syringe and 26-gauge needle, if the vesicle is sufficiently large. Material for a Tzanck preparation, which is not commonly performed, can be collected by vigorously scraping the base of the lesion with the edge of a scalpel blade; the material on the blade is then touched to a glass slide and allowed to air dry. The Tzanck preparation has largely been replaced by DFA and culture, and more recently by FDA-approved PCR methods for the HSV. These assays are often constructed so that HSV types 1 and 2 are differentiated, without any additional effort or cost.

As a general rule, the frequency with which viruses are recovered decreases as the duration of illness increases, so every effort should be made to obtain specimens as early in the infection as possible. Additionally, there are certain viruses that are notably

difficult to recover and may be lost in transit, if culture-based methods are used. Examples include RSV and VZV. Although the culture for these viruses may fail, the presence of virus can be demonstrated by traditional DFA or by more sensitive molecular methods. For example, when we studied the detection of VZV using four methods, DFA, culture and two PCR assays, we found the sensitivity of the culture was a dismal 46.3% compared with 87.8% for the DFA. The PCR assays had sensitivities of 97.6% and 100%.[491]

Transportation and Storage of Specimens

Aspirates, fluids, and tissues should be transported to the laboratory in a sterile, leakproof container. Every effort should be made to minimize the interval between collection of the specimen and its inoculation into cell culture, if culture-based methods are used. In the past, inoculation of cell cultures at the bedside had been recommended for some fragile viruses, particularly RSV, but is impractical and is usually not performed, particularly in the era of nucleic acid detection.[429]

Swabs should be placed into a transport medium that includes antibiotics; dry swabs are not acceptable. The type of transport medium is probably not critical, although it is difficult to conduct definitive comparative studies in which all variables are controlled. Data are most complete for HSV. Commercial transport systems, such as the Culturette swab products (BD Diagnostics, Franklin Lakes, NJ), have been satisfactory. The sucrose–phosphate–glutamate medium (SPG) that was designed for *Chlamydia trachomatis* (CT) has been effective, as has been a variant without the glutamate (2SP medium).[248] Traditionally, a nutrient medium has been supplemented with a source of protein in an attempt to stabilize fragile viruses and with antibiotics to minimize bacterial contamination. Transport media that are currently commonly used includes M4 and Universal Transport Media (UTM), among a few others.

Specimens should be refrigerated, if cell cultures will be inoculated. To select the best temperature for storage, one must balance the decrease in viral titer that occurs progressively at 4°C against the sudden decrease that occurs when specimens are frozen and thawed. It is clear that (1) the specimens should be maintained at −70°C if they are to be stored for a very long time (weeks or months) and (2) the best temperature is 4°C if the delay will be short (i.e., less than 24 hours). A reasonable recommendation is that specimens be refrigerated for up to 96 hours and frozen at −70°C if the delay will be longer. The worst temperature is −20°C, especially in a frost-free freezer, where repeated cycles of defrosting and freezing are extremely traumatic to all forms of life. Specimens should never be frozen in the freezing compartment of a standard refrigerator. Johnson has thoroughly reviewed the transport of specimens for traditional viral diagnostics.[261]

Isolation of Viruses in Culture

Although a few of the largest research and public health laboratories may have facilities for inoculation of animals, most diagnostic facilities are restricted to the use of in vitro analogs. Even these, in vitro analogs (i.e., cell culture systems)

are becoming less common, as more rapid and user-friendly, often molecular, methods are being employed. The following sections of text are retained for those performing cell cultures.

Preparation and Maintenance of Cell Cultures

Cell culture is the cultivation in vitro of dissociated single cells. Tissue and organ culture is the maintenance in vitro of a portion of an organ, usually for short, delimited periods of time. The use of organ culture has been restricted almost completely to the research laboratory. For example, cultures of trachea have been used to isolate human coronaviruses, most of which do not grow in cell culture. Occasionally, organ and cell cultures must be combined. For example, an explant of infected brain and an indicator monolayer of susceptible cells were used for the isolation of measles virus from patients with subacute sclerosing panencephalitis. Embryonated eggs are an inexpensive method for cultivating selected viruses, such as the orthomyxoviruses, but given the complexity of use and the development of superior methods, they are rarely used in diagnostic laboratories.[285]

Cell cultures are of three basic types (Table 23-19). Primary cell cultures consist of a mixture of cells, usually kidney, lung, or skin, obtained by dissociation of cells from the minced organ. These cells can be maintained in culture for a limited time only. Once subcultured repetitively in vitro, a primary cell culture becomes a cell line. The most commonly used cell lines are composed of fibroblasts, obtained from skin or embryonic lung. A cell line is diploid if at least 75% of the cells have a normal complement of chromosomes. A cell line is heteroploid if more than 25% of the cells have an abnormal complement of chromosomes. Readers interested in detailed choices of cell lines should see the previous edition of this text. Innovative thinking has produced even more variety in the choices for cell cultures. By combining cell lines, the spectrum of viruses detected can be expanded while limiting the number of tubes required and even avoiding the need for primary cell cultures.[238] Some of the combinations of cell lines that have been developed as Fresh Cells or R-Mix (Quidel, Athens, OH) are included in Table 23-19. The mixed cell lines may be combined with other approaches, such as spin amplification (i.e., shell vials) to enhance detection further.[18,123] A further innovation is the storage of the mixed cultures at −80°C for up

to 4 months before inoculation.[240]

Still another innovation has been the engineering of cell cultures to facilitate isolation of particular viruses or to enhance their detection. One of the cell lines that has been used successfully for detection of enteroviruses is buffalo green monkey kidney (BGMK) cells. By engineering BGMK cells to express a receptor for enteroviruses (decay-accelerating factor, DAF) investigators were able to increase the diagnostic yield.[239]

A different approach to cellular engineering is the ELVIS (*e*nzyme-*l*inked *v*irus-*i*nducible *s*ystem) HSV test system (Quidel). In this case, an HSV-specific gene promoter sequence in the baby hamster kidney (BHK) cell line is linked to a reporter gene,β-galactosidase. When the cells are infected with either serotype of HSV, the promoter gene is turned on and the reporter gene is then activated, producing a visible

TABLE 23-19 Types of Cell Cultures

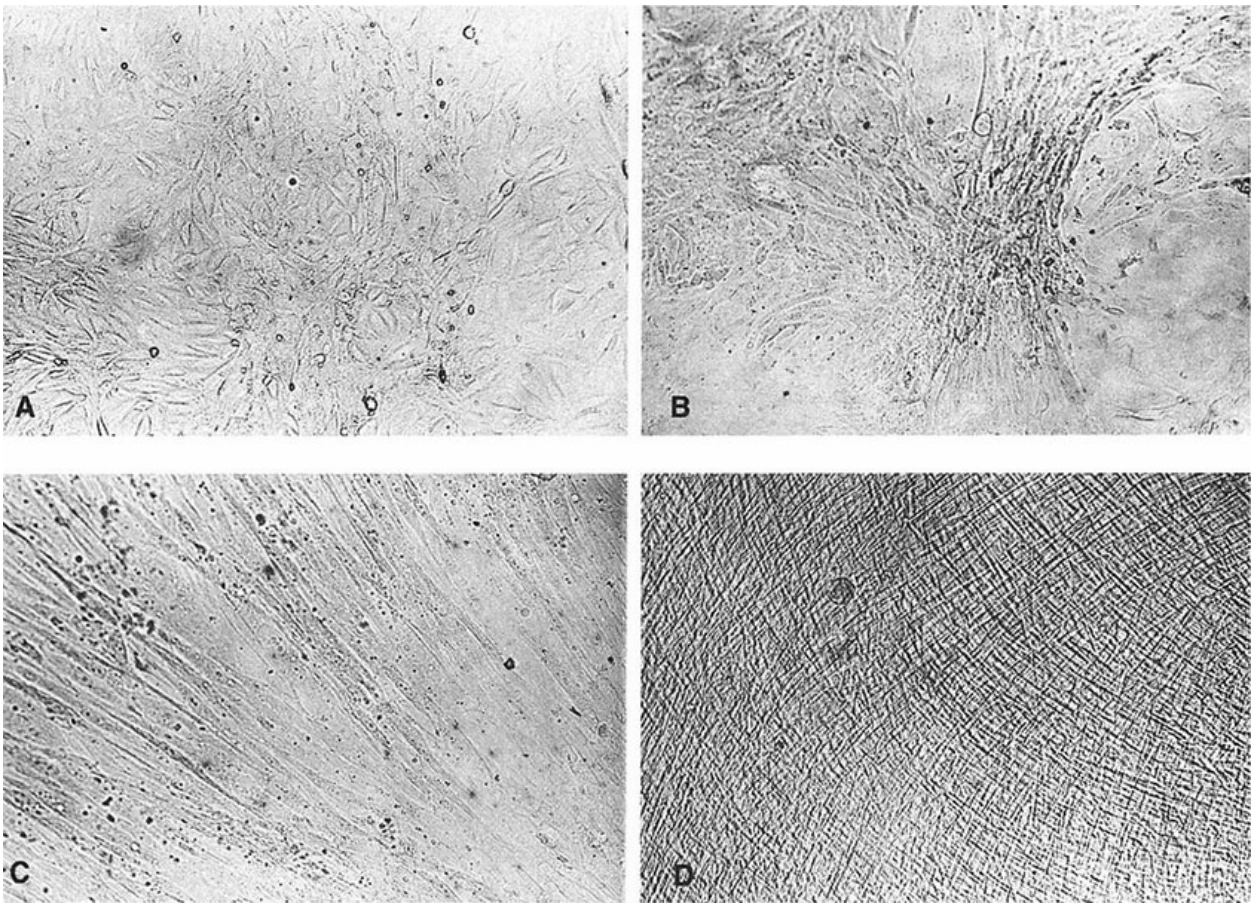
Type of Culture	Characteristics	Examples	Primary Use
Primary	Diploid; mixed cell types; one or two passages	Primary monkey kidney	Influenza; parainfluenza; some enteroviruses
		Primary rabbit kidney	Herpes simplex
Cell lines	Diploid; fibroblastic; limited passages (<50–70)	Human diploid fibroblast (WI-38, MRC-5, HEL, FS-9)	Herpes simplex; cytomegalovirus; varicella-zoster; rhinovirus
Established cell lines	Heteroploid; continuous passage in vitro	HeLa; HEp-2	Adenovirus; RSV; Coxsackie B viruses
		A549	Herpes simplex; adenovirus; varicella-zoster; some enteroviruses
		MDCK	Influenza virus
		LLC-MK2	Parainfluenza virus
		Vero; ML cells	Herpes simplex
		RD cells	Some Coxsackie A viruses
		BGM cells	Coxsackie B viruses
		293 cells	Enteric adenovirus
Mixed cell lines	Combinations of established cell lines	MRC-5 + CV-1	Herpes simplex; varicella-zoster
		ML Cells + A549	Respiratory viruses
		RD + H292; BGMK + A549	Enteroviruses
Genetically modified cell lines	Introduction of a gene to produce a visible indicator after infection	Enzyme-linked-virus-inducible system (ELVIS)	Herpes simplex

change in the color of the monolayer.[362] As with the mixed cell lines, the ELVIS cells can be stored at −80°C until use.[240] HSV is the most common virus sought in diagnostic laboratories, and a targeted approach to detection of this agent is sensible.

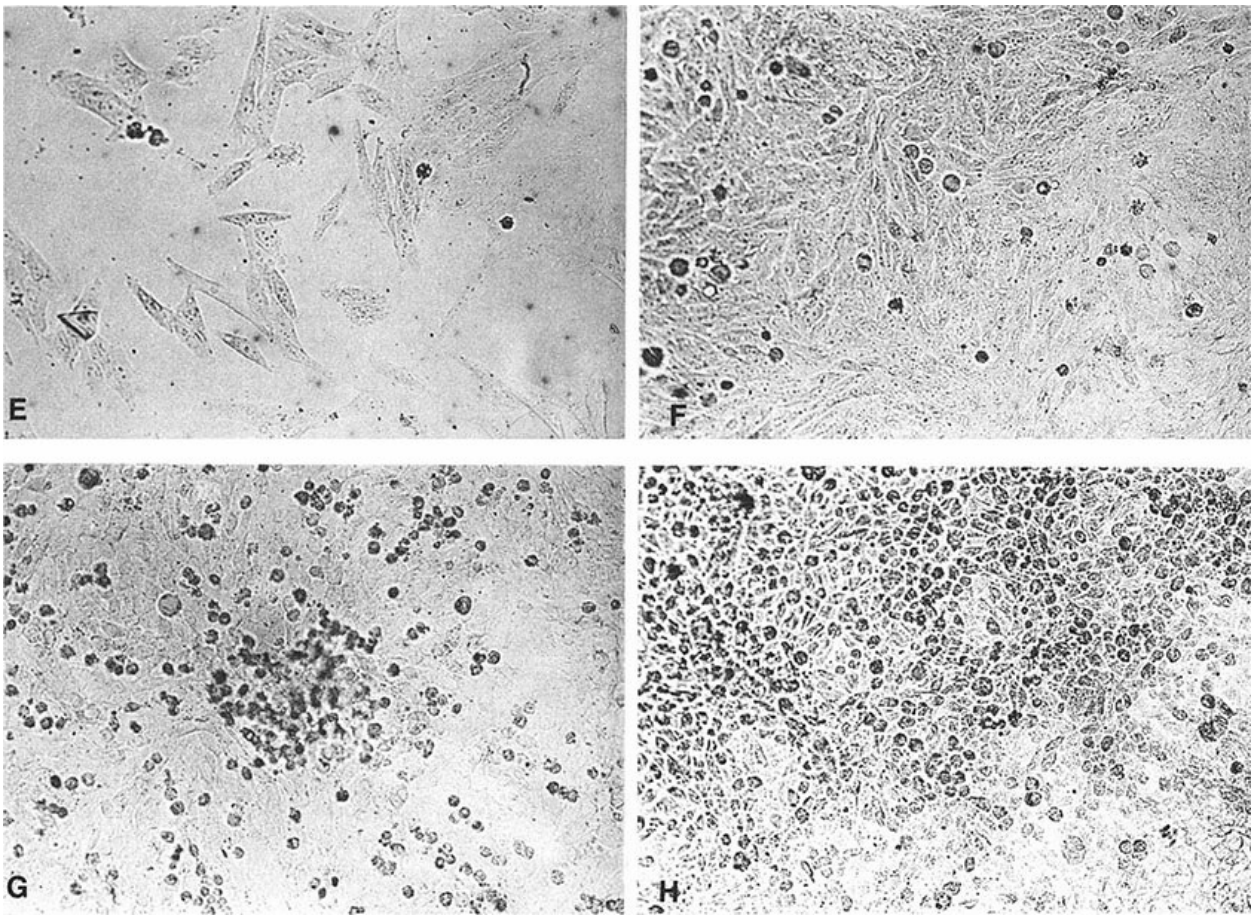
The life expectancy of normal diploid cells is approximately 50 serial doublings in

vitro[208]; those cell lines that have been transferred at least 70 times are considered to be established cell lines. These established or continuous lines may be derived from normal tissue, as was the Vero cell line from African green monkey renal cells. Alternatively, they may originate from neoplastic epithelium, such as the HeLa cells that came from a cervical adenocarcinoma and the HEp-2 cells that were derived from a carcinoma of the larynx. The appearance of uninoculated cell cultures is illustrated in Figure 23-6. The fibroblastic cells are usually long, spindle-shaped and oriented in parallel, whereas the established cell lines consist of polygonal epithelial cells. The primary cultures naturally contain a mixture of cell types.

Conditions for growth and maintenance of cell cultures vary considerably, and only a few generalizations are possible. The temperature of incubation is optimal at 36°C to 37°C but may be lowered to 35°C after confluence of cells is achieved. This maneuver may facilitate isolation of viruses, such as myxoviruses and rhinoviruses that grow optimally at 33°C. A physiologic pH must be maintained. Usually a CO_2–bicarbonate buffering system is used, with CO_2 being supplied by the metabolizing cells in a closed tube or flask. In an open system, a CO_2–air mixture must be provided. Buffering compounds that do not depend on CO_2–bicarbonate, such as HEPES buffer (*N*-2-hydroxyethylpiperazine-*N*-2-ethanesulfonic-acid), may be used in open systems if an incubator with CO_2 is not available. A pH indicator is often included in the media to monitor closely shifts in pH during incubation.



1546



■ **FIGURE 23-6** Normal cell cultures. **A.** Normal rhesus monkey kidney monolayer. This primary culture is just at confluence—there are no spaces between the cells, but cells have not begun to pile on each other. The variability of the cells in the monolayer is a reflection of their origin from diverse cell types (×180). **B.** Normal rhesus monkey kidney monolayer. After continued incubation, areas of more luxuriant growth have become evident. The variability of the cells in the monolayer can still be appreciated (×180). **C.** Normal MRC-5 fibroblast monolayer. These diploid fibroblastic cells have the elongated, spindly character of their type. They are just reaching confluence; a few spaces remain between some of the cells (×180). **D.** Normal MRC fibroblast monolayer. After continued incubation, the crisscross pattern of fibroblasts piled one on top of the other is apparent. The detail of the individual cells is less apparent. Such senescent monolayers should not be inoculated (×180). **E.** Normal HEp-2 cells. An established cell line has been subcultured, and new cells have begun to grow. There are large spaces between individual cells, which have a spindle shape as they spread over the new glass surface (×180). **F.** Normal HEp-2 cells. The subcultured cells have now multiplied to the point of confluence but are still easily visible as distinct polygonal cells. The ideal point for inoculation of most viruses is at this stage or slightly earlier (×180). **G.** Normal HEp-2 cells. After continued incubation, the cell line has multiplied so that cells are piled one on top of the other. Cells that are dividing or detaching from the glass appear rounded. As the monolayers age, they become

less susceptible to the cytopathic effect of viruses, and it becomes increasingly difficult to detect cytopathic effect visually. **H.** Normal McCoy cells. This established cell line, the origin of which is unknown, is pictured at a point at which confluent growth has been obtained. The cells are compact and polygonal. Specimens should be inoculated at this stage or when the cells are slightly less confluent (×180).

Phenol red, which is red at physiologic pH, turning yellow at acidic pH and purple at alkaline pH, is frequently used.

Essential vitamins and amino acids must be supplied in viral culture media.[249] These compounds are stable when stored at 4°C, except for L-glutamine, which must be replenished periodically.[340] Eagle's minimum essential medium (MEM) is commonly used, both for growth and for maintenance of cells. It is usually supplemented with small amounts of serum (up to 5%) for maintenance of a monolayer after cells have reached confluent growth. To enhance initial growth, larger amounts of serum (usually 10%) are used. It is important that the serum be free of infectious agents, including the mycoplasmas, and does not contain antibodies to any viruses that might be present in clinical specimens. For this reason, fetal, newborn, or a gammaglobulinemic calf serum is most commonly used. Other formulations, such as Medium 199 or RPMI 1640, contain a richer mixture of nutrients and may be optimal for maintenance of some cell lines. Two forms of balanced salt solution are most frequently used, both for washing of cells and for incorporation into complete media. The formulations of Hanks' and Earle's solutions differ in several respects, notably the amount of buffering capacity. The two solutions are used virtually interchangeably, but Earle's balanced salt solution with its greater buffering power may be desirable for prolonged maintenance of monolayers.

Contamination of Cell Cultures

Contamination of media is reduced by inclusion of antibiotics. Penicillin (200 mg/mL) and streptomycin (200 mg/mL) or gentamicin (50 mg/mL) is commonly used for suppression of bacterial growth; amphotericin B (1.25 mg/mL) is used for inhibition of fungal growth.[249] The use of antibiotics does not substitute, however, for careful aseptic technique.

Contamination of culture media by *Mycoplasma* species is a common and troublesome problem.[324] *Mycoplasma* species usually are introduced in the serum additives or from contaminated stock viruses; once in the culture, they are very difficult to eradicate. The effects on the cells include suboptimal growth and disturbances in the interactions of cells and viruses. The presence of contaminating *Mycoplasma* species may be monitored by recovering them in culture, by staining for

Mycoplasma DNA, by biochemical measurement of uracil incorporation, or by nucleoside phosphorylase activity techniques. Commercial suppliers of cells should be able to document their efforts at surveillance and quality control.

In addition, cell cultures may be contaminated with viruses (i.e., usually ones that were present in the original tissue)[249] or even with other cells.[351] The most frequent type of viral contamination is the presence of indigenous simian viruses in primary monkey cell cultures, such as the vacuolating agent (SV40), foamy viruses, or the monkey parainfluenza virus (SV5). Simian viruses that have hemagglutinins (e.g., SV5 virus) produced misleading results when hemadsorption tests were performed to detect human respiratory viruses; fortunately, these test have been largely replaced by DFA for those wishing to confirm a cytopathic effect (Individuals interested in hemagglutination and hemabsorption should refer to previous editions of this text) (see Fig. 23-12E). The frequency with which tubes in a shipment of

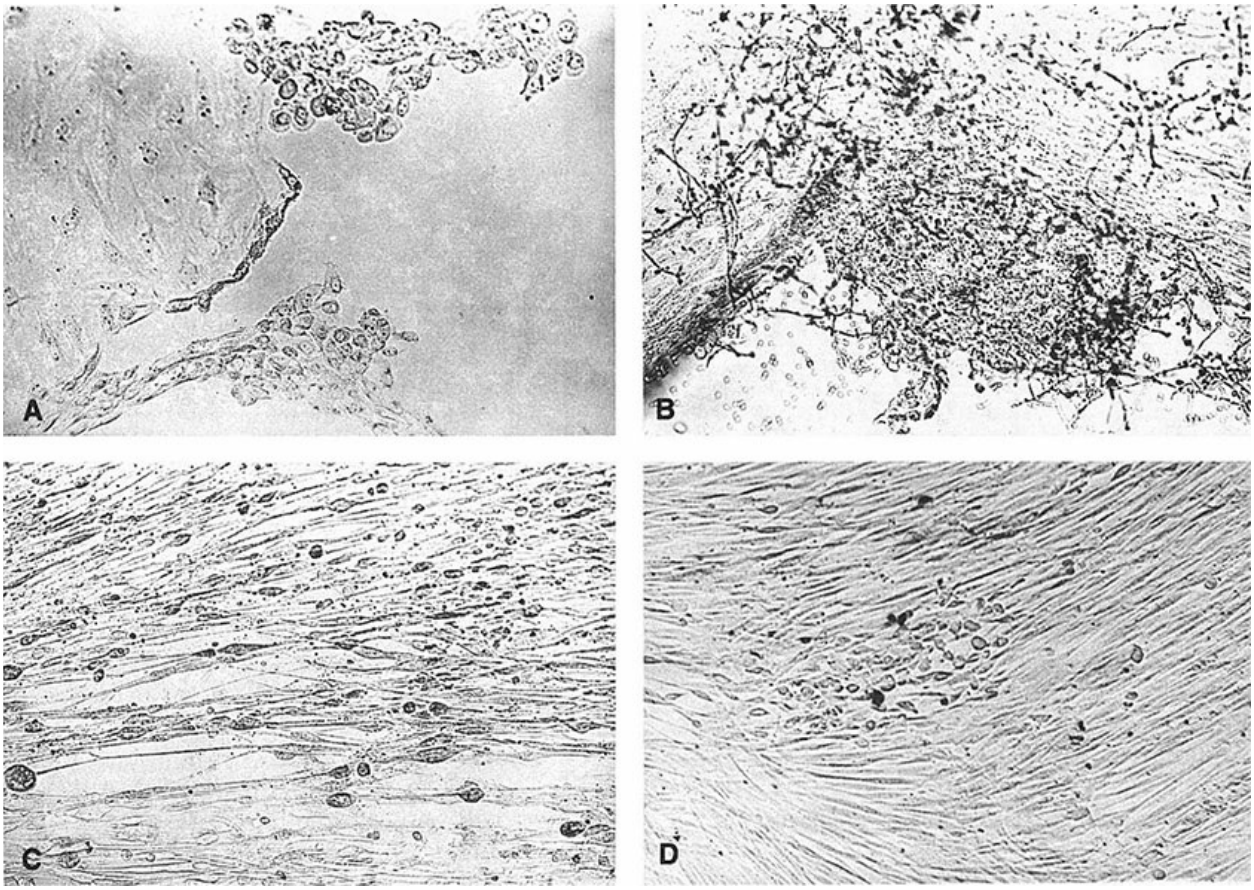
monkey kidney cells are contaminated may vary from 5% to 100%. Reserving a few uninoculated tubes for hemadsorption controls is not foolproof. If an unusual number of patients have hemadsorbing viruses on a given day, the possibility of simian virus contamination should be considered. Contamination of a commercial lot of A549 cells with infectious bovine rhinotracheitis virus has also caused diagnostic problems in several laboratories.[148] An extremely rare but potentially serious problem can be caused by the presence of pathogenic viruses in the tissues of monkeys. Although fortunately very rare, the simian herpes virus and Marburg virus, which produces a hemorrhagic fever, have caused lethal laboratory infections.[89,403,405] These agents provide justification for working with primary cell cultures of simian origin in a biologic safety cabinet.

Contamination of cell cultures with other cells has resulted in the erroneous supposition that a new cell line has been established in more than one research laboratory. In fact, a hardy HeLa cell may have found its way into the flask and taken over.[374] In the diagnostic laboratory, cross-contamination of an established cell line onto a diploid cell line or primary cell culture may give the appearance of cytopathic effects in the original cell culture line (Fig. 23-7D).

Technical Aspects of Cell Culture

A variety of containers are used for the support of cell monolayers. The most common cell cultures in use are commercially available in tubes or vials that are ready for inoculation of specimens. Many laboratories may prefer, for reasons of economy, to maintain cell lines in their own laboratories. T-shaped plastic flasks have generally

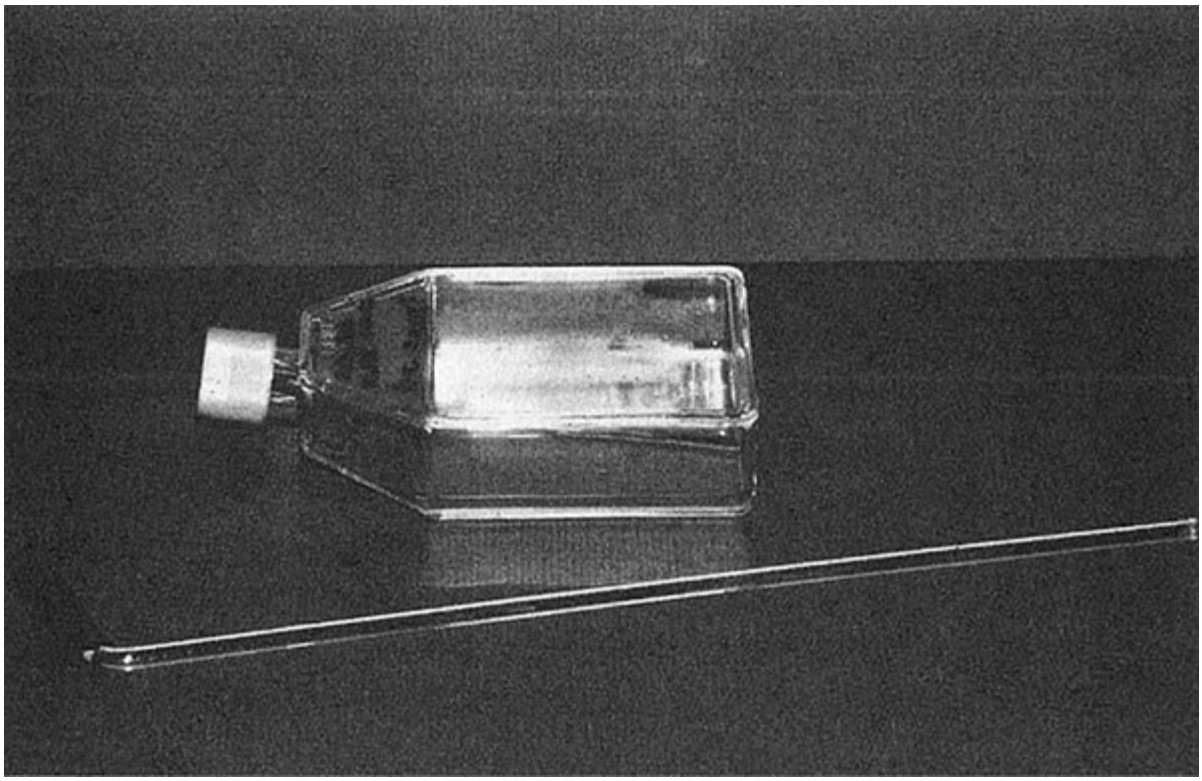
replaced glass bottles for the propagation of cell lines (Fig. 23-8).



■ **FIGURE 23-7** Artifacts in cell culture. **A.** Rhesus monkey kidney cells. The tube has been inoculated with a specimen that contained nonspecific toxic material. Cells in the monolayer have rounded up focally, and many cells have detached from the glass. The nonviral effect can be distinguished from the viral cytopathic effect by the overall pattern, by the rapidity of occurrence, and by the inability to reproduce the nonspecific effect after subculture into fresh monolayers (×180). **B.** Rhesus monkey kidney cell culture. A stool specimen was inadequately decontaminated before inoculation. Bacterial and fungal hyphae are evident on the monolayer, which is granular and will soon degenerate. The media may become acidic and cloudy. Retreatment of the specimen with additional antibiotics is necessary. The specimen may also be filtered, but cell-associated viruses may be lost (×180). **C.** MRC-5 fibroblasts. A filtrate of stool that contained *Clostridium difficile* was inoculated onto the monolayer 24 hours earlier. The generalized disorganization of the monolayer with rounding and sloughing of cells is typical of this toxin. Specific identification of the cause of toxicity is provided by neutralization of the effect with specific antiserum. *C. difficile* toxin may give an initial impression of viral cytopathic effect, but the effect will not be reproduced when material from the suspect tube is subcultured onto additional monolayers (×180). **D.** MRC-5 fibroblasts. Focal cell rounding

and enlargement appeared on these fibroblasts that had been inoculated with CSF, suggesting viral cytopathic effect. The atypical progression of cytopathic effect and observation that some of the foci were superimposed on the fibroblasts suggested cellular contamination. HEp-2 cells were subsequently recovered from the tube and demonstrated to have a karyotype that was identical to that of the HEp-2 cells used in the laboratory. The mechanism by which the contamination occurred was never elucidated (×180).

1548



■ **FIGURE 23-8** T-shaped plastic flask and rubber-tipped glass rod, known as a "rubber policeman." Monolayers of cell lines may be grown in large flasks. Many individual tubes for virus culture may be prepared from a single large flask. Mechanical disruption by pipetting or by the rubber policeman helps to dislodge the cells during trypsinization for subculture.

Cell lines may be maintained in the laboratory by dissociation of cells, which are then distributed into new vessels (Box 23-5).

Established monolayers are dissociated by brief incubation in a solution of trypsin or a mixture of trypsin and ethylenediaminetetraacetic acid (EDTA), which is also known as Versene. Damage to cells may occur if the suspension of trypsin is too concentrated

or if the contact is too prolonged. Neutralization of the trypsin is provided by serum in the growth medium that is added after cells have been dissociated. Detachment of the cells from the surface may be enhanced physically by agitation or by scraping with a rubber-tipped glass rod, a device known colloquially as a "rubber policeman" (Fig. 23-8). The dissociated cells are then dispensed into tubes for inoculation of specimens or into additional flasks for continued propagation of stock cells. The density of the suspension can be adjusted to provide confluent monolayers after one or more days of incubation. After inoculation of clinical specimens, the same protocol may be used to prepare infected cells for subculture to additional monolayers.

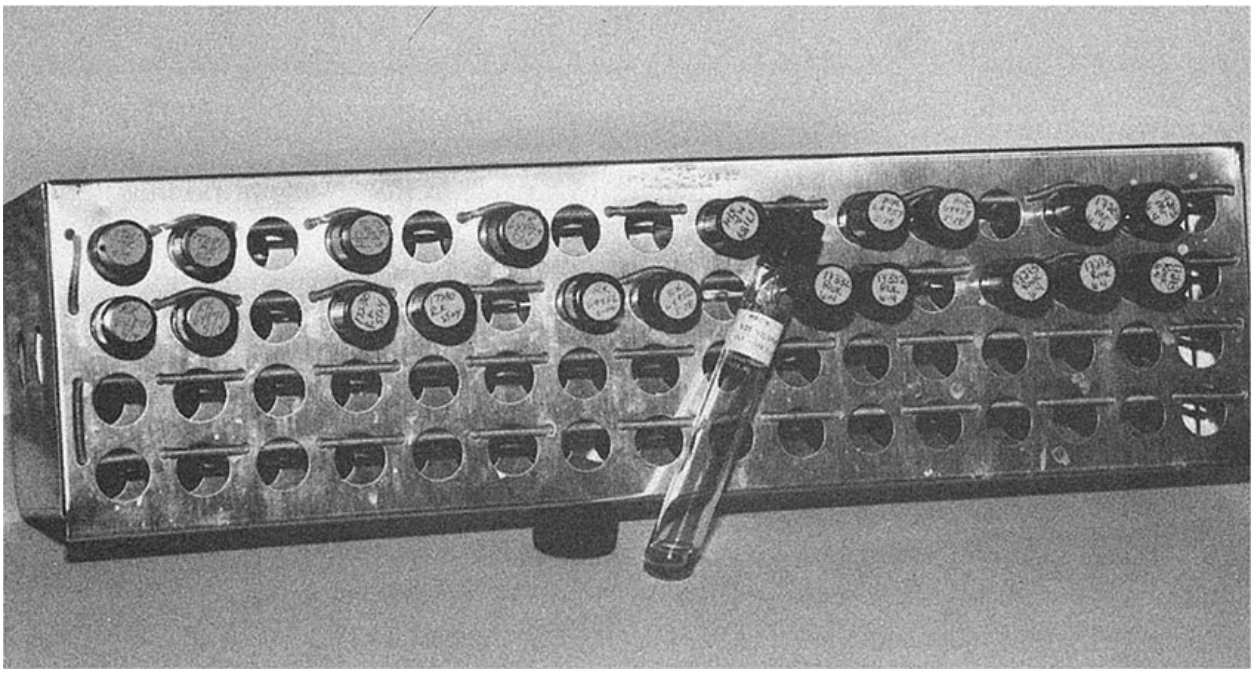
BOX 23-5

Procedure for Maintaining Cell Lines

1. The monolayer is washed with phosphate-buffered saline, pH 7.5.
2. A suspension of 0.25% trypsin or equal parts of 0.25% trypsin and 1:2,000 Versene is added for 15 to 30 seconds, and then removed.
3. The monolayer is incubated at 35°C until the cells have dissociated. Gentle shaking of the flask may enhance dissociation.
4. Growth medium is added and the cells resuspended at the concentration desired for subculture. Alternatively, the cells may be divided arbitrarily (1:2 or 1:3) as dictated by past experience.

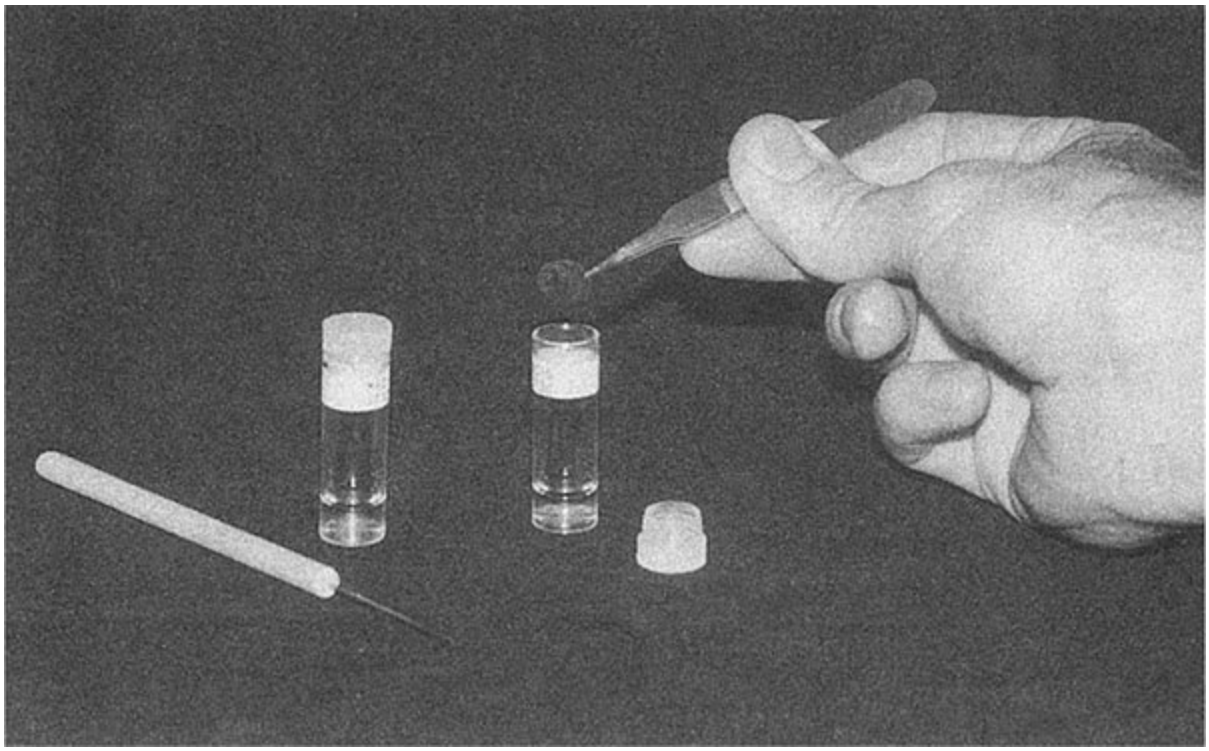
Round-bottomed glass tubes (16 × 125 mm) have been traditionally used for viral isolation (Fig. 23-9). These tubes are incubated at a 5-degree fixed angle, so that the monolayer forms on one side of the tube. The heaviest aggregation occurs near the center and at the butt of the tubes; the thinnest layer is at the edges and toward the mouth. Round Petri dishes or glass slides, onto which are affixed plastic chambers may also be used for diagnostic purposes. The slide-chamber system is expensive but useful if morphologic study of an undisrupted monolayer is planned.

The use of shell vials, originally used for isolation of *Chlamydia trachomatis*, have largely replaced tubes, given the decreased space requirements, ease of use and more rapid time to detection that may be achieved when used in conjunction with DFA. A cell monolayer is prepared on a round glass coverslip that has been placed on the bottom of a flat-bottomed vial (Fig. 23-10). If the inoculum is centrifuged onto the monolayer, as is essential for the recovery of *C. trachomatis,* and the monolayer stained with fluorescein-conjugated antiserum or tested with a molecular probe, almost all isolates of HSV can be detected within 24 hours.[134] Presumably,



■ **FIGURE 23-9** Viral culture tubes are slanted at a fixed angle of 5 degrees in a stationary rack. Metal springs hold the tubes in place. Round labels for the tops of the tubes facilitate identification of cultures without removing the tubes from the racks.

1549



■ **FIGURE 23-10** Shell vials for isolation of *Chlamydia trachomatis* and viruses. The vials are round with a flat bottom and contain a round coverslip on which the cells are grown. The top may be rubber or plastic as shown here. The coverslip is removed with forceps or with a needle.

the shell vial centrifugation technique increases contact of inoculum with the cellular monolayer.

A far more dramatic improvement in the speed of isolation has been reported for CMV.[149,363] The technique is more sensitive than conventional culture for most specimens other than blood, but use of both approaches maximizes results. The preferred method for detecting CMV in blood is quantitative PCR (see below). The gain from shell vial culture comes both from centrifugation and from the use of a fluorescein-labeled monoclonal antibody of high quality. Even supposedly uniform reagents, such as monoclonal antibodies, may vary from lot to lot. Nonspecific staining of cell nuclei may occur with some lots of antisera. The appearance of a shell vial culture containing CMV is shown in Image Plate 23-2F. An advantage of this technique is that infected cells are detected prior to the development of cytopathic effect.

Paya and colleagues[364] have studied the number of shell vials required for each specimen. They found that three vials were required for maximal yield from blood specimens, whereas two vials were needed for urine, bronchoalveolar lavage, and

tissue. Fedorko and colleagues[140] found that the age of fibroblasts in the shell vials was important for recovery of CMV. Old monolayers (8 to 15 days) were less sensitive for virus recovery but more sensitive to toxic components in the specimens than were young monolayers. It is difficult for manufacturers to provide very young monolayers, and unfortunately most laboratories must depend on commercial suppliers for shell vials.

Gleaves and colleagues[173] have reported success with still a third cell-associated herpesvirus, VZV. They examined 68 specimens from 60 patients. VZV was identified by some method in 57% of patients. The sensitivity of diagnostic techniques in decreasing order was direct immunofluorescence of skin scrapings, shell vial culture, and conventional culture. Wilson et al.[491] also demonstrated that DFA was superior to culture for VZV, but also showed that the most sensitive method was PCR.

The shell vial technique has also been applied to viruses other than the herpes group, particularly influenza virus.[123] Other respiratory viruses are also detected using the shell vial technique, but experience is more limited and somewhat less satisfactory than with influenza. The shell vial technique has also been used for BK virus.[311] As noted elsewhere, although the recovery of these viruses is feasible with this method, testing has largely migrated to molecular diagnostic platforms (see below).

Selection of Cell Cultures for Isolation of Viruses

The basic requirements for isolation of viruses in culture are a primary culture of simian kidney cells (for isolation of myxoviruses and enteroviruses) and a diploid cell line of human origin (essential for isolation of CMV, rhinovirus, and VZV; useful for isolation of HSV). The addition of an established cell line of human origin (e.g., HEp-2 or A549) is also useful for isolation of adenovirus and RSV.

Other cell lines may provide satisfactory substitutes for these three basic cell types if isolation of a specific virus is desired (Table 23-19). The quality and provenance of the cells used for isolation are important. Careful studies of cloned fibroblasts from a single fetus demonstrated a large variation in the degree to which the clones supported the growth of respiratory viruses.[458] Variants of established cell lines, such as HeLa and HEp-2, differ also in the sensitivity with which they support some viruses. It is important to ensure that the selected cell variant is of adequate sensitivity.

Once a cell line has been found acceptable, multiple aliquots should be frozen in liquid nitrogen. Cells for daily use may be maintained in continuous culture. The original stock should be used periodically to replenish the working stock so that the cells do not mutate to a state that is less susceptible to viral growth.

Rhesus and cynomolgus monkey kidney cells are comparable for isolation of myxoviruses. Medical Research Council 5 (MRC-5) fibroblasts, on the other hand, have been reported to be more sensitive than WI-38 fibroblasts for the isolation of

CMV.[187]The sensitivity of all diploid cell lines decreases as the number of passages increases. The lowest passage level from a reliable supplier should be sought. If cell sheets, particularly those of established cell lines, are too thick, recovery of viruses may be reduced and evaluation of cytopathic effects is difficult. For some viruses, islands of cells or a barely confluent monolayer are preferable to a fully confluent cell sheet.[457]

In addition, the cells must be in sufficiently good condition to last the several weeks necessary for isolation of slowly growing viruses. Contamination with *Mycoplasma* species should be avoided if maximal isolation rates are to be ensured. Viruses, such as VZV, that spread directly from cell to cell rather than through the culture medium require a healthy monolayer.

Use of growth medium with 10% serum may enhance development and progression of cytopathic effects caused by these viruses,[480] although not all are convinced that this manipulation is necessary. In contrast, serum contains inhibitors of myxoviruses and paramyxoviruses. The maintenance medium in the cells used for these viruses (usually primary monkey kidney) should be free of serum.

Inoculation and Incubation of Cell Cultures

1550

Transport vials that contain swabs should be vortexed and material from the swab expressed into the medium, which contains antibiotics. Tissues are minced and homogenized in a small volume of transport broth. It may be necessary to suspend fecal specimens in 10 volumes of transport medium. Feces, tissues, and respiratory aspirates that contain excessive debris or mucus may be clarified by low-speed centrifugation. Antibiotics are present in most transport and tissue culture media. If bacterial or fungal contamination of the specimen is expected, additional antibiotics should be added to the specimen before inoculation (penicillin and streptomycin or gentamicin plus amphotericin at twice the concentration used in cell culture media).[249] After processing, the specimen may be inoculated into the culture media. Alternatively, the inoculum may be placed directly onto the monolayer after most of the culture medium has been removed. The more direct contact of viral particles with cells enhances infectivity and may increase both the number of isolates and the speed with which they are recovered. After adsorption of the inoculum onto the monolayer for 30 to 60 minutes at 36°C to 37°C, the medium is replaced and incubation of the culture is continued. Toxic substances in the specimen may also be more evident after adsorption of the inoculum. If two tubes of each cell type are used, one may be inoculated by introducing a specimen into the medium and the other by adsorption. Any remaining specimen should be retained at 4°C or frozen at −70°C in case toxicity

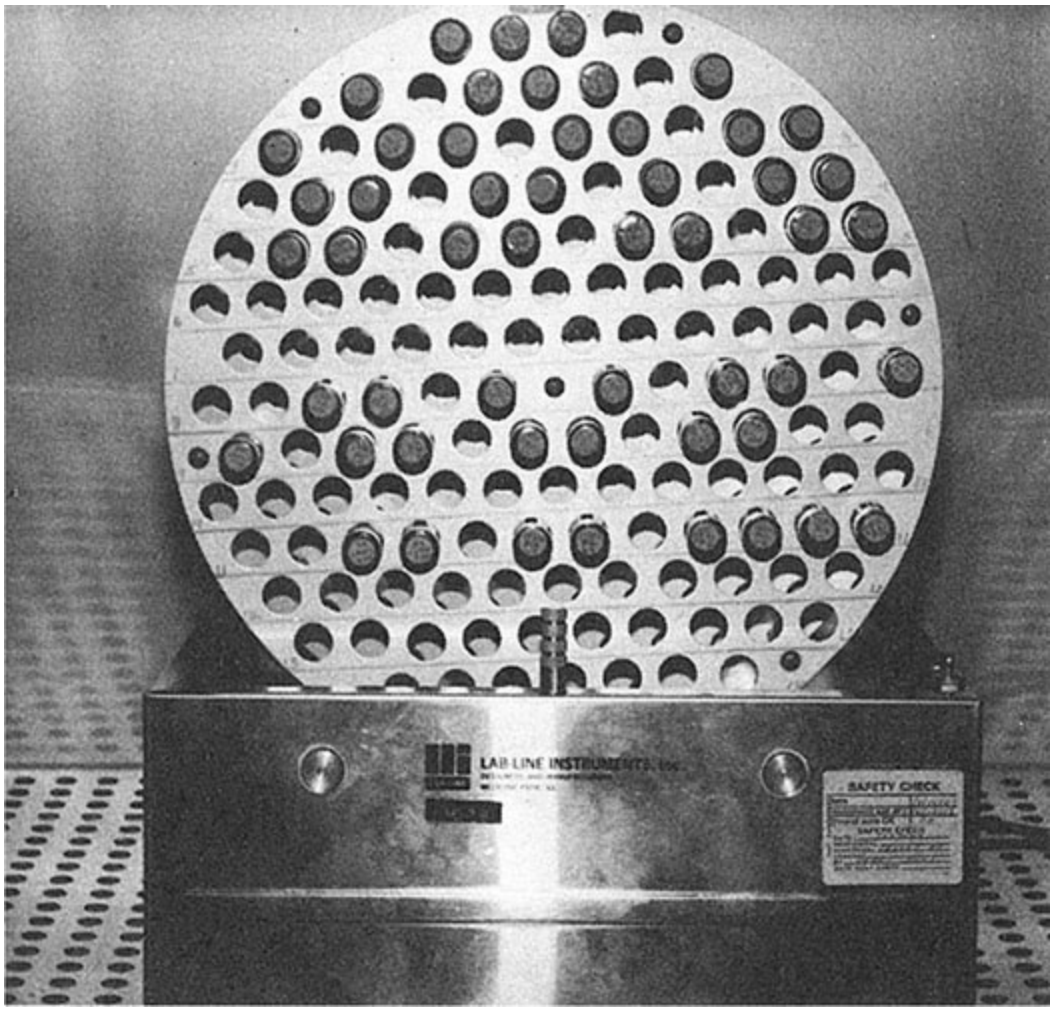
or bacterial contamination occurs. If bacterial or fungal growth results, additional antibiotics may be added to the specimen. The specimen may be passed through a 0.45-μm micropore filter before additional cultures are inoculated, but viruses that are cell-associated, such as CMV and VZV, may be lost when infected cells are trapped in the filter.[291] Nonspecific toxicity to the monolayer is usually evident within 24 hours; the specimen may then be reinoculated after making a 1:10 dilution in balanced salt solution. The pH of the specimen should also be checked and adjusted to neutrality if the specimen is very acidic or alkaline. If nonspecific degeneration of the monolayer occurs after incubation for several days, the cells and fluid may be subcultured onto fresh monolayer.

Monolayers should be incubated at 36°C to 37°C for recovery of most viruses. The optimal temperature of incubation for respiratory viruses, especially rhinovirus, is 33°C, but recovery of other viruses may be reduced at this temperature. Use of a roller drum (Fig. 23-11) facilitates isolation of pathogens in primary monkey kidney and diploid fibroblast cells, especially from respiratory specimens.

Two weeks of incubation is adequate for the recovery of most other viruses. CMV may require longer incubation, but Gregory and Menegus found that 92% of CMV isolates were recovered within 14 days when MRC-5 fibroblasts were used.[187] If the recovery of only HSV is sought, the period of incubation may be further abbreviated to 7 days. Centrifugation of the inoculum and detection of antigen will dramatically shorten the detection time for several viruses, including CMV and VZV.

Detection of Virus and Provisional Identification

Cytopathic Effect. The most common method for detecting virus in culture is examination of cultures for virus-induced damage to the monolayers or cytopathic effect. Monolayers should be examined daily if HSV is sought and at least three times a week if more slowly growing viruses are suspected. Glass tubes can be examined with a conventional light microscope, using simple holders to prevent the round tubes from rolling on the microscope stage (Fig. 23-12). If the monolayer is to be examined in shell vials, an inverted microscope must be used.



■ **FIGURE 23-11** Roller drum for viral cultures. The cytopathic effect of many viruses, especially those that cause respiratory infections, is enhanced by slow rotation of the tubes, so that one revolution occurs every 3 minutes.

Provisional identification of the specific virus (or at least the virus group) can often be provided on the basis of the

■ **FIGURE 23-12** Examination of cultures for cytopathic effect. Examination of cultures for cytopathic effect is usually performed with an inverted microscope, but may also be performed using a traditional microscope, as shown here. A rack, which fits in the specimen holder of the microscope stage, prevents the round tubes from rolling. High magnification is not possible, but is not needed for recognition and characterization of cytopathic effect.

type of cytopathic effect and the type of cell that is affected. Typical patterns of cytopathic effect and the rate of isolation for viruses most commonly isolated in hospital laboratories are summarized in Table 23-20.

When one examines a culture in the laboratory, the pattern of cytopathic effect is known but the name of the virus is not. A flow chart for analyzing cytopathic effect in a clinical specimen is presented in the previous edition of this text for those interested in additional information on this subject.

The effects of the virus on the cells may be subtle initially. Although quantitation of

the viral inoculum based on the extent of cytopathic effect is not precise, it is useful to make a laboratory record of the semiquantitative estimate for comparative purposes (1+, <25% of the monolayer affected; 2+, 25% to 50%; 3+, 51% to 75%; 4+, >75%). These estimates make it easier to document progression of cytopathic effect and establish the presence of a cytopathic agent. It may be necessary to subculture the cells from a tube with a possible cytopathic effect onto fresh monolayers. If possible, such a subculture should be performed after cytopathic effect has reached 2+, using trypsinization, physical disruption of the monolayer with a rubber policeman, or several cycles of quick freeze/thawing. Then, an aliquot is inoculated onto the type of cell in which cytopathic effect was originally observed and any other cell type that might aid in making a provisional identification.

Viral cytopathic effects for three commonly used cell cultures are demonstrated sequentially in Figures 23-13 through 23-16. Although cell culture is largely being replaced by molecular methods, we have chosen to retain these images through this transitional period. Additionally, cell culture is still used for "test of cure" in some settings, in laboratories that have not introduced molecular diagnostics, and in select public health and reference laboratory settings. In most cases early and late changes have been depicted.

TABLE 23-20 Differential Diagnosis of Viral Cytopathic Effect

Virus	Cell Culture			Days of Isolation		Description
	PMK	HDF	HEP-2	Mayo Mean[a]	Mt. Zion Mean[b]	
Influenza virus	+++	–	–	4	3.8	None or focal enlarged granular cells followed by sloughing; rapid progression
Parainfluenza virus	+++	+	+	11	6.4	None or focal rounding and multinucleated giant cells (types 2 and 3)
Respiratory syncytial virus	++	+	+++	8.3	6.1	Enlarged, glassy syncytial giant cells or granular, rounded cells
Mumps virus	+++	+	–	6.9		Enlarged, syncytial giant cells
Measles virus	+	–	+			Vacuolated, syncytial giants cells; rarely isolated
Poliovirus	+++	+++	+++	4.6		Random, swollen, glassy cells; rapid progression and detachment of cells from glass
Coxsackievirus B	+++	+	+++	3.5	4.2	Focal, swollen, glassy cells; detachment from glass
Echoviruses	+++	+++	+	3.9	4.2	Focal, swollen, glassy cells; detachment from glass
Rhinovirus	+	+++	–	6.6		Focal, swollen, or granular cells
Adenovirus	++	+	+++	6.2	6.4	Enlarged, clustered cells (bunches of grapes or lattice)
Herpes simplex virus	++	+++	++	3.5	2.7	Enlarged or shrunken granular cells starting at edge; rapid progression and sloughing; may have giant cells
Varicella-zoster virus	++	++	–	7.6	6.1	Discrete, elongated foci of enlarged or shrunken cells; slow, contiguous progression enhanced by use of growth medium
Cytomegalovirus	–	+++	–	10	5.8	Compact foci of enlarged cells; slow, contiguous progression

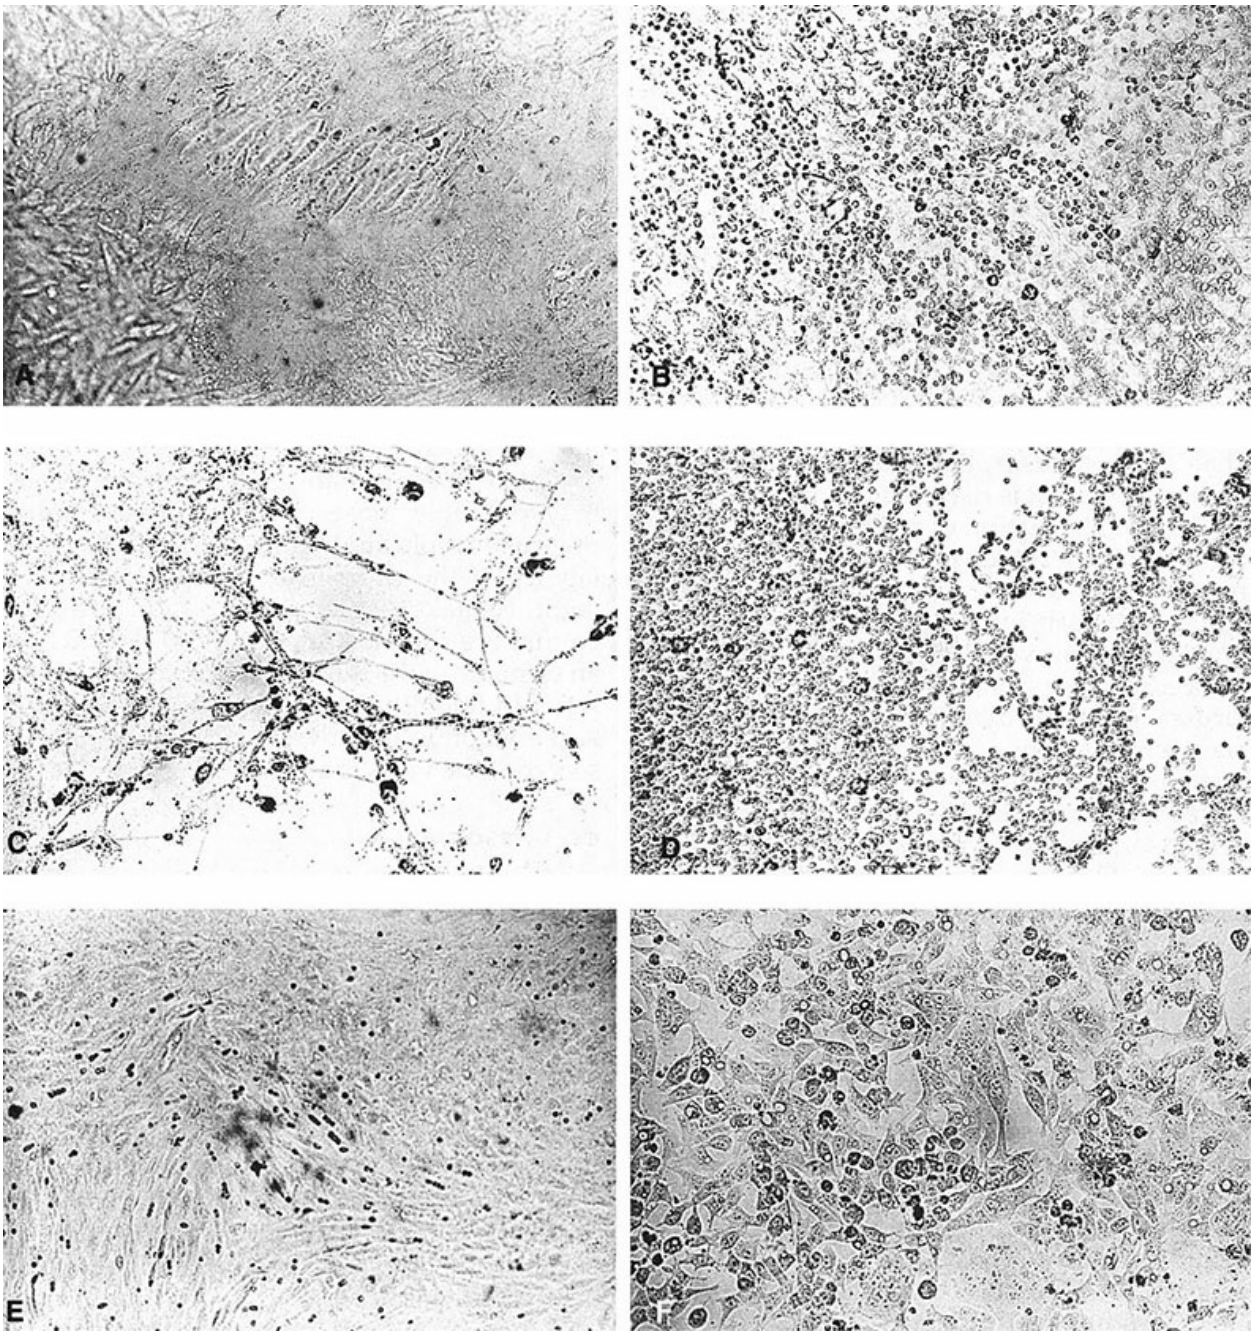
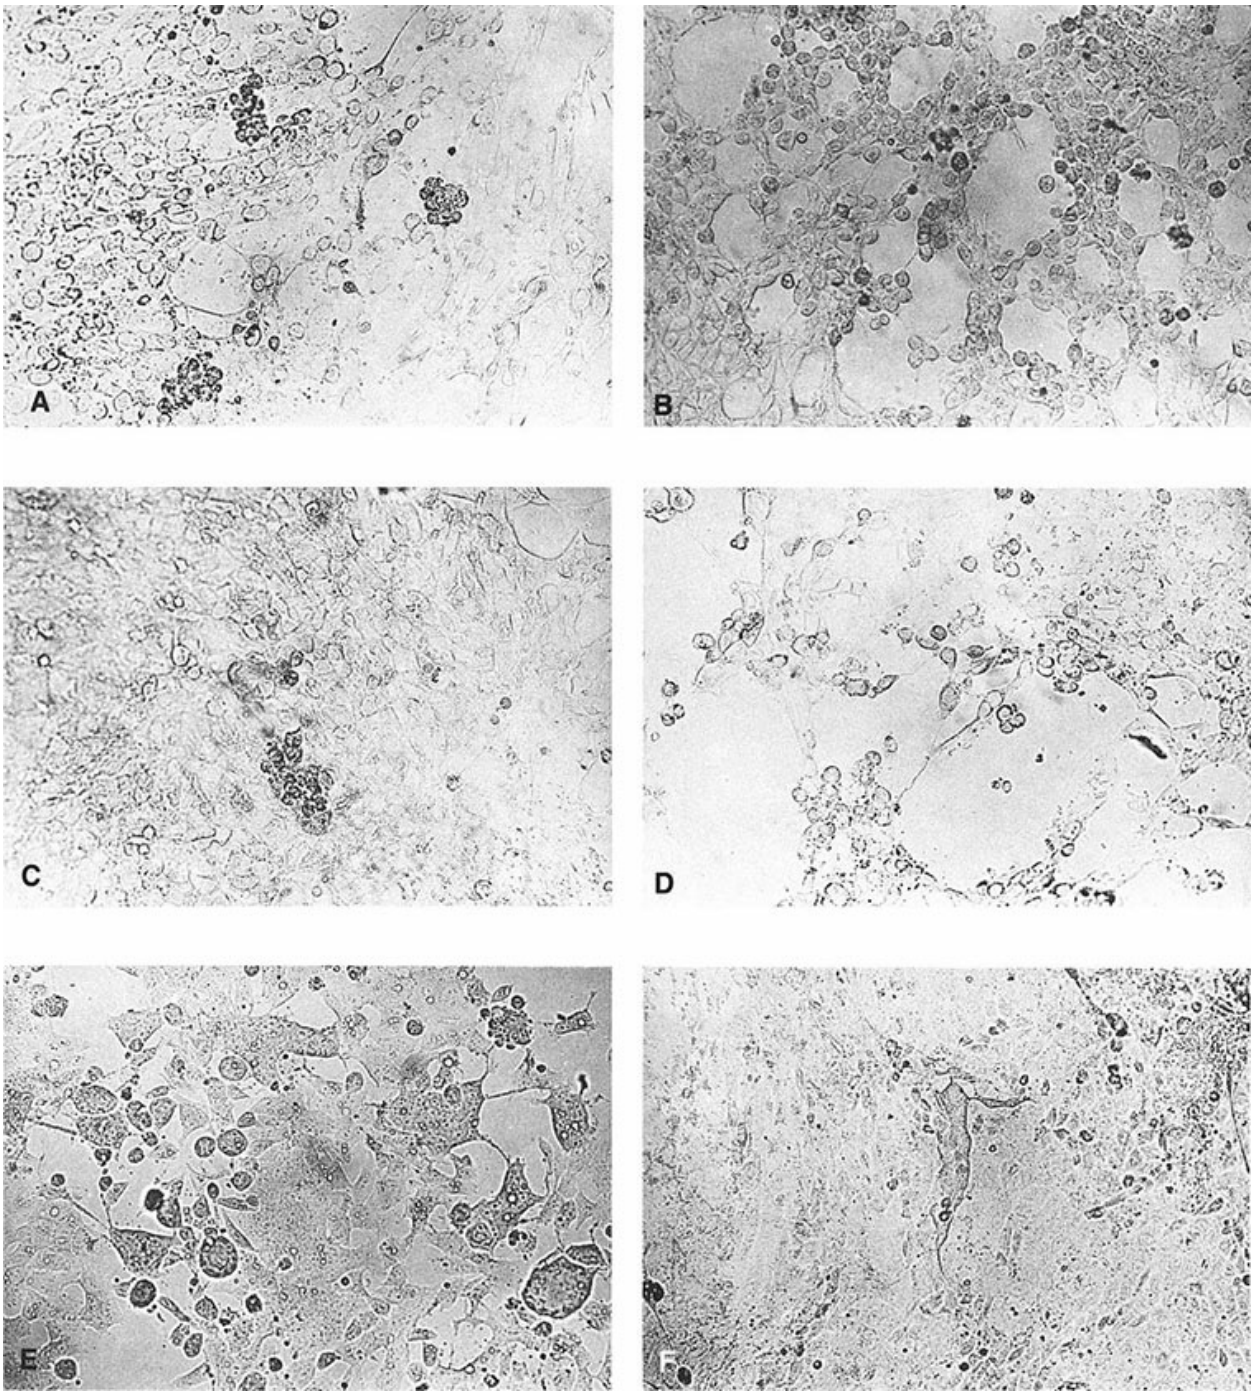
1552



■ **FIGURE 23-13** Cytopathic effect of myxoviruses. **A.** Rhesus monkey kidney cells infected with influenza A virus. This isolate produces no cytopathic effect in the monolayer. A hemadsorption test identified the presence of a virus. Many of the current strains of influenza A virus and most strains of influenza B virus produce cytopathic effect, which often develops more rapidly than that produced by the parainfluenza viruses (×180). **B.** Rhesus monkey kidney cells infected with influenza A virus. The monolayer is intact but is covered with numerous guinea pig red cells. The red cells have adhered to the viral hemagglutinins on the surface of the infected cells. Hemagglutination of red cells in the fluid phase by free virus can often be detected but is not shown in the photograph (×180).

C. Rhesus monkey kidney cells infected with parainfluenza virus 3. The monolayer has degenerated, and cells have fallen off the glass. Many of the remaining cells are enlarged or granular. Often, isolates of parainfluenza viruses do not produce obvious cytopathic effect and must be detected by hemadsorption (×180). **D.** Rhesus monkey kidney cells infected with parainfluenza virus 3. A hemadsorption test has been performed. The remaining cells are covered with guinea pig red cells that have attached to the viral hemagglutinin on the cell membranes (×180). **E.** Rhesus monkey kidney cells that are uninfected demonstrate a negative hemadsorption test. A few guinea pig red blood cells have stuck to the monolayer, but the massive adherence of red blood cells that characterizes a positive test is not present. The settled cells are also dislodged more easily from an uninfected monolayer than from a myxovirus-infected monolayer by shaking the tube. **F.** HEp-2 cells infected with parainfluenza virus 3. Large multinucleated giant cells (known as syncytial cells) have formed in the monolayer by fusion of adjacent cells. This type of cytopathic effect is characteristic of parainfluenza viruses 2 and 3 in monkey kidney cells and parainfluenza virus 3 in HEp-2 cells. Syncytial cells are also formed by other viruses, notably respiratory syncytial virus. The parainfluenza viruses can be differentiated from respiratory syncytial virus easily by performance of a hemadsorption test (×180).

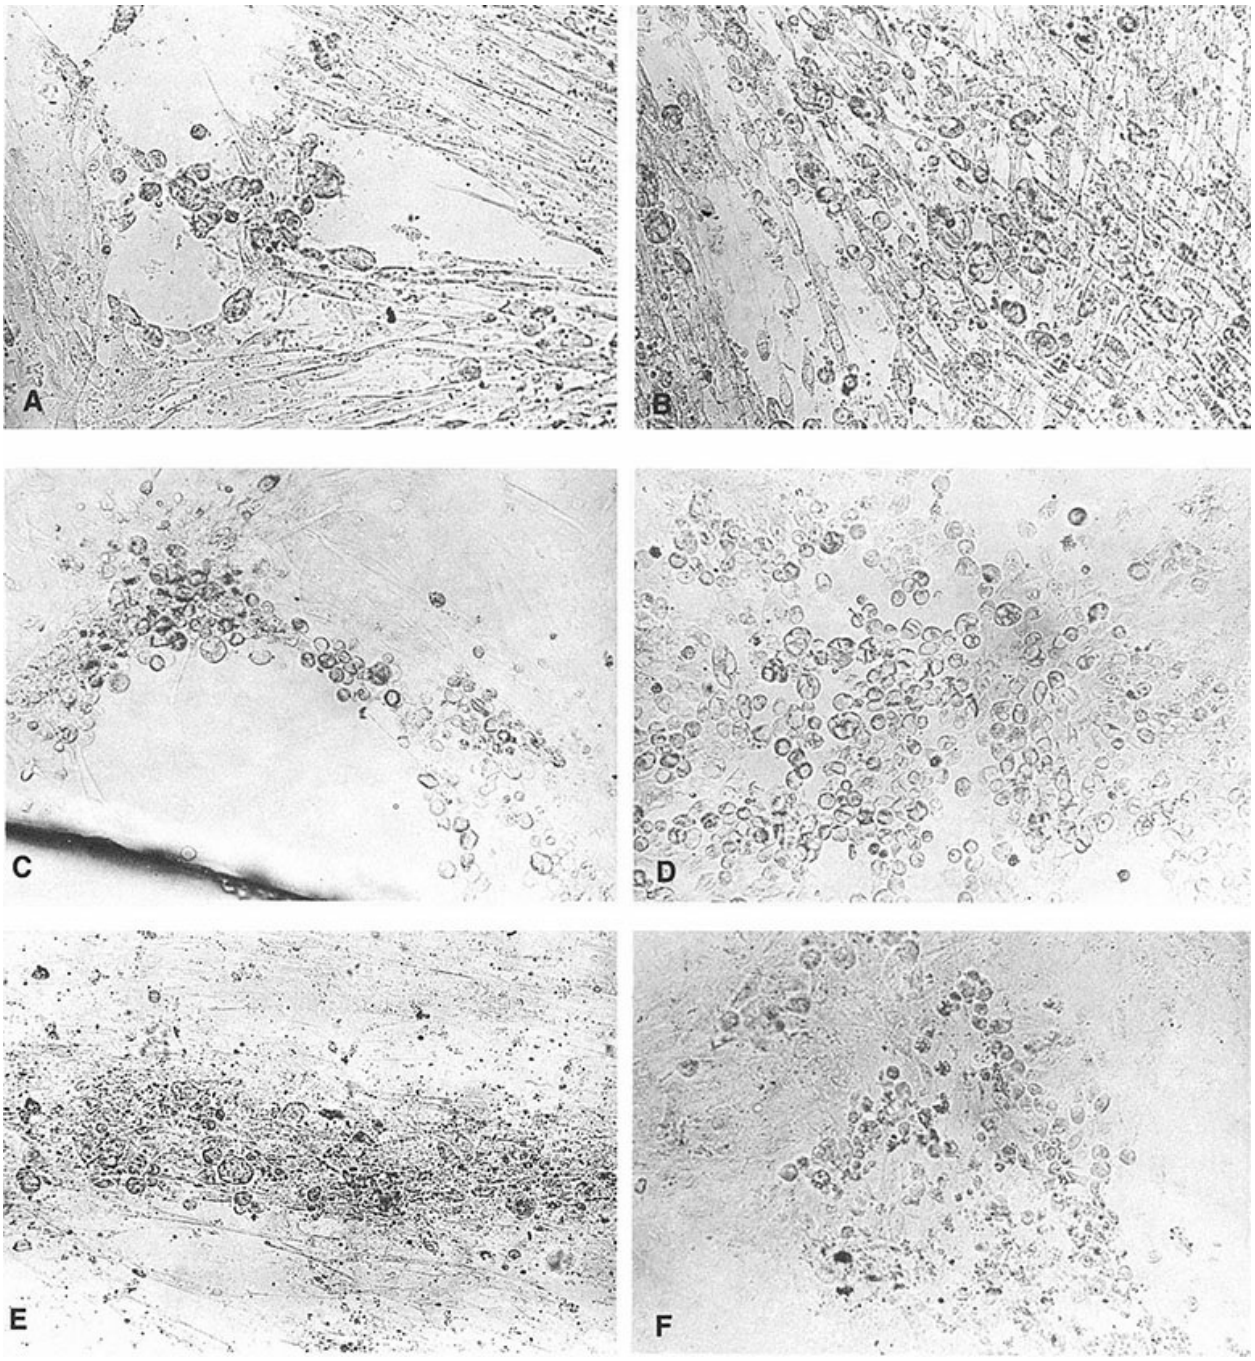
1553



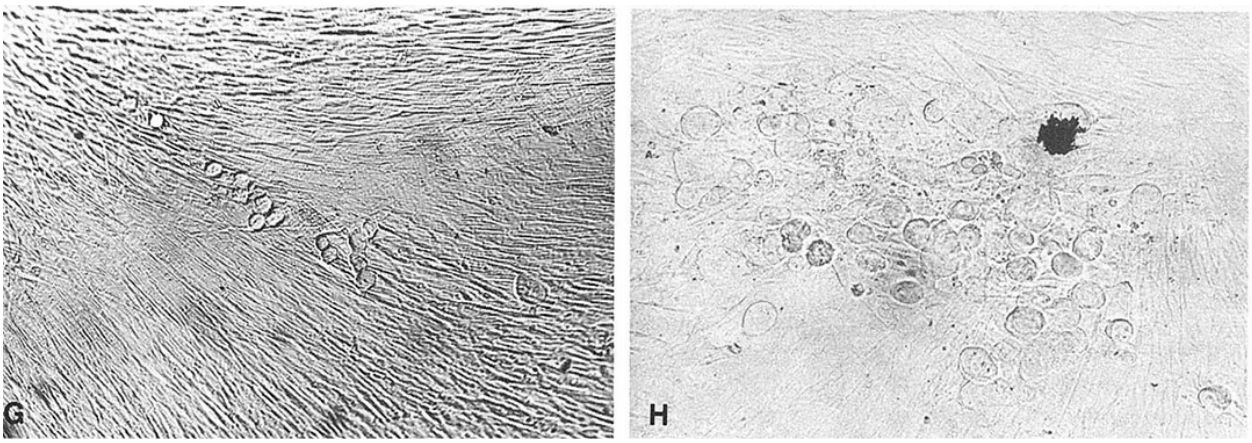
■ **FIGURE 23-14** Cytopathic effect of other respiratory viruses. **A.** HEp-2 cells infected with adenovirus. Several foci of enlarged, granular cells are evident. Adenovirus cells are often clustered like bunches of grapes, much as are staphylococci in a Gram stain (×180). **B.** HEp-2 cells infected with adenovirus. Most of the cells in the monolayer are now rounded; many cells have detached from the glass, leaving multiple holes. In several places, clustering of cells can be seen. Strands of cytoplasm connect some of the residual infected cells, producing the beginning of a lattice effect. (×180). **C.** Rhesus monkey kidney cells infected with adenovirus. One cluster of granular, enlarged cells is evident. A preliminary

report could be issued if multiple foci were present in the culture. If only a few are present, it would be best to observe the monolayer for progression of cytopathic effect. (×180). **D.** Rhesus monkey kidney cells infected with adenovirus. The extent of cytopathic effect has increased considerably. Clustered, swollen cells with intercellular cytoplasmic bridges are evident. Many cells have detached from the glass. Eventually, there will be only scattered cells left on the glass tube as evidence that a monolayer was once present (×180).**E.** HEp-2 cells infected with respiratory syncytial virus. Many of the cells in the monolayer have been fused by the virus to form syncytial giant cells, much like those formed by parainfluenza viruses. Other cells are enlarged or have detached from the glass. A hemadsorption test on this monolayer would be negative. (×180). **F.** Rhesus monkey kidney cells infected with respiratory syncytial virus. One large syncytium has formed in the monolayer. One could differentiate this isolate from parainfluenza virus by hemadsorption or by identification of specific antigen.

1554

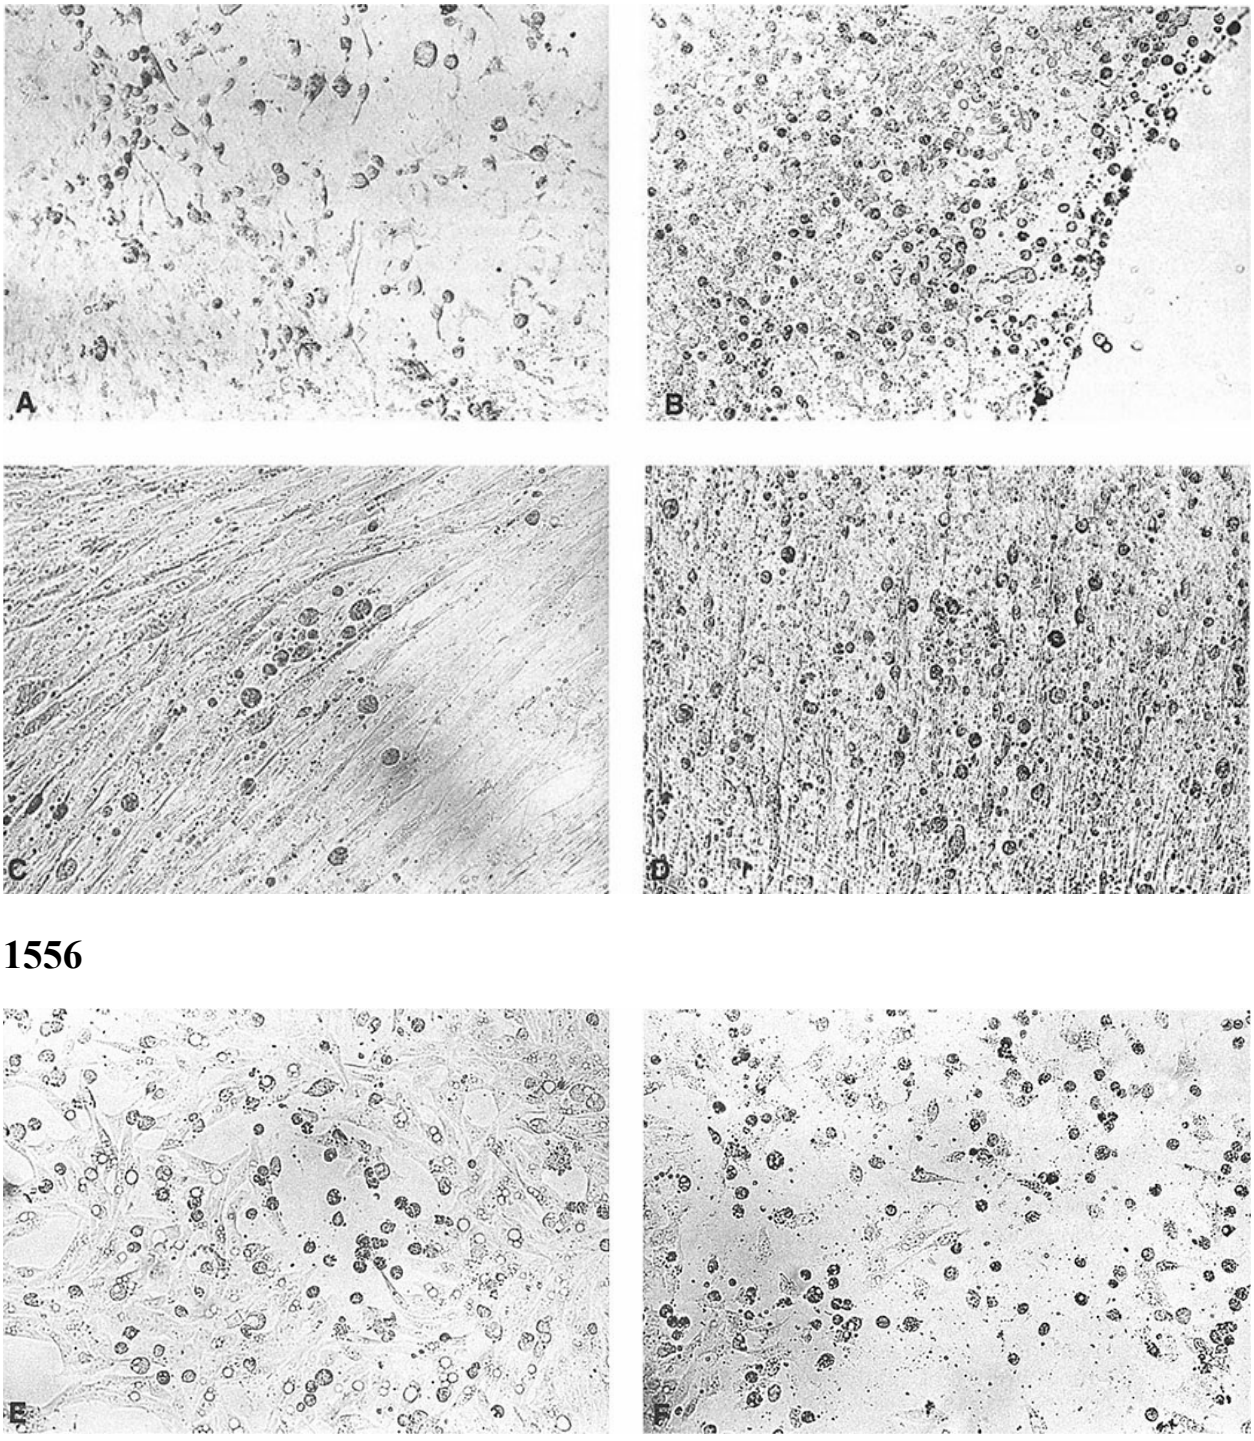


1555



■ **FIGURE 23-15** Cytopathic effect of herpesviruses. **A.** MRC-5 fibroblasts infected with herpes simplex virus. There is a focus of enlarged, rounded cells in the monolayer. Many cells have detached from the glass. Such foci will enlarge rapidly, and the entire monolayer is usually involved within a few days (×180). **B.** MRC-5 fibroblasts infected with herpes simplex virus. Cytopathic effect has progressed so that virtually every cell in the monolayer is affected. Again, the cells are enlarged, even ballooned and granular. This type of generalized cytopathic effect can occasionally be seen with cytomegalovirus if very large quantities of virus are present. Cytomegalovirus can be distinguished from herpes simplex virus by identification of specific antigens (×180). **C.** Rhesus monkey kidney cells infected with herpes simplex virus. As often happens at the outset, this focus of cytopathic effect is at the edge of the monolayer. Enlarged, ballooned cells surround the center of the focus, where the cells have already detached from the glass (×180). **D.** HEp-2 cells infected with herpes simplex virus. There is a large focus of swollen cells in the monolayer. Some of the cells have the appearance of multinucleated giant cells, although it is difficult to delineate the cellular structure in an unstained preparation at low magnification. (×180).. **E.** MRC-5 fibroblasts infected with varicella-zoster virus. A cytopathic focus consists of large swollen cells and granular degenerated cells. The focus is elongating in the direction of the underlying fibroblasts. The slow appearance and slow progression of the foci are characteristic of this virus. Transfer of cytopathic effect requires the inclusion of infected cells. Cytopathic effect has some similarities to that of cytomegalovirus; the foci of cytomegalovirus tend to be more compact and spread centrifugally without such a pronounced linear orientation (×180). **F.** Rhesus monkey kidney cells infected with varicella-zoster virus. A focus of enlarged, swollen cells is less distinctive than cytopathic effect in MRC-5 cells. It can be differentiated from that produced by herpes simplex virus by the speed with which it appears and progresses. Cytomegalovirus does not produce cytopathic effect in monkey cells (×180). **G.** WI-38 fibroblasts infected with cytomegalovirus. There is a small focus of enlarged, granular cells in the monolayer (×180). **H.** MRC-5 fibroblasts infected with cytomegalovirus. A developing focus of cytopathic effect is evident. The cells are swollen, and the focus is quite compact. Cytopathic effect of cytomegalovirus appears late and progresses slowly. It tends to be more compact and less linear than that of varicella-zoster virus. Differentiation from

varicella is by clinical history, by demonstration of multinucleated giant cells in varicella monolayers, and by demonstration of specific antigen (×180).



1556

■ **FIGURE 23-16** Cytopathic effect of enteroviruses. **A.** Rhesus monkey kidney cells

infected with coxsackievirus B. There is a focus of cytopathic effect in which cells are either small and shrunken or enlarged. Some of the cells have a refractile or glassy appearance that is typical of enteroviral cytopathic effect. Elongated "tadpole" cells are also typical of the cytopathology produced by this group of viruses (×180). **B.** Rhesus monkey kidney cells infected with coxsackievirus B. Cytopathic effect progresses relatively rapidly with the enteroviruses; poliovirus may cause complete destruction of the monolayer overnight. In this photomicrograph, virtually every cell in the monolayer has been damaged, and large segments of the cell sheet (lower right) have peeled off entirely (×180). **C.** MRC-5 fibroblasts infected with echovirus 11. An early focus of enteroviral cytopathic effect is evident. The cells appear enlarged and granular. It would be very difficult at this stage to guess the identity of the virus. Most isolates of echovirus grow well in human diploid fibroblasts, whereas isolates of coxsackievirus do not (×180). **D.** MRC-5 fibroblasts infected with echovirus 11. Cytopathic effect has extended to involve almost the entire monolayer. Virus is spread extracellularly through the medium so that cytopathic effect tends to change from focal to generalized in nature relatively rapidly (×180). **E.** HEp-2 cells infected with coxsackievirus B. A small focus of cytopathic effect in the HEp-2 cells is manifested by rounded, shrunken granular cells and detachment of cells from the glass. Early cytopathic effect is much more difficult to recognize if the cell sheet is too heavy and the cells are piled one on top of the other (×180). **F.** HEp-2 cells infected with coxsackievirus B. Almost all of the cells in the monolayer have detached from the glass. Those that remain are abnormal. Most coxsackievirus B isolates grow well in HEp-2 cells, whereas coxsackievirus A and echovirus do not (×180).

There are relatively few ways in which cells can express cytotoxicity. Rounding is a common expression of damage, but cells may appear either swollen or shrunken and granular or glassy. Some viruses produce factors that cause cell fusion, leading to the formation of multinucleated giant cells, which are also called syncytial cells; RSV, parainfluenza viruses 2 and 3, measles virus, and mumps virus can produce syncytial giant cells. In addition, HSV and VZV produce smaller multinucleated giant cells.

Not all isolates of RSV produce syncytial cells. Production of the F(usion) glycoprotein by the virus is required for cell fusion. Shahrabadi and Lee demonstrated that calcium must be present in the culture medium for RSV-induced fusion of HEp-2 cells to occur.[422] The formation of syncytial giant cells also appears related, at least in part, to the concentration of glutamine in the culture medium.[309]

Cytopathic effect usually starts focally and often is most readily seen at the edges of the monolayer, where the density of cells is low. For viruses that spread from cell to cell through the culture media, cytopathic effect progresses from focality to totality, sometimes with great rapidity. If the number of virions in the specimen is very large, most of the monolayer may be infected simultaneously; in this case, widespread degeneration must be differentiated from nonspecific cytotoxicity by subculture of fluid to fresh cell cultures. For viruses that spread directly from cell to cell (CMV and

VZV), cytopathic effect progresses more slowly and by local extension of the initial foci. When a very large amount of CMV is present in the specimen, the cytopathic effect may be produced through the whole monolayer, mimicking the effect produced by HSV.

It is, of course, somewhat artificial to try to capture the considerable variability of a biologic process in a single photographic frame. In a clinical laboratory, it will be possible to examine other parts of the monolayer, view other cell cultures, and even reexamine a suspect culture after incubation for a few more hours. It will often be possible, therefore, to detect cytologic changes that are even earlier than those that make convincing photographs.

The majority of respiratory viruses are now detected by direct molecular methods rather than culture. However, in some instances, a "test of cure" may be requested by clinicians, particularly in immunocompromised patients who are having difficulty clearing the virus. Additionally, viral culture for these pathogens has been retained in highly specialized laboratories and other settings. Figures 23-13 and 23-14 have, therefore, been retained in this addition of the text. The use of guinea pig red blood cells (i.e., the hemadsorption test), however, has been replaced by direct detection of antigen (i.e., DFA) using high-quality, commercially available product.

Light Microscopy. As they replicate, some viruses produce masses of nucleoprotein and virions in various stages of assembly. The anatomic pathologist or cytologist uses these viral inclusions to detect the presence of a viral infection and identify the agent presumptively.[446,494] Currently, the anatomic pathologist supplements the morphology features present in routinely stained histologic sections or cytologic preparations with the use of highly specific immunohistochemical stains. These stains employ antibodies, often monoclonal antibodies, that have a high degree of specificity for the particular viral target.

The virologist also uses light microscopy. They use it to examine unstained cellular monolayers for cytopathic effect caused by the replicating virus. Although the characteristics of cytopathic effect in unstained monolayers are usually sufficient to render a provisional diagnosis, the virologist may gain additional information using simple stains (Image Plate 23-1). Although feasible, this is rarely performed in practice. Today, virus-specific immunofluorescent stains are used to determine the cause of the cytopathic effect.

Electron Microscopy. For laboratories with access to an electron microscope, the ultrastructural morphology of an isolate may identify the group to which it belongs.[4,344] These methods were used with much greater frequency in the past, prior to the availability of specific immunohistochemical and immunofluorescent reagents. Negative-staining electron microscopy is simple and may be accomplished rapidly on supernatant fluid or lysed cells. This technique may be particularly useful for

differentiation of nonspecific toxicity from a large viral inoculum. Currently, electron microscopy is most useful for the categorization of emerging viruses, as was accomplished with the SARS outbreak.[190,425]

Biochemical Differentiation. The cytolytic changes produced by rhinoviruses may resemble those of enteroviruses,

1557

although rhinoviruses replicate less rapidly and demonstrate the lability to an acid environment. To make this assessment, aliquots of infected cell culture are adjusted to pH 3.0 or 7.4 for 3 hours. Then an estimate of the infectivity is obtained by inoculating serial 10-fold dilutions of the aliquots into cell cultures. A reduction in infectivity of 2 to 4 $\log_{10}$ should be observed if the virus is a rhinovirus.[249] This is currently only performed in highly specialized laboratories, but remains important to investigate the cross-reactivity of molecular assays for enteroviruses and rhinovirus, which occurred recently with the outbreak of enterovirus, EV D-68.

Cell Association. The demonstration of the association of virions with infected cells is useful to differentiate members of the herpesvirus group. HSV is released freely into the culture medium, whereas CMV and VZV remain cell-associated. HSV rapidly infects the whole monolayer (Fig. 23-15B). Alternatively, the cytopathic effect of CMV and VZV is usually focal (Fig. 23-15E through H), because virions do not spread through the medium. The type of cytopathic effect present informs the virologist regarding the type of DFA that should be selected for confirmatory studies. Occasionally, however, large numbers of viral particles of CMV or VZV in the inoculum may produce widespread cytopathic effect resembling that of herpes simplex. In this instance, the DFA stains for HSV would be negative, whereas the subsequent studies with DFA reagents for CMV or VZV should confirm the identification.

Detection of Viral Antigens. In addition to confirmation of the identity of a cytopathic agent, the demonstration of specific antigens in culture has been used as a method for detecting the presence of a virus, even in the absence of cytopathic effect. Tests for antigen may be performed after a brief incubation if rapid diagnosis is desired, an approach that has been used more commonly with the use of shell vials. The most dramatic improvements in the rapidity with which isolates are detected will occur with viruses that have the slowest growth in conventional systems, such as RSV, CMV, and VZV (Image Plates 23-2D, E, and F).

The literature is replete with disparate reports on the sensitivity of such expedited approaches to viral diagnosis. For instance, the percentage of influenza virus isolates

recovered after spin amplification, incubation overnight, and staining with monoclonal antibodies has ranged from 56%[135] to 98%.[123] Differences in operational variables, such as cell lines and source of monoclonal antibodies as well as varied patient populations, make universal recommendations treacherous. Perhaps it is fortunate that the detection of this virus in particular is now predominantly performed using molecular methods.

It is clear that expedited culture techniques can contribute useful information but that there is a trade-off between sensitivity and rapidity when deciding on the length of incubation. Including conventional cultures and/or sampling shell vials at several times will increase sensitivity, but also increase costs. Although it is difficult to document, provision of results more rapidly may have clinical and financial impact.[17] These techniques have also been used to facilitate the detection of fastidious viruses, such as the rubella virus.[414] The convenience of using DFA reagents for the confirmation of cytopathic effect is that these are usually the same reagents employed in the laboratories performing these tests for the direct assessment of virally infected cells in clinical specimens; ergo, there are two uses for one reagent.

Artifacts and Non–Virus-Induced Changes. As cells age in culture, morphologic changes unrelated to viral infection may occur (Fig. 23-7). The density of cells in diploid cell lines and, in particular, established cell lines may become very high; dying or dividing cells may appear rounded or granular. Scattered atypical cells occur in any culture and are especially noticeable in less-dense areas, such as the edge of the monolayer, where viral cytopathic effect may also become apparent first. It is important, therefore, to maintain uninoculated controls of cells from the same batch as those used for specimens.

Primary monkey kidney cells may be infected with simian viruses that produce a variety of degenerative changes,[249] including a foamy or vacuolated appearance in the monolayer.

The presence of extraneous cells that settle on the monolayer may also cause confusion (Fig. 23-7D). Cytopathic effect may be mimicked because the contaminating cells differ in appearance from the original monolayer. Usually a virus that produces focal abnormalities in the monolayer, such as CMV, is simulated. The artifact may be suspected because the cells are on top of the monolayer, rather than becoming an integral part of it. Contaminating cells may be of human origin, such as epithelial or mesothelial cells present in the specimen, or may have originated in other cell cultures, particularly if a subculture from one cell line to another has been performed.

A variety of nonviral agents or substances in clinical specimens may be toxic to cell monolayers (Fig. 23-7A). If bacterial or fungal growth occurs (Fig. 23-7B), the nature of the problem is obvious; the specimen must then be treated again with antibiotics or

filtered and inoculated into additional cell cultures.

Usually the nature of the cytotoxicity is unknown. The ordinary remedy is to dilute the specimen and inoculate additional monolayers. Howell and associates[236] found that the toxicity of semen from patients with AIDS could be avoided by inoculating the monolayer with a cell pellet, obtained by high-speed centrifugation. CMV, which is a frequent pathogen in patients with AIDS, is associated with leukocytes. Conversely, toxic substances were concentrated in the supernatant fraction.

On occasion, cytopathic effect may be "specific," although the cause is unexpected and perhaps unwanted. *Clostridium difficile* toxin, for example, in fecal specimens (Fig. 23-7C) may produce cytopathic effect resembling enteroviral damage.[415]

Gentry and associates[168] reported the isolation of *Trichomonas vaginalis* in BHK cell cultures. These flagellates produced a cytopathic effect that mimicked that of HSV; cytopathic effect was reproduced when viable *Trichomonas* or lysates from axenic cultures were added to cell cultures. Motile trichomonads could be seen when the cultures were inspected closely.

Isolation of *Pneumocystis jirovecii* from immunocompromised patients with AIDS has been reported. It is difficult

to propagate this atypical fungus serially in the laboratory, but organisms have been grown in cell cultures, including MRC-5 human diploid fibroblasts.[286] The *P. jirovecii* isolates produced a cytopathic effect that resembled viral effects. *Toxoplasma gondii* may also be recovered in cell culture lines, such as human diploid fibroblasts, although the sensitivity of culture has not been evaluated.[79]

Definitive Identification of Isolates

In a diagnostic laboratory, the combination of clinical history and cytopathic effect provides sufficient information to identify some viruses, including HSV, CMV, VZV, adenovirus, and RSV. Enteroviruses can usually be identified to the genus level. Unfortunately, too often, limited clinical information is available. The complete identification of isolates, including typing, requires immunologic characterization of the viral antigens or viral nucleic acid.

Immunologic tests can be adapted either for identification of antigens or antibodies against those antigens. Antisera, traditionally polyclonal, are increasingly monoclonal (see Chapter 3). The most specific immunologic test for the majority of viral infections is the neutralization assay, but this is no longer performed in most clinical laboratories. A review of these methods may be found in previous editions of this text.

Many viral tests are important for epidemiologic analysis, but are rarely necessary

for routine diagnostic purposes. In instances in which complete characterization is necessary (e.g., paralytic disease), the isolate may be sent to a reference laboratory. A thorough discussion of antigenic characterization, which is beyond the scope of this chapter, may be found in textbooks of virology and viral diagnosis.[237,271,436]

For many hospital laboratories immunofluorescence assays provide a viable alternative by which definitive identification of many viruses to the genus and/or species level can be made. Fortunately, the expanding catalog of commercially available reagents, which are of increasingly high quality, simplifies the task. The enteroviruses and rhinoviruses are notable exceptions because their complicated antigenic composition makes definitive identification difficult without neutralization tests.

The immunofluorescence test has been used for many years and in many variations. The DFA assay is the simplest to perform, but specific conjugated antisera are required. Indirect immunofluorescent tests (IFA)—using antiglobulin, staphylococcal protein A, or complement—are more sensitive but often suffer from lower specificity. In contrast to the direct test, multiple conjugated reagents are not needed to perform the indirect test, but the procedure is more time-consuming because of the serial steps required. DFA assays are simple to perform and in the hands of a skilled microscopist deliver very high sensitivity and specificity, in some instances, rivaling PCR. These assays represent a viable alternative to molecular diagnostics, if the clinical setting and test volumes dictate. The limitations of these tests are that they require fluorescent microscopy, and if test volumes are high (e.g., during influenza season), then the test may be tedious and time-consuming, ergo, the migration to molecular diagnostic methods.

Storage of Viral Isolates

If the necessity for additional characterization of an isolate seems probable, infected cell culture fluid should be frozen at −70°C. A general rule is that mammalian cells should be frozen slowly, whereas infectious agents should be frozen quickly. The dramatic decrease in viability that accompanies the freezing process is minimized if the cultures are snap-frozen and if a stabilizing agent is included in the medium. A mixture of dry ice and alcohol is a convenient means for snap-freezing viral isolates. Many stabilizing agents have been used and many are commercially available. Howell and Miller found that the sucrose phosphate broth that is used for transport of swabs for isolation of *Chlamydia* functioned as well as 70% sorbitol for maintenance of some of the most fastidious viruses, including CMV and RSV.[235]

Summary of Culture-Based Detection and Identification of Viruses

The orthomyxoviruses, paramyxoviruses, and RSV (Figs. 23-13 and 23-14) produce a

variety of cytopathic effects in cell culture. Many isolates of influenza and parainfluenza viruses produce no visible changes in the monolayer and must be detected by other means. Cytopathic strains can be differentiated from other viruses with similar effects by noting the restriction of cytopathic effect to monkey kidney cells, in the past by hemadsorption, and currently through the use of virus-specific immunofluorescence reagents. Multinucleated giant cells occur in monolayers that have been infected with measles, respiratory syncytial (Fig. 23-14E and F), parainfluenza (Fig. 23-13F), and mumps viruses; they are produced by virus-directed fusion of adjacent cells (syncytium formation). Such cells may also be seen in the clinical specimens from infected patients (Image Plate 23-1F and G).[446,494]

Isolates are now definitively identified by immunologic means. Antisera of good quality are available for most of the common myxoviruses. The genus or type of virus (e.g., influenza A virus or RSV) may be identified by immunofluorescence of infected cells.

Adenoviruses (Fig. 23-14A through D) can be identified presumptively by observing the characteristic cytopathology in cell cultures. Clusters of swollen infected cells or a lattice appearance to the monolayer are typical. Group-specific antigens that are common to all adenovirus serotypes have been identified, and monoclonal antibodies to the common determinants have been prepared. For most clinical applications, confirmation of the genus of adenovirus by immunofluorescence is sufficient. If the type of adenovirus must be determined, neutralization tests are available in specialized laboratories.

The herpesvirus group produces a variety of cytopathic effects in cell culture. EBV does not grow in the cell cultures commonly used in clinical laboratories; human infections with this virus are usually diagnosed serologically. CMV and VZV are highly cell-associated (Fig. 23-15E through H). They are difficult to grow in cell culture, and they grow slowly. Successful subculture requires transfer of infected cells. Both CMV and VZV produce swollen cells in foci that slowly enlarge by direct spread; the plaques of VZV, in

1559

particular, tend to follow the orientation of the fibroblastic tissue culture cells. In contrast, HSV is spread extracellularly (Fig. 23-15A through D); cytopathic effect starts focally but spreads rapidly to affect other parts of the monolayer.

Centrifugation of the inoculum onto the monolayer has accelerated the recovery of HSV, VZV, and CMV. Monoclonal antibodies have proved valuable for both detection and identification of CMV, VZV, and HSV. Separation of isolates of herpes simplex into types 1 and 2 can be accomplished reliably with fluorescein-labeled monoclonal antibodies.[294]

Enteroviruses grow relatively rapidly in cell cultures, producing a widespread cytopathic effect (Fig. 23-16). Although there is an FDA-approved RT-PCR assay for enterovirus, it is only approved for CSF, so stool and other specimens are usually submitted for enteroviral culture. In cell culture, affected cells may be shrunken and granular or may have a refractile, glassy appearance. Most serotypes of coxsackievirus A do not grow well in commonly used cell cultures. Isolates of coxsackievirus B usually do not grow well in human diploid fibroblast lines; echovirus strains do not grow well in HEp-2 cells. Definitive identification of an enterovirus requires immunologic identification. Fluorescein-labeled monoclonal antibodies directed against a genus-specific antigen and selected serotypes are available commercially. Immunofluorescence is not foolproof, especially for nonpolio enteroviruses.[397] The reference method for identification is the neutralization test, but differentiation is now more commonly accomplished by nucleic acid sequencing.[307]

Direct Detection of Viruses in Clinical Specimens

The desire for greater rapidity in diagnosis of viral infections has been stimulated by the availability of rapid diagnostic methods in other areas of the laboratory and by the development of effective antiviral chemotherapy. A variety of methods are available, ranging from the traditional to the experimental. The greatest area of growth, which is discussed thoroughly below is the introduction of advanced and often easy-to-use molecular methods of detection.

Light Microscopic Detection of Inclusions

The detection of viral inclusions in smears or tissues by light microscopy has been the traditional means of directly demonstrating viral infections.[446,494] In general, viruses that are assembled in the nucleus (i.e., usually DNA viruses) produce intranuclear inclusions, whereas cytoplasmic assembly (i.e., predominantly RNA-containing viruses) yields cytoplasmic inclusions. Fortunately, some viruses produce obvious cytopathic changes in routinely stained specimens. The identity of these, which may be highly suspected based on the routine H&E findings, may be definitively confirmed using specific immunohistochemical stains.

Intranuclear inclusions may be produced in cells that have been infected by HSV, VZV, CMV, adenovirus, papilloma virus, and the BK and JC polyoma viruses. The inclusions of HSV (Image Plate 23-1A, B, and C) and VZV are indistinguishable in routinely stained material, but can be differentiated with specific immunohistochemical stains. The infected nuclei have a homogeneous, eosinophilic, or slightly basophilic appearance, and the granular, basophilic nuclear chromatin is pushed against the edge

of the nuclear membrane (i.e., marginization of the chromatin). Other infected cells may have a more eosinophilic inclusion that is accentuated by a halo between the inclusion and the nuclear membrane. This halo is an artifact of fixation, but is useful diagnostically. Ultrastructurally, the inclusions are composed of a mixture of deoxyribonucleoprotein and assembled virions (Fig. 23-3A); as the virions pass through the nuclear membrane, they acquire a lipid membrane. The infected cells may be mononuclear or multinuclear.

CMV produces basophilic nuclear inclusions in an enlarged cell (Image Plate 23-1D). These distinctive cells, which are essentially pathognomonic of CMV infection, were originally believed to be protozoa that were invading tissue.[259] A halo is often present around the inclusion. Granular, basophilic inclusions may be found in the cytoplasm of some infected cells.

A variety of inclusions may be found in adenovirus infections. Early inclusions are eosinophilic and may closely resemble herpesvirus-infected cells. Inclusions become more basophilic as they mature and increasingly fill the nucleus (Image Plate 23-1E). Eventually, they become extremely basophilic and may completely distort the cell; these diagnostic cells are referred to as "smudge cells" and must be distinguished from uninfected cells with hyperchromatic nuclei. The adenovirus inclusions are composed of nucleoprotein and numerous virions, which often demonstrate a paracrystalline array because their icosahedral shape permits tight packing of the particles (Fig. 23-3B).

The intranuclear inclusions of the papilloma viruses will not be encountered frequently by clinical virologists because these viruses are difficult or impossible to grow in culture. The inclusions in human warts begin as granular eosinophilic matter, later condensing into rounded, basophilic masses; cytoplasmic inclusions in the epidermal cells of warts are condensed keratin and are not virus-specific. In cervical cytology specimens, the nuclei of koilocytes are enlarged and hyperchromatic with cleared perinuclear halo.

The intranuclear inclusions of the BK and JC polyoma viruses will also not be encountered by clinical virologists, as these viruses do not grow in commonly used cell lines. The inclusions in progressive multifocal leukoencephalopathy occur in oligodendroglia (nonnerve cells that perform a supportive function); the inclusions vary from small granular material to large basophilic masses that fill the nucleus. The BK viral inclusions appear similarly but occur in tubular epithelial cells and urothelial cells. Immunohistochemical or immunofluorescent studies or in situ hybridization should be used to confirm the nature of these inclusions.

Intracytoplasmic inclusions may be found in cells that have been infected by RSV, rabies virus, and viruses of the pox group. The intracytoplasmic inclusions of RSV are brightly eosinophilic (Image Plate 23-1G); they are present regularly in cell culture but less frequently in clinical specimens. Ultrastructurally, the inclusions of RSV consist of

fibrillar ribonucleoprotein (Fig. 23-3C). The intracytoplasmic

inclusions of rabies virus are known as Negri bodies (Image Plate 23-1H). They may be single or multiple and occur in neurons that appear otherwise normal. The edges of the inclusions are sharply defined, as if bounded by a membrane. Clear spaces or basophilic stippling, which may be seen within the inclusion, result from the incorporation of some cytoplasmic material into the mass of viral ribonucleoprotein (Fig. 23-3E). Fortunately, the intracytoplasmic inclusions of the poxviruses, known as Guarneri bodies, are unlikely to be encountered today.

Intranuclear and intracytoplasmic inclusions are found in measles infection. During the prodromal stage of measles, giant cells appear in lymphoid tissue throughout the body. These so-called Warthin–Finkeldey giant cells contain as many as 100 nuclei and rarely may contain inclusion bodies. A second type of giant cell may arise later from epithelial tissue, such as that lining the lower respiratory tract. There are fewer nuclei in these giant cells, but inclusions are almost constant. The intranuclear inclusions resemble those produced by the herpesviruses, may be single or multiple, and vary in their degree of eosinophilia (Image Plate 23-1F).

Detection of inclusions provides valuable information in selected clinical situations. The Tzanck test, performed by preparing a Giemsa-stained smear of vesicular scrapings, can be used to document the presence of a herpesvirus by demonstrating multinucleated giant cells (Image Plate 23-1C). Although this approach is less commonly performed, hematoxylin–eosin or the Papanicolaou stain may also be used with the submission of the specimen to surgical pathology and cytology, respectively. The nuclei should have a ground-glass and molded or multifaceted appearance.[433] Intranuclear inclusions, which are accentuated in histologic sections by the artifactual halo produced by the fixation of tissues in formalin, may not always be visualized in the smears. A presumptive diagnosis of herpes infection can be made, although differentiation between HSV and VZV is not possible by morphology alone.

Solomon and colleagues found positive Tzanck tests in 11 patients with clinical chickenpox (varicella virus) and in 12 of 15 patients (80%) with shingles (herpes zoster virus). However, varicella virus was recovered in only 7 of the 11 patients with chickenpox, which corroborates the insensitivity of culture for VZV.[433] Multinucleated giant cells or inclusions or both have been demonstrated in skin lesions from 18 of 21 patients (86%) from whom HSV was isolated.[342] An analysis of the proficiency with which dermatologists correctly interpreted a study set of 10 smears demonstrated a "reverse learning curve."[188] Second- and third-year residents correctly interpreted a mean of 91% of the slides; dermatologists in practice for less than 10 years, 84%; and dermatologists in practice for more than 10 years, 67%.

Although the direct smears have worked well in the study of skin lesions, the sensitivity has unfortunately been low for other applications. Only a minority of culture-positive specimens from the genital tract[452] or the respiratory tract[349] contained inclusion-bearing cells. Similarly, Nahmias and colleagues[348] found intranuclear inclusions in only 56% of 113 cases of herpes simplex encephalitis. The specificity was considerably higher (86%) than the sensitivity in this collaborative study of antiviral chemotherapy, but false-positive results are potentially dangerous if therapy for another condition, such as bacterial brain abscess, is omitted. Intranuclear inclusions were reported in 10 patients from whom HSV was not isolated; in 7 of these patients, an alternative diagnosis not associated with inclusions was established. These results emphasize the importance of verifying the nature of the inclusion using immunohistochemistry, immunofluorescence, or other assays.

Histologic detection of CMV inclusions in tissue is less sensitive than culture, but may be equivalent using more "sophisticated" techniques, such as immunohistochemistry and in situ hybridization, for revealing CMV in tissue.[447] Morphologic methods have the advantage of better correlation with disease produced by CMV than does the more sensitive culture, since low levels of virus may be shed without producing overt disease.

In parvovirus B19 infection, intranuclear inclusions are also found in giant pronormoblasts, which are found in the bone marrow.[274] These characteristic cells may also be seen in peripheral blood and other tissues in infected fetuses.

Electron Microscopic Detection of Viral Particles

Electron microscopy can be applied to the study of both clinical specimens and cell cultures, either in thin sections of tissue or by negative stain microscopy. The inaccessibility of electron microscopes to most clinical laboratories and the sampling errors inherent in the examination of small samples of tissue have limited the routine application of this technique in making diagnoses of viral disease. The use of electron microscopy was specific for the diagnosis of herpes simplex encephalitis in one study (98%), but herpes virions were detected in only 45% of the infected patients.[348] The technique has been used effectively in the detection of viral agents of gastroenteritis, especially those that are not recovered by conventional cell culture (rotavirus, Norwalk-like agents, and enteric adenoviruses). However, ultrastructural diagnosis remains a research technique in most laboratories.

Negative stain electron microscopy has drawn renewed interest as a result of increased concern about bioterrorism. When examining a specimen with the electron microscope, there is no requirement for predetermining the antigens or nucleic acids to be detected. The diagnosis of important viral infections, such as smallpox, can be made quickly and safely, as the specimen is rendered non-infectious before

examination.[209]

Immunologic Detection of Viral Antigen

A variety of immunologic methods have been used to expedite diagnoses of certain viral infections. Immunofluorescence stains of clinical specimens and immunohistochemical stains of tissues are frequently used techniques. These techniques have many advantages and have functioned well when applied by trained persons. The risks of erroneous results are great in the absence of proper equipment and training.[116] The sensitivity of direct immunofluorescence studies varies by pathogen, as will be covered more thoroughly below. An understanding of the test performance helps the laboratory director determine whether these tests are sensitive and specific enough to "stand alone," or whether they should be performed in conjunction with culture or, more recently,

1561

molecular studies. Immunoassays, often lateral flow immunoassays, have been used in physician's offices and other laboratories for many years, as some of these are CLIA-waived tests. Although these assays are usually chosen because of the rapid result that is achieved and the ease of use, the results may be incorrect. Therefore, many of the package insert denote a need to follow-up negative test results with a more sensitive assay. These tests are best used when there is a high prevalence of infected individuals (e.g., respiratory virus season) wherein the tests have a high positive predictive value (i.e., a positive test is likely valid and diagnostic of the condition). The real limitation of these assays is the sensitivity (i.e., negative results may be falsely-negative). It is possible to reduce the likelihood of obtaining a falsely-negative specimen by collecting the highest quality specimen possible. Nevertheless, the package inserts must be followed and specimens that yield negative test results must be submitted for testing by a more definitive method.

Respiratory Viruses. The most reliable antigenic method for detection of respiratory viruses is direct immunofluorescence (DFA). In one study, DFA was as efficient as culture for all respiratory viruses except adenovirus. When the slides for immunofluorescence were prepared in a cytocentrifuge, less than 10% of the specimens had an inadequate number of respiratory cells.[280] In contrast, the sensitivity of enzyme immunoassays, particularly the rapid formats, has been considerably lower in most reports.[1,73,281,391] In addition, some immunoassays have yielded sufficient numbers of false-positive and false-negative reactions that confirmation by a second method has been recommended.[1]

Although direct immunofluorescence is clearly the better of the two approaches, practical considerations often lead to the selection of enzyme immunoassays particularly for in-office testing. These tests can be performed quickly and simply without the need for a fluorescent microscope or extensive training of personnel. Although positive tests are very useful during the respiratory virus season, it is imperative that clinicians know the limitations of these assays and the requirement for reflex testing of specimens for which a negative result has been obtained.

Herpes Group Viruses

Herpes Simplex Virus. Direct immunofluorescence has generally performed well in comparison with culture, particularly when performed on visible lesions and enhanced by cytocentrifugation.[282,392,406] Varying results may reflect different reagents, patient populations, types of lesions, and serotypes of virus. DFA testing for HSV on CSF specimens should not be performed because of poor sensitivity. Excellent immunohistochemical stains are available for the anatomic pathologist who is examining a tissue specimen with pathologic changes suggestive of HSV. HSV grows quickly, however, so the gains from expedited diagnosis are not as great as with more slowly growing viruses.

Varicella-Zoster Virus. VZV grows slowly in culture. Not surprisingly, direct immunofluorescence performs comparatively better for VZV than with HSV. In fact, DFA of skin lesions may be the superior means for making this diagnosis compared to culture.[97] Wilson and colleagues[491] found that the DFA had a sensitivity of 87.8%, whereas the sensitivity of culture was only 46.3%; only PCR was more sensitive than DFA, but also more expensive. In addition to direct examination of smeared material, staining of cytocentrifuged viral transport medium has proved useful.[322]

Cytomegalovirus. Monoclonal antibodies have facilitated the rapid immunologic diagnosis of CMV infections in patients' specimens as well as in cell culture. Hackman and colleagues[194] were able to detect CMV by immunofluorescence in 25 of 27 lung biopsy specimens from which the virus was subsequently cultured; light microscopic inclusions were demonstrated in only 20 of the specimens. Preliminary studies with bronchoalveolar lavage specimens from immunosuppressed patients[94,127,312]have yielded greatly differing estimates of sensitivity, varying from 31.6% to 100%. The numbers of patients in these studies were small, the antibodies were different, and the composition of the patient groups may have been different. The correlation of immunologic detection of viral antigen in tissue (without inclusions or histopathologic abnormalities) and clinical disease is not clear. Currently, excellent immunohistochemical stains are available for CMV for the anatomic pathologist.

Rotavirus. Human rotavirus is difficult to recover in cell culture. Infections by these viruses can be diagnosed effectively either by an enzyme immunoassay (EIA) or by latex agglutination. The sensitivity for both methods has ranged from 80% to 90%; the specificity has been 90% to 100%.[86,126,454] Krause and colleagues[275] have questioned the reliability of the Rotazyme immunoassay in neonates.

Human Immunodeficiency Virus. Antigen detection is a relatively new component in HIV screening. The new fourth-generation HIV test includes the detection of p24 antigen, in addition to the detection of antibodies directed to the HIV-1 and HIV-2.

This is designed to detect HIV-infected individuals who are early in the course of disease and have not yet generated an antibody response. The CDC recommended testing algorithm may be found at www.cdc.gov/hiv/pdf/hivtestingalgorithmrecommendation-final.pdf.

Molecular Techniques

The molecular era has been inextricably intertwined with infectious diseases from the outset, and the pace of innovation shows no sign of slowing. We have passed through several stages already, beginning with nucleic acid hybridization and advancing to molecular amplification technology and now NGS (see Chapter 4). The PCR and other molecular diagnostic approaches have made it into the mainstream of clinical laboratories. A substantial number of commercially available, high-quality molecular diagnostic products are available for the detection and, in some instances, quantitation of critical pathogens.[464] The pace is so rapid in this area that this section will be dated before the ink of this publication has dried. There are hospital laboratories that have replaced the entire virology section with molecular testing for viruses. Most laboratories, however, are somewhere in the middle, utilizing molecular diagnostics where most appropriate, while retaining DFA, immunoassays and culture for the areas where these make the most sense. The laboratory director

will need to evaluate the clinical needs and test volumes at a local level to determine which test is best to employ.

Human Immunodeficiency Virus. Testing for HIV includes serologic and antigen testing, as well as quantitative RT-PCR. In brief, the current recommendations for screening for HIV infection uses what has been termed a fourth-generation assay; CDC recommendations may be found at www.cdc.gov/hiv. This assay assesses for antibodies to HIV-1 and HIV-2, and includes p24 antigen detection. The latter was added in an effort to detect more individuals in the window period. For indeterminate results with the screening assay, the recommended algorithm (Fig. 23-17) reflexes to HIV RNA detection and quantitation. Similarly, if there is a high index of suspicion and the screening assaysare negative, many clinicians will request HIV RNA studies.

Once the diagnosis has been made, management of HIV-1 infection is based entirely on molecular methods. A quantitative viral load determined by an RT-PCR assay is the standard of care for the monitoring of patients with HIV. Although RT-PCR is the usual method used to determine the viral load, at that time of this writing a small minority of laboratories are still using a bDNA method. The manual and automated versions of RT-PCR that have been developed over the past decade perform

similarly.[227] An increasing viral load may disclose noncompliance with the therapeutic regimen or may indicate the emergence of resistance in the virus to the current antiretroviral regimen. There are a number of commercial vendors that offer HIV RT-PCR assays. In many instances these are FDA-approved, which is often preferred by users. The reporting of HIV has migrated from copies to Log_{10} values. Although there may be variation by clinicians, a 0.5 log change is usually considered clinically significant, as is a change from an undetectable viral load to a detectable viral load.

Both plastic and glass Vacutainer tubes for collecting blood for viral load testing have been evaluated and function equivalently.[283] Vacutainer plasma preparation tubes (PPTs) are a convenient method for collecting blood if it is to be frozen and/or shipped to a reference laboratory for testing.[226] A wide variation in patient reports provided to physicians by clinical laboratories, including reports that were incomplete or unhelpful, has been noted.[151]

There are two situations wherein which viral load testing is appropriate for initial diagnosis. In both situations, there may not have been time for a serologic response to develop. The first situation is acute infection with HIV, which may manifest itself as a multifaceted febrile illness with symptoms referable to any organ system.[256] This initial illness is transient, usually lasting no longer than 14 days. Large quantities of virus may be present before the immune response has been generated. The second clinical scenario is neonatal infection when the mother is known to be infected. Molecular detection of virus is required, because antibody passively transferred across the placenta to the neonate complicates serologic analysis.

The HIV virus is difficult to eradicate because it integrates into the human DNA and will persist as proviral DNA. There are PCR assays that are used, usually in newborns of infected mothers, to determine whether pro-viral DNA (i.e., integrated HIV DNA) is present. The only company (Roche) that manufactures such an assays has changed it to a qualitative HIV assay that will detect the presence of both integrated HIV DNA and HIV RNA, which is an improvement in testing.

1563

With the advent of effective antiviral chemotherapy, detection of resistance in clinical isolates has become a priority. The clinical relevance of resistance testing soon became evident,[124] and evolving consensus recommendations have been promulgated and continue to evolve.[218] Resistance testing is recommended in pregnant women and after failure of antiviral chemotherapy, either primary therapy or subsequent regimens. It is now clear that evaluation of resistance is useful for treating newly infected patients (infected within 12 months of testing), particularly if the individual who is the source of the infection is known to have been taking antiretroviral drugs. This provides the clinician with baseline information concerning the genetic determinants of resistance that may be present in the patient's strain. In addition, testing of patients who have been infected for up to 2 years (and perhaps longer) has been found to be useful for designing therapeutic regimens.[217]

Two approaches to the detection of resistance have been used. Evaluation of phenotypic resistance involves isolation of virus and traditional assessment of inhibition by antiviral drugs. The complexity of viral isolation has led to an alternative

mechanism in which plasma RNA of the polymerase and protease genes is amplified and used to form a recombinant virus with laboratory constructs. By using a standard virus backbone into which the two most important genes of the patient strain have been inserted, standardization of the assay has been improved. Drug susceptibility testing can be performed within several weeks by using automated methods and reporter genes. Phenotypic assays include PhenoSense (Monogram Biosciences, LabCorp Specialty Testing Group, South San Francisco, CA) and The Antivirogram (Virco, Mechelin, Belgium).

In contrast to phenotypic assays, which measure viral susceptibility, genotypic assays pinpoint the mutations that confer phenotypic resistance.[421] The initial step in PCR-based assays is similar to the recombinant phenotypic approach—amplification of HIV-1 sequences from plasma samples that contain 500 to 1,000 copies per milliliter. As a result, this genotypic approach will not work with samples that contain a small quantity of virus. The next step involves either genotyping all relevant codons or detecting selected codons by hybridization.[201,218] Several companies have attempted to predict the phenotype by analysis of the genotypic result, a so-called virtual phenotype. Genotypic assays most commonly used at the time of this writing are TruGene (Siemens), ViroSeq (Celera), or laboratory-developed sequencing assays. Phenotypic assays have the attractiveness of more direct (and traditional) assessment of resistance, although the clinical interpretation of the results is neither completely defined nor straightforward. In addition, these are very expensive, time-consuming, and some argue provide little, if any, value over genotypic testing.

Genotypic assays are more straightforward, more rapid, and less expensive; the concern has been that important phenotypic resistance may not be pinpointed and that the significance of new mutations may not be clear. For both approaches, reproducibility and sophistication of analysis represent important factors. An additional concern is that a minority of resistant virions in the diverse population of virions that comprise the infecting strain in any individual patient may be missed (analogous to the problem with detecting resistant cells in a population of heteroresistant bacteria, as discussed in Chapter 17).[421]

Although the concern about genotypic assays has not been dissipated, comparative studies have demonstrated good correspondence of genotypic and phenotypic assays for the clinically important resistance mechanisms.[40] As experience has been gained and commercial products have been fine-tuned, the reproducibility and reliability of genotyping has been established.[159,183]

There is evidence that resistance testing can predict the response to antiviral therapy or time to suppression of virus.[182,509] The factors that determine success or failure in treatment of any infection are complex, however. As with all laboratory reports, the results of HIV resistance testing should be interpreted by an experienced clinician in light of all available data. Attempts to develop useful algorithms to facilitate clinical

decisions continue.[421] HIV genotyping involves the assessment of four genes of the HIV virus, which are initially amplified using RT-PCR. The DNA sequence of the genes are determined and the sequences are then compared with genetic databases that include known resistance-inducing mutations. HIV genotyping helps the clinician tailor or individualize therapy. Some of the advantages of NGS are expected to enhance this even further. NGS will provide not only the sequence of the predominant quasi-species of HIV, but also the sequences of less abundant quasi-species. In this manner, therapy can be tailored to address not only the major quasi-species, but also the minor quasi-species, which may represent the next emerging resistant clone.

Hepatitis C Virus. The diagnostic approach to hepatitis C virus and HIV infections has been similar.[22,373] Identification of infected patients is best accomplished serologically. To differentiate patients who have cleared their infection from those who are chronically infected and at risk for chronic disease, however, it is necessary to determine if circulating virus is present.[373] Molecular detection is the only option, because hepatitis C virus has never been cultured in vitro.

The quantitative detection of HCV is currently the standard of care for infected patients.[273,334] The viral loads are used to monitor the response to therapy and also provide an amplicon for HCV genotyping. Currently, the majority of the quantitative assays in use employ RT-PCR (Roche and Abbott), but there are still some laboratories using bDNA (Siemens). As with HIV, the standard reporting is in Log_{10} values.

There are currently 6 HCV genotypes, and genotype 1 has traditionally been subtyped into 1a and 1b for therapeutic/prognostic purposes. HCV genotyping can be performed using a variety of methods.[24,164,354] Current assays include real-time PCR (Real-Time HCV Genotype II; Abbott Molecular), a reverse hybridization assay (VERSANT HCV Genotype 2; Siemens), DNA sequencing (laboratory-developed assays and TRUGENE HCV genotyping assay; Siemens), and most recently by bioelectric array (GenMark). The need for and utility of HCV genotyping and subtyping remains fluid as new therapeutics are introduced. For example, a new therapeutic consisting of multiple antiretroviral agents in combination has been approved for the treatment of HCV genotype 1, which obviates the need for subtyping.

1564

Hepatitis B Virus. Molecular diagnostic tests for hepatitis B virus have not achieved the currency of those for hepatitis C, because the variety of serologic tests available for hepatitis B has served much of the need. Detection of viral DNA in blood, the definition of active infection, is more sensitive than the presence of HBeAg, however,

and may be found with pre-core mutants in the absence of seroconversion to HBeAg.[24]

The molecular detection HBV DNA is useful in few scenarios. Most commonly, it is used to distinguish chronic active infection from inactive infection. This is of prognostic significance, since patients with chronic active infection are at higher risk for more serious sequelae. The quantitative measure of HBV DNA is also used to monitor the response of the patient to therapy, with the end goal being long-term viral suppression with undetectable an undetectable viral load. An elevating viral load may herald the emergence of a resistant strain. Finally, as with HIV RNA, the detection of HBV DNA is possible in the window period, before the emergence of HBsAg.

Quantitative rapid-cycle PCR is the test most commonly used by laboratories for HBV. Commercially available FDA-approved assays are available (e.g., Roche Diagnostics and Abbott Molecular). In addition, several genotyping assays have been developed commercially. As experience with therapy of chronic hepatitis B infection expands and resistance becomes more prevalent, these tests will undoubtedly assume greater prominence.

Human Papillomaviruses. The molecular detection of HPV is now part of the cervical screening guidelines for women 30 to 65 years of age. Women in this group should receive either cervical cytology every 3 years or they may lengthen the screening interval to 5 years if both cervical cytology and high-risk HPV testing are performed and these are negative. The consensus recommendation for testing is that tests should include only high-risk HPV subtypes.[499]

The use of molecular diagnostics is the only practical approach for the detection and characterization of this group of viruses. The earlier, labor-intensive techniques, such as nucleic acid hybridization by the Southern blot method (see previous edition of this book), have been replaced by more convenient and sensitive methods. There are now four FDA-approved methods for the detection of high-risk HPV subtypes.

The hybrid capture assay (digene HC2 High-Risk HPV DNA Test, Qiagen, Gaithersburg, MD) was the first assay to market, and was the only option available for quite some time. Subsequent generations of this test have greatly improved sensitivity over the initial version.[51,52] The digene HPV Genotyping PS Test (Qiagen) is available as a reflex test for determining if types 16, 18, or 45 are present.

Target amplification methods, such as transcription-mediated amplification (TMA) and real-time PCR, have now been cleared by the FDA for high-risk HPV detection. The Aptima HPV assay (Hologic) is the assay that utilizes TMA technology and takes the novel approach of targeting the E6/E7 mRNA of HPV. The proponents of this approach claim that by detecting the E6/E7 mRNA of actively oncogenic HPV, the user is more likely to detect HPV causing dysplasia in contrast to that causing a transient infection that would naturally be cleared. This assay is performed on their

highly automated Tigris and Panther instruments, with the latter allowing for random access. Cervista HPV is another Hologic assay that target high risk HPV. This assay uses Invader amplification technology.

The cobas HPV test is the first assay that has been cleared by the FDA for primary screening. Although this is true, the recommendations from professional societies such as the ACOG and the American Society of Cytopathology (ASC) have not yet embraced this use of the test in the absence of Pap testing. One of the claimed advantages of this assay is that in addition to detecting the myriad of high-risk HPV genotypes that cause dysplasia, it also reports the presence of the more highly oncogenic types 16 and 18, without the need for subsequent, reflex testing. This assay is performed on the highly automated cobas 4800 System.

Parvovirus B19. Parvovirus infections are usually diagnosed clinically or serologically; assessment of risk is based on immunologic (i.e., immune) status. Sometimes, viral inclusions may be seen in erythrocytic precursors in bone marrow biopsy specimens. Occasionally, however, it is useful to document a serious infection virologically. Parvovirus does not grow in culture, so molecular detection is the only approach available. Several amplification assays have been developed[98,109,202]; although not cleared by FDA. Assays are available as Analyte Specific Reagents (ASR) or primers, and probes may be derived from the literature. Regardless of the approach, the testing laboratory is responsible to undertake a full and thorough validation, as the test is considered an LDT. Additionally and as test volumes in any one location are usually low, the option to send these to a high-quality reference laboratory may prove the best option.

Influenza, RSV, and Other Respiratory Viruses. Likely one of the greatest impacts in recent years has been the expanded availability and expanded use of molecular diagnostic products for influenza A and B viruses and RSV. It was not long ago that these tools were unavailable and patients were being screened by insensitive immunoassays that required labor-intensive DFAs or time-consuming culture to render the final result. The earliest assays targeted influenza A and B; these were offered as an influenza RT-PCR alone or in combination with RSV. The RSV assay was also offered as a stand-alone test. These assays, originally produced by Prodesse, are now supplied by Hologic, which is working to automate the amplification process, as they have done so successfully with their other assays. These assays, and many of the others that followed, have received FDA clearance. Cepheid followed with products that targeted these viruses using their Xpert system, which was extremely attractive to laboratories with limited molecular diagnostics experience. Still other groups have made attempts to address both the need for quick time-to-result and, if desired, batch testing. For example, the Focus group offers two such applications on their integrated cycler. The first is an eight-well cartridge wherein each well may be used individually,

until all the eight have been utilized. This affords the opportunity to perform testing as the specimens are received, similar to the Cepheid applications. Conversely, they also offer a reaction disc that accommodates many more specimens for batch-style testing.

The next substantial application that has been introduced is the multiplex respiratory panel. In some instances, these

1565

assays include the most commonly occurring respiratory viruses, as well as the bacterial respiratory pathogens *Mycoplasma pneumoniae, Bordetella pertussis,* and *Chlamydophila pneumoniae*. These assays, too, have received FDA clearance and are relatively simple to perform. The appropriate use of these assays is important, as they are more expensive than the assays directed toward a single target (e.g., RSV). However, they may be more cost-effective for those instances wherein all the analytes present would have been ordered individually. These have largely replaced the traditional virology tests for respiratory viruses in many laboratories. Additionally, there are antimicrobial stewardship opportunities (i.e., to discontinue unnecessary antibiotics once a viral etiology is identified), but this requires substantial coordination with an antibiotic stewardship team and exclusion of the possibility of a bacterial superinfection.

Herpes Simplex Virus. The primary diagnostic approach to HSV infections has been culture, but rapid, cost-effective and FDA-approved assays are challenging this approach. HSVs are the most rapidly proliferative of the viruses commonly recovered within the clinical laboratory. Results in cell culture based on cytopathic effect may be available within a few days, whereas results based on modified culture systems, such as the ELVIS system described above, may be complete within 24 hours. In addition to these assays, the HSV DFAs for use on specimens from vesicular lesions are very sensitive and have a high positive predictive value.

There are now several commercially available PCR assays that are FDA-cleared for use on genital specimens. In addition to the high level of sensitivity offered by these assays, they are attractive in that the turnaround time is within the same day, and the testing not complicated. This is in contrast to culture-based methods wherein after the cell culture is inoculated, it must be incubated and subsequently examined or processed further. These nucleic acid amplification assays have proven more sensitive than culture for detecting HSV in mucosal infections.[468]

In the past, the diagnosis of HSV encephalitis was substantially more challenging. After highly suggestive radiologic findings were denoted, then a brain biopsy was generally required to get an adequate specimen for the culture-based diagnosis of herpetic encephalitis or histopathologic diagnosis. The use of PCR on CSF specimen is sufficiently sensitive to detect viral DNA in both in encephalitis and in recurrent

meningitis for most affected patients.[329,426] A number of HSV PCR assays have been described, some of which have been validated as LDTs. Recently, however, the first PCR-based assay has been FDA-approved for use on CSF for the diagnosis of meningitis/meningoencephalitis, and other assays are currently in clinical trials.

Preparation of DNA for amplification can be accomplished equally well by manual or automated methods.[133] Fortunately, DNA is sufficiently stable that specimens can be stored without a decrease in sensitivity at 4°C, either as extracted DNA or as an unextracted specimen, for as long as 16 months before testing by real-time PCR.[245] The use of laboratory resources can be increased by screening specimens for pleocytosis in the CSF before testing, because neutrophils have been demonstrated in all positive specimens, at least in adults.[424] Children with encephalitis, however, may have very few neutrophils in CSF and initial PCR examinations may be negative if performed very early in the course of the infection.[106] The use of PCR on CSF for the diagnosis of HSV CNS disease represents a considerable advance in diagnostics over intrusive methods, such as brain biopsy.

Cytomegalovirus. The ability to determine the amount of CMV present in the blood of the patient in a reliable and reproducible way afforded the opportunity to change from prophylactic antiviral therapy to preemptive antiviral therapy for patients at risk for CMV. CMV antigenemia assay was an early reference method, but it was time-consuming and visually interpreted, and therefore especially susceptible to operator errors. Subsequently, quantitative assays of several varieties correlate well with clinical disease and with the antigenemia assay. The methods that were used successfully include PCR, real-time PCR, and hybrid capture.[46,112,221,293]

One caveat must be kept in mind for users of molecular amplification. In contrast to HSV, early studies demonstrated that the quantity of CMV detected in plasma increased over time when the specimen was stored at 4°C, apparently by leakage of nucleic acid from infected leukocytes.[409] For specimens that were positive in the antigenemia assay, there was little effect on the amplification result; if the patient was latently infected and the antigenemia test negative, however, the amount of plasma virus increased significantly over time.

The detection of quantitative CMV is now uniformly or nearly uniformly accomplished by rapid-cycle PCR methods. Although there are a minority of laboratories that utilize LDTs, there are commercially available FDA-approved products available that are often preferred. There are a number of ASRs that facilitate the validation of LDTs. If laboratories desire to extend the acceptable transport time beyond that which was cleared by the FDA, then stability validation studies should be performed.

Enteroviruses. Culture, which has been the mainstay of enteroviral diagnosis, has

been suspected to be relatively insensitive. This impression was validated soon after the appearance of amplified genetic tests. There is one FDA-cleared assay; this or validated LDT assays are available in many reference laboratories. Early assays used traditional RT-PCR and nucleic acid sequence-based amplification (NASBA), whereas current assays are predominantly RT-PCR assays modified for a real-time platform.[34,278,284] As there are no generally used antiviral agents for enteroviral infection, prompt diagnosis is not quite as imperative as for HSV, but prompt laboratory diagnosis can be used to facilitate clinical management.

There is known cross-reactivity between rhinovirus and enterovirus in molecular assays. In some instances, manufacturers simply result a positive reaction as positive for rhinovirus/enterovirus. Others have gone to great lengths to try to construct a rhinovirus-specific assay, just to have it demonstrated that there is still cross-reactivity with some enterovirus strains.

SARS and MERS Coronaviruses. During the SARS outbreak, it was discovered that viral RNA was detectable in clinical specimens for more than 1 month in some patients. Recovery of nucleic acid was found to increase progressively

until a peak about 11 days after the onset of clinical illness.[84] Viral nucleic acid could be detected in 60% of patients with clinically diagnosed infection and in a very small number of patients without clinically evident disease. Nasopharyngeal aspirates, throat swabs, and sputum were the most useful specimens in the first 5 days of illness. Later in the illness, virus was more readily detected in stool specimens.[84] Real-time PCR assays for this virus have also been developed.[508] At this juncture, diagnostic tests are largely confined to public health laboratories.

The MERS-CoV is also detectable using a CDC-developed rapid-cycle RT-PCR assays that is available at the CDC and in most state public health laboratories. Testing is restricted to patients with appropriate travel and/or exposure history, and appropriate clinical findings.

Other Viral Infections. Molecular amplification assays have been developed for virtually every medically important virus, many of which are real-time PCR assays. Examples include exotic viruses, such as hemorrhagic fever viruses,[117] and highly virulent agents that have potential for bioterrorism, such as smallpox.[432] Assays have also been developed for less commonly considered viruses, such as JC and BK polyomaviruses,[483] measles,[122] rubella,[122]and mumps.[374] These assays are available through reference laboratories, and in some instance materials for the assays may be purchased from commercial vendors. More recently, RT-PCR assays have been

developed for the chikungunya virus, which may be used for detection in the first 8 days of illness. The first RT-PCR for the diagnostic detection of the Zika virus was recently developed and made available from researchers at Texas Children's Hospital and Houston Methodist Hosptial.

In the past, nucleic acid amplification-based assays were also predominantly available only through reference or university laboratories. With the increasing availability of reliable commercial reagents, more and more of which are receiving FDA approval, we are witnessing the same kind of expansion that occurred after immunofluorescence and immunoenzyme reagents became widely available. These include the detection of virus that were routinely detected by DFA and culture, such as respiratory viruses and other herpes group viruses.[95,189,462,465,484] These are available from a number of vendors in a variety of formats, so most laboratories should be able to find a platform to fit their specific needs. Most recently, at least one molecular platform has received "waived" status and another is seeking this certification. It is likely that molecular virology for select pathogens will be performed at the point-of-care for many of our patients in the very near future.

Selection of Tests for Rapid Diagnosis

The choice of a technique for direct detection of virus must depend foremost on the performance of the assay, but also on the availability of equipment, the experience of personnel, and the number of specimens to be tested. The microscopic detection of inclusions is simple and inexpensive, but the sensitivity compared with culture or PCR varies depending on the application. For example, it works well for documentation of herpetic skin lesions, but does not perform as well for influenza viruses compared to RT-PCR and culture. Electron microscopy has restricted indications and is not considered rapid or cost-effective for common pathogens. Microscopic solid-phase immunoassays (immunofluorescence and enzyme assays) have advantages over assays for soluble antigens: (1) the location and type of staining can be assessed morphologically and (2) small numbers of specimens may be processed quickly. These attributes may be outweighed by the disadvantages of subjectivity in interpretation and the need to acquire an expensive microscope for fluorescence.

EIA may be performed in batches, but in most instances wherein they are used a rapid result is desired so they are often performed soon after collection and often at the point of need. The end point for many of these is visually determined at a particular time, which introduces error and subjective decisions. There are newer assays available that are associated with small, inexpensive instruments that perform automated interpretation at the appointed time, which reduces the errors associated with manual visual interpretation. One of these assays, the Sofia (Quidel, San Diego, CA), utilizes fluorometric detection, rather than colorimetric detection, and claims enhanced sensitivity due to this method. To study tissue sections for viral elements,

immunoperoxidase methods are most commonly employed. Endogenous peroxidases in the sections must be blocked completely. Antigen-recovery, using either microwave techniques or treatment with a proteolytic agent, such as trypsin, improves sensitivity.[76,228] In situ hybridization has also been used for the detection of many viruses. However, the commercial availability of high-quality commercial antibodies and the ability to perform staining on an automated platform usually tip the balance in favor of immunohistochemistry.

There has been and will be continued significant advances in molecular products available for the clinical laboratory. By the next edition of this text, we will have experienced many of the contributions of NGS, and we will understand how it best fits into the clinical laboratory. Currently, molecular applications are commercially available for almost every laboratory setting for the most common pathogens. Now, patients in the 200-bed community hospital will have the same benefits as those in a tertiary care medical center and university hospitals. The promises of rapid molecular diagnostics are being realized and what is most exciting is that there is more to come.

Serologic Diagnosis of Viral Infections

Serologic tests are the mainstay of diagnosis for certain viral infections, such as those caused by hepatitis viruses, EBV, and rubella virus. Whenever recovery of the virus in culture is difficult or impossible, documentation of an immunologic response to the agent will continue to be important. In certain cases, such as the evaluation of rubella infections, serologic diagnosis may be as rapid as culturing the virus, even if one has to wait 2 or 3 weeks for collection of a convalescent serum specimen. In situations in which culture of the virus is reliable and readily available, serologic diagnosis has a supportive or adjunctive role. Even in the molecular era serology retains an important role. For example, the viremia and viral RNA in the plasma and CSF is relatively short-lived for West Nile virus, so serology is an important diagnostic tool for the diagnosis of disease caused by this and similar viruses.

1567

General immunologic principles also apply when establishing a diagnosis of viral disease using serologic methods. Antibodies to many viral antigens remain for months or years after an acute infection. Demonstration of a significant increase (i.e., generally considered a fourfold rise) in titer of antibody is considered diagnostic of recent infection with the agent, unless the possibility of an immunologic cross-reaction exists.

If antibodies were not present in the initial specimen, this diagnostic increase in antibody titer is referred to as a seroconversion. In this case, the infection probably

represents a primary encounter with the virus. The infection may be either a primary infection, a repeat infection, or reactivation of a latent infection if antibodies are present, even in low titer, at the time of initial testing.[348] The serologic diagnosis of herpes infections is frequently complicated by recrudescent disease. For example, in a patient with CNS disease, oral herpes lesions may be reactivated by the stress of the acute illness. A serologic response that may result from the reactivated oral lesions could be misinterpreted as evidence that the CNS disease was caused by herpesvirus.

Serologic cross-reactions within many virus groups and even across groups do exist, notably, among enteroviruses, paramyxoviruses and togaviruses. Therefore, all serologic diagnoses must be considered presumptive to some degree.

A fourfold or greater decrease in antibody titer suggests an infection at some time in the past. Most antibodies disappear slowly, however, so that it is usually difficult to determine the time of the original infection.

A significance advance since the last edition of this text has been the rapid development and validation of the specific IgM and IgG assays. These largely negate the traditional need for an acute and convalescent serum titer comparison.

In general, IgM antibody appears earlier than IgG after an acute infection and is more transient. In addition, IgM, unlike IgG, does not readily cross the placenta, so demonstration of this antibody in a neonate indicates a congenital or perinatal infection, rather than passive transfer of antibody from the mother.

Therefore, the demonstration of IgM antibody to any microbial antigen suggests a recent infection. It is extremely important that the procedure for detection of the IgM class be demonstrably specific.

If an anti-IgM antibody is used to determine the acuteness of an infection, the specificity of the antiglobulin must be documented. False-negative results may be generated if there are very high levels of IgG, which may block the sites that would have reacted with IgM. False-positive results may be encountered if antiglobulins, such as rheumatoid factor, are present in the patient's serum. If a serum reacts with multiple antigens (i.e., rubella, CMV, HSV, and *Toxoplasma gondii*), an antiglobulin should be suspected.

Finally, although IgM antibody in serum is usually transient, there are documented instances in which IgM antibody has persisted for months or even years. Furthermore, it is now recognized that IgM can be detected when some latent infections are reactivated.[116]

The clinical setting must be considered when assigning a diagnosis. Even a seroconversion documents only a recent infection with the agent; association with the clinical illness is by inference.

Human Immunodeficiency Virus

HIV persists in patients in whom antibody to the virus has developed. Serologic tests

for HIV have been used as a screening tool because isolation of the virus in cell culture is difficult and not readily available. The molecular tests for detection of viral nucleic acid are predominantly used for monitoring patients who already have serologically documented infection, but may also be used to document early infection (i.e., prior to antibody development).

The traditional serologic method, repeatedly reactive EIA followed by Western blot testing, has been replaced by the fourth-generation assay, which includes the detection of antibodies directed against HIV-1 and HIV-2, as well as the p24 antigen (Fig. 23-17). The ARCHITECT HIV Ag/Ab Combo (Abbott Park, IL) and the GS HIV Combo Ag/Ab EIA are the two FDA-approved fourth-generation HIV assay. The Western blot has been replaced by the Multi-Spot assay (Bio-Rad) as a confirmatory test. Specimens from screening tests that cannot be confirmed by the Multi-Spot are submitted for nucleic acid amplification studies. This new method of standard screening is usually performed in batches at reference or larger laboratories (i.e., the results are not rapidly available for infection prevention purposes [e.g., assessment of individuals following a needlestick]).

There are two FDA-approved HIV tests that have been approved for home use, the Home Access HIV-1 Test System (Home Access Health Corporation, Hoffman Estates, IL) and the OraQuick In-Home HIV test (OraSure Technologies, Inc., Bethlehem, PA). The Home Access HIV-1 Test System uses a blood sample obtained from a finger stick that is mailed to a licensed laboratory. There are two options for this test, the Standard version, wherein results are available within 7 days after the specimen arrives in the laboratory, or the Express, wherein results are available the same day when it arrives in the laboratory. The OraQuick In-Home HIV test uses a mouth swab to collect oral secretions, similar to their other products. The results from this test are available in about 20 minutes. Both manufacturers provide counseling, and follow-up confirmatory laboratory testing is recommended.

Additional rapid immunoassays are available for use within the laboratory. The VIKIA HIV 1/2 (bioMérieux) uses blood from a finger stick and claims sensitivity and specificity >99%. Although widely used throughout the world, it has not been FDA-cleared for use in the United States.

Assays that are characterized as rapid immunoassays by the FDA include the Multi-Spot HIV-1/HIV-2 Assay (Bio-Rad Laboratories, Redmond, WA), which uses plasma or serum; the SURE CHECK HIV 1/2 ASSAY (Chembio Diagnostic Systems, Medford, NY), which is approved for use with blood from a fingerstick, venous whole blood, serum, or plasma; HIV 1/2 STAT-PAK (Chembio Diagnostic Systems), which is approved for the same specimen types as the CHECK HIV 1/2 ASSAY; the OraQuick ADVANCE Rapid HIV 1/2 Antibody Test, which in addition to venous whole blood or plasma, may be used with oral fluid; the Uni-Gold Recombigen HIV 1/2 (Trinity Biotech, Jamestown, NY); and a rapid immunochromographic assay, the Chembio DPP HIV 1/2 Assay, which like the OraQuick ADVANCE in addition to whole blood

and plasma can be performed on oral

1568

fluid. A review of comparisons of these assays is beyond the scope of this text. However, it is recommended that all patients tested with positive rapid immunoassays should have follow-up traditional laboratory studies. Negative results should be followed-up with new fourth-generation HIV testing. These rapid assays are particularly useful in infection prevention situations (e.g., following a needlestick) to determine if antiretroviral therapy is needed for the person at risk.

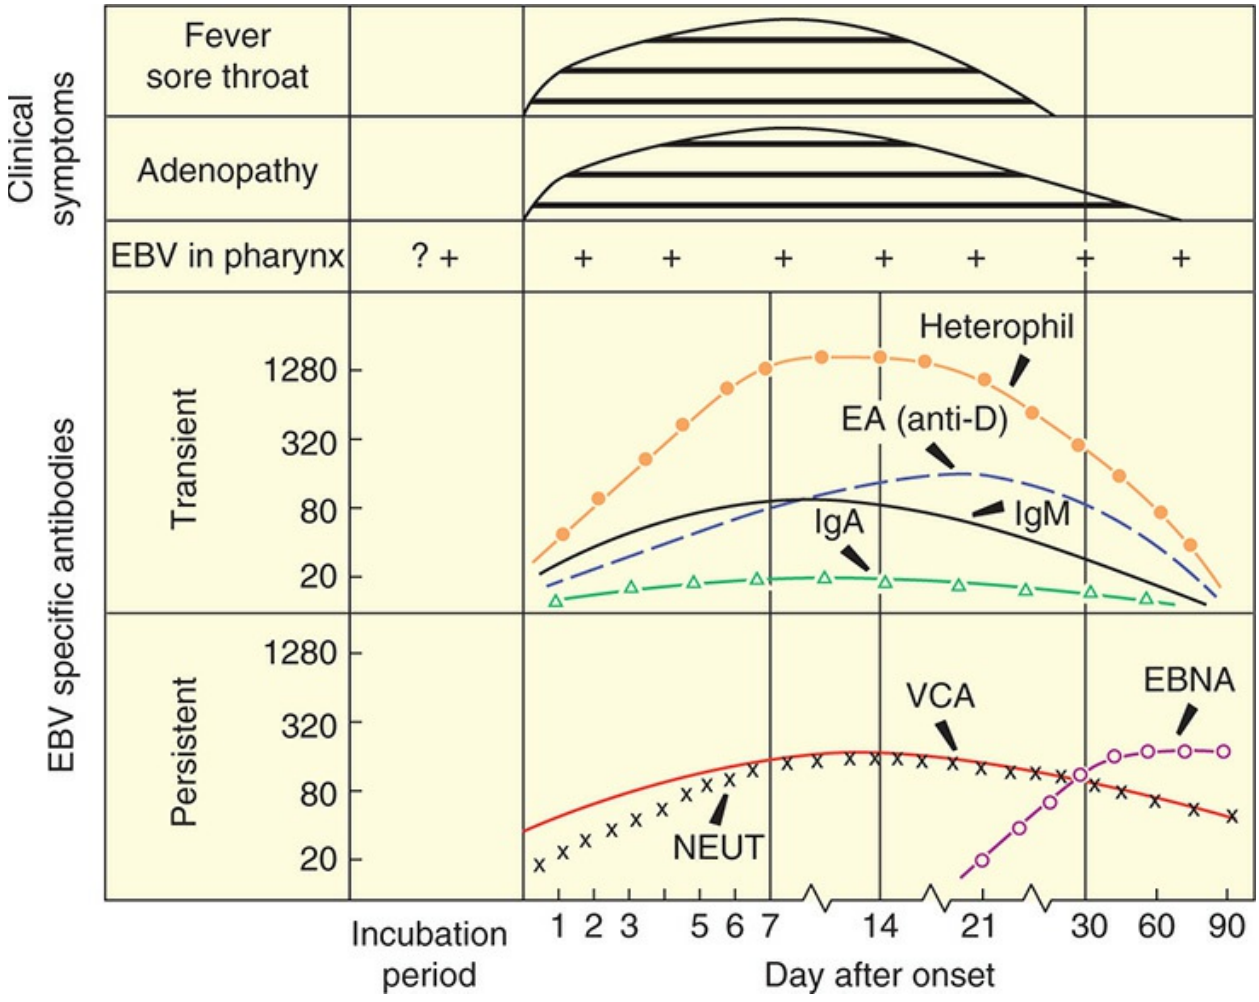
Hepatitis B Virus and Epstein–Barr Virus

There are a few exceptions to the general rule that a seroconversion must be documented to establish a diagnosis. In a few viral infections, antibodies to a variety of antigens appear at different times after infection and persist for varying lengths of time. It may be possible to establish a definitive diagnosis with a single serum when an antibody is detected that appears only acutely. The two prime examples are infectious mononucleosis caused by EBV (Fig. 23-18) and hepatitis B (Fig. 23-19) infections. If the infectious agent is not eliminated by the immune response, the presence of antibody means that the patient may still harbor the microbe. For instance, patients who have antibody to CMV, which often produces a latent infection, are more likely to transmit the virus than if blood or an organ is transplanted from a seronegative individual.[220]

Knowledge of the sequence of events is particularly important for the diagnosis of hepatitis B virus infection. Detection of viral antigen, especially the surface antigen (HBsAg), plays an important role in the diagnosis of acute infection. The e-antigen of hepatitis B virus is detected at the same time as DNA polymerase activity, which is a marker for infectious virus; the presence of e-antigen has correlated with acute, communicable disease in many studies,[346] as discussed above. Antibody to the viral core (HBc) is important diagnostically during the time when surface antigen has been cleared from the circulation and antibody to the surface antigen is not yet detectable. The presence of core antigen correlates with circulating viral DNA.[266] In some patients, a chronic infection develops in which antigenemia persists in the absence of serum antibody; this group has an increased risk for the development of chronic liver disease. It is now apparent that many of these patients have circulating antibody, which is not detected by commercial systems because it is complexed with antigen.[316] In addition, it has been demonstrated that some patients who have circulating antibody and no detectable surface antigen have circulating viral DNA detectable by amplification techniques for as long as 5 years.[327]

Likewise, the diagnosis of infectious mononucleosis can be made on a single serum if antibody to early antigen (EA) and IgM antibody to viral capsid antigen (VCA) are present. A high titer of IgG antibody to VCA in the absence of both antibody to EA and IgM antibody to VCA suggests a past infection. It is important to know the time course of the infection when interpreting the serologic results.[388]

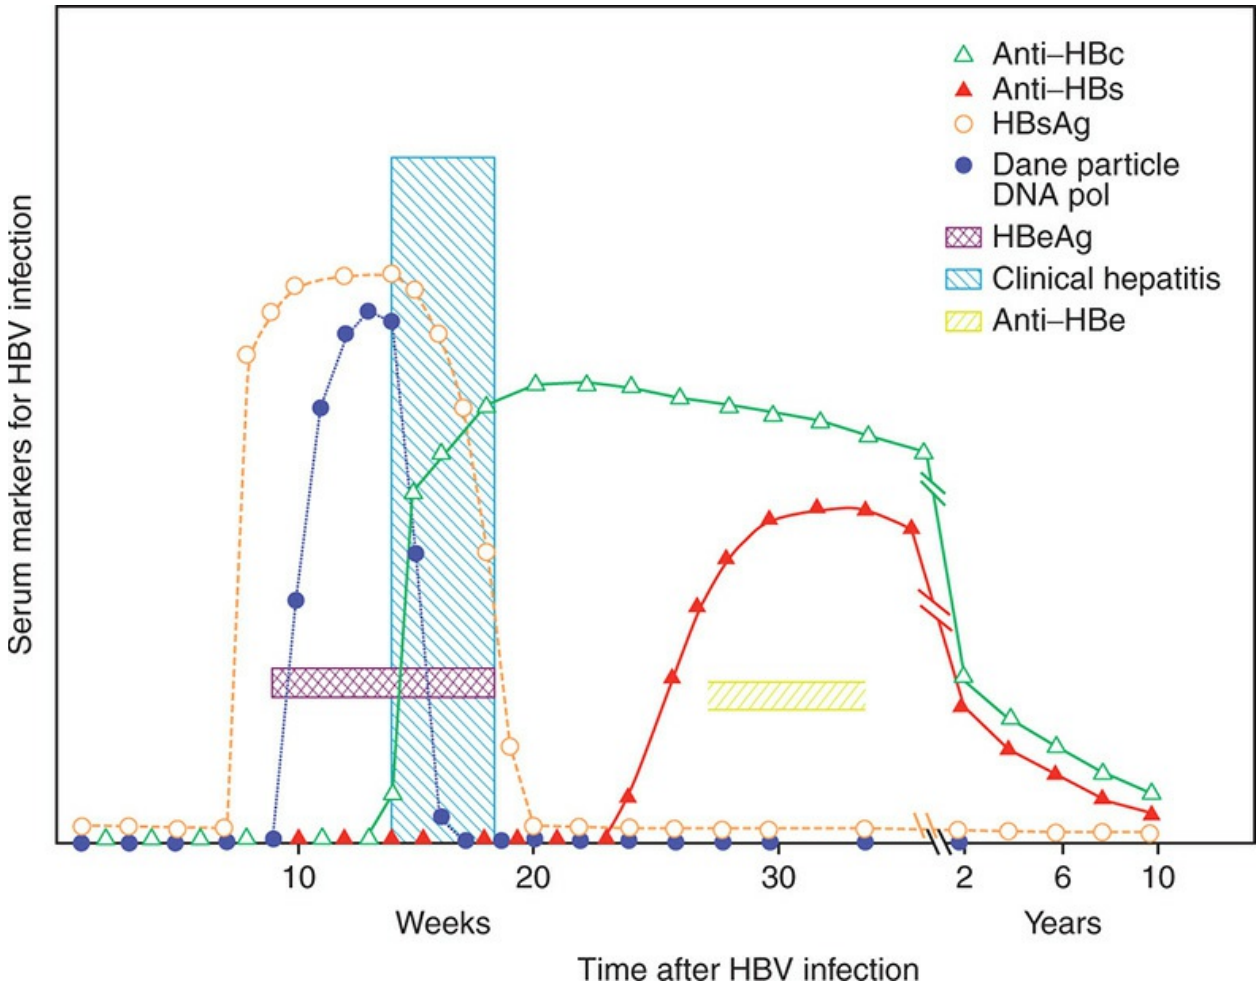
The most common test for detecting infections by EBV is the heterophil antibody test. Heterophil antibodies are immunoglobulins that react with substances from another species. In the course of an EBV infection, antibodies are produced to a variety of extraneous antigens. Agglutinins



■ **FIGURE 23-18** Time course of an Epstein–Barr virus (EBV) infection and serologic response. Although virus may be identified in oral secretions, the techniques for culture are difficult and are available only in research laboratories. The heterophil antibody response (i.e., the monospot test) is the classical means of documenting infectious mononucleosis and is still the most useful test. The transient appearance of heterophil antibody, IgM antibody to viral capsid antigen, and antibody to early antigen (EA) allows one to associate

the presence of antibody with the current illness. Neutralizing antibody and IgG antibody to viral capsid antigen (VCA) persist for months or years. These tests are useful to determine that the patient has been infected previously, and is, therefore, immune; they may also be useful diagnostically if the first specimen is collected sufficiently early and a seroconversion is documented. If the patient is seen late in the course of the illness, diagnosis may be made by detection of a seroconversion to viral nuclear antigen (EBNA). (Modified with permission from James C. Niederman, Yale University School of Medicine, New Haven, CT.)

1569



■ **FIGURE 23-19** Antigens and antibodies after self-limited infection with hepatitis B virus. The appearance of antigens and antibodies after self-limited infection with hepatitis B virus is an example of how knowledge of the biology of infection led to very effective diagnostic strategies, although the virus itself was difficult or impossible to culture. An assessment of both antigen and antibody is necessary to detect cases efficiently. Hepatitis B

surface antigen (HBsAg) appears first; after it is cleared from the blood, antibody to that antigen can be detected (anti-HBsAg). There may be a time wherein when antigen has been cleared but antibody is not detectable; measurement of antibody to the core antigen (anti-HBc) is necessary to detect patients in the "window" period. The presence of HBsAg does not equal acute, self-limited infection because some persons become chronic carriers. (Modified with permission from William S. Robinson, MD, Stanford University Medical Center, Stanford, CA.)

for sheep and horse red cells, hemolysins for beef red cells, and antibodies to the *Proteus* OX19 antigen of the Weil–Felix test are all produced. The heterophil antibodies that are very specific for infectious mononucleosis are absorbed by beef red cells but not by guinea pig kidney. The Paul-Bunnell–Davidsohn differential test for infectious mononucleosis is designed to characterize these heterophil antibodies; it is highly specific for EBV and confirmatory for making the laboratory diagnosis of infectious mononucleosis.[103] A variety of simplified tests for detecting the heterophil response in infectious mononucleosis are now available commercially.[145,232] Results that do not conform to clinical or hematologic data should be evaluated by performing the differential tube test or testing for EBV-specific antibodies. The agglutination tests for heterophil antibody are "simple" tests, which can be performed by "anyone" with no difficulty. In 1990, a pseudoepidemic of infectious mononucleosis was recognized in Puerto Rico.[55] Quality control and proficiency-testing results gave no hint of problems, but careful investigation revealed that two technicians with limited experience had been reporting examinations as positive based on "weak reactivity," a category that did not exist for the method used.

Ninety percent of adults with infectious mononucleosis will have heterophil antibodies. The frequency with which these antibodies develop in young children is much lower. Heterophil antibodies developed in only 3 of 11 infants less than 2 years of age after a primary EBV infection, whereas such antibodies developed in 16 of 21 children between the ages of 2 and 4 years.[230] Heterophil-negative infectious mononucleosis with circulating atypical lymphocytes is usually caused by EBV (i.e., demonstrable by specific antibodies to viral components) or by CMV.[231] Horwitz and colleagues[231] found that sera from 38.1% of patients with heterophil antibody-positive mononucleosis cross-reacted in an IgM-CMV test, but sera from patients with acute CMV infection did not react in the EBV VCA-IgM test. Cross-reacting antibodies to either the D or R component of the EA were detected in sera from 9 of 36 patients (25%) with mononucleosis caused by agents other than EBV (i.e., six cases of CMV infection, one of toxoplasmosis, one of probable hepatitis, and one of unknown cause).

The IgG antibody to EBV persists for long periods; other antibodies, such as those

against the EA of EBV, appear transiently and may serve as markers of acute infection.[388]

Hepatitis A Virus

Hepatitis A is the only primary hepatitis virus to have been cultured in vitro. The virus will grow in a variety of simian cells, most notably early passages of African green monkey kidney cells.[25] Culture is not a viable diagnostic option, however, because recovery from primary specimens is not reliable. Hepatitis A is diagnosed serologically by detection of specific IgM antibody.[383,431,448] Very early in the infection IgM antibody may not be detectable, so the test should be repeated after 2 weeks, if the clinical suspicion is high.[216]

1570

Hepatitis C Virus

The laboratory diagnosis of hepatitis C infections requires a combination of serologic and molecular tests. Early methods employed an EIA screen, with reflex testing to a specialized Western blot.[5]

At the time of this writing, there are several immunoassays that have been cleared by the FDA for diagnostic use. These include the Abbott HCV EIA 2.0 and the Abbott PRISM EIA (Abbott Laboratories), the Chiron RIBA HCV 3.0 Strip Immunoblot assay (Chiron Corp), the Ortho HCV version 3.0 Elisa (Ortho-Clinical Diagnostics, Raritan, NJ), and Vitros Anti-HCV Assay (an enhanced chemiluminescence assay; Ortho-Clinical Diagnostics). The use of HCV-encoded recombinant antigens has been important in the development of HCV screening assays.[6]

The current algorithm has retained the screening EIA, but reflexes positive specimen to quantitative RT-PCR for HCV rather than the immunoblot.

Parvovirus

Parvovirus infections in children are usually transient and do not require laboratory support for diagnosis. Concern is focused on immunosuppressed patients, patients with sickle cell disease, and pregnant women. Enzyme immunoassays, immunoblot tests, and radioimmunoassays have been developed.[41] Determination of IgG is sufficient to determine immune status in a pregnant woman who has been exposed to the virus; measurement of IgM is necessary for documenting acute infection. If hydrops fetalis is feared or suspected, a combination of serologic and virologic approaches is complementary.[507]

Herpes Simplex Virus

In the past, the serologic diagnosis of HSV infections was not useful because of the high prevalence of antibody to type 1 virus early in life and the inability of commercially available assays to distinguish between the two serotypes. However, it has been shown that the glycoprotein G antigen of herpes simplex elicits type-specific antibodies, for which there are now commercially available enzyme and immunoblot assays for IgG. Modern serologic assays for IgM and IgG provide a convenient way to document immune status and/or recent infection in pregnant women.[13,467] When measured against culture-documented genital infections, the type-specific serologic assays have good sensitivity and specificity.[339] Assays are also available for type 1 virus, although the diagnostic imperative is less compelling than for type 2 virus.[467]

Potentially the greatest use for these serologic assays is defining the risk of a primary herpes infection developing in the near term in pregnant women, when it may be transmitted to the neonate. The highest risk is in a woman who lacks antibody (i.e., not previously infected) and a partner who is seropositive. Avoidance of a primary infection is imperative in that situation. It should be noted that recurrent shedding of virus is not uncommon in seropositive women,[470] although the risk for the neonate is less in recurrent infection than in primary disease.

Varicella-Zoster Virus

An important use for serology in the diagnosis of VZV infections is for determination of immune status in patients or healthcare personnel. There have been a variety of methods developed including latex agglutination, a fluorescent test,[270,442] and these were found more sensitive than an enzyme immunoassay.[442] Others, however, have found that enzyme immunoassays yielded satisfactory results.[113]

Cytomegalovirus

Serology is useful in particular clinical settings and of secondary importance in others.[310] Infection with CMV, which is often asymptomatic or subclinical, may be accompanied by DNA in peripheral blood for many months after primary infection, even in the presence of a vigorous antibody response.[506] Recrudescence of this latent virus may be accompanied by an IgM response, so this usual marker of primary infection is flawed in this situation.[116] Challenges with the valid detection of IgM class antibodies complicate results interpretation. In one careful study of intrauterine CMV disease, only 10% of women with IgM antibody as determined by an EIA delivered a congenitally infected fetus.[287] When the presence of IgM antibody was confirmed with a specific immunoblot assay,[288] however, the risk was similar to documented

infection during the first trimester. The detection of primary CMV infection during pregnancy, however, remains an important use for CMV serology.

Serology also plays an important role in assessing risk of recipients of transplant for the risk of future CMV disease. This is based on the serologic status of both the donor and the recipient. The highest risk for serious CMV infection developing is transplantation of an organ from a seropositive donor into a seronegative recipient.[449] When possible, attempts are made to avoid this combination.

Once an immunocompromised individual is known to have contracted CMV, then serology is no longer useful. The detection and quantitation of CMV is accomplished by molecular methods, predominantly quantitative rapid-cycle PCR.

West Nile Virus and Chikungunya Virus

As with other flaviviruses, the West Nile virus does not grow readily in the cell cultures used in most virology laboratories. The diagnosis of this infection is made by serology and, to a lesser extent by molecular techniques. The clinical disease is primarily encephalitis, so the focus is on CSF. IgG and IgM antibody can be detected reliably in serum and CSF.[377] The presence of specific IgM antibody documents a recent infection. The initial outbreak was at first thought to be caused by the St. Louis encephalitis virus, because the two flaviviruses share common antigens. The recommendation for the early positive antibody tests was that positives should be confirmed with a different serologic approach.[306]

The chikungunya virus generates an antibody response close to the 1st week of illness that may be used for diagnosis.

Rubella

The traditional test for assessing immunity to rubella virus was hemagglutination-inhibition, but it has been replaced

by more convenient assays, particularly enzyme immunoassays.[181] These tests work well for determining immune status. For diagnosis of congenital infection, measurement of IgM antibodies with a rigorously validated method is necessary.

SARS and MERS Coronavirus

Antibody to the SARS coronavirus can be detected in >90% of patients with clinically evident disease, using an indirect immunofluorescence technique.[74] A transient IgM response occurs at approximately 20 days from the onset of disease, which is soon

replaced by an IgG response. A very small percentage of patients without clinically evident disease also had seroconversion. At present, serologic diagnosis appears to be the most sensitive method for diagnosing the infection.

Serologic tests for these coronaviruses are available at the CDC for prevalence and surveillance studies, but not for diagnostic purposes.

Miscellaneous Serologic Procedures

A wide variety of procedures can be used for serologic diagnosis of viral infections (Table 23-21). EIA and immunofluorescence tests are gaining in popularity in clinical laboratories; many of these tests are available commercially in kit form.

Diagnosis of Other Viral Infections

Diagnosis of some viral infections is beyond the scope of most hospital laboratories because the infections are rare or exotic, the etiologic agents are hazardous, or special diagnostic facilities are necessary. Tests for rabies, arbovirus infections, and viral hemorrhagic fevers are usually performed in a reference laboratory, such as those in state departments of health or at the CDC.

When the Ebola virus was imported to the United States through an infected individual, the CDC provided guidance regarding safe means in which to perform routine laboratory testing on potentially infected individuals, as well as directions for the packaging and shipping of specimens for testing (www.cdc.gov/vhf/ebola/healthcare-us/).[69] The guidelines were collated on the College of American Pathologist's website for ready access by all laboratorians. Although assays with "Emergency Use" clearance have been released, companion specimens from persons suspected to possibly have Ebola virus disease must also be sent to the authorized state public health laboratory for testing.

Antiviral Susceptibility Testing

Resistance to antiviral agents occurs more commonly in RNA viruses than DNA viruses, since RNA polymerase lacks the proofreading functions of DNA polymerase. The lack of proofreading causes a higher rate of errors in RNA replication, which translates into a large number of quasi-species, in addition to the replication of the parent RNA molecule. Although some of these mutations may produce dysfunctional viruses, others may produce viruses with some evolutionary advantage. One such advantage is resistance to an antiviral drug.

In some instances, the viral population acquires resistance so rapidly that susceptibility testing becomes unnecessary, since the majority of the population is resistant. This is what occurred during the H1N1 influenza epidemic. Initially, the isolates were uniformly susceptible to oseltamivir (i.e., Tamiflu), but soon resistance to

this agent became the rule.[207]

The area wherein antiviral resistance is routinely evaluated is in the care of individuals infected with HIV. Although phenotypic assays, which are expensive, time-consuming and complex, are available, the vast majority of this assessment is done via nucleic acid sequencing (i.e., HIV genotyping). This is commonly done to establish a baseline after the initial infection, which determines the resistance pattern of the virus with which the patient has been infected. HIV genotyping is also performed in patients who have rising viral loads and decreasing CD4 counts, despite compliance with therapy. In brief, the RNA from the virus is reverse-transcribed and select genes are amplified by RT-PCR. The products of amplification are submitted for DNA sequencing to determine if the wild-type sequence is present, or if resistance-inducing mutations are present.

Resistance in other viral agents, particularly the herpes group of viruses, is well recognized, but fortunately uncommon. Although extremely uncommon, occasionally ganciclovir-resistance may arise in patients on chronic suppressive therapy with this drug. Susceptibility testing of clinical isolates, which should be used judiciously, is available in selected reference laboratories.[450]

Infections with *Chlamydia* and *Chlamydophila* Species

Chlamydiae are obligate intracellular bacterial pathogens. Although genetic studies demonstrate that the three organisms considered below are closely related, there have been taxonomic changes.[165] Since the last edition of this text, two of the three species of *Chlamydia* have been reassigned to a new genus, *Chlamydophila.*[444] *Chlamydophila psittaci* causes an acute respiratory infection that is usually transmitted by infected birds.[410] *Chlamydophila pneumoniae* also causes respiratory infections, but is transmitted from person to person. This bacterium was originally referred to as the TWAR bacillus, using the initials of two patients from whom the bacterium was isolated. *Chlamydia trachomatis*, which includes 15 serologic variants (serovars), remains in the genus *Chlamydia.* Infections caused by *C. trachomatis* are common, given the sexual means of transmission and the and often cause asymptomatic infections in women.[407] *C. trachomatis* serovars L1, L2, and L3 produce another sexually transmitted disease, lymphogranuloma venereum. Finally, trachoma, a chronic conjunctivitis often complicated by blindness, is associated with serovars A, B1, B2, and C. Trachoma remains an important cause of blindness in resource-poor countries throughout the world.

All of the chlamydiae may be isolated in embryonated eggs and cell culture.

Recovery of *C. psittaci* in cell culture should not be attempted unless stringent isolation facilities are available for protection of laboratory personnel. Care to prevent laboratory-acquired infections should also be exercised if the serovars that cause lymphogranuloma venereum are suspected. It is rare to culture for these pathogens in modern laboratories, as infections are more commonly documented by molecular or serologic methods.

1572

TABLE 23-21 Serologic Diagnosis of Viral Infections

Virus	Tests Commonly Performed	Comments
RESPIRATORY INFECTIONS		
Influenza A and B	CF; HAI; EIA	HAI performed for strain-specific immunity
Parainfluenza	CF; HAI; EIA	
Respiratory syncytial	FA; EIA; IB	
Adenovirus	CF; HAI; EIA	Rhesus or rat RBC for HAI
Coronavirus	NT; EIA; FA; IB	Limited data for SARS and MERS virus
CENTRAL NERVOUS SYSTEM INFECTIONS		
Enteroviruses	NT	Not commonly performed
Mumps	CF; HAI; FA; EIA	
Herpes simplex	EIA; IB	Type-specific reagents required
Rabies	NT; EIA	For immune status
Hepatitis		
Hepatitis A	EIA	
Hepatitis B	EIA; RIA	See text
Hepatitis C	EIA; IB	Screening test followed by confirmatory assay

Hepatitis D	EIA; RIA	Rarely performed
Hepatitis E	EIA	
CUTANEOUS INFECTIONS		
Measles	HAI; EIA	
Varicella-zoster	EIA; ACIF; FAMA; LA	For immune status
GENITAL INFECTIONS		
Herpes simplex	EIA; IB	Type-specific reagents necessary
HIV	EIA; IB	Screening test followed by confirmatory test
OTHER INFECTIONS		
Cytomegalovirus	EIA; IFA; Passive latex agglutination	Primarily for immune status
Rubella	HAI; EIA; LA; IB	HAI reference method
Epstein–Barr	CF; FA;EIA	See discussion
Parvovirus	RIA; EIA	
Human herpes 6 and 7	NT; FA; EIA; IB	

ACIF, anti-complement immunofluorescence; CF, complement fixation; EIA, enzyme immunoassay; IFA, indirect immunofluorescent assay; FA, immunofluorescence; FAMA, fluorescent antibody staining of membrane antigens; HAI, hemagglutination-inhibition; IB, immunoblot or immunochromatograph; LA, latex agglutination; NT, neutralization test (the reference test for most viruses, although infrequently necessary); RIA, radioimmunoassay.

Chlamydia trachomatis

Clinical Features and Epidemiology. Inclusion conjunctivitis (an infection distinguished from trachoma by the absence of corneal scarring), pneumonia in neonates, and sexually transmitted infections in adults, all of which are caused by serovars D through K, are the chlamydial diseases of most importance for diagnostic laboratories.[254] The sexually transmitted infections include urethritis, mucopurulent cervicitis, and salpingitis. The sexually transmitted and neonatal infections are directly connected. Schachter and colleagues[408] followed 131 infants born to mothers from

whose cervix *C. trachomatis* was cultured. Culture-confirmed inclusion conjunctivitis developed in 18% of the infants, and 16% had neonatal chlamydial pneumonia.

Collection of Specimens. Cervical and ocular specimens are best collected by scraping the mucosa. Swabs are readily available and minimally traumatic. Wood-tipped swabs and

swabs made of calcium alginate should be avoided; some cotton swabs have been toxic to *Chlamydia*. Dacron or rayon material is preferred.[100] Urethral and nasopharyngeal specimens may be collected with a fine swab on a flexible wire. The swab should be inserted 3 to 5 cm into the urethra. Semen and purulent urethral discharge are not considered adequate specimens for culture.[88] *C. trachomatis* can be detected in first morning urine specimens with amplification techniques, as discussed later.

Cervical specimens are collected from the endocervix after carefully removing mucus. The isolation rate is increased if a urethral and cervical swab are placed in the same transport vial. Vaginal specimens are also acceptable for many of the amplification-based assays.

Isolation of *Chlamydia trachomatis* in Cell Culture. Although chlamydiae are bacteria, they are obligate intracellular pathogens. Methods for isolation in culture are similar to those used in the virology laboratory. It is essential, however, that the infective elementary bodies of chlamydiae be centrifuged onto the monolayer in a shell vial (Fig. 23-10). Isolation of the bacteria is optimized if a force of 3,000 *g* for 60 minutes can be achieved.[430] Cells that have been irradiated or treated with a metabolic inhibitor are used for culture. Cycloheximide-treated McCoy cells are the most commonly used cell line[502]; inclusion bodies of *C. trachomatis* contain glycogen, which may be stained with iodine. After incubation for 48 to 72 hours, the coverslips are removed and stained with iodine or, for somewhat greater sensitivity, with a fluoresceinated monoclonal antibody[438] (Image Plate 23-2C). Species-specific monoclonal antibodies directed against outer-membrane proteins and genus-specific antibodies directed against lipopolysaccharide are available. Chlamydial inclusions are well-demarcated, cytoplasmic structures.

Culture for chlamydia is not commonly performed in many laboratories, given the superior sensitivity of molecular methods for the detection of sexually transmitted chlamydial disease. Additional information regarding culture-based methods is present in previous editions of this textbook for those requiring additional information.

Direct Detection of *Chlamydia trachomatis* in Clinical Specimens

Morphologic Detection of Inclusions. If large numbers of chlamydial inclusion bodies are present, a provisional diagnosis may be established easily by staining smears by the Giemsa or Gimenez methods. The Gimenez stain, which contains carbolfuchsin, is preferred because the inclusions are colored well, but the Giemsa stain is more generally available. The inclusions, which are located in the cytoplasm of epithelial cells, often have a perinuclear location and must be distinguished from artifacts, such as fragmented nuclei (Image Plate 23-2A). The frequency with which inclusions are detected in smears is highest in neonatal conjunctivitis, lower in inclusion conjunctivitis of adults and in trachoma, and lowest in urethritis and cervicitis, where inclusions are rarely found. In practice, direct visualization is rarely attempted.

Detection of Antigen. The initial approaches to nonculture laboratory diagnosis were direct immunofluorescence (Image Plate 23-2B) and subsequently enzyme immunoassay. Although commercial products for some of these tests are still available, they have been supplanted by more sensitive molecular methods. Interested readers should consult the previous edition of this book.

Detection of Nucleic Acid. The first commercial molecular test applied to *C. trachomatis* was a DNA probe against rRNA (Pace 2 Systems Assays, Gen-Probe, San Diego, CA). The sensitivity of the test has ranged from approximately 80% to 95%, depending on the population of patients tested, the source of the specimen, the version of the test evaluated, and the "gold standard" applied.

The second-generation molecular tests were amplification tests of several kinds, many of which constitute the standard of practice today. Most comparative studies have evaluated either the hybridization assays (and/or antigen assays) versus culture, or amplification assays and culture. Numerous studies have been done comparing a variety of detection methods. The most valuable are those studies that compared all three approaches head to head[500]; amplification assays are more sensitive than previous technologies, and now are significantly more automated.

The most commonly used molecular tests at present use PCR (Amplicor CT/NG Test and Cobas Amplicor *Chlamydia trachomatis* [CT]/*Neisseria gonorrhoeae* [NG] Test; Roche Diagnostics),[296] strand-displacement amplification (BD ProbeTec CT and CT/GC assays; BD Diagnostic),[461] and TMA (Gen-Probe Aptima Combo 2 assay; Hologic).[166] There are hybrid capture methods (Hybrid Capture 2 CT/NG DNA test; Qiagen) still available, but these are used less frequently than nucleic acid amplification-based assays.[99] The various amplification methods appear to function in a similar fashion. All are more sensitive than other culture-based methods and immunoassays, but they are also more expensive.[20] In addition to sensitivity, the amplification methods also offer convenience. Some platforms list urine as a valid

specimen type, which increases the convenience of collection; users should refer to individual package inserts for approved specimen types. Research studies have documented the acceptability of self-collected vaginal swabs,[420] which may be an approved collection method in the future. In general, endocervical specimens are marginally more sensitive than urine in women, but urine is more sensitive than urethral swabs in asymptomatic men.[250]

It should be noted that most authorities consider all positive screening tests to be presumptive,[251] requiring confirmation unless the specificity is absolute (a criterion that only culture fulfills). The issue is more pressing for *N. gonorrhoeae* than for *C. trachomatis*, because the prevalence of the former is less. Most assays for *C. trachomatis* are performed in the absence of clinical symptoms and are, therefore, screening tests. Each laboratory director must make a determination. If the economics of repeat testing make universal adoption of confirmatory testing unlikely, it is certainly true that repeat testing is indicated should there be any question about the validity of the result from a clinical perspective. The complexity of the issue has been carefully reviewed by an expert panel.[264] For instance, if the test is repeated, should a different method be used? A second specimen? If the two results differ, which is correct? Although these assays are considered "screening" tests, they are commonly used as definitive tests, and follow-up, confirmatory tests are not usually performed.

1574

A challenge with any amplification-based assay is the presence of inhibitors of amplification in clinical specimens. This is addressed by the inclusion of an amplification control. Given the issues concerning laboratory-accreditation and competition among vendors, internal amplification controls are present in FDA-cleared, commercially available products. Some methods, such as TMA and helicase-dependent amplification, appear to be affected less by inhibitors.[83]

A common approach to endocervical cytology is the use of a liquid collection medium. This specimen type has been validated for the molecular detection of *C. trachomatis*, as well as HPV, *N. gonorrhoeae*, and in some instances, *Trichomonas vaginalis*.[24]

Serologic Diagnosis. Antibodies to *C. psittaci* and the lymphogranuloma venereum serovars of *C. trachomatis* are useful for establishing the diagnosis of disease caused by these organisms. A microimmunofluorescence test for antibodies to *C. trachomatis* has been found more sensitive for diagnosis of lymphogranuloma venereum infections and can also be used to document infections by other serovars.[153] This test is less widely available, and multiple antigens must be tested. It is most useful for

seroepidemiologic studies of populations at high risk for chlamydial infection.[264]

Other Methods for Diagnosis. Cytologic detection of *Chlamydia/Chlamydophila* has not generally been considered reliable. Kiviat and colleagues,[267] however, have reported a cytologic inflammatory pattern that strongly suggested the presence of chlamydial infection. If "transparent" lymphocytes and increased numbers of histiocytes were present, *C. trachomatis* was isolated in 53% of patients; in the absence of those findings *C. trachomatis* was isolated only from 4% of patients. If these cytologic features are noted in a cervical smear, specific tests for chlamydia should be considered.

Diagnosis of Sexual Abuse. The sexual abuse of children or members of other vulnerable populations may result in the contraction of sexually transmitted diseases, including *Chlamydia trachomatis*, among others.[100] The type of tests that are admissible in court varies from state to state, so local guidance is recommended regarding the use of nucleic acid amplification methods in this setting. Traditionally, the test of choice for investigation of suspected sexual abuse or in case of other legal considerations has been to obtain a culture.[251] This, however, may change in the future.

Chlamydophila psittaci

Chlamydophila psittaci is the causative agent of psittacosis or ornithosis. The source of infection is a variety of birds, especially psittacine species such as parakeets.[203] An outbreak of psittacosis occurred at a turkey-processing plant in North Carolina.[53]Many organ systems may be affected in the natural host. When this agent infects humans, the primary target is the lung.[410] The resulting pneumonia is usually subacute or chronic, but mild or inapparent infection[336] and acute, fulminating infection[45] can result. *C. psittaci* is also a rare cause of culture-negative endocarditis.[477]

The diagnosis of psittacosis is usually accomplished by serology. The traditional test was complement fixation, but the microimmunofluorescence test has become the reference serologic test.[153] In patients suspected of being infected by *Chlamydophila*, complement-fixing antibodies to *C. psittaci* were detected in 36 of 78 sera (46%) submitted for chlamydial serology.[492] An additional 12 sera (15%) were positive by microimmunofluorescence, and 9 more had antibodies to *C. pneumoniae* by microimmunofluorescence.

The organism can be isolated in cell culture using methods designed for *C. trachomatis*, but this agent has high potential for producing laboratory infections, and so this practice is discouraged. If culture is performed, then great care should be taken

with the specimen. Species-specific antisera are necessary for definitive identification of the isolate. Presumptive identification of *C. psittaci* directly in respiratory secretions has been reported by using antisera to chlamydial lipopolysaccharide.[355] The PCR has been used to identify the organism directly in clinical specimens[107] and after isolation in culture.[136]

Chlamydophila pneumoniae

Chlamydophila pneumoniae was originally isolated from patients with respiratory infections and was first called the TWAR agent after the source patients. It produces sporadic and epidemic lower respiratory disease characterized as atypical pneumonia.[185]It has been estimated that 10% of pneumonias worldwide are caused by *C. pneumoniae*,[264] but most infections do not require admission to the hospital. Asymptomatic infection occurs in 2% to 5% of individuals. *C. pneumoniae* was detected by culture or PCR in the nasopharynx of 2 of 104 (1.9%) asymptomatic adults.[242] The prevalence of antibody to *C. pneumoniae* in this population was 82%.

Primary infection occurs in children and young adults, but immunity is not protective and reinfections are possible.[264] The onset of pneumonia is often insidious, without purulent sputum or leukocytosis. The chest radiograph varies from normal to extensive involvement, and there are no diagnostic features. In primary infection, the most common pattern is unilateral alveolar infiltrates.[323] Chronic pulmonary infections occur, and patients may be symptomatic for weeks or months.[200]

Chlamydophila pneumoniae is a cause of pharyngitis; it may be the sole cause or may occur in combination with other agents.[241] It has also been reported as a cause of culture-negative endocarditis.[167] Multiple studies have documented an association between *C. pneumoniae* and atherosclerosis with or without coronary artery disease.[257] The organism has been demonstrated repeatedly in the pathologic lesions. The causality of the association, however, remains a matter for discussion and further investigation.[184]

Chlamydophila pneumoniae can be cultured in the laboratory using a variety of cell lines, but this is usually not attempted. Eagle's MEM or SPG with an added protein source, such as fetal calf serum, as used for viruses and *C. trachomatis*, serves as a useful transport medium.[299] Laboratory-adapted strains of *C. pneumoniae* are relatively stable, but wild-type strains are more labile and do not survive well for more than a few hours even at 4°C. If culture is to be attempted, samples should be frozen, preferably at −70°C, if they cannot be processed on the day of collection. Cultures

are incubated for 72 hours. Fluorescein-conjugated monoclonal antisera are available for detection and identification of isolates in culture.[332] The laboratory diagnosis of *C. pneumoniae* infections is complicated by the difficulty of culture and the absence of an alternative reliable gold standard. Most infections are diagnosed serologically. The serology may be more complicated than realized at present. Antigenic variation among isolates was sufficiently great in one study that some patients produced measurable antibody only against their own isolate.[26] The reference test is microimmunofluorescence. Enzyme immunoassays have been developed, but are variable in their performance.[213] Demonstration of seroconversion has been traditionally used, but this is being replaced by IgM- and IgG-specific assays.[366] Reproducibility of IgM determinations among collaborating laboratories was quite variable.[366]

Molecular amplification methods for direct detection of *C. pneumoniae* in respiratory specimens have been developed because of the difficulties inherent in cultural and serologic approaches. Lack of standardization limits the utility of these potentially important assays at present.[32] These tests are available through reference laboratories.

Infections with *Rickettsia*, *Coxiella*, *Ehrlichia*, and *Anaplasma*

The order Rickettsiales includes the families *Rickettsiaceae* and *Anaplasmataceae*.[121] The most numerous and important genus is *Rickettsia*. The former *Rickettsia tsutsugamushi* has been reclassified as *Orientia tsutsugamushi*. These organisms are found in the alpha-1 subgroup of *Proteobacteria*. *Coxiella*, once classified in the order Rickettsiales, is actually more closely related to *Legionella* and *Francisella*, members of the gamma subgroup of Proteobacteria.[321] Laboratory diagnosis of rickettsial infections and identification of *Rickettsia* in ticks have been reviewed by La Scola and Raoult.[276] A century after the recognition of these infectious agents, Dr. David Walker has described the origins of the field of rickettsiology and the life of Howard Ricketts, who ultimately died of typhus in Mexico City.[474]

Rickettsia *and* Coxiella

Clinical Features and Epidemiology. *Rickettsia* species infect vascular endothelial cells. The clinical manifestations of infection are consequently protean and may reflect damage to any organ system. The skin, lung, and brain are most frequently involved

symptomatically. *Rickettsia* can be divided into the typhus, scrub typhus, and spotted fever groups (Table 23-22). The agent of Q fever, *Coxiella burnetii*, is also an obligate intracellular pathogen. The primary means of transmission of rickettsial infections is by the bite of an infected arthropod, with the exception of *C. burnetii*, which is most commonly transmitted through infected milk or by aerosol.

Epidemic typhus has been one of the great scourges of humankind, appearing during periods of crowding and starvation. *R. prowazekii* has been demonstrated in flying squirrels in the eastern United States,[493] and a small number of associated human infections have occurred. A patient with epidemic typhus has also been recorded in the Southwest.[317]

Although epidemic (louse-borne) typhus is not a serious problem in North America, as recently as 1996 to 1997, this classical disease killed 6,000 people in Burundi. In the United States, endemic (flea-borne or murine) typhus has received renewed attention. A focus of murine typhus was identified in Southern California and in South Texas in the 1990s. It was found to be transmitted by the cat flea and maintained in cats and opossums.[435] The etiologic agent is the classical *R. typhi*[435] and additionally a newly recognized *Rickettsia*, initially named the El Labs (ELB) agent.[416,490] It is difficult to distinguish the two rickettsiae serologically, so molecular analysis is necessary.[416] The ELB *Rickettsia* has now been classified as *R. felis*.[215] By molecular analysis it belongs in the spotted fever group, rather than the typhus group, of *Rickettsia*.[35]

In the United States, the most important rickettsial infection is Rocky Mountain spotted fever, caused by *R. rickettsii*.[471] This multisystemic febrile disease is usually accompanied by a skin rash that begins on the extremities.[472] The infection is widely distributed throughout the country, wherever the tick vectors exist (see Chapter 22; Appendix I). Paradoxically, it is more common in the midwestern and south central states than in the western and mountain states.[206] Similar infections, caused by other rickettsial species, are widely distributed around the world (Table 23-22).[385s]

Scrub typhus, caused by *Orientia tsutsugamushi*, is not endemic in the United States. Scrub typhus is often accompanied by a primary eschar, which is seen only rarely in Rocky Mountain spotted fever. Primary eschars are also seen in rickettsialpox, which is caused by *Rickettsia akari*. The infection was first documented in New York City and associated with the bites of blood-sucking mites. Rickettsialpox is a mild disease and is not commonly recognized, but occurs worldwide. It remains endemic in New York City.[262]

Q fever usually causes asymptomatic infection, undifferentiated febrile disease, granulomatous hepatitis or atypical pneumonia.[321,386] It may be transmitted through milk, products of conception, or excreta of infected cattle, sheep, and goats. The

organism is easily transmitted to susceptible humans, and epidemics have occurred in laboratories where sheep were used for research purposes.[198] A chronic form of the infection may result in subacute bacterial endocarditis. Rash is rare in Q fever.

Collection of Specimens. Culture of *Rickettsia*, which is dangerous, is performed only in reference, public health or laboratories with enhanced precautions. Blood or biopsy tissue from a lesion should be frozen at −70°C. Direct immunofluorescence may be performed on a frozen or formalin-fixed biopsy or autopsy specimen. Rickettsial infections are usually diagnosed serologically, using acute and convalescent sera.

Isolation of *Rickettsia* and *Coxiella* in Culture. *Rickettsia* and *Coxiella* may be isolated in small laboratory animals or in embryonated eggs.[475] *Coxiella burnetii* has been isolated in shell vial cultures of human embryonic lung fibroblasts from blood of 17% of untreated patients

with acute Q fever and 53% of untreated patients with chronic disease.[347] All of these bacteria are highly infectious when they are aerosolized. They have been responsible for many laboratory-acquired infections, some of which were fatal.[356] Isolation of the agents should be attempted only in laboratories where adequate containment of infection is possible. Whole blood or biopsied tissues may be cultured.

Direct Detection of Antigen and Nucleic Acid in Clinical Specimens. Antigens of *Rickettsia rickettsii*, the cause of Rocky Mountain spotted fever, can be detected directly by staining sections of infected skin lesions using the direct or indirect immunofluorescence or immunoenzymatic techniques.[378,475] The sensitivity of the procedure is approximately 70%, and the specificity approaches 100%. Usually, petechial skin lesions are biopsied. The rickettsiae are most likely to be in the blood vessel at the center of the lesion, so it is important to ensure that such vessels are included in the tissue section. Antigens can also be demonstrated in paraffin-embedded, formalin-fixed specimens if the section is treated first with proteases to

early diagnosis of Rocky Mountain spotted fever, it is available in very few laboratories.

Patients with fatal disease may die before a serologic response develops. Identification of rickettsial antigens in tissue is the only method available for making a specific etiologic diagnosis in that situation.[358]

Molecular amplification assays for documentation of *Rickettsia* in clinical specimens have been described, but are not widely available.[131,276]

Serologic Diagnosis. Most diagnoses of rickettsial infections are made by serology.[118] The microimmunofluorescence assay has become the reference test.[372] This procedure appears to be the most sensitive and specific method for the diagnosis of rickettsial infections.[260] The degree of cross-reaction among rickettsial species varies from patient to patient.[372] Cross-reactions are strongest within the rickettsial subgroups. It may be difficult to distinguish between epidemic and endemic typhus or between Rocky Mountain spotted fever and rickettsialpox.[475] Antibodies first appear 7 to 10 days after infection. A fourfold rise in serum antibody is desired for diagnosis, but a single titer of more than 1:64 is highly suggestive of infection.

The microimmunofluorescence test requires highly trained personnel and a fluorescence microscope. Latex agglutination tests, which are now commercially available for Rocky Mountain spotted fever, are in more general use. The

latex tests appear to produce positive reactions only during an acute infection, so a single positive test is diagnostic.[210] The sensitivity has ranged from 70% to 95%.[210,260] After infection by *Coxiella burnetii*, antibodies may be produced to two biologic phases of the organism. Antibodies to phase II are produced first. Antibodies to phase I, which appear weeks or months later, may reach high levels in patients with Q fever endocarditis. If antibodies to both phases of *Coxiella* are high in a patient with culture-negative endocarditis, a diagnosis of Q fever is likely.[265,437]

Historically, the most common diagnostic test for rickettsial disease has been the Weil–Felix test, in which anti-rickettsial antibodies that cross-react with strains of *Proteus* species are detected. The test originated from the chance observation that sera from patients with typhus agglutinated strains of *Proteus vulgaris*. As experience with immunologically specific serologic tests has been accumulated, it has become apparent that the Weil–Felix test is both insensitive and nonspecific.[211,260,475] In some populations, a positive Weil–Felix test result has been more common in those who did not have Rocky Mountain spotted fever than in those who were infected.[475] This test,

not have Rocky Mountain spotted fever than in those who were infected.[475] This test, therefore, has been appropriately relegated to the archives of laboratory medicine history.

Ehrlichia *and* Anaplasma *Species*

The family *Anaplasmataceae* constitutes Rickettsia-like bacteria that can infect humans and a variety of animal species, producing diseases such as tropical canine pancytopenia and Potomac horse fever (Table 23-23).[398] These organisms are obligate intracellular parasites and, like rickettsiae, grow in the cytosol of infected cells.

Human ehrlichial infection, which is a recently recognized phenomenon, is caused by several distinct species, of which two are most important: *Ehrlichia chaffeensis*, which infects human monocytic cells,[6,104] and *Anaplasma phagocytophilum* that infects granulocytic cells.[77] Both species are transmitted to humans by ticks and produce a febrile illness with leukopenia, thrombocytopenia, and elevated serum aminotransferase.[120]

TABLE 23-23 Some *Ehrlichia* and Related Organisms with Associated Diseases[a]

Organism	Disease	Host
Ehrlichia chaffeensis	Human monocytic	Humans
Ehrlichia ewingii	Canine granulocytic ehrlichiosis	Dogs
	E. ewingii ehrlichiosis	Humans
Ehrlichia canis	Canine monocytic ehrlichiosis	Dogs
Anaplasma phagocytophilum	Human granulocytic anaplasmosis	Humans
	Canine granulocytic anaplasmosis	Dogs
	Equine granulocytic anaplasmosis	Horses
Neorickettsia sennetsu	Sennetsus fever	Humans
Neorickettsia risticii	Potomac horse fever	Horses
Neorickettsia

Human Monocytic Ehrlichiosis. The monocytic variety of ehrlichiosis, caused by *Ehrlichia chaffeensis*, was recognized first. It is distributed widely through the Southeast, Midwest, and Far West of the United States. Monocytic ehrlichiae have been documented worldwide. In areas where tick vectors are prevalent, seroconversions to *Rickettsia rickettsii* occurred in 2.5% and to *E. chaffeensis* in 1.3% of military personnel.[501] In southern Georgia, human monocytic ehrlichiosis was seven to eight times more prevalent than Rocky Mountain spotted fever.[144] Contact with ticks is a risk factor for both monocytic ehrlichiosis and Rocky Mountain spotted fever.[7] An outbreak of monocytic ehrlichiosis occurred in a golf-oriented retirement community (community A) that abutted a natural wildlife area.[440] Cases were not recognized at a nearby community and golf course (community B) that were not surrounded by a natural area. The prevalence of antibody to *E. chaffeensis* in community A was 12.5%, whereas in community B the prevalence was 3.3%. Thousands of *A. americanum* ticks were found in community A, but only three ticks were detected in community B. The risk factors for ehrlichiosis included tick bites, contact with wildlife, failure to use insect repellent, and golfing. Among golfers, those at greatest risk were the hookers and slicers, who were constantly retrieving their balls from the rough. The moral is that if you golf in a rural area, you should wear insect repellent and hit the ball straight.

The clinical symptoms of monocytic ehrlichiosis range from nonspecific febrile disease to severe systemic infection with multiorgan failure.[120,143] In one study of 237 infected patients, 60.8% were hospitalized.[156] Severe monocytic ehrlichiosis with failure of multiorgan systems has been mistaken for thrombotic thrombocytopenic purpura[315] and toxic-shock syndrome.[141] Life-threatening disease may occur in individuals who are infected with HIV.[357]

Masses of ehrlichiae (morula) may be seen within the cytoplasm of infected monocytes (Image Plate 23-2G), but these diagnostic structures are infrequently seen with *E. chaffeensis* infection.[120,122] The diagnosis is made serologically, less commonly by culture of the agent,[78] and more commonly by molecular methods.[8,137]

Human Granulocytic Anaplasmosis. The second major pathogenic organism is the agent of human granulocytic anaplasmosis (HGA), which was first recognized in Minnesota and Wisconsin by an alert infectious disease physician, who recognized the similarity of the intracellular granulocytic inclusions to those described in *E. chaffeensis* infection.[15,87] The agent of HGA has been classified as *Anaplasma*

similarity of the intracellular granulocytic inclusions to those described in *E. chaffeensis* infection.[15,87] The agent of HGA has been classified as *Anaplasma phagocytophilum*; it is genetically related to the human monocytic agent, *E.* chaffeensis, and *E. equi*, but sufficiently distinct to warrant a new genus designation.[121] Although variants have been described,[318] *A. phagocytophilum* strains in the United States show a high degree of genetic uniformity.[119]

1578

The most important vector in the United States is *Ixodes scapularis* (Chapters 20 and 22 and Appendix I), the same tick that transmits the microbes that cause Lyme disease and babesiosis.[360] The duration of attachment required for transmission of *A. phagocytophilum* appears to be somewhat less than that required for infection with *Borrelia burgdorferi*,[110,263] but the exact dynamics are not yet clear. Patients in the North Central United States appear from serologic studies to have been infected with all three pathogens.[328] Not surprisingly, the distribution of HGA is expanding to cover the range of the host tick. Infections have been reported from multiple areas in the North Central and Eastern United States. HGA has also been documented in California,[147] as well as in Europe and Asia. In some parts of the country, rickettsial and ehrlichial infections must all be included in the differential diagnosis of febrile disease.[49] Dual infections with ehrlichia and *Rickettsia* have been described.[419] It may be important, therefore, to include antigens of all possible pathogens when attempting serologic diagnosis; demonstration of seroconversion assumes even greater diagnostic importance.[92]

The clinical disease appears to be similar to that produced by *E. chaffeensis*. Thrombocytopenia is more common than leukopenia. Leukocytosis is accompanied by relative and absolute lymphopenia.[14] Instances of interstitial pneumonitis[393] and facial diplegia[289] also occur. Reinfection has been reported.[229]

Laboratory diagnosis favors the use of serology and molecular diagnostics.[2] Intracellular inclusions (morula) in granulocytes (Image Plate 23-2H) appear to be more common than are inclusions in monocytic ehrlichiosis,[15] but there may be an ascertainment bias without readily available laboratory diagnostic support. The morphologic detection of morulae in either of these infections is an insensitive method of detection, but if positive is highly specific. Culture of the organism in vitro has been reported,[180] but confirmation of most cases is by serologic techniques, which are available in reference laboratories.[473] The most common technique is indirect immunofluorescence. Antibodies reach their peak within a month after infection and are still detectable a year later in approximately half of patients.[2] The vast majority of

ehrlichiosis/anaplasmosis, the major outer-membrane proteins do not share antigenic determinants.[460] Western blot analysis may help to resolve confusing serologic results.

Molecular amplification assays for these agents have been described, and reagents are available commercially.[319] The validated assays are available through reference laboratories.

Other Ehrlichial Infections. *Ehrlichia ewingii* and *E. canis* are both agents of canine granulocytic ehrlichiosis that can also cause disease in humans.[43,143,303] Additional agents within this group, termed *Neorickettsia,* have also been described and cause disease in humans (*N. sennetsu*), horses (*N. risticii*), and salmon (*N. helminthoeca*).[398] Other agents that will likely be classified as *Ehrlichia, Anaplasma,* or *Neorickettsia* species are under investigation.

Lice
Pediculus humanus subsp. *humanus*
Pediculus humanus subsp. *capitis*
Phthirus pubis

Ectoparasites are organisms that live in or on the skin of a host, from which they receive nourishment. The relation is, therefore, parasitic or possibly symbiotic. Intimacy of contact varies for the time required for a blood meal from days, weeks, or even months of association. Organisms that contact a host casually (e.g., houseflies) or

without deriving benefit (e.g., scorpions, bees, and spiders) are not, strictly speaking, ectoparasites, but are of medical importance.[64]

Arthropods are invertebrates with jointed appendages (hence the name) and a chitinous exoskeleton. They have long been recognized as direct or indirect causes of human disease. In addition to causing direct injury to the human host, they may serve as the vectors for transmission of infectious agents and facilitate entry of the agent into the human host. In some instances, the arthropod serves as a mere carrier, depositing the infectious agent in the proximate environment, where it can contact the potential victim. An example of such a scenario is the transmission of bacterial pathogens, such as *Shigella,* from one site to another on the bodies of flies or cockroaches.[2,45] A much more intimate relationship occurs when the arthropod is the direct mediator of cellular damage or when a biting insect transmits an infectious agent into the tissue of the victim. Most biting insects ingest the infectious agent when they take a blood meal from an infected human or from an infected nonhuman mammal, which is referred to as a reservoir of infection. When an insect bites an animal or human, it often injects salivary secretions that contain enzymes and anticoagulants designed to permit the ingestion of a blood meal. If the infectious agent has moved from the gut of the insect into the hemolymph and subsequently made its way to the salivary glands, the infection is transmitted in the salivary secretions at the time of the bite.[43] If the infectious agent is present in the gut—with or without infectious material in the saliva—the microbial agent may be excreted in the feces when the arthropod defecates after ingestion of the blood meal. Entry of the agent

from the feces into the injection site is facilitated when the host scratches the site of irritation.

The list of medically significant arthropods continues to expand, as does the list of diseases they can produce. At the same time, clinical laboratories are receiving increasing numbers of specimens for identification. Many arthropods that are very important in human infectious disease are rarely, if ever, seen in clinical microbiology laboratories because the insects were not seen, were exterminated, or were not collected for examination. Other important insects, such as scorpions, are seen in localized geographic distributions. Conversely, clinical microbiologists may be called on to identify insects that caused alarm at their presence even though they have done no harm.

This section is designed to assist the reader in understanding the medical significance and laboratory identification of some arthropods that may be encountered in the clinical laboratory. An abbreviated classification schema is detailed in Table A-1, and select definitions and related taxonomy of the ectoparasites of importance to

humans are listed in Box A-1. The reader is referred to several excellent reference textbooks for more detailed information.[17–20,40,49,54,56]

Submission of Specimens to the Laboratory

Because of the diversity of specimens encountered in medical entomology, it is difficult to recommend a single method for submission of specimens. In general, 70% ethanol will work well as a preservative for most specimens, also preventing escape or infection. It should be added to the specimen in a clean container so that the arthropod is completely submersed. Specimens can darken after extended periods of preservation, negating the utility of color differences for identification after long periods of fixation. We have observed no degradation of color in specimens preserved in 70% ethanol over a period of days, which is the usual time from collection to processing.

Formalin and sterile saline may be satisfactory but generally have more disadvantages when compared with ethanol. Flying insects should be killed using gases, such as chloroform, and then preserved as a dry mount.[18] Garcia lists a recipe for Berelese's medium, which she suggests is a good solution to use for most specimens.[18] Killing in hot water has been suggested for examination of fly larvae.[17] If in doubt, check with the facility that will be handling the specimen for specific recommendations.

The preferred method for removal of ticks is to grasp the tick with fine tweezers as close to the site of penetration as possible without pinching the skin. Steady outward pressure, while lifting the tick upward and forward, usually removes the specimen intact.[36] The capitulum of hard ticks is an important identifying feature. Specimens that are degraded because of improper removal are more difficult to identify.

The materials and techniques required for examination of arthropods are simple. Low magnification can be obtained with a hand lens or optimally with a stereomicroscope. Low- to moderate-power magnification can also be obtained with a low-power objective (e.g., 2× or 4×) and a compound microscope. A good light source is essential for observation. Fiberoptic lights provide excellent illumination without heating and excessive drying of the specimen. Lights with flexible arms allow maximal control of the illumination angle. The specimen can be manipulated best with a pair of dissecting needles.

TABLE A-1 Classification of Arthropods of Medical Importance

Class	Order or Subclass	Examples	Direct Injury or Infections Transmitted
Diplopoda		Millipedes	Direct
Chilopoda		Centipedes	Direct
Hexapoda (Insecta)	*Hemiptera*	Bedbugs Kissing bugs	Direct
Hexapoda (Insecta)	*Siphonaptera*	Fleas	Direct
Hexapoda (Insecta)	*Anoplura*	Sucking lice	Direct; typhus; trench fever; relapsing fever
Hexapoda (Insecta)	*Dictyoptera*	Cockroaches	Sanitation problems; allergic reactions
Hexapoda (Insecta)	*Hymenoptera*	Ants, wasps, bees	Direct
Hexapoda (Insecta)	*Coleoptera*	Beetles	Direct
Hexapoda (Insecta)	*Diptera*	Flies, mosquitoes, midges	Direct; arboviruses; parasitic infection; *Bartonella; Francisella*
Hexapoda (Insecta)	*Lepidoptera*	Moths, butterflies, caterpillars	Direct
Pentastomida		Tongue worms	Direct
Arachnida	Subclass: *Scorpiones*	Scorpions	Direct
Arachnida	Subclass: *Araneae*	Spiders	Direct
Arachnida	Subclass: *Acari*	Ticks, mites, chiggers	Direct; *Borrelia*; arboviruses; *Ehrlichia; Anaplasma; Rickettsia; Francisella*

BOX A-1

Ectoparasites: Definitions and Taxonomy

Phylum *Arthropoda*: Organisms within this phylum have a hard, jointed exoskeleton and symmetrical paired, jointed legs. Of the five classes of arthropods, only the *Arachnida* and the *Insecta* serve as vectors of human disease.

Class *Arachnida* (ticks, mites, and spiders): This group of arthropods are characterized by the absence of wings, presence of four pairs of legs, and the fusion of the head and thorax into a cephalothorax.

Ticks are larger than mites, have a leathery body that is either hairless or covered with short hairs, an exposed hypostome, and a pair of spiracles near the coxae of the fourth pair of legs. They are divided into the argasid, or soft ticks (*Ornithodoros* species being of human importance), and the ixodid, or hard ticks, including the genera *Dermacentor, Amblyomma,* and *Ixodes,* which are responsible for transmitting the agents of several rickettsial, viral, bacterial, and spirochetal diseases.

Mites are smaller than ticks, do not have a leathery covering, and have a hypostome that may be unarmed. Of importance to humans are the trombiculid mites, causing chiggers, and the mange mites of the family *Sarcoptidae,* which include *S. scabiei,* the agent of scabies, and *Demodex folliculorum,* which infest the hair follicles and sebaceous glands.

Spiders are unsegmented, and have a hairy abdomen to which are attached four pairs of legs through a slender constriction. They also possess a pair of poisonous jaws through which venom flows from a pair of glands in the cephalothorax. The brown recluse, black widow, and hobo spiders most commonly cause painful and toxic bites in humans.

Class *Insecta* (flies, mosquitoes, bugs, fleas, and lice): This group of arthropods include organisms with a body divided into three parts, head, thorax, and abdomen, and possess three pairs of legs. The order *Hemiptera* includes True Bugs, which include winged or wingless bugs and lice that have mouth parts adapted for piercing and sucking; the order *Diptera* (two-winged) includes flies, gnats, and mosquitoes, and the order *Siphonaptera* includes the fleas, which are wingless and have mouth parts adapted for sucking blood.

Flies are two-winged insects that serve as vectors for the transmission of several agents of human disease. Included are the *Phlebotomus* sandflies (leishmaniasis),*Simulium* black fly (onchocerciasis),*Chrysops* deer fly (*Loa loa*), and the *Glossina* or tsetse fly (trypanosomiasis). Mosquitoes transmit a variety of viral, protozoan, and helminthic diseases, most notably malaria and filariasis. Humans may also be infested with the larval forms of flies, a condition known as myiasis.

The biting and blood-sucking True Bugs of importance in human disease include *Cimex lectularius,* the common bedbug, and the "kissing bugs" of the family *Reduviidae,* which transmit the causative agent of South American trypanosomiasis (Chagas' disease).

Fleas are small, brown, wingless, laterally compressed, blood-sucking insects most notably cited as vectors for transmission of the agents of bubonic plague and murine typhus. Fleas are also involved in the transmission of parasitic diseases, including the dog tapeworm,*Dipylidium caninum,* and the rat tapeworm,*Hymenolepis diminuta*.

Lice are dorsoventrally flattened, wingless insects that include three species of importance to humans: *Pediculus humanus* subspecies *capitis* (head louse),*Pediculus humanus* subspecies *corporis* (body louse), and *Phthirus pubis* (crab louse). The order includes both biting and sucking lice; however, only the latter, in the suborder *Anoplura,* are ectoparasitic for humans. Lice are important vectors for epidemic typhus and relapsing fever.

In the exceptional circumstance that culture of the potential pathogen from the vector is under consideration, the insect must be unfixed. If the specimen was fixed before submission to the laboratory, modern molecular methods allow specific identification of infectious agents by amplification of nucleic acids.

Arachnida: Ticks, Mites, and Spiders

Ticks are arthropods in the suborder *Ixodida*, which is divided into three families, two of which, *Ixodidae* (hard ticks) and *Argasidae* (soft ticks), have been established as vectors for human disease.[36,51] In *Ixodidae*, the anterior portion of the body is sclerotized and includes a scutum ("dorsal shield") and an anterior-facing capitulum ("head"), thus the term "hard tick."[51] The genera most commonly submitted to microbiology laboratories are *Ixodes*, *Dermacentor,* and *Amblyomma*. *Argasidae* have a leatherlike outer surface with no scutum and have ventrally located mouthparts.[51] Increasingly in past decades, hard ticks have been recognized as important vectors for a wide variety of human diseases, the diversity of which is greater than for any other group of arthropods.[51] In the United States, hard ticks are more prevalent than soft ticks and are more important vectors of human pathogens. Identification of a submitted tick should include description of the species, life cycle stage, gender for adults, level of engorgement, and status of mouthparts.

1590

Ixodidae

Biology of Hard Ticks. Hard ticks have a life cycle that consists of four stages (instars): egg, larva, nymph, and the sexually dimorphic adult. Larval ticks have six legs, a key identifying feature (Image Plate A-1A), whereas nymphs and adults have eight. Immature stages lack a genital aperture but otherwise resemble adult females. Both have a scutum that covers one-third to one-half of the dorsum in female ticks and allows the prolific intake of blood and tissue fluids (Image Plate A-1B). Feeding is necessary for females to achieve fertility, and their body weight can increase as much as 100 times while feeding.[36,51] Males have a scutum that covers almost the entire dorsum (Image Plate A-1B) as well as sclerotized ventral plates that limit engorgement in most species, if the male tick feeds at all.

The important vectors of human disease in the United States are three-host ticks, meaning each instar feeds once on a host, after which the tick leaves the host to molt into the next instar in a suitable microenvironment, such as leaf litter or a nest.[51] The process proceeds until adult mating takes place. Mating can occur on the host or off, depending on the species. After mating, the female finds a suitable environment, lays hundreds to thousands of eggs depending on the species,[36,51] and then dies. The duration of a life cycle, averaging 1 to 2 years, varies with the presence or absence of suitable environmental conditions and availability of a suitable host.[51] In adverse conditions, ticks are capable of long periods of diapause, a torpid phase in which the

tick secretes a hygroscopic saliva that allows them to absorb moisture, enhancing survival until host-seeking conditions improve.

Most hard ticks are burrow or nest dwellers, living out their lives in a closed environment, feeding on a readily available host. In these species, human contact is rare or nonexistent.[51] *Ixodes spinipalpus* and wood rats perpetuate an enzootic cycle of *B. burgdorferi* infection in Colorado.[31] The absence of human infection can be attributed to the lack of contact between *I. spinipalpus* and humans.

In only few instances does host specificity place infected ticks in an environment that promotes human contact, which makes them more competent as vectors for disease. The preferred host of *I. scapularis* in early life stages is *Peromyscus leucopus*, the white-footed mouse, known to be the reservoir for *Babesia microti* as well as *Borrelia burgdorferi* in these locations. Although the reservoir for *Anaplasma* (*Ehrlichia*) *phagocytophila* remains unclear, *I. scapularis* is the documented vector. The preferred host of adult ticks is the white-tailed deer (*Odocoileus virginianus*), a far-ranging animal with a distribution that is expanding to include areas of dense human population. With the ability to harbor and transmit multiple pathogens and the willingness to feed on humans, *I. scapularis* is a competent vector. In contrast, *I. scapularis* in the Southeast and *I. pacificus* in the Northwest are less competent as vectors of Lyme borreliosis. Host selectivity appears to be the reason. The preferred hosts in both cases are lizards, in which the spirochetes multiply poorly. This biologic phenomenon could account for fewer cases reported in the West and the virtual absence of reported cases in the Southeast.[31,55]

Ticks seek their host by questing, a passive ambush style of host-seeking, in which they climb low grasses and herbaceous vegetation, waiting to attach themselves to a passing host.[51] A few species, on the other hand, actively seek their prey. *Amblyomma americanum* is the only species in the group of ticks discussed here that actively seeks a host.[36] The species that commonly seek human hosts appear to have anatomic preferences for their attachment.[14] *Dermacentor variabilis* prefers the head and neck, whereas *Amblyomma americanum* is more likely to attach to the buttocks, groin, or legs. *Ixodes scapularis* is ubiquitous, attaching to all parts of the body without any obvious preference for a particular site.

The geographic ranges of ticks seem to be expanding. The explosion in the white-tailed deer population into areas of dense human population may be one reason. Another explanation could be that current lifestyles in the United States promote outdoor activities that place people in close proximity with ticks in their natural environment.

Within the life cycle of a tick, a pathogen may be acquired in one of two ways: (1) transstadial (horizontal; i.e., larva to nymph, nymph to adult) or (2) transovarial (vertical; i.e., gravid female to egg).[51] The larval forms of *Ixodes scapularis* are

unable to transmit Lyme disease because *B. burgdorferi* is not transmitted vertically, but must be acquired from a reservoir host.[36,51,54] The preferred host for *I. scapularis* larvae and nymphs is the white-footed mouse (*Peromyscus leucosis*), a principal reservoir for *B. burgdorferi*, *B. microti*, and *A. phagocytophilum* in endemic areas. A parallel cycle for *A. phagocytophilum* has been documented between cottontail rabbits and *Ixodes dentatus*,[21] although this species feeds on humans much less frequently than does *I. scapularis*. Ticks acquire *B. burgdorferi* or *A. phagocytophilum* while feeding. In contrast, *Rickettsia rickettsii*, the agent of Rocky Mountain spotted fever, is transmitted vertically from infected *Dermacentor variabilis* females to their progeny,[36,51] making larvae potential vectors.

The level of engorgement gives a rough estimate of feeding time. *B. burgdorferi* dwells in the midgut of infected *I. scapularis*. When the tick feeds, the spirochete multiplies and begins to migrate via the hemolymph. It requires 2 to 3 days for the spirochete to reach the salivary glands of the tick,[13,41,52] where in the process of shedding excess water to make room for the blood meal the tick regurgitates into the feeding site, thus inoculating and infecting the host with the spirochete.[50] In experimental studies, *I. scapularis* nymphs and females were allowed to feed on rodent hosts for defined periods. Given the fact that body length increases while the size of the rigid scutum remains constant, regression equations based on a ratio of body length to scutum width, termed the "scutal index," were developed. The scutal index is considered a more accurate predictor of feeding time than subjective visual estimates.[13,52] In the case of Lyme borreliosis, the identification of an unengorged specimen of *I. scapularis* with intact mouthparts would suggest brief host contact and would make transmission doubtful even if the patient had traveled to an endemic area. *Anaplasma* (*Ehrlichia*) *phagocytophilum* appears to be transmitted somewhat more quickly than is *B. burgdorferi*, so the degree of engorgement and scutal index may be less useful for assessing the likelihood that the pathogen has been inoculated into the patient.[10,26] More studies are required to elucidate this issue.

Nymphs are considered the most likely instar to transmit disease because their small size often allows them to complete feeding undetected (Image Plate A-1B). A high percentage of tick-related diseases present in late spring and the summer months because of increased nymph activity.

1591

TABLE A-2 Hard Ticks and Associated Disease with Geographic Distribution

Tick Species	Disease	Geographic Range

Ixodes scapularis	Lyme disease Human granulocytic anaplasmosis Babesiosis	Eastern and upper midwestern United States
Ixodes pacificus	Lyme disease	Northwest United States
Dermacentor variabilis	Rocky Mountain spotted fever Tularemia Tick paralysis	Eastern two-thirds of the United States, West coast of the United States
Dermacentor andersoni	Rocky Mountain spotted fever Colorado tick fever Tick paralysis	Rocky Mountain states
Amblyomma americanum	Human monocytic ehrlichiosis	South Central United States, southeastern United States, Mid-Atlantic states as far north as southern New York State
Ixodes cookei	Tularemia Powassan virus	Northeastern United States and southeastern Canada
Ixodes marxi	Powassan virus	Northeastern United States and southeastern Canada

Relation to Disease. The history of *Ixodidae* is long in veterinary medicine and more recently intense in human disease. *Ixodidae* (hard ticks) are vectors for a wide variety of pathogens associated with human disease,[51] including spirochetes, *Rickettsia*, gram-negative bacilli, viruses, protozoa, and neurotoxins. The species described here are associated with one or a combination of these agents (Table A-2).

Infections transmitted by ticks may present with similar vague early symptoms of fever, fatigue, and other flu-like symptoms that make a quick accurate diagnosis problematic,[11,32,36,54] considering that antibiotic therapy differs depending on the agent involved. In most cases, tick-transmitted diseases are mild and resolve with an early accurate diagnosis, when followed by proper treatment. Misdiagnosis can lead to increased morbidity, chronic infection, and in rare cases, death.

Coinfection after tick bites seems likely.[32,39] Although not proof of coinfection as opposed to sequential infection, serologic studies have shown that, in overlapping endemic areas, patients with clinical Lyme disease have antibodies to *Babesia* or *Ehrlichia* as well.[32] At one point, *Babesia* was considered the agent of Lyme disease because patients diagnosed as having babesiosis presented with erythema migrans,

which is now known to be characteristic of *B. burgdorferi* infection.

Certain species are the vectors for specific pathogens. For instance, Lyme borreliosis is well documented worldwide. *Ixodes scapularis* is defined as the vector for *Borrelia burgdorferi*, the Lyme disease spirochete, in the northeastern and upper Midwestern sections of the United States. Elsewhere, *I. ricinus* (Europe), *I. persulcatus* (Asia), and *I. pacificus* (northwestern United States) are vectors. Currently, other *Ixodes* species are not considered competent vectors. In the eastern United States, identification of an *Ixodes* sp. other than *I. scapularis* would all but rule out Lyme disease, although if the clinical presentation were classical (erythema migrans present)[35,50,54] the presence of a second unnoticed tick would need to be considered. In the southern United States, a Lyme-like borreliosis caused by *Borrelia lonestari*, similar to *B. theileri* (the agent of bovine borreliosis), has been attributed to exposure to *Amblyomma americanum* (the Lonestar tick).[24]

Tick paralysis is a fascinating disease of unknown pathogenesis.[12,15,46] The acute flaccid paralysis can mimic botulism and Guillain–Barré syndrome; removal of the tick produces a rapid and dramatic reversal of the paralysis. There are no sequelae. Although over 60 species of ticks can produce tick paralysis in animals, only *Dermacentor andersoni*, *Dermacentor variabilis,* and *Ixodes holocyclus* (the Australian marsupial tick) bite humans. In North America, the disease occurs most commonly in the southeastern and northwestern states of the United States and in British Columbia.

Geographic Distribution. The geographic distribution of the hard ticks is summarized in Table A-2; this is also available online from the Centers for Disease Control and Prevention at http://www.cdc.gov/ticks/geographic_distribution.html, and elsewhere.

Ixodes scapularis. Once referred to as *Ixodes dammini* in the Northeast and *Ixodes scapularis* elsewhere, the two are now considered by most authorities to be a northern and southern variety of the same species because of their ability to mate successfully.[34,54] The name *Ixodes scapularis* has taxonomic precedence. *I. scapularis* occupies a wide range east of the Rocky Mountains, although infectious populations appear to be focal in the upper Midwest and in the Northeast from Maryland to southern New England.

Ixodes cookei. The range of *Ixodes cookei* (the woodchuck tick) overlaps that of *I. scapularis*; it is found primarily in the northeastern United States and southeastern Canada.

Ixodes marxi. *Ixodes marxi* (the squirrel tick) also has a range that overlaps *I. scapularis* in the northeastern United States and southeastern Canada.

***Dermacentor* spp.** *Dermacentor variabilis* (the dog tick) is widely distributed throughout the United States east of the Rocky Mountains. The wide range and host-

seeking habits of *D. variabilis* increase the incidence of contact with humans when compared with other *Dermacentor* spp.

Dermacentor andersoni is distributed in the Rocky Mountain states and is the tick that was described by Ricketts as the vector of Rocky Mountain spotted fever in the Bitter Root Valley of Idaho.[60]

1592

Amblyomma americanum. *Amblyomma americanum* (the Lonestar tick) is widely distributed in the South (east of the Rocky Mountains) and in the East to southern New York State. There are indications that the range may be extending into New England. *A. americanum* is unique among the tick species described here in that it actively seeks a host.[36,51]

Identification. Acari (ticks and mites) are distinguished from other arachnids by the absence of obvious segmentation. An anterior prosoma (appendages) is fused with the opisthosoma (abdomen). A gnathosoma (capitulum) bearing the mouthparts is unique to Acari.[51] Figures A-1 and A-2 represent the dorsal and ventral view, respectively, of a generic hard tick. The drawings were made to place as many key features in view as possible. A glossary of identifying features depicted in these figures follows. All features are useful for identification of ticks; size, placement, color, and presence or absence of each characteristic may be important.

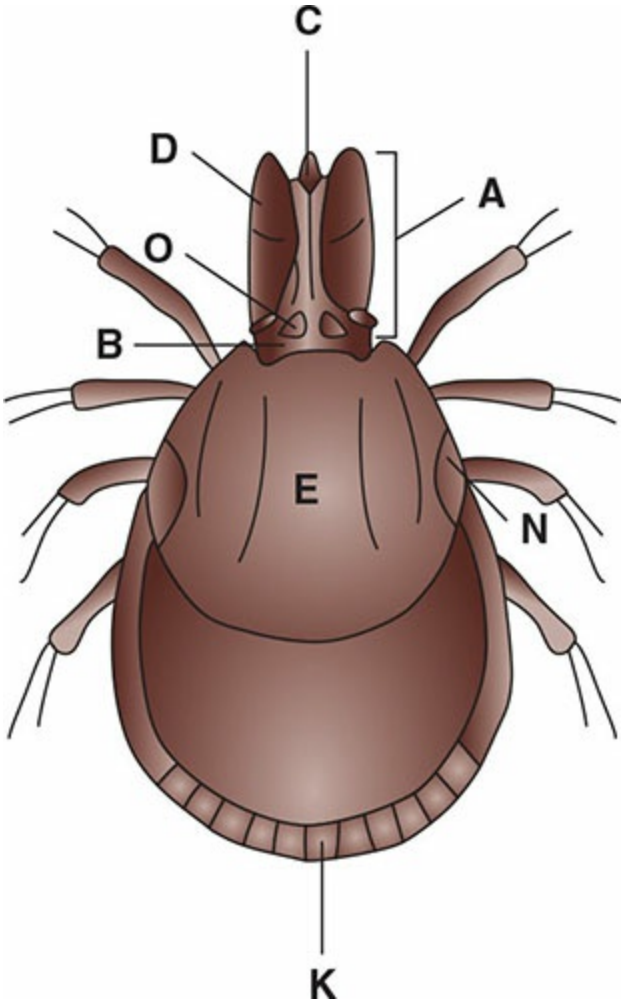

FIGURE A-1 Generic diagram of the dorsum of a hard tick.

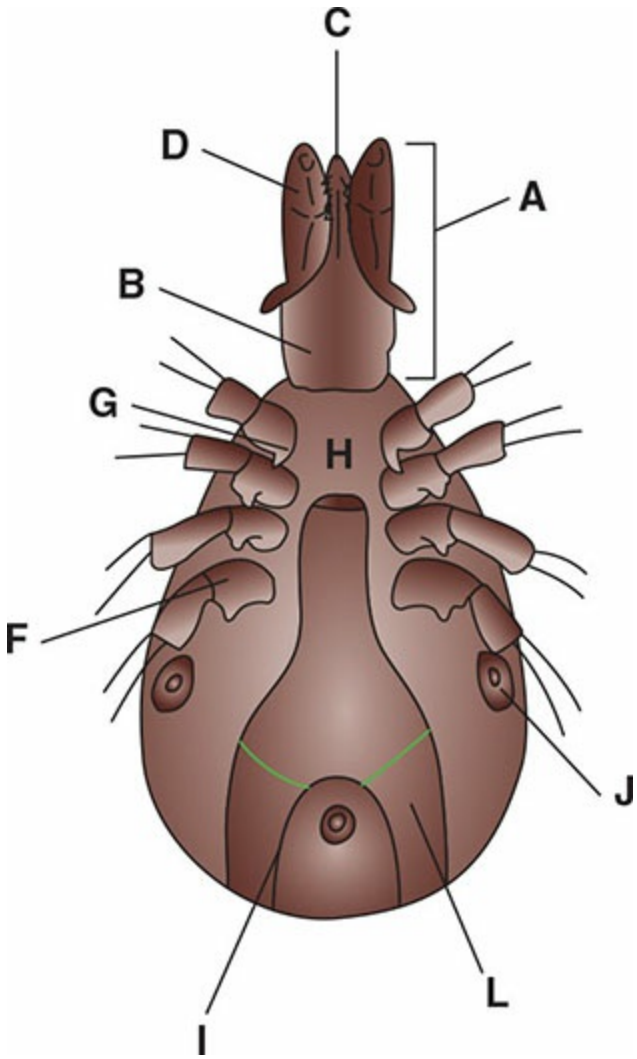

FIGURE A-2 Generic diagram of the ventral aspect of a hard tick.

A. Capitulum: The anterior portion of the body, including the basis capituli, hypostome, chelicerae, and palpi.
B. Basis capituli: The base of the capitulum to which the mouthparts are attached. (The length of the capitulum in proportion to the basis capituli is useful in identification.)
C. Hypostome: The median structure of the mouthparts parallel to and between the palpi. The hypostome holds teethlike structures called denticles. Denticles appear on the hypostome in a specific arrangement called the "dentition formula" (ratio of left denticles to right denticles). *Ixodes scapularis*, for instance, has a dentition formula of 3/3, becoming 2/2 as it progresses posteriorly.
D. Palpi: Paired movable appendages lying parallel to the hypostome.
E. Scutum: The sclerotized dorsal plate posterior to the capitulum.
F. Coxa: The basal segment of the legs. Coxa are numbered I through IV, with coxa I

located closest to the capitulum.

G. Coxal spurs: Projection on the posterior margin of the coxa. Spurs on the median side are called internal spurs while those on the lateral side are external spurs. There is little or no variation in spur size or configuration from specimen to specimen of the same species.

H. Genital aperture: External opening of the genital organs, located ventrally on the median axis between the coxae.

I. Anal groove: Semicircular groove curving around the anus of some species. In *Ixodes* spp., the curve is anterior to the anus. In other genera, the curve is posterior or absent.

J. Spiracular plates: External opening of the respiratory system, located ventrally, posterior to coxa IV on the lateral margins. These are useful in differentiating male *I. scapularis* from male *I. cookei* and male *I. marxi*.

K. Festoons: Rectangular areas separated by distinct grooves located on the posterior margin of some hard ticks. Festoons are absent in *Ixodes* spp.

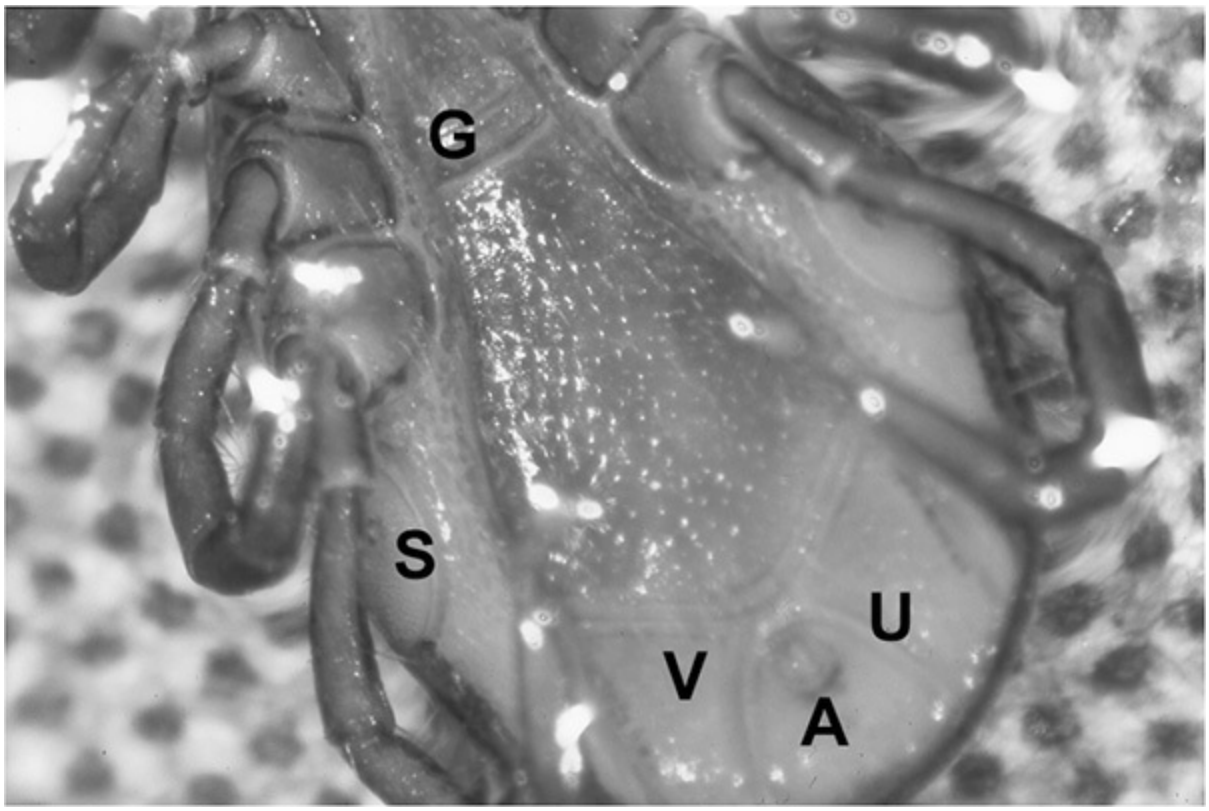
L. Ventral plates: A group of plates of definite shape and size on the ventral surface of adult males. We will specifically refer to the anal plate when describing *Ixodes* spp.

M. Ornamentation: Some ticks are referred to as ornate ticks based on the presence of colorful markings distinct to certain species. *D. variabilis* and *A. americanum* are ornate ticks.

N. Eyes: Ornate ovoid markings on the lateral margins of the scutum of some ticks.

O. Porose areas: Areas resembling "eyes" found on the dorsal basis capituli of adult ticks.

Ixodes scapularis. An important feature of all *Ixodes* spp. is an anterior-facing U-shaped groove that surrounds the anus and terminates at the posterior margin of the ventral surface (Fig. A-3 and Image Plate A-1C). Other genera of hard ticks lack this feature.[51] *I. scapularis* nymphs and adult females have an oval-shaped scutum (Image Plate A-1B) that is approximately half the size of the dorsum in unengorged specimens. The scutum of adult males covers essentially the

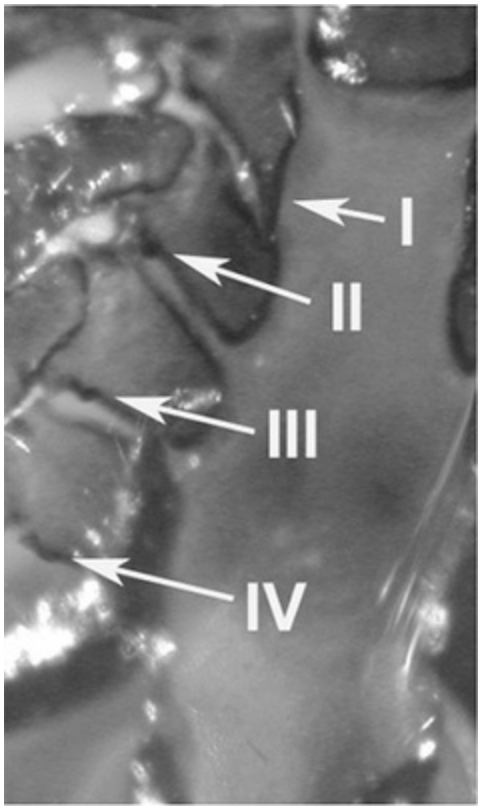


■ **FIGURE A-3** Ventral aspect of adult male *Ixodes scapularis*, demonstrating the anus (A), U-shaped anal groove (U), genital pore (G), ventral plates (V), and spiracular plates (S).

entire dorsum (Image Plate A-1B), a characteristic of all hard ticks that will not be mentioned in further descriptions. The presence of coarse hairs over the entire scutum is one of the characteristics that distinguish *I. scapularis* males from *I. cookei* and *I. marxi* specimens, in which they are fine or absent. When viewed ventrally (Image Plate A-1C), mouthparts appear twice as long as the basis capituli. The hypostome of nymphs and adult females has a dentition formula of 3/3, progressing to 2/2 anterior to posterior. Adult males have a more "businesslike" hypostome than most other *Ixodes* spp., with severe lateral denticles that get blunt to crenulated as they approach the median.

Color can help in distinguishing *I. scapularis* from other *Ixodes* spp. The sclerotic anterior portion of nymphs and adult females (includes the capitulum, legs, and scutum) is dark brown, in sharp contrast to the abdomen, which appears reddish-brown in unengorged specimens (Image Plate A-1B) to gray-tan in engorged specimens, and thus the name *black-legged tick.* Adult males appear entirely dark brown (Image Plate A-1B). Coxal spurs (Image Plate A-1D and Fig. A-4) are present, with coxa I having a severe internal spur that overlaps coxa II. Coxae I through IV have blunt external spurs. The internal spur on coxa I appears less severe in nymphs. The spiracular plates of nymphs and females are round (Image Plate A-1C); in males,

they are elongated anterior to posterior (Fig. A-3). The spiracular plates in males of *I. cookei* and *I. marxi* appear round. The anal plate in males is short anterior to posterior in comparison to *I. cookei* and *I. marxi*.



■ **FIGURE A-4** Detail of Image Plate A-1D. Coxal spurs of adult *Ixodes scapularis*. The spur on coxa I is long, pointed, and oriented internally. The spurs on coxae II through IV are short, blunt, and oriented externally.

Ixodes cookei. The scutum of nymphs and female adults is angular from the posterior apex to the midlateral margins (Image Plate A-1E). In adult females, the scutum appears about as wide to the lateral margins as it is anterior to posterior, whereas in nymphs the scutum appears wider laterally than anteriorly to posteriorly. The mouthparts of all life stages appear proportional in length to the basis capituli (Image Plate A-1E). When compared to *I. scapularis*, the hypostome of females and nymphs is similar, with a dentition formula of 3/3, progressing to 2/2, although in *I. cookei* females the apex is more rounded. The hypostome of nymphs is more rounded still. The hypostome in males is short, round, and crenulated. An interesting feature, most pronounced in the nymph of this species, is the projection of the first segment of the palpi laterally from the posterior margin. These projections have a spurlike appearance and are often referred to as palpal spurs. In all stages, the color is a lightly-

creamed-coffee brown. Color is consistent over the entire tick. The arrangement of coxal spurs is similar to that of *I. scapularis,* with a pronounced internal spur on coxa I and blunt external spurs on coxae I through IV. Spiracular plates in nymphs and females are similar to *I. scapularis*. In males they appear more round, not elongated, as is the case in *I. scapularis* males. The anal plate in males of this species appears twice as long anterior to posterior in proportion to lateral width, which helps distinguish this species from *I. scapularis*.

Ixodes marxi. The scutum of nymphs and females of this species is similar to *I. cookei* in that it is angular from the midlateral margin to the posterior apex (Image Plate A-1F). This fact can confuse the identification of these species. In females, there are differences in length and width. The scutum of *I. marxi* females is noticeably longer anterior to posterior in relation to lateral width. In *I. cookei,* length and width are equally proportional. In *I. marxi* nymphs, length and width are basically equal, whereas in *I. cookei*, the scutum appears laterally wider than it is long anterior to posterior. Given the similarity in scutal proportion of an *I. marxi* nymph and an *I. cookei* adult female, identification should be made by observing the presence or absence of a genital aperture. The male scutum appears to be absent of hair.

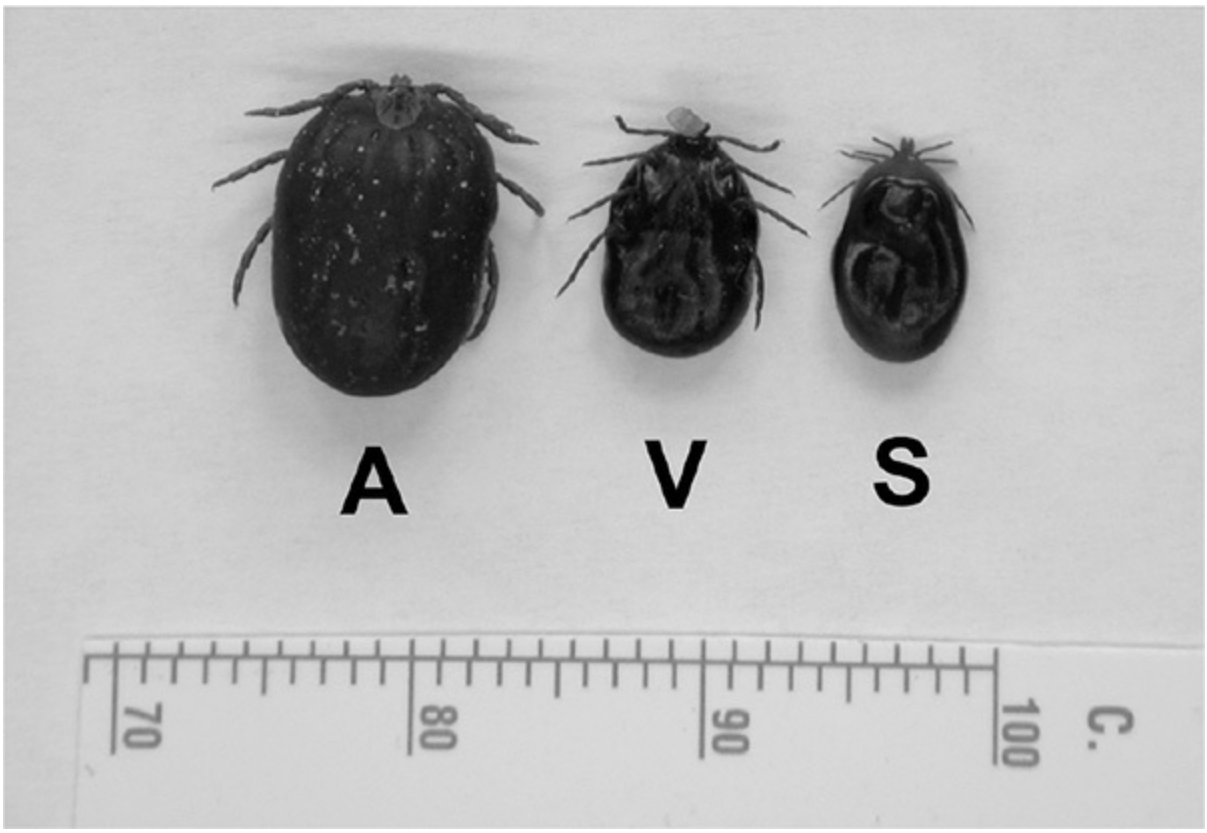
When viewed ventrally, the mouthparts of all three stages appear proportional in length to the basis capituli. The hypostome of nymphs and females is similar to *I. scapularis*, with a dentition formula of 3/3 at the apex, and then 2/2 as it approaches the posterior end. The apex in females is severely pointed. The male hypostome appears short, rounded at the apex, and crenulated. Color in this species is similar to *I. cookei*, in which the entire body of all three stages appears a lightly-creamed-coffee brown. The arrangement of coxal spurs is a key characteristic in the identification of *I. marxi*. Nymphs and females have a blunt internal spur and the hint of an external spur on coxa I. The notable absence of spurs on coxae II through IV distinguishes the females and

nymphs of this species from the other *Ixodes* described here. The coxal spur arrangement of males is similar to that of *I. cookei,* with the exceptions of a less severe internal spur on coxa I and the notable absence of spurs on coxa IV. Round spiracular plates in all stages help distinguish males of this species from *I. scapularis*, in which they appear elongated. The anal plate in male *I. marxi* is longer anteriorly to posteriorly in proportion to lateral width than in *I. scapularis*, in which proportions appear equal.

Dermacentor variabilis. *D. variabilis* is an ornate tick, meaning the tick is quite colorful, with contrasting markings. Coloration in ornate ticks is described as the base color (the predominant overall color of the tick) and the pattern color (contrasting

markings) (Image Plates A-1G and A-1H).[8] Pattern color is present on the scutum as well as the legs of *D. variabilis*. Eleven festoons are arranged in a semicircle around the posterior margin (Image Plate A-1G). They can be observed in both the dorsal and ventral view of all stages. The scutum of females is angular and appears roughly equal in length anteriorly to posteriorly as side to side. Pattern color is predominantly pearl-white to gray and appears in stark contrast to the rest of the tick, in which the base color is chestnut brown. Brown lines and spots in random patterns, not consistent from specimen to specimen, are present. The presence of "eyes" can be observed at the midlateral margins (Image Plate A-1H). Color and contrast are similar in males and females. Ornamental markings cover the entire dorsum because of the nature of the male scutum. Base color areas appear larger as they approach the midlateral and posterior margins. Markings on each side of the median axis are roughly mirror-imaged. The scutum of nymphs is long and does not appear as angular as it is in the female; from the midlateral margins it is rounded to the posterior median. Pattern color appears to be more prominent. "Eyes" are present at the angles of the lateral margins, as they proceed to the posterior apex. Nymphs are not commonly seen in the laboratory and are known to have infrequent human contact.[8]

The basis capituli of all stages appears wider than it is deep (Image Plate A-1H). The basis capituli of nymphs in the dorsal view have pronounced posterior lateral spurlike projections that make the basis look triangular. The hypostome in all stages is short and rounded. Palpi appear short and thick in adults, but narrow in nymphs. Coxal spurs are similar in adults. Coxa I has large internal and external spurs that converge in the median, conveying a notched appearance. Coxae II through IV have smaller external spurs. Nymphs have a predominant external spur and less dominant internal spur on coxa I, with unremarkable external spurs on coxae II and III and no spurs on coxa IV. In the Northeast, *D. variabilis* must not be confused with *Dermacentor albipictus* (i.e., the moose tick, also called the winter tick). Just as a moose is bigger than a dog or a deer, *D. albipictus* is appreciably larger than *D. variabilis* or *I. scapularis* (Fig. A-5). A mean of 2 mm divides unengorged specimens of these species.[8] A fed *D. variabilis* can achieve impressive dimensions (Image Plate A-1G), but a fully engorged *D. albipictus* female can achieve the size of an adult's fourth fingernail. In optimal environmental conditions, *D. albipictus* has been known to exsanguinate a moose because of the number of ticks feeding simultaneously. Fortunately, human contact with *D. albipictus* is minimal to absent.



■ **FIGURE A-5** Size comparison of engorged ticks. An engorged moose tick, *Dermacentor albopictus* (A), dwarfs an engorged American dog tick, *Dermacentor variabilis* (V), which in turn is larger than the enlarged deer tick, *Ixodes scapularis* (S). All are adult females.

Amblyomma americanum. *A. americanum* is another ornate tick (Image Plate A-2A). Eleven festoons are present. Base color is more predominant than in *D. variabilis,* and pattern colors are more consistent. The scutum in females is angular and about as long as wide. Approaching the lateral margins it becomes darker than the base color, which is red-tan. "Eyes" are present at the lateral apices (Image Plate A-2B). The remarkable scutal pattern in females is an iridescent patch at the posterior apex (Image Plate A-2A). Depending on the angle of the light source, this marking appears blue-green to pearl-pink and brings to mind gasoline on water. The scutum of nymphs appears wider than long, with "eyes" at the lateral apices. The iridescent patch found at the posterior apex of female nymphs is missing. The male scutum is most remarkable for the presence of two, inverted, pattern-colored "horse shoes" at the posterior margin (Image Plate A-2C). "Eyes" are present at the lateral margins. Pattern color markings proceed below the "eyes" toward the median and give the appearance of a pseudoscutum resembling that of the female. Male and female specimens may be confused by an inexperienced observer. Random pattern color

markings follow the posterior lateral margins as well.

The mouthparts on all stages are long in proportion to the basis capituli. The hypostome appears bulbous in that it is narrow posteriorly and is wide and rounded anteriorly. Coxal spur arrangement is similar in all stages. There is a severe internal spur and a short, rounded external spur on coxa I. A short, pointed spur on coxae II through IV appears closer to the median, though is most likely an internal spur. Males have a long severe internal spur on coxa IV (Image Plate A-2D). All stages have an anal groove. The groove appears as a semicircle posterior to the anus. From the median of the semicircle, a single groove descends toward the posterior margin. The overall appearance is that of a wineglass or chalice (Image Plate A-2D).

Summary of Identification. The following sequence of observations has been found useful for tick identification.

1595

When a specimen is presented with an anterior-facing U-shaped groove, *Ixodes scapularis* must be identified or ruled out. When distinguishing *I. cookei* from *I. marxi*, coxal spur arrangement and scutal configuration are key. When the tick is ornate, distinctions are made based on scutal configuration, pattern color markings versus base color, configuration of pattern color markings, the length of the mouthparts in relation to the basis capituli, and coxal spur arrangement. The diagnostic features are summarized in Table A-3.

Good reference books make these descriptions more comprehensive.[8,9,27,37] Appropriate tick identification is important as emergent disease, as well as established disease, is now being associated with tick transmission. An accurate identification of a recovered tick from a patient who presents with vague flu-like symptoms can and should influence early therapy.

Ornithodoros *Species*

Relation to Disease. *Ornithodoros* spp. transmit the *Borrelia* spp. that cause endemic relapsing fever.

Identification. *Ornithodoros* spp. are soft ticks. By definition, their mouthparts are not visible from above, and they do not have a scutum. They have a prominent hypostome covered with teeth (Image Plate A-2E).

Geographic Distribution. It is difficult to differentiate among the several species that may transmit relapsing fever. In the northwestern United States and western Canada, *O. hermsi* is the primary vector. This species feeds on small rodents as well as

humans and typically inhabits cracks and crevices in shacks and cabins. A famous outbreak in a Boy Scout troop was concentrated in senior scouts and scoutmasters, who commandeered an abandoned cabin, leaving the younger scouts to spend their night unbitten under the stars.[58]

In the Southwest and southern Midwest, the common vector is *O. turicata*, which is found on a variety of small and large mammals, rodents, birds, and reptiles. This species is often found in animal burrows.

Mites

Numerous species of mites exist in nature. Species of the family *Trombiculidae* (chigger mites) produce intense itching or dermatitis as they feed transiently. Members of the genus *Leptotrombidium* transmit scrub typhus in Southeast Asia and Australia.[65]House-dust mites in the genus *Dermatophagoides* serve as allergens for certain individuals. The mouse mite, *Liponyssoides* (*Allodermanyssus*) *sanguineus*, transmits *Rickettsia akari*, the agent of rickettsialpox. Rickettsialpox was first described in New York City and continues to be a problem there.[25]

The itch mite, *Sarcoptes scabiei*, and the follicle mite, *Demodex folliculorum*, are the two mites that have an intimate and prolonged parasitic association with humans.

Sarcoptes scabiei (Scabies)

Relation to Disease. *Sarcoptes scabiei* is known as the "itch mite." The mite causes mange by burrowing into the skin and laying eggs in the burrows. Resulting larval and nymph stages of the mite live in the burrows and adjacent hair follicles. Fecal deposits left by the mites provoke intense itching, leading to significant irritation and hair loss. Recurrence of disease is usually by reinfestation from mites on inadequately treated contacts, but relapse may also occur even after a standard course of treatment.[61]

Identification. Microscopic examination of skin scrapings reveals the characteristic mite, which measures 0.2 to 0.4 mm in length, eggs, or fecal pellets (scybala) (Image Plate A-2F). Specimens are collected after placing a drop of mineral oil on a sterile scalpel blade and allowing some of the oil to cover the papule. Scrape the papule vigorously six or seven times to remove the top; then transfer the scraped material, which should contain some flecks of blood in the oil, to a glass slide, using an applicator stick if necessary. After adding a couple of drops of mineral oil to the preparation and mixing, place a glass coverslip on top.[18]

Geographic Distribution. Itch mites are distributed worldwide.

Demodex folliculorum (Hair Follicles) and *Demodex brevis* (Sebaceous Glands)

Relation to Disease. Infections are usually found on the face. Organisms can cause pruritus and local tissue reaction as they burrow into the skin. They are also found, however, in asymptomatic individuals.

Identification. Microscopic examination of specimens from skin reveals the characteristic mite, which measures 0.1 to 0.4 mm in length.

Geographic Distribution. Follicle mites are distributed worldwide.

Spiders

Thousands of species of spiders exist in nature. Most possess potent toxins, but only a small number are capable of penetrating human skin when biting.[17]

Loxosceles reclusa

Relation to Disease. *Loxosceles reclusa*, known commonly as the brown recluse spider, prefers to exist in stored clothes and sleeping bags, basements, closets, and other sites with reduced human activity.[17,18] Their venom is injected through biting, and can cause serious desquamation and necrosis of skin. Large doses of venom are associated with dissemination and significant mortality. The bite of the brown recluse spider does not produce a diagnostic lesion; several reports suggest that dermonecrotic lesions are incorrectly attributed to spiders on a regular basis.[59]

Identification. The brown recluse spider is 1 to 2 cm in size and is characterized by its yellow to brown coloration and a violin- or fiddle-shaped marking on the back of the cephalothorax (Image Plate A-2G).[17,18] There are several related species, which may require expert help for correct identification.

Geographic Distribution. The brown recluse spider is found in most of the continental United States except for the extreme western sections.

Latrodectus mactans

Relation to Disease. Several species of widow spiders exist. *Latrodectus mactans*, the most common black widow spider, may cause a serious systemic reaction, even death, after

TABLE A-3 Diagnostic Features of Hard Ticks

Species	Stage	Scutum	Anal Groove	Coxal Spurs	Mouthparts/Basis Capituli	Eyes	Festoons	Color
Ixodes scapularis	Nymph	Oval; covers one-third of the dorsum and is dark in contrast to the abdomen	Anterior-facing U-shaped; surrounding the anus	Prominent internal spur on coxa I; blunt external spurs on coxae I through IV	Mouthparts twice as long as basis capituli when viewed ventrally	No	Absent	Capituli, legs, and scutum are black-coffee brown with contrasting red-tan abdomen
	Adult female	Covers half the dorsum, otherwise resembles nymph	Same as nymph	Same as nymph	Same as nymph	No	Absent	Same as nymph
	Adult male	Covers entire dorsum; hairy	Same as nymph	Same as nymph	Same as nymph; more "businesslike" hypostome than other *Ixodes* spp.	No	Absent	Overall black-coffee brown
Dermacentor variabilis	Nymph	Covers half the dorsum; predominant pattern color	Absent	Prominent external spur on coxa I; less blunted external spurs on coxae II and III	Dorsal basis capituli looks triangular; palpi are narrow	Yes	Present	Pattern colors more predominant
	Adult female	Angular; as long as wide; pattern-colored with random base color markings	Absent	Prominent internal and external spurs on coxa I, giving a notched appearance	Thick palpi; basis capituli wider than mouthparts are long	Yes	Present	Base color is chestnut brown; pattern color is gray-white
	Adult male	Base color and pattern color roughly equal	Chalice-shaped	Same as female	Same as female	Yes	Present	Same as female
Amblyomma americanum	Nymph	Angular; wider than long; predominant base color; "eyes" at lateral apices	Chalice-shaped	Spurs appear at the posterior median of all four coxae; spur on coxa I is more pronounced	Mouthparts appear much longer than the basis capituli; hypostome is bulbous	Yes	Present	Predominant caramel base color; pattern color is iridescent blue-green to yellow
	Adult female	Angular; about as wide as long; predominant base color with "eyes"; pattern-colored patch (Lone-star) at posterior apex	Chalice-shaped	Coxa I has a prominent median spur; spurs appear absent on coxae II through IV	Same as nymph	Yes	Present	Same as nymph
	Adult male	Predominant base color; inverted pattern color "horseshoes" at posterior margin	Chalice-shaped	Similar to the female with a severe internal spur on coxa IV	Same as nymph	Yes	Present	Same as nymph

1597

Ixodes cookei	Nymph	Angular; wider than long	Anterior-facing U-shaped; surrounding the anus	Similar to *I. scapularis*	Mouthparts equal in length to the basis capituli; hypostome similar to *I. scapularis*, though more rounded at the apex; palpal spurs present	No	Absent	Lightly-creamed-coffee brown
	Adult female	Angular; as wide as long	Same as nymph	Same as nymph	Same as nymph	No	Absent	Same as nymph
	Adult male	Less hairy in comparison with *I. scapularis*	Same as nymph	Same as nymph	Proportional to nymph; hypostome rounded and crenulated	No	Absent	Same as nymph
Ixodes marxi	Nymph	Angular; as wide as long	Anterior-facing U-shaped; surrounding the anus	Blunt internal spur and presence of external spur on coxa I; absence of spurs on coxae II through IV	Mouthparts equal in length to the basis capituli	No	Absent	Lightly-creamed-coffee brown
	Adult female	Angular; longer than wide	Same as nymph	Same as nymph	Same as nymph; hypostome is severely pointed	No	Absent	Same as nymph
	Adult male	Appears hairless	Same as nymph	Coxa I has prominent internal spur and blunt external spur; coxae II through IV have blunt external spurs; spurs absent on coxa IV	Proportional to nymph; hypostome rounded and crenulated	No	Absent	Same as nymph

1598

the injection of venom. Fortunately, most patients do not become gravely ill and recover quickly.[17,18] Most bites occur on the hands.[56] Male spiders produce mild or no symptoms after their bite.[20]

Identification. The black widow female is 3 cm long (including legs), glossy black, and displays a characteristic red hourglass marking on the abdomen (Image Plate A-2H).[17,18,56] Differentiation among related species is difficult and best left to experts.

Geographic Distribution. Different species of widow spiders exist throughout the

entire continental United States. *Latrodectus mactans* occurs from southern New England south to Florida and west to California and Oregon; it is more common in the southern part of this range. The northern black widow spider, *L. variolus*, is present in New England and southern Canada south to Florida and west to eastern Texas, Oklahoma, and Kansas; it is more common in the northern part of this range.

Tegenaria agrestis

Relation to Disease. There have been increasing reports of toxic reactions to the bite of the hobo spider, *T. agrestis*. Many bites are not followed by serious reactions, but some bites may produce a dermonecrotic lesion similar to that of the brown recluse spider. Erythema is followed by blistering and then ulceration. An eschar forms and subsequently sloughs, with or without formation of a scar. Systemic effects are usually mild but may be severe. The male spider is more venomous than the female.[7]

Identification. Hobo spiders are brown with gray markings. They are moderately large, measuring 7 to 14 mm in body length and 27 to 45 mm in leg span.

Geographic Distribution. *Tegenaria agrestis* is distributed throughout the Pacific Northwest, southwestern Canada, and the Alaskan panhandle. The distribution of this spider does not overlap that of *Loxosceles reclusa*. The hobo spider builds funnel-shaped webs in damp, moist places, such as wood piles and crawl spaces. It is rarely found above foundation or ground level.

Insecta: Flies, Bugs, Fleas, and Lice

Myiasis-Producing Fly Larvae

Myiasis occurs when fly larvae infect humans either accidentally or by penetrating skin directly to form subcutaneous skin lesions, for the purpose of feeding on tissue. Imported cases of myiasis are increasing because of more frequent travel to endemic areas.[4,62] The two most common genera that parasitize humans are *Dermatobia* and *Cordylobia*. Larvae of flies in the genera *Wohlfahrtia*, *Cochliomyia*, *Hypoderma,* and *Oestrus* affect humans much less commonly and will not be discussed here.[17,20,49]

Dermatobia hominis *(Human Bot Fly)*

Relation to Disease. The fascinating life cycle of this organism requires some discussion to understand infection. The female attaches her eggs to another insect vector, often a mosquito. While the insect is biting a host, the eggs release larvae, which immediately penetrate the skin. Larvae mature in the skin for approximately 6 to 12 weeks, after which they leave the subcutaneous tissue for the soil, where they require another 3 weeks of maturation before an adult fly emerges.[4,49,62]

While in the skin, the larvae produce a lesion that resembles a "boil," which is often quite pruritic and occasionally painful. Complete excision of the larvae eliminates the disease and allows confirmation of the diagnosis. Secondary bacterial infections of the lesions occur occasionally.

Identification. Larvae range in size from several millimeters to 18 to 25 mm, depending on maturity at the time of excision. Rows of spines that are easily visible with a dissecting microscope encircle the larva (Image Plate A-3A). Larval stages may have a distinct "flask" shape, with a long tapered neck. Microscopic examination of the spiracles (stigmal plates) is useful when making an identification.[17,18]

Geographic Distribution. *Dermatobia hominis* is common in Central and South America.[4,17,47]

Cordylobia anthropophaga *(Tumbu Fly)*

Relation to Disease. Larvae emerge from eggs that have contaminated bed linen, clothing, or other materials and penetrate the host's skin shortly after contact.[4,28] Development in the subdermal layer occurs much faster than with *Dermatobia hominis*, usually within 2 weeks,[4] reducing the relative number of imported infections.[28] Patients are generally exposed to a larger number of eggs, so numerous lesions are more likely with *Cordylobia* infection than with *Dermatobia*.[4]

Identification. Larvae reach 7 to 12 mm at maturation. Their more conical shape readily distinguishes them from *Dermatobia*.[28] Spiracles appear at the widest end.

Geographic Distribution. *Cordylobia* is found primarily in sub-Saharan Africa.

Other Flies

Several other medically important flies warrant brief discussion, although specimens are rarely submitted to clinical laboratories.

Sandflies belonging to the genera *Lutzomyia* and *Phlebotomus* are responsible for transmission of leishmaniasis. These flies are hairy, small, and tend to have wings held in an erect V shape. *Chrysops* spp., commonly known as deer flies, are involved in transmission of *Loa loa*, the African eye worm. Black flies (*Simulium* spp.) are the vectors for the microfilariae causing onchocerciasis. Different *Simulium* species exist in distinct geographic regions, but all reproduce near fast-flowing waterways near which is where the largest number of bites occur. Tsetse flies (*Glossina* spp.) exist only in tropical Africa and transmit African trypanosomiasis (sleeping sickness). These

elongated flies possess a powerful proboscis capable of inflicting painful bites.[56]

1599

Mosquitoes

Mosquitoes are responsible for transmitting diseases causing greater morbidity and mortality than any other arthropod.[17,18,20,56]

Relation to Disease. Mosquitoes produce pruritic skin lesions that appear shortly after they take a blood meal. They are also capable of transmitting serious infections. *Anopheles* spp. are the arthropod vectors responsible for transmitting malaria. Filariasis is spread by some *Aedes* spp., *Mansonia* spp., and *Anopheles* spp. A variety of arthropod-borne viruses (arboviruses) use *Aedes* spp., *Culex* spp., *Culiseta* spp., *Haemagogus* spp., and *Sabethes* spp. as vectors of serious infections, such as equine encephalitis, West Nile fever, yellow fever, dengue and, now, Zika virus.[5,42,56] Both male and female mosquitoes feed on nectar and pollinate flowers. The female mosquito must take a blood meal to complete development of eggs.[20]

Mosquitoes use olfactory clues to find their human targets. A specific component of human sweat has been identified as an important compound for *Anopheles gambiae*, an important vector for *Plasmodium falciparum*.[22] A variety of insect repellents are available to discourage mosquitoes from biting. Products based on botanicals are attractive options for those who wish to avoid chemical deterrents; unfortunately, these options are not as effective as products that contain *N,N*-diethyl-3-methylbenzamide (DEET).[16] Perhaps in the future, compounds that block relevant components in sweat will make effective deterrents.

Identification. Mosquitoes are dainty-appearing, flying insects easily recognized by most. Identification to genus and species level requires significant experience and should be left to the experts. Mosquito bites are sufficiently common that patients rarely bring specimens to the clinical laboratory for identification.

Geographic Distribution. Mosquitoes are found worldwide, but individual species have well-defined environmental niches. For instance, classical yellow fever was an urban disease because the primary vector, *Aedes aegypti*, was limited to standing water in the vicinity of human dwellings. It was hoped that the disease could be completely eliminated by controlling the mosquito vector. Unfortunately, control of urban yellow fever revealed a sylvatic cycle among monkeys and several forest mosquito species, and it soon became clear that the virus could be controlled but never eliminated.[56]

The range of certain mosquitoes has been expanded secondary to global commerce. *Aedes albopictus*, also known as the "tiger mosquito," is a resident of Southeast Asia, but it hitched a ride to the United States by laying eggs in accumulated water in automobile tires.[33] This aggressive mosquito species is a competent vector for important human pathogens. Eastern equine encephalitis virus, Cache Valley fever virus and Zika virus are transmitted by this mosquito species.

True Bugs or Hemiptera

Bedbugs (*Cimex* spp.) and reduviid (family *Reduviidae*) bugs suck the blood of vertebrates, including humans, and the latter acts as an important vector in transmission of disease.[17,56] They are nocturnal, feeding at night and hiding and resting during the day. The common bedbug (*C. lectularius*) has been submitted to microbiology laboratories for identification more recently secondary to the rise in bedbug infestations.

Cimix lectularius

Relation to Disease. The common bedbug can cause numerous small lesions on the skin wherever a blood meal is taken. The severity of the lesions is related to the sensitivity of the individual. Bedbugs feed primarily at night, otherwise hiding in the bed linen, loose wallpaper, and mattresses.[17] They do not act as vectors of infectious agents.

Identification. Bedbugs are light to orange-brown, and 5 mm long by 3 mm wide.[17,18,20] Adults have small, nonfunctional wing appendages (Image Plate A-3B).

Geographic Distribution. *Cimex lectularius* is distributed worldwide, although more common in temperate zones, whereas *C. hemipterus* is more common in tropical climates.[56]

Kissing Bugs: *Panstrongylus*, *Rhodnius*, and *Triatoma* Species

Relation to Disease. The family *Reduviidae* has several popular names. These bugs are sometimes known as "cone-nose bugs" because of the elongated shape of the head. The majority of the group are known as assassin bugs from their lethal aggression against other insects. Assassin bugs may also bite humans and cause painful lesions.[20]

Medically, the most important group are the "kissing bugs," so-named because they may take their blood meals from the skin around the lips. Kissing bugs transmit the causative agent of Chagas' disease, *Trypanosoma cruzi*. They are unable to bite through clothing, so lesions are most common on exposed parts of the body.[20] Feces containing *T. cruzi* are deposited on the host while the bugs feed. Subsequent scratching of pruritic skin at the bite site introduces organisms into the wound.

Transmission also occurs when fecally-contaminated fingers are rubbed in the eyes, nose, or mouth.[56]

Identification. Unlike bedbugs, reduviid (triatomid) bugs possess functioning wings. They range in size from 1 to 4 cm, are more elongated than bedbugs, and have relatively long, thin heads (Image Plate A-3C).[17,18,20,56]

Geographic Distribution. Kissing bugs occur in southern portions of the United States and in Central and South America.

Fleas

Relation to Disease. Fleas may cause irritating, itchy bites after sucking blood from a host. The species that transmit the most serious human infections most commonly are considered here. The Oriental rat flea, *Xenopsylla cheopis*, is the classical vector of plague[30] and murine typhus.[20] *Tunga penetrans*, the "jigger" flea found in Africa and in Central and South America, penetrates the skin and lays eggs while inside the host (Image Plate A-3D).

The cat flea, *Ctenocephalides felis*, and the dog flea, *Ctenocephalides canis*, can infect either species of domestic animal (Image Plate A-3E). In North America, the dog flea is uncommon, and most human disease is caused by the cat

flea.[20] Either species can bite humans. The dog tapeworm, *Dipylidium caninum*, may occasionally infect humans when a flea containing the cysticercoid stage of the tapeworm is accidentally ingested.[17,18] Several species of fleas, in addition to other insects, may transmit the larvae of the rat tapeworm, *Hymenolepis diminuta,* to humans. It has been recognized that endemic plague may be associated with exposure to cats, and endemic typhus, caused by *Rickettsia typhi*, may be transmitted by the cat flea.[53] A *Rickettsia*, known as the ELB agent,[48,63] also infects the cat flea and causes an illness that resembles murine typhus. This rickettsial organism can be maintained by transovarial transmission in cat fleas.[1] The ELB agent has now been classified as *Rickettsia felis*.[23] In developed countries, cats may be more important than rats in transmission of these infections.

Identification. Recognition of fleas is relatively easy. They are wingless, and have long, muscular legs[17,18,56] hanging down from a body that looks "hunched over" (Image Plates A-3D and E). Species level differentiation of fleas is very difficult, usually requiring considerable expertise.

Geographic Distribution. Fleas are found worldwide, following the distribution of

the mammalian host. *Xenopsylla cheopis* is associated primarily with brown rats (*Rattus norvegicus*, also known as Norwegian sewer rats) and black rats (*Rattus rattus*, also known as house or roof rats). *Ctenocephalides* spp. are found on cats and dogs.

Lice

Lice are a considerable public health concern, producing diseases that range from relatively benign to life-threatening. As agents of direct injury, they cause minor, yet irritating, skin and hair infestations. As arthropod vectors, they are capable of transmitting important bacterial pathogens. Individual subspecies of *Pediculus humanus* are associated with different parts of the body, and some overlap does occur, whereas *Phthirus pubis* resides in the pelvic region.

Pediculus humanus subsp. *humanus*

Relation to Disease. *Pediculus humanus* subspecies *humanus* is also known of as the human body louse. It parasitizes most parts of the human body other than the head. Body lice are primarily found in the hairier regions, where they migrate back and forth from clothing to skin to take blood meals.[17] They may be found in the cuffs and folds of the clothing of infested individuals. Feeding causes irritating, pruritic bite wounds, a general characteristic of infestations with lice. Most eggs, called nits, are laid on clothing.

Body lice transmit *Borrelia recurrentis*, one of the less common causes of relapsing fever,[3,57] and *Rickettsia prowazekii* and *Bartonella quintana*,[29] which cause epidemic typhus and trench fever, respectively.[17,56] In relapsing fever, crushed lice release organisms onto the skin that then enter through abrasions, likely secondary to biting. Typhus and trench fever agents, which are present in louse feces, enter when scratched into the skin by the host.[56] The mortality rate in untreated epidemic typhus may be as high as 60%,[56] perhaps because of the presence of other complicating factors, but antimicrobial therapy effectively controls the infection.[38]

Body lice are spread by fairly close contact with infected individuals. Shared clothing, bedding, and close communal habitation are associated with transmission.[17] Not surprisingly, louse-borne infections occur under conditions of extreme privation, such as war and famine.

Identification. Body lice reach 2 to 4 mm in length, with a relatively long, slender abdomen. They have three pairs of legs, with clawlike hooks on the ends that aid in securing the louse to its host (Image Plate A-3F).

Geographic Distribution. Body lice occur worldwide.

Pediculus humanus subsp. *capitis*

Relation to Disease. Head lice produce irritating infections of the head, hair, and neck regions.[44] They infect only humans; pets and other animals are not susceptible. Unlike the body louse, head lice do not serve as vectors for transmission of bacteria, although secondary bacterial infection of the bite wound may occur.[6] The 1-mm-sized nits (eggs) are most often glued to a hair shaft near the scalp (Image Plate A-3G).

Infestations are most common in children.[6] They occur through close contact and sharing of fomites such as combs, hats, and scarves.[17]

Identification. Head lice closely resemble body lice. Although size overlap does occur, they may be slightly shorter than body lice, averaging 1 to 3 mm.[17,18,20] The elongated abdomen and the three pairs of legs with hooks are virtually identical to those found on the body louse. Nits are easily confused with dandruff, seborrheic scales, hair spray, or fungal infection (Image Plate A-3G).[6]

Geographic Distribution. The head louse is found throughout the world.

Phthirus pubis

Relation to Disease. *Phthirus pubis*, also known as the crab or pubic louse, causes an irritating infection of the pubic area. It may be found less frequently in the armpits, chest, thighs, and short facial hairs of mustaches, eyebrows, and eyelashes.[17,18,20]The lice leave a pruritic bite wound on the skin after taking a blood meal. Secondary infection of the bite wound may occur, but is uncommon. Nits are laid on the lower portion of hair shafts as with head lice. Pubic lice do not transmit infectious agents. Transmission occurs primarily through intimate contact.

Identification. Pubic lice are 1 to 2 mm long and have a short, round abdomen. Their shape has been described as "turtlelike." Pubic lice possess three pairs of legs, with claws that appear larger and thicker than those of the body or head louse (Image Plate A-3H).

Geographic Distribution. Pubic lice can be found worldwide.

Interpretation of the Significance of Free-Living Amebae Isolated in Culture

Treatment

Introduction

Small, free-living water and soil amebae of the genera *Naegleria, Acanthamoeba,* and *Balamuthia* are capable of producing opportunistic infections in humans. The major diseases produced by this group are forms of devastating, usually fatal meningoencephalitis. *Acanthamoeba* species may also cause keratitis, an ulcerative, vision-threatening infection involving the cornea of the eye; this disease is not caused by *Naegleria* or *Balamuthia*.[30] In rare instances, skin infections may be caused by *Acanthamoeba* or *Balamuthia.*[9,45] The free-living amebae are not related to the intestinal amebae discussed previously and do not inhabit the intestines of humans or other mammals.

Ecology, Epidemiology, Pathogenesis, and Disease

Naegleria, Acanthamoeba, and *Balamuthia,* along with many other genera of free-living amebae, have a worldwide distribution in various freshwater habitats, including rivers, lakes, ponds, hot springs and spas, domestic water systems, air-conditioning systems, humidifiers, and cooling towers.[19,20] They are believed to play a role in a hypersensitivity pneumonitis known as humidifier fever.[41] They are ubiquitous in soils, dust, air, and composts; have been found on the surfaces of vegetables; and have been isolated from sewage sludge and water polluted by domestic or industrial waste. *Acanthamoeba* and *Balamuthia* species have been isolated from soil, sea water, especially associated with discharges of inadequately treated sewage from hotels, and municipal sewage effluents (D. A. Munson, personal communication, 1991).[20,42] *Naegleria* and *Acanthamoeba* have also been found associated with thermally polluted discharges in ponds and lakes connected with electric power plants, nuclear power plants, or thermal polluting factories.[19,20]

In nature, free-living amebae feed on bacteria, including *Legionella* species,[3,37,41,46] and the amebae form cysts that are resistant to adverse environmental conditions, such as drying in soil. De Jonckheere and Van de Voorde reported that the cysts of some strains of *Acanthamoeba* are highly resistant to chlorine and are not killed by the usual concentrations of chlorine maintained in municipal or domestic water supplies or in chlorinated swimming pools.[21] Conversely, the cysts of *Naegleria fowleri* were more sensitive to chlorine; these authors concluded that viable *N. fowleri* is not likely to be found in clean water where low concentrations of chlorine (e.g., 0.5 mg free available chlorine per milliliter) are maintained.[21] Rowbotham was the first to show that *L. pneumophila* can grow within *Acanthamoeba* species, thus providing an explanation of

how nutritionally fastidious legionellae can maintain viability in pristine, low-nutrient waters.[41] *Legionella* species also proliferate within various other free-living amebae.[46] It has been speculated that legionellae could be aerosolized through the air to humans in droplets of water while residing within amebae.[41] This seems feasible, especially if amebic cysts could protect legionellae from chlorine in domestic water supplies (Chapter 10).

In addition, free-living amebae, including *Naegleria fowleri, Hartmanella* species, and various *Acanthamoeba* species, have been isolated from the throats and nasal passages of humans[1,6,28,40,46,47]—probably as cysts that were inhaled with dust in the air, in aerosols, or were present in ingested food or water.[17]Trophozoites of *Naegleria* or *Acanthamoeba* have not been demonstrated in the human nasopharynx in the absence of CNS disease.[17]

1603

Primary Amebic Meningoencephalitis

Prior to 1958, none of the free-living water and soil amebae were recognized as pathogenic. Then Culbertson and associates observed an ameba contaminant in tissue culture cells.[18] This strain, now called *Acanthamoeba culbertsoni* strain A-1, when instilled intranasally into young mice or various other animals, produced infection within the nasal mucosa and submucosa that spread from there along the olfactory nerve through the cribriform plate of the skull to produce invasion of the brain and a rapidly fatal meningoencephalitis.[13,14,18] Based on his experimental work with animals, Culbertson predicted that similar disease could occur in humans.[13,16,18] In 1965, the first human case was reported in a child from Australia by Fowler and Carter.[23] The following year, three additional infected patients were reported by Butt from Florida, who called the disease "primary amebic meningoencephalitis."[10] Thus, conceptually, primary amebic meningoencephalitis differed from amebic disease of the CNS involving *Entamoeba histolytica* because primary amebic meningoencephalitis was not "secondary" to amebic disease of the colon.

It is now known that the portal of entry for *Naegleria* is the nose and the true "primary" site of the infection is the upper respiratory tract.[11,14,17] Most patients with *Naegleria* CNS infections have been children or young adults who were swimming in lakes or rivers or otherwise had an opportunity for water, which is believed to contain the *Naegleria*, to enter the nose.[3,4,31,33] After infecting the nasal mucosa, *N. fowleri* then spreads along the olfactory nerve, through the cribriform plate into the brain via the route originally observed in animals by Culbertson and colleagues.[13,18] Pathologic findings in humans with acute meningoencephalitis caused by *N. fowleri* have been

remarkably similar to those seen originally in the experimental animal models by Culbertson and associates with *Acanthamoeba culbertsoni* strain A-1, which is the most virulent of the *Acanthamoeba* species.[10,11,14–17,25,30,32] Other *Acanthamoeba* species are not as virulent and tend to produce subacute or chronic brain abscesses, with or without granulomas.

N. fowleri produces a diffuse and fulminant meningoencephalitis characterized by large areas of hemorrhagic necrosis, especially involving the olfactory bulbs, frontal lobes, base of the brain, proximal spinal cord, and/or temporal lobes of the brain. The parietal lobes and occipital cortex may also be involved. Acute purulent exudate is found in the leptomeninges and within the cortex. Amebic trophozoites are scattered or may be seen focally in clusters within necrotic cortex. They especially show a predilection for blood vessels; small arteries, arterioles, veins, venules, and capillaries may be surrounded by 10- to 15-µm *Naegleria* trophozoites containing a large prominent karyosome.[14,16,33] Importantly, cysts are not formed in the tissue by *Naegleria,* which is a differentiating feature between this organism and both *Acanthamoeba* spp. and *Balamuthia mandrillaris.*

Granulomatous Amebic Encephalitis

In humans, a more indolent CNS infection may be caused by two genera of amebae. *Acanthamoeba* species have long been recognized as a cause of meningoencephalitis, with a presentation distinct from that of *N. fowleri*. This is a rarely encountered disease and is not a reportable infection, so the incidence is not known; it is, however, well reported in the medical literature.[30] In 1986, *Balamuthia mandrillaris* was also shown to be a cause of chronic granulomatous amebic meningoencephalitis. Most patients with granulomatous amebic encephalitis (GAE) have been immunocompromised and, unlike PAM, have not had a history of exposure to water.[17,30,32,33] Even more rarely, infections have been reported in otherwise healthy individuals.

The cysts of these organisms are ubiquitous and may be present in soil or dust; it is possible that the organisms could have been inhaled into the nasal cavity or even the lower respiratory tract.[17] It is conceivable that in humans, *Acanthamoeba* species might spread either from the nasal cavity to the brain by way of the olfactory nerve or intravascularly from the lungs or possibly from skin lesions (reported rarely) to the brain.[17,33]

Within the brain, *Acanthamoeba* species produce acute inflammation in early stages of the disease in animals. However, species less virulent than *A. culbertsoni* strain A-1 tend to produce focal or multifocal chronic abscesses, with or without granulomas. Trophozoites and cysts may be focal or scattered in small numbers throughout involved areas but may be located in perivascular spaces and can be seen within the

walls of small vessels in association with perivascular hemorrhage and intravascular thrombosis. Amebic cysts are seen within tissue in *Acanthamoeba* and *Balamuthia* infections but have not been observed in tissues infected with *Naegleria*.[14,16,33] The cysts and trophozoites of *Acanthamoeba* and *Balamuthia* are morphologically indistinguishable. Molecular techniques must be used to differentiate these amebae. PCR-based assays are available at the Centers for Disease Control and Prevention (CDC).

Acanthamoeba *Keratitis*

Acanthamoeba keratitis is a serious, often devastating infection of the cornea involving certain species of *Acanthamoeba* (e.g., *A. polyphaga, A. castellanii, A. rhysodes, A. culbertsoni,* and *A. hatchetti*).[5,30,35] Since the first infected patient was described in 1975,[26] more than 200 cases have been reported worldwide; this number is likely significantly lower than the true frequency of infection, since this is not a publicly reportable disease.[30] Until about 1984, the majority of infections were associated with trauma to the cornea and exposure to contaminated water. Although this is still a means of infection, many infections are now associated with the use of contact lenses, especially daily-wear or extended-wear soft contact lenses.[5,12,35,44] Other factors involved in *Acanthamoeba* keratitis include trauma to the cornea and the use of contaminated homemade saline or tap water rinses to clean lenses, the failure to disinfect lenses properly or as often as recommended by manufacturers, and wearing lenses while swimming.[8,30,44] Acanthamoebae may be present in contact lens cases and contact lens wash solutions, and they are capable of adhering to contact lens surfaces.[8,29,35,44,48] *Acanthamoeba* keratitis presents as an ophthalmologic emergency. Most age groups have been affected, from children to the elderly.[44] The infection progresses relentlessly with corneal ulceration and may result in blindness. It is a disease that is difficult to diagnose and treat. The disease has often

been misdiagnosed as herpes simplex keratitis, fungal keratitis, or bacterial or mycobacterial infection, sometimes resulting in delays of weeks or months before a diagnosis has been made and proper treatment is begun. Detailed clinical findings have been published elsewhere in several excellent reviews.[29,35,39,44,48]

Laboratory Investigation

Collection and Transport of Specimens

When amebic disease is suspected, fresh cerebrospinal fluid or tissue (e.g., corneal biopsy, corneal scrapings, CNS tissue) should be collected aseptically and submitted for examination. Specimens intended for culture must never be frozen or refrigerated and should be maintained at 20°C to 30°C during transport to the laboratory.[3,15] If immediate examination is not possible or not practical, amebae have survived in sterile fluid or otherwise sterile tissue for several days at room temperature prior to processing, but extended transport times are not recommended. If a transport medium is needed for transport of tissue biopsy samples or corneal scrapings, the minimal essential medium used in virology laboratories is preferred (Chapter 23) over Page's ameba saline (D. Place, F. Curtis, E. Powell, and A. Newsome, personal communication, 1991).

Direct Microscopic Examination

Small drops of cerebrospinal fluid, other body fluids, or tissue suspensions should be examined in wet mounts (on slides under coverslips) by light microscopy under reduced light, or by phase microscopy for motile trophozoites (using a 40× objective). Keeping the microscope stage warmed to 30°C to 37°C may enhance motility, especially of *Acanthamoeba* species.[15] *Naegleria* may be actively motile at 22°C to 25°C, but the motility of *Acanthamoeba* species at room temperature is very sluggish. These amebae tend to be more actively motile than leukocytes, and the nuclei and nucleoli of *Naegleria* and *Acanthamoeba* species differ from those of granulocytes or macrophages.

Material to be stained on slides should first be fixed in 10% neutral buffered formalin. After the slide is air-dried, it can then be stained with trichrome, the Papanicolaou stain, or hematoxylin and eosin.[3,15] Tissue sections should be stained with hematoxylin and eosin. Other stains preferred for direct examination preparations by some include lactophenol cotton blue, Giemsa, acridine orange, and calcofluor white.[30] Specific detection methods, such as indirect fluorescent antibody procedures, immunohistochemistry, and PCR-based assays, are available through CDC (http://www.cdc.gov/dpdx/dxassistance.html) or select reference laboratories.[3,30]

Culture of Free-Living Amebae

Culbertson's method for culturing amebae with *Escherichia coli* on salt-free, water agar,[15] a slight modification of Singh's original procedure, has proven to be useful for culturing body fluids, suspensions of eye tissue, and other specimens. Agar plates are prepared with 20 to 25 mL of 1.5% agar in distilled water without nutrients or salt added. A loopful or one drop of a heavy suspension of *E. coli*, from a 24- to 48-hour

blood agar plate culture is either placed in the center of the plate in a 1 cm diameter area or is used to make a lawn on the plate.

The inoculum (a drop of cell suspension, sediment, or tissue fragments) is placed in the center of the bacterial lawn and the plate is sealed with tape. Duplicate plates are incubated at 30°C and 37°C, or a single plate is incubated at 34°C to 35°C. After 18 to 24 hours of incubation, the plate is kept sealed and examined agar side up with a 10× objective. Alternatively, an inverted microscope can be used. If no amebae are seen, the plate is reincubated and examined daily for 10 days. The amebae may be in clusters of cells or will appear as small refractile bodies that migrate from the inoculum, often leaving irregular trails or tortuous tracks behind them where they have moved through the bacteria.[15] Individual amebae can be transferred from the agar to a slide to view as a wet mount or stained preparation. Subculture can be made by cutting out a plug of agar at the "front" containing amebae (using a sterile scalpel) from outside the zone of bacteria, where the amebae are more likely to be free of bacteria, and then transferring the amebae to another water agar plate containing *E. coli* (the addition of amphotericin B in final concentration of 2.5 mg/mL in the agar aids in minimizing fungal contaminants) (E. Powell, personal communication, 1991). From there, the amebae are transferred to a broth medium (e.g., trypticase-soy broth) containing antibiotics (e.g., penicillin 1,000 µg/mL and streptomycin 0.1 mg/mL final concentration).

After the amebae are free of bacteria (axenic), they can be transferred to trypticase-soy broth without antibiotics to be used as a growth medium.[3,15] *Naegleria* will not grow in trypticase-soy broth unless it contains 10% sterile fetal calf serum. The growth of amebae in trypticase-soy broth is optimized by using plastic tissue culture tubes so that the amebae will attach to the tubes.[3,15] The cultures are incubated at 35°C almost horizontally at a 15 to 20 degree angle, analogous to what is often done with cell cultures in virology laboratories. Not all amebae grow in trypticase-soy broth. Alternative media include Plate Count Broth (BD, Sparks, MD) and broth media recommended in the American Type Culture Collection Catalogue (www.atcc.org), including *Acanthamoeba* medium, PYNFH medium, and Fresh Water Ameba medium (E. Powell, personal communication, 1991). Neroad and co-workers[36] have also described a chemically defined medium for cultivating pathogenic and high temperature tolerant species of *Naegleria*.

Tissue Culture

The more virulent free-living amebae (e.g., *A. culbertsoni* strain A-1) grow in mammalian cell cultures, including monkey kidney, McCoy cells, and others, and may produce cytopathogenic effects (CPE) resembling those seen with viruses.[18,47] Less virulent amebae may grow poorly in tissue (cell) culture without producing CPE.

Amebae can be extremely difficult to see when growing with tissue culture cells; fluid should be removed from a tissue culture tube or flask, centrifuged at 500 to 800 *g* (×5 minutes), or can be prepared using a Cytospin; then, the sediment is used to prepare a wet mount that is examined by phase or light microscopy using low illumination. Alternatively the slide preparation can be dried, fixed in formalin, and stained with H&E to aid

1605

in observing amebic features.[3] Once isolated in tissue culture, isolates can be transferred to a broth medium and/or to water agar with *E. coli*., as described in the preceding section.

Morphologic Features

When rounded up, the trophozoites of *Naegleria* are 8 to 15 µm and usually smaller than those of *Acanthamoeba* species, which are usually 10 to 25 µm in diameter.[2,4] The nuclei of both genera are similar and contain large, prominent karyosome. *Naegleria* have one or more smooth, lobate pseudopodia and are actively motile at room temperature or 35°C to 37°C. *Acanthamoeba* species are very sluggish at 22°C to 25°C but may become more actively motile at 35°C and 37°C. Acanthamoebae have numerous, spiny pseudopodia on their surface called acanthopodia.*Naegleria* species are characterized by a temporary ameboflagellate stage; when *Naegleria* trophozoites are put in distilled water, they may develop pear-shaped, actively motile forms containing two or more flagella (within 1 to 3 hours). The cysts of acanthamoebae and *Balamuthia* are more thick-walled than those of *Naegleria* and have distinctive appearances that aid in identification.[38] In addition, *Naegleria* species produce a distinctive form of mitosis (promitosis) in which the nuclear membrane remains intact.[38] In contrast, acanthamoebae produce a more classical type of mitosis (metamitosis) in which the nucleolus and nuclear membrane disappear and the mitotic spindle appears with the chromosomes in metaphase.[15,38] For more detailed descriptive information, readers are referred to references.[3,15,17,27,30,38]

Identification of *Naegleria*, *Acanthamoeba,* and *Balamuthia* beyond the genus level is now usually achieved by nucleic acid sequencing. In the past, a detailed morphologic study but also the use of other procedures, including tests with species-specific immunologic reagents (e.g., immunofluorescent antibody tests, coagglutination tests) and tests for pathogenicity (in mice) were used more commonly.[22] Identification of these organisms to species level may be useful in an epidemiologic investigation or research projects, but its practical value for the clinical laboratory to assist clinicians in the management of patients has not been demonstrated.

Interpretation of the Significance of Free-Living Amebae Isolated in Culture

Because free-living amebae are ubiquitous in water, soil, dust, and the air, it is possible that cysts, carried about in the air, could contaminate the surface of a corneal scraping, tissue biopsy, or fluid specimen during the time of specimen collection, processing, during the inspection of primary plates for growth, or following prolonged incubation. Amebae could also be on the skin, lid margin, or in the conjunctival sac of an eye without causing keratitis, although this has not been demonstrated. As with any positive culture, it should be correlated with the findings of the direct microscopic examination of the specimen, histopathologic examination, and clinical findings.[3]

Treatment

The treatment for primary amebic meningoencephalitis and GAE has not been standardized. At least two patients with *Naegleria* meningoencephalitis have survived. Each received amphotericin B. One of the patients, in addition to receiving amphotericin B, also received miconazole, rifampin, and sulfasoxazole.[3,7,39,43]

The treatment of choice for *Acanthamoeba* CNS disease has not been established. It is clear that therapy should be promptly administered and that a multidrug regimen should be considered. Agents with activity include azoles, such as fluconazole, itraconazole, and related drugs, pentamidine, sulfadiazine and trimethoprim–sulfamethoxazole, paromomycin, and others.[3,17,24]

The treatment of *Acanthamoeba* keratitis has been successful in several patients using an intensive treatment protocol involving topical propamidine isethionate (Brolene drops) and neomycin sulfate–polymyxin B sulfate–gramicidin drops (Neosporin Ophthalmic Solution).[34,35,39,49]

IMAGE PLATE 1-1

Gram's Stain Evaluation of Sputum Smears

The quality of sputum samples can be evaluated by counting the relative numbers of squamous epithelial cells and segmented neutrophils per low-power field in a Gram-stained smear. The presence of squamous epithelial cells indicates contamination with oropharyngeal secretions. In contrast, bacterial pneumonia will produce large numbers of neutrophils that can be detected in sputum samples. The following are photomicrographs of Gram-stained smears of sputum samples illustrating the relative presence of the various cellular components.

A. Low-power view of Gram-stained sputum smear, revealing full field of squamous epithelial cells and absence of segmented neutrophils. This specimen represents saliva, would give a low quality score, and is not acceptable for culture.

B. The squamous epithelial cell shown here is heavily colonized with gram-positive bacteria. The overgrowth of bacterial cells in sputum specimens generally indicates that the specimen has been delayed in transit to the laboratory and that any semiquantitative results will be of little value.

C. This Gram-stained sputum smear shows a mixture of squamous cells and segmented neutrophils. The presence of segmented neutrophils indicates that a nidus of infection exists somewhere in the respiratory tract; however, the squamous epithelial cells indicate contamination with upper respiratory tract secretions. This type of sputum smear is difficult to interpret because upper respiratory tract infections cannot be distinguished from lower respiratory tract infections (i.e., the predictive value of the result is significantly decreased).

D. Full field of neutrophils and virtual absence of squamous epithelial cells. This is a

high-quality sputum sample that provides a good chance for producing relevant results.

E. Higher-power view of sample in **D**, revealing scattered segmented neutrophils against a background of pink-staining mucus threads.

F. This smear of an induced sputum sample, stained with Diff-Quik, illustrates several ciliated, columnar epithelial cells. These cells have their origin in the lower respiratory tract and, when present in a sputum smear such as that seen here, indicate a high-quality specimen from which relevant results can potentially be obtained.

G. High-power view of a Gram-stained sputum specimen illustrates the morphology of a ciliated columnar epithelial cell. Note the distinct cilia atop the flared terminal end of this eosinophilic staining columnar epithelial cell.

H. Toluidine blue stain of an induced sputum specimen revealing mononuclear inflammatory cells consistent with alveolar macrophages. As with columnar epithelial cells, alveolar macrophages have their origin deep within the lower respiratory tract, and their presence in sputum samples increases the significance of any bacterial species recovered.

IMAGE PLATE 1-2

Miscellaneous Stains Used in Microbiology

Stains are needed to make possible the detection and study of many of the microbes of medical importance, since they have refractive indices near that of water. A variety of stains have been developed over the years, each designed to highlight specific components of the cell wall or specific aspects of the cell (e.g., flagella or spores). The following are illustrations of selected stains and some of their applications.

A. Gram's stain. The most common stain used in the microbiology laboratory is designed to differentiate bacteria that can retain crystal violet dye and appear deep blue-black after decolorization (i.e., gram-positive) from those that cannot and stain red (i.e., gram-negative). Illustrated here is a Gram-stained preparation revealing red-staining, gram-negative bacilli.

B. Acid-fast. This stain and a modification thereof (i.e., the partial or modified acid-fast stain) are commonly used to demonstrate a variety of "acid-fast" organisms, including *Nocardia* species in sputum specimens and *Cryptosporidium* oocysts in fecal samples. Shown here are clusters of red-staining, acid-fast bacilli in a liver biopsy specimen from a patient with AIDS. The organisms stain red with the acid-fast stain, and those shown here were identified as belonging to the *Mycobacterium avium/M. intracellulare* complex.

C. Direct fluorescence. Fluorescent dyes (rhodamine and auramine) react directly with the cell wall of mycobacteria. Fluorescein-conjugated antibodies are also available to demonstrate a variety of microbial agents using the direct fluorescent antibody test. Shown here are yellow-green, fluorescing mycobacteria in a sputum concentrate from a patient with pulmonary tuberculosis.

D. Acridine orange. This rapid fluorescent stain is used to demonstrate bacterial forms in direct smears and mounts of biologic fluids. It is particularly useful in detecting gram-negative bacteria in positive blood culture broths, which may be missed in Gram's stains because of the deep red-staining debris in the background. Shown here is a long, rod-shaped bacterium, with a characteristic orange glow, when microscopically observed with a fluorescence microscope.

E. Methylene blue. This nonspecific, rapid stain is occasionally used to demonstrate bacteria and other microbes in direct smears. Illustrated here are bacilli that have taken the blue stain. One important application is in the detection of bacteria in

direct smears of cerebrospinal fluid in specimens from patient with suspected acute meningitis, particularly gram-negative species, which may be obscured by the red background staining of the proteinaceous material.

F. Calcofluor white. This autofluorescent whitening agent has the property of coupling with carbohydrate moieties in the cell walls of fungi. Shown here are brilliant yellow-green staining hyphae in a direct calcofluor white-stained mount as observed with a fluorescence microscope.

G. Wright–Giemsa. This stain is commonly used to demonstrate the cellular elements in peripheral blood and bone marrow smears. In microbiology, the stain is most commonly used in parasitology to detect intraerythrocytic (plasmodia, babesiae) and exoerythrocytic (trypanosomes, microfilaria) parasites. Chlamydial inclusions are highlighted by this stain, as well as the intracellular yeast forms of *Histoplasma capsulatum* (Illustrated here).

H. Periodic acid-Schiff (PAS). This general stain is used to demonstrate polysaccharide-rich cell walls. It has specific applications in detecting fungi in tissue sections and smears. Recognized here is the fruiting body of an *Aspergillus* species in an aspirate of a fungus ball lesion of the lung surrounded by red-staining *Aspergillus* conidia.

IMAGE PLATE 1-3

Presumptive Bacterial Identification Based on Observing Microscopic Cellular Morphology in Stained Smear Preparations

The Gram's stain of bacteria, in addition to other staining techniques, is one of the more important determinations in the presumptive identification of microorganisms. The morphology of the bacterial cells, their arrangement, and their staining characteristics are often distinctive enough to allow a presumptive identification in a Gram-stained smear. The microscopic characteristics suggestive of several groups of bacteria are included in this plate.

A. Relatively slender, gram-positive bacilli arranged in a "Chinese letter" pattern, suggests one of the coryneform (diphtheroid) bacteria.

B. Gram-positive, spore-forming bacilli. The aerobic spore formers belong to the genus *Bacillus*; the anaerobic spore formers belong to the genus *Clostridium*. Illustrated here are spore-forming cells of *Bacillus sphaericus*.

C. Direct Gram's stain of purulent exudates illustrating gram-positive cocci arranged in small clusters, characteristic of a *Staphylococcus* species.

D. Direct smear of necrotic exudate from a patient with myonecrosis. The tiny, gram-positive cocci seen in this photomicrograph are streptococci.

E. This direct Gram's stain of a smear of purulent sputum demonstrating gram-positive diplococci, characteristic of *Streptococcus pneumoniae*.

F. This purulent exudate was from the chest wall of a patient with acute, suppurative empyema. The branching, club-shaped gram-positive bacilli are suggestive of a *Bifidobacterium* species, which was what was recovered in anaerobic culture. Some of the *Actinomyces* species may have a similar morphology.

G. Gram-stained preparation of a direct smear of urine sediment from a patient with acute cystitis. Note the several gram-negative bacilli amid the background segmented neutrophils. *Escherichia coli* was recovered in pure culture.

H. The Gram-stained preparation of a direct smear prepared from purulent urethral exudates of a sexually active male, illustrates the intracellular, gram-negative, diplococci characteristic of *Neisseria gonorrhoeae*. The bacterial cells in this photograph are paler staining than normally seen by direct microscopic

examination.

I. This photomicrograph of a sputum smear illustrates a few segmented neutrophils in the background and a diffuse infiltration with many short, gram-negative bacilli some of which appear to be surrounded by a halo. *Klebsiella pneumoniae* grew out in culture.

J. This photomicrograph of delicate, branching gram-positive filaments is suggestive of *Propionibacterium acnes*, which is what grew out in culture. Some of the *Actinomyces* species may have a similar morphology in Gram's stain.

IMAGE PLATE 1-4

Pitfalls and Artifacts in Gram's Stain

A. *Acinetobacter* sp. in a blood culture. These organisms are coccobacillary and tend to retain the crystal violet. Thus, a Gram-stained smear may be misinterpreted as gram-positive cocci *(arrows)*, or gram-positive bacilli. The microscopist must evaluate the pattern of all the bacterial cells in the smear. The presence of cells that stain magenta is one clue that the true reaction may be gram-negative. Original magnification, 1000×.

B. Overdecolorized staphylococci in a genital specimen misinterpreted as gram-negative cocci. Although both gonococci and staphylococci may appear as diplococci, with a rare exception *(arrow)* the "kidney bean" shape of gonococci is not present here, and the bacterial cells are not intracellular. It is important not to imply the presence of *Neisseria gonorrhoeae* unless the morphology is characteristic. Original magnification, 1000×.

C. Elongated cells of *Streptococcus pneumoniae (arrows)* in a sputum smear may be misinterpreted as gram-positive bacilli, and their importance as a major respiratory pathogen may be missed. Other cells in the smear had the characteristic "lancet-shaped" appearance of pneumococci. The microscopist must assess the overall pattern and not be misled by occasional outliers. Original magnification. 1000×.

D. *Clostridium perfringens* decolorizes easily and may appear gram-negative. Clues to the true nature of the bacterial cells are provided by the occasional gram-positive cells *(arrow)* and the large "boxcar" appearance that does not resemble a typical enteric bacillus. *Bacillus* spp. may also decolorize and appear gram-negative. Original magnification, 1000×.

E. Gram's stain debris masquerading as gram-positive cocci. The true nature of the material is suggested by the small size and the marked variation in size. Artifactual material often appears refractile when the focus is varied. Original magnification, 1000×.

F. Retinal rods and cones masquerading as gram-positive cocci and bacilli in a vitreous specimen. The true nature of the structures is suggested by the anatomical site and their refractile appearance. Original magnification, 1000×.

G. Conidia of *Aspergillus fumigatus* mimicking gram-positive cocci in a sputum

specimen. The true nature of the structures is suggested by the enlarged size and by roughened edges of the conidia if present. A search of the smear may reveal septate hyphae. Original magnification, 1000×.

H. The exfoliated cilia from a respiratory cell *(arrow)* resemble gram-negative bacilli. A pale-staining bacillus such as *Fusobacterium nucleatum* may be suggested. On closer inspection, however, the structures do not have the morphologic detail of a bacterium. Further search will usually reveal intact cells with their attached cilia. Original magnification, 1000×. (Image enhanced.)

IMAGE PLATE 1-5

Presumptive Bacterial Identification Based on Observing Colonial Morphology

Microbiologists use various characteristics of bacterial colonies that grow on the surface of agar culture media to make a presumptive identification of the group or genus and as a guide in selecting differential tests to make the final species identification. Size, shape, consistency, color, and pigment production by the colonies, as well as the presence of hemolytic reactions on blood agar, are the criteria commonly used.

A. Blood agar plate on which are growing round, yellow-white, entire, convex, nonhemolytic colonies of coagulase-negative *Staphylococcus* species.

B. Colonies growing on blood agar illustrating distinct zones of β-hemolysis around the colonies. The relation between the size of the colonies and the zones of hemolysis is used to differentiate between certain species. Shown here are *Streptococcus* species, which commonly have a lower ratio of colony size to hemolytic zones, in contrast with *Staphylococcus* species, in which the relative size of the colonies is generally larger.

C. These off-white colonies of *Listeria monocytogenes* are weakly β-hemolytic upon transillumination (i.e., the colony color, but not the hemolysis is appreciable in this photograph). This organism was cultured from a CSF specimen from a patient with meningitis.

D. Opaque, dull gray, somewhat moist colonies growing on blood agar (right) and MacConkey agar (left), suggestive of one of the members of the family *Enterobacteriaceae*. The growth on MacConkey agar shows no red pigmentation, indicating that the organism is a nonlactose fermenter. The isolate shown here is one of the *Salmonella* species.

E. Dry, wrinkled colonies of a *Bacillus* species. Similar-appearing, wrinkled colonies are also seen with *Pseudomonas stutzeri*.

F. Yellow-pigmented colonies on blood agar. Pigment production is an important feature in the differential identification of many bacterial species, particularly those belonging to several groups of nonfermentative bacilli. The colonies shown here are those of *Flavobacterium* species after 48 hours of incubation, with the last 24

hours of incubation being at room temperature. The intensity of pigment is often accentuated after additional incubation at room temperature.

G. Distinctly mucoid colonies growing on blood agar. The mucoid consistency of colonies is sometimes secondary to the production of capsules, a protective mechanism used by several bacterial species in defense against phagocytosis. *Pseudomonas* species, *Klebsiella pneumoniae*, *Streptococcus pneumoniae*, and *Cryptococcus neoformans* are among the more commonly recovered microbial species producing mucoid colonies. The colony shown here is *Streptococcus pneumoniae*.

H. Gray semi-translucent colonies of *Eikenella corrodens* growing on blood agar. Note the halo around the colonies, illustrating the "pitting" characteristic of the species.

I. Gray, smooth, semitransparent colonies of *Capnocytophaga ochracea*. Note the mist-like extension of the colonies, illustrating the gliding motility characteristic of *Capnocytophaga* species.

J. White, dry, chalky colony of *Nocardia* species. *Streptomyces* species produce similar-appearing colonies. These presumptive identifications can be confirmed if the musty basement odor characteristic of these species can be detected.

IMAGE PLATE 6-1

PRESUMPTIVE IDENTIFICATION OF THE ENTEROBACTERIACEAE

Presumptive identification of the *Enterobacteriaceae* is based on the appearance of colonies growing on primary isolation media and on an assessment of certain biochemical reactions. By definition, for an organism to be classified within the *Enterobacteriaceae*, it must ferment glucose, producing acid or acid and gas; reduce nitrates to nitrites; and exhibit no cytochrome oxidase activity.

A. A Gram's stain of a sputum smear showing characteristic short, plump, gram-negative rods that are typical for members of the *Enterobacteriaceae*. Also depicted are two polymorphonuclear leukocytes, suggesting an ongoing infectious process in this patient. In this instance, the culture confirmed the organism to be *Klebsiella pneumoniae*.

B. Mixed culture showing 24-hour growth on blood agar of two morphotypes of large gram-negative rods and a third morphotype of a smaller organism that can be suspected to be a gram-positive species. One morphotype can be seen as large, shiny, white colonies, while the other appears as large, gray colonies with irregular edges. Both of these colony types can be suspected to be gram-negative rods typical for members of the *Enterobacteriaceae*. Also present are many small, white, entire colonies typical of one of the gram-positive cocci.

C. Large, mucoid, glistening, pink colonies on MacConkey agar typical of many *Klebsiella* and *Enterobacter* species. By their appearance alone, these colonies can be suspected to be one of the species of *Enterobacteriaceae*.

D. Swarming pattern of a motile strain of *Proteus* species on chocolate agar plate.

E. Series of Kligler's iron agar (KIA) slants illustrating several reaction patterns. The tube on the far left illustrates an acid (yellow) slant and acid (yellow) butt, indicating both glucose and lactose fermentation. Also note the space at the bottom of the tube and the split in the agar in the middle of the tube, which indicates gas (CO_2) production by the organism. Copious amounts of CO_2, such as seen here, are usually produced only by organisms belonging to Tribe V (*Klebsielleae*). The second tube from the left shows an acid–acid reaction, but without the presence of gas, typical of the type of reaction seen with *E. coli*. The third tube from the left illustrates an alkaline (red) slant/acid butt characteristic of a nonlactose fermenter. The fourth tube illustrates a red slant/black butt, indicating hydrogen sulfide (H_2S)

production. When this type of reaction is seen with an oxidase-negative organism, the assumption is made that the butt portion of the tube is acid (yellow), indicating glucose fermentation even though the yellow color is masked due to the H_2S production. The reaction in the fifth tube (far right; red/red) is typical of nonfermenting gram-negative bacilli that ferment neither lactose nor glucose.

F. Three tubes of purple broth media containing Durham tubes to demonstrate gas formation. The two tubes on the right illustrate acid from glucose (yellow), compared with the negative control on the left. The tube on the far right shows the collection of gas within the Durham tube, characteristic of an organism that produces both acid and gas from glucose.

G. Cytochrome oxidase test revealing a positive purple color reaction (left) compared with a negative reaction (right; no blue color within 10 seconds—see Chart 1-5). Any organism giving a positive reaction can be excluded from the family *Enterobacteriaceae*.

H. Nitrate test media containing Durham tubes to demonstrate nitrogen gas formation. The tube on the left shows a positive (red) reaction after addition of α-naphthylamine and sulfanilic acid. The test organism had reduced the nitrates in the medium to nitrites, which reacted with the reagents to form the red pigment *p*-sulfobenzene-azo-naphthylamine (Chart 6-2). The tube in the middle also depicts a positive nitrate reaction, but in this case all the nitrate was first reduced to nitrite and then further reduced to nitrogen gas, indicated by the collection of gas within the Durham tube. Since there is no nitrite in the tube, there is no red color when the reagents are added. The tube on the far right shows no red color and no gas and depicts a negative test for nitrate reduction.

IMAGE PLATE 6-2

APPEARANCE OF THE *ENTEROBACTERIACAE* COLONIES ON MACCONKEY AND EMB AGARS

MacConkey and eosin methylene blue (EMB) agars are two commonly used selective primary isolation media for the presumptive differentiation of lactose-fermenting from non–lactose-fermenting members of the *Enterobacteriaceae*. On MacConkey agar, lactose-fermenting colonies appear red because of the acid conversion of the indicator, neutral red. On EMB, a green metallic sheen is produced by avid lactose fermenters when the production of acid is sufficient to lower the pH to approximately 4.5 or below.

A. Surface of MacConkey agar with 24-hour growth of purple, lactose-fermenting colonies. The diffuse purple color in the agar surrounding the colonies is produced by organisms that avidly ferment lactose, producing large quantities of mixed acids, and cause precipitation of the bile salts in the medium surrounding the colonies (e.g., *Escherichia coli*).

B. Surface of MacConkey agar illustrating both purple, lactose-fermenting colonies and smaller, clear non–lactose-fermenting colonies.

C and **D.** Surface of EMB agar plates illustrating the green sheen produced by avid lactose (or sucrose) fermenting members of the *Enterobacteriaceae*. Most strains of *E. coli* produce colonies with this appearance of EMB agar, and since *E. coli* is among the most frequent isolates from clinical specimens, the appearance of such colonies can often serve as presumptive identification of *E. coli*. However, characteristics other than the production of a green sheen on EMB must be assessed before an organism can be definitely identified as *E. coli*, since other lactose-fermenting *Enterobacteriaceae* can have a similar appearance.

E and **F.** Surface of EMB agar plates illustrating a mixed culture of *E. coli* (green sheen colonies) and *Shigella* species. Most *Shigella* species do not ferment lactose, and thus produce nonpigmented, semitranslucent colonies on EMB agar. Other species incapable of fermenting lactose produce colonies that appear similar to those illustrated in these photographs.

G. Surface of MacConkey agar illustrating growth of red-pigmented colonies of *Serratia marcescens*. Note that this species is non–lactose-fermenting and that the colonies appear red due to pigment production, which must be differentiated from

the purple appearance of lactose-fermenting colonies as seen in Image Plate 6-2 A and B

H. Hypermucoviscous colonies of *K. pneumoniae* on BAP showing positive string test. String test is positive when an inoculation loop or needle is able to generate a viscous string >5 mm in length by touching the bacterial colony and raising the loop above the rim of the agar plate creating a string of bacteria.

IMAGE PLATE 6-3

APPEARANCE OF THE *ENTEROBACTERIACEAE* ON XLD AND HE AGAR PLATES

Several types of media more selective than MacConkey or EMB agars are commonly used in clinical microbiology laboratories for recovering select members of the *Enterobacteriaceae*. Xylose-lysine-deoxycholate (XLD) and Hektoen enteric (HE) agars are most commonly used; highly selective media such as bismuth sulfate agar are used only for special applications. These media not only have the capability of separating lactose fermenters from nonlactose fermenters but can detect hydrogen sulfide (H_2S)-producing microorganisms as well.

A. Surface of XLD agar illustrating yellow conversion of the medium from acid-producing colonies of *E. coli*.

B. Non–lactose-fermenting colonies (no acid conversion of the medium) of *Salmonella* species growing on the surface of XLD agar. Note the black pigmentation of some of the colonies, indicating H_2S production.

C. Photograph illustrating an XLD agar plate inoculated with a 50/50 mixture of *E. coli* and *Salmonella* species. Note the preponderant growth of the *Salmonella* species (red colonies) compared with the few yellow, lactose-fermenting colonies of *E. coli* that have been effectively inhibited. The distinct pink halo around the *Salmonella* colonies indicates the decarboxylation of lysine, a helpful feature in differentiating *Salmonella* species (positive) from H_2S-producing colonies of *Proteus* species.

D. XLD agar plate inoculated with an H_2S-producing strain of a *Proteus* species. Note the lack of a light pink halo around the colonies, indicating the lack of lysine decarboxylation (compare with the colonies shown in panel **C**).

E. Surface of HE agar illustrating yellow acid production by colonies of *E. coli*.

F. Surface of HE agar illustrating the faint green (colorless) colonies of non–lactose-fermenting members of the *Enterobacteriaceae*.

G. Thermo Scientific Remel Salmonella Shigella Agar (SS Agar) illustrating black colored colonies typical of H_2S-producing *Salmonella* species. The sodium thiosulfate and ferric citrate in the medium enable the detection of hydrogen sulfide production as evidenced by colonies with black centers.

H. Thermo Scientific Remel Salmonella Shigella Agar (SS Agar) illustrating growth of lactose-fermenting coliform bacteria. Organisms that ferment lactose produce acid, which in the presence of the neutral red indicator, results in the formation of red colonies.

IMAGE PLATE 6-4

DIFFERENTIAL CHARACTERISTICS OF THE *ENTEROBACTERIACEAE*

A. Ortho-nitrophenyl-D-galactopyranoside (ONPG) test showing a positive (yellow) reaction (left) compared with the negative control (right). A positive reaction indicates that the organism is capable of producing β-galactosidase, an enzyme required for the initial degradation of lactose, releasing the yellow-colored *ortho*-nitrophenol.

B. Sulfide indole motility (SIM) semisolid agar tube (right) and Kligler's iron agar (KIA) slant (left), illustrating the differences in sensitivity in detecting hydrogen sulfide (H_2S) by different media. The diffuse delicate blackening in the SIM tube is produced by a motile, weak H_2S-producing organism (in this case *S. enterica* serogroup Typhi). Note that the H_2S produced in the less sensitive KIA tube appears only in the middle of the tube at the interface of the slant and butt and is the typical appearance of *S.* Typhi in this medium.

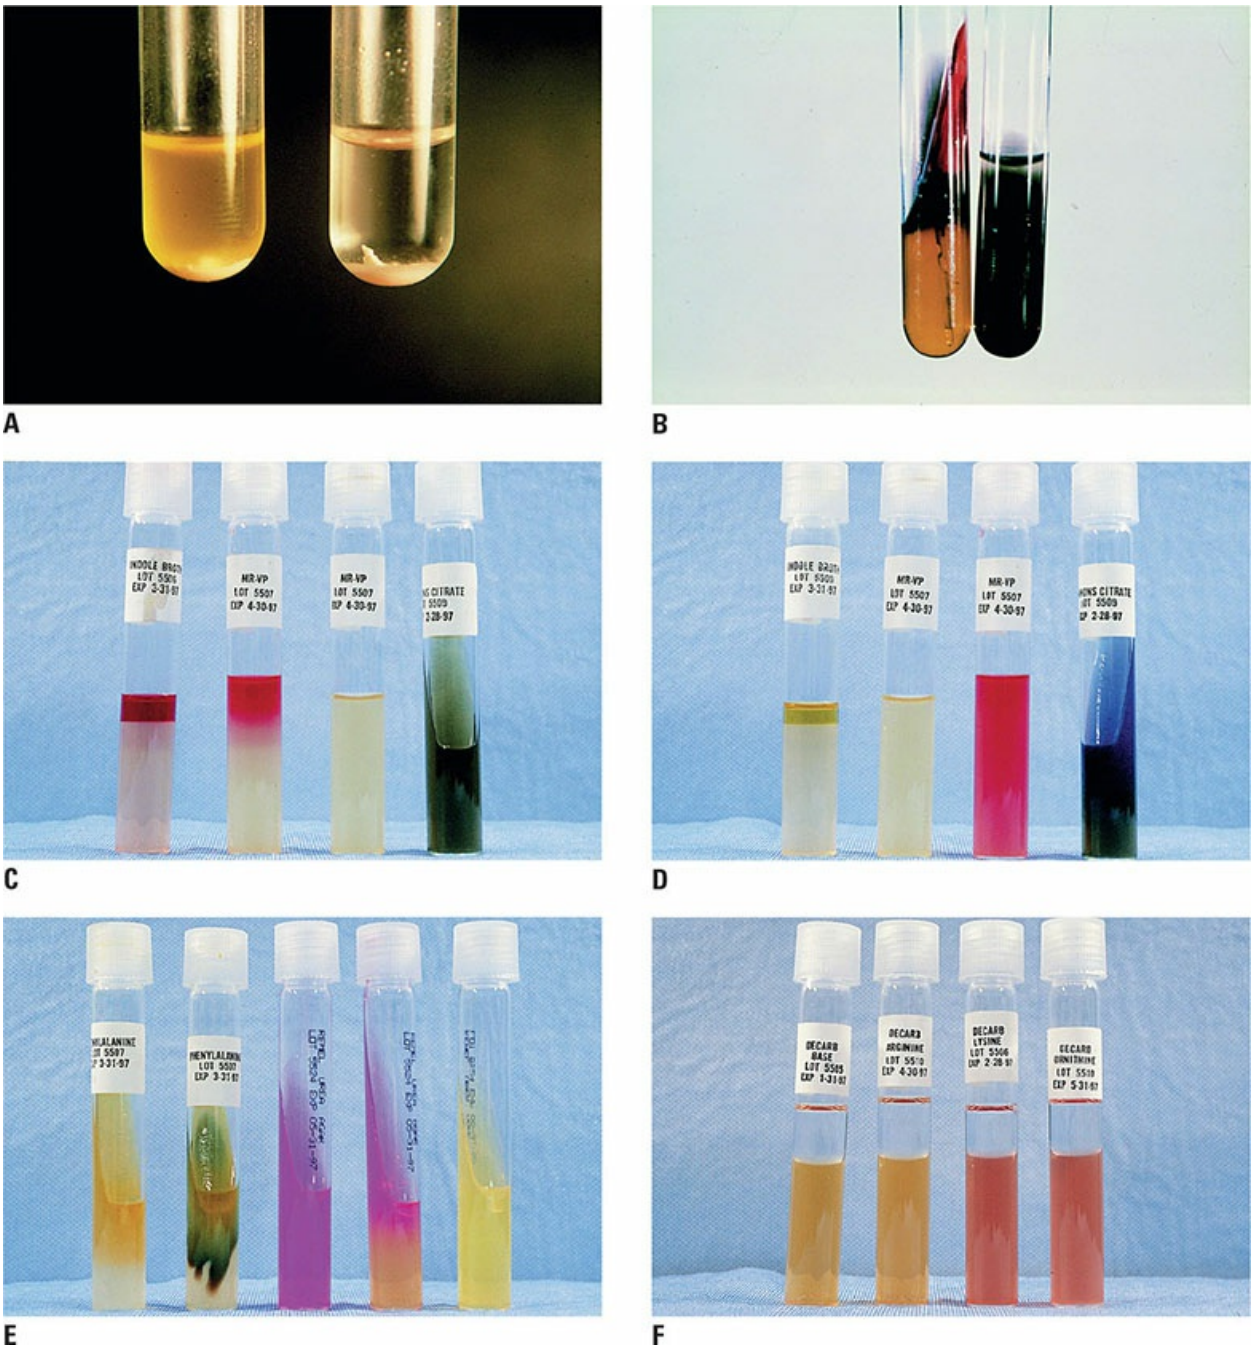
C and **D.** Four tubes demonstrating the indole (I), methyl red (MR), Voges-Proskauer (VP), and citrate (C) tests. These four tests when performed together constitute the classic IMViC reactions. The formation of indole from tryptophan is indicated by a red color on the addition of Kovac's reagent (far left tube, panel **C**). The development of a red color in the MR tube indicates a drop in pH to 4.4 or below, indicative of strong mixed acid fermenters (second tube from left, panel **C**). A red color in the VP tube indicates the presence of acetoin (acetylmethylcarbinol) formed from pyruvate in the butylenes glycol metabolic pathway (third tube from left, panel **D**). Growth on the slant of Simmon's citrate agar and conversion of the bromthymol blue indicator to an alkaline blue color indicates that the organism can utilize sodium citrate as the sole source of carbon (right most tube, panel **D**). **C** shows the reactions for *E. coli* (+, +, −, −). Panel **D** shows the reactions for *Klebsiella/Enterobacter* (−, −, +, +).

E. The two tubes on the left show negative (light yellow) and positive (dark green) phenylalinine deaminase reactions. The green color is produced by the reaction between the $FeCl_3$ reagent and phenylpyruvic acid in the medium, resulting from the deamination of phenylalinine (Chart 6-8). The three tubes on the right are Christensen's urea agar slants. The third from the right shows a strong positive reaction (red color throughout the medium, indicating an alkaline reaction from the degradation of urea), compared with the negative control on the far right (yellow

color throughout). The reaction in the second tube from the right (red color in slant only) is produced by organisms such as *Klebsiella* species and certain *Enterobacter* species that are weak urease producers.

F. Four tubes containing Møller decarboxylase medium covered with a layer of mineral oil to effect an anaerobic environment (Chart 6-7). From left to right: A growth control tube devoid of the amino acids (growth is indicated by conversion to a yellow color due to the fermentation of glucose in the medium), arginine, lysine, and ornithine. The bromcresol purple indicator is yellow at an acid pH and purple at an alkaline pH. Thus, any tube that appears purple indicates an alkaline pH, the reaction produced by organisms that can decarboxylate the amino acid contained in the medium. The organism pictured here is arginine-negative and lysine- and ornithine-positive and is the typical reaction seen with *E. aerogenes*.

IP-19



IP-20

G. Lysine iron agar (LIA) is used to differentiate enteric organisms based on their ability to decarboxylate or deaminate lysine and to form H_2S. Organisms that decarboxylate lysine produce an alkaline (purple) reaction in the butt of the tube (middle tube). Organisms that deaminate lysine produce a red slant over an acid (yellow) butt (leftmost tube). Bacteria that produce H_2S cause blackening of the

medium mainly in the middle and the butt of the tube (also seen in tube on far left). The tube on the far left is lysine deaminase–positive and lysine decarboxylase–negative. The middle tube is lysine deaminase–negative and lysine decarboxylase–positive. The tube on the far right is negative for both lysine deaminase and lysine decarboxylase. (Butt reddish but not yellow.)

H. Tubes of motility medium. Motile organisms will show diffuse growth away from the line of inoculation (left tube); nonmotile organisms show growth only along the stab line (right tube). Also available is motility medium to which 2,3,5-triphenyltetrazolium chloride (TTC) is added. Growth of organisms capable of reducing TTC will appear red along the stab line as well as in the area into which the cells have migrated, making it easier to differentiate between motile and nonmotile bacteria (Image Plate 7-1E). (Photo courtesy of Health and Education Resources, Bethesda, MD.)

IP-22

Human Plague

A. Hematogenous dissemination of *Y. pestis* from the portal of entry to other organs and tissues may cause intravascular coagulation and endotoxic shock, producing small hemorrhages on the skin. (CDC, Public Health Image Library.)

B. Gram stain of *Y. pestis* showing short, plump, gram-negative rods with bipolar staining. Organisms appear pink at the polar ends with a white area or nonstaining

in the center.

C. Peripheral blood smear stained with Wright's stain showing "safety pin" appearance of *Y. pestis*. Bacteria stain dark blue, leukocytes stain light blue with purple-staining nuclei, erythrocytes stain light tan. (CDC, Public Health Image Library.)

D. Colonies of *Y. pestis* growing on a blood agar plate at 72 hours. *Yersinia pestis* grows well on most standard laboratory media, after 48-72 hours, showing gray-white to slightly yellow opaque raised, irregular "fried egg" morphology; alternatively colonies may have a "hammered copper" shiny surface. (CDC, Public Health Image Library)

Chromogenic Agar

E. BBL CHROMagar O157 is designed for use as a primary plate for stool cultures when screening for *E. coli* O157. Distinguishes *E. coli* O157 (mauve colonies) from *E. coli* non-O157 (blue colonies). Also inhibits most *Proteus*, *Pseudomonas*, and *Aeromonas* strains using selective agents. (Courtesy of BD Diagnostic Systems.)

F and **G.** BBL CHROMagar Orientation medium is a non-selective, differential medium for presumptively identifying bacterial isolates from primary clinical specimens. Allows isolation and presumptive identification of both gram-positive and gram-negative pathogens with a single plate. Useful for identification and enumeration of urinary tract pathogens. Identifies *E. coli* (pink colonies) and *Enterococcus* (blue or turquoise colonies, small) from primary plate. Frame **F** shows Orientation agar with a pure culture of *E. coli*. Frame **G** shows a mixed culture of *E. coli* and *Enterococcus* together with some colonies of *Proteus* spp. (beige with brown halo) (Courtesy of BD Diagnostic Systems.)

H. BBL CHROMagar *Salmonella* is designed for use in *Salmonella* screening of either clinical or industrial samples. Detects *Salmonella* with a highly specific chromogenic reaction (purple colonies with purple halo), while minimizing interference from other hydrogen sulfide-producing colonies such as *Proteus* and *Citrobacter* spp. (Courtesy of BD Diagnostic Systems.)

IMAGE PLATE 6-6

COMMERCIAL IDENTIFICATION SYSTEMS

A number of commercially manufactured identification systems are currently available that contain stable reagents and media designed for determining biochemical characteristics. These products range from those that are inoculated and read manually to those that are fully automated.

A. API 20E strips illustrating method of inoculation and the appearance of a strip following inoculation and incubation. A suspension of the organism to be tested is transferred with a pipette into each of the 20 media compartments. Color reactions are read after 18 to 24 hours of incubation at 35°C. The manufacturer supplies worksheets for recording the visual interpretation of the color reactions, which are then converted into a seven-digit biotype number.

B. The BBL Crystal Enteric/Nonfermenter identification system contains a lid with 30 dehydrated substrates on the tips of the plastic prongs. A test suspension is prepared and added to all 30 wells in the base unit. The lid is then aligned with the base and snapped in place, whereby the test inoculum rehydrates the dried substrates and initiates test reactions. After incubation, panels are read upside-down using the BBL Crystal light box. The wells are examined for color changes and a 10-digit profile number is generated and entered on a personal computer in which the BBL Crystal Electronic codebook has been installed, to obtain the identification.

C. The REMEL RapID ONE (Oxidase-Negative *Enterobacteriaceae*) panel has 19 substrates for identification of over 70 organisms belonging to the family *Enterobacteriaceae*. The system consists of a plastic tray with 18 reaction cavities. Reaction cavities contain dehydrated reactants, and the tray allows the simultaneous inoculation of each cavity with a predetermined amount of inoculum. Test 18 is bifunctional, containing two separate tests in the same cavity. Each test is interpreted visually for color changes after 4 hours of incubation at 35°C. The 19 test results plus oxidase are scored in the appropriate boxes of the report form and a seven-digit profile code is generated similar to that shown in A. The biocode number is entered on a PC in which the ERIC (Electronic RapID Compendium) has been installed, to obtain the identification.

D. Biolog GN Microplate system consisting of a 96-well microtiter plate containing 95

carbon substrates and a redox indicator-tetrazolium dye. If a carbon substrate is utilized by the inoculated bacteria, the colorless dye is irreversibly reduced and forms a purple color. With the use of a computer screen, purple wells are coded as positive and colorless wells are coded as negative. The computer then matches the metabolic profile of the inoculated organism with those in the database and generates the most likely identification.

E and **F.** In the MicroScan gram-negative ID panel, the microtiter wells are inoculated with a heavy suspension of the organism to be identified and incubated at 35°C for 15 to 18 hours. The panels can be interpreted visually (Frame **E**), after which the biochemical results are converted into a seven- or eight-digit biotype number that is looked up in a codebook that is supplied by the manufacturer. An automated tray reader, autoSCAN-4 System, can also be used along with the LabPro information manager. Some trays also include antibiotics for performing both microdilution susceptibility testing and bacterial identification in the same panel. The same panels can also be used with the fully automated WalkAway System. (Frame **F**) The instrument processes both rapid and conventional overnight panels on one system and is available in both 40 and 96 panel capacity models. (Courtesy of Dade Behring.)

G. The VITEK2 is a system from bioMérieux that performs bacterial identification and susceptibility testing analyses using a standardized inoculum. The VITEK 2 features the AES (Advanced Expert System) that integrates artificial intelligence technologies in the VITEK 2 instrument. AES interprets the results of the antibiotic susceptibility test using a highly developed knowledge database. This base contains

most of the known resistance mechanisms (approximately 2,000 phenotypes, 20,000 MIC distributions). (Courtesy of bioMérieux.)

H. The BD PHOENIX Automated Microbiology System for Identification and Susceptibility Testing offers fully automated ID and susceptibility testing with no off-line tests, handwritten labels, or reagent additions required. The sealed test panel never moves once placed inside, so it cannot dislodge, jam, crack, or leak while in the instrument. The PHOENIX comes with integrated software combined with the BD EpiCenter (Courtesy of BD Diagnostic Systems.)

IP-28

IMAGE PLATE 7-1

IMPORTANT CHARACTERISTICS FOR DISTINGUISHING NONFERMENTATIVE GRAM-NEGATIVE BACILLI

A. Detection of fermentation. The Kligler's iron agar (KIA) tube on the right shows an alkaline slant/alkaline butt reaction characteristic of a nonfermenting organism; the tube on the left shows an alkaline slant/acid deep reaction, indicating fermentation of glucose but nonfermentation of lactose (characteristics of lactose-negative species of the *Enterobacteriaceae*). No acid production in KIA or in triple sugar iron (TSI) agar indicates the inability of nonfermenting bacteria to utilize the lactose or glucose in KIA (or the lactose, glucose, or sucrose in TSI).

B. Cytochrome oxidase test. The formation of a blue color within 10 seconds after smearing a test colony on filter paper saturated with the oxidase reagent (tetramethyl- *p*-phenylenediamine dihydrochloride) indicates cytochrome oxidase activity, a characteristic helpful in identifying many species of nonfermenters. All members of the *Enterobacteriaceae* are cytochrome oxidase-negative.

C. Failure to grow on MacConkey agar or inhibited growth on MacConkey agar is a clue that a gram-negative rod may be a nonfermenter. Although many species of nonfermenters are capable of growing on MacConkey agar, the lack of growth on this medium, as illustrated on the right side of this split frame, excludes the *Enterobacteriaceae*, all members of which grow well on MacConkey (left side).

D. Oxidative utilization of glucose. Illustrated here are two tubes of Hugh–Leifson oxidative fermentative (OF) medium. The tube on the right is open to the atmosphere, whereas the tube on the left is covered with mineral oil to exclude exposure to atmospheric oxygen. Acid (yellow) is seen only in the top portion of the open tube, indicating that the organism is capable of oxidizing glucose but incapable of fermenting glucose.

E. Tubes of Motility B medium containing 2,3,5-triphenyltetrazolium chloride (TTC). Motility is often difficult to observe with nonfermentative bacteria since the organisms tend to grow only in the upper (most aerobic) portion of the tube. The addition of tetrazolium aids in detecting motility because organisms capable of reducing TTC will appear red along the stab line as well as in the area into which the cells have migrated, making it easier to differentiate between motile (left) and nonmotile (right) bacteria.

F. Blood agar plate inoculated with a yellow pigment-producing bacterium. Pigment production is an important differential characteristic in identifying nonfermentative gram-negative bacilli. The organism depicted here is *Sphingomonas paucimobilis*.

G. Tubes of Flo and Tech agar inoculated with *Pseudomonas aeruginosa* viewed under visible light. These media are used to enhance the production of two pigments: pyoverdin (fluorescein), which appears as a yellow diffusible pigment on Flo agar (left) in visible light, and pyocyanin, which appears as a turquoise-blue pigment on Tech agar (right) in visible light. Although three species of nonfermenting bacilli produce pyoverdin (*P. aeruginosa, P. fluorescens*, and *P. putida*), only one species (*P. aeruginosa*) produces pyocyanin.

H. Tubes of Flo and Tech agar inoculated with *Pseudomonas aeruginosa* viewed under ultraviolet (UV) light using a Wood's lamp. Note that the Flo agar tube (left) fluoresces, while the Tech agar tube (right) does not fluoresce under UV light. Only pyoverdin pigment, which is enhanced by growing the organism on Flo agar,

fluoresces under UV light.

IP-30

IMAGE PLATE 7-2

Tests Used in the Identification of Nonfermentative Gram-Negative Bacilli

A. Two tubes of Christensen's urea illustrating the fuchsia red color of a positive test (right) compared with a negative control (left). A rapid positive urease reaction (4 hour) is seen with the following species of nonfermentative bacilli: *Bergeyella zoohelcum, Bordetella bronchiseptica, Cupriavidus pauculus,* and *Oligella ureolytica*.

B. Two tubes demonstrating nitrate reduction (left) and nitrite reduction (right). Both tubes contain a Durham tube to demonstrate nitrogen gas formation. The tube on the left depicts the reduction of nitrate to nitrogen gas, and the tube on the right demonstrates the reduction of nitrite to nitrogen gas. Note that there is more gas formed in the tube on the right, indicating that quantitatively more nitrogen gas is formed from nitrite than nitrate during the same incubation period. Production of gas from both nitrate and nitrite is typical of the *Pseudomonas stutzeri* group and *Achromobacter denitrificans*.

C. Three tubes of heart infusion broth showing a positive indole reaction (left), an orange indole reaction (center), and a negative indole reaction (right). The reactions shown here were obtained using the xylene extraction method followed by the addition of Ehrlich's reagent (Chart 1-4). A positive indole reaction is noted by the appearance of a red band at the interface of the tryptophan broth and the xylene layer. The indole-positive nonfermentative bacilli include *Balneatrix, Bergeyella, Chryseobacterium, Elizabethkingia, Empedobacter, Weeksella,* and some unnamed CDC groups. A peculiar orange indole reaction (center tube) is observed with *Delftia acidovorans* and is due to the formation of anthranilic acid from tryptophan by this bacterium. An orange pigment is produced upon the addition of either Ehrlich's of Kovac's reagent. The reaction may take over 1 hour to develop following the addition of reagents.

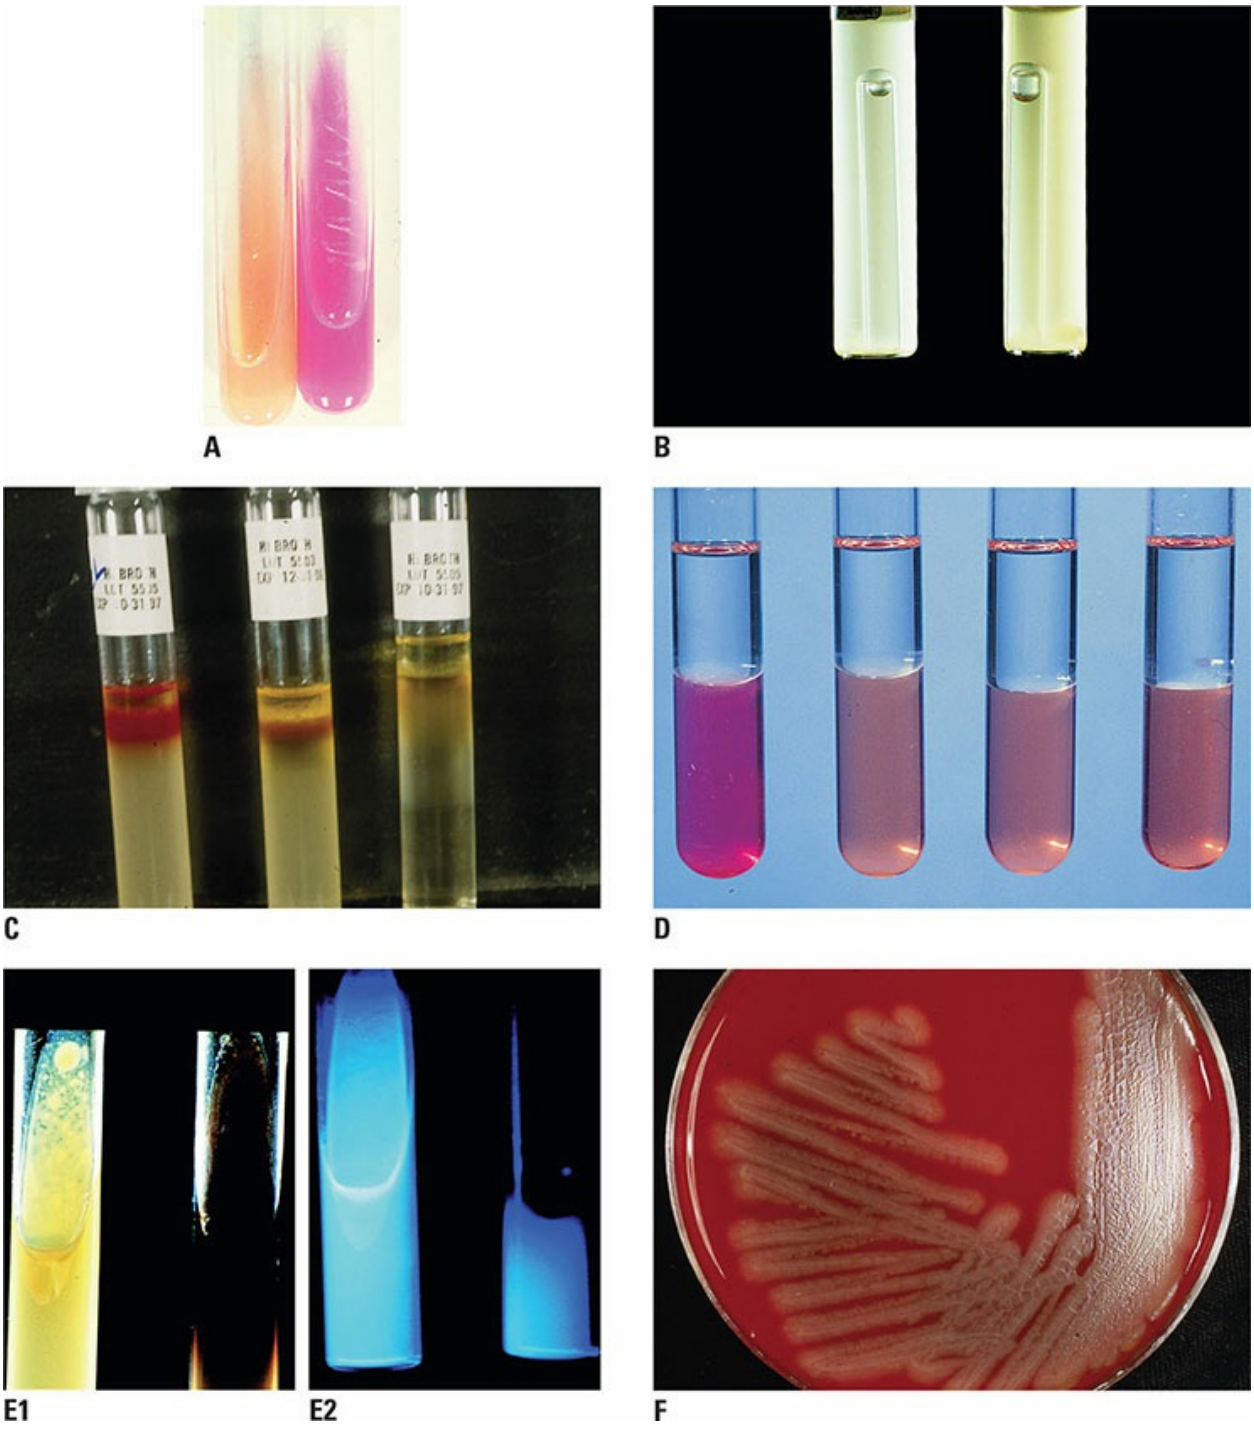
D. Four tubes of Møller decarboxylase medium covered with a layer of mineral oil. Reading from left to right: lysine, arginine, ornithine, and the control tube which is devoid of amino acid. With the nonfermentative bacilli, negative tests remain the same color as the original uninoculated tubes, while positive decarboxylation reactions appear darker purple owing to the formation of alkaline amines causing a more alkaline pH in the tube. The positive lysine decarboxylase reaction illustrated

here occurs with only two species of nonfermenting bacilli: *Stenotrophomonas maltophilia* and *Burkholderia cepacia* complex.

E. Split frame showing two tubes of esculin agar viewed under visible light (left), and the same two tubes viewed under ultraviolet light from a Wood's lamp (right). When esculin is hydrolyzed by a microorganism, the glycoside esculin is converted to esculetin and glucose. The esculetin reacts with an iron salt (ferric citrate) in the medium to form a dark brown of black complex (second tube from left). The production of a dark brown of black pigment may be difficult to discern if the organism itself produces a brown or deep-colored pigment. Since esculin is a fluorescent compound, true esculin hydrolysis can be determined by observing for the absence of fluorescence. The brightly fluorescing tube in the right frame (second tube from the far right) depicts the reaction observed with a negative esculin reaction. The tube on the far right shows marked squelching of fluorescence, particularly in the slant, indicating that the test organism is capable of hydrolyzing esculin.

F. Blood agar plate demonstrating the typical appearance of *Pseudomonas aeruginosa* after 24-hour incubation at 35°C. Colonies are large with a spreading periphery and are frequently beta hemolytic. Colonies in the heaviest area of growth appear to have a metallic sheen and a scaling appearance sometimes described as alligator skin morphology. Colonies appearing like this typically produce a sweet grape-like odor.

IP-31



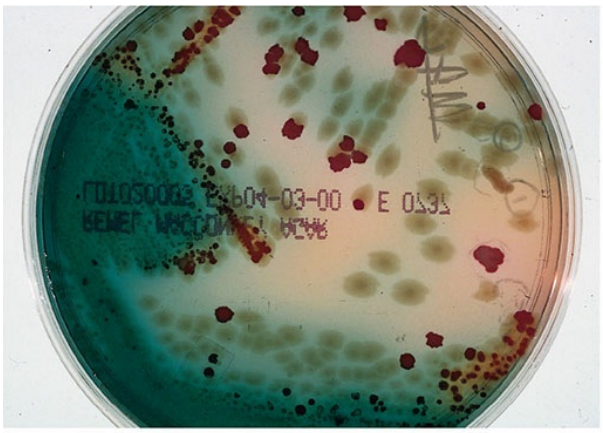
IP-32

G. MacConkey agar plate demonstrating growth of two colony types. The dark purple colonies are lactose-positive and have the typical appearance of *E. coli*. The lactose-negative colonies are producing a turquoise-blue diffusible pigment

noted best in the area of heaviest growth. This is the typical appearance of colonies of *Pseudomonas aeruginosa* that are producing pyocyanin.

H. MacConkey agar plate demonstrating growth of a mucoid variety of *Pseudomonas aeruginosa* typical of the strains isolated from the sputum of patients with cystic fibrosis. Colonies can be extremely mucoid and runny. Note that several colony variants can be seen, which is the typical presentation for these mucoid variants of *P. aeruginosa*. Note that in the heaviest growth area, there appears to be some pyocyanin pigment developing.

IP-33



G

H

IP-34

IMAGE PLATE 7-3

COLONIAL AND MICROSCOPIC MORPHOLOGY OF CERTAIN NONFERMENTATIVE BACILLI

Some species of nonfermentative gram-negative bacilli have characteristic features that can be observed on growth media or in Gram-stained preparations. An awareness of these functions can be an aid in making a correct species identification.

A. *Pseudomonas stutzeri* on blood agar medium. Note the characteristic dry, wrinkled colonies that are typical of this species. One should immediately think of *P. stutzeri* when an oxidase-positive, nonfermenting bacillus produces this type of colony on blood agar.

B. Blood agar plate showing the yellow, dry, and wrinkled appearance of *Pseudomonas luteola*. Colonies are often adherent to the agar and difficult to remove. Colonial morphology resembles that of *Pseudomonas oryzihabitans* and *Pseudomonas stutzeri*. Both *P. luteola* and *P. oryzihabitans* are oxidase-negative, while, *P. stutzeri* is oxidase-positive.

C. MacConkey agar (left) and BAP (right) inoculated with a pure culture of *Brevundimonas vesicularis*. Note that this organism fails to grow on MacConkey agar and appears as deeply yellow colored, slightly wrinkled colonies on BAP. This organism is also susceptible to vancomycin and resistant to polymyxin B, additional features that can help in identification.

D. Blood agar plate illustrating growth of *Stenotrophomonas maltophilia*. The dull yellow pigment is distinctive for this species but at times may be difficult to visualize. Colonies may also appear dark tan to lavender upon continued incubation, particularly if left at room temperature.

E. *Methylobacterium* species growing on Sabouraud dextrose agar. Colonies appear dry and exhibit a deep pink or coral pigmentation. These colonies absorb ultraviolet light and appear dark when held under a Wood's lamp.

F. Gram's stain of *Methylobacterium* species showing characteristic gram-negative bacilli containing vacuoles.

G. Gram's stain of *Roseomonas* species showing characteristic faint staining, gram-negative coccoid forms, some containing vacuoles.

H. *Roseomonas* species growing on Sabouraud dextrose agar. They appear as light pink, mucoid, almost runny colonies. Like *Methylobacterium* species, *Roseomonas* species grow best on Sabouraud's agar; however, they do not absorb UV light and do not appear dark when held under a Wood's lamp.

IP-36

IMAGE PLATE 7-4

Colonial and Microscopic Morphology of Certain Nonfermentative Bacilli

A. Blood agar plate demonstrating growth of *Alcaligenes faecalis* after 48 hours of incubation at 35°C. Colonies are white and glistening; in older cultures, colonies tend to spread at the outer border of the colonies and turn the agar green. This species typically gives off a fruity odor sometimes described as smelling like green apples.

B. MacConkey agar plate showing growth of *Rhizobium radiobacter*. Even though these bacteria are nonfermenters, they rapidly oxidize lactose and consequently appear as pink-colored, extremely mucoid colonies on MacConkey agar. These organisms can be easily confused with a lactose-positive fermenter; however, they are oxidase-positive, which readily excludes any members of the *Enterobacteriaceae*.

C. Blood agar plate showing growth of *Chryseobacterium indologenes*. Colonies have a deep yellow to orange appearance after 48 hours of incubation particularly if incubated at 30°C. Phenotypically these organisms are difficult to distinguish from *Chryseobacterium gleum*, and some laboratories choose to report such isolates as *C. indologenes/gleum.*

D. Blood agar plate showing characteristic growth of *Myroides odoratus*. Colonies have a deep yellow pigment and may be spready. Most strains exhibit a characteristic fruity odor like that of *Alcaligenes faecalis*.

E and **F.** A useful test for distinguishing between *Neisseria* species and *Moraxella* species is to grow the organisms on blood agar around a penicillin disk. Both organisms are susceptible to penicillin and will demonstrate a zone of inhibition around the penicillin disk (**E**). After overnight incubation, a Gram's stain can be performed on colonies taken from the edge of the zones of inhibition. *Neisseria* species are true cocci and in the presence of subinhibitory concentrations of penicillin will continue to stain as gram-negative diplococci (left side, F). *Moraxella* species are coccobacilli and in the presence of subinhibitory concentrations of penicillin will form bizarre rod-shaped cells (right side, F).

G. Blood (left) and MacConkey agar plates showing growth of *Paracoccus yeei* (CDC group EO-2) after 72 hours incubation at 30°C. Colonies appear white and

mucoid in appearance. On MacConkey agar, they appear slightly pink in color.

H. Gram's stain of *Paracoccus yeei* (CDC group EO-2) prepared from broth culture. These organisms stain peripherally giving the appearance of "O-shaped" cells.

IMAGE PLATE 7-5

Colonial and Microscopic Morphology of Certain Nonfermentative Bacilli

A. Gram's stain illustrating gram-negative coccobacilli. *Acinetobacter* and *Moraxella* species are the nonfermentative bacilli that characteristically have this staining morphology. The smear depicted here was made from a broth culture of *A. baumannii*. *Acinetobacter* species have a tendency to retain crystal violet and may appear gram-positive in some Gram's stain preparations particularly those made directly from positive blood culture bottles.

B. *Acinetobacter baumannii* on MacConkey agar showing a pink to light lavender appearance that is typical for this species. Often a bluish pigmentation may be observed, particularly striking in colonies grown on EMB agar, where it is described as a "cornflower blue" in appearance.

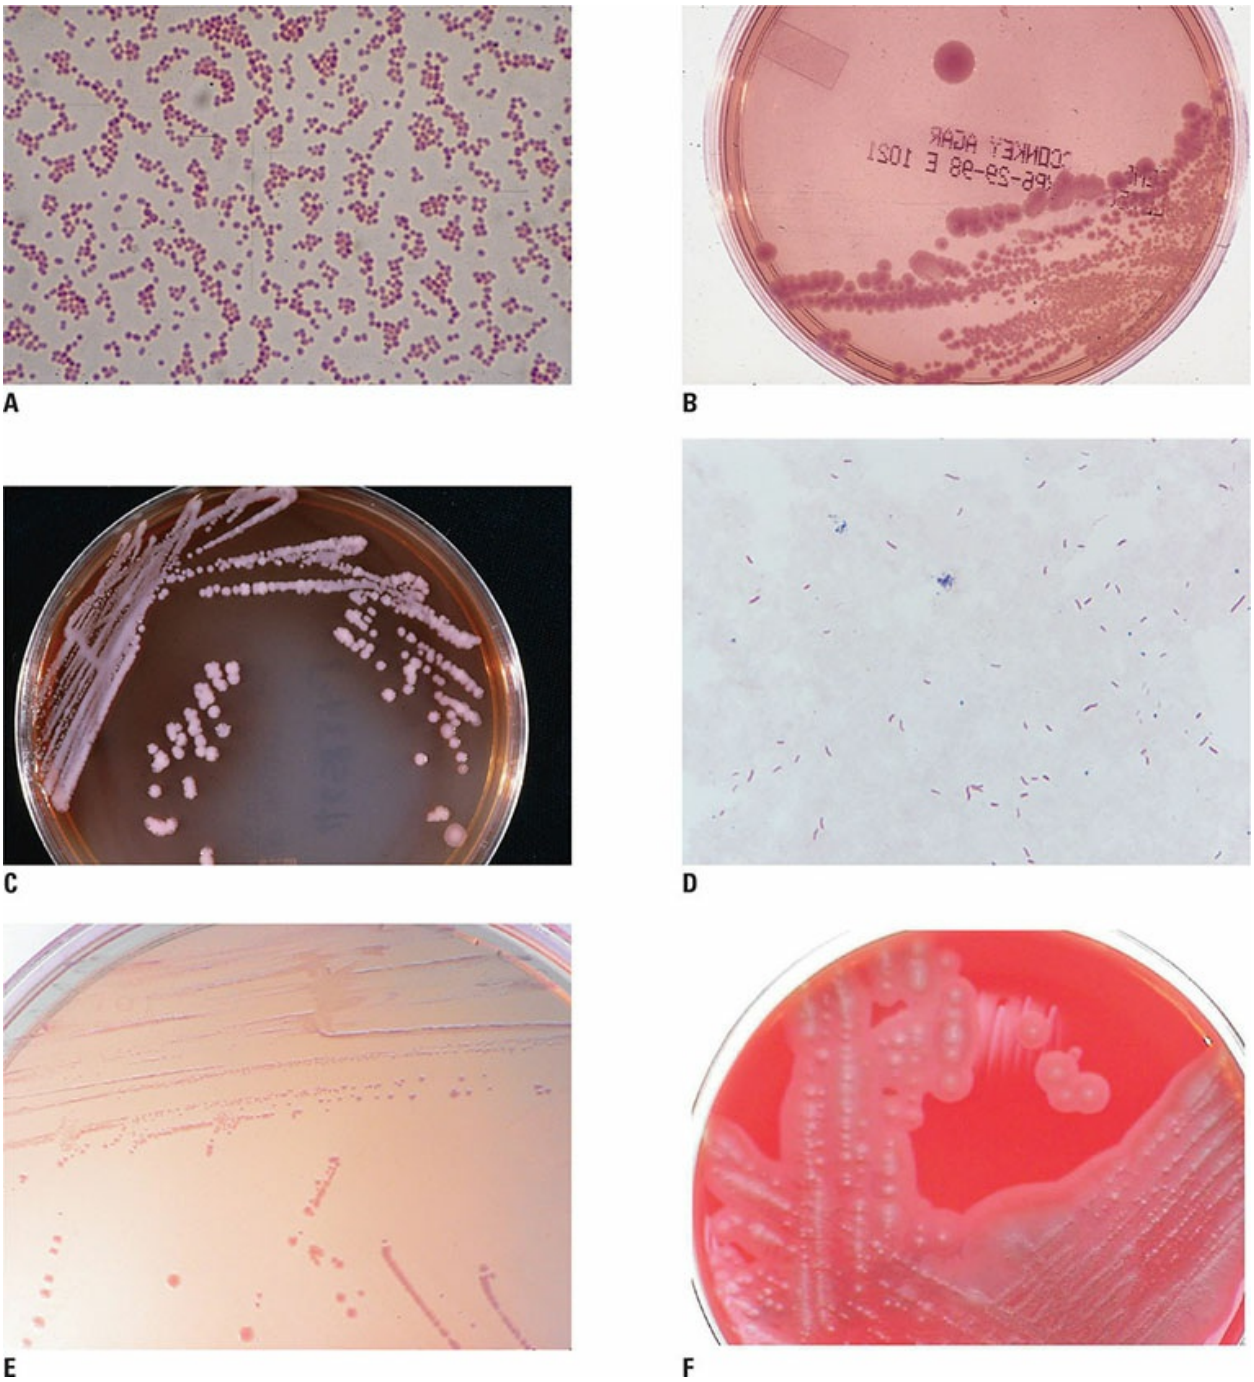
C. Certain glucose-oxidizing acinetobacters may produce a unique brown discoloration of heart infusion agar with tyrosine or blood agar into which glucose is incorporated. This phenomenon may also be observed on MacConkey and Mueller–Hinton agars. Shown here is a clinical isolate of *A. baumannii* producing a brown diffusible pigment on MacConkey agar.

D. Gram's stain of *Laribacter hongkongensis* prepared from 48-hour BAP. Note that the organisms appear as gram-negative, seagull-shaped or spiral rods.

E. *Laribacter hongkongensis* on MacConkey agar after 48-hour incubation in room atmosphere. Colonies are small and lactose-negative, but may have a lavender appearance similar to *Acinetobacter* species due to the uptake of crystal violet contained in the medium.

F. *Kerstersia gyiorum* on BAP at 24-hour incubation in room atmosphere. Colonies are gray, dull, and spread, giving a swarming appearance.

IP-39



IP-40

G. *Kerstersia gyiorum* on MacConkey agar at 24-hour incubation in room atmosphere. Colonies are small and lactose-negative with a characteristic spread appearance.

H-1. (Upper Frame) API 20 NE strips illustrating the 24-hour (top) and 48-hour

(bottom) reactions. Note that the first 8 tests (reading left to right) are conventional colorimetric reactions, while the remaining 12 tests are carbon assimilation reactions that are read as positive if turbid and negative in the absence of turbidity. Users of this system should note that the strip is incubated at 30°C rather than the usual 35°C used for most other commercial identification kits.

H-2. (Lower Frame) The Remel RapID NF Plus system consists of a plastic tray containing 10 reaction cavities. Seven of the reaction cavities (4 through 10) are bifunctional, containing two separate tests in the same cavity. The system is inoculated with a heavy suspension of the test organism and incubated for 4 hours at 35°C. Following incubation, bifunctional tests are first scored before the addition of reagent, providing the first test result (top row). The same cavities are scored again after the addition of reagent to provide the second test result (bottom row). The reactions obtained with these 17 tests plus oxidase provide 18 test scores.

IMAGE PLATE 8-1

LABORATORY IDENTIFICATION OF *CAMPYLOBACTER* SPECIES

A. Gram's stain of *Campylobacter jejuni* illustrating pleomorphic gram-negative bacilli, with short, curved, and spiral forms. Note that some cells connect to form gull-winged and "S" shapes.

B. *C. jejuni* growing on nonselective Brucella agar plate following isolation from stool using the membrane filter technique (described in text). Note that growth has occurred only in the area of the plate underneath where the filter had been placed.

C. Close-up view of *C. jejuni* on blood agar, illustrating raised, gray-white, and somewhat mucoid colonies.

D. Growth of *C. jejuni* on Campy BAP agar, illustrating the tendency of the organism to grow along the streak lines.

E. Tubes showing the rapid hippurate reaction. Purple color develops with the addition of Ninhydrin when hippurate has been hydrolyzed to form glycine and benzoic acid (positive tube on left compared with negative control on right). Of the *Campylobacter* species, only *C. jejuni* gives a positive hippurate reaction.

F. Brucella blood agar plate showing growth of *C. jejuni* around cephalothin and nalidixic acid disks. Note that with *C. jejuni* a zone of inhibition forms around the nalidixic acid disk (right), indicating that this species is susceptible to nalidixic acid but resistant to cephalothin. This test is easy to perform and allows presumptive identification of *C. jejuni*.

G. Triple sugar iron (TSI) agar slant reactions illustrating the hydrogen sulfide (H_2S) reactions of several species. The tube to the extreme left illustrates the lack of H_2S, characteristic of *C. jejuni, C. fetus* subsp. *fetus*, and *C. fetus* subsp. *venerealis*. Tubes 2, 4, and 5 (reading from left) illustrate a strong butt reaction, characteristic of *C. sputorum* biovar *bubulus*, *C. sputorum* biovar *fecalis,* or *C. sputorum* biovar *sputorum*. Tube 3 illustrates a strong slant reaction characteristic of *C. mucosalis*.

H. Silver-stained tissue section of superficial gastric mucosa demonstrating clusters of blue-black staining bacilli along the epithelial lining, consistent with the bacillary forms of *Helicobacter pylori*. When observed in a Gram-stained preparation, the

individual cells are long, thick, and curved.

IMAGE PLATE 8-2

LABORATORY IDENTIFICATION OF *VIBRIO CHOLERAE* AND OTHER *VIBRIO* SPECIES

A. Appearance of *Vibrio cholerae* on thiosulfate citrate bile sucrose (TCBS) agar. The yellow colonies result from citrate utilization and the formation of acid from utilization of the sucrose in the medium. The appearance of yellow colonies on this medium is virtually diagnostic of *V. cholerae*.

B. Colonies of *V. parahaemolyticus* growing on TCBS agar illustrating the characteristic semi-translucent, green-gray appearance.

C. Gelatin agar with white, opaque colonies of *V. cholerae*. Note the opalescence of the agar adjacent to the colonies, indicating hydrolysis and denaturation of the gelatin.

D. Gram's stain of *V. vulnificus* illustrating gram-negative bacterial cells with the curved, rod-shaped morphology typical of *Vibrio* species.

E. Positive string test with *V. cholerae*. When colonies of *V. cholerae* are mixed in a drop of 0.5% sodium deoxycholate, they produce a viscous suspension that can be drawn into a string when the inoculating loop is slowly raised from the side.

F. Positive slide agglutination test for *V. cholerae* using polyvalent O antiserum.

G. Blood agar plate illustrating the relatively large, intensely-hemolytic colonies of the El Tor biotype of *V. cholerae*.

H. Chicken erythrocyte agglutination test. Classical strains of *V. cholerae* do not agglutinate chicken erythrocytes (top), in contrast to the El Tor biotype (bottom), which is capable of agglutinating the erythrocytes.

IMAGE PLATE 9-1

IDENTIFICATION OF *HAEMOPHILUS* SPECIES AND *AGGREGATIBACTER*

A. A Gram-stained smear of centrifuged cerebrospinal fluid showing polymorphonuclear cells and scattered gram-negative bacilli of *Haemophilus influenzae*. These organisms characteristically appear as small, poorly staining coccobacilli on Gram's stains of clinical specimens. Occasionally, longer, filamentous bacilli may be seen.

B. Growth of moist, smooth, gray colonies of *H. influenzae* type b on chocolate agar after 24 hours of incubation at 35°C to 37°C in 5% to 7% CO_2. This medium contains hematin (X factor) and is enriched with other cofactors, such as NAD (V factor), that allow the growth of *Haemophilus* and other fastidious microorganisms.

C. Satellite growth of *Haemophilus* around streaks of *Staphylococcus aureus* on sheep blood agar. X factor, or hemin, is provided by the lysed sheep erythrocytes surrounding the *Staphylococcus* streak, while the staphylococci themselves provide the V factor, or NAD. These factors enable the tiny, dewdrop colonies of *Haemophilus* to grow adjacent to the *Staphylococcus* streak.

D. Growth factor test for identification of *H. influenzae*. The organism is inoculated onto a plate of trypticase-soy or brain–heart infusion agar, and disks containing X factor and V factor are placed in proximity to one another on the inoculated plate surface. After incubation in a CO_2-enriched environment at 35°C to 37°C, factor requirements are determined by observing the pattern of organism growth relative to the two disks. In this picture, growth is observed between the X factor and V factor disks, indicating that the organism requires both exogenous X and exogenous V factors for growth.

E. Growth factor test for *Haemophilus parainfluenzae*. The organism is inoculated as described for **D** above, but in this photograph, filter paper strips that are impregnated with X factor, V factor, and both X and V factors are placed on the lawn of inoculum. After incubation in a CO_2-enriched environment at 35°C to 37°C, growth is observed around the V factor strip and around the XV factor strip, but not around the X factor strip. This growth pattern indicates that the organism requires only V factor for growth.

F. The ALA–porphyrin agar test. This is an alternative method for determining the X factor requirements of *Haemophilus* isolates. The agar medium contains δ-aminolevulinic acid (ALA). Organisms are inoculated onto the medium, and after overnight incubation at 35°C to 37°C in a CO_2-enriched environment, the growth is observed under a Wood's (ultraviolet) light. If the colony growth fluoresces "brick red," the organism is able to synthesize X factor (hemin) from ALA and does not require exogenous X factor. This picture shows growth of both *H. influenzae* (left), with its negative ALA-porphyrin test (i.e., requires exogenous hemin for growth), and *H. parainfluenzae* (right), with its positive ALA-porphyrin test (i.e., synthesizes hemin from ALA).

G. ALA-porphyrin disk method. This picture also shows the ALA-porphyrin test, but in this approach, a δ-aminolevulinic acid-impregnated disk is used. The disk is moistened with water, and some of the colony growth is rubbed onto the surface of the disk. After incubation for 4 hours at 35°C to 37°C, the disks are observed in the dark under a Wood's light. If the disk fluoresces "brick red," the organism is able to synthesize its own X factor. If no fluorescence is observed, the organism requires exogenous X factor. In this picture, *H. influenzae* (left) shows no fluorescence (i.e., requires exogenous X factor), while *H. parainfluenzae* (right) shows fluorescence (i.e., synthesizes X factor from ALA).

H. Nitrate reduction and biotyping reactions for *H. influenzae* biotype I. Isolates of *H. influenzae* and *H. parainfluenzae* reduce nitrate to nitrite and can be grouped into distinct biotypes by their reactions in three biochemical tests: production of indole, ornithine decarboxylase, and urease. This picture shows the nitrate and biotyping reactions of *H. influenzae* biotype I. Tests shown (left to right) are a positive nitrate reduction test, indole production in tryptone broth following Xylene extraction (positive), Møller's decarboxylase broth base (negative), Møller's ornithine decarboxylase broth (positive), and a urea slant (positive).

IMAGE PLATE 9-2

IDENTIFICATION OF *HAEMOPHILUS* SPECIES (CONTINUED)

A. The MicroScan *Haemophilus-Neisseria* Identification (HNID) panel (Dade-MicroScan, West Sacramento, CA). The manual microtiter format system identifies both *Haemophilus* and *Neisseria* species and provides biotype designations for *H. influenzae* and *H. parainfluenzae*. This picture shows a panel inoculated with *H. influenzae* biotype I (urease [URE]-positive, ornithine decarboxylase [ODC]-positive, and indole [IND]-positive. (Courtesy of Dade-MicroScan.)

B. A lesion of chancroid on the external female genitalia. Lesions of chancroid may resemble chancres of syphilis; however, chancroid lesions are usually painful and soft, while lesions of primary syphilis are usually painless and indurated. The etiologic agent of chancroid, *Haemophilus ducreyi*, may be cultured from these lesions.

C. RapID NH panel (Remel) inoculated with *H. ducreyi*. The top panel is before addition of reagents to the three bifunctional wells of the cuvette (PO_4/NO_2, ORN/NO_3, and URE/IND), while the bottom panel is after reagent addition for development of the NO_2, NO_3, and IND reactions. The only positive reactions observed with *H. ducreyi* on the RapID NH panel are the phosphatase reaction (top, eighth reaction from the left [yellow]) and the nitrate reductase reaction (bottom, ninth reaction from the left [red]).

D. Gram-stained smear of *Aggregatibacter aphrophilus*, showing small, pale-staining coccobacilli.

E. Growth of *A. aphrophilus* on sheep blood agar (left) and chocolate agar (right) after 48 hours of incubation at 35°C to 37°C in 5% to 7% CO_2. *A. aphrophilus* does not require either exogenous X or V factors and, consequently, is able to grow on sheep blood agar. Colonies are characteristically small and have a slight yellowish pigmentation.

F. *Haemophilus paraphrophilus* on sheep blood agar (left) and chocolate agar (right) after 48 hours of incubation at 35°C to 37°C in 5% to 7% CO_2. *H. paraphrophilus* is biochemically identical to *A. aphrophilus*, but it requires V factor for growth. Consequently, *H. paraphrophilus* grows on chocolate agar

(right) but not on sheep blood agar (left).

G. Biochemical tests for identification of *A. aphrophilus*. The tubes shown in this photograph (left to right) include nitrate broth, indole–tryptone broth, Møller's decarboxylase base broth, Møller's lysine decarboxylase broth, Møller's ornithine decarboxylase broth, and a urea agar slant. As shown here, *A. aphrophilus* is nitrate-positive, but negative for indole, lysine decarboxylase, ornithine decarboxylase, and urease.

H. Rapid carbohydrate utilization tests for *A. aphrophilus*. In this procedure, a balanced salts-phenol red solution (BSS) is dispensed in a series of tubes in 0.10-ml aliquots. A single drop of a filter-sterilized carbohydrate solution (20% w/v) is added to each tube. A heavy suspension of the organism is prepared in the BSS without added carbohydrate, and a single drop of this suspension is added to each of the BSS-carbohydrate tubes. After 4 hours of incubation at 35°C to 37°C, the reactions are interpreted. With the production of acid, the phenol red indicator turns from red to yellow. In this frame, the tubes (left to right) are the BSS organism suspension (without added carbohydrate), BSS with glucose (G), maltose (M), sucrose (S), lactose (L), mannitol (MN), xylose (X), and mannose (MA). As can be seen from these reactions, *A. aphrophilus* produces acid from glucose, maltose, sucrose, lactose, and mannose, but not from mannitol or xylose. Details of this procedure, which can also be used for identifying *Neisseria* species, are presented in Chart 11-1.

IMAGE PLATE 9-3

Aggregatibacter, *Cardiobacterium*, and *Eikenella* Species

A. Gram-stained smear of *Aggregatibacter actinomycetemcomitans*, showing the pale-staining, gram-negative bacilli and coccobacilli of this species.

B. *A. actinomycetemcomitans* growing on chocolate agar after 72 hours of incubation at 35°C to 37°C in 5% to 7% CO_2.

C. Rapid carbohydrate utilization tests for *A. actinomycetemcomitans*. As shown here, *A. actinomycetemcomitans* produces acid from glucose (G), mannitol (MN) and mannose (MA), but not from maltose (M), sucrose (S), lactose (L), or xylose (X). Failure to produce acid from lactose, along with a positive catalase test, helps to differentiate *A. actinomycetemcomitans* from *A. aphrophilus* (see Image Plate 9-2H above) Nitrate reduction, lysine and ornithine decarboxylases, and urease reactions are the same for both *A. actinomycetemcomitans* and *A. aphrophilus* (see Image Plate 9-2G above).

D. Gram-stained smear of *Cardiobacterium hominis*. These organisms are often gram-variable, but are staining uniformly gram-negative in this photograph. The cells of *C. hominis* are generally longer than the other HACEK bacteria and show considerable pleomorphism (e.g., cells with pointed or swollen ends, teardrop-shaped and dumbbell-shaped cells, etc.). The characteristic palisading of the cells in "picket fence" arrangements and the clustering of cells to form compact rosettes are also evident in this picture.

E. Growth of *C. hominis* on sheep blood agar after 72 hours of incubation at 35°C to 37°C in 5% to 7% CO_2. Colonies of this organism are small, opaque, and glistening. Some strains may also pit the agar like *E. corrodens*.

F. Gram-stained smear of *Eikenella corrodens*. The cells of *E. corrodens* appear as "regular" gram-negative bacilli, and are not coccobacillary or pleomorphic like other members of the HACEK bacteria.

G. Growth of *E. corrodens* on sheep blood agar after 72 hours of incubation at 35°C to 37°C in 5% to 7% CO_2. The incident light on the plate in this photograph demonstrates the pitting of the agar surface that is characteristic of most strains. Nonpitting strains may also be identified, and both pitting and nonpitting variants may be observed in the same culture.

H. Biochemical tests for identification of *E. corrodens*. The tubes shown here are (left to right) nitrate broth, indole–tryptone broth, Møller's decarboxylase base, Møller's lysine decarboxylase broth, Møller's ornithine decarboxylase broth, and a urea slant. *E. corrodens* is nitrate-positive, urease-negative, and is the only HACEK member that is both lysine and ornithine decarboxylase–positive. *E. corrodens* also differs from the other HACEK bacteria in not producing acid from carbohydrates either fermentatively or oxidatively.

IMAGE PLATE 9-4

KINGELLA, *CAPNOCYTOPHAGA*, AND *DYSGONOMONAS* SPECIES

A. *Kingella kingae* on sheep blood agar. The plate on the left is after 24 hours of incubation at 35°C to 37°C in 5% to 7% CO_2, while the plate on the right is the same isolate after 48 hours of incubation. The β-hemolysis produced by this organism may be apparent only underneath and immediately adjacent to the colony after 24 hours of incubation, but after 48 hours of incubation, the β-hemolysis is more apparent.

B. Colonies of *Kingella denitrificans* on chocolate agar after 24 hours of incubation at 35°C to 37°C in 5% to 7% CO_2. Colonies of this organism resemble the small colony types of *Neisseria gonorrhoeae*.

C. RapID NH panel (Remel) inoculated with *K. denitrificans*. Two identical panels are depicted in this photograph. The upper panel is before the addition of nitrate and indole reagents to the appropriate bifunctional cuvette wells. Positive reactions on the panel for this oxidase-positive, catalase-negative organism include prolyl aminopeptidase (PRO), glucose fermentation (GLU), and positive nitrite reduction (NO_2), and nitrate reduction (NO_3) tests. All other test results are negative.

D. Human isolate of *Capnocytophaga* species on sheep blood agar after 48 hours of incubation at 35°C to 37°C in 5% to 7% CO_2. This photograph shows the characteristic colony morphology of these organisms and illustrates the fringe of "gliding motility" at the periphery of the colonies. Toward the centers of the areas of growth, the colonies have a mottled appearance.

E. Gram-stained smear of human *Capnocytophaga* species. These organisms characteristically appear as gram-negative, slightly curved, fusiform bacilli with pointed ends. In this respect, these bacteria resemble the obligately anaerobic species *Fusobacterium nucleatum*.

F. Colonies of *Capnocytophaga canimorsus* on sheep blood agar after 5 days of incubation at 35°C in 5% to 7% CO_2. Colonies of this species are entire, circular, convex, and shiny, as shown here.

G. Gram-stained smear of *C. canimorsus*. This photograph shows the fusiform cells typical of the genus. Like the *Capnocytophaga* species that are found in the

human oropharynx, some of the cells of this species are also slightly curved.

H. Colonies of *Dysgonomonas capnocytophagoides* (formerly CDC group DF-3). This organism grows as pinpoint colonies after 24 hours of incubation that subsequently form larger, gray to white colonies. This photograph shows a 48-hour culture of *D. capnocytophagoides* growing on sheep blood agar after incubation at 35°C to 37°C in 5% to 7% CO_2. Colonial growth of this organism has been reported to have a characteristically "sweet" odor.

IMAGE PLATE 9-5

Pasteurella, *Brucella*, and *Bordetella* Species

A. Colonies of *Pasteurella multocida* growing on sheep blood agar after 48 hours of incubation at 35°C to 37°C in 5% to 7% CO_2. The organism is nonhemolytic and does not grow on MacConkey, EMB, or other selective/differential enteric media. *P. multocida* is most frequently isolated from bite wounds from domesticated animals, especially cats and dogs.

B. Gram-stained smear of *P. multocida*, showing the small, gram-negative coccobacilli that are characteristic of this species and other species in the genus *Pasteurella*.

C. Positive spot-indole reaction of *P. multocida*. A piece of filter paper is saturated with a few drops of *p*-dimethylaminocinnamaldehyde reagent, and colony growth of the organism is removed from the agar surface and rubbed onto the reagent along with a negative control organism. The appearance of a teal-blue color on the filter paper is a positive test, whereas the negative control organism results in a pale pink color, as shown here. *P. multocida* is also oxidase-positive.

D. *Brucella melitensis* growing on sheep blood agar after 48 hours of growth in 5% to 7% CO_2-enriched atmosphere at 35°C to 37°C. The colonies are small, nonpigmented, nonhemolytic, entire, and convex.

E. Direct fluorescence antibody (DFA) test for *Bordetella pertussis*. The DFA test is an important adjunct to culture for the detection of *B. pertussis* in nasopharyngeal specimens. This photograph shows a positive DFA preparation, with the organisms appearing as apple-green fluorescent coccobacilli. As demonstrated here, the bacteria may appear singly or in clusters resulting from the trapping of bacteria in mucous strands. (Photo courtesy of Marty Roe, Children's Hospital, Denver, CO.)

F. Gram-stained smear of *B. pertussis*, showing the characteristic, small, coccobacillary morphology.

G. Growth of *B. pertussis* on Regan-Lowe agar without (left) and with (right) cephalexin incorporated into the medium. The small white colonies present on both plates are colonies of *B. pertussis*, while the large colonies on the medium lacking cephalexin represent contaminant organisms present in the specimen. Culture for pertussis should include media with and without antibiotics, since some strains of

both *B. pertussis* and *B. parapertussis* may be inhibited by cephalexin.

H. Colonies of *B. pertussis* on Regan-Lowe agar after 72 hours of incubation at 35°C to 37°C in 5% to 7% CO_2. This medium contains horse blood (10% w/v) in a charcoal agar base. The high concentration of blood and the incorporation of activated charcoal in the medium help to neutralize any toxic materials that may be present in the specimen and to facilitate recovery of the bacteria.

H

IP-56

IMAGE PLATE 10-1

LABORATORY DIAGNOSIS OF LEGIONELLOSIS

A. Gram's stain of *Legionella pneumophila* culture using basic fuchsin instead of safranin for the counterstain. The organisms are thin rods of various lengths.

B. Gram-Weigert-stained touch preparation of open-lung biopsy specimen revealing small, thin intracellular and extracellular bacilli (original magnification, 100× objective lens). Note the short, blunt rods in the macrophage nearest the center of the slide. *L. pneumophila* serogroup 1 was the only organism isolated in culture; a tissue imprint of the lung was DFA-positive when stained with the conjugate specific for this organism.

C. Heavy growth on buffered charcoal yeast extract agar (BCYE) after 3 or more days of incubation and no growth on blood agar are characteristic of *Legionella* species.

D. Dissecting microscopic view of *L. pneumophila* colonies on BCYE. Note the crystalline-like internal structures within 3- to 5-mm colonies that have entire margins (original magnification, approximately 40×).

E. Blue-white autofluorescence of *L. bozemanii* on BCYE; photographed under long-wave ultraviolet light. Other species that autofluoresce blue-white include *L. dumoffii*, *L. gormanii*, *L. anisa*, *L. tucsonensis*, *L. cherrii*, *L. parisiensis*, and *L. steigerwaltii*. This characteristic is absent in *L. pneumophila*, *L. micdadei*, *L. feeleii*, *L. longbeachae*, *L. oakridgensis*, and many other *Legionella* species.

F. Modified Kinyoun's acid-fast stain of *L. micdadei* grown on BCYE. Some of the rod-shaped bacteria in the preparation are acid-fast (red), whereas some are not acid-fast (blue). These are partially acid-fast. Using the traditional Ziehl–Neelsen stain, or an auramine–rhodamine stain, they are not likely to be acid-fast (see text for details).

G. Paraffin section of lung tissue from a patient with acute Legionnaires' disease. The section shows an area of consolidation. Inflammatory exudates consisting of fibrin, many neutrophils, few macrophages, and some erythrocytes fill alveolar spaces and alveolar ducts (hematoxylin and eosin stain; original magnification, approximately 200×).

H. This traditional Gram's stain from a legionellosis demonstrates polymorphonuclear leukocytes and macrophages, but there are "no organisms seen." This is typical in the traditional Gram's stain, since legionellae stain poorly with the safranin counterstain (Gram's stain, 1000× magnification).

IP-58

IMAGE PLATE 11-1

IDENTIFICATION OF *NEISSERIA* SPECIES

A. Gram-stained smear of a urethral discharge from a male with gonococcal urethritis. Note the presence of intracellular gram-negative diplococci within pale-staining segmented neutrophils.

B. Skin lesion of disseminated gonococcal infection (DGI) on the index finger of the left hand. Skin lesions associated with DGI are usually located on the extremities.

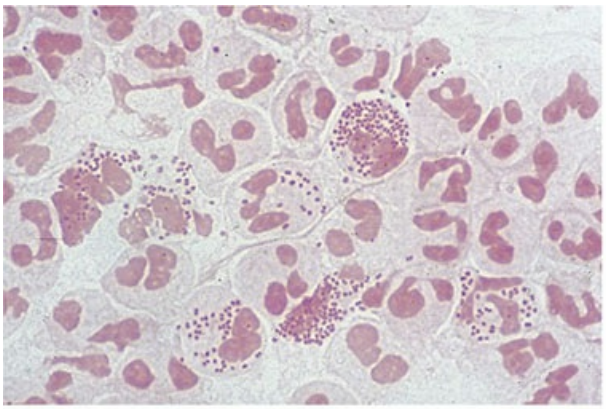
C. Typical colonies of *Neisseria gonorrhoeae* on modified Thayer–Martin (MTM) medium after 24 hours of incubation at 35°C to 37°C in 5% to 7% CO_2. MTM is a chocolate agar–based formulation that contains vancomycin, colistin, and nystatin to inhibit gram-positive, gram-negative, and fungal organisms, respectively. Pathogenic *Neisseria* species, notably *N. gonorrhoeae* and *N. meningitidis*, grow well on MTM medium.

D. Close-up view of colonies of *N. gonorrhoeae* growing on MTM agar after 24 hours of incubation at 35°C to 37°C in 5% to 7% CO_2.

E. Conventional cystine-tryptic digest semisolid agar (CTA) for identification of *Neisseria* species. This photograph shows the typical battery of carbohydrates used for identification. The battery includes (left to right) CTA-glucose, CTA-maltose, CTA-sucrose, and CTA-lactose (the control CTA tube without carbohydrate is not shown). The CTA basal medium contains a phenol red indicator, and a change in the color of the medium from red to yellow indicates acid production from the respective carbohydrate. In this photograph, acid has been produced from glucose only, identifying the organism as *N. gonorrhoeae*.

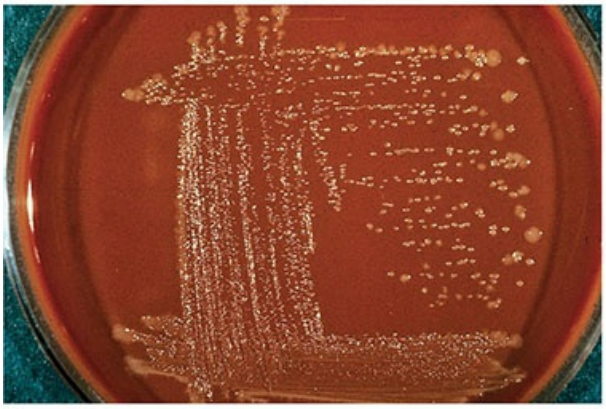
F. Close-up view of colonies of *Neisseria meningitidis* growing on sheep blood agar after incubation for 24 hours at 35°C to 37°C in 5% to 7% CO_2.

IP-59

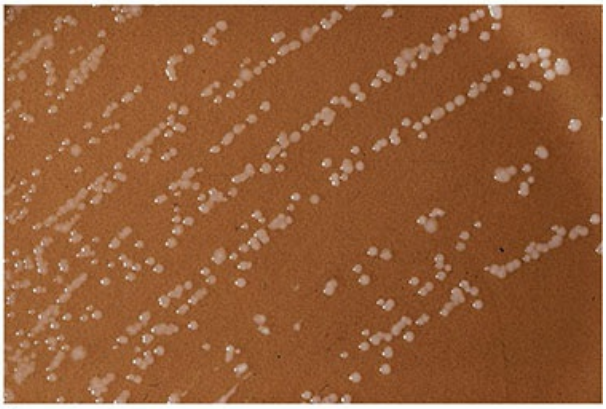


A

B

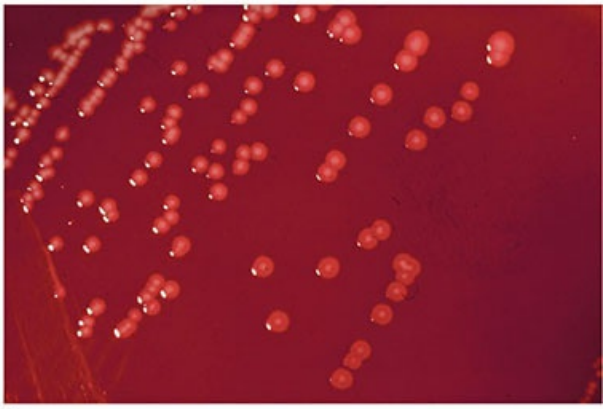


C



D

E



F

IP-60

G. Rapid carbohydrate utilization test for identification of *Neisseria* species (see Chart 11-1). The rapid carbohydrate utilization test is performed using a balanced salts–phenol red solution (BSS, 0.10 mL per tube), with a single drop of carbohydrate (20% w/v aqueous solution, filter-sterilized) added for each carbohydrate tested. A dense suspension of the organism is prepared in BSS

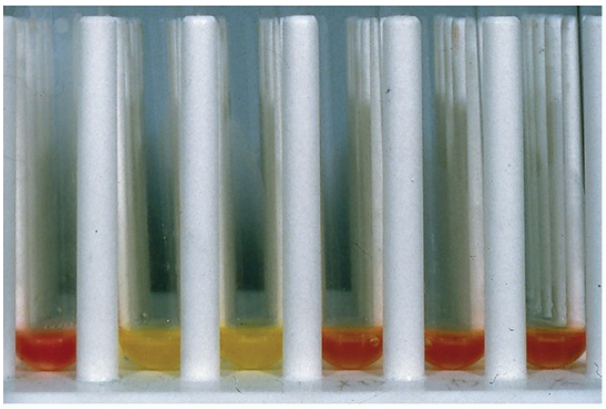
without carbohydrate, and a single drop of this heavy suspension is added to each of the BSS carbohydrate tubes. The inoculated tubes are incubated at 35°C for 4 hours. This photograph shows a set of BSS-carbohydrates composed of (left to right) BSS only (for the organism suspension), BSS-glucose, BSS-maltose, BSS-fructose, BSS-sucrose, and BSS-lactose. Because acid has been produced in the BSS-glucose and BSS-maltose tubes (color change from red to yellow), the organism is identified as *N. meningitidis*.

H. The CarboFerm Neisseria kit consists of an 8-well reagent cuvette that comes packaged as 12 strips snapped into a plastic frame. The frame is labeled with row designations A through H. The wells of the cuvette are sealed with a plastic cap strip, which is removed prior to inoculation. The wells in row A contain dehydrated peptone medium base with phenol red indicator and no added carbohydrates (control wells). The wells in rows C, D, E, and F contain the same medium base with added carbohydrates; these wells contain glucose (wells in row C), maltose (wells in row D), lactose (wells in row E), and sucrose (wells in row F) along with the dehydrated peptone medium and phenol red indicator. The wells in row H contain bromo-chloro-indolyl butyrate (butyrate esterase substrate) impregnated on a filter paper disk at the bottom of the well. The wells in rows B and G are empty. The kit also includes screw-capped test tubes containing inoculation fluid. The kit is designed to identify the gram-negative, oxidase-positive diplococci belonging to the genus *Neisseria* and *Moraxella catarrhalis*.

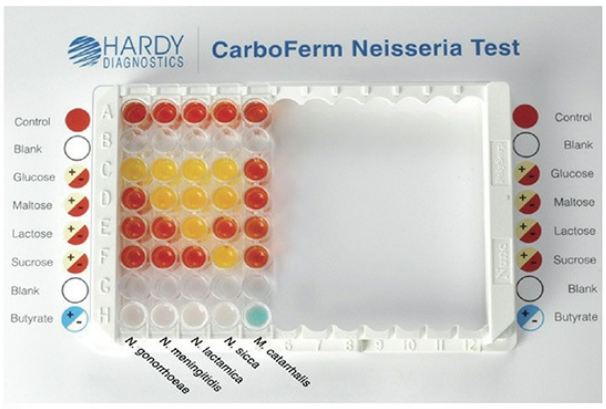
In order to inoculate the CarboFerm Neisseria, an organism suspension equal to or exceeding the turbidity of a No. 4 McFarland standard is prepared in the inoculation buffer. This inoculum is prepared from an 18- to 24-hour culture of the organism on chocolate, blood, or selective media (e.g., modified Thayer–Martin medium). Four to five drops of the inoculum are placed in wells A (control), C (glucose), D (maltose), E (lactose), F (sucrose), and H (butyrate esterase substrate). The cuvette is placed in an ambient air incubator at 35°C.

After 15 minutes, well H (the butyrate esterase substrate) is examined for the presence of a blue color. If the filter paper disk is teal-blue in color, the organism is identified as *M. catarrhalis*, and testing is completed. If the disk in well H is colorless (white), the butyrate esterase reaction is recorded as negative, and the cuvette is re-incubated for a total of 4 hours. At this time, the carbohydrate control and each of the carbohydrate wells are inspected for color changes. A red or red-orange color is recorded as negative, while orange, yellow-orange, and yellow are recorded as positive.

IP-61



G



H

IP-62

IMAGE PLATE 11-2

IDENTIFICATION OF *NEISSERIA* SPECIES AND *MORAXELLA CATARRHALIS*

A. GONOCHEK II (EY Laboratories, San Mateo, CA). Three chromogenic substrates are included in a single plastic tube to detect glycosidase and aminopeptidase enzymes specifically found in *N. meningitidis*, *N. lactamica*, and *N. gonorrhoeae*. Hydrolysis of substrates in the tube results in the small inoculum volume turning various colors. Identification patterns observed are: blue (upper left)—*N. lactamica* (β-galactoside hydrolysis); yellow (upper right)—*N. meningitidis* (γ-glutamyl- *p*-nitroanilide hydrolysis); and red (lower left)—*N. gonorrhoeae* (prolyl-naphthylamide hydrolysis). Lack of a color reaction (**lower** right) following the 30-minute incubation presumptively identifies the organism as *Moraxella catarrhalis*.

B. BactiCard *Neisseria* (Remel Laboratories, Lenexa KS). This identification strip contains four chromogenic enzyme substrate tests for identification of the pathogenic *Neisseria* species and *Moraxella catarrhalis*. After hydration of each of the four test circles with a drop of buffer, growth from selective media or a suitable subculture is applied onto each of the four test areas. If a blue-green color develops in the IB (butyrate esterase) test area within 2 minutes (strip at left), the organism is identified as *M. catarrhalis*. If no color develops in this area, the strip is incubated for an additional 13 minutes. If a blue-green color develops in the BGAL (β-galactosidase) test area (strip at far right) during this time, the organism is identified as *N. lactamica*. If no color reaction develops in this area during the incubation period, a single drop of color-developing reagent is added to the PRO and GLUT test areas. The appearance of a red color in the PRO (prolyl

aminopeptidase) test area identifies the isolate as *N. gonorrhoeae* (second strip from the left), whereas the development of a red color in the GLUT (γ-glutamyl aminopeptidase) test area identifies the isolate as *N. meningitidis* (third strip from the left)

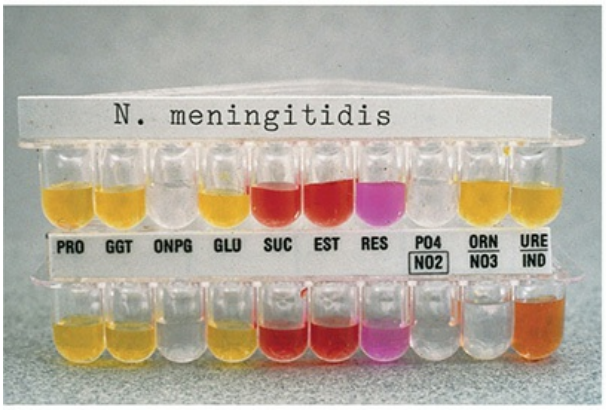
C. RapID NH system (Remel). The RapID NH system is a 4-hour commercial system for identification of *Neisseria* species, *Haemophilus* species, and several other species of fastidious gram-negative bacteria. The photograph actually shows two duplicate panels inoculated with *N. meningitidis*. The top panel in the photo is the system prior to the addition of reagents, while the bottom panel is the system after the addition of reagents to the last three bifunctional test wells. The reactions that identify the isolate as *N. meningitidis* are the positive prolyl aminopeptidase (PRO) and γ-glutamyl aminopeptidase (GLUT) reactions, the positive glucose (GLU) reaction, and the positive NO_2 (reduction of nitrite) test.

D. MicroScan HNID panel (Dade-MicroScan, West Sacramento, CA). The MicroScan HNID panel is a 4-hour test panel for the identification of *Haemophilus* and *Neisseria* species, Positive tests on the panel shown in the photograph include the nitrate reduction (NO_3) and nitrite reduction (NO_2) tests, production of acid from glucose (GLU), sucrose (SUC), maltose (MAL), fructose (FRU), and prolyl aminopeptidase (PRO). These characteristics identify this isolate as *N. mucosa*.

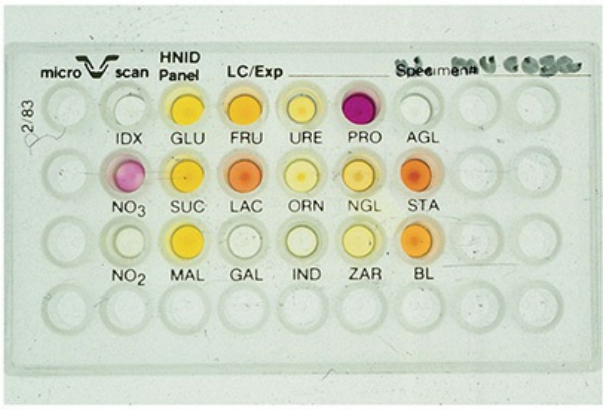
IP-63

A

B



C



D

IP-64

E. API NH panel (bioMérieux, Durham, NC). The API NH is a strip format identification system for the 2-hour identification of *Neisseria* and *Haemophilus* species. The strip includes seven single-substrate cupules and three bifunctional cupules. The single-substrate tests include (left to right), β-lactamase-test (PEN), acid production from glucose (GLU), fructose (FRU), maltose (MAL), sucrose (SAC), ornithine decarboxylase (ODC), and urease (URE). The bifunctional cupules include butyrate esterase plus prolyl aminopeptidase (LIP/PRO A), alkaline phosphatase (PAL) plus γ-glutamyl aminopeptidase (PAL/GGT), and β-galactosidase plus indole (GAL/IND). The entire strip is read first, including the LIP, PAL, and GAL tests, and then a color development reagent is added to the PRO A and GGT wells, and indole reagent is added to the IND well. These last three cupules are then reread to provide the fourth number of a four-digit biocode. The carbohydrate cupules, LIP, PRO A, GGT, and GAL address the identification of *Neisseria* species and *Moraxella catarrhalis*, while the carbohydrate cupules, ODC, URE, PAL, GAL, and IND are used for identifying and biotyping *Haemophilus* species. In this photograph, the GLU and PRO A tests are positive,

providing a biocode of 1001. Consultation with the API NH database provides an identification of *N. gonorrhoeae*. The PEN well is an acidometric β-lactamase detection cupule that is not used for identification purposes. The PEN test is positive here, indicating that the isolate is β-lactamase positive.

F. API NH inoculated with *N. meningitidi* s. Positive tests on the strip include glucose (GLU), maltose (MAL), prolyl aminopeptidase (PRO A), and GGT (γ-glutamyl aminopeptidase). These reactions result in an API biocode of 5003, which provides an identification of *N. meningitidis*. This isolate is β-lactamase-negative, as indicated by the blue color in the PEN cupule.

G. The M.cat butyrate disk test (Carr-Scarborough Microbiologicals, Decatur, GA). *M. catarrhalis* strains produce a butyrate esterase enzyme that is able to hydrolyze indoxyl butyrate. An indoxyl butyrate-impregnated filter paper disk is moistened with water, and growth from a colony is rubbed onto the disk. The butyrate esterase enzyme hydrolyzes the compound and a blue-green color appears on the disk within 2 minutes. This figure shows three positive M. Cat. butyrate disks on a glass slide.

H. API NH inoculated with *M. catarrhalis*. In this photograph, the only positive test is the LIP cupule (blue is a positive reaction). The API biocode for these reactions is 0010, which identifies it as *M. catarrhalis*. The PEN cupule is not used to determine the API biocode, but only to detect β-lactamase production. The blue color in the PEN cupule indicates that this strain is β-lactamase.

IMAGE PLATE 12-1

IDENTIFICATION OF STAPHYLOCOCCI AND RELATED SPECIES

A. Adult patient with staphylococcal cellulitis of the upper lip.

B. Adult patient with the bullous, vesicular lesions of facial staphylococcal impetigo. Culture of the serosanguinous fluid within these vesicles reveals large numbers of *Staphylococcus aureus*.

C. Neonate with staphylococcal scalded skin syndrome. This syndrome is seen in newborns infected with *S. aureus* strains that produce exfoliatins (i.e., epidermolytic toxins). These toxins dissolve the mucopolysaccharide matrix of the epidermis, resulting in intraepithelial splitting of the cellular linkages in the stratum granulosum. Bullous formation occurs over large areas of the body, with subsequent sloughing of the superficial skin layers, as shown here.

D. Gram-stained smear from a lesion of staphylococcal cellulitis. The organisms appear as small extracellular gram-positive cocci arranged in clusters along with the pink-staining polymorphonuclear leukocytes.

E. Colonies of *S. aureus* on sheep blood agar. This photograph shows typical colonies of *S. aureus* after 24 hours of incubation at 35°C to 37°C. A zone of β-hemolysis is seen immediately surrounding the colonies.

F. Gram-stained smear from a broth culture of *S. aureus*, showing the typical gram-positive cocci in grape-like clusters.

G. Positive catalase test. The catalase test differentiates staphylococci and micrococci from the streptococci, enterococci, and the *Streptococcus*-like bacteria (Chapter 13). The test is performed by placing growth from a colony onto a glass slide and adding a drop of 3% hydrogen peroxide to the inoculum. Immediate and vigorous bubbling owing to the production of oxygen gas, as shown here, indicates a positive test. Micrococci and staphylococci are catalase-positive, whereas streptococci and enterococci are catalase-negative.

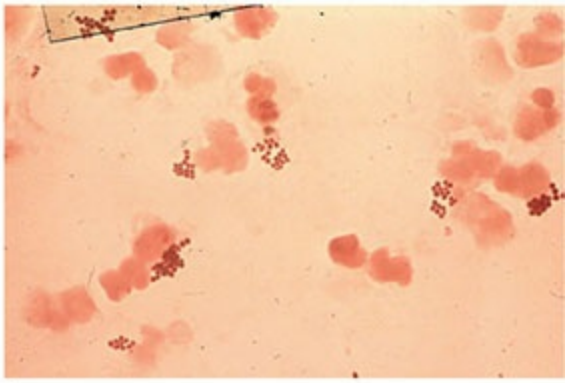
H. Colonies of *Micrococcus luteus* on sheep blood agar. This species produces yellow-pigmented colonies. Other micrococci and organisms in related genera may be nonpigmented or may produce orange- or red-pigmented colonies on agar media. Micrococci and related organisms may be differentiated from staphylococci by resistance to furazolidone, susceptibility to bacitracin, or other methods as shown in Table 12-1.

IP-67

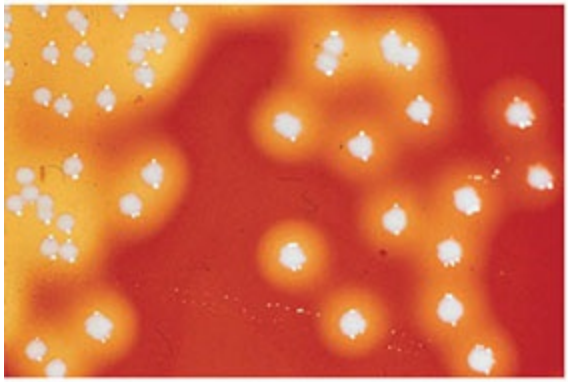
A

B

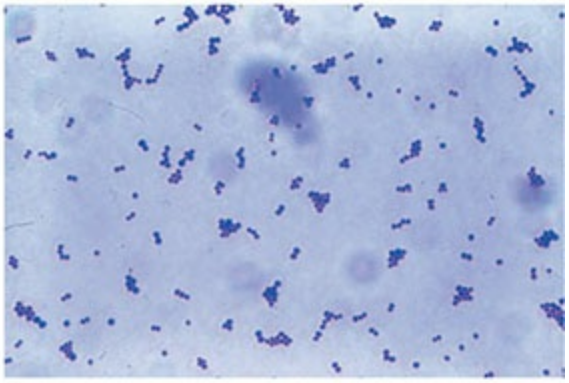
C



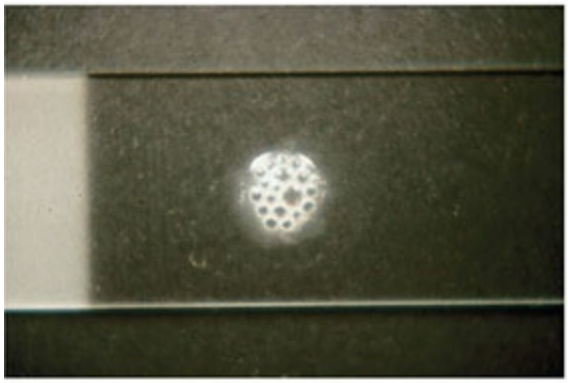
D



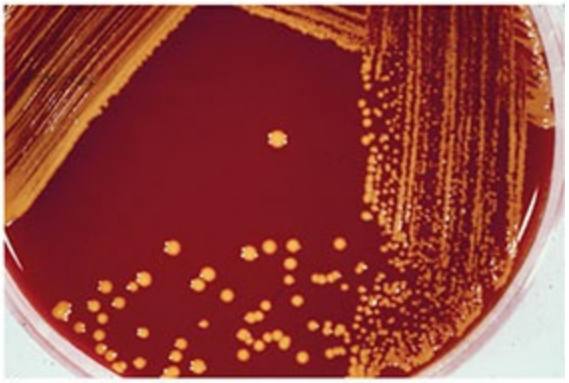
E



F



G



H

IP-68

IMAGE PLATE 12-2

IDENTIFICATION OF STAPHYLOCOCCI

A. Furazolidone disk test with a *Micrococcus* species. Several tests are available for differentiating micrococci and related genera from staphylococci. The furazolidone susceptibility test is a reliable overnight method for making this differentiation. Micrococci are resistant to furazolidone and will usually grow right up to the edge of the 6-mm furazolidone disk.

B. Furazolidone disk test with a *Staphylococcus* species. The growth of staphylococci is inhibited by furazolidone and will show an area of growth inhibition around the disk, as depicted in this figure.

C. Modified oxidase test. This test is a rapid, 30-second method for differentiating staphylococci from micrococci and related species. The oxidase reagent (tetramethyl- *p*-phenylenediamine dihydrochloride) is made up of dimethyl sulfoxide (DMSO), which allows the reagent to penetrate the staphylococcal cell wall. The test is performed by rubbing a portion of colony growth from a plate onto a filter paper disk that is impregnated with the reagent. Most micrococci and related species are modified oxidase-positive, producing a blue-purple color on the disk within 30 seconds, whereas most *Staphylococcus* species are modified oxidase-negative.

D. Slide coagulase test. This test is a rapid method for identifying *S. aureus*. Most strains of this species produce a cell-bound coagulase or "clumping factor" that is detected by mixing a saline suspension of the organism with EDTA-rabbit plasma. A saline control (left) must be included with each test to assess autoagglutination. Not all *S. aureus* strains possess clumping factor, so negative slide coagulase tests must be confirmed with the tube coagulase test for colonies with a morphology suggestive of *S. aureus* (Image Plate 12-2E).

E. Tube coagulase test. In this test, extracellular coagulase produced by *S. aureus* forms a complex with a component in plasma, called coagulase-reacting factor. This complex, in turn, reacts with fibrinogen in the plasma to form fibrin and, consequently, the development of a visible clot in the tube. A positive test is shown in the tube at the bottom of the figure, whereas a negative test is shown in the tube at the top of the figure.

F. Latex agglutination test for identification of *S. aureus*. This alternative coagulase

test procedure uses latex beads that are coated with plasma. Fibrinogen bound to the latex detects clumping factor, and the immunoglobulins, also present on the latex, detect protein A on the surface of the *S. aureus* cell. Newer formulations of these tests also contain latex beads coated with antibodies against *S. aureus* capsular types 5 and 8, which enable more reliable detection of oxacillin-resistant *S. aureus* strains. Mixing of colonial growth of *S. aureus* with the latex reagent results in rapid agglutination (left). A coagulase-negative *Staphylococcus*, which produces a negative latex agglutination reaction, is also shown (right).

G. DNase medium with toluidine-blue. This medium detects the production of deoxyribonuclease by *S. aureus*. The organisms are spot-inoculated heavily onto the agar surface and the plate is incubated at 35°C to 37°C for 24 hours. A positive test is indicated by the appearance of a pink color under and around the inoculum. As shown here, *S. aureus* ("SA" on plate) is DNase-positive, while the control (*S. saprophyticus*, "SS" on plate) is DNase-negative. The DNase test serves as a helpful adjunct test for *S. aureus* strains that have weak or equivocal coagulase test results.

H. API ID32 Staph system (bioMérieux) for identification of staphylococci and micrococci. This strip-format identification system contains 26 biochemical substrates. Positive and negative reactions are recorded to generate a biotype number that is used along with a computerized database (apiweb) to identify the organism.

IMAGE PLATE 12-3

IDENTIFICATION OF STAPHYLOCOCCI (CONTINUED)

A. Colonies of *Staphylococcus epidermidis* on sheep blood agar (SBA) after 24 hours of incubation at 35°C to 37°C.

B. *S. saprophyticus* on SBA with furazolidone and novobiocin disks. *S. saprophyticus* is a cause of urinary tract infections in young women. Like other staphylococci, this species is susceptible to furazolidone (FX), as shown by the zone of inhibition around the FX disk. The other disk (designate c-) on this slide is a novobiocin disk. *S. saprophyticus* is one of several *Staphylococcus* species that is resistant to novobiocin.

C. API Staph identification panel inoculated with *S. saprophyticus*. This picture shows the reactions on the first half of the panel. The interpretations of the test reactions shown are as follows:

CHO Control	Negative	GLU	Positive	FRU	Positive
MNE	Negative	MAL	Positive	LAC	Positive
TRE	Positive	MAN	Positive	XLT	Negative
MEL	Negative				

D. API Staph identification panel inoculated with *S. saprophyticus*. This picture shows the second half of the panel. The interpretations of the test reactions shown are as follows:

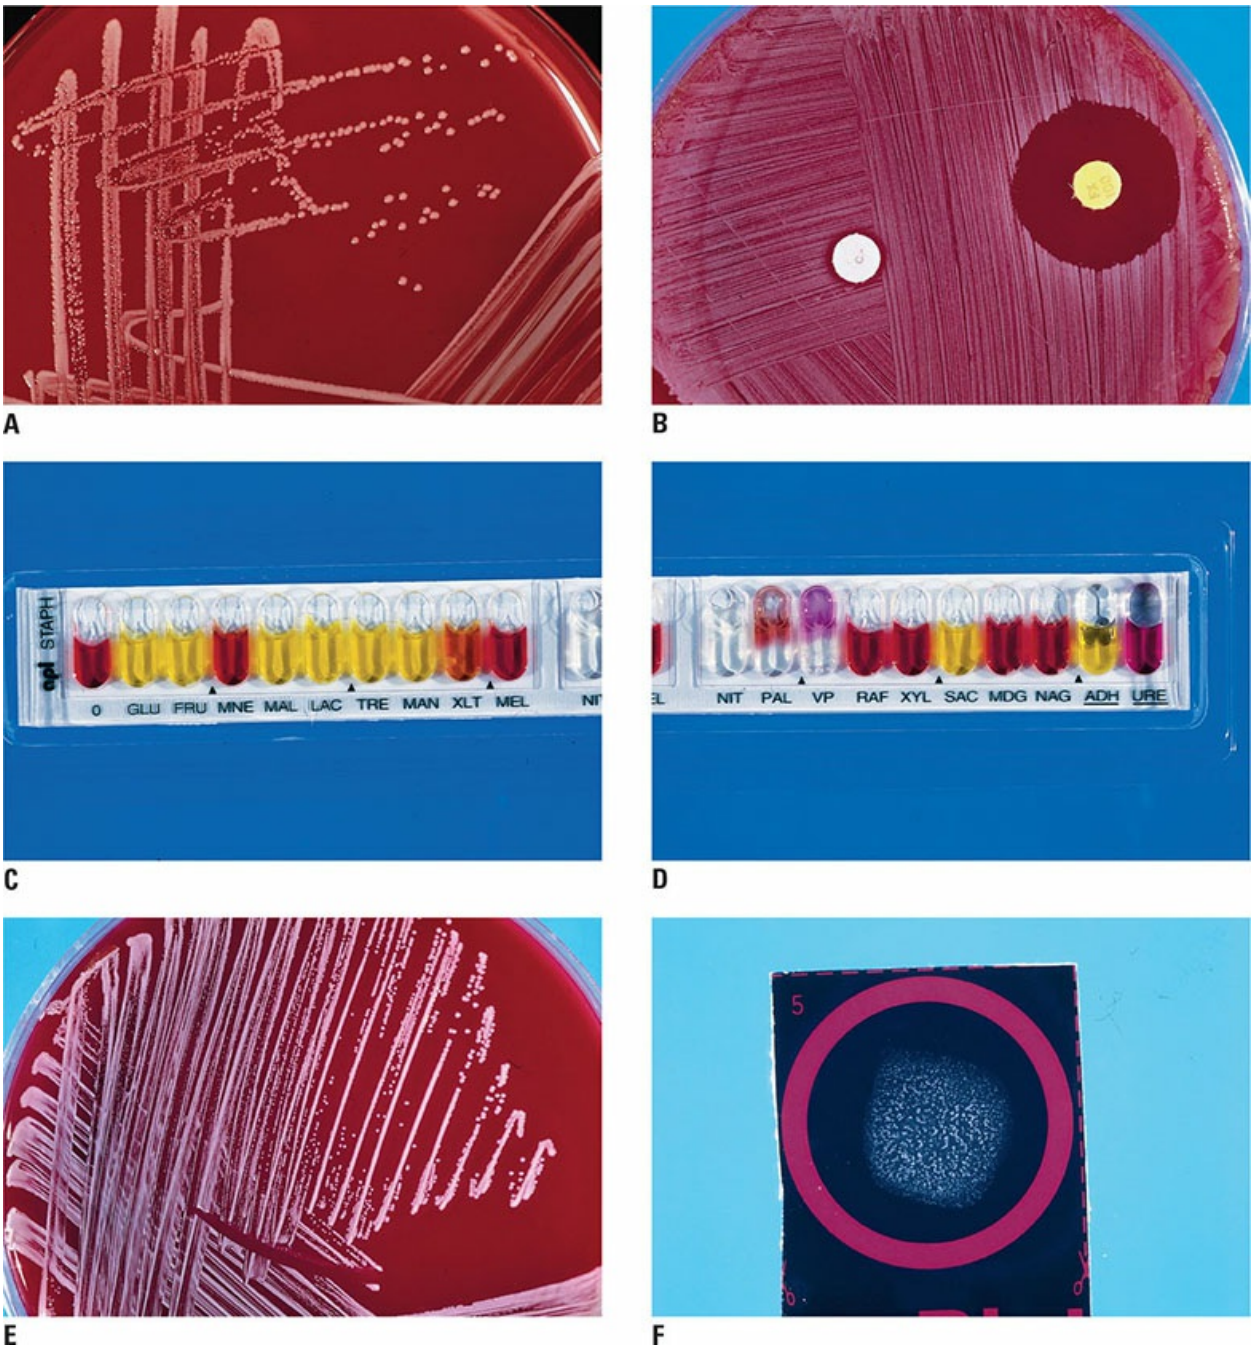
		NIT	Negative	PAL	Positive
VP	Positive	RAF	Negative	XYL	Negative
SAC	Positive	MDG	Negative	NAG	Negative
ADH	Negative	URE	Positive		

The API biocode numbers for these reactions, shown in Image Plate 12-3C and D, is 6634112. Consultation with the computer-assisted API Staph database provides a list of possible identifications, including *S. saprophyticus* (71.9% likelihood), *S. warneri* (19.3% likelihood), or *S. hominis* (6.6% likelihood). Since *S. saprophyticus* is the only species that is novobiocin-resistant, the organism can be identified as *S. saprophyticus*.

E. This slide shows an isolate growing on sheep blood agar after incubation at 35°C to 37°C for 24 hours. This isolate was recovered from several blood cultures of a 38-year-old patient with presumed staphylococcal endocarditis. This isolate is nonpigmented and nonhemolytic, and was also furazolidone- and novobiocin-susceptible (not shown).

F. This photograph shows the latex agglutination reaction of the isolate from Image Plate 12-3E. The isolate is coagulase-positive by the latex test. Since the isolate did not "look" like *S. aureus*, the technologist inoculated an API Staph identification strip. These reactions are shown in Image Plate 12-3G and H.

IP-71



IP-72

G. API Staph identification strip inoculated with the blood culture isolate shown in Image Plate 12-3E. This photograph shows the reactions on the first half of the strip. The interpretations of these test reactions are as follows:

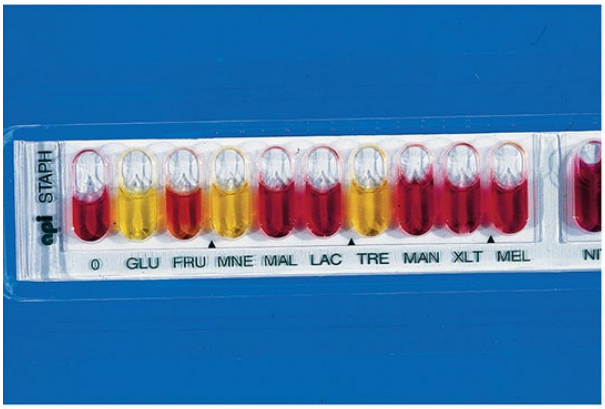
CHO Control	Negative	GLU	Positive	FRU	Negative
MNE	Positive	MAL	Negative	LAC	Negative
TRE	Positive	MAN	Negative	XLT	Negative
MEL	Negative				

H. API Staph identification strip inoculated with the blood culture isolate from Image Plate 12-3E. This photograph shows the reactions on the second half of the strip. The interpretations of these test reactions are as follows:

	NIT	Positive	PAL	Positive
VP Positive	RAF	Negative	XYL	Negative
SAC Negative	MDG	Negative	NAG	Positive
ADH Positive	URE	Negative		

The API biocode for the reactions shown in Image Plate 12-3G and H is 2116141. Consultation with the API Staph computer-assisted database provides an identification of this isolate as *S. schleiferi*. This is consistent with the positive latex reaction shown in Image Plate 12-3F, as this species can be slide, latex, and/or tube coagulase-positive.

IP-73



G

H

IP-74

IMAGE PLATE 13-1

IDENTIFICATION OF STREPTOCOCCI

A. Patient with erysipelas due to group A β-hemolytic streptococci. This infection

involves the soft tissues and cutaneous lymphatics and results in systemic manifestations of infection, including fever. Note the bullous lesions adjacent to the chin.

B. Gram-stained smear of streptococci growing in a broth culture. As their name suggests, streptococci characteristically grow in chains. These chains are most frequently seen when the organisms are grown in broth. On Gram-stained smears prepared from growth on agar media, the organisms usually appear in pairs or in shorter chains.

C. Gram-stained smear of *Streptococcus pneumoniae*. This photograph shows the typical appearance of pneumococci in blood culture broth. These bacteria characteristically grow in pairs in which the cells have a slightly elongated "lanceolate" morphology. With some cells in this photograph, a clear area or "halo" may be observed surrounding the organism pairs, indicating the presence of the polysaccharide capsule of *S. pneumoniae.*

D. β-Hemolytic streptococci on sheep blood agar. β-Hemolytic streptococci produce hemolysins that lyse the sheep erythrocytes, resulting in a clearing of the medium surrounding the colonies. The group A *Streptococcus* shown here demonstrates this type of hemolysis, as do groups B, C, and G streptococci. The zones of β-hemolysis surrounding colonies of group B streptococci, however, are not as large relative to the size of the colony as those seen with groups A, C, and G β-hemolytic streptococci.

E. α-Hemolytic streptococci on sheep blood agar. Streptococci initially may be classified on the basis of their hemolytic properties on sheep blood agar. Partial hemolysis of the erythrocytes results in a "greening" of the agar medium surrounding the colonies (α-hemolysis). Streptococci that are β-hemolytic include *S. pneumoniae*, the viridans group of streptococci, and most *Enterococcus* (formerly *Streptococcus*) species.

F. α-Hemolytic streptococci on sheep blood agar. More intense β-hemolysis is noted in areas where the medium has been "stabbed," pushing some of the bacteria under the medium surface. The hemolysis in these areas is due to the combined activities of streptolysin O and streptolysin S, the principal hemolysins of group A streptococci. Streptolysin O is oxygen-labile and does not show maximal activity on the surface of the agar; the surface β-hemolysis is largely due to streptolysin S, which is oxygen-stable.

G. Direct latex agglutination test for group A streptococci. Both latex agglutination and rapid enzyme immunoassays are currently available for the direct detection of group A streptococci in throat swab specimens. With the latex agglutination method

shown here, the throat swab is enzymatically treated to extract the group A antigen and the extract is reacted with a latex bead suspension coated with anti–group A streptococcal antibodies and with a control, uncoated latex suspension. Agglutination of the latex with the test latex reagent (left) but not the control latex (right) is a positive test. Although most of these tests are highly specific for the group A cell wall antigen, the sensitivities of these assays vary widely.

H. Strep OIA (Biostar, Boulder, CO). The Strep OIA is an immunoassay for direct detection of group A streptococci in throat swab specimens. The swab is extracted with acetic acid, neutralized, and then mixed with anti–group A antibodies bound to horseradish peroxidase (HRP). A drop of this mixture is placed on the surface of an OIA slide, which is coated with anti–group A streptococcal antibodies. After a 2-minute incubation, the slide is rinsed and HRP substrate is added and allowed to react on the slide for 4 minutes. After rinsing, the slide is read by examining the hue of light reflected from the reaction area on the OIA slide. If group A streptococcal antigen is present, the slide shows a purple spot (left). If no antigen is present, the slide surface retains its gold color, with or without a tiny blue dot, as shown here (right).

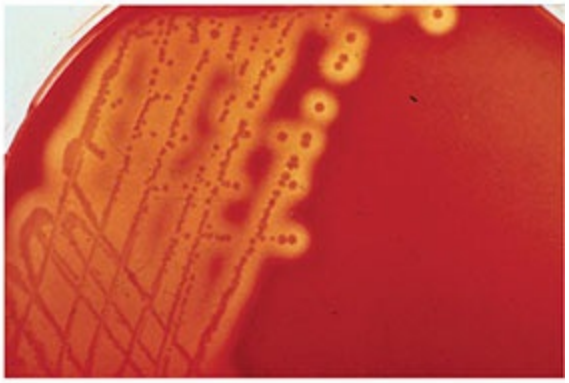
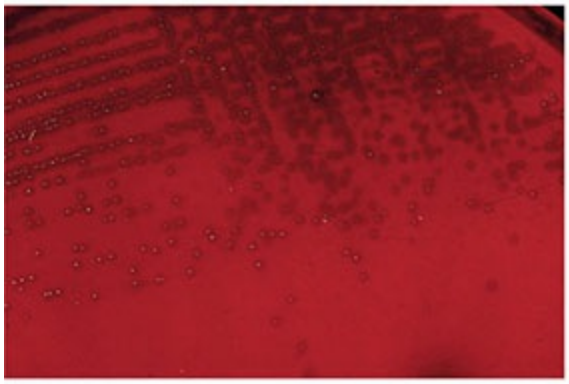
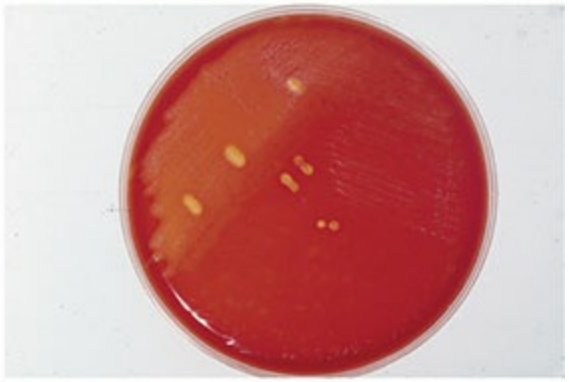
C



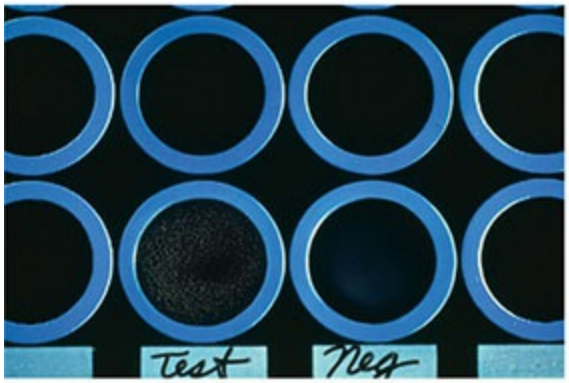
D



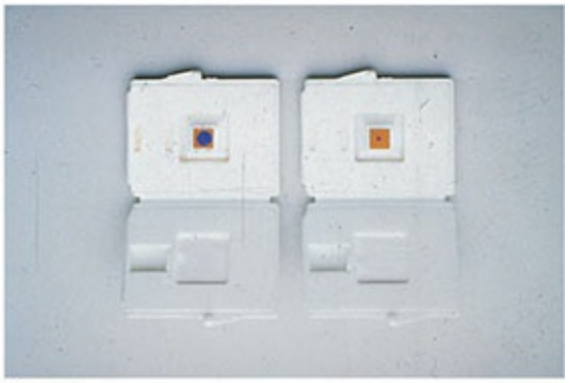
E



F



G



H

IMAGE PLATE 13-2

IDENTIFICATION OF STREPTOCOCCI AND ENTEROCOCCI

A. *S. pneumoniae* colonies on sheep blood agar. Two characteristics of *S. pneumoniae* can be used for presumptive identification. On the left is shown a typical α-hemolytic, mucoid strain of *S. pneumoniae* growing on sheep blood agar. Its appearance is due to the production of large amounts of capsular polysaccharide. On the right is a close-up photograph illustrating the collapse of the central portion of the colonies owing to organism autolysis, resulting in the so-called checker-piece and nail-head colony morphologies shown here.

B. Bacitracin susceptibility test. Group A streptococci are susceptible to low concentrations of bacitracin. The Taxo A bacitracin disk (BD Microbiology Systems) shown here contains 0.04 unit of bacitracin. This photograph shows the bacitracin test reactions for a group A β-hemolytic *Streptococcus* (left) and a group B β-hemolytic *Streptococcus* (right). Any zone of inhibition around the bacitracin disk is considered a positive test.

C. Susceptibility to bacitracin and sulfamethoxazole-trimethoprim. The β-hemolytic *Streptococcus* shown here is susceptible to bacitracin (right), but also shows a large zone of growth inhibition around the sulfamethoxazole-trimethoprim (SXT) disk (left). Group A β-hemolytic streptococci are susceptible to bacitracin, but are resistant to SXT, while group B β-hemolytic streptococci are resistant to both bacitracin and SXT. Some non–group A β-hemolytic streptococci (e.g., groups C, F, and G) are susceptible to bacitracin, but will also be susceptible to SXT, as shown here. Therefore, the performance of these two tests together increases the specificity of the presumptive identification that would be obtained by using the bacitracin test alone. This isolate would be called "presumptive β-hemolytic *Streptococcus*, not groups A or B, by bacitracin/SXT."

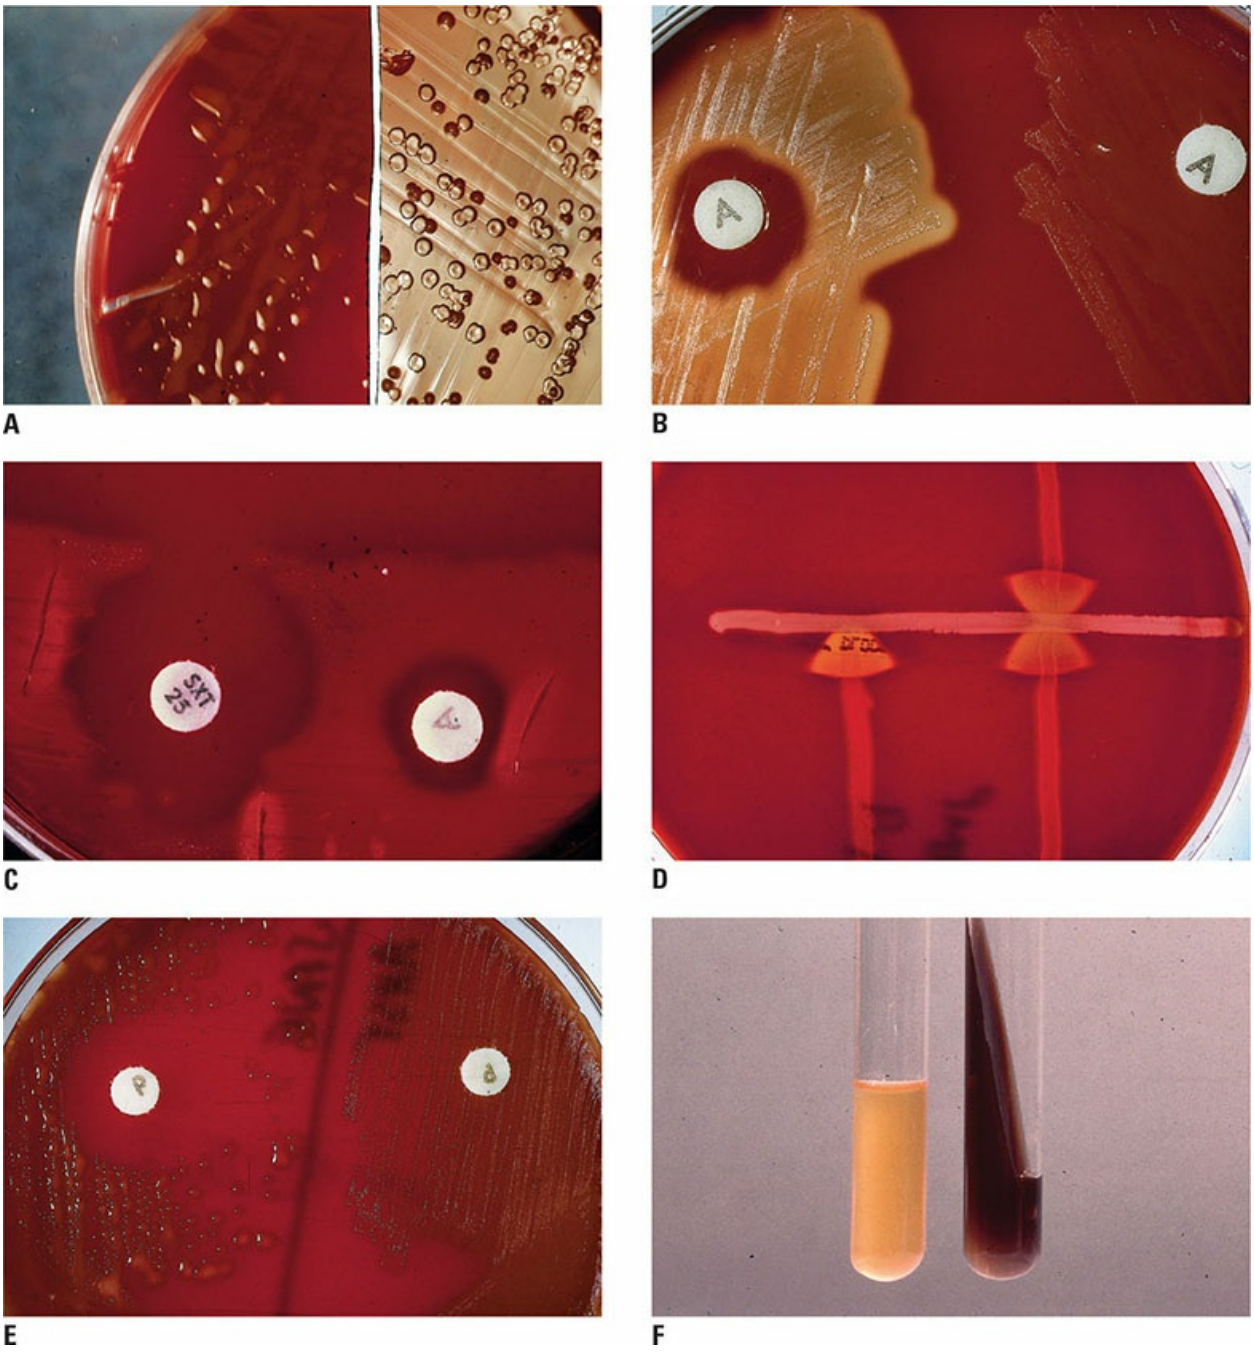
D. CAMP test for presumptive identification of group B β-hemolytic streptococci. The CAMP test reaction depends on the interaction between CAMP factor, a product of the group B *Streptococcus*, with the β-hemolysin of *Staphylococcus aureus*. Possible group B streptococci are streaked at right angles to a streak of *S. aureus* (without the streaks touching) on a sheep blood agar plate. Following overnight incubation at 35°C to 37°C, an arrowhead-shaped area of synergistic hemolysis is found in the intersecting area where the CAMP factor and the β-hemolysin have diffused into the medium. Nonhemolytic variants of group B

streptococci will also be CAMP test-positive. This photograph shows three positive CAMP tests.

E. Susceptibility to optochin for identification of *S. pneumoniae*. Susceptibility to ethyl hydrocuprene hydrochloride (optochin) is used to differentiate *S. pneumoniae* from other viridans streptococci. α-Hemolytic colonies are subcultured onto a sheep blood agar plate and an optochin disk (P disk; BD Microbiology Systems) is placed on the inoculum. The presence of a zone of growth inhibition of 14 mm around a 6-mm optochin disk after overnight incubation at 35°C to 37°C identifies the organism as *S. pneumoniae*.

F. Bile esculin hydrolysis and salt-tolerance tests. These tests are used for the presumptive identification of *Enterococcus* species and group D streptococci. The bile esculin test (right) is performed by inoculating a slant of bile esculin medium and incubating it overnight at 35°C to 37°C. Enterococci and group D streptococci are able to grow in the presence of 40% bile and to hydrolyze esculin to esculetin (which forms the black precipitate). The salt-tolerance test (left) is performed with a broth medium containing 6.5% NaCl. *Enterococcus* species will grow, whereas nonenterococcal group D streptococci will not grow in this medium. The photograph shows a positive reaction for both tests, identifying this organism as a group D *Enterococcus* species.

IP-77



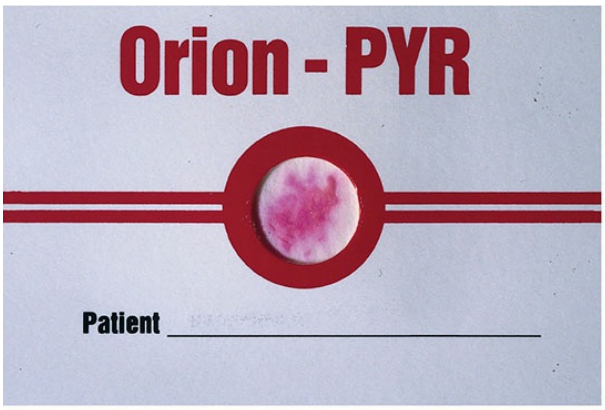
IP-78

G. PYR test. Hydrolysis of L-pyrrolidonyl-naphthylamide (PYR) is a presumptive test for identification of group A β-hemolytic streptococci and *Enterococcus* species that can replace the bacitracin-SXT disk tests and the salt-tolerance tests, respectively. In the disk test shown, colony growth is applied to a moistened disk impregnated with the PYR substrate. After 2 minutes, a drop of

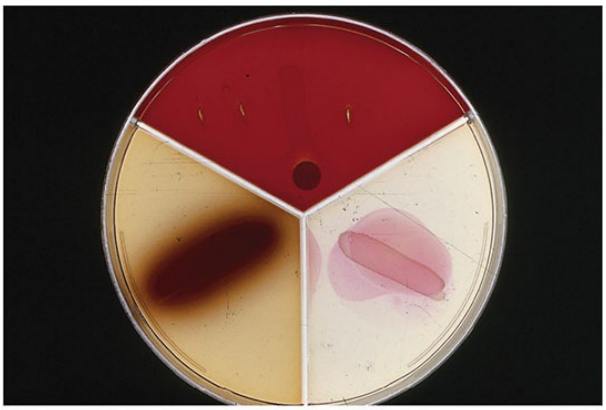
dimethylaminocinnamaldehyde reagent is placed on the disk to detect the free naphthylamide that is released on hydrolysis of PYR (red).

H. Tri-Plate for presumptive identification of streptococci. This single plate is designed to provide the results of several tests for the presumptive identification of streptococci and enterococci. The three sectors of the plate contain sheep blood agar, bile esculin agar, and PYR agar, respectively. Determination of hemolysis and a CAMP test are performed in the blood agar sector, and the bile esculin and PYR reactions are read in the other two sectors. This photograph shows the Tri-Plate inoculated with an *Enterococcus* species: α-hemolytic, CAMP test-negative, bile esculin–positive, and PYR-positive.

IP-79



G



H

IP-80

IMAGE PLATE 13-3

Identification of Streptococci and Enterococci and *Streptococcus*-Like Bacteria

A. Latex agglutination test for serologic grouping of β-hemolytic streptococci. Although the Lance field extraction method and the capillary precipitin tests are the time-honored techniques for definitive identification of the groupable streptococci, other methods, such as the one shown here, have been adopted in most laboratories and are considered standard procedures. In this test, the cell wall grouping antigen is extracted from the bacterial cell wall enzymatically, and the extract is subsequently reacted with latex beads to which group-specific antibodies

are bound. A positive test is indicated by agglutination of the latex beads in the homologous latex reagent. As shown here, agglutination has occurred with the group A reagent, but not with the group B, C, D, F, or G reagents, thereby identify the isolate as a group A β-hemolytic *Streptococcus*.

B. Quellung test for identification of *S. pneumoniae*. This microscopic "precipitin test" can be used to identify pneumococci or to determine the capsular serotype of individual pneumococcal isolates. Reaction of the anticapsular antibodies with the carbohydrate material of the capsule causes a microprecipitin reaction on the surface of the organism and a change in the refractive index of the capsule itself. Microscopically, the capsule appears to "swell." A small amount of methylene blue is added to the preparation to allow visualization of the cells and to provide contrast so that subtle refractile changes in the capsule can be more easily discerned.

C. Pneumoslide latex agglutination test (BD Microbiology Systems). The Pneumoslide test uses latex beads that are sensitized with antipneumococcal antibodies. Mixture of the sensitized latex with colony material from a culture plate results in visible agglutination of the suspension, thereby identifying the isolate as *S. pneumoniae*.

D. *Abiotrophia/Granulicatella* species. These organisms were formerly called satelliting or nutritionally variant streptococci because they require thiol compounds, cysteine, or the active form of vitamin B_6 (pyridoxal or pyridoxamine) for growth on media. This requirement may be met by cross-streaking a *Staphylococcus* across an inoculum of the probable nutritionally variant isolate, as shown in this photograph. The small colonies of the organism are observed growing adjacent to the *Staphylococcus* streak following incubation in a manner similar to the satellite test for presumptive identification of *Haemophilus* species. Members of the satelliting streptococci have now been placed in either the genus *Abiotrophia* or the genus *Granulicatella*.

E. *Enterococcus faecium*. This photograph shows a sheep blood agar plate inoculated with *E. faecium*. Colonies of this organism are smooth, gray, and nonhemolytic or α-hemolytic. The swab, which was used to pick up some of the colony growth from the plate, shows that the organism is nonpigmented. This becomes important for the identification of certain other enterococcal species.

F. API Strep identification panel (bioMérieux) inoculated with *E. faecium*. This photograph shows the first half of the identification panel. Interpretations of the reactions shown are as follows:

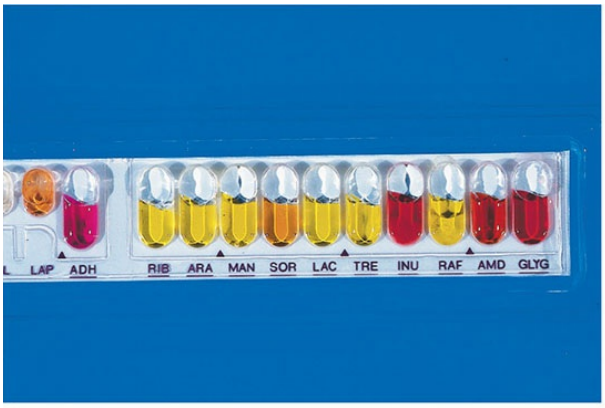
G. API Strep identification panel inoculated with *E. faecium*. This photograph shows the second half of the identification panel. Interpretations of the reactions shown are as follows:

ADH	Positive	RIB	Positive	ARA	Positive
MAN	Positive	SOR	Positive	LAC	Positive
TRE	Positive	INU	Negative	RAF	Positive
AMD	Negative	GLYG	Negative	HEM	Negative

The API biocode for the reactions shown in Image Plate 13-3F and G is 5357750. Consultation with the API computer-assisted database provides an identification of *E. faecium*, with 99% likelihood.

H. Vancomycin screening agar. Vancomycin screening agar consists of brain–heart infusion agar containing vancomycin (6 g/mL). This medium can be used to detect vancomycin-resistant enterococci, the majority of which are *E. faecium*. As shown in this photograph, isolates A, B, C, and D are vancomycin-resistant and are able to grow on this medium. Isolate E is a strain of *E. faecalis*, most of which are vancomycin-susceptible, as indicated by growth inhibition on this medium.

IP-83



G

H

IP-84

IMAGE PLATE 13-4

IDENTIFICATION OF ENTEROCOCCI AND VIRIDANS GROUP STREPTOCOCCI

A. *Enterococcus casseliflavus* on sheep blood agar. *E. casseliflavus* is one of two motile *Enterococcus* species. In addition, *E. casseliflavus* produces a yellow pigment. This pigment is evident on inspection of the swab in the photograph, which has been used to pick up some of the colony growth.

B. *Enterococcus gallinarum* in semisolid motility agar. As mentioned above, *E. gallinarum* and *E. casseliflavus* are the two motile *Enterococcus* species. In this photograph, *E. gallinarum* has been stab-inoculated into a tube of semisolid motility medium containing tetrazolium. On incubation of the inoculated tube, the motile organisms move out from the streak line to create turbidity in the medium. The purple color results from the motile organisms reducing the tetrazolium to formazan, which appears as a purple precipitate anywhere that viable organisms are found.

C. *Streptococcus* bovis on sheep blood agar. *S. bovis* is a nonenterococcal group D *Streptococcus*. This organism is bile esculin–positive, but does not grow in 6.5% NaCl broth and is PYR-negative. Isolation of *S. bovis* from blood cultures is associated with colonic neoplasia.

D. API Strep identification panel inoculated with *S. bovis*. This photograph shows the first half of the identification panel. The interpretations of the reactions shown are:

VP	Positive	HIP	Negative	ESC	Positive
PYRA	Negative	α-GAL	Positive	β-GUR	Negative
β-GAL	Positive	PAL	Negative	LAP	Positive

E. API Strep identification panel inoculated with *S. bovis*. This photograph shows the second half of the identification panel. The interpretations of the reactions shown are:

ADH	Negative	RIB	Negative	ARA	Negative
MAN	Positive	SOR	Negative	LAC	Positive
TRE	Positive	INU	Positive	RAF	Positive
AMD	Positive	GLYG	Positive	β-HEM	Negative

The API biocode for the reactions shown in Image Plate 13-4D and E is 5250573. Consultation with the API computer-assisted database provides an identification of this isolate as *S. bovis* I (99.9% probability). According to the new nomenclature for this organism complex, *S. bovis* I is now called *Streptococcus gallolyticus* subsp. *gallolyticus* (Table 13-7).

F. *Streptococcus mitis* growing on sheep blood agar after 24 hours of incubation. This

particular isolate appears to be γ-hemolytic or nonhemolytic. Other strains of this species may be α-hemolytic.

G. API Strep identification panel inoculated with *S. mitis*. This photograph shows the first half of the identification panel. Interpretations of the reactions are as follows:

VP	Negative	HIP	Negative	ESC	Negative
PYRA	Negative	α-GAL	Negative	β-GUR	Negative
β-GAL	Negative	PAL	Positive	LAP	Positive

H. API Strep identification panel inoculated with *S. mitis*. This photograph shows the second half of the identification panel. The interpretations of the reactions are as follows:

ADH	Negative	RIB	Negative	ARA	Negative
MAN	Negative	SOR	Negative	LAC	Positive
TRE	Positive	INU	Negative	RAF	Negative
AMD	Positive	GLGY	Negative	β-HEM	Negative

The biocode for the reactions shown in Image Plate 13-4G and H is 0060411. Consultation with the API computer-assisted database provides an identification of S. mitis (80%)/oralis (20%). *S. mitis* and *S. oralis* belong to the "mitis group" of viridans streptococci. Some isolates of *S. mitis* have been shown to be resistant to penicillin and may be resistant to other antimicrobial agents as well.

LISTERIA AND *ERYSIPELOTHRIX* SPECIES

A. Gram-stained smear of *Listeria monocytogenes*, showing short, gram-positive bacilli.

B. Small, β-hemolytic colonies of *L. monocytogenes* on sheep blood agar (SBA) after 72 hours of incubation at 35°C to 37°C.

C. *L. monocytogenes* growing on SBA after 24 hours (left) and 48 hours (right) of incubation. After 24 hours, the β-hemolytic nature of the organism may not be obvious. After 48 hours, the zone of hemolysis extends beyond the margin of the colony, but is still rather subtle.

D. *L. monocytogenes* on bile esculin agar (right). The tube on the left is an uninoculated bile esculin agar slant. Like the enterococci, *L. monocytogenes* is able to hydrolyze esculin in the presence of 40% bile. Esculin hydrolysis is indicated by blackening of the medium.

E. Umbrella-shaped zone of motile growth produced by *Listeria monocytogenes* after 24 hours of growth in semisolid motility medium at 25°C.

F. API Coryne inoculated with *Listeria monocytogenes*. The API biocode of the isolate shown is 0170164. Consultation with the API Profile Index provides an identification as "Listeria *monocytogenes*/innocua, 97.1% likelihood." Differentiation of *L. monocytogenes* and *L. innocua* is determined by assessment of hemolysis on SBA and by reactivity of *L. monocytogenes* in the CAMP test with *S. aureus*.

G. Gram-stained smear of *Erysipelothrix rhusiopathiae*, showing the long, thin, gram-positive rods of this species.

H. Colonies of *Erysipelothrix rhusiopathiae* on SBA after 24 hours of incubation at 35°C.

IMAGE PLATE 14-2

ERYSIPELOTHRIX AND *BACILLUS* SPECIES

A. *Erysipelothrix rhusiopathiae* after overnight growth in a streak-and-stab inoculated tube of Kligler's iron agar. Note the production of H_2S along the line of the stab in the butt of the tube.

B. Gram-stained smear of a *Bacillus* species. Note the presence of central/subterminal, nonstaining endospores that do not swell the cell.

C. Gross specimen of intestinal tract from a patient who died of gastrointestinal anthrax. The appendix is noted in the lower left portion of the photograph. Lesions of gastrointestinal anthrax are usually noted in the cecum and adjacent areas of the bowel. Symptoms include abdominal pain, hematemesis, and bloody diarrhea.

D. Gram's stain (left) and malachite-green spore stain (right) of *B. anthracis*. *B. anthracis* grows as rather large gram-positive bacilli, with the individual cells having squared-off or slightly concave ends. Often, the organisms are arranged in chains that have the appearance of bamboo, as depicted here. The spore stain shows the ovoid spores that do not swell the cell. (Courtesy of Elmer W. Koneman.)

E. Off-white, dull, nonhemolytic colonies of *Bacillus anthracis* on SBA.

F. Close-up of *B. anthracis* colonies on SBA. Colonies of *B. anthracis* have a ground-glass morphology with comma-shaped outgrowths along the colony margins, as shown here. These outgrowths are even more apparent microscopically. Such colonies have been described as "Medusa head" colonies, after the Greek sorceress who had hair composed of serpents. (Courtesy of Elmer W. Koneman.)

G. Close-up of the rough, nonhemolytic colonies of *B. anthracis*. A few of the colonies have been touched with an inoculating loop, resulting in the colonies "standing up" like beaten egg whites.

H. β-Hemolytic colonies of *Bacillus cereus* on SBA. *B. cereus* is one of the more frequently isolated *Bacillus* species in the clinical laboratory. Unlike *B. anthracis*, this species is hemolytic, motile, and α-lactamase-positive.

IMAGE PLATE 14-3

IP-90

CORYNEBACTERIUM SPECIES

A. Gram-stained smear showing the typical morphology of members of the genus *Corynebacterium*. Regularly shaped rods, club-shaped bacilli, "Chinese-letter" and "picket-fence" cellular arrangements can be observed in this photograph.

B. BHI agar inoculated with a lipophilic and a nonlipophilic *Corynebacterium* species. On the right side of the plate, a lipophilic species has been inoculated as a lawn on the plate, and a drop of 0.1% Tween 80 has been placed in the center of the inoculum. A nonlipophilic *Corynebacterium* species is inoculated as a lawn on the left half of the plate. After incubation for 24 hours at 35°C to 37°C, growth of the lipophilic species is observed only where the drop of Tween 80 was placed, while the nonlipophilic species grows all over the surface of the medium on the right side of the plate.

C. *Corynebacterium amycolatum* growing on SBA after 3 days of incubation at 35°C. Note the dry, matte appearance of the colonies and the "wrinkling" of the growth in confluent areas. *C. amycolatum* is the most frequently isolated *Corynebacterium* species and is found on the skin.

D. API Coryne panel inoculated with *Corynebacterium amycolatum*. The photograph shows first half of the identification panel. The interpretations of the reactions shown are:

NIT	Positive	PYZ	Positive	PYRA	Negative
PAL	Positive	β-GUR	Negative	β-GAL	Negative
α-GLU	Negative	β-NAG	Negative	ESC	Negative
URE	Negative				

E. API Coryne panel inoculated with *Corynebacterium amycolatum*. This photograph shows the second half of the identification panel The interpretations of the reactions shown are:

GEL	Negative	CHO Control	Negative		
GLU	Positive	RIB	Positive	XYL	Negative
MAN	Negative	MAL	Negative	LAC	Negative
SAC	Positive	GLYG	Negative	CAT	Positive

The API Coryne biocode for the reactions shown in Image Plate 14-3D and E is 3100305, which gives a cross-call identification of *Corynebacterium* group G, *C. striatum,* or *C. amycolatum. C. amycolatum* is nonlipophilic, while group G coryneform strains are lipophilic; so this isolate is not a group G coryneform. Additional tests (e.g., gas-liquid chromatography of glucose broth cultures) are needed to differentiate *Corynebacterium amycolatum* and *Corynebacterium striatum* from one another. This isolate produced propionic acid from glucose as determined by gas-liquid chromatographic analysis of culture broth, so this organism can be identified as *C. amycolatum*.

F. Local inflammation and pseudomembrane formation in the oropharynx produced by toxigenic strains of *Corynebacterium diphtheriae*.

G. Growth of *Corynebacterium diphtheriae* on modified Tinsdale agar. On this medium, *C. diphtheriae* grows as black colonies with brown halos. Isolates with this colonial morphology are first identified biochemically as *C. diphtheriae*, and subsequent testing involves demonstrating the production of diphtheria toxin.

H. Growth of *C. diphtheriae* from Loeffler's coagulated serum medium. This medium is inoculated with material from the posterior pharynx (i.e., the diphtheritic pseudomembrane), and a smear is prepared after about 8 hours of incubation and stained with methylene blue. As shown here, *C. diphtheriae* appears as pleomorphic beaded bacilli. The beaded appearance is due to the production of metachromatic granules by the organism on this medium.

IMAGE PLATE 14-4

Corynebacterium Species

A. Growth of *C. diphtheriae* on SBA after 24 hours of incubation at 35°C. Colonies of this organism are nonlipophilic, white, and creamy. This isolate was inoculated onto the API Coryne identification kit, and the biochemical reactions for identification are shown in **B** and **C** below.

B. API Coryne inoculated with *C. diphtheriae*. This photograph shows the first half of the identification panel. The interpretations of the reactions shown are:

NIT	Positive	PYZ	Negative	PYRA	Negative
PAL	Negative	β-GUR	Negative	β-GAL	Negative
α-GLU	Positive	β-NAG	Negative	ESC	Negative
URE	Negative				

C. API Coryne inoculated with *C. diphtheriae*. This photograph shows the other half of the identification panel. The interpretations of the reactions shown are:

GEL	Negative	CHO Control	Negative		
GLU	Positive	RIB	Negative	XYL	Negative
MAN	Negative	MAL	Positive	LAC	Negative
SAC	Negative	GLYG	Negative	CAT	Positive

The API Coryne biocode for these reactions is 1010124, which corresponds to an identification of *Corynebacterium diphtheriae* (97.8% probability). Additional testing must be performed to determine whether the isolate produces diphtheria toxin.

D. *Corynebacterium jeikeium* on SBA after 48 hours of incubation at 35°C to 37°C. This lipophilic species produces small, nonhemolytic colonies on SBA.

E. API Coryne inoculated with *Corynebacterium jeikeium*. This photograph shows the first half of the identification panel. The interpretations of the reactions shown are:

NIT	Negative	PYZ	Positive	PYRA	Negative
PAL	Positive	β-GUR	Negative	β-GAL	Negative
α-GLU	Negative	β-NAG	Negative	ESC	Negative
URE	Negative				

F. API Coryne inoculated with *C. jeikeium*. This photograph shows the second half of the identification panel. The interpretations of the reactions shown are:

GEL	Negative	CHO Control	Negative		
GLU	Positive	RIB	Positive	XYL	Negative
MAN	Negative	MAL	Negative	LAC	Negative
SAC	Negative	GLYG	Negative	CAT	Negative

The API Coryne biocode for these reactions is 2100304, which corresponds to an identification of *C. jeikeium* (93.6% probability).

G. Gram-stained smear showing the rather plump, gram-positive bacilli of *Corynebacterium glucuronolyticum* ("*C. seminale*").

H. *C. glucuronolyticum* on SBA after 24 hours of incubation at 35°C to 37°C.

IMAGE PLATE 14-5

CORYNEBACTERIUM SPECIES

A. API Coryne inoculated with *C. glucuronolyticum*. This photograph shows the first half of the identification panel. The interpretations of the reactions shown are:

NIT	Negative	PYZ	Positive	PYRA Negative	Negative
PAL	Negative	β-GUR	Positive	β-GAL	Negative
α-GLU	Negative	β-NAG	Negative	ESC	Positive
URE	Positive				

B. API Coryne inoculated with *C. glucuronolyticum*. This photograph shows the second half of the identification panel. The interpretations of the reactions shown are:

GEL	Negative	CHO Control	Negative		
GLU	Positive	RIB	Negative	XYL	Negative
MAN	Negative	MAL	Positive	LAC	Negative
SAC	Positive	GLYG	Negative	CAT	Positive

The API biocode for these reactions is 2241125, which corresponds to an identification of *C. glucuronolyticum* (99.9% probability). This species has been recovered from semen specimens and is the only *Corynebacterium* species that is β-glucuronidase (β-GUR)-positive. This species was also described by another research group and was given the name "*C. seminale*." However, the name "*C. glucuronolyticum*" has taxonomic precedence.

C. Creamy, smooth, nonlipophilic, nonhemolytic colonies of *Corynebacterium pseudodiphtheriticum* growing on SBA after 24 hours at 35°C to 37°C.

D. API Coryne inoculated with *Corynebacterium pseudodiphtheriticu m*. The interpretations of the reactions shown are:

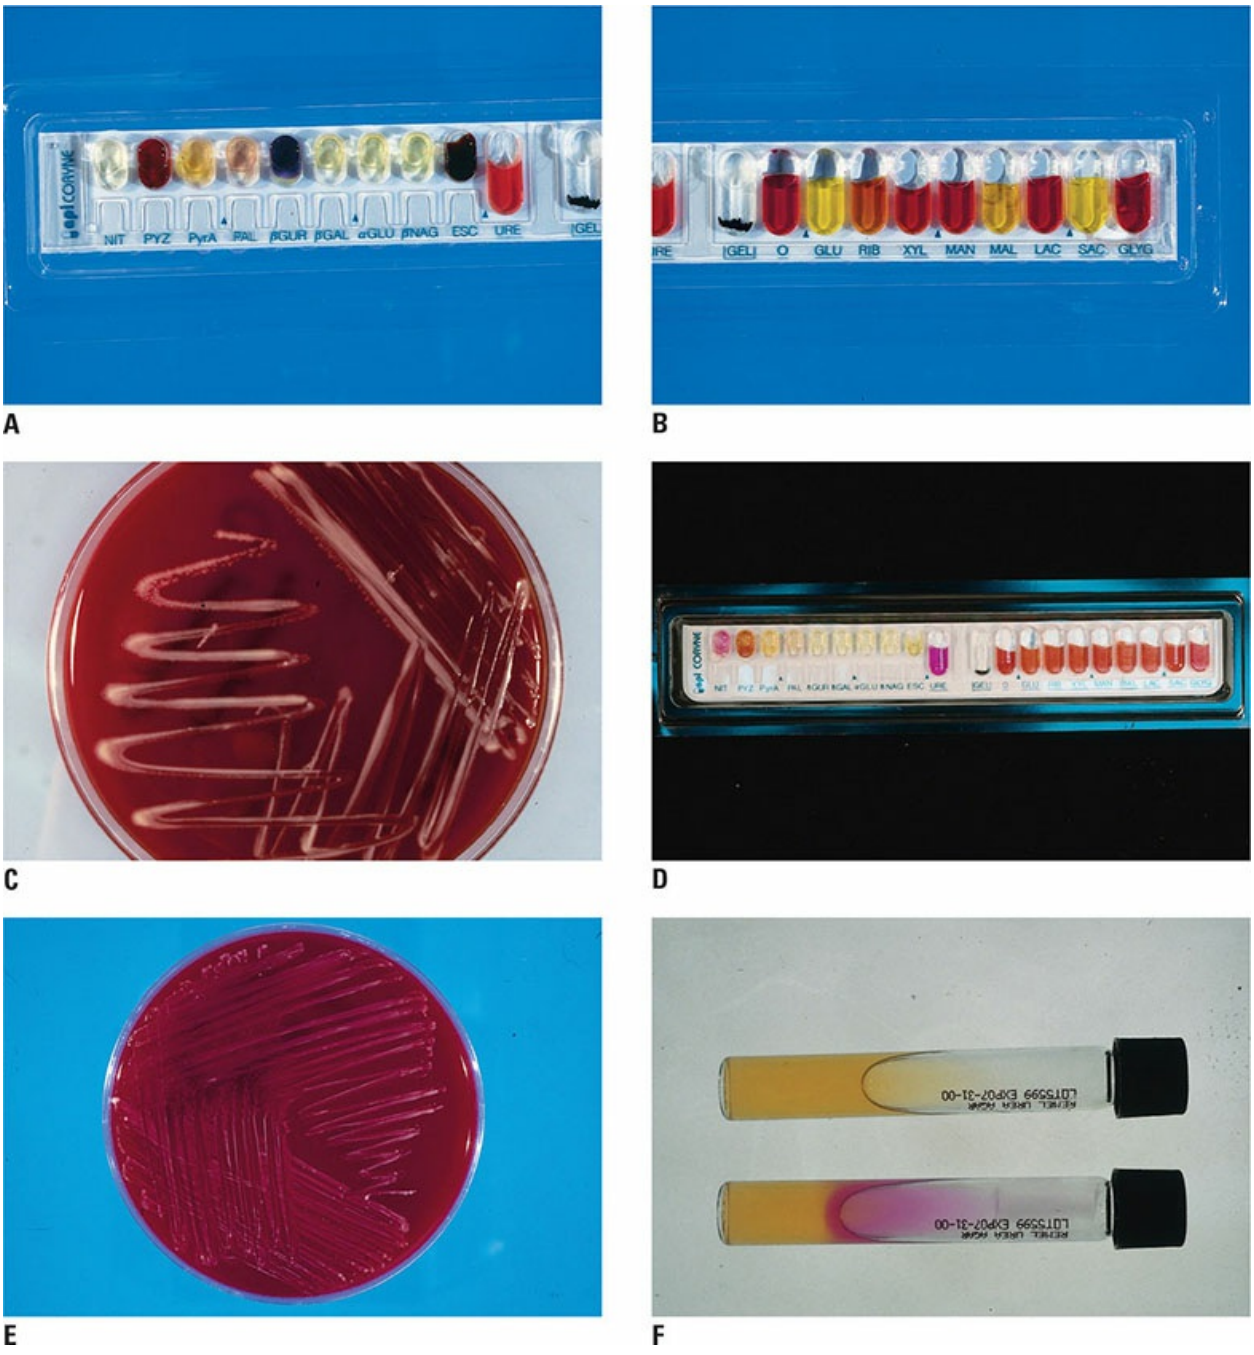
NIT	Positive	PYZ	Positive	PYRA	Negative
PAL	Negative	β-GUR	Negative	β-GAL	Negative
α-GLU	Negative	β-NAG	Negative	ESC	Negative
URE	Positive	GEL	Negative	CHO Control	Negative
GLU	Negative	RIB	Negative	XYL	Negative
MAN	Negative	MAL	Negative	LAC	Negative
SAC	Negative	GLYG	Negative	CAT	Positive

The API Coryne biocode for these reactions is 3001004, which corresponds to an identification of *C. pseudodiphtheriticum* (96.7% probability).

E. Creamy, nonlipophilic, nonhemolytic colonies of *C. riegelii* on SBA after 24 hours of incubation at 35°C to 37°C.

F. Rapid urease reaction of *C. riegelii*. *C. riegelii*, like *C. urealyticum*, is rapidly urease-positive. This photograph shows an uninoculated urea agar slant (**top**) and a urea agar slant inoculated with *C. riegelii* (**bottom**). This reaction was photographed after the slant on the right was incubated for 30 minutes at 35°C to 37°C.

IP-95



IP-96

G. API Coryne inoculated with *C. riegelii*. This photograph shows the first half of the identification panel. The interpretations of the reactions shown are:

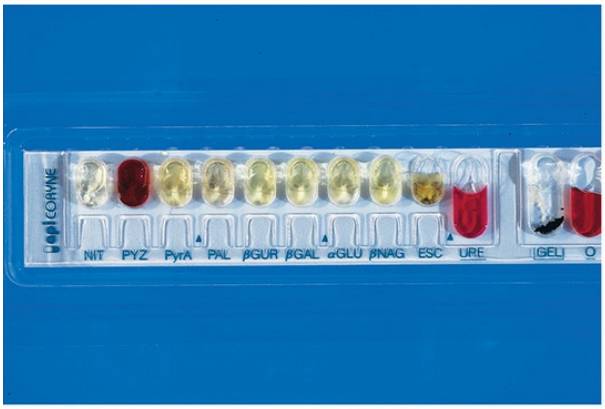
NIT	Negative	PYZ	Positive	PYRA	Negative
PAL	Negative	β-GUR	Negative	β-GAL	Negative
α-GLU	Negative	β-NAG	Negative	ESC	Negative
URE	Positive				

H. API Coryne inoculated with *C. riegelii*. This photograph shows the second half of the identification panel. The interpretations of the reactions shown are:

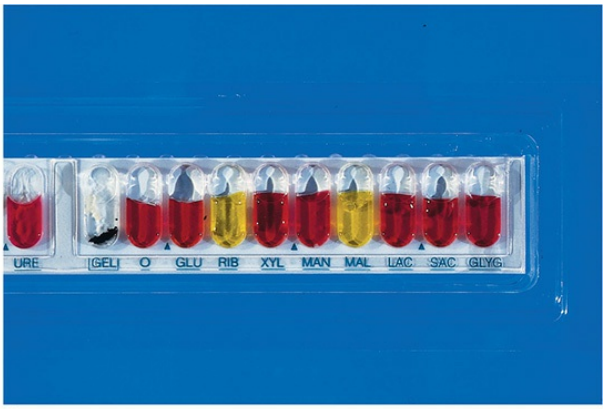
GEL	Negative	CHO Control	Negative		
GLU	Negative	RIB	Positive	XYL	Negative
MAN	Negative	MAL	Positive	LAC	Negative
SAC	Negative	GLYG	Negative	CAT	Positive

The API biocode for these reactions is 2001204. This biocode was not included in the API Coryne database at when this image was taken, but it is the same biocode that was published with the original description of this new species. *C. riegelii* is associated with urinary tract infections. Besides being rapidly urease-positive, this species is also atypical in that it produces acid from maltose and ribose, but not from glucose, as shown here.

IP-97



G



H

IP-98

IMAGE PLATE 14-6

Corynebacterium, *Arcanobacterium*, and *Brevibacterium* Species

A. Creamy, nonlipophilic, nonhemolytic colonies of *Corynebacterium striatum* on

SBA after 48 hours of incubation at 35°C to 37°C. Note the "target" morphology of the individual colonies.

B. API Coryne inoculated with *C. striatum*. The interpretations of the reactions shown are:

NIT	Positive	PYZ	Positive	PYRA	Negative
PAL	Positive	β-GUR	Negative	β-GAL	Negative
α-GLU	Negative	β-NAG	Negative	ESC	Negative
URE	Negative	GEL	Negative	CHO Control	Negative
GLU	Positive	RIB	Negative	XYL	Negative
MAN	Negative	MAL	Negative	LAC	Negative
SAC	Positive	GLYG	Negative	CAT	Positive

The API Coryne biocode for these reactions is 3100105, which corresponds to an identification of *Corynebacterium* group G, 55.5%/*C. striatum-amycolatum*, 43.6%. Since group G strains are lipophilic, this organism is either *C. striatum* or *C. amycolatum*. This isolate did not produce propionic acid from glucose on gas-liquid chromatographic analysis, and so this isolate is identified as *C. striatum*.

C. *Corynebacterium* group G after 24 hours of incubation at 35°C to 37°C. After 24 hours, individual colonies are extremely small, with good growth occurring only in the heavily inoculated areas. This lipophilic species has been isolated from vitreous, blood, cerebrospinal fluid, and urogenital tract specimens.

D. API Coryne inoculated with *Corynebacterium* group G. The interpretations of the reactions shown are as follows:

NIT	Negative	PYZ	Positive	PYRA	Negative
PAL	Positive	β-GUR	Negative	β-GAL	Negative
α-GLU	Negative	β-NAG	Negative	ESC	Negative
URE	Negative	GEL	Negative	CHO Control	Negative
GLU	Positive	RIB	Positive	XYL	Negative
MAN	Negative	MAL	Positive	LAC	Negative
SAC	Positive	GLYG	Negative	CAT	Positive

The API biocode for these reactions is 2100325. Consultation with the computer-assisted database provides an identification of *Corynebacterium* group G (76.6% likelihood)/*C. striatum/amycolatum* (22.7% likelihood). Since this organism is lipophilic and both *C. striatum* and *C. amycolatum* are nonlipophilic, this isolate can be identified as *Corynebacterium* group G.

E. Growth of *Arcanobacterium haemolyticum* on SBA after 48 hours of incubation at

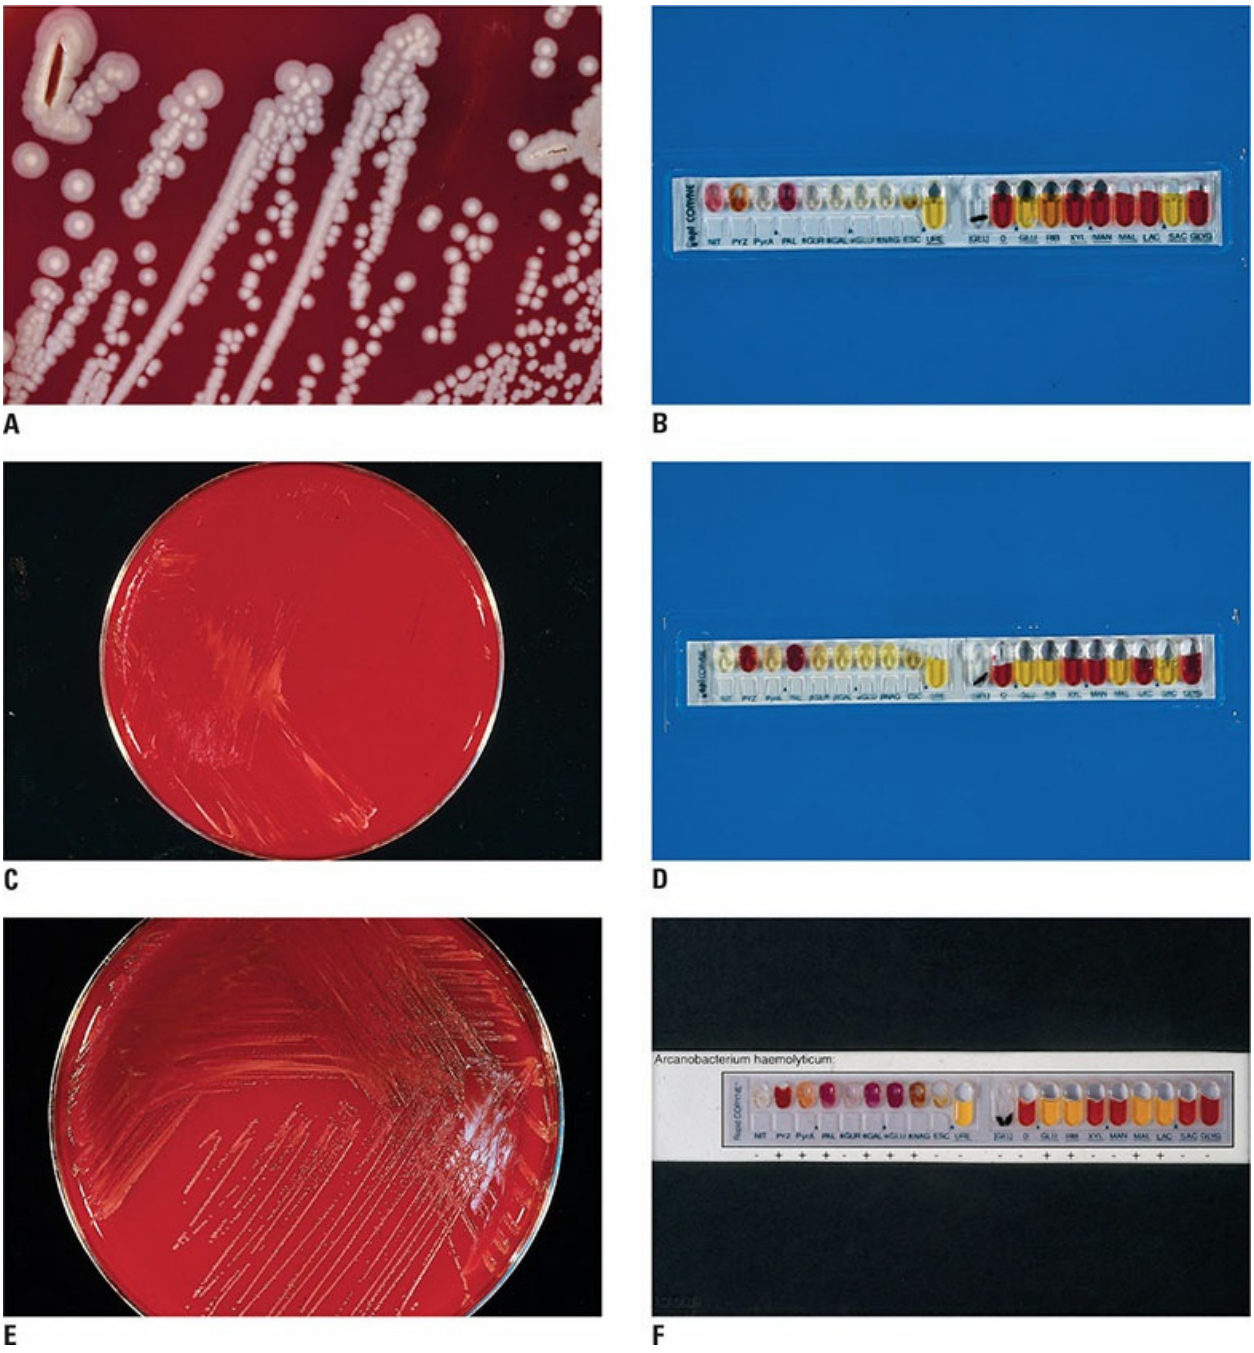
35°C to 37°C. Note the zone of β-hemolysis surrounding the colonies.

F. API Coryne inoculated with *A. haemolyticum*. The interpretations of the reactions shown are:

NIT	Negative	PYZ	Positive	PYRA	Positive
PAL	Positive	β-GUR	Negative	β-GAL	Positive
α-GLU	Positive	β-NAG	Positive	ESC	Negative
URE	Negative	GEL	Negative	CHO Control	Negative
GLU	Positive	RIB	Positive	XYL	Negative
MAN	Negative	MAL	Positive	LAC	Positive
SAC	Negative	GLYG	Negative	CAT	Negative

The API Coryne biocode for these reactions is 6530360, which corresponds to an identification of *A. haemolyticum* 99.9% (excellent identification)

IP-99



IP-100

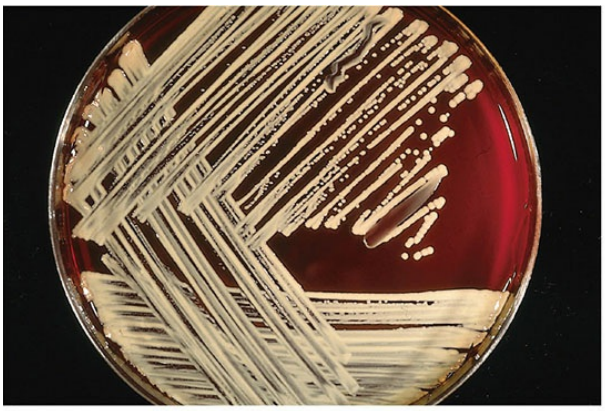
G. Growth of *Brevibacterium casei* on SBA after 24 hours of incubation at 35°C to 37°C. Colonies of this organism are pigmented pale yellow, which intensifies during incubation beyond 24 hours. These isolates also have a strong odor reminiscent of "stinky feet." This particular isolate was recovered from multiple blood culture of a patient with AIDS who had a central-line-associated infection.

H. API Coryne inoculated with *B. casei*. The interpretations of the reactions shown are:

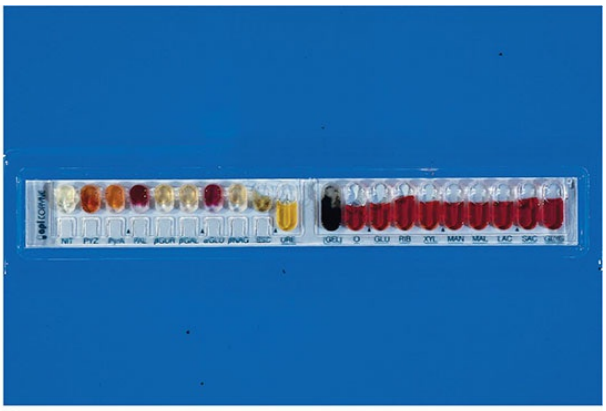
NIT	Negative	PYZ	Positive	PYRA	Positive
PAL	Positive	β-GUR	Negative	β-GAL	Negative
α-GLU	Positive	β-NAG	Negative	ESC	Negative
URE	Negative	GEL	Positive	CHO Control	Negative
GLU	Negative	RIB	Negative	XYL	Negative
MAN	Negative	MAL	Negative	LAC	Negative
SAC	Negative	GLYG	Negative	CAT	Positive

The API Coryne biocode for these reactions is 6112004, which corresponds to an identification of *Brevibacterium* species. Additional testing confirmed that this blood culture isolate was indeed *B. casei*.

IP-101



G



H

IP-102

IMAGE PLATE 14-7

Rothia, *Cellulosimicrobium*, *Cellulomonas/Microbacterium*, and *Lactobacillus* Species

A. Growth of *Rothia dentocariosa* on SBA after 48 hours of incubation at 35°C to 37°C. This gram-positive bacillary organism is related to the nocardioform organisms and forms dry, white, cerebriform colonies on agar media, as shown here.

B. API Coryne inoculated with *R. dentocariosa*. The interpretations of the reactions shown are:

NIT	Positive	PYZ	Positive	PYRA	Positive
PAL	Negative	β-GUR	Negative	β-GAL	Negative
α-GLU	Positive	β-NAG	Negative	ESC	Positive
URE	Negative	GEL	Negative	CHO Control	Negative
GLU	Positive	RIB	Negative	XYL	Negative
MAN	Negative	MAL	Positive	LAC	Negative
SAC	Positive	GLYG	Negative	CAT	Positive

The API biocode for these reactions is 7050125, which corresponds to an identification of *R. dentocariosa*, 99.5% likelihood.

C. Growth of *Cellulosimicrobium cellulans* on SBA after 24 hours at 35°C to 37°C. This bright yellow-pigmented organism was formerly called *Oerskovia xanthineolytica*.

D. API Coryne inoculated with *C. cellulans*. The interpretations of the reactions shown are:

NIT	Positive	PYZ	Positive	PYRA	Positive
PAL	Positive	β-GUR	Negative	β-GAL	Positive
α-GLU	Positive	β-NAG	Positive	ESC	Positive
URE	Negative	GEL	Positive	CHO Control	Negative
GLU	Positive	RIB	Positive	XYL	Positive
MAN	Negative	MAL	Positive	LAC	Negative
SAC	Positive	GLYG	Positive	CAT	Positive

The API biocode for these reactions is 7572727, which corresponds to an identification of *Oerskovia xanthineolytica* (*C. cellulans*), 99.9% probability.

E. Growth of a yellow-pigmented *Microbacterium* species on SBA after 24 hours at 35°C to 37°C.

F. API Coryne inoculated with *Microbacterium* species. The interpretations of the reactions shown are:

NIT	Negative	PYZ	Positive	PYRA	Negative
PAL	Positive	β-GUR	Negative	β-GAL	Positive
α-GLU	Positive	β-NAG	Positive	ESC	Positive
URE	Negative	GEL	Negative	CHO Control	Negative
GLU	Positive	RIB	Positive	XYL	Positive
MAN	Positive	MAL	Positive	LAC	Negative
SAC	Positive	GLYG	Positive	CAT	Positive

The API biocode for this organism is 2570737, which corresponds to an identification of *Cellulomonas* spp./*Microbacterium* spp. (99.9% likelihood). Additional tests are needed to separate these two genera.

G. Gram-stained smear of a blood culture that grew *Lactobacillus* species. These organisms are regular, gram-positive bacilli that occur singly, in pairs, or in short chains.

H. Small colonies of a nonhemolytic *Lactobacillus* species growing on SBA after 24 hours of incubation at 35°C to 37°C.

IMAGE PLATE 14-8

Lactobacillus and *Gardnerella* Species

A. *Lactobacillus* species inoculated as a lawn on an SBA plate with a vancomycin disk. Some lactobacilli are resistant to the glycopeptide antibiotics vancomycin and teicoplanin, as indicated by growth of the organisms to the edge of the vancomycin disk, as shown here.

B. Gram-stained smear of a normal vaginal specimen. Note the presence of the large epithelial cells and the gram-positive bacilli that correspond to the "*Lactobacillus* morphotype."

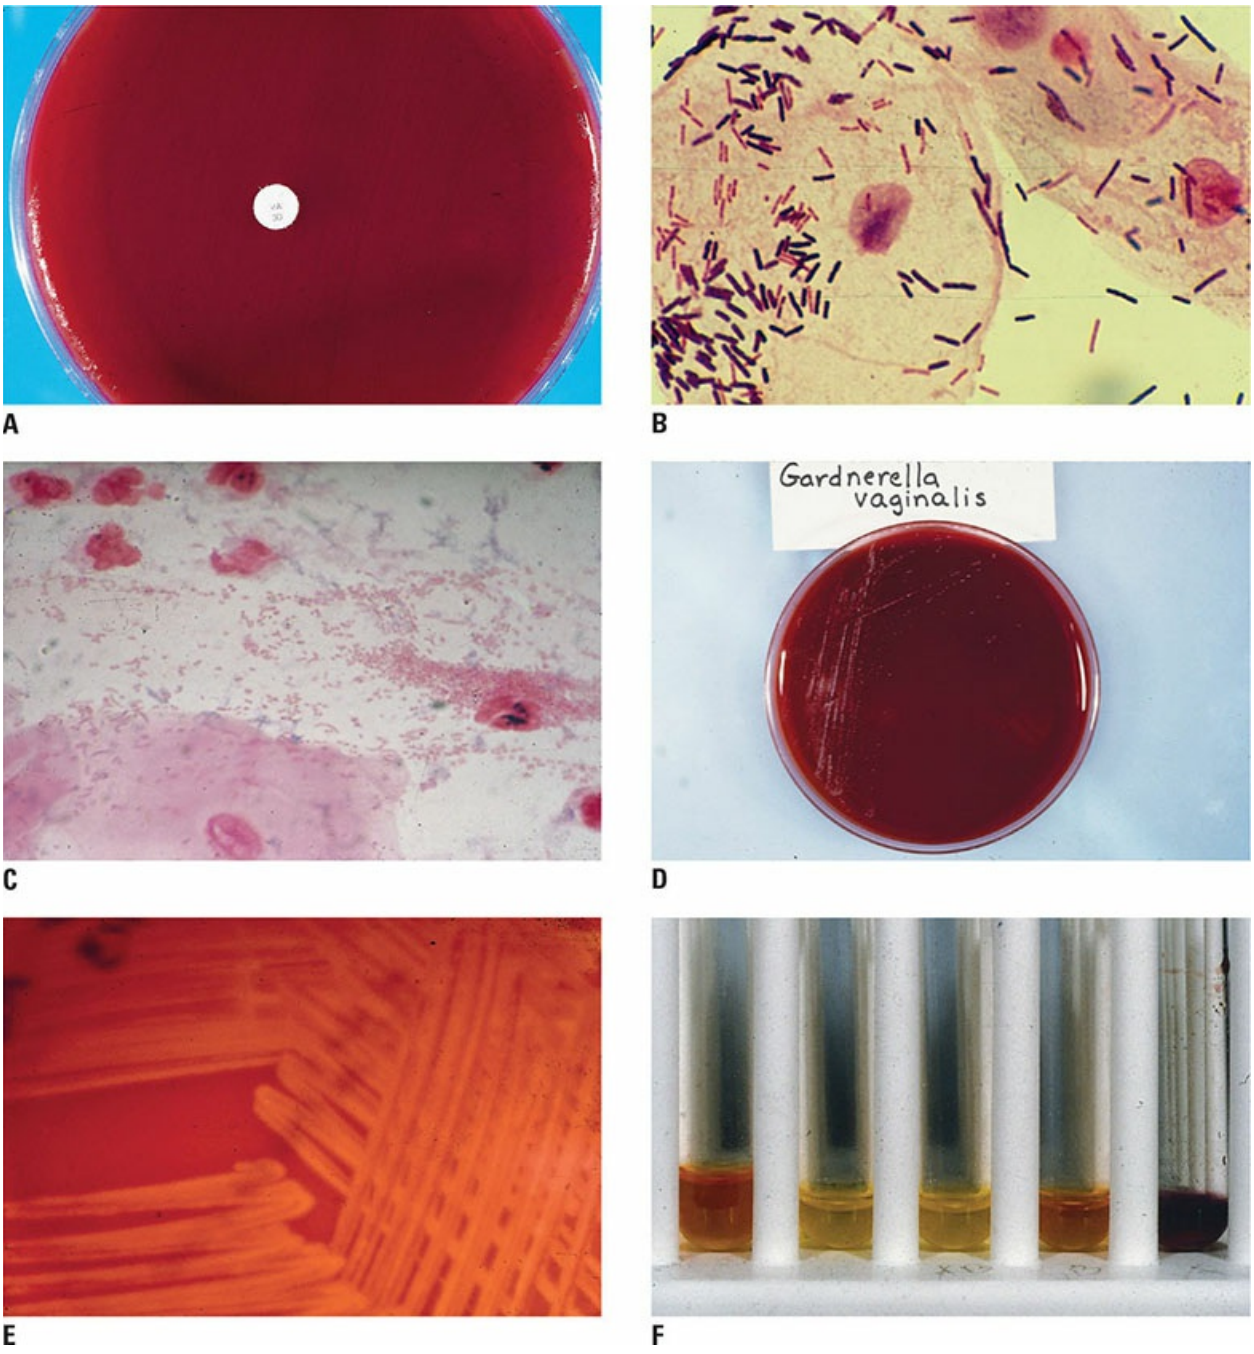
C. Gram-stained smear of material collected from the vagina of a patient with bacterial vaginosis. The epithelial cell shown in the slide is covered with a preponderance of gram-negative bacilli and coccobacilli, which represent anaerobic gram-negative bacilli and "*Gardnerella* morphotypes."

D. Growth of *G. vaginalis* on CNA blood agar after 48 hours of incubation at 35°C to 37°C in 5% to 7% CO_2. After this time, colonies are very small and are best observed in areas of confluent growth.

E. Small, β-hemolytic colonies of *Gardnerella vaginalis* growing on HBT (human blood bilayer-Tween) medium after 72 hours of incubation at 35°C to 37°C in 5% to 7% CO_2. This organism is β-hemolytic on medium containing human blood (like HBT agar).

F. Rapid carbohydrate utilization technique for identification of *G. vaginalis*. This 4-hour identification procedure is similar to that used for identification of *Neisseria* species (Chapter 11). A balanced salt solution with phenol red and no carbohydrates (BSS) is dispensed in small tubes in 0.10-mL volumes, and single drops of 20% filter-sterilized carbohydrates are added to the BSS. A dense suspension of the organism is prepared in BSS with no carbohydrate (0.5 mL), and single drops of this suspension are added to the carbohydrate-containing tubes. In the photograph, the individual tubes are (left to right) the BSS organism suspension, BSS-glucose, BSS-maltose, and BSS-mannitol. The last tube (far right) is a hippurate-hydrolysis test. As shown, *G. vaginalis* produces acid from glucose and maltose, but not mannitol, and is strongly hippurate-hydrolysis–positive.

IP-105



IP-106

IMAGE PLATE 15-1

Identification of Aerobic and Facultatively Anaerobic Gram-Positive Bacilli

A. Close-up view of *Nocardia asteroides* complex after 7 days of incubation at 30°C on Middlebrook 7H11 agar. Seen here are the typical orange, glabrous, wavy colonies that tend to be adherent to the agar surface. Other species produce white, dry, chalky colonies (Image Plate 1-5J). It is noteworthy that *Nocardia* species will grow on the selective isolation media used for the recovery of *Mycobacterium* species; in fact, the laboratory diagnosis of nocardiosis is often first suspected in the mycobacteriology section of the laboratory. The detection of a distinct musty basement odor is an initial clue to the identification.

B. Middlebrook 7H11 agar plate on which a 48-hour culture of *Rhodococcus* species is growing. The colonies are relatively large, ranging from 2 to 4 mm in diameter, and are entire and smooth. Note the salmon-pink pigmentation, an initial clue to the identification of this species.

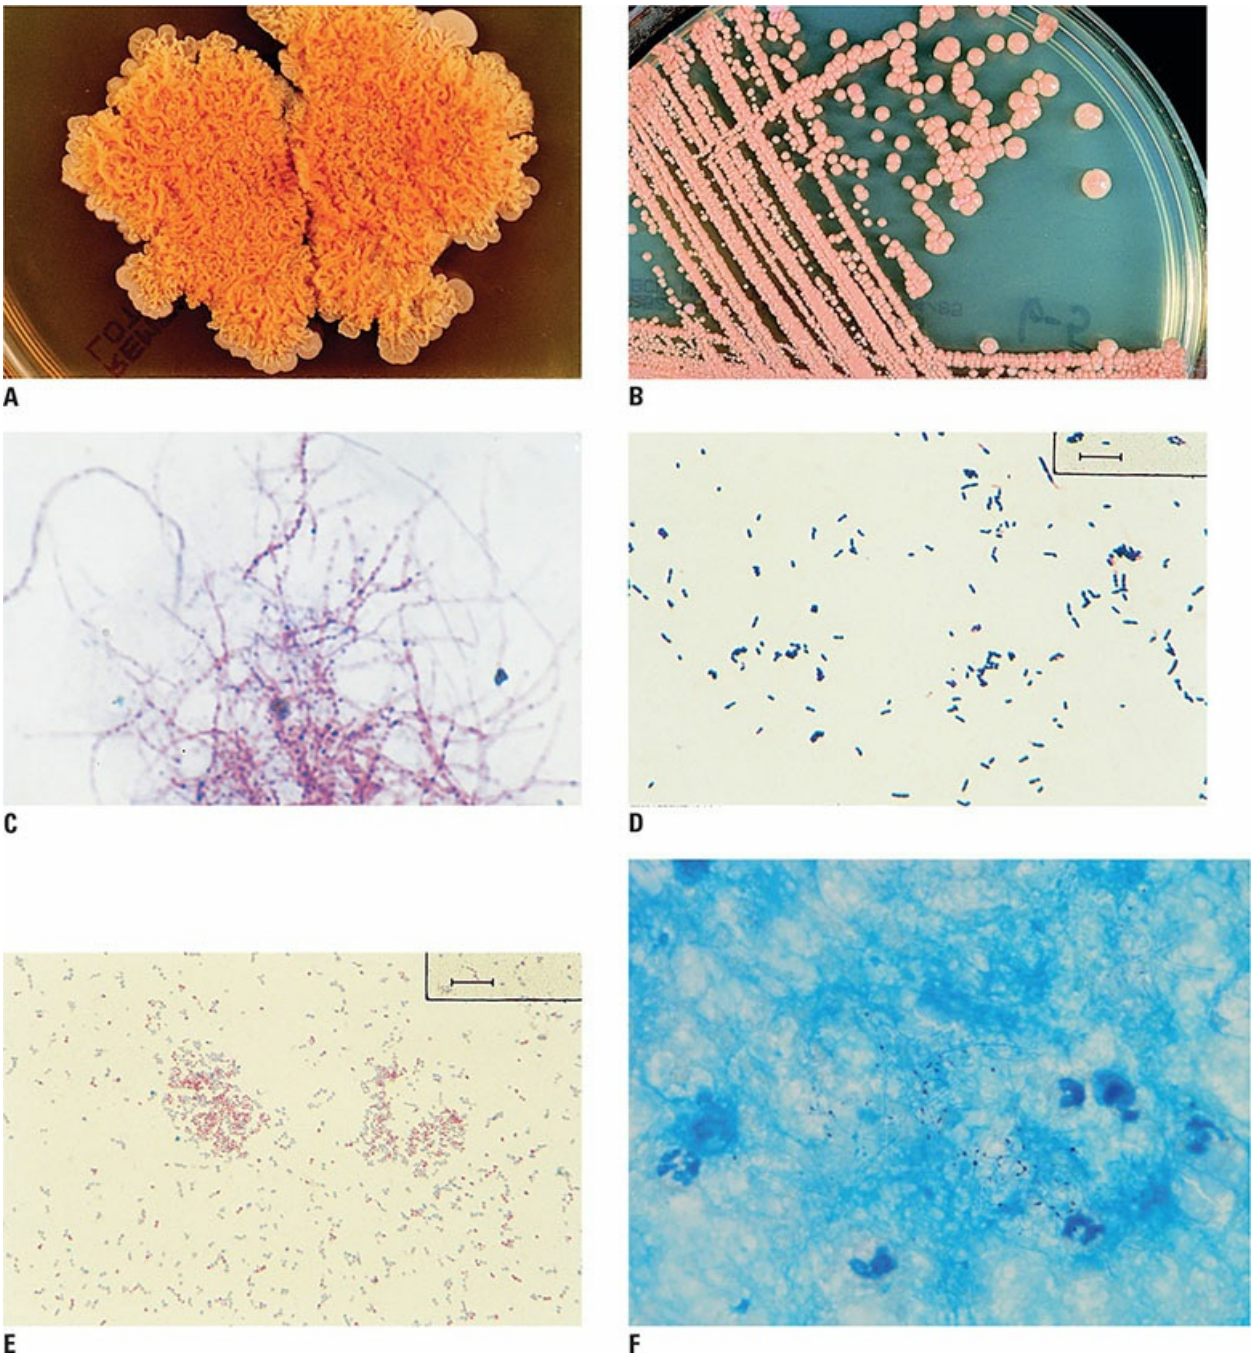
C. Modified or partial acid-fast stain of an exudate containing acid-fast, delicate, branching filaments characteristic of *Nocardia* species. *Nocardia asteroides* complex was recovered from the culture obtained from this specimen.

D. Gram's stain of *Rhodococcus* species illustrating short gram-positive coccobacilli arranged singly and in "Chinese letters" clusters.

E. Modified acid-fast stain of *Rhodococcus* species showing short coccobacilli, many of which are modified acid-fast-positive.

F. In some instances, when *Nocardia* is stained in direct clinical specimen, the filaments may not take up the stain and the organism stains in this "beaded" manner, wherein only the beaded foci are modified acid-fast-positive. Modified acid-fast stain, 1000× magnification.

IP-107



IP-108

IMAGE PLATE 16-1

IDENTIFICATION OF ANAEROBIC BACTERIA: GRAM-NEGATIVE BACILLI

A. *Bacteroides fragilis*. Gram's stain of cells in 48-hour thioglycolate broth culture.

B. *Bacteroides fragilis*. Colonies on anaerobic blood agar after 48 hours of incubation at 35°C.

C. *Prevotella melaninogenica*. Gram's stains of cells from a 48-hour colony on blood agar.

D. *Prevotella melaninogenica*. Black colonies on blood agar after 5 days of incubation at 35°C.

E. *Fusobacterium nucleatum*. Gram's stain of cells from a 48-hour colony on anaerobic blood agar. Note long, gram-negative bacilli with pointed ends.

F. *Fusobacterium nucleatum*. Characteristic colonies on anaerobic blood agar after 48 hours of incubation at 35°C, illustrating the opalescent effect.

G. *Fusobacterium necrophorum*. Gram's stain of cells from a 48-hour colony on anaerobic blood agar. Note pleomorphism.

H. *Fusobacterium necrophorum*. Colonies on anaerobic blood agar after 48 hours of incubation at 35°C.

IMAGE PLATE 16-2

IDENTIFICATION OF ANAEROBIC BACTERIA: GRAM-POSITIVE, NON–SPORE-FORMING ORGANISMS

A. Gram-stained direct smear of a purulent exudate showing degenerated neutrophils and a mixture of gram-negative bacilli of different sizes. The smallest coccobacilli suggest one of the pigmented *Prevotella–Porphyromonas* species; the larger, pleomorphic bacilli suggest a member of the *Bacteroides fragilis* group.

B. Gram-stained direct smear of a purulent exudate from an intra-abdominal abscess, showing segmented neutrophils, gram-positive cocci in pairs and short chains, and tiny gram-negative bacilli. Anaerobic infections usually contain a mixture of bacterial microbiota.

C. Dissecting microscope view of actinomycotic "sulfur granules." This exudate from an abdominal wound infection was photographed within a Petri dish.

D. Appearance of a Gram-stained smear from the same specimen as in C, showing a "sulfur granule" with thin, branching filaments of an *Actinomyces* species.

E. *Actinomyces israelii*. Gram-stained preparation of growth from a colony on blood agar. Note the branching of the cells.

F. The characteristic "molar tooth" colonies of *Actinomyces israelii* shown here were produced on brain–heart infusion agar after 7 days of anaerobic incubation at 35°C.

G. This Gram's stain demonstrates the cells of *Eubacterium alactolyticum* from growth in enriched thioglycolate broth after 48 hours of incubation at 35°C.

H. The colonies of *Eubacterium alactolyticum* on anaerobic blood agar are shown here after 48 hours of incubation.

IMAGE PLATE 16-3

IDENTIFICATION OF ANAEROBIC BACTERIA: CLOSTRIDIA

A. This is a Gram's stain of *Clostridium perfringens* from a 24-hour colony on blood agar. Note the lack of spores and that of some cells that tend to stain red (i.e., gram-negative).

B. This is a Gram's stain of *Clostridium perfringens* from a 24-hour thioglycolate broth culture. Note the lack of spores and presence of a few filamentous forms.

C. This is the typical appearance of *C. perfringens* on blood agar after 24 hours of incubation at 35°C. Note the double zone of hemolysis. The inner zone of complete hemolysis is due to theta-toxin and the outer zone of incomplete hemolysis to alpha-toxin (i.e., lecithinase activity).

D. *C. perfringens*. This is the direct Gram's stain of a muscle tissue aspirate from a patient with gas gangrene myonecrosis. There is a necrotic background, without intact inflammatory cells or muscle cells, and relatively large "box car"-shaped gram-positive bacilli and a gram-negative bacillus that is either a gram-variable *C. perfringens* cell or another organism.

E. Colonies of *C. perfringens* on modified McClung egg yolk agar. The precipitate surrounding the colonies indicates lecithinase activity of alpha-toxin produced by the organism.

F. Lipase production on egg yolk agar. A few clostridia, such as *C. botulinum*, *C. sporogenes*, and *C. novyi* type A, exhibit lipase activity on egg yolk agar, as shown here. Note the iridescent pearly layer on the surface of the colonies extending onto the surface of the medium immediately surrounding them.

G. These rough, irregular, flat, rhizoid, spreading colony on a 48-hour anaerobic blood agar plate is characteristic of *C. septicum*.

H. This is a direct Gram-stained smear of a positive blood culture that contained *C. septicum*. Numerous ovoid or citron-shaped, subterminal spores are present.

IMAGE PLATE 16-4

IDENTIFICATION OF ANAEROBIC BACTERIA: CLOSTRIDIA (CONTINUED)

A. These are colonies of *C. tetani* on stiff blood agar (4% agar), which is used to inhibit the swarming of the microorganism so that it can be isolated from other bacteria present in mixed cultures.

B. This is a Gram's stain of *C. tetani* from a chopped meat glucose broth culture. Some of the cells have round, terminal spores, which are characteristic of *C. tetani*.

C. The "Medusa-head" colonies on this anaerobic blood agar after 48 hours of incubation are characteristic of *C. sporogenes*.

D. This Gram's stain of *C. ramosum* is from a thioglycolate broth culture after 48 hours of incubation.

E. These are colonies of *C. difficile* on anaerobe blood agar after 48 hours of incubation.

F. This is *C. difficile* on cycloserine-cefoxitin fructose agar after 48 hours of incubation.

G. This is *C. sordellii* on an anaerobe blood agar following prolonged anaerobic incubation. Colony is 5 × 10 mm.

H. This Gram's stain of *C. sordellii* is from a 2-day-old blood agar plate. It reveals clumps of free spores and bacteria distended with ovoid subterminal spores.

IMAGE PLATE 16-5

Identification of Anaerobic Bacteria: Use of Presumpto Quadrant Plates and Disks on Anaerobe Blood Agar

A. Overview appearance of three quadrant plates (described in detail in the text).

B. A Presumpto 1 quadrant plate and a plate of CDC anaerobe blood agar. After inoculation with an active broth culture or cell suspension of the isolate to be identified, antibiotic disks (penicillin, 2 units; rifampin, 15 g; kanamycin, 1,000 g) are placed on the blood agar medium, and a blank filter-paper disk is placed on the LD agar portion of the quadrant plate for use in detection of indole production. The Presumpto 1 plate contains the following media: LD agar, LD esculin, LD egg yolk agar, and LD bile agar.

C. Growth of *Bacteroides fragilis* on Presumpto 1 plate after 48 hours of incubation at 35°C. On the first quadrant (top, far right), LD agar shows moderate growth. Indole production can be detected by adding a drop of para-dimethylaminocinnamaldehyde to the paper disk (see **F**). The LD esculin agar to the left of the LD agar is diffusely dark because of the hydrolysis of the esculin. The LD egg yolk agar underneath the esculin agar shows good growth but no lecithinase, lipase, or proteolytic activity. There is abundant growth in the LD bile agar (bottom, far right), and a characteristic precipitate was produced in the medium by this strain.

D. Antibiotic disk tests. A zone of growth inhibition is seen around the 15-g rifampin disk, but no growth inhibition is seen around the 2-unit penicillin disk or the 1,000-g kanamycin disk. This pattern is characteristic of the *B. fragilis* group.

E. Reactions of *B. thetaiotaomicron* of the Presumpto 1 quadrant plate. The first quadrant (top, far right) shows a weak, positive indole reaction, as indicated by the pale blue color of the disk on LD agar after addition of para-dimethylaminocinnamaldehyde reagent. Black (amber) appearance of esculin agar (left of first quadrant) indicates esculin hydrolysis. There is adequate growth but no lecithinase, lipase, or proteolysis on LD egg yolk agar (bottom, far left). There is good growth on LD bile agar but no precipitate as exhibited by *B. fragilis* (bottom, far right).

F. Reactions of *Fusobacterium necrophorum* on the Presumpto 1 quadrant plate after 48 hours of incubation at 35°C. The first quadrant (bottom, far right) shows strong

indole reaction as evidenced by the dark blue color of the paper disk on LD agar after the addition of para-dimethylaminocinnamaldehyde reagent. Growth is inhibited on LD bile agar (top, right). Although not visible in this photograph because of the lighting arrangement, there is good growth in LD egg yolk agar (top, far left) and characteristic lipase activity as evidenced by an iridescent sheen—a pearly layer—on the surface of the colonies and in the medium immediately surrounding the bacterial growth. This is best demonstrated with reflected light. On LD esculin agar (bottom, left), the *F. necrophorum* shows good growth and hydrogen sulfide production, as evidenced by the black appearance of the colonies, but no darkening of the medium to suggest esculin hydrolysis.

G. Presumpto 2 quadrant plate (uninoculated). The plate contains the following quadrants (clockwise, starting at 12 o'clock): LD starch agar, LD glucose agar, LD-DNA agar, and LD milk agar.

H. Presumpto 2 quadrant plate following inoculation, incubation, and addition of reagents. Note positive reactions for hydrolysis, deoxyribonuclease activity, and glucose fermentation.

IMAGE PLATE 18-1

MYCOPLASMAS AND UREAPLASMAS

A. Colony of *M. pneumoniae* on mycoplasma glucose agar. This photograph shows a single colony of the organism to which guinea pig erythrocytes have become adsorbed. *M. pneumoniae* is the only species that demonstrates this hemadsorbing property. (Photograph courtesy of Health and Education Resources, Bethesda, MD.)

B. Colonies of *M. hominis* and *U. urealyticum* growing on Shepard's A7B differential agar. *M. hominis* colonies have the typical "fried egg" morphology; the blue color is due to the Diene's stain. *U. urealyticum* colonies are smaller, denser, and have a brownish pigmentation because of precipitation of manganese oxide in the colony due to the action of urease enzymes. IP-119

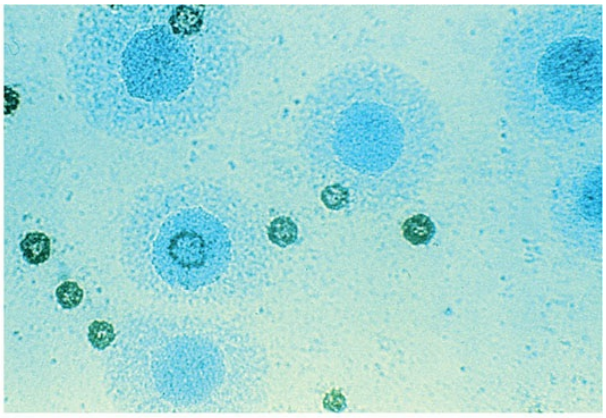
A



B

IP-120

IMAGE PLATE 19-1

THE LABORATORY IDENTIFICATION OF *MYCOBACTERIUM TUBERCULOSIS*

A. This photomicrograph is of a smear prepared from a colony similar to that

illustrated in Image Plate 19-1C, stained with auramine–rhodamine. Note the bright yellow fluorescence of the very short, slightly curved bacilli.

B. This photomicrograph is of a smear prepared from material obtained from a necrotic tuberculoma of the lung stained with the Kinyoun acid-fast stain. Note the relatively short, thin, beaded, slightly curved, red-staining acid-fast bacilli.

C. A microcolony growing on the surface of Middlebrook 7H10 agar, observed microscopically under low-power optics. Note that the bacterial cells are arranged in an undulating, serpiginous pattern. This indicates the production of cording factor, as illustrated in the acid-fast stain shown in Image Plate 19-1I.

D. A niacin-accumulation test. The tubes contain a filter paper strip impregnated with cyanogen bromide. The fluid in the tube on the right had been extracted from the surface of Löwenstein–Jensen culture medium after colonial growth of an unknown *Mycobacterium* species, compared with a negative water control on the left. The development of a yellow color on the strip and in the underlying fluid indicates the presence of niacin. *M. tuberculosis* has the uncommon property of accumulating niacin when colonies are grown on Löwenstein–Jensen medium, a property that is shared by the less commonly encountered species, such as *M. simiae* and occasional strains of *M. marinum*.

E. Tubes illustrating the nitrate-reduction test. The tube on the right had been inoculated with an unknown *Mycobacterium* species, which is compared with an uninoculated control on the left. The development of a red color after addition of sulfonamide and α-naphthylethylenediamine reagents indicates the presence of nitrites and a positive test. *M. tuberculosis* is an active nitrate reducer.

F. A quadrant plate containing Middlebrook 7H10 agar in which thiophene-2-carboxylic acid hydrazide (T2H) had been incorporated. The three quadrants in which growth is observed are different strains of *M. tuberculosis* (i.e., resistant to T2H); the quadrant without growth was inoculated with a strain of *M. bovis*. The ability to grow or not grow on medium containing T2H is helpful in separating *M. tuberculosis* from *M. bovis*, respectively.

G. A flask of Löwenstein–Jensen medium on which are growing colonies of *M. tuberculosis* after a 22-day incubation at 35°C in a 10% CO_2 incubator. The colonies seen here are distinctly rough in consistency. Although this isolate was determined to be *M. tuberculosis,* it should be considered unusual, as it has more of a yellow pigmentation than the buff-colored colonies usually observed (**H**).

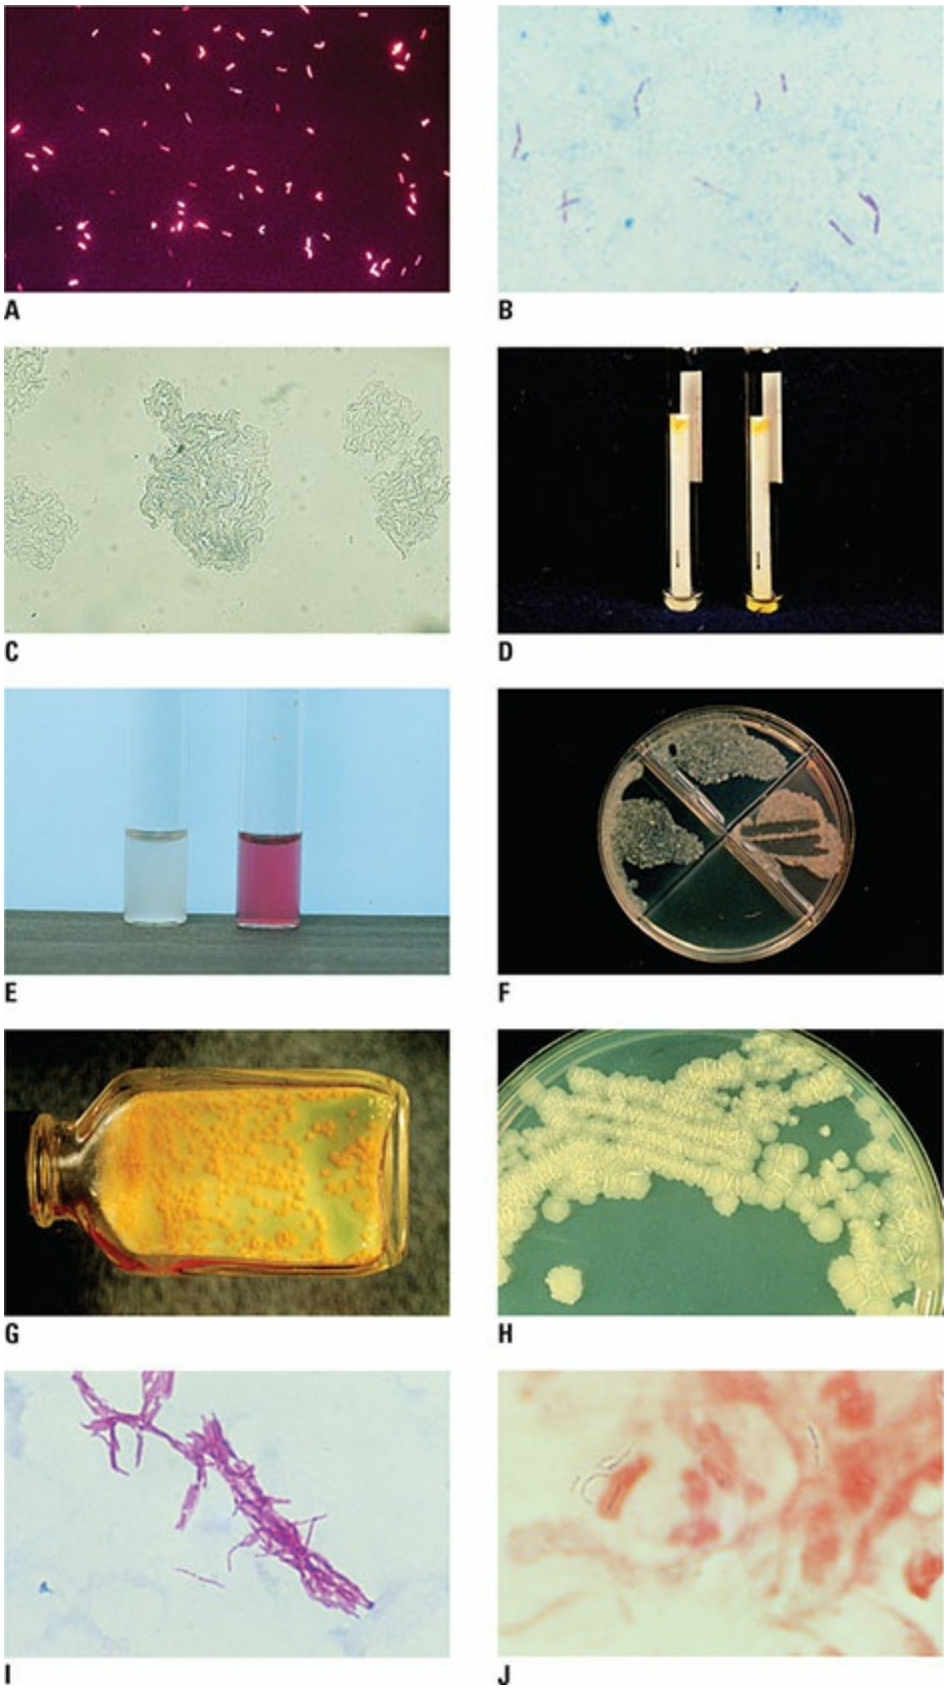
H. These are typical colonies of a subculture of *M. tuberculosis* growing on Middlebrook 7H10 agar after a 25-day incubation at 35°C in 10% CO_2 incubator.

The colonies have a rough, buff appearance, characteristic for the species.

I. This photomicrograph is of a Kinyoun acid-fast stain prepared from the broth of a BACTEC 12A blood culture vial after a 10-day incubation at 35°C. Numerous acid-fast bacilli are seen, arranged in parallel sheaths. When the aggregate of bacterial cells, as illustrated here, is observed in smears prepared from a broth preparation, the isolate is likely *M. tuberculosis*, because the phenomenon is due to the production of cording factor, thought to be a virulence factor.

J. This photomicrograph is of a Gram's stain prepared from a smear of pleural fluid from a patient with AIDS who developed an empyema. Note the relatively long, slender, delicately beaded, poorly staining gram-positive bacilli. Because of their thick waxy outer coating, the bacterial cells of mycobacteria do not stain well with crystal violet, the primary stain used in the Gram's stain. *M. tuberculosis* grew out in the culture from this patient specimen.

IP-121



A B C D E F G H I J

IMAGE PLATE 19-2

LABORATORY IDENTIFICATION OF *MYCOBACTERIUM* SPECIES OTHER THAN *M. TUBERCULOSIS*

A. Photomicrograph of microcolonies of *M. avium* growing on Middlebrook 7H10 agar after a 6-day incubation at 35°C in 10% CO_2. The flat, thin, translucent microcolonies, with a central darker umbonate elevation, suggestive of a fried egg, are characteristic of the smooth strains of *M. avium* commonly recovered from patients with AIDS. The observation of this type of microcolony may be helpful in directing one to perform an *M. avium*/*M. intracellulare* complex nucleic acid probe in the rapid culture confirmation of an unknown isolate.

B. Close-up photomicrograph of a single microcolony of *M. avium*/*M. intracellulare* complex, again illustrating the thin, translucent colony described in Image Plate 19-2A. The rhizoid-like peripheral extensions, as illustrated here, are often seen and provide an added clue to the presumptive identification of *M. avium*/*M. intracellulare* complex organisms.

C. Two Middlebrook 7H10 agar plates, each inoculated with the same subculture of *M. kansasii*. The plate on the left was exposed to light; the one on the right remained in the dark until just before the photograph was taken. The yellow pigment of the colonies in the light-exposed plate is characteristic of a photochromogen.

D. Two Middlebrook 7H10 agar plates each inoculated with the same subculture of *M. scrofulaceum*. The plate on the left was exposed to light; the one on the right remained in the dark until just before the photograph was taken. The yellow pigment of the colonies in both the light-exposed and non–light-exposed plates is characteristic of a scotochromogen.

E. A Middlebrook 7H10 agar plate previously inoculated with a strain of *M. gordonae*. This organism is a scotochromogen and characteristically produces a deep yellow pigment, as illustrated here.

F. Several tubes containing varying concentrations of buffered sodium nitrate inoculated with various strains of *Mycobacterium* species to illustrate 1+ (second tube from the left) through 4+ (rightmost tube) reactions. The red color develops after the addition of sulfanilamide and *N*-naphthylethylenediamine reagents; the intensity of color reflects the concentration of nitrites produced. The quantitative

nitrate-reduction test may be helpful in differentiating strains of *M. tuberculosis* (4+ positive) from *M. bovis* (1+ positive), and *M. kansasii* (4+ positive) from other photochromogens (negative to 1+ positive).

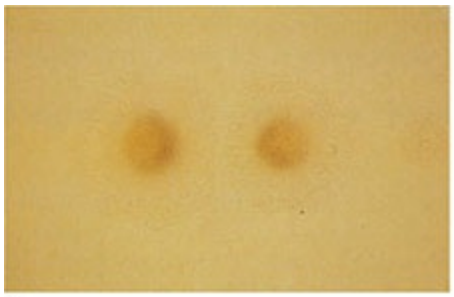
G. Two tubes containing Tween 80 reagent. The tube on the left had been inoculated with a negative control strain, whereas the tube on the right with a subculture of *M. kansasii*. The development of a red color (right tube) after incubation for 3 to 10 days is a positive test, indicating the ability of the test strain to hydrolyze Tween 80. The color change from yellow to red in this assay is not due to a shift in pH; rather, it results from a change in optical density as oleic acid and polyoxyethylated sorbitol are produced as breakdown products of Tween hydrolysis.

H. Two tubes of Löwenstein–Jensen deeps previously inoculated with a catalase-negative control (left tube) and a subculture of *M. kansasii* (right tube). Note the tall column of bubbles formed in the right tube after the addition of hydrogen peroxide to the surface of the agar. A column exceeding 45 mm is indicative of a positive test and strong catalase activity.

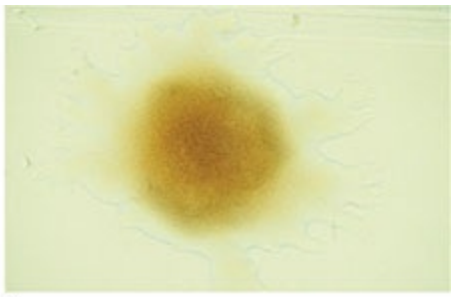
I. A positive catalase test. Immediately before the photomicrograph was taken, a few drops of hydrogen peroxide were placed on isolated colonies of the photochromogenic colonies of *M. kansasii*. The evolution of rapid bubbles, as illustrated here, indicates a positive test, indicating active catalase activity.

J. Two tubes of Dubos broth base. The right tube contains the tripotassium phenolphthalein disulfate reagent (arylsulfatase reagent) compared with a negative control tube on the left devoid of reagent. Both tubes had been previously inoculated with a subculture of a strain

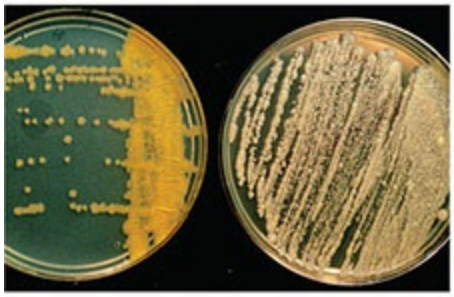
IP-123



A



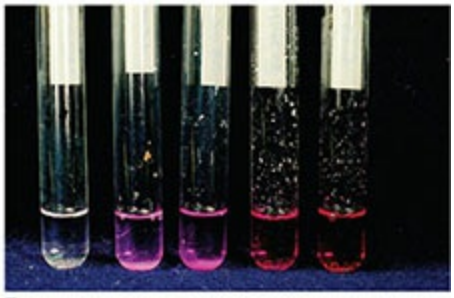
B



C

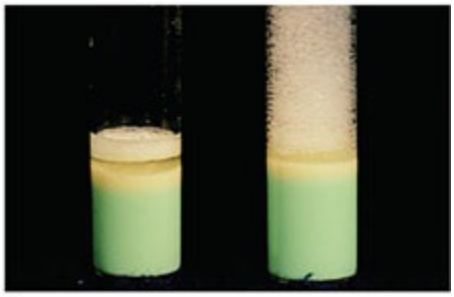
D

E

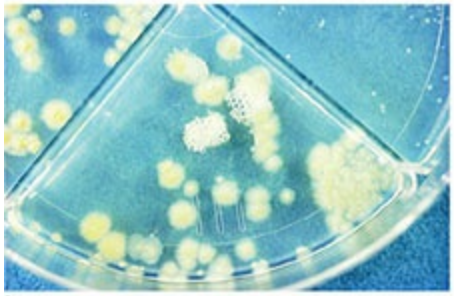


F

G



H



I

J

of *M. fortuitum*. The development of a pink color after the addition of sodium carbonate reagent in the right tube indicates a positive test and arylsulfatase activity of the test strain.

K. Two tubes of urea broth previously inoculated with a negative control (left tube) and a subculture of *M. gordonae* (right). Mycobacterial strains having urease activity will turn the broth pink within several hours (strong positive) to a few days, owing to the release of ammonia and alkalinization of the medium. Assessment of urease activity may be helpful in separating *M. gordonae* (strong positive) from other scotochromogens, and *M. fortuitum*/*M. chelonae* from other rapidly growing mycobacteria.

L. Two tubes of Dubos broth base. The tube on the left contains pyrazinamide, whereas the tube on the right is a negative control devoid of reagent. Both tubes had previously been inoculated with a subculture of a strain of *M. avium*. The development of a pink-red band at the reagent layer toward the surface of the agar in the left tube, after addition of ferrous ammonium sulfate reagent, indicates a positive test and the ability of this strain to deaminate pyrazinamide.

M. Photomicrograph of an acid-fast smear prepared from a subculture of *M. kansasii*. The bacterial cells of *M. kansasii* are described as rectangular, straight, and banded, which is reasonably represented here. Because of variation between strains and between other species, a presumptive identification of *Mycobacterium* species based on acid-fast stain morphology is not recommended; the banding of *M. kansasii,* however, is the best indicator of this particular species to the experienced mycobacteriologist.

N. A Middlebrook 7H10 agar plate previously inoculated with a subculture of a classical strain of *M. avium*. The classical strains of *M. avium* were originally included in the group III non-photochromogens in the Runyon classification. Note that the colonies here are relatively small, smooth, and gray-white, without evidence of pigmentation.

O. A Middlebrook 7H10 agar plate previously inoculated with a strain of the *M. avium*/*M. intracellulare* (MAI) complex recovered from a patient with AIDS. Many of the MAI strains recovered from patients with AIDS have this distinct yellow pigmentation. The peculiar doughnut-shaped colonies are a well-described colonial morphology, but not so for all strains.

P. Low-power photomicrograph of a liver biopsy from a patient with AIDS who was

also infected with a member of the *M. avium*/*M. intracellulare* complex. Note the tight intracellular clusters of short, acid-fast bacilli in the central part of the photograph.

Q. A Middlebrook 7H10 agar plate inoculated 3 days before with a strain of *M. fortuitum* and incubated at 35°C in 10% CO_2. The colonies average 1 to 2 mm in diameter and are entire, smooth, moist, and devoid of pigmentation. *Mycobacterium fortuitum* is one of the rapidly growing mycobacteria that were classified by Runyon as group IV.

R. A modified MacConkey agar plate, which is devoid of crystal violet, demonstrates colonies of *M. fortuitum*. Strains of *M. fortuitum*-chelonae have the unique ability to grow on modified MacConkey agar. The colonies average 2 mm in diameter and are entire, moist, and have a slight pink-yellow tinge due to pigment derived from the agar.

S. A 5% sheep blood agar plate with a 48-hour growth on *M. fortuitum*. Rapidly growing mycobacteria such as this will grow on routine 5% sheep blood agar within 48 to 72 hours and may cause confusion with other gram-positive bacillary organisms if a partial acid-fast stain is not performed.

T. Photomicrograph of a Gram's stain of a smear prepared from an isolated colony illustrated in Image Plate 19-2S. The bacterial cells appear as short, slender, almost filamentous, faintly staining gram-positive coccobacilli. Microscopists must be alerted to these microscopic findings and not make a presumptive misidentification of an *Actinomyces* species or *Corynebacterium*. An acid-fast stain of a second smear will be helpful in making the correct identification.

IMAGE PLATE 19-3

Clinical Manifestations of Select Mycobacterial Diseases

A. Chest roentgenogram from a patient with pulmonary tuberculosis. Note the extensive area of dense infiltration of the right upper lobe.

B. A solitary nodular lesion with well-defined margins is seen in the upper segment of the left lower lung field. A coin lesion of pulmonary coccidioidomycosis, histoplasmosis, and cryptococcosis must be included in the differential diagnosis of such a lesion, as well as malignancy. This lesion turned out to be a tuberculoma.

C. A resected lobe of lung illustrating centrally a well-circumscribed, 2.5-cm-diameter, white, firm-appearing nodule. This histologically was a tuberculoma, similar to what may have been removed from the patient whose chest radiograph is shown in Image Plate 19-3B.

D. This photomicrograph of a hematoxylin and eosin-stained section taken from a tuberculoma illustrates varying degrees of background fibrosis and a cellular infiltration composed of lymphocytes and macrophages, many of the latter forming characteristic Langhans giant cells.

E. The base of the brain in a patient dying from tuberculous meningitis. The pia arachnoid covering the base of the brain, particularly in the area of the optic chiasm, appears cloudy, as a manifestation of the chronic inflammatory reaction.

F. A patient with cutaneous tuberculosis of the fifth digit. The lesion shown here appears active and inflammatory. The radiograph revealed bone and joint involvement of the middle and distal phalanx. Lesions of the fingers similar to that shown here were, at one time, common among individuals who milked cows.

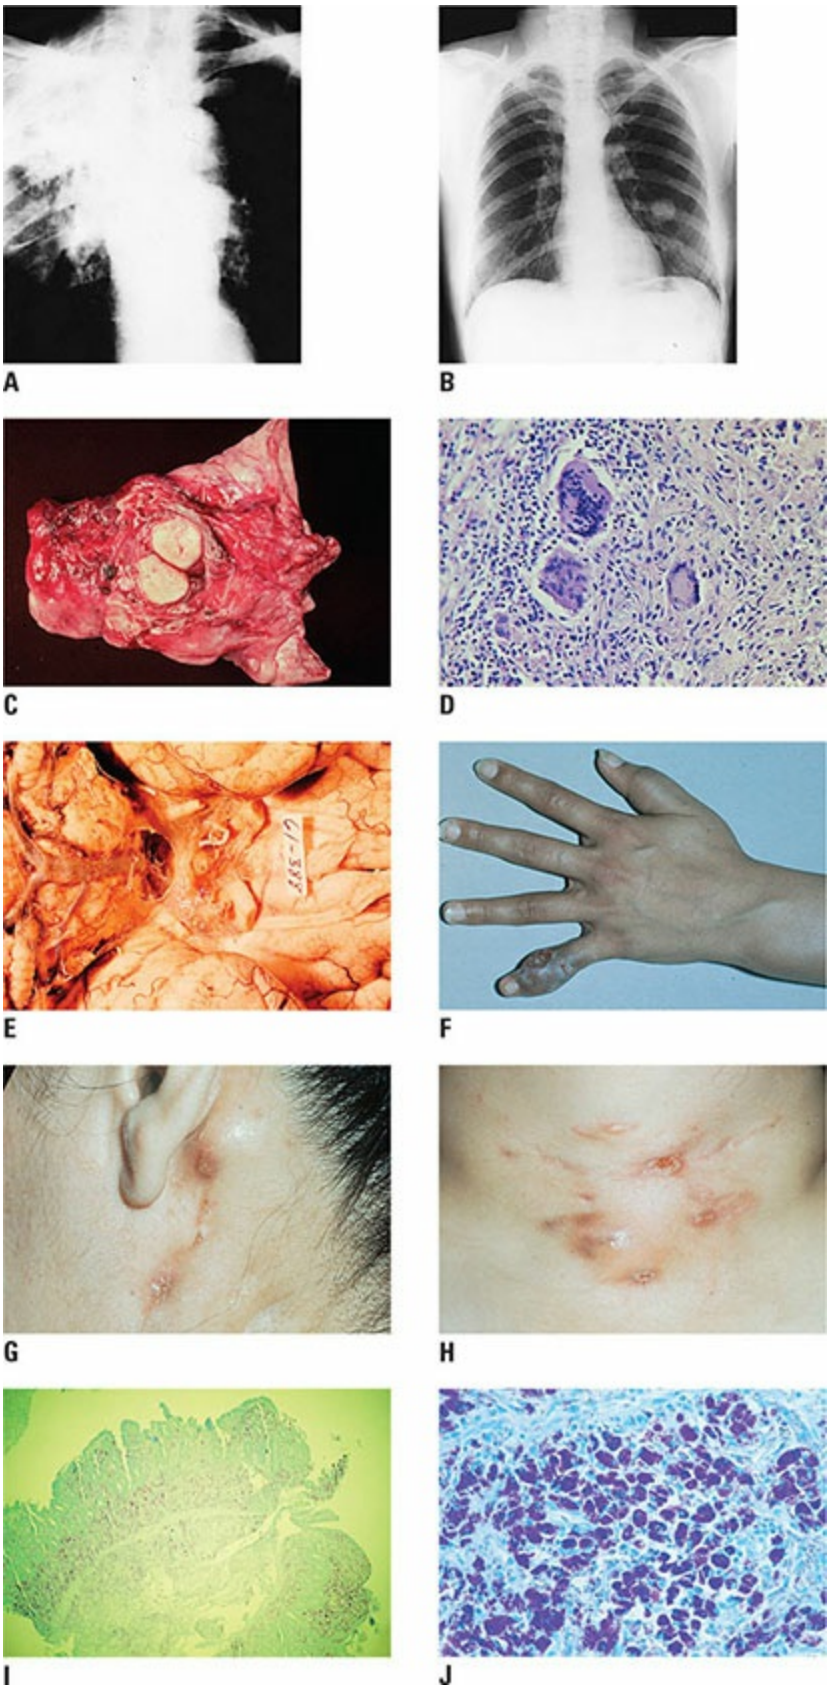
G. The posterior neck of this patient demonstrates an enlarged, postauricular lymph node with healed draining sinuses along the route of the lymphatic drainage. This is a classical picture of "scrofula" or mycobacterial lymphadenitis, typically caused by *M. scrofulaceum* and mycobacteria other than *M. tuberculosis*, such as *M. avium*. The route of infection is oral, and commonly occurs in two age groups during periods of teething—in children 3 to 7 years of age, when secondary teeth are coming in, and in persons in their late teen years, when molars are being cut. The causative agent of mycobacterial lymphadenitis in areas with a high prevalence of tuberculosis is *M. tuberculosis*.

H. The anterior portion of the neck illustrates multiple healed sinus tracts in this patient with chronic tuberculous lymphadenitis.

I. Low-power photomicrograph of a section of small bowel stained with a carbol-fuchsin-based acid-fast stain. The pink mottling seen in the submucosa is dense aggregates of acid-fast bacilli from a patient with AIDS with an intestinal infection caused by *M. avium*/*M. intracellulare* complex.

J. High-power photomicrograph of an area shown in Image Plate 19-3I, better illustrating the dense intracellular aggregates of acid-fast bacilli.

IP-127



IP-128

IMAGE PLATE 20-1

Laboratory Diagnosis of Spirochetal Diseases

A. *Treponema pallidum*. This photomicrograph shows a Warthin–Starry stain of a histologic section of placenta from a patient with congenital syphilis. The tight spiral coils of the spirochete are clearly evident (original magnification, ×1,000).

B. *Treponema pallidum*. This control for the FTA-ABS test demonstrates 4+ staining of the spirochetes. The helical shape is evident, and the tightly coiled spirals can be visualized in some of the bacterial cells. This photomicrograph is an indirect immunofluorescence preparation of *T. pallidum* using fluorescein-conjugated antihuman globulin (original magnification, ×600). (Courtesy of Burton Wilcke, PhD, and Mary Celotti, Vermont Department of Public Health, Burlington, VT.)

C. Wright-stained peripheral blood smear from a case of *Borrelia* infection. The loose coils of the *Borrelia* organisms are evident, but the thin structure is easy to overlook. These spirochetes may be detected when examining smears for malaria or for cellular morphology, even if the physician does not suspect the diagnosis (original magnification, ×1,000). (Courtesy of Thomas Fritsche, MD, PhD.)

D. An acridine orange stain of peripheral blood demonstrates *Borrelia* spp. dramatically. If the diagnosis is suspected, this technique, which may be more sensitive than Giemsa or Wright's stains, may be used (original magnification, ×1000). (Courtesy of Brian Lauer, MD.)

E. *Ixodes scapularis* (*dammini*) ticks. These dark-colored hard ticks, also known as black-legged ticks or deer ticks, contain a dorsal scutum that covers the whole back on the male (M) but only a portion of the back on the female (F), nymph (N), and larva (L). It is the principal vector of *Borrelia burgdorferi*, the agent of Lyme disease, in the eastern United States. *Ixodes pacificus*, the vector in the Pacific region, looks very similar. The primary vectors are nymphs and adult females. Adult males bite only rarely, and the larval stage has not usually been infected when it bites humans. Nymphal ticks are a particular problem, because their small size makes it difficult to detect their presence.

F. *Borrelia burgdorferi* in a culture pellet stained with a monoclonal antibody to OspA protein conjugated to streptavidin-alkaline phosphatase. The typical polymorphism of *B. burgdorferi* is demonstrated. (Courtesy of Paul Duray, MD.)

G. A histologic section of dog kidney stained with a silver impregnation stain (Warthin–Starry) demonstrates several renal tubules in longitudinal orientation. Even at low power, the masses of *Leptospira* organisms are evident as blackening of the surface of the tubular epithelium. It is clear that this privileged site, where the leptospires are protected from host defenses, can serve as a productive source for spread of infection as the leptospira-contaminated urine is passed onto the ground (original magnification, ×1000). (Courtesy of David Miller, DVM, MS.)

H. Tubes of polysorbate 80-bovine albumin (PSO-BA) semisolid medium. An uninoculated tube is shown on the left. The tube on the right was inoculated with *Leptospira interrogans*. The subsurface growth in semisolid culture media is typical of leptospires, such as *L. interrogans* sv. *pomona*. Growth appears as a gray-white horizontal band about 1 cm below the medium surface after incubation for 2 to 6 weeks at room temperature. The band grows denser with continued incubation, but may be very scant with fastidious isolates, such as with *L. interrogans* sv. *hardjo*. (Courtesy of David Miller, DVM, MS.)

IP-130

IMAGE PLATE 21-1

COLONY MORPHOLOGY OF *ZYGOMYCETES* SPECIES AND SELECT *ASPERGILLUS* SPECIES

Members of the *Zygomycetes* and certain *Aspergillus* species are commonly encountered in clinical laboratories as agents of opportunistic infections. These fungi grow rapidly in culture, particularly the *Zygomycetes* species, which can fill a culture plate within 48 hours. Of the aspergilli, *A. fumigatus*, *A. flavus*, *A. niger,* and *A. terreus* are the most commonly recovered from specimens obtained from patients with aspergillosis. Other species, when recovered, are usually not identified to the species level. *A nidulans* and *A. glaucus* are two uncommonly encountered species that often produce cleistothecia, which are sexual reproductive structures that contain ascospores.

A. Sabouraud's dextrose agar plate inoculated with a *Zygomycetes* species. Notice that the entire plate is filled with a wooly, gray-white surface mycelium.

B. Close-up view of a colony of a *Zygomycetes* species after 96 hours of incubation. As this fungus colony matures, it takes on a gray-brown color, often with black, pepper-like stipples, indicating the production of sporangia.

C. The surface of a colony of *Aspergillus fumigatus* after a 5-day incubation on Sabouraud's dextrose agar. Mature colonies of *A. fumigatus* are generally powdery or granular, and have some shade of green-blue from the production of pigmented conidia. The growing margin often appears as a white apron, as illustrated here, which represents the outward growth of new mycelium.

D. The surface of a colony of *Aspergillus flavus* growing on Sabouraud's dextrose agar. The texture of mature colonies is usually granular from the production of conidia, and as the species name suggests, some shade of yellow pigmentation is characteristic, which becomes mixed with dark green with time.

E. The surface of a colony of *Aspergillus niger* after a 4-day incubation on Sabouraud's dextrose agar. The deep black, densely stippled surface is characteristic. The black surface pigmentation of *A. niger* can be distinguished from one of the dematiaceous fungi by observing the reverse side. The reverse of *A. niger* is a light gray or buff color, as the pigmentation is caused by surface conidia; in contrast, the reverse of dematiaceous fungi is jet black, as the vegetative hyphae contain the pigment.

F. The surface of a colony of *Aspergillus terreus* after a 6-day incubation on Sabouraud's dextrose agar. *A. terreus* characteristically has a granular surface and some shade of yellow or brown pigmentation, often described as cinnamon. Rugae radiating from the center are often seen, and the concentric zones of light and dark pigmentation as seen here are not unusual.

G. The surface of an albino strain of *Aspergillus nidulans*. Although most strains have some light pigmentation, albino strains of most *Aspergillus* species may occasionally be encountered and must be kept in the differential identification. The granular surface, with radiating rugae, is also common.

H. The surface of a colony of *Aspergillus glaucus*. The green and yellow variegated appearance seen here is not specific, because other *Aspergillus* species may have a similar appearance. Microscopic examination is necessary to make a species identification.

IP-132

IMAGE PLATE 21-2

Colony Morphology of Other Commonly Encountered Hyaline Molds

The colonies of the hyaline fungi have a varied appearance. Most display light pastel or deeper pigmentation, with combinations of green, yellow, orange, and brown hues commonly observed. The texture of the colonies may be smooth (glabrous), granular, cottony, or wooly, depending on their maturity and degree of sporulation. Microscopic studies must be performed to confirm the genus and species identification.

A. The surface of a colony of *Penicillium* species after a 5-day incubation on Sabouraud's dextrose agar, illustrating the distinctive green color, granular surface, radial rugae, and white apron at the periphery. Most strains of *Penicillium* species display some shade of green; colony colors, as well as microscopic features, are useful for differentiating *Penicillum* species from *Paecilomyces*.

B. The surface of a colony of *Penicillium marneffei,* a dimorphic fungus, after a 4-day incubation on Sabouraud's dextrose agar, illustrating the distinctive red pigmentation of a portion of the colony. Note that the pigment has diffused out into the agar, which has a light wine-red coloration. The surface tends to be granular to fluffy, depending on the degree of sporulation; note the distinct white apron at the margin of peripheral new growth.

C. The surface of a colony of *Paecilomyces variotii*. The colonies of *Paecilomyces* species are usually granular and often have a yellow-brown pigmentation, as illustrated here.

D. The surface of a colony of *Scopulariopsis brevicaulis* after 5 days of growth on Sabouraud's dextrose agar. The yellow pigmentation, granular texture, and radiating rugae, as illustrated here, are characteristic.

E. The surface of a colony of an *Acremonium* species after 5 days of incubation on Sabouraud's dextrose agar. The colonies of *Acremonium* may have a smooth, almost yeast-like appearance, as illustrated here, in the early phase of growth. These will become more mold-like, with production of delicate hyphae and fruiting bodies. Light pastel yellow, light green, and peach-red hues may be observed.

F. The surface of a typical colony of a *Fusarium* species after 6 days of growth on Sabouraud's dextrose agar. *Fusarium* species can be suspected when a rapidly

growing granular or fluffy colony, with a distinct rose-red, lavender, or purple pigmentation, is observed.

G. The surface of a typical fluffy, "house mouse gray" colony of a member of the *Pseudallescheria boydii* complex after 5 days of incubation on Sabouraud's dextrose agar. A rapidly growing colony with the "mouse gray" appearance, as illustrated here, always suggests this fungus. The unique pigmentation is caused by darkly pigmented conidia.

H. A colony of a *Gliocladium* species after 5 days of growth on Sabouraud's dextrose agar. The green pigment, extension of the colony from border to border without a well-defined growing margin, and granular texture (i.e., a so-called green lawn) are unique for *Gliocladium* and *Trichoderma* species. The latter more frequently may show a yellow, rather than a green, pigmentation.

IP-133

IP-134

IMAGE PLATE 21-3

COLONY MORPHOLOGY OF COMMONLY ENCOUNTERED DEMATIACEOUS MOLDS

The dematiaceous (dark) molds are characterized by the growth of deep green, brown, or black colonies, with black pigmentation on the reverse surface. Most environmental species grow rapidly, producing mature colonies within 5 days. Slower-growing species, at times requiring 2 weeks or more before mature colonies are observed, are often recovered from clinical specimens taken from patients with phaeohyphomycosis, mycetomas, or chromomycosis. Photographs of representative colonies of select dematiaceous molds growing on Sabouraud's dextrose agar are illustrated here.

A. Fluffy, gray-black surface of a colony of an *Alternaria* species after 6 days of growth. The appearance shown here is characteristic, but not distinctive for an *Alternaria* species, but may also be observed with other species of environmental dematiaceous molds.

B. Reverse surface of a dematiaceous mold, illustrating the dark appearance caused by the dark brown pigmentation of the vegetative hyphae.

C. Surface view of a subculture of an *Ulocladium* species, illustrating a wooly, dark brown-to-black pigmentation. Although frequently seen with certain strains of dematiaceous fungi, the light and darker concentric rings observed here are not distinctive for any given species.

D. Surface view of a colony of *Phialophora verrucosum* after 14 days of incubation. This particular strain has a dark gray-black hue, with a hair-like texture. Microscopic study is necessary, because other slow-growing species may produce similar-appearing colonies.

E. Surface view of a colony of *Fonsecaea pedrosoi* after 16 days of incubation. The colony is quite small, typical for the species, and the typical dark brown-black pigmentation is evident. This strain has a flatter, almost suede-like or velvet-like consistency.

F. Surface view of a colony of a more rapidly growing (5 days) environmental strain of *Cladosporium* species, illustrating a dark green, suede-like surface interrupted by irregular rugae. Environmental strains of *Cladosporium* species may appear dark green, as shown here, or may be gray, gray-brown, or brown-black,

simulating other dematiaceous fungi.

G. Surface view of another variant of an environmental *Cladosporium* species showing a dark gray, leather-like consistency. Colony texture among the dematiaceous molds range from wooly, to downy or hair-like, to suede-like, to leathery.

H. Appearance of the flat, smooth, yeast-like surface of *Aureobasidium pullulans* after 6 days of incubation. *Aureobasidium pullulans* and, morphologically similar, *Hormonema dematioides* should be considered when a tan-to-white yeast-like colony is isolated that darkens into a dematiaceous fungus with time. When the yeast-like colony is brown-to-black from first isolation, then an *Exophiala* species should be considered.

IMAGE PLATE 21-4

COLONY MORPHOLOGY OF DERMATOPHYTES

The colonies representative of the dermatophytic molds on culture media are not distinctive. There is sufficient strain variation and differences in appearance of the same strain, depending on the type of culture medium used and the environmental conditions during incubation, that colonial morphology is not a reliable criterion for making presumptive species-level identifications in most instances. Microscopic studies are almost always necessary to derive a definitive identification. Illustrated here are photographs of the colonies of select dermatophytes growing on Sabouraud's dextrose agar at 30°C, chosen to show certain characteristics that may offer clues to making a presumptive identification.

A. A colony of *Microsporum canis* after 5 days of incubation. The colonies tend to be fluffy or, at times, granular if conidiation is heavy. The lemon-yellow apron seen here, with pigment also extending to the reverse surface, is one clue suggesting *M. canis*.

B. Surface of a powdery, off-yellow colony of *Microsporum gypseum* after 6 days of incubation. *M. gypseum* tends to sporulate heavily; therefore, it is more prone to produce granular colonies than *M. canis*.

C. The surface of a smooth, white variant of *Trichophyton mentagrophytes*, with no evidence of background pigmentation of the agar. The colony illustrated here is not distinctive, and microscopic study is required to make an identification.

D. Surface of a fluffy variant of *Trichophyton mentagrophytes* demonstrating a reddish pigmentation of the background agar. Wine-red pigmentation is one feature that suggests *T. rubrum*; however, certain strains of *T. mentagrophytes* may also produce reddish pigment when growing on Sabouraud's dextrose agar. The pigmentation of these isolates, however, is never as intense as with *T. rubrum* when colonies are grown on cornmeal or potato dextrose agar.

E. The reverse of a colony of *Trichophyton rubrum* growing on potato dextrose agar. The deep wine-red pigmentation is characteristic of the species, and is particularly intense when the colony is grown on potato dextrose or cornmeal agar.

F. Comparative growth of *T. mentagrophytes* (bottom) and *T. rubrum* (top) on cornmeal agar, illustrating the distinct difference in pigmentation between the two

species.

G. The surface of a small colony of *Trichophyton tonsurans* after 14 days of incubation is illustrated. *T. tonsurans* grows slower on Sabouraud's dextrose agar. Most strains produce some shade of yellow-brown pigment. The surface tends to be granular and radial rugae are frequently seen.

H. The surface of *Epidermophyton floccosum* after 6 days of incubation. This colony appears more fluffy than granular and has an off-yellow pigmentation. Classical colonies of *E. floccosum* are described as khaki green. The colony texture tends to be more fluffy than granular, as microconidia are not produced by this genus.

IMAGE PLATE 21-5

COLONY MORPHOLOGY OF DIMORPHIC FUNGI

The dimorphic fungi, so-called because they grow in a mold form at 25°C to 30°C (i.e., room temperature) and a yeast or yeast-like form within the human body and, with the exception of *Coccidioides* species, at 37°C. These fungi are pathogenic in humans and are the agents of the deep-seated mycoses. Although definitive species identification depends on microscopic study, confirmation that a given species belongs to the dimorphic group depends on either molecular confirmation or by demonstrating both the mold and yeast forms in laboratory isolates. The mold form may be converted to the yeast form by incubating subcultures on enriched media at 37°C and observing microscopically for the appearance of yeast forms typical of the species. *Coccidioides* species are the exception and are not thermally dimorphic. In the past, the exoantigen technique was used to more rapidly confirm the identification of a dimorphic fungus, but this has largely been replaced by commercially-available nucleic-acid probe assays.

A. The surface colony of a dimorphic mold, illustrating evidence of the residual yeast form centrally, which has not yet converted to the mold form, which is seen at the periphery. This colony was incubated for 14 days at 30°C. When this mixture of yeast and mold texture is observed, one of the dimorphic fungi can be suspected, particularly if the colony is relatively slow-growing and the mold appears more hair-like or cobweb-like in consistency.

B. Colonies of *Blastomyces dermatitidis* growing on 5% sheep blood agar after 5 days of incubation. Note the cobweb-like appearance of these colonies, a clue that the isolate may be a dimorphic fungus. All molds should be handled within appropriate biologic safety cabinets to avoid a laboratory-acquired infection.

C. Appearance of colonies of *Blastomyces dermatitidis* incubated at 37°C, during a mold-to-yeast conversion. There is an intermediate form, shown here, of the colonies between mold and yeast, known as the "prickly stage." Note the rather coarse spicules formed by these white colonies. A microscopic preparation would show a mixture of hyphae, budding yeasts, and forms intermediated between the two.

D. Colonies of *Histoplasma capsulatum* on brain–heart infusion agar after 25 days of incubation at 30°C. The colonies appear white and cobweb-like in consistency.

These colonies are nondescript and could represent a variety of filamentous fungi. Microscopic examination is necessary to make an identification.

E. Surface of a 5% sheep blood agar plate incubated at 37°C on which are growing small, yellowish yeast colonies of *Histoplasma capsulatum* after a successful conversion from the mold form. The yeast forms are similar to other true yeasts, except that growth is very slow-growing and the colonies remain quite small.

F. The surface of colonies of *Coccidioides immitis* growing on 5% sheep blood agar after 7 days of incubation. The colonies are gray-white and have a delicate hair-like texture. Colonies of *C. immitis* growing on blood agar often show a red discoloration from leaching of hemoglobin from the culture medium (not shown here).

G. The surface of a smooth, gray-brown yeast colony of *Sporothrix schenckii*. Colonies of *S. schenckii* often appear more yeast-like than mold-like in the early phase of recovery, even when incubated at 25°C to 30°C, then these become more filamentous with extended incubation. After prolonged incubation, colonies of *S. schenckii* also tend to darken considerably, becoming almost jet black with some strains (see Image Plate 21-5H).

H. Tubes of brain–heart infusion agar that contrast the yeast (top) and mold (bottom) forms of *S. schenckii*. The mold form is after extended incubation wherein the colonies tend to darken with maturity, becoming distinctly black in some cases, as illustrated here.

IP-140

IMAGE PLATE 21-6

MORPHOLOGY OF COMMONLY RECOVERED YEASTS

The laboratory identification of medically important yeasts involves a visual assessment of colony characteristics and the interpretation of supplemental results. Traditionally, these have included carbohydrate fermentation and assimilation tests, which are still used as needed. More commonly, MALDI-TOF and, in some instances, molecular assays are being used to identify these fungi.

A. The surface of a smooth, off-white yeast colony, obtained from a subculture of *Candida albicans* after 3 days of incubation, is demonstrated. The colony shown here is not distinctive for *C. albicans*, but may be seen with other *Candida* species and yeasts of other species. Additional studies are required when a yeast-like colony, as illustrated here, is recovered.

B. Surface of 5% sheep blood agar plate on which are growing white colonies of a yeast. The foot-like extensions from the margins of the colonies are typically produced by *C. albicans*.

C. Colonies of *Cryptococcus neoformans* on Sabouraud's dextrose agar after 4 days of incubation. The distinct mucoid consistency of the colonies is indicative of a capsule-forming yeast, suggesting a *Cryptococcus* species. Additional tests are required to identify *C. neoformans*.

D. Colonies of *Cryptococcus neoformans* growing on niger seed (i.e., birdseed) agar. The darkly pigmented colonies are characteristic of *C. neoformans*.

E. Colonies of *Candida glabrata* growing on Sabouraud's dextrose agar after 3 days of incubation at 30°C. *C. glabrata* is suggested when small, more translucent yeast colonies are observed, although additional studies are necessary to confirm the identification.

F. Colonies of a *Rhodotorula* species, illustrating the distinctive orange-red pigmentation characteristic of this genus. Additional studies are necessary to make a definitive species-level identification.

G. Surface of a blood agar plate on which are growing the colonies of *Malassezia furfur* only in the area where olive oil had been spread. *M. furfur* is a lipophilic yeast commonly found on human skin. A medium rich in long-chain fatty acids,

which can be supplied by an olive oil overlay on the surface, as shown here, or using Tween, is necessary for the recovery of this yeast. Laboratory personnel must be notified if an infection by a *Malassezia* species is suspected, so that an oil overlay preparation can be made.

H. A photomicrograph of an acid-fast-stained smear prepared from an isolated colony of *Saccharomyces cerevisiae* growing on the surface of ascospore agar. The spherical, red-staining (acid-fast) bodies seen here are ascospores. *Wickerhamomyces* (*Hansenula*) *anomalus* also produces acid-fast-staining ascospores when grown on ascospore agar; however, they are cap-shaped, rather than spherical, in outline.

IMAGE PLATE 22-2

INTESTINAL AMEBA/FLAGELLATES

A. Photomicrograph of fecal smear stained with trichrome. In the center of the field is a two-lobed segmented neutrophil simulating an *Entamoeba*-type cyst. Care must always be taken to be sure that polymorphonuclear leukocytes in fecal specimens are not mistaken for amebic cysts.

B. Photomicrograph of a fecal smear stained with iron hematoxylin, illustrating a single trophozoite of *Entamoeba histolytica*, measuring 10 µm in greatest dimension. Note the spherical nucleus containing a tiny, compact, centrally placed karyosome, and even, beadlike distribution of chromatin along the nuclear membrane (the *Entamoeba*-type nucleus). The extension of a single pseudopod reflects a purposeful, directional motility.

C. Photomicrograph of a direct iodine mount of a cyst of *Entamoeba histolytica*, measuring 12 µm in diameter. Four nuclei are observed, each of which contains a small centrally placed karyosome and a fine, even band of nuclear chromatin around the nuclear membrane.

D. Hematoxylin- and eosin-stained section of colon mucosa illustrating many infiltrating *Entamoeba histolytica* trophozoites. The trophozoites are the light-staining, irregularly spherical bodies, some of which show an *Entamoeba*-type nucleus. (×400)

E. Iron hematoxylin-stained fecal smear illustrating a single trophozoite of *Entamoeba coli*. Note the large karyosome, the uneven distribution of the chromatin along the nuclear membrane, and the coarse "junky" cytoplasm containing undigested debris and several irregular-sized vacuoles. The trophozoites of *E. coli* tend to be larger than those of *E. histolytica*, ranging, on average, between 14 and 25 µm in diameter.

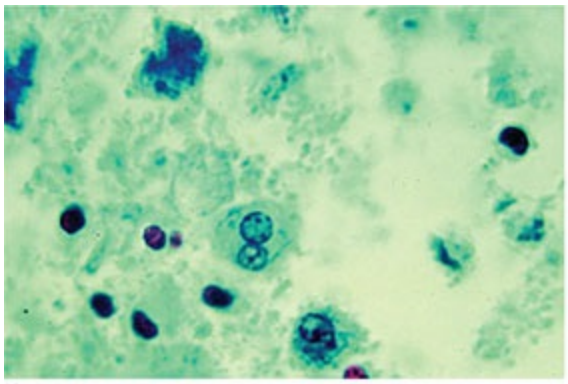
F. Trichrome-stained cyst of *Entamoeba coli* illustrating five nuclei, each containing a relatively large centrally or slightly eccentrically placed karyosome. The presence of more than four nuclei rules out *Entamoeba histolytica*. A single red-staining intracytoplasmic chromatoidal bar with pointed ends is seen in the 8 o'clock position.

G. Iron hematoxylin stain of a precyst of *Entamoeba histolytica*, measuring 8 µm in

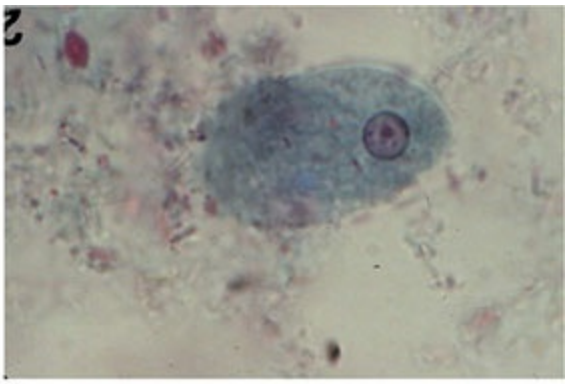
diameter. Precysts often have a single vacuole, simulating a cyst of *Iodamoeba bütschlii*. Note in the photograph the distinct "*Entamoeba*-type" distribution of chromatin around the nuclear membrane, ruling out *I. bütschlii*.

H. Iron hematoxylin stain of a small (6 µm in diameter) cyst of *Entamoeba hartmanni*. The size is in the range of *Endolimax nana*; however, the *Entamoeba*-type nucleus and the chromatoidal bars with rounded ends rule out that possibility.

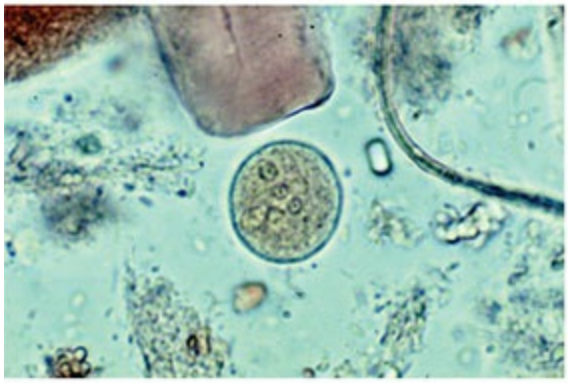
IP-145



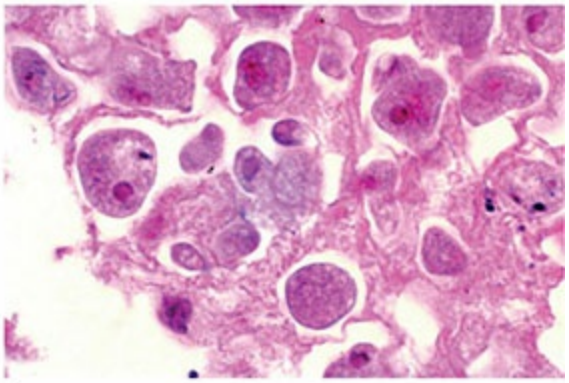
A



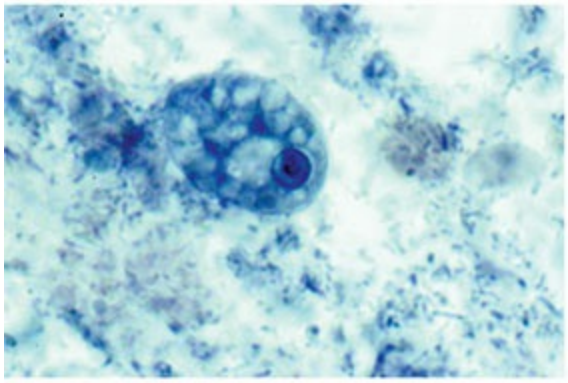
B



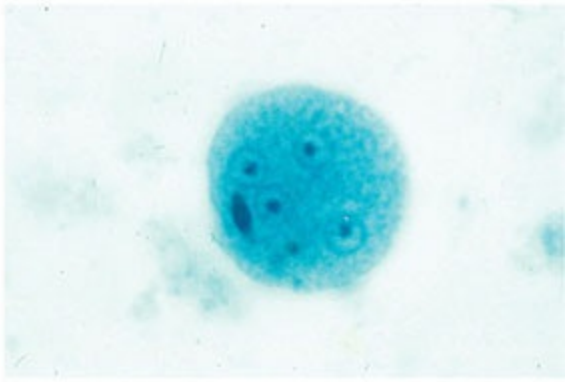
C



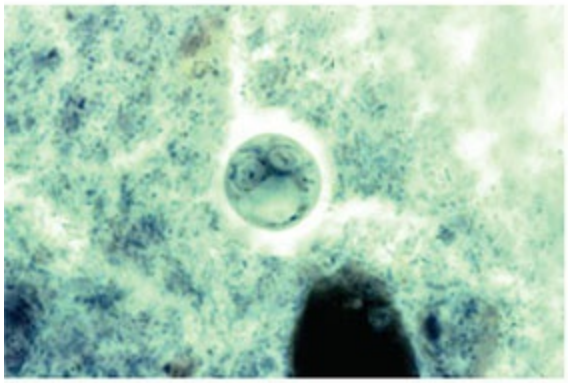
D



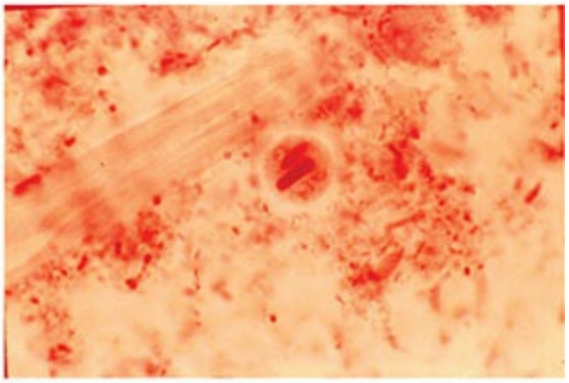
E



F



G



H

IP-146

I. Trichrome-stained fecal smear illustrating a trophozoite of *Iodamoeba bütschlii*. This form measures approximately 14 µm in diameter; the size range is 6 to 25 µm. Note the nucleus with a large karyosome surrounded by an empty space, with no visible nuclear membrane (so-called ball-in-socket nucleus). The smaller trophozoites are difficult to distinguish from those of *Endolimax nana*; other fields must be examined to detect the more characteristic cysts in making a final diagnosis.

J. Trichrome-stained fecal smear illustrating a cyst of *Iodamoeba bütschlii*, measuring 10 µm in diameter. The nucleus has a large central karyosome surrounded by a clear area with absence of peripheral chromatin (ball-in-socket nucleus). Note the single large vacuole in the cytoplasm, which stains positive with an iodine stain, indicating glycogen content.

K. Trichome-stained fecal smear illustrating a small trophozoite of *Endolimax nana*, measuring 8 µm in diameter. Note the small central nucleus with a prominent karyosome, and a narrow surrounding clear space and absence of nuclear chromatin.

L. Methylene blue–stained preparation illustrating a cyst of *Endolimax nana*, measuring 6 to 8 µm in diameter. Note the four tiny nuclei, each of which contains a minute karyosome, surrounded by a clear space.

M. Trichrome-stained fecal smear illustrating a single, spherical form of *Blastocystis hominis*, with a prominent central body surrounded by nuclear material that is plastered in clumps against the inner membrane of the cyst wall. The form here measures 10 µm; however, they vary considerably in size between 5 and 20 µm, with a mixture within any given preparation.

N. Photomicrograph of a hematoxylin- and eosin-stained section of small bowel epithelium. Note the small, pear-shaped trophozoite of *Giardia intestinalis*, with its familiar "face." *Giardia* trophozoites attach to the mucosa, where they cause local damage, leading to the characteristic symptoms of diarrhea and flatulence.

O. Trichrome-stained smear illustrating a *G. intestinalis* (formerly *G. lamblia*) trophozoite recognized by its distinctly oval to elliptical shape, the two nuclei, with prominent central karyosomes, lying anteriorly on either side of the rodlike axostyle, which runs the length of the organism. Note also the eosinophilic staining parabasal body (the "mustache") lying posteriorly on the axostyle. These features provide for the so-called monkey face appearance. *G. intestinalis* trophozoites

have six flagella, two each at anterior, posterior, and caudal positions; only three of these are visible in the photograph.

P. Trichrome-stained smear of intestinal debris including a *Giardia intestinalis* cyst. The cyst is typically oval and has a thin, smooth outer wall. The cyst ranges from 9 to 12 µm in diameter, and typically includes double the number of organelles seen in the trophozoite. Each cyst typically has four nuclei, only two or three of which are usually seen in a single plane of focus, two axostyles, multiple parabasal bodies, and flagella that are wrapped beneath the smooth-walled cyst, all of which may not be observed in a single plane of focus.

IMAGE PLATE 22-3

FLAGELLATES

A. Photomicrograph of two trophozoites of *Chilomastix mesnili*, one seen on end and the other from a lateral view. The trophozoite is typically pear-shaped and can be readily identified by observing the extreme anterior placement of a single nucleus, the posterior protrusion of the axostyle, and a spiral groove, which is difficult to observe in most preparations. A tuft of three anterior flagella, adjacent to the nucleus, is an additional identifying feature that is difficult to observe in most microscopic mounts.

B. Photomicrograph of a cyst of *C. mesnili*. A single nucleus, with central karyosome and a distinct cytostome, appearing as a well-outlined clear area in the cyst shown here, is easily observed. The outline of the cytostome, described as appearing as a shepherd's crook, is seen in this photomicrograph. Cysts typically are lemon-shaped, have a smooth cell wall, range from 6 to 70 µm in diameter and, in addition to the cytostome, often have an anterior knob that, when seen, is helpful in making an identification (see Image Plate 22-3C).

C. View of another cyst of *Chilomastix mesnili*, in which the anterior hyaline knob is better seen *(arrow)*. The nucleus and cytostome are also visible.

D. Trichrome-stained fecal smear highlighting a single trophozoite of *Dientamoeba fragilis*. This cyst measures 8 to 12 µm, and one can readily observe the characteristic double nucleus, each with a large karyosome and indistinct nuclear membrane. The cytoplasm of this trophozoite is finely granular and shows early evidence of disintegration, as reflected by the species name.

E. Iron hematoxylin preparation illustrating a single trophozoite of *Pentatrichomonas* (*Trichomonas*) *hominis*. Note the typical tear-drop shape and single nucleus placed anteriorly, but not against the cell wall, as is characteristic of the trophozoite of *Chilomastix mesnili* (Image Plate 22-3A). The longitudinally running axostyle is visible in this photomicrograph, as is a single posterior flagellum. Typically *P. hominis* has three to five anterior flagella and one posterior flagellum and an undulating membrane that runs along the full length of the body, a structure that is readily seen only in preparations made from cell cultures.

F. Photomicrograph of a hematoxylin- and eosin-stained section of an intestinal biopsy illustrating many invading trophozoites of *Balantidium coli*. Note the distinct rod

or horseshoe-shaped macronucleus, a feature that, along with its large size (80 µm in diameter), is helpful in making an identification. The identification of cilia is key, as this is the only ciliated human parasite.

G. View of a trophozoite of *Balantidium coli* illustrating an oval outline with a smooth wall that is covered throughout the circumference with short, delicate cilia. These trophozoites range between 40 and 70 µm wide by 50 and 100 µm long. The presence of an anterior cytostome and the circumference of cilia and large rod or horseshoe-shaped macronucleus are the key characteristics leading to an identification.

H. A cyst of *Balantidium coli* is illustrated in this trichrome-stained mount. These cysts range from 50 to 75 µm in diameter, are spherical to ellipsoid, and have a characteristic dumbbell-shaped macronucleus, clearly observed in this photograph. A single indistinct micronucleus is observed adjacent to the macronucleus, and the cytoplasm includes a metabolic vacuole.

IMAGE PLATE 22-4

COCCIDIA

A. Photomicrograph of a hematoxylin- and eosin-stained section of bowel mucosa along the brush border of which are attached many tiny, 2- to 3-µm-diameter oocysts of *Cryptosporidium* species. A histologic diagnosis is possible when these aggregates of oocysts are observed in this location.

B. Acid-fast stain of fecal smear illustrating two red-staining, acid-fast, spherical, homogeneous staining, 4- to 5-µm-diameter oocysts of *Cryptosporidium* species (arrows). These forms are diagnostic when seen in modified acid-fast smear preparations.

C. Photomicrograph of an acid-fast-stained fecal smear illustrating a single spherical, acid-fast oocyst of *Cyclospora* species. These oocysts are about two times the size of the oocysts of *Cryptosporidium* species, ranging from 8 to 10 µm in diameter, ergo the need for a calibrated ocular micrometer. Also in contrast, the *Cyclospora* oocysts have an ill-defined internal structure and lack the homogeneous staining of *Cryptosporidium* oocysts. It is common to have well-stained *Cyclospora* oocysts adjacent to unstained oocysts; this heterogeneous staining is characteristic of *Cyclospora.*

D. Low-power (×250) view of an acid-fast-stained spindle-shaped oocyst of *Cystoisospora belli* located in the center field of view. These oocysts measure 25 to 30 µm in length, a relatively large size that cannot be appreciated by this low-power view, except when compared with the very tiny, almost dot-like, 5-µm-diameter oocysts of *Cryptosporidium* species that are scattered in this field. The coexistence of these two species in the same stool specimen is highly suggestive of a person with HIV infection, which should always be ruled out in such a clinical scenario.

E. Photomicrograph of a direct mount preparation illustrating an elliptical-shaped, immature oocyst of *Cystoisospora belli*. These oocysts measure 25 to 30 µm in the long axis, and when immature, enclose only a single spherical sporocyst, as illustrated in the photograph. Compare with the mature oocyst illustrated in Image Plate 22-4F.

F. View of a direct mount of fecal material illustrating a mature oocyst of *Cystoisospora belli*, enclosing two spherical sporocysts. The sporocysts, now

mature, are infective for a second host, and ready to release sporozoites into the intestine on ingestion.

G. Hematoxylin- and eosin-stained section of skeletal muscle within which are two cysts of *Sarcocystis* spp. These cysts measure as large as 300 µm in diameter, and are filled with inactive, encysted bradyzoites. Humans are infected with this form if, as accidental intermediate hosts, infective oocysts are ingested in contaminated food or water.

H. Weber stain of a stool preparation illustrating many small, 2- to 3-µm, rod-shaped spores of a Microsporidium. With this stain, the spores stain a salmon-yellow. Note the characteristic thin, transverse septum that divides some of the spores *(arrow)* seen in this field of view, a helpful feature in making a genus identification. These organisms are now classified as Fungi, but testing often remains in the parasitology section of the laboratory for practical purposes.

IMAGE PLATE 22-5

NEMATODES

A. Adult male and female worms of *Ascaris lumbricoides*. The adult males are generally shorter (20 to 25 cm) than the females (25 to 30 cm) and have a curved tail (lower worm in the photograph). The smooth, nonsegmented cuticle is a helpful feature in distinguishing adult ascarids from common earthworms, which on occasion may find their way into toilets and sewage systems, where they may be mistaken for worms passed in the feces.

B. Bile-stained, yellow-brown, slightly ovoid egg of *Ascaris lumbricoides*, which range in size from 45 to 60 µm in diameter. They possess a thick shell covered by a characteristic undulating albuminous coat. The retraction and development of the internal cleavage indicates fertilization and potential infectivity.

C. Illustrated is a spherical, decorticate egg of *Ascaris lumbricoides* featuring a well-developed larva that is at the stage of near hatching. This egg obviously is highly infective.

D. Fertilized egg of *Ascaris lumbricoides* showing a smooth outer shell. When exposed to bile within the intestinal lumen, the albuminous outer coat is dissolved, leaving a decorticate surface as seen here.

E. Composite photograph illustrating an adult worm of *Enterobius vermicularis* in the left frame. These worms, measuring 0.3 to 0.5 mm in diameter and between 8 and 1.3 mm long, have a well-developed intestinal tract and internal reproductive organs. The pointed tail and paraoral alae (arrow in the left photograph) are diagnostic. The close-up view in the right frame better demonstrates the paraoral alae.

F. Split-frame photograph illustrating gravid *Enterobius vermicularis* eggs, the one to the left possessing a well-developed larva. These eggs have a thin, smooth wall, and measure approximately 55 × 25 µm. Each egg is elongated, asymmetrical, and flattened on one side, resembling an underinflated football.

G. Photograph of adult *Trichuris trichiura* worms demonstrating the characteristic long, attenuated whip-like anterior segment and the shorter, thicker more handle-like posterior body. These worms are relatively small, measuring 35 to 45 mm in length.

H. Photomicrograph of a typical bile-stained, yellow-brown egg of *Trichuris trichiura* with a relatively thick, smooth wall. Note the characteristic barrel-shape and the distinctive, dome-shaped, hyaline plug at each polar extremity. (From "A Pictorial Presentation of Parasites" by H. Zaiman.)

IP-154

I. Photograph of the mouthpart of an adult hookworm. The chitinous teeth observed here are characteristic of the old-world hookworm, *Ancylostoma duodenale*. This mouthpart is well suited for the deep attachment of the worm to the intestinal mucosa and the cutting of capillaries enabling the ingestion of blood from the circulation.

J. Similar view of the mouthpart of the new-world hookworm, *Necator americanus*, illustrating the characteristic cutting plates *(arrows)*. As with *Ancylostoma duodenale*, this mouthpart is also well suited for the deep attachment of the worm to the intestinal mucosa, the laceration of capillaries, and the ingestion of blood.

K. Photomicrograph of a direct iodine mount of fecal material containing a typical oval-shaped hookworm egg measuring approximately 40 to 60 µm, with the characteristic thin, smooth wall, and a clear space beneath the shell. These eggs cannot be distinguished from those of *Strongyloides stercoralis*. This differential identification is generally not necessary as *S. stercoralis* rarely passes eggs in the feces and only in instances of hyperinfection, when larvae are abundant.

L. Split-frame photomicrograph in which the buccal cavities of the rhabditiform larvae of hookworm (left) and *Strongyloides* (right) are compared. The buccal cavity of the hookworm rhabditiform larva is characteristically long *(arrows)* compared with the shorter *(arrows)* distance observed with *Strongyloides*. Hookworm rhabditiform larvae are rarely seen in fecal specimens.

M. Microscopic field of view of a direct mount of fecal material, within which a small, coiled rhabditiform larva of *Strongyloides stercoralis* is present, as it would be observed under low magnification (×100). These larvae are highly motile when observed in direct mounts. Observation of the buccal cavity as described above is necessary to confirm the identification. These larvae average 15 µm in diameter and over 200 µm long.

N. Rhabditiform larvae of *S. stercoralis*, after a short feeding period of 2 to 3 days, develop into long, slender, nonfeeding, infective filariform larvae, that can reach 700 µm in length. These filariform larvae can penetrate directly into the skin of a human host on direct contact.

O. Hematoxylin-and-eosin-stained section of small intestine in which round, smooth filariform larvae of *Strongyloides stercoralis*, characteristic of the histologic findings of individuals with *Strongyloides* hyperinfection syndrome. These are observed burrowing into the lamina propria. In patients with *Strongyloides* in

whom a compromised immune system develops, the life cycle from oviposition to rhabditiform larva to filariform larva formation may be sufficiently short that autoinfection may occur within the intestine before stools are formed, as observed in this photograph.

P. Photomicrograph of a yellow-brown, bile-stained egg of *Capillaria philippinensis*. These eggs are lemon-shaped or elongated, measure approximately 60 × 35 µm, and resemble those of *Trichuris trichiura*, except that the shell is striate and the polar protuberances are broad and flat.

IMAGE PLATE 22-6

CESTODES

A. An adult *Taenia saginata* tapeworm illustrating the small scolex *(arrow)* and a strobila extending several feet long, and composed of a long chain of proglottids.

B. Close-up view of the scolex of a *Taenia solium* tapeworm demonstrating the four suckers characteristic of the genus. The protruding, rostellum armed with a circular row of hooklets, permits the identification of *Taenia solium*. The scolex of *Taenia saginata* is not armed.

C. Close-up view of a single *Taenia saginata* proglottid that has been injected with India ink through the genital pore to outline the branching uterine segments. The proglottids of *T. saginata* possess more than 13 lateral uterine branches, as shown in the photograph, to distinguish them from the proglottids of *Taenia solium*, that typically have fewer than 13 branches. This observation permits a species identification based on an examination of proglottids that may have been passed intact in the feces.

D. Split-frame photographs of a piece of measly pork (left) including several small cystic spaces, each inhabited by a cysticercus larva of *Taenia solium*. A cysticercus is illustrated in more detail in the right frame. Within the fluid-filled sac is contained an invaginated scolex. The suckers and hooklets of which are obscured by the stain.

E. Hematoxylin-and-eosin-stained section of brain illustrating a cystic space occupied by a *Taenia solium* cysticercus. The cyst has two walls, the outer composed of reactive fibrous tissue produced by the host tissue, and the second an inner thin membrane produced by the worm (bladder worm). The invaginated scolex is cut in cross section in this photograph and demonstrates internal structures.

F. Photograph of a cysticercus of the rat tapeworm, *Hymenolepis diminuta*. The invaginated scolex is better visualized in this field of view. These cysticerci form in an intermediate insect host, including fleas, cockroaches, and beetles. Humans are infected through ingestion of insect-contaminated foods, and the adult worms develop in the intestine after evagination and attachment of the scolex to the mucosa.

G. Photograph of the uterus of a gravid female of the *Taenia* species, illustrating the

dense aggregation of thick-walled, spherical eggs, some of which show the characteristic striations.

H. Close-up view of *Taenia* species eggs as they would be observed microscopically in direct mounts of infected material. These eggs average 30 to 45 µm in diameter and have a thick, smooth wall, interrupted by distinctive radial striations. Many eggs also enclose three pairs of hooklets (hexacanth embryo) not observed in this photograph, but similar in appearance to those seen within the inner membrane of the *Hymenolepis diminuta* egg included in Image Plate 22-6N. The species of *Taenia* cannot be determined by the morphology of the eggs.

H

IP-158

I. Photograph of the tiny scolex *(arrow)* and the broad and narrow proglottids of *Diphyllobothrium latum*, the giant adult tapeworm. This tapeworm is the longest that infests humans, reaching between 3 and 10 m in length, often including more than 3,000 proglottids.

J. Close-up view of the spatula-shaped scolex of *D. latum*, demonstrating the characteristic central, longitudinal groove (bothrium), flanked on either side by a distinctive fold (phyllo "leaf"), the structures from which the genus name, *Diphyllobothrium*, is derived.

K. Close-up view of a proglottid of *Diphyllobothrium*, demonstrating the characteristic width-greater than-length dimensions, from which the genus name "*latum*" is derived. Note the nondescript centrally and linearly placed branching uterus, appearing as a compact rosette.

L. Photomicrograph of an egg of *Diphyllobothrium latum*. These eggs are relatively large, measuring from 60 to 75 µm long by 40 to 50 µm wide. They are oval in shape and have a thin, smooth shell, and the cleavage extends to the inner shell membrane. Characteristic is the presence of an inconspicuous, nonshouldered operculum, which is used to distinguish it from the egg of *Paragonimus westermani*, the operculum of which is distinctly shouldered (Image Plate 22-7P).

M. Photomicrograph of a *Hymenolepis nana* egg, comprised of a double membrane —an outer thin, smooth shell, and an inner membrane enclosing an oncosphere. Three pairs of hooklets are commonly contained (hexacanth), as illustrated in this photograph. These eggs range between 40 and 60 µm in diameter and are usually oval to subspherical in outline. The eggs of *H. nana* are also distinctive for the presence of polar thickenings on either side of the inner hexacanth membrane, from which four to eight slender filaments are derived, extending into the intermembrane space.

N. Photograph of an egg of *Hymenolepis diminuta*. These eggs are larger than those of *Hymenolepis nana*, with an average diameter of 60 to 80 µm, and usually are distinctively spherical in outline. The absence of polar thickenings and intermembrane filaments also distinguish this egg from those of *H. nana*. The six hooklets are clearly illustrated *(arrow)*.

O. Photomicrograph of an egg packet of *D. caninum*, demonstrating an aggregate of spherical eggs held in a matrix. The eggs shown in the photograph are immature, as the presence of internal hooklets indicate maturity and infectivity.

P. Photograph of a *Dipylidium caninum* proglottid, demonstrating a genital pore on either side, into which flow the delicate vitelline ducts. This double-pore arrangement is unique to *D. caninum* (from which the genus name is derived, pyle "gate or orifice"), in that the proglottids of other tapeworms possess only one lateral genital pore that alternates from one side to the other on adjacent segments. The proglottids are vase-form in shape, being longer than wide.

IMAGE PLATE 22-7

TREMATODES

A. Photograph of adult male and female *Schistosoma* adults. The male in this photograph is lighter staining and possesses a gynecophoric canal from which the copulating female, darker in staining, has become detached. Adult males average 20 to 30 mm in length, and females 14 to 17 mm. These flukes are threadlike in diameter, allowing them to occupy the lumina of venules without causing blockage of the blood flow, thus resulting in minimal edema.

B. Photomicrograph of an egg of *Schistosoma mansoni*, with its characteristic smooth, thin wall and oval outline with a prominent lateral spine. These eggs are relatively quite large, ranging from about 115 to 180 µm long by 45 to 70 µm wide. On maturity, the larval miracidium hatches intact, precluding a period of development in the external environment.

C. Photomicrograph of an egg of *Schistosoma haematobium*, also having a thin, smooth shell and an oval outline, but differing from the egg of *S. mansoni* by possessing a terminal, rather than a lateral spine. These eggs also are relatively large, ranging from 110 to 170 µm long, and 40 to 70 µm wide.

D. Illustrated here is an egg of *Schistosoma japonicum*, which is smaller (80 to 100 µm in diameter), more oval to spherical in outline, and has an internal cleavage that extends to the inner shell. Although a spine is not observed, a small lateral knob (not seen in this photograph), is distinctive.

E. Photomicrograph of a forked-tail cercaria, the infective stage in the *Schistosoma* life cycle. These free-swimming cercaria are released from the rediae of infected snails and have the capacity, through enzymatic activity, to directly penetrate the skin of an unsuspecting human, who may be wading or swimming in infested freshwater estuaries.

F. An adult fluke of *Fasciola hepatica*. These flukes are hermaphroditic and possess both female and male reproductive organs. The anterior portion of *F. hepatica* projects into a cone-shaped cephalic end, just posterior to which is the anterior sucker. Immediately posterior to the sucker, and darkly staining in this photograph, is the branching convoluted uterus. Immediately posterior to the uterus is the ventral sucker. The bulk of the posterior portion of the fluke includes the testes, appearing as a pink-staining meshwork in this photograph. These flukes measure

about 3 × 1 cm (about the size of a glass microscope slide). (From "A Pictorial Presentation of Parasites" by H. Zaiman.)

G. An adult fluke of *Fasciolopsis buski*, the giant intestinal fluke, which is also hermaphroditic and has structures similar to those described for *F. hepatica*. In contrast, the cephalic end is rounded and devoid of the conical protrusion. These flukes range from about 2 to 7.5 cm long, by 0.8 to 2 cm wide.

H. Photomicrograph of an egg of *F. hepatica* (which cannot be distinguished from those of *F. buski*), demonstrating a thin, smooth wall and an internal cleavage that extends to the inner shell membrane. Notice the nick on either side of the shell toward the narrow end *(arrow)*, representing the operculum, a lid-like structure that opens at the time the larva hatches. These eggs are large, averaging approximately 150 × 80 m in greatest dimensions.

IP-161

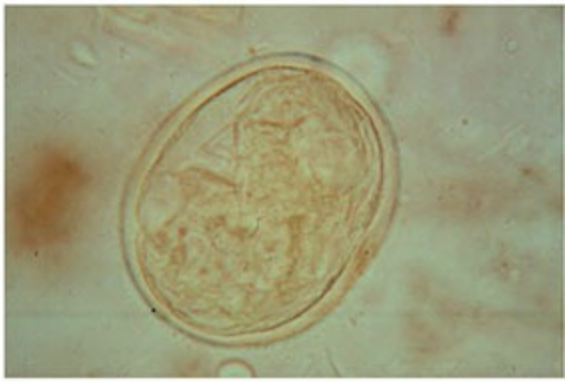
B

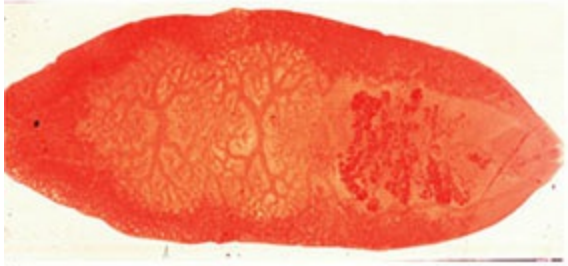
C



D

E

F



G

H

IP-162

I. Photograph of an adult fluke of *Clonorchis sinensis*, demonstrating the long, bottle-shaped cephalic end with a prominent terminal sucker, dark brown-staining uterus, and the extensively branched, lighter pink-staining testes posteriorly. These internal structures, moving from mouth to tail, are illustrated in greater detail in Image Plates 22-7J-M.

J. Illustrated in this photograph is the anterior mouth or oral sucker, which leads to a blind digestive tract, called the ceca, a branch of which runs along the lateral margins of the worm.

K. Posterior to the oral sucker is the ventral sucker, which is immediately in front of the dark staining uterus, flanked on either side by the branches of the ceca. The delicate-staining vitelline glands are seen at the upper margin of the worm between the ceca and the outer integument. These glands produce the yolk for the eggs produced in the ovaries.

L. This field of view is just posterior to the uterus illustrating the ovary. Note the delicate vitelline duct entering the ovary on the right side.

M. This field of view is the posterior part of the worm, highlighting the extensively branching tests, from which the genus name (*clon* = divided; *orchis* = testes) is derived. Note that the ceca end in blind alleys. The excretory bladder is the ill-defined white space at the immediate posterior margin.

N. Hematoxylin-and-eosin-stained section through a dilated bile duct within which resides three *Clonorchis sinensis* adult flukes cut in cross section. Although a mild chronic inflammatory infiltrate is noted in the surrounding submucosa, extensive fibrosis and lumen occlusion is not evident.

O. Photomicrograph of an egg of *Clonorchis sinensis*, illustrating a thin, smooth wall. Characteristic is the prominent, shouldered operculum at the broader end. A tiny knob, not visible in this photograph, may be seen at the narrower, antiopercular end of the egg. These eggs are relatively small, ranging from 25 to 35 µm long by 14 to 17 µm wide.

P. Photomicrograph of an egg of *Paragonimus westermani*. The shell is smooth, relatively thin, and interrupted at one end by a prominent shouldered operculum. This egg appears morphologically similar to that of *Clonorchis sinensis*; however, these comparative photographs are deceiving, as *P. westermani* eggs are two to three times the size, ranging from 65 to 120 µm long by 40 to 70 µm wide. With this larger size, *P. westermani* eggs appear similar to those of *Diphyllobothrium*

latum, which, however, can be distinguished by its flat rather than raised, shouldered operculum.

IMAGE PLATE 22-8

PLASMODIUM

A. Photomicrograph of a Wright-Giemsa-stained peripheral blood smear illustrating several erythrocytes that are infected with ring forms of *Plasmodium* species. The infected erythrocytes are no larger in size than the surrounding cells, and Schüffner's dots are not present. The small size of the rings without development into advanced trophozoite forms and the high parasitemia are indicators of an infection with *Plasmodium falciparum*.

B. The infected erythrocytes in this photomicrograph of a stained peripheral smear also support a diagnosis of *Plasmodium falciparum*, both for the high parasitemia, and also the peripheral placement of tiny rings along the inner cell membranes, a so-called accolade effect or appliqué forms. Indeed, this smear was obtained from a patient with fulminant falciparum malaria.

C. Falciparum malaria can be definitively identified in the peripheral blood smear if the large, sickle or crescent-shaped gametocyte, as illustrated in the lower part of this photograph *(blue arrow)* is observed. Also note the small *Plasmodium* ring in the cell near the top of the field of view *(red arrow)*, again consistent with *Plasmodium falciparum*.

D. The infected erythrocyte illustrated in this stained peripheral smear is distinctly larger and paler than the surrounding cells and also has a distinctly stippled cytoplasm from the presence of Schüffner's dots. Note also that the ringed trophozoite is relatively large. These features are diagnostic for *Plasmodium vivax* infection.

E. *Plasmodium vivax* can be further suspected if a multicelled schizont, as illustrated by the enlarged erythrocyte in the center of this photomicrograph, is observed in a stained peripheral blood smear. These schizonts typically have more than 13 merozoites per schizont.

F. Illustrated in this stained peripheral smear is an enlarged, pale erythrocyte containing a uninucleated gametocyte of *Plasmodium vivax*.

G. Illustrated in this photomicrograph of a Wright-Giemsa-stained peripheral blood smear is an erythrocyte infected with a trophozoite of *Plasmodium malariae*. Note that the cytoplasm is condensed, does not develop into a typical ameboid form, but

rather bridges in a band form from one side of the cell membrane to the other. The red blood cell is not enlarged and Schüffner's dots are absent.

H. *Plasmodium malariae* can also be suspected if one observes a multinucleated schizont with less than 13 merozoites. Characteristically, the merozoites are arranged in a circular rosette pattern as seen in this photograph, often surrounding a coarse mass of malarial pigment that is absent in this particular infected cell.

IMAGE PLATE 22-9

BABESIOSIS/LEISHMANIASIS/TRYPANOSOMIASIS

A. Illustrated in this photomicrograph of a Wright-Giemsa-stained peripheral blood smear are several erythrocytes that are infected with the tiny pleomorphic ring-like forms of *Babesia* species. Tiny rings may be observed, suggestive of *Plasmodium falciparum*, as seen in one of the erythrocytes in the lower center field of view. The infected erythrocytes are not enlarged, are not pale, and never accumulate malarial pigment. Noteworthy is the arrangement of these forms into doublets resembling rabbit ears; or, more characteristically, into tetrads resembling a Maltese cross.

B. Photograph of the lower legs of a patient infected with *Leishmania tropica*, a species that typically causes cutaneous leishmaniasis, also called Chiclero ulcers. The ulcerating lesions as seen in this photograph result from the granulomatous inflammation caused by the infiltrating amastigotes.

C. Hematoxylin-and-eosin-stained section from subcutaneous tissue taken from the margin of an ulcer similar to that shown in Image Plate 22-9B. Note the tiny yeast-like forms seen in the cytoplasm of many of the infiltrating histiocytes and macrophages. These represent the amastigotes, the infective forms seen both in visceral and cutaneous leishmaniasis. These forms are difficult to differentiate from the intracytoplasmic yeast cells of *Histoplasma capsulatum*, but they often can be differentiated in stained smears of aspirates by demonstrating the rodlike kinetoplasts, as illustrated in Image Plate 22-9D and E.

D. Wright-Giemsa-stained impression smear illustrating a few background macrophages and numerous tiny 2 to 3 µm amastigotes of *Leishmania*. As mentioned before, these forms are often difficult to differentiate from the yeast cells of *Histoplasma capsulatum*. Careful observation, however, will reveal that many of these forms have a small, rod-shaped kinetoplast *(arrow)*, characteristic of *Leishmania* amastigotes.

E. Close-up view of a stained aspirate illustrating amastigotes of *Leishmania* species, identified by the distinctive kinetoplasts included within many of these forms.

F. Photomicrograph of a Wright-stained peripheral blood smear in which several extracellular trypanosomes are observed. This smear was obtained from a patient with African trypanosomiasis. Each individual organism is long, slender, spindle-

shaped, and ranges from 15 to 30 µm long by 1.5 to 4 µm wide. The darker-staining, dot-like structure seen posteriorly in each trypanosome is the kinetoplast, from which a single flagellum originates. Each flagellum follows the outer contour of an undulating membrane that runs the length of the body, and then extends for some distance from the anterior end.

G. Photomicrograph of a Wright-stained peripheral smear obtained from a patient with American trypanosomiasis, also known as Chagas' disease. Note the characteristic "C" form of the trypanosomes. Each trypanosome has a deep-staining, dot-like structure posteriorly, the kinetoplast, from which a single flagellum originates. he kinetoplast of *T. cruzi* is larger and appears "bulging" compared with that of *T. brucei*.

H. Photograph of a triatomid (reduviid) bug, the vector for transmission of Chagas' disease. Meta cyclic trypanosomes develop in the hindgut of this bug, following ingestion of trypanosomes through the bite of an infected patient. The trypanosomes reenter the subcutaneous tissue after the bite of the second human host, not from the bite itself, but when contaminated fecal material discharged from the bug is scratched by the fingernails into the painful bite wound.

IMAGE PLATE 22-10

FILARIA

A. Photomicrograph of a peripheral blood smear demonstrating a sheathed microfilaria. Microfilaria are extracellular parasites that measure about 245 to 295 µm in length and between 7 and 10 µm wide. They are released into the circulation from gravid female worms that reside within lymphatic channels in infected parts of the body. The microfilaria released by species pathogenic for humans have a sheath, as illustrated in this photograph *(arrow)*. As the column of nuclei seen in the parasite illustrated in this photograph does not appear to extend to the tip of the tail, the identification is *Wuchereria bancrofti*.

B. Photomicrograph of a peripheral blood smear illustrating the tail section of a microfilaria, high lighting the nuclear arrangement. Note that two detached nuclei extend into the tail, a feature characteristic of *Brugia malayi*.

C. A column of nuclei that extends into the tail section of a microfilaria, as illustrated in this photomicrograph, is characteristic of *Loa loa*.

D. Photomicrograph of a hematoxylin-and-eosin-stained section of a subcutaneous nodule, to include the cross section through the body of a female filarial worm, *Onchocerca volvulus*. Within the cavity of this organism are numerous microfilariae, which ultimately are released into the surrounding tissue, where they cause an inflammatory reaction ending in fibrosis. The microfilaria of *O. volvulus* rarely circulate in the peripheral blood, or they circulate in such small quantities that they virtually are never detected in stained smears.

E. Photograph of a dog heart heavily infested with the adult worms of *Dirofilaria immitis*. Canines serve as the definitive host for this tissue nematode. In humans, who may serve as inadvertent hosts, the larval forms never fully develop in the heart, but rather are swept into the pulmonary vasculature, where they produce infarcts and multifocal inflammatory granulomata.

F. Photomicrograph of a Giemsa-stained impression smear demonstrating numerous blue-staining, bow-shaped tachyzoites of *Toxoplasma gondii*. Each tachyzoite measures approximately 3 × 6 µm, is crescent or bow-shaped, and has a nucleus and various internal organelles. The tachyzoites are the infective form of the parasite, which enter the circulation and are carried to various organs, particularly the central nervous system, where they cause microfocal inflammatory lesions.

Tachyzoites can also transmigrate the placenta of pregnant women, enter the circulation of the developing fetus, and cause congenital infections in newborns.

G. Photomicrograph of a Giemsa-stained histologic section of a brain biopsy obtained from a patient with latent cerebral toxoplasmosis. Demonstrated are three cysts, ranging between 15 and 30 µm in diameter, within which are packed myriad tiny blue-staining bradyzoites. These are bradyzoite cysts, which will remain latent, unless the patient becomes immunocompromised.

H. A close-up view of a bradyzoite cyst. While the disease is latent in this cyst form, on suppression of immunity in a previously infected person, these cysts release active tachyzoites.

IMAGE PLATE 22-11

Tissue Parasites

A. Hematoxylin-and-eosin-stained section of heart muscle, including a swollen fiber from top to bottom along the center of the field of view that is inhabited by dense collections of the amastigotic forms of *Trypanosoma cruzi*. Cardiac involvement in patients with Chagas' disease commonly results in heart failure and death.

B. Photograph of a liver cyst from which multiple small, variable-in-size, hydatid cysts were contained.

C. Close-up view of two hydatid cysts removed from the mesentery of a person with echinococcal disease, illustrating a thin, smooth outer membrane to the outer surface of which aggregates of fat are attached.

D. Hematoxylin-and-eosin-stained section taken through an echinococcal cyst. The cyst wall is composed of a layer of dense fibrous tissue derived from the host reaction. The inner parasite membrane is germinal, from which three daughter embryos (brood capsules), each with an inverted scolex, have been produced. On breaking free from the germinal membrane, these daughter cysts, along with released protoscolices, form free-floating hydatid sand.

E. Illustrated are single protoscolices (fragments of "hydatid sand"), each containing an inverted rostellum with a prominent row of hooklets, representing the anlage of the protruding armed rostellum of the adult worm.

F. Photomicrograph of an adult *Echinococcus granulosus* tape worm. These adult worms, which reside in the intestinal tract of dogs and other canines, are very small, measuring no more than 6 mm long, and are composed of only three segments—an armed scolex, a neck, and a single proglottid, from which a relatively small number of eggs are released. However, as several hundred such worms may occupy the dog intestine, and the times of survival for each worm can reach 20 months, therefore, the total number of eggs released over a long period of time can be enormous, thereby guaranteeing completion of the life cycle.

G. Hematoxylin-and-eosin-stained section of skeletal muscle, including an encysted, coiled larval form of *Trichinella spiralis*. The dense infiltration of inflammatory cells into the tissue surrounding the cyst indicates relatively recent infection, most likely associated with local and possibly constitutional symptoms.

H. A second view of a muscle biopsy specimen including a coiled *Trichinella spiralis* larva. The absence of an inflammatory reaction and the laying down of dense fibrous tissue around the cyst indicate a chronic infection. In time, this inactive cyst may become calcified, representing the last stage of infection.

IP-172

IMAGE PLATE 23-1

Viral Inclusions

A. Varicella-zoster virus hepatitis. The nuclei of several hepatocytes contain typical herpes virus inclusions. The mass of the inclusion is eosinophilic and colored red, and the residual nuclear chromatin, which is basophilic and colored blue, is crowded around the rim of the nuclear membrane. The inclusion stands out because of an artifactual clear halo between the inclusion and the peripheralized nuclear chromatin. This artifact is caused by formalin fixation. The inclusions of herpes simplex virus and varicella-zoster virus cannot be distinguished (Hematoxylin and eosin stain).

B. Herpes simplex cervicitis. The Papanicolaou stain demonstrates numerous multinucleated giant cells in a cervical scraping. The nuclei are molded against each other, and inclusions are present. The inclusions appear homogeneous, and nuclear chromatin is peripheralized to the rim of the nuclear membrane. The cytologic preparation was fixed promptly in ethanol, and the formalin halo artifact is not present. A mature squamous epithelial cell stains pink.

C. Herpes simplex vesicular lesion—Tzanck test. These cells were scraped from the base of a herpetic vesicle. The multinucleated cell is characteristic of herpes infection, but one cannot differentiate the effects of herpes simplex virus from those of varicella-zoster virus. The multiple nuclei are molded and homogeneous, but inclusions are difficult to see in air-dried smears that have been stained with a Giemsa or similar stain. The direct scrapings can also be stained by the Papanicolaou method or with hematoxylin and eosin.

D. Cytomegalovirus sialadenitis. The epithelial cells of a salivary gland contain the inclusions of cytomegalovirus. The large basophilic (blue or purple) inclusions fill much of the nucleus. In some cells, there are artifactual clear halos between the inclusion and the nuclear membrane that are produced by formalin fixation. Granular cytoplasmic inclusions are also visible in some cells. The architecture of the salivary gland is distorted by an intense lymphocytic infiltrate. Enlargement of the infected cells and nuclei inspired the name of the virus. Salivary gland virus was the original name for the virus, and salivary gland inclusion disease was the original name for the infection, because of the prominence of infection of this organ in neonatal disease (Hematoxylin and eosin stain).

E. Adenovirus pneumonia. In this biopsy from a patient with an adenovirus infection, there is a large amount of proteinaceous exudate, which is eosinophilic, in the air spaces, but there are few inflammatory cells. The nuclei of the infected respiratory epithelial cells are completely replaced by viral DNA, which produces a dense basophilic inclusion. Early inclusions may resemble those of herpes simplex virus. The mature inclusions, as seen here, fill the nucleus and obliterate the outline of the nuclear membrane. They are referred to as smudge cells (Hematoxylin and eosin stain).

F. Measles virus pneumonia. Several large multinucleated giant cells are in the airways of this patient with measles pneumonia. The multiple nuclei contain eosinophilic nuclear inclusions that resemble those of herpes simplex virus. The nuclear chromatin is pushed to the rim of the nuclear membrane, but the formalin clear halo artifact is not present in this section. In addition, in this biopsy there are also eosinophilic cytoplasmic inclusions, some of which are coalescent and/or surrounded by a clear space (Hematoxylin and eosin stain).

G. Respiratory syncytial virus infection. This is a monolayer of HEp-2 cells infected with respiratory syncytial virus. Two large syncytial giant cells have formed in the monolayer. There are no inclusions in the nuclei of the cells, but several brightly eosinophilic intracytoplasmic inclusions can be seen. (Hematoxylin and eosin stain.)

H. Rabies encephalitis. Two neurons each have an eosinophilic intracytoplasmic inclusion, which is known as a Negri body. Some vacuoles are evident in the inclusion. The irregular appearance comes from an admixture of normal cytoplasmic structures with masses of viral ribonucleic acid (Hematoxylin and eosin stain). (Courtesy of Daniel Perl, MD.)

IMAGE PLATE 23-2

DIAGNOSIS OF INFECTIONS CAUSED BY VIRUSES, *CHLAMYDIA*, AND *EHRLICHIA*

A. *Chlamydia trachomatis* inclusion conjunctivitis. An epithelial cell that contains a chlamydial inclusion body is depicted. The cell has degenerated, leaving only the nucleus and the large inclusion. The large inclusion is molded around or capped over the underlying nucleus. Although these findings are not 100% specific, if present these should prompt diagnostic testing. Smear stained by the Giemsa method. (Photograph reproduced with permission of Julius Schachter and PSG Publishing Company, Inc., Littleton, MA.)

B. *C. trachomatis* cervicitis. Innumerable elementary bodies are present in this very heavy infection. The Evans blue counterstain causes the cells to fluoresce red, and the inclusions appear yellow in the photomicrograph. In areas with less background material or without a counterstain, the fluoresceinated antibody causes the elementary bodies to fluoresce apple green. A very heavily infected cell is present in the center of the photograph. Such specimens are of little challenge, but detecting positive specimens in which only a few elementary bodies are present is considerably more difficult.

C. This McCoy cell monolayer is infected with *C. trachomatis*. The specimen was centrifuged onto this monolayer of cycloheximide-treated McCoy cells, which were incubated for 48 hours. The cells have been stained with a fluorescein-conjugated monoclonal antibody to a major outer-membrane protein (MOMP) of *C. trachomatis*. Multiple intracytoplasmic inclusions, which correspond to the inclusion demonstrated in Image Plate 23-2A, stain bright green.

D. These HEp-2 cells are infected with herpes simplex virus, type 1. When a cytopathic effect became evident, the cells were scraped from the monolayer and placed on a slide. The cells have been stained with a fluorescein-conjugated monoclonal antibody to herpes simplex virus, type 1. There is bright, specific fluorescence, which is both nuclear and cytoplasmic.

E. This nasal aspirate contains cells that are infected with respiratory syncytial virus. Two cells in the smear show bright green cytoplasmic fluorescence. In addition to diffuse fluorescence, the discrete, punctate fluorescence represents viral inclusions, which are characteristic of this virus and help to confirm the specificity of the fluorescence. (Fluorescein isothiocyanate-conjugated monoclonal antibody to

respiratory syncytial virus.)

F. This is a cytomegalovirus-infected human diploid fibroblast monolayer in a shell vial. The elongated fibroblast cells are colored by the counterstain. The infected cells are distinguished by the bright green fluorescence of the oval nuclei. (Fluorescein isothiocyanate-conjugated antibody to cytomegalovirus early-intermediate antigen.)

G. Human monocytic ehrlichiosis caused by *Ehrlichia chaffeensis*. A circulating mononuclear cell contains a distinct cytoplasmic inclusion (morula) that is made up of individual bacterial cells. Inclusions are rarely seen in cases of monocytic ehrlichiosis. (Wright stain. Slide contributed by J. Stephen Dumler, MD.)

H. Human granulocytic anaplasmosis is caused by *Anaplasma phagocytophilum*. A distinct bluish inclusion is present in the cytoplasm of a circulating neutrophil. (Wright stain. Slide contributed by J. Stephen Dumler, M.D.)

IMAGE PLATE A-1

IDENTIFICATION OF TICKS

A. Larval ticks, in this case *Ixodes scapularis*, are distinguished by the presence of six legs, three on each side. Nymphs and adults have a total of eight legs.

B. Instars (life stages) of *Ixodes scapularis* on a dime for comparison of size. From left to right: adult female (F), adult male (M), nymph (N), larva (L).

C. Ventral aspect adult female *Ixodes scapularis*, demonstrating relationship of mouthparts to basis capituli (B). Palp (P), hypostome (H), genital pore (G), anus (A), anal groove (U), spiracular plate (S). Inset shows detail of mouthparts. Note the teethlike denticles protruding from the lateral edges of the hypostome.

D. Coxal spurs of adult *Ixodes scapularis*. The spur on coxa I is long, pointed, and oriented internally. The spurs on coxae II through IV are short, blunt, and oriented externally.

E. *Ixodes cookei* female dorsum. The scutum (S) is angular. The length of the palps (P) is approximately the same as the basis capituli (B). In this specimen, the hypostome (H) is broken.

F. *I. marxi* female dorsum. The scutum (S) is angular and resembles that of *I. cookei* (compare Image Plate A-1F), but the scutum of *I. marxi* is longer than it is wide in comparison to *I. cookei*.

G. *Dermacentor variabilis* adult females. The scutum demonstrates ornamentation (O). Festoons (F) are present at the posterior margin. One of the specimens is considerably engorged (E), changing the color of the dorsum from brown to cream.

H. *Dermacentor variabilis* adult female. The scutum is intensely ornamented (O). The basis capituli (B) is wider than it is tall. Note the "eyes" at the lateral margin bilaterally *(arrows)*.

IMAGE PLATE A-2

IDENTIFICATION OF TICKS AND OTHER ARTHROPODS

A. *Amblyomma americanum* female dorsum. The ornamentation on the scutum (S) takes the form of a patch at the posterior edge—the lone star *(arrow)*. Festoons (F) are present around the posterior edge of the tick. "Eyes" are present, but are difficult to see in this partially engorged specimen.

B. *Amblyomma americanum* male dorsum. A very prominent "eye" *(arrow)* is present at the lateral edge of the scutum, which covers the entire dorsum. The mouthparts are missing.

C. *Amblyomma americanum* male dorsum. The prominent festoons (F) are evident at the posterior margin. The arrows delineate two horseshoe-shaped markings just lateral to the midline bilaterally.

D. *Amblyomma americanum* male ventral surface. A prominent internal spur is evident on coxa IV *(arrows)*. A detail of the spur is shown in the inset (I). The anus (A) is surrounded by a posterior facing groove (GR), in contrast to the anterior facing groove of *Ixodes* spp. The genital pore (G) is prominent. All of the mouthparts and the basis capituli are missing from this specimen.

E. Dorsal view of *Ornithodoros* spp. This soft tick lacks a scutum, and the mouthparts are not visible from above.

F. *Sarcoptes scabiei* in its burrow. The mite has deposited eggs and defecated in its newfound home, adding to the discomfort of the victim.

G. *Loxosceles reclusa*, the brown recluse spider. The brown color and characteristic head marking distinguish this venomous spider. (Photograph courtesy of Robert Suter, Ph.D.)

H. Black widow spider. The deep black color and characteristic red, hourglass-shaped marking on the ventral side are clearly visible. (Photograph courtesy of Robert Suter, Ph.D.)

IMAGE PLATE A-3

IDENTIFICATION OF MISCELLANEOUS ARTHROPODS

A. *Dermatobia hominis*. The human botfly has been extracted from a pustular lesion. The flask shape, tapered neck, and encircling spines of the larva are evident. The neck was damaged at the time of surgical extraction.

B. Ventral view of *Cimex* spp., the bedbug. The orange-brown color and characteristic shape provide identifying features.

C. Dorsal view of *Triatoma* spp., a reduviid or kissing bug. The elongated body and long, thin head are characteristic. A pair of wings is evident.

D. *Tunga penetrans*, the jigger flea. Most fleas bite their host quickly and depart for completion of their life cycle, but the jigger flea remains embedded in the skin while producing eggs.

E. Female *Ctenocephalides* spp., the dog or cat flea. The long, muscular legs hang from the body and make the flea a prodigious jumper. The "hunched" appearance of the body is evident.

F. Female *Pediculosis humanus*, the human body louse. The long slender body supports three pairs of legs, each of which has clawlike hooks at the terminus.

G. Nit of a head louse. The egg is firmly attached to a hair shaft.

H. Female *Phthirus pubis*, the crab louse. The squat body and well-developed pincers on three pairs of legs make the derivation of the popular name clear. The louse hangs onto a hair shaft, which also supports a nit.

I-4

Antimicrobial susceptibility tests (testing) (*continued*)
of *S. moniliformis*, 504
of *S. pneumoniae*, 761–763
in serologic diagnosis of viral infections, 1571
API 20E identification system, IP 6-6A, 298, 299t
in nonfermenter identification, 394, 405b
API 20E strip, 295–296, 295t
API 20NE system, in nonfermenter identification, IP 7-5D, 394, 400, 405b
API Campy, 448
API Coryne, 869
API Rapid Strep, in identification of streptococci, enterococci, and selected "*Streptococcus*-like" bacteria, IP 13-3C, 816
API Staph, in coagulase-negative staphylococci identification, IP 12-2G, 713–714
API Staph-IDENT, in coagulase-negative staphylococci identification, 713
API ZYM, 1021
Apophysis, 1340
APTIMA assays, 148
APTIMA Combo 2 assay, in *N. gonorrhoeae* identification, 645
Arabinogalactan(s), 192
Arachnida sp., 1589–1598. *See also* Spider(s); Tick(s); *specific types*, *e.g.* Mite(s)
Arcanobacterium sp., IP 14-2G, 901, 912–913
A. haemolyticum pharyngitis, 70

identification of
flow chart for, 898f
phenotypic characteristics for, 914t–915t
Arcobacter sp., 438t, 442
A. butzleri, 438t, 442
A. cryaerophilus, 438t, 442
A. nitrofigilis, 439t
A. skirrowii, 439t, 442
Arenaviridae sp., described, 1511t
Arenavirus(es), clinical manifestations of, 1518, 1518t
ARF. *See* Acute rheumatic fever (ARF)
Arginine, decarboxylation of, in *Enterobacteriaceae* identification, IP 6-4F–G, 227
Armed Forces Institute of Pathology (AFIP), 1186
Arsenophonus nasoniae, 286t
Arthritis, septic
S. aureus and, 679b
symptoms of, 90
Arthrobacter sp., 917–918
identification of, phenotypic characteristics for, 917t
Arthroconidia, 1327b
Arthropod(s). *See also* Mite(s); *specific types*, *e.g., Arachnida*. sp.
Arachnida sp., 1589–1598. *See also* Spider(s); Tick(s); *specific types*, *e.g.,* Mite(s)
classification of, 1587–1588, 1588t, 1589b
described, 1587–1588, 1588t, 1589b
specimens of, laboratory submission of, 1588–1589
Arthrospore(s), defined, 1326
Artifact(s)
in cell cultures, 1547f
in detection and provisional identification of viral infections, 1557–1558
Arylsulfatase
activity, in mycobacteria identification, IP 19-2J, 1233
Asaia sp., 368
Ascariasis, IP 22-5A–D, 1446–1448, 1447–1448b, 1447f
Ascaris lumbricoides, IP 22-5A–D, 1446–1448, 1447–1448b, 1447f
life cycle of, 1447f
Ascomycete(s), 1327b
Ascospore(s), 1327b, 1329f
ASIP. *See* American Society of Clinical Pathologists (ASCP)

disseminated, 1351b
fungus ball infections with, 1350b
invasive pulmonary, 1350–1351b
Aspergillus sp., 1328f, 1344–1350
A. flavus, IP 21-1D, 1345–1346, 1347f
A. fumigatus, IP 21-1C, 1345, 1346f
A. nidulans, IP 21-1G, 1347–1348, 1348f, 1349f
A. niger, IP 21-1E, 1346, 1347f
A. terreus, IP 21-1F, 1347, 1348f
colony morphology of, 1345
described, 1345
histopathology of, 1348–1349, 1349f, 1350–1351b
laboratory presentation of, 1345
microscopic features of, 1345–1348, 1345f–1348f
Aspirate(s)
endotracheal, in lower respiratory tract infection diagnosis, collection of, 75
for parasite detection, 1427
transtracheal, direct examination of, in infectious disease diagnosis, 21t
Aspiration
pneumonia, 74
suprapubic, 83, 83f
translaryngeal, in lower respiratory tract infection diagnosis, 75
Assimilatory nitrate reduction, 199
Astroviridae sp., described, 1510t
Astrovirus(es), clinical manifestations of, 1522–1523, 1522t
ATCC. *See* American Type Culture Collection (ATCC)
Atopic inflammation, 7
ATP. *See* Adenosine triphosphate (ATP)
Aureobacterium sp., 927–928
identification of, phenotypic characteristics for, 925t–926t
Autolysin, of *S. pneumoniae*, 757
Autoscan-4 System, in nonfermenter identification, 407
Auxotrophic organisms, 199
Auxotype(s), 648
Avibacterium sp., 473, 474b
A. avium, 474 *b*
A. endocarditidis, 474 *b*
A. gallinarum, 474b, 505b
A. paragallinarum, 474 *b*
A. volantium, 474 *b*
phenotypic characteristics of, 476t
Azospirillum sp., IP 7-3G–H, 367

B

B lymphocyte, 7
B virus, clinical manifestations of, 1531–1532
Babesia sp., IP 22-9A, 1471, 1471b
Babesiosis, IP 22-9A, 1471, 1471b
Bacillary angiomatosis (BA)
  Bartonella sp. and, 546–547
Bacillary dysentery, 259b
Bacillus sp., IP 14-1H–J, 856–868
  antimicrobial susceptibility of, 868
  B. anthracis, 857–862. *See also* Anthrax
    antimicrobial susceptibility of, 861
    identification of, 866–868, 867t
    infections, treatment of, 861
    virulence factors of, 858
  B. cereus, 862–863
    gastroenteritis due to, 862
    identification of, IP 14-1J, 866–868
      phenotypic characteristics for, 859t
    virulence factors of, 862
  B. mycoides, identification of, 866–868
  B. thuringiensis, identification of, 866–868
  bacteremia due to, 863
  bone infections due to, 865
  endocarditis due to, 863
  identification of, IP 14-1J, 866
    laboratory safety in, 866, 867t
    specimen collection in, 866, 867t
    specimen processing in, 866, 867t
  infections
    caused by, 864–865 *b*
    in compromised hosts due to, 863
  isolation of, IP 14-1J, 866–868
  nosocomial infections due to, 865–866
  ocular infections due to, 863–865
  opportunistic infections due to, 863–866
  skin infections due to, 865
  soft tissue infections due to, 865
  taxonomic dissection of, 856–857
  taxonomy of, 856–857
Bacillus(i), 179b
  acid-fast, staining of, in mycobacteria recovery and identification, IP 19-1A–B, 1225–1228, 1226t,

1227t
defined, 182, 183f
gram-negative. *See* Gram-negative bacilli
gram-positive. *See also* Gram-positive bacilli
rod-shaped, nonmotile, oxidase-positive, in nonfermenter identification, 396t
Bacitracin susceptibility tests
in differentiation of micrococci and staphylococci, 694
in streptococci identification, IP 13-2A, 788
BacT/Alert 3D Blood Culture System, in blood culture processing, 102–103
BACTEC AFB System, in mycobacteria detection, 1232
BACTEC MYCO/F LYTIC, in mycobacteria detection, 1231
BACTEC TB system, in mycobacterial identification, 1251
BACTEC TB-DNA probe combination, in mycobacterial identification, 1251

I-5

Bacteremia
Bacillus sp. and, 863
Bartonella sp. and, 547–548
catheter-associated, 98
special considerations related to, 103–104
described, 96
Haemophilus species and, 479 *b*
mortality rates due to, 97, 97t
P. multocida and, 508 *b*
prognosis of, 96–97, 97t
risk factors for, 96–97, 97t
types of, 96–97, 97t
Bacteria, 207–210
anaerobic, 984–1073
characterization of, 1019, 1020b
classification of, 986t
cultivation of
anaerobic bag system in, 1016
anaerobic glove box in, 1015–1016, 1015f
anaerobic holding jar in, 1016, 1017b, 1017f
anaerobic jar techniques in, 1014–1016, 1014f, 1015f
anaerobic systems for, 1014–1016, 1014b, 1014f–1016f, 1017b
optimal recovery in, 1014b
results of, preliminary reporting of, 1019
roll-streak system in, 1016
defined, 984
described, 984

determination of metabolic products of, GLC in, 1022–1023, 1022f, 1023f
habitats of, 985–986, 986b
human infections due to, 996–1009, 997f, 998b, 998t
described, 996–1009, 997f, 998b, 998t
of endogenous origin, 998t
of exogenous origin, 998t
incidence of, 998b
sites of, 997f
identification of isolates
determination of cultural and biochemical characteristics in, 1019, 1020b
differential agar media and spot tests, 1020–1021
presumptive identification in, 1019–1020
presumpto plates in, IP 16-5, 1020–1021
identification of specific groups
anaerobic cocci, 1053–1054, 1056t–1058t
C. difficile-associated intestinal disease, 1048–1053
Clostridium species, 1042, 1045, 1046t–1048t
in different laboratories, 1026–1027, 1028t–1029t
gram-negative bacilli, 1027, 1029, 1029t, 1030t
gram-positive NSF bacilli, 1036–1042, 1037t–1038t, 1039t
isolation of
aerotolerance tests in, 1019, 1019f
blood culture in, 1010–1011
direct examination of clinical materials in, IP 16-1–16-3, 1011
incubation of cultures in, 1016–1018, 1017f
inspection and subculture of colonies in, IP 16-1–16-3, 1018–1019
media in, IP 16-1–16-4, 1011–1014, 1012t–1013t, 1014b
specimen collection and transport in, 1009–1010
specimen selection for culture in, 1009, 1010t
specimens that should not be cultured, 1010t
management of diseases involving anaerobic, 1054–1106, 1062t
antibiotic susceptibility/treatment protocols for anaerobes, 1054–1059
antimicrobial susceptibility testing of anaerobes, 1059–1060
antimicrobial susceptibility results for groups of anaerobes, 1060–1061
nomenclature associated with, 986–996, 987t–993t
phenotypic characteristics, 1021–1026, 1024t–1025t
conventional approaches, 1021
commercial microsystems, 1021–1022
gas-liquid chromatography, 1022–1023
MALDI-TOF, 1023–1026, 1024t–1025t
present and former names of, 988t–992t
taxonomic classification of, 986–996, 987t–993t
anatomy of, 182–205

antimicrobial resistance to, mechanisms of, 1084t
capsules of, 194
chemolithotrophic, 198–199
classification of, phylogenetic criteria, 176–182, 178–181b
coryneform, 868, 872–884b, 883b, 896–929
  antimicrobial susceptibility testing of, 890
cytoplasm of, 186–187
described, 3
energy generation of, 201–205, 202f–205f
fermentation of, 201–202, 202f–203f
fimbriae of, 195–196
flagella of, 194–195, 195f
genetic exchange in, 196–198, 197f
growth of, kinetics of, 200–201, 201f
hierarchical classification of, in *Bergey's Manual of Systematic Bacteriology*, 178–181b
horizontal transfer of resistance determinants in, 1081f
identification of
  abbreviated, 40t–41t
  bypass as resistance mechanism, 1096
  colonial types in, 35t–36t
  colonies used in, characteristics of, 32–33, 34b
  reactions in agar in, 34b
mechanisms of antibiotic resistance in, 1080f
  antibiotic inactivation by destruction or modification, 1088–1093, 1088f, 1090t, 1091b, 1093f
    aminoglycoside modifying enzymes, 1092–1093, 1093f
    β-lactamases, 1088–1092, 1088f, 1090t, 1091t
    other enzymes, 1093
  prevention of access to target, 1083–1088, 1085f, 1086f, 1087f
    efflux pumps, 1087–1088, 1087f
    porins, 1083–1087, 1084t, 1085f, 1086f
  target modification, 1093–1096
    DNA gyrase, 1094–1095
    other targets, 1095–1096
    penicillin-binding proteins, 1093–1094
metabolism of, 201–205, 202f–205f
  requirements for, 198–200, 199t, 200f
morphologies of, 183f
multiple antibiotic resistance mechanisms in, 1096
naming of, 174, 174b
nocardioform, 963–971
phenotypic identification of, 175–176, 175–176b
photolithotrophic, 198
physiology of, 182–205

pili of, 195–196
pyruvate utilization effects on, 202–205, 204f, 205f
recombination in, 196–198, 197f
relationships to oxygen, 984–985
requirements for, 198–200, 199t, 200f
surface structures of, 194–196, 195f
taxonomy of, 173–182, 174–176b, 178–181b
vaginosis, 1003
Bacterial agents, of bioterrorism, 1150
Bacterial cell walls
"acid-fast," 192–193, 193f
gram-negative, 189–192, 190f, 191f
gram-positive, 188–189, 191f
structure of, 187–193, 188f–191f, 193f
Bacterial cell(s)
cytoplasmic membrane of, 187
DNA replication in, 183–186
growth of, kinetics of, 200–201, 201f
nuclear structure of, 183–186, 185f–187f
shape of, 182–183, 183f, 184f
size of, 182–183, 183f, 184f
transcription in, 184, 186
translation in, 185–186
Bacterial endospores, 193–194
Bacterial exotoxins, 208
Bacterial infections, site-related, diagnosis of, 67t–68t
Bacterial isolates
preliminary identification of, procedures for, 37–38
and selection of differential characteristics, 38
Bacterial morphotypes, in mixed cultures, separation of, 35–36, 36t
Bacterial motility, in *Enterobacteriaceae* identification, IP 6-4H, 228–229, 229b
Bacterial products, tests for, 84
Bacterial species
CDC alphanumeric designations for, 321t
defined, 177
Bacterial superantigens, 210
Bacterial vaginosis, 87, 931–932
Bacterial virulence
factors affecting, 205–210
pathogenicity of, requirements for, 206–207

I-6

Bacteriophage(s), lysogenic, 196
Bacteriuria
detection of, culture in, 84
microscopic examination of, 84
screening tests for, 84
Bacteroides sp.
B. fragilis, identification of, IP 16-1, 1029, 1030t, 1034
B. ureolyticus, 1035
Bacteroidia, 181b
BactiCard, in *Neisseria* sp. identification, IP 11-2A, 642
Bactiuria infections, *S. aureus* and, 680b
Balamuthia mandrillaris, 1603
Balantidium coli, IP 22-3F–H, 1440–1441, 1441f
life cycle of, 1441f
Balneatrix sp., 361t, 362
B. alpaca, 362
Barbour-Stoenner-Kelly medium, for *B. burgdorferi* culture, 1300b, 1301
Bartlett, Raymond, 15
Bartlett's grading system, in sputum assessment, 17, 17b
Bartonella sp., 542–557
B. alsatica, 542, 543b, 550
B. australis, 543 *b*
B. bacilliformis, 543b, 545
Oroya fever due to, 545
verruga peruana due to, 545
B. birtlesii, 542, 543b
B. bovis, 542, 543b
B. capreoli, 542, 543b
B. chomelii, 543 *b*
B. clarridgeiae, 542, 543b, 544
cat scratch disease due to, 549
endocarditis due to, 548
B. coopersplainsensis, 543 *b*
B. doshiae, 542, 543b
B. elizabethae, 543b, 544
cat scratch disease due to, 549
endocarditis due to, 548
miscellaneous infections due to, 550
trench fever due to, 546
B. grahamii, 542, 543b
miscellaneous infections due to, 550
B. henselae, 542, 543b, 544
bacillary angiomatosis due to, 546, 547

bacteremia due to, 547–548
cat scratch disease due to, 549
endocarditis due to, 548
miscellaneous infections due to, 549–550
peliosis due to, 547
trench fever due to, 546
B. japonica, 543 *b*

serologic diagnosis of, 1567–1568
syphilis and, 1272–1273, 1272f, 1273f
treatment of, laboratory support for, 1528t
Human immunodeficiency virus type 1 (HIV-1) infection
clinical manifestations of, 1524, 1524t, 1526
Western blot procedures for, 119–120, 120f
Human infections, anaerobic bacteria and, 996–1009, 997f, 998b, 998t
Human metapneumovirus, 1515
Human papillomaviruses (HPVs), 86
clinical manifestations of, 1533–1535, 1534f, 1534t
molecular detection of, 1565
Human pathogens, infrequent, 1249–1250
Human polyomaviruses, clinical manifestations of, 1535
Human rotavirus, 1510f, 1510t
immunologic detection of, 1561
Human wart virus, 1513f, 1513t
Hyaline molds, 1343–1357
Aspergillus sp., 1344–1350. *See also Aspergillus* sp.

colony characteristics of, 1351
conidia in chains produced by, IP 21-2B–D, 1351–1352, 1352f, 1353f
conidia in clusters produced by, IP 21-2E, F, H, 1352–1354, 1354f–1355f
described, 1343–1344
diagnosis of, nonculture techniques in, 1349–1350, 1350–1351b
histopathology of, 1348–1349, 1349f, 1350b
preliminary observations suggestive of, 1407
rapidly growing, 1351
Hyalohyphomycete(s), conidia produced singly by, IP 21-2G, 1354–1357, 1356f–1357f, 1357–1359b
Hyalohyphomycosis, 1325, 1343–1357, 1357–1359b
Hyaluronic acid lyase, 208, 747
Hyaluronidase
of *S. pneumoniae*, 757
as streptococcal virulence factor, 740, 743
Hybrid Capture, 141–143, 142f
Hybridization
DNA-DNA, 176
probes
FRET probes, 156, 157–158, 158f, 159f
hydrolysis probes, 157, 157f
molecular beacons, 158–159, 159f
in real-time nucleic acid amplification, 157–159, 157f–159f
TaqMan probes, 157
reverse
in mycobacterial identification, 1253–1254, 1254f
in postamplification analysis, 152, 153f
Hydatid disease, IP 22-11B–F, H, 1488–1490, 1489f
Hydrogen sulfide, production of, in *Enterobacteriaceae* identification, IP 6-4B, 227–228, 228b, 228t
Hydrolysis
esculin, in nonfermenter identification, IP 7-2E, 327
probes, in real-time nucleic acid amplification, 157, 157f
in mycobacteria identification, IP 19-2G, 1233
of urea, in nonfermenter identification, IP 7-2A, 326
Hymenolepiasis, 1460b
Hymenolepis sp., IP 22-6F, M, N, 1457, 1459, 1459f, 1460b
H. diminuta, IP 22-6M, N, 1457, 1459, 1459f, 1460b
Hyphae, 1326b
species failing to produce, 1394–1395, 1395f, 1396–1397b
species producing, 1394–1399, 1399–1400b, 1399f

characteristics for, 638t–639t
chromogenic enzyme substrate tests in, 640–642, 641t

coagglutination tests in, 642
colony morphology in, IP 11-1B, 635–636
confirmatory tests in, 637
differentiation of other organisms on selective media in, 637
Gonochek II test in, 641–643
Gram's stain in, 636
MALDI-TOF for, 647
multitest identification systems in, IP 11-2D–E, 643
oxidase test in, 636
superoxol test in, 636
introduction, 615
isolation of, IP 11-1A, 631–635, 632b, 633b, 634t, 636b
MALDI-TOF for identification of, 647
N. animaloris, 630
cultural characteristics of, 651
N. bacilliformis, cultural characteristics of, 651
N. cinerea, 629
cultural characteristics of, 638t, 650
N. elongate, 383–384
subsp. *elongata,* cultural characteristics of, 638t, 651
subsp. *glycolytica,* cultural characteristics of, 638t, 651
N. flavescens, cultural characteristics of, 638t, 651
N. gonorrhoeae, 1136–1137
antimicrobial susceptibility of, 652–654
clinical significance of, 616–620, 617f
cultural characteristics of, 638t, 650–652
culture confirmation of
DNA probe test for, 643
immunologic methods for, 642–643
epidemiology of, 616–617
historical background of, 615
identification of
nucleic acid hybridization tests in, 643
nucleic acid amplication tests in, 643–647
presumptive criteria for, 637, 638t–639t
typing methods for, 648–649
sexual abuse/assault and, 647–648
infections caused by, 617–620, 617f, 619f
isolation of, IP 11-1A, 631–634, 632b, 633b, 634t
direct Gram's-stained smears in, IP 11-1A, 631–632

Neisseria sp. (*continued*)
selective culture media in, inoculation and incubation of, 633–634, 634t
specimen collection and transport in, 632–633, 632b, 633b
N. lactamica, 629
cultural characteristics of, 638t, 650
N. meningitides, 1137–1138
antimicrobial susceptibility of, 654–656
carriage of, 623–624
cultural characteristics of, 638t
historical background of, 615
identification of, molecular methods for, 649
infections caused by, 624–626
isolation of
direct capsular antigen tests in, 635
direct Gram's-stained smears in, 635
isolation and incubation in, 635
laboratory safety in, 634–635
specimen collection and transport in, 634
meningitis due to, 91
meningococcal epidemiology of, 620–623, 620–622b
serogroups, serotypes, and serosubtypes, 620–623, 620–622b
molecular methods for detection of, 649
serogrouping and typing of, 649–650
N. mucosa, cultural characteristics of, 650
N. polysaccharea, cultural characteristics of, 638t, 651
N. shayeganii, cultural characteristics of, 651–652
N. sicca, 629
cultural characteristics of, 650
N. subflava, 629
N. wadsworthii, cultural characteristics of, 651
N. weaver, 384
cultural characteristics of, 651
N. zoodegmatis, 384, 630
cultural characteristics of, 651
Neisseria subflava biovars, cultural characteristics of, 650
nonpathogenic, identification of, 638t–639t, 650
other species, 629–630
Neisseriaceae, IP 7-5D–E, 363–365, 382t, 383–384
taxonomy of, 615
Neisseria–Haemophilus (NH), 448
Neisseria-Kwik test kit, in *Neisseria* sp. identification, 640
Nematode(s), 1446–1454
Ascaris lumbricoides, IP 22-5A–D, 1446–1448, 1447–1448b, 1447f

Capillaria philippinensis, IP 22-5P, 1454
described, 1446, 1449b
Enterobius vermicularis, IP 22-5F–G, 1448, 1450, 1450b
filarial, IP 22-10A–C, 1481–1485, 1482f, 1484f
hookworms, IP 22-5K–L, 1450, 1451–1452b, 1451f
nonfilarial, 1485–1490, 1486f, 1489f
Strongyloides stercoralis, IP 22-5L–M, 1450, 1452–1454, 1452f, 1453b
Trichostrongylus sp., 1454
Trichuris trichuria, IP 22-5E, F, P, 1448, 1449f, 1449b
tissue, 1485–1490, 1486f, 1489f
Neonatal infections
Haemophilus species and, 480 *b*
S. epidermidis and, 690b
Nested PCR, 150–151
Neuraminidase enzymes, of *S. pneumoniae*, 757
Neurosyphilis, 1275–1276
Next-generation sequencing (NGS), IP 4-2 E–F, 155
NGP Wee-Tabs, 292
Niacin, accumulation of
in mycobacteria identification, IP 19-1D, 1233
Niclosamide, for parasitic infections, 1493t
Nicoletella sp., 473, 474b
N. semolina, 474 *b*
phenotypic characteristics of, 476t
Nicotinamide adenine dinucleotide (NAD), 1101
Nigrospora sp., 1382, 1383f
Nipah virus, 1516
Nitrate(s)
denitrification of, in nonfermenter identification, IP 7-2B, 326–327
disk test, 1021
in nonfermenter identification, IP 7-2B, 326–327
to nitrites, in mycobacteria identification, IP 19-1E–F, 1233, 1234t–1235t
reduction
in *Enterobacteriaceae* identification, IP 6-1H, 217
test, in nonfermenter identification, 326–327
Nitrogen
assimilation and metabolism of, 199, 200f
in bacterial growth and metabolism, 199, 200f
o-Nitrophenyl-β-D-galactopyranoside (ONPG), 486
in *Enterobacteriaceae* identification, IP 6-4A, 216–217
Nocardia sp., 963–964
bacterial cells of, 965
clinical disease due to, 965–966

described, 965
differentiation of, IP 15-1A–E, 974–976, 974f, 975t
identification of
lysozyme test in, 967
modified acid-fast stain for, 973
N. asteroides, 964 – 966
isolates of, antimicrobial susceptibility profiles of, 964, 964t
N. brasiliensis, 964
N. otitidiscaviarum, 965
non- *N. asteroides* complex, 964–966, 966b
taxonomy of, 963
in vitro susceptibility of, 977–978
Nocardia(ae), described, 963
Nocardioform bacteria, 963–971
Nocardiopsis sp., 964–965, 971
Nomenclature
defined, 1502
viral infections-related, 1502–1504, 1503b, 1503f, 1505f, 1507t–1508t
Nonbiologic hazards, safety precautions for, 56–57
Noncellular defenses, innate, 6
Nonfermentative gram-negative bacilli, 316–409. *See also* Nonfermenter(s)
defined, 317
identification of
decarboxylation in, IP 7-2D, 327
denitrification of nitrates and nitrites in, IP 7-2B, 327
esculin hydrolysis in, IP 7-2E, 327
failure to grow on MacConkey agar in, IP 7-1C, 325
flagella morphology in, 328
glucose utilization test in, IP 7-1D, 325, 325f
indole production in, IP 7-2C, 327
lack of evidence for glucose fermentation in, IP 7-1A, 324
Leifson staining method in, IP 7-2B, 327
motility in, IP 7-1E, 325–326, 326f
nitrate reduction in, 326–327
pigment production in, IP 7-1F–H, 326
positive cytochrome oxidase reaction in, IP 7-1B, 324
Ryu staining method in, 327
tests in, IP 7-1D–H, IP 7-2A–E, 6–2, 6–6, 6–7, 7–1–7–4, 325–328, 325f, 326f, 328b
urea hydrolysis in, IP 7-2A, 326
wet-mount technique in, 327–328
nomenclature for, 318t–320t
pink-pigmented, 366–369
yellow-pigmented, 360–363, 361t

Nonfermenter(s), 219, 1146–1150
acetamide-positive, in nonfermenter identification, 399t
computer-aided schemes, 391
denitrifying, in nonfermenter identification, 402t
described, 328
dextrose-negative, in nonfermenter identification, 404t
dextrose-positive, in nonfermenter identification, 403t
fluorescent, in nonfermenter identification, 398t
gram-negative
P. aeruginosa, 1146–1150
MBL-producing, 1146–1148, 1147f, 1148f
susceptibility testing of cystic fibrosis isolates, 1149–1150
A. baumannii, 1148–1149, 1149t
identification of
API 20NE system in, IP 7-5D, 394, 400, 405b
in nonfermenter identification, 394, 405b
approach to, 388–409
automated identification system in, 400, 406–407
Autoscan-4 System in, 406
Biolog System in, 400
commercial kit systems in, 391, 400, 405–406b
computer-aided schemes in, 391
conventional tests in, 390–391, 391b, 392t–404t

I-25

Crystal Enteric/Nonfermenter system in, 400
initial clues in, IP 7-1A–C, 324–325
levels of service in, 388, 388b
matrix-assisted laser desorption/ionization time-of-flight mass spectrometry, 407–408
oxidase-negative nonmotility in, 393t
oxidase-positive motility in, 398t
P. aeruginosa, 389 – 390
Phoenix Automated Microbiology System in, 407
pigmentation in, 401t
practical approach to, 391, 392t
problems associated with, 388, 388b
RapID NF Plus System in, IP 7-5F, 400, 406b
Remel N/F system in, 400

phenotypic characteristics for, 792t–793t
prevention of, 748–750, 749–750b
serologic, IP 13-3A–B, 790
classification of, 734 *b*
defined, 182, 183f
described, 734
general characteristics of, 739
identification of, IP 13-1A–H, IP 13-1H, 781–816
bile-esculin test in, IP 13-2D, 788
bile-solubility test in, 791
capillary precipitin test in, 790
colony morphology and catalase testing in, IP 13-1H, 785–786
coagglutination in, 790
commercially available systems for, 816–821
culture media in, 781–782
direct Gram's-stained smears in, IP 13-1A, 781
hemolysis on blood agar in, IP 13-1E, 782, 782b, 783f
hydrolysis of sodium hippurate in, 788
LAP test in, IP 13-2F, 790
phenotypic characteristics of, 787t
pigment production in, IP 13-2C, 788

presumptive, 788–790, 789t
bile esculin test, 788
CAMP test and pigment production, 788
commercialH, 790
leucine aminopeptidase test, 788, 790
phenotypic criteria for, 788, 789t
pyrrolidonyl arylamidase test, 790
salt tolerance test, 788
sodium hippurate, hydrolysis of, 788
susceptibility to bacitracin, 788
susceptibility to sulfamethoxazole-trimethoprim, 788
susceptibility to Optochin in, IP 13-2G, 791
isolation of, IP 13-1A–H, 781–816
preliminary characterization of, 786, 787t
recognition of, 786, 787t
S. agalactiae, 746–752, 749–750b
S. pneumoniae, 1131–1133, 1132t
decreased susceptibility
to penicillin, 1131–1133, 1132t
macrolides and lincosamides, 1133
viridans, 763–765
other group streptococci, 1133
identification of, 794–801, 797f, 799t, 800t
flow chart for, 797 *f*
phenotypic characteristics for, 795t–796t
S. anginosus group, 798, 799t
S. bovis group, 798, 800t, 801
S. constellatus, 799t
S. intermedius, 799t
S. mitis group, 794t–796t, 797–798
S. mutans group, 794t–796t, 798
S. salivarius group, 796t–796t, 798
S. sanguis group, 794t–796t, 797–798
phenotypic differentiation of, 794t
Streptococcus sp., 733–821. *See also* Streptococci
β-hemolytic, group B, early-onset disease due to, 747
classification of, 734 *b*
described, 734
group(s) of, based on small-subunit rRNA sequence analysis, 735–739 *b*
identification of, phenotypic characteristics for, 802t–803t
S. agalactiae
clinical significance of, 747–748, 749–750b
early-onset disease due to, 747

evaluation of, collecting and processing clinical specimens for, 749–750 *b*
late-onset disease due to, 747–748

I-33

meningitis due to, 91
virulence factors for, 746–747
S. anginosus, 765–766
identification of, 798, 799t
S. bovis group, 766–768
identification of, 798, 800t, 801
S. constellatus, 765–766
S. iniae, 755–756
S. intermedius, 765–766
S. mitis group, identification of, 794t–796t, 797–798
S. mutans group, identification of, 794t–796t, 797–798
S. pneumoniae, 756–763
antimicrobial susceptibility of, 761–763
clinical spectrum of, 758–761
identification of, serologic, IP 13-3B, 791, 794
meningitis due to, 91
otitis media due to, 478 *b*
pneumococcal vaccines for, 757–758, 759–760b
sinusitis due to, 478 *b*
virulence factors for, 756–757
S. porcinus, 755
S. pseudoporcinus, 755
S. pyogenes, 740–746, 741f
clinical significance of, 743–746
virulence factors for, 740–743, 741f
S. salivarius group, identification of, 794t–796t, 798
S. sanguis group, identification of, 794t–796t, 797–798
S. suis, 754–755
identification of, 801
"Streptococcus-like" bacteria, 733–821, 741f, 774–781
Abiotrophia sp., 774–776
Aerococcus sp., 776–777

Charts

CHART 1-1

Catalase

I. Principle

Catalase is an enzyme that decomposes hydrogen peroxide (H_2O_2) into water and oxygen. Chemically, catalase is a hemoprotein, similar in structure to hemoglobin, except that the four iron atoms in the molecule are in the oxidized (Fe^{3+}), rather than the reduced (Fe^{2+}), state. Excluding the streptococci, enterococci, and a few other genera, most aerobic and facultative bacteria possess catalase activity.

Hydrogen peroxide forms as one of the oxidative end products of aerobic carbohydrate metabolism. If allowed to accumulate, it is lethal to bacterial cells. Catalase converts hydrogen peroxide into oxygen and water as shown by the following reaction:

$$2H_2O_2 \rightarrow 2H_2O + O_2 \text{ (gas bubbles)}$$

The catalase test is most commonly used to differentiate members of the *Micrococcaceae*, which are positive, from members of the *Streptococcaceae*.

II. Reagents

A. Hydrogen peroxide 3% stored in a brown bottle under refrigeration

B. An 18- to 24-hour culture of the organism to be tested

III. Quality Control

The hydrogen peroxide reagent must be tested with positive and negative control organisms each day or immediately before unknown bacteria are tested.

A. Positive control: *Staphylococcus aureus*

B. Negative control: *Streptococcus* species

IV. Procedure

1. With an inoculating needle or a wooden applicator stick, transfer growth from the center of a colony to the surface of a glass slide.
2. Add one drop of 3% hydrogen peroxide and observe for bubble formation.

V. Results

A. Interpretation

The rapid and sustained appearance of bubbles or effervescence constitutes a positive test. Because some bacteria possess enzymes other than catalase that can decompose hydrogen peroxide, a few tiny bubbles forming after 20–30 seconds is not considered a positive test. In addition, catalase is present in red blood cells; so care must be taken to avoid carryover of red blood cells with the colony material.

CHART 1-2

Bile-Solubility Test

I. Principle

Bile salts, specifically sodium deoxycholate and sodium taurocholate, have the capability to lyse *Streptococcus pneumoniae* selectively when added to actively growing bacteria in agar or broth media. *S. pneumoniae* produces autolytic enzymes (autolysins) that account for the central depression or umbilication characteristic of older pneumococcal colonies on agar media. The addition of bile salts activates the autolysins and accelerates the natural lytic reaction observed with cultures or pneumococci.

C-2

The bile-solubility test can be performed either with a broth culture of the organism or with colonies growing on agar media. The turbidity of a broth suspension visibly clears on addition of bile salts if the organism is soluble. On agar medium, bile-soluble colonies dissolve when drops of the reagent are placed on them. Because sodium deoxycholate may precipitate at a pH of 6.5 or less, the broth culture medium used must be adjusted to pH 7.0 to prevent false-negative reactions.

II. Media and Reagents

1. A pure culture of the test organism grown at 35°C for 18–24 hours in Todd–Hewitt broth (or equivalent)
2. Sheep blood agar plate
3. Sodium deoxycholate (10% for tube test, 2% for plate test)
4. Phenol red solution (1% aqueous)
5. Sodium hydroxide (NaOH) solution, 0.10 N

III. Quality Control

A. Positive (bile-soluble) control: *Streptococcus pneumoniae*

B. Negative (bile-insoluble) control: Any of the viridans group streptococci

IV. Procedure

A. Broth Test

1. Transfer approximately 0.5 mL of an 18- to 24-hour broth culture to two clean test tubes. Alternatively, a suspension of the organism may be prepared from growth on agar media in phosphate-buffered saline, pH 7.0. If the latter is done, the pH need not be readjusted.
2. Add one drop of the phenol red indicator to each tube.
3. Add 0.10 N NaOH to adjust the pH to 7.0 (indicator a light pink color).
4. Add 0.5 mL of 10% sodium deoxycholate to one of the tubes (labeled "test").
5. Add 0.5 mL sterile normal saline to the other tube (labeled "control").
6. Gently agitate both test tubes and place them in an incubator or a water bath at 35°C for 3 hours, checking hourly.

B. Plate Test

1. To a few well-isolated colonies on the test organism growing on sheep blood agar, place a drop of 2% sodium deoxycholate.
2. Without inverting the plate, place it in a 35°C incubator for 30 minutes.

V. Results

A. Interpretation

1. Broth Test

   Bile-soluble (positive reaction): there is visible clearing of the suspension in the tube containing the sodium deoxycholate, with no change in the saline control suspension.

   Bile-insoluble (negative reaction): there is no change in the turbidity of the sodium deoxycholate–containing tube relative to the control saline suspension.

2. Plate Test

Bile-soluble (positive reaction): colonies on which the reagent was placed dissolve, leaving a partially hemolyzed area where the colony had been.

Bile-insoluble (negative reaction): colonies where the reagent was placed remain intact and visible.

VI. Limitations of Test

Only 86% of pneumococcal strains will lyse completely. Optochin susceptibility or other studies are useful for the identification of incompletely lysed strains.

CHART 1-3

The Slide Coagulase Test

I. Principle

Staphylococcal coagulase is a protein that has a prothrombin-like activity, which can convert fibrinogen into fibrin. A visible clot will result. Coagulase is believed to function in vivo by producing a fibrin barrier at the site of staphylococcal infection. This enzyme probably plays a role in localizing the abscesses (e.g., carbuncles and furuncles). In the laboratory, the coagulase test is used to identify *Staphylococcus aureus* and differentiate it from most other species of staphylococci.

Coagulase is present in two forms, bound and free, each having different properties that require the use of separate testing procedures.

C-3

Bound coagulase (slide test): Bound coagulase, also known as clumping factor, is attached to the bacterial cell wall and is not present in culture filtrates. Fibrin strands are formed between the bacterial cells when suspended in plasma (fibrinogen), causing them to clump into visible aggregates.

Free coagulase (tube test): Free coagulase is a thrombin-like substance present in culture filtrates. When a suspension of coagulase-producing organisms is prepared in plasma in a test tube, a visible clot forms as the result of coagulase reacting with a serum substance (coagulase-reacting

factor) to form a complex that, in turn, reacts with fibrinogen to produce the fibrin clot.

II. Media and Reagents

Rabbit plasma with EDTA (commercially available in lyophilized form). Reconstituted plasma should be refrigerated.

III. Quality Control

The coagulation of properties of plasma may be tested, for quality control purposes, by adding one drop of 5% calcium chloride to 0.5 mL of the reconstituted plasma. A clot should form within 10–15 seconds. A known *Staphylococcus aureus* strain and a *Staphylococcus epidermidis* strain serve as positive and negative controls, respectively. Each reconstituted vial of rabbit plasma with EDTA should be tested with 18- to 24-hour cultures of the control strains.

IV. Procedure

1. *Slide test* (bound coagulase): Place two drops of sterile water or saline in two circles drawn on a glass slide with a wax pencil. Gently emulsify colony material from the organism to be identified in liquid in each of the circles. Place a drop of coagulase plasma in the suspension in one of the circles and mix with a wooden applicator stick. Place another drop of water or saline in the other circle as a control. Rock the slide back and forth, observing for agglutination of the test suspension.
2. *Tube test* (free coagulase): Emulsify a small amount of the colony growth of the organism in a tube containing 0.5 mL of coagulase plasma. Incubate the tube at 35°C for 4 hours and observe for clot formation by gently tilting the tube. If no clot is observed at that time, reincubate the tube at room temperature and read again after 18 hours.

V. Results

A. Interpretation

1. *Slide test:* A positive reaction will be detected within 10–15 seconds of mixing the plasma with the suspension by the formation of a white precipitate and agglutination of the organisms in the suspension. The test is considered negative if no agglutination is observed after 2 minutes. The saline control should remain smooth and milky. If the control suspension agglutinates as well, then the test is uninterpretable. All strains that are coagulase-positive can be reported as coagulase-positive *Staphylococcus* or, if the colonial morphology is appropriate as, *Staphylococcus aureus*. All strains producing negative slide tests must be tested with the tube coagulase test.
2. *Tube test:* The tube coagulase test is considered positive if any degree of clotting is noted. The tube should be gently tilted and not

agitated, because this may disrupt partially formed clotted material. Fibrinolysins produced by the organism may also dissolve the clot soon after formation. Tube tests that are negative after 4 hours should be incubated at room temperature overnight and read after 18 hours.

CHART 1-4

Indole Test

I. Principle

Indole, a benzyl pyrrole, is one of the metabolic degradation products of the amino acid tryptophan. Bacteria that possess the enzyme tryptophanase are capable of hydrolyzing and deaminating tryptophan with the production of indole, pyruvic acid, and ammonia. Indole production is an important characteristic in the identification of many species of microorganisms, being particularly useful in separating *Escherichia coli* (positive) from members of the *Klebsiella- Enterobacter- Hafnia- Serratia* group (mostly negative).

The indole test is based on the formation of a red complex when indole reacts with the aldehyde group of *p*-dimethylaminobenzaldehyde. This is the active chemical in Kovac's and Ehrlich's reagents. A medium rich in tryptophan must be used. In practice, combination media such as sulfide indole motility (SIM), motility indole ornithine (MIO), or indole nitrate are used. Rapid spot tests, using filter paper strips impregnated with *p*-dimethylaminocinnamaldehyde reagent, are useful in screening for bacteria that are prompt indole producers.

II. Media and Reagents

A. Tryptophan Broth (1% tryptophan)

Peptone or pancreatic digest of casein (trypticase)	2 g
Sodium chloride	0.5 g
Distilled water	100 mL

B. Kovac's Reagent

Pure amyl or isoamyl alcohol	150 mL
p-Dimethylaminobenzaldehyde	10 g
Concentrated HCl	50 mL

C. Ehrlich's Reagent

p-Dimethylaminobenzaldehyde	2 g
Absolute ethyl alcohol	190 mL
Concentrated HCl	40 mL

III. Quality Control

Each new batch of medium or reagent should be tested for positive and negative indole reactions. The following organisms serve well as controls:

A. Positive control: *Escherichia coli*

B. Negative control: *Klebsiella pneumoniae*

IV. Procedure

Inoculate tryptophan broth (or other suitable indole media) with the test organism and incubate at 35°C for 18–24 hours. At the end of this time, add 15 drops of reagent down the inner wall of the tube. If Ehrlich's reagent is used, this step should be preceded by the addition of 1 mL xylene. This is not necessary with Kovac's reagent.

V. Results

A. Interpretation

The development of a bright fuchsia red color at the interface of the reagent and the broth (or the xylene layer) within seconds after adding the reagent is indicative of the presence of indole and is a positive test (Color Plates 6-4C and 7-2C).

C-5

CHART 1-5

Cytochrome Oxidase Test

I. Principle

The cytochromes are iron-containing hemoproteins that act as the last link in the chain of aerobic respiration by transferring electrons (hydrogen) to oxygen, with the formation of water. The cytochrome system is found in aerobic, microaerophilic, and facultatively anaerobic organisms, and so the oxidase test is important in identifying organisms that either lack the enzyme or are obligate anaerobes. The test is most helpful in screening colonies suspected of being one of the *Enterobacteriaceae* (all negative) and in identifying colonies suspected of belonging to other genera such as *Aeromonas*, *Pseudomonas*, *Neisseria*, *Campylobacter*, and *Pasteurella* (positive).

The cytochrome oxidase test uses certain reagent dyes, such as *p*-phenylenediamine dihydrochloride, that substitute for oxygen as artificial electron acceptors. In the reduced state, the dye is colorless; however, in the presence of cytochrome oxidase and atmospheric oxygen, *p*-phenylenediamine is oxidized, forming indophenol blue.

II. Media and Reagents

A. Tetramethyl- *p*-phenylenediamine dihydrochloride, 1% (Kovac's reagent)

B. Dimethyl- *p*-phenylenediamine dihydrochloride, 1% (Gordon and McLeod's reagent)

III. Quality Control

Bacterial species showing positive and negative reactions should be used as controls at appropriate intervals. The following are suggested:

A. Positive control: *Pseudomonas aeruginosa*

B. Negative control: *Escherichia coli*

IV. Procedure

The test is commonly performed by one of two methods: (1) the direct plate technique, in which two to three drops of reagent are added directly to isolated bacterial colonies growing on plate medium; and (2) the indirect paper strip procedure, in which either a few drops of the reagent are added to a filter paper strip or commercial disks or strips impregnated with dried reagent are used. The tetramethyl derivative of *p*-phenylenediamine is recommended because the reagent is more stable in storage and is more sensitive to the detection of cytochrome oxidase and is less toxic than the dimethyl derivative. In either method, a loopful of suspected colony is smeared into the reagent zone of the filter paper.

V. Results

A. Interpretation

Bacterial colonies having cytochrome oxidase activity develop a deep blue color at the inoculation site within 10 seconds (Color Plate 6-1G). Any organism producing a blue color in the 10- to 60-second period is considered negative, and it can be concluded that it does not belong to the *Enterobacteriaceae*. *Pasteurella multocida* is unique in that it is tetramethyl oxidase-positive, but often dimethyl oxidase-negative; a feature to remember for isolates suspected to possibly represent this organism. Stainless steel or Nichrome inoculating loops or wires should not be used for this test because surface oxidation products formed when flame-sterilizing may result in false-positive reactions.

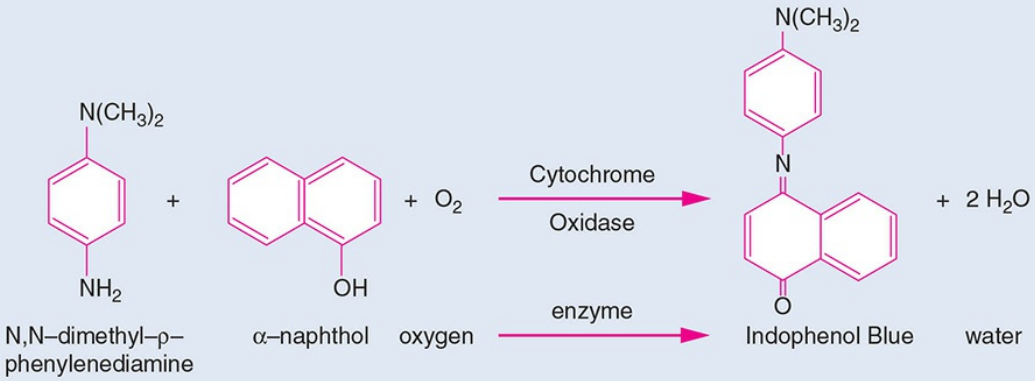
MECHANISM OF THE CYTOCHROME OXIDASE REACTION



C-6

CHART 1-6

PYR Test

I. Principle

The PYR test was first described by Facklam and coauthors in 1982; since that time, it has been widely used and is now a standard assay for the presumptive identification of both group A β-hemolytic streptococci and enterococci. Whereas the original test was described as a 16- to 20-hour agar test, subsequent PYR test formats included a 4-hour broth assay and now several rapid (minutes) tests in which the PYR reagent is impregnated in filter paper disks or strips that are inoculated with the organism to be tested. The PYR test also appears on several of the kit systems for identification of streptococci and *Streptococcus*-like bacteria. This chart describes the 4-hour

broth PYR test. Disks impregnated with the PYR substrate can also be used for an even more rapid test.

The substrate used for the PYR test is L-naphthylamide-β-naphthylamide. This compound is hydrolyzed by a specific bacterial aminopeptidase enzyme. Hydrolysis of the substrate by this enzyme releases free β-naphthylamide, which is detected by the addition of *N, N*-dimethylaminocinnamaldehyde. This detection reagent couples with the naphthylamide to form a red Schiff base.

II. Media and Reagents

1. PYR broth (Todd–Hewitt broth with 0.01% L-pyrrolidonyl-β-naphthylamide) dispensed into sterile tubes in 0.20-mL volumes
2. PYR reagent (0.01% *p*-dimethylaminocinnamaldehyde)

III. Quality Control

A. Positive control: *Enterococcus faecalis* or *Streptococcus pyogenes*

B. Negative control: *Streptococcus agalactiae*

IV. Procedure

1. With a sterile bacteriologic loop, pick up the growth of two to three morphologically similar colonies and emulsify them in the small volume of PYR broth.
2. Incubate the tube at 35°C for 4 hours.
3. Add one drop of the PYR reagent and observe for color change. The reaction should be read and recorded 1 minute after the addition of reagent.

V. Results

A. Interpretation

1. Positive: the development of a deep cherry red color within a minute of addition of the reagent
2. Negative: a yellow or orange color

VI. Procedure Notes

Other organisms (e.g., some aerococci, staphylococci, nutritionally variant streptococci, *Arcanobacterium haemolyticum*) may also be PYR-positive. Most laboratories now use commercially available products that work within minutes after exposure of the bacterium on filter paper to the reagents; PYR-positive organisms produce a purple color, whereas PYR-negative organisms produce no color change.

CHART 3-1

Complement Fixation (CF) Test

I. Principle

The complement fixation test is one of the major traditional tests for demonstration of antigens from infectious agents and the corresponding antibodies. It requires many reagents and numerous preparatory steps, which is why laboratories favor enzyme immunoassays and other methods to this one. There are almost as many versions as there have been users; the microtiter version developed at the Centers for Disease Control and Prevention (LBCF test) includes rigorous controls and is commonly used. The CF test depends on the ability of antibodies to fix complement, and the sera must be free of anticomplementary activity.

The terminal components of the complement cascade, C789 (i.e., the attack complex), can damage cell membranes in the presence of specific antibody, which fixes complement to the cell surface. In the CF test, erythrocytes are used as the target cell, because complement-induced cell lysis can be visualized or measured colorimetrically as an increase in free hemoglobin. In the presence of specific antibodies to an infectious agent, any complement in the system is bound, leaving no residual complement for reaction with antibodies to the indicator erythrocytes. Thus, the presence of specific antibody is indicated by the absence of hemolysis.

II. Materials and Reagents

Sheep erythrocyte suspension
Hemolysin (rabbit anti-sheep red blood cell antibody)
Guinea pig complement, free of antibodies to the agent of interest

C-7

Barbital-buffered diluent
Plastic microtiter plate
Centrifuge adapter for microtiter plates
Water bath for incubation of plates
Color standards for judging hemolysis (prepared by lysing various concentrations of red blood cells)

III. Quality Control

Known positive antibody or antigen
Known negative antibody or antigen
Serum control without antigen (to detect anticomplementary activity)
Antigen controls without serum (to detect anticomplementary activity)
Tissue control (the cells or tissue in which the antigen was prepared)

Buffer control without antigen or antibody
Back titration of complement to document the use of 5 CH_{50} units
Cell control to demonstrate absence of hemolysis
Reference hemolysis standards

IV. Procedure

1. Sensitization of Erythrocytes

Serial dilutions of hemolysin are incubated with a 2.8% solution of sheep red blood cells in barbital buffer. As the concentration of hemolysin increases, the percentage hemolysis will increase to a plateau level. The concentration of hemolysin that represents the second point on the plateau is used for the test.

2. Quantitation of Complement

Varying amounts of a 1:400 dilution of cold, reconstituted guinea pig complement are incubated with sensitized cells. The volume of complement that produces 50% lysis of the red blood cells (CH_{50} unit) is calculated from the graphed results of the hemolysis. The complement stock may be aliquoted and frozen at –70°C, but adequate reactivity must be demonstrated before use in the test.

3. The Complement Fixation Test

A block titration of serial dilutions of both antigen and antibody is performed in the presence of 5 CH_{50} units of complement at 4°C for 18 hours. Serum is heated at 56°C for 30 minutes to inactivate any endogenous complement. The characteristics of either the antigen or antibody will be known; the serial dilutions of the known reagent may be abbreviated to include the dilution on each side of the expected optimum. Subsequently, sheep red blood cells that have been sensitized with the optimal dilution of hemolysin are incubated at 37°C for 30 minutes. Plates are centrifuged at low speed to sediment the unlysed erythrocytes.

V. Results

A. Interpretation

The highest dilution of antigen or antibody that provides 3+ to 4+ fixation of complement (<30% hemolysis) is the end point. All reagents must be free of anticomplementary activity, the correct quantity of complement must have been added, and the control specimens must react as expected.

CHART 3-2

Hemagglutination Inhibition (HAI) Test

I. Principle

The nucleic acids of many viruses encode surface proteins that agglutinate the red blood cells of a variety of species. The phenomenon is most commonly used for diagnosis of infections produced by orthomyxoviruses, paramyxoviruses, and the arboviruses–togaviruses (including rubella), flaviviruses, and bunyaviruses. The presence of virus in infected cell cultures can be detected by hemagglutination; the identity of the virus or of antibodies in a patient's serum can be determined by specific inhibition of that hemagglutination. Reagents and conditions for the test vary by virus.

Reaction of viral hemagglutinins with red blood cells results in a lattice of agglutinated cells which settle irregularly in a tube or microtiter well. Unagglutinated cells settle in a compact button. As with the complement fixation test, the HAI assay has largely been replaced by enzyme immunoassays and other techniques. This Chart is retained, since not all laboratories have made these transitions.

C-8

II. Materials and Reagents

1. Red blood cells from an appropriate species (chicken, goose, guinea pig, trypsinized human O) collected in Alsever's solution or heparin
2. Diluent at appropriate pH
3. Solutions to remove nonspecific hemagglutinins from serum
4. Infected culture fluid or standard antigen for serology

III. Quality Control

A. Known positive serum
B. Known negative serum
C. Serum and cells without antigen (to detect nonspecific agglutination)
D. Back titration of hemagglutination activity of the antigen (to ensure that 4 hemagglutinating units [HAU] were tested)

IV. Procedure

A. Determination of Hemagglutinating Titer

1. A diluted suspension of red blood cells is incubated at 4°C or room temperature with serial dilutions of antigen until red blood cells in tubes without virus settle in a compact button (1–4 hours). The highest dilution that produces partial or complete agglutination represents 1 HAU.

B. Treatment of Sera

1. Removal of nonspecific inhibitors in sera is necessary for most viruses. Removal may be accomplished by physical means, such as kaolin; by enzymes, such as neuraminidase or the receptor-destroying enzyme (RDE) of *Vibrio cholerae*; or by a combination. The choice varies with the virus to be tested.

C. Inhibition Test

1. A dilution of antigen that contains 4 HAU is mixed with appropriate red blood cells and serial two-fold dilutions of treated serum. The suspension is incubated as for the hemagglutination test.

V. Results

A. Interpretation

The end point is the last well at which partial or complete agglutination of the red blood cells occurs. A smooth or jagged shield of cells or an irregular button indicates agglutination. Observation of the movement of the button of red blood cells when the plate is tilted may help to clarify the end point.

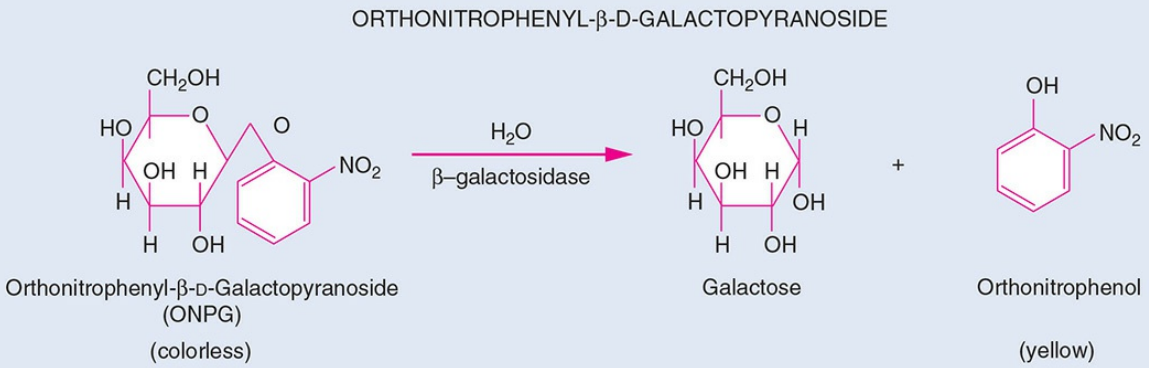
CHART 6-1

o -Nitrophenyl-β-D-Galactopyranoside

I. Principle

o-Nitrophenyl-β-D-galactopyranoside (ONPG) is structurally similar to lactose, except that orthonitrophenyl has been substituted for glucose, as shown in the following chemical reaction:



C-9

On hydrolysis, through the action of the enzyme β-galactosidase, ONPG cleaves into two residues, galactose and *o*-nitrophenol. ONPG is a colorless compound; *o*-nitrophenol is yellow, providing visual evidence of hydrolysis.

Lactose-fermenting bacteria possess both lactose permease and β-galactosidase, two enzymes required for the production of acid in the lactose fermentation test. The permease is required for the lactose molecule to penetrate the bacterial cell where the β-galactosidase can cleave the galactoside bond, producing glucose and galactose. Non–lactose-fermenting bacteria are devoid of both enzymes and are incapable of producing acid from lactose. Some bacterial species appear to be non–lactose-fermenters because they lack permease, but do possess β-galactosidase and give a positive ONPG test. So-called late lactose fermenters may be delayed in their production of acid from lactose because of weak permease activity. In these instances, a positive ONPG test may provide a rapid identification of delayed lactose fermentation.

II. Media and Reagents

1. Sodium phosphate buffer, 1 M, pH 7.0
2. *o*-Nitrophenyl-β-D-galactopyranoside (ONPG), 0.75 M (Buffered ONPG tablets are commercially available.)
3. Physiologic saline
4. Toluene

III. Quality Control

A. Positive control: *Escherichia coli*

B. Negative control: *Proteus* species

IV. Procedure

Bacteria grown in medium containing lactose, such as Kligler's iron agar (KIA) or triple-sugar iron (TSI) agar, produce optimal results in the ONPG test. A loopful of bacterial growth is emulsified in 0.5 mL of physiologic saline to produce a heavy suspension. One drop of toluene is added to the suspension and vigorously mixed for a few seconds to release the enzyme for the bacterial cells. An equal quantity of buffered ONPG solution is added to the suspension, and the mixture is placed in a 37°C water bath.

When using ONPG tablets, a loopful of bacterial suspension is added directly to the ONPG substrate resulting from adding 1 mL of distilled water to a tablet in a test tube. This suspension is also placed in a 37°C water bath.

V. Results

A. Interpretation

The rate of hydrolysis of ONPG to *o*-nitrophenol may be rapid for some organisms, producing a visible yellow color reaction within 5–10 minutes (Color Plate 6-4A). Most tests are positive within 1 hour; however, reactions should not be interpreted as negative before 24 hours of incubation. The yellow color is usually distinct and indicates that the organism has produced *o*-nitrophenol from the ONPG substrate through the action of β-galactosidase.

CHART 6-2

Nitrate Reduction: General Applications

I. Principle

The capability of an organism to reduce nitrates to nitrites is an important characteristic used in the identification and species differentiation of many groups of microorganisms. All *Enterobacteriaceae* except certain biotypes of *Pantoa agglomerans* and certain species of *Serratia* and *Yersinia* demonstrate nitrate reduction. The test is also helpful in identifying members of the *Haemophilus, Neisseria,* and *Moraxella* genera.

Organisms demonstrating nitrate reduction have the capability of extracting oxygen from nitrates to form nitrites and other reduction products. The chemical equation is

$$\underset{\text{Nitrate}}{NO_3^-} + 2e^- + 2H \rightarrow \underset{\text{Nitrite}}{NO_2} + H_2O$$

The presence of nitrites in the test medium is detected by the addition of α-naphthylamine and sulfanilic acid, with the formation of a red diazonium dye, *p*-sulfobenzeneazo-α-naphthylamine. See Figure in Chart 19-12.

II. Media and Reagents

A. Nitrate Broth or Nitrate Agar (Slant)

Beef extract	3 g
Peptone	5 g
Potassium nitrate (KNO_3)	1 g
Agar (nitrite-free)	12 g
Distilled water	1 L

B. Reagent A

α-Naphthylamine	5 g
Acetic acid (5 N), 30%	1 L

C. Reagent B

Sulfanilic acid	8 g
Acetic acid (5 N), 30%	1 L

III. Quality Control

It is important to test each new batch of medium and each new formulation

of test reagents for positive and negative reactions. The following organisms are suggested:

A. Positive control: *Escherichia coli*

B. Negative control: *Acinetobacter baumannii*

IV. Procedure

1. Inoculate the nitrate medium with a loopful of the test organism isolated in pure culture on agar medium, and incubate at 35°C for 18–24 hours.
2. At the end of incubation, add 1 mL each of reagents A and B to the test medium, in that order.

V. Results

A. Interpretation

The development of a red color within 30 seconds after adding the test reagents indicates the presence of nitrites and represents a positive reaction for nitrate reduction (Color Plate 6-1H). If no color develops after adding the test reagents, this may indicate either that nitrates have not been reduced (a true negative reaction) or that they have been reduced to products other than nitrites, such as ammonia, molecular nitrogen (denitrification), nitric oxide (NO) or nitrous oxide (N_2O), and hydroxylamine. Because the test reagents detect only nitrites, the latter process would lead to a false-negative reading. Thus, it is necessary to add a small quantity of zinc dust to all negative reactions. Zinc ions reduce nitrates to nitrites, and the development of a red color after adding zinc dust indicates the presence of residual nitrates and confirms a true negative reaction.

CHART 6-3

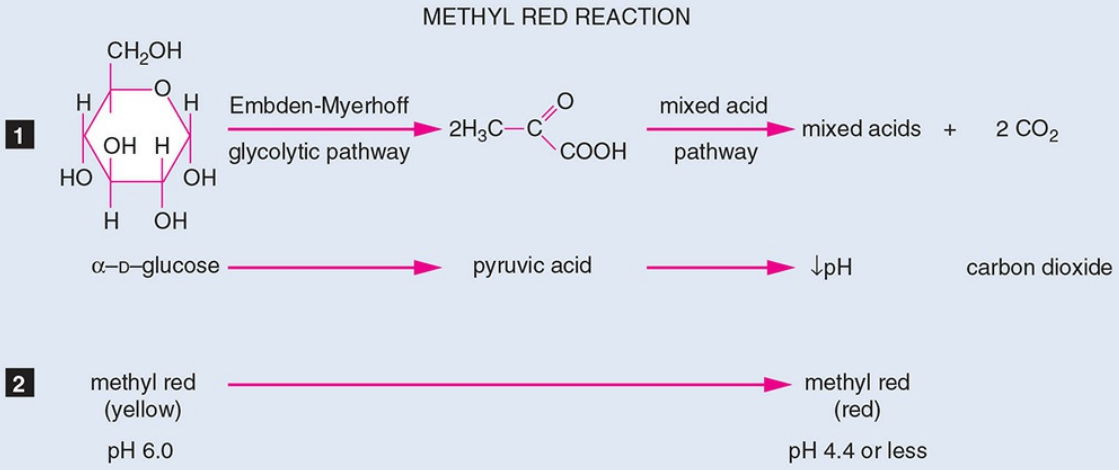
Methyl Red

I. Principle

Methyl red is a pH indicator, with a range between 6.0 (yellow) and 4.4 (red). The pH at which methyl red detects acid is considerably lower than the pH for other indicators used in bacteriologic culture media. Thus, to produce a color change, the test organism must produce large quantities of acid from the carbohydrate substrate being used.

C-11

The methyl red test is a quantitative test for acid production, requiring positive organisms to produce strong acids (lactic, acetic, formic) from glucose through the mixed acid fermentation pathway (Figure 6-2). Because many species of the *Enterobacteriaceae* may produce sufficient quantities of strong acids that can be detected by methyl red indicator during the initial phases of incubation, only organisms that can maintain this low pH after prolonged incubation (48–72 hours), overcoming the pH-buffering system of the medium, can be called methyl red–positive.



II. Media and Reagents

The medium most commonly used is methyl red–Voges-Proskauer (MR/VP) broth, as formulated by Clark and Lubs. This medium also serves for the performance of the Voges–Proskauer test.

A. MR/VP Broth

Polypeptone	7 g
Glucose	5 g
Dipotassium phosphate	5 g

Distilled water	1 L
Final pH	6.9

B. Methyl Red pH Indicator
Methyl red, 0.1 g, in 300 mL of 95% ethyl alcohol
Distilled water, 200 mL

III. Quality Control

Positive and negative controls should be run after preparation of each lot of medium and after making each batch of reagent. Suggested controls include the following:

A. Positive control: *Escherichia coli*

B. Negative control: *Enterobacter aerogenes*

IV. Procedure

1. Inoculate the MR/VP broth with a pure culture of the test organism. Incubate the broth at 35°C for 48–72 hours (no fewer than 48 hours).
2. At the end of this time, add 5 drops of the methyl red reagent directly to the broth.

V. Results

A. Interpretation

The development of a stable red color in the surface of the medium indicates sufficient acid production to lower the pH to 4.4 and constitutes a positive test (Color Plate 6-4C). Because other organisms may produce smaller quantities of acid from the test substrate, an intermediate orange color between yellow and red may develop. This does not indicate a positive test.

C-12

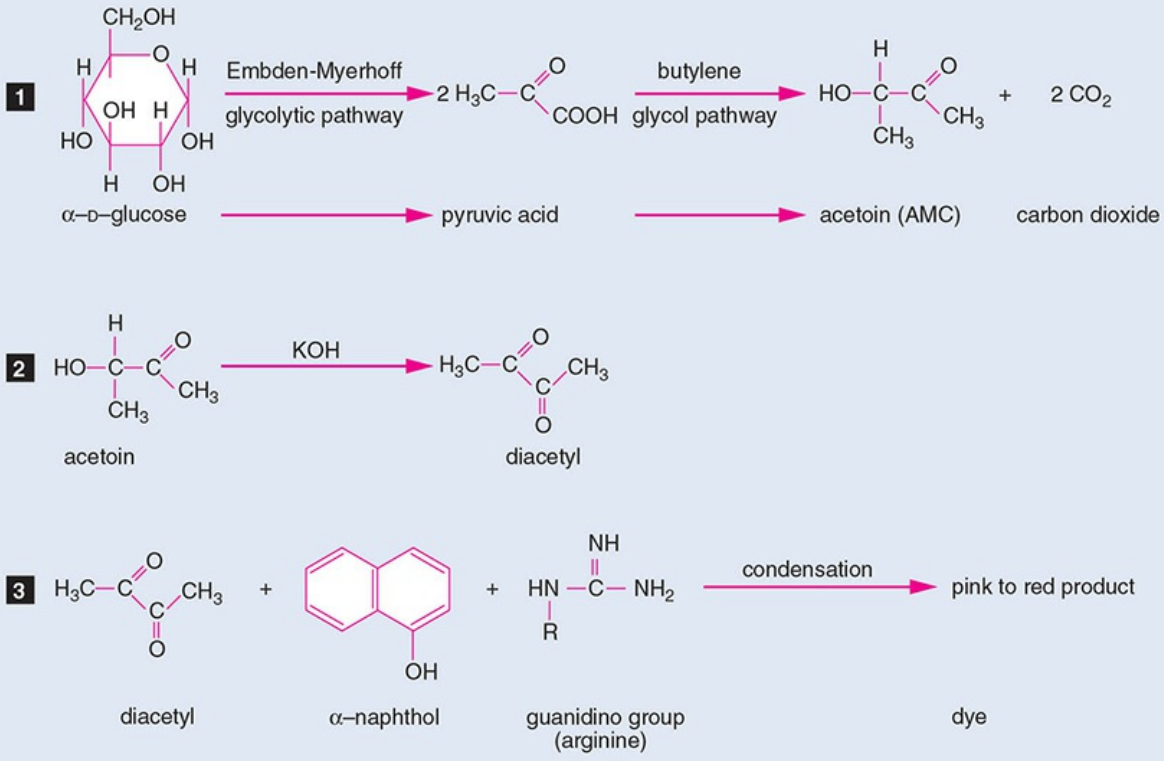
CHART 6-4

Voges-Proskauer Test

I. Principle

Voges-Proskauer is a double eponym, named after two microbiologists who worked at the beginning of the 20th century. They first observed the red color reaction produced by appropriate culture media after treatment with potassium hydroxide. It was later discovered that the active product in the medium formed by bacterial metabolism was acetyl methyl carbinol, a product of the butylene glycol pathway.

Pyruvic acid, the pivotal compound formed in the fermentative degradation of glucose, is further metabolized through various metabolic pathways, depending on the enzyme systems possessed by different bacteria. One such pathway results in the production of acetoin (acetyl methyl carbinol), a neutral-reacting end product. Organisms such as members of the *Klebsiella-Enterobacter-Hafnia-Serratia* group produce acetoin as the chief end product of glucose metabolism and form smaller quantities of mixed acids. In the presence of atmospheric oxygen and 40% potassium hydroxide, acetoin is converted to diacetyl, and α-naphthol serves as a catalyst to bring out a red complex.



II. Media and Reagents

A. Medium

1. The medium is the MR/VP broth described in Chart 6-3.

B. Reagents

1. α-Naphthol, 5% color intensifier

α-Naphthol	5 g
Absolute ethyl alcohol	100 mL

2. Potassium hydroxide, 40%, oxidizing agent

Potassium hydroxide	40 g
Distilled water	100 mL

III. Quality Control

Positive and negative controls should be performed after preparation of each lot of medium and after making each batch of reagent. Suggested controls include the following:

A. Positive control: *Enterobacter aerogenes*

B. Negative control: *Escherichia coli*

IV. Procedure

Inoculate a tube of MR/VP broth with a pure culture of the test organism. Incubate for 24 hours at 35°C. At the end of this time, aliquot 1 mL of broth to a clean test tube. Add 0.6 mL of 5% α-naphthol,

followed by 0.2 mL of 40% KOH. It is essential that the reagents be added in this order. Shake the tube gently to expose the medium to atmospheric oxygen and allow the tube to remain undisturbed for 10–15 minutes.

V. Results

A. Interpretation

A positive test is represented by the development of a red color 15 minutes or more after addition of the reagents, indicating the presence of diacetyl, the oxidation product of acetoin (Color Plate 6-4D). The test should not be read after standing for over 1 hour because negative Voges-Proskauer cultures may produce a copper-like color, potentially resulting in a false-positive interpretation.

CHART 6-5

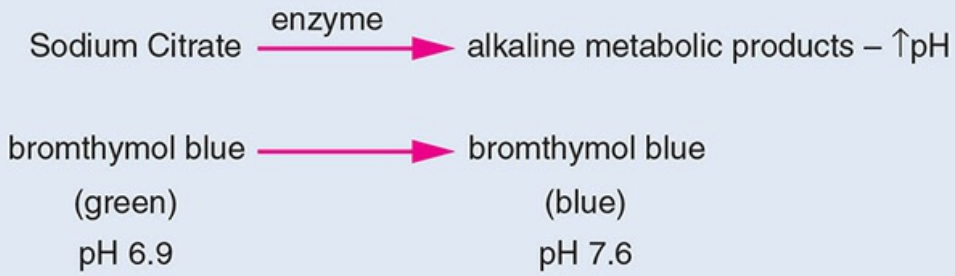
Citrate Utilization

I. Principle

Sodium citrate is a salt of citric acid, a simple organic compound found as one of the metabolites in the tricarboxylic acid cycle (Krebs cycle). Some bacteria can obtain energy in a manner other than by the fermentation of carbohydrates by using citrate as the sole source of carbon. The measurement of this characteristic is important in the identification of many members of the *Enterobacteriaceae.* Any medium used to detect citrate utilization by test bacteria must be devoid of protein and carbohydrates as sources of carbon.

The utilization of citrate by a test bacterium is detected in citrate medium by the production of alkaline by-products. The medium includes sodium citrate, an anion, as the sole source of carbon, and ammonium phosphate as the sole source of nitrogen. Bacteria that can use citrate can also extract nitrogen from the ammonium salts in the medium, producing sodium bicarbonate ($NaHCO_3$) and ammonia (NH_3), which results in an alkaline pH. Bromthymol blue—yellow below pH 6.0 and blue above pH 7.6—is the indicator.

THE CITRATE TEST



II. Media and Reagents

The citrate medium most commonly used is the formula of Simmons. The medium is poured into a tube on a slant. The formula of Simmons citrate medium is shown below:

Ammonium dihydrogen phosphate	1 g
Dipotassium phosphate	1 g
Sodium chloride	5 g
Sodium citrate	2 g
Magnesium sulfate	0.20 g
Agar	15 g
Bromthymol blue	0.08 g
Distilled water	1 L
Final pH	6.9

III. Quality Control

Each new batch of medium should be tested with a positive- and a negative-reacting organism. The following species are suggested controls:

A. Positive control—*Enterobacter aerogenes*

B. Negative control—*Escherichia coli*

IV. Procedure

1. A well-isolated colony is picked from the surface of a primarily isolation medium and inoculated as a single streak on the slant surface of the citrate agar tube. The tube is incubated at 35°C for 24–48 hours.

V. Results

A. Interpretation

A positive test is represented by the development of a deep blue color within 24–48 hours, indicating that the test organism has been able to utilize the citrate contained in the medium, with the production of alkaline products (Color Plate 6-4D). A positive test may also be read without a blue color if there is visible colony growth along the inoculation streak line. This is possible because, for growth to be visible, the organism must enter the log phase of growth, possible only if carbon and nitrogen have been assimilated. A positive interpretation from reading the streak line can be confirmed by incubating the tube for an additional 24 hours, when a blue color usually develops.

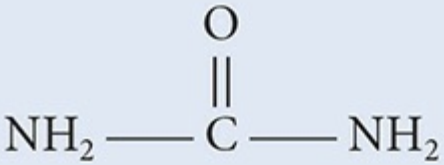
CHART 6-6

Urease: Conventional

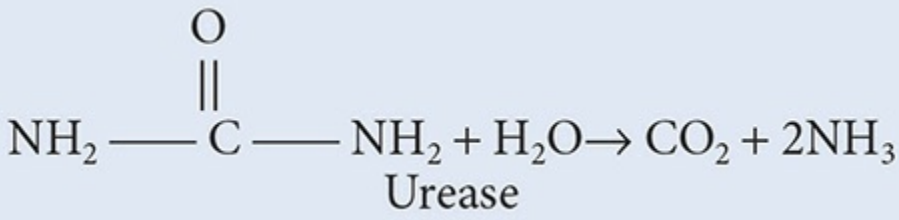
I. Principle

Urea is a diamide of carbonic acid with the formula



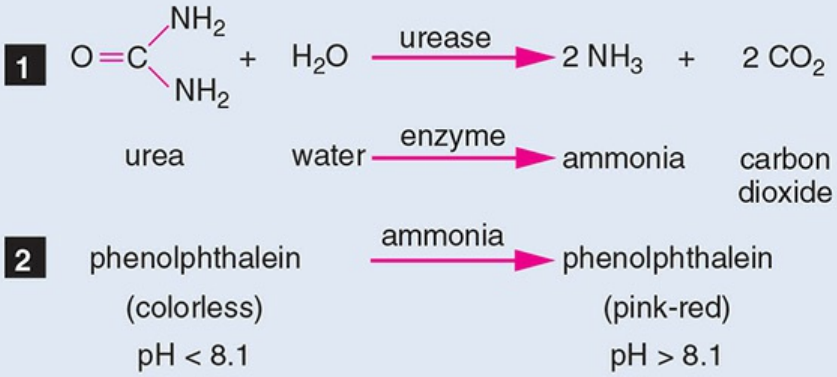
All amides are easily hydrolyzed with the release of ammonia and carbon dioxide.

Urease is an enzyme possessed by many species of microorganisms that can hydrolyze urea following the chemical reaction



The ammonia reacts in solution to form ammonium carbonate ($(NH_4)_2CO_3$), resulting in alkalinization and an increase in the pH of the medium.

MECHANISM OF THE UREASE REACTION



II. Media and Reagents

Stuart's urea broth and Christensen's urea agar are the two media most commonly used in clinical laboratories for the detection of urease activity.

Stuart's Urea Broth		Christensen's Urea Agar	
Yeast extract	0.1 g	Peptone	1 g
Monopotassium phosphate	9.1 g	Glucose	1 g
Disodium phosphate	9.5 g	Sodium chloride	5 g
Urea	20 g	Monopotassium phosphate	2 g
Phenol red	0.01 g	Urea	20 g
Distilled water	1 L	Phenol red	0.012 g
Final pH	6.8	Agar	15 g
		Distilled water	1 L
		Final pH	6.8

III. Quality Control

Positively and negatively reacting control organisms should be run with each new batch of medium. The following organisms are suggested:

A. Positive control: *Proteus* species

B. Positive control (weak): *Klebsiella* species

C. Negative control: *Escherichia coli*

IV. Procedure

The broth medium is inoculated with a loopful of a pure culture of the test organism; the surface of the agar slant is streaked with the test organism. Both media are incubated at 35°C for 18–24 hours.

V. Results

A. Interpretation

Organisms that hydrolyze urea rapidly may produce positive reactions within 1 or 2 hours; less active species may require 3 or more days. The reactions are as follows:

1. Stuart's broth

Red color throughout the medium indicates alkalinization and urea hydrolysis

2. Christensen's agar

Rapid urea hydrolyzers (*Proteus* species): red color throughout medium

Slow urea hydrolyzers (*Klebsiella* species): red color initially in slant only, gradually converting the entire tube

3. No urea hydrolysis: medium remains original yellow color (Color Plate 6-4E).

CHART 6-7

Decarboxylases

I. Principle

Decarboxylases are a group of substrate-specific enzymes that are capable of reacting with the carboxyl (COOH) portion of amino acids, forming alkaline-reacting amines. This reaction, known as decarboxylation, forms carbon dioxide as a second product. Each decarboxylase enzyme is specific for an amino acid. Lysine, ornithine, and arginine are the three amino acids routinely tested in the identification of the *Enterobacteriaceae.* The specific amine products are as follows:

Lysine	→	Cadaverine
Ornithine	→	Putrescine
Arginine	→	Citrulline

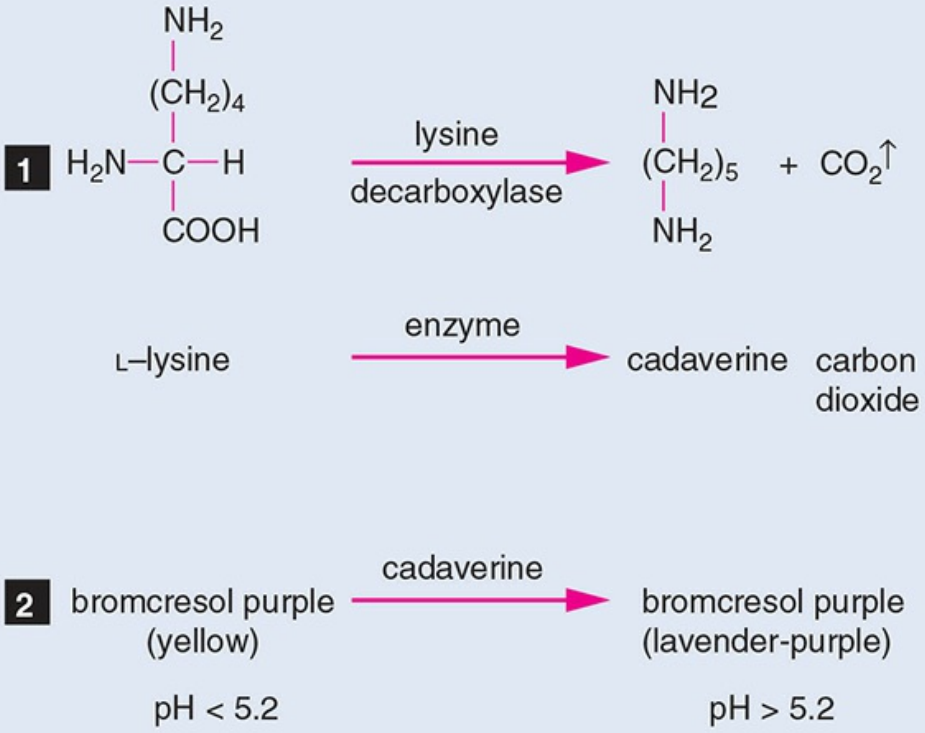
The conversion of arginine to citrulline is a dihydrolase, rather than a decarboxylase reaction, in which an NH_2 group is removed from arginine as a first step. Citrulline is next converted to ornithine, which then undergoes decarboxylation to form putrescine.

C-16

Møller decarboxylase medium is the base most commonly used for determining the decarboxylase capabilities of the *Enterobacteriaceae.* The amino acid to be tested is added to the decarboxylase base before inoculation with the test organism. A control tube, consisting of only the base without the amino acid, must also be set up in parallel. Both tubes are anaerobically incubated by overlaying with mineral oil. During the initial stages of incubation, both tubes turn yellow, owing to the fermentation of the small amount of glucose in the medium. If the amino acid is decarboxylated, alkaline amines are formed and the medium reverts to its original purple

color.

MECHANISM OF THE LYSINE DECARBOXYLASE REACTION



II. Media and Reagents

A. Møller Decarboxylase Broth Base

Peptone	5 g
Beef extract	5 g
Bromcresol purple	0.01 g
Cresol red	0.005 g
Glucose	0.5 g
Pyridoxal	0.005 g
Distilled water	1 L
Final pH	6.0

B. Amino Acid

Add 10 g (final concentration = 1%) of the L (*levo*) -form of the amino acid (lysine, ornithine, or arginine). Double this amount if the D (*dextro*) -form is to be used, because only the L-form is active.

III. Quality Control

The following organisms are suggested for positive and negative controls:

Amino Acid	Positive Control	Negative Control
Lysine	*Enterobacter aerogenes*	*Enterobacter cloacae*
Ornithine	*Enterobacter cloacae*	*Klebsiella pneumoniae*
Arginine	*Enterobacter cloacae*	*Enterobacter aerogenes*

IV. Procedure

From a well-isolated colony of the test organism previously recovered on primary isolation agar, inoculate two tubes of Møller decarboxylase medium, one containing the amino acid to be tested and the other to be used as a control tube devoid of amino acid. Overlay both tubes with sterile mineral oil to cover about 1 cm of the surface and incubate at 35°C for 18–24 hours.

V. Results

A. Interpretation

Conversion of the control tube to a yellow color indicates that the organism is viable and that the pH of the medium has been lowered sufficiently to activate the decarboxylase enzymes. Reversion of the tube containing the amino acid to a blue-purple color indicates a positive test owing to the formation of amines from the decarboxylation reaction (Color Plate 6-4F).

CHART 6-8

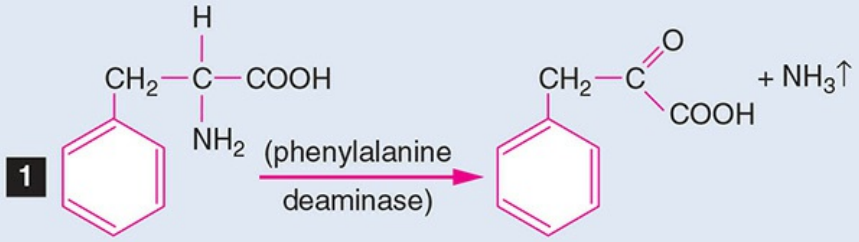
Phenylalanine Deaminase

I. Principle

Phenylalanine is an amino acid that on deamination forms a keto acid, phenylpyruvic acid. Of the *Enterobacteriaceae,* only members of the *Proteus, Morganella,* and *Providencia* genera possess the deaminase enzyme necessary for this conversion.

The phenylalanine test depends on the detection of phenylpyruvic acid in the test medium after growth of the test organism. The test is positive if a visible green color develops on addition of a solution of 10% ferric chloride.

MECHANISM OF THE PHENYLALANINE DEAMINASE REACTION



L–phenylalanine —(enzyme)→ phenylpyruvic acid + ammonia

2 phenylpyruvic acid + ferric ion (Fe^{+++}) —acid→ green complex

II. Media and Reagents

Phenylalanine agar is poured as a slant into a tube. Meat extracts or protein hydrolysates cannot be used because of their varying natural content of phenylalanine. Yeast extract serves as the carbon and nitrogen source. The formula is shown below:

Medium

DL-Phenylalanine	2 g
Yeast extract	3 g
Sodium chloride	5 g
Disodium phosphate	1 g
Agar	12 g
Distilled water	1 L
pH	7.3

Reagent	
Ferric chloride	12 g
Concentrated HCl	2.5 mL
Distilled water	100 mL

C-18

III. Quality Control

Each new batch of medium or reagent must be tested with positive- and negative-reacting organisms. The following are suggested:

A. Positive control: *Proteus* species

B. Negative control: *Escherichia coli*

IV. Procedure

The agar slant of the medium is inoculated with a single colony of the test organism isolated in pure culture of primary plating agar. After incubation at 35°C for 18–24 hours, 4 or 5 drops of the ferric chloride reagent are added directly to the surface of the agar. As the reagent is added, the tube is rotated to dislodge the surface colonies.

V. Results

A. Interpretation

The immediate appearance of an intense green color indicates the presence of phenylpyruvic acid and a positive test (Color Plate 6-4E).

CHART 7-1

Oxidative-Fermentative Test (Hugh and Leifson)

I. Principle

Saccharolytic microorganisms degrade glucose either fermentatively or oxidatively, as shown in Fig. 7-1. The end products of fermentation are relatively strong mixed acids that can be detected in a conventional fermentation test medium. However, the acids formed in oxidative degradation of glucose are extremely weak, and the more sensitive oxidation-fermentation medium of Hugh and Leifson (OF medium) is required for their detection.

The OF medium of Hugh and Leifson differs from carbohydrate fermentation media as follows:

The concentration of peptone is decreased from 1% to 0.2%.

The concentration of carbohydrate is increased from 0.5% to 1.0%.

The concentration of agar is decreased from 1.5% to 0.3%, making it semisolid.

The lower protein/carbohydrate ratio reduces the formation of alkaline amines that can neutralize the small quantities of weak acids that may form from oxidative metabolism. The relatively larger amount of carbohydrate serves to increase the amount of acid that can potentially be formed. The semisolid consistency of the agar permits acids that form on the surface of the agar to permeate throughout the medium, making interpretation of the pH shift of the indicator easier to visualize. Motility can also be observed in this medium.

II. Media and Reagents

For comparison, the formulas for a conventional carbohydrate fermentation medium and OF medium are as follows:

Carbohydrate Fermentation Medium

Peptone	10 g
Sodium chloride	5 g

D-glucose	5 g
Bromcresol purple	0.02 g
Agar[a]	15 g
Distilled water	1 L
pH	7.0

[a]Agar is omitted from broth medium.

C-19

OF Medium of Hugh and Leifson

Peptone	2 g
Sodium chloride	5 g
D-glucose	10 g
Bromthymol blue	0.03 g
Agar	3 g
Dipotassium phosphate	030
Distilled water	1 L
pH	7.1

The OF sugar reactions listed in the Weaver CDC tables, described in Chapter 7, are based on tests using a "special" base with phenol red as the indicator:

Bacto casitone	2 g
Bacto agar	3 g
Phenol red, 1.5% aqueous	2 mL
Distilled water	1 L

The basal medium is adjusted to a pH of 7.3 and autoclaved. Carbohydrate solutions are passed through a Seitz filter and added to the basal medium to a final concentration of 1.0%. Studies at the CDC revealed that the correlation of test results between the Difco and the special CDC OF basal media is excellent and that either can be used when making interpretations from the Weaver tables.

OF medium should be poured without a slant into tubes with an inner diameter of 15–20 mm to increase surface area.

III. Quality Control

A. Glucose fermenter: *Escherichia coli*

B. Glucose oxidizer: *Pseudomonas aeruginosa*

C. Nonsaccharolytic: *Moraxella* species

IV. Procedure

Two tubes are required for the OF test, each inoculated with the unknown organism, using a straight needle, stabbing the medium three to four times halfway to the bottom of the tube. One tube of each pair is covered with a 1-cm layer of sterile mineral oil or melted paraffin, leaving the other tube open to the air. Incubate both tubes at 35°C and examine daily for several days.

V. Results

A. Interpretation

Acid production is detected in the medium by the appearance of a yellow color. In the case of oxidative organisms, color production may be first noted near the surface of the medium. Following are the reaction patterns:

Open Tube	Covered Tubes	Metabolism
Acid (yellow)	Alkaline (green)	Oxidative
Acid (yellow)	Acid (yellow)	Fermentative
Alkaline (green or blue)	Alkaline (green or blue)	Nonsaccharolytic

These color reactions are shown in Color Plate 7-1D. For slower-growing species, incubation for 3 days or longer may be required to detect positive reactions.

C-20

CHART 7-2

Flagellar Stain

I. Principle

Most motile bacteria possess flagella, the shape, number, and position of which are important characteristics in the differentiation of genera and species identification, particularly when biochemical reactions are weak or equivocal. The Leifson staining technique (or modification) is most commonly used in clinical laboratories and is not difficult to perform, providing exact details that are followed in each step of the procedure.

Bacterial flagella can be stained by alcoholic solutions of rosaniline dyes that form a precipitate as the alcohol evaporates in the staining procedure. Basic fuchsin (pararosaniline acetate) serves as the primary stain with tannic acid added to the solution as a mordant. A counterstain, such as methylene blue, may be used to better visualize the bacteria in instances in which the primary stain is weak or does not react at all with the bacterial cell wall.

II. Media and Reagents

A. Leifson Method

1. Basic fuchsin, 1.2% in 95% alcohol

a. Commercial product must be certified for flagellar stain.

b. Pararosaniline acetate is preferred. If the dye solution is a mixture of pararosaniline acetate and pararosaniline hydrochloride, the hydrochloride compound must not compose more than two-thirds of the solution.

c. The stain must have the odor of acetic acid to be satisfactory.

d. When new stain is prepared, at least 1 day must be allowed for the dye to enter completely into solution.

2. Tannic acid, 3% in water

a. The suspension must have a light yellow color to be satisfactory.

b. Add phenol in a 1:200 concentration to discourage emergence of molds during storage.

3. Sodium chloride, 1.5% in water

4. Final stain

a. Combine the three stock solutions in equal volumes. The stain is ready for use immediately after preparation and should be stored in a tightly stoppered bottle.

b. A precipitate will form during storage. This should not be disturbed; rather, remove the staining solution from the top with a pipette.

c. Shelf life of the staining solution is 1 week at room temperature, 1 month in the refrigerator, and indefinite if frozen.

B. Ryu Method

1. Solution I

a. 5% phenol, 10.0 mL

b. Powdered tannic acid, 2.0 g

c. Saturated aluminum potassium sulfate 12-hydrate (crystals) (prepare 14 g potassium alum in 100 mL distilled H_2O), 10.0 mL

2. Solution II

a. Saturated solution of crystal violet in alcohol (prepare 12 g in 100 mL of 95% ethanol)

3. Final stain

a. Ten parts of solution I (mordant) are mixed with one part of solution II and stored in a plastic bottle at room temperature.

III. Quality Control

The following bacterial species may serve as controls:

A. Positive: peritrichous, *Escherichia coli*; polar, monotrichous, *Pseudomonas aeruginosa*; multitrichous, *Burkholderia cepacia*

B. Negative: *Acinetobacter baumannii*

IV. Procedure

A. Leifson Method

1. Using a young culture on an appropriate agar medium, prepare a light suspension of the bacteria in water.

2. Place 2 drops of the bacterial suspension toward one end of an acid-cleaned microscope slide. Allow to air-dry. With a wax pencil, draw a perpendicular line on the glass surface toward the opposite end from the dried suspension.

3. Place the slide on a tilted rack and overlay the dried bacterial suspension with a thin film of stain. The wax pencil mark prevents the stain from running off the end of the slide.

C-21

4. Stain for 5–15 minutes, allowing a precipitate to form as the alcohol evaporates. The staining time is decreased if the stain is fresh, if the room temperature is high, if there are air currents in the laboratory, or if the layer of stain is thin. The opposite effects increase the staining time.

5. When a precipitate forms, rinse the slide gently with distilled water, drain off excess water, and allow to air-dry.

B. Ryu Method

1. Prepare the smear by picking up some young growth from carbohydrate-free culture medium on an inoculating needle and lightly touching the center of each of 2 drops of distilled water on a new, precleaned slide. Let the drops air-dry at room temperature.

2. Flood the air-dried smears with the staining solution for 1–5 minutes (some trial and error may be needed to determine the time that best produces satisfactory staining of the flagella, but avoids excessive debris in the background). Wash the staining solution off in tap water.
3. After the smears have dried, examine them under the oil-immersion objective of the microscope. Cell bodies and flagella stain violet.

V. Results

A. Interpretation

Observe the stained slide under the oil-immersion (100×) objective of the microscope. Dark-staining red to blue-black flagella should be observed. Compare morphology with the photomicrographs provided in Leifson's *Atlas of Bacterial Flagellation,* cited in the bibliography, and see also Fig. 7-3.

CHART 7-3

Fluorescence-Denitrification

I. Principle

The ability to produce fluorescein pigment and to reduce nitrate or nitrite completely to nitrogen gas are two important characteristics in the identification of the pseudomonads and other nonfermentative bacilli. Fluorescence-denitrification (FN) medium is formulated to detect these two characteristics. Fluorescence-lactose nitrate (FLN) medium is a modification in which lactose and phenol red indicator are added to permit detection of acid formed from utilization of lactose, which is helpful in identifying the strongly lactose-positive group of nonfermenters.

A. Fluorescence Test

Fluorescein is an organic luminescent pigment that on excitation with

ultraviolet light emits a green-yellow fluorescence. A few of the nonfermentative bacilli, notably *Pseudomonas aeruginosa,* are capable of producing fluorescein, detection of which is helpful in their identification. Fluorescence of colonies may not be detected on an ordinary isolation medium, such as blood agar or MacConkey agar; rather, media containing cationic salts, such as magnesium sulfate (included in FN medium), which act as activators or co-activators to intensify luminescence, often must be used.

B. Denitrification Test

The reduction of nitrate to nitrogen gas (N_2) or nitrous oxide (N_2O) is called denitrification and is shown by the following chemical equation:

$$2NO_3^- + 10e- + 12H^- \rightarrow N_2\uparrow + 6H_2O$$

In this reduction process, five electrons are accepted by the nitrate radical, resulting in formation of nitrogen gas and six molecules of water. The denitrification test is helpful in the separation of *Pseudomonas stutzeri* group (most strains are positive) from other nonfermentative bacilli (see Table 7-5).

II. Media and Reagents

A. The formula for FN medium is as follows:

Proteose peptone 3 (Difco Laboratories, Detroit MI)	1 g
Magnesium sulfate $7H_2O$	0.15 g
Dipotassium hydrogen phosphate	0.15 g
Potassium nitrate	0.2 g
Sodium nitrite	0.05 g
Agar	1.5 g
Distilled water	100 mL
pH	7.2

1. Suspend all the ingredients except the magnesium sulfate in distilled water. The magnesium sulfate is dissolved separately in a small amount of water before adding to the agar medium to avoid the formation of an insoluble precipitate.
2. If FLN medium is to be prepared, add 2 g of lactose and 0.002 g of phenol red indicator. Dispense 4 mL of medium into 13-mm

screw-cap tubes and let solidify to give a deep and a slant of approximately equal length.

3. Sellers' medium, available commercially, is also suitable for determination of fluorescence and denitrification by nonfermentative bacteria.

B. The formula for nitrate/nitrite reduction medium is as follows:

Heart infusion broth (Difco Laboratories, Detroit, MI)[a]	25 g
Potassium nitrate	2 g
Distilled water	1 L
pH	7.0

III. Quality Control

The following organisms are appropriate controls:

Positive fluorescence/positive denitrification: *Pseudomonas aeruginosa*
Negative fluorescence/positive denitrification: *Pseudomonas stutzeri*
Negative fluorescence/negative denitrification: *Escherichia coli*

IV. Procedure

Incubate the medium by stabbing the deep with a heavy suspension of the culture and then streaking the slant. Incubate at 35°C for 24–48 hours.

V. Results

A. Interpretation

Examine the tube for fluorescence with an ultraviolet light source (Wood's lamp). A bright yellow-green glow constitutes a positive test. The presence of gas bubbles in the deep of the medium indicates that nitrogen gas has been produced from denitrification, and a yellow slant with FLN medium indicates acid has been produced from the utilization of lactose by the microorganism. In broth medium, nitrogen gas formation is detected by noting the presence of a gas bubble in the upper portion of the inverted Durham tube (Color Plate 7-2B).

VI. Bibliography

Pickett MJ, Pedersen MM. Screening procedure for partial identification of nonfermentative bacilli associated with man. Appl Microbiol 1968;16:1631–1632.

[a] Agar is omitted from broth medium and inverted Durham tubes added to detect gas.

CHART 7-4

Esculin Hydrolysis Test

I. Principle

Esculin medium without bile is useful in differentiating several species on nonfermenting bacilli. Esculin is a substituted glucoside that can be hydrolyzed by certain bacteria to yield glucose and esculetin. Esculin is a fluorescent compound that fluoresces under long-wave UV light at 360 nm. When esculin is hydrolyzed, fluorescence is lost, and the medium turns black due to the reaction of esculetin with the ferric ions in the medium. Several species of *Chryseobacterium, Sphingobacterium,* as well as *C. luteola, B. vesicularis, S. paucimobilis, S. maltophilia, R. radiobacter,* and some species of *B. cepacia, B. pseudomallei,* and *O. anthropi* are esculin-positive.

II. Media and Reagents

The formula for esculin medium is as follows:

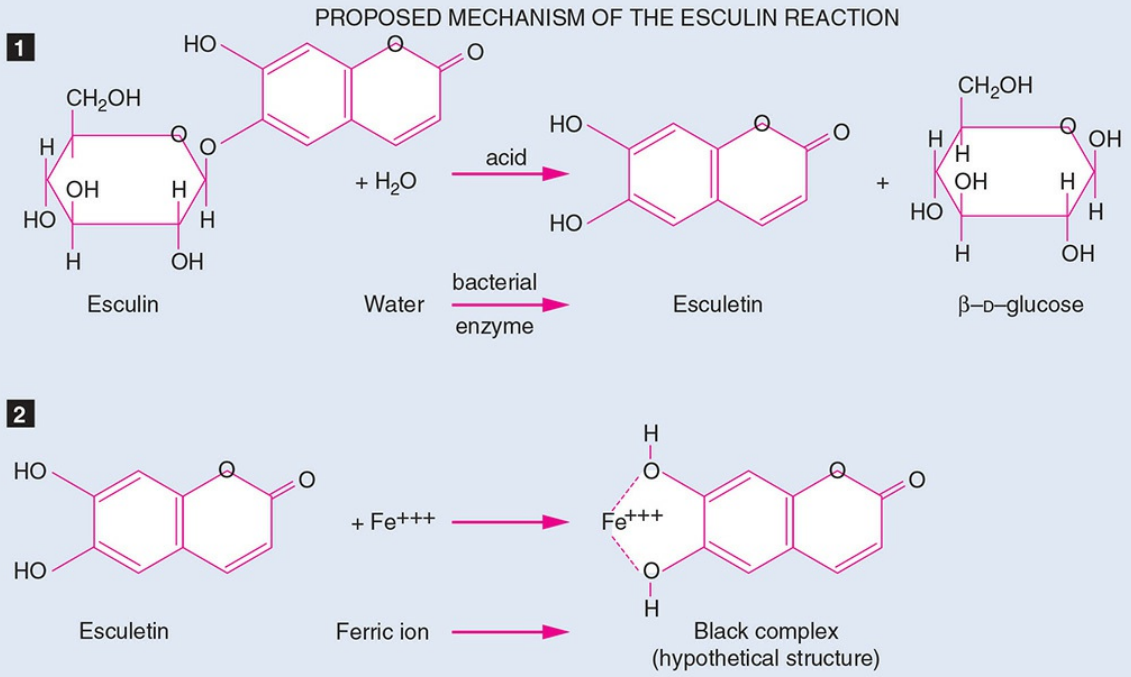
Esculin Agar Modified

Esculin	1 g
Ferric citrate	0.5 g
Heart infusion agar	40 g
Distilled water	1 L

C-23

Esculin Broth

Heart muscle, infusion	10 g
Peptic digest of animal tissue	10 g
Sodium chloride	5 g
Esculin	1 g
Distilled water	1 L



III. Quality Control

A. Positive control: *Aeromonas hydrophila* ATCC 7965

B. Negative control: *P. aeruginosa* ATCC 27853

IV. Procedure

After touching the center of one well-isolated colony with a sterile inoculation loop or wooden stick, inoculate the organism onto the surface of the agar slant or into the broth. Incubate for 18–24 hours at 35°C.

V. Results

A. Interpretation

The development of a black color or the loss of fluorescence under UV light (360 nm) is interpreted as a positive test. Fluorescence or lack of a black color is interpreted as a negative test (Color Plate 7-2 E).

VI. Bibliography

MacFaddin JF. Biochemical Tests for Identification of Medical Bacteria. 2nd Ed. Baltimore, MD: Williams & Wilkins, 1980:4–12.

CHART 8-1

The CAMP Test

I. Principle

The presumptive identification of group B β-hemolytic streptococci can be done with the CAMP test, which is reliable and easy to perform. The hemolytic phenomenon was first described in 1944 by Christie, Atkins, and Munch–Petersen, and it is their names that provide the acronym (CAMP) for the test.

The hemolytic activity of the β-hemolysin produced by most strains of *Staphylococcus aureus* is enhanced by an extracellular protein produced by group B streptococci. Interaction of the β-hemolysin with this factor causes "synergistic hemolysis," which is easily observed on a blood agar plate. This phenomenon is seen with both hemolytic and nonhemolytic isolates of group B streptococci. Other bacteria, such as *Listeria monocytogenes*, *Rhodococcus equi,* and certain strains of *Vibrio cholera*, are also CAMP-positive.

II. Materials

1. β-hemolysin-producing strain of *Staphylococcus aureus*
2. Sheep blood agar plate

III. Quality Control

A. Positive control: group B *Streptococcus*

B. Negative control: group A *Streptococcus*

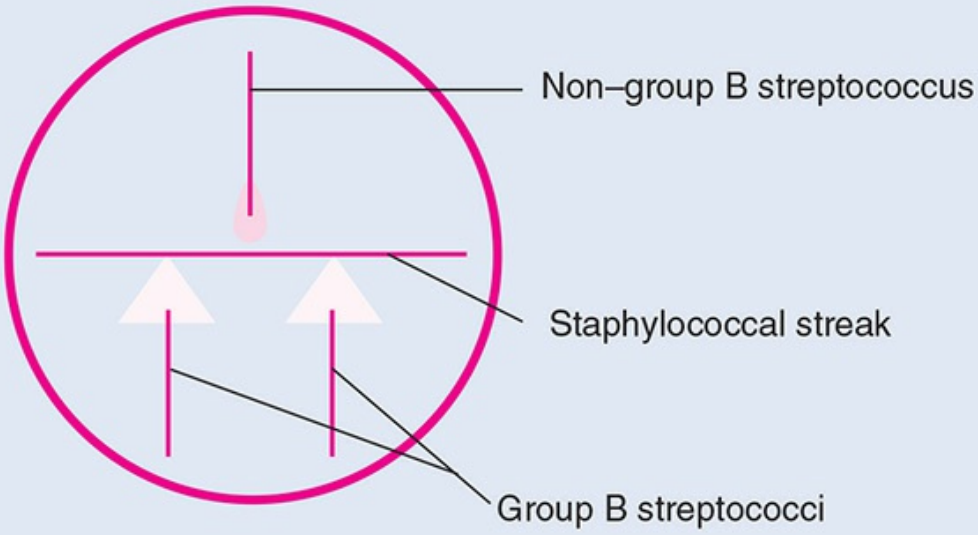
IV. Procedure

1. Down the center of a blood agar plate, and make a single straight line streak of β-hemolysin-producing *S. aureus.*
2. Taking care not to intersect the staphylococcal streak, inoculate a streak of the β-hemolytic streptococcus to be identified perpendicular to the staphylococcal streak. Make these streaks so that, after incubation, the growth of the two organisms will not be touching. The streptococcal streak should be 3–4 cm long. Known group A and B streptococcal strains should be similarly inoculated on the same plate as negative and positive controls, respectively.
3. Incubate the plate at 35°C in ambient air for 18–24 hours.

V. Results

A. Interpretation

As illustrated below, the area of increased hemolysis occurs where the β-hemolysin secreted by the *Staphylococcus* and the CAMP factor secreted by the group B *Streptococcus* intersect. Any bacitracin-resistant, trimethoprim-sulfamethoxazole–resistant, CAMP test-positive, β-hemolytic *Streptococcus* can be reported as "β-hemolytic *Streptococcus*, presumptive group B by CAMP test."



VI. Limitations

Some group A streptococci will be CAMP test-positive if the test plate is incubated in a candle jar, in a CO_2 atmosphere, or under anaerobic conditions. Therefore, ambient-air incubation should be used.

CHART 9-1

Test for X and V Factor Requirements

I. Principle

X factor (hemin, hematin) and V factor (NAD) are required either singly or in combination to support the growth of various species of *Haemophilus* on agar media. Filter paper strips or disks impregnated with X and V factors are

commercially available.

X and V factors, each being water-soluble, readily diffuse in agar culture media. Filter paper disks or strips impregnated with these factors are placed on the surface of a medium deficient in these factors, such as trypticase-soy or brain–heart infusion agar, which has been inoculated as a lawn with the test organism. Factor requirements of the organism are then determined, after overnight incubation, by observing the patterns of growth around the paper strips or disks (see following illustration).

II. Media and Reagents

1. Paper strips or disks impregnated with X and V factors
2. An agar medium deficient in X and V factors. Trypticase-soy or brain–heart infusion agars are suitable.
3. Brain–heart infusion broth

III. Quality Control

A. *Haemophilus parainfluenzae*: requires V factor only

B. *Haemophilus influenzae:* requires both X and V factors

IV. Procedure

1. From a pure culture of the organism to be identified, prepare a light suspension of the growth in the brain–heart infusion broth. Be careful when transferring the growth not to pick up any of the hemin-containing medium from the culture plate. From this suspension, inoculate the surface of the factor-deficient agar medium.
2. Place an X and a V factor strip on the surface of the agar in the area of inoculation.
3. Position the strips about 1 cm apart.
4. Incubate the plate in 3%–5% CO_2 at 35°C for 18–24 hours.

V. Results

A. Interpretation

Visually inspect the agar surface, observing closely for visible growth between or around one or more of the strips or disks. The following patterns indicate the need for X factor only (*left*), V factor only (*center*), or both X and V factors (*right*):

CHART 10-1

Protocol for Acid-Wash Decontamination of Sputum and Other Contaminated Specimens

1. Before performing the acid treatment of the specimen, prepare six smears for DFA testing, if this is performed, or obtain aliquots for PCR.
2. Inoculate one BCYE and one BMPA plate with three to five drops of untreated respiratory specimen and streak for isolation.
3. Add 0.5 mL of respiratory specimen to 4.5 mL of acid solution (0.2 M KCl–HCl) in a screw-cap tube.
   a. Tightly seal the tube, and thoroughly mix by vortexing under a safety hood.
   b. Allow the suspension to stand at room temperature for 5 minutes.
4. Inoculate a second set of BCYE and BMPA plates with three to five drops of the acid-specimen mixture prepared in step 3 and streak for isolation. Mark plates with an "A" to identify plates inoculated after acid treatment.
5. Place the four inoculated plates in CO_2-permeable plastic bags (two per bag), and incubate in CO_2 at 35°C for 2 weeks. Examine every 2–3 days for growth.

CHART 11-1

Rapid Carbohydrate Utilization Test for Identification of *Neisseria* Species

I. Principle

The rapid carbohydrate utilization test procedures have largely supplanted the use of cystine-tryptic digest semisolid agar with carbohydrates for the identification of *Neisseria* species. These, in turn, are largely being replaced by identification using mass spectrometry.

The rapid carbohydrate utilization test uses a balanced phosphate-buffered saline solution containing phenol red indicator. Small (0.10-mL) aliquots of the buffer are distributed in a series of tubes, one for each carbohydrate tested. Single drops of the individual carbohydrates (20% w/v) are added to individual tubes. A heavy suspension of the organism to be tested is prepared in the buffer without carbohydrates, and one drop of this suspension is added to each of the carbohydrate tubes. After 4 hours of incubation, the reactions are interpreted. Production of acid from carbohydrates is indicated by a change in the color of the phenol red indicator from red to yellow.

II. Media and Reagents

A. Phosphate Balanced Salt Solution (BBS) (a 10× stock solution having the following formula)

K_2HPO_4	0.40 g
KH_2PO_4	0.10 g
KCl	8.0 g
Distilled water	100 mL

Filter-sterilize and store at 4°C–8°C

B. Working Solution

Add 10 mL of the 10× BSS–90 mL of distilled water. After this, 0.5–0.8 mL of a 1% aqueous solution of phenol red is added to the solution, so that the final product is "cherry red." This working solution is then filter-sterilized. To ensure that the distilled water has the proper pH, the use of pharmacy-grade sterile distilled water is recommended.

C. Stock Carbohydrate Solutions

Weigh out 10 g each of glucose, maltose, sucrose, and lactose (and, if desired, fructose) individually. Each is dissolved in 50 mL of distilled water. The solutions are filter-sterilized, dispensed into sterile vials, and frozen at 20°C. It is important that "reagent-grade" carbohydrates be used, because the maltose from some bacteriologic media vendors may be contaminated with glucose. Carbohydrates may be obtained from Sigma Chemical Company (St. Louis, MO), Fisher Scientific Company (Fairlawn, NJ), or Mallinckrodt Chemical Works (St Louis, MO).

III. Quality Control

A. Positive glucose: *N. gonorrhoeae*
B. Positive maltose: *N. meningitidis*
C. Positive lactose: *N. lactamica*
D. Positive sucrose and fructose: *N. mucosa*

IV. Procedure

1. A series of nonsterile 12 × 75-mm tubes are labeled with the carbohydrate to be tested. Generally, glucose, maltose, sucrose, and lactose are tested. Some laboratories will also include fructose in the test battery. An additional tube, labeled with the isolate or specimen number, is also included for preparation of the inoculum.
2. For each of the carbohydrate tubes, 0.10 mL of working BSS is added. For the inoculum tube, 0.30–0.40 mL of BSS is placed in the tube.
3. A single drop of each of the carbohydrates is added to the appropriately labeled tube with a Pasteur pipette.
4. A heavy suspension of the organism to be tested is prepared in the inoculum tube using a sterile bacteriologic loop. The inoculum is prepared from an 18- to 24-hour, pure chocolate agar subculture of the organism. The inoculum suspension is carefully vortexed to obtain a uniform, heavy suspension.
5. Single drops of the inoculum suspension are added to each of the carbohydrate-containing tubes. The tubes are briefly agitated to ensure thorough mixing and are placed in an incubator or water bath at 35°C for 4 hours.

V. Results

A. Interpretation

The development of a yellow color in any of the carbohydrate-containing tubes indicates utilization of that carbohydrate by the organism. Negative carbohydrate-utilization tests remain red or red-orange.

C-27

CHART 12-1

Furazolidone Disk Test

I. Principle

There are several methods available for differentiation of staphylococci from micrococci (Table 12-2). One of these is susceptibility to the compound furoxone (also called furazolidone). This test is performed as a disk susceptibility procedure: Staphylococci are susceptible to this compound, whereas micrococci are resistant.

II. Reagents

1. Furazolidone disks, 100 mg (FX 100, BD Microbiology Systems, Franklin Lakes, NJ)
2. Sheep blood agar plate

III. Quality Control

Known strains of *Staphylococcus* (either *S. aureus* or a coagulase-negative strain) and *Micrococcus* species should be tested with each new lot of disks, or on a weekly basis.

IV. Procedure

1. Prepare a suspension of the organism to be tested in sterile distilled water or broth. The suspension should be equivalent to a 0.5 McFarland turbidity standard.
2. With a swab, spread the organism suspension onto one-half of a blood agar plate.
3. Aseptically place an FX disk in the center of the inoculated area, and gently tap the disk so that it adheres to the agar surface.
4. Incubate the plate at 35°C in an ambient-air incubator for 18–24 hours.

V. Results

A. Interpretation

1. *Micrococcus* species are FX-resistant and will have zones of 6 mm (no zone)–9 mm.
2. *Staphylococcus* species are FX-susceptible and will have zones of inhibition of 15 mm or larger.

CHART 12-2

Novobiocin Disk Test

I. Principle

Coagulase-negative staphylococci can be divided into novobiocin-susceptible and novobiocin-resistant species. Among the novobiocin-resistant species, *S. saprophyticus* is the one commonly recovered from humans as a cause of urinary tract infections. Therefore, screening coagulase-negative staphylococci isolated from quantitative urine cultures for susceptibility to novobiocin provides a reliable presumptive identification of this species.

II. Reagents

1. Novobiocin disks, 5 mg (NB 5, BD Microbiology Systems, Franklin Lakes, NJ)
2. Sheep blood agar plate

III. Quality Control

A known *S. saprophyticus* strain and an *S. epidermidis* strain should be tested according to guidelines, possibly using the Individualized Quality Control Plan (IQCP) for this assay.

IV. Procedure

1. Prepare a suspension of the organism to be identified in sterile distilled water or broth.
2. The suspension should be equivalent in turbidity to a 0.5 McFarland standard.
3. With a sterile swab, spread some of the suspension over half of a blood agar plate.
4. Aseptically place a novobiocin disk on the inoculated area. Susceptibility to furazolidone (Chart 12-1) may be assessed on the same plate by placing the disks about 4 cm apart on the inoculated area. Gently tap the disk(s) with sterile forceps to assure contact with the agar surface.
5. Incubate the plate aerobically for 18–24 hours at 35°C.

V. Results

A. Interpretation

1. *S. saprophyticus* are novobiocin-resistant and will show zones of inhibition of 6 mm (no zone)–12 mm.
2. Other coagulase-negative staphylococci and *S. aureus* are novobiocin-susceptible and will show zones of 16 mm or larger.

C-28

CHART 13-1

Bacitracin and SXT Susceptibility Tests

I. Principle

Susceptibility to low concentrations of the polypeptide antibiotic bacitracin and to the combination sulfonamide–trimethoprim–sulfamethoxazole (SXT) provides an easy and inexpensive method for the presumptive identification of both group A and group B β-hemolytic streptococci. Although still used in many laboratories, this test has largely been supplanted by reliable and relatively inexpensive serologic procedures, and more recently by mass spectrometry.

Group A streptococci are susceptible to relatively low concentrations of bacitracin and are resistant to SXT. Group B streptococci are resistant to both antibiotics. Other β-hemolytic streptococci show varying susceptibility to bacitracin, but these organisms are usually susceptible to SXT. Therefore, the performance of the SXT test along with the bacitracin test increases the sensitivity and predictive value of the bacitracin test.

II. Reagents

A. Sheep blood agar plate
B. Taxo "A" bacitracin differential disks (0.04 units/disk)
C. SXT disks (trimethoprim–sulfamethoxazole, 1.25 µg/23.75 µg)

III. Quality Control

A. Bacitracin S, SXT R: Group A *Streptococcus*
B. Bacitracin R, SXT R: Group B *Streptococcus*
C. Bacitracin S or R, SXT S: β-Hemolytic *Streptococcus*, groups C, F, or G

IV. Procedure

1. Pick three to four isolated colonies of the β-hemolytic *Streptococcus*, and streak the inoculum down the center of half of a blood agar plate.
2. Using a sterile swab or a bacteriologic loop, spread the inoculum as a lawn over the entire half of the plate.
3. Aseptically place a Taxo "A" bacitracin disk and an SXT disk on the inoculated area. Make sure that the disks are spaced evenly. Using flamed forceps, gently tap down the disks so that they adhere to the agar surface.
4. Incubate the plate in ambient air at 35°C.

V. Results

A. Interpretation

1. Susceptible (S): Any zone around either of the disks
2. Resistant (R): Growth up to the edge of the disk

Bacitracin	SXT	Identification
S	R	Presumptive group A
R	R	Presumptive group B
S/R	S	Not groups A or B

3. A reporting recommendation is: "β-hemolytic streptococci, presumptive group A, by bacitracin/SXT," or "β-hemolytic streptococci, presumptively not group A by bacitracin/SXT."
4. Because these tests are generally performed on throat isolates, for which group A streptococci are being sought, the presumptive group B is generally not reported.

VI. Limitations of Test

Only β-hemolytic streptococci should be tested, because many α-hemolytic streptococci (including pneumococci) are susceptible to low concentrations of bacitracin.

No data are available to indicate that zones of inhibition should be measured. Interpretation of SXT susceptibility may be difficult, because the organisms may grow slightly before total inhibition of growth occurs.

The lawn of bacterial inoculum should be confluent. Too light an inoculum will cause non–group A streptococci to appear susceptible to bacitracin.

CHART 13-2

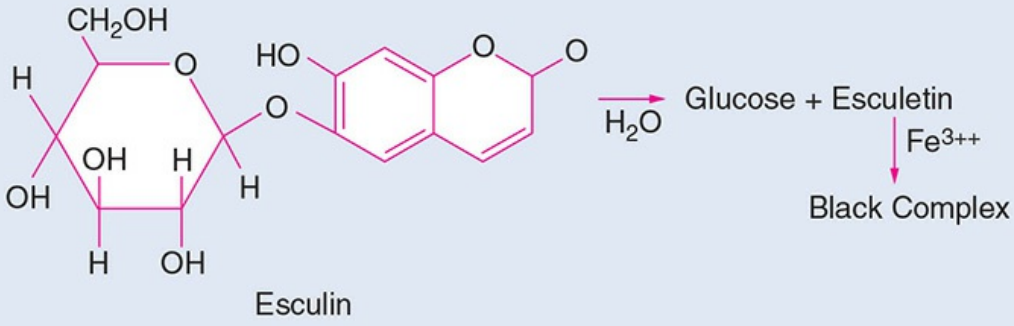
Bile Esculin Test

I. Principle

The bile esculin test is based on the ability of certain bacteria, notably the group D streptococci and *Enterococcus* species, to hydrolyze esculin in the presence of bile (4% bile salts or 40% bile). Esculin is a glycosidic coumarin derivative (6-β-glucoside-7-hydroxy-coumarin). The two moieties of the molecule (glucose and

7-hydroxycoumarin) are linked together by an ester bond through oxygen. For this test, esculin is incorporated into a medium containing 4% bile salts.

Bacteria that are bile esculin–positive are able to grow in the presence of bile salts. Subsequent hydrolysis of the esculin in the medium results in the formation of glucose and a compound called esculetin. Esculetin, in turn, reacts with ferric ions (supplied by the inorganic medium component ferric citrate) to form a black diffusible complex.



Esculin

II. Materials

A. Medium

Bile esculin agar medium is prepared as agar slants or plates. The medium has the following formula:

Peptone	5 g
Beef extract	3 g
Oxgall (bile)	40 g
Esculin	1 g
Ferric citrate	0.5 g

Agar	15 g
Distilled water	1 L
pH	7.0

III. Quality Controls

A. Positive control: *Enterococcus* species (e.g., *E. faecalis*)

B. Negative control: Viridans group streptococci, not group D

IV. Procedure

1. With an inoculating wire or loop, touch two or three morphologically similar streptococcal colonies and inoculate the slant of the bile esculin medium with an S-shaped motion, or streak the surface of a bile esculin plate for isolation.

2. Incubate the tube or plate at 35°C for 24–48 hours in an ambient air incubator.

V. Results

A. Interpretation

Diffuse blackening of more than half of the slant within 24–48 hours indicates esculin hydrolysis. On plates, black haloes will be observed around isolated colonies and any blackening is considered positive. All group D streptococci will be bile esculin–positive within 48 hours.

VI. Limitations of Test

Some viridans streptococci (approximately 3%) may also hydrolyze esculin in the presence of bile.

CHART 13-3

Optochin Susceptibility Test

I. Principle

Ethylhydrocupreine hydrochloride (optochin), a quinine derivative, selectively inhibits the growth of *Streptococcus pneumoniae* at very low concentrations (5 mg/mL or less). Optochin may also inhibit other viridans streptococci, but only at much higher concentrations. The test has a sensitivity of more than 95%, is simple to perform, and is inexpensive.

Optochin is water-soluble and diffuses readily into agar medium. Therefore, filter paper disks impregnated with optochin can be used in a disk diffusion test format to determine susceptibility of suspected pneumococci and, thereby, confirm their identity as such. *S. pneumoniae* cells surrounding

the disk are lysed owing to changes in the surface tension, and a zone of inhibition is produced.

II. Media and Reagents

1. Well-isolated colonies of the organism to be tested on sheep blood agar
2. Sheep blood agar plate

C-30

3. Optochin disks (5 µg): Bacto Differentiation Disks, Optochin (Difco) Taxo "P" disks (BD Microbiology)
4. Disks should be stored at 4°C when not in use.

III. Quality Control

A. Positive control: *Streptococcus pneumoniae*

B. Negative control: Viridans streptococcus or *Enterococcus faecalis*

IV. Procedure

1. Using an inoculating loop or wire, select three to four well-isolated colonies of the organism to be tested and streak onto one-half to a one-third of a blood agar plate. The inoculated area should be about 3 cm^2.
2. Place an optochin disk in the upper third of the streaked area. Tap down the disk with flamed or otherwise sterilized forceps so that the disk adheres firmly to the agar surface.
3. Incubate the plate at 35°C for 18–24 hours in a candle jar or in 5%–7% CO_2.

V. Results

A. Interpretation

A viridans streptococcus can be presumptively identified as *S. pneumoniae* if it shows a zone of inhibition of 14 mm or more around a 6-mm (Taxo A) disk, or a zone of 16 mm or more around a 10-mm disk (Bacto). Organisms showing zones smaller than these should be tested for bile solubility.

VI. Limitations of Procedure

Occasionally, viridans streptococci will show small zones of inhibition around the optochin disk. These organisms, however, will not be bile-soluble.

CHART 13-4

Salt-Tolerance Test

I. Principle

Ability to grow in the presence of variable amounts of sodium chloride (NaCl) is a test that has been used to characterize several bacteria, including the viridans streptococci. It is particularly useful, however, for presumptive identification of the enterococcal group D organisms, which have the specific ability to grow in the presence of 6.5% NaCl incorporated into either a broth or an agar medium. This test, along with the bile esculin test, is used in many laboratories to distinguish *Enterococcus* species from the group D streptococci, *S. bovis* and *S. equinus*.

Heart infusion broth is a general-purpose nutritional broth that is used for the cultivation of many bacteria. It normally contains 0.5% NaCl. By increasing the salt concentration to 6.5%, the medium becomes semiselective for the growth of enterococci.

II. Medium

1. 6.5% NaCl broth has the following formula:

Heart infusion broth	25 g
Sodium chloride	60 g
Indicator (1.6 g of bromcresol purple in 100 mL of 95% ethanol)	1 mL
Glucose	1 g
Distilled water	1 L

2. The indicator may be omitted.

3. Dispense into tubes in 3- to 5 mL volumes and autoclave at 121°C for 15 minutes.

III. Quality Control

A. Positive growth: *Enterococcus faecalis*

B. Negative growth: *Streptococcus bovis*

IV. Procedure

1. Inoculate two or three colonies into broth.

2. Incubate overnight at 35°C in ambient air incubator.

V. Results

A. Interpretation

A positive test is the presence of obvious bacterial growth in the medium, with or without a color change in the indicator. If the organism is bile esculin–positive and grows in the 6.5% NaCl broth, the organism is an *Enterococcus* species. If the organism is bile esculin–positive and fails to grow in the 6.5% NaCl broth, the organism is a group D

Streptococcus.

C-31

VI. Limitations of Procedure

1. If the medium is inoculated too heavily, inoculum may be interpreted as growth, resulting in a false-positive reaction.
2. To prevent interpretation of the test falsely as negative, agitate the tube gently before reading, as the growth may settle out during incubation.
3. Up to 80% of group B streptococci may be salt-tolerant, as will occasional isolates of group A streptococci. Aerococci may also be bile-esculin-positive and may grow in 6.5% NaCl.

CHART 13-5

Bile Solubility Test

I. Principle

Bile solubility reagent (10% sodium desoxycholate) is recommended for use in qualitative procedures for presumptive identification and differentiation of *Streptococcus pneumoniae* from other α-hemolytic streptococci. The bile solubility test is based on the observation that *S. pneumoniae* cells visibly lyse when 10% sodium desoxycholate is applied, while other α-hemolytic streptococci do not. *S. pneumoniae* produces an autolytic, intracellular enzyme that causes the organism to undergo rapid autolysis when cultivated on artificial medium. The actual mechanism for bile solubility is not fully understood, but it is speculated that bile salts lower surface tension at the medium–membrane interface and under these conditions, *S. pneumoniae* is particularly susceptible to disruption by enzyme action or by chemical agents.

II. Reagents

A. Sodium desoxycholate, 10% aqueous solution—store in its original container atom temperature until used. Some flocculation may occur if product is stored below 20°C. This will not reduce the effectiveness of the reagent. Protect product from light. This product should not be used if the color has changed, the expiration date has passed, or there are other signs of deterioration. Keep away from heat and flame. May cause

irritation to skin, eyes, and respiratory tract. Avoid breathing vapor and eye/skin contact.

B. Blood agar plate with growth of an α-hemolytic *Streptococcus*.

III. Quality Control

A. Bile (desoxycholate) soluble: *Streptococcus pneumoniae*

B. Bile (desoxycholate) insoluble: *Streptococcus sanguinis*

IV. Procedure

Perform preliminary tests (i.e., Gram's stain, catalase test) and note type of hemolysis to verify that the isolate is a viridans streptococcal species.

A. Tube Test

1. Prepare a saline suspension of the test isolate from an 18- to 24-hour, pure culture. Adjust turbidity to that of a 0.5 to 1.0 McFarland standard or equivalent.
2. Aliquot 0.5 mL of the suspension into each of two tubes. Label one tube as Test, the other as Control.
3. Add 0.5 mL of 10% bile solubility reagent to the tube marked Test, and 0.5 mL of saline (pH 7.0) to the tube marked Control. Gently agitate tubes to suspend bacteria.
4. Incubate tubes at 35°C to 37°C and examine periodically for up to 3 hours.
5. Observe for clearing in the Test suspension. The Control suspension should remain turbid.

B. Plate Spot Test

1. Place one drop of 10% bile solubility reagent near suspected 18- to 24-hour-old colonies growing on sheep blood agar. Gently roll the drop over several representative colonies by tilting the plate. Take care not to dislodge the colonies.
2. Incubate the plate aerobically in an upright position at 35°C to 37°C, and examine periodically for up to 30 minutes. Leave lid slightly ajar to enhance evaporation of the reagent.
3. Observe the colony for disintegration or solubility.

V. Results

A. Tube Test

1. **Positive test**—Clearing or loss of turbidity of the test suspension within 3 hours. The Control suspension remains turbid.
2. **Negative test**—Test and Control suspensions remain turbid after 3 hours.

B. Spot Test

1. **Positive test**—Disintegration of colonies and/or the appearance of an α-hemolytic zone on the plate where the colony was located within 30 minutes.

2. **Negative test**—Colonies on the plate remain intact with no change in colony integrity within 30 minutes.

C-32

VI. Limitations

Test only α-hemolytic streptococci.

When performing the spot test, keep the plate level to prevent reagent from running, which may cause some nonpneumococcal colonies to be washed away and result in a false-negative test.

Colonies that are older than 24 hours may have lost their active enzyme, resulting in a false-negative test.

Optochin-susceptible and -resistant, bile-insoluble isolates of *S. pneumoniae,* and optochin-resistant, bile-soluble viridans streptococcal isolates have been reported.

CHART 14-1

Loeffler's Methylene Blue Stain

I. Principle

Methylene blue is a simple stain that has historically been useful in the identification of *Corynebacterium* species.

The metachromatic granules of *C. diphtheriae* readily take up methylene blue dye and appear deep blue. Although some authors have stated that the cytoplasmic granule formation characteristic of *C. diphtheriae* is rarely seen with saprophytic species of *Corynebacterium,* this criterion is unreliable and cannot be used for definitive identification of *C. diphtheriae* without further studies.

II. Media and Reagents

Methylene blue (80% dye content)	0.3 g
Ethyl alcohol (95%)	30 mL
Distilled water	100 mL

III. Procedure

1. Heat-fix the smear. Flood the surface of the smear with the methylene blue-staining solution for 1 minute. Wash the slide with water and blot dry.

2. In the past, it was necessary to add alkali to the above solution before use. However, methylene blue dyes prepared in recent years do not require this additional step because acid impurities found in older stains have been removed.

IV. Results

A. Interpretation

The corynebacteria are pleomorphic bacilli that range in size from 0.5 to 1.0 μm in width and from 2 to 6 μm in length and appear as straight, curved, or club-shaped rods. Characteristics for the microorganisms are the metachromatic granules that take up the methylene blue stain and appear dark blue. Although this finding is characteristic of the corynebacteria, species of *Propionibacterium,* some of the actinomycetes, pleomorphic strains of streptococci, and other bacteria may also morphologically resemble the corynebacteria and must be differentiated by other cultural and biochemical characteristics.

CHART 14-2

Loeffler's Serum Medium

I. Principle

Loeffler's serum medium is used primarily for the recovery of *C. diphtheriae* from clinical specimens. Because of this serum content, the medium may also be used more generally to determine the proteolytic activity of various microorganisms.

C. diphtheriae produces cells with characteristic morphologic features on Loeffler's medium. The medium is also helpful in the determination of pigment production by some bacteria.

II. Media and Reagents

A. Formula

Beef serum	70 g/L
Infusion dextrose broth (dry powder)	2.5 g/L
Egg (whole, dried)	7.5 g/L
Final pH	7.6

B. Preparation

1. To rehydrate the medium, dissolve 80 g of Loeffler's medium

(BBL) in 1 L of distilled water and warm to 42°C–45°C. The powder should be gradually added while the flask is gently rotated to minimize mixing air into the suspension.

C-33

2. The medium should be dispensed in tubes and coagulated-sterilized in the autoclave as follows:
   a. When the suspension is uniform, dispense in tubes.
   b. Arrange the tubes in a slant position not more than four deep with several layers of newspaper or paper towels below and above the tubes to prevent rapid coagulation.
   c. Tightly close the autoclave, turn on the steam, and allow pressure to remain at 10 psi for 20 minutes.
   d. During this time, allow no air or steam to escape.
   e. Adjust the steam-inlet valve and open the air-escape valve such as to maintain a pressure of 10 psi. Abrupt changes in pressure may cause the medium to bubble.
   f. Close the outlet valve when all air has been replaced by steam and allow the pressure to reach 15 psi and hold there for 15 minutes.
   g. Allow the autoclave to cool slowly. When properly prepared, the slants are smooth and grayish white. Before inoculation, the slants should be incubated for 24 hours at 35°C as a sterility check.

III. Procedure

1. When *C. diphtheriae* is suspected, inoculate the Loeffler's medium as soon as possible after collection of the specimen.
2. Examine the slants for growth after 8–24 hours of incubation.
3. Prepare smears and stain with methylene blue.

IV. Results

A. Interpretation

See Chart 14-1 for interpretation of these stained smears.

V. Comment

Because Loeffler's medium is difficult to prepare, purchase of commercially prepared medium in sealed tubes is recommended.

diphtheriae. J Lab Clin Med 1949;34:582–583.

CHART 14-3

Tinsdale's Agar (as Modified by Moore and Parsons)

I. Principle

Tinsdale's medium supports the growth of all species of *Corynebacterium* while inhibiting the growth of normal inhabitants of the upper respiratory tract. Moore and Parsons modified the original Tinsdale's formula, simplifying the composition, but retaining the specificity for the recovery of *C. diphtheriae* and *C. ulcerans.*

The potassium tellurite is deposited within the colonies of *Corynebacterium,* turning them black. Tinsdale's medium is cystine-sodium thiosulfate tellurite, which is specifically helpful in the identification of *C. diphtheriae,* colonies of which are surrounded by a brown halo (Color Plate 14-3G).

II. Media and Reagents

A. Formula (Modified Tinsdale's Base)

Thiotone peptone	20 g
Sodium chloride	5 g
Agar	14 g
L-Cystine	0.24 g
Sodium thiosulfate	0.24 g
Distilled water	1 L

B. Preparation

1. Suspend 39 g of powder in 1 L of distilled water and heat with agitation. Boil for 1 minute. Autoclave for 15 minutes at 121°C.

2. Cool the modified base to 50°C and add:

Sterile bovine serum	100 mL
Tellurite solution, 1%	30 mL

3. Pour 15–20 mL of this medium into petri dishes and allow to harden.

4. The Tinsdale's agar base medium without serum and tellurite is stable indefinitely if stored in closed screw-capped tubes or bottles. However, the medium is ordinarily stable for only 2 or 3 days when

stored in the refrigerator following the addition of serum and tellurite.

C-34

III. Procedure

Streak the plate so as to obtain well-isolated colonies. It is recommended that the agar be stabbed at intervals, because browning of the medium can be detected early in the stab areas.

IV. Results

A. Interpretation

A brown halo around the colony is considered presumptive evidence of *C. diphtheriae.* This can sometimes be seen after 10–12 hours of incubation, although 48 hours may be required for the appearance of typical dark-brown halos. The only related species other than *C. diphtheriae* that produces this halo is *C. ulcerans.* Other bacteria, such as coagulase-positive staphylococci, grow well on this medium, but do not have a brown halo. Bacteria, such as species of *Proteus* that produce a heavy, diffuse blackening of the medium, can be distinguished by their Gram stain reaction and biochemical characteristics.

CHART 15-1

Hydrolysis of Xanthine, Hypoxanthine, Tyrosine, and Casein

I. Principle

Aerobic actinomycetes may be characterized by their ability to hydrolyze xanthine, hypoxanthine, tyrosine, and casein. These compounds are incorporated into nutrient agar, and the organisms are seeded heavily on the agar surface. Results are interpreted by observing for clearing of the medium

under and around the bacterial growth, indicating hydrolysis.

II. Media and Reagents

A. Xanthine, Hypoxanthine, and Tyrosine Suspensions

1. Basal Medium

Beef extract	3.0 g
Peptone	5.0 g
Agar	15.0 g
Distilled water	1 L

2. Suspensions

Tyrosine	0.5 g
Xanthine	0.4 g
Hypoxanthine	0.4 g
Distilled water	100 mL

Heat the basal medium to bring the ingredients into solution and place 100-mL aliquots into 250-mL flasks. Sterilize by autoclaving at 15 psi for 15 minutes. Allow medium to cool almost to solidification. To each aliquot, add 10 mL of xanthine, hypoxanthine, or tyrosine suspensions. The suspensions are autoclaved before adding to the basal media. It is essential that the granules of xanthine, tyrosine, and hypoxanthine be kept in suspension until the medium solidifies; hence, the addition of the biochemical granules and the pouring of the medium into Petri dishes should be done when the basal medium has cooled just short of solidification. The media are poured into sterile 15 × 100-mm Petri dishes.

3. Casein Medium

a. Solution A

Skim milk (powdered)	10.0 g
Distilled water	100 mL

b. Solution B

Agar	2.0 g
Distilled water	100 mL

Autoclave solutions A and B separately, allow each to cool to about 50°C, and combine A with B and pour into 15 × 100-mm Petri dishes.

III. Quality Control

A. Negative control: *Nocardia asteroides* complex

B. Positive control: *Streptomyces* species

C-35

IV. Procedure

Each xanthine, hypoxanthine, tyrosine, and casein plate is commonly divided into wedge-shaped thirds, providing an area to inoculate positive and negative controls along with the organism to be identified. The plates are incubated at 30°C and read at the following times:

A. Casein hydrolysis: Read after 2 weeks
B. Xanthine hydrolysis: Read after 3 weeks
C. Hypoxanthine hydrolysis: Read after 3 weeks
D. Tyrosine hydrolysis: Read after 3 weeks

V. Interpretation

Hydrolysis may be evident prior to the incubation end points provided above. Casein hydrolysis is read by observing for a complete clearing to transparency of the white, milky medium. The other three hydrolysis tests are read by observing the dissolution of the crystalline compounds around the colonies growing on the media.

VI. Bibliography

Gordon RE, Mihm JM. Identification of *Nocardia caviae* (Erickson) nov. comb. Ann NY Acad Sci 1962;98:628–636.

CHART 15-2

Lysozyme Test for the Identification of *Nocardia* Species

1. Prepare glycerol broth by adding 5 g of peptone and 70 mL of glycerol to 1,000 mL of distilled water (reduce amounts proportionately if smaller quantities are desired). Sterilize by autoclaving at 15 psi for 15 minutes.
2. Prepare lysozyme solution by dissolving 100 mg of lysozyme powder in 100 mL of 0.01 N HCl.
3. Combine 95 mL of glycerol broth with 5 mL of lysozyme solution and dispense in 5-mL aliquots into screw-capped tubes. Use 5-mL aliquots of glycerol broth without lysozyme for the growth control.
4. Prepare a light suspension of the unknown organism in sterile saline. Using a Pasteur pipette, inoculate 1 or 2 drops into the lysozyme and control tubes (keep the inoculum light).
5. Incubate at 25°C. Examine each tube for growth in 7–14 days. Growth will appear as a pellicle on the surface, as a sediment, or as both. The tubes can be gently shaken to observe bread crumb-like particles in the tubes showing

positive growth.

6. An organism resistant to lysozyme will grow in both the lysozyme tube and the control tube; an organism that is susceptible will grow only in the control tube.

CHART 16-1

Components of CDC Anaerobe Blood Agar

Ingredient	Amount
Trypticase-soy agar (BDMS)	15 g
Phytone (BDMS)	5 g
Sodium chloride	5 g
Agar	20 g
Yeast extract (Difco)	5 g
Hemin	5 mg
Vitamin K_1 (3-phytylmenadione)	10 mg
L-Cystine	400 mg
Demineralized water	1 L
Blood (sheep or rabbit), defibrinated	50 mL

CHART 16-2

Media and Characteristics Used for Identifying Anaerobes

Media	Characteristics
Blood agar	Relation to O_2[a], colony characteristics, hemolysis, pigment, fluorescence with UV light (Wood's lamp), pitting of agar, cellular morphology, Gram's stain reaction, spores, motility (wet mount); inhibition by penicillin, rifampin, and kanamycin
	Appearance of growth, rapidity of growth, gas production,

odor, cellular morphology

C-36

Presumpto Plate 1	
LD agar	Indole, growth on LD medium, catalase[b]
LD esculin agar	Esculin hydrolysis, H_2S, catalase
LD egg yolk agar	Lipase, lecithinase, proteolysis
LD bile agar	Growth is in presence of 20% bile (2% oxgall), insoluble precipitate under and immediately surrounding growth
Presumpto Plate 2	
LD glucose agar	Glucose fermentation; stimulation of growth by fermentable carbohydrate
LD starch agar	Starch hydrolysis
LD milk agar	Casein hydrolysis
LD DNA agar	Deoxyribonuclease activity
Presumpto Plate 3	
LD Mannitol agar	Mannitol fermentation
LD Lactose agar	Lactose fermentation
LD Rhamnose agar	Rhamnose fermentation
LD Gelatin	Gelatin hydrolysis

[a] By comparing growth on anaerobe plate with blood agar (or chocolate agar) incubated in 5%–10% CO_2 incubator (or candle jar) or in room air.

[b] The catalase test can be performed by adding 3% hydrogen peroxide to the growth on LD agar, but the actions of catalase-positive cultures are more vigorous on LD esculin agar.

CHART 16-3

How to Inoculate Presumpto Quadrant Plates, Antibiotic Potency Disks, Nitrate Disks, and SPS Disks?

1. Prepare the inoculum from fresh growth of a pure culture of the anaerobic isolate. Use either a turbid cell suspension (McFarland 3) in LD broth prepared from isolated colonies or a 24- to 48-hour enriched thioglycolate medium subculture from an isolated colony. As an alternative, a 24- to 48-hour chopped-meat glucose broth subculture can be used.
2. Inoculate the quadrant plates as follows:
   a. Saturate one sterile swab for each quadrant plate to be inoculated in either the cell suspension or broth culture.
   b. Streak the middle portion of each quadrant with the swab containing bacteria.
3. Place a sterile, blank, 1/2-inch-diameter paper disk on the LD agar near the outer periphery of the quadrant. This disk is used in the test for indole after incubation of the plates.

   In addition to setting up the Presumpto plates, also:

   1. Inoculate the surface of an anaerobic blood agar plate evenly with a sterile swab that has been dipped in the cell suspension or broth culture.
   2. Place the antibiotic disks (penicillin, 2 U; rifampin, 15 µg; kanamycin, 1,000 µg) on the blood agar with sterile forceps. Space the disks evenly such that overlapping zones of inhibition will not be a problem.
   3. Place the sodium polyanetholsulfonate (SPS) and nitrate disks on a second anaerobic blood agar plate, if they are used in addition to the antibiotic disks. To prepare the SPS disk, pipette 20 µL of 5% SPS onto 1/4-inch (0.635-cm) sterile blank disks (Becton Dickinson [BD], Sparks, MD) and dry. SPS disks are stable at room temperature for 6 months. To prepare the nitrate disk, dissolve 30 g KNO_3 and 0.1 g sodium molybdate (Na_2MoO_4. $2H_20$) in 100 mL of distilled water and filter-sterilize the solution using a 0.45-µm membrane filter. Then add 20 µL of this reagent to 1/4-inch (0.635-cm) sterile blank disks and dry at room temperature for at least 72 hours.[519]

CHART 16-4

Interpretation of Presumpto Quadrant Plates (Color Plate 16-5)

I. Presumpto Quadrant Plate 1

LD Agar. Note and record the degree of growth on LD agar (light, moderate, heavy). Test for indole by adding two drops of para-dimethylaminocinnamaldehyde reagent to the paper disk on the medium. Observe for the development of a blue or bluish green color in the disk within 30 seconds, which is a positive

C-37

reaction for indole. Development of another color (pink, red, violet) or no color is negative for indole. A lavender to violet color indicates a positive reaction for indole derivative(s).

LD Egg Yolk Agar. Formation of a zone of insoluble precipitate in the medium surrounding the bacterial colonies indicates a positive reaction for lecithinase production. This is best seen with transmitted light.

The presence of an iridescent sheen (a pearly layer on the surface of colonies and on the medium immediately surrounding the bacterial growth, best demonstrated with reflected light) indicates lipase production. If the reaction is questionable, add a few drops of water and look for a film that floats on top of water.

Clearing of the medium in the vicinity of the bacterial growth indicates proteolysis, as exhibited by certain proteolytic clostridia.

LD Esculin Agar. A positive test for esculin hydrolysis is indicated by the development of a reddish brown to dark brown color in the esculin agar surrounding the bacterial growth after exposure of the quadrant plate cultures to air for at least 15 minutes. Additional evidence for esculin hydrolysis can be obtained by examining the esculin agar quadrant under a Wood's lamp. Esculin agar exhibits a bright blue fluorescence under the ultraviolet light that is not present after the esculin is hydrolyzed.

Blackening of the bacterial colonies on the esculin agar indicates H_2S production. The blackening dissipates very rapidly after exposure to air. Therefore, the bacterial growth should be observed for blackening under anaerobic conditions (anaerobic glove box) or immediately after opening anaerobic jars to air. To test for hydrogen peroxide degradation as an indication of catalase, expose the plates to air for at least 30 minutes and then flood the esculin agar quadrant with a few drops of fresh 3% H_2O_2. Sustained bubbling after addition of the H_2O_2 is a positive reaction for catalase. In some cases, rapid bubbling may not be evident until after 30 seconds to a minute.

LD Bile Agar. Compare the degree of bacterial growth on the LD bile agar

with that on the plain LD agar and record as I (growth less than on the LD agar control) or E (growth equal to or greater than on the LD agar control). Using transmitted light, look for the presence or lack of an insoluble white precipitate underneath or immediately surrounding the bacterial growth. If in doubt, inspect under a stereomicroscope using transmitted light.

II. Presumpto Quadrant Plate 2 (Color Plate 16-5)

LD Glucose Agar. Fermentation of glucose is indicated by acid production or a yellow color in and around the growth in the medium. A blue color around the growth is a negative reaction. Some bacteria reduce the indicator; therefore, it is sometimes necessary to flood the quadrant with dilute bromthymol blue reagent to determine if acid has been produced.

Glucose stimulation can be observed by comparing the amount of bacterial growth on LD glucose agar with that on plain LD agar.

LD Starch Agar. To detect hydrolysis of starch, flood the quadrant with Gram's iodine solution; clearing around the growth indicates a positive reaction. A brownish color indicates unhydrolyzed starch and a negative reaction.

LD Milk Agar. A clear zone around the growth in the quadrant indicates hydrolysis of casein (i.e., digestion of milk proteins) and a positive reaction. If casein is unhydrolyzed, the medium remains cloudy (a negative reaction).

LD DNA Agar. A pink to reddish zone around the growth on the quadrant indicates a positive reaction for the degradation of DNA (i.e., deoxyribonuclease activity). If the medium remains blue around the growth, DNA was not degraded and the reaction is negative.

III. Presumpto Quadrant Plate 3

LD Gelatin Agar. To detect the hydrolysis of gelatin, flood the quadrant with acidified mercuric chloride reagent. This reagent binds to unhydrolyzed gelatin. A zone of complete clearing around the growth on the quadrant indicates that gelatin has been hydrolyzed and is recorded as a positive test.

LD Mannitol Agar, LD Lactose Agar, and LD Rhamnose Agar. Examine and interpret these quadrants as described for LD glucose agar.

CHART 16-5

Description of Presumpto Plates for Identification of Anaerobes

Three types of quadrant plates (Presumpto 1, 2, and 3) containing 12 differential

agar media were developed by Dowell, Lombard, and associates into a system that allows determination of 20 different characteristics (Chart 16-4) of anaerobic isolates at a minimal cost.[519] The information derived from using the three-quadrant plates, along with the other characteristics obtained from anaerobe blood agar and enriched thioglycolate medium plus metabolic product analysis using GLC, permits definitive identification of many clinically significant anaerobic bacteria that are encountered in the laboratory. In addition, the quadrant plates, especiall y the Presumpto 1 and 2

C-38

plates, can be used to supplement several of the commercial packaged kit systems, as well as traditional broth identification systems, with important tests or characteristics these nonagar systems lack.

The basal medium in the Presumpto quadrant plate system is Lombard–Dowell (LD) medium. This is a specially designed medium that supports growth of a wide variety of anaerobes, including fastidious species. It is noteworthy that LD broth (the same medium without agar or with only a small amount) is the inoculum broth for some of the commercial packaged ID systems. The Presumpto 1 plate is a four-quadrant Petri dish containing the following media: LD agar, LD esculin agar, LD egg yolk agar, and LD bile agar, initially devised for presumptive identification of *Bacteroides* and *Fusobacterium* (without Presumpto plates 2 and 3) but since has been useful for identifying other anaerobic bacteria.

The Presumpto 2 plate contains LD glucose agar, LD DNA agar, LD milk agar, and LD starch agar. It is useful for characterization of clostridia, the anaerobic, non–spore-forming gram-negative and gram-positive bacilli and the anaerobic cocci. Like the Presumpto 1 plate, it can be used along with packaged micromethod kits that lack the tests it contains, or along with conventional tube tests.

The Presumpto 3 plate contains LD gelatin agar, LD mannitol agar, LD lactose agar, and LD rhamnose agar. Use of LD gelatin agar and the use of the carbohydrates in this quadrant plate have been described.[123,519]

CHART 16-6

Identifying Volatile Fatty Acids

1. Inoculate tubes containing 7–8 mL of prereduced peptone-yeast extract-glucose

(PYG) broth with a few drops (0.05–0.1 mL) of an actively growing culture.

2. Incubate under anaerobic conditions for 48 hours, or until adequate growth is obtained.
3. Transfer 2 mL of the culture to a clean, 13- × 100-mm screw-capped tube.
4. Acidify the culture to pH 2.0 or lower by adding 0.2 mL of 50% (v/v) aqueous H_2SO_4.
5. Add 1 mL of ethyl ether, tighten the cap, and mix by gently inverting the tube about 20 times.
6. Centrifuge briefly in a clinical centrifuge (1,500–2,000 rpm) to break the ether–culture emulsion.
7. Place the ether-culture mixture in a freezer at −20°C or lower or in an alcohol–dry ice bath until the aqueous portion (bottom) is frozen.
8. Rapidly pour off the ether layer into a clean screw-capped tube. If desired, add one or two anhydrous $CaCl_2$ pellets to the ether extract to allow removal of residual water.
9. Inject 14 µL of the extract into the column of a gas chromatograph packed with SP-1220.

C-40

CHART 16-7

Identifying Nonvolatile Fatty Acids

1. Transfer 1 mL of the original PYG culture to a clean 13 × 100-mm screw-capped tube.
2. Add 0.4 mL of H_2SO_4 (v/v) and 2 mL of methanol.
3. Place the tube in a 55°C water bath for 1 hour or overnight.
4. Add 1 mL of distilled water and 0.5 mL of chloroform, and centrifuge briefly to break any emulsion in the chloroform layer. (Note: The chloroform layer will be in the bottom of the tube.)
5. Fill a syringe with the chloroform extract after placing the tip of the needle

beneath the aqueous layer.

6. Wipe off the outside of the needle with a clean tissue and inject 14 µL into a GLC column packed with SP-1000.

CHART 16-8

The Nagler Test and the CAMP Test for *C. perfringens*

Historically, the Nagler test has been used for the presumptive identification of *Clostridium perfringens*, even though the antitoxin used in the test is not specific. The popularity of the Nagler test has waned because the antitoxin has not been widely available. Additional details describing the Nagler test are given in previous editions of this textbook.

An alternative to the Nagler test, used in some laboratories, is the so-called reverse CAMP test.[62,519] To perform the test, inoculate an anaerobe blood agar plate with a single streak of an unknown organism that is thought to possibly represent *C. perfringens* isolate. Next, make a single streak at a 90-degree angle to within 1–2 mm of the first streak, using an inoculum of a group B β-hemolytic *Streptococcus*. An arrowhead of synergistic hemolysis, with the tip of the arrow pointing from the *Streptococcus* toward the *C. perfringens*, is a positive test. Both false-positive and false-negative results may occur. Additional data on the specificity of this test for clinical isolates of *C. perfringens* are needed; however, most laboratories experienced in anaerobic bacteriology may find the Nagler test and the reverse CAMP test, while perhaps "novel," to be unnecessary.

CHART 16-9

Assay for Toxin in Feces by Tissue Culture Cytotoxicity Procedure[a]

1. Centrifuge liquid stool or extract of formed stool (2,000 *g* for 20 minutes or 10,000 *g* for 10 minutes).
2. Filter through 0.45-µm membrane filter.

3. Add 0.1 mL of cell-free supernatant plus 0.1 mL buffered gelatin diluent (pH 7.0–7.2) or phosphate-buffered saline (PBS) to a tissue culture tube. Commercially available human diploid lung fibroblasts (WI-38 cells) are convenient to use.
4. Observe the tissue culture cells for cytotoxicity at 4, 24, and 48 hours. Most positives will be observed at 24 hours.
5. For the antitoxin neutralization test, add 0.1 mL of *C. difficile* antitoxin (TechLab, Blacksburg, VA) to 0.1 mL cell-free supernatant and carry out steps 1 and 4. Rounding of WI-38 cells (so-called actinomorphic change) or other cytopathic effects should not be seen if toxin that is present in the stool is neutralized.
6. The toxin titer is determined using serial twofold or tenfold dilutions of the filtered fecal sample in buffered gelatin diluent (pH 7.0–7.2) or PBS. Correlation between the toxin titers and severity of illness is very crude.

[a]Commercial kits for performing *C. difficile* cytotoxin neutralization assays are available from at least two manufacturers (Bartels Diagnostics; Bio-Whittaker/Wampole). The kits can be purchased complete with human foreskin fibroblasts in microbroth dilution trays, and they provide the necessary antitoxin and other reagents to accomplish the cytotoxin neutralization assay.

CHART 17-1

Disk Diffusion (Bauer–Kirby) Susceptibility Test for Nonfastidious Bacteria

I. Principle

Continued evaluation and revision of the disk diffusion procedure has been performed by a committee of the Clinical Laboratory Standards Institute (CLSI). Designating a national standard test for disk diffusion has not only permitted more exacting quality control, but has also allowed valid comparison of results among different laboratories using the procedure. The CLSI publishes periodic updates that incorporate new information and changes that have been suggested by users. It is important to maintain currency of the procedure. This chart summarizes the basic procedure; consult the referenced CLSI document for variation used to test fastidious bacteria.

C-44

The principle of the disk diffusion procedure has been discussed in the text. The zone diameters that are generated by the test are meaningless without reference to the minimum inhibitory concentration (MIC) correlates and interpretive guidelines published by the CLSI.

II. Media and Reagents

- **A.** Bacterial isolate from an infectious process
- **B.** Nutrient broth (tryptic soy broth is recommended) for growth of the inoculum
- **C.** McFarland 0.5 standard for adjusting the turbidity of the inoculum
- **D.** Vortex mixer for suspension of the inoculum
- **E.** Viewbox for comparison of broth with standard. A photometer may be used if satisfactory results are documented.
- **F.** Mueller–Hinton agar plates (100 mm diameter for a maximum of five disks; 150 mm diameter for a maximum of 12 disks) from a lot that produces satisfactory quality control results. The pH must be 7.2–7.4, and the depth must be approximately 4 mm.
- **G.** Calipers, ruler, or template for measuring the diameters of inhibitory zones

III. Quality Control

Reference strains of *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa* should be tested each time a new batch of disks or agar is used. Additional controls should be performed each day the test is done or according to the laboratory's Individualized Quality Control Plan (IQCP) for this test (Table 17-14).

IV. Procedure

- **A.** Preparation of Inoculum (Growth Method)
  1. With a wire loop, touch the tops of four or five similar-appearing, well-isolated colonies on an agar plate culture. Transfer the growth

to a tube that contains 4–5 mL of a suitable broth medium.

2. Allow the culture to incubate at 35°C until it matches the turbidity of the standard prepared in the foregoing (usually 2–6 hours). Vigorously agitate the standard on a mechanical vortex mixer immediately before use. Use adequate light to read the tube against a white background with a contrasting black line. Add sterile saline or broth if necessary to obtain a turbidity that is visually comparable with that of the standard. For the *E. coli* quality control strain, approximately 1–2 $\times 10^8$ colony-forming units (CFU)/mL should result. Alternatively, a direct broth or saline suspension of colonies from an 18- to 24-hour agar plate may be adjusted to the standard. In this case, the bacteria must have been grown on a nutrient, nonselective medium, such as blood agar. Commercially available devices to standardize the inocula without adjustment of turbidity and without preincubation in broth media have also performed acceptably.
3. Within 15 minutes after adjusting the turbidity of the inoculum suspension to that of the standard, dip a sterile nontoxic cotton swab into the inoculum suspension and rotate the swab several times with firm pressure on the inside wall of the tube to remove excess fluid.
4. Inoculate the dried surface of a Mueller–Hinton agar plate that has been brought to room temperature by streaking the swab three times over the entire agar surface, rotating the plate approximately 60 degrees each time to ensure an even distribution of the inoculum. Finally, swab the rim of the agar. Replace the lid of the dish. Allow at least 3–5 minutes but no longer than 15 minutes for the surface of the agar to dry before adding the antibiotic disks.

B. Alternative Inoculum Preparation (Direct Colony Suspension; DCS)

1. Make a direct saline or broth suspension of colonies from a nutrient nonselective agar plate (e.g., blood agar) that has been incubated for 18–24 hours.
2. Immediately adjust the inoculum to the standard density, as for the growth method.
3. This method is recommended for *Haemophilus* species, *Neisseria gonorrhoeae*, *Streptococcus pneumoniae*, and *Staphylococcus* species when testing susceptibility to oxacillin.

C. Testing of Antibiotics

1. Place the appropriate antimicrobial-impregnated disks on the surface of the agar, using either forceps or a multidisk dispenser.
2. Gently tap each disk down onto the agar to provide uniform

contact. Do not move a disk once it has contacted the agar, because some of the drug diffuses almost immediately. Disks must be evenly distributed on the agar so that they are no closer than 24 mm from center to center.

3. Invert the plates and place them in a 35°C air incubator for 16–18 hours (24 hours when testing staphylococci against methicillin or oxacillin or enterococci against vancomycin).

C-45

V. Results

A. Interpretation

Measurement of zone diameters: Examine the plates after overnight incubation. With the use of sliding calipers, a ruler, or a template, the zones of complete growth inhibition around each of the disks are carefully measured to within the nearest millimeter; the diameter of the disk is included in this measurement.

All measurements are made with the unaided eye while viewing the back of the Petri dish with reflected light against a black, nonreflecting background. The plates should be viewed from a directly vertical line of sight to avoid any parallax that may result in misreadings. Susceptibility plates prepared with blood must be viewed from the agar surface and measurements made with the cover of the Petri dish removed, again using reflected light to illuminate the plate. Common problems in delineation of zone sizes are discussed in the text.

An interpretive correlate (susceptible, moderately susceptible, intermediate, or resistant) is provided by reference to published guidelines. Zones that fall into the intermediate range should be considered equivocal; if therapy with the drug is desired, a dilution susceptibility test should be performed to clarify the issue.

Clinical Laboratory Standards Institute. Performance Standards for Antimicrobial Disk Susceptibility Tests: approved Atandard- Twelfth Edition (M02-A12). Wayne, PA: Clinical Laboratory Standards Institute, 2015.

CHART 17-2

Performance of Microbroth Dilution Susceptibility Tests With Nonfastidious Bacteria

I. Principle

The microdilution test is an adaptation of the reference macroscopic test. Large numbers of isolates can be tested against multiple drugs easily, so the procedure is well adapted to routine use. This test generates more quantitative information, which may be useful or even essential in certain circumstances, than does the disk diffusion test. This chart summarizes the basic procedure; consult the referenced Clinical Laboratory Standards Institute (CLSI) document for the variation used to test fastidious bacteria.

The principle of the microdilution test is the same as that of the macroscopic test. Bacterial isolates are exposed to serial dilutions of each antimicrobial agent, after which the concentration of drug that inhibits growth is determined by visual inspection.

II. Media and Reagents

A. Nutrient broth (tryptic soy broth is recommended)

B. 0.5 McFarland standard for adjusting inoculum

C. White background with black lines for comparison of turbidity of inoculum with 0.5 McFarland standard

D. Frozen or lyophilized microtiter plates containing antibiotics in cation-supplemented Mueller–Hinton broth

E. Multiprong inoculators—either wire loops or disposable plastic pins

F. Viewing mirror and template for visualization of endpoints. A photometric or fluorometric analysis of endpoints may be done if demonstrated to be equivalent to visual inspection.

III. Quality Control

Quality control should be performed with each new lot of plates or according to the laboratory's Individualized Quality Control Plan (IQCP).

The organisms used for the dilution test are *Staphylococcus aureus* (American Type Culture Collection [ATCC] 29213), *Enterococcus faecalis* (ATCC 29212), *Escherichia coli* (ATCC 25922), *Pseudomonas aeruginosa* (ATCC 27583), *Neisseria gonorrhoeae* (ATCC 49226), and *Haemophilus influenzae* (ATCC 49247). Note that the *S. aureus* strain differs from that used in the disk diffusion test. *E. coli* (ATCC 35218) may be used to control combinations that include clavulanic acid, a b-lactamase inhibitor (Table 17-22).

IV. Procedure

A. Preparation of Inoculum: Proceed as for the disk diffusion test (Chart 17-1).

B. Inoculation of Plates

Inoculate the bacterial suspension into each well of the microplate within 15 minutes of adjusting the density of the inoculum. One well should contain bacteria without antibiotic (growth control) and one should contain broth only (sterility control). If the volume of the inoculum exceeds 10% of the volume

C-46

of the well, the dilution effect on the antimicrobial agent must be calculated. To prevent drying, seal the plates in a plastic bag, with plastic tape, or with a tight-fitting plastic cover. A portion of a nutrient agar plate, such as blood agar, should be inoculated to detect contamination.

C. Incubation

Incubate the plates at 35°C for 16–20 hours (24 hours when testing staphylococci against oxacillin, methicillin, or vancomycin or when testing enterococci against vancomycin) in a forced-air incubator. Do not place more than four plates in a stack, so that a uniform temperature of incubation is maintained.

V. Results

A. Interpretation

The minimum inhibitory concentration (MIC) is the lowest concentration of antibiotic that inhibits growth of the isolate. It may be determined by viewing the wells with the unaided eye, comparing the growth in the wells that contain antibiotics with that in the growth control well. A viewing mirror, with which the bottom of the microtubes may be visualized, facilitates observation. A template on which the contents of each well are detailed is useful. For a test to be valid, adequate growth must be present (diffuse turbidity or at least a 2-mm button). For trimethoprim-sulfamethoxazole, the endpoint is at least 80% inhibition of growth. A single skipped well may be ignored; if there are more skipped wells, the test should be repeated.

Refer to the guidelines for interpretation of MIC results as susceptible, dose-dependent susceptible, intermediate, or resistant.

Examine the purity plate and repeat the test if contamination is present.

CHART 17-3

Gradient Diffusion Test (Etest) for Bacterial Susceptibility

I. Principle

The gradient diffusion test uses a nonporous plastic strip that has been calibrated with minimum inhibitory concentration (MIC) values that cover 15 twofold dilutions. A predefined antibiotic gradient is immobilized on the surface of the strip that is opposite the MIC scale. When transferred to agar, antibiotic diffuses from the strip, similar to the disk diffusion test. This chart summarizes the general procedure, which should be used only for combinations of antibiotic and organism that have been validated by comparison to reference methods.

II. Materials and Reagents

- **A.** Nutrient broth or 0.85% saline
- **B.** Sterile swabs (not too tightly spun)
- **C.** 0.5 and/or 1.0 McFarland standard
- **D.** Etest strips
- **E.** Etest applicator kit or forceps
- **F.** Mueller–Hinton agar plates (100 mm or 150 mm) with supplements if appropriate

III. Quality Control

is performed using strains appropriate for dilution tests (Chart 17-2).

IV. Procedure

- **A.** Allow the Etest strips to reach room temperature, approximately 30 minutes after removal from a –20°C freezer.
- **B.** Preparation of inoculum is performed as for the disk diffusion or microbroth dilution tests (Charts 17-1 and 17-2, respectively).
- **C.** Inoculate the agar plate as for the disk diffusion test (Chart 17-1).
- **D.** Allow the agar surface to dry 10–15 minutes at room temperature or in the incubator before proceeding.
- **E.** Open the Etest package and place the strip(s) in a dry Petri dish or applicator tray.

C-47

F. Apply the strip(s) to the surface of the agar with forceps or an applicator, with the MIC scale facing up. If the strip is positioned upside down, the positioning can be corrected if the error is recognized immediately. If the strip is incubated in the inverted position, the test is invalid.

G. Incubate as appropriate for the organism being tested.

V. Results

A. After the appropriate incubation period, interpret the test only if there is adequate growth and the ellipse of inhibition is clearly visible.

B. Read the MIC where a clearly defined zone of inhibition intersects the strip. Factors to be considered when determining the MIC are discussed in the text.

C. As the antibiotic gradient is continuous (linear) and the interpretive criteria are discontinuous (twofold dilutions), round up the MIC value to the next twofold dilution when reporting the result.

CHART 18-1

Diene's Stain Procedure for Identification of Mycoplasmas

I. Principle

Mycoplasma colonies from genital cultures are easily identified by observing typical colonies on agar medium. Visualization of colony morphology is facilitated by application of Diene's stain directly to the agar surface.

Diene's stain is a nonspecific stain that imparts a contrasting appearance to *Mycoplasma* colonies on agar, allowing easier visualization of colony morphology and characteristics.

II. Reagents

A. Modified Diene's Stain (Stock Solution)

Methylene blue	2.5 g
Azure II	1.25 g
Maltose	10.0 g

Na_2CO_3	0.25 g
Distilled water	100 mL

Diene's stain working solution is prepared by diluting an aliquot of the stock solution 1:3 with distilled water.

III. Procedure

1. Flood an agar plate containing mycoplasmal growth with 1 mL of Diene's stain working solution.
2. Immediately rinse the agar surface with distilled water to remove the stain.
3. Decolorize the medium by adding 1 mL of 95% ethanol. Leave the ethanol in contact with the agar for 1 minute, and then remove. Repeat the wash step a second time.
4. Rinse the plate with distilled water and allow to dry.
5. Observe for colonies under the low power of a microscope (50× to 100×).

IV. Results

A. Interpretation

Mycoplasmas with the "fried-egg" colony morphology will stain with a dark blue center and a light blue periphery and will appear highly granular. The agar background will be clear or slightly violet.

Mycoplasmas other than *M. pneumoniae* will remain stained; *M. pneumoniae* reduces the methylene blue after a time and will become colorless. If the isolate is from the genital tract and produces typical colonies and staining, the isolate can be reported as *M. hominis*.

V. Bibliography

Velleca WM, Bird BR, Forrester FT. Laboratory Diagnosis of *Mycoplasma* Infections. Atlanta: Department of Health and Human Services, 1980.

CHART 18-2

Hemadsorption Test for Identification of *Mycoplasma pneumoniae*

I. Principle

Among the respiratory mycoplasmas, *M. pneumoniae* is the only species that will specifically absorb red blood cells. This property, therefore, provides a method for the presumptive identification of *M. pneumoniae*.

C-48

When colony growth is noted on mycoplasma isolation media inoculated with respiratory tract specimens, a suspension of guinea pig erythrocytes is placed on the agar surface for a given time and then washed off. *M. pneumoniae* colonies will adsorb some of the red blood cells to the colony surface.

II. Reagents

A. *Mycoplasma* glucose agar with colonies thought to possibly represent *Mycoplasma* present.

B. Washed guinea pig erythrocytes (0.2%–0.4%) suspended in *Mycoplasma* broth medium.

III. Quality Control

A. Positive control: *M. pneumoniae*

B. Negative control: *Mycoplasma* species other than *M. pneumoniae*

IV. Procedure

1. Flood the surface of the agar plate with 2 mL of the red blood cell suspension.

2. Incubate the plate at 35°C for 30 minutes and periodically rotate the plate to prevent the red blood cells from settling out.

3. Wash the surface of the plate three times with 3 mL of *Mycoplasma* broth by gently rotating the plate. Remove wash fluid by aspiration with a pipette.

4. Examine the colonies at 50× to 100× magnification under a dissecting microscope.

V. Results

A. Interpretation

1. Positive test: Colonies with red blood cells adsorbed onto the surface = *M. pneumoniae*.

2. Negative: Colonies with no red blood cells adsorbed = *Mycoplasma* species, not *M. pneumoniae*.

CHART 18-3

Manganous Chloride–Urea Test for Identification of *Ureaplasma urealyticum*

I. Principle

Of the human mycoplasmas, *U. urealyticum* is the only species that is able to hydrolyze urea to ammonia. This property not only facilitates isolation of the organism, but also provides a rapid and convenient way to identify the species in culture. The manganous chloride ($MnCl_2$)–urea test provides a visual method for detecting ammonia formed by *U. urealyticum*.

Urease activity of *U. urealyticum* is detected by exposing the colonies to a solution of $MnCl_2$ in the presence of urea. The urease of the organism hydrolyzes urea to ammonia, and then the following reaction occurs:

$$2NH_3 + 2\ H_2O \rightarrow 2NH_4OH \rightarrow 2NH_4^+ + 2OH^-$$

$$MnCl_2 + 2OH^- \rightarrow MnO_2 + 2\ HCl$$

The manganese oxide formed in the reaction is insoluble and forms a dark brown precipitate around the colonies. This reaction is then detected under a dissecting microscope.

II. Reagents

A. $MnCl_2$-Urea Reagent

Urea (Sigma, St Louis, MO)	1.0 g
$MnCl_2$ (Fisher Scientific, Hampton, NH)	0.8 g
Distilled water	100 mL

B. Sterilize by filtration, dispense in 3-mL aliquots, and freeze at –20°C

C. Growth of suspect colonies on agar medium

III. Quality Control

A. Positive control: *U. urealyticum*

B. Negative control: *M. hominis*

IV. Procedure

1. Flood the plate with 2–3 mL of the $MnCl_2$–urea reagent.
2. After 5 minutes at room temperature, examine the colonies under 50× to 100× magnification with a dissecting microscope.

C-49

V. Results

A. Interpretation

Colonies of *U. urealyticum* will stain dark brown. Other mycoplasmas (e.g., *M. hominis*) will remain unstained.

VI. Comments

This test works optimally on colonies that are not too close together on the agar medium. Colonies should not be older than 48 hours when the test is performed.

CHART 18-4

Medium for Isolation of *Mycoplasma pneumoniae*

I. Base Reagents for Preparation of Complete Media

A. *Mycoplasma* Base Agar

This medium may be prepared using commercial PPLO agar as directed according to the package insert, or may be prepared from raw materials using the following formula:

Beef heart infusion	50 g
Peptone	10 g
NaCl	5 g
Purified agar	14 g
Distilled water	1 L

Mix together and melt the agar in a boiling water bath. Dispense in 70-mL aliquots and autoclave at 15 psi for 15 minutes. Store at 4°C.

B. Yeast Extract

1. Purchase commercial 25% yeast extract or prepare as follows: Weigh out 250 g of active bakers' yeast and place in 1 L of distilled water. Heat to boiling, cool, and filter to remove particulate matter. Adjust the pH to 8.0, and filter-sterilize.

2. Yeast extract (20 mL) is then mixed with uninactivated horse serum (10 mL) in a 2:1 ratio and frozen in 30-mL aliquots at –20°C.

3. Phenol red solution (0.4%): Phenol red (1 g) is dissolved in 3 mL of 1 N NaOH and then 247 mL of distilled water is added. Solution

is filter-sterilized and stored at 4°C to 8°C.

4. Methylene blue solution (1%): Methylene blue (1 g) is dissolved in 100 mL of distilled water and autoclaved for 15 minutes.

C. Thallium Acetate Solution (10%): Thallium acetate (10 g) is dissolved in 100 mL of distilled water and filter-sterilized.

D. Glucose Solution: Glucose (50 g) is dissolved in 100 mL of distilled water and filter-sterilized.

E. Penicillin Solution: Penicillin powder is dissolved in distilled water to achieve a concentration of 100,000 units/mL.

II. Methylene Blue-Glucose Diphasic Medium

1. Melt 70 mL of *Mycoplasma* agar in a boiling water bath. Cool to 50°C and add 30 mL prewarmed yeast extract-serum.
2. Add the following:

Methylene blue solution (1%)	0.1 mL
Phenol red solution (0.4%)	0.5 mL
Glucose solution	2.0 mL
Thallium acetate solution (10%)	0.25 mL
Penicillin solution	3.0 mL

3. Adjust the pH to 7.8 with sterile 1 N NaOH.
4. Dispense agar in 1-mL aliquots into sterile 13 × 100-mm screw-capped tubes.
5. Mix 140 mL of mycoplasma broth (A, above, without agar) with 60 mL of the yeast extract-serum. Add the following to this mixture:

Methylene blue solution (1%)	0.2 mL
Phenol red solution	1.0 mL
Glucose solution	4.0 mL
Thallium acetate solution (10%)	6.0 mL
Penicillin solution	0.5 mL

Adjust the pH to 7.8 with sterile 1 N NaOH. Dispense 2.0 mL into each of the tubes containing the solidified agar medium.

III. Mycoplasma Glucose Agar Medium

1. Melt 70 mL of mycoplasma agar in a boiling water bath. Cool to 50°C.
2. Prewarm 30 mL of yeast extract-serum and mix with the agar medium.
3. Aseptically add the following reagents:

Glucose solution	2.0 mL

Thallium acetate solution (10%)	0.25 mL
Penicillin solution	3.0 mL

4. Adjust the pH to 7.8 with sterile 1 N NaOH.
5. Dispense 6 mL of medium into 60 × 15-mm petri dishes. Allow to cool. Store media at 4°C.

IV. SP-4 Medium (also used for culture of M. pneumoniae, but mostly for culture of highly fastidious species)

A. Basal Medium

Mycoplasma Broth Base (BBL)	3.5 g/L
Bacto Tryptone (Difco)	10.0 g/L
Bacto Peptone (Difco)	5 g/L
Glucose	5.0 g/L
Deionized water	615 mL

Adjust to pH 7.5 to 7.6
Autoclave at 121°C, 15 minutes

B. Sterile Supplements

CMRL 1066 Tissue Culture Supplement with glutamine (Gibco)	50.0 mL
Fresh yeast extract (25% solution)	35.0 mL
Yeastolate (2% solution)	100.0 mL
Fetal bovine serum (heated to 56°C for 1 hour)	170.0 mL
Penicillin (100,000 U/mL stock)	10 mL
Phenol red solution (0.1%, aqueous)	20 mL

C. Final Formulation

Combine basal medium (615 mL) with supplements (385 mL) and dispense aseptically in 3-mL volumes into 4-mL, screw-capped vials.

V. Bibliography

Velleca WB, Bird BR, Forrester FT. Laboratory Diagnosis of Mycoplasma Infections. Atlanta, GA: Department of Health and Human Services, 1980.

CHART 18-5

Medium for Isolation of the Genital Mycoplasmas

A-8 Agar

This differential agar is used to differentiate *Ureaplasma* spp. from other genital *Mycoplasma* spp., including *M. hominis*. It is often used for primary plating in conjunction with a broth such as 10B broth or bromthymol blue broth.

Colonies of *U. urealyticum* will be brown and granular; colonies of *M. hominis* will have the typical larger and "fried-egg" appearance.

To prepare one liter, mix the following:

Ultrapurified (filtered) water	825 mL
$CaCl_2$ dihydride	0.15 g

(dissolve before adding the following ingredients)

TSA broth	25 g
Yeast extract	2 g
Putrescine dihydrochloride	1.7 g
DNA	0.2 g
Agar	10.5 g

Mix in flask; adjust pH to 5.5 with 2 N HCl; sterilize in autoclave, 121°C; cool in 56°C waterbath.

Supplements (filter-sterilize each separately (except serum) before adding:

Horse serum	200 mL
IsovitaleX	5 mL
10% urea	10 mL

C-51

	1 mL
GHL tripeptide solution[a]	
2% L-cysteine (Freshly prepared)	5 mL
Penicillin	1000 IU/mL

[a] GHL tripeptide solution can be purchased from many chemical distributors, such as CalbioChem-Novabiochem.

Add supplements under sterile conditions. Adjust pH to 6.0. Pour into petri dishes; can be stored at 4°C for up to 3 months.

10B Broth

This broth is used for isolation of *M. hominis* and *Ureaplasma* spp. It is often used in conjunction with A8 Agar for primary plating. 10B broth is

also referred to as Shephard's broth when made without arginine and used specifically for isolation of *Ureaplasma* spp.

To prepare one liter, mix the following:

Ultrapurified water	825 mL
Mycoplasma broth w/o crystal violet) Base (purchase from BD or other)	14 g
Arginine	2 g
DNA	0.2 g
1% phenol red	1 mL

(Can store for 1 month)

Mix in flask; adjust pH to 5.5 with 2 N HCl; sterilize in autoclave, 121°C; cool in 56°C waterbath.

Supplements (filter-sterilize each separately [except serum] before adding):

Horse serum[a]	200 mL
25% Yeast extract	100 mL
IsovitaleX	5 mL
10% urea	4 mL
4% L-cysteine	2.5 mL

(Freshly prepared)

Adjust pH after addition of supplements to pH 5.9–6.1

Can store broth at 4°C for up to 3 months

[a]Can use fetal bovine serum in place of horse serum.

SP-4 Broth or Agar

This broth or agar medium can be used for isolation of *M. pneumoniae*, *M. hominis,* and *Ureaplasma spp*. The agar and broth can be used as a primary plating media. Supplements such as arginine, urea, and antibiotics can be added for coverage of all mycoplasmas and for inhibition of bacterial contamination. This is probably one of the most commonly used media for isolation of genital mycoplasmas.

Mix the following in a liter flask:

Ultrapurified (filtered) water	643 mL
Mycoplasma broth base w/o Crystal violet (BD)	3.5 g
Tryptone	10 g

Peptone	5.3 g
Arginine	2.0 g
1% phenol red (prepared fresh monthly)	2 mL
DNA	0.2 g
Agar (if making SP-4 agar)	15 g

Mix in flask; adjust pH to 5.5 with 2 N HCl; sterilize in autoclave, 121°C; cool in 56°C waterbath.

Supplements (filter-sterilize each separately [except serum] before adding):

Fetal bovine serum	170 mL
25% Yeast extract	35 mL
2% yeastolate (BD)[a]	100 mL
10X CMRL 1066 (Sigma)[b]	50 mL
50% glucose	10 mL
Penicillin	1,000 IU/mL

[a] Yeastolate products are animal-free and water-soluble portions of autolyzed yeast or *Saccharomyces cerevisiae*. Yeastolate is a mixture of peptides, amino acids, carbohydrates, simple and complex, as well as vitamins; distributed by BD Biosciences.

[b] CMRL-1066 is a chemically defined medium developed in the late 1950s by Connaught Medical Research Laboratories; distributed by SIGMA.

C-52

Adjust pH after addition of supplements to pH 7.4–7.6, if media is to be used primarily for *M. pneumoniae* isolation.

Can be stored for up to 3 months at 4°C.

Bromthymol Blue Broth

This medium contains the indicator bromthymol blue instead of phenol red and is used for isolation and differentiation of *M. hominis* and *Ureaplasma* spp. The uninoculated broth is yellow. The presence of *M. hominis* is suggested if the color does not go beyond chartreuse, whereas *Ureaplasma* spp. is demonstrated by a full-green color. A blue-green color may indicate a mixture of *M. hominis* and *Ureaplasma* spp. Subculturing onto an agar media is usually needed for definitive identification. The advantage of this media is the lower concentration of urea, that reduces the likelihood of killing of the organisms in the culture, which may occur in media that afford the generation of higher urea concentrations. When the color change occurs,

the organisms are in their logarithmic phase, which is optimal for other studies.

Mix the following in a 1-L flask.

Distilled-deionized water	900 mL
Mycoplasma broth base w/o Crystal violet	21 g
Yeast extract	1 g
Bromthymol blue (0.4%, wt/vol)[a]	10 mL

[a] Dissolve powder in a minimal amount of 1 N NaOH and make up to 10 mL with water.

Mix in flask; sterilize in autoclave, 121°C; cool in 50°C waterbath.

Supplements (filter-sterilize each separately [except serum] before adding):

Horse serum, pH 6.0	100 mL
GHL tripeptide[a]	1 mL
10% urea	2.5 mL
Ampicillin	0.25 mg/mL
Nystatin	50 U/mL

[a] GHL tripeptide solution can be purchased from many chemical distributors, such as CalbioChem-Novabiochem.

Adjust pH after addition of supplements to pH 6.0–6.1

Store at −20°C until use.

Tetrazolium Reduction Test for the Presumptive Identification of *Mycoplasma pneumoniae*

CHART 18-6

Medium for Isolation of the Genital Mycoplasmas *Continued*

I. Principle

Mycoplasma pneumoniae is able to reduce the colorless compound

tetrazolium to the red-colored compound formozan. Among the large-colony mycoplasmas, this is a unique feature of *M. pneumoniae* and provides the laboratory with a rapid and easy method for identification of *M. pneumoniae* colonies directly on isolation medium.

By using enzymes that are associated with the cell membrane of the organism, *M. pneumoniae* can reduce the compound 2-(p-iodophenyl)-3-nitrophenyl-5-phenyl tetrazolium chloride to formozan, a red-insoluble compound that precipitates in the cells and renders the colony red to purple-black on prolonged exposure to the substrate.

II. Reagents

1. Isolated colonies on mycoplasma glucose agar
2. 2-(*p*-iodophenyl)-3-nitrophenyl-5-phenyl tetrazolium chloride (Aldrich Chemical)–0.21 g/100 mL distilled water. Sterilize by filtration and store in brown-glass bottle at room temperature.

III. Quality Control

A. Positive control: *M. pneumoniae*

B. Negative control: *Mycoplasma* species other than *M. pneumoniae*

IV. Procedure

1. Flood the surface of the agar plate containing the colonies of the organism with 2 mL of the tetrazolium reagent.
2. Incubate the plate at 35°C for 30 to 60 minutes (incubation for 60 minutes intensifies reactions that are already apparent at 30 minutes).
3. Examine the colonies under 50× to 100× magnification with a dissecting microscope.

V. Results

A. Interpretation

1. Positive test: Colonies of *M. pneumoniae* will visibly darken, becoming red to purple after 60 minutes. On prolonged incubation (3–4 hours), the colonies will become black.
2. Negative test: No color change will be noted after 60 minutes.

VI. Comments

Although equivalent to the hemadsorption test, tetrazolium reduction can be performed on the same plate after doing the hemadsorption procedure.

VII. Bibliography

Johnson JE, Smith TF. A simplified tetrazolium reduction test for *Mycoplasma pneumoniae*. Med Lab Sci 1976; 33:235.

CHART 19-1

Digestion and Decontamination: *N* -Acetyl-L-Cysteine–Sodium Hydroxide (NALC)

I. Principle

Mycobacteria are optimally recovered from clinical specimens when they are released from mucin, body fluids, and cells; this is commonly termed *digestion*. *N*-acetyl-L-cysteine (NALC) is a mucolytic agent that in concentrations of 0.5%–2% can rapidly digest tenacious sputum and other mucoid specimens within 2 minutes. Growth of mycobacteria in culture media is also enhanced when the concentration of competing organisms is minimal; this is commonly termed *decontamination*. The addition of 4% sodium hydroxide to the digestion mixture to reach a final concentration of 2% is the most commonly used decontaminating agent.

II. Specimen

A. Type of Specimen

Any specimen that is mucoid in consistency or is known to be contaminated with bacteria should undergo digestion and decontamination. Included are all respiratory specimens, gastric lavage fluid, stools, urine (when Gram's stain shows the presence of bacteria), postmortem tissue, and biopsy samples.

B. Patient Preparation

When collecting specimens through a contaminated area, such as collection of expectorated sputum, every effort should be made to cleanse or decontaminate the area. For example, before patients are asked to produce expectorated sputum, they should rinse out their mouth two or three times with water or a proprietary mouth wash. If a biopsy is to be taken, then the skin adjacent to a biopsy site should be carefully cleaned with iodine followed by an alcohol swab.

C. Special Collection Procedures

In patients in whom pulmonary tuberculosis is suspected and who cannot produce adequate sputum, induced sputum should be collected. In instances in which diagnosis has been difficult to establish, invasive procedures, such as bronchial brush biopsies, bronchial washings, or bronchoalveolar lavage, may be required.

D. Special Handling Conditions

All specimens submitted for the culture of mycobacteria must be handled in a properly functioning biohazard hood. Care must also be

taken in the preparation, examination, and storage of stained smears, as all acid-fast bacilli may not be killed in the fixation and staining procedure. Care must be taken not to produce aerosols when subcultures are made, when specimens are centrifuged, and when various biochemical tests are performed.

III. Materials

A. Equipment

1. Centrifuge with aerosol-free centrifuge cups
2. Vortex mixer

B. Supplies

1. Discard container containing disinfectant solution
2. Sterile 50-mL conical polypropylene screw-capped tubes (aerosol-free and graduated)
3. 10 mL sterile transfer pipette
4. Clean, unscratched, 1" × 3" microscope slides

C. Reagents

1. *N*-acetyl-L-cysteine (NALC) digestant-decontaminant: TB base digestant, 50 mL (available commercially)
2. TB phosphate buffer: 0.067 M, pH 6.8, 250 mL (commercially available)
3. *N*-acetyl-L-cysteine (NALC): Mucomyst, 20% solution (commercially available)

C-54

IV. Quality Control

The percentage of clinical specimens that grow bacterial contaminants in TB cultures following the digestion and decontamination procedure should average about 3%. A contamination rate significantly less than 3% may indicate overly harsh decontamination, and the concentration of NaOH should be reduced. A contamination rate significantly greater than 5% suggests either too weak a decontamination or incomplete digestion. Increasing the concentration of NaOH or the time of exposure, or both, may correct this problem.

V. Procedure

1. Add 1.5 mL NALC–50 mL TB base digestant to make a working solution.
2. Add a volume of working NALC–NaOH solution (no more than 24 hours old) equal to the volume of specimen in a sterile 50-mL conical polypropylene screw-capped centrifuge tube. If more than 20 mL of specimen is submitted, use a sterile transfer pipette to select 10 mL of

the most purulent blood, or mucoid portion. Secure the cap tightly.

3. Agitate the tube on a vortex mixer for not more than 30 seconds. Be sure to move the tube so that the NALC–NaOH comes in contact with the entire inner surface of the tube.
4. Let the tube stand for 15 minutes at room temperature to decontaminate the specimen.
5. Dilute the mixture to the 50-mL mark with either sterile distilled water or sterile 0.067 phosphate buffer (pH 6.8). This will reduce the continued action of the NaOH and lower the viscosity of the mixture.
6. Recap the tube tightly and invert several times to mix the contents.
7. Centrifuge the tube at 3000 *g* for 15–20 minutes. Use aerosol-free sealed centrifuge cups.
8. Pour the supernatant into a splash-proof discard container filled with disinfectant.
9. Use a sterile 3-mm-diameter bacteriologic loop or the end of two sterile wooden applicator sticks to remove a portion of the sediment, and prepare a smear over an area 1 × 2 cm on a new, clean, unscratched glass slide.
10. Suspend the remaining sediment in 1–2 mL of TB buffer or sterile distilled water if media are to be inoculated immediately. Otherwise, suspend the sediment in 1–2 mL of sterile 0.2% bovine albumin fraction V. If the amount of the sediment is very small, reconstitute the sediment in 1 mL only.
11. Add several drops to at least one solid medium (Löwenstein–Jensen slant or Middlebrook agar plate).
12. Inoculate a liquid medium according to the manufacturer's directions.

VI. Results

Not applicable

VII. Procedure Notes

1. Excessive agitation of the NALC–NaOH solution should be avoided because NALC is unstable in the presence of oxygen.
2. Bovine serum albumin serves to buffer the inoculum and enhance adhesion of the sample to solid media.
3. Sterile water only should be used: Tap water may contain environmental mycobacteria that can confuse observations of stained smears and contaminate culture media.

VIII. Limitation of Procedure

The concentration of NaOH and the time of exposure of specimen to reagent during the decontamination procedure must be carefully controlled to avoid undue loss of mycobacterial cells during this procedure.

IX. Bibliography

CHART 19-2

Carbol Fuchsin Stains

I. Principle

The mycolic acids within the lipid-rich, waxy cell wall of mycobacteria have the unique capability of binding fuchsin dye so that it is not destained by acid–alcohol. The Ziehl–Neelsen stain is known as a "hot stain," as heat is used for the dye to penetrate through the cell wall. The Kinyoun stain is known as a "cold stain" because the high concentration of phenol in the reagent serves to "dissolve" the lipid material in the cell wall, allowing penetration of the carbol fuchsin dye without the use of heat. Once stained, the cell wall holds the dye "fast," giving the characteristic red color.

C-55

II. Specimen

A smear is prepared either directly from the specimen following concentration or from a suspension of organisms obtained from colonies grown on primarily culture media.

III. Materials

A. Equipment: 3" × 1" glass slides and reagents
B. Media: Not applicable
C. Reagents
  1. Carbolfuchsin (commercially available)
  2. Acid–alcohol (commercially available)
  3. Methylene blue counterstain (commercially available)

IV. Quality Control

A. Unstained positive control smears (*M. gordonae* or another

nontuberculous mycobacteria) and negative control smears (*Nocardia* spp. or any aerobic bacterium such as *E. coli*) have been prepared.

B. Control smears are reviewed before the patient smears are read to confirm that the mycobacteria stain acid-fast:

1. Positive: *Mycobacterium* spp.; magenta red against blue background
2. *Nocardia* or other bacterium: no acid-fast cells; background blue

C. If control slide is unacceptable, review procedures and reagent preparation. Unacceptable control slides include the following:

1. Bacilli in positive control do not stain red.
2. Negative control remains red after destaining.
3. Background is not properly decolorized.

V. Procedure

A. Ziehl–Neelsen

1. Place a 2 × 3-cm filter paper strip on the slide to help hold the stain on the slide and filter undissolved crystals.
2. Flood the paper strip with Ziehl–Neelsen carbol fuchsin.
3. Using a Bunsen burner or electric staining rack, heat the slide slowly just before steaming (i.e., short of boiling).
4. Stain for 5 minutes. If the stain dries, add more stain without heating.
5. Carefully remove the paper slip from the slide using forceps.
6. Rinse the slide thoroughly with water.
7. Flood the smear with 3% acid–alcohol decolorizer for 2 minutes.
8. Rinse with water and drain excess water.
9. Flood the slide with methylene blue counterstain for 1 minute. Do not blot.
10. Examine the smear with a 100× oil-immersion objective.

B. Kinyoun

1. Heat-fix smears on slide warmer at 72°C–75°C.
2. Cover the smear with the Kinyoun's carbol fuchsin reagent. A small 2" × 3" rectangular piece of filter paper can be placed over the smear and the stain applied to the filter paper to avoid spilling over the sides of the smear. Do not steam (i.e., this method does not involve heating).
3. Stain for 5 minutes.
4. Remove the filter paper with forceps, and rinse the stain off the slide with distilled water.
5. Decolorize for 3 minutes with acid–alcohol or until no red stain appears.
6. Flood smear for 3–4 minutes with methylene blue counterstain.

7. Rinse dry and examine under a 100× oil-immersion objective.

VI. Results

Examine smears with a 100× oil-immersion objective and report as follows:

Smear Observation	Report
1 or 2 per 300 fields (3 sweeps)	(Questionable, repeat and report the result of the repeat)
1–9 per 100 fields	Rare, 1+
1–9 per 10 fields	Few, 2+
1–9 per immersion field	Numerous, 3+
9 per immersion field	4+

VII. Procedure Notes

1. Avoid underdecolorization with acid–alcohol. Organisms that are truly acid-fast are difficult to overdecolorize.
2. Avoid making thick smears, which may interfere with proper decolorization.

3. If an inordinate number of smear-positive, culture-negative results are encountered, check water reservoirs for contaminating acid-fast organisms. Also check for the transfer of material from slide to slide and from immersion oil are other possible sources of false-positive smear results.
4. Strong counterstains may mask the presence of acid-fast bacilli. Brilliant green may have a slight advantage over methylene blue as a counterstain.

VIII. Limitation of Procedure

1. Acid-fast smears do not stand alone, and final interpretation must always be correlated with culture results.
2. Organisms other than mycobacteria may demonstrate various degrees of acid-fastness: *Rhodococcus* spp., *Nocardia* spp. *Legionella micdadei* and the cysts of *Cryptosporidium* spp. Use differences in smear morphology and correlation with culture appearance and other biochemical tests.
3. Rapidly growing mycobacteria may stain poorly or not at all. The Ziehl–Neelsen stain may provide better staining than the Kinyoun method for weakly acid-fast organisms.

CHART 19-3

Fluorescent Stain: Auramine O; Auramine–Rhodamine

I. Principle

When stained with this method acid-fast organisms emit a bright yellow fluorescence when activated with a short-wave ultraviolet light. The potassium permanganate counterstain causes the nonspecific background debris to fluoresce a pale yellow, in contrast with the bright yellow appearance of acid-fast bacilli.

II. Specimen

Smear prepared either directly from the specimen or from a suspension of organisms obtained from colonies grown on primary culture media.

III. Materials

A. Equipment

1. 3" × 1" glass slides

B. Reagents

1. Auramine O

a. Solution 1: Dissolve 1.5 g of Auramine O in 10 mL of 95% ethanol.

b. Solution 2: Dissolve 3.0 g of phenol crystals in 87 mL of distilled water

c. Working solution: Combine solutions 1 and 2. Label with name of reagent and dates of preparation and expiration. Shelf life is 3 months if stored in a brown bottle.

2. Auramine–Rhodamine

a. Solution 1: Dissolve 1.5 g of Auramine O and 0.75 g of rhodamine B in 75 mL of glycerol

b. Solution 2: Mix 10 mL of phenol with 50 mL distilled water

c. Working solution: Combine solutions 1 and 2 and mix for 24 hours with a magnetic stirrer. Filter stain through glass wool and store in a glass bottle. Affix a label with the name of the reagent and dates of preparation and expiration. Shelf life is 3 months if

stored in a brown bottle.

3. Permanganate Counterstain: 0.5%
   a. Dissolve 0.5 g of potassium permanganate in 100 mL distilled water.
   b. Affix a label with the name of the reagent and dates of preparation and expiration.
4. 0.5% Acid–Alcohol Decolorizer.
   a. Add 0.5 mL of concentrated hydrochloric acid to 100 mL of 70% ethanol.
   b. Affix label with name of reagent and dates of preparation and expiration.
   c. Shelf life is 3 months when stored at room temperature.

C. Special Supplies

1. Fluorescence microscope fitted with a BG-12 or 52112 primary filter and an OG-1 barrier filter.

D. Biosafety Instructions

1. Handle all slides carefully. Heat-fixing may not kill all of the mycobacteria. Dispose of all slides in a biohazard container.
2. Heat-sterilize bacteriologic loops in the electric incinerator contained in the biologic safety hood.
3. Perform all operations in a biosafety hood. Place a paper towel soaked with disinfectant under the field of operation. Thoroughly clean all work surfaces with a disinfectant solution before and after use.

C-57

4. Carcinogenic
5. Work under a fume the hood (i.e., the type of hoods used in the special chemistry laboratory).

IV. Quality Control

A. Control Materials to be Used

A positive and negative control smear for mycobacteria is included with each run of stains. Control slides are reviewed before the patient smears are read to confirm that the positive control contains mycobacteria that fluoresce and that the negative smear has no fluorescing cells.

1. Positive control: *Mycobacterium* spp.; bacilli with yellow to orange fluorescence.
2. Negative control: A non–acid-fast bacterium (e.g., *E. coli*); no fluorescing cells.

If either of the control smears is unacceptable, reagent preparations and

procedure are checked.

V. Procedure

1. Heat-fix smears on slide warmer at 72°C–75°C.
2. Flood surface of the smear with Auramine O stain. Let stand at room temperature for 15 minutes.
3. Rinse with tap water. Drain.
4. Decolorize with 0.5% acid alcohol for 2 minutes.
5. Rinse with tap water. Drain.
6. Flood smear for 2 minutes with 0.5% potassium permanganate counterstain.
7. Rinse with tap water. Drain.
8. Air dry. *Do not blot.*
9. Observe the smear as soon as possible using the fluorescence microscope. If there is a delay, refrigerate the smears at 4°C in the dark.

VI. Results

A. Interpretation (Readout or Calculations)

Acid-fast bacilli (AFB) are 1–10 mm long, and appear as slender, rod-shaped bacilli emitting a bright yellow fluorescence against the pale yellow background. First, scan the smears briefly with the 25× objective; move to the 63× objective to confirm the bacterial morphology of any suspicious fluorescing forms. Thoroughly examine each slide for the presence of AFB. Mycobacteriologists recommend that a minimum of 100 fields be examined before a smear is reported as negative. Three passes along the long axis of the slide or nine passes along the short axis usually provide ample area for reading this technique minimizes the possibility of reading the same area more than once.

B. Reporting Format

The American Lung Association has recommended the following method for fuchsin stains, also applicable to fluorescent stains:

Number of Bacilli	Report
0	No AFB seen
1–2 on entire smear	Report number seen and ask for repeat
1–9 per 10 fields	Rare or 1+
1–9 per field	Few or 2+
10–90 per field	Numerous or 3+
>90 per field	4+

VII. Procedure Notes

Fluorochrome-stained smears may be directly restained with any of the carbol fuchsin staining procedures. This is done to confirm positive slides

and to study the morphology of the organisms present.

VIII. Limitation of Procedure

Organisms other than mycobacteria, including *Rhodococcus* spp., *Nocardia* spp., *Legionella micdadei,* and the cysts of *Cryptosporidium* and *Cystoisospora* spp. may demonstrate varying degrees of acid-fastness. These can often be suggested by differences in morphology; recovery of contaminating bacteria in subcultures may be necessary in equivocal cases.

Rapidly growing mycobacteria may vary in their abilities to retain acid-fast dyes. It is thought that some of these will not fluoresce or not fluoresce well in fluorochrome-stained smears. A carbol fuchsin procedure is recommended for these microorganisms.

Dead AFB may still stain positive in fluorescent stains, a feature that must be considered when using smears to assess efficacy of treatment.

C-58

CHART 19-4

Arylsulfatase

I. Principle

Arylsulfatase is an enzyme that splits free phenolphthalein from the tripotassium salt of phenolphthalein disulfite. The test for the identification of *Mycobacterium* species is performed in a tube containing a substrate of phenolphthalein in oleic acid agar. After 3 (or 14) days of incubation of a subculture of the unknown species, the appearance of a pink color after addition of sodium carbonate indicates a positive reaction.

II. Specimen

Mature colony of the unknown *Mycobacterium* species recovered from clinical material, grown on a solid medium. Prepare a suspension of the organism in sterile water and incubate for 3 days (14 days).

III. Materials

A. Equipment

1. Biologic safety cabinet

B. Media

1. Arylsulfatase stock substrate

a. Dissolve 2.6 g of phenolphthalein disulfate tripotassium salt in 50 mL of sterile deionized water.

b. Sterilize by membrane filtration (0.22-mm–pore size filter)

c. Store in the refrigerator at 2°C–8°C

d. Shelf life is indefinite if stored properly. Discard if solution becomes cloudy.

2. Arylsulfatase broth: 3-day test

a. Aseptically add 2.5 mL of stock substrate to 200 mL of sterile Dubos Tween broth.

b. Aseptically dispense 2.0 mL amounts into screw-capped test tubes (16 × 125 mm)

c. Store at 2°C–8°C. Discard if the solution becomes cloudy.

3. Arylsulfatase broth: 2-week test

a. Aseptically add 7.5 mL of stock substrate to 200 mL of sterile Dubos Tween broth.

b. Aseptically dispense 2.0 mL amounts into screw-capped test tubes (16 × 125 mm).

c. Store at 2°C–8°C.

Wayne's arylsulfatase agar is commercially available from several sources.

C. Reagents

1. 2 N sodium carbonate (Na_2CO_3): Dissolve 10.6 g of anhydrous sodium carbonate in 100 mL of distilled water.

IV. Quality Control

A. Three-Day Test

1. Positive control: *Mycobacterium fortuitum* American Type Culture Collection (ATCC) 6841 (if positive control is negative, repeat tests with a fresh subculture of the positive organism. If the negative controls are positive, repeat the tests with a new lot of media).

2. Negative control: *Mycobacterium intracellulare* ATCC 13950

3. Uninoculated medium and reagent only: No color

B. Fourteen-Day Test

1. Positive control: *Mycobacterium fortuitum* ATCC 23292

2. Negative control: *Mycobacterium intracellulare* ATCC 13950
3. Uninoculated medium and reagent only: No color

V. Procedure

1. Inoculate each tube of substrate with a slightly turbid suspension of the test organism in sterile water. Thoroughly emulsify the culture in the broth.
2. Incubate tube for 3 days or 14 days (2-week test) at 35°C in the non-CO_2 incubator
3. Following incubation, add 1 mL of the 2 N sodium carbonate reagent, mix, and observe for color change.

VI. Results

A. Interpretation

Visually observe for a color change from pale pink to deep red. The lack of color change indicates a negative reaction.

VII. Procedure Notes

Include an actively growing control organism with each batch of test. For slow growers, use a 3- to 5-week subculture; for rapid growers, a 1- to 3-week subculture. If the positive control is negative, repeat the tests with a fresh subculture of the positive organism. If the negative controls are positive, repeat the tests with a new lot of media.

C-59

VIII. Limitation of Procedure

A. False-negative results can be due to control cultures that are too old.

B. False-positive results may occur if medium contains free phenolphthalein.

CHART 19-5

Assessment of Photoreactivity of Mycobacteria

I. Principle

The appearance of yellow pigment in the colonies of photochromogenic mycobacteria is the result of yellowish-orange carotene crystals that are produced by actively metabolizing microorganisms after exposure to bright light. Scotochromogenic species have the capability of producing yellow pigment without exposure to light; however, the type of pigment is unknown. The pigmentation of young colonies of mycobacteria after growth in the dark or following exposure to light can be an important aid in the identification of certain *Mycobacterium* species.

II. Specimen

A primary broth culture of the test organism, diluted sufficiently to produce isolated colonies when inoculated to agar culture

III. Materials

A. Equipment
- **1.** Biologic safety cabinet
- **2.** 37°C incubator

B. Supplies
- **1.** Sterile screw-capped test tubes, 20 × 110 or 20 × 125 mm
- **2.** Sterile Pasteur pipettes
- **3.** Inoculating wires and loops

C. Medium
- **1.** Three slants of Löwenstein–Jensen medium
- **2.** Three Middlebrook 7H10 agar plates

IV. Standards and Controls (Include Controls With Each Batch of Tests)

A. Positive photochromogen: *M. kansasii* ATCC 12478

B. Positive scotochromogen: Stock strains of *M. scrofulaceum* or *M. gordonae*

C. Negative chromogen: *M. tuberculosis* ATCC 25177

V. Procedure

1. Inoculate the surfaces of three Löwenstein–Jensen slant media or three Middlebrook 7H11 agar plates with fluid from a dilute broth culture of the organism to be tested. Wrap two of the tubes or plates with aluminum foil; leave the third exposed to the ambient light in the incubator.
2. Incubate one of the wrapped tubes or plates at 25°C–30°C; the other wrapped tubes or plates at 37°C.
3. Several days after growth is noted in the light-exposed control tube or plate, examine the wrapped tubes or plates for growth.

4. If early growth is detected in the wrapped tubes or plates, expose one of each pair to a strong light for approximately 5 hours. A 100-W tungsten bulb or fluorescent equivalent is adequate. Loosen the cap of the culture tube during this period of light exposure.
5. Following exposure to light, the tube or plate is returned to the incubator and inspected after 24–48 hours for the appearance of yellow pigment.

VI. Results

A. Interpretation

Mycobacteria that are scotochromogenic produce an equal amount of pigment whether light-exposed or left in the dark. *M. scrofulaceum, M. gordonae, M. flavescens, M. xenopi,* and *M. szulgai* (the latter is scotochromogenic only when incubated at 37°C) are examples of scotochromogens.

Mycobacteria that are photochromogenic produce yellow pigment only after exposure to light. The more commonly encountered photochromogens include *M. kansasii, M. marinum, M. simiae,* and *M. asiaticum.*

Nonchromogenic mycobacteria are incapable of producing pigment either in the dark or after exposure to light. *M. tuberculosis, M. bovis, M. ulcerans,* and classical strains of *M. avium* are the more commonly encountered nonchromogens.

VII. Procedure Notes

When *M. szulgai* is suspected, the light-exposed tubes or plates should be incubated at 25°C for 3–5 days. If incubated at 37°C, the photochromogenic potential will be masked by the development of the scotochromogenic pigment at that temperature.

VIII. Limitation of Procedure

Regarding *M. avium,* although the classical strain is a nonchromogenic mycobacteria, there are strains that are slightly pigmented yellow in the light and dark (i.e., scotochromogenic).

IX. Bibliography

CHART 19-6

Catalase 68°C and Semiquantitative Catalase

I. Principle

Catalase splits hydrogen peroxide into water and oxygen. The evolution of oxygen appears as bubbles. Some forms of catalase are inactivated by heating at 68°C for 20 minutes, a valuable identifying feature for certain *Mycobacterium* species. The hydrogen peroxide used for the identification of *Mycobacterium* species differs from that used to detect catalase in other types of bacteria, by using a 30% concentration (Superoxol) in a strong detergent solution (10% Tween 80). The detergent helps disperse the hydrophobic tightly clumped mycobacteria from large aggregates to individual bacilli, maximizing the detection of catalase.

II. Specimen

Mature colony of the unknown *Mycobacterium* species recovered from clinical material, grown on a solid medium.

III. Materials

A. Equipment
- **1.** 68°C water bath or heat block

B. Media
- **1.** Middlebrook 7H9 broth
- **2.** Löwenstein–Jensen deeps in 25- × 150-mm screw-capped test tubes

C. Reagents
- **1.** 30% hydrogen peroxide (commercially available as Superoxol)
- **2.** 10% Tween 80
- **3.** M/15 phosphate buffer (0.067 M)

IV. Quality Control

A. Negative control: *M. tuberculosis* American Type Culture Collection (ATCC) 15177, bubbles at 22°C–25°C, but not at 68°C.

B. Positive control: *M. fortuitum* ATCC 6841, bubbles at 22°C–25°C and at 68°C.

C. Controls are included with each batch of tests.

V. Procedure

A. Heat-Stable Catalase Test
- **1.** Set up one screw-capped tube per organism specimen to be tested in sterile water.
- **2.** Label each tube with the number of the specimen.

3. Add 0.5 mL of sterile 0.067 M phosphate buffer to each tube.
4. Inoculate the buffer with a 2–3 heaping loopfuls of growth from an actively growing subculture of the organism to be tested (2–4 weeks old).
5. Thoroughly emulsify the culture in the buffer.
6. Incubate the tubes in a 68°C water bath for exactly 20 minutes.
7. Remove the tubes from the water bath. Cool to room temperature.
8. Add 0.5 mL of freshly prepared Tween 80–hydrogen peroxide reagent.
9. Allow the tubes to sit at room temperature for 20 minutes. Do not shake the tubes.
10. Visually observe for the evolution of bubbles.

C-61

B. Semiquantitative Catalase Test

1. Inoculate a liquid medium, such as Dubos Tween broth or Middlebrook 7H9 broth with a loopful of the culture to be tested. Include controls.
2. Incubate for 7 days at 37°C.
3. Mix for 5–10 seconds on a vortex mixer.
4. Transfer six drops to a Löwenstein–Jensen deep (prepared in 25- × 150-mm tubes).
5. Incubate the deeps for 14 days at 37°C. Be sure caps are loose.
6. Add 1 mL of freshly prepared Tween 80–hydrogen peroxide reagent. Avoid contact of reagent with skin.
7. Allow tests to sit at room temperature for 5 minutes.
8. Measure the column of bubbles.

VI. Results

A. Interpretation (Readout or Calculations)

1. Heat-stable catalase test: The appearance of bubbles indicates a positive test; lack of bubbles is a negative reaction. *M. tuberculosis* and other mycobacteria lose their catalase activity when heated to 68°C.
2. Semiquantitative catalase test:
   High catalase reaction: >45 mm of foam
   Low catalase reaction: <45 mm of foam

VII. Procedure Notes

Failure of control cultures to give expected results is usually due to the use of cultures that are too old—use only actively growing cultures.

VIII. Limitation of Procedure

False-negative results can be due to use of cultures with inadequate growth, the use of cultures that are too old, or reagents that are outdated. Inadequate growth may result from an inadequate inoculum or from screwing lids too tightly.

False-positive results may occur if the culture contains catalase-positive, contaminating bacterial species.

IX. Bibliography

Kubica GP, Jones WD Jr, Abbott VD, et al. Differential identification of mycobacteria. I. Tests on catalase activity. Am Rev Respir Dis 1966;95:400–405.

CHART 19-7

Growth on MacConkey Agar

I. Principle

The ability to grow on special MacConkey agar, formulated without crystal violet, differentiates *M. fortuitum*, *M. chelonae,* and *M. abscessus*, which can grow within 5 days, from other rapidly growing mycobacteria that show only slight growth after 11 days.

II. Specimen

A mature colony of the unknown *Mycobacterium* species recovered from clinical material, grown on a solid medium is tested.

III. Materials

A. Equipment: None
B. Media: MacConkey agar without crystal violet (commercially available)
C. Reagents: None
D. Supplies: None

IV. Quality Control

A. Positive control: *M. fortuitum* American Type Culture Collection (ATCC) 6841
B. Negative control: *M. phlei* ATCC 11758; uninoculated medium and reagent only

V. Procedure

1. Inoculate a fresh MacConkey plate with three drops of the organism grown for 7–10 days in 7H9 broth and streak for isolation.
2. Incubate at 28°C–30°C for 11 days without CO_2.

3. At 5 and 11 days, visually observe the surface of the agar plate for growth.

VI. Results

A. Interpretation

A positive test for *M. fortuitum* will show growth along the entire streak area and possibly a color change in the medium in 5 days. The absence of growth indicates a negative test.

C-62

VII. Procedure Notes

Include controls with each batch of tests. If results are not as expected, repeat the test with fresh control organisms and a new lot of media.

VIII. Limitation of Procedure

About 25% of *M. smegmatus* strains grow on MacConkey agar without crystal violet. To obviate any diagnostic difficulties, the 3-day arylsulfatase test may be used to separate *M. smegmatus* (negative) from *M. fortuitum, M. chelonae,* and *M. abscessus* (positive).

IX. Bibliography

Jones WD, Kubica GP. The use of MacConkey agar for differential typing of *M. fortuitum.* Am J Med Technol 1946;30:182–195.

CHART 19-8

Inhibition by Thiophene-2-Carboxylic Acid Hydrazide (T2H, 1 mg/mL)

I. Principle

Thiophene-2-carboxylic acid hydrazide has the property of inhibiting *Mycobacterium bovis,* but not other species of mycobacteria, a helpful feature differentiating *M. bovis* from *M. tuberculosis.*

II. Specimen

A. 3- to 4-week-old culture of the test organism growing on a solid medium.

III. Materials

A. Equipment

1. Biologic safety cabinet

2. 10% CO_2 incubator at 37°C

B. Supplies

1. Sterile applicator sticks
2. Sterile 9.0 mL water blanks
3. Sterile deionized water
4. Quadrant petri dishes

C. Media

1. Thiopene-2-carboxylic acid hydrazide (T_2H) (also known as TCH) susceptibility medium (10 mg/mL)
   - **a.** Make two 200-mL batches of Middlebrook 7H10 medium in separate flasks.
   - **b.** Sterilize by autoclaving. Cool to 50°C in a water bath.
   - **c.** Pipette 5.0 mL of cooled medium from one of the flasks into quadrants I and III of a quadrant petri dish.
   - **d.** Add 2.0 mL of a 1,000 mg/mL TCH stock solution into the remaining flask (final concentration of 10 mg/mL). Swirl well to mix.
   - **e.** Dispense 5.0 mL of this medium into quadrants II and IV of each plate.
   - **f.** Protect the plates from light by covering with brown paper. Store plates at 2°C–8°C; shelf life is approximately 1 month.

IV. Quality Control

A. Positive control: *M. bovis* American Type Culture Collection (ATCC) 35734 (susceptible to TCH at 10 mg/mL)

B. Negative control: *M. tuberculosis* ATCC 25177 (resistant)

V. Procedure

1. Prepare a suspension of the unknown mycobacterium in sterile water equivalent to a McFarland 1 standard.
2. Dilute to make a suspension of 10^3–10^4 in sterile deionized water.
3. Inoculate three drops of each dilution onto a control quadrant and a TCH quadrant on the quadrant plates.
4. Cover the plates with brown paper to prevent exposure to light, letting the plates sit at room temperature to allow adsorption of the inoculum.
5. Place each plate into a CO_2-permeable zipper bag, invert the plates, and incubate at 37°C in 8%–10% CO_2 for 3 weeks.
6. After incubation, count the colonies on the control quadrant and on the quadrant that contains the TCH at 10 mg/mL.

C-63

VI. Results

A. Calculate the percentage of resistance as follows:

Number of colonies on quadrant containing TCH × 100 = percent of colonies resistant on control quadrant.

B. Record the test culture as resistant to TCH if the derived number is higher than 1%.

VII. Bibliography

Wayne LG, Engel HWB, Grassi C, et al. Highly reproducible techniques for use in systematic bacteriology in the genus *Mycobacterium:* tests for niacin and catalase and for resistance to isoniazid, thiophene 2-carboxylic acid hydrazide, hydroxylamine and *p*-nitrobenzoate. Int J Syst Bacteriol 1976;26:311–318.

CHART 19-9

Iron Uptake

I. Principle

The ability to take up iron from an inorganic iron-containing reagent helps to differentiate *Mycobacterium fortuitum* and *M. phlei* (positive) from *M. chelonae* and *M. abscessus* which do not take up iron.

II. Specimen

Mature colony of the unknown *Mycobacterium* species recovered from clinical material, grown on a solid medium.

III. Materials

A. Equipment

1. Biologic safety hood
2. 28°C–30°C incubator
3. Sterile Pasteur pipettes

B. Medium

1. Löwenstein–Jensen slants (commercially available)

C. Reagents

20% ferric ammonium citrate

1. Add 20 g of ferric ammonium citrate to 100 mL of deionized water

2. Swirl to dissolve
3. Autoclave for 15 minutes at 121°C
4. Store in the refrigerator at 2°C–8°C

IV. Quality Control

A. Positive control: *M. fortuitum,* American Type Culture Collection (ATCC) 6841

B. Negative control: *M. chelonae,* ATCC 35751; uninoculated medium and reagent only

V. Procedure

1. Use an actively growing (1- to 2-week-old) subculture of a rapidly growing mycobacterium on a Löwenstein–Jensen slant.
2. Add as many drops of sterile 20% ferric ammonium citrate as there are milliliters of medium in the slant. For example, for 8 mL of medium, add eight drops of ferric ammonium citrate.
3. Reincubate the slant at 28°C–30°C for up to 3 weeks.
4. Visually examine the surface of the slants for the presence of a dark, rust brown color.

VI. Results

The color of a truly positive iron uptake test will be very dark rust. A positive reaction seen in a rapidly growing strain of mycobacteria is indicative of *M. fortuitum.*

VII. Procedure Notes

If the results are not as expected, repeat the test with new ferric ammonium citrate reagent and new control cultures.

VIII. Limitation of Procedure

Some isolates of *M. chelonae* will turn tannish brown, a color sometimes referred to as "turtlelike," giving a false-positive reaction. Look for a very dark rust color.

IX. Bibliography

C-64

CHART 19-10

Niacin Accumulation

I. Principle

All *Mycobacterium* species produce niacin ribonucleotide; however, virtually all strains of *M. tuberculosis* and *M. simiae* and some strains of *M. chelonae* lack the enzymes to further convert niacin to nicotinamide adenine dinucleotide (NAD). Niacin accumulates in the culture medium, from which it can be extracted with sterile water or physiologic saline. The extract is placed in a small test tube to which is added a reagent-impregnated niacin filter strip.

II. Specimen

A longer than 3-week-old heavy growth on Löwenstein–Jensen of the organism is needed for testing. Growth on other culture media does not produce sufficient niacin to produce a positive test reaction by this method.

III. Materials

A. Equipment
1. Biologic safety cabinet
2. 37°C incubator

B. Supplies
1. Sterile screw-capped test tubes, 20 × 110 or 20 × 125 mm
2. Sterile Pasteur pipettes
3. Sterile 5 mL pipettes

C. Reagents
1. Niacin filter paper strips (commercially available)
2. Sterile H_2O

IV. Standards and Controls (Include Controls with Each Batch of Tests):

A. Positive control: *M. tuberculosis* American Type Culture Collection (ATCC) 25177

B. Negative control: *M. intracellulare* ATCC 13950

V. Procedure

1. Flood the surface of the Löwenstein–Jensen slant over the heavy growth of the test organism with 1 mL sterile H_2O. Stab the medium with the tip of the pipette to allow access of the water to the underlying medium.
2. Tilt the tube so the water covers the surface of the slant. Let stand for 20–30 minutes.
3. Rotate the tube so that the slant faces downward. Carefully remove 0.6 mL of extract without touching the slant and transfer to the screw-capped test tube.
4. Using a pair of forceps, drop a niacin test strip with the arrow pointing downward into the tube. Stopper the tube immediately.
5. Gently shake the tube and repeat shaking after 5 and 10 minutes.

6. After 12–15 minutes, and not longer than 30 minutes, read the test for the presence of a yellow color.

VI. Results

A. Interpretation

The development of a yellow color indicates a positive test. If a culture resembles *M. tuberculosis,* but the niacin test is negative, reincubate the slant for an additional 2–4 weeks and repeat the test.

VII. Limitation of Procedure

False-negative reactions may occur, due to: (1) an insufficient amount of growth on the slant, (2) failure to stab the agar if the growth is confluent, or (3) the presence of contaminating bacteria that may have metabolized any niacin that may have accumulated.

M. simiae and occasional strains of *M. bovis, M. marinum,* and *M. chelonae* may accumulate niacin in the test medium. These species can be readily differentiated from *M. tuberculosis* by several key characteristics described in the interpretation section of this manual.

C-65

CHART 19-11

Nitrate Reduction: Mycobacteria

I. Principle

Mycobacteria producing nitroreductase are capable of catalyzing the reduction of nitrate to nitrite. The nitrate produced is detected by the addition of α-naphthalamine and sulfanilic acid, forming the red diazonium dye, *p*-sulfobenzene-azo-α-naphthalamine.

II. Specimen

A. 3- to 4-week-old culture of the test organism growing on Löwenstein–Jensen medium or other coagulated egg medium.

III. Materials

A. Equipment

1. Biologic safety hood

2. 37°C water bath or heating block

B. Supplies

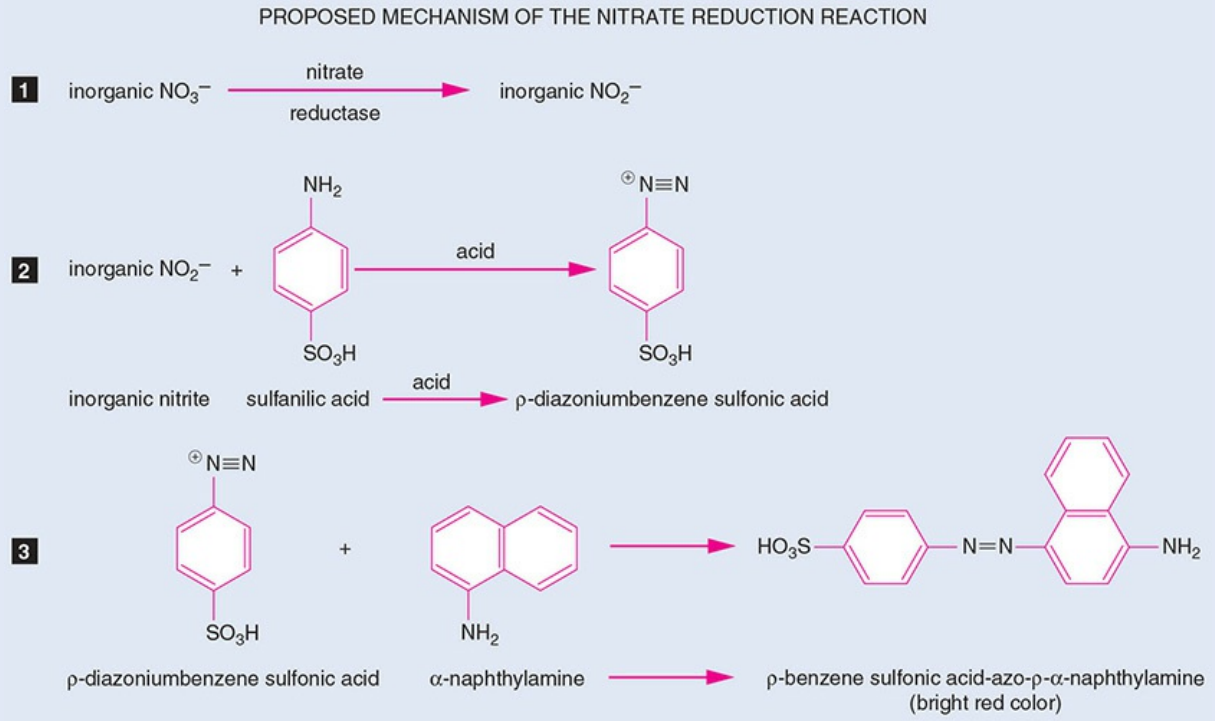
1. Sterile Pasteur pipettes

2. Sterile forceps

C. Reagents

1. Nitrate test substrate (0.01 M) in M/45 phosphate buffer (0.02 M, pH 7.0)

$NaNO_3$	0.8 g
KH_2PO_4	1.17 g
Na_2HPO_4	1.93 g
H_2O	999 mL (final volume)



Dissolve and mix the chemicals. Adjust pH to 7.0. Autoclave and store, and dispense in 2.0-mL aliquots in sterile tubes. When stored at 2°C–8°C, the shelf life is 1–2 months.

2. 0.2% sulfanilamide: Completely dissolve 0.1 g of sulfanilamide in 50 mL of deionized water. It may be necessary to warm the water to 47°C–50°C for complete solubility. When stored in brown glass bottles at 2°C–8°C, the shelf life is about 1 month.
3. 0.1% *N*-(1-naphthyl) ethylenediamine dihydrochloride: Dissolve 0.05 g of *N*-(1-naphthyl) ethylenediamine dihydrochloride in 50 mL of deionized water. The shelf life is 1 month if stored in a brown-glass bottle at 2°C–8°C.

C-66

IV. Quality Control

A. Positive control: *M. tuberculosis* American Type Culture Collection (ATCC)

B. Negative control: *M. avium* complex ATCC

C. Negative reagent control: Uninoculated tube containing appropriate substrate

V. Procedure

1. Emulsify one loopful or spadeful of colonies from solid medium into 2 mL of nitrate substrate.
2. Shake by hand to mix and incubate at 35°C–37°C for 2 hours.
3. Add reagents to mixture in the following order:
   1 drop concentrated HCl
   2 drops of 0.2% sulfanilamide
   2 drops of 0.1% *N*-(1-naphthyl) ethylenediamine dihydrochloride
4. Allow mixture to sit at room temperature for 5 minutes.
5. Read for the development of a pink to red color.

VI. Results

The appearance of a red or pink color is indicative of a positive test. A quantitative reading can be made by comparing with nitrate reduction standards. Quantitation is not performed in most laboratories.

VII. Procedure Notes

If no color change occurs, confirm negative results by adding a small amount of zinc dust. A deep red to pink color after the addition of zinc dust indicates that nitrate was reduced. Reagents are stored at 2°C–8°C in the refrigerator, away from direct light.

VIII. Limitation of Procedure

The color may fade rapidly in some instances and can lead to a false-negative test if a reading is not made soon after the reagents are added.

IX. Bibliography

Virtanen S. A study of nitrate reduction of mycobacteria. Acta Tuberc Scand Suppl 1960;418:119.

CHART 19-12

Pyrazinamidase

I. Principle

The deamidation of pyrazinamide to pyrazinoic acid in 4 days is a useful phenotypic characteristic by which *M. marinum* (positive) can be differentiated from *M. kansasii* (negative) and by which weakly niacin-positive strains of *M. bovis* (negative) can be distinguished from *M.*

tuberculosis complex (positive).

II. Specimen

Mature colonies of the unknown *Mycobacterium* species recovered from clinical material, grown on a solid medium.

III. Materials

A. Equipment: None

B. Medium

1. Pyrazinamidase Substrate Medium

a. Dissolve 6.5 g of Dubos broth base in 1 L distilled water.

b. Add

Pyrazinamide	0.1 g
Sodium pyruvate	2.0 g
Agar	15 g

c. Heat to dissolve. Dispense in 50.0-mL amounts into screw-cap tubes.

d. Autoclave for 15 minutes at 121°C.

e. Allow agar to harden with tubes in upright position.

f. Shelf life is 6 months when stored at 2°C–8°C. Discard if agar appears dehydrated or contaminated.

C. Reagents

1% ferrous ammonium sulfate (prepare immediately before use): Place 0.1 g of ferrous ammonium sulfate in sterile screw-capped test tubes. Add 10 mL of sterile deionized water immediately before use, and allow the crystals to dissolve.

D. Supplies

1. Sterile applicator sticks

2. Sterile 1.0 or 5.0-mL pipettes

IV. Quality Control

A. Positive control: *M. intracellulare* American Type Culture Collection (ATCC) 13950

B. Negative control: *M. kansasii* ATCC 12478

V. Procedure

1. Inoculate a large loopful of growth from an actively growing subculture to the surface of two pyrazinamidase agar deeps.

2. Incubate the tubes with caps loose at 37°C.

3. Remove one of the tubes from the incubator after 4 days. Remove one of the control tubes also.

4. Add 1.0 mL of freshly prepared 1% ferrous ammonium sulfate to each tube.
5. Examine the tubes for a pink band in the agar after 30 minutes at room temperature.
6. Refrigerate any negative tubes for 4 hours more and reexamine for the presence of a pink band.

VI. Results

A. Interpretation

After 4 hours, examine the tubes for a pink band in the reagent layer on the surface of the agar (positive reaction), using incident room light against a white background. Repeat the procedure with the remaining tube after 7 days of incubation.

VII. Procedure Notes

Perform all tests under a biologic safety hood.

VIII. Bibliography

Wayne LG. Simple pyrazinamidase and urease tests for routine identification of mycobacteria. Am Rev Respir Dis 1974;109:147–151.

CHART 19-13

Sodium Chloride Tolerance: Mycobacteria

I. Principle

Of the slowly growing mycobacteria, only *M. triviale* grows in media containing 5% NaCl; of the medically significant rapidly growing mycobacteria, only *M. chelonae* subsp. *chelonae* fails to grow in such media.

II. Specimen

A. 3- to 4-week-old culture of the test organism growing on Löwenstein–Jensen medium or other coagulated egg medium.

III. Materials

A. Equipment

1. Biologic safety hood
2. Slant racks

B. Supplies

1. Sterile applicator sticks
2. Sterile 1.0-mL pipettes

3. McFarland 1 standard

C. Media

1. Löwenstein–Jensen without 5% NaCl in slants
2. Löwenstein–Jensen with 5% NaCl in slants
3. Dubos Tween or Middlebrook 7H9 broth

IV. Quality Control

A. Positive control: *M. fortuitum* American Type Culture Collection (ATCC) 6841

B. Negative control: *M. gordonae* ATCC 14470

Set up controls for each new lot number of medium received. Reject medium if results on control organisms are not as expected. Purchase Löwenstein–Jensen with and without NaCl in the same size tubes for consistency in interpretation.

V. Procedure

1. Use an actively growing culture (2–4 weeks for slow growers; 1–2 weeks for rapid growers). Make a suspension of organisms in Middlebrook 7H9 broth equal to a McFarland 1 standard.
2. Take one Lowenstein–Jensen slant with 5% NaCl and one slant without 5% NaCl and inoculate into each tube, 0.1 mL of the described suspension.

3. Incubate the slants with the caps loose in a 5%–10% CO_2 incubator. Lie slants flat in a rack during incubation. Incubate for 1 week at 29°C–30°C for rapid growers and 37°C for slow growers. Stand negative tubes up straight; incubate 3 more weeks. Visually examine slants weekly for growth.

VI. Results

1. When numerous colonies are seen on the control slant and more than 50 colonies on the medium containing 5% NaCl, record the test as positive.
2. When there are colonies on the control slant and no visible growth on the slant containing NaCl, continue incubation for up to 4 weeks.

VII. Procedure Notes

Use the slant without 5% NaCl to check for viability of the organism. It is not necessary to have equal growth in both tubes. If the organism does not grow on the slant without 5% NaCl, repeat the test.

VIII. Limitation of Procedure

Some strains of *M. fortuitum* and *M. chelonae* grow on a NaCl-containing

media only at temperatures lower than 35°C. For this reason, all test specimens should be incubated at 29°C–30°C.

IX. Bibliography

Silcox VA, Good RA, Floyd MM. Identification of clinically significant *Mycobacterium fortuitum* complex. J Clin Microbiol 1981;4:686–691.

CHART 19-14

Tween-80 Hydrolysis

I. Principle

Tween 80 is the trade name of the polyethylene derivative of sorbitan mono-oleate. Some *Mycobacterium* species possess an enzyme that releases oleic acid from the Tween 80. The color change from orange to pink is due to hydrolysis of Tween 80, which modifies the optical rotation of light passing through the substrate.

II. Specimen

Mature colony of the unknown *Mycobacterium* species recovered from clinical material, growth on a Löwenstein–Jensen slant.

III. Materials

A. Supplies
  1. Sterile applicator sticks
  2. Screw-capped tubes (12 × 100 mm) containing 2.0 mL of deionized water per tube

B. Medium
  1. Löwenstein–Jensen slants

C. Reagents
  1. Tween-80 hydrolysis reagent
  2. 2 drops of Difco (Detroit, MI) reagent added to distilled water in screw-capped tubes.

D. Equipment
  1. Biohazard hood

IV. Quality Control

A. Positive control: *M. kansasii,* American Type Culture Collection (ATCC) 12478 incubated for 12 days

B. Negative control: Stock culture of *M. intracellulare* ATCC 13950

C. Negative reagent: Uninoculated tube of substrate, incubated for 12 days

V. Procedure

1. Add two drops of Tween reagent to 1 mL of sterile distilled water in screw-capped tubes.
2. Inoculate a loopful of the organism to be tested.
3. Incubate at 35°C in the dark with caps tight.
4. Visually read tubes at 24 hours. If negative, read again at 5 and 10 days. Compare the color of the liquid with that in the control tubes.

VI. Results

A positive result is recorded when the liquid, not the cells, turns from light orange to pink or red. *M. kansasii* usually turns positive within 24 hours. Read again at 3, 5 and 10–12 days. Record results and discard positives. Discard all tubes at 12 days.

C-69

VII. Procedure Notes

Keep Tween hydrolysis reagent in the dark. Do not store or incubate tubes in the light. The red color of a positive reaction is not due to a pH change, rather to release of neutral red.

VIII. Bibliography

Kilburn JO, O'Donnell KF, Silcox VA, et al. Preparation of a stable mycobacterial Tween hydrolysis test substrate. Appl Microbiol 1973;26:826.

CHART 19-15

Urease: Mycobacteria

I. Principle

Urease is an enzyme possessed by many *Mycobacterium* species that can hydrolyze urea to form ammonia and carbon dioxide. The ammonia reacts in solution to form ammonium carbonate, resulting in alkalinization and an increase in the pH of the medium.

II. Specimen

A. Type of Specimen

Mature colony of the unknown *Mycobacterium* species recovered from clinical material, grown on a Lowenstein–Jensen slant.

III. Materials

A. Equipment

1. Biologic safety hood

2. 37°C incubator

B. Medium

1. Urea Broth

a. Add 10 g of Difco (Detroit, MI) Bacto urea agar base concentrate to 90 mL of sterile deionized water. Mix well to dissolve.

b. Aseptically aliquot 3.0 mL portions into sterile screw-capped test tubes.

c. Store at 2°C–8°C; shelf life is 1 month.

IV. Quality Control

A. Positive control: *M. kansasii* American Type Culture Collection (ATCC) 12478

B. Negative control: *M. avium/M. intracellulare* ATCC 13950

V. Procedure

1. Inoculate each substrate tube with a loopful of growth from an actively growing culture. Thoroughly emulsify the culture in the broth.

2. Incubate at 35°C for 5 days.

3. Visually read the tubes at 1, 3, and 7 days.

VI. Results

Color change from yellow to dark pink or red indicates a positive reaction. No color change is a negative reaction.

VII. Procedure Notes

Repeat tests that appear slightly pink; if the repeat test result is still ±, report as negative.

VIII. Limitation of Procedure

1. False-positive tests are usually due to incorrect interpretation of results, incubation beyond 5 days, or contaminated test or control cultures.

2. False-negative results are due to the use of an incorrect medium (i.e., one used for testing bacteria other than acid-fast bacilli), insufficient inoculum, or cultures that are too old.

mycobacteria. J Clin Microbiol 1975;1:465–468.

C-70

CHART 20-1

Darkfield Microscopy of Genital Lesions

I. Principle

Darkfield detection of spirochetes allows presumptive diagnosis of syphilis during the primary phase before antibody has developed. There are few contaminating spirochetes in genital sites; so detection of spirochetes with a morphology compatible with *Treponema pallidum* subsp. *pallidum* provides a solid diagnosis. The prevalence of spirochetes in the oral cavity essentially precludes the use of darkfield microscopy in this anatomic location.

II. Equipment and Reagents

Microscope with transmitted light and a darkfield condenser. Use a 10× objective to focus the specimen and center the darkfield condenser. Use a 40× to 63× objective to search the specimen. Final identification is made with a 100× objective.

Microscope slides, 1" × 3" Thickness should match that recommended in microscope manual.
Coverglass #1, 22 mm × 22 mm
Immersion oil, nondrying, Cargille type A or equivalent
Lens paper and lens cleaner
Applicator sticks
Sterile saline
Disinfectant, such as iodine or 70% alcohol

III. Quality Control

A scraping of gingival mucosa may be used as a control with which to set up the darkfield condenser.

IV. Procedure

A. Collection of Specimen

1. General

a. Remove any scab or crust covering the lesion.

b. Remove any exudate with a gauze sponge.

c. If necessary, compress the base of the lesion or apply a suction

cup to promote accumulation of tissue fluid on the ulcer surface.

d. Apply a glass slide with a sterile bacteriologic loop.

e. Place a glass coverslip on the specimen and press it down to remove bubbles.

f. Examine immediately.

2. Dry papulosquamous lesions of the skin

a. Gently remove the superficial layer of skin, trying not to cause bleeding.

b. Compress the lesion if very little fluid appears.

c. Touch a microscope slide to the lesion or transfer a small amount of fluid to a slide with a bacteriologic loop.

d. Alternatively, a small amount of sterile saline can be injected into the lesion, aspirated back, and placed on a slide.

e. Place a coverslip on the slide and examine immediately.

3. Cervical/vaginal lesions

a. Under visualization with a bivalve speculum, remove any cervical or vaginal discharge.

b. Obtain serous exudate with a bacteriologic loop.

c. If necessary, serous exudate can be produced by compressing the lesion with a Kelly clamp.

d. Prepare slides as above.

4. Mucous patches

a. Using a sterile bacteriologic loop, collect some of the mucus and place it on a glass slide.

b. Place a coverslip on the slide and examine immediately.

V. Examination of the Specimen

Prepare the darkfield microscope before collection of the specimen.

Using a 40× to 63× objective, search the slide systematically.

When a suspicious structure is found, examine under 100× magnification.

When observation is completed, discard the slide in disinfectant.

Characteristics of *T. pallidum* and saprophytic genital species, *T. refringens*.

Characteristic	*T. pallidum*	*T. refringens*
Morphology		
Shape	Delicate corkscrew shape	Loose coiled, coarse
Length	6–14 μm	8–20 μm

Width	0.25–0.3 µm	0.4–0.75 µm
Spiral wavelength	Approx. 1.0–1.5 µm	

C-71

Motility

Translation	Slow, deliberate back and forth movement	Rapid, writhing motion
Rotation	Slow to rapid rotation (corkscrew); may rotate in place	Active serpentine rotation
Flexion	Rotation accompanied by soft bending and twisting	
Bending occurs stiffly in middle of organism	Marked flexion	
Distortion	May occur as a ring or attached to cells	None noted

VI. Results

A. Interpretation

Positive: Spirochetes present

Negative: Spirochetes absent

False-positive results may occur if specimens from the oral cavity are tested due to the presence of non- *Treponema* spirochetes in such locations.

A few red blood cells in the preparation are a sign that exudate was obtained, but the specimen should not be bloody. The membranes of lysed erythrocytes can form serpentigenous bodies that resemble spirochetes; it is therefore important to differentiate true motility from movement secondary to Brownian motion. Bubbles should also be carefully removed from the preparation.

False-negative results may be obtained if insufficient exudate was obtained, if there was too long an interval between collection and examination, if the lesion is late, or if the patient has been treated with antitreponemal drugs.

CHART 20-2

Venereal Disease Research Laboratory (VDRL) Slide Test on Serum

I. Principle

The VDRL slide test is the reference nontreponemal antibody test for syphilis. It is the only generally recognized test for diagnosing neurosyphilis.

The VDRL is a nontreponemal microflocculation test. It uses an antigen that contains cardiolipin, lecithin, and cholesterol. The antigen forms microscopic clumps when mixed with antibodies to cardiolipin complex.

II. Equipment and Reagents

A. Equipment

1. Nondisposable needles without a bevel
- **a.** Serum test: 18 gauge

2. Bottles: 30-mL, round, narrow-mouthed, 35 mm in diameter, with glass or equivalent stoppers and flat inner-bottom surface (Corning Glass Works, Corning, NY, cat. no. LG-1 MW-90530).

3. Safety pipetting device with disposable tip to deliver 50 mL.

4. Pipettes, serologic, graduated to tip:
- **a.** 1.0 mL, graduated in 1/100 mL
- **b.** 5.0 mL, graduated in 1/10 mL
- **c.** 10.0 mL, graduated in 1/10 mL

5. Slides
- **a.** Serum test: 2 × 3 in., with 12 paraffin or ceramic rings approximately 14 mm in diameter (rings must be high enough to prevent spillage during rotation).
- **b.** 12 concavities measuring 16 mm in diameter and 1.75 mm in depth.

6. Slide holder for 2 × 3-inch slides.

7. Ringmaker to make paraffin rings if ceramic rings not used.

8. Mechanical rotator adjustable to 180 ± 2 rpm, circumscribing a circle 19 mm in diameter on a horizontal plane.

9. Discard containers or disinfectants, disposable latex gloves.

10. Humidifying covers (in dry climates).

B. Reagents

1. VDRL antigen: Store in the dark at room temperature or in refrigerator. Discard vials that contain a precipitate.
2. VDRL-buffered saline, pH 6.0 ± 0.1 (1.0% NaCl) (purchased or prepared)
3. Control serum samples: reactive (R), weakly reactive (W), nonreactive (N)
4. 0.9% saline
5. 10.0% saline

III. Procedures for Serum Tests

A. Preparing the Antigen Suspension

1. Prepare a fresh VDRL antigen suspension each day. The temperature of all reagents should be at 23°C–29°C.
2. Pipette 0.4 mL of VDRL-buffered saline to the bottom of a round, 30-mL, glass-stoppered bottle with a flat inner surface.
3. Add 0.5 mL VDRL antigen directly into the saline while continuously but gently rotating the bottle on a flat surface. Add antigen drop by drop at a rate allowing approximately 6 seconds for each 0.5 mL of antigen. Keep the pipette tip in the upper third of the bottle and do not splash saline onto the pipette tip. The proper speed of rotation is obtained when the center of the bottle circumscribes a 2-inch-diameter circle approximately three times per second.
4. Expel the last drop of antigen from the pipette without touching the pipette to the saline. Continue rotation of the bottle for 10 seconds.
5. Add 4.1 mL buffered saline from a 5-mL pipette.
6. Cap the bottle and shake it from bottom to top and back approximately 30 times in 10 seconds. The antigen suspension must be used within 8 hours.
7. Mix the suspension by gently swirling it each time it is used. Do not mix it by forcing it back and forth through the syringe and needle.

B. Testing Accuracy of Antigen Suspension Needle

1. The accuracy of the test depends on the amount of antigen dispensed. Check the calibrated needle periodically for accuracy.
2. For the qualitative and quantitative tests on serum, dispense the antigen suspension from a syringe fitted with an 18-gauge needle without a bevel, which will deliver 60 ± 2 drops of antigen suspension per milliliter (17 mL/drop) when held vertically.
3. Place the needle on a 2-mL syringe or on a 1-mL pipette and fill the syringe or pipette with VDRL antigen suspension. Holding the syringe or pipette vertically, count the number of drops delivered in 0.5 mL. The needle is correctly calibrated if 30 ± 1 drops are delivered in 0.5 mL. Adjust or replace the needle if it does not meet

the specifications.

C. Testing and Storing the VDRL Antigen Suspension

1. Prepare a fresh antigen suspension each day. Store the suspension at room temperature, 23°C–29°C.

2. Test the antigen suspension with control sera that are reactive, weakly reactive, and nonreactive.

3. Use only suspensions that reproduce the established reactivity pattern of the controls.

4. After completing the day's tests, discard the antigen suspension and clean the dispensing needle and syringe by rinsing with water, alcohol, and acetone, in that order. Remove the needle from the syringe after cleaning.

D. Preparing and Storing Specimens

1. Observe recommended safety precautions for handling human sera.

2. Centrifuge clotted blood at room temperature at 1,500–2,000 rpm for 5 minutes to sediment the cellular elements.

3. Transfer the serum to a clean, dry test tube and heat it in a 56°C water bath for 30 minutes.

4. Recentrifuge any specimen that contains debris after heat-inactivation.

5. Reheat the serum at 56°C for 10 minutes if testing is delayed more than 4 hours.

6. Specimens must be at room temperature (23°C–29°C) at the time of testing.

E. Performing the Qualitative Test on Serum

1. With all reagents at room temperature, place 50 µL of serum into one ring of a paraffin- or ceramic-ringed slide, using a safety pipetting device. Do not use glass slides with concavities, wells, or glass rings.

2. Gently resuspend the VDRL antigen suspension.

C-73

3. Holding the VDRL antigen suspension dispensing needle and syringe in a vertical position, dispense several drops to clear the needle of air. Then add exactly 1 free-falling drop (17 µL) of antigen suspension to each circle that contains serum.

4. Place the slide on a mechanical rotator. Rotate for 4 minutes at 180 ± 2 rpm. In a dry climate, cover the slide with a moist humidifying cover during rotation.

5. Immediately after the completion of rotation, remove the slide from the rotator and read the test results microscopically, using a 10× ocular and a 10× objective.
6. Report the results as follows:

Reading	Report
Medium or large clumps	Reactive (R)
Small clumps	Weakly reactive (W)
No clumping or slight roughness	Nonreactive (N)

7. Test quantitatively to an endpoint all serum specimens that produce reactive, weakly reactive, or "rough" nonreactive results in the qualitative test.

F. Performing the Quantitative Test in Serum

1. Quantitate the serum samples to an endpoint titer. Quantitative tests through the 1:8 dilution for three serum specimens may be performed on one slide.
2. Place 50 mL of 0.9% saline in circles numbered 2 through 4, but do not spread the saline.
3. Using a safety pipetting device, place 50 µL of serum in both circle 1 and circle 2.
4. Mix the saline and the serum in circle 2 by drawing the mixture up and down in the safety pipette eight times. Avoid formation of bubbles.
5. Transfer 50 µL from circle 2 (1:2) to circle 3 and mix.
6. Transfer 50 µL from circle 3 to circle 4 and mix. Discard the last 50 µL.
7. Gently resuspend the VDRL antigen suspension.
8. Holding the VDRL antigen suspension–dispensing needle and syringe in a vertical position, dispense several drops to clear the needle of air. Then add exactly 1 free-falling drop (17 µL) of antigen suspension to each circle.
9. Place the slide on the mechanical rotator. Rotate the slide for 4 minutes at 180 ± 2 rpm. Add a humidifying cover in dry environments.
10. Immediately after rotation, read the test microscopically using a 10× ocular and a 10× objective.
11. If the highest dilution tested (1:8) is reactive, proceed as follows:
    a. Prepare a 1:8 dilution of the test specimen. Add 0.1 mL serum to 0.7 mL of 0.9% saline and mix thoroughly.
    b. Place 50 µL of 0.9% saline into the second, third, and fourth

paraffin rings in a row on the slide. Prepare additional serial dilutions for strongly reactive specimens.

c. Add 50 µL of the 1:8 dilution of the test specimen to paraffin rings 1 and 2.

12. Report titers in terms of the highest dilution that produces a reactive (not a weakly reactive) result:

Serum Dilutions						Report
Undiluted	1:2	1:4	1:8	1:16	1:32	
R	W	N	N	N	N	Reactive, undiluted, 1 dil.
R	R	W	N	N	N	Reactive, 1:2 dilution, 2 dils
R	R	R	W	N	N	Reactive, 1:4 dilution, 4 dils
W	W	R	R	W	N	Reactive, 1:8 dilution, 8 dils
N (Rough)	W	R	R	R	N	Reactive, 1:16 dilution, 16 dils
W	N	N	N	N	N	Weakly reactive, undiluted, 0 dil

IV. Results

A. Interpretation

1. The VDRL test is an aid in the diagnosis of syphilis. A positive test may indicate a past or present infection. False-positive results occur because of laboratory error, infection with other treponemes, or the presence of antibodies unrelated to treponemal infection. The predictive value of a positive VDRL result is increased when combined with a reactive treponemal test, such as the fluorescent treponemal antibody absorption test (Chart 20-4) or the microhemagglutination test.

2. A nonreactive result may indicate no infection, adequately treated infection, or infection in the remote past. A nonreactive result may be obtained in incubating or early primary syphilis. A prozone phenomenon occurs, especially with high titers in secondary syphilis. Sera should be diluted if a rough result is obtained or if clinical information indicates the likelihood of syphilis.

3. A fourfold increase in titer may indicate a reinfection or treatment failure. A fourfold decrease in titer in early syphilis usually indicates adequate therapy.

4. All sera should be titered to the endpoint. Unusually high titers may be seen in some patients who are concurrently infected with human immunodeficiency virus, type 1. Unusually high false-positive titers may be seen in some patients with lymphomas.

V. Sources of Error

1. Reactivity is decreased if the specimen, testing area, or reagents are at temperatures lower than 23°C. Reactivity is increased if any of these are at temperatures higher than 29°C.
2. Test results are unpredictable if hemolyzed, contaminated, or extremely turbid sera are tested.
3. Reactivity will be unpredictable if reagents are outdated, inadequately tested, or if procedures are not followed strictly. Forcing the VDRL antigen through the needle and syringe repetitively will cause the suspension to lose reactivity.

VI. Test Limitations

1. The prozone phenomenon described in the foregoing may produce false-negative results on high-titered sera.
2. The VDRL antigen suspension must be prepared daily.
3. The VDRL cerebrospinal fluid (CSF) test should be performed only if the serum test is reactive.
4. Plasma cannot be used for the VDRL test.
5. Biologic false-positive results occur with cardiolipin antigens, especially in specimens from persons who abuse drugs; individuals with diseases such as lupus erythematosus, mononucleosis, malaria, leprosy, or viral pneumonia; or those who have recently been immunized.
6. Note: The VDRL slide test on CSF is similar to the serum test, but there are important methodologic differences (see bibliography). Only reactive and nonreactive results are reported on CSF.

VII. Bibliography

CHART 20-3

Rapid Plasma Reagin (RPR) Card Test

I. Principle

The RPR Card Test was instituted as the routine screening test in the Maryland State Department of Health Laboratories on January 13, 1964. The main advantages of the RPR over the VDRL test are that the serum does not have to be heat-treated, interpretations are made macroscopically

instead of microscopically, the antigen is stable, and components are disposable. Tests can be performed rapidly and inexpensively, thereby making the technique suitable for large-volume operations. The sensitivity and specificity of the RPR test are equal to those of the VDRL and other nontreponemal serologic tests.

The RPR antigen suspension is a carbon-containing cardiolipin antigen that detects "reagin," an antibody-like substance present in the plasma and sera of persons with syphilis or previous exposure to the treponema spirochete. When a specimen contains specific antibody, flocculation occurs with coagglutination of the carbon particles of the RPR card antigen, appearing as black clumps against a white background of the plastic-coated card. This coagulation can be read macroscopically; nonreactive specimens have a smooth, milky light-gray color.

II. Equipment, Supplies, and Reagents

1. Disposable, calibrated 20-gauge needle without bevel, silicone-treated
2. Plastic antigen-dispensing bottle, 1 dram
3. Plastic-coated RPR cards with 10 circles, each approximately 18 mm in diameter
4. Dispenstirs, a disposable (plastic) dispensing-stirring device that delivers 50 µL
5. Mechanical rotator, fixed speed or adjustable to 100 ± 2 rpm, circumscribing a circle 3/4 in. in diameter on a horizontal plane
6. Humidifying cover for rotator
7. High-intensity incandescent lamp
8. Safety pipetting device with disposable tip that delivers 50 µL
9. Discard containers and disinfectants

10. Disposable latex gloves, safety glasses, and protective clothing
11. RPR antigen suspension (a variation of the VDRL antigen): a stabilized combination of 0.003% cardiolipin, 0.020%–0.022% lecithin, 0.09% cholesterol, 10% choline chloride, 0.0125 M EDTA, 0.1875% charcoal, 0.1 M Na_2HPO_4, 0.01 M KH_2PO_4, 0.1% thimerosal, and distilled water
12. Control serum samples: lyophilized reactive (R), minimally reactive (MR), and nonreactive (N) control serum specimens on a card
13. 0.9% saline as a diluent

III. Procedures

A. Testing Accuracy of Antigen Needle

1. Check the calibrated needle periodically to be sure that it delivers

60 ± 2 drops/mL (17 µL). The accuracy of the test depends on the amount of antigen used.

2. Consult the procedure for calibrating needles in the VDRL test (Chart 20-2).

B. Testing and Storing the Antigen Suspension

1. Store ampules of antigen at 2°C–8°C. Do not store in the bright sunlight. Do not store above 29°C and do not freeze. Antigen in an opened ampule is stable for up to 12 months.
2. Attach the needle hub to the fitting on the plastic dispensing bottle. Open the ampule after shaking it to resuspend the particles. Squeeze the dispensing bottle to collapse it, insert the needle into the ampule, and withdraw all the antigen suspension into the dispensing bottle. Shake the dispensing bottle gently before each series of antigen drops is delivered.
3. Test each lot of antigen suspension in parallel with an antigen of known standard reactivity before putting it into use.
4. At each routine test run, test the reactivity of the antigen with control cards or sera of known reactivity. Use only suspensions that produce appropriate activity.
5. After completion of the day's work, remove the needle from the antigen-dispensing bottle, rinse in distilled water, and air-dry. Do not wipe the needle, as this action will remove the silicone coating.

C. Preparing and Storing Specimens

1. Either serum or plasma may be tested. Plasma is obtained by collecting blood into a tube that contains EDTA as an anticoagulant.
2. Do not test specimens that are grossly contaminated, excessively hemolyzed, or chylous.

D. Performing the Qualitative Test

1. All reagents should be at room temperature (23°C–29°C) before tests are performed.
2. Place 50 µL of serum or plasma into an 18-mm circle of the RPR test card, using a disposable Dispenstir or a safety pipetting device.
3. With the inverted Dispenstir (closed end) or flat toothpicks, spread the serum or plasma to fill the entire circle, but not to extend beyond the bounds of the circle.
4. Gently shake the antigen-dispensing bottle to resuspend the particles.
5. While holding the dispensing bottle and needle in a vertical position, dispense several drops to clear the needle of air. Then add exactly 1 free-falling drop (17 µL) of antigen suspension to each circle containing serum or plasma. Do not mix the antigen and serum

or plasma.

6. Place the card on the mechanical rotator under a humidifying cover. Rotate the card for 8 minutes at 100 ± 2 rpm.
7. Immediately remove the card from the rotator. Briefly rotate and tilt the card by hand to aid in differentiating nonreactive from minimally reactive results. Read the test reactions in the "wet" state, using a high-intensity incandescent light, without magnification.
8. Report the results as follows:

Reading	Report
Characteristic clumping ranging from marked and intense (reactive) to slight but definite (minimally reactive)	Reactive (R)
Slight roughness or no clumping	Nonreactive (N)

9. Perform the quantitative test on serum specimens showing any degree of reactivity or "roughness."

IV. Performing the Quantitative Test

1. Quantitate to an endpoint all serum specimens with reactive or rough nonreactive results in the qualitative test. Test each specimen undiluted (1:1) and in 1:2, 1:4, 1:8, and 1:16 dilutions.
2. Place 50 µL of 0.9% saline in circles numbered 2 through 5. Do not spread the saline.
3. Using a safety pipette device, place 50 µL of serum in circle 1 and 50 µL of serum in circle 2. Mix the saline and the serum in the circle by drawing the mixture up and down in the safety pipette eight times. Avoid forming bubbles.

4. Transfer 50 µL from circle 2 (1:2) to circle 3 and mix.
5. Transfer 50 µL from circle 3 (1:4) to circle 4 and mix.
6. Transfer 50 µL from circle 4 (1:8) to circle 5 (1:16) and mix. Discard the last 50 µL.
7. With the broad end of a clean Dispenstir, spread the serum dilution to fill the entire surface of circle 5, the highest dilution (1:16). With the same Dispenstir, do the same for circles 4 (1:8), 3 (1:4), 2 (1:2), and 1 (undiluted).
8. Gently shake the dispensing bottle to resuspend the antigen particles.
9. Holding the antigen-dispensing bottle in a vertical position, dispense 1 or 2 drops to clear the needle of air. Then add exactly 1 free-falling drop

(17 µL) of antigen suspension in each circle. Do not mix.

10. Place the card on the rotator under the humidifying cover and rotate the card for 8 minutes at 100 ± 2 rpm.
11. Immediately remove the card from the rotator; briefly rotate and tilt the card by hand (three or four to-and-fro motions) to aid in differentiating nonreactive from minimally reactive results. Read the results in the wet state with the unaided eye, using a bright incandescent light.
12. Report the results in terms of the highest dilution that has given a reactive result, including a minimally reactive result, as follows:

Serum Dilutions					Report
Undiluted	**1:2**	**1:4**	**1:8**	**1:16**	
RM	N	N	N	N	Reactive, undiluted
R	R	R	N	N	Reactive, 1:4 dilution
R	R	R	RM	N	Reactive, 1:8 dilution

R, Reactive; RM, Reactive, minimally; N, nonreactive.

Note: Report the result as either reactive or nonreactive; there is no minimally reactive report in the RPR card test.

V. Results

A. Interpretation

1. Clinicians must combine the results of this test with the clinical and epidemiologic information. The predictive value of a positive RPR test is increased if the specimen is also reactive in a specific treponemal test, such as the fluorescent treponemal antibody absorption test (FTA-ABS).
2. A reactive test indicates present or past inadequately treated infection or a false-positive reaction. Technical false-positive reactions may be detected by a negative RPR test when repeated. Biologic false-positive reactions are detected by a negative specific treponemal test, such as the FTA-ABS test.
3. A negative test in the absence of clinical symptoms may indicate no infection or adequately treated infection in the past. A negative test may also occur during the incubation period before the first symptoms have manifested. A negative test in the presence of clinical symptoms may occur during early primary syphilis, as a prozone during secondary syphilis, or occasionally in tertiary syphilis.
4. When the quantitative RPR test is performed on patients with syphilis, a fourfold rise in titer may indicate an active infection, a reinfection, or failure of therapy. A fourfold fall in titer usually

means adequate syphilis therapy.

5. All reactive qualitative RPR tests should be titered to an endpoint and the endpoint titer reported. Very high RPR card titers may occur in patients with HIV infection. Very high false-positive titers may occur in patients with lymphomas.

B. Acceptable Variations

1. Prepare a 1:16 dilution for further quantitation, using 50 µL of specimen to 750 µL of 0.9% saline.
2. If, after screening, the serum to be quantitated seems likely to exceed 1:16, prepare all dilutions directly on the card, using a 1:50 nonreactive serum as the diluent beginning with circle 6 (1:32) and continuing for the remainder of the card.

VI. Sources of Error

1. If the temperatures of the sera, reagents, or testing area are lower than 23°C, test reactivity decreases; if temperatures are higher than 29°C, test reactivity increases.
2. If the speed of the mechanical rotator is too fast or too slow, improper mixing of antigen and antibody will yield unpredictable results.
3. If the card is excessively rotated and tilted by hand after removal from the rotator, a false-positive reaction may occur.
4. If lighting produces a glare on the card, results may be obscured.
5. If the antigen is outdated or not tested for standard reactivity, results may be unpredictable.

6. If the serum is unevenly spread in the circle, the antigen and antibody may not mix properly.
7. If hemolyzed, contaminated, or improperly collected serum or plasma samples are tested, the reaction may be masked.
8. If plasma specimens are stored at –20°C for longer than 1 week, the specimens become unsuitable for testing.
9. If the moistened humidifying cover is not used to cover tests as they are being rotated, proper humidity will not be maintained, and test components may dry on the card, causing false-positive reactions to occur.

VII. Test Limitations

1. The RPR card tests cannot be used to test spinal fluids.
2. A prozone reaction may be encountered occasionally. In a prozone reaction, complete or partial inhibition of reactivity occurs with undiluted serum. The prozone phenomenon may be so pronounced that only a

rough reaction is produced in the qualitative test by a serum that will be strongly positive in the quantitative test. Any specimen that produces any degree of roughness or reactivity in the qualitative test should be retested in the quantitative test.

3. The RPR test may be reactive in persons from areas where yaws, pinta, or nonvenereal syphilis is endemic. As a general rule, residual titers from these infections will be less than 1:8.
4. Biologic false-positive reactions occur occasionally, particularly in persons who abuse drugs; who have diseases such as lupus erythematosus, mononucleosis, malaria, leprosy, or viral pneumonia; or who have been vaccinated recently.
5. Nontreponemal test titers of persons who have been treated in latent or late stages of syphilis or who have been reinfected do not decrease as rapidly as those who are treated in early primary infection. Some of these individuals may become "serofast," retaining their reactivity for life.

CHART 20-4

Fluorescent Treponemal Antibody Absorption Test (FTA-ABS)

I. Principle

The fluorescent treponemal antibody absorption test (FTA-ABS) is an indirect fluorescent antibody technique (Chapter. 3). The patient's serum, which has been diluted 1:5 in sorbent (an extract from cultures of *Treponema phagadenis,* the Reiter treponeme), is layered on a microscope slide to which *T. pallidum* subsp. *pallidum* has been fixed. If the patient's serum contains antibody to *T. pallidum,* it will coat the treponeme. When fluorescein isothiocyanate (FITC)-labeled anti-human globulin is added, it will fix to any antibodies that have become affixed to the spirochete. The fluorescent reaction is visible when viewed by fluorescence microscopy.

II. Materials

A. Equipment

Incubator, 35°C–37°C
Water bath, adjustable to 56°C
Safety pipetting devices
Micropipettors delivering 10–200 µL
Loop, bacteriologic standard, 2 mm, 26-gauge, platinum
Bibulous paper
Slide board with moist chamber and paper towels
Staining dishes, glass or plastic, with removable slide carriers
Microscope slides, 1 × 3 in., with frosted end, 1-mm thick, with two etched circles, 1-cm inside diameter
Coverslips, No. 1, 2-mm square
Test tubes (12 × 75 mm) and holders
Discard containers and disinfectants
Disposable latex gloves, safety glasses, and protective clothing
Fluorescence microscope set up for fluorescein microscopy
Mixer; Vortex Jr. or equivalent

C-78

B. Reagents

1. Purchased

a. *T. pallidum* antigen: A suspension of *T. pallidum* (Nichols strain) extracted from rabbit testicular tissue and washed in phosphate-buffered saline to remove rabbit globulin.

b. FITC-labeled antihuman IgG.

c. Sorbent: Prepared from cultures of nonpathogenic Reiter treponemes, usually with no preservative added. Frequently dispensed in 5-mL amounts and freeze-dried, but also sold in liquid state.

d. Reactive control serum: A pool of human serum samples obtained from syphilitic donors that are 4+ reactive. Used to prepare 4+ serum controls and minimally reactive 1+ control. The 1+ control demonstrates the minimal degree of fluorescence reported as reactive and is used as a reading standard.

e. Nonspecific control serum: A serum pool obtained from nonsyphilitic individuals. No preservative is added. This control demonstrates a ≥2+ nonspecific reactivity at a 1:5 dilution in phosphate-buffered saline (PBS) and essentially no staining when diluted 1:5 in sorbent.

f. Oil: Low fluorescence, nondrying, immersion oil, type A,

Cargille No. 1248

g. Acetone: ACS reagent grade

2. Prepared

a. PBS, pH 7.2

b. 2% Tween 80 (polysorbate 80) in PBS. Heat the reagents in a 56°C water bath. To 49 mL of sterile PBS, add 1 mL of Tween 80, by measuring from the bottom of a pipette and rinsing the pipette in the mixture. Check pH and adjust to pH 7.2 with 1 N NaOH. Discard if a precipitate develops or the pH changes.

c. Mounting medium: Add 1 part PBS to 9 parts glycerin (reagent grade).

d. Distilled water

III. Preparing Test Reagents

A. *T. pallidum* Antigen

1. Rehydrate antigen according to manufacturer's instructions. Opened vials, stored at 2°C–8°C, are stable for 1 week.

2. To prepare slides, mix antigen suspension thoroughly on a mixer for 10 seconds. Determine by darkfield examination that treponemes are adequately dispersed before making slides for the FTA-ABS test.

3. Wipe slides with clean gauze to remove dust particles. Clean slides by sonic vibration or alcohol wiping if treponemes are not clearly observed after staining.

4. Prepare very thin *T. pallidum* antigen smears within each circle by using a 2-mm wire loop. Place one loop of antigen within the two 1-mm circles. Allow to air-dry at least 15 minutes.

5. Fix slides in acetone for 10 minutes and air-dry. Fix no more than 60 slides with 200 mL of acetone. Store acetone-fixed smears at –20°C. Do not thaw and refreeze smears.

6. Store unopened vials of antigen at 2°C–8°C. The unopened antigen is stable until the expiration date.

B. Titration of Antihuman IgG Globulin

1. Rehydrate conjugate according to directions. If the conjugate is cloudy, centrifuge it at 500 *g* for 10 minutes. Aliquot in small volumes and store at –20°C. Do not refreeze thawed conjugate, but store at 2°C–8°C.

2. Prepare 4+ and 1+ dilutions of the reactive control serum to determine conjugate working dilution.

3. Run the control pattern with a reference or a known conjugate. An example is shown:

Conjugate Dilutions	Nonspecific-Staining Control (PBS)	Reactive (4+) Control Serum (1:5 in PBS)	Reaction (1+) Control Serum
Reference Conjugate			
Dilution 1:400	–	4+	1+
New Conjugate			
1:12.5	<1+	4+	3+
1:25	–	4+	3+

1:50	–	4+	3+
1:100	–	4+	2+
1:200[a]	–	4+	1+
1:400	–	4+	<1+
1:800	–	3+	±

[a]The dilution selected for the working titer is 1:200, one doubling dilution below the 4+ endpoint (1:400), 1 + staining with the 1 + control dilution (1:200), and no nonspecific staining for three doubling dilutions below the working dilution (1:25).

C. Sorbent

1. Rehydrate freeze-dried material with sterile distilled water or according to manufacturer's instructions. The rehydrated sorbent may be stored at 2°C–8°C or at –20°C. It can be used as long as acceptable reactivity is obtained and the product is not contaminated.

D. Test Serum

1. Observe recommended safety precautions for handling human serum.

2. Heat the test and control sera at 56°C for 30 minutes before testing.

3. Reheat previously heated test sera for 10 minutes at 56°C on the day of testing.

E. Control Test

1. Rehydrate serum according to manufacturer's instructions.

2. Aliquot in 0.25 mL amounts and store at −20° for as long as acceptable reactivity is obtained.

3. Prepare the following controls for each test run:

a. Reactive (R) 4+ control serum: a syphilitic serum showing 4+ fluorescence in the unabsorbed test and only slightly reduced fluorescence in the absorbed test. To produce unabsorbed serum, add 50 mL of reactive control serum to a tube containing 200 µL PBS and mix well. To produce absorbed serum, transfer 50 µL of reactive control serum to a tube containing 200 µL PBS

and mix well. To produce absorbed serum, transfer 50 µL of reactive control serum to a tube containing 200 µL of sorbent and mix well.

b. Minimally reactive (MR) control serum: This is a dilution in PBS of the reactive control serum, which will give the minimal degree of fluorescence (1+) considered reactive.

c. Nonspecific (NS) control serum: a nonsyphilitic serum showing ≥2+ fluorescence in the unabsorbed test. To produce the unabsorbed serum, transfer 50 µL of nonspecific control serum to a tube containing 200 mL of PBS and mix well. To produce the absorbed serum, transfer 50 µL of nonspecific control serum to a tube containing 200 µL of nonspecific control serum into a tube containing 200 µL of sorbent and mix well.

d. Controls for nonspecific staining by conjugate consist of an antigen smear overlaid with 30 µL of PBS in place of serum and an antigen smear overlaid with 30 µL of sorbent in place of serum.

F. The FTA-ABS Test

1. Identify previously prepared antigen slides by numbering the frosted end.

2. Number each tube and slide to correspond to the test serum and the control serum to be used.

3. Prepare reactive (4+), minimally reactive (1+), and nonspecific control serum dilutions in sorbent or PBS according to the directions.

4. Pipette 200 µL of sorbent into a test tube for each test serum.

5. Add 50 µL of the heated test serum to the appropriate tube and mix eight times.

6. Cover the appropriate antigen smears with 30 mL of the reactive (4+), minimally reactive (1+), and nonspecific control serum dilutions.

7. Cover the appropriate antigen smears with 30 µL of the PBS and 30 µL of the sorbent for nonspecific-staining controls a and b. The controls should give the following pattern:

Control Pattern for the FTA-ABS Test

Reactive control	a. 1:5 PBS dilution b. 1:5 Sorbent dilution	R4+ R(4+ −3+)
Minimally reactive control	1+ Control dilution	R1 +

Nonspecific serum controls	a: 1:5 PBS dilution b. 1:5 Sorbent dilution	R(2+ −4+) N−±
Nonspecific-staining controls	a. Antigen, PBS, conjugate b. Antigen, sorbent, conjugate	N N

8. Cover the appropriate antigen smears with 30 µL of the test serum dilutions.
9. Prevent evaporation by placing slides in a moist chamber and incubate at 35°C–37°C for 30 minutes.
10. At the completion of the incubation perform the following rinses:
    a. Place slides in slide carriers and rinse 5 seconds with running PBS.
    b. Place slides in staining dish containing PBS for 5 minutes.
    c. Agitate slides by dipping them into the PBS at least 30 times.
    d. Using fresh PBS, repeat the above two steps.
    e. Rinse slides for 5 seconds in running distilled water and gently blot with bibulous paper.
11. Dilute FITC-labeled antihuman IgG to its working titer in PBS containing 2% Tween 80 and place approximately 30 µL of the diluted conjugate on each smear.
12. Repeat incubation and rinsing of slides.
13. Mount slides immediately by placing a small drop of mounting medium on each smear and applying a cover glass.
14. Place slides in a darkened room and read within 4 hours.
15. Check smear by darkfield microscopy using the tungsten lamp first, to verify the presence of treponemes on the smear, then read FITC (test) fluorescence.
16. Using the minimally reactive (1+) control slide as the reading standard, record the intensity of fluorescence of the treponemes:

RECORDING INTENSITY OF FLUORESCENCE

Reading	Intensity of Fluorescence
2+ to 4+	Moderate to strong
1+[a]	Equivalent to minimally reactive (1+) control
± to <1+	Visible staining but less than 1+
−	None or vaguely visible but without distinct fluorescence

Atypical[b]	Varied: treponemes appear to be "moth-eaten" or to have "beads" of fluorescence throughout their length

[a]Retest all specimens that initially give a 1+ intensity of fluorescence.

[b] Atypical or beaded pattern of fluorescence has been described in patients with lupus and other autoimmune diseases.

17. Report the result as follows:

REPORTING SYSTEM FOR FTB-ABS TEST

Initial Test Reading	Repeat Test Reading	Report
4+		Reactive
3+		Reactive
2+		Reactive
1+	>1+	Reactive
1+	1+	Reactive minimal[a]
1+	<1+	Nonreactive
<1+		Nonreactive
N		Nonreactive
Beaded fluorescence		Atypical Fluorescence Observed[b]

[a] In the absence of evidence of treponemal infection, this test result should be considered equivocal. A second specimen should be obtained 1–2 weeks after the initial specimen and submitted to the laboratory for serologic testing.

[b] Beaded fluorescence has been observed in serum from patients with active systemic lupus erythematosus and from patients with other autoimmune diseases. The DNA absorption procedure can be requested from the Treponemal Pathogenesis and Immunobiology Branch, Division of Sexually Transmitted Diseases, CDC, Atlanta, GA, 30333. The request must be routed through the appropriate State Health Department.

C-81

IV. Acceptable Variations

1. Reading of slides may be delayed beyond 4 hours if slides are protected

from light and stored at 2°C–8°C. For the test to be valid with a delayed reading, *the complete control pattern must be clearly satisfactory when the slides are read.*

2. Conjugate that has been filter-sterilized and contains a preservative, such as sodium azide, to prevent bacterial contamination may be stored at 2°C–8°C. Any precipitate or cloudiness must be removed by centrifugation.
3. Slides may be held from 30 minutes–1 hour in PBS if the test is interrupted. For the results to be valid, control slides must react appropriately when the test is read.
4. Multicircle slides may be used rather than the two-circle slide. Add only 10 µL volumes to the antigen smears. Exercise care in handling and washing slides to prevent serum runover.
5. With accurate micropipettors, the 1:5 test dilution may be prepared by pipetting 25 µL of serum into 100 µL of diluent.

V. Sources of Error

1. If reagent evaluation procedures are not strictly followed, results will be unreliable.
2. If multicircle slides are used and serum from one well is allowed to run onto another well, serum from a person without syphilis may appear reactive.
3. If microscope slides are not clean, the test may be difficult to read and the results unreliable.
4. If the FTA-ABS test is used as a screening procedure, rather than to confirm the reactive results of a nontreponemal test, or as a specific diagnostic test in patients with signs or symptoms of late syphilis, the positive predictive value of the FTA-ABS test is decreased.
5. If the microscope is not properly aligned and the control pattern is not obtained, the test results are invalid.
6. If reagents become contaminated with bacteria, the antibody may be reduced and the results may be invalid.
7. If reagent storage instructions are not followed, the reagents will not produce satisfactory control results.
8. If frozen antigen slides are thawed and refrozen, the treponemes will be difficult to see and the test results will be unsatisfactory.
9. If a serum is contaminated with bacteria or is excessively hemolyzed, the test results may be invalid.
10. If antigen slides are not dried and stored according to the procedure or if too much volume is placed on the slide, the antigen may wash off. One loop of antigen is sufficient for two 1-cm circles.
11. If too many smears are fixed in a given volume of acetone, the

background staining may be increased.

12. If rehydrated antigen does not adhere to the slide, too few treponemes may be observed.
13. If a precipitate is observed in conjugate preparation, nonspecific staining may be observed.
14. If the atypical staining pattern of beaded fluorescence is not recognized, these specimens may be incorrectly reported as reactive.
15. If FTA-ABS slides are read on a microscope equipped with incident illumination, the nonreactive slides must be examined by darkfield examination for the presence of treponemes.

VI. Test Limitations

1. The FTA-ABS test is not intended for routine use or as a screening procedure. Its greatest value is in distinguishing true-positive nontreponemal results from false-positive results and to establish the diagnosis of late latent or late syphilis.
2. Problems arise when the FTA-ABS test is used as a screening procedure, because approximately 1% of the general population will be falsely positive.
3. Although false-positive results in the FTA-ABS test are often transient and the cause is unknown, a definite association has been made between false-positive FTS-ABS results and the diagnosis of discoid, systemic, and drug-induced varieties of lupus erythematosus.
4. Unexplained FTA-ABS reactive results may occur in elderly patients.

CHART 22-1

Fecal Concentration Techniques for the Recovery of Intestinal Parasites

I. Principle

The number of parasitic forms in fecal specimens is often too low to be observed microscopically in direct wet mounts or in stained smear

preparations. Concentration procedures must therefore be used for their detection. The two most commonly used techniques are sedimentation and flotation.

A. Sedimentation Techniques

Sedimentation techniques are performed most commonly in general diagnostic microbiology laboratories because they are easier to perform and less prone to technical errors. Sedimentation takes advantage of the high-specific gravity of protozoan cysts and helminth eggs compared to water. Their natural tendency to settle out in aqueous solutions can be accelerated by low-level centrifugation. A formalin–ethyl acetate mixture, or other preservative that avoids the problems of the potential flammability of ether, may be added to the final suspension to clear out fecal debris and fix any parasitic forms that may be present.

B. Flotation Techniques

The main advantage of the flotation technique is that preparations for microscopic study have a cleaner background. Flotation takes advantage of the property of many protozoan cysts and helminth eggs to float to the surface of a solution of high-specific gravity. A zinc sulfate solution with a specific gravity of 1.180 is most commonly used. The parasites that float to the top can be harvested by skimming the surface layer of solution with a wire loop. Flotation techniques have the disadvantages that some parasite eggs do not float, and of those that do, the walls of eggs and cysts will often collapse, compromising their identification.

II. Reagents

1. Sedimentation Procedure:

Ethyl acetate
10% buffered formalin
0.85% NaCl
D'Antoni's or Lugol's iodine

2. Flotation Procedure:

10% buffered formalin
0.85% NaCl
Zinc sulfate (33% aqueous solution)
Zinc sulfate 330 g
Distilled water 670 mL

Dissolve zinc sulfate in distilled water in an appropriate flask with a magnetic stirrer. Adjust the specific gravity to 1.20 by adding more zinc sulfate or distilled water as needed. Store in a bottle with a glass-stopper. Shelf life is 2 years.

III. Procedure

A. Sedimentation Technique

1. Wear gloves when handling stool specimens.
2. In a suitable container, thoroughly mix a portion of stool specimen about the size of a walnut into 10 mL of saline solution. Mix thoroughly.
3. Filter the emulsion through fine mesh gauze into a conical centrifuge tube.
4. Centrifuge the suspension at relative centrifugal force (RCF) of 600 *g* (about 2,000 rpm) for no less than 10 minutes. The suspension should yield about 0.75 mL of sediment for fresh specimens and 0.5 mL for formalin-fixed feces.
5. Decant the supernatant and wash the sediment with 10 mL of saline solution. Centrifuge again and repeat washing until the supernatant is clear.
6. After the last wash, decant the supernatant and add 10 mL of 10% formalin to the sediment. Mix and let stand for 5 minutes to effect fixation.
7. Add 1–2 mL of ethyl acetate, stopper the tube, and shake vigorously.
8. Centrifuge at 450 *g* RCF (about 1500 rpm) for 10 minutes. Four layers should result as follows: (1) a top layer of ethyl acetate; (2) plug of debris; (3) layer of formalin; and (4) sediment.
9. Free the plug of debris from the side of the tube by ringing with an applicator stick. Carefully decant the top three layers.
10. With a pipette, mix the remaining sediment with the small amount of remaining fluid and transfer one drop each to a drop of saline and iodine on a glass slide. Cover with a coverslip and examine microscopically for the presence of parasitic forms. Systematically examine the entire surface of

C-83

each coverslip with the 10× objective; if nothing is seen, scan about half of each coverslip with the 40× objective.

B. Flotation Technique

1. Add 1 part feces (a quantity sufficient to yield about 0.75 mL of sediment) to 3–5 parts of 10% formalin. Mix thoroughly and allow to stand for 30 minutes to effect fixation.
2. Strain the well-mixed fecal-formalin suspension through one layer of gauze into a round-bottom tube (100 × 26 mm) to within 3/4 inch (19.05 mm) of the top of the rim.
3. Centrifuge the suspension at 600 *g* RCF (about 2000 rpm) for 3–5

minutes. Let centrifuge come to rest without mechanical braking.

4. Decant the supernatant and drain the last drop onto a clean section of paper towel.
5. Add $ZnSO_4$ solution to within 1 inch (25 mm) of the rim of the tube.
6. With two applicator sticks, resuspend the packed sediment until no coarse particles remain.
7. Immediately centrifuge the suspension for 1.5 minutes at 450 *g* RCF (about 1500 rpm). Again, allow the centrifuge to stop without mechanical braking.
8. Carefully transfer the tube to a rack that will hold it in a straight, upright position. Allow the tube to stand for 5–10 minutes.
9. With a 7-mm-diameter wire loop bent at a right angle at the stem, transfer two loops of surface film to a drop of 0.85% saline and to a drop of D'Antoni's or Lugol's iodine reagent on a glass slide, separated sufficiently so that the fluids do not mix when a coverslip is added. Mix each suspension with an applicator stick.
10. Place a clean #1 coverslip on each fluid mount. Examine each preparation within 1 hour. Systematically examine the entire surface of each cover slip with the 10× objective; if nothing is seen, scan about half of each coverslip with the 40×objective.

IV. Quality Control

1. Check solutions with each use to be sure that they are clear and free of any bacterial contamination.
2. Run known positive specimens through the procedure to verify organism recovery. This should be done at least two times per year.

V. Results

Report protozoan cysts, trophozoites, and helminth eggs and/or larvae as may be appropriate. Semiquantitation of results may be helpful in some cases. A permanently stained smear may be required to confirm the species identification of parasitic forms seen in the sediment or flotation preparations.

VI. Procedure Notes

A. Sedimentation

1. The sedimentation procedure can also be used to process polyvinyl alcohol (PVA)-fixed specimens. Alter the procedure by filling one half of a tube with the stool-PVA mixture and add 0.85% NaCl almost to the top of the tube. Then filter the mixture through wet gauze into a 15-mL centrifuge tube and follow the remaining standard procedure.
2. If ethyl acetate is used, swab the insides of the tube with a cotton-

tipped applicator stick after the plug of debris is rimmed and the excess fluid is decanted. Excess ethyl acetate in the sediment at the time smears are prepared will lead to bubbles that may obscure the parasitic forms.

3. Errors in interpretation may occur if the amount of feces is too much or too little in the sedimentation procedure. Adhere to the recommended formula of 0.75 mL of sediment for fresh specimens and 0.5 mL for formalin-fixed feces as outlined in step 4 of the procedure.
4. Allow the centrifuge to reach maximum speed before the time is monitored. If the centrifugation time is too little, certain smaller parasitic forms, such as the oocysts of *Cryptosporidium* species, may not reach the sediment.

B. Flotation

1. Zinc sulfate flotation techniques have the general advantage that the background fecal debris is eliminated, exposing any cysts or eggs that may be present.
2. The flotation mount should be prepared within 12 hours after preparation because cysts and eggs begin to resettle after that time.
3. In preparing the mount, do not use the wire loop as a "dipper." Only the very surface of the flotation mixture should be touched; make sure the loop is not below the surface film.
4. An alternative procedure for preparing the mount is to add a small amount of zinc sulfate to the tube after the final centrifugation step to form a slightly convex meniscus. A coverslip can be gently placed on top of the meniscus and left undisturbed for 5 minutes. Carefully remove the coverslip and place it on a glass slide for examination.
5. When calibrating the specific gravity of the zinc sulfate, spin the hydrometer lightly to free it from the sides of the tube. Read the bottom of the meniscus and correct for temperature (add or subtract 0.001 for each degree above or below the calibration temperature of hygrometer, which is usually 20°C).

C-84

VII. Limitation of Procedure

Certain parasites such as *Giardia*, hookworm eggs, and *Trichuris* eggs may not concentrate well from PVA-preserved specimens. The oocysts of *Cystoisospora belli* do not routinely appear in concentrates. Therefore, examination of permanently stained smears is highly recommended.

Protozoan cysts and helminth eggs with thin shells may collapse on

prolonged exposure to the high-specific-gravity environment of the zinc sulfate solution. Therefore, preparations should be made as soon as possible after the centrifuge stops. Operculate eggs may open, causing them to sink to the bottom. Thus, both the surface film and the sediment should be examined to ensure that no parasitic forms are being missed.

With both the sedimentation and the flotation techniques, species identification may not be possible in all cases, depending on the clarity of the forms observed. Permanently stained smears are usually required to make the final identification, particularly when attempting to confirm the identity of *Entamoeba histolytica* cysts.

CHART 22-2

Trichrome-Staining Technique for Fecal Smears

I. Principle

Because the refractive index of protozoan cysts and some helminth eggs is near that of water, staining procedures are required for optimal detection and for detailed study of their internal structures. Permanent stains enhance the identification of *Entamoeba histolytica* and the detection of *Giardia*, two of the more commonly encountered and important protozoa. The Wheatley trichrome technique, a modification of the original Gomori technique, which contains chromotrope 2R and light green SF as the primary staining agents, is the stain used in most clinical parasitology laboratories. It is easy to perform, rapid, and it produces uniformly excellent staining of most parasitic

forms. Smears made from fresh fecal material must be fixed; polyvinyl alcohol (PVA) samples are already fixed and need no additional treatment.

II. Reagents

Chromotrope 2R	0.6 g
Light green SF	0.3 g
Phosphotungstic acid	0.7 g
Acetic acid (glacial)	1.0 mL
Distilled water	100 mL

Add 1.0 mL of acetic acid to the dry components. Allow the mixture to sit for 15–30 minutes at room temperature before adding 100 mL of distilled water. The stain should appear purple. When properly stored in glass or plastic bottles at room temperature, the shelf life is 2 years.

Iodine–Alcohol Solution.

70% ethanol plus iodine

Add sufficient iodine crystals to 70% alcohol to make a dark, concentrated stock. At the time of use, dilute the desired amount of stock solution with 70% alcohol until a port-wine working solution is obtained. The exact concentration is not critical.

III. Quality Control

1. It is recommended that several smears of material containing parasitic organisms of known staining properties be stained in parallel with each unknown smear. If staining is of poor quality, the smears may have been too thick or poorly fixed, or residual $HgCl_2$ may not have been removed owing to the use of an alcohol–iodine mixture that was too weak. Properly fixed smears produce a blue-green cytoplasm of protozoan trophozoites with a slight tinge of purple. Nuclei and inclusions are red, tinged with purple. Cloudy preparations may result if dehydration is incomplete owing to failure to change

alcohol solutions that may have become contaminated with water. Staining quality can be improved by draining slides between transfers from one reagent to another.

IV. Procedure

1. Wear gloves when handling stool specimens.
2. With a small portion of the fresh stool specimen, prepare two smears on a microscope slide by using an applicator stick or brush.
3. Immerse smears immediately in Schaudinn's fixative and allow to fix

for a minimum of 30 minutes. Overnight fixation is preferred.

4. If the specimen is liquid, mix several drops of fecal material with three or four drops of PVA on a glass slide and let it dry for several hours in a 37°C incubator.
5. If the specimen is in PVA, pour some of the mixture onto a paper towel to absorb out the PVA. Prepare slides of the material from the paper towels as described.

V. Staining Procedure

1. After smears are properly fixed and dried, place slides in the 70% ethyl alcohol for 3 minutes.
2. Place slides in alcohol-iodine working solution for 2–5 minutes.
3. Wash with two changes of 70% alcohol, one for 5 minutes and one for 2–5 minutes.
4. Place in trichrome-staining solution for 10 minutes.
5. Place in acidified 90% ethyl alcohol for 5 seconds.
6. Dip slides several times in 100% ethanol.
7. Place in two changes of 100% ethyl alcohol.
8. Remove alcohol with two changes of xylene or toluene for 2–5 minutes each.
9. Add mounting medium and overlay with a #1 coverslip.
10. Examine under oil immersion for parasitic forms.

VI. Results

The cytoplasm of thoroughly fixed and well-stained cysts and trophozoites is blue-green, tinged with purple. The nuclear chromatin, chromatoid bodies, and ingested red blood cells appear red or red-purple. Background material is green.

VII. Procedure Notes

1. If specimens are improperly fixed, protozoan forms may take on a dirty red color.
2. Incomplete removal of mercuric chloride (Schaudinn's fixative) may result in the deposit of highly refractive granules that may interfere with detection of parasitic forms. Be sure to change the 70% ethanol–iodine solution regularly so this does not happen.
3. Smears that are too green may indicate inadequate removal of iodine by 70% ethanol. Lengthening the time of wash in 70% alcohol and frequent changes of solution will minimize this problem.

CHART 22-3

Preparation of Thick and Thin Blood Films

Preparation of the Thin Blood Film

I. Principle

The thin blood film, prepared similarly to that for the differential white-cell count, allows optimal assessment of the morphology of any parasitic forms that may be present. This is reviewed after the review of the thick film, which is the more sensitive of the two preparations for the detection of blood parasites.

II. Specimen

The blood smear may either be prepared from fresh blood obtained by a finger stick or from an EDTA-anticoagulated specimen collected by venipuncture.

III. Materials

A. Equipment: None

B. Supplies

1. 3 × 1-inch microscope slides, alcohol-washed

2. Glass marker

3. Blood-collection supplies

C. Reagents

1. Absolute methanol for Giemsa stain

IV. Quality Control

A. Visually, the smear should appear even, without ridges, smudges, or streaks, and gradually thin out to a rounded, feather edge.

V. Procedure: Thin Film

1. Blood from Finger Stick

Puncture the skin of the side of the finger with a sharp lancet and carefully wipe away the first drop of blood. Then touch the next small

drop of blood to the surface of a clean glass microscope slide about 1 cm from one end. Turn the slide blood side up and place on a horizontal surface.

2. Venipuncture Specimen
   Place a clean glass slide on a horizontal surface. With the tip of the needle, place a small drop of blood on the surface of the glass slide about 1 cm from one end.
3. With a second glass slide held at an angle of 40 degrees to the glass with the blood drop, back into the drop of blood, hesitate momentarily while the blood extends to both margins of the spreader slide, then quickly and steadily advance the angled slide to the opposite end. The result is a thin, feathered film that becomes progressively thinner.
4. Label the smear and allow it to air-dry for about 10 minutes.
5. Stain the smear either with Giemsa or Wright's. If the Giemsa stain is used, the smear must first be fixed in absolute alcohol.

VI. Procedure Notes

a. Use a diamond marking pen to label the smear.

b. Make sure films are protected during drying from the deposition of dust from the air.

VII. Limitations of the Procedure

a. Parasitic forms may be missed in light infections. In such instances, a thick film must be examined.

b. Smears must be prepared from anticoagulated blood within 1 hour after venipuncture. The morphology of parasitic forms and the erythrocytes become atypical after that time from direct action of the anticoagulant.

Preparation of the Thick Blood Film

I. Principle

The thick blood film samples a relatively large volume of blood providing a better opportunity to recover parasitic forms in light infections. Red blood cells are lysed, providing a better opportunity to detect parasitic forms against a more transparent background.

II. Specimen

The blood smear may either be prepared from fresh blood obtained by a finger prick or from an EDTA-anticoagulated specimen collected by venipuncture. Heparin or sodium citrate anticoagulated blood samples may be used if the presence of trypomastigotes or microfilaria is suspected.

III. Materials

A. Equipment: None

B. Supplies

1. 3 × 1-inch microscope slides, alcohol-washed
2. Glass marker
3. Blood-collection supplies
4. Newspaper
5. Applicator sticks

C. Reagents

1. Absolute methanol for Giemsa stain

IV. Quality Control

A. Visually, the smear should appear as a round to oval smear of blood about 2 cm in diameter. It should be of such thickness that newsprint can barely be seen through the wet or dry smear.

B. The spread of blood should be even, without ridges, smudges, or streaks.

C-87

V. Procedure

1. Blood from Finger Stick

   Puncture the skin of the side of the finger with a sharp lancet and carefully wipe away the first drop of blood. Then touch a large drop of blood to the surface of the middle of a clean glass microscope slide. Without breaking contact with the blood, rotate the slide on the finger to make a circle about the size of a nickel. Remove the slide and place it on a horizontal surface. The thickness should be such that newsprint can barely be seen through the slide. If it is too thick, spread it with a circular motion using an applicator stick until the correct thickness is achieved. If too thin, a second slide must be prepared.

2. Venipuncture Specimen

   Place a clean glass slide on a horizontal surface. With the tip of the needle, place a large drop of blood on the surface of the glass slide.

3. With the tip of an applicator stick, spread the blood into a circle about the size of a dime or nickel, to achieve a thickness through which newsprint can barely be seen.
4. Label the smear and allow it to air-dry for several hours or overnight.
5. Stain the smear either with Giemsa or Wright's. If the Giemsa's stain is not to be performed until 3 days or more after preparation, or if the Wright's stain is used, lyse the red blood cells by placing the thick film in buffered water (pH 7.2) for 10 minutes. Then place the slide in a

vertical position to let it drip dry. Do not fix the thick smear.

VI. Procedure Notes:

a. Use a diamond marking pen to label the smear.

b. Make sure films are protected during drying from the deposition of dust from the air.

VII. Limitations of Procedure

a. Making a species identification of malarial parasites may be difficult to impossible, even for experienced workers. This, however, is not the purpose of this preparation. The purpose of this preparation is the detection of the presence of a blood parasite.

b. A thin film should always be examined to determine the definitive identification. This is the purpose of the thin film.

c. Smears must be prepared from anticoagulated blood within 1 hour after venipuncture. The morphology of parasitic forms and the erythrocytes become atypical after that time from direct action of the anticoagulant.

Calibration of the Ocular Micrometer

CHART 22-4

Preparation of Thick and Thin Blood Films *Continued*

I. Principle

Ocular micrometers are etched with a fixed scale, usually consisting of 50 parallel lines. Depending on the magnifying power of the set of objectives used in a compound microscope, each division in the ocular micrometer scale represents different measurements. Therefore, for each set of oculars and objectives used, the ocular scale must be calibrated using a stage micrometer etched with a scale (0.1-mm divisions are commonly used). It is important to remember that a calibration for a given set of oculars and objectives cannot be interchanged with corresponding components from another microscope.

II. Specimen: Not applicable

III. Materials

A. Equipment

1. Binocular microscope with 10×, 40×, and 100× objectives. Other objective magnifications may be used as required.

2. Oculars should be 10×. A single ocular may be used to calibrate all laboratory microscopes.

B. Supplies

1. An ocular micrometer disk, with scale-line divisions of 50 U. These are available from several laboratory supply companies.

2. A stage micrometer with scale divisions of 0.1 and 0.01 mm

3. Immersion oil

4. Lens paper

C. Reagents: Not applicable

IV. Quality Control

1. All microscopes used for parasitology examinations should be recalibrated at a minimum of once per year.

2. The width of red blood cells can be used to check the calibrations at various magnifications.

3. Latex or polystyrene beads of standardized diameter can be used to check calculations and measurements. Beads with diameters of 10 and 90 µm are recommended. These are available from several laboratory supply companies.

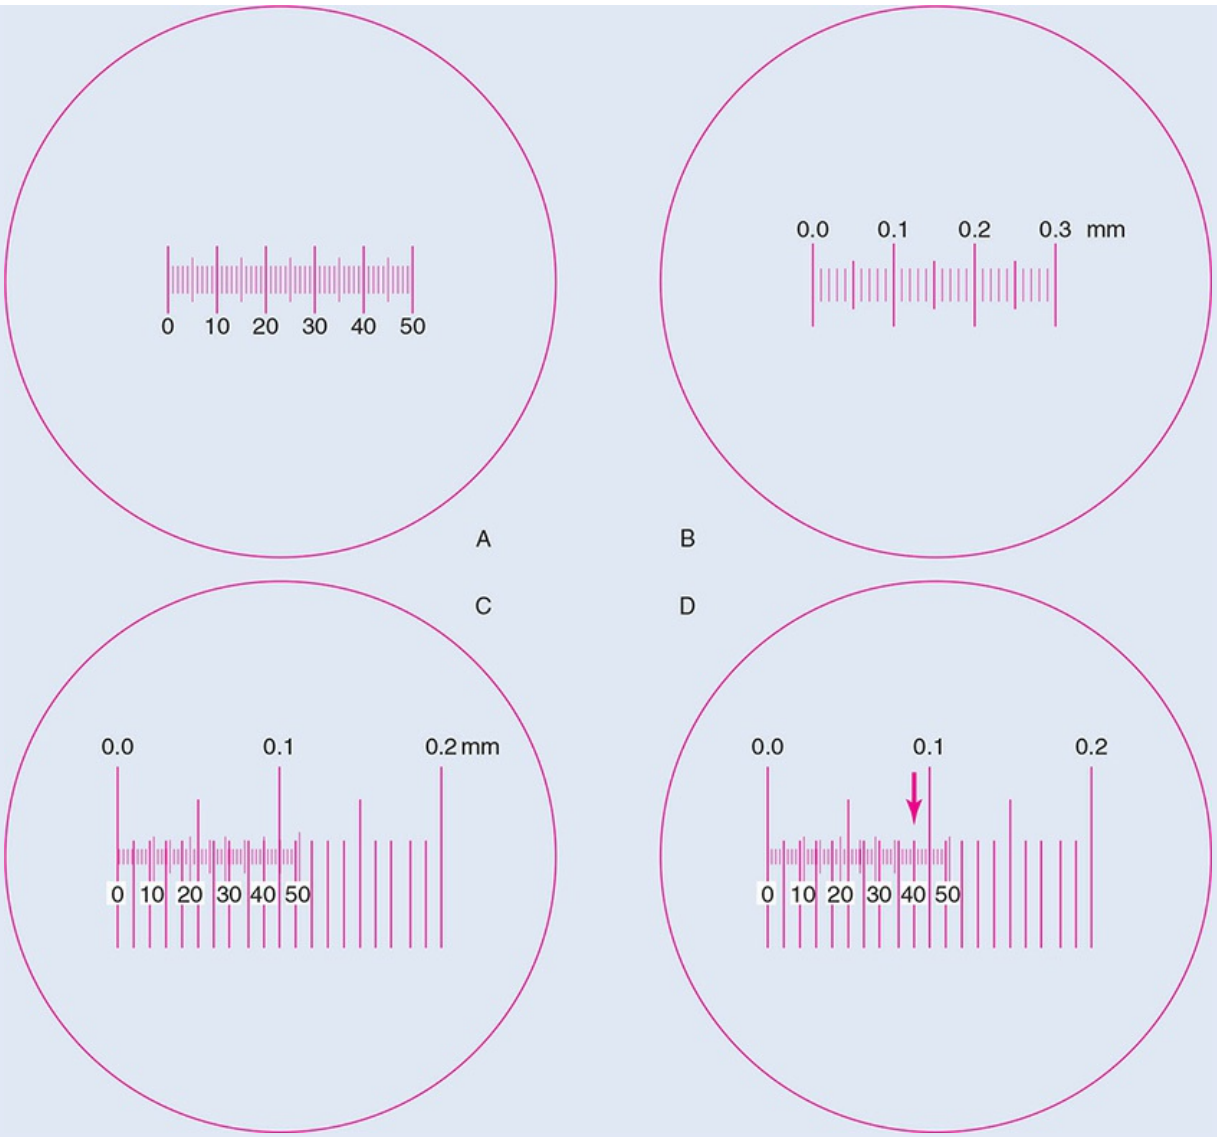
V. Procedure

1. Remove the ocular from the microscope to be used. If a binocular microscope is used, it is customary to remove the right 10× ocular.

2. Unscrew the eye lens (top lens) of the ocular and insert the micrometer wafer so that it rests on the diaphragm ring inside the ocular. Place the micrometer with the engraved side down. The micrometer should be handled with lens paper and every effort made to prevent lint from adhering to the surface.

3. Replace the ocular in the housing. When viewed through the ocular, the micrometer scale appears as a series of lined division, illustrated in A.

4. Place the stage micrometer under the objective of the microscope that is to be calibrated. Bring into view the stage micrometer scale, which appears as a series of lines divided into 0.1-mm and 0.01-mm divisions, as shown in the simulated view through the microscope in B.



C-89

5. Adjust the stage micrometer so that the 0 line on the ocular micrometer is exactly superimposed with the 0.0 line on the stage micrometer scale. When viewed under high magnification (450×), the superimposition of the two scales appears as in the simulated view through the microscope shown in C.

6. Without further manipulation, look across the two scales and find the next pair of lines that exactly coincide. In D (a simulated high-power 450× view), the coinciding lines are the 40 mark on the ocular scale and the 0.09-mm mark on the stage micrometer *(arrow)*.

7. The object of the calibration is to determine the width in micrometers

of each ocular scale division, when calibrated against the stage micrometer scale. Determine the calibration as follows:

a. As illustrated in D, 40 units on the ocular scale are equal to 0.09 mm on the stage micrometer scale.

b. Therefore, each ocular division is equal to 0.09 mm/40, or 0.00225 mm. Since there are 1,000 µm in each millimeter, each ocular micrometer division in the calibration illustrated in D is equal to 0.00225 × 1000, or 2.25 µm.

VI. Results

Thus, based on the procedure just described, if an object viewed under the microscope occupies 10 ocular scale divisions, it would measure 2.25 × 20, or 22.5 µm. These same interpolations can be made for other magnifications. Once the number of ocular lines per width and length of the organism is measured, then, depending on the objective lens being used, the ocular/microns multiplication factor can be applied to the number of ocular scale lines spanning the length and width of the organism being viewed. Comparison of these measurements for any given parasitic form can be compared with published results in standard textbooks in making a final identification.

VII. Procedure Notes

1. As a rule of thumb, the high dry objective (40×) factor should be approximately 2.5 times the factor obtained from the oil immersion objective (100×). Likewise, the 10× low-power objective should be about 10 times that of the oil immersion objective.

2. The multiplication factors for each objective should be posted on the base of each microscope to be used for parasitology examinations.

Cellulose Tape Preparation for Pinworm Examination

CHART 22-5

Calibration of the Ocular Micrometer *Continued*

I. Principle

The eggs discharged by adult female *Enterobius vermicularis* worms are characteristically deposited on the perianal skin during periods of extraintestinal migration. These eggs stick to the glued surface of cellulose tape. By applying the sticky surface of the tape to a glass slide, the mount can be examined under a microscope.

II. Specimen

The specimen is collected from the perianal skin. An early-morning sample, before the patient has bathed or used the toilet, is optimal. Up to 6 successive daily morning samples should be collected before a negative result is issued.

III. Materials

A. Equipment

1. Binocular microscope with 10×, 40×, and 100× objectives. Other objective magnifications may be used as required.
2. Oculars should be 10×. A single ocular may be used to calibrate all laboratory microscopes.

B. Supplies

1. Clear cellulose tape
2. Tongue depressors
3. 3 × 1-in. glass microscope slides

C. Reagents

1. Xylene or xylene substitute

IV. Quality Control

1. All microscopes used for parasitology examinations should be recalibrated at a minimum of once per year.
2. The availability of a textbook or atlas with photomicrographs and/or illustrations of *E. vermicularis* eggs may be helpful to confirm suspected results.

V. Procedure

1. Prepare the microscope slide by attaching a piece of transparent cellulose tape sticky side down about 1.5 cm from one end of the slide. Run the tape over the edge and along the entire length of the opposite side and cut it even with the distal end. Place a paper label under the edge just cut to serve as a tab for removing the tape.
2. To obtain the specimen from the perianal skin, grip the paper label and tear the tape from the glass slide. Rest the glass slide on a tongue blade in such a way that the tape can be looped sticky side out over and

extending beyond the end of the tongue blade by about 2.5 cm. The tongue blade then serves as a support as the sticky side of the tape is pressed in several areas against the perianal skin.

3. Once the sample is obtained, remove the slide from the tongue depressor and affix the tape sticky side down on the glass slide. Label the slide with the patient name and date of collection.
4. Examine the slide under a microscope using the low-power (10×) objective. The eggs can be made more visible by detaching the tape from the slide, adding a drop of xylene or toluene, and again affixing the tape.

VI. Results

The eggs of *E. vermicularis* measure about 50–60 µm × 20–30 µm and have a relatively thick, smooth shell and an ovoid shape flattened on one side, much like a flattened, partially inflated football. Adult worms may occasionally be seen in transparency tape preparations. They measure about 1 cm long, have a pointed tail posteriorly and transparent wings flanking the anterior end.

VII. Procedure Notes

1. The person obtaining the specimen must take care, as the eggs are infectious if swallowed. Gloves can be worn or the hands thoroughly washed following the procedure. A paddle with a sticky adhesive coat is commercially available (BD Falcon, Swube, Pinworm Paddle, BD Diagnostic Systems, Sparks, MD), serving as a less cumbersome collection device that is also safer to use.
2. If an opaque tape has been used by mistake, adding immersion oil to the surface will facilitate microscopic examination.

VIII. Limitations of Procedure

1. Female *E. vermicularis* worms deposit eggs on an irregular schedule. Thus, several daily samples must be obtained before ruling out infection.

Formulations of Commonly Used Stool Preservatives[a]

CHART 22-6

Cellulose Tape Preparation for Pinworm Examination *Continued*

I. Merthiolate–Iodine–Formalin (MIF)

A. Solution I

Tincture of merthiolate, 1:1000	40 mL
Formaldehyde, 10% aqueous (USP)	5 mL
Glycerol	1 mL
Distilled water	50 mL

B. Solution II

Potassium iodide crystals (KI)	10 g
Iodine crystals (add after KI dissolves)	5 g
Distilled water	100 mL

The shelf life of each solution is many months if stored at room temperature in a brown bottle. In a small vial, combine 9.4 mL of solution I with 0.6 mL of solution II just before use. Add the equivalent

of about 1/4 teaspoon of fresh feces and thoroughly mix with an applicator stick. Allow the suspension to settle for 24 hours; then, with a pipette, remove a small portion of the pale orange middle layer and the deeper staining lower layer for preparation of smears.

II. LV-PVA

A. Formulation

Polyvinyl alcohol	10.0 g
95% ethyl alcohol	62.5 mL
Mercuric chloride, saturated aqueous	125.0 mL
Glycerin	3.0 mL

The liquid ingredients are mixed in a 500-mL beaker and the polyvinyl alcohol (PVA) powder added without mixing. Cover the beaker with paper or foil and allow the PVA to soak overnight. Slowly heat the mixture to 75°C and gently swirl for about 30 seconds until a light milky

suspension is achieved.

III. Sodium Acetate–Acetic Acid–Formalin (SAF)

A. Formulation

Formaldehyde (37%–40% solution)	0.6 mL
Glacial acetic acid	0.3 mL
Sodium acetate	225.0 mg
Distilled water	13.88 mL

Dissolve the sodium acetate in the distilled water, slowly add the glacial acetic acid and formalin solutions, mix, and store. The shelf life is several months.

IV. Schaudinn's Fixative (Mercuric Chloride in Ethyl Alcohol and Glacial Acetic Acid)

A. Formulation

Mercuric chloride, saturated aqueous solution ($HgCl_2$)	110 g
Distilled water	1,000 mL

Into a beaker in a water bath placed in a hood, boil the mercuric chloride until dissolved, and let stand for several hours until crystals form.

V. Schaudinn's Fixative (Stock)

Mercuric chloride, saturated aqueous solution	600 mL
Ethyl alcohol, 95%	300 mL

Add 5 mL of glacial acetic acid per 100 mL of stock solution just before use.

[a] These preservatives are commercially available, as are stool preservatives that are mercury-free.
