Pulmonary infections	Pulmonary infections caused by *S. aureus* may arise from aspiration or by hematogenous spread from another site. Aspiration pneumonia acquired in the community is usually seen in the elderly as a complication of influenza pneumonia, while that acquired in the hospital is usually secondary to intubation and ventilatory assistance.[332] *S. aureus* is emerging as the most frequent cause of nosocomial pneumonia, and more than half of these cases are due to MRSA.[385] Pneumonia due to *S. aureus* progresses rapidly, with tissue necrosis and cavitations, and complications of both types of pulmonary infections include bacteremia, lung abscesses and development of pleural empyemas.[192] Chest X-rays from these patients may show scattered, patchy infiltrates, defined abscesses or nodules, consolidation, or cavitation. In small children, thin-walled pneumatoceles with air–fluid levels may be seen. Pneumonia due to CA-MRSA presents with severe respiratory symptoms, fever, hypotension, and purulent, bloody respiratory secretions.[185,375] In these cases, the chest X-ray usually shows multiple cavitating infiltrates and abscesses. This clinical presentation is typically seen in young adults with CA-MRSA infection following an initial, influenza-like illness. Hematogenous pulmonary infection occurs as a complication of right-sided endocarditis and is secondary to embolization from valvular lesions, resulting in pulmonary infarcts. Complications of *S. aureus* pneumonia include pleural empyema and bronchopleural fistula formation.[67] These complications usually result from direct extension of infection from a contiguous site in the lung tissue and various scanning procedures (e.g., ultrasound, CT scans) can be diagnostically useful.
Bone and joint infections	*S. aureus* is the most common pathogen associated with bone and joint infections, and the relative frequency of MRSA involvement has increased in both hospital-acquired and CA infections.[3] *S. aureus* osteomyelitis most often occurs as a complication of local infection via direct extension or via hematogenous seeding. Hematogenous osteomyelitis is usually seen in children and characteristically involves the long bones, although rib and the lumbar spine involvement also occurs. Various types of scans, including MRI and CT, are helpful in ascertaining the extent of involvement and, in the case of spinal lesions, the presence of paravertebral abscesses. Abscesses and lytic bone lesions must be aspirated and cultured to provide a definitive diagnosis. Patients usually present with nonspecific symptoms of fever, weight loss, and bone pain. Osteomyelitis due to *S. aureus* can mimic malignancies such as osteosarcoma on radiologic studies, and needle biopsies are essential in identifying the microbial cause.[137] Septic arthritis due to *S. aureus* occurs primarily in prepubertal children and is usually a complication of bacteremia in both children and adults.[404] In these cases, the patient presents with a swollen, hot joint (most often involving the knee, hip, elbow, shoulder, or interphalangeal joints) that is painful on movement. Aspiration of the joint, Gram's stain, and culture of the purulent exudate are required for management. Osteomyelitis and septic arthritis resulting from CA-MRSA and CA-MSSA are seen primarily in children and are rare among adults.[137,570] In most cases, no underlying disease is present. In the case of CA-MRSA, skin and soft tissue infections are usually the source of the organism. Treatment of these infections usually involves vancomycin, and clindamycin has also been effective when isolates were demonstrated not to have inducible clindamycin resistance.[24,349,559] MSSA and MRSA infections of prosthetic joints has also been reported.[295] These infections usually develop shortly after joint replacement and require antimicrobial therapy and replacement of the prosthesis to effect cure.
Pyomyositis	Pyomyositis is an infection of the skeletal muscles that usually occurs secondary to trauma, often in the neighborhood of an existing focus of infection (e.g., a furuncle).[413] Patients usually present with fever and muscle pain; aspiration and culture yield *S. aureus*. Cure is effected by incision and drainage in association with the use of an appropriate antimicrobial agent.
Staphylococcal food poisoning	Staphylococcal food poisoning results from ingestion of food contaminated with *S. aureus* strains that produce heat-stable enterotoxins. The implicated foodstuff usually becomes contaminated by a food handler, with subsequent organism growth and toxin production. Implicated foods include potato salads, ice cream, custards, bakery goods, canned foods, and processed meats. Symptoms, including nausea, vomiting, abdominal cramps, and diarrhea, usually begin 2–6 hours after ingestion and abate after 8–10 hours. Fever and neurologic signs are characteristically absent. Treatment involves replacement of fluids lost due to vomiting and diarrhea until recovery is complete.

Staphylococcal scalded skin syndrome	Staphylococcal scalded skin syndrome (SSSS) is caused by *S. aureus* strains that produce exfoliative toxins and is usually seen in neonates and infants less than 5 years[304]. In cases of SSSS, infections with *S. aureus* may involve the conjunctivae, the nares, the umbilicus, and perineum. SSS may also result from extracutaneous staphylococcal infections, including urinary tract infection, septic arthritis, pneumonia, and endocarditis.[500] With localized infections, SSSS may appear as bullous lesions resembling bullous impetigo, When the toxins are absorbed systemically by the bloodstream, generalized SSSS results, with the development of widespread erythema and the appearance of bullous lesions over large areas of the body, with subsequent sloughing of the superficial skin layers. This results in the exposure of large areas of denuded and raw skin. In most cases, desquamation occurs and symptoms wane over 5–7 days. The responsible toxins are antigenic and antibodies against them are protective (Box 12-4). Outbreaks of SSSS have occurred in neonatal intensive care units and nurseries.[147] Culture of lesions may be noncontributory, so other possible sites of infection (i.e., nares, conjunctivae, umbilicus, nasopharynx) should be sampled.[305] SSSS caused by MSSA requires therapy with a penicillinase-resistant penicillin or clindamycin based on the susceptibility of the isolate. Assiduous supportive care (e.g., contact isolation, pain management, gentle skin cleansing) is necessary to prevent secondary superinfections.
Staphylococcal toxic shock syndrome	Toxic shock syndrome (TSS) is a multisystem illness characterized by a clinical syndrome that includes fever, hypotension, orthostatic dizziness, erythroderma (blanching rash), and varying degrees of vomiting, diarrhea, renal failure, headache, chills, sore throat, and conjunctivitis.[97,446,489] Initially, the disease was noted most frequently in women, with onset mainly occurring during menstruation. Investigations of the initial cases noted an association between the onset of disease and the use of high-absorbancy tampons during menses (menstrual TSS).[489] The fiber material used in high-absorbancy tampons created the ideal milieu for toxin production when introduced in the vagina. Elevated levels of oxygen trapped within the absorbent material along with the protein- and CO_2-rich, pH-neutral environment provided by the blood stimulated the production of TSS toxin (TSST-1) by *S. aureus* The toxin is produced locally and passes through the mucous membranes into the bloodstream; positive blood cultures are generally not seen in patients with TSS. Subsequently, nonmenstrual-associated TSS was reported in males and females as a complication of staphylococcal abscesses, osteomyelitis, postsurgical wound infections, burns, nasal packing, and postinfluenza pneumonia.[446] About 20% of *S. aureus* isolates from carriers and from clinical specimens produce TSST-1.[35] Although TSST-1 is implicated in most cases of menstrual TSS, nonmenstrual TSS may result from enterotoxins SEB and SEC as well.[357] The role of TSST-1, SEB, SEC, and other superantigens (SAgs) in the disease is supported by the acute onset of symptoms, with vascular congestion developing over a 1- to 2-day period. With the increase in capillary leakage and the system-wide decrease in vascular resistance, there is loss of intravascular fluids into the interstitial spaces. Fluid loss is also exacerbated by the presence of diarrhea in some patients. Loss of intravascular volume leads to hypotension and tissue hypoxia. Acute respiratory distress syndrome and disseminated intravascular coagulation are common and life-threatening complications of TSS. TSST-1 also appears to have some direct toxic effects on the myocardium, skeletal muscle, liver and kidney tissue. Interestingly, patients who develop TSS lack or have low titers of antibody against TSST-1 and other implicated SAgs before and during acute disease, and more than half of the patients remain susceptible to TSS as protective antibody levels are not produced.[521] Other conditions that may be included in the differential diagnosis of TSS include other toxin-mediated infections, (e.g., scalded skin syndrome, gastroenteritis, scarlet fever), local infections with shock and/or acute abdominal pain (e.g., infectious gastroenteritis, salpingitis, septic abortion, acute urinary tract infections) and multisystem illnesses of infectious (e.g., septic shock associated with pneumococci, meningococci, or *Haemophilis influenzae* type b; rubeola, Rocky Mountain spotted fever, tick-borne typhus, leptospirosis, *Legionella* infection; toxoplasmosis; and adenoviral or enteroviral syndromes) and noninfectious (Kawasaki's disease, systemic lupus erythematosus, acute rheumatic fever, rheumatoid arthritis, drug reactions) etiologies. Diagnosis of TSS is generally based on the clinical signs and symptoms according to the case definition (Box 12-3). Treatment of TSS involves antibiotic therapy, supportive care and, in some cases, surgery. Antimicrobial agents that inhibit toxin synthesis (e.g., clindamycin, fluoroquinolones, rifampin) may occasionally be recommended. Immune serum globulin may be helpful in severe cases. Prevention of TSS involves rapid attention to *S. aureus* wound and soft tissue infections and discontinuation of hyperabsorbent tampons. Nasal carriage can be eliminated by use of mupirocin. The mortality associated with staphylococcal TSS is about 3%.
Bactiuria and urinary tract infections	Isolation of *S. aureus* from urine can be associated with bacteremia and invasive disease with the urinary tract as the source of the organism.[9] Conversely, presence of the organism in the urinary tract may result from hematogenous dissemination to the kidney from another source. The emergence of methicillin resistance was associated with a concomitant increase in the frequency of MRSA in urine cultures. Most patients with *S. aureus* in the urine are asymptomatic, but up to one-third may present with symptoms suggesting urinary tract infection (i.e., fever, dysuria, hematuria, and pyuria.[377] Risk factors for *S. aureus* bactiuria include advanced age, urinary tract catheterization or instrumentation, residence in long-term-care facilities, and urinary tract surgery, obstruction, or malignancy.

predisposing factor. Nosocomial pneumonia due to *S. aureus* occurs in the clinical settings of obstructive pulmonary disease, intubation, and aspiration. Underlying malignant diseases are recognized as important risk factors for the development of *S. aureus* bacteremia. Bacteremia may also "seed" distant sites throughout the body, leading to endocarditis, osteomyelitis, pyoarthritis, and metastatic abscess formation, particularly in the skin, the subcutaneous tissues, lungs, liver, kidneys, and brain.[311,347] *S. aureus* meningitis occurs in patients with central nervous system abnormalities related to trauma, surgery, malignancy, and hydrocephalus. *S. aureus* is also one of many microorganisms associated with peritonitis in patients receiving continuous ambulatory peritoneal dialysis. Toxins produced by *S. aureus* are responsible for toxic epidermal necrolysis (staphylococcal scalded skin syndrome) and toxic shock syndrome (Boxes 12-3, 12-4, and 12-5) (Image Plate 12-1C).[168] *S. aureus*strains may also cause food poisoning because of the elaboration of exotoxins during growth in contaminated

BOX 12-4

Virulence Factors of *Staphylococcus aureus*

Virulence Factor	Comments
Capsular polysaccharides and biofilm formation	Over 90% of *S. aureus* produce exopolysaccharides that act to promote adherence of the organisms to host cells and prosthetic devices and prevent ingestion of the organism by polymorphonuclear cells.[261,316,380,541] Capsular polysaccharides of *S. aureus* are also able to alter the binding and functionality of complement. These exopolysaccharides have been observed by electron microscopic examination of *S. aureus*-infected pacemaker leads, peritoneal catheters, and intravenous lines and have been demonstrated immunologically in vitro. To date, 13 capsular polysaccharide types have been described in *S. aureus*; about 70%–80% of significant clinical isolates belong to capsular serotypes 5 or 8.[456,582] The other capsular serotypes are very rare among clinical isolates. These capsular types are found in both MRSA and MSSA isolates. In one study, 64% of MRSA were capsular types 5, whereas 60% of MSSA strains were capsular type 8.[575] About 10%–20% of clinical isolates are nontypeable by the methods used to characterize these capsular polysaccharide, and nontypeable strains often possess the genes for capsular types 5 or 8 but these genes are not expressed.[108] Some nontypeable isolates express a cell surface polysaccharide termed 336PS that is structurally similar to polyribitol-phosphate *N*-acetylglucosamine and teichoic acids of *S. aureus*.[334,394] Capsular polysaccharides are major components of biofilms, which are surface-attached organism clusters encased in an extracellular polymeric matrix consisting of exopolysaccharides, teichoic acids, proteinaceous material, and extracellular DNA. The DNA found in *S. aureus* biofilms originates from thermonuclease degradation of cellular DNA. Organisms embedded in the matrix display decreased metabolism and are recalcitrant to antimicrobial penetration and activity. The initiation of biofilm formation involves attachment via serum proteins (e.g., fibrinogen, fibronectin, vitronectin) coating catheters or other indwelling devices or via attachment directly to the plastic indwelling material itself. This attachment is promoted by a group of surface molecules belonging to the MSCRAMM (Microbial Surface Components Recognizing Adhesive Matrix Molecules) family of adhesins. Following initial surface interactions, intercellular cross-linking via PIA occurs. Nuclease activity from lysed staphylococcal cells degrades the extracellular DNA in the biofilm and helps disperse the biofilm surface. There has been renewed interest in these capsular polysaccharides because they are essential factors for virulence and antibodies against them appear to be protective. As a result, a capsular antigen-based vaccine for serotypes 5 and 8 has been developed that contains these particular polysaccharides chemically conjugated to a haptenic protein carrier (StaphVAX, Mabi Biopharmaceuticals, Rockville, MD).[159,491,492] A conjugate vaccine against *S. aureus* 336PS is also in development.
Adhesins	The MSCRAMM (Microbial Surface Components Recognizing Adhesive Matrix Molecules) adhesin family includes over 20 small proteins that are bound to the cell wall peptidoglycan of *S. aureus*.[415] Genes for these molecules are located on the chromosome and are present in all *S. aureus* strains. These proteins mediate adherence to host-matrix proteins (e.g., fibronectin, fibrinogen, elastin, other cellular lipids) and plastic implanted devices. Other adhesins function in binding hemoglobin, hemin, transferrin, and haptoglobin. Some adhesins are virulence factors that correlate with staphylococcal ecology and specific disease conditions. For example, clumping factor B (ClfB), fibronectin binding proteins A and B (FnPBA, FnBPB), and collagen-binding protein (Cna) are associated with *S. aureus* nasal colonization, ventricular assist device-related infections, and osteomyelitis, respectively.[25,433,598] Several other proteins (*S. aureus* surface proteins B, C, D, F, G, H, and K) have been described that have as-yet undetermined targets and ligand specificities.
Peptidoglycan, teichoic and lipoteichoic acids	*S. aureus* cell walls contain peptidoglycans (cross-linked polymers of *N*-acetylglucosamine and *N*-acetylmuramic acid), which are similar to those found in other gram-positive bacteria, and teichoic acids, which are unique ribitol (five-carbon monosaccharide)-phosphate polymers (see Chapter 5). Teichoic acids function in promoting adherence to mucosal surfaces and anchoring cell wall-associated enzymes. Lipoteichoic acids are found in the plasma

membrane and maintain linkage of the peptidoglycan to the cell membrane. In addition to providing rigidity and resilience to the staphylococcal cell wall, peptidoglycan components, and teichoic and lipoteichoic acids also have biologic activities that may contribute to virulence. These properties include the ability to activate complement, enhancement of chemotaxis of polymorphonuclear cells, elicitation of interleukin-1 production by human monocytes, and stimulation of the production of opsonic antibodies. Serologic tests for antibodies to these molecules have been investigated for their possible diagnostic and/or prognostic value; results have been disappointing because of considerable overlap of antibody titers among infected and noninfected individuals, the wide spectrum of infection and disease caused by *S. aureus*, and the host-dependent variability of the immune response due to age, other infections, and general immunocompetence. Several other proteins, including MSCRAMM adhesins, are covalently incorporated into the structure of the *S. aureus* peptidoglycan.[415]

Protein A

Protein A is a 42,000-Da MSCRAMMS adhesin that is found on both the cell surface and in medium during growth. This unique protein binds to the Fc region of all human IgG subclasses except IgG_3. Protein A interferes with opsonization and ingestion of the organisms by polymorphonuclear cells, activates complement, and can elicit immediate and delayed type hypersensitivity reactions. Protein A is also a "B-cell superantigen" because it can bind to certain B-cell receptors and consequently limits their ability to synthesize specific antibodies.[194] Protein A also binds vonWillebrand factor and complement protein C3, thereby promoting adherence of bacteria to platelets and is able to catalyzing the conversion of C3 to C3b.[106] The protein A molecule also binds to the receptor for TNF-α and, in so doing, reduces proinflammatory cytokine signaling.[191] Protein A is encoded by the chromosomal *spa* gene. The presence of protein A on *S. aureus* provides the basis for coagglutination test procedures that are used in many clinical laboratories for organism identification and for detection of bacterial antigens in body fluids.

Enzymes

S. aureus produces several enzymes that contribute to its virulence. **Catalase** production by these organisms may function to inactivate toxic hydrogen peroxide and free radicals formed by the myeloperoxidase system within phagocytic cells after ingestion of the microorganisms. **Clumping factor**, a cell-bound material that is able to bind fibrinogen, is responsible for the binding of *S. aureus* to both fibrin and fibrinogen. **Coagulase**, which can exist free in the medium or in a cell-bound form, binds and activates prothrombin and promotes the conversion of fibrinogen to fibrin. This enzymatic activity may act to coat the bacterial cells with fibrin, rendering them more resistant to opsonization and phagocytosis.[356] **Fibrinolysins** break down fibrin clots and facilitate the spread of infection to contiguous tissues. Similarly, **hyaluronidase** hydrolyzes the intercellular matrix of acid mucopolysaccharides in tissue and, thus, may act to spread the organisms to adjacent areas in tissue.[212] Strains of *S. aureus* causing chronic furunculosis have been found to be producers of potent **lipases** that may help to spread the organisms in cutaneous and subcutaneous tissues.[459,469] A **phosphatidylinositol-specific phospholipase C** has also been described that is associated with strains recovered from patients with adult respiratory distress syndrome and disseminated intravascular coagulation. Tissues affected by this enzyme become more susceptible to damage and destruction by bioactive complement components and products during complement activation. *S. aureus* also produces a **nuclease** or **phosphodiesterase** having both exo- and endonuclease activities. Immunologic and substrate-specificity studies indicate that several different types of **β-lactamase enzymes** are produced by *S. aureus*. Production of these enzymes may be inducible (i.e., they are produced only in the presence of β-lactam antimicrobial agents) or constitutive (i.e., they are produced continually) and render these organisms resistant to penicillin and ampicillin. Genes coding for these enzymes usually reside on plasmids (extrachromosomal DNA) that also carry genes for resistance to several antibiotics, such as erythromycin and tetracycline. These resistance genes may be transferred to other bacteria by transformation and transduction.

Hemolysins and leukocidins

S. aureus hemolysins have several biologic activities.[557] **α-Hemolysin** is lethal for a variety of cell types in vitro and will lyse erythrocytes from several animal species, but human erythrocytes are much less sensitive. Human monocytes, macrophages, and lymphocytes are susceptible to lysis by α-hemolysin, but granulocytes are highly resistant. This toxin is a protein with a molecular weight of 33,000 Da and is secreted into the medium during late logarithmic growth. Clusters of phosphatidylcholine, various membrane-associated lipids, and other cell-associated proteins act in concert for specific binding of α-hemolysin to susceptible target cells.[552,553] Individual monomers interact and aggregate on the target cell membrane, forming cylindrical homoheptamers with an aqueous central pore. These pores allow rapid efflux of potassium ions and other small molecules and influx of sodium and calcium ions, leading to osmotic swelling and rupture of the cell. This toxin is also active against platelets and may contribute to septic thrombotic events during *S. aureus* bacteremia.[483] α-Hemolysin is dermonecrotic on subcutaneous injection, and is lethal for animals when administered intravenously. α-Hemolysin toxin is responsible for the zone of hemolyzed red blood cells observed around colonies of some *S. aureus* strains growing on SBA. **β-Hemolysin** is a neutral sphingomyelinase (hydrolyzes the lipocarbohydrate sphingomyelin) that is active on a variety of cell types. β-Hemolysin is a protein exotoxin with a molecular weight of 35,000 Da and is secreted into the medium towards the end of the logarithmic growth phase.[237] Hemolytic activity requires magnesium ions and substrate specificity is restricted to sphingomyelin, which is hydrolyzed to form ceremide and phosphorylcholine. *S. aureus* β-hemolysin is cytotoxic for human monocytes and is inactive against granulocytes, lymphocytes,

and fibroblasts.[584] The varying susceptibilities of erythrocytes from different animal species to β-hemolysin-mediated lysis is probably due to differences in membrane sphingomyelin content. β-Hemolysin is a "hot–cold" hemolysin; that is, its hemolytic properties are enhanced by subsequent exposure of the red blood cells to low temperatures. This property may be caused by initial disruption of cohesive forces within the membrane and subsequent phase separation within the membrane as the temperature is lowered. Cell death probably results from disruption of host cell plasma membrane fluidity.[246] The β-hemolysin, along with the CAMP factor produced by group B streptococci, is responsible for the synergistic hemolysis observed in a positive CAMP test for presumptive identification of group B streptococci. **δ-Hemolysin** and **γ-hemolysin** are found in some *S. aureus* strains and also cause lysis of a variety of cell types. The δ-hemolysin is a small amphipathic peptide with a molecular weight of 3,000 Da that is secreted into the medium towards the end of the exponential growth phase. This hemolysin is produced by over 97% of *S. aureus* strains and is also found in 50%–70% of coagulase-negative staphylococci. The δ-hemolysin acts primarily as a surfactant or detergent-like molecule that interacts with cell membranes and forms channels that destabilize the membrane and increase in size over time, resulting in slow leakage of cellular contents.[576] The γ-hemolysin and the **PVL** are both bi-component pore-forming toxins that are composed polypeptides that are differentiated in the laboratory by the rate of migration on gel electrophoresis into "slow" (S) or fast (F) components.[199] The γ-hemolysin is composed of combinations of either HlgA or HlgC polypeptides (S components) with HlgB (F component). **PVL** is transmitted among staphylococcal strains by lysogenic bacteriophages (φSLT phage) and is composed of a combination of LukS and LukF. Luk ED and LukGH (also called LukAB) are additional bi-component pore-forming toxins. Monomers of these toxins bind sequentially to susceptible cell membranes and oligomerize into pores composed of four "S" components and four "F" components each. Affected cells undergo degranulation of the cytoplasm, cell swelling, and lysis.[397,418] The components of PVL are secreted, extracellular proteins, although LukGH is found as a predominant cell surface protein during the late exponential growth phase.[574] PVL is lytic for a variety of cell types including human neutrophils, murine alveolar macrophages, and rabbit neutrophils, but the role of PVL in the pathogenesis of human infections is unclear.[328] Animal models (i.e., mice, rabbits, monkeys) and studies with human cell types used in PVL research have produced conflicting results and have raised concerns about applicability of these models to human disease. A role for PVL in the pathogenesis of CA-MRSA infections, particularly skin and soft tissue infections, hemorrhagic pneumonia, and osteomyelitis, has been proposed and several studies have examined this association.[121] Large patient-centered studies have not documented a specific role for PVL in association with adverse clinical outcomes in skin and soft tissue infections or hospital-acquired pnemonias.[27,490] PVL genes are highly conserved and are present in nearly every CA-MRSA, including the USA300 strain that causes most CA-MRSA infections in the United States.[49,373,540] HCA-MRSA isolates and MSSA have a low prevalence of PVL gene carriage.[558,580] PVL-producing CA-MRSA strains usually have SCC*mec* type IV. Because the structural genes of PVL in CA-MRSA are found on lysogenic phages, lineages of PVL types reflect the phage type, the location of PVL gene insertion in the staphylococcal chromosome, and the degrees of PVL gene expression.[58] A group of small cytotoxic peptides termed PSMs have been described in *S. aureus, S. epidermidis,* and other coagulase-negative staphylococci.[588] PSMs are secreted α-helical peptides related to δ-hemolysin that also act by destabilizing membranes and causing cellular leakage. The role of PSMs in human staphylococcal infections is unclear, but one PSM gene, *psm-mec* is found within the SCC*mec* mobile genetic element in SCC*mec* types II, III, and VIII.[90] Several superantigen-like molecules have also been described in *S. aureus* that are able to inhibit the migration of neutrophils.[617]

Toxins

Exfoliatins or **epidermolytic toxins** are produced by 1%–2% of *S. aureus* strains and consist of two proteins, designated ET-A and ET-B, each of 24,000 Da molecular weight. The gene for ET-A (*eta*) is carried on a bacteriophage integrated into the chromosome, while the ET-B gene (*etb*) is on a plasmid[303]. These molecules are biochemically and immunologically distinct, have similar biologic activities, and also have superantigenic activities. Both ET-A and ET-B have serine protease activity and target desmoglein 1 (Dsg1), one of four adhesion glycoproteins that are located within desmosomes in the epidermis.[387,611] Dissolution of the mucopolysaccharide matrix of the stratum granulosum in the epidermis results in intraepithelial splitting of cellular linkages in the stratum granulosum.[305] The exfoliatins are responsible clinical presentation of "SSSS". Both exfoliatins also can function as superantigens. Other epidermolytic toxin isoforms (i.e., EF-C and EF-D) have also been identified. **Enterotoxins A through E, H, and I** are heat-stable molecules which are responsible for the clinical features of staphylococcal food poisoning, which is the most common cause of food poisoning in the United States. The exact mode of action of these enterotoxins is unknown, but they have been shown to increase intestinal peristalsis. Ingestion of preformed enterotoxins in food supporting staphylococcal growth (e.g., bakery goods, custards, potato salad, processed meats, ice cream) results in vomiting with or without diarrhea within 2–8 hours. These toxic conditions are self-limited (within 24–48 hours) and require only supportive therapy. Inflammatory changes (e.g., a hyperemic mucosa, neutrophilic infiltrates, mucopurulent duodenal exudates, brush border disruption) are seen throughout the gastrointestinal tract, with the more severe and extensive lesions being found in the stomach and the upper small intestine.

Superantigens

The **staphylococcal enterotoxins** (SEs) belong to a group of at least 15 toxins collectively known as pyrogenic exotoxins, which also includes the **toxic shock syndrome toxin** (TSST-1, see below). The SEs include SE A, B, C_n, D, E, G, H, I, J, K, L, M, N, and O. All of these molecules behave as **superantigens (SAgs)**, and, consequently, have parallel capital-letter designations as SAgs. All of these toxins share three biologic characteristics: pyrogenicity, superantigenicity, and the ability to enhance the lethal effects of minute amounts of endotoxin in rabbits up to 100,000-fold. Most superantigens are small (20–28 kDa) secreted proteins and most are encoded on mobile genetic elements.[398] **Superantigenicity** refers to the ability of these toxins to stimulate the proliferation of T lymphocytes without regard for their antigenic specificities. All of these toxins induce polyclonal T-cell proliferation through co-ligation between major histocompatibility complex class II molecules on antigen-presenting cells and the variable portion of the T-cell antigen receptor β-chain.[169] Following activation by superantigens, a large burst of cytokine release leads to an overwhelming inflammatory response and shock syndrome. In toxic shock syndrome, TSST-1, a small protein with a molecular weight of 22,000 Da, is able to cross adjacent mucosal membranes and enter the circulation after being produced locally by TSST-1-producing strains of *S. aureus*. Systemic release of cytokines and their broad physiologic effects results in rapid development of multisystem disease with TSS.

BOX 12-5

Case Definition of Toxic Shock Syndrome

Feature	Comment
Fever	Temperature ≥38.9°C (102.0°F)
Rash	Diffuse macular erythroderma
Desquamation	1–2 weeks (usually 10–14 days) after onset of illness; particularly of palms, soles, fingers, and toes
Hypotension	Systolic blood pressure ≤ 90 mm Hg for adults or less than fifth percentile by age for children less than 16 years of age. Orthostatic drop in diastolic pressure of ≥15 mm Hg from lying to sitting; Orthostatic syncope or orthostatic dizziness.
Involvement of Three of More Organ Systems:	
Gastrointestinal	Vomiting or diarrhea at onset of illness
Muscular	Severe myalgia or creatinine phosphokinase greater than twice the upper limit of normal
Mucous membranes	Vaginal, oropharyngeal, or conjunctival hyperemia
Renal	Blood urea nitrogen (BUN) or serum creatinine greater than twice the upper limit of normal for laboratory *or* urinary sediment with pyuria (≥5 leukocytes per high power field) in the absence of urinary tract infection
	Total bilirubin, alanine aminotransferase, or aspartate

Hepatic	aminotransferase levels at least twice the upper limit of normal for laboratory
Hematologic	Platelet count <100,000/mm^3
CNS	Disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent
Laboratory Criteria	Negative Results on the Following Tests:

Blood, throat, and spinal fluid cultures (blood cultures may be positive for *S. aureus*)

Serologic tests for Rocky Mountain spotted fever, leptospirosis, and measles

Case Classification

Confirmed	A case in which all six of the clinical findings described above are present
Probable	A case with five of the six clinical findings described above are present

Additional Laboratory Findings Pathognomic for TSS, but Presently Not Included in the Case Definition:

- Isolation of *S. aureus* from a mucosal or normally sterile body site
- Production by an incriminated staphylococcal isolate of TSST-1 or an alternative toxin known to cause TSS
- Serologic susceptibility to the relevant toxin at the time of acute illness
- Development of antibody to the relevant toxin during convalescence

685

foods. *S. aureus* possesses several properties which are believed to contribute to their ability to cause disease (Box 12-4). These virulence factors are not found in all strains of *S. aureus*, however, and this organism continues to be a constant source of surprise as new and different pathogenic properties are discovered.[592] Additional information regarding infections associated with *S. aureus* is presented in Box 12-3. The case definition of toxic shock syndrome can be seen in Box 12-5.

Penicillin was the original drug of choice for treatment of serious *S. aureus* infections and the emergence of resistance was due to acquisition of plasmid-borne genetic elements encoding β-lactamases. Semisynthetic, penicillinase-resistant penicillins (i.e., oxacillin, methicillin, nafcillin) were developed for treatment and introduced for clinical use in 1959. During the 1980s, resistance to these agents also

emerged. Resistance to methicillin is due to the presence of an altered penicillin-binding protein called PBP2a (or PBP2′) that results from acquisition of a chromosomal gene called *mecA,* which is located within the large mobile staphylococcal chromosomal element known as the SCC*mec* (staphylococcal cassette chromosome). Many SEC*mec* types and subtypes have been identified since these genetic elements were first described (see typing section, below).[195] Interestingly, it is believed that *S. aureus* acquired the SCC*mec* transposon from *S. sciuri*, a coagulase-negative staphylococcal species found on animals and in the environment.[609] The PBP2a protein has a low affinity for all β-lactam agents, including cephalosporins. Once the normally present PBPs have been inactivated by a β-lactam agent, PBP2a continues to function and allows synthesis of a stable peptidoglycan structure, thereby allowing the organism to grow and divide. *S. aureus* strains that contain SCC*mec* are termed *methicillin-resistant S. aureus* (MRSA) in order to distinguish them from *S. aureus* that lack this element and are therefore susceptible to methicillin (i.e., MSSA, or methicillin-susceptible *S. aureus*).

In order to further characterize these organisms, MRSA from US hospitals were examined by pulsed-field gel electrophoresis (PFGE) and eight clusters—USA100 through USA800—were delineated.[358] All but two PFGE types—USA300 and USA400—were from infections associated with healthcare facilities and nosocomial infections. USA300 subsequently emerged as the predominant clone causing community-acquired MRSA infections, with severe skin and soft tissue infections as the predominant clinical presentation.[401,540,558] At present, two types of MRSA infections are recognized: healthcare-associated MRSA (HA- or HCA-MRSA) and community-acquired MRSA (CA-MRSA) infections.[34] HCA-MRSA infections occur mostly among elderly individuals and include predominantly bloodstream infections, pneumonia, and co-infections with other nosocomial agents. Individuals at risk for these infections usually have a history of recent hospitalization, living in a long-term-care facility, having an indwelling catheter in place, or recent surgery. HCA-MRSA isolates also tend to be multiresistant. Infections with CA-MRSA occur in those without healthcare-associated risk factors, and infections include soft tissue infections (including necrotizing fasciitis), severe necrotizing pneumonia, sepsis, and bone and joint infections.[34,68,87,121,149,267,269,571] CA-MRSA outbreaks have occurred among diverse populations in the community such as prisoners, children in day care centers, participants in contact sports, and military recruits, and are disproportionately represented among medically underserved populations in urban areas.[34,68,87,121,149,267,269] Reported increases in the incidence of pediatric skin/soft tissue infections caused by MRSA have largely been driven by the emergence of CA-MRSA.[178] The community-associated USA300 MRSA clone has now spread from the community and back into healthcare facilities, where it has now become a significant

cause of healthcare-associated and nosocomial bloodstream infections.[485] A study examining bloodstream and skin/soft tissue infections due to MRSA from 2000 to 2008 found that USA300 accounted for 55% of bacteremias and was the predominant strain causing community-associated, healthcare-associated, community-onset, and hospital-onset bloodstream infections.[537] The USA300 MRSA clone has now been reported on 5 continents and in over 36 countries.[324,386] HCA-MRSA and CA-MRSA also differ in their SCC*mec* types. Types I, II, and III are found in HCA-MRSA strains, while types IV, V, and VII predominate among CA-MRSA. The predominant subtype of the USA300 CA-MRSA clone in the United States, USA300-0114, possesses SEC*mec* type IV and SCC*mec* type 4a. Recently, several new SCC*mec* types and subtypes (SCC*mec* IIA-IIE, SCC*mec* types IVa–IVg, SCC*mec* types IX, X, V [5C2 and 5], subtype C) have been described.[174,323] The SCC*mec* types seen on CA-MRSA strains do not carry multiple antibiotic-resistant genes as seen in HCA-MRSA strains, and CA-MRSA SCC*mec*types are more likely to carry genes for the phage-associated Panton–Valentine leukocidin (PVL).[558] Subtypes of the USA300 clonal type have been reported in other countries (e.g., USA300-LV, USA300-P) and appear to cause diseases similar to the predominant USA300 subtype in the United States, with an emphasis on skin and soft tissue infections (e.g., furunculosis).[12,184,268,571]

In colonized individuals, *S. aureus* is carried predominantly in the anterior nares, but it can also be isolated from other sites, including the groin, axilla, and the external auditory canal. Healthy infants become colonized during the second or third month of life with strains that are usually acquired from the mother or the environment. Carriage rates at this time may be as high as 60%. With the development of the normal oropharyngeal microbiome and maturation of the immune system, carriage rates usually decrease several-fold after this time. Children and teenagers have higher rates of carriage than adults, and rates in the latter group are influenced by many factors (age, general health, comorbidities, chronic diseases). Currently, prevalence rates of *S. aureus* nasal colonization in healthy adults range between 25% and 35%, depending on the population surveyed. Individuals may persistently carry the same strain for extended periods, while others carry a single strain for a few months that is eventually replaced by another.[291] Nasal carriage of *S. aureus* can have serious clinical implications as well. Carriers have higher rates of staphylococcal infections than noncarriers, and nosocomial *S. aureus* infections are often caused by the strain being carried in the nares of the patients themselves. Reduction or eradication of nasal carriage can have significant effects on the rates of nosocomial infections. Carriage of MRSA, in particular, emerged early in the last decade and

presents particular issues for healthcare facilities since these colonized individuals are the most significant reservoirs of MRSA in both healthcare facilities and in the community upon discharge of carriers from hospitals or long-term-care facilities.[291]

Because MRSA causes severe infections with significant morbidity and mortality, preventing the spread of MRSA has become a priority over the last 10 to12 years. As with MSSA, MRSA carriers or those with MRSA infections are the most significant reservoirs of the organism in the hospitals and other healthcare facilities.[471] In 2001, the Veterans' Administration Hospital in Pittsburgh, PA, implemented a multifaceted MRSA surveillance program involving active surveillance for MRSA nasal colonization, isolation and contact precautions for colonized patients, and attention to hand hygiene. This approach succeeded in decreasing HCA-MRSA infections in the intensive care unit by 75%.[251] In 2003, a preventive strategy for both MRSA and vancomycin-resistant *Enterococcus* (VRE) was proposed by the Society for Healthcare Epidemiologists (SHEA) and the Centers for Disease Control and Prevention (CDC), but a proactive approach was not documented at that time. In 2004, Davis and colleagues[122] at Brooke Army Medical Center demonstrated that 19% of patients who were colonized with MRSA in the nares on hospital admission and 25% who become colonized with MRSA during hospitalization developed MRSA infection, compared with the 1.5% and 2% of patients colonized with MSSA, respectively, on admission. During 2007, the Veterans Administration became the first healthcare system to mandate surveillance testing for MRSA, and subsequently Illinois passed legislation requiring MRSA screening and reporting of at-risk patients. Legislation was subsequently passed in Pennsylvania, New Jersey, Minnesota, Maine, and California. The point of these proactive preventive strategies is to rapidly detect individuals who are colonized with MRSA, and several studies have documented that surveillance for MRSA in patients being admitted to the hospital is associated with reduction in MRSA-associated infections and disease.[120,210,426,452,522,591] In some institutions, every individual admitted to a healthcare facility is screened, while other programs screen only those patients who are considered high risk for MRSA colonization. Such patients include those who have been transferred from a long-term-care facility or from another healthcare facility, those who have been hospitalized within the past 6 months, and those who have a documented history of MRSA colonization or infection. Some healthcare facilities also screen individuals who have come from or traveled to countries with high MRSA prevalence rates.[452] Screening methods for detection of MRSA colonization include culture-based and molecular-based techniques (see sections covering culture- and molecular-based methods below). Molecular approaches for detection of MRSA offer several advantages over culture-based methods, including lower limits of detection, higher-throughput screening, and shorter times to detection. Reduced transmission of MRSA has been demonstrated when surveillance testing was done using real-time PCR, but no significant impact on

transmission was seen when culture-based testing was performed.[210] Detection of MRSA results in isolation of the patient and, in some cases, decolonization protocols to reduce the burden of MRSA prevalence and to decrease transmission. Decolonization protocols usually involve treatment with mupirocin nasal ointment and bathing with chlorhexidine.

With the emergence of resistance to the penicillinase-resistant penicillins, the glycopeptide agent vancomycin became the treatment of choice for infections due to MRSA.[563] Vancomycin-susceptible *S. aureus* (VSSA) has vancomycin minimum inhibitory concentrations (MICs) of ≤2 μg/mL.[107] However, in May of 1996, the first documented infection caused by an *S. aureus* strain with intermediate resistance to vancomycin was reported from Japan.[229] These isolates have been given the mnemonic "GISA" for "glycopeptide-intermediate *S. aureus*" as these strains have diminished susceptibility to both vancomycin and teicoplanin glycopeptide antibiotics; VISA (vancomycin-intermediate *S. aureus*) is the name used in the United States.[374] These strains have vancomycin MICs of 4 to 8 μg/mL and display a homogeneous phenotype. Strains of VISA have thickened cell walls, which is thought to prevent vancomycin from reaching its site of action in the bacterial cell wall division septum.[236] The Clinical and Laboratory Standards Institute (CLSI) defines *S. aureus* isolates requiring concentrations of vancomycin of ≤ 2 μg/mL for growth inhibition as "susceptible," those requiring 4 μg/mL to 8 μg/mL as intermediate, and those requiring ≥16 μg/mL vancomycin as resistant.[19,107,202] Among VISA strains, a heterogenous phenotype has also been recognized. Those isolates appear susceptible to glycopeptides (vancomycin MIC ≤ 4μg/mL) but contain subpopulations of cells with reduced susceptibility to vancomycin (vancomycin MIC 8 to 16 μg/mL) that occur at low frequencies. These strains are termed hVISA. Rare isolates of vancomycin-resistant *S. aureus* (VRSA) have been reported, and these isolates will have vancomycin MICs of ≥16 μg/mL. The vancomycin-resistant strains contain the *vanA* resistance determinant found in vancomycin-resistant enterococci. Reduced susceptibility to vancomycin is not reliably detected by disk diffusion; this method cannot differentiate vancomycin-intermediate and vancomycin-susceptible strains and the zone diameters do not correlate with staphylococcal vancomycin MICs. The disk diffusion test will only detect VRSA containing the *vanA* determinant and will show no zone around the 30-μg disk. VRSA strains can be reliably detected by current reference and commercial methods, including reference microbroth dilution, agar dilution, Trek Sensititre MIC panels, Microscan overnight and Synergies-Plus panels, Etest strips, and vancomycin screen agar.[202] Both the BD Phoenix and the VRSA screen on the Vitek 2 will also detect these strains. VISA strains are most easily detected by reference broth microdilution, Etest with a 0.5 McFarland-standardized inoculum, and agar dilution. Automated methods may detect VISA strains with MICs

of 8 μg/mL, but may not detect those with MICs of 4 μg/mL. The use of BHI agar with 6 μg/mL vancomycin is a useful adjunctive test for detection of both VISA and VRSA strains. In fact, CDC recommends that laboratories incorporate the vancomycin agar screening plate for all *S. aureus* isolates.[202] BHI agar with 6 μg/mL vancomycin is spot-inoculated with a 10 μL inoculum from a suspension equivalent to a 0.5 McFarland turbidity standard and inspected for growth after a full 24 hours' incubation. All isolates with vancomycin MICs of 8 μg/mL and some with

MICs of 4 μg/mL will grow on these screening plates. Isolates that grow on the screening plate should then be tested by a broth microdilution procedure to confirm resistance. Etest performed on Müeller–Hinton agar with an inoculum prepared from a 0.5 McFarland-equivalent suspension and incubated a full 24 hours is also a very sensitive and specific method for detection of these strains; with Etest, VISA strains have vancomycin MICs of ≥4 μg/mL and VRSA have MICs of ≥16 μg/mL. According to the CDC, three criteria must be met to verify that a given strain is a VISA: broth microdilution vancomycin MICs of 8 to 16 μg/mL, Etest vancomycin MICs of ≥6 μg/mL, and growth within 24 hours on a BHI agar plate containing 6 μg/mL vancomycin (Table 12-1).[202] Prompt and accurate detection and confirmation of these strains is necessary and critical for optimal treatment of individual patients and for prevention of transmission of these strains to other patients. Jacob et al.[249] have reviewed and performed a meta-analysis of the clinical outcomes of adults with MRSA infections wherein the isolates had a high MIC to vancomycin.

Staphylococcus aureus *subsp.* anaerobius

S. aureus subsp. *anaerobius* causes Morel's disease in sheep, which is characterized by subcutaneous abscess formation in and around the superficial lymph nodes.[525] This bacterium has not been isolated from human infections or clinical specimens. However, in 2006, a similar obligately anaerobic staphylococcal isolate was recovered from a 45-year-old male farm hand who presented with septicemia, septic arthritis, and multiple pulmonary abscesses.[416] While true isolates of *S. aureus* subsp.*anaerobius* are catalase-negative, the isolate from this patient was weakly catalase-positive and differed from *S. aureus* subsp. *anaerobius* and *S. saccharolyticus* (the other obligately anaerobic *Staphylococcus* species) by several phenotypic characteristics. Genotypic methods could not differentiate this organism from *S. aureus* subsp. *aureus,* subsp. *anaerobius,* or *S. saccharolyticus;* the authors surmised that this isolate was either a variant strain of *S. aureus* subsp. *anaerobius* or an undescribed subspecies of *S. aureus*.

Coagulase-Negative Staphylococci

In the past, coagulase-negative staphylococci were generally considered to be contaminants having little clinical significance. Some of these are important in the cheese industry.[434,435] Over the last four decades, however, these organisms have become recognized as important agents of human disease.[33,186,585] While several different species of coagulase-negative staphylococci have been described (Box 12-2), relatively few of them cause infections in humans. However, as more laboratories have attempted to identify the coagulase-negative staphylococci, infections caused by other species are being recognized more frequently. The types of infections associated with coagulase-negative staphylococci are described in Box 12-6.

Staphylococcus epidermidis. When clinical findings are correlated with the isolation of coagulase-negative staphylococci, *S. epidermidis* is by far the most frequently recovered organism, accounting for 50% to over 80% of isolates. Almost all infections caused by *S. epidermidis* are nosocomially acquired, except for native valve endocarditis and infections of semipermanent venous access devices. In addition to both native valve and prosthetic valve endocarditis, *S. epidermidis* has been isolated and documented as a pathogen in urinary tract infections, surgical wound infections, infections of various prosthetic devices, cerebrospinal fluid (CSF) shunt infections, peritoneal dialysis-related infections, and ophthalmic infections (Box 12-6).[103] Several virulence factors have now been described in *S. epidermidis*.[400,601] Scanning and transmission electron microscopic studies and immunologic examination of *S. epidermidis* strains from infections of indwelling medical devices demonstrated that these bacteria produce cell surface and extracellular macromolecules that initiate and subsequently enhance bacterial adhesion to foreign bodies, eventually forming a biofilm.[469] When plastic prosthetic devices are implanted they become rapidly coated with serum proteins, and *S. epidermidis* is able to specifically bind to fibronectin, fibrinogen, collagen, and vitronectin as well as to the plastic catheter material itself. A wide spectrum of adhesin molecules that are able to bind these serum proteins are found on the cell surface of *S. epidermidis* and include Aae and AltE (autolysin-adhesins), Ebp (Elasin-binding protein), Empb (extracellular matrix-binding protein), Fbe (fibrinogen-binding protein), and GehD (glycerol ester hydrolase).[60,213,223] Several staphylococcal surface proteins (e.g., Ssps) that bind directly to polystyrene have also been

TABLE 12-1 CDC Confirmatory Test for Detection of VISA and VRSA[202]

Method	Results for VRSA	Results for VISA	Comments
Reference broth microdilution	Vancomycin MIC ≥16 μg/mL in Mueller–Hinton broth	Vancomycin MIC of 4–8 μg/mL in Mueller–Hinton broth	Incubate for a full 24 hours.
Brain–heart infusion agar with 6 μg/mL vancomycin (commercial source)	Growth of >1 colony in 24 hours	Growth of >1 colony in 24 hours	Two or more colonies is a positive test.[a]
Etest	Vancomycin MIC ≥16 μg/mL on Mueller–Hinton agar	Vancomycin MIC ≥4 μg/mL on Mueller–Hinton agar	Use a 0.5 McFarland standard to prepare the inoculum suspension and incubate for a full 24 hours.

[a]For QC, use *Enterococcus faecalis* ATCC 29212 as a susceptible control and *Enterococcus faecium* ATCC 51299 as a resistant control.

BOX 12-6

Infections Associated With *Staphylococcus epidermidis* and Other Coagulase-Negative Staphylococci

Infection	Comments
Urinary tract infections	Among the coagulase-negative staphylococci, *S. saprophyticus* causes both upper and lower urinary tract infections, primarily in young, sexually active women. This organism is the second most common cause of urinary tract infections after *Escherichia coli*, and is found in 3%–9% of acute, uncomplicated cystitis.[219,444] Complications of *S. saprophyticus* urinary tract infections include pyelonephritis, sepsis, kidney stones, and, rarely, endocarditis.[100,165,219,496] *S. saprophyticus* may also cause urinary tract infections with or without attendant complications in male children and men.[163,544] In clean-voided urine or catheterized specimens, colony counts of *S. saprophyticus* may be less than 100,000 cfu/mL and, consequently, the organism may be dismissed as a contaminant. Other coagulase-negative staphylococci are rare causes of urinary tract infections, and about 80%–90% of these infections are caused by *S. epidermidis*. Urinary tract infections caused by *S. epidermidis* and other coagulase-negative staphylococci are usually nosocomial and associated with indwelling urinary catheters. These infections occur in elderly male patients with prior urinary tract instrumentation, renal transplantation, urolithiasis, or other urological abnormalities. Pyuria and significant upper tract disease are usually seen in only about 10% of the latter group of patients. Coagulase-negative isolates from these patients are often multiply-resistant.
Implanted prostheses-related infections	Device-related infections in this category include various types of prostheses (e.g., knee and hip replacements). Coagulase-negative staphylococci, particularly *S. epidermidis*, are the most common cause of infections of implanted prosthetic devices.[126,581] Small numbers of organisms may be introduced during device placement or manipulation, leading to device loosening and failure, usually within 2 months to 2 years after implantation. Patients may also have histories of underlying diseases, including malignancy, corticosteroid use, sickle cell anemia, solid organ transplantation, and HIV infection. Other conditions such as obesity also may contribute. Patients usually present with dull recurring pain at the affected area. Prostheses-associated infections are diagnosed by direct examination and culture of needle aspirates from the affected site, by bone biopsy, or removal and culture of the implanted material. It has been shown that sonication of the explanted device prior to culture may increase the yield of organisms.[545] Following device removal and tissue debridement, patients are generally treated with antibiotics (i.e., usually vancomycin alone or combined with rifampin), and the device is reimplanted. Osteomyelitis due to coagulase-negative staphylococci may occur as a complication of prostheses implantation. Hematogenous osteomyelitis may result from bacteremia with coagulase-negative staphylococci arising from infections of shunts or other prosthetic devices.
Native valve endocarditis	Coagulase-negative staphylococci are rare causes of native valve endocarditis, accounting for about 7%–11% of all cases, excluding those cases associated with intravenous drug use.[10,102,104,128,378,381,430] Pathogenesis involves seeding of previously damaged heart valves or endocardium during transient bacteremia, although rare cases of native valve infection without prior underlying cardiac disease do occur.[10] *S. epidermidis* causes about 85% of cases of native valve endocarditis, with the remainder being caused by *S. hominis* (~6%), *S. lugdunensis* (~5%), *S. haemolyticus*, *S. capitis*, *S. caprae*, and *S. simulans*.[116,156,258,495,520] *S. lugdunensis* is the cause of 3%–8% of native valve endocarditis, often in the setting of preexisting cardiac and valvular disease (e.g., mitral valve prolapse). *S. lugdunensis* infective endocarditis can be unusually severe, with massive valvular destruction.[167,417,495] Complications (e.g., embolic phenomena, conduction defects, congestive heart failure) occur commonly in these patients and more than 50% of patients ultimately require valve replacement.[73,102,417] Mortality associated with this condition may be as high as 36%–40%.[104] Infections of cardiac pacemakers may occur at the time of placement or via hematogenous seeding of the device from a distant site.
Prosthetic valve endocarditis	In contrast to native valve endocarditis, coagulase-negative staphylococci are common etiologic agents of prosthetic valve endocarditis and cause from 20%–40% of cases, with *S. epidermidis* being the most frequently isolated species, almost to the exclusion of all others.[104,308,586] In this infection, organisms infect the ring of sutures holding the valve in place, causing the formation of micro-abscesses that are relatively protected from antibiotics. These organisms are usually inoculated into the site during surgery with symptoms becoming apparent 8–12 months later. The patient usually presents with fever and evidence of valve dysfunction. Diagnosis is made by blood cultures, which will be repeatedly positive with the same organism, and by transesophageal echocardiography. Complications are common and include dehiscence of the valve, intracardiac abscesses, valve obstruction due to formation of bulky vegetations, and occasionally cardiac dysrhythmia.[104,308,586] Since most of these infections are probably due to inoculation of small numbers of organisms into the site at the time of valve placement, the symptoms of endocarditis appear slowly over a period of several months. In addition to prosthetic valves, staphylococci may also infect pacemaker wires, implanted defibrillators, and vascular grafts. These infections also have an indolent presentation and transesophageal echocardiography is very helpful for delineating the extent of infection. Sequential blood cultures are usually positive. Treatment involves removal of the device and antimicrobial therapy, followed some time later by device replacement.

Intravenous catheter infections	Coagulase-negative staphylococci are responsible for 50%–70% of nosocomial bloodstream infections involving intravascular catheters, including both central venous and peripheral intravenous catheters.[209] Other implicated catheter types include central hyperalimentation catheters, subclavian hemodialysis catheters, Hickman and Broviac central lines, and Swan–Ganz catheters. For peripheral catheters, infection usually results from skin organisms that enter via the cutaneous surface along the catheter, thereby gaining access to the bloodstream. For longer-term and tunneled catheters, the hub of the catheter becomes colonized with skin or environmental bacteria. Organisms then gain access to the bloodstream via the lumen of the catheter itself.[146] Infected catheters may be the source of bacteremias, which may seed distant sites to create additional infectious complications. Infected catheters and catheter insertion sites often do not appear infected (e.g., erythema or purulence may not be present) and catheter-related bacteremia may be minimally symptomatic. While assiduous care of catheters may decrease the incidence of these bacteremic episodes, other innovations, such as antibiotic-impregnated catheters (e.g., rifampin- or minocycline-impregnated catheters) appear to significantly decrease the incidence of catheter-related infections.[118] Therapy for these infections includes removal of the catheter, if possible, along with systemic antimicrobial therapy. Documentation of intravenous catheter-related infections and bacteremias involves culture of peripheral blood by venipuncture, culture of blood drawn through the catheter, and, oftentimes, culture of the catheter tip itself. Several protocols have been proposed for documentation of catheter-related infections. Incubation time to positivity of less than 25 hours has been considered as an indicator of catheter-related bacteremia in immunocompromised pediatric patients, as the blood collected through the catheter would have a larger microbial burden than the peripheral blood collection.[337,348,614] A difference in detection time of 2 hours or more between blood cultures collected through the catheter and a peripheral blood culture has also been promulgated as a sensitive and specific way to diagnose catheter-related bacteremia.[176,441]
Cerebrospinal fluid shunt infections	*S. epidermidis* and other coagulase-negative staphylococci are common causes of infection associated with ventricular shunts, indwelling CSF catheters, intrathecal pumps, and ventriculostomy sites.[439,587] These infections usually occur within 2 weeks to 2 months after shunt placement, but may also occur during other shunt manipulations. Patients with CSF shunt infections may be asymptomatic, although some may present with subtle symptoms, including low-grade fever, nausea, vomiting, and headache. Examination of CSF aspirated from the shunt may show mild pleocytosis, with glucose being normal or slightly low. Diagnosis is made by culture of CSF from the shunt or from the cerebral ventricles. Prophylactic antimicrobial therapy following shunt placement may reduce shunt-related infection in up to 50% of patients.[443] Shunt removal and subsequent replacement is often necessary to effect cure, although some staphylococcal shunt infections have been effectively treated with antimicrobial agents alone.[482] Therapeutic agents usually include vancomycin, rifampin, and an aminoglycoside administered intraventricularly, since these nosocomially acquired infections are often due to staphylococci that are resistant to methicillin.
Peritoneal dialysis catheter-associated infections	Coagulase-negative staphylococci are the most frequently isolated organisms from patients with CAPD-associated peritonitis.[155,526] Peritonitis is characterized clinically by abdominal pain, nausea, vomiting, fever, and a cloudy effluent after dialysis, although many patients may have only a few or very mild symptoms. Peritoneal fluid may appear cloudy and may contain >100 leukocytes per mL. Gram stains of unconcentrated fluid may be negative, necessitating centrifugation or filtration for recovery of small numbers of organisms. Antimicrobial therapy of CAPD-associated staphylococcal peritonitis may be administered parenterally, orally, and/or intraperitoneally and usually includes oxacillin or methicillin, cephalosporins, vancomycin, or trimethoprim-sulfamethoxazole.
Vascular graft infections	Vascular graft infections are often caused by coagulase-negative cocci, particularly *S. epidermidis*.[84,320] The incidence of vascular graft infections ranges from 0.6% to 3% and depends on the graft location, with aortic vascular grafts having the highest morbidity and mortality rates, and inguinal grafts involving the groin area having higher infection rates. Vascular graft infections that occur early after graft placement are more acute in clinical presentation and usually involve gram-negative bacteria (e.g., *Enterobacteriaceae*, *Pseudomonas aeruginosa*) and *S. aureus,* while infections occurring months later usually involve coagulase-negative staphylococci. Staphylococcal isolates recovered from these infections are often multiply-resistant, suggesting that the infections are due to the presence of contaminating organisms in the grafts themselves. Patients may be considered to have definite vascular graft infection if the patient has clinical signs of infection (e.g., fever, chills, shock, pain/erythema in the area of the prosthesis), biologic evidence of infection (e.g., elevated white blood cell count, elevated C-reactive protein, abscess, perigraft air or fluid on CT scans), and positive blood cultures and/or positive intraoperative specimens from the graft itself.[319] In addition to blood cultures, the most suitable specimens for microbiologic diagnosis of vascular graft infections include explanted graft tissue, perigraft fluid obtained by CT-guided aspiration, or specimens from the graft obtained during surgery.[320] Oftentimes, removal of the vascular graft along with antimicrobial therapy, is necessary to prevent additional morbidity and motality.[470]

Bloodstream infections	In some medical centers, coagulase-negative staphylococci (particularly *S. epidermidis*) are the most common agents of bloodstream infections, being responsible for 30%–40% of these cases.[602] These organism usually reach the bloodstream via infected vascular access devices.[362] Patients who develop catheter-related staphylococcal bacteremia usually have multiple access devices in place for treatment of hematologic malignancies or administration of chemotherapeutic agents for bone marrow transplantation. Patients usually present with signs and symptoms of bacteremia, with fever, hypotension, and leukocytosis, but obvious clinical signs and symptoms may be absent.[595] The issue is complicated by the fact that coagulase-negative staphylococci are the most common blood culture contaminants and intravenous catheters often become contaminated with coagulase-negative staphylococci.[38] Blood cultures collected through catheters should be accompanied by peripheral cultures collected by venipuncture to assess whether the catheter is the source of possible bloodstream infection.[362] Semiquantitative cultures of intravenous catheter tips are commonly performed in laboratories. The catheter roll technique described by Maki and colleagues[337] indicates that colony counts of 15 cfu or greater suggests a possible diagnosis of catheter-related bloodstream infection. Positive semiquantitative cultures with negative peripheral blood cultures indicate catheter colonization.[468] Empiric therapy should be directed against methicillin-resistant coagulase-negative staphylococci, but also requires catheter removal, if possible.
Neonatal and pediatric infections	Most pediatric infections are nosocomial staphylococcal bacteremias occurring in neonatal intensive care units.[264,573] These infections are associated with prematurity, low birth weight, the presence of indwelling peripheral and/or central lines, ventilatory assistance, and administration of total parenteral nutrition.[169,581] While most staphylococcal agents in such infections are *S. epidermidis*, other species (e.g., *S. haemolyticus*, *S. hominis*, *S. warneri*, *S. cohnii*, *S. capitis*) have also been involved. In some instances, coagulase-negative staphylococci causing infections in neonatal intensive care units originate from nurses and other caregivers or from the hospital environment. Neonates with bacteremia due to coagulase-negative staphylococci may present with neutropenia, thrombocytopenia, metabolic acidosis, and apnea. In addition to bacteremia, coagulase-negative staphylococci can also cause pneumonia, meningitis, urinary tract infections, and cutaneous manifestations.
Ocular infections	Coagulase-negative staphylococci are the most frequently implicated pathogen causing postsurgical endophthalmitis. Surgical procedures associated with these infections include lens implantation and cataract surgeries.[1,46,119,309] The diagnosis is made by aspiration and culture of vitreous fluid. Treatment of coagulase-negative staphylococcal endophthalmitis requires both parenteral and intraventricular administration of antimicrobial agents, including linezolid, rifampin, and/or vancomycin. Coagulase-negative staphylococci have also caused hospital-acquired conjunctivitis in neonatal ICUs, suture-related corneal infections following penetrating keratoplasty, blepharokeratoconjunctivitis, and purulent conjunctivitis.[59,235,607] Coagulase-negative staphylococci may also be a cause of bacterial keratitis, particularly in the settings of previous corneal surface disease and ocular trauma.[197] Coagulase-negative staphylococci are the predominant organisms causing chronic dacryocystitis (inflammation of the lacrimal sac). In a study conducted in India, 44.2% of isolates from patients with chronic infection were coagulase-negative staphylococci, while *S. aureus* and *S. pneumoniae* accounted for 10.8% and 10% of isolates, respectively.[29] Coagulase-negative staphylococci are also significant causes of conjunctivitis in newborns.[583] A susceptibility survey of 117 coagulase-negative staphylococcal corneal isolates found that all were susceptible to vancomycin, linezolid, and rifampin, and that susceptibility to gentamicin, tetracycline, and fluoroquinolones varied considerably.[150] The ARMOR ocular surveillance studies have noted that resistance among coagulase-negative staphylococci to ophthalmic fluoroquinolones (e.g., ofloxacin, gatifloxacin, moxifloxacin) will need to be monitored prospectively to prevent treatment failures and provide guidance for empiric therapy of ocular infections.[201]
Cutaneous infections	Coagulase-negative staphylococci may be recovered from a variety of cutaneous lesions (cysts, carbuncles, furuncles) both alone and along with other pyogenic bacteria, including *S. aureus* and β-hemolytic streptococci. Coagulase-negative staphylococci are also common in polymicrobial surgical site infections, particularly following cardiothoracic surgery.[502] The most commonly implicated species have included *S. epidermidis*, *S. haemolyticus*, *S. lugdunensis*, and *S. hominis*. Unusual cutaneous infections involving *S. epidermidis* include malignant external otitis.[504]

discovered. Following initial adhesion, the microorganisms synthesize a polysaccharide intercellular adhesin (PIA) that crosslinks cells together within the developing biofilm. PIA is a linear polysaccharide composed of β-1,6-linked 2-deoxy-2-amino-D-glucopyranosyl residues, of which 80% to 85% are *N*-acetylated, with the rest being either non–*N*-acetylated and positively charged or modified with phosphate or

succinate residues and negatively charged.[335,465,466]PIA structural genes reside within a four-gene chromosomal operon called *ica*, with the four genes being designated *icaA*, *icaB*, *icaC*, and *icaD*. *S. epidermidis* also produces phenol-soluble modulins (PSMs) like *S. aureus* that act to disperse the outer biofilm layers, which subsequently interact with neutrophils, causing degranulation and cell lysis.[400] *S. epidermidis* also

produces a variety of bacteriocins that bind to and lyse other bacteria, allowing the organism to compete more effectively with other bacteria and efficiently colonize skin surfaces. Once established on cutaneous surfaces, some *S. epidermidis* produce proteases, lipases, and fatty acid modifying enzymes that contribute to cutaneous staphylococcal and polymicrobial infections.[469] Resistance to methicillin is also highly prevalent among *S. epidermidis* isolates, with rates ranging from 75% to over 90%, and SCC*mec* types I, IIa, IIb, III, IV, IVa-IVd, V, and several variants of these types have been detected in *S. epidermidis* isolates from humans.[174,239,372,467,621] SCC*mec* types conferring resistance to methicillin are also found in other human- and animal-associated coagulase-negative staphylococcal species, including *S. haemolyticus* (SCC*mec* types I-V, III variant), *S. warneri* (SCC*mec* type IVE), *S. saprophyticus* (SCC*mec* type III, *S. hominis* (SCC*mec* III), *S. capitis* (SCC*mec* types I, IA, II-V), *S. sciuri* (SCC*mec* type III),*S. xylosus* (SCC*mec* type III), and *S. lentus* (SCC*mec* type III).[174,342,467,618,621]

Staphylococcus saprophyticus* subsp. *saprophyticus. The coagulase-negative species *S. saprophyticus* deserves special mention as this species is a well-documented cause of acute urinary tract infections. In 1996, a new subspecies *of S. saprophyticus* was characterized among coagulase-negative, novobiocin-resistant strains recovered from 7% of nostril cultures from healthy cows.[207] Phenotypic characteristics, cell wall and fatty acid analysis, and genetic relatedness studies showed that these isolates were similar to but distinct from *S. saprophyticus* isolates recovered from humans. These bovine strains have since been named *S. saprophyticus* subsp. *bovis*, while human isolates are now called *S. saprophyticus* subsp. s *aprophyticus* (hereafter referred to as *S. saprophyticus*).

S. saprophyticus causes both upper and lower urinary tract infections, primarily in young, sexually active women of childbearing age. This organism is the second most common cause of urinary tract infections after *Escherichia coli* and is found in 3% to 9% of acute, uncomplicated cystitis.[221,444,601] In urine specimens from these patients, the organism is usually present in quantities ≤100,000 cfu/mL, but will be detected in sequential specimens. Patients usually present with dysuria, pyuria, and hematuria.

Upper urinary tract infections (i.e., pyelonephritis) may be seen in 41% to 86% of patients and, occasionally, *S. saprophyticus* bacteremia may occur as a complication of upper urinary tract infection.[100,188] Complications of *S. saprophyticus* urinary tract infections include pyelonephritis, sepsis, and kidney stones.[100,165,219,496] *S. saprophyticus* may be a cause of acute, symptomatic urinary tract infections in both male and female children and teenagers in the absence of urinary tract structural abnormalities.[4,263,544] This organism has also caused acute urinary tract infections, urethritis, and catheter-associated urinary tract infections in men, prostatitis in elderly men, and rarely, bacteremia, sepsis, and endocarditis.[50,188,263,382,496] In 1999, Hell and colleagues[224] reported the isolation of *S. saprophyticus* as a cause of nosocomially acquired pneumonia. The rectal canal likely serves as the reservoir for the organism and food may be the ultimate source for the organism, as it has been isolated from farm animals, raw beef and pork, pasture grass, and fodder.[220,221] Molecular studies of isolates from urinary tract infections indicate that multiple clonal types of *S. saprophyticus* are capable of causing disease and these pathogenic clones are widely disseminated and persist in the population for several years.[601]

Other Coagulase-Negative Staphylococci. Other staphylococcal species are found in humans and animals as part of the normal microbiome and as causes of several types of infections (Box 12-2). Some species are environmental and have uses in various industries, including food processing. While coagulase-negative species other than *S. epidermidis* and *S. saprophyticus* are frequently found as contaminants in clinical specimens, medical progress has created an important role for many other coagulase-negative staphylococci in human infections and disease. Several species have been reported as causes of human infections, principally in wounds, urinary tract infections, bloodstream infections, osteomyelitis, catheter-related sepsis, ventriculoperitoneal shunt infections, and both native valve and prosthetic valve endocarditis (Boxes 12-2 and 12-6). They are important opportunistic pathogens in immunocompromised patients, including premature neonates, neutropenic cancer patients, elderly persons with serious underlying diseases, and hospitalized patients following invasive procedures and with indwelling plastic devices. Infections with many of these other species are acquired in the hospital setting. Commonly implicated species include *S. haemolyticus*, *S. lugdunensis*, *S. schleiferi*, *S. warneri*, *S. hominis*, *S. simulans*, *S. capitis*, *S. cohnii*, *S. xylosus*, and *S. saccharolyticus*.[455] Some of these agents, such as *S. schleiferi* and *S. warneri*, produce a variety of extracellular products (i.e., glycocalyx, DNase, lipase, esterase, protease, and α- and β-hemolysins) that contribute to virulence. *S. haemolyticus* has demanded increased interest due to emergence of glycopeptide resistance in this species. *S. lugdunensis* has emerged as a significant pathogen causing primarily endocarditis and skin/soft tissue infections. The

ecological niches and clinical significance of staphylococci other than *S. aureus*, *S. epidermidis*, and *S. saprophyticus* are described in Box 12-2, while infectious processes associated with *S. epidermidis* and other coagulase-negative staphylococci are described in Box 12-6.

Micrococcus *Species and Related Genera*

Several micrococcal species have been recovered from human clinical specimens, particularly *Kocuria* species, *Kytococcus* species, and *Micrococcus* species. *Kocuria kristinae* has been isolated as a cause of catheter-related bacteremia, infective endocarditis, peritoneal dialysis-associated infections, and cholecystitis-associated infections.[11,32,307,333] *K. kristinae, K. marina*, and *K. rosea* have all been described as causes of peritonitis in CAPD-patients.[75,141,317] *K. rhizophila* also caused persistent bacteremia related to a damaged central line, and, in another case, this organism colonized the Port-A-Cath of a pediatric patient, resulting in septic episodes over a 2-year period when both line and peripheral blood cultures were positive.[36,371] *K. varians*was

isolated as the sole agent in a brain abscess in a diabetic patient.[549] *Kytococcus* species, particularly *K. schroeteri*, have emerged as unusual agents in a variety of human infections. Several cases of aortic- and mitral-prosthetic and bioprosthetic valve endocarditis due to *K. schroeteri* have appeared since 2002.[37,314,370,447,616] Therapy often requires surgical intervention, although successful treatment outcomes with vancomycin/gentamicin plus rifampin and daptomycin monotherapy have been reported.[326] Bacteremic pneumonia due to *K. schroeteri* was documented in three patients with acute myeloid leukemia. These isolates were generally susceptible to linezolid, trimethoprim-sulfamethoxazole, rifampin, gentamicin, imipenem, meropenem, and vancomycin.[57,231,321] *K. schroeteri* has also been isolated from cases of chronic implant-related arthritis, osteomyelitis, and postoperative spondylodiscitis.[85,250] In the latter case, the patient had undergone surgical discectomy for treatment of chronic sciatica.[250] *K. schroeteri* has been isolated from shunt-associated ventriculoperitoneal fluid specimens, and both *K. schroeteri* and *K. sedentarius* have been isolated from peritoneal fluids of patients who are treated with continuous ambulatory peritoneal dialysis (CAPD).[93,255,476] *Micrococcus* species have been isolated from cases of bacteremia, peritoneal dialysis-associated peritonitis, septic arthritis, meningitis, and both native valve and prosthetic valve endocarditis.[260,367,551]

Rothia mucilaginosa

Since 1978, *R. mucilaginosa* has been reported as an opportunistic agent in a variety of clinical scenarios. Several cases of native valve and prosthetic valve endocarditis caused by *R. mucilaginosa* have appeared in the literature; in some cases, cardiac infection was associated with use of intravenous drugs.[112] *R. mucilaginosa* sepsis has been reported in association with head-and-neck trauma, central and peripheral access devices, cancer chemotherapy, cardiac catheterization following myocardial infarction, CAPD, and extreme prematurity.[232,369,436,464] *R. mucilaginosa* also has emerged as a significant pathogen in both adults and children with underlying malignancies (e.g., leukemia, lymphoma, breast cancer, Hodgkin's disease, squamous cell carcinoma, osteosarcoma, rhabdomyosarcoma, and AIDS) and in recipients of bone marrow transplants.[2,17,190,294,315,546,550] Infections have included transient and sustained bacteremias, peripheral and central line-associated sepsis, pneumonia, meningitis, vertebral osteomyelitis, and cholangitis.[2,17,158,190,315] Recovery of *R. mucilaginosa* from these patients was associated with severe neutropenia as a result of underlying disease, immunosuppression, or cytotoxic chemotherapy. Colonized indwelling access devices (e.g., intravenous or intraarterial lines, Brouviac and Hickman catheters) were the source of the organism in some patients, while mucosal or esophageal ulcerations secondary to cytotoxic chemotherapy, periodontal disease, or dental infections or procedures were believed to be possible sources in others. *R. mucilaginosa* may rarely cause bone and joint infections, including septic arthritis, vertebral osteomyelitis, and postoperative spondylodiskitis.[69,257] In rare cases, *R. mucilaginosa* may cause severe disease (e.g., meningitis) in healthy individuals.[451]

Isolation and Preliminary Differentiation of Staphylococci and Related Gram-Positive Cocci

Direct Gram-Stained Smears

On direct Gram-stained smears from clinical specimens, staphylococci appear as gram-positive or gram-variable cocci ranging in size from 0.5 µm to about 1.5 µm in diameter (Image Plate 12-1D and 12-1F). Larger cells are seen among members of the genus *Macrococcus*, but these species are not causes of human infections.[281] The organisms may appear singly, in pairs, in short chains, or in clusters, both within and outside of polymorphonuclear cells. Variations in cell size and Gram reaction are probably due to the action of the inflammatory cells and their hydrolytic enzymes on the bacterial cells. On direct smears, pairs and short chains of organisms cannot be differentiated from streptococci, micrococci, or peptostreptococci, although

streptococci frequently appear as chains of diplococci rather than as chains of discrete, individual cells. Reports of direct smears should include quantitation of cell types and microorganisms (e.g., "many PMNs, moderate gram-positive cocci"). If the Gram's stain appearance is more typical, a report of "gram-positive cocci resembling staphylococci" can be issued, with culture confirmation to follow. Gram's stain morphology cannot be used to differentiate staphylococci from micrococci and related genera or from planococci.

Isolation From Clinical Specimens

For recovery of staphylococci and related organisms, clinical specimens should be inoculated onto sheep blood agar (SBA) and other bacteriologic media. For isolation of organisms from heavily contaminated specimens, specimens should also be inoculated onto Columbia colistin-nalidixic acid (CNA) media or phenylethyl alcohol (PEA) agar, which inhibit growth of gram-negative bacteria and allow the growth of gram-positive organisms. Mannitol salts agar is a good selective medium for assessing the presence of *S. aureus* in specimens such as nasal cultures. On SBA, most staphylococci produce good growth within 24 hours, although micrococci may require 48 hours for the growth of sizable colonies. Some species of staphylococci may also require more than 24 to 48 hours' incubation in order to discern whether a specimen contains a pure or a mixed culture. Longer incubation—up to 72 hours—may be necessary to ensure that identification and susceptibility tests are being performed on a pure culture, especially if multiple colonies are being sampled to obtain a representative inoculum.

Colony Morphology

Micrococcus and *Staphylococcus* species form distinctive colonies on SBA. Colonies of most staphylococcal species grow more rapidly than micrococci, and are 1 to 3 mm in diameter after 24 hours' incubation, although some (e.g., *S. warneri, S. simulans, S. auricularis, S. vitulinus, S. lentus*) may form smaller colonies during this time. Strains of some staphylococcal species will show considerable variation in the size of colonies on the same culture plate, giving

the appearance of a mixed culture. Staphylococcal colonies are usually smooth, butyrous, and have a low-convex profile with an entire edge. Colonies of some *S. aureus* strains are usually large (4 to 6 mm in diameter) smooth, entire, and butyrous in consistency, although some strains may be wet looking or "sticky." Some strains may be pigmented yellow or yellow-orange (hence the name "aureus," meaning "golden"), while other strains may produce off-white or gray colonies. The latter strains may resemble group D streptococci and enterococci (catalase-negative).

Pigment production in both *S. aureus* and among the coagulase-negative staphylococci usually becomes more pronounced after incubation at room temperature for 2 to 3 days. Some *S. aureus* and some coagulase-negative species may have a distinct or hazy zone of β-hemolysis around the colonies (Image Plate 12-1E); this hemolytic property may become apparent only after prolonged incubation.

Isolates of *S. aureus* from patients who have been treated with antimicrobials for long periods or who have certain persistent underlying conditions such as cystic fibrosis may grow as small, atypical colonies that are known as small-colony variants. These colonies are usually very small, nonpigmented, and grow better in the presence of CO_2. These isolates may also be difficult to test for antimicrobial susceptibility due to their poor growth. Broth used in microdilution susceptibility testing of these isolates may require supplementation, and agar dilution, disk diffusion, and Etest-susceptibility methods should be performed on Müeller–Hinton agar containing 5% sheep blood.

Micrococci and related species generally grow more slowly, often requiring 48 hours' incubation before typical colony morphology can be discerned. After this time, micrococcal colonies are 1 to 2 mm in diameter, are dull or matte in textural appearance, and have a high-convex profile with entire edges. Colonies of *Micrococcus*, *Nesterenkonia, Dermacoccus*, *Kocuria* species, and *A. agilis* may be smooth or matte in appearance. Some species are nonpigmented (*M. lylae, N. halobia*), or may produce yellow (*M. luteus*, *K. sedentarius*, *K. varians*, *K. palustris*, *K. rhizophila*), orange (*D. nishinomiyaensis*, *K. kristinae*), or pink-to-red (*K. rosea*, *A. agilis*) colonies on agar media (Image Plate 12-1H). Pigmentation usually becomes more obvious or intense if plates are incubated at room temperature for several days. Colonies of *R. mucilaginosa* are gray to white and may be mucoid in appearance. They tend to adhere to the agar and, when removed from the media, are rubbery and difficult to emulsify.

The Catalase Test

Staphylococci and micrococci are differentiated from the streptococci, enterococci, and "*streptococcus*-like" bacteria by the catalase test. This test detects the presence of cytochrome oxidase enzymes (see Chart 1-1). The catalase test is performed with 3% hydrogen peroxide (H_2O_2) on a glass slide. Immediate and vigorous bubbling indicates conversion of the H_2O_2 to water and oxygen gas (Image Plate 12-1G). Ideally, the catalase test should be performed from a medium that does not contain blood, since red blood cells themselves may produce a weakly positive catalase reaction. However, since most clinical laboratories recover staphylococci on either nonselective or selective blood-containing media (e.g., SBA and CNA agar, respectively), care should be taken to sample only the tops of colonies for the catalase test to avoid carry-over of blood and possible false-positive reactions. This can be done most expeditiously with a wooden applicator stick. Rare strains of staphylococci may be catalase-negative, and

some enterococci produce a "pseudocatalase" and are weakly reactive with H_2O_2. *R. mucilaginosa* is usually catalase-negative or weakly positive.

Methods for Differentiating Micrococci and Staphylococci

Several methods are available for differentiating *Micrococcus* and related species and *Staphylococcus* species, the two catalase-positive genera most frequently seen in the clinical laboratory, from other catalase-positive, gram-positive cocci. Some require special media and prolonged incubation, while others are commercially available and provide results within 18 to 24 hours or less. Table 12-2 lists the phenotypic tests for differentiation of *Micrococcus*, *Macrococcus*, and *Staphylococcus* species. Although *Macrococcus* species are primarily equine isolates, reactions for these species are included for primary recognition of macrococcal isolates recovered in laboratories that provide services to veterinary practices.

Fermentation of Glucose. This test is performed in a manner similar to the oxidation-fermentation (OF) tests for nonfermentative gram-negative bacilli. The OF medium for staphylococci contains additional nutrients such as yeast extract to fulfill the more exacting growth requirements of staphylococci. This method, regarded as the reference procedure for differentiation of the *Micrococcaceae*, requires prolonged incubation and is not readily adaptable or amenable to routine laboratory use.

Susceptibility to Lysostaphin. Lysostaphin is an endopeptidase that cleaves the glycine-rich pentapeptide cross-bridges in the staphylococcal cell wall peptidoglycan. This activity renders the cells susceptible to osmotic lysis. Certain staphylococcal species (i.e., *S. aureus*, *S. simulans*, *S. cohnii*, *S. xylosus*) are more susceptible to lysostaphin than others (e.g., *S. hominis*, *S. saprophyticus*, *S. haemolyticus*), hence standardization and interpretation of this test is sometimes difficult. A tube test for lysostaphin susceptibility is commercially available from Remel (Remel Inc., Lenexa, KA). A heavy suspension of the organism is prepared in 0.2 mL of sterile saline, after which 0.2 mL of the Remel lysostaphin solution is added. The suspension is incubated at 35°C for 2 hours. Clearing of the suspension indicates susceptibility to lysostaphin. Lysostaphin susceptibility can also be determined using a filter paper-disk diffusion method. A plate of Müeller–Hinton agar is inoculated with the organism to be tested (0.5 McFarland turbidity standard) and a disk impregnated with 10 µg of lysostaphin filter-sterilized solution, 287 units/mL) is placed on the plate. The plate is incubated for 24 hours at 35°C. *Staphylococcus*species will generally show zones of inhibition of 10 to 16 mm in diameter. *Micrococcus* and related species will show no zones. In order to obtain optimal results with the lysostaphin susceptibility test, the organism should be grown on a beef peptone-based medium rather than on a casein peptone- or soy peptone-based medium. The crucial factor is the glycine content of the medium,

since glycine is an

TABLE 12-2 Phenotypic Characteristics for the Differentiation of *Staphylococcus, Micrococcus* and Related Species, and *Macrococcus*

Characteristic	Reaction/Description for: *Staphylococcus*	*Micrococcus* and Related Species[a]	*Macrococcus*
Organism size	0.6–1.6 µm	1–1.8 µm	1.3–2.5 µm
Colony profile	Raised, low convex	Convex	Low convex, domed
Growth rate	Slow to rapid	Very slow	Slow
Fermentation of glucose	+	–	–
Furazolidone susceptibility (100 µg furazolidone disk)	S	R	S
Bacitracin susceptibility (0.04 unit TaxoA disk)	R	S	R
Modified oxidase test	–[b]	+	+
Susceptibility to lysostaphin	S	R	S
Facultative growth under a coverslip on blood agar	1+ to 4+	–/1+	NA
Acid production aerobically from glycerol in the presence of 0.4 µg/mL erythromycin	+	–	NA

[a] Includes the genera *Micrococcus, Kytococcus, Dermacoccus, Nesterenkonia,* and *Kocuria.*
[b] All *Staphylococcus* species are modified oxidase-negative except for *S. vitulinus, S. sciuri,* and *S. lentus.*
+, positive reaction; –, negative reaction; S, susceptible; R, resistant; NA, data not available.

important part of the staphylococcal cell wall and is essential for the action of lysostaphin.

Production of Acid From Glycerol in the Presence of Erythromycin. In this test, medium containing glycerol (1%) and erythromycin (0.4 µg/mL) is prepared with an enriched agar base containing bromcresol purple indicator and poured into Petri plates. Several colonies of the isolate are streaked as a single line on the medium and the plate is incubated for up to 3 days at 35°C. Staphylococci will produce acid on this medium, while micrococci and related species will not.

Susceptibility to Furazolidone. This test is performed as a disk susceptibility procedure using commercially available disks (FX disks, 100 µg, BD Biosciences, Sparks, MD). The procedure for this test is described in detail in Chart 12-1. Staphylococci are inhibited by furazolidone and show zones of 15 mm or more, while micrococci and related species are resistant and show zones of 6 mm (no zone) to 9 mm (Image Plate 12-2A and 12-2B).[28] However, coagulase-negative staphylococci that are resistant to furazolidone may be seen occasionally.

Modified Oxidase Test.[28,157] This test is also commercially available from Remel

(Microdase Test Disks, Remel, Inc.). Filter paper disks impregnated with tetramethyl-*p*-phenylenediamine dihydrochloride (oxidase reagent) in dimethyl sulfoxide (DMSO) are used. The DMSO renders the cells permeable to the reagent. A colony from the growth medium is removed with an applicator stick and rubbed onto the disk. The development of a blue-purple color within 30 seconds is a positive test. No color development within this time is a negative test (Image Plate 12-2C). *Micrococcus* species, *N. halobia*, *D. nishinomiyaensis*, *A. agilis*, *K. kristinae*, and *Macrococcus* species are modified oxidase-positive, while strains of *K. sedentarius*, *K. rosea*, *K. varians, K. palustris*, and *K. rhizophila* are modified oxidase-negative.[281,292,512] All *Staphylococcus* species are modified oxidase-negative except for strains of *S. sciuri*, *S. lentus*, and *S. vitulinus*.[282]

Susceptibility to Bacitracin. This procedure employs the same bacitracin disk used for the presumptive identification of group A β-hemolytic streptococci. A lawn of growth is prepared on a Müeller–Hinton agar or a blood agar plate as described above for the FX disk test, and a bacitracin differential disk (Taxo A, 0.04 units bacitracin, BD Biosciences) is placed on the inoculum. After overnight incubation, zone sizes are measured. Staphylococci are resistant and grow to the edge of the disk, while micrococci and related species are susceptible, producing zones of 10 mm or greater.[28]

Coverslip Growth Method. This method takes advantage of the strictly aerobic character of micrococci and related species and the facultative metabolism of the staphylococci.[360] To perform the test, the organism is streaked for isolation onto a blood agar plate and a sterile coverslip is placed onto a heavily inoculated area of the plate (i.e., the second quadrant of a four-quadrant inoculation). After overnight incubation at 35°C to 37°C, the plate is checked for growth underneath the coverslip. In the original description of this test, 15 *S. aureus* strains, 20 coagulase-negative staphylococcal isolates, 18 *M. luteus* isolates, and single isolates of other

Micrococcus-like organisms (*K. rosea*, *D. nishinomiyaensis, K sedentarius*, *K, kristinae*, *K. varians*) were tested. All micrococci and related species failed to grow under the coverslip, while all staphylococci except a few animal isolates (e.g., *S. equorum*, *S. intermedius*, *S. kloosii*, *S. lentus*, *S. sciuri*) demonstrated at least 1+ growth. The test correlated well with furazolidone and bacitracin susceptibility tests.

The choice of the method used in a given laboratory depends upon the type of work performed (e.g., reference laboratory, environmental microbiology, clinical laboratory). In most clinical microbiology laboratories, the modified oxidase test, the furazolidone disk test, and the Taxo A bacitracin disk test are probably the most logical choices,

since they are rapid, reliable, inexpensive, and commercially available.

Methods for Direct Detection of MRSA in Clinical Specimens

Chromogenic Media for Surveillance of MRSA Colonization

Several chromogenic media are available for detection of MRSA in nares specimens and other sites that are sampled to determine colonization with this organism (e.g., axilla, groin). These media contain cefoxitin for detection of methicillin resistance and chromogenic substrates that, when hydrolyzed by specific bacterial enzymes, produce colored colonies. Currently available chromogenic media include Spectra MRSA agar (Remel, Lenexa, KA), BBL CHROMagar MRSA II (Becton-Dickinson, Sparks, MD), MRSA*Select* (Bio-Rad, Hercules, CA), chromID MRSA agar (bioMérieux, Durham, NC), Brilliance MRSA agar (Oxoid/Remel) CHROMagar (CHROMagar Microbiology, France), and Oxacillin-Resistance Screening Agar (ORSA, Oxoid, dehydrated form only). Brilliance MRSA obtained FDA clearance as Spectra MRSA (Remel) in the United States, so these two media are the same. Chromogenic media are inoculated and incubated for specified periods of time as recommended by the manufacturer. For example, Spectra MRSA, chromID MRSA, and Brilliance MRSA are read after 24 hours' incubation at 35°C to 37°C, while MRSA*Select* agar can be read after 18 hours and incubated up to 28 hours before being considered negative for MRSA. In most evaluations of these media, incubation periods of up to 48 hours have been generally used, with a first reading occurring at 18 to 24 hours, depending on the product in use. The sensitivity of these chromogenic media for detection of MRSA varies from as low as 78% to 80% up to 97% to 99% when compared with conventional methods for detection of MRSA (Table 12-3).[79,129,214,217,298,340,376,424,448,564,566,597,604] The specificities of these MRSA media are in the 92% to 99% range. In some cases, prolonging the incubation of these cultures results in a slight increase in sensitivity with a concomitant decrease in specificity. For example, in one study of MRSA*Select* agar, the specificity of the medium for detection of MRSA decreased from 97.2% after 24 hours' incubation to 92.1% after 48 hours while the sensitivity increased from 80.7% to 92.6% during that time period.[340] In the same study, the sensitivity of chromID MRSA increased from 82.8% at 24 hours to 93.5% after 48 hours, with a decrease in specificity of from 96.3% after 24 hours to 89.7% after 48 hours. Chromogenic media for detection of MRSA has also been shown to increase the yield of MRSA over conventional methods (i.e., blood and CNA agar) for polymicrobial wound and selected pulmonary specimens and has been used as a method for easy detection of MRSA in blood cultures.[211,425] In some institutions, nares and other surveillance

specimens are inoculated into enrichment broth (usually TSB with 6.5% NaCl) and incubated for 18 to 24 hours prior to plating on chromogenic media. While this may increase the yield of positive specimens, the advantage of a rapid turnaround time is lost, particularly if chromogenic plates are incubated for 48 hours before final reading.

Molecular Methods for Surveillance of MRSA Colonization

Molecular approaches are also available and FDA-cleared for detection of MRSA in surveillance and infection control programs. These assays are real-time PCR-based assays with short turnaround times compared with culture-based methods. Currently available tests include the BD GeneOhm MRSA assay (Becton-Dickinson Diagnostics, San Diego, CA), the BD Max MRSA assay (Becton-Dickinson), GeneXpert MRSA (Cepheid, Sunnyvale, CA), and the Roche LightCycler MRSA Advanced assay. The BD GeneOhm assay was first marketed as the IDI-MRSA assay.[462] These assays are FDA-cleared for nares specimens only, although studies have examined use of these tests with groin, axilla, and throat specimens, or combined nares/groin specimens.[56,215,234,272] Both the BD GeneOhm and the Cepheid GeneXpert assays co-amplify the extremity of SCC*mec* and part of the adjacent *S. aureus*-specific *orfX* gene at the SCC*mec* insertion site; these assays do not specifically target the *mecA* gene. The BD GeneOhm assay is performed with the SmartCycler instrument (Cepheid) while GeneXpert MRSA is performed with the GeneXpert real-time PCR platform. In this assay, the specimen is placed in a single-use disposable cartridge, which contains freeze-dried beads with all of the reagents needed for specimen DNA extraction, amplification, and detection. This assay requires minimal hands-on time and can be performed in less than 90 minutes. Rates of specimen inhibition for the BD GeneOhm assay are 1.3% to 1.7%, while rates for the GeneXpert MRSA test are 1.6% to 1.8%. The LightCycler MRSA Advanced test is a carousel-based thermal cycler system that can run up to 32 specimens (30 tests and 2 control) at a time and is performed with the LightCycler instrument.[22] The LightCycler MRSA Advanced assay uses swab extraction and mechanical lysis for specimen prep, real-time PCR amplification of MRSA DNA and fluorogenic target-specific hybridization probes for detection of amplified DNA. Each reaction mixture contains an internal control to detect specimen inhibition. These molecular assays have been evaluated individually and in several side-by-side comparisons (Table 12-4).[22,56,61,95,117,139,215,234,248,272,312,341,392,412,427,457,461,518,590,591,605] These studies differ in the populations tested (both low and high prevalence), comparator methods used (direct culture on chromogenic medium, enrichment culture followed by subculture to chromogenic medium), and methods for analyses of discrepant results. In general, these molecular assays have high sensitivity and specificity, with negative predictive values ranging from 93% to 100%.

272	• Specimens from 43 patients • Known high rate of MRSA colonization (12%–15%) • Nares, groin, and combined swabs collected • Cultured directly on chromogenic MRSA agar, incubated 24–48 hours • Swab then placed in TSB with 6.5% NaCl, incubated 48 hours, then subcultured to chromogenic MRSA agar	X		X		84.8/ 73.2	92.7/ 93.5	76.5/ 80.4	95.6/ 90.6	87.0/ 75.0	93.8/ 94.7	80.0/ 84.0	96.2/ 91.1					• Combined specimen data shown • Data: Performance compared with 48 hour enrichment culture • Similar levels of accuracy using the combined specimen approach. Use of combined specimens enhances MRSA colonization detection.
392	• Belgian study • 500 nares specimens • Prevalence of 1.6% • Enriched culture in TSB-3.5% NaCl, incubated overnight • Subcultured to MRSA*Select* and incubated 48 hours	X				62.5	99.0	50.0	99.4	62.5	97.7	31.3	99.4					• Sensitivity noted to be lower in the low prevalence population being tested.
590	• Study performed in the Netherlands • 1,764 at-risk patients • Prevalence of 3.3% • Broth enriched for 24 hours and subcultured to chromogenic MRSA-ID agar and incubated 24 hours	X				82.5	96.5	44.2	99.5	75.0	94.5	33.3	99.1					• Sensitivity, specificity, PPV, and NPV of culture reported as 85.7%, 96.6%, 46.2%, and 99.5%, respectively.
312	• Belgian study • 246 specimens from high-risk patients • Prevalence rates have increased from 4.7% to 19% from 2002 to 2005 • Direct culture on MRSA*Select* incubated 24 hours • Swab placed in TSB with 6.5% NaCl incubated 24 hours • Broth subcultured to MRSA*Select* and incubated 24 hours	X								78.3/ 89.2	97.7/ 97.7	78.3/ 78.3	97.7/ 96.3					• Data: Performance with direct culture/performance with enriched culture. • In vitro data showed Xpert MRSA detected 39/40 representative MRSA strains belonging to SCC*mec* types I, II, IV, and V. • Of the seven isolates missed by Xpert, four were SCC*mec* type IV variant not targeted by the current genXpert MRSA assay.

699

605	• Multicenter evaluation of Xpert MRSA • 1,077 nares specimens from seven US sites • Prevalence: 5.2%–44% • Direct culture on CHROMagar incubated 18–24 hours • Enrichment in TSB-6.5% NaCl and subculture to CHROMagar, with incubation for 24 and 48 hours	X								94.3/ 86.3	93.2/ 94.9	73.0/ 80.5	98.8/ 96.6					• Data: Performance with direct culture/performance with enrichment culture.
139	• Netherlands study • Low prevalence, of 3.9% ("search and destroy" national policy) • Enrichment in phenyl-mannitol broth with ceftizoxime and aztreonam • Subculture to chromogenic medium with confirmation 24 and 48 hours	X		X	X					91.6	97.0	54.3	99.7					• Combined performance data for three body sites • Four of 12 positives detected only after enrichment culture.
461	• Study performed in Ireland • Swab specimens from four sites from 204 patients • Direct cultures on MRSA*Select* agar • Enrichment with subculture to MRSA*Select*	X X		X X	X X					88/ 79 84 92 63	92/ 94 92 94 98	53/ 71 67 69 83	99/ 96 97 99 93					• Data: Performance with direct culture/performance with enrichment culture • Performance data for individual body sites compared with enriched culture results only • Evaluated Xpert with 114 MRSA representing SCC*mec* types IVa, IVb, IVc, IVd, Vt and Vi, and all 114 MRSA isolates and seven control strains were detected. • Level of detection of detection (LOD) was 610 cfu/mL (equiv to 58 cfu/swab)
56	• Eswab fluid used for PCR and enriched culture • Staph broth incubated overnight and subcultured to MRSA*Select* • 50 known MRSA carriers	X	X	X	X					89 68 78	99 98 98							• Pooled results from separate analysis of all three sites increased sensitivity to 92% • Testing of pooled specimens over 12 months had PPV of 77% and a NPV of 99%

700

341	• Belgian study • 52 nose and groin specimens from previously-identified MRSA carriers • Direct culture and after overnight enrichment on CHROMagar	X	X	90.9/ 71.4 100/ 90.5		100/ 57.1 88.2/ 76.1							• Data: Performance with direct culture/performance with enrichment culture • Overnight enrichment drastically increased the number of MRSA true-positive status of screening samples. • For 14 samples that did not show MRSA on direct culture, Xpert detected 2 and BD detected 7 • Compared diagnostic sensitivities of BD and Xpert assays. Sensitivities were high at 10^3 cfu/mL MRSA concentrations (92.3% for BD, 96.3% for Xpert)
457	• 1,891 nasal swabs collected • Direct culture on chromID MRSA (bioMerieux) and incubated 48 hours					60.7	97.3						• Of 24 MRSA isolated from Xpert-Negative sample 3 harbored composite SCC*mec* • Among 61 samples that were culture-negative and Xpert-Positive, 15 MSSA tested positive with pure colonies on Xpert • MSSA included strains with SCC*mec* deletions encompassing *mecA* and MLST clonal complexes
22	• 1,202 collections of double swabs used for PCRs culture • Direct culture on MRSASelect • Cultures incubated 18–28 hours • No enrichment • Prevalence not stated	X				99	95.5	95.2	95.5				• Sequencing of discordant samples confirmed MRSA in 40% of specimens that were culture-negative and PCR-positive by both methods
427	• Multicenter study comparing LightCycler Advanced assay to BD GeneOhm • 1,402 nares specimens from five centers • Direct culture on CHROM agar MRSA read after 24 and 48 hours • Enrichment in TSB-6.5% NaCl, with subculture on CHROMagar and incubation for 24 and 48 hours			95.7/ 88.8	91.7/ 91.8			95.2/ 89.9	96.4/ 96.8	37.8	99.9		• Data: Performance with direct culture/performance with enrichment culture • Following discrepancy analysis, the relative sensitivity of LightCycler and GeneOhm were 92.2% and 93.2% respectively • Specificity was significantly better with the LightCycler Advanced assay • Sensitivity of direct culture was 80.4%.

701

As experience with these assays has accumulated, so has the recognition of staphylococcal isolates that have lost all or part of SCC*mec*. These isolates are termed *mecA* "dropouts," because they lack a functional *mecA* gene, but contain the SCC*mec*junction sequence. These junction sequences can also vary, and coagulase-negative staphylococci may contain similar sequences that can lead to false-identifications of coagulase-negative staphylococci as MRSA.[31,55,312,421,514] MSSA isolates can arise from MRSA following partial or complete excision of SCC*mec*, and, conversely, MRSA can result from MSSA by site-specific integration of SCC*mec* into the *orfX* chromosomal site. Because assays like the BD GeneOhm and the GeneXpert MRSA target the SCC*mec*-*orfX* junction and do not specifically target the *mecA* gene, MSSA strains that lack a functional *mecA* gene may be detected as *mecA* positive ("false-positive MRSA").[20] Shore and colleagues[493] investigated 25 isolates of multiresistant MSSA from hospitals in Ireland for the presence of SCC*mec* and performed multilocus sequence and *spa* typing. Several of these isolates contained remnants of SCC*mec,* and three of the MSSA isolates were detected as MRSA by both the GeneXpert and BD GeneOhm assays. The clinical sensitivities of these direct molecular MRSA assays is influenced by the prevalence of these aberrant isolates. In a report from Belgium, the Cepheid GeneXpert MRSA performed with a sensitivity of only 60.7% due to the presence of new SCC*mec* variants and some MSSA isolates

that carried cross-reactive SCC*mec*-like genetic sequences.[457] Based on such reports, it is possible that these direct molecular tests may someday outlive their usefulness unless MRSA and MSSA strains are monitored for the loss or acquisition of SCC*mec*, SSC*mec*-like, and neighboring sequences (e.g., *orfX*) that may affect the sensitivity and specificity of these gene target-specific assays.

Molecular Methods for Detection of MRSA and MSSA in Blood Cultures and Skin/Soft Tissue Infections

Commercially available molecular assays are also available and FDA-cleared for detection of MSSA and MRSA in positive blood cultures and in specimens from skin and soft tissue infections. Tests include the GeneXpert MRSA/SA BC and GeneXpert MRSA/SA SSTI (Cepheid) and the BD GeneOhm StaphSR assay (Becton-Dickinson). The GeneXpert assay contains primers and probes that simultaneously detect three targets—sequences within the *spa* (protein A) gene, the SCC*mec cassette*, and the gene for PBP2a-mediated methicillin resistance (*mecA).* Wolk et al.[606] evaluated both GeneXpert assays and found that the BC test performed with sensitivities of 100% for MSSA and 98.3% MRSA, with specificities of 98.6% and 99.4%, respectively. For wound specimens, MSSA and MRSA were detected with sensitivities of 100% and 97.1%, respectively, with specificities in excess of 96%. Spencer and colleagues[510] evaluated the GeneXpert MRSA/SA when gram-positive cocci in clusters were observed on Gram stains from positive blood cultures. The assay was 100% sensitive and specific for detection of MRSA and was 100% sensitive and 99.5% specific for MSSA. Another study of the GeneXpert MRSA/SA system found phenotypic and genotypic concordance of results in 94.6% of cases.[53] In an evaluation by Kelley and coworkers,[271] 21 of 102 blood culture specimens were positive with *S. aureus*; 17 were MSSA and 4 were MRSA. The GeneXpert currently identified 20 (95.4%) of 21 MSSA and 3 (75%) of 4 MRSA. A single MRSA strain was identified as an MSSA. These workers also challenged the system with spiked blood cultures containing 28 heterogeneously vancomycin-intermediate *S. aureus* (i.e., VISA and hVISA). The GeneExpert test identified 84.6% of VISA and 80% of hVISA isolates as MRSA. The Xpert MRSA/SA SSTI test has also been evaluated and compared with culture for the diagnosis of staphylococcal osteoarticular infections.[144] Sensitivities of 100% and specificities of 95.3% to 100% were obtained for detection of MSSA, MRSA, and methicillin-resistant coagulase-negative staphylococci. The rapidity of the assay (72 minutes) versus culture (requiring 1 to 4 days for completion) enables targeted therapy to be initiated much earlier in cases of staphylococcal bone infections.

The BD GeneOhm StaphSR has also been evaluated by several groups. Using spiked blood culture media, Grobner and colleagues[198] found the test to be 100%

sensitive and specific for detecting *S. aureus*. For MRSA detection, the assay was 95.6% sensitive and 95.3% specific. Of the five discrepant MRSAs, three were methicillin-susceptible revertant MRSAs and two were not detected.[198] A 2007 clinical evaluation using consecutive blood cultures positive for gram-positive cocci in clusters found the BD test to have a sensitivity and specificity of 98.9% and 96.7%, respectively, for MSSA detection, and 100% and 98.4%, respectively, for detection of MRSA.[513] In a 2009 study of 100 blood cultures containing gram-positive cocci in clusters, 23 yielded MSSA, 36 grew MRSA, and 41 grew non–*S. aureus* isolates. The BD GeneOhm StaphSR test misidentified 3 (8.3%) of 36 MRSA as MSSA and 1 (4.3%) of 23 blood cultures that grew MSSA tested negative.[501] The three MRSAs that were misidentified as MSSA were SCC*mec* variants that lacked part of the SCC*mec* integration site, the molecular target used in the BD assay. Frey and colleagues[172] used the BD GeneOhm StaphSR assay to detect and differentiate staphylococci in 24 valvular tissue specimens (12 fresh and 12 formalin-fixed, paraffin-embedded specimens) from patients with *S. aureus* endocarditis.[172] The assay was 100% sensitive and specific in detecting *S. aureus* in valvular tissues, including specimens from deparaffinized tissue blocks. Twenty-two valvular specimens (11 fresh and 11 embedded) from those without staphylococcal endocarditis were uniformly negative. In this study, there was an 87.5% correlation between presence of the *mecA* gene and the oxacillin result using BD GeneOhm MRSA/SA BC.

Identification of *Staphylococcus aureus*

The single most reliable characteristic for identifying *S. aureus* is the coagulase test. The conventional coagulase test may be performed by the slide or tube procedures. The medium for both procedures is rabbit plasma with EDTA. Citrated plasma should not be used, as organisms that are able to utilize citrate (e.g., *Enterococcus* species) will yield

positive results if they are mistaken for staphylococci; always perform a catalase test first. Human plasma (e.g., outdated material from blood banks) may contain anti-staphylococcal antibodies and should not be used to perform coagulase test procedures.

Slide Coagulase Test

Most strains of *S. aureus* have a bound coagulase or "clumping factor" on the surface

of the cell wall. This factor reacts directly with fibrinogen in plasma, causing rapid cell agglutination (Image Plate 12-2D). Performance of this test is described in detail in Chart 1-3. The test can be performed with growth from blood agar, CNA agar, or other nonselective nutrient medium, but should not be performed from media having a high salt content (e.g., mannitol salts agar) since the high salt causes some strains of *S. aureus* to autoagglutinate. Strains that are negative with the slide coagulase test must be confirmed with a tube coagulase test; strains deficient in clumping factor will usually produce free coagulase. Some human coagulase-negative species (e.g., *S. lugdunensis* and *S. schleiferi* subsp *schleiferi)* produce clumping factor and may be slide coagulase-positive. With chromogenic media for detection of MRSA, consult the package insert regarding whether coagulase testing can be performed directly from the media or whether subculture is required.

Tube Coagulase Test

The coagulase detected by this method is secreted extracellularly and reacts with a substance in the plasma called "coagulase-reacting factor (CRF)" to form a complex, which, in turn, reacts with fibrinogen to form fibrin (clot formation) (Image Plate 12-2E). Tests that are negative after 4 hours incubation at 35°C should be held at room temperature and read again after 18 to 24 hours, because some strains will produce fibrinolysin on prolonged incubation at 35°C, causing dissolution of the clot during the incubation period. Rare *S. aureus* strains may be coagulase-negative, and some animal isolates (*S. intermedius*, *S. hyicus*, S. delphini, and *S. schleiferi* subsp. *coagulans)* may be tube coagulase-positive.[134,204,205,556,569] Strains of *S. schleiferi* subsp. *schleiferi* that are clumping factor- and tube coagulase-positive and also produce heat-stable endonuclease have been recovered from human infections and may be misidentified *S. aureus*. These strains can be differentiated by failure to produce acid from maltose, lactose, mannitol, and sucrose. *S. schleiferi* subsp. *coagulan*s, a cause of canine external otitis, has been isolated from humans and may be misidentified as clumping factor-negative *S. aureus*. Phenotypic tests distinguish these strains.

Alternative Coagulase Test Procedures

Agglutination Tests. Several products that use this approach are commercially available and include Staphaurex and Staphaurex Plus (Remel, Lenexa. KA), Slidex Staph-Kit (bioMérieux), BBL Staphyloslide latex test (BD), Pastorex Staph Plus (Bio-Rad) (Image Plate 12-2F). Dryspot Staphytect Plus, Staphytect Plus, and Staphylase Test (Oxoid, Basingstoke, England). These procedures use latex beads coated with plasma except the Staphylase Test, which uses erythrocytes as the carrier particles and the Slidex Staph-Kit, which uses both latex beads and erythrocytes as the carrier particles. Fibrinogen bound to the carriers detects clumping factor and IgG molecules

also present on the carriers detect protein A, the staphylococcal cell wall protein that is able to bind immunoglobulin G molecules by the Fc region.[16] Mixing of these latex reagents with colonial material from agar media and rapid agglutination is a positive test and identifies the isolate as *S. aureus*. These reagents may also provide identifications from agar media inoculated with pellets obtained from blood cultures positive for gram-positive cocci in clusters and incubated for 4 to 6 hours.[273] Early evaluations comparing latex agglutination kits with 4-hour and 24-hour tube coagulase tests reported that false-negative latex agglutination results may be encountered when MRSA are tested. Among MRSA, the predominate capsular type is capsular serotype 5, with most others being capsular serotype 8.[163,164] Hence, some manufacturers have added antibody to the serotype 5 capsular polysaccharide as one of the detection molecules bound to the latex or stabilized red blood cells. Thus, the Dry Spot Staphytect Plus, the Staphytect Plus, the Pastorex Staph Plus also have antibody against staphylococcal capsular polysaccharide types 5 and 8 bound to the latex beads, while the Staphaurex Plus has antibodies against capsular type 5 and staphylococcal glycopolysaccharide antigen 18 bound to the latex beads. The Slidex Staph-kit consists of a mixture of latex particles sensitized with monoclonal IgG antibodies and antibody against cell surface proteins and stabilized red cells sensitized with fibrinogen to detect clumping factor. The Staphaurex test and the Pastorex Staph Plus are single-reagent tests, while the Staphaurex Plus, BBL Staphyloslide, Slidex Staph-kit, Staphytect Plus, DrySpot Staphytect Plus, and Staphylase include a negative control reagent with nonsensitized latex particles and/or stabilized red blood cells. Mixing of the test reagent with growth from an agar plate results in rapid clumping of the carrier-organism suspension, while no clumping occurs with the nonsensitized latex/red blood cell control reagents. Comparative evaluations of these tests have shown sensitivities of between 93% to 100% for identification of MSSA, and 82% to 100% for MRSA isolates.[14,596] Staphaurux Plus and the Staphylase test showing markedly lower sensitivities for identifying MRSA isolates. The specificity of these tests are generally in the range of 96% to 99%, with some having lower specificities (i.e., 91% to 92%) in some evaluations. Depending on the kit used, false-positive test results may occur with some strains *S. intermedius*, *S. lugdunensis, S. schleiferi, S. saprophyticus, S. hyicus, and S. delphini*.

Additional Confirmatory/Identification Tests for Staphylococcus aureus

Deoxyribonuclease Test. Some *S. aureus* strains may produce weak or equivocal tube coagulase reactions and rare isolates may indeed be coagulase-negative. Fortunately, other tests correlate highly with coagulase production. *S. aureus* produces both deoxyribonuclease (DNase) and a thermostable nuclease having endo- and

exonucleolytic

703

activities (Image Plate 12-2G). DNase can be detected by heavily spot-inoculating the organism on DNase test medium containing the metachromatic dye toluidine blue O (commercially available from several vendors). After 24 hours' incubation at 35°C, the medium under and around the inoculum turns from azure blue to pink, indicating DNA hydrolysis. The toluidine blue O content in the medium should not exceed 0.005%; higher concentrations may mask detection of DNase activity. Spot inoculation is necessary because *S. aureus* strains do not grow well on the media and growth is not required for enzyme detection. While this test is a helpful adjunct for identification of *S. aureus*, other staphylococci may also produce DNase.

Thermostable Endonuclease Test. The same DNase test medium is used, only 3-mm holes are cut into the agar with a sterile cork borer, and the wells are filled with a 24-hour broth culture of the test organism that has been boiled in a water bath for 15 minutes. The plate is incubated overnight at 35°C. *S. aureus* strains will show a pink zone surrounding the well containing the boiled suspension. Certain animal isolates (e.g., *S. caprae*, *S. schleiferi*, *S. intermedius*,*S. hyicus*) also produce heat-stable thermonuclease, and some coagulase-negative staphylococci (i.e., *S. epidermidis*, *S. simulans*, *S. capitis*, *S. carnosus*) may produce weak positive reactions. Specificity of this assay for *S. aureus*thermostable endonuclease may be confirmed by sero-inhibition of the reaction by polyclonal or monoclonal antibodies directed against the *S. aureus* enzyme, or by PCR amplification and sequencing of the *nuc* gene that encodes the *S. aureus* heat-stable endonuclease (see below).[63] A modification of this method was superior to the tube coagulase test for direct identification of *S. aureus* in blood cultures.[306] Primers and probes for amplification and detection of the *nuc* gene of *S. aureus* have also been synthesized and examined for their utility in culture confirmation and direct detection.[62] For identification, the lower limit of sensitivity of the PCR assay was 5 to 20 cfu of the organism. Using staphylococci-free clinical specimens that were seeded with serial dilutions of *S. aureus*, the lower limit for direct detection of *S. aureus* by the PCR assay ranged from 10 to 20 cfu up to 1,000 cfu, depending on the type of clinical specimen. The PCR-based assay was 100% specific for *S. aureus*.[62]

Mannitol Fermentation. *S. aureus*, unlike *S. epidermidis* and several other coagulase-negative species, produces acid from mannitol. This property is exploited in epidemiologic studies to detect *S. aureus* in soil, feces, and in screening nasal carriers of *S. aureus*. **Mannitol salts agar** contains mannitol (1%), 7.5% NaCl, phenol red,

and peptones. The high salt concentration discourages growth of other organisms (except for enterococci) and selectively recovers staphylococci. *S. aureus* colonies can be detected by a yellow zone around isolated colonies. Other infrequently isolated staphylococcal species may also ferment mannitol, so isolates recovered on this medium must be confirmed by other tests.

AccuProbe *Staphylococcus aureus*. The AccuProbe *Staphylococcus aureus* test (Gen-Probe, San Diego, CA) uses a chemiluminescent probe directed against rRNA genes to provide an identification from colonies on agar media.[88] The test uses a chemiluminescent acridinium ester-labeled, single stranded DNA probe that is complimentary to specific ribosomal RNA sequences of *S. aureus*. Cells from colonial growth are lysed and the probe is added. The probe binds to the rRNA sequence in a specific manner and unhybridized probe is removed using a proprietary hybridization-protection step. After removal of the unhybridized probe, a Leader 50i luminometer (Gen-Probe) is used to detect hydrolysis of the acridinium ester present on the nucleic acid sequence that is hybridized to the rRNA of the organism. A flash of light from probe hydrolysis is reported in relative light units (RLUs), with a result of ≥50,000 RLUs being considered positive. The test performs well for identification of *S. aureus* from agar media, but less well with pellets obtained from blood cultures positive with gram-positive cocci in clusters. For testing from blood culture pellets, sensitivities and specificities of 72.4% to 95% and 99.1% to 99.8%, respectively have been reported.[325,499] This test has also performed well when used as a direct detection method for *S. aureus* in other specimen types (e.g., bronchoalveolar lavage fluids).[6]

Rapid Tests for Detection of Methicillin Resistance

Although not an identification method, rapid detection of methicillin resistance in *S. aureus* is as critical as species identification. The *mecA* gene is the structural gene for a low-affinity penicillin-binding protein (PBP2′ or PBP2a) that is found in methicillin/oxacillin-resistant *S. aureus* (MRSA) strains. Initially, kits for *mecA* detection used cycling probe amplification (Velogene Rapid MRSA identification assay, ID Biomedical Corp., Vancouver, BC, Canada) or fluorescence technology (Crystal MRSA-ID System, BD Biosciences) for detection of methicillin resistance. The Velogene assay required PCR expertise followed by detection methods using fluorescein-conjugated probes.[21,331] The Crystal MRSA-ID system depended on detection of fluorescence during growth of a putative MRSA isolate in broth. These assays performed well and provided accurate results within 2 (Velogene) to 4 hours (Crystal MRSA). These kits were marketed in the late 1990s but are no longer available in the United States. Current commercially available methods use latex agglutination (MRSA-Screen, Denka-Seiken Co., Niigata, Japan, marketed in the United States by Hardy Diagnostics, Santa Maria, CA; Oxoid Penicillin-Binding

Protein latex agglutination test, Oxoid, Ltd., England, marketed in the United States by Remel; Slidex MRSA Detection, bioMérieux) or immunochromatographic strip approaches for detection of PBP2a (Clearview Exact PBP2a, Inverness Medical Innovations, Scarborough, MA; BinaxNOW PBP2a test, Alere Healthcare). These tests provide results in 15 to 30 minutes, with the Oxoid product being most widely used at present.

Both MRSA-Screen and Oxoid PBP2′ use latex beads that are coated with monoclonal antibodies against PBP2′ and the tests are performed similarly. Sufficient colonial growth is suspended in four drops of extraction reagent #1 (0.1 mol/L NaOH) in a microfuge tube, and the suspension is boiled for 3 minutes. After cooling, a single drop of extraction reagent #2 (0.5 mol/L KH_2PO_4) is added. The tube is centrifuged at

1,500×*g* for 5 minutes and the supernatant is removed. Aliquots (50 μL) of the supernatant are placed in "control" and "test" circles of a reaction card. A single drop of the test latex reagent (latex beads coated with monoclonal antibodies against PBP2a) is placed on the "test" circle and a single drop of control latex reagent (no anti-PBP2a antibodies) is added to the "control" circle. Each reaction area is mixed with a loop and the card is rocked for 3 minutes and observed for visible agglutination. Agglutination with the test but not the control latex reagent is a positive test for PBP2a (MRSA), while no agglutination in test or control areas on the card is a negative test (MSSA). These tests are not substitutes for specific identification tests for *S. aureus*, since MSSA isolates will be latex agglutination negative for *mecA*, and methicillin-resistant coagulase-negative staphylococci that also carry the *mecA* gene will also be positive. Evaluations of the MRSA-Screen have reported sensitivities and specificities of 97% to 100% and 99% to 100%, respectively, for detection of *mecA* in *S. aureus*, and sensitivity/specificity of 100% for *mecA* detection in coagulase-negative staphylococci.[21,330,331,565,613] A study of the Oxoid product from the Netherlands reported a sensitivity of 97% and a specificity of 100% when testing 90 genetically diverse MRSA and 106 MSSA isolates. All 10 methicillin-resistant *S. epidermidis* isolates were also positive with the PBP2a latex test.[565] A Canadian evaluation of the MRSA-Screen latex agglutination assay evaluated 71 MSSA, 213 MRSA, and 25 BORSA isolates and found a sensitivity of 99% and a specificity of 100%.[21] Similar high sensitivities and specificities have been obtained with the Oxoid latex agglutination test for PBP2′.[64,74,138,345] The Oxoid product was evaluated using growth from blood agar subcultures of positive blood culture bottles showing gram-positive cocci in clusters that had been incubated for only 3 hours. The results of the PBP2′ latex test correlated 100% with oxacillin-resistance determined by microbroth dilution.[345] Discrepancies have been noted between the two latex agglutination kits when testing

directly from blood cultures.[89,138] Chapin and Musgnug evaluated the Oxoid latex test using bacterial pellets obtained from positive blood cultures showing gram-positive cocci in clusters. Seventy cultures were positive for *S. aureus*, including 44 MRSA and 26 MSSA. The PBP2a assay performed on these pellets was 100% specific, but had a sensitivity of only 18%, so the predictive value of a negative test was very low (42%).[89] Diab and colleagues[138] examined 56 blood cultures positive for gram-positive cocci in clusters, performed direct tube coagulase tests and Oxoid latex tests on pellets from these positive blood cultures, and compared the results with those obtained from colonial growth the next day. Of these 56 isolates, 25 were *S. aureus* and 31 were coagulase-negative staphylococci. Compared with *mecA* detection by PCR, the direct Oxoid latex agglutination test was 100% sensitive for detection of *mecA* in both *S. aureus* and coagulase-negative staphylococci, while the specificity for *S. aureus* and coagulase-negative staphylococci were 100% and 75%, respectively. The Oxoid assay has been used for detection of methicillin resistance in veterinary isolates (*S. intermedius* and *S. schleiferi* subspecies) and was found to correlate highly with the *mecA* PCR "gold standard."[40] The bioMérieux Slidex MRSA Detection latex test is similar in format and procedural details to the Denka-Seiken and Oxoid tests, but it is not available in the United States at present. More information on methicillin resistance in staphylococci and the methods for its detection are available in Chapter 15 on antimicrobial susceptibility testing.

The Clearview Exact PBP2a and the BinaxNOW PBP2a immunochromatographic strip assays are rapid, qualitative tests for detection of PBP2a (PBP2′). The two assays are performed in a similar manner. Two drops of reagent 1 are placed in a small tube and three-well isolated colonies are emulsified in the liquid. Two or three drops of a second reagent are added to the tube and it is briefly vortexed. The immunochromatographic strip is placed in the tube and incubated at room temperature for 5 minutes. After this time, a positive control line appears along with a line for the presence of PBP2a if the isolate is *mecA* positive, while a single control line appears if the isolate is PBP2a-negative. No lines on the strip or absence of a control line are invalid tests. Evaluations of the Clearview assay have reported sensitivities of 96.6% to 100% and specificity of 100% compared with the Denka-Seiken and bioMérieux latex agglutination and cefoxitin disk susceptibility tests.[83,388,567] In an evaluation conducted in Spain, the BinaxNOW PBP2a test, 20 (95% sensitivity) of 21 MRSA isolates were positive, while none of 27 MSSA isolates were positive (100% specificity).[458] At the present time, neither of these kits are available in the United States.

Genotype MRSA. Genotype MRSA (Hain Life Science, Germany) is an immunochromatographic strip that detects the presence of the *mecA* gene and also identifies the organism as either *S. aureus* or *S. epidermidis*. Following cell lysis, DNA

extraction and amplification using biotinylated primers, amplicons are detected by hybridization to membrane-bound probes on the immunochromatographic strip using a streptavidin alkaline phosphatase conjugate and an alkaline phosphatase-mediated detection step. Each immunochromatographic strip has lines for a conjugate control (CC), a universal control (UC), and lines specific for *mecA*, *S. aureus*, and *S. epidermidis*, respectively. MSSA strains yield three lines on the strip (CC, UC, and an *S. aureus* line), while MRSA yield these lines, plus a fourth line for the *mecA* gene. Similar results for methicillin-susceptible and methicillin-resistant *S. epidermidis* are obtained, only the identification line on the strip corresponds with the *S. epidermidis*-specific probe immobilized on the strip instead. Non–*S. aureus*, non–*S. epidermidis* isolates (e.g., *S. warneri*, *S. hominis*, *S. haemolyticus*) will produce the control lines (UC and CC), plus a line for *mecA* if the isolate possesses the gene. An evaluation of the Genotype MRSA test found a 100% correlation with an in-house PCR-based method for detection of *mecA*.[437] No equipment is needed except for a thermocycler for the amplification steps, and results are available within 2 hours.

Identification of Coagulase-Negative Staphylococci

Because the importance of *S. epidermidis* as an agent involved in several infectious processes and the recognized clinical significance of *S. saprophyticus* in urinary tract infections, it is important for laboratories to employ methods for

705

identification of these two species (Image Plate 12-3A). Kit systems are available that reliably identify *S. epidermidis, S. saprophyticus*, and several staphylococcal species. Relatively few species are seen with regularity in actual practice. A 1996 examination of 415 significant coagulase-negative staphylococci recovered from blood cultures in Denmark found that 68.7% were *S. epidermidis*, followed in frequency by *S. hominis* (14.7%), *S. haemolyticus* (10.4%), *S. warneri* (2.9%), and *S. cohnii* (1.7%), with *S. saprophyticus*, *S. capitis,* and *S. lugdunensis* each accounting for 1% or less of the total.[253] The distribution of clinically significant species reported in these studies generally reflects the literature that has accumulated regarding the clinical significance of the individual species.

Conventional Identification Methods

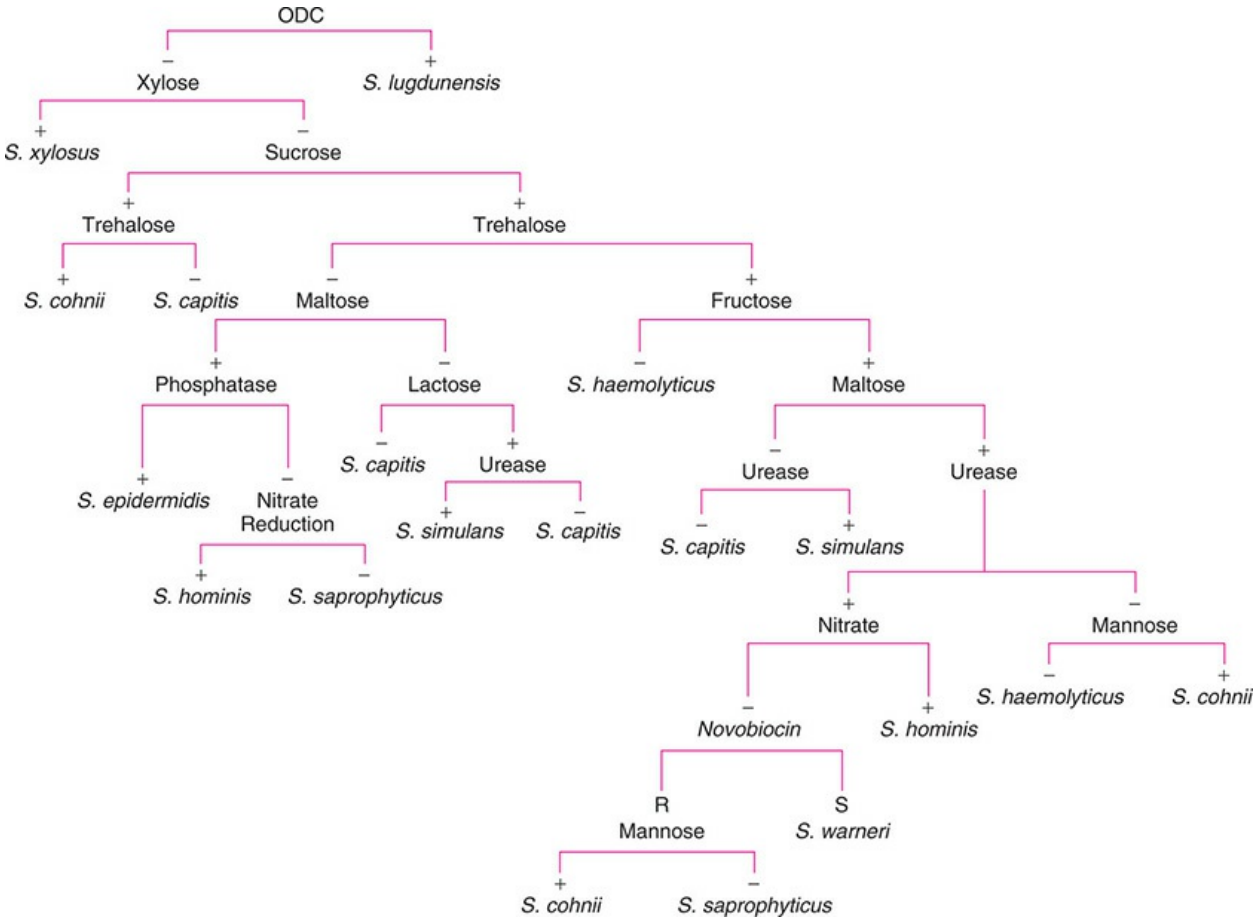
In 1975, Kloos and Schleifer published a scheme for the phenotypic identification of

coagulase-negative staphylococcal species.[284] With the coagulase test for identifying *S. aureus*, this scheme used a large number of physiologic and biochemical tests for differentiating coagulase-negative isolates. Updates and expansions of the scheme led to a 1999 publication by the Subcommittee on the Taxonomy of Staphylococci and Streptococci of the International Committee on Systematic Bacteriology setting forth minimum standards for genus *Staphylococcus* and for descriptions of new *Staphylococcus* species.[171] Modified conventional identification schemes incorporating other tests (e.g., PYR) desferrioxime susceptibility), have been published, and newer schemes have demonstrated improvements in accuracy and turnaround times. Modified conventional procedures use biochemical tests (i.e., PYR, alkaline phosphatase, urease, ornithine decarboxylase, arginine dihydrolase, nitrate reduction acetoin production), acid production from carbohydrates (i.e., D-cellobiose, lactose, maltose, D-mannitol, D-mannose, D-ribose, sucrose, D-trehalose, D-xylose), and susceptibility tests (i.e., susceptibility to desferroxamine, 100 µg, novobiocin 5 µg, and polymyxin B, 300 IU) for species identification. These tests are inoculated with heavy organism suspensions (e.g., a #2 McFarland turbidity standard). Disk tests are read after 24 hours and other tests are interpreted after 72 hours' incubation. Iorio and colleagues[245] developed a 9-test identification scheme and compared the identifications obtained with the modified conventional procedure. Tests included in this simplified scheme were clumping factor, novobiocin and desferrioxamine susceptibility, PYR, urease, alkaline phosphatase, and acid production from mannose, trehalose, and xylose. This simplified 9-test scheme was 98.5% accurate when compared to the reference method when challenged with 198 clinical staphylococcal isolates and 11 control strains. De Paulis and colleagues[130] evaluated a 5-test (novobiocin susceptibility, urease, PYR, ornithine decarboxylase, and aerobic acid production from mannose) conventional identification scheme and compared it to the reference method of Kloos and Schleifer. One or two additional tests were required for identification of certain species and species groups. This scheme showed excellent correlation with the reference phenotypic method, particularly for identifying *S. epidermidis*, *S. saprophyticus*, and *S. haemolyticus*. Conventional identification is too time-consuming and labor-intensive for clinical laboratories. Fortunately, a relatively small number of species are recovered from significant human infections, and most commercially available kit systems described briefly below can serve this purpose. Table 12-5 presents the phenotypic characteristics for identification of those staphylococci that are most commonly isolated from human clinical specimens. Table 12-6 includes the phenotypic criteria for identification of human, animal, and environmental species in the genus *Staphylococcus*. Figure 12-1 presents a dichotomous key that is helpful for conventional identification of several clinically important coagulase-negative staphylococci.

Pyrrolidonyl Arylamidase Activity. The PYR test is also useful as a phenotypic test for identifying coagulase-negative staphylococci. As with the enterococci, L-pyrrolidonyl-β-naphthylamide is cleaved by the arylamidase to L-pyrrolidone and free β-naphthylamide, which combines with the PYR reagent (*p*-dimethylaminocinnamaldehyde) to produce a red color. The test is performed with PYR broth inoculated to approximate a #2 McFarland turbidity standard. After 2 hours' incubation at 35°C, the PYR reagent is added. The appearance of a red color within 2 minutes constitutes a positive test, with a yellow, orange, or pink color being negative. Alternatively, any of the commercial rapid PYR disk tests may be used. Hydrolysis of PYR is also found on some of the kit systems that are available for identifying staphylococci. Both *S. aureus* and *S. epidermidis* are PYR-negative, while *S. haemolyticus*, *S. intermedius*, *S. lugdunensis*, and *S. schleiferi* subsp. *schleiferi* are PYR-positive.

Susceptibility to Polymyxin B. The disk diffusion test for susceptibility to polymyxin B is also helpful for identifying coagulase-negative staphylococci. The test can be done on SBA along with that for novobiocin susceptibility (see below). A suspension of the organism equivalent to a 0.5 McFarland turbidity standard is prepared in saline and swabbed onto a plate as for a Bauer–Kirby disk diffusion test. A polymyxin B disk (300 units, BD Biosciences) is applied to the inoculum and the plate is incubated overnight. Resistance is indicated by the presence of a zone of less than 10 mm. Susceptible strains have zones that are equal to or greater than 10 mm. *S. aureus*, *S. epidermidis*, *S. hyicus*, and some *S. lugdunensis* strains are polymyxin resistant.

Ornithine Decarboxylase Test. The ornithine decarboxylase (ODC) test is most useful for confirming the identity of *S. lugdunensis*, as this species is the only one that is consistently ornithine decarboxylase-positive. A tube of decarboxylase base and base with added ornithine (Remel) are inoculated heavily and overlaid with sterile mineral oil. On incubation at 35°C, both tubes will turn from pale-gray to yellow as glucose is fermented. Following this, the ornithine in the test tube will be decarboxylated, resulting in the ornithine broth turning a violet color. The base tube will turn and remain yellow, and the ornithine tube will remain yellow if ODC is not produced. While most positive tests may be detected within 6 to 8 hours, the test is read after 24 hours' incubation. The ODC test is not included in some of the kit systems for identifying staphylococci and must be set up as an additional test. This test is a useful indicator for *S. lugdunensis* as this species is the only coagulase-negative *Staphylococcus* that is ODC-positive.



■ **FIGURE 12-1** Dichotomous key for identification of the more common human coagulase-negative staphylococci.

Urease Production. Some staphylococci are urease-positive, including *S. epidermidis*, *S. intermedius*, and most isolates of *S. saprophyticus*. Regular urease broth or urea agar slants can be used for this test. The slant or the broth is inoculated and incubated at 35°C for 18 to 24 hours. A change in the phenol red indicator from yellow to pink/red is a positive test.

Acetoin Production. Production of acetoin (the Voges–Proskauer test) is helpful in distinguishing *S. aureus*, which are acetoin-positive, from other coagulase-positive species (*S. intermedius* and *S. hyicus*), which are both acetoin-negative. The conventional enteric acetoin production test (MR–VP broth) or the rapid disk method may be used with comparable results.

Susceptibility to Novobiocin for Presumptive Identification of Staphylococcus saprophyticus

Some human staphylococcal species (*S. saprophyticus, S. cohnii subspecies, S. hominis* subsp. *novobiosepticus, S. xylosus*, some *S. pseudolugdunensis*) and several animal species (*S. sciuri* subspecies, *S. lentus, S. gallinarum, S. kloosii, S. equorum, S. arlettae, S. vitulinus, S. nepalensis*, and *S. stepanovicii*) and one environmental species (*S. succinus*) are resistant to novobiocin, with MICs of ≥1.6 µg/mL (Image Plate 12-3B). Since novobiocin-resistant species other than *S. saprophyticus* are infrequently encountered in human clinical specimens, the novobiocin susceptibility test provides a useful method for presumptive identification of *S. saprophyticus*. The novobiocin test is performed as a disk susceptibility test using a novobiocin disk (5 µg) and is described in detail in Chart 12-2. Strains resistant to novobiocin will show zones measuring 6 mm (no zone) to 12 mm; susceptible strains will have zones of 16 mm to 27 mm. This test was originally described using a medium called P agar, which is not available commercially. However, studies with the routine media (e.g., SBA) have shown that comparable results are obtained.

Commercial Identification Systems

All of the kits available for identifying coagulase-negative staphylococci use modified carbohydrate fermentation tests, standard identification tests (e.g., nitrate reduction, urease, acetoin), and chromogenic enzyme substrates for organism identification. Test systems are adapted to manufacturer-specific formats.

712

Marcy l'Étoile, France) is a gram-positive organism identification card designed for use with the automated Vitek 2 bacterial identification/susceptibility testing system. The 64-well card contains 43 colorimetric substrates for phenotypic identification of *Staphylococcus* species, *Streptococcus* species, and several gram-positive bacillary species (e.g., *Corynebacterium* species,*Erysipelothrix rhusiopathiae*, and *Listeria monocytogenes*). A suspension of the organism is prepared in saline (0.45% to 0.50% NaCl) in a polystyrene tube to a density equivalent to a McFarland 0.50 to 0.63, as determined with the Vitek 2 DensiChek spectrophotometer. The tube and card are inserted into the Vitek 2 cassette and the card is autoinoculated by a vacuum-release method within the Vitek 2 instrument. Wells in the card are optically scanned and read every 15 minutes, with a total incubation time of about 8 hours.

Several evaluations of the Vitek 2 GP identification card indicate that the system works well for identifying staphylococci. Funke and Funke-Kissling performed an

evaluation of the Vitek 2 GP identification card and compared the results to reference methods.[173] The card identified 100% of 45 *S. aureus*, 32 of 33 S. *epidermidis*, 25 of 29 *S. haemolyticus*, 13 of 13 *S. hominis* and all of five *S. lugdunensis* isolates. Single strains of several other species and all three *R. mucilaginosa* isolates were also identified correctly. Layer and colleagues[313] compared the GP identification card to the Phoenix system using 27 reference and type culture strains and molecular methods for reference identification. The card identified 70.1% of reference strains to the species level.Delmas and colleagues[125] compared the Vitek 2 GP identification card to an oligonucleotide array-based molecular identification method using 190 *Staphylococcus* strains, including 38 type strains representing 35 species and 152 previously characterized isolates from clinical, food, and environmental sources. The Vitek 2 GP card identified 93.3% of 60 clinical isolates and 73% of 92 environmental staphylococcal isolates. A comparative study of the GP identification card with 16S rRNA and MicroSeq 500 sequencing performed in Korea found that the card identified 87.5% of 120 clinical isolates correctly, including 88.7% of 53 *S. epidermidis*, 88% of 25 *S. hominis*, 100% of 16 *S. capitis*, and 83.3% of 6 *S. lugdunensis* isolates.[278] An evaluation performed in Greece with 147 clinical staphylococcal isolates and using molecular reference identification methods (i.e., *tuf* gene PCR–restriction fragment length polymorphism [RFLP]) found that the Vitek 2 card identified 98% of the 147 strains correctly, including 100% of 52 *S. aureus* and 96.8% of coagulase-negative staphylococcal species.[92] All 50 *S. epidermidis*, 13 *S. haemolyticus*, 8 *S. cohnii*, and 6 *S. lugdunensis* isolates were identified correctly. The Vitek 2 GP identification card was also examined in a 20-laboratory collaborative study for its ability to identify reference staphylococcal strains found in food products.[115] The card correctly identified 117 of 120 *S. aureus*, and 100% of 60 *S. epidermidis*, 60 *S. hyicus*, and 60 *S. intermedius* isolates, respectively. Lastly, Lee and colleagues[318] reported that the Vitek 2 GP identification card identified 86.6% of 34 presumptive *S. saprophyticus* isolates that were confirmed as such by the Bruker Biotyper MALDI-TOF MS instrument.

Phoenix (Becton-Dickinson Diagnostic Systems, Sparks, MD). The BD Phoenix system is an automated identification and susceptibility test system that uses an ID panel called PMIC/ID-13 for identification of gram-positive cocci. The panel contains 45 wells containing 20 enzymatic substrates, 16 carbohydrates utilization tests, and seven assimilation carbon sources, and susceptibility to colistin and polymyxin B. A standardized suspension of the bacterial isolate is prepared in broth and poured into the panel within 30 minutes of preparation. The panel is then loaded into the instrument where it is incubated and read by the optics of the instrument. Time to providing an identification ranges from 3 to 4 hours.

The BD Phoenix gram-positive identification panel has been evaluated and

compared with several other identification methods. In a study performed at Johns Hopkins University, the Phoenix system was evaluated using cell wall fatty acid analysis (i.e., Sherlock Microbial Identification System [MIDI, v 3.1]) and conventional methods for reference identification.[78] Phoenix identified 100% of 218 *S. aureus* isolates and 99% of 102 coagulase-negative staphylococcal isolates. The only misidentification was one of 12 *S. hominis* strains. In a German evaluation, the Phoenix identified 76.2% of 42 *S. epidermidis*, 90% of 30 *S. hemolyticus,* 100% of 6 *S. capitis*, and 75% of 4 *S. hominis* isolates.[313] Single isolates of *S. lugdunensis* and S. *warneri* were also identified. In this study, the BD Phoenix was tested side-by-side with the Vitek 2 GP identification card. The GP identification card correctly identify 80 of 86 clinical staphylococcal isolates and misidentified 6, while the BD Phoenix correctly identified 70 of the 86 isolates and incorrectly identified 12 isolates.[313] A 2008 study performed in Greece compared the Phoenix system with the API ID32 Staph with discrepancies being resolved by 16S rRNA and *tuf* gene sequence analysis.[65] The Phoenix system correctly identified 90.5% of 200 coagulase-negative staphylococcal isolates, with 6% being incorrectly identified, and 3.5% having no identification reported by the testing system. A 2012 study also done in Greece examined the BD Phoenix in comparison with the Vitek 2.[92] The BD Phoenix correctly identified all 52 *S. aureus* strains and 84.2% of 95 coagulase-negative staphylococci, while the Vitek 2 performed the same as Phoenix for *S. aureus* but identified 96.8% of the 95 coagulase-negative staphylococci correctly. The BD Phoenix identified 86.7% of *S. saprophyticus* isolates when compared with MALDI-TOF mass spectrometry.[318]

MicroScan Panels. Siemens HealthCare Diagnostics (Deerfield, IL), manufacturers of the Microscan WalkAway-96 automated system for identification and antimicrobial susceptibility testing using a microtiter format, has several panels for identification of gram-positive cocci, including conventional, overnight identification/antimicrobial susceptibility microtiter panels (Microscan Pos Combo ID/AST panels), rapid panels (2- to 2.5-hour identifications), and "Synergies-Plus" panels, which provide rapid identification along with certain antimicrobial susceptibility results within 4.5 hours. In the United States, only conventional (Microscan Pos Combo panels) and "Synergies-Plus" panels (Microscan "Synergies-plus" Pos Combo 2 panels) are available. The database for identification includes other gram-positive organisms, including micrococci, streptococci, enterococci, and listeriae. The Microscan Pos Combo panels are microtiter plate format combination ID/AST panels that have 26 conventional and chromogenic phenotypic tests plus various antimicrobial agents for simultaneous microbroth

dilution testing (six different panels are available). A Microscan Pos Breakpoint Combo ID/AST panel is also available and offers the same phenotypic identification tests but fewer dilutions of antimicrobial agents. Following manual inoculation and placement of the plates in the WalkAway-96 instrument, the plates are incubated for 16 to 24 hours at 35°C, and then the panels are read by the WalkAway optics. The biochemical profile of an isolate is compared with the database and an identification is generated.

The Microscan Pos Combo panels have been evaluated and are comparable to other commercially available systems. The Microscan Combo Pos panel was used as part of the reference identification in a study of a modified conventional identification method reported by Iorio and colleagues[245] in Brazil. The Microscan panel identified 59 of 69 *S. epidermidis*, 32 of 44 *S. haemolyticus*, 10 of 16 *S. hominis* subsp. *hominis*, 8 of 9 *S. hominis* subsp. *novobiosepticus*, and 5 or 6 *S. lugdunensis* strains. Overall, 157 (79.3%) of the 198 isolates were correctly identified. An evaluation of the Microscan Combo Pos panel was performed by Patteet and colleagues[414] in Belgium with 428 coagulase-negative staphylococcal isolates from a variety of clinical specimens. These isolates were identified by conventional and other commercial methods in past studies. The panel correctly identified 405 (94.5%) of the 428 isolates, with low-level (<85%) identifications and misidentification comprising 11 (2.6%) and 12 (2.8%) of isolates, respectively. For *S. epidermidis*, 97.3% were correctly identified, as were 96% of 50 *S. haemolyticus*, and 80% of 5 *S. lugdunensis*.

Sherlock Microbial Identification System. The Sherlock Microbial Identification System (MIDI, Microbial ID Inc., Newark, DE) uses high-resolution gas-liquid chromatography (GLC) of cellular fatty acid derivatives for the identification of bacteria. The database of the system is composed of libraries containing analyses of cellular fatty acid methyl ester profiles of various bacteria and compares the composition of individual isolates with those in the database using covariance matrix/pattern recognition software. A similarity index is used to express the relatedness of a profile of an unknown organism to representative profiles of known organisms. Recent evaluations of the MIDI system as a stand-alone method for identification of staphylococci are not available, although, when combined with a few phenotypic tests, the system appears to perform well as a for routine identification of coagulase-negative staphylococci.[78]

Biolog Microplate Identification System. The Biolog Microplate Identification System (Biolog, Inc., Hayward, CA) identifies microorganisms on the basis of oxidation of a variety of substrates. Manual, semiautomated, and automated configurations of this system are available. The automated versions of the system include the OmniLog Gen III data collection/data management software, a reader/incubator, computer, printer, pipettor, and turbidometer. The GEN III Omnilog system enables the identification of aerobic bacteria only, while the GEN III Omnilog-

Plus system also includes databases for identification of anaerobic bacteria, yeasts, and filamentous fungi. Additional software is available for phenotypic array analysis. The database for staphylococci includes human, animal, and environmental species. The system uses 96-well microplates with 95 substrates plus a control well lacking substrate. Combo plates and separate plates for identification of either gram-positive or gram-negative bacteria are available. Plates are inoculated with a suspension of the organism and incubated for 4 or 24 hours. If the organism oxidizes a substrate in an individual well, the respiration of the organism during oxidative substrate assimilation causes the reduction of a tetrazolium indicator dye, turning the well from colorless to purple. This system is not approved for human in vitro diagnostic work at the present time and no recent evaluations of this system are available. Results of a 1993 evaluation reported an accuracy of 69% to 73%, suggesting that the Biolog system is not acceptable as an identification method for these organisms.[366]

Sensititre GPID Plate (Trek Diagnostic Systems, Inc., Cleveland, OH). The Sensititre GPID plate is a identification system that was configured to identify the eight most common staphylococcal species encountered in clinical specimens (i.e., *S. aureus*, *S. epidermidis*, *S. capitis* subsp. *capitis*, *S. haemolyticus*, *S. hominis* subsp. *hominis*, *S. lugdunensis*, *S. saprophyticus* subsp. *saprophyticus*, and *S. warneri*). Garza-Gonzalez and colleagues[175] compared this system with API Staph, with discrepancies being resolved by manual phenotypic tests and partial sequencing of the 16S rRNA gene. While the API Staph (Image Plate 12-2H) currently identified 91% of 155 isolates tested, the Sensititre GPID plate identified 68%. The plate system correctly identified 73% of 86 *S. epidermidis*, 86% of 35 *S. haemolyticus*, 54% of 13 *S. hominis*, one of two isolates of *S. saprophyticus*, and one of four *S. capitis* isolates. None of 8 *S. warneri* strains were identified. Isolates belonging to other species included in the Sensititre GPID database were not tested.

Manual Identification Systems

API Staph-Ident. The API Staph-Idnet (bioMérieux, Inc.) is a 10-test gallery that is inoculated with a heavy organism suspension, and identification is determined by generation of a four-digit octal code derived from the positive tests on the strip and interpreted with an online database (i.e., APIweb) (Image Plate 12-3C and 12-3D). API Staph-Ident has been extensively evaluated, and agreement with conventional procedures has ranged from 43% to 95%, depending on the species tested. Rhoden and Miller published a 4-year prospective study comparing the API Staph-Ident with reference methods on 1,106 isolates and found an overall agreement of 81.1%.[449] Percent agreements for the five most common isolates were 97.1% for *S. epidermidis*, 82.5% for *S. hominis*, 77.2% for *S. aureus*, 75.8% for *S. haemolyticus*, and 64.1% for *S. warneri*. These workers concluded that the database of the current Staph-Ident system is inadequate for identifying both common and uncommon

staphylococcal species.[449]

API Staph. API Staph (bioMérieux, Marcy l'Étoile, France) is an 18- to 24-hour identification system for micrococci and staphylococci. This system contains 19 tests arranged in a strip format and is inoculated with a suspension of the organism (0.5 McFarland standard) prepared in a peptone yeast extract broth medium provided with the kit. After reading the biochemical reactions, a seven-digit octal code is generated and identification of the organism is obtained with the APIweb software-assisted database. The database consists of 25 taxa and includes staphylococci of human and veterinary origin, *Micrococcus* species, and *R. mucilaginosa*. Although the database of this system is large, it has not

been extensively evaluated. A study by Perl and colleagues[423] found that the API Staph system correctly identified 73% of 277 coagulase-negative staphylococci. (While 94% of 94 *S. epidermidis* isolates were correctly identified, the system performed poorly with less common isolates like *S. haemolyticus* (85% correct), *S. hominis* (75% correct), *S. simulans* (67% correct), and *S. warneri* (22% correct). The API Staph was used as an identification method to characterize 33 coagulase-negative, non-*epidermidis* staphylococci recovered from ocular infections and compared with microbial genotyping for identification.[338] The API Staph and genotyping corresponded for only 48.4% of the isolates. While most strains of *S. haemolyticus* were correctly identified, isolates of *S. warneri*, *S. hominis*, *S. capitis*, and *S lugdunensis* were identified with likelihoods ranging from 40% to 75%. More recent evaluations of this kit have dealt with veterinary isolates (i.e., goat milk isolates, bovine mastitis isolates); in these studies, overall agreement of the API Staph ID with molecular methods was only 72% to 76%.[293,411,535]

API ID32 Staph. ID32 Staph (bioMérieux, Marcy l'Étoile, France) is a 24-hour gallery system for identifying staphylococci and related species. The system can be read manually to generate a profile number that is interpreted by the APIweb online database or the test panel can be used with an automated bioMérieux ATB system, which includes a densitometer, an inoculator, a reader, a microcomputer, and a printer. ID32 Staph has the most extensive database of the manual systems, with many human staphylococcal species and several animal and environmental species included. The system also identifies six micrococcal species and *R. mucilaginosa*. In a study of 440 consecutive coagulase-negative staphylococcal isolates, Ieven and coworkers[240]reported that the ID32 Staph panel identified 95.2% of *S. epidermidis*; *S. haemolyticus*, *S. lugdunensis, S. schleiferi,* and *S. capitis* were identified with accuracies of 98% to 100% (Image Plate 12-3E, 12-3F, 12-3G and 12-3H). Layer and

colleagues[313] used the ID32Staph as a reference method in an evaluation of the BD Phoenix and Vitek 2 system, with arbitration of discrepant identifications by two molecular methods, and found that 89.4% of the reference and clinical isolates tested were correctly identified by ID32Staph. The ID32 Staph had more correct identification results than either of the two automated systems. In an evaluation of the Phoenix and the Vitek 2 automated identification systems, ID32 Staph was used as a reference system. Isolates were also analyzed by 16S rRNA and *tuf* gene sequencing. The ID32 Staph system identified 96.5% of the 200 isolates tested isolates tested and showed 93% to 100% concordance with molecular identifications.[65]

RapID Staph Plus (Remel). The RapID Staph Plus uses modified conventional phenotypic tests and chromogenic enzyme substrates for identification of clinically relevant *Staphylococcus* species. A suspension of the organism is prepared in inoculation fluid to match a #3 McFarland turbidity standard and poured into the inoculation port of the cuvette. Manual manipulation of the cuvette simultaneously hydrates and inoculates the substrates in the wells of the cuvette. After incubation for 3 to 6 hours at 35°C to 37°C, the reactions for the various substrates are recorded; 12 of the phenotypic tests are read directly, while tests 13 through 17 requires addition of RapID Staph Plus dimethylaminocinnamaldehyde reagent and test 18 requires nitrate reagents A and B. The reactions are used to derive a six-digit octal code which is entered into the Electronic RapID Compendium (ERIC) computer-assisted database. This database provides the organism identification. The database includes 33 species and subspecies of staphylococci, and also includes *Kocuria* species, *Kytococcus* sedentarius, *Micrococcus* species, and *R. mucilaginosa*. Evaluations of this system are not available.

BBL Crystal Gram-Positive (GP) Identification Kit. The Crystal GP Identification kit (BD Biosciences) is a miniaturized identification panel consisting of 29 fluorogenic, chromogenic, and modified conventional tests plus a negative control for the identification of gram-positive isolates belonging to several genera, including *Staphylococcus*, *Micrococcus*, *Stomatococcus*, *Streptococcus, Enterococcus*, *Aerococcus*, and *Lactococcus*. The system is inoculated with a suspension of organisms (a #2 McFarland turbidity standard), incubated for 4 hours at 35°C to 37°C in an ambient atmosphere, and read with a special Crystal system panel viewer. The Crystal GP kit was evaluated along with Vitek 2 and the MicroScan systems and compared with identifications obtained by 16S rRNA sequencing and an in-house molecular method using the MicroSeq 500.[278] The Crystal GP kit correctly identified 92.5% of 16 *S. epidermidis*, and correctly identified all *S. warneri* (6 isolates), *S. simulans* (2 isolates), *S. cohnii* (3 isolates), *S. haemolyticus* (4 isolates), and a single *S. saprophyticus* isolate. Only 2 of 6 *S. lugdunensis* and 1 of 25 *S. hominis* isolates were correctly identified; some *S. capitis* and all *S. caprae* isolates were misidentified.

Microbact Staphylococcal 12S Identification System (Oxoid). The Microbact

Staphylococcal 12S (Oxoid) is a 12-test identification system based on six carbohydrate utilization tests, arginine dihydrolase, urease, and four chromogenic enzyme substrates. Only 20 of the more common staphylococcal species are included in the database. The wells of the strip are inoculated with a suspension of the organism and the strip is incubated for 18 to 24 hours at 35°C to 37°C. In addition, the results of a coagulase/latex agglutination test, a DNase test, and notation of pigment production are also required. After addition of color development reagent to the enzymatic tests, the reactions are recorded on the report form along with results of the three additional tests and the resulting five-digit octal code is entered into the Microbact Computer Aided Identification software, which then provides a species identification. No evaluations of this system are available and this system is not available in the US market.

RapiDEC Staph. RapiDEC Staph (bioMérieux) is a manual kit for identifying *S. aureus*, *S. epidermidis*, and *S. saprophyticus* within 2 hours. An organism suspension is dispensed into four cupules, which include a negative control, a fluorescent coagulase substrate, an alkaline phosphatase substrate (PAL), and a β-galactosidase substrate (BGAL), respectively. "Aurease" is a proteolytic enzyme that reacts with prothrombin to form staphylothrombin that, in turn, cleaves a fluorescent peptide in the cupule, releasing a fluorescent radical. After 2 hours incubation, greater UV fluorescence in the "coagulase" cupule relative to the control identifies *S. aureus*. The other two cupules are read either directly or after reagent addition. A positive alkaline

phosphatase test or a positive β-galactosidase test identifies *S. epidermidis* and *S. saprophyticus*, respectively. The system does well for identifying *S. aureus*, but *S. epidermidis* isolates that produce low levels of or are negative for alkaline phosphatase are not identified by RapiDEC Staph.[252] Similarly, some *S. saprophyticus* isolates are not identified because they lack β-galactosidase activity or are misidentified since the enzyme is found in novobiocin-susceptible and -resistant staphylococci (e.g., *S. cohnii*, *S. hominis*, *S. simulans*). The control and "aurease" cupules have been used for identification of *S. aureus* directly in positive blood cultures using a centrifuged aliquot from the positive blood culture. With a protocol slightly modified from the suggested procedure, van Griethuysen and colleagues[562] identified 100% of 42 *S. aureus* isolates directly in blood culture bottles with a specificity of 96.6%. A similar study by Chapin and Musgnug[88] found that the "aurease" test had a sensitivity and specificity of 96% and 99%, respectively, when used directly from blood cultures growing gram-positive cocci in clusters.

Staphylococcus aureus/Coagulase-Negative Staphylococci PNA

FISH Culture Confirmation Kit (AdvanDx, Woburn, MA)

PNA FISH technology combines fluorescence in situ hybridization (FISH) with unique peptide nucleic acid (PNA) molecules wherein the negatively charged carbohydrate-phosphate moieties comprising the backbone of DNA and RNA are replaced with uncharged PNA probes containing the same nucleotide bases as DNA, allowing them to hybridize with complementary nucleic acid sequences. The uncharged, hydrophobic backbone of PNA probes allows the probes to penetrate the hydrophobic cell walls of bacteria and enables tighter and more specific hybridization to nucleic acid sequence targets.[603] The PNA probes hybridize with *S. aureus*-specific rRNA sequences or with rRNA sequences of selected coagulase-negative staphylococcal species. These PNA probes are labeled with tags that fluoresce under UV light. PNA FISH technology has found its greatest application in direct identification of pathogenic bacteria directly in positive blood cultures. The *S. aureus*/CNS PNA FISH test reagent contains fluorescein-labeled *S. aureus*-specific PNA probes and Texas Red-labeled PNA probes targeting sequences in other coagulase-negative staphylococci. A drop of blood/broth from a positive blood culture showing gram-positive cocci in clusters is mixed with fixative in the well of a single-well microscope slide provided in the kit and fixed with heat or methanol. One drop of the *S. aureus*/CNS PNA is added to the well on the smear and a coverslip is placed. The slide is incubated for 30 minutes at 55°C. The slide is the placed in wash solution, the coverslip is removed, and the slide is incubated in the wash solution for 30 minutes at 55°C in the slide warmer of the PNA FISH Workstation. Following the wash step, the slide is air-dried, a drop of mounting medium is placed on the smear and a coverslip is placed. The slide is examined under fluorescence microscope. *S. aureus* appears as bright, apple-green fluorescent clusters of cocci, while coagulase-negative staphylococci appear as multiple, bright-red fluorescent cocci. Other microbial, nonstaphylococcal cells are nonfluorescent. The test takes approximately 2½ hours to perform, with less than 30 minutes hands-on time.

More recently, the *Staphylococcus* QuickFISH BC was approved for use. This test identifies *S. aureus* and coagulase-negative staphylococci from blood cultures in less than 30 minutes by the elimination of a wash step.[124] This modification uses a drop from a positive blood culture that is prepared on FISH slides, with positive and negative controls already present on the slide. The slide is heat-fixed at 55°C for up to 5 minutes. Single drops of two PNA solutions—*Staphylococcus* PNA Blue and *Staphylococcus* PNA Yellow—are mixed together on a coverslip that is placed inside a template. Mixture of the two reagents in the oval window of the template results in a uniform green color. The coverslip is then turned over and applied to the dried/fixed blood culture drop on the specimen slide within the borders of the viewing area. The slide is incubated at 55°C for 15 to 20 minutes at the workstation. The slide is read on a fluorescence microscope by first inspecting the controls, then moving over to the

specimen well in the same plane of focus. As with the longer procedure, *S. aureus* appears as bright, apple-green fluorescent clusters of cocci, while coagulase-negative staphylococci appear as multiple, bright-red fluorescent cocci. This test has a turnaround time of less than 30 minutes with a hands-on time of less than five minutes.

Published evaluations of *S. aureus* PNA FISH over several years have shown very high sensitivity, specificity, and positive and negative predictive value.[226,396] A blinded multicenter comparative study of *S. aureus* PNA FISH was performed in eight different laboratories using a variety of blood culture media from three different manufacturers (ESP medium, Trek Diagnostics, Inc. Westlake, OH; BACTEC medium, Becton-Dickinson; BacT/Alert (bioMérieux). The sensitivity of the PNA FISH test for detection of *S. aureus* ranged from 98.5% to 100%, with specificities of 98.5% to 99.2% regardless of the blood culture medium being used.[395] A study performed in Spain evaluated 285 blood cultures containing gram-positive cocci in clusters on Gram's stain. The *S. aureus* PNA FISH assay demonstrated 100% sensitivity and 99.4% specificity with positive and negative predictive values for detection of *S. aureus* bacteremia being 99.2% and 100%, respectively.[193] A five-center study evaluated 722 positive blood culture bottles containing gram-positive cocci in clusters. For detection of *S. aureus,* sensitivity of the QuickFISH test was 99.5% with a specificity of 98.8%.[124] A single *Micrococcus* isolate fluoresced green (i.e., *S. aureus*) initially, but did not fluoresce when repeated. This study also addressed the specificity of the assay using reference strain-spiked blood cultures. Of 34 coagulase-negative staphylococcal strains representing 31 species, all produced positive (red fluorescence) except for single isolates of *S. simulans* and *S. felis*. Several other organisms (i.e., gram-positive and gram-negative coccal and bacillary bacteria) produced uniformly negative results. An Italian evaluation of the *Staphylococcus* QuickFISH BC test performed on 173 blood cultures found that 100% of 35 *S. aureus* were correctly identified by rapid PNA FISH, with a specificity of 100%. The test also identified 98.6% of coagulase-negative staphylococci, again with 100% specificity.[77]

716

Molecular Identification and Typing Methods for Staphylococci

Several molecular methods using DNA as the basis for identification have been described for species level identification and strain typing of *Staphylococcus* species for epidemiologic studies and in outbreak investigations. Methods have included 16S rRNA gene sequencing, amplified fragment length polymorphism (AFLP) analysis of plasmid, ribosomal, and chromosomal nucleic acids, polymerase chain reaction/nucleic

acid probe hybridization procedures, PCR analysis of insertion elements and 16S to 23S rRNA intergenic spacer regions, *IS256* spacer length polymorphisms, and ribotyping.[76,131,132,222,230,486] Closely related species in the genus *Staphylococcu*s may not be adequately resolved by 16S rRNA sequence-based methods and these issues limit the usefulness of this approach for staphylococcal species identification.[76] Other gene sequences have been evaluated for their ability to robustly discriminate individual species and include the heat-shock protein 60 (*hsp60*) gene, the heat-shock protein 40 (*dnaJ*) gene, the gene for the β-subunit of RNA polymerase (*rpoB*), the thermostable endonuclease gene (*nuc*), the superoxide dismutase (*sodA*) gene, the gene encoding glyceraldehyde-3-phosphate dehydrogenase (*gap*), and the gene encoding elongation factor Tu (*tuf*).[142,181,182,222, 275,302,486,498] Sequencing of the *tuf* gene, in particular, is more discriminatory for species identification than 16S rRNA sequence analysis for staphylococcal identification.[238,429] The availability of various primary and secondary databases (e.g., GenBank, BIBI, EzTaxon, MicroSeq) containing published staphylococcal gene sequences complicates identifications and different databases may produce slightly different results. Hwang and colleagues[238] compared 16S rRNA and *tuf* sequences for 97 clinical coagulase-negative staphylococcal isolates and found slightly different results with each of the published and online databases. Ghebremedhin and colleagues[181] found that PCR amplification of the *gap* gene, direct sequencing of the amplicon, and comparison with the GenBank database-enabled reliable species identification. The standardization of databases, the adoption of reference or reference-equivalence agreement, and specific criteria for species designations will improve reliability.

A commercial molecular system for simultaneous identification and detection of *mecA* called the Templex StaphPlex I (Genaco Biomedical Products, Inc., Huntsville AL) is also available.[533] This multiplex uses PCR amplification primers specific for *tuf*gene sequences that are conserved for all coagulase-negative staphylococci, primers for genes specific to *S. epidermidis, S. haemolyticus, S. hominis, S. lugdunensis,* and *S. simulans,* and primers for SCC*mec* types I, II, III, and IV. In addition, primers are included for the detection of the *aac, ermA and ermC, tetM* and *tetK,* for detection of resistance to gentamicin, erythromycin, clindamycin, and tetracycline, respectively. Following extraction and amplification by PCR, identifications are obtained by detection of specific amplicons using a suspension array of labeled beads that are tagged with gene sequences that bind specifically with the amplicons. Detection of labeled amplicons is obtained using the Luminex 100 instrument (Luminex, Austin, TX). In an evaluation of this system with blood culture broths showing gram-positive cocci in clusters, the StaphPlex I system correctly identified 186 of 203 *S. epidermidis*, 10 of 12 *S. haemolyticus*, 25 of 34 *S. hominis*, and 1 of 1 *S. lugdunensis*. *S. capitis* (10 isolates), *S. warneri* (2 isolates), *S. pasteuri* (2 isolates),

and *S. pettenkoferi* (9 isolates) were identified as "other coagulase-negative staphylococci" by the system.[533] The StaphPlex I also detected SCC*mec* type II (most HCS-MRSA) and SCC*mec* type IV (most CA-MRSA) with 100% sensitivity and greater than 95% specificity. The StaphPlex also contains primers and probes for the detection of the PVL genes.

For strain typing of staphylococci, genotypic and molecular methods have largely supplanted older phenotypic methods, such as phage typing, plasmid profiles, and protein analysis. Genotypic typing methods are based on either DNA banding patterns as detected by electrophoresis or by DNA sequencing approaches. PFGE was used initially to delineate the eight MRSA clonal types USA100 through USA800.[358] The typing methods that are currently used for *S. aureus* include *spa* sequence typing, double-locus *spa-clfb* typing, multilocus sequence typing (MLST), and SCC*mec* typing.[515] The *spa* gene encodes protein A, which is found on the surface of *S. aureus*, and the typing method involves sequencing of the variable 24-nucleotide X region of *spa*.[208] Double-locus *spa-clfb* typing involves sequencing of both *spa* and the clumping factor B gene (*clfB*), which contains variable numbers of serine-aspartate repeating units depending on acquisition or loss of complete or partial gene segments.[300]MLST addresses the sequence variability of several core variable (CV) housekeeping genes (usually 7 to 10 genes) to determine a type. SCC*mec* typing deals with sequencing of the *mecA* gene. For these three typing methods, online databases are available that contain analyses of thousands of isolates from several countries (e.g., http://www.SeqNet.org, www.mlst.net, www.saureusmlst.net). Availability of online resources has enabled more standardized approaches to procedural testing issues and nomenclature. Standardization and reference databases are essential for worldwide communication regarding *S. aureus,* and are invaluable to public health officials, research laboratories, and published scientific communications. Additional markers (PVL typing, sequencing of the PVL genes *luk*S-PV and *luk*F- PV, and *arc*A typing (which encodes the arginine catabolic mobile element) may also be helpful for type delineation particularly in outbreak investigations and for nationwide and worldwide epidemiology.[386] Shallcross et al.[488] have reviewed the role of PVL in staphylococcal disease. Multilocus variable-number tandem repeat (MLVA, VNTR) analysis and PFGE are used less frequently for *S. aureus*, although various researchers have examined this approach. For MLVA, the procedure and the nomenclature are not standardized.

PFGE is the most discriminatory method for molecular typing of *S. epidermidis* and other coagulase-negative staphylococci.[368] Strains are identified based on RFLPs of the whole chromosome using restriction enzymes that produce rare DNA cuts and result in large DNA fragments that can be resolved by gel electrophoresis. PFGE analysis requires training and is technically demanding. Different laboratories may

produce slightly different results even with the same set of strains. Standards for interpretation are available, but slight procedural variations may result in slightly different results that may present difficulties

717

in interpretation.[539] In addition to PFGE, several other methods have been described for genotyping of coagulase-negative staphylococci, including RFLP, random amplified polymorphic DNA (RAPD), AFLP, repetitive sequence-based PCR (rep-PCR), and multilocus variable-number tandem repeats (VNTR) analyses.[76,80,131,166,254,290,383] The DNA sequencing-based typing method of choice is MLST. This method involves sequencing a set of housekeeping genes that evolve slowly over time. For *S. epidermidis*, seven of these genes are sequenced and compared to published sequences in an online MLST database.[153,543] Because these genes are highly conserved, with very low mutation rates over time, this method can be used to establish lineages and relationships between and among different *S. epidermidis* isolates over months to years. Conversely, PFGE lends itself more readily to analysis of short-term hospital outbreaks (e.g., investigations of an outbreak of *S. haemolyticus* in a neonatal ICU). At the present time, MLST is only available for *S. epidermidis,* while PFGE can be used for other coagulase-negative staphylococci.[225,507,600]

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry

Matrix-assisted desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) is currently being introduced as a method for bacterial identification in clinical laboratories. At this time two systems are available: the MALDI Biotyper (Bruker Daltronics, Bremen, Germany) and the AXIMA/Shimadzu mass spectrometer (marketed in the United States by bioMérieux). The latter system uses the SARAMIS (Spectral ARchiving And Microbial Identification System, AnagnosTec, Am Muehlenberg 11, 14476 Potsdam/Golm, Germany) as its reference database. A subset of SARAMIS referred to as Superspectra represents the automated system that is available for bacterial identification. The Bruker database currently contains 28 staphylococcal species, while the SARAMIS reference database contains 38 species and subspecies of staphylococci. DuPont and colleagues[145] in France evaluated the Bruker mass spectrometer for identification of 234 clinical coagulase-negative staphylococcal isolates representing 20 species, which were identified by *sodA* gene sequencing. Results were also compared with those obtained with the Vitek 2 and Phoenix systems. When species not common to the databases were eliminated, MALDI-TOF MS correctly identified 97.4% of the isolates, while the Vitek 2 and

Phoenix identified 78.6% and 79%, respectively. Dubois and coworkers[143] also examined the Bruker MS for the identification of 152 staphylococcal strains belonging to 22 different species. These isolates were characterized using a *sodA* gene-based oligonucleotide array for reference identification. Of these 152 isolates, 99.3% were correctly identified to the species level, with one strain identified to the genus level. An evaluation of the Bruker system conducted in the Netherlands found that MS identified 94.3% of 261 gram-positive cocci representing two genera and nine species, whereas phenotypic methods (Vitek 2 and API strips) identified only 63.2%.[568] An Italian evaluation used the Bruker MS for the identification of 450 bloodstream isolates, with *rpoB* gene sequencing as the reference method.[508] MS correctly identified 447 (99.3%) of the isolates with only three misidentifications. Bergeron and others evaluated the AXIMA/Shimadzu system and the SARAMIS database with 186 clinical isolates (including 35 species and subspecies) and 47 *Staphylococcus* species type strains.[48] The clinical isolates were also identified by *tuf* gene sequencing as the reference method. While *tuf* sequencing provided the identification of all but one of the isolates, MALDI-TOF MS correctly identified only 138 (74.2%) of the isolates. The reason for the poor performance of MS in this evaluation was likely due to the absence of Superspectra for many of the animal and environmental staphylococcal species included in this particular evaluation. MALDI-TOF MS is a reliable and relatively inexpensive bacterial identification method that is faster and superior to most phenotypic panels and has accuracy approaching those of molecular methods. As more isolates are examined by MS techniques, the databases of MALDI-MS instrumentation and the applications of a variety of spectral databases will revolutionize microbial identification, characterization, and systematics.

Identification of Micrococcus *and Related Species*

Micrococci and related species are not generally identified to species level in clinical laboratories because they are rarely clinically significant. Using the tests described above and in Table 12-2, laboratories may issue reports of "*Micrococcus* species" without further testing. However, with the recognition of these agents as opportunistic pathogens, it may be necessary to identify these organisms to species on occasion. Identification criteria for the newly reclassified members of the former genus *Micrococcus* are presented in Table 12-7. On Gram's stains, these organisms generally occur in pairs, tetrads, and clusters. All members of the micrococcal species are aerobic, catalase-positive, furazolidone-resistant, and bacitracin-susceptible. The micrococcal species that have been isolated from human clinical specimens and infections include *Kytococcus species (K. schroeteri*, *K. sedentarius)*, *Kocuria* species (*K. kristinae*, *K. rhizophila*, *K. varians*, *K. rosea*, *K. marina),* and *M. luteus.* Colonies of *K. schroeteri* can be smooth and shiny or rough, dry, and "volcano-like"

with irregular edges. Colonies also can vary in pigmentation from a dark, muddy yellow color to creamy white. *K sedentarius* colonies vary in pigmentation from a creamy white to a deep buttercup yellow. Colonies of *K. kristinae* are smooth or rough, with colony pigmentation ranging from pale cream to pale orange, with pigmentation becoming more intense with time. *K. rhizophila* and *K. varians* form pale yellow-pigmented, smooth, shiny colonies, although rough variants of *K. varians* have been described. *K. marina* colonies are smooth and orange in color, while those of *K. rosea* are cream to pale pink. Some species are included in the databases of commercial automated and manual identification systems used in laboratories and may be misidentified as *Staphylococcus* species and vice versa. For example, the Vitek 2 system erroneously identified 20 isolates as *Kocuria* species that were confirmed as coagulase-negative staphylococcal species by 16S rRNA gene sequencing.[41]

Identification of Rothia mucilaginosa

R. mucilaginosa colonies are sticky or mucoid, clear to gray–white in color, and adherent to the agar surface. They appear on Gram-stained smears as large gram-positive cocci arranged in pairs or clusters. They are weakly catalase-positive, although some strains are catalase-negative. *R. mucilaginosa* can be differentiated from *Micrococcus* and *Staphylococcus* species by failure to grow on nutrient agar medium containing 5% NaCl and by the presence of a capsule. These organisms are also included in the database of the API Staph-Ident, the API Staph, and ID32 Staph systems. Other biochemical characteristics are shown in Table 12-8.

Laboratory Approach to the Identification of Staphylococci

Because staphylococci are among the most frequently isolated organisms in the clinical laboratory, decisions must be made on "how far to go" in identifying them. This is especially true regarding the coagulase-negative organisms. Many laboratories have adopted rapid coagulase procedures (i.e., latex tests), so these tests may quickly be performed on colonies that appear to represent staphylococci and are catalase-positive. If the colonies are coagulase-positive, the organism is identified as *S. aureus*. For isolates that are coagulase-negative, a furazolidone or bacitracin disk test, or the modified oxidase test, may be performed to differentiate coagulase-negative staphylococci from *Micrococcus* and related species. Significant staphylococcal isolates from urine cultures should also be tested for susceptibility to novobiocin for presumptive identification of *S. saprophyticus*. Complete species identification using a reference procedure, a kit, or a molecular approach should be reserved for clinically significant isolates, including those isolates that have been recovered from multiple sets of blood cultures, from infected intravenous catheters (where the patient may have the same isolate in multiple blood cultures), or from other normally sterile sites where the same coagulase-negative *Staphylococcus* sp. has been repeatedly isolated. Decisions involving further identification of these organisms should be made on a case-by-case basis with inputs from both the laboratory director and the physicians caring for the patient.

TABLE 12-8 Identification of *Rothia mucilaginosa*

CHAPTER 13

Gram-Positive Cocci

Part II: Streptococci, Enterococci, and the "*Streptococcus* -Like" Bacteria

thePoint For additional ancillary materials related to this chapter, please visit the point.

General Characteristics of the Streptococci

Group A β-Hemolytic Streptococci (*Streptococcus pyogenes*)

- Virulence Factors
- Clinical Spectrum of Group A Streptococcal Disease

Group B β-Hemolytic Streptococci (*Streptococcus agalactiae*)

- Virulence Factors
- Clinical Spectrum of Group B Streptococcal Disease
- Prevention of Group B Streptococcal Disease
- Other Infections Caused by Group B Streptococci
- Antimicrobial Susceptibility of Group B Streptococci

Group C and Group G β-Hemolytic Streptococci

Group F β-Hemolytic Streptococci

Emerging Pathogens Among the Streptococci

Streptococcus suis

Streptococcus porcinus and *Streptococcus pseudoporcinus*

Streptococcus iniae

Streptococcus pneumoniae

Virulence Factors

Pneumococcal Vaccines

Clinical Spectrum of *S. pneumoniae*

Antimicrobial Susceptibility of *S. pneumoniae*

Viridans Streptococci

The Anginosus Group: Streptococcus anginosus, Streptococcus constellatus, and Streptococcus intermedius

Group D Streptococci: The "*Streptococcus bovis*" Group

***Enterococcus* Species**

Taxonomy

Virulence Factors

Clinical Spectrum of Enterococcal Infections

Antimicrobial Susceptibility of Enterococci

Genus *Melissococcus* and Genus *Catellicoccus*

The "*Streptococcus-Like*" Bacteria

Abiotrophia and *Granulicatella* Species

Aerococcus and *Helcococcus* Species

Leuconostoc Species

Pediococcus and *Tetragenococcus* Species

Gemella Species

Vagococcus Species

Alloiococcus Species

Globicatella Species

Facklamia Species

Dolosigranulum, Ignavigranum, Dolosicoccus, and *Eremococcus* Species

Lactococcus Species

Isolation and Identification of Streptococci and the "*Streptococcus-Like*"

Bacteria

Direct Gram-Stained Smears

Culture Media

Hemolysis on Blood Agar

Nonculture, Direct Detection Techniques for Group A β -Hemolytic Streptococci in Pharyngeal Specimens

Nonculture, Direct Detection Techniques for Group B β -Hemolytic Streptococci

Nonculture, Direct Detection Techniques for *Streptococcus pneumoniae*

Nonculture Techniques for the Detection of Enterococci in Blood Cultures

Colony Morphology and Catalase Testing

Recognition and Preliminary Characterization of Streptococci and the "*Streptococcus*-Like" Bacteria

Presumptive Identification of Streptococci and Enterococci

- Susceptibility to Bacitracin
- Susceptibility to Sulfamethoxazole-Trimethoprim (SXT)
- CAMP Test and Pigment Production
- Hydrolysis of Sodium Hippurate
- Bile Esculin Test
- Salt Tolerance Test (6.5% NaCl Broth)
- Leucine Aminopeptidase (LAP) Test
- Pyrrolidonyl Arylamidase (PYR) Test
- Commercial Presumptive Identification Tests

Serologic Identification of β -Hemolytic Streptococci

- Capillary Precipitin Test
- Coagglutination
- Latex Agglutination

Phenotypic Characteristics for Identification of Groupable Streptococci

Identification of *S. pneumoniae*: Susceptibility to Optochin, the Bile Solubility Test, and AccuProbe *Pneumococcus* Test

Serologic Identification of *Streptococcus pneumoniae*

Anginosus Group
Bovis Group
Identification of *Streptococcus suis* and Other Streptococci Isolated From Animals
Detection of Vancomycin-Resistant Enterococci
Identification of *Enterococcus* Species
Identification of *Abiotriophia* and *Granulicatella* Species
Identification of *Aerococcus* and *Helcococcus* Species
Identification of *Leuconostoc*, *Pediococcus*, and *Tetragenococcus* Species
Identification of *Gemella* Species
Identification of *Vagococcus* Species
Identification of *Alloiococcus* Species, *Globicatella* Species, *Facklamia* Species, *Dolosigranulum* Species, *Ignavigranum* Species, and *Dolosicoccus* Species
Identification of *Lactococcus* Species
Commercial Systems for Identification of Streptococci, Enterococci, and Selected "Streptococcus-Like" Bacteria
Vitek 2
Phoenix (Becton-Dickinson Diagnostic Systems, Sparks, MD)

The streptococci, enterococci, and *Streptococcus*-like bacteria are gram-positive, catalase-negative bacteria that tend to grow in pairs and chains (Image Plate 13-1B). The detection of cytochrome enzymes with the catalase test distinguishes members of the various micrococcal and staphylococcal species groups (catalase-positive) from the streptococci, enterococci, and "*Streptococcus*-like" bacteria, which are catalase-negative. As with other microbial groups, the classification and taxonomy of the streptococci and *Streptococcus*-like bacteria have changed radically with the descriptions of several new genera of catalase-negative cocci. These changes have more than academic significance for clinical microbiologists in the 21st century because previously uncommon organisms belonging to these groups are being recovered from human infections with increasing regularity, and the pathogenic potentials of both old and newly described species are still not understood and are being actively investigated.

The application of molecular taxonomic methods and the description of several new genera of catalase-negative, gram-positive cocci have resulted in a complete reorganization of streptococcal taxonomy compared with that published in the 1984

edition of *Bergey's Manual of Systematic Bacteriology*. Molecular methods such as DNA–DNA hybridization, DNA–ribosomal RNA (rRNA) hybridization, and small-subunit (16S) rRNA sequencing were initially used to validate the division of the family *Streptococcaceae* into the genera *Streptococcus*, *Enterococcus*, and *Lactococcus*, and are now being applied to newly described viridans streptococci, enterococci, and other catalase-negative isolates to determine their relationships to these three genera.[71] In the new edition of *Bergey's Manual*, catalase-negative, gram-positive cocci of human origin are classified among six families in the proposed order "*Lactobacillales*" and one family in the order *Bacillales*, both of which are in the proposed class "*Bacilli*" in phylum *Firmicutes* (Box 13-1). The genus *Streptococcus*, which contains the most important human pathogens, can be operationally divided into seven groups, as shown in Box 13-2.

BOX 13-1

Current Classification of the Streptococci, Enterococci, and the "*Streptococcus-Like*" Bacteria

Order	Family	Genus
"Lactobacillales"	*Streptococcaceae*	*Streptococcus, Lactococcus*
	Enterococcaceae	*Atopobacter, Bavaricoccus, Catellicoccus, Enterococcus, Melissococcus, Pilibacter, Tetragenococcus, Vagococcus*
	"Aerococcaceae"	*Abiotrophia, Aerococcus, Dolosicoccus, Eremococcus, Facklamia, Globicatella, Ignavigranum*
	Leuconostocaceae	*Leuconostoc, Oenococcus, Weissella*
	Lactobacillaceae	*Pediococcus*
	"Carnobacteriaceae"	*Alloiococcus, Dolosigranulum, Granulicatella*
Bacillales	*Staphylococcaceae*	*Gemella, Macrococcus*

Organisms listed in this Table belong to: Domain Bacteria, Phylum *Firmicutes*, Class "Bacilli"

BOX 13-2

735

Classification ofStreptococcusSpecies Groups Based on Small-Subunit rRNA Sequence Analysis[71]

Group Members	Habitat and Comments
Group I. Pyogenic Group	
S. pyogenes (Group A β-hemolytic *Streptococcus*)	This species is a well-known human pathogen (see text).
S. agalactiae (Group B β-hemolytic *Streptococcus*)	*S. agalactiae* is a well-known agent of neonatal disease, in particular (see text).
S. dysgalactiae subsp. *dysgalactiae* (Groups C and L β-hemolytic streptococci)	This streptococcal species causes infections in several animal species, including pigs, cattle, and humans (see text).
S. dysgalactiae subsp. *equisimilis* (Groups C and G β-hemolytic streptococci)	This streptococcal species causes infections in several animal species, including pigs, cattle, and humans (see text).
S. equi subsp. *equi* (Group C β-hemolytic *Streptococcus*)	This species causes disease primarily in animals, with occasional infections being seen in humans (see text).
S. equi subsp. *ruminatorum*[336]	This fairly recently described subspecies causes mastitis in sheep and goats (see text).
S. equi subsp. *zooepidemicus* (Group C β-hemolytic *Streptococcus*)	Many animal species (see text)
S. canis (Groups G, L, and M streptococci)[284]	This β-hemolytic species has been isolated from a variety of animal species, especially dogs (see text).
S. castoreus (reacts with Lancefield group A antisera)[616]	*S. castoreus* was isolated from wound, liver, and spleen specimens from a European beaver carcass.
S. didelphis (No Lancefield group)[877]	*S. didelphis* are β-hemolytic streptococci that were isolated from skin lesions, splenic, liver, and lung tissues of opossums that developed skin bruising followed by sudden death.
S. halichoeri (reacts with Lancefield group B antisera)[615]	This species was described in postmortem and clinical specimens from several gray seals in the United Kingdom.
S. hongkongensis[599]	This newly described species has been isolated from marine flatfish and from a thumb wound in a 44-year-old fishmonger following a puncture injury from a fish fin. This new species is most closely related to *S. iniae*, *S. pseudoporcinus*, *S. uberis*, and *S. paruberis*.
S. ictaluri (No Lancefield group)[919]	This species was isolated during an investigation of suspected bacterial disease in Channel Catfish (*Ictaluris punctatus*) broodstock. The isolates were associated with meningitis, myositis, osteolysis, and arthritis in the fish.
S. iniae (No Lancefield group designation)[830]	This emerging pathogen causes disease in many species of fish and is also pathogenic for humans (see text).
S. phocae (Groups C, F, or nongroupable streptococci)[942]	*S. phocae* was originally described as a cause of pneumonia in seals and has subsequently been isolated from respiratory tract infections in porpoises. *S. phocae* also causes septicemic infections in Atlantic salmon.[871]
S. porcinus (Groups E, P, U, and V streptococci)[216]	This β-hemolytic streptococcal species found in both swine and humans (the latter isolates have been re-named *S. pseudoporcinus*, see text).
S. pseudoporcinus (No Lancefield group)[67]	This novel *Streptococcus* species was described in 2006. It is found in the human female genitourinary tract and has been isolated from bloodstream, placental, and wound infections (see text).[923] Phenotypic methods do not adequately differentiate *S. pseudoporcinus* from *S. porcinus*, and sequencing of 16S rRNA or the *rpoB* gene is required for definitive identification.[371,923] Isolation of an organism from the female genitourinary tract that is phenotypically *S. porcinus* is likely to be *S. pseudoporcinus*. Some evidence suggests that presence of *S. pseudoporcinus* in the genitourinary tract of reproductive-aged women may contribute to the pathogenesis of premature rupture of fetal membranes and endocervical insufficiency.[820] Shewmaker and colleagues[923] have proposed that *S. pseudoporcinus* be divided into two subspecies. *S. pseudoporcinus* subsp. *hominis* grows in 6.5% NaCl, hydrolyzes hippurate, utilizes pyruvate, and is lactose-negative, while *S. pseudoporcinus* subsp. *lactis* does not grow in 6.5% NaCl, is negative

	for hippurate hydrolysis and acidification of pyruvate, and produces acid from lactose. Human isolates belong to the former subspecies, while dairy and animal isolates comprise the latter subspecies.
S. urinalis (No Lancefield group)[223]	This novel *streptococcus* was first isolated from a urine culture of a patient with cystitis and lower abdominal pain, and, subsequently, *S. urinalis* was isolated from a blood culture of a 60-year-old man with a history of urethral stricture.[817] Even though *S. urinalis* is an α-hemolytic *streptococcus*, it is considered as a member of the pyogenic streptococcal group, with *S. pyogenes* and *S. canis* as its nearest phylogenetic relatives.
Group II. Mitis/Sanguinis Group	
S. australis[1131]	*S. australis* was first were isolated from the saliva of children attending a dental hospital in Sydney, Australia. Initially thought to be *S. mitis,* additional biochemical and hybridization studies demonstrated that these isolates were a separate species. In 2011, this organism was the cause of bacterial meningitis in a 77-year-old man.[449]
S. cristatus[422]	*S. cristatus* is oral *streptococcus* that is unusual in possessing tufts of short fibrils located in a lateral position on the cell surface that help the organism to co-aggregate with other organisms in dental plaque. *S. cristatus* is a rare cause of endocarditis.[694]
S. danieliae[202]	This species was isolated from the caecum of a mouse. The organism is genotypically related to *S. alactolyticus*, *S. gordonii*, *S. sanguinis*, and *S. intermedius*. It does not react with any Lancefield antisera and it is β-hemolytic.
S. gordonii[556]	This viridans streptococcal species is found in the oral cavity of humans and has been isolated from bloodstream infections in cancer and endocarditis patients, joint fluid in two cases of septic arthritis, and peritoneal fluid from a patient on continuous ambulatory peritoneal dialysis.[183,421,1158]
S. infantis[545]	*S. infantis* is a member of the Mitis Group and is found on the teeth and in the nasopharynx of humans.
S. lactarius[681]	This recently described species was isolated from breast milk of healthy women.
S. massiliensis[383]	This species is based on a single isolate from a blood culture. On 16S rRNA gene sequencing, this isolate clustered with the Mutans Group streptococci, but *rpoB* and *sodA* gene sequence comparisons placed the organism in the Mitis/Sanguinis Group of streptococci.
S. mitis[556]	*S. mitis* is an α-hemolytic *Streptococcus* that is found in the oral cavity, the gastrointestinal tract, the female genital tract, and on skin (Image Plate 13-4F, 13-4G and 13-4H). *S. mitis* is a cause of infective endocarditis and meningitis, particularly in patients with risk factors that include prior valvular damage, poor dentition/oral hygiene, malignancies, stem cell transplantation, other underlying disease (e.g., hemolytic anemia, alcoholism, hypertension, diabetes), immunosuppressive therapies (e.g., corticosteroids, chemotherapy agents), head and neck infections (e.g., maxillary sinusitis) and neurosurgical procedures.[290,585,659,691] Complications of endocarditis and bacteremia include embolic phenomena, endophthalmitis, and osteomyelitis.[290,771] *S. mitis* is also a cause of viridans streptococcal shock/respiratory distress that occurs in profoundly immunosuppressed patients with malignancies and hematopoietic stem cell transplant recipients 1–28 days posttransplant.[179,666] *S. mitis* is one of the more frequently isolated species from blood cultures and isolates with reduced susceptibility or frank resistance to β-lactam agents are increasing in prevalence.[507,577,691] Matsui and colleagues[691] reported a case of *S. mitis* infective endocarditis in which the isolate was resistant to all penicillins, cephalosporins (all generations), all carbapenems, and erythromycin, and susceptible only to vancomycin, levofloxacin, and clindamycin. Levofloxacin resistance was documented in an otherwise pan-susceptible *S. mitis* strain recovered from blood and vitreous cultures in a patient with endocarditis and endogenous endophthalmitis.[290] Linezolid has been used for treatment of *S. mitis* endocarditis with success.[759] Fulminant *S. mitis* peritonitis in a CAPD recipient has also been reported.[720] Some isolates of *S. mitis* may be optochin-susceptible, but they are not soluble in bile or desoxycholate.[259]
S. oligofermentans[1033]	*S. oligofermentans* was first described in 2003 when it was isolated from dental plaque and saliva of nasopharyngeal carcinoma patients. In 2009, *S. oligofermentans* was documented as the cause of a left forearm abscess complicated by endocarditis in a 43-year-old woman.[693]

S. oralis[556]	*S. oralis* has been isolated from cases of native- and prosthetic valve endocarditis.[860,1057] *S. oralis* is phenotypically similar to *S. mitis*, and can be differentiated by certain enzymatic tests (e.g., β-GLU and NAGA).
S. parasanguinis[1125]	This species has been isolated from respiratory tract, blood, and urine specimens from humans and has also been associated with asymptomatic mastitis in sheep.[337] Endocarditis due to penicillin-resistant *S. parasanguinis* was reported in 2008 and peritoneal dialysis-associated peritonitis due to *S. parasanguinis* was reported in 2011.[361,882]
S. peroris[545]	*S. peroris* is a newer member of the Mitis Group and is found on the teeth and in the nasopharynx of humans.
S. pneumoniae	See text
S. pseudopneumoniae	See text
S. sanguinis[556]	This species is found in the human oral cavity and has been isolated from patients with endocarditis and as a cause of mycotic aneurysm.[61,175,539] Complications of hematogenous dissemination during endocardial and bloodstream infections include brain abscess and septic arthritis.[539,800] This organism also caused purulent meningitis in a patient with cirrhosis who underwent endoscopic ligation of bleeding esophageal varices.[653] Molecular methods (e.g., PCR-generated, species-specific DNA probes) have been designed to facilitate study of the interaction of *S. sanguinis* and other oral streptococci with the cariogenic species, *S. mutans*.[639] Resistance to β-lactam antibiotics has been noted for both *S. mitis* and *S. sanguinis*.[61]
S. sinensis[1142]	This species is part of the bacterial flora of the human oral cavity and was first isolated from blood cultures of patients with endocarditis.[326,1060,1142–1144] This organism may carry the Lancefield group F antigen.[1143]
S. tigurinus[1169]	This streptococcal species was described in 2012 and has been isolated from blood cultures of patients with endocarditis, meningitis, and spondylodiscitis.[1169] This species is most closely related to *S. mitis*, *S. pneumoniae*, *S. pseudopneumoniae*, *S. oralis*, and *S. infantis*.[1168]
S. troglodytidis[1173]	This species was isolated from a foot abscess of a chimpanzee (*Pan troglodytes*).
Group III. Mutans Group	
S. cricetus	This species is found in the oral cavities of hamsters, rats, and, rarely, humans.
S. dentaprl[992]	This species, described in 2010, was isolated from the oral cavities of wild boars.
S. dentirousetti[994]	This species was isolated from the oral microflora of bats.
S. devriesei	This species is found in the oral cavity of horses and cows.
S. downei	This species is found in the oral cavity of monkeys.
S. ferus	This species is found in the oral cavity of rats.
S. macacae	This species is found in the oral cavity of monkeys.
S. mutans[1124]	This species is the principal cause of dental caries in humans. Isolates of *S. mutans* produce glucosyltransferase enzymes that synthesize the polysaccharides forming the matrix of dental plaque from dietary sucrose (see text).
S. orisratti[1176]	This species is found in the oral cavities of Sprague-Dawley rats. Phylogenetic studies of the 35 serotypes of *S. suis* revealed that types 32 and 34 were distant from other *S. suis* serotypes and, when additional sequencing studies were completed, these two "*S. suis*" serotypes were actually *S. orisratti*.[455]
S. orisuis[993]	This *Streptococcus* species was recovered from the oral cavities of swine.
S. ratti	This species is found in the oral cavity of rats (and occasionally humans).
S. sobrinus	This species is constitutes a portion of the cariogenic streptococci found in the human oral cavity.
S. ursoris[926]	This streptococcal species was cultured from the oral cavities of bears.
Group IV. Salivarius Group	
S. hyointestinalis[285]	This species was isolated from the intestines of pigs and characterized in 1988.
S. infantarius[901]	*S. infantarius* has been isolated from humans and food products. *S. infantarius* strains are also included in the Bovis Group because some strains are bile esculin–positive.

S. salivarius[1124]	This species is found in the oral cavity and saliva of humans. "*S. thermophilus*" is related *to S. salivarius*, and may be a subspecies of *S. salivarius* or a distinct species.
S. thermophilus	This species is found in dairy products.
S. trolodytae[781]	This species was isolated from the oral cavity of a chimpanzee. *S. mutans* was shown to be the most closely related species.
S. vestibularis[1128]	This species was first isolated from the vestibular mucosa of the oral cavity of humans. In 2010, this species was isolated from a 65-year-old woman as a cause of native aortic valve endocarditis and spondylodiscitis.[1050]
Group V. Anginosus Group	
S. anginosus	Humans (see text)
S. constellatus subspecies	Humans (see text)
S. intermedius	Humans (see text)
Group VI. Bovis Group	
S. bovis/S. equinus	These isolates are found in the genitourinary and gastrointestinal tracts of cattle and horses.
S. caballi[714]	This species and *S. henryii* were isolated from horses with experimentally-induced laminitis, a serious disease of the equine foot that is associated with dietary intact of excess carbohydrate.
S. gallolyticus subsp. *gallolyticus* (*S. bovis* I)	See text
S. gallolyticus subsp. *macedonicus*[675,1048] (formerly "*S. macedonicus*," "*S. waius*")	*S. gallolyticus* subsp. *macedonicus* is found in cheeses and other dairy products. *S. macedonicus* was originally called *S. waius* and then *S. macedonicus* before being incorporated as a subspecies of *S. gallolyticus* in the *Bovis* group (see text).
S. gallolyticus subsp. *pasteurianus* (*S. bovis* II.2)	See text
S. henryi[714]	*S. henryi* and *S. caballi* were isolated from horses with experimentally-induced laminitis, a serious disease of the equine foot that is associated with dietary intact of excess carbohydrate. This species reacts with Lancefield group D antisera.[714]
S. infantarius subsp. c*oli*	Swine, dogs, chickens
S. infantarius subsp. *infantarius* (*S. bovis* II.1)	Humans, cattle
Group VII. Miscellaneous Streptococci	
S. acidominimus	*S. acidominimus* strains have been poorly characterized since the original species description in 1922. Reexamination of *S. acidominimus* strains recovered from humans established the true identity of these isolates as *Facklamia sourekii*.[220] This organism has been isolated from cattle, poultry, and humans. Infections with *S. acidominimus* in humans have included pneumonia with empyema, pericarditis, meningitis, endocarditis, otitis media, and brain abscess.[48,115,236,342,991]
S. entericus[1088]	This α-hemolytic species was recovered from intestinal specimens obtained from a cow with catarrhal enteritis, a relentless wasting diarrheal syndrome in calves.
S. gallinaceus[222]	This species was first isolated from blood cultures of a broiler chicken with sepsis and has subsequently been documented as a major cause of sepsis and endocarditis in chicken flocks in Denmark.[164,222] In 2006, *S. gallinaceus* was isolated from a blood culture of an abattoir worker with a febrile illness in New Zealand.[50]
S. hyointestinalis	This species was isolated from the intestines of swine.
S. hyovaginalis[286]	This species was recovered from vaginal specimens of swine.
S. marimammalium[614]	This species was recovered from respiratory specimens obtained from gray seals and common seals.
S. merionis[1010]	This species was isolated from parasite vesicles inoculated into the peritoneal cavities of Mongolian jirds to study the larval stage of *Echinococcus multilocularis*.
S. minor[1072]	This α-hemolytic species was isolated from tonsils, anal swabs, and feces of dogs and from tonsillar tissues of a cat and a calf.

739

S. ovis[224]	This species is based on seven isolates obtained from chest wall, navel, abdominal, lung abscesses and joint fluid specimens from sheep.
S. pluranimalium[287]	This species is unusual in that isolates have been recovered from a variety of animals, including cattle (genital tract and mastitis isolates, lung isolates), lungs and crops of canaries, and tonsillar tissues of cattle, a goat, and a cat. This species was the cause of an outbreak of endocarditis and septicemia in hens.[438]
S. plurextorum[1087]	This species was isolated from lung and kidney tissues of swine that had died of pneumonia and septicemia.
S. porci[1091]	This organism was isolated from pericardial tissues and bronchial lymph node specimens from swine with pericarditis and pneumonia, respectively. This species reacts with Lancefield group B antisera.
S. porcorum[1092]	This species, described in 2011, was isolated from wild and domestic pigs. It is most closely related to *S. suis*.
S. rupicaprae[1090]	This streptococcal species was isolated from clinical samples from a Pyrenean chamois.
S. suis (Lancefield groups R, S, and T)	This novel species is a cause of disease in piglets, cattle, and is an emerging agent in human disease (see text).
S. thoraltensis[286]	This species was isolated from the intestinal contents of a pig.
S. uberis/S. paruberis[761]	*S. uberis* and *S. parauberis* are causes of bovine mastitis and have not been isolated from humans. These two species are indistinguishable from one another using phenotypic criteria, and species-specific molecular probes for these two organisms have been developed. Human isolates that were phenotypically identified as *S. uberis* have been reidentified as *Globicatella sanguinis*.[761] *S. parauberis* is a cause of streptococcosis in olive flounder. Some isolates carry the Lancefield group E antigen, while others are nongroupable.

General Characteristics of the Streptococci

Streptococci are facultative anaerobes, although some strains grow better under anaerobic conditions. Although most species will grow in air, the growth of most species is stimulated by increased CO_2. Medically important streptococci, enterococci, and aerococci are **homofermentative**, meaning that the sole product of glucose fermentation is lactic acid with no gas formation. Streptococci are also catalase-negative and oxidase-negative, a property that, together with the Gram's stain, differentiates streptococci from *Neisseria* species. Members of the genus *Streptococcus* characteristically grow in chains (or chains of diplococci) when grown in broth media (Image Plate 13-1B and13-1C). This characteristic is shared with the enterococci, the lactococci, and some of the newly recognized genera (i.e., *Leuconostoc* species, *Vagococcus* species, and *Globicatella* species). Other *Streptococcus*-like bacteria (i.e., aerococci, *Alloiococcus* species, *Gemella* species, *Pediococcus* species, *Tetragenococcus* species, and *Helcococcus* species) grow as pairs or tetrads in broth. Assessment of the cellular arrangement is best made by performing a Gram's stain from a culture of the organism growing in thioglycolate

broth. When thioglycolate broth is used, the smear preparation should be fixed in methanol after air-drying, rather than heat-fixed, to prevent the bacteria from "washing off" the slide during the staining process.

The cell wall composition of the streptococci is similar to that of other gram-positive bacteria, being composed primarily of peptidoglycan, in which are embedded a variety of carbohydrates, teichoic acids, lipoproteins, and surface protein antigens (see Chapter 5). Some streptococcal species may be serologically classified on the basis of cell surface carbohydrate antigens. The pioneering work of Rebecca Lancefield established the Lancefield-grouping system for the β-hemolytic streptococci (Image Plate 13-3A). The antigens detected in the Lancefield-grouping system are either cell wall polysaccharides (as in the human group A, B, C, F, and G streptococci) or are cell wall lipoteichoic acids (group D streptococci and *Enterococcus* species). Originally, these cell wall grouping antigens were extracted with dilute hydrochloric or nitrous acid, formamide, or by autoclaving, and groups were determined by capillary precipitin reactions. Commercially available streptococcal grouping kits use enzymatic extraction techniques and either coagglutination or latex particle agglutination for antigen detection (Image Plate 13-1G). Other streptococci, particularly members of the viridans streptococcal groups, do not possess any of the recognized Lancefield cell wall grouping antigens, although some strains may possess similar antigens that will cross-react with β-hemolytic streptococcal group-specific antisera. Well-studied viridans streptococci, such as the cariogenic organism *S. mutans*, have been divided into serotypes based on their own cell wall carbohydrate antigens. The various serotypes of *S. mutans* have subsequently been elevated to species status and now comprise the "*Mutans* group" of oral streptococci.

740

Group A β-Hemolytic Streptococci (*Streptococcus pyogenes*)

The pathogenic streptococci have several characteristics that contribute to their virulence. The virulence mechanisms of the group A, β-hemolytic streptococci (*S. pyogenes*), in particular, have been studied most extensively. This organism remains an extremely important human pathogen, and the only known reservoirs of group A streptococci in nature are the skin and mucous membranes of humans. The World Health Organization estimates that over 500,000 people die each year from severe group A streptococcal infections, particularly invasive disease and the sequelae of acute rheumatic fever and consequent rheumatic heart disease.[135,276] Twenty-five to 35 million cases of group A streptococcal pharyngitis occur each year in the United

States.[739] In the United States, group A streptococcal infections occur at an annual rate of about 3.5 cases per 100,000 population, resulting in over 9,600 cases and 1,100 to 1,300 fatalities per year.[775] In addition to acute infections, the group A *Streptococcus* is also associated with two nonsupperative sequelae—acute rheumatic fever and acute poststreptococcal glomerulonephritis—that continue to occur particularly in developing countries. More than 95% of the estimated 294,000 fatal cases of rheumatic heart disease worldwide occur in developing countries, which also bear the overwhelming number of other invasive group A streptococcal diseases.[135,964]

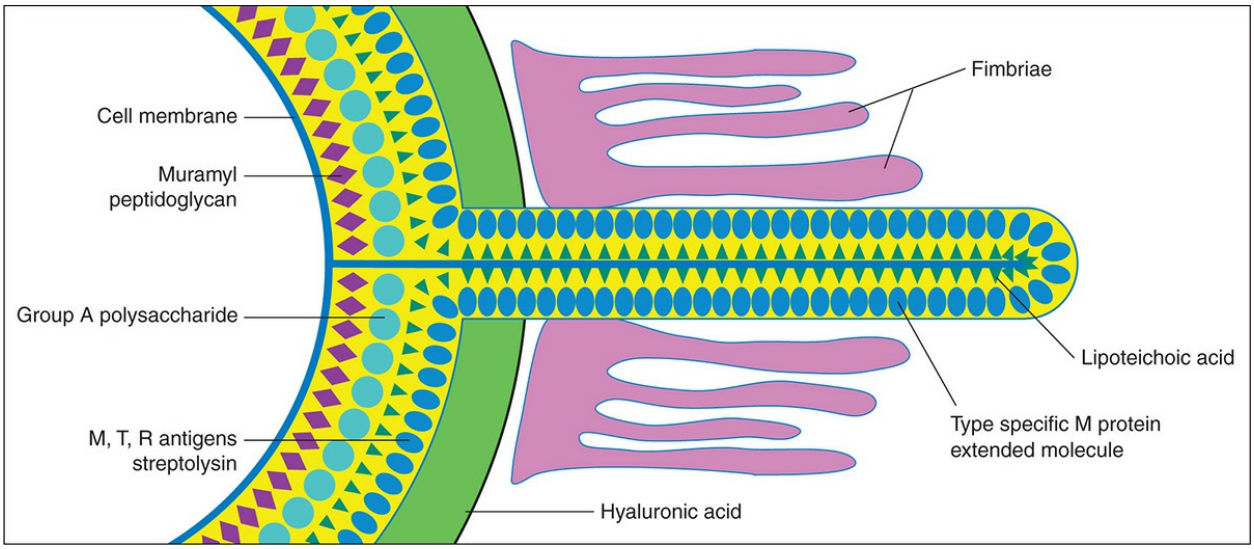
Virulence Factors

The cell wall of group A β-hemolytic streptococci consists of a thick peptidoglycan along with integral **lipoteichoic acids (LTAs**) and other surface associated molecules, as described in Chapter 5. LTAs are believed to play a central role in promoting initial adherence of group A streptococci to pharyngeal epithelial cells, to other cell types, and to host proteins such as fibronectin.[247] In addition to LTAs, several other group A streptococcal adhesins have been described, including several fibronectin-binding proteins (e.g., protein F1 [SfbI, streptococcal fibronectin-binding protein], protein F2 [SbfII], FPB54, and PFBP).[247,424,504,866] These surface-binding proteins promote adherence to both pharyngeal and cutaneous cell types. M proteins play a role in adherence to keratinocytes in skin via interaction with the keratinocyte membrane cofactor CD46.[780] The major group A cell wall antigen is a complex polysaccharide consisting of L-rhamnose and *N*-acetyl-D-glucosamine in a 2:1 ratio.[90] The antigen is covalently attached to the peptidoglycan. The role of the cell wall grouping antigen as a virulence factor is not known, although the peptidoglycan material itself has biologic activity, including the induction of fever, dermal and cardiac necrosis in animals, lysis of erythrocytes and platelets, and enhancement of nonspecific resistance.

Some group A strains possess a **capsule** composed of hyaluronic acid, which is a high molecular weight linear polymer composed of β(1-4)-linked disaccharide repeating units of D-glucuronic acid and (1-3)-β-D- *N*- acetylglucosamine.[970,1119] This material is the product of enzymes encoded by a three-gene cluster consisting of *hasA*, *hasB*, and *hasC*. These three genes encode a hyaluronic acid synthase, a UDP-glucose dehydrogenase, and a glucose pyrophosphorylase, respectively.[19] These genes are highly conserved among group A streptococcal strains, and variations in the degree of capsular gene expression likely reflect differences in regulation of gene transcription. Strains that maximally express these genes appear mucoid when grown on sheep blood agar (SBA).[1121] Two gene products, **CrsS** and **CrsR**, appear to function as a two-component regulatory system that is able to increase or decrease the degree of encapsulation by up- or downregulation of *has* gene expression.[634] Chemically, this

capsular hyaluronate material is indistinguishable from the ground substance of connective tissue, which may explain the lack of immunogenicity of this substance in the infected host. In vitro, capsule production is maximal during logarithmic growth, and the organisms shed their capsules as they enter the stationary phase of growth; this loss is probably due to the elaboration of **hyaluronidase** during the latter stages of the logarithmic growth phase. The hyaluronic acid capsule functions to help the organisms resist complement-dependent killing by phagocytic cells. In animal models, the hyaluronic acid capsule has been shown to contribute to the capacity of group A streptococci to produce invasive soft tissue infections.[38] The capsule also influences the ability of group A streptococci to adhere to epithelial cells by modulating the interaction of M protein and other surface molecules and by serving as a ligand for binding to the CD44 receptor on epithelial cell surfaces.[907,1119]

The major virulence factor of the group A *Streptococcus* is a cell surface antigen designated **M protein.**[90,709,777] M proteins are acid- and heat-stable, trypsin-labile, fibrillar proteins associated with the outer surface of the cell wall. M proteins are composed of two polypeptide chains complexed together in an α-helical coiled-coil configuration.[343] The M protein is anchored in the cell membrane, extends through the peptidoglycan layer, and projects from the surface of the bacterial cell (Fig. 13-1). The amino acid sequence and structure of the carboxy-terminal end of the molecule is located within the cell membrane and cell wall of the organism and is highly conserved among group A strains. The *N*-terminus extends beyond the cell surface and terminates with a sequence of about 11 amino acid residues. This terminal sequence varies among clinical isolates and constitutes the basis for the Lancefield serologic classification of group A streptococci. Strains that are rich in M protein are resistant to phagocytosis and intracellular killing by polymorphonuclear cells, thereby allowing the organisms to persist in infected tissues; cells lacking demonstrable M protein are readily phagocytosed and killed.[90] M protein apparently exerts its antiphagocytic effects by interfering with opsonization of the bacterial cells via inhibition of both the classical and the alternate complement pathways. M proteins are also able to form complexes with fibrinogen that consequently bind to β2 integrins of neutrophils. Binding triggers release of inflammatory mediators that induce vascular leakage, a pathologic component of streptococcal toxic shock.[447] Some M proteins can act as superantigens, causing T-cell proliferation and release of cytokines, and M proteins from classically "rheumatogenic" M types elicit the formation of antibodies that cross-react with several mammalian host cell proteins, including myosin, laminen, and



■ **FIGURE 13-1** The major known antigenic determinants on the surface of virulent, encapsulated group A streptococci.

keratin.[709] Eventually, antibodies against the more prevalent M types emerge, and with development of herd immunity, these types disappear and new M types appear and expand through increased transmission. Serologic M typing is usually performed on hot acid extracts of group A streptococci using capillary precipitin or agarose gel immunodiffusion techniques. Only a single M-type antigen is expressed by group A strains, and 93 different M serotypes have been identified using these methods.[318] Cloning of the M protein gene, called the *emm* gene, has resulted in the expansion and standardization of *emm* typing to replace the conventional serologic method. Consequently, there are now over 200 known *emm* types. The *emm* typing system is performed by sequence analysis of the NH_2-terminal nucleotide residues and has resulted in the identification of over 124 recognized *emm* genotypes.[323] The definition of a new *emm* type sequence is based on identification of more than 160 nucleotide bases at the 5′ terminus of the hypervariable region. Different *emm* types will have less than 80% sequence homology with other *emm* types.

Since its introduction, *emm* typing has been used in several large population-based studies in the United States, Canada, and other countries. These studies have shown differences in *emm* type distribution worldwide. Similarities in *emm* types were noted in higher-income countries (i.e., Europe, North America, urban Australia, New Zealand, Japan), with the greatest diversity in *emm* type occurring in Africa, indigenous Australian populations, and the Pacific Island region.[963,964] Amino acid sequence analysis of M proteins of many types has also identified portions of the M protein molecule that are common among several M protein types; that is, this sequence of amino acids is highly conserved. Sera from individuals living in different

geographic areas with high rates of streptococcal infection reacted with this conserved M peptide in an enzyme-linked immunosorbent assay (ELISA).[963] Furthermore, antibodies directed against this peptide were able to opsonize streptococci belonging to a variety of M types. This highly conserved part of the M protein molecule is being investigated further as a possible candidate vaccine antigen against group A streptococcal infection and rheumatic fever.[963,964] Use of M proteins as vaccine candidates is challenged by the realization that, even within established *emm* types, various subtypes also exist. For example, analysis of over 300 *emm3* strains from three separate Canadian group A streptococcal epidemics showed that each epidemic was caused by emergence of distinct *emm3* subtypes within previously immune populations.[74]

In addition to M protein, several other M-related cell surface proteins have been identified on group A streptococci, and the genes encoding these molecules (e.g., *enn*, *mrp*, *arp*, *fcrA*, *protH*) have been grouped together as members of the "*emm* gene superfamily."[517] In addition to M protein, some streptococci have other "M-like" proteins (e.g., the Spa protein of M-type 18 group A streptococci) that have been shown to contribute to and augment group A streptococcal virulence.[704] These molecules apparently work in concert with M proteins to help the organisms resist phagocytosis. M-protein-like molecules are also able to bind to several host proteins such as plasminogen and fibrinogen, and, via this interaction, also exert anti-opsonic effects. The sequences of the recognized *emm* types may be found online at http://www.cdc.gov/nci-dod/biotech/infotech_hp.html.

Opacity factor (OF) is another M-protein-associated cell surface antigen of group A streptococci that is a virulence factor. OF is an α-lipoproteinase that is able to opacify media containing mammalian serum. Antibodies directed against OF are specific in inhibiting the opacity reaction of the M-type producing it; so OF typing can be used as a supplementary or complementary typing reaction. OF is produced by strains that belong to 29 different M types and can be detected in those M types even if M-type-specific reactivity is lost or undetectable (i.e., the presence of OF is associated only with specific M types). Therefore, OF-positive and OF-negative reactions are consistently associated with specific M types. OF is primarily associated with strains of group A streptococci isolated from skin infections.[79]

742

Group A streptococci produce two hemolysins: streptolysin O and streptolysin S. **Streptolysin O** (SLO) is oxygen-labile, antigenic, inhibited by cholesterol, and toxic to a variety of cell types, including leukocytes, monocytes, and cultured cells. Because of its oxygen lability, streptolysin O is primarily responsible for the β-hemolysis seen

around subsurface colonies of group A streptococci in pour plates or in the stabbed regions of surface-inoculated SBA plates. Streptolysin O is also produced by some group C and group G streptococci. SLO appears to exist in two active forms, with molecular weights of between 50,000 and 70,000 Da; cleavage of these molecules during secretion results in the fully active form of SLO having a molecular weight of about 57,000 Da. SLO causes the formation of pores in the membrane of susceptible cells by initial binding of SLO monomers to cholesterol in the cell membrane. This binding results in a conformational change in the molecule that causes the co-aggregation of additional SLO monomers on the membrane. These aggregates initially form arc-shaped structures on the membrane that eventually become fully formed pores, resulting in osmotic lysis of the affected cell. SLO also induces degranulation and lysis of PMNs, inhibits phagocytosis by macrophages, and impairs the response of lymphocytes to mitogens. SLO may also stimulate the production of cytokines. Measurement of antibodies against streptolysin O (antistreptolysin O [ASO] titers) in serum is useful for retrospective diagnosis of recent pharyngeal streptococcal infections. The ASO response following skin infections is poor, presumably because of inactivation of the antigen by cholesterol present in skin. In such cases, anti-DNase B titers are more reliable (see later discussion).

Streptolysin S (SLS) is oxygen-stable, nonantigenic, and, like SLO, is toxic to a variety of cell types. SLS exists in intracellular, cell surface bound, and intracellular forms and is usually associated with some type of carrier molecule, such as serum albumin, RNA, or α-lipoprotein. SLS, a small molecule having a molecular weight of about 1,800 Da, is maximally produced during the late logarithmic and early stationary phases of growth, and requires iron for maximal production. SLS is believed to interact with membrane phospholipids in exerting its toxic effects. Erythrocytes exposed to SLS undergo swelling, followed by lysis due to the disruption of the osmotic barrier and leakage of ions from the cell. Unlike SLO, no slits or pores are observed on affected erythrocyte cell membranes by electron microscopy. SLS is active in both surface and subsurface hemolysis when the organisms are grown on SBA. The hemolytic activity of SLS is inhibited by serum lipoproteins and other simple phospholipids. Like SLO, SLS is able to damage the membranes of polymorphonuclear cells, platelets, and internal subcellular organelles.

Group A streptococci also produce several extracellular products; many of these play real or theoretical roles in virulence of group A streptococci. **Streptococcal pyrogenic exotoxins (SPEs)** (particularly SPE A and SPE B) are responsible for the rash of scarlet fever and are also the principal virulence determinants in the pathogenesis of the streptococcal toxic shock-like syndrome. Three immunologically distinct SPEs, designated SPE types A, B, and C, have been well described, and the genes that encode them have been identified and characterized. The genes for SPEs A and C (*speA* and *speC*) are encoded on a streptococcal lysogenic bacteriophage, whereas the gene for the type B exotoxin (*speB*) is chromosomal. The *speB* gene is

found in all group A streptococci, whereas the other two genes may or may not be present. SPE B, the product of the *speB* gene, is actually a **cysteine protease** enzyme that is able to cleave human immunoglobulin, fibronectin, vitronectin, and other host cell proteins, resulting in the formation of small, biologically active peptides, including interleukin-1, histamine, and kinins.[1109] Expression of cysteine protease SPE B and other virulence determinants is regulated by the ***CovR/S* gene system**, which mediates the group A streptococcal stress response and regulates the repression and derepression of major virulence genes.[87,200] Following colonization with group A streptococci, mutations in *CovR/S* genes cause upregulation of several virulence factors, including capsule production and the secretion of several virulence factors, including the newly described serine protease SpyCEP.[1054] The latter virulence factor mediates the cleavage of various cytokines (e.g., interleukin 8), enabling dissemination of the organisms within soft tissues and the respiratory tract in vivo.[584] Pyrogenic exotoxins such as SPE A and SPE C not only induce fever, as their name implies, but they also function as superantigens. **Superantigens** are molecules that are able to induce proliferation of host T-lymphocytes, regardless of their antigenic specificity, by binding to class II major histocompatibility complex (MHC) molecules.[357] Activation of T cells by superantigens results in the massive release of cytokines by human monocytes and lymphocytes (e.g., tumor necrosis factor-α [TNFα], interleukin 1β, interleukin-2, interferon-γ).[357,414,415] These cytokines activate the complement, coagulation, and fibrinolytic cascades and cause capillary leakage with resulting hypotension and shock, the most severe manifestations of streptococcal toxic shock syndrome. Superantigens also potentiate the host response to minute amounts of gram-negative endotoxin by a factor greater than 100,000-fold, and have direct toxic effects on endothelial cells lining the capillaries. SPEs have molecular weights of about 25 to 28 kDa and contain T-cell receptor binding and class II MHC binding sites, plus a zinc binding site that functions in mediating the binding of the class II molecules to the exotoxin. With the complete sequencing of several group A streptococcal genomes, at least 11 streptococcal superantigens have been described and include SPE A, SPE C, SPE G, SPE H, SPE I, SPE J, SPE K, SPE L, SPE M, SSA (streptococcal superantigen), and the polymorphic SMEZ.[357] Production of superantigens varies among streptococcal strains belonging to different M or *emm* types In addition to group A streptococci, various streptococcal superantigen genes (e.g., *ssa*, *speM*, *smeZ*) are also found in some group C and G β-hemolytic streptococci (*S. dysgalactiae* subsp. *equisimilis* and *S. canis*).[489]

Group A β-hemolytic streptococci also produce several other products that contribute to virulence. As mentioned, SPE B is actually a **C5a peptidase** that is bound to the cell surface. This molecule contributes to disease because of its peptidase activity rather than as a superantigen. C5a peptidase inactivates C5a, the chemotactic

complement component, resulting in limiting recruitment and chemotaxis of polymorphonuclear leukocytes. This peptidase also cleaves immunoglobulins, fibronectin, vitronectin, and other proteins with the generation of biologically active peptides (e.g.,

743

histamine, kinins).[1109] These organisms also produce four immunologically and electrophoretically distinct **deoxyribonucleases**, designated DNase A, B, C, and D. Antibodies against DNase B (anti-DNase B) are helpful, along with ASO titers, for serologic documentation of prior group A streptococcal pharyngeal or skin infections. **Hyaluronidase** produced by group A streptococci depolymerizes the ground substance of connective tissue, resulting in contiguous spread of the organism. **Streptokinases** produced by group A streptococci hydrolyze fibrin clots and may function in virulence by preventing the formation of fibrin barriers at the periphery of spreading streptococcal lesions. The contribution of these enzymes and toxins to infection is uncertain. Many of these factors are produced by other β-hemolytic streptococci as well.

Clinical Spectrum of Group A Streptococcal Disease

Humans are the natural reservoir for group A, β-hemolytic streptococci, and the organism is transmitted from person to person by the respiratory route. The most common infection caused by group A streptococci is **streptococcal pharyngitis**.[929,1120]Group A streptococci are responsible for 5% to 15% of pharyngitis in adults and 20% to 30% of cases in children. Most cases of pharyngitis are seen in school-aged children (5 to 15 years old) during the winter or spring. Following an initial incubation period of 2 to 4 days, onset is generally abrupt, with fever, sore throat, headache, malaise, and abdominal pain. The posterior pharynx is usually inflamed and swollen, and a grayish white exudate may be present on the tonsils. The anterior cervical lymph nodes are usually tender and swollen. The presence of rhinorrhea, hoarseness, cough, or diarrhea speaks against group A streptococcal infection, instead suggesting a viral or mycoplasmal etiology. Infection with strains that elaborate pyrogenic exotoxins A, B, or C may also cause a scarlatiniform rash (i.e., classic scarlet fever). Complications of group A streptococcal pharyngitis may be suppurative (i.e., peritonsillar abscess, retropharyngeal abscess, suppurative cervical adenitis, otitis media, sinusitis, mastoiditis, bacteremia), nonsuppurative (i.e., acute and chronic rheumatic fever, glomerulonephritis), or toxin-mediated (streptococcal toxic shock-like syndrome). In the absence of complications, streptococcal pharyngitis is self-limited. Fever usually resolves in 3 to 5 days and throat pain resolves in 7 to 10 days without therapy. However, treatment (ideally, culture followed by antimicrobial

therapy) is usually sought. About 10% to 15% of individuals with streptococcal pharyngitis may become asymptomatic carriers of the organisms following treatment.[90] Treatment guidelines are published by the FDA, the American College of Physicians, the Centers for Disease Control, the American Heart Association, and the Infectious Diseases Society of America.[88,374,929,1120] Current recommendations for treatment of streptococcal pharyngitis include oral penicillin V (children < 27 kg, 250 mg two or three times/day; adolescents and adults ≥ 27 kg, 500 mg two or three times/day for 10 days), or intramuscular benzathine penicillin G (children < 27 kg, 600,000 units IM; weight ≥ 27 kg, 1.2 million units IM).[90,374] Amoxicillin (50 mg/kg once daily to a maximum of 1 g) may also be used in place of either penicillin V or benzathine penicillin. Erythromycin was the standard alternative agent for penicillin-allergic patients, but, largely due to the gastrointestinal side effects experienced by some patients with erythromycin, alternative agents (e.g., clindamycin, azithromycin, cephalexin, and cefadroxil) have been approved. Clindamycin (7 mg/kg/dose PO, twice a day to a maximum of 300 mg/dose for 10 days) is an approved alternate drug, and the FDA has also approved a 5-day azithromycin course (12 mg/kg PO once per day to maximal dose of 500 mg for 5 days).[1120] Group A β-hemolytic streptococci remain highly susceptible to penicillin G.

The "nonsuppurative" complications of group A streptococcal infections include acute rheumatic fever and glomerulonephritis. **Acute rheumatic fever (ARF)** is associated with prior group A streptococcal pharyngitis, while glomerulonephritis usually occurs after prior pharyngeal or skin infections. ARF is a multisystem disease characterized by major manifestations of carditis, polyarthritis, subcutaneous nodules, erythema marginatum, and chorea.[86,87,374,1148] Onset usually occurs 2 to 5 weeks after streptococcal pharyngitis and is not usually initiated by cutaneous group A streptococcal infections. Cardiac pathology involves the endocardium, myocardium, pericardium and, oftentimes, the mitral valves. Clinically, the patient develops characteristic heart murmurs, cardiac enlargement, congestive heart failure, or intractable cardiac arrest and death.[668] ARF-associated arthritis is migratory, involves multiple joints, and usually resolves spontaneously. Painless, firm, subcutaneous nodules appear simultaneously with carditis and occur around the bony areas of the hands and feet. Erythema marginatum appears as inflamed eruptions with raised, serpiginous borders and central areas of clearing that usually appear on the trunk, arms, and legs. Chorea is a neurologic condition characterized by muscle spasms, incoordination, and weakness that develop simultaneously with or several months after the appearance of ARF. Attacks of ARF generally last 3 to 6 months. Because of the protean clinical manifestations of ARF, the differential diagnosis is diverse and includes rheumatoid arthritis, systemic lupus erythematosus, sickle cell disease, rubella, septic arthritis, disseminated gonococcal infection, Lyme disease, bacterial endocarditis, and myocarditis. Laboratory findings of ARF include elevated sedimentation rates and C-

reactive protein, and evidence of antecedent streptococcal infection, as determined by a positive throat culture, a positive direct antigen test for group A streptococci, and/or elevated anti-streptolysin O (ASO), anti-DNase B, and anti-hyaluronidase titers. All three of these antibody tests should be performed if ARF is suspected. Therapy for ARF includes analgesics, salicylates, and corticosteroids for treatment of fever and inflammation, in addition to supportive therapy for prevention of cardiac failure.

Acute glomerulonephritis (AGN) is associated with glomerular lesions, hypertension, hematuria, and proteinuria. Glomerular lesions contain deposits of complement component C3, properdin, and immunoglobulin, and these deposits can be demonstrated by immunofluorescence techniques. Glomerulonephritis may occur as soon as 10 days following pharyngitis or 3 to 6 weeks after cutaneous infections. Disease manifestations include malaise, weakness, anorexia, headache, edema, and circulatory congestion, as evidenced by hypertension and encephalopathy. Anemia, elevated

744

sedimentation rate, decreased C3 and total complement, hematuria, and proteinuria are pertinent laboratory findings. Urinalysis usually reveals red blood cells, leukocytes, and casts. Prior streptococcal infection is demonstrable by isolation of the organisms from the throat or from skin lesions or by elevation of anti-streptococcal antibodies. Anti-DNaseB and anti-hyaluronidase assays should be performed because ASO antibody titers are not reliably elevated following skin infections.

The mechanism by which group A streptococci induce ARF and AGN is not clear, but the prevailing theories are that streptococcal infection results in production of antibodies against various streptococcal components (e.g., capsular materials, cell wall carbohydrate and protein antigens, cell membrane antigens) that cross-react with antigenic epitopes of heart tissues, including myocardial, endocardial, and valvular heart tissues, myocardial sarcolemma, skeletal muscle, and joints.[405] Studies with monoclonal antibodies have shown that certain streptococcal M protein antigens and group A streptococcal carbohydrate antigens (e.g., *N*-acetyl-β-D-glucosamine) cross-react with cardiac myosin and several other proteins (e.g., tropomyosin, vimentin) found in heart muscle and heart valve tissue.[253,334,405,663] In this model, antibodies developed during acute streptococcal pharyngitis subsequently bind to these cross-reactive epitopes, activating the complement cascade and resulting in immunologically-mediated damage to cardiac muscle and adjacent tissues and the development of ARF.[668] Group A β-hemolytic streptococci that are responsible for ARF are usually rich in M protein, and M types M1, M3, M5, M16, M18, M19, M24, and a few others are known to be "rheumatogenic"; they have an increased capacity to trigger nonsupperative sequelae. Isolates with these M types have a mucoid colony

morphology, are usually OF negative, are associated with pharyngitis, and evoke a strong type-specific immune response. These M types share antigenic determinants with cardiac muscle, sarcolemma membrane proteins, and synovial membranes. A similar mechanism is believed to operate in the pathogenesis of poststreptococcal glomerulonephritis. Antibodies elicited various non–M-protein antigens of "nephritogenic" group A streptococcal (e.g., cytoplasmic endostreptosin, extracellular "nephritis strain-associated protein [NSAP]," streptococcal pyrogenic exotoxin B [speB]) may react with renal tissues to produce glomerular injury.[305,868] Similarly, some group A streptococcal strains have been deemed as "nephritogenic," (i.e., M types M-2, M-49, M-55, M-57, M-59, M-60, and M-61) and have been disproportionately associated with glomerulonephritis following cutaneous infections, while others (i.e., M-1, M-4, M-12, and M-25) have been associated with glomerulonephritis after pharyngeal infection. Glomerular pathology may result from deposition of preformed immune complexes containing streptococcal antigens and host antibodies or from binding of streptococcal products to the glomerulus, with subsequent antibody binding to create immune complexes. Recent evidence suggests that group A streptococcal pharyngitis may not always be required for development of ARF and that skin infections (pyoderma and impetigo, see below) may play an antecedent role as well.[699,808] Areas of the world with the highest prevalence rates of ARF (and AGN) are tropical regions (i.e., Australia, Fiji, Samoa Pacific Islands) that also have the highest prevalence rates of group A streptococcal impetigo and low rates of pharyngitis. During 2001 to 2005, when prevalence of ARF in indigenous Australians was 254 per 100,000, 80% of impetigo and pyoderma cases were due to group A streptococci while pharyngeal infection remained low (3.7%) during the same period.[136,700]

In addition to pharyngitis, group A β-hemolytic streptococci cause a variety of cutaneous infections, puerperal sepsis, and post-partum infections. **Impetigo** is usually seen in children and constitutes the most common skin infection in this age group worldwide, particularly in developing countries with tropical climates.[76,89] **Pyoderma** usually occurs in children ages 2 to 15 years, with peak incidence in the 2- to 5-year age group. This skin infection is characterized by the development of papules that develop into vesicular lesions that evolve into pustules. These pustules break down over the next 5 to 7 days to form thick scabs. These lesions are usually on the lower extremities and may also involve other pathogens, such as *Staphylococcus aureus*. Interestingly, the *emm* types of strains causing pyoderma are distinct from pharyngitis strains. As mentioned, cutaneous infection with nephritogenic group A streptococcal strains may give rise to poststreptococcal glomerulonephritis. In pyoderma patients, the ASO titer may not be elevated, but DNase B titers will be elevated.[89] **Erysipelas** is an acute infection that is associated with soft tissue involvement and cutaneous lymphatics, resulting in systemic evidence of infection (i.e., fever) (Image Plate 13-

1A).[149] The lesions present as areas of edema and erythema that spread rapidly and have a raised, well-demarcated margin. Lesions of erysipelas are frequently on the face and patients often have accompanying streptococcal pharyngitis.[101] Lesions of erysipelas on other body sites start as areas of redness and swelling, with rapid spread and a raised, well-demarcated border. Complications of erysipelas include necrotizing fasciitis, abscess formation, and septicemia.[149] **Cellulitis** usually results from streptococcal infection of preexisting lesions, such as wounds, burns, or surgical incisions. This infection presents as a spreading inflammatory process that may involve larges areas of the skin and subcutaneous tissues, along with fever, chills, lymphangitis and, occasionally, bacteremia. Cellulitis is usually seen in intravenous drug users and may be complicated by bacteremia and other sequelae (e.g., osteomyelitis, deep tissue infection, endocarditis).[304] **Puerperal sepsis** is seen in women following delivery (either vaginal or abdominal) or abortion.[73,669] Organisms colonizing the genital tract or from obstetrical personnel invade the upper genital tract, causing endometritis, lymphangitis, bacteremia, necrotizing fasciitis, and streptococcal toxic shock syndrome.[55,124,388] Genital tract infection may be complicated by pelvic cellulitis, peritonitis, and abscess formation. Intrapartum transmission of group A streptococci, leading to severe and often fatal group A streptococcal disease in the neonate has also been observed. Manifestations in the neonate include stillbirth, septicemia, jaundice, and cellulitis. **Necrotizing fasciitis** describes infection of deep subcutaneous tissues that results in progressive devitalization and destruction of the fascia.[508,884] This infection sometimes presents with erythema at a site of localized trauma or previous surgery, or via hematogenous seeding of subcutaneous muscles and soft tissue. The infection spreads very rapidly, resulting in cutaneous bullous lesions containing

745

serosanguinous fluid. The tissues become gangrenous, with sloughing of devitalized tissues and extensive subcutaneous tissue necrosis. Spread along the fascial planes occurs to involve adjacent soft tissue and muscle. Imaging studies such as MRI can help to define the extent of tissue involvement prior to clinically apparent necrosis. Despite appropriate antimicrobial coverage and surgical debridement of devitalized tissues, mortality rates may be 30% to 60%; deaths may occur as rapidly as 48 hours after the onset of signs and symptoms. Patients with extensive muscle involvement may have fatality rates as high as 80% to 100%. Aggressive medical and surgical interventions are necessary and lifesaving in many cases.

Streptococcal toxic shock syndrome (STSS) first appeared in the United States during the late 1980s and is now a well-recognized clinical entity associated with group

A β-hemolytic streptococci.[967–969] (The attack rate has been estimated to be approximately 3.5 cases per 100,000 population in the United States, with higher rates among the very young (5.3 case per 100,000) and the elderly (9.4 cases per 100,000).[785,968] Patients who develop invasive group A streptococcal infections often have comorbid diseases, especially diabetes mellitus, congestive heart failure, malignancies, and immunosuppression.[68] Some patients present with a viral-like prodrome of fever, chills, and myalgias; diarrhea and vomiting may also be prominent features. Soft tissue infection, indicated by swelling, tenderness, erythema and/or pain, may be evident if the primary infection is cutaneous, but infection may not be apparent in up to 50% of cases and may already have progressed to severe cellulitis or necrotizing fasciitis by the time the patient seeks emergency medical care.[969] These individuals may develop several severe complications and disease manifestations, including myocarditis, hepatitis, peritonitis, septic arthritis, endophthalmitis, puerperal sepsis, meningitis, and overwhelming toxemia.[148,567,785,1029] Pulmonary symptoms include cyanosis, tachypnea, and respiratory failure. Renal involvement occurs in over 80% of patients and often persists despite aggressive treatment with antibiotics and intravenous fluids. The disease is characterized by the sudden onset of overwhelming shock and organ system failure. Patients become hypotensive with little or no response to albumin and electrolyte administration. The acute respiratory distress syndrome develops in more than half of patients, requiring intubation and mechanical ventilation. In fulminant, ultimately fatal infections, the Waterhouse–Friderichsen syndrome and disseminated intravascular coagulation may occur.[535] Almost 80% of these patients have bacteremia with group A streptococci, and the organism may also be isolated from surgical specimens, tissue, peritoneal fluid, pleural fluid, and rarely CSF. If soft tissue infection is present, surgical procedures may be necessary to remove infected, devitalized and necrotic tissues. This syndrome characteristically results in shock and multiorgan system failure shortly after the onset of symptoms and may have a mortality rate of 30% to over 80%.[62] Management requires aggressive antimicrobial chemotherapy, volume resuscitation, and intensive supportive care. Even with these interventions, case fatality rates are 36% and 24% for STSS and necrotizing fasciitis, respectively.[785]

SPEs appear to play a major role in STSS pathogenesis. In a study of 34 STSS group A streptococcal isolates, 74% were either type M-1 or M-3, 53% produced SPE A and 85% contained the *speA* gene, 100% contained the gene coding for SPE B (*speB*), and 21% contained the SPE C gene (*speC*).[433] In a study of TSLS isolates from nine states, more than half of the isolates belonging to types M-1 or M-3 contained the gene for SPE A. SPE A and other pyrogenic exotoxins have been shown to be superantigens that are capable of inducing the release of various cytokines and lymphokines These cytokines and lymphokines trigger and mediate the events that

promote streptococcal dissemination and precipitate the profound multiorgan system involvement that characterizes the syndrome.[845] Combination therapy with penicillin and clindamycin is recommended. Clindamycin has greater efficacy than penicillin, and this drug is often used for therapy along with high-dose penicillin.[53]Clindamycin inhibits protein synthesis at the ribosomal level and, thereby, is able to inhibit the synthesis of the pyrogenic exotoxins more efficiently than cell wall–active agents such as penicillin and other β-lactams. Inhibition of protein synthesis also inhibits expression of M proteins and the synthesis and export of toxins including SPE A, SPE B, and enzymes (e.g., DNase, SLO, and SLS).[121,685,958]

Group A β-hemolytic streptococci cause a variety of other infections, including pneumonia, meningitis, osteomyelitis, endocarditis, peritonitis, and nosocomial infections. Pneumonia due to group A streptococci usually occurs in debilitated hosts with other conditions, including influenza or other intercurrent respiratory virus infections, chronic obstructive pulmonary disease (COPD), alcoholism, and neoplastic disease.[56] Pneumonia may also be a part of the clinical presentation of invasive group A streptococcal diseases, such as STSS. Streptococcal pneumonia often presents with an abrupt onset of fever, chills, malaise, dyspnea, and chest pain. Chest films usually show basilar infiltrates with pleural effusions. Diagnosis is usually made by culture of sputum, pleural fluid, empyema fluid, and/or blood.[731,874] Sputum is usually purulent and streaked with blood. Complications of pulmonary group A streptococcal infections include sepsis, pleural effusions, empyema, pneumothorax, pericarditis, mediastinitis, shock, pulmonary cavitation, bronchiectasis, metastatic abscesses, and osteomyelitis.[56] Mortality may be as high as 38%.[731] Osteomyelitis due to group A streptococci is seen as a complication of varicella infections in children; in adults, streptococcal osteomyelitis usually occurs as a complication of bacteremia.[17] Meningitis due to group A streptococci occurs in about 2% of all patients with systemic group A streptococcal infection and accounts for anywhere from 0.2% to 1% of all cases of meningitis.[327,814] This infection is similar in presentation to other acute bacterial meningitides, with headache, fever, nuchal rigidity, and focal neurologic deficits. Patients with meningitis usually have a focus of infection (e.g., otitis media) that results in bacteremia, with subsequent invasion of the meninges.[327] In a review of 41 adult patients with this infection, 60% had a history of otitis media, sinusitis, pneumonia, recent head injury, recent neurosurgery, or the presence of a neurosurgical device.[1077] Group A streptococcal endocarditis is a rare infection that occurs in infants, children, and adults. Pediatric endocarditis may be associated with bacteremia and varicella infection.[721,1134] Endocarditis in adults usually occurs in patients with no antecedent cardiac abnormalities and is associated with a

high rate of complications, including cerebral or other systemic emboli, arthritis, diskitis, and osteomyelitis. Group A streptococci have also joined the growing list of other microorganisms implicated in continuous ambulatory peritoneal dialysis-associated peritonitis.[148]

Group B β-Hemolytic Streptococci (*Streptococcus agalactiae*)

Virulence Factors

Group B β-hemolytic streptococci (*S. agalactiae*) (GBS) contain a Lancefield-grouping antigen, a type-specific cell surface polysaccharide and protein antigens. The group B antigen is composed of a rhamnose–glucosamine polymer attached to the peptidoglycan layer. Type specificity is provided by both capsular polysaccharide and protein antigens. Group B streptococci are invariably encapsulated and belong to 1 of 10 recognized capsular serotypes. The capsular types are composed of glucose, galactose, *N*-acetylglucosamine, and *N*-acetyl-neuraminic acid (sialic acid); serotype specificity is determined by differing arrangements of these four components in each of the nine capsular types. The **polysaccharide capsular antigens** are designated Ia, Ib, and II through IX; in the United States, serotypes Ia, Ib, III and V are the predominant serotypes.[495,946] About 4% to 7% of isolates may be nontypeable. The lower-numbered serotypes were detected using Lancefield extraction methods, but the newer capsular serotypes were delineated by detection of serotype-specific genes in the capsular region of the group B streptococcal genome.[201,576,852] Kong and colleagues[576] developed primers and PCR-based sequencing assays for the capsular *cps* genes of all serotypes that correlated 100% with serologic approaches. The **protein antigen** is designated by the single letter c, which exists in two forms, designated cα and cβ. This c antigen is found in all Ib strains (type Ia strains lack the c protein), in 60% of type II strains, and is rarely found in type III strains (not enough serotype IV-VIII strains have been examined for the presence of the c antigen). Therefore, serotype designations for c-antigen-containing strains are expressed as Ib/c and II/c. Amplification and sequencing of the genes for cα (*bca* gene), cα-like (*alp2*, *alp3*, and *alp4* genes), Rib (*rib* gene), and cβ (*bac* gene) cell surface proteins have also been developed to further subtype group B streptococcal isolates.[576] The importance of group B streptococcal capsular components as virulence factors is demonstrated by both in vivo and in vitro data. Opsonizing antibodies against group B

streptococci are serotype-specific as demonstrated by studies using PMNs and macrophages, and lack of maternal antibodies to these type-specific antigens is a recognized risk factor for development of group B streptococcal disease in the neonate.

The prevalence of the various GBS capsular serotypes varies over time and may differ from place to place. Prior to the 1990s, most group B streptococcal disease was caused by serotypes Ia, Ib, II, III; serotypes IV through VIII were relatively uncommon, and serotype IX isolates were likely among those strains designated as nontypeable. During the early- to mid-1990s, serotype V strains began to emerge, with the percentage of isolates in this group increasing from 2.6% in 1992 to 20% in 1994.[306] More recent studies conducted in the United States indicate that serotype prevalence still varies widely from place to place, but, in most regions, serotype Ia is predominant (26.8% of isolates), followed by serotypes III (24.8%), V (14.97%), II (10.86%), and Ib (8.12%).[495] In some regions of the country (e.g., Ohio), serotype V emerged between 2001–2002 and 2003 to become the predominant serotype, accounting for 27% of the 349 isolates.[250,701] In most regions of Europe, serotypes III, Ia, V, and II account for 85% to 100% of isolates. During the 1990s, serotypes VI and VIII appeared as the predominant serotypes in Japan, and neonatal early-onset disease due to serotype VIII has also been reported in that country.[588,688] While serotype VIII still accounts for 3.16% of isolates in Asia, in other parts of the world, serotype VIII represents only 0.0% to 0.56% of isolates). Serotypes III, V, Ia, and Ib are currently the most prevalent serotypes in Asia.[495] In eastern Europe and the Middle East, serotypes II, III, Ia, and V predominate, and data from United Arab Emirates indicates that, at least during the late 1990s, serotypes IV and Ia accounted for 26% and 21% of isolates, respectively.[28] Data from Africa indicate that serotypes II and V account for 42% to 62% of group B streptococcal isolates and 24% to 43% of group B streptococcal isolates, respectively.[495]

Type III strains of group B streptococci account for 60% of isolates from cases of neonatal sepsis and over 80% of isolates from infants with meningitis, suggesting that this group B streptococcal serotype possesses enhanced virulence. The type III capsular polysaccharide is composed of a repeating structural backbone consisting of galactose, glucose, and *N*-acetyl-glucosamine with side chains consisting of galactose and a terminal *N*-acetyl-neuraminic acid moiety. The structural component of the type III capsule that appears to be associated with augmented virulence is the presence of *N*-acetyl-neuraminic acid (sialic acid). The presence of this molecule on the surface of the organism inhibits activation of the alternative complement cascade and prevents phagocytosis. Removal of sialic acid residues with neuraminidase leads to complement activation, phagocytosis, and intracellular killing of the organisms and diminished virulence on intravenous challenge in a rat model.[303] Like the group A streptococci,

Group B streptococci also produce **C5a peptidase**. C5a is a complement component cleavage product that is produced by alveolar epithelial cells, acts as an attractant for inflammatory cells, and is involved in the process of pulmonary inflammation. The C5a peptidase produced by the streptococci cleave this molecule and thereby interfere with C5a-mediated neutrophil chemotaxis.[97] This peptidase also binds to fibronectin and serves as a bacterial adhesin and invasin.[65,182] This enzyme exists in a cell-associated form and also requires the presence of the group B capsule for maximal activity. Opsonization of Group B streptococci belonging to serotypes Ia, Ib, II, III, and V with anti-C5a peptidase antibodies results in increased killing by both macrophages and polymorphonuclear cells.[181] C5a peptidase is also produced by group A and group G β-hemolytic streptococci, and the genes encoding the C5a peptidase in group B (*scpB*) and group A strain (*scpA*) demonstrate 98% sequence homology with each other. The **β-hemolysin/cytolysin** of group B

747

streptococci is a pore-forming hemolysin that is able to lyse pulmonary alveolar epithelial and endothelial cells in vitro and augments the ability of the organism to invade endothelial cells, suggesting a role for the hemolysin as a virulence factor in neonatal lung infection and subsequent sepsis.[768,769] **Lipoteichoic acid** is also found in group B streptococci and may participate in facilitating adherence as a first step in infection. Several **cell surface proteins** (e.g., c, R, BPS, and Rib antigens) are also found in various combinations in different group B streptococcal serotypes.[312] The **c antigen**, in particular, may act to mediate internalization of organisms within human cervical epithelial cells following attachment and to protect organisms from intracellular killing following phagocytosis.[98] Jones and colleagues[523] identified a **cell surface penicillin-binding protein** (PBP1a) that enabled streptococcal cells to resist intracellular killing by phagocytic cells. Group B streptococci also produce a **hyaluronic acid lyase**, which may act to spread infection by breakdown of hyaluronic acid in the extracellular matrix, and may also act on the hyaluronic acid present in high concentrations in placental tissues, fetal tissues, and amniotic fluids. The presence of CAMP factor, protease enzymes, and various nucleases have also been identified in some group B streptococci, but the role of these molecules in disease pathogenesis is uncertain.

Clinical Spectrum of Group B Streptococcal Disease

Group B β-hemolytic streptococci are a major cause of disease in the neonatal and perinatal periods.[707] Women become colonized in the gastrointestinal tract, which is the source for vaginal colonization. Among pregnant women, rectovaginal colonization

is found in 10% to 37% of pregnant women; up to 60% of the colonized women will carry the organism intermittently.[423,855,1093] Vaginal colonization with group B streptococci is usually asymptomatic, although reports have appeared that document vaginitis associated with heavy colonization and resolution of vaginal symptoms with treatment.[467,468] Vaginal colonization may be transient, intermittent, or persistent. Colonization generates a serotype-specific immune response, with cumulative increases of antibodies with increasing age; lower antibody levels in teenaged girls may translate to increased risk of group B streptococcal disease in babies born to these younger women.[130] The presence of group B streptococci in the female genital tract at the time of birth can lead to infection of the neonate. Of neonates born to women who are colonized with group B streptococci, 30% to 70% become transiently colonized on the skin or mucosal surfaces by vertical transmission from the colonized mother either in utero or during delivery; 1% to 4% of these babies may develop systemic disease. Among colonized infants, disease may occur in one to four infants per 1,000 live births.[303,1093] In addition, the neonate may become colonized by nosocomial exposure to the organism after birth. Neonatal disease with group B streptococci follows two patterns, termed **early-onset disease** and **late-onset disease**.

In the United States, early-onset group B streptococcal disease occurs with an incidence of 0.7:1,000 to 3.7:1,000 live births and is associated with in utero or perinatal organism acquisition.[303] This incidence is probably an underestimate; a study conducted in the United Kingdom on early-onset disease reported an incidence of three to four infections per 1,000 live births based on the number of neonates requiring screening for possible sepsis during the first 72 hours of life.[661] The incidence of early-onset disease varies from country to country and likely reflects differences in group B streptococcal carriage rates, ethnic/racial susceptibility to infection, variations in diagnostic criteria, differences in virulence among streptococcal strains, and the type/availability of prenatal, natal, and postnatal care.[707] The organism is acquired either by ascending infection in utero before delivery, through ruptured fetal membranes, or during passage through a birth canal that is colonized with group B streptococci. Although a substantial proportion of these infants (approximately 50%) will be colonized with group B streptococci, only 1% to 2% of them become infected.[303] Mucous membrane colonization and aspiration of infected amniotic fluid introduce the streptococci into the lung alveoli of the neonate, where they adhere, replicate, and produce various virulence factors (e.g., capsular polysaccharides, β-hemolysin) The bacteria then invade pulmonary endothelial and epithelial cells, thereby gaining access to the bloodstream.[766–769] Onset of disease occurs during the first 5 to 6 days of life; in more than half the cases, infants become ill within the first 12 to 20 hours after birth. The disease spectrum includes bacteremia, pneumonia, meningitis, septic shock, and neutropenia. Although more than 50% of cases occur in

term infants, a higher attack rate and greater morbidity are associated with preterm infants. Preterm neonates are at 3- to 30-fold increased risk of developing early-onset disease than full-term infants, and this may be related to relative immunologic immaturity and incomplete receipt of transplacental maternal antibodies against the capsular polysaccharide of the infecting group B strain. Mortality owing to early-onset disease in term infants ranges from 2% to 8%; higher mortality rates are seen in premature infants and are inversely proportional to the birth weight of the neonate.[1153] Maternal factors that increase the risk for early-onset infection of the neonate include preterm labor with delivery before 37 weeks, rupture of the fetal membranes >18 hours before delivery, maternal chorioamnionitis, heavy vaginal colonization with group B streptococci, group B streptococcal bacteriuria, and postpartum bacteremia.[156,303,707] During the 1970s, about half of the infants who developed early-onset disease died of the infection. Among those children who survive group B streptococcal meningitis, about half will have some type of neurologic deficit and up to 30% will have severe neurologic sequelae.[1093]

Late-onset disease occurs with an incidence of 0.5:1,000 to 1.8:1,000 live births.[303] Disease becomes clinically evident 7 days to 3 months (average 3 to 4 weeks) after birth. Whereas about half of the late-onset infections are acquired from the birth canal of colonized mothers, the remaining cases result from postnatal organism acquisition from the mother, other caregivers, or nosocomially; breast milk has also been implicated as a source of the organism.[386] Bacteremia is the predominant clinical presentation, and about 25% of these infants also develop group B streptococcal meningitis.[351,842] A pediatric case report described late-onset disease presenting as necrotizing fasciitis of the face and thigh in a 5-month-old preterm infant.[596] Mortality associated with late-onset disease is about 10% to 15%. Up to 50% of children

with late-onset meningitis will have permanent neurologic complications and sequelae.[1093] The distribution of group B streptococcal serotypes varies with early-onset versus late-onset disease.[303] Among neonates with early-onset disease without meningitis, the serotype distribution is equally divided among types Ic, II, and III. Among similarly infected neonates with meningitis, serotype III strains predominate. On the other hand, group B streptococcal meningitis in adults is primarily associated with serotype II organisms.

Prevention of Group B Streptococcal Disease

By the mid-1980s, increased knowledge about group B streptococcal infections and recognition of symptoms in at-risk patients lead to improvements in neonatal care that resulted in reduction of the fatality rate to about 15%. Since infants born to heavily colonized mothers are more likely to develop early-onset disease and because infants who acquire a large bacterial inoculum during birth have significantly increased likelihoods of developing both early- and late-onset disease, identification of colonized mothers became a central focus for prevention strategies. Investigators examined various interventions to prevent group B streptococcal disease, and clinical trials demonstrated that intrapartum administration of antimicrobial agents interrupted transmission of group B streptococci from the mother to the neonate and reduced the incidence of early-onset infections.[114,707] This approach prevented about 70% to 75% of early-onset disease, but had no effect on the development of late-onset disease. Commercial vendors began developing products for rapid direct detection of group B streptococci in vaginal swab specimens similar to those used for detection of group A streptococci in throat swab specimens. Theoretically, these tests could be performed in the immediate prepartum period to determine colonization status, and antimicrobial chemoprophylaxis could be administered prior to and during delivery if the assays were positive. Commercial rapid tests for direct detection of group B streptococci varied significantly in sensitivity (i.e., 11% to 88%) when compared with overnight broth techniques and identified only those women who were heavily colonized. The validity of the assumption that the risk of neonatal infection is greater for infants born to heavily colonized women was confounded by clinical studies. In an evaluation of one rapid EIA kit, Towers and coworkers[1037] reported that two of nine infants born to mothers with light colonization and negative rapid EIA results developed fatal early-onset disease. In another study of a rapid method for detection of group B streptococcal colonization, Morales and Lim reported that, among 37 women with light colonization and negative rapid screening tests, six delivered babies with early-onset sepsis.[726] The timing of antepartum testing for group B streptococcal colonization was also an issue, since 60% to 70% of women with positive vaginal cultures in the second trimester will be colonized at term, and up to 30% of women with negative cultures during the second trimester will be culture-positive at delivery. Consequently, the development of methods for rapid, sensitive, and specific detection of group B streptococcal colonization in women at or near the time of delivery became a central focus of clinical and microbiologic research.

In 1996, the Centers for Disease Control and Prevention (CDC), together with the American Academy of Pediatrics (AAP) and the American College of Obstetrics and Gynecology (ACOG) issued consensus recommendations on a prevention strategy for group B streptococcal disease.[151,1093] These guidelines recommended that obstetrical healthcare providers adopt either a culture-based or a risk-based strategy for the prevention of early-onset group B streptococcal disease. Subsequent implementation

of and compliance with these guidelines has resulted in a significant decrease in the incidence of early-onset neonatal group B streptococcal disease. A critical component of these guidelines is the use of maternal antimicrobial prophylaxis during labor and delivery. This raised concerns regarding the adverse effects of increased antibiotic usage and the increased risk of anaphylactic reactions to penicillin, the drug of choice for chemoprophylaxis. Another concern has been the potential emergence of antimicrobial resistance in group B streptococci. To date, no penicillin-resistant strains of group B streptococci have been isolated, although clindamycin and erythromycin resistance has become relatively common. A third concern was that increased penicillin administration in the newborn period may provide sufficient selective pressure to result in neonatal infections due to penicillin-resistant organisms like *E. coli*, which is the second most common agent of sepsis in the newborn period. This scenario has not developed to date, and continued surveillance will be required to detect and contain this possibility. In 2002, the Committee on Obstetrical Practice issued a statement supporting the use of culture-based prevention strategies based on data from the Active Bacterial Core Surveillance/Emerging Infections Program network suggesting that the culture-based approach was superior to the risk-based approach.[26] New guidelines were issued by the CDC in 2002, replacing the 1996 guidelines and recommending universal, prenatal, culture-based screening for vaginal and rectal colonization of all pregnant women at 35 to 37 weeks' gestation.[156] The culture protocol recommended by the CDC, ACOG, and the FDA involved collection of vaginal and rectal swab specimens during the 35th to 37th week of gestation, followed by 18- to 24-hour growth enrichment, subculture to SBA, and identification of group B streptococci by phenotypic (e.g., CAMP test, hippurate hydrolysis, API Rapid Strep), serologic (i.e., serogrouping by coagglutination or latex agglutination), or chemiluminescent hybridization (i.e., Gen-Probe Accuprobe) methods. The entire screening procedure could take 2 to 3 days.

In 2010, the CDC updated and revised the guidelines for prevention of group B streptococcal disease (Box 13-3).[27,157] Screening for group B streptococci is still recommended at 35 to 37 weeks of gestation. Rectovaginal swab specimens are collected from the lower third of the vagina and from the anal canal (a single swab from the vagina, then the anal canal, or one swab collected from each site). The swab(s) are placed in Trans-Vag, LIM broth (Todd–Hewitt broth with 10 μg/mL nalidixic acid, 15μg/mL colistin, and 10 mg/mL yeast extract), or chromogenic broth (e.g., Carrott Broth, Hardy Diagnostics, Santa Maria, CA), and incubated for 18 to 24 hours. In the 2010 document, group B streptococcal identification options were expanded to include use of the chromogenic medium and nucleic acid amplification tests (NAATs) performed on the Lim or Trans-Vag enrichment broth for group B streptococcal detection in addition to DNA probe or latex agglutination as in the previous document. The previous guideline also recommended that laboratories

identify and report group B streptococci in urine specimens in any concentration, while the 2010 guidelines clarified this to require that laboratories identify and report group B streptococci in urine in colony counts of $\geq 10^4$/cfu/mL urine.[27,157] Use of NAAT tests directly on rectovaginal specimens is not recommended, but in settings where NAAT testing is available, an intrapartum NAAT test may be done when the colonization status of the patient is unknown, when there are no intrapartum risk factors, and when the patient is at term.[157] In the 2010 guidelines, penicillin remains the drug of choice, with ampicillin as an alternative, and cefazolin remains the drug of choice in penicillin-allergic patients if penicillin-allergy is doubtful (i.e., no urticaria, angioedema, or respiratory distress). Group B streptococcal isolates from women at high risk for penicillin anaphylaxis should be tested for susceptibility to clindamycin, erythromycin, and vancomycin. Erythromycin is no longer recommended for treatment and testing is performed along with the D-zone test to determine inducible clindamycin resistance in isolates that are erythromycin-resistant. Group B streptococcal early-onset infection in newborns due to clindamycin-resistant isolates has been reported.[93] Even with timing of screening between 35 and 37 weeks' gestation, up to 6% of women colonized with group B streptococci are not detected at this time (94% predictive value of a negative test).[1070] Prevention of group B streptococcal disease in the newborn is a practical reality. Globally, only five group B serotypes (i.e., Ia, Ib, II, III, and V) cause more than 85% of disease in infants less than 3 months of age, and a conjugate vaccine directed against these serotypes could conceivably prevent infection.[302,495,906] Such a vaccine would be administered to pregnant women and could potentially also reduce other conditions associated with group B streptococci (i.e., late-onset disease, premature birth, intra-amniotic infections, puerperal sepsis, and peri-/postpartum bacteremia).[437] Several vaccines against group B streptococci are in clinical trials at the present time, and perhaps soon, group B streptococcal disease of the newborn will go the way of type b *Haemophilus influenzae* in neonates.[278,906]

749

BOX 13-3

Procedures for Collecting and Processing Rectovaginal Specimens for Perinatal Detection of Group B Streptococci[26,27,156,157]

Procedure for Collecting Clinical Specimens for Culture of Group B

Streptococci (GBS) at 35 to 37 Weeks' Gestation

- Swab the lower vagina (vaginal introitus) followed by the rectum (i.e., insert swab through the anal sphincter) using the same swab or two different swabs. Culture should be collected in the out-patient setting by the health care provider or the patient, with appropriate instruction. Cervical cultures are not recommended and a speculum should not be used for culture collection.
- Place the swab(s) into a nonnutritive transport medium. Appropriate transport systems (e.g., Amies of Stuart's without charcoal) are commercially available. If vaginal and rectal swabs were collected separately, both swabs can be placed in the same container of medium. Transport media will maintain GBS viability for up to 4 days at room temperature or under refrigeration.
- Specimen labels should clearly identify that specimens are for group B streptococcal culture. If susceptibility testing is ordered for penicillin-allergic women, specimen labels should also identify the patient as penicillin-allergic and should specify that susceptibility testing for clindamycin should be performed if GBS is isolated. The isolates should be tested for inducible clindamycin resistance (e.g., D-zone test, see below).

Procedure for Processing Clinical Specimens for Culture of GBS

- Remove swab(s) from transport medium. Inoculate swab(s) into a recommended selective broth medium, such as Todd-Hewitt broth supplemented with either gentamicin (8 μg/mL) and nalidixic acid (15 μg/mL), or with colistin (10 μg/mL) and nalidixic acid (15 μg/mL). Examples of appropriate commercially available options include Trans-Vag broth or LIM broth. The addition of 5% sheep blood to these media can increase the recovery of GBS. Selective enrichment broth also can contain chromogenic substrates that provide for a change in color in the setting of β-hemolytic GBS (Carrot Broth, Hardy Diagnostics, Santa Maria, CA); however, nonhemolytic isolates will not be detected in this medium, so subculture of the broth in the case of no color change is required.[94]
- Incubate inoculated selective broth for 18–24 hours at 35°C–37°C in ambient air or 5% CO2. Subculture the broth to a SBA plate (e.g., tryptic soy agar with 5% defibrinated sheep blood).
- Inspect and identify organisms suggestive of GBS (i.e., narrow zone of β-hemolysis, gram-positive cocci, catalase-negative). Note that hemolysis may be difficult to observe, so typical colonies without hemolysis should also be further tested. If GBS is not identified after incubation for 18–24 hours, reincubate and inspect at 48 hours to identify suspected organisms.
- Various streptococcus grouping latex tests or other tests for GBS antigen detection (e.g., genetic probe, NAATs) may be used for specific identification, or the CAMP test may be employed for presumptive identification. The sensitivity of NAATs for GBS increases to 92.5%–100% with the use of an enrichment step before testing the specimen.[94,391,911] Data on the currently available NAATs do not support their use as a replacement for antenatal culture. The additional time required for

enrichment of samples makes it not feasible for intrapartum testing, and the sensitivity of NAATs in the absence of enrichment is not adequate in comparison with culture. Such tests may be of value for the circumstance of a woman at term with unknown colonization status and no other risk factors. Other rapid tests (e.g., EIAs) have been developed to detect GBS rapidly from nonenriched samples; however, none are sufficiently sensitive when used directly on a specimen for reliable detection of group B streptococcal colonization in the intrapartum setting (see text).

Procedure for Clindamycin and Erythromycin Disk Susceptibility Testing of Isolates, When Ordered for Penicillin-Allergic Patients

- CLSI recommends disk diffusion or broth microdilution testing for antimicrobial susceptibility testing of GBS
- Commercial systems that have been cleared or approved for testing of streptococci other that *S. pneumoniae* may also be used.
- To ensure accurate results, laboratories should include a test for detection of inducible clindamycin resistance. The double-disk diffusion method (D-zone test) is recommended for testing erythromycin-resistant and clindamycin-susceptible GBS. Other validated tests to detect inducible clindamycin resistance may be used in place of the D-zone test.[861,1004]
- CLSI disk diffusion/D-zone test procedure[203]
  - Use a cotton swab to make a suspension from 18- to 24-hour growth of the organism in saline or Mueller-Hinton broth to match a 0.5 McFarland turbidity standard.

  - Within 15 minutes of adjusting the turbidity, dip a sterile cotton swab into the adjusted suspension. The swab should be rotated several times and pressed firmly onto the side wall of the tube above the fluid level. Use the swab to inoculate the entire surface of a Mueller-Hinton SBA plate. After the plate is dry, use sterile forceps to place a clindamycin (2 μg) disk onto half of the plate and an erythromycin (15 μg) disk 12 mm apart for D-zone testing.
  - Incubate at 35°C in 5% CO2 for 20–24 hours.
  - Measure the diameter of the zone of inhibition using a ruler or calipers. Interpret according to CLSI guidelines for *Streptococcus species* β-hemolytic Group.[203]
- For disk diffusion
  - Clindamycin: ≥19 mm = Susceptible, 16–18 mm = Intermediate, and ≤15 mm =Resistant
  - Erythromycin: ≥21 mm = Susceptible, 16–20 mm = Intermediate, and ≤15 mm =Resistant
- For broth microdilution

- Clindamycin: ≤0.25 µg/mL = Susceptible, 0.5 µg/mL = Intermediate, and ≥1.0 µg/mL = Resistant
- Erythromycin: ≤0.25 µg/mL = Susceptible, 0.5 µg/mL = Intermediate, and ≥1.0 µg/mL = Resistant
- Isolates with blunting of the inhibition zone around the clindamycin disk adjacent to the erythromycin disk (D-zone positive) should be considered to have inducible clindamycin resistance and are presumed to be resistant (other validated tests to detect GBS with inducible clindamycin resistance may be used).

- The following comment should be included in patient reports for isolates that show inducible clindamycin resistance:
  - "This isolate is presumed to be resistant on the basis of detection of inducible clindamycin resistance. Clindamycin still might be effective clinically in some cases."

Other Infections Caused by Group B Streptococci

Group B streptococci are associated with about 20% of postpartum endometritis, 25% of bacteremias following cesarean section, 25% to 30% of cases of asymptomatic bacteriuria during and after pregnancy, and a variety of other infections in nonpregnant adults.[168,458, 687,689] With the decline in neonatal group B streptococcal disease, over two-third of infections now occur in adults and are not associated with pregnancy. Adults with group B disease usually have significant underlying disease, including diabetes, liver cirrhosis, stroke, neoplasia, or urinary tract abnormalities.[536,979] Skin and soft tissue infections are the most common clinical entities associated with invasive group B streptococci and include cellulitis, erysipelas, abscesses, infected decubitus ulcers, and invasive wound infections following surgical procedures.[45,718,914] Cellulitis and other cutaneous infections are often manifestations of bacteremia in both adults and children.[718,952] Group B streptococci may also cause necrotizing fasciitis and STSS that

are clinically similar to those condition involving group A streptococci. Up until 1998, only four cases of necrotizing fasciitis due to group B streptococci had been reported, but then Gardam and colleagues[369] reported three cases of group B streptococcal necrotizing fasciitis in adults that occurred in Quebec and Ontario over a 10-month period. In this report, all three patients were immunocompromised (i.e., chronic lymphocytic leukemia, type 2 diabetes mellitus, alcoholism). These patients were

treated with multiple antimicrobial agents and required wide excisional debridement of involved devitalized tissue (including a below-the-knee amputation) and one case resulted in a fatality. Several reports have subsequently appeared describing necrotizing fasciitis and toxic shock syndrome due to group B streptococci in both infants and adults, including three fatal cases of invasive serotype VI necrotizing fasciitis and toxic shock in Japan.[251,570,596,689] In one pediatric case, necrotizing fasciitis developed in a 5-month-old preterm infant as a manifestation of late-onset disease.[596] Toxic shock syndrome reminiscent of that caused by *Staphylococcus aureus* and group A streptococci has been reported primarily in immunocompromised adults. Patients are usually female, greater than 50 years of age, and have diabetes, hematologic malignancies, liver and/or heart disease, or splenectomy as their underlying condition; toxic shock syndrome in nonimmunocompromised patients has also been reported.[66,171,914,935] In Japan, isolates causing toxic shock syndrome belonged to a variety of serotypes (Ib, III, V, VII) and had different PFGE patterns.[171] Strains that cause this toxic shock-like syndrome display enhanced resistance to phagocytic clearance due to increased production of capsular material and induce higher levels of interleukin-8 than wild-type isolates.[914] This is of considerable importance since there is a known association between serum levels of interleukin-8 and severity of sepsis.[1136]

Several types of group B streptococcal osteoarticular infections have also been reported, including septic arthritis, osteomyelitis, spondylodiscitis and prosthetic hip and joint space infections.[199,244,466,625,751,770,1041] Most native bone, joint, and prostheses infections have been reported in elderly, nonpregnant patients with underlying diseases or chronic medical predisposing conditions (e.g., diabetes, malignancies, chronic liver disease).[244,625,1171] Pyogenic arthritis usually affects the knee or the shoulder and is monoarticular in 68% of cases and bacteremia can be documented in two-thirds of patients.[770] Septic arthritis with group B streptococci usually presents with fever and joint pain following or concomitant with bacteremia. Antimicrobial therapy with aspiration or open drainage of infected joints and removal of prosthetic devices, if present, are necessary to effect cure. Osteomyelitis may occur as a complication of cellulitis by contiguous spread, particularly in association with decubitus ulcers, or as a result of hematogenous seeding from another site of infection or from the gastrointestinal tract. Group B streptococci are also a cause of osteomyelitis in neonates, with hematogenous seeding of bone being the source of the organism; osteomyelitis may present as an uncommon manifestation of late-onset group B streptococcal disease.[466] Spondylodiscitis and vertebral osteomyelitis are complications of bacteremia and usually occur in adults.[199,751]

Orbital infections and endophalmitis due to group B streptococci are rare manifestations of infection and occur in both infants and adults. In infants,

endogenous endophthalmitis is generally a complication of late-onset bacteremic disease and usually occurs along with meningitis.[697,956,1151] Endophthalmitis in adults occurs in those with underlying disease and complications may include cataract formation, scleral perforation, and anterior-chamber neovascularization.[408,1151] Infection may be so severe that enucleation of the eye may be required.[697] Endophthalmitis in adults has also been reported as a complication of endocarditis.[187]

Group B streptococcal bacteremia can be complicated by endocarditis and meningitis. Endocarditis is a rare manifestation of group B streptococcal infection. Endocarditis occurs in both men and women, may present acutely or subacutely, and accounts for 2% to 18% of invasive group B disease in adults.[46] Patients usually have underlying predisposing conditions (diabetes, immunosuppression, renal transplantation), and the infection can involve native or prosthetic heart valves.[46,813,886] Preexisting cardiac abnormalities are usually present before disease onset, and once established, vegetations usually develop on the valves, with the mitral valve being the most commonly affected. Vegetations on the heart valves are often large, and embolic phenomena occur in about 50% of cases.[886] Complications caused by embolic phenomena or rapid destruction of valvular tissue may necessitate valve replacement. The mortality rate associated with group B streptococcal endocarditis can be up to 40%, but if combined medical/surgical intervention occurs, mortality decreases to about 20%. A mortality rate of almost 90% may be seen with cases of prothetic valve infection.[813,886] Endocarditis in neonates and infants occurs rarely but resembles adult cases with extensive valvular destruction and the occurrence of embolic phenomena. Group B streptococcal endocarditis has been diagnosed in a 15-year-old girl following an elective abortion.[129] Meningitis is rare, accounts for about 4% of bacterial meningitis in adults, and occurs most frequently in postpartum women and older adults with chronic underlying diseases, such as diabetes, cirrhosis, neurologic impairment, malignancy, renal failure, cardiovascular/pulmonary disease, and HIV infection.[404] Group B streptococcal meningitis following severe head trauma or associated with cerebrospinal rhinorrhea has also been reported.[1083]

Group B streptococci are also a cause of urinary tract infections (UTIs). The clinical spectrum of group B streptococcal UTIs include asymptomatic bactiuria, cystitis, pyelonephritis, urethritis, and urosepsis.[1063] UTIs usually occur in women greater than 50 years of age without underlying disease, but with prior histories of UTI. Bacteriuria with group B streptococci has also been associated with adverse pregnancy outcome, increased rates of premature labor, and premature rupture of fetal membranes.[29] Besides being a well-recognized cause of urinary tract infection in pregnant women, this organism is also a cause of cystitis and pyelonephritis in men, nonpregnant women, and children. Anywhere from 5% to over 20% of nonpregnant

adults with bacteremia will have group B streptococcal urinary tract infection.[733] Risk factors for urinary tract infection caused by group B streptococci include advanced age, underlying disease (especially diabetes), presence of an indwelling urinary catheter, prior UTIs, structural abnormalities of the urinary tract, and other comorbid conditions (e.g., prostatic disease). Pyelonephritis and renal abscess are potential complications

752

of both ascending infection and hematogenous dissemination of group B streptococci.[450,537]

Antimicrobial Susceptibility of Group B Streptococci

Like the group A *Streptococcus*, isolates of group B streptococci remain susceptible to penicillin G, the drug of choice for treatment of infections and for perinatal chemoprophylaxis.[157,826] Ampicillin, cefotaxime, ceftriaxone, cefazolin, quinupristin-dalfopristin, and meropenem are also highly active, with most strains having MICs of ≤0.06 μg/mL.[103,145,189] Very rare isolates from Japan and the United States have decreased susceptibilities to penicillin due to a point mutation in the group B streptococcal *pbp2x* gene.[255,564,798] These isolates have penicillin MICs that are at the threshold of susceptibility (i.e., ≤0.12 μg/mL for penicillin and ≤0.25 μg/mL for ampicillin) These isolates also have elevated MICs to cefazolin (MIC, 1 μg/mL). During the last 15 to 20 years, resistance to macrolides and clindamycin among the group B streptococci has increased from less than 5% to between 20% and 30% depending on locality.[157,377] Most erythromycin resistance is due to a ribosomal modification due to erythromycin ribosome methylase, encoded by the *erm* gene. This also confers inducible or constitutive resistance to clindamycin (MLSB phenotype). Macrolide-lincosamide resistance genotypes that have been detected in group B streptococci include *ermA* (erythromycin-resistant, clindamycin-susceptible), *ermB* (erythromycin-resistant, clindamycin-resistant), and *mef* (erythromycin-resistant, clindamycin-susceptible).[289] All group B streptococcal strains tested to date have been susceptible to vancomycin.

Group C and Group G β-Hemolytic Streptococci

The group C β-hemolytic streptococci currently include *S. dysgalactiae* subsp. *equisimilis*, *S. dysgalactiae* subsp. *dysgalactiae, S. equi* subsp. *equi, S. equi* subsp. *zooepidemicus* and *S. equi* subsp. *ruminatorum.* Former *S. equisimilis* strains

isolated from humans have been shown to carry the group C or group G Lancefield (and, rarely group A) antigens and are genetically similar enough to animal group C strains (subsp. *dysgalactiae)* to be placed in the same species, but different subspecies.[1076,1095] *S. dysgalactiae* subsp. *equisimilis* grows as large colonies on SBA and is usually β-hemolytic. Related strains that carry the C or the L grouping antigen and are isolated primarily from animals are now named *S. dysgalactiae* subsp. *dysgalactiae*.[1076] Isolates of this subspecies may be α-, β-, or nonhemolytic. Molecular genetic studies have demonstrated extensive similarities between the former species *S. equi* and *S. zooepidemicus* and these species are now called *S. equi* subsp. *equi* and *S. equi* subsp. *zooepidemicus*, respectively. These subspecies carry the Lancefield group C carbohydrate cell wall antigen and produce hemolysins similar to those of group A streptococci. *S. equi* and *S. dysgalactiae* subspecies form large colonies on SBA, which differentiate them from the "minute" or "small-colony" α-, β-, or nonhemolytic streptococci of the Anginosus Group of viridans streptococci, which also may carry the group C polysaccharide antigen. *Anginosus* group organisms also differ from the "large-colony" group C streptococci genetically and phenotypically.[139]

S. dysgalactiae subsp. *equisimilis,* the most common human isolate, can colonize the human upper respiratory, gastrointestinal, and female genital tracts; colonization serves as a potential reservoir of infection to other humans.[118,995,996] This subspecies has been recovered from the pharynges of carriers and from cases of exudative pharyngitis and tonsillitis.[118,1055] In young adult populations, pharyngitis due to group C β-hemolytic streptococci has been associated with the same clinical features as group A streptococci, including headache, fever, exudates, and cervical lymphadenopathy.[1027] *S. dysgalactiae* subsp *equisimilis* can cause potentially severe infections in adult and pediatric age groups and usually presents as acute sepsis without a defined source.[118,853] Soft tissue infections and cellulitis, the other most common presentation, may serve as a nidus for bloodstream infection and can lead to hematogenous complications, including endocarditis, endophthalmitis, meningitis, and septic arthritis.[118,640,665,810,853,937,1130] *S. dysgalactiae* subsp. *equisimilis* carrying group C or G antigens have also been associated with STSS, necrotizing fasciitis, and ARF.[432,500,568] Patients with invasive disease are usually adult males and at least three-fourths of patients have underlying medical conditions.[123,995,996]

S. dysgalactiae subsp. *equisimilis* is one of several streptococcal species that is currently regarded as an emerging pathogen. Increasing prevalence of invasive *S. dysgalactiae* subsp. *equisimilis* disease has been noted in Japan, Europe, Asia, and the Americas.[116,123,568,640,996] In Japan, the prevalence of toxic shock syndrome and invasive disease (defined as isolation from a normally sterile site) caused by *S. dysgalactiae* subsp. *equisimilis* has been increasing gradually since 2003. A study performed there found that most patients with *S. dysgalactiae* subsp *equisimilis*

infections were male, elderly, and had underlying disease, including diabetes, malignancy or stroke.[995,996] Of interest was a report from France where a patients developed a near-fatal septic transfusion reaction following pooled platelet transfusion.[63] *S. dysgalactiae* subsp. *equisimilis* was isolated from the blood culture of the recipient and from the residual blood component container. Virulent strains of *S. dysgalactiae* subsp. *equisimilis* in Japan have caused invasive wound infections, toxic shock syndrome, peritonitis, pneumonia and gas gangrene requiring amputation.[469,470,690,1061] These invasive isolates possess virulence factors similar to *S. pyogenes*, including M proteins (encoded by *emm* gene) and production of cellular toxins and hemolysins (e.g., streptokinase A, C5a peptidase, hyaluronidase, streptolysin S, streptolysin O, hemolysin).[14,996]Several superantigen genes (i.e., *speA, speC, speM, ssa,* and *smeZ*) have been identified in *S. dysgalactiae* subsp. *equisimilis.*[118,844] Igwe and colleagues[489] examined 21 group C and group G β-hemolytic streptococcal isolates and found that 11 strains were PCR-positive for at least one of the *speM*, *ssa*, or *smeZ*, genes, which are members of the group A streptococcal superantigen family. In a study using a microarray containing 216 group A streptococcal virulence genes (including those for adhesins, fibronectin-binding proteins,

753

toxins, extracellular proteins, and superantigens) tested with 58 isolates of *S. dysgalactiae* subsp *equisimilis,* each isolate possessed an average of 34% of the genes on the microarray, and 44 of these virulence genes were found in every isolate.[263]

S. equi subsp. *zooepidemicus* is a commensal organism found in the upper respiratory and urogenital tracts of horses and other animal species that acts as an opportunistic pathogen, usually causing respiratory tract or cutaneous infections. Infections in animals include bovine mastitis, equine respiratory infections, purulent arthritis in lambs and goats, and genital tract infections in poultry. *S. equi* subsp *zooepidemicus* is an infrequent cause of infections in dogs, but wound infections and bacteremia have been reported particularly in kennels.[595,819] The first outbreak of *S. equi* subsp. *zooepidemicus* respiratory tract infection ever described in cats was reported from a cattery in Israel in 2010.[95] *S. equis* subsp. *zooepidemicus* has rarely been implicated in human infections, and those who develop infections have had significant exposure to animals (especially horses) or have consumed unpasteurized milk products. Outbreaks of pharyngitis and bacteremia caused by *S. equi* subsp. *zooepidemicus* have been traced to consumption of unpasteurized cows' milk and to fresh unpasteurized goat cheese.[356,587] Transmission of *S. equi* subsp. *zooepidemicus*

from a dog with respiratory tract infections to his handler was reported in 2010.[2] The handler developed signs of sepsis and nose and throat cultures were positive for the organism. Infections in humans have included pneumonia, bacteremia, endocarditis, meningitis, septic arthritis, abdominal aortic aneurysm, deep vein thrombosis, nephritis, and cervical lymphadenitis.[208,317,840,850] In some of these individuals, poststreptococcal glomerulonephritis was observed.[356,1025] *S. equi* subsp. *equi* causes a respiratory tract infection in horses called "strangles." Strangles is characterized by a high fever, mucopurulent nasal discharge, and abscesses in the submandibular and retropharyngeal lymph nodes that eventually rupture and drain into the respiratory tract of the infected animal.[1031] This organism is extremely rare in humans and has been isolated from cases of bacteremia and meningitis.[307,838] *S. equi* subsp. *ruminatorum* is a recently described subspecies that is associated with mastitis in sheep and goats.[336]

Group G β-hemolytic streptococci constitute a part of the normal human gastrointestinal, vaginal, and skin flora. Human isolates that carry the group G antigen are also named *S. dysgalactiae* subspecies *equisimilis*, while animal isolates correspond to *S. canis*.[284] Infections caused by human-associated group G strains include pharyngitis, otitis media, pleuropulmonary infections, cellulitis, septic thrombophlebitis, bacteremia, endocarditis, and meningitis.[665,1140,1145,1167] Group G streptococcal cellulitis and septic arthritis at or near sites of parenteral injection, with bacteremia and subsequent hematogenous complications, have been reported in intravenous drug users.[249] Bacteremia also occurs in the clinical settings of underlying malignancies, puerperal sepsis, septic abortion, chronic pulmonary disease, and HIV infection.

S. canis is a species that was originally proposed in 1986 for β-hemolytic streptococci isolated from dogs and cows.[284] This species causes respiratory tract, cutaneous, genital tract infections, and UTIs in a variety of animals, including dogs and cats.[980]This bacterium has also been recovered from milk specimens from dairy cows with subclinical mastitis. *S. canis* was first isolated from a human with sepsis and leg ulcers in 1997.[78] It was subsequently recovered from blood cultures of a 76-year-old male with leukemia and from an ear wound culture of a 50-year-old female.[1123] Sepsis with cellulitis due to *S. canis* was also reported in a 75-year-old female who has been bitten on the hand by her dog.[998] Analysis by restriction fragment length polymorphism showed that the isolate from the patient's blood and bite wound were identical to that isolated from the oral cavity of her dog. A 5-year retrospective review of *S. canis* infections in 54 patients from Bordeaux, France reported that isolates of *S. canis* had been recovered from cutaneous infections, blood cultures, ENT specimens, vaginal specimens, urine, joint biopsies, and

bronchoalveolar lavage (BAL) specimens.[364] *S. canis* has been isolated and identified in nonhealing or gangrenous ulcers of compromised patients who lived in close companionship with their dogs.[594] In one case, the organism was isolated from blood cultures of a paraplegic patient with multiple open, draining skin lesions and chronic osteomyelitis. The authors of this report point out that the true incidence of *S. canis* infection is not known since most laboratories do not set up phenotypic identification tests on β-hemolytic streptococci that possess the group G Lancefield antigen.[594]

Group C and group G β-hemolytic streptococci are generally susceptible to penicillin, ampicillin, and third-generation cephalosporins like ceftriaxone.[52] Occasional isolates may show intermediate susceptibility to penicillin G, but these are susceptible to the third- and fourth- generation cephalosporins. Some strains may be resistant to erythromycin and other macrolides (e.g., clindamycin, clarithromycin, and azithromycin). Analysis of the susceptibility of β-hemolytic streptococci to fluoroquinolones in the Sentry Antimicrobial Surveillance Program, 1997 through 2004, identified 14 group C and G streptococci among 47 β-hemolytic streptococci with reduced susceptibility to the fluoroquinolones.[83] A study from Portugal found that 12% of 314 *S. dysgalactiae* subsp. *equisimilis* strains were levofloxacin resistant.[833] This latter study found that single mutations in either *parC* or *gyrA* were sufficient to raise the levofloxacin MIC, while higher-level resistance occurred in strains with mutations in both *parC* and *gyrA*. This study also found significant evidence for frequent horizontal gene transfer of *parC* gene sequences between *S. dysgalactiae* subsp. *equisimilis* and *S. pyogenes*.[833] All strains tested to date have been susceptible to vancomycin.

Group F β-Hemolytic Streptococci

Organisms of this group have been called *S. milleri* in the British taxonomic scheme and the **anginosus group** (i.e., *S. anginosus, S. constellatus,* and *S. intermedius*) in American taxonomic schemes. These organisms may be α-, β, or nonhemolytic and may possess the group F, C, G antigen or may be nongroupable. These streptococci characteristically grow as minute colonies on agar media. The colonies are pinpoints after 24 hours and, if β-hemolytic, have a large zone of hemolysis that extends well beyond the margin of the colony. Group F β-hemolytic streptococci are recognized causes of severe suppurative infections, including cellulitis, deep tissue

abscesses, bacteremia, osteomyelitis, and endocarditis (see section on the anginosus

group of the viridans streptococci). The anginosus group will be discussed under the viridans streptococci.

Emerging Pathogens Among the Streptococci

Streptococcus suis

Streptococcus suis deserves special mention because of its economic importance as an important swine pathogen and an occasional zoonotic pathogen for humans.[794,1046,1117] *S. suis* is also an uncommon isolate from dogs, cats, deer and horses. *S. suis* was officially recognized as an extant *Streptococcus* species in 1987.[557] Strains are groupable by Lancefield antisera into groups R, S, RS, and T or are ungroupable. Some strains also react with group D streptococcal antiserum, suggesting possession of the group D lipoteichoic antigen, but this reactivity is due to spurious cross-reactions between groups D and R. Other serotypes having Lancefield groups RS (reacts with both R and S antisera) and T reactivity may be found in both asymptomatic and diseased pigs. *S. suis* strains are encapsulated, and 33 different capsular serotypes, designated 1 through 31, 33, and 1/2 have been recognized; serotypes 32 and 34 have been shown to actually be *Streptococcus orisratti*.[455] Recent evidence from 16S sRNA sequencing showed that *S. suis* serotypes 20, 22, 26, and 33 shared only 94.08% to 97.4% relatedness with the type strain of *S. suis* and that these serotypes may represent different species.[959,960,1028] Sequence analysis of the superoxide dismutase gene (*sodA*) and the recombination/repair protein gene (*recN*) confirmed that serotypes 20, 22, 26, and 33 should be removed from the taxon of *S. suis*.[1028] Multilocus sequence typing (MLST) has been used to divide serotype 2 *S. suis* strains into at least 16 sequence types, with closely related STs being grouped into ST complexes. ST complexes 1, 27, and 87 are found most frequently in Japan, China, and Thailand.[565] Members of ST complex 1 cause the most invasive disease. In North America, most *S. suis* belong to ST28 (51%), ST25 (44%), and ST1 (5%).[345] *S. suis* serotype 1 is found in piglets younger than 6 weeks of age and includes strains bearing the Lancefield group S antigen.

S. suis causes a wide spectrum of severe disease in piglets and pigs, including pneumonia, meningitis, septicemia, and purulent arthritis.[664] Healthy pigs are colonized in the tonsils, nares, respiratory, and gastrointestinal tracts between 5 and 10 weeks of age; carriage rates among healthy animals may be as high as 80%. *S. suis* serotype 2 causes systemic disease in piglets 3 to 20 weeks of age and is also the predominant serotype isolated from infected humans. In infected animals, *S. suis* initially causes fever, anorexia, and other constitutional symptoms, with meningeal

involvement being manifested by rapid onset of seizures, paralysis, and death.[664] Human infection is caused mainly by direct contact with sick or carrier pigs, or raw/undercooked pork contaminated with *S. suis*. Consequently, infections with *S. suis* occur mostly in individuals who work directly with swine (e.g., abattoir and slaughterhouse workers, pig farmers, meat inspectors, veterinarians) or in the industrial processing and manufacture of pork products.[354,671] Slaughtering animals, cutting up carcasses, and handling sick or dead swine were identified as risk factors for *S. suis* infection.[1163] A study in Germany found that 5.3% of 132 persons with exposure to pigs (i.e., butchers, abattoir workers) were colonized with *S. suis* in the nasopharynx, while none of 130 control subjects, with no contact with pigs or pork products, were colonized.[972] Some human cases reported from Hong Kong and Vietnam suggest that processing, preparing, and consuming uncooked or partially cooked pork may also be a risk factor for disease.[494,671] The first human cases of *S. suis* infection were reported in 1968 in Denmark, and the total number of reported cases worldwide is now well over 700.[662] Most reports have come from Asia (China, Japan, Vietnam, Thailand), Europe (the UK, the Netherlands, France, Denmark, Norway, Germany, Spain, Belgium), and North and South America (the United States, Canada, Brazil).[662,1132] China, Thailand, and the Netherlands account for 69%, 11%, and 8% of the total number of cases reported worldwide, respectively. Many of the reported cases occurred during outbreaks of *S. suis* disease. Two large outbreaks of human infection occurred in rural Jianjsu Province during 1998 to 1999, with 25 cases and 14 deaths. In the summer of 2005, the largest outbreak of human *S. suis* infection occurred in the Sichuan Province of China, when 204 human infections and 38 deaths due to *S. suis* septic shock and meningitis were documented.[392,1162,1163] At the time of the human outbreak, a large porcine outbreak of *S. suis* serotype 2 was occurring simultaneously and almost all the patients had a history of contact with pigs or pork products from them. In addition, over 100 cases have been reported from Vietnam over the last 10 years.[671]

S. suis is believed to infect humans percutaneously through cuts, scratches, or abrasions in the skin. Entry via the nasopharynx and the gastrointestinal tract has also been documented, and acute gastroenteritis may be a prominent part of the septic presentation. After infection and following an incubation period of 2–3 to 14 days, disease onset is heralded by an "influenza-like" prodrome, followed by the rapid development of meningitis and bacteremia.[295,344,1117,1166] Initial symptoms include high fever, headache, nausea, vomiting, and nuchal rigidity. Overwhelming bacteremia without the development of purulent meningitis may also occur, and multiorgan system failure, pneumonia, peritonitis, and arthritis may also develop.[559] Toxic shock syndrome, with liver dysfunction, disseminated intravascular coagulation, acute renal failure, and acute respiratory distress syndrome may supervene over time. A common

feature of *S. suis* meningitis is hearing loss with cochlear–vestibular involvement resulting in ataxia and dizziness at presentation or after a few more days.[192,295] Involvement of the eighth cranial nerve is commonly seen and results in unilateral or bilateral hearing loss.[481] This hearing loss may be mild to severe in 4% to 66% of patients.[671] Patients may also develop pechial rashes that evolve into extensive purpura and ecchymoses resembling those of meningococcal disease.[671] Hemorrhagic bullous lesions, skin necrosis, and gangrene of the digits and extremities may result from extensive subcutaneous and skin involvement. A severe sepsis syndrome with a blanching rash reminiscent of toxic shock syndrome and high mortality has also been reported with substantial frequency.[1003,1162,1163]

755

Sudden death due to *S. suis* sepsis was reported in a 49-year-old Thai male who had eaten a meal of raw pork 10 days before death.[425] Hematogeous complications of *S. suis* include arthritis, spondylodiscitis, endophthalmitis, peritonitis, pneumonia, and endocarditis.[559,790,1086,1097,1101] In fact, the first case of a human infection reported in North America was a case of *S. suis* endocarditis in a patient in Canada.[1045] Although disease in swine in the United States is not common, *S. suis* has been isolated from swine herds in the United States (e.g., Minnesota and Nebraska). Prior to 2011, only three cases of human infections with *S. suis* had been described in the United States.[345] These patients were diagnosed in New York and Hawaii, with the third case being acquired in the Philippines and diagnosed in California. In 2013, meningitis and bacteremia due to *S. suis* was described in a 60-year-old truck driver who transported swine across the Midwest.[354] He had been on a swine farm where the farmer reported pulmonary infections in some of the animals. A genetically confirmed isolate of *S. suis* was also isolated from the urine of a sick spayed Labrador retriever that had been fed commercial "pigs' ear" treats.[730] The animal responded to therapy with cephalexin.

S. suis strains are susceptible to penicillin, amoxicillin, cefazolin, ceftriaxone, ofloxacin, trimethoprim-sulfamethoxazole, and vancomycin. Some strains are resistant to tetracyclines, erythromycin, and clindamycin; in porcine populations, resistance to tetracyclines and macrolides exceeds 90% and 70%, respectively.[459,540,671,676,794] Sequencing studies have identified resistance determinants for tetracyclines, macrolides, and aminoglycosides, and genetic elements that carry these resistance genes include integrative/conjugative elements, transposons, genomic pathogenicity islands, and bacteriophages.[794] Ceftriaxone is recommended for empiric therapy with or without vancomycin until the bacterial identification is known. Penicillin is also effective as a front-line agent, but should be administered for at least 10 days, as

relapses of *S. suis* meningitis have occurred after 14 days treatment that responded to more prolonged courses of 4 to 6 weeks.

Streptococcus porcinus *and* Streptococcus pseudoporcinus

S. porcinus strains belong to Lancefield groups E, P, U, V, or are nongroupable with Lancefield antisera and cause infections in swine. In human infections, *S. porcinus* has been isolated from the female genital tract (both vaginal and cervical isolates), placental tissues, blood, skin, urine, and wound infections. In 2004, *S. porcinus* was identified as a cause of spontaneous preterm human stillbirth. The organism was isolated from amniotic fluid, endocervical swabs, and gastric fluid from the fetus.[680]Histopathologic examination of the expulsed placental tissues and the fetal viscera showed microabscesses consistent with bacterial chorioamnionitis. Isolates of *S. porcinus* were also shown to cross-react with group B streptococci using commercial reagents from 12 different manufacturers.[371,1024] An analysis of 25 human and 16 nonhuman isolates phenotypically identified as *S. porcinus* using randomly amplified polymorphic DNA-PCR and PFGE analysis revealed two clusters, with all human isolates belonging to one cluster, and all nonhuman isolates belonging to a second cluster.[298] Bekal and associates[67] in Quebec performed 16S rRNA gene sequencing on nine human and seven animal strains of *S. porcinus* and found the same type of clustering, with more than 2.1% dissimilarity between the human and the animal *S. porcinus* isolates. These workers proposed that human isolates be re-named *S. pseudoporcinus*. Like *S. porcinus*, S. *pseudoporcinus* produces small, smooth colonies on blood agar that are surrounded by very large zones of β-hemolysis. A study of 663 nonpregnant women in Pittsburgh enrolled in a group B *Streptococcus* conjugate vaccine trial determined a population prevalence of *S. pseudoporcinus* of 5.4%.[971] Higher rectovaginal colonization rates were associated with increased numbers of sexual partners and sexually transmitted infections. Pereira and colleagues[820] reported on two patients with positive vaginorectal cultures for *S. pseudoporcinus.* One patient lost a pregnancy with twins due to previable rupture of the fetal membranes. The following year during a second pregnancy, vaginorectal cultures were again positive for *S. pseudoporcinus*, and cervical shortening prompted cerclage and antimicrobial therapy. However, the patient delivered without incident 2 weeks later. The second patient delivered preterm after premature rupture of membranes and chorioamnionitis, but the infant did well subsequently. *S. pseudoporcinus* isolates are susceptible to penicillin, clindamycin, erythromycin, trimethoprim-sulfamethoxazole, and vancomycin; resistance to tetracycline has been noted in many isolates.[371,680] Similar antimicrobial susceptibilities have been found for isolates of *S. porcinus*.[320] *S. pseudoporcinus* has also been isolated from a posttraumatic thumb wound.[670]

Streptococcus iniae

S. iniae is pathogen of fish and has been isolated from humans as a cause of bacteremia, meningitis, and endocarditis in individuals who handle contaminated fish. *S. iniae* infects at least 27 different species of fish, including tilapia, rainbow trout, Barramundi cod, Coho salmon, Japanese flounder, and snapper.[10] Infections can be severe and depend on the virulence of the isolate, the host species, the route and location of the infection, and the quality of the aqueous environment. *S. iniae* has become an important fish pathogen, with an estimated annual impact on the US aquaculture industry that exceeds $10 million.[10] The first reported case of human infection associated with *S. iniae* was reported in 1997, when Weinstein and coworkers[1113] from the Public Health Agency in Canada reported nine cases from 1995 to 1996 of invasive *S. iniae* infections. All nine individuals had positive blood cultures, eight had cellulitis of the hands, and one had meningitis, arthritis, and endocarditis. All patients had recently handled live or freshly killed fish, and infection usually followed penetrating injuries from bones or spines of the fish during the cleaning/deboning process. The fish most commonly implicated in these cases was tilapia (*Oreochromis* spp.) raised on aquaculture farms. These investigators reviewed their hospital records and found an additional four patients with *S. iniae* infection. Two additional cases were reported by the CDC retrospectively and included a patient in Texas with bacteremic cellulitis from 1991 and a patient with arthritis of the knee in Ottawa, Canada from 1994.[152] In 2003, two elderly male patients (79 and 81 years

old) in Hong Kong were diagnosed with bacteremic cellulitis and bacteremic osteomyelitis due to *S. iniae*, respectively.[602] Spinal discitis was diagnosed by culture of material from paravertebral abscesses in a 73-year-old Chinese female who regularly cleaned fish and sustained cuts on her fingers.[573] Both patients reported handling fresh fish recently, but had not sustained any penetrating injuries. Isolates of *S. iniae* have also been characterized by the CDC. Facklam and colleagues[321] examined seven clinical isolates; six of these were isolated from blood cultures and the seventh was from a thyroid cyst. Three of these patients have sepsis with cellulitis, while the others presented with an infected mass lesion, toxic shock, pneumonia, and cellulitis. As in previous reports, all patients were of Asian ethnicity, showed equal distribution among males and females, and were of similar ages (60 to 88 years) to the patients in previous reports. Invasive infections with *S. iniae* have been reported in patients with underlying diseases, including diabetes mellitus septic arthritis, gout, and hepatitis C-related liver cirrhosis.[601,978]Asian ethnicity may be important primarily because of the methods involved in handling and cleaning fish for the preparation of

various Asian foods.[601] Isolates of *S. iniae* produce a variety of virulence factors (e.g., M protein-like SiM proteins, C5a peptidase, interleukin-8 protease, streptolysin S, capsular polysaccharides) that are homologous to those found in *S. pyogenes* and that likely play major roles in the pathogenesis of severe *S. iniae* infections.[47] *S. iniae* is included in the database of the Biolog system; in a study comparing this system with amplification of *S. iniae*-specific 16S-23S spacer regions using two primer sets, the Biolog identified 70% of 25 US and Canadian *S. iniae* isolates.[864] Isolates of *S. iniae* are generally susceptible to β-lactams, macrolides, quinolones, and vancomycin.

Streptococcus pneumoniae

S. pneumoniae is the major cause of community-acquired bacterial pneumonia. The organism is transmitted from person to person by close contact. The organism may be harbored in the upper respiratory tract of 5% to 10% of adults, although carriage rates higher than 60% have been reported in closed populations.[738,774] Infants usually become colonized at about 3 to 4 months of age and remain colonized for about 4 months with a given serotype; the peak incidence of pneumococcal colonization occurs by age 1 to 3 years, when the rate may be 40% to 60%.[96,486] In adults, colonization and carriage persist from 2 to 4 weeks but may remain much longer, and carriage rates among adults usually range from 5% to 10%. The duration of carriage decreases with age, and, therefore, tends to be longer in pediatric populations than in adults. Colonization of infants with pneumococci is related to the absence of specific anticapsular antibody and the poorly immunogenic serotypes that are common in this age group.[774] The susceptibility of elderly persons to pneumococcal disease reflects aging of the immune system and consequent diminished production of antibodies, along with general changes in levels of activity, compromised mucociliary clearance mechanisms, malnutrition, or debilitation owing to other underlying chronic diseases such as diabetes and alcoholism. Prior to the availability of highly effective conjugate vaccines, the overall rate of disease due to *S. pneumoniae* was about 15 cases per 100,000 persons per year. The organism classically causes disease in newborns and infants up to 3 years of age, and in adults ages 65 and over.[712,738] Attack rates are four to five times greater among African-Americans than among Caucasians, and this difference appears to be real, although several other factors (e.g., access to health care, other underlying biological or environmental conditions) may also influence these rates. Attack rates are also higher among native Alaskan populations, native American Indian populations, and among Australian Aborigines.[260,431,1036,1111] Patients with underlying abrogations of various host defense mechanisms such as hypogammaglobulinemia, complement component deficiencies, and sickle cell disease,

are also at increased risk for invasive pneumococcal disease. Persons with functional asplenia or those who have had surgical splenectomies are at particularly high risk for development of invasive, often fatal, pneumococcal bacteremia.

Virulence Factors

The virulence of *S. pneumoniae* is primarily related to its ability to resist opsonization, phagocytosis, and intracellular killing by phagocytic cells.[717] This resistance is primarily related to the **polysaccharide capsule** of the organism. There are at least 91 capsular types of *S. pneumoniae*; 23 of these types account for over 88% of pneumococcal bacteremia and meningitis.[738] Capsular polysaccharides in *S. pneumoniae* are comprised of long polymers of repeating units comprised of two to seven monosaccharides, some of which may be in long or branching chains. These polymers are synthesized by addition of carbohydrate moieties to the proximal end of the chain, and most types are anchored to the peptidoglycan and the C polysaccharide of the cell wall. Certain pneumococcal capsular types (e.g., type 3) have biological properties that render these organisms more virulent than others, and pneumococci that belong to different capsular serotypes vary in their ability to elicit humoral antibody responses. These characteristics may account for the greater virulence associated with some capsular types over others. The capsule of these organisms is antiphagocytic and prevents C3b and the Fc region of immunoglobulin molecules from interacting with their receptors on the surface of bacterial cells. Initial adherence of pneumococci to the nasopharyngeal mucosa apparently is not mediated by capsular material but is related to bacterial adhesins that interact with receptors on pharyngeal epithelial cell surfaces. Interaction may occur with mucosal sialic acid via pneumococcal neuraminidase or via pneumococcal cell surface ligands that bind to *N*-acetyl-D-galactosamine-galactose disaccharide residues on respiratory tract cell surfaces. Pneumococci also possess both teichoic acids and LTAs. **Teichoic acids** are covalently linked to the peptidoglycan of the cell wall by phosphodiester linkages, while the **LTAs** are linked to the cell membrane. These molecules are structurally similar and are composed of repeating units containing glucose, 2-acetamido-4-amino-2,4,6-trideoxy-D-galactose, *N*-acetyl-glucosamine, phosphocholine, and ribitol-5-phosphate. Repeating units are linked to each other by phosphodiester bonds. Teichoic acids and LTAs of *S. pneumoniae* are also called C polysaccharide and

757

F antigen, respectively, and all pneumococcal serotypes possess both of these antigens.

Other cellular products of *S. pneumoniae*, such as the pneumolysin, autolysin, and cell surface molecules, also play a role in pneumococcal virulence.[717] Mutants that are

defective in the production of these various components have diminished virulence in animal models, and immunization with purified products results in the production of specific antibodies that confer partial resistance to challenge infection. **Pneumolysin** is a 53-kDa thiol-activated cytotoxin protein that accumulates within the cells during growth and is released on cell lysis by the autolysin.[875] Pneumolysin interacts with cholesterol in the cell membranes of a variety of host cells, forms oligomers on and in the membrane that evolve into pores, and ultimately lyses the cells. Pneumolysin inhibits the bactericidal activity of phagocytic cells, arrests ciliary motility, stimulates cytokine production by macrophages (especially IL-1, IL-8 and TNF), and activates the classical complement pathway.[205,875] In animal models, pneumolysin has been shown to play a role the pathogenesis of pneumococcal bacteremia, pneumonia, and aspects of inflammation and deafness associated with otitis media and the sequelae of meningitis.[72,1114,1133] **Autolysin** is an *N*-acetyl-muramoyl-L-alanine amidase that, along with a glycosidase enzyme, functions during cell division to separate daughter cells, and at the end of exponential growth, to break down the organisms, causing lytic dispersal of both pneumolysin and α-hemolysin.[77]Autolysin-negative mutants have reduced virulence as compared to wild-type strains. Reduced virulence is likely due to failure to release toxic cell wall components and pneumolysin and, hence, the generation of a greatly reduced inflammatory response. Pneumococci also have several surface proteins that are termed LPXTG-anchored proteins. These proteins are covalently linked to the cell wall peptidoglycan and include hyaluronidase, neuraminidase, and serine protease PrtA. *S. pneumoniae* strains produce two different **neuraminidase enzymes (NanA and NanB**), which cleave terminal sialic acid from cell surfaces to expose *N*-acetyl-glucosamine-galactose moieties that mediate bacterial cell adherence.[128] The NanA enzyme plays an important role in biofilm formation by the organism, and the sialic acid that is release by neuraminidase activity in involved in cell-to-cell signaling, leading to enhanced colonization and invasion.[809,1040] Neuraminidase activity also plays a part in the pathogenesis of otitis media in animal models.[1034] **Hyaluronidase** hydrolyzes hyaluronic acid in the connective tissue and facilitates spread of the organisms. **PrtA serine protease** is produced by all *S. pneumoniae* isolates and antibodies directed against it are found in patients with pneumococcal infections and in healthy individuals.[1178] The exact role of this enzyme in disease pathogenesis is not known, but animal models have demonstrated a role in disease pathogenesis, as mutants lacking PrtA are less virulent and vaccination of animals with the enzyme engenders protective antibodies.[80] **PspA** (pneumococcal surface protein A) is a surface protein that is found on all pneumococci and comprises the immunodominant antigenic protein of pneumococci. PspA inhibits phagocytosis by blocking the deposition of complement on the bacterial cell surface.[738] Antibodies directed against PspA from a given pneumococcal strain protect experimental animals

against challenge with both the homologous strain and heterologous strains and mutant pneumococci that are defective in PspA production are avirulent. Intranasal inoculation of mice with PspA prevents both respiratory tract colonization and the development of invasive disease. For this reason, PspA has potential for use as a vaccine candidate antigen.[120]

Pneumococcal Vaccines

Two types of vaccines are now available for the prevention of disease due to *S. pneumoniae*: pure polysaccharide vaccines and polysaccharide-protein conjugate vaccines. The **pneumococcal polysaccharide vaccines** (PPSV23; Pneumovax23, Merck Sharpe and Dohme) is composed of a mixture of 23 pneumococcal capsular polysaccharides. The 23 capsular serotypes included in these vaccines are 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F. The Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (CDC) recommends vaccination of (a) persons who are aged 65 years or greater, (b) persons aged 19 to 64 years who have chronic illness (e.g., chronic cardiovascular disease, cardiomyopathies), chronic pulmonary disease (e.g., COPD, emphysema, but not asthma, smokers), diabetes mellitus, alcoholism, liver disease (e.g., cirrhosis), or CSF leaks, (c) those who have functional or anatomic asplenia (e.g., sickle cell disease, splenectomy), (d) persons aged 19 to 64 who live in environments or settings that render them at risk for invasive pneumococcal disease (i.e., Alaskan Natives, certain American Indian populations, residents of nursing homes and other long-term care facilities), (e) individuals 2 years of age or greater who are immunocompromised (e.g., those with HIV infection, leukemia, lymphoma, Hodgkin's disease, multiple myeloma, malignancies, chronic renal failure, nephrotic syndrome, other conditions associated with immunosuppression [e.g., bone marrow transplantation]), and (f) persons receiving immunosuppressive chemotherapy.[153,158,161] A second dose of PPSV23 is recommended 5 years after the first one for individuals aged 19 through 64 years for those who are immunocompromised or have functional or anatomic asplenia. The full immunization schedule for PPSV23 is found in Box 13-4. PPSV23 has been demonstrated to be safe and efficacious and is relatively inexpensive. Pure polysaccharide vaccines provoke a B-cell antibody response but are T-cell-independent antigens, so a protective immune response is not seen in children less than 2 years old. Other drawbacks to the pneumococcal polysaccharide vaccines include its inability to affect nasopharyngeal pneumococcal carriage and, therefore, the spread of organisms from person to person, and its limited efficacy in patients with underlying hematologic malignancies or immunodeficiency states.

In February of 2000, PCV7 (**P** neumococcal **C** onjugate **V** accine **7**), a new 7-valent pneumococcal conjugate vaccine (Prevnar, Wyeth Lederle Vaccines, Pearl

River, NY) was licensed for use in infants and children.[155] PCV7 was composed of an inert diphtheria toxin carrier protein (CRM197) covalently linked to the capsular polysaccharide antigens of seven *S. pneumoniae* serotypes. The capsular serotypes that were included in PCV7 were serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F. At the time, these serotypes were associated with

about 80% of pneumococcal disease occurring in children less than 5 years of age.[155,824,832] The PCV7 conjugate vaccine provoked the brisk T-cell dependent antibody response that is required for optimal antibody production and ability to mount an anamnestic response via immunologic memory. Large studies have demonstrated that the pneumococcal heptavalent conjugate vaccine was efficacious in preventing invasive disease in young children due to vaccine serotypes of *S. pneumoniae*.[531,859] Following widespread use of PCV7, the reduction in invasive pneumococcal infections due to serotypes included in the vaccine was 100% in children less than 5 years of age and 94% when all ages were considered. Interestingly, no increases in infections due to nonvaccine serotypes were observed during the clinical efficacy trials, and the rates of nasopharyngeal carriage of *S. pneumoniae* were found to be decreased in vaccinated children, a phenomenon not seen in polysaccharide vaccine recipients. A small efficacy study found that PCV7 provoked protective antibody responses in children with sickle cell disease as well.[776] By the end of 2007, only about 2% of invasive pneumococcal disease in children less than 5 years of age was due to serotypes included in PCV7. During this post PCV7-vaccination period, some communities noted an increase of disease (e.g., meningitis) caused by nonvaccine serotypes (e.g., serotype 7F) in children less than 30 days of age.[783] A review of the literature on the global impact of the seven-valent conjugate vaccine found that, among vaccine eligible children in the postvaccination period, a reduction in invasive pneumococcal diseases ranging from 39.9% in Spain to 99.1% in the United States was documented.[740] Since the introduction of the PCV7 pneumococcal conjugate vaccine in 2000, hospitalizations for childhood pneumonia have declined, and this has been sustained over the subsequent 12 years. Less drastic but measurable declines in hospitalization of older adults with community-acquired pneumonias has also occurred over the same period.[400]

In 2010, a new pneumococcal polysaccharide conjugate vaccine—PCV 13—was licensed by the FDA and recommended for use in children by the CDC and the ACIP.[25,158] This vaccine includes the serotypes found in PCV7 plus six additional serotypes: 1, 3, 5, 6A, 7F, 19A. The additional serotypes included in PCV13 accounted for 64% of 4,600 cases of invasive pneumococcal disease documented in

2007 in children less than 5 years of age.[159] PCV13 is recommended for all children aged 2 to 59 months and children aged 60 to 71 months with underlying conditions that increase their risk for invasive pneumococcal disease. The complete immunization schedule for PCV13 includes recommendations that should be followed for children who may have received previous PCV7 vaccinations.[160,161] At the end of 2011, PCV13 was approved for adults aged 50 years and greater for the prevention of invasive *S. pneumoniae* disease.[162] Box 13-4 provides additional information on PPSV23 and PCV13 regarding target groups for receipt of vaccines and immunization schedules.

Clinical Spectrum of S. pneumoniae

In the appropriate host, *S. pneumoniae* gains access to the alveolar spaces by aspiration or inhalation and eventually may cause a lobar pneumonia, with consolidation and bacteremia.[490,738] Conditions that are recognized to predispose adults to pneumococcal disease include underlying bronchopulmonary disease and compromised humoral immunity. Conditions that abrogate the humoral immune response (e.g., myeloma, lymphoma, chronic lymphocytic leukemia, hepatic cirrhosis, complement component deficiencies) probably have the greatest influence on individual susceptibility to pneumococcal infection. The incidence and severity of pneumococcal disease are also increased among those persons with defects in upper respiratory tract clearance mechanisms, including smokers, and individuals with asthma, chronic bronchitis, COPD, or bronchogenic and squamous cell carcinoma of the lung. Viral respiratory tract infections also predispose to pneumococcal infection of the respiratory tract because these agents also damage the bronchial clearance mechanisms. The onset of pneumococcal pneumonia is generally abrupt, even in patients in whom a prior respiratory viral infection is the principal predisposing factor. In older children and young adults, symptoms include shaking chills, followed by sustained fever, cough, and production of purulent, often blood-tinged sputum. In elderly patients, the infection may present insidiously over several days.[655] Symptoms may vary from a minimal cough, with an actual decrease in temperature, to a fulminant presentation, leading rapidly to shock and death. Blood cultures are positive in 20% to 30% of patients with pneumococcal pneumonia. Older adults usually have additional conditions that put them at higher risk for serious disease, including malignancies, alcoholism, heart disease, COPD, and diabetes. Chest X-rays from patients with pneumococcal pneumonia demonstrate lobar consolidation in about 40% to 50%, with the remaining showing a patchy bronchopneumonic pattern. Infiltrates due to pneumococcal disease tend to be unilateral and involve the alveoli rather than the bronchioles and interstitial tissues. Complications of pneumococcal pneumonia include lung abscess, pericardial infections, empyema, pleural effusions, and

endocarditis.[315,402,465,645,729,746,1005] Pleural effusions and empyemas may be visualized on chest films, but are more accurately delineated by computed axial tomography (CT) and ultrasound diagnostic approaches. If these fluid collections are sufficiently large, drainage via chest tube placement may be necessary to effect cure, along with antimicrobial therapy. CT scans and ultrasound are also helpful for diagnosing necrotizing pneumonias and deep lung abscesses due to *S. pneumoniae*. Hemolytic uremic syndrome (HUS) may also occur as a complication of pediatric *S. pneumoniae* infection and accounts for 4.6% to 15% of all childhood HUS.[180,240,957,1085] This complication occurs with an incidence of 0.04% to 0.6% and is seen primarily in children less than 2 years of age. Of the described cases of HUS, 72% were associated with pneumonia with or without effusion/empyema, 29% occurred with pneumococcal meningitis, and 5% was seen in patients with both conditions.[240] HUS associated with pneumococcal pneumonia was recently reported in adults as well.[22] The case fatality rate for pneumococcal pneumonia is about 5% but may approach 20% to 30% when accompanied by bacteremia. Pneumococcal bacteremia without pulmonary involvement is an entity that occurs in immunologically compromised hosts. Underlying diseases or conditions that predispose patients to recurrent or relapsing pneumococcal bacteremia include splenectomy, acute myelogenous leukemia, bone marrow transplantation, sickle cell disease, HIV infection, and short bowel syndrome.[186]

759

BOX 13-4

Pneumococcal Vaccines and Immunization Schedules for Infants and Children (see text as well)[25,153,155,158-162]

PPSV23—23 Valent Pneumococcal Polysaccharide Vaccine

Pneumovax 23 (Merck, Sharpe & Dohme) and Pneu-Immune 23 (Lederle)

Composed of a mixture of 23 pneumococcal capsular polysaccharides, including types 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F.

Recommended for (a) persons greater than or equal to 65 years of age, (b) persons aged 2–64 years who have chronic or advanced cardiovascular disease, chronic pulmonary disease (e.g., COPD, emphysema, asthma), diabetes mellitus, alcoholism, liver disease, chronic renal insufficiency, or CSF leaks, (c) those who have functional or anatomic asplenia (e.g., sickle cell disease, splenectomy), (d) individuals 2 years of age or greater who are immunocompromised, (e.g., HIV infection, leukemia, lymphoma, Hodgkin's disease, multiple myeloma, malignancies, chronic renal failure, nephrotic syndrome, bone marrow transplantation, and persons receiving chemotherapy) and (e) persons aged 2–64 who live in environments or settings that place them at risk for invasive pneumococcal disease (i.e., Alaskan Natives, certain American Indian populations, residents of nursing homes and other long-term care facilities).

Children aged more than 2 years with underlying medical conditions should receive PPSV23 after completing all recommended doses of PCV13. One dose should be given at ages 2 years or more and at least 8 weeks after the last PSV13 dose. Those children who received PPSV23 previously should receive the recommended PSV13 doses (at right).

Children aged 24–71 months with underlying medical conditions who received less than 3 doses of PCV7 before the age of 24 months should receive 2 doses of PCV13 followed by one dose of PPSV23 8 or more weeks later.

Children aged 24–71 months with underlying conditions and who received any incomplete schedule of 3 doses of PCV7 before age 24 months should receive one dose of PCV13 followed by one dose of PPSV23 after 8 weeks or more.

A second PPSV23 dose is recommended 5 years after the first PPSV23 dose for children with underlying medical conditions (i.e., sickle cell hemoglobinopathies, congenital/acquired/functional asplenia, congenital or acquired immunodeficiencies, immunosuppressive therapies, chronic illnesses, presence of cochlear implants or cerebrospinal fluid leaks).

PCV13—13 Valent Polysaccharide Conjugate Vaccine

Prevnar 13 (Wyeth Pharmaceuticals, a subsidiary of Pfizer, Inc.)

Composed of an inert diphtheria toxin carrier protein (CRM197) that is covalently linked to the capsular polysaccharide antigens of thirteen pneumococcal serotypes, including serotypes 1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F.

PCV13 is recommended for children aged 2 through 59 months who have not received any previous PCV7. PCV13 is administered as a 4-dose series beginning at 2 (may be administered as early as 6 weeks of age), 4, 6 months, and 12–15 months of age. For infants aged 2–6 months, those children receiving the first dose at 6 months of age should receive 3 subsequent doses at intervals of 4–8 weeks. A fourth booster is recommended at age 12–15 months and at least 8 weeks after the third dose.

Healthy children aged 7–59 months who were not previously vaccinated with PCV7 or PCV13 should receive 1–3 doses of PCV13 depending on when vaccination begins and whether underlying conditions are present.

Children aged 24–71 months with underlying conditions should receive 2 doses of PCV13. Three doses of PCV13 are recommended for infants aged 7–11 months, with a 4 week interval between doses, with the third dose being given at age 12–15 months.

Two doses of PCV13 are recommended for children aged 1–23 months, with 8 weeks between the two doses. Unvaccinated healthy children aged more than 24–59 months should receive one dose of PCV13, but unvaccinated children with underlying medical conditions should receive 2 doses with 8 weeks between them.

In those children aged less than 24 months who have received one or more doses of PCV7 should complete the series with PCV13. Those children aged 12–23 months who have received 3 doses of PCV7 should receive a single dose of PCV13 at least 8 weeks after the last PSV7 dose (fourth and final PCV dose). No additional PCV13 doses are required for children aged 12–23 months who received 2–3 doses of PCV7 before age 12 months and at least one dose of PCV13 at an age more than 12 months.

For those children greater than 2 years of age, a single PCV13 dose if recommended for all children aged 24–59 months with any incomplete vaccination schedule. For children aged 24–71 months with underlying medical conditions who have received any incomplete schedule of less than three doses of either PCV7 or PCV13 before age 24 months, two doses of PCV13 are recommended. For children with underlying medical conditions who have received three doses of either PC7 or PCV13, a single dose of PCV13 is recommended through age 71 months.

A single PSV13 dose is recommended for all children aged 14–59 months who received 4 doses of PCV7. For children with underlying medical conditions, a single PCV13 dose is recommended through 71 months of age.

For children aged 6–18 years with certain at-risk conditions (i.e., children with sickle cell hemoglobinopathies, congenital/acquired/functional asplenia, congenital or acquired immunodeficiencies, immunosuppressive therapies, chronic illnesses, presence of cochlear implants or cerebrospinal fluid leaves) who have not received PCV13 previously, a single PCV13 dose should be given.

Pure polysaccharide vaccines provoke a B-cell antibody response but are T-cell-independent antigens. Protective immune responses are not seen in children less than 2 years old. The vaccine also has marginal effects on nasopharyngeal pneumococcal carriage has limited efficacy in patients with underlying hematologic malignancies or immunodeficiency states.	Provokes a T-cell-dependent antibody response that is required for optimal antibody production and ability to mount an anamnestic response. Studies have demonstrated efficacy in preventing invasive disease in young children due to vaccine serotypes, with prevention of greater than 90% of invasive pneumococcal disease due to vaccine serotypes. Rates of nasopharyngeal carriage of *S. pneumoniae* are also decreased in vaccinated children.

S. pneumoniae is also the most common cause of bacterial meningitis in older adults, followed by *N. meningitidis*, *S. aureus*, and other miscellaneous gram-positive organisms (e.g., *L. monocytogenes*).[462] With the increasing use of the conjugate vaccines for *Haemophilus influenzae* type b, a 2001 to 2004 multicenter study reported that the pneumococcus was the third most common agent in children 1 to 3 months of age (14%), with group B streptococci and *N. meningitidis* being the first and second most common agents (39% and 32%, respectively).[765] *S. pneumoniae* was the most common agent in children ages 3 months to 3 years (45%), followed by *N. meningitidis* (34%) and group B streptococci (11%). In the 3-year- to 10-year-old age group, *S. pneumoniae* (47%) and *N. meningitidis* (32%) were the most common etiologic agents, with *N. meningitidis* exceeding *S. pneumoniae* in the 10- to 19-year-old children.[765] A 2011 report found that, while group B streptococci remained the most common agent of meningitis in children less than 2 months of age (86%) and the meningococcus was the cause of meningitis in the 11- to 17-year-old age group, the pneumococcus prevailed in all other pediatric age groups.[1021] The introduction of the PCV7 vaccine in 2000 caused a significant decline in the incidence of pneumococcal meningitis in those countries where it is part of the national immunization schedule. This decline was most evident among children less than 2 years of age, but there was a notable increase in meningitis due to pneumococcal serotypes not included in the PCV7 vaccine (e.g., serotype 19A).[580] This serotype in included in the PVC13 vaccine formulation. In adults, *S. pneumoniae* accounts for about one-third of community-acquired meningitis in the United States and has an associated mortality of 20% to 25%. *S. pneumoniae* meningitis usually occurs as a result of seeding of the meninges during bacteremia, with the organisms probably entering via the choroid plexus. In adults, about 60% to 70% present with symptoms of fever, nuchal rigidity, and mental status changes. In infants, crying, irritability, malaise, failure to feed, vomiting, and seizures may dominate the clinical picture; only about one-third of these babies will develop a bulging fontanelle. In elderly and/or compromised adults, the presentation may be insidious, with lethargy, obtundation, and little or no fever being the norm.[462] However, meningitis along with ultimately fatal septic shock may occur in patients who are profoundly immunosuppressed (e.g., bone marrow transplant patients).[416] Pneumococcal endocarditis is an uncommon complication of

pneumococcal meningitis and is associated with an unfavorable clinical outcome.[660] *S. pneumoniae* is also the leading cause of meningitis following skull fractures. Head trauma resulting in basilar skull fracture with leakage of cerebrospinal fluid interrupts the integrity of the dura mater and may allow direct entry of organisms into the central nervous system from an adjacent site of infection (e.g., sinusitis, mastoiditis, otitis media).[738] Rare complications of pneumococcal meningitis include spinal epidural abscess, vertebral osteomyelitis, and paraspinal abcess.[81]

In pediatric populations, *S. pneumoniae* accounts for 40% to 50% of cases of acute otitis media and has been associated with sinusitis and mastoiditis.[829,953] Because of vaccination with conjugate pneumococcal vaccines, the etiology of acute otitis media continues to change over time. In patients with otitis media, the tympanic membrane appears inflamed, immobile, and bulging on examination with an otoscope. Most children with otitis media will also have rhinorrhea and nasal congestion, and about two-thirds will be febrile. Complications include tympanic membrane perforation, mastoiditis, facial nerve paralysis, bacteremia, and septic arthritis.[579] Specimens for diagnosis are best obtained via myringotomy or tympanocentesis. Pneumococci, along with nontypeable *H. influenzae*, are also responsible for about 70% of acute and subacute sinus infections.

S. pneumoniae is an infrequent cause of endocarditis, pericarditis, osteomyelitis, septic arthritis, peritonitis, female pelvic infections, neonatal infections, and skin/soft tissue infections. Most patients have underlying disease, such as diabetes, malignancies, alcoholism, systemic lupus erythematosus, or HIV infection, and have other foci of pneumococcal disease, such as meningitis or pneumonia. Pneumococci account for less than 3% of cases of bacterial endocarditis and 3% to 7% of all cases of pediatric endocarditis.[382] Pneumococcal endocarditis follows an acute course, is associated with valve destruction and formation of aortic perivalvular abscesses, and has a mortality rate of 24% up to over 50%.[529,621,931,1005] Treatment of pneumococcal endocarditis with medical therapy alone is associated with poor outcomes. Many patients actually have normal heart valves, however, in one study of pneumococcal endocarditis in children, congenital heart disease was the only identifiable risk factor.[190]Primary peritonitis caused by pneumococci was once a common clinical entity in children in association with nephrotic syndrome, but it now occurs primarily in adults with cirrhosis and other liver diseases. The pathogenensis of pneumococcal peritonitis is via the hematogenous route or local inoculation.[300] Osteoarticular infections, osteomyelitis and septic arthritis caused by *S. pneumoniae* often occur in children with sickle cell disease.[188,772,789,1160] Higher rates of pneumococcal septic arthritis have also been documented in

children with HIV infection.[865] In adults, pneumococcal septic arthritis usually occurs in patients with a focus of infection at another site (i.e., bloodstream infection, meningitis, sinusitis) and involves more than one joint in about one-quarter to one-third of patients.[413,848] Pneumococcal septic arthritis occurs more frequently in patients with underlying joint disease (e.g., rheumatoid arthritis) and usually involves native joints, although prosthetic joint involvement has been described.[848] In Japan, polyarticular pneumococcal septic arthritis was diagnosed in a 28-year-old man following a single infusion of infliximab for rheumatoid arthritis.[435] The patient had no evidence of pneumococcal disease elsewhere, except for positive joint fluid and blood cultures. Most cases can be managed with appropriate antimicrobial coverage and arthrocentesis. In some women, *S. pneumoniae* may be a transient part of the vaginal flora, and pelvic, obstetric, and gynecologic infections (e.g., bartholinitis, pelvic inflammatory disease) may occur, particularly with predisposing conditions, such as the presence of an intrauterine device or recent gynecologic surgery.[632,811] Tubo-ovarian abscesses due to *S. pneumoniae* may also be a source of pneumococcal peritoneal infections.[835] Neonatal pneumococcal infections have been reported and represent 1% to 11% of cases of neonatal sepsis.[461,698] These babies may present with meningitis, bacteremia, and/or pneumonia arthritis/osteomyelitis, or otitis media, and are usually 2 to 3 weeks of age and full-term at presentation. The likely source of infection in these babies is the mothers' genital tract.[390,698] *S. pneumoniae* has also been recognized as a rare but significant cause of soft tissue infections, including facial and periorbital cellulitis, necrotizing fasciitis, rhabdomyolysis, pyomyositis, and abscesses.[58,92,367,373,498,553,806,1137,1154,1165,] Facial and periorbital cellulitis occurs predominantly in children as a complication of upper respiratory tract infection, pneumococcal sinusitis, or trauma involving the eyelids.[373,818] In one report on 56 patients with soft tissue infections caused by *S. pneumoniae*, surgical wound infections were the most common, followed by burn wound infection, pyomyositis, cellulitis, and perineal or scrotal abscesses.[367] Most patients had underlying diseases or conditions, including burns, diabetes, neoplasms, psoriasis, or HIV infection. Necrotizing fasciitis due to *S. pneumoniae* occurs in elderly patients with multiple risk factors, including minor trauma, immunosuppression secondary to medication, alcoholism, underlying disease (e.g., diabetes, systemic lupus erythematosus), and cirrhosis.[264,498,806,1154] Pneumococcal rhabdomyolysis is a rare condition that occurs in elderly individuals with pneumococcal pneumonia, although other infected sites (e.g., meningitis, cellulitis, arthritis) may be present.[58,92,924] Disease presentation usually occurs at the onset of pneumococcal infection and includes limb weakness and generalized or localized muscle pain. Muscle biopsies may appear normal or may show focal fiber degeneration, muscle tissue breakdown, and necrosis, and peripheral leukocytosis,

elevated creatinine kinase, and myoglobinuria are usually present.

Antimicrobial Susceptibility of S. pneumoniae

A major concern surrounding *S. pneumoniae* is the emergence of resistance to antimicrobial agents, especially penicillin.[241,503,909,1129] Pneumococci with decreased susceptibility to penicillin were first reported in the 1960s. During the 70s and 80s, penicillin resistance among *S. pneumoniae* was rare in the United States, with only 0.2% of strains showing resistance. By the mid-1990s, 35% of the aggregate pneumococcal isolates from the United States demonstrated reduced susceptibility to penicillin.[49,909] A study published in 1998 on 845 pneumococcal isolates from US medical centers found that the percentages of strains with intermediate- and high-level resistance to penicillin were 21.8% and 16.0%, respectively.[294] Studies published at the beginning of the new millennium among populations in the US national surveillance system indicated that decreased susceptibility to penicillin among *S. pneumoniae* isolates ranged from 14.7% to 35.1% depending on the geographic region, and were more commonly seen in children less than 5 years of age.[1129] Pneumococcal serotypes included in PCV7 and PSV23 accounted for 78% and 88% of the penicillin-resistant strains, respectively. A study of 1,531 clinical isolates of *S. pneumoniae* collected from 33 US medical centers during the winter of 1999 to 2000 found that 34.2% of isolates were penicillin–nonsusceptible (MIC $\geq$ 0.12 μg/mL) and 21.5% demonstrate high-level penicillin resistance (MIC $\geq$ 2 μg/mL).[293] Among 10,103 community-acquired respiratory tract isolates of *S. pneumoniae* collected in 2000 to 2001 from 206 centers in 154 regions of the United States, 38.9% showed decreased susceptibility to penicillin.[292] During the same period, decreased susceptibility to penicillin was also documented in foreign isolates of *S. pneumoniae*. In a 2003 study, the percent of strains with diminished susceptibility to penicillin was 6.5% in the United Kingdom, 9.1% in Germany, 12.4% in Italy, 36.4% in Greece, 54.5% in Spain, and 56.7% in France.[524] International data collected on 3,778 *S. pneumoniae* isolates from 1999 to 2000, found that resistance to penicillin was very high in Middle eastern countries (65.5%), Africa (64%), and Asia (60.4%), but lower in North America (40.3%), Europe (36.9%), and the South Pacific (31.8%).[106] Data from the PROTEKT US longitudinal surveillance study on 39,495 *S. pneumoniae* isolates collected in the United States from 2004 through 2008 found that the percent of isolates resistant to penicillin increased from 12.5% in 2004 to 20% in 2008.[513] Again, marked regional differences in penicillin susceptibility were noted. Isolates of *S. pneumoniae* that showed decreased susceptibility or full resistance to penicillin G were also less susceptible to other penicillins and cephalosporins of all generations, and MICs to all β-lactam agents increased as the penicillin MICs increased.[293] As a corollary to this

observation and trend, treatment failures for serious pneumococcal infections were reported with previously useful agents such as cefotaxime, cefuroxime, and ceftriaxone.[134,146,503,520]

Penicillin resistance in *S. pneumoniae* is associated with altered penicillin-binding proteins (PBPs) that have a decreased affinity for binding penicillin to the bacterial cell wall.[477] PBPs are actually transpeptidase enzymes that are involved in peptidoglycan synthesis, and six PBPs—designated 1a, 1b, 2a, 2b, 2x, and 3—have been identified in *S. pneumoniae*. Strains that are resistant show mosaic arrangements in PBP-encoding genes 1a, 2b, and 2x.[858] When penicillin resistance determinants in *S. pneumoniae* were initially described, alterations in PBP1a were reported to be essential for high-level penicillin resistance, but additional work has

shown that changes in PBP1a along with simultaneous mutations in PBPs 2b and 2x are associated with high-level penicillin and ceftriaxone resistance, with such isolates having MICs of >4 μg/mL.[394,395,478,734,856] Mutations in these genes leading to high-level penicillin and ceftriaxone resistance are seen among a wide range of pneumococcal serotypes, including serotypes 14, 19F, and 23F. Accumulated mutations in the *pbp* genes are associated with the simultaneous increases in MICs of penicillin and third-generation cephalosporins. Other non–PBP-mediated β-lactam resistance determinants are also involved in penicillin and cephalosporin resistance in *S. pneumoniae*.[125] Breakpoints for pneumococci differ depending on the site of isolation. Isolates from the CSF (i.e., meningitis) with penicillin MICs of ≤0.06 μg/ml are susceptible, and those with MICs of ≥12 μg/ml are considered resistant. For nonmeningeal infections (i.e., isolates from sites other than CSF), isolates with penicillin MICs of ≤2.0 μg/mL are considered susceptible, those with MICs of 4.0 μg/mL are intermediate, and those with MICs ≥ 8 μg/mL are considered resistant.[204]

Besides the penicillins and cephalosporins, pneumococcal resistance to several other antimicrobial agents, including macrolides, sulfonamides, and tetracyclines, and fluoroquinolones has been reported.[241,293,294,525,526,1129] In an international study published in 2004, macrolide resistance among *S. pneumoniae* isolates was highest in Asia (51.7% resistant), followed by Europe (26.0% resistant), North America (21.6% resistant), the Middle East (13.7% resistant), the South Pacific (10.6% resistant), and Africa (10% resistant).[106] Prior to 1998, the percentages of US *S. pneumoniae* strains resistant to erythromycin, clarithromycin, and azithromycin were 14.3%, 12.7%, and 11.7%, respectively.[294] For the period from 1994 through 2000, pneumococcal resistance to erythromycin increased from 23.6% to as high as 34%.[293] Data from the PROTEKT US longitudinal surveillance study conducted between 2000 and 2004

found that resistance rates for macrolide antimicrobial agents (erythromycin, clarithromycin, and azithromycin) have remained fairly stable during this time period, ranging from 27.5% and 31%.[513] In the 2010 LEADER Surveillance study, 38.5% of 803 pneumococcal isolates were resistant to erythromycin and 20.4% were resistant to clindamycin.[347] Macrolide resistance in *S. pneumoniae* is mediated either by the *erm(B)* gene or the *mef(A)* gene.[619,990,1177] The former encodes a methylase enzyme that results in resistance to the macrolide-lincosamide-streptogramin B agents, while the latter gene encodes an antibiotic efflux pump. The *erm(A)* gene is not often found in pneumococci, but other mechanisms of macrolide resistance may involve mutations in the genes encoding ribosomal proteins (e.g., proteins L4 and L22) or mutations in the rRNA (i.e., 23S rRNA).[857] Resistance to sulfonamides, particularly trimethoprim-sulfamethozaxole (SXT) has also increased substantially. The 1997 SENTRY surveillance project found that 19.8% of 845 US and 15.8% of 202 Canadian pneumococcal isolates were resistant to SXT.[294] Of 1,531 *S. pneumoniae* collected during 1999 through 2000, 30.3% were SXT-resistant.[293] The data from the 2000 to 2004 PROTEKT US survey reported that SXT resistance slightly decreased between 2000 (33.9%) and 2004 (24.1%).[513] Data from the 2010 LEADER Surveillance program placed pneumococcal resistance to SXT at 23.8%.[347] Resistance to tetracycline in North America has remained fairly stable, ranging from about 9.0% to 10.9% in the mid-1990s to between 14.6% and 15.9% in the period 2000 through 2004. However, tetracycline resistance was observed in 22.6% of 803 *S. pneumoniae* tested in the 2010 surveillance study.[347] Interestingly, fluoroquinolone resistance has been slow to develop in *S. pneumoniae*.[106] Fluroquinolone resistance in pneumococci is due to chromosomal mutations involving the *parC* gene for topoisomerase IV and the *gyrA* gene of DNA gyrase.[503] In the period from 1994 through 2000, rates of ciprofloxacin resistance ranged from 1.4% to 1.8% in the United States.[293] An international surveillance study found that only 0.4% of 1,870 pneumococcal isolates were resistant to levofloxacin, moxifloxacin, or gatfloxacin.[524] In the 2003 SENTRY study, none of over 6,000 *S. pneumoniae* isolates were resistant to levofloxacin, and less than 1% were resistant to ciprofloxacin. The PROTECKT US data for 2000 through 2004 reported levofloxacin resistance rates of 0.8% to 1.1%.[513] Low rates of fluoroquinoline resistance in *S. pneumoniae* have been corroborated in many surveillance surveys.[106,347] In a study of 803 *S. pneumoniae* isolates tested as part of the LEADER Surveillance program, 99.9% and 99.6% were susceptible to linezolid and tigecycline, respectively.[347] Ceftaroline, a broad-spectrum parenteral cephalosporin with activity against MRSA, demonstrates good activity against *S. pneumoniae*. In multicenter studies, ceftaroline inhibited 98.7% of isolates at the FDA-susceptible breakpoint of ≤0.25 μg/mL and was 16-fold more active than ceftriaxone.

This agent also showed good activity against multidrug-resistant *S. pneumoniae*, with 90% of isolates having MICs of ≤0.25 μg/mL. The 44 nonsusceptible isolates in this group had ceftaroline MICs that were only one dilution higher (i.e., 0.50 μg/mL).[331] *S. pneumoniae* remains susceptible to vancomycin. Additional information regarding antimicrobial susceptibility of *S. pneumoniae* and methods for antimicrobial susceptibility testing are found in Chapter 17.

In 2004, Arbique and coworkers[36] isolated an unusual α-hemolytic *Streptococcus* that resembled *S. pneumoniae*. Because of certain phenotypic characteristics, this organism was named *Streptococcus pseudopneumoniae*. A subsequent study conducted by Keith and colleagues[550] in New Zealand evaluated the clinical, laboratory and treatment data on 33 patients whose respiratory tract specimens grew *S. pseudopneumoniae*. These patients ranged in age from 15 to 89 years and all patients had lower respiratory tract symptoms with cough. Over 75% of the patients presented with exacerbations of COPD. A case-control study suggested that COPD was significantly more common among those patients with *S. pseudopneumoniae* than among control patients who did not have the organism in respiratory tract specimens.[550] These workers stressed that subsequent studies were needed to determine the natural habitat of *S. pseudopneumoniae* and the role of this newly described organism in other infections, including pneumonia. A subsequent study by Harf-Monteil and colleagues[428] in France determined that the organism was quite uncommon, with only a single isolate recovered over a 7-month period during which 120 isolates of *S. pneumoniae* were isolated. These workers also showed that the type strain of *S. pseudopneumoniae* had pathogenic potential in a mouse peritonitis sepsis model, while the single clinical patient isolate was avirulent. A study performed

763

in India found that the six isolates of *S. pseudopneumoniae* were the predominant or only isolate from purulent sputum specimens and all six patients had symptomatic lower respiratory tract infections.[892] In a study of the antimicrobial susceptibility profile of 95 sputum isolates of *S. pseudopneumoniae*, 32% showed reduced susceptibility to penicillin and ampicillin.[549] Among these isolates, resistance to erythromycin, azithromycin, clindamycin, and tetracycline was seen in 35%, 32%, 16%, and 45%, respectively. All isolates were susceptible to cefotaxime, ceftriaxone, cefepime, meropenem, levofloxacin, and vancomycin. Laurens and colleagues[603] also examined the susceptibility of 140 *S. pseudopneumoniae* isolates and found that 21% showed reduced susceptibility to penicillin, 57% were resistant to erythromycin, and 43% were resistant to tetracycline. All isolates were susceptible to vancomycin, levofloxacin, and gentamicin. In the study conducted by Sariya Mohammadi and

Dhanashree, all six *S. pseudopneumoniae* isolates were resistant to erythromycin and trimethoprim-sulfamethoxazole, and four had reduced susceptibility to penicillin, three were tetracycline-resistant, and two were ciprofloxacin-resistant.[892] Both *S. pneumoniae* and *S. pseudopneumoniae* belong to the Mitis Group of the viridans streptococci. Molecular genetic studies of *S. mitis* and *S. pseudopneumoniae* have identified homologues of virulence genes that are found in *S. pneumoniae*. In five *S. mitis* isolates, Johnston et al.[522] identified genes having 67% to 82% sequence homology with the pneumolysin (*ply*) and neuraminidase A (*nanA*) genes of *S. pneumoniae*, and that the *nanA* genes identified in these organisms shared 99.4% to 99.75% sequence homology with the corresponding genes of *S. pneumoniae*.

Viridans Streptococci

The viridans streptococci include several species of α- and nonhemolytic streptococci, and most of them constitute part of the normal upper respiratory and genitourinary tract microbiota. Before the 1980s, species of viridans streptococci were described entirely by their phenotypic characteristics and were placed into groups based on some of these characteristics. As shown in Box 13-2, these organisms are divided into the Mitis/Sanguinis Group, the Mutans Group, the Anginosus Group, and the Bovis Group. This section deals primarily with the Mitis/Sanguinis, Mutans, and Salivarius groups and their clinical significance. Because of certain unique characteristics and their clinical manifestations, the Anginosus and Bovis Groups will be described in subsequent sections. Analysis of the viridans streptococci by molecular and genetic techniques and expanded batteries of phenotypic tests has considerably altered the taxonomy of the viridans streptococci.[1017] Emended descriptions of well-recognized species (e.g., *S. mitis*, *S. sanguinis*) have been published over the years and several new species have emerged with the availability of molecular techniques such as 16S rRNA sequencing. The frequency of isolation and the roles of these newer species in infectious diseases await clarification as more data and case reports appear in the literature.

Viridans streptococci in Mitis/Sanguinis, Mutans, and Salivarius Groups are involved in about 20% of cases of subacute bacterial endocarditis, and in this setting cause a sustained bacteremia, leading to their recovery from multiple sets of blood cultures. Viridans streptococcal endocarditis occurs most frequently in individuals with preexisting native valvular disease due to rheumatic or congenital heart disease, in particular, or may also involve prosthetic valves. Sources of the organisms causing infective endocarditis are usually the oropharynx, the urogenital tract, and the gastrointestinal tract. Poor oral hygiene and/or periodontal disease are often noted in patients with infective endocarditis. Oral surgery and other invasive procedures (e.g.,

fiberoptic sigmoidoscopy, upper gastrointestinal endoscopy) can cause transient bacteremias that may initiate vegetations on previously damaged heart valves. Viridans streptococcal endocarditis presents insidiously, with fever, fatigue, and weight loss being the most common findings. Heart murmurs, peripheral stigmata of endocarditis (e.g., splinter and conjunctival hemorrhages, petechiae), and vegetations on the heart valves are frequently present. Complications of viridans streptococcal endocarditis include multi-valvular disease, mitral valve aneurysms, paravalvular abscesses and glomerulonephritis associated with circulating immune complexes. Reference identifications of viridans streptococcal species associated with subacute bacterial endocarditis have found that *S. mitis*, *S. sanguinis*, *S. parasanguinus, S. oralis*, *S. gordonii*, *S. mutans*, *S. salivarius, S. vestibularis*, and *S. sinensis* are the viridans streptococci most frequently found in endocarditis. The new viridans streptococcal species *S. tigurinus*, was first described in a 74 year old male with endocarditis complicated by meningitis and spondylodiscitis.[1169]

While transient bacteremias are usually cleared without any adverse effects, prolonged bacteremia with viridans streptococci in neutropenic patients undergoing cancer chemotherapy or human stem cell transplantation is a recognized clinical entity that occurs in both adult and pediatric patients.[15,144,257,420,677,792,1052] In this setting, bacteremia is associated with aggressive cytotoxic chemotherapy for treatment of leukemias (particularly acute myeloid leukemia), lymphomas, solid tumors, and bone marrow transplantation. Viridans streptococcal bacteremia generally occurs 8 to 21 day after preceding chemotherapy at a median of 6 to 7 days after onset of neutropenia. Risk factors for viridans streptococcal bacteremia include administration of high-dose cytotoxic agents (e.g., especially high-dose cytarabine), presence of oral mucositis secondary to cytotoxic chemotherapy or radiation, presence of indwelling lines (e.g., Hickman catheters), and profound neutropenia.[15,420,792] Oral mucositis, mucosal lesions in the gastrointestinal tract, and indwelling lines serve as portals of entry into the bloodstream.[35,257] In this regard, poor underlying dental health and periodontal disease are also risk factors for the development of viridans streptococcal bacteremia in neutropenic hosts.[393] Viridans streptococcal bacteremia in these patients may be complicated by the development of adult respiratory distress syndrome (ARDS), hypotension, shock, and bacterial endocarditis.[15,782] Streptococcal species associated with neutropenic bacteremia include *S. mitis*, *S. oralis*, *S. salivarius*, *S. sanguinis, S. gordonae; S. parasanguinis,* and *S. vestibularis,* with *S. mitis* being the predominant species isolated from blood cultures of patients with malignancies. (Box 13-2).[35,421] In the past, this syndrome was associated

with severe complications in 15% to 40% of patients and a high mortality rate of up to 20%, but recent studies have documented fewer complications (about 7%), with mortality attributable to viridans streptococcal bloodstream infection at less than 2%.[15,485,677,792] Improved outcomes in these patients are likely due to better diagnostic capabilities and supportive care for neutropenic patients in intensive care settings. Bacteremic infections with viridans streptococci have also been reported in low-birth-weight term and preterm neonates. Mothers often have risk factors that adversely affect pregnancy outcomes, including chorioamnionitis, premature rupture of fetal membranes, premature onset of labor, and urinary tract infection at the time of delivery.

Viridans streptococci may rarely be isolated from other serious infections, such as meningitis, pneumonia, and other miscellaneous infections, particularly in compromised hosts. Meningitis caused by viridans streptococci may occur in both adults and children, and the clinical presentation differs little from that of the other pyogenic meningitides (i.e., nuchal rigidity, seizures, meningeal inflammation, and altered mental status).[362,659,1169] The source of the organism is usually endogenous and associated with congenital structural abnormalities of the head and neck, head and neck infections (e.g., odontogenic maxillary sinusitis, mastoiditis), endocarditis, or extracranial infections.[539,843,1169] Previous head trauma or neurosurgical procedures (e.g., craniotomy) are risk factors for and have been associated with the development of viridans streptococcal meningitis.[173,659] Complications include intracranial suppuration and cerebral vasculitis.[659] Other CNS infections such as brain abscess may occur following cranial trauma or surgery, or secondary to a primary focus of infection elsewhere via direct extension from a contiguous site or via the hematogenous route.[539] Direct extension may occur from dental infections, paranasal sinus infections, or otogenic sources. Brain abscesses are usually singular, located in the frontal or temporal lobes, and may be polymicrobial. Predisposing conditions for viridans streptococcal brain abscess include congestive heart failure, chronic otitis media, otogenic infections, head injuries with CSF rhinorrhea, sinusectomy, immunosuppression, and craniotomy followed by ventriculoperitoneal shunt placement.[843,1094] Bacteremic viridans streptococcal pneumonia has been reported but is rare. Viridans streptococcal pneumonia occurs in older patients in the setting of oropharyngeal aspiration.[1018] These patients often have poor dentition, carious lesions, COPD, and underlying medical conditions such as diabetes. Complications (e.g., empyema, lung abscesses) associated with viridans streptococcal pneumonia are also rare. However, in one series describing organizing pneumonia that mimicked lung carcinoma, viridans streptococci and saprophytic *Neisseria* species were identified as the sole etiologic agents in 55.6% of 27 cases.[1150] Most of the patients were male and between 41 and 80 years of age. The resected tumors were variable in size (1.5 to 8.5

cm), sharply demarcated, showed inflammation with organization, and sometimes were associated with bronchial necrosis. Miscellaneous infections caused by various species of viridans streptococci have included septic arthritis, vertebral osteomyelitis secondary to bacteremia/endocarditis, pericarditis, Lemierre's syndrome, and infectious crystalline keratitis.[626,800,1047,1049,1066,1158]

Certain viridans streptococci in the oral cavity are associated with the initiation and pathogenesis of dental caries. *S. mutans*, *S. sobrinus*, and other members of the Mutans Group of oral streptococci produce enzymes called **glucosyltransferases**, which hydrolyze dietary sucrose (a disaccharide of glucose and fructose) and connect the glucose moieties together in α1,6 and α1,4 glycosidic linkages to form insoluble glucans.[51,472,582] Glucans enable bacteria to adhere to the tooth surfaces of the teeth and form the matrix of dental plaque. Attachment of *S. mutans* and other organisms to the insoluble, adherent glucans and subsequent formation of acid leads to demineralization of the tooth enamel and the initiation of carious lesions.[51] Other oral streptococci, including *S. sanguinis*, *S. salivarius*, and possibly *S. gordonii*, are able to synthesize similar polysaccharides, but only the streptococci within the Mutans Group display sucrose-induced enhancement of oral colonization. Molecular approaches for direct detection of *S. mutans* in plaque and gingival samples have been developed and monoclonal antibodies against *S. mutans* are used by workers in dental microbiology for identification and enumeration of these organisms in saliva and dental plaque specimens.[51,561] Epitopic regions of these glucosyltransferase enzymes are being identified in efforts to develop a component vaccine against dental caries.[473]

In the past, the viridans streptococci were generally susceptible to penicillin, ampicillin, and most other antimicrobial agents. However, antimicrobial susceptibility surveys of viridans streptococci have clearly shown that resistance to several classes of antimicrobial agents is increasing.[651] In 2001, Levy and colleagues[635] reported two patients with endocarditis caused by penicillin-resistant strains of *S. mitis* and *S. sanguinis*, respectively. Among 50 blood isolates from Memorial Sloan-Kettering Cancer Center, 44% were penicillin-resistant.[1052] In the 2010 LEADER Surveillance program, 29.9% of 411 viridans group streptococci had penicillin MICs of ≥0.12 μg/mL, and 53.5% and 9.7% were resistant to erythromycin and clindamycin, respectively.[347] In the same survey, resistance to levofloxacin increased from 5.9% to 8.5% in the period from 2006 through 2010. A 2011 study from Turkey documented penicillin and erythromycin resistance rates for 50 blood culture isolates at 30% and 36%, respectively.[313] Resistance to third- and fourth-generation cephalosporins (e.g., cefotaxime, cefepime) has also been reported, with rates as high as 30% to 41%.[420] Among the viridans group streptococci, *S. mitis* strains show the highest levels of antimicrobial resistance. A study published in 2004 from Finland found that *S. mitis* constituted 82% of the viridans streptococci isolated from neutropenic patients, and

that 5% and 4% of these *S. mitis* isolates exhibited high-level resistance to penicillin (MIC ≥ 4 μg/mL) and cefotaxime (MIC ≥ 4 μg/mL), respectively.[666] In a 2006 study of isolates recovered from blood cultures of cancer patients, 28% of 25 *S. mitis* isolates were resistant to penicillin, with MICs ranging from 4 to 12 μg/mL, while none of the 15 non- *S. mitis* isolates were penicillin-resistant.[421] *S. mitis* isolates also showed higher rates of resistance to the fluoroquinolones than non- *S. mitis* strains, although all 50 isolates tested in the study showed fluoroquinolone resistance rates ranging from 44% to 64% depending on the agent. The mechanism of penicillin resistance involves altered PBPs due to mutations in *pbp2b* and *pbp2x* genes; these genes were likely transferred

765

to *S. pneumoniae* from viridans streptococci.[1177] Erythromycin intermediate and resistant phenotypes are mediated by mutations in *ermB*, *mefA,* and *mefB* genes, alone and in combinations, and the prevalence of strains carrying these mutations vary from place to place.[313,651,1177] Linezolid, daptomycin, tigecycline, and vancomycin remained highly active against the viridian streptococci, with rates of susceptibility ranging from 99.8% to 100%.[347,527,870]

The Anginosus Group: *Streptococcus anginosus, Streptococcus constellatus*, and *Streptococcus intermedius*

Organisms belonging to the Anginosus group have gone through repeated taxonomic revisions. British taxonomy refers to these species as the "*Streptococcus milleri*" group, and this pneumonic is still seen in the literature. Anginosus group streptococci correspond to three species—*S. intermedius, S. constellatus,* and *S. anginosus*—that form small, "minute" colonies on agar media. These organisms can be nonhemolytic, α-, or β-hemolytic; β-hemolytic isolates may carry Lancefield group antigens (group A, C, F, or G) or may be nongroupable. The small-colony size and the matte appearance of the colonies distinguish these group C and G Anginosus Group organisms from the "large-colony" β-hemolytic streptococci (*S. dysgalactiae* subspecies). Most *S. anginosus* isolates are nonhemolytic, while more than half of *S. constellatus* strains may be β-hemolytic; isolates of *S. intermedius* are rarely β-hemolytic. These organisms are part of the human oropharyngeal microbiome and may be isolated from the throat, the nasopharynx, and the gingival crevices. They are also found in the

gastrointestinal tract and in the vagina. A subspecies of *S. constellatus*—*S. constellatus* subsp. *pharyngis*—was described that expresses the group C antigen and is associated with phayngitis.[1127] In 2012, a molecular taxonomic study of this group used MLSA, 16S rRNA sequencing, and phenotypic tests to divide the Anginosus Group into seven distinct clusters, including two clusters of β-hemolytic, Lancefield group C-bearing members that suggested two new subspecies. *S. anginosus* includes two subspecies —*S. anginosus* subsp. *anginosus* and *S. anginosus* subsp. *whileyi*. *S. constellatus* includes three subspecies: subsp. *constellatus,* subsp. *pharyngis*, and subsp. *viborgensis*.[515] Virulence of this group may be related to the presence of a capsule on some strains, production of a partially characterized immunosuppressive protein, and the production of a variety of hydrolytic and glycosaminoglycan-degrading enzymes (e.g., neuraminidase, DNase, chondroitin sulfate depolymerase, and hyaluronidase).[716,1126] In vitro studies have shown that the Anginosus Group streptococci inhibit polymorphonuclear leukocyte chemotaxis and are ingested by PMNs more readily than *S. aureus*; once ingested, however, they are killed more slowly than *S. aureus*.[1105] *S. intermedius* strains also produce a staphylococcal leukocidin-like toxin called **intermedilysin** that may be virulence-associated, although neither the toxin nor its genes are found in *S. constellatus* or *S. anginosus.*[401,667,743]

S. intermedius, *S. constellatus*, and *S. anginosus* are recognized for their propensity to cause purulent tissue abscesses, intra-abdominal infections, pulmonary infections, bacteremia, CNS infections, oral infections, and endocarditis. Bacteremia is usually attributable to a focus of infection within the gastrointestinal or upper respiratory tract. Supperative metastatic abscesses are a significant complication of bacteremia, with *S. intermedius* and *S. constellatus* being more often associated with abscess formation than *S. anginosus*.[174] *S. anginosus* is involved in mixed infections having gastrointestinal or genitourinary sources. Up to 40% of infections caused by Anginosus Group streptococci are intra-abdominal infections that develop following gastrointestinal surgery or as a result of colonic perforation caused by trauma or other gastrointestinal lesions (e.g., colonic carcinoma). Complications include appendicular, subphrenic and pancreatic abscesses, pyogenic liver abscesses, and peritonitis.[150,296,427,673,702,735,756,891] Mucosal bowel trauma and disease apparently facilitate bloodstream invasion. *S. anginosus* and *S. constellatus* bacteremias have occurred in patients with vascular graft infections secondary to vasculo-digestive fistulas, sigmoid diverticulitis, severe postsurgical wound infections, peritonitis, and chorioamnionitis following gynecologic surgical procedures (e.g., cesarean delivery).[100,606,735,1042] Anginosus Group bacteria are significant pathogens in solid-organ transplant recipients, particularly liver, kidney, combined kidney/liver, pancreas, and small bowel transplants, causing intra-abdominal abscesses, pleural empyemas, and recurrent cholangitis due to biliary stricture and inflammation.[932,965] Potentially

lethal complications related to bacteremia include septic shock, pulmonary infections, central nervous system infections, and endocarditis. These organisms are causative agents in 8% to over 30% of skin and subcutaneous infections, and may cause severe soft tissue infections in patients with underlying conditions such as HIV infection, uncontrolled diabetes, and intravenous drug use.[1157] Osteomyelitis due to the Anginosus Group can arise from hematogenous dissemination, but more frequently occurs due to a contiguous infected site (e.g., decubitus ulcers).[399,562] Osteolytic lesions caused by these bacteria have been documented in infected foot wounds, and mandibular, cranial, and vertebral infections, and required aggressive management. Like other viridans streptococci, Anginosus Group streptococci cause bacteremia in neutropenic patients with underlying diseases who are being treated with cytotoxic regimens, although fulminant bacteremia in previously healthy individuals may also occur. These pathogens are also emerging as veterinary pathogens. In 2012, the first report appeared describing *S. constellatus* as a cause of deep chronic pyoderma in a 4-year-old male hound.[271]

Anginosus Group organisms resident in the oral cavity may cause a variety of supperative periodontal, maxillofacial, and head/neck infections, including periapical abscess, lymphadenitis, endophthalmitis, and brain abscesses.[131,185,453,716,773,802,1149]Pleuropulmonary and head and neck infections often occur as mixed-flora infections that can spread contiguously into the soft tissues via fascial planes and that can serve as a source for hematogenous dissemination and its complications. Organisms from infected dental sites, paranasal sinuses, soft tissues, and peritonsillar regions may spread by direct extension to involve the cranium, orbit,

deep tissue spaces in the neck, and the central nervous system. A review of cases in Japan from 2002 to 2003 described 17 patients with head and neck infections due to the Anginosus Group.[453] Orofacial infections included maxillary sinusitis, peritonsillar, subcutaneous, submandibular, and retropharyngeal space infections, with deep neck, mediastinal, parotid, tonsillar, and masseter muscle involvement.[453] Anaerobic bacteria were co-isolated from one-third of the patients' lesions. Descending, fatal, deep neck space infection due to *S. anginosus* occurred in a liver transplant recipient.[131] The patient developed a crepitant neck mass involving the tonsillar region and extending down into the mediastinum. Park et al.[802] described necrotizing fasciitis due to *S. anginosus* and *Bacteroides* species in a patient due to periapical abscesses surrounding several molars and pyomyositis of the masseter muscles. *S. constellatus* was isolated from a man who developed septic shock immediately following extraction of an infected lower molar.[760] The clinical course was further complicated by septic emboli

to the brain. *S. anginosus* thyroiditis with bacteremia and abscess formation were described in two patients who presented with space-occupying neck lesions on CT and MRI accompanied by changes in thyroid function tests.[1149] Lemierre's disease associated with *S. intermedius* bacteremia was described in a middle-aged woman who presented with pharyngitis following a tooth cleaning.[407] Scans revealed a neck mass with a thrombus in the left jugular vein extending into the sigmoid sinus and chest roentgenogram showed bilateral infiltrates and pleural effusions. Pulmonary infections can result from aspiration of oropharyngeal contents, leading to pneumonia, which may be complicated by empyema and lung abscesses. Anginosus Group bacteria have also been isolated from sputum specimens of cystic fibrosis patients in association with disease exacerbations and clinical deterioration.[401,807,930] Brain abscesses caused by all three Anginosus group members have been described in young previously healthy children, middle-aged adults, and the elderly.[110,185,316,566,716,843,883] Diagnosis and treatment often required brain biopsy and drainage. In one case, a young, previously healthy male initially presented with an abdominal pain due to a splenic abscess; *S. intermedius* was isolated from blood and pus drained from the abscess.[673] Two weeks later, the patient returned with a recurrence of the splenic abscess plus three abscesses in the frontal and occipital lobes of the brain. Aspirates from the splenic abscess and brain lesions failed to grow the organism, but the lesions resolved on ertapenem therapy. *S. constellatus*, along with *Actinomyces viscosus*, was isolated from subdural empyema fluid from a 7-year-old girl with poor oral hygiene and multiple dental caries. Multiple brain abscesses subsequently developed despite therapy, leading to a fatal outcome.[110] Multiple brain abscesses due to *S. constellatus* were diagnosed in a middle-aged male who initially presented with endogenous endophthalmitis.[185]

S. constellatus, S. intermedius, and S. anginosus have been involved as causes of rare but severe endocarditis and septic shock.[235,252,793,1039,1146] Tran and colleagues[1039] described a patient with mitral valve endocarditis where the organism originated from liver multiple liver abscesses that required chemotherapy and several percutaneous drainage procedures to clear the bacteremia. *S. constellatus* endocarditis involving the aortic bicuspid valve and the mitral valve and requiring replacement of both was described in a patient in Italy. The isolate was broadly susceptible, but resistant to penicillin G. Woo and colleagues reported 6 cases of Anginosus Group endocarditis out of 377 cases of endocarditis that occurred in Hong Kong over a 5-year period. Five patients had underlying diseases (i.e., rheumatic heart disease, ischemic heart disease, COPD, supraventricular tachycardia) and one was an IV-drug user. All isolates from these patients were identified as *S. anginosus*. *S. anginosus* endocarditis was complicated by endogenous endophthalmitis in a 60-year-old male patient; the source of the isolate was likely the oral cavity, and the patient required

total dental extraction to clear his bacteremia.[499]

Anginosus Group isolates are generally susceptible to a variety of antimicrobial agents, but resistance to some agents is emerging. A 1999 examination of 180 Anginosus Group isolates found that 94.4%, 92.8%, 87.1%, 97.3%, and 97.3% of isolates were susceptible to penicillin, ampicillin, cefuroxime, cefazolin, and cefotaxime, respectively.[646] Individual case reports have cited resistance to penicillin in otherwise susceptible isolates.[235,453] A study of 44 genotypically characterized strains found no penicillin resistance among 12 *S. intermedius*, 16 *S. constellatus*, and 16 *S. anginosus* isolates, although four isolates showed decreased susceptibility to penicillin and four isolates were intermediate to ampicillin; all isolates were ceftriaxone susceptible.[1038] A study of 22 β-hemolytic group C *S. anginosus* and 5 *S. constellatus* isolates found that all were susceptible to penicillin, cefotaxime, and vancomycin; one *S. constellatus* was resistant to levofloxacin and 10% to 20% of all isolates were resistant to erythromycin and clindamycin.[174] Other studies and case reports have documented emerging MLS (macrolide–lincosamide–streptogramin) resistance.[646,1039] A 1999 study found that 17.7% and 18.3% of 180 strains tested were resistant to erythromycin and clindamycin, respectively.[646] Surveillance studies indicate that erythromycin resistance may be found in 3.2% to 17.7% of isolates, depending on geographic location, and only slight differences have been noted in MLS resistance among the three anginosus group species.[502,1038] Genetic analysis of some MLS-resistant strains has documented the presence of *erm* (B), *erm* (TR), and *mef* (A)- *mef* (E) genes that result in constitutive erythromycin resistance, inducible macrolide resistance, and macrolide efflux-mediated resistance, respectively.[174] Most Anginosus Group isolates are resistant to aminoglycosides and about 30% of isolates may be resistant to fluoroquinolones.[756,965] A daptomycin-resistant *S. anginosus* isolate (MIC, 4 μg/mL) caused breakthrough bacteremia in a 47-year-old male patient after 21 days of daptomycin therapy.[793] The isolate was otherwise susceptible to all agents including the macrolides.

Group D Streptococci: The "*Streptococcus bovis*" Group

Group D streptococci are found among the intestinal flora of vertebrates. These streptococci have the group D cell wall antigen that is composed of lipoteichoic acid. Formerly, group D species that were predominant normal inhabitants of the human gastrointestinal tract were called group

D enterococci on the basis of a growth on bile esculin agar and growth in 6.5% NaCl broth, whereas other streptococci that possessed the group D antigen and grew on bile esculin agar but failed to grow in salt broth were termed "nonenterococcal Group D streptococci." The practical consideration behind this division was that the enterococci are more resistant to penicillins, cephalosporins, and aminoglycosides than nonenterococcal group D streptococci. In the mid- to late 1980s, the enterococcal group D streptococci were reclassified in the new genus *Enterococcus*, while the group D nonenterococcal species remained in the genus *Streptococcus*. Nonenterococcal group D streptococci were designated as *S. bovis* or *S. equinus*. *S. bovis* strains were divided into two biotypes based on mannitol fermentation: *S. bovis* biotype I strains were mannitol-positive, while biotype II (or *S. bovis* variant) strains were mannitol-negative. *S. bovis* biotype II was further divided by β-glucuronidase (β-GUR): *S. bovis* II.1 were β-GUR-negative, while *S. bovis* biotype II.2 were β-GUR-positive.

Beginning in 1984, extensive taxonomic changes were proposed for organisms in the "*S. bovis*" group, and several new species designations were proposed and rejected over the subsequent 20 years. Because the name "*Streptococcus gallolyticus*" had taxonomic precedence over *S. bovis* and related organisms prior to the species reorganization, this name has been appropriated for members of the former *S. bovis* group.[902,947] Clinically important species in the group D streptococci are *S. gallolyticus* subsp *gallolyticus* (formerly *S. bovis* I), *S. gallolyticus* subsp. *pasteurianus* (formerly *S. bovis* II.2), and *S. infantarius* (formerly *S. bovis* II.1), which includes two subspecies, subsp. *coli* and subsp. i *nfantarius*.[64,900] *S. gallolyticus* subspecies are also found in several animals as inhabitants of the gastrointestinal tract, and strains of *S. gallolyticus* subsp. *gallolyticus* have been isolated from the feces of cows, horses, pigs, dogs, guinea pigs, and the rumen of sheep.[64] The type strain of *S. bovis* was originally recovered from cow dung and differs phenotypically from human isolates. Some strains also cause septicemia and meningitis in pigeons, ducks, broiler chicken flocks, and other animals.[165,636] Sequencing of the genome of *S. gallolyticus* subsp. *gallolyticus* has revealed several unique features that may enable this organism to adapt to the colonic environment of a wide spectrum of animals, including humans.[878] These characteristics include its ability to synthesize all 20 amino acids and several vitamins, its ability to degrade a variety of carbohydrates of plant origin, and the production of a variety of enzymes (e.g., tannase, phenolic decarboxylases, and bile-acid hydrolases). *S. bovis*-like strains isolated from the gastrointestinal tracts of pigs and chickens have been identified as *S. alactolyticus*. *S. equinus* corresponds to certain equine "*S. bovis*" strains and human isolates of "*S. equinus"* were actually *S. bovis*. These studies confirmed that *S. alactolyticus* and *S. intestinalis* are identical as well. In 2008, two new animal

streptococcal species, *S. henryi* and *S. caballi*, were isolated from the hindgut of horses with equine laminitis.[714] Although these two species are genotypically most closely related to *S. suis*, certain phenotypic characteristics are similar to those for *S. gallolyticus* (e.g., bile esculin–positive, no growth in 6.5% NaCl, positive reaction with group D antisera [*S. henryi* only]).

S. gallolyticus (S. bovis) causes bacteremia, meningitis, and native and prosthetic valve endocarditis.[444,575,617,1084] An important clinical correlate of *S. gallolyticus* bacteremia is its association with colorectal carcinoma.[99,243,563] In a case–control study done in Spain, colonoscopy was performed on 98 of 109 patients with *S. gallolyticus* subsp. *gallolyticus* bacteremia. Sixty-nine cases of colorectal neoplasia were detected, including 12 invasive carcinomas and 57 adenomas (including 39 advanced lesions).[243] The prevalence of bacteremia with this organism in 196 matched control patients with other underlying disease or malignancies (32%) was lower than those patients with colorectal neoplasia (70%). *S. gallolyticus* endocarditis may also occur as a complication of bacteremia.[563,575] In some cases, the isolation of this organism in association with endocarditis often prompts a search for colorectal neoplasms. In a 2012 case report, a 76-year-old man presented with a prosthetic knee joint infection with *S. gallolyticus*. The patient underwent colonoscopy and an adenocarcinoma of the ascending colon was detected.[642] *S. gallolyticus* is found significantly more often in the stool of patients with colorectal malignancies than in that of healthy controls. Associations have also been noted between *S. gallolyticus* bacteremia, liver disease, inflammatory bowel disease, idiopathic ulcerative colitis, and chronic radiation enterocolitis.[3] Underlying colonic disease may affect the colonic microbiota, leading to the accumulation of different, novel materials (e.g., plant-derived carbohydrates and fibers) in the vicinity of colonic dysplasia and creating an environment for the proliferation of *S. gallolyticus*.[878] Changes in hepatic secretion of bile or immunoglobulins into the intestinal lumen may promote the overgrowth of *S. gallolyticus* and the movement of the organisms from the intestine into the portal venous circulation.[3] In vitro studies have also established that *S. gallolyticus* is able to adhere to and subsequently invade human endothelial cells.[1099] Failure of the hepatic reticuloendothelial system to contain the organisms results in bacteremia and endocarditis. Patients with *S. gallolyticus* bacteremia, endocarditis, or meningitis should have a colonoscopy to detect occult gastrointestinal lesions. *S. gallolyticus* meningitis and bacteremia may also occur in patients with no underlying malignancies. Some evidence suggests that *S. infantarius* subspecies may be associated with noncolonic cancers.[242] In a retrospective study of all "*S. bovis*" group bacteremias in Spain from 1988 through 2007, *S. gallolyticus* was isolated from 48.5% of 105 bacteremias associated with colon tumors, while *S. infantarius* was isolated from

11%.[242] For 28 bacteremias occurring in noncolonic cancer patients, *S. infantarius* was isolated from 57%, while *S. gallolyticus* was isolated from only 6%. The 16 noncolonic cancers associated with *S. infantarius* bacteremia included biliary tract and pancreatic cancer (12 patients) and cholangitis. Laboratories should report the isolation of *S. gallolyticus* subspecies to clinicians, but should also report the former species names (e.g., *S. bovis* I, *S. bovis* II.1, and *S. bovis* II.2) in the same report in order to avoid confusion and the omission of diagnostic steps (e.g., colonoscopy) that may be lifesaving for the patient.[1081]

Other *S. gallolyticus* subspecies are also emerging as causes of serious human infections. *S. gallolyticus* subsp. *pasteurianus* is increasingly being reported as an agent of bacteremia and meningitis in children and adults.[350,569,742,787,846,1019]

768

Children with meningitis due to this organism have included preterm infants and neonates from 5 to 13 days old. In one case report, the infant was born at home to a mother with a history of exposure to farm animals (i.e., chickens, horses, dogs, cats, dairy cattle) and 1 week prior to delivery, 70 baby chicks died of an unknown illness.[569] *S. gallolyticus* subsp *pasteurianus* was also the cause of a cluster of bloodstream infections in five infants in a neonatal intensive care unit.[350] Although no source was identified for the organism, it was surmised that one of the first three neonatal cases was the index case and that caregivers likely infected the other infants via transient hand carriage. The first case of adult meningitis and bacteremia due to *S. gallolyticus* subsp. *pasteurianus* was described in a 75-year-old man with a history of prostate cancer that was treated by radiation; the patient subsequently developed radiation proctitis, which was believed to be the portal of entry for the organism.[973] *S. gallolyticus* subsp *pasteurianus* meningitis was also described in a 61-year-old patient who had no underlying history of colonic lesions or other malignancies, but had experienced painful hemorrhoids during the previous 2 weeks that were associated with intermittent low-level rectal bleeding on defecation.[948] In 2008, *S. gallolyticus* subsp. *macedonicus* was detected as the etiologic agent of multivalve infective endocarditis in a 61-year-old man.[674] A retrospective review of endocarditis isolates at the Mayo Clinic revealed a case of *S. gallolyticus* subsp. *macedonicus* native mitral valve endocarditis that occurred in 1978 in a 70-year-old-man.[446] This patient also had documented gastrointestinal pathology (i.e., a cecal polyp). *S. gallolyticus* subsp. *macedonicus* (formerly *S. macedonicus* and *S. waius*) is an α-hemolytic species that was originally isolated from Greek cheese and skim milk biofilms.[675,900,1048] Bacteremia and hematogenous dissemination of *S. gallolyticus* subspecies can result in a several other types of clinical presentations. *S. gallolyticus* subsp. *pasteurianus* has

been isolated from intrauterine infections and postpartum bacteremia, spontaneous bacterial peritonitis, brain abscess, septic discitis, and continuous ambulatory peritoneal dialysis-associated peritonitis.[85,309,471,1138,1156] Septic arthritis has been reported in patients with infective endocarditis, liver cirrhosis, and as the presenting sign in patients with "silent" colonic carcinoma.[256,368,745] Penicillin remains highly active against most strains of *S. gallolyticus*, although occasional isolates may show diminished susceptibility to penicillin.

Enterococcus Species

Taxonomy

The genus *Enterococcus* includes the enterococcal members previously classified with the group D streptococci.[903,904] Enterococci are microbiota of humans and animals. They are normal residents of the gastrointestinal and biliary tracts and, in lower numbers, of the vagina and male urethra. Enterococci produce smooth, gray colonies that are either non-hemolytic or alpha-hemolytic (Image Plate 13-3E). The taxonomy of *Enterococcus* species has undergone considerable change since the mid-1980s. Before the widespread use of genetic techniques for taxonomic analysis, enterococci were distinguished from streptococci and related taxa by their ability to grow at 10°C and 45°C, growth in the presence of 6.5% NaCl, growth at pH 9.6, ability to hydrolyze esculin in the presence of 40% bile, and production of pyrrolidonyl arylamidase (PYR). More than 90% of strains also possessed the Lancefield group D lipoteichoic antigen in their cell walls. Molecular studies have revealed several species that are members of the genus *Enterococcus* by genetic criteria, but that lack many of the phenotypic characteristics typical of the genus (Box 13-5). Most of these species are not often found in human clinical specimens. *Enterococci* have emerged as important agents of human disease, largely because of their resistance to antimicrobial agents to which other streptococci are generally susceptible. In vitro, enterococci have penicillin MICs that are 10- to 100-fold higher than for other streptococci, are resistant to most cephalosporins, and are nonsusceptible to the aminoglycosides. Enterococci are important agents of nosocomial infections in the United States, ranking as the second most common organisms causing bloodstream, urinary tract, and skin/soft tissue infections.[37] *E. faecalis* is the most commonly isolated species, causing about 70% of human infections. However, enterococci with acquired resistance to vancomycin (VRE, vancomycin-resistant enterococci) now account for more than 30% of enterococcal infections, and greater than 90% of VRE isolates are *E. faecium*. Only about 5% to 10% of *E. faecalis* isolates are vancomycin-resistant.[451] The emergence of VRE as nosocomial pathogens is related to the increased use of

vancomycin and broad-spectrum agents like third-generation cephalosporins. Because of their resistance to penicillins and cephalosporins of several generations, the acquisition of high-level resistance to aminoglycosides, resistance to clindamycin, and emergence of vancomycin resistance, these bacteria are often involved in serious superinfections among patients receiving broad-spectrum antimicrobial chemotherapy.

Virulence Factors

Unlike other streptococcal species discussed thus far, factors that determine virulence of the enterococci are not well understood, but ongoing research and study of these organisms has revealed several putative microbial virulence factors in enterococci.[895]About 30% of *E. faecalis* strains produce an extracellular **cytolysin/hemolysin** that acts on human, rabbit, and equine erythrocytes but not bovine or ovine erythrocytes and has demonstrable toxicity in rabbit endophthalmitis and endocarditis models.[37,102,194,516] This cytolysin/hemolysin is cidal for a number of eukaryotic cell types, including macrophages, and polymorphonuclear neutrophils. Other secreted enterococcal virulence factors include two proteases: gelatinase (GelE) and extracellular serine protease (SprE). GelE protease degrades host tissue proteins and is also involved in the activation of enterococcal autolysins and the development of biofilms.[791,1023] GelE may also be involved in the translocation of enterococci across intestinal cell barriers and the development of peritoneal infections.[1172] There is also evidence suggesting that these molecules may cause modulation of the immune response by inactivation of complement proteins.[805] **Aggregation substance proteins** are surface-bound, plasmid-encoded proteins that promote clumping of the organisms to facilitate plasmid exchange.[194] Aggregation substance proteins facilitate enterococcal adherence to cultured intestinal and renal epithelial cells and promote aggregative growth of cardiac vegetations in animal endocarditis models.[905,1110] Other studies suggest that aggregation substance may be involved in binding of *E. faecalis* to neutrophils and cultured intestinal epithelial cells and in subsequent internalization and intracellular survival of these organisms.[784,851,1080] Plasmids encoding aggregative substance proteins also carry antibiotic resistance genes. *E. faecalis* and *E. faecium* produce a unique surface protein termed called **Esp (extracellular surface protein**) and **Esp**$_{fm}$ that enable the organisms to evade antibodies by their ability to be retracted away from the cell surface. These molecules are involved in formation of biofilms and play roles in the pathogenesis of endocarditis and UTIs in animal models.[439,440,628,791,916] **Ace** and **Acm**, found in *E. faecalis* and *E. faecium*, respectively, are members of the MSCRAMM (microbial surface components recognizing adhesive matrix molecules) group, specifically bind to collagen and laminen, and play roles as virulence factors in animal endocarditis

models.[519,652,748,939]Pili are also found on the enterococcal cell surface and are involved in attachment, biofilm formation, and the pathogenesis of UTIs and endocarditis in animal models.[749,938] In *E. faecalis*, cell surface-associated polysaccharides encoded by the ***cps* (capsular polysaccharide) locus, LTAs,** and **Epa (enterococcal polysaccharide antigen**) enable these organisms to resist complement-mediated opsonization and phagocytosis, facilitate organism translocation across cellular membranes, and play pivotal roles in the pathogenesis of enterococcal urinary tract and peritoneal infections.[1016,1020,1026] Most *E. faecalis* and some *E. faecium* isolates from bacteremias produce large amounts of extracellular superoxide dismutase that may enhance enterococcal virulence in mixed-flora abscesses. Correlations have also been found between possession of various virulence factors described above and the presence of antibiotic resistance among clinical and environmental strains of *E. faecalis* and *E. faecium*.[854]

769

BOX 13-5

Members of the Genus *Enterococcus*

Group/Species	Comments
Group 1	
Enterococcus avium[225]	This species is found in avian, canine, and human gastrointestinal tracts. This species may carry Lancefield group D and group Q antigens and produce H_2S. *E. avium* has been isolated from humans as a cause of bacteremia, osteomyelitis, endocarditis, meningoencephalitis, breast prosthesis infection, and brain abscesses.[8,246,277,314,528,715,722,741,816,986,1000] Bacteremia with *E. avium* is commonly of gastrointestinal or biliary origin and is often polymicrobial.[741]
Enterococcus gilvus[1058]	This 2002 species was originally isolated from bile of a patient with cholecystitis.
Enterococcus malodoratus[225]	This species was isolated from Gouda cheese and unpasteurized milk products. It is the only *Enterococcus* species that produces H_2S.
Enterococcus pallens[1058]	*E. pallens* was originally isolated from a peritoneal dialysate of a patient with peritonitis.
Enterococcus pseudoavium[211]	*E. pseudoavium* was first isolated from cases of bovine mastitis and is a rare human isolate.
Enterococcus raffinosus[211]	*E. raffinosus* is named for its ability to produce acid from raffinose. *E. raffinosus* has been isolated from blood cultures as a cause of endocarditis and has also been isolated from wounds, abscesses, decubitus ulcers, peritoneal fluid, bile, urine, sinusitis, traumatic endophthalmitis, and vertebral osteomyelitis.[178,543,686,889,1000] Multi-drug resistant and vancomycin-resistant strains of *E. raffinosus* have been a cause of nosocomial outbreaks in populations of immunocompromised hosts (e.g., hematology/oncology units).[359,888,896,898,1006] A vancomycin-resistant *E. raffinosus* was the cause of mitral valve endocarditis in an elderly male; treatment with linezolid resulted in cure.[511]
Enterococcus saccharolyticus[867]	This *S. bovis*-like organism was originally isolated from cows. Its phenotypic characteristics are similar to *Enterococcus* species (e.g., growth at 10°C and 45°C, growth in 6.5% NaCl), but it does not react with group D antisera.
E. hawaiiensis[142]	*E. hawaiiensis* is the name given to CDC "proposed new species (PNS) E3." This organism was isolated from brain tissue of an 11-month-old patient.
Enterococcus devriesei[983]	This new "*E. raffinosus*-like" species was isolated from bovine sources, from the air of a poultry slaughter by-product processing plant, and from vacuum-packaged charcoal broiled river lampreys.
Enterococcus viikkiensis[849]	This new species is based on five isolates recovered from broiler products and a broiler processing plant.
Group 2	
Enterococcus faecalis	*E. faecalis* is the most frequent isolate from human specimens and the human gastrointestinal tract; also found in the intestinal tracts of poultry, cattle, pigs, dogs, horses, sheep, and goats. It is an important cause of human infections (see text).
Enterococcus faecium	*E. faecium* is found in human clinical specimens and in the gastrointestinal tracts of various species of animals, It is an important cause of human infections and is more resistant to antimicrobial agents than *E. faecalis* (see text).
Enterococcus casseliflavus[225]	*E. casseliflavus* has been isolated from plants, soil, and the feces of chickens and was originally a subspecies of *E. faecium*. The organism is yellow-pigmented and motile. *E. casseliflavus* is an rare opportunistic agent of human infections, including bacteremia, meningitis, and endophthalmitis.[191,277,487,801,876,885,1000] Naser et al.[753] reported that *E. flavescens* (described in 1992) is a later synonym of *E. casseliflavus*, which was described in 1979 and emended in 2004. Strains of *E. casseliflavus* expressing the VanA, and VanB phenotype along with vanA-vanC genotype have been encountered in cattle.[417]
Enterococcus gallinarum[225]	The organism was originally isolated from chicken feces and is one of the motile *Enterococcus* species. This unusual *Enterococcus* has been isolated from cases of bacteremia related to the biliary and gastrointestinal tracts, hemodialysis-associated infections, native valve endocarditis, arthroplasty-associated infections, posttraumatic endophthalmitis, and meningitis.[34,54,191,239,258,456,552,788,987,997,1000] Strains of *E. gallinarum* may harbor the *vanA*, *vanB*, and *vanC* genes, resulting in high-level glycopeptide resistance.[237,641,708,757,927]
Enterococcus mundtii[217]	This species has been isolated from plants, soil, and the gastrointestinal tracts of cattle, pigs, and horses. It is named after J. O. Mundt, an American microbiologist. This species is yellow-pigmented and motile, and has been isolated from a human thigh abscess, sinus mucosa, bacteremia, and endophthalmitis.[277,452,541]

Enterococcus. haemoperoxidus[981]	*E. haemoperoxidus* is an environmental enterococcal species found in surface waters, swimming pools, and drinking water in the North Moravia region of the Czech Republic.
"E. sanguinicola"[143]	"*E. sanguinicola*" was the name given to the CDC "proposed new species" E2, which was isolated from blood cultures of a patient in Los Angeles. Subsequent hybridization and sequencing of the 16S rRNA and *rpo* genes confirmed that "*E. sanguinicola*" is the same as *E. thailandicus*, which was validly published.[921]
Enterococcus silesiacus[984]	This new species was isolated from surface water. The closest phylogenetic relatives of this species include *E. haemoperoxidus* (group 2) and *E. moraviensis* (group 5).
Enterococcus termitis[984]	*E. termitis* was isolated from the gut of a termite. This new species showed the greatest 16S rRNA sequence similarity with *E. haemoperoxidus* (group 2) and *E. moraviensis* (group 5).
Enterococcus camelliae[976]	Described in 2007, this organism was isolated from fermented tea leaves in Thailand.
Enterococcus thailandicus[143,1001]	This enterococcal species was isolated from fermented sausage in Thailand. Isolates of the proposed new species "*E. sanguinicola*" that were isolated from blood cultures are identical to *E. thailandicus*, which is validly published.[921]
Enterococcus ureasiticus[941]	This new species was isolated from water samples in Quebec.
Enterococcus quebecensis[941]	This new species was isolated from water samples in Quebec.
Enterococcus plantarum[985]	This species, described in 2011, was isolated from plants.
Group 3	
Enterococcus dispar[233]	*E. dispar* has been isolated from human stool and synovial fluid.
Enterococcus durans[225]	*E. durans* has been isolated from milk and other dairy products. This is a rare clinical isolate in cases of bacteremia, endocarditis, and ventriculoperitoneal shunt infections.[277,403,966,1000,1032,1096] Green and colleagues[397] reported a case of bacteremia in a bone marrow transplant recipient caused by a vancomycin-resistant *E. durans* strain that developed resistance to daptomycin during therapy.
Enterococcus hirae[332]	*E. hirae* was first isolated from chicken crops, chicken feces, and the gastrointestinal tracts of cattle, pigs, dogs, horses, sheep, goats, and rabbits. The type strains of this species are used in the food industry as a bioassay organism for amino acids and vitamins. In humans, *E. hirae* has been associated with bacteremia in a hemodialysis patient with end-stage renal disease, native and prosthetic valve endocarditis, bacteremic spondylodiscitis, pyelonephritis, cholangitis, and spontaneous bacterial peritonitis.[132,170,380,841,934,999,1000]
Enterococcus ratti[1011]	*E. ratti* was isolated from the intestines and feces of rats with diarrhea.
Enterococcus villorum[267,1073]	This species was first isolated from the gastrointestinal tract of dogs and pigs. *E. porcinus* is a junior synonym of *E. villorum*.
Enterococcus canintestini[752]	This species was isolated from fecal specimens from healthy dogs. 16S rRNA gene sequences showed the highest similarities with *E. dispar* (group 3), *E. asini* (group 4), and *E. asini* (group 5). This species was isolated from a case of catheter-associated bacteremia in a 72-year-old woman in Taiwan who was receiving chemotherapy for cervical cancer.[1000]
Group 4	
Enterococcus asini[279]	This enterococcal species was first isolated from the caecum of donkeys.
Enterococcus cecorum[281,283]	*E. cecorum* is found in the intestinal tracts of chickens. This species lacks the group D antigen, is PYR-negative and is unable to grow in 6.5% NaCl broth. *E. cecorum* has been isolated from humans as a cause of peritoneal dialysis-associated peritonitis, recurrent peritonitis, spontaneous bacterial peritonitis with empyema, catheter-associated bacteremia, and aortic valve endocarditis.[16,266,398,478,1000,1141]
Enterococcus sulfureus[683]	This species was isolated from plants and has not been seen in humans.
Enterococcus phoeniculicola[605]	This avian organism was isolated from the preen glands of wild red-billed Woodhoopoes. This species does not grow on BE agar or in 6.5% NaCl broth.
Enterococcus caccae[141]	This species was isolated from human stool specimens.
Enterococcus aquamarinus[982]	*E. aquamarinus* was isolated from sea water. Phenotypically, this species resembles other species in enterococcal group 4 (e.g., mannitol-, sorbitol-, arabinose-, and arginine dihydrolase-negative), but it is most closely related genotypically to *E. saccharolyticus* (group 1), *E. sulfureus* (group 4) and *E. italicus* (group 5).

Group 5	
Enterococcus columbae[282]	*E. columbae* was isolated from the intestinal tract of pigeons and it is related to *E. cecorum* and *E. avium*. This species is PYR-negative and is unable to grow in 6.5% NaCl broth.
Enterococcus canis[267]	This species was isolated from a dog with otitis externa. The organism is a resident of the canine intestine. *E. canis* grows on BE agar, grows 6.5% NaCl broth, and is PYR-positive.
Enterococcus moraviensis[981]	*E. moraviensis* is an environmental enterococcal species found in surface and drinking water in North Moravia, Czech Republic.
Enterococcus hermanniensis[578]	New species isolated from the microbial spoilage population of broiler chickens legs and also recovered from canine tonsillar tissues.
Enterococcus italicus[142,143]	This species was isolated from the blood of a patient in 1991. *E. saccharominimus* has been established to be a later synonym of *E. italicus*.[753,1074]
Newly Described *Enterococcus* Species	
Enterococcus alcedinis[360]	This species was isolated from the cloacae of common kingfishers (*Alcedo atthis*) during a study of the microbial microbiome of free-living birds.
Enterococcus lemanii[245]	This species (along with *E. eurekensis*) was isolated from swine manure storage pits.
Enterococcus eurekensis[245]	This species, and the species listed above, were isolated from swine manure storage pits.
Enterococcus lactis[727]	*E. lactis* was isolated from Italian raw milk cheeses (Bitto cheese).
Enterococcus ureilyticus[912]	This newly described yellow-pigmented, urease-positive species was isolated along with *E. rotai* from environmental sources (drinking water, plants, insects).
Enterococcus rotai[912]	This newly described yellow-pigmented, urease-positive species was isolated along with *E. ureilyticus* from environmental sources (drinking water, plants, insects).
Enterococcus rivorum[764]	This new species was isolated from "pristine" bodies of water in Finland. In this context, pristine means no human habitation, agriculture, or industry in the catchment region surrounding the flowing streams.

Clinical Spectrum of Enterococcal Infections

Enterococcus species cause complicated UTIs, bacteremia, endocarditis, intra-abdominal and pelvic infections, wound and soft tissue infections, neonatal sepsis, and, rarely, meningitis. While community-acquired enterococcal UTIs are very uncommon in the absence of anatomic predisposing factors or prior instrumentation, enterococci are the third most common agents of nosocomial UTIs.[451] While many patients with catheter-associated enterococcal UTIs are primarily colonized and not infected, catheter removal at the earliest possible time is often curative and no therapy is needed. The presence of enterococci in the urine is often asymptomatic, and, according to IDSA evidence-based guidelines, should not be treated with antibiotics except under certain conditions (i.e., pregnant women, patients undergoing urologic manipulations, patients with significant underlying disease/comorbidities).[649,762] In a study of 289 episodes of enterococcal bacteriuria, pyuria was present in 70% of 140 enterococcal UTI's (defined as significant bacteriuria with one or more additional signs/symptoms, including fever,

urgency/frequency, dysuria, suprapublic/flank pain, gross hematuria), but in only 42% of 149 episodes of asymptomatic bacteriuria (bacteriuria without other signs/symptoms).[647] Of the 339 episodes of enterococcal bacteriuria, only 7 subsequent infectious complications (6 bacteremias, 1 peritonitis) occurred within 30 days of the bacteriuria. The investigators in this study emphasized the need for adherence to established and recommended diagnostic criteria to avoid overtreatment and misuse of anti-enterococcal chemotherapy. Enterococci can, however, cause cystitis, pyelonephritis, prostatitis, perinephric abscesses, and bacteremia in older populations. Most of these are nosocomial or are associated with structural abnormalities or instrumentation of the urinary tract.

Enterococcal bacteremias can usually be traced to enterococcal infections at other sites besides the urinary tract (e.g., intravenous catheter infections, biliary tract infection, gastrointestinal/genitourinary infections) and are most often hospital-acquired. The organisms can also gain entry into the bloodstream through intra-abdominal or pelvic abscesses, wounds, decubitus ulcers, or intravenous access devices. Risk factors for the development of enterococcal bacteremia include advanced age, immunosuppression, underlying diseases and conditions (e.g., prematurity, diabetes, malignancy, congestive heart failure, renal insufficiency, deep-seated infections, prior gastrointestinal, genitourinary, or respiratory tract instrumentation, long-term hospitalization, indwelling devices, and the use of broad-spectrum antibiotics having little or no anti-enterococcal activity (e.g., cephalosporins).[434] Bacteremias caused by *E. faecium* are associated with a poorer prognosis than those due to *E. faecalis* primarily because of increased antimicrobial resistance among the former species and the inherent difficulties of adequately treating more resistant isolates.[376,696] Enterococci also cause 5% to 20% of all cases of endocarditis, and are the second or third most common cause of this infection depending on the population of patients under consideration. Enterococci, particularly *E. faecalis*, are also a common cause of prosthetic valve endocarditis.[338] Endocarditis usually occurs in older male patients with underlying valvular disease or with prosthetic valves and is generally subacute in clinical presentation, with patients having fevers, weight loss, malaise, and other vague constitutional symptoms. Endocarditis in these patients often follows procedures involving the gastrointestinal (e.g., transrectal prostatic biopsies, colonoscopy, fiberoptic sigmoidoscopy) or genitourinary (e.g., cystoscopy, prostatectomy) tracts. Complications of this infection include embolic phenomena frequently involving the CNS. In up to half of patients, enterococcal endocarditis results in acute heart failure that requires valve replacement

In intra-abdominal and pelvic infections, enterococci usually are found admixed with other indigenous aerobic and anaerobic organisms; pure spontaneous enterococcal peritonitis and enterococcal peritonitis associated with continuous ambulatory peritoneal dialysis have also been reported. Though many invasive enterococcal

infections originate in intra-abdominal sites, controversy exists regarding the organisms' role in the pathogenesis of intra-abdominal infections and peritonitis. Studies have shown that empiric anti-enterococcal antimicrobial coverage is beneficial for immunocompromised patients with nosocomially-acquired postoperative peritonitis, patients with abdominal sepsis who have received antimicrobials that select for enterococci, and patients with peritonitis and co-existing heart disease or prostheses who are at risk for enterococcal endocarditis.[426] Enterococci are often found in wound and soft tissue infections (e.g., burns, decubitus ulcers) with other facultative and anaerobic bacteria, and complications associated with such infections (e.g., enterococcal osteomyelitis) are rare. Early-onset neonatal enterococcal infections and sepsis usually result from organisms acquired from the mother during vaginal delivery and can result in bloodstream, pulmonary, wound/surgical site infections, and UTIs. Premature neonates are also at greater risk of developing serious late-onset nosocomial enterococcal infections, particularly following invasive procedures, placement of peripheral access devices or feeding tubes, and treatment with broad-spectrum antimicrobial agents. Enterococcal meningitis is a rare enterococcal infection that may be seen in both adults and children.[834] Enterococcal meningitis may develop spontaneously or as a postoperative infection. Individuals with spontaneous enterococcal meningitis usually have enterococcal infection at other sites, have severe underlying disease, and have concomitant enterococcal bacteremia more frequently than those with postoperative infections.[571] Underlying disease in patients with spontaneous meningitis include malignancy, diabetes, renal failure, and treatment with immunosuppressive agents. Patients with postsurgical enterococcal meningitis usually have an antecedent history of intracerebral hemorrhage, CNS neoplasms, head trauma, and hydrocephalus.[403] Patients with this condition often have intraventricular catheters, surgical site CSF leakage, or ventriculoperitoneal shunts in place prior to diagnosis. In these cases, fever, obtundation, and meningismus are usually present, and the CSF indices include high white blood cell counts, elevated protein, and low or normal glucose. Postsurgical enterococcal meningitis may or may not be associated with enterococcal infections at other sites.[403] In a review of enterococcal meningitis, *E. faecalis* accounted for 76% of isolates, and 15 of the 25 cases that were due to *E. faecium* were caused by vancomycin-resistant strains.[834] Although enterococcal airway and respiratory tract infections are uncommon, these organisms have been established as etiologic agents of nosocomial, aspiration-related, ventilator-associated, and community-acquired pneumonias, lung abscess, pleural empyemas, sinusitis, and bronchitis. These infections occurred in debilitated patients with various comorbidities (e.g., malignancies, postpneumonectomy esophageal–pleural fistulas, endocarditis, HIV infection, hepatic cirrhosis, myelodysplastic syndrome) and risk factors (e.g., old age, smoking, alcoholism).[897] Causative agents have included *E. faecalis*, *E. faecium*,

and *E. raffinosus*.

Antimicrobial Susceptibility of Enterococci

Resistance of enterococci to various antimicrobial agents contributes substantially to their pathogenicity.[464] Resistance genes are acquired by conjugative transfer mechanisms involving plasmids, and transposons carrying multiple antibiotic resistance genes. Enterococci display intrinsic, low-level resistance to the aminoglycosides and lincosamides, have

relatively high MICs for penicillins and cephalosporins, and are resistant to the action of sulfonamide agents in vivo. High-level aminoglycoside resistance usually results from acquisition of a transposon encoding an aminoglycoside-modifying enzyme that confers resistance to all aminoglycosides except streptomycin; high-level streptomycin resistance usually results from a ribosomal mutation involving a specific ribosomal protein or from acquisition of aminoglycoside nucleotidyltransferases such as ANT(3″)-Ia or ANT(6′)-Ia.[193] These enzymes alter the structure of the aminoglycoside molecule resulting in decreased binding of the drug to its ribosomal target. Intrinsic resistance of *E. faecium* to tobramycin, in particular, results from the presence of an AAC(6′)-modifying enzyme found all *E. faecium* isolates.[193] High-level aminoglycoside resistance has disseminated among enterococcal species other than *E. faecalis* and *E. faecium* and has been documented in strains of *E. avium*, *E. casseliflavus*, *E. gallinarum*, *E. raffinosus*, and *E. mundtii*. Elevated MICs for β-lactam agents are due to diminished affinity of cell wall PBPs for these agents. While ampicillin resistance in *E. faecalis* is uncommon, ampicillin resistance is seen in >90% of *E. faecium* isolates and is due to the presence of PBP5, which has a decreased binding affinity for penicillin and ampicillin.[352] Serious infections with enterococci are usually treated with penicillin or ampicillin in combination with an aminoglycoside. High-level resistance to aminoglycosides (i.e., streptomycin MICs higher than 2,000 μg/mL; gentamicin MICs higher than 500 μg/mL) in enterococci significantly alters the therapeutic approach to and clinical response of patients with bacteremia, endocarditis, and other serious infections, as strains with high-level resistance to aminoglycosides are not killed by the synergistic activity of theβ-lactam agent along with the aminoglycoside. Bactericidal synergism between penicillin and aminoglycosides requires that the organism not only have MICs for aminoglycosides lower than the values cited above, but also is predicated on serum penicillin/ampicillin concentrations exceeding the MIC; increasing β-lactam resistance among enterococci along with high aminoglycoside MICs further abrogates synergism. Because of the lack of reliable

penicillin–aminoglycoside synergism among high-level aminoglycoside-resistant enterococci and the emergence of methicillin-resistant *S. aureus*, vancomycin became a first-line drug effective against both staphylococci and enterococci.[799] Prior to the early 1980s, the susceptibility of enterococci to glycopeptide agents (i.e., vancomycin and teicoplanin) remained fairly predictable, but in 1986, high-level glycopeptide resistance emerged The appearance of vancomycin resistance in *E. faecium* and some *E. faecalis* heralded a major change in the enterococcal susceptibility.[620,1068]

The glycopeptides vancomycin and teicoplanin act by binding to the "D-alanyl-D-alanine" terminus of cell wall peptidoglycan intermediates and inhibiting cell wall cross-linking.[248] Acquired resistance to glycopeptides results from the synthesis of different peptidoglycan precursors that become incorporated into the cell wall and have decreased binding affinity for vancomycin, teicoplanin, or both.[37,975] Normally, vancomycin-susceptible strains have peptidoglycan side chains that terminate with the depsipeptide "D-alanyl-D-alanine," and the glycopeptide antibiotic binds to this depsipeptide. In glycopeptide-resistant strains, the "D-alanyl-D-alanine" depsipeptide is replaced by "D-alanyl-D-lactate" or by "D-alanyl-D-serine." Acquired glycopeptide resistance in *Enterococcus* species corresponds to eleven different *van* gene clusters based on DNA sequences and organization. These gene clusters encode either a D-alanyl-D-lactate (i.e., *vanA*, *vanB*, *vanD*, and *vanM*) ligase enzyme or a D-alanyl-D-serine (*vanC1*, vanC2, *vanC3*, *vanE*, *vanG*, *vanL,* and *vanN*) ligase enzyme for synthesis of peptidoglycan precursors with low affinities for glycopeptide agents. These eleven genotypes have correlated resistance phenotypes (i.e., VanA, VanB, VanC1, VanC2, VanC3, VanD, VanE, VanG, VanL, VanM and VanN), with VanA and VanB phenotypes being the most prevalent and important clinically.[111–113,341] The *vanA*, *vanB*, and *vanD* gene clusters can be differentiated on the basis of the level of expressed resistance, inducibility, and the location of the gene cluster.[378,387,1147] Genes encoding the VanA and VanB phenotypes are the most common and are carried on transposons that may be inserted into the chromosome or into plasmids. *E. faecium* and *E. faecalis* isolates that have the *vanA* genotype and VanA phenotype display vancomycin- and teicoplanin-inducible, transposon-mediated, high-level resistance to both vancomycin (MIC, 64 to 1,000 μg/mL) and teicoplanin (MIC, 16 to 512 μg/mL).[1147]Strains with the *vanB* genotype (VanB phenotype) have acquired vancomycin-inducible resistance to various concentrations of vancomycin (MIC, 4 to 1,000 μg/mL) but remain susceptible to teicoplanin (MIC, 0.5 to 1 μg/mL), although rare *vanB* strains may also be resistant to the latter antibiotic.[378,1147] Isolates expressing the VanB phenotype also include *E. faecalis* and *E. faecium* strains. Isolates that have the *vanC* genotype display intrinsic, constitutive, low-level resistance to vancomycin (MIC, 2 to 32μg/mL) and are susceptible to teicoplamin (MIC, 0.5 to 1 μg/mL). The *vanC* genotype corresponds to the intrinsic glycopeptide resistance seen

in *E. gallinarum, E. casseliflavus,* and *E. flavescens*. This *vanC* gene cluster is not transferred by conjugation to other organisms, is generally constitutively expressed, and is chromosomal in origin.[621,755] Some *E. faecium* and *E. faecalis* strains express the VanD phenotype (*vanD* genotype); these strains are intermediately and constitutively resistant to both vancomycin (MIC, 64 to 128 μg/mL) and teicoplanin (MIC, 4 to 64 μg/mL) and resistance is not transferable to other enterococci as the vanD gene cluster is chromosomal.[275,822] VanD-type vancomycin resistance is also found in some *E. avium* isolates.[274] Rare *E. faecalis* strains expressing the *vanE* genotype express inducible, low-level resistance to vancomycin (MIC, 16 μg/mL), yet remain susceptible to teicoplanin (MIC, 0.5 μg/mL).[1,111,341] The VanG phenotype is associated with low-level resistance to vancomycin (MIC, 16 μg/mL), but susceptibility to teicoplanin (MIC, 0.5 μg/mL) and was initially found in *E. faecalis* isolates from Australia and Canada.[112,703] The *vanF* genotype refers to the glycopeptide resistance gene cluster found in the former *Bacillus* species, *Paenibacillus popillae.*[812] The VanL phenotype (*vanL* genotype) is characterized by low-level vancomycin resistance (MIC of 8 μg/mL) encoded by a nontransferable, chromosomal gene cluster (*vanL*) and was detected in an *E. faecalis* isolate from VRE screening medium.[113] The *vanM* genotype was first found among glycopeptide-resistant *E. faecium* isolates that lacked the *vanA*, *vanB,* and *vanD* gene clusters.[1152] The responsible gene cluster was sequenced, found to be unique and distinct from other isolates, and was

named *vanM*. The *vanM* gene encoded a "D-alanyl-D-lactate" ligase enzyme that was related to *vanA*, vanB, and *vanD* and could be transferred by conjugation. The *vanN* operon was identified in *E. faecium* isolated from blood and showed constitutive low-level resistance to vancomycin (MIC, 16 μg/mL) and susceptibility to teicoplanin (MIC, 0.50 μg/mL).[618] The *vanN* resistance operon is located on a plasmid and is transferable. The genotypes, phenotypes, and their characteristics are summarized in Table 13-1.

Another enterococcal phenomenon is that of vancomycin dependence. This refers to strains of enterococci that grow only in the presence of vancomycin. Vancomycin-dependent enterococci (VDE) were first described in 1994, when these organisms were cultured from the urine of a patient receiving long-term therapy with vancomycin.[330,355] Since that time, other isolations of VDE have been reported.[280,396] Patients exposed to vancomycin and other agents (e.g., extended-spectrum cephalosporins) are at risk for colonization with VRE, and this exposure also places them at risk for becoming colonized with VDE as well. VRE and VDE have the ability

to use cell wall ligases to make an alternative cell wall depsipeptide ("D-alanine-D-lactate"), which replaces the normally found "D-alanine-D-alanine." If vancomycin is not present in the milieu, VRE retain their ability to make the "D-alanine-D-alanine" depsipeptide and proceed to grow normally. Because of mutations in the ligase genes that result in amino acid deletions/substitutions in the ligase enzyme, VDE strains are unable to make the original "D-alanine-D-alanine" depsipeptide.[1071] The presence of vancomycin enables these strains to use the "D-alanine-D-lactate" as a cell wall constituent, so their growth is actually dependent on vancomycin. These VDE strains are relatively uncommon. VDE strains derived from both *E. faecalis* and *E. faecium* have been described.[280,330,355,396]

Identification of *Enterococcus* species is discussed later in this chapter. Antimicrobials such as linezolid and daptomycin are commonly employed to treat patients with infections caused by VRE.[1030] Additional information on antimicrobial resistance and methods for antimicrobial susceptibility testing are discussed in detail in Chapter 17.

Genus Melissococcus *and Genus* Catellicoccus

The genus *Melissococcus* contains one species, *M. plutonius*. *M. plutonius* causes a disease of bees called "European foulbrood." Using 16S rRNA sequence data, Cai and Collins demonstrated that *M. pluton* was most closely related to genus *Enterococcus*.[126] *Catellicoccus* represents a new genus that is related to *M. plutonius,* enterococci, vagococci, and tetragenococci. The species, *C. marimammalium* was isolated from clinical specimens obtained from a porpoise and a gray seal.[608]

The "*Streptococcus* -Like" Bacteria

Abiotrophia and Granulicatella Species

"Nutritionally variant streptococci" were originally thought to be viridans streptococci that required thiol compounds (e.g., cysteine) or the active form of vitamin B_6 (i.e., pyridoxal, pyridoxamine) for growth and were also referred to as nutritionally deficient, thiol-requiring, pyridoxal-requiring, and "satelliting" streptococci. DNA relatedness studies of these organisms identified two DNA hybridization groups that corresponded to two species that were named *Streptococcus defectivus* and *Streptococcus adjacens*.[109] In 1995, Kawamura and associates in Japan performed 16S rRNA sequence studies with these species and found that they were unrelated to other species in genus *Streptococcus*. Genus *Abiotrophia* was proposed to accommodate these bacteria, and two new species—*Abiotrophia adiacens* and

Abiotrophia defectiva—were proposed.[544] In 1998 and 1999, two new members of this genus were characterized: *Abiotrophia elegans* (from a patient with endocarditis), and *Abiotrophia balaenopterae* (isolated from the minke whale, *Balaenoptera acutorostrata*).[612,869] In 2000, Kanamoto and colleagues[533] identified and characterized another new *Abiotrophia* species using genetic and phenotypic criteria that was closely related to *A. adiacens* and proposed the species name *Abiotrophia para-adiacens* for this new isolate. These new species were subsequently demonstrated to have a closer phylogenetic affinity with *A. adiacens* than with *A. defectiva,* with the latter species being phylogenetically related to non- *Abiotrophia* "*Streptococcus*-like" species, including *Globicatella sanguinis*, *Facklamia*, *Eremococcus*, and *Ignavigranum* species. The polyphyletic nature of the genus *Abiotrophia* and the close affinity between *A. adiacens*, *A. elegans*, *A. para-adiacens*, and *A. balaenopterae* resulted in reclassification of these four species in the genus *Granulicatella* as *Granulicatella adiacens*, *Granulicatella elegans, Granulicatella para-adiacens*, and *Granulicatella balaenopterae*.[230] *A. defectiva* is retained as the sole species in the genus *Abiotrophia*.

A. defectiva, *G. adiacens*, and *G. elegans* are part of the normal flora of the upper respiratory, urogenital, and gastrointestinal tracts.[713,894] *Abiotrophia* and *Granulicatella* species cause sepsis and bacteremia and are the cause of 4% to 6% of cases of infective endocarditis and bacteremic complications associated with endocarditis.[122] Endocarditis caused by *G. adiacens* is more common than that caused by *A. defectiva*, with *G. elegans* endocarditis being rare in comparison.[195] Over 17 cases of *Granulicatella* endocarditis involving mostly *G. adiacens* have been reported since 1997 and have included native valve, prosthetic valve, and pacemaker lead infections.[23,137,172,512,779,873,1078] The ability of *G. adiacens* to bind fibronectin has been postulated to be partially responsible for the higher prevalence of this organism in endocarditis than either *A. defectiva* or *G. elegans*.[915] Endocarditis caused all three species are highly associated with the development of embolic phenomena, valvular destruction, and treatment failure.[172,574,1078] *A. defectiva* and *Granulicatella* species have also been involved in other bloodstream and endovascular infections, including bacteremia without endocarditis, early-onset neonatal sepsis, infected aortic atheroma with aortic dissection, central venous catheter–related infections in compromised hosts, and Lemierre's syndrome.[6,91,827,1082] *A. defectiva*, and *G. adiacens* have been documented as causes of CNS infections, including meningitis, and brain and epidural abscesses.[163,711,1015] In almost all cases, infection was associated with prior neurosurgical procedures, including craniotomy, VP shunt placement, CT-guided myelography,

775

TABLE 13-1 Genotypes and Phenotypes of Vancomycin-Resistant Enterococci

Genotype (Gene Clusters)	Phenotype	Type of Resistance	Vancomycin Resistance		Teicoplanin Resistance		Expression of Resistance	Location	Conjugative Transfer	Species With Resistance Type
			Level	MIC's (μg/mL)	Level	MICs (μg/mL)				
vanA	VanA	Acquired	High level	64 to ≥1,000	High	16–512	Inducible	Plasmid, transposon on chromosome	Yes	*E. faecium, E. faecalis, E. avium, E. casseliflavus, E. durans, E. gallinarum, E. hirae, E. mundtii, E. raffinosus*

and tumor resection. These organisms have also been isolated from significant ocular infections, including conjunctivitis, endophthalmitis following cataract surgery, infectious crystalline keratopathy, corneal ulcer following penetrating keratoplasty, and keratitis associated with extended wear hydrogel contact lenses.[548,750,815] Other infections involving *Abiotrophia* and *Granulicatella* species include pneumonia, scrotal abscess, bullous impetigo, sinusitis, septic arthritis, vertebral osteomyelitis, arthroplasty and breast implant infections, and continuous ambulatory peritoneal dialysis-associated peritonitis.[24,30,195,270,445,492] These organisms produce extracellular factors including neuraminidase and aminopeptidases that may contribute to virulence. Because of their clinical significance and exacting cultural requirements, clinical microbiologist must be familiar with the clinical settings and laboratory methods necessary for their isolation from patient specimens.

Abiotrophia and *Granulicatella* species are more resistant to antimicrobial agents than the viridans streptococci. For antimicrobial susceptibility testing, CLSI recommends broth microdilution MIC testing using cation-adjusted Mueller-Hinton broth with 2.5% to 5% lysed horse blood supplemented with 0.001% pyridoxine hydrochloride. Even with these modifications, some isolates fail to grow in this medium. Isolates in these genera display decreased susceptibility to penicillin, cefotaxime, and cefuroxime, and have variable susceptibilities to other cephalosporins

and aminoglycosides. *G. adiacens* (55% susceptible) is more susceptible to penicillin than *A. defectiva* (8% susceptible) and up to 60% and 47% of isolates may be resistant to ceftriaxone and cefipime, respectively.[137,1053,1175] Resistance to clindamycin, tetracycline, erythromycin, and ciprofloxacin but not to rifampin or vancomycin has been reported.[137,1053,1175]

Aerococcus *and* Helcococcus *Species*

Aerococci are *Streptococcus*-like organisms that are found in the environment, including air, dust, soil, vegetation, meat products, and the hospital environment. *Aerococcus viridans* causes a disease in lobsters called gaffkemia, but in humans this organism is primarily an opportunistic pathogen.[60] *A. viridans* is a rare cause of endocarditis, bacteremia, urinary tract infection, meningitis, and wound infections.[630,754,837,988] Aerococci can easily be confused with the viridans streptococci and enterococci. Aerococci tend to form tetrads when grown in broth and they are microaerophilic, with little or no growth under anaerobic conditions. Strains of *A. viridans* are usually susceptible to penicillin, macrolides, sulfonamides, and trimethoprim, although, in one case report, the blood culture isolate from an endocarditis patient was resistant to penicillin, ampicillin, cefotaxime, and gentamicin.

A second *Aerococcus* species, *Aerococcus urinae* was described in 1989 and named in 1992.[11,196,197] Inclusion of *A. urinae* in the genus *Aerococcus* is supported by 16S rRNA sequencing, and these data also support inclusion of both esculin-positive and esculin-negative biotypes within the same species.[198] When it was initially recognized, this organism was isolated in pure culture and in significant numbers from patients who were older than 50 years, and more than half of the patients had localized or systemic conditions that predisposed them to infection with opportunistic organisms, such as diabetes, urinary tract and nonurinary tract malignancies (e.g., underlying prostate disease), and urolithiasis. Subsequent studies have confirmed these findings.[917,933] Patients may be colonized in the urinary tract or may have overt symptoms; catheterized patients tend to have true infections and more debilitating underlying conditions. *A. urinae* can also cause severe, fatal bloodstream infections. DeJong and colleagues[268] described four elderly patients with various underlying diseases (e.g., benign prostatic hyperplasia, ischemic heart disease with stage IV non–small cell lung carcinoma, basal cell carcinoma, glaucoma, urolithiasis, diabetes mellitus) who developed *A. urinae* bacteremia. All of these patients also had underlying urologic conditions but all the urine cultures were negative. In recent years, *A. urinae* has emerged as a significant cause of endocarditis.[538,944,1013] Again, patients were elderly and debilitated from underlying diseases (e.g., myocardial infarction, prostate cancer, diabetes). *A. urinae* has been isolated from soft tissue infections, and

as a cause of acute pyelonephritis, spondylodiscitis, lymphadenitis, and spontaneous bacterial perionitis.[41,207,737,890] *A. urinae* may also cause peritonitis in patients on continuous ambulatory peritoneal dialsysis.[744] *A. urinae* is usually susceptible to penicillin, amoxicillin, and the fluoroquinolones, and some isolates have elevated MICs for the cephalosporins.[207,268] Susceptibility to clindamycin, erythromycin, and the tetracyclines is variable, and most isolates are resistant to the aminoglycosides and trimethoprim-sulfamethoxazole.[910,943] In a study of 66 *A. urinae* isolates, all were susceptible to penicillin, vancomycin, and ceftriaxone, but 17% of the isolates had elevated erythromycin MICs (MIC ≥ 0.5 μg/mL) and 23% had elevated levofloxacin MICs (>4 μg/mL).[917]Penicillin or vancomycin combined with an aminoglycoside (i.e., gentamicin) show bactericidal synergy, suggesting that combination therapy is the therapeutic choice for endocarditis and other serious *A. urinae* infections.

Since 1989, five new *Aerococcus* species have been described: *Aerococcus christensenii, Aerococcus urinaeequi, Aerococcus urinaehominis, Aerococcus sanguinicola*, and *Aerococcus suis*.[227,333,610,611,1089] *A. christensenii* was isolated from vaginal specimens and was originally identified as *Streptococcus acidominimus*. This organism has not been associated with any infections or pathology since its description in 1999. *A. urinaeequi* was transferred from the genus *Pediococcus* in 2005, and this species is most closely related to *A. viridans*.[333] The description of *A. sanguinicola* is based on a single isolate from a blood culture in 2001, and since then, this organism has been isolated from urine and from blood cultures.[488,917] Some patients with *A. sanguinicola* bacteremia had endocarditis caused by this organism.[488] As with *A. urinae*, patients with *A. sanguinicola* infection are usually elderly and have underlying or predisposing urologic disease, such as prostatic cancer and benign prostatic hypertrophy.[147,917] In a study of 66 *A. saguinicola* isolates, all were susceptible to penicillin, vancomycin, and ceftriaxone, but 41% of the isolates had elevated erythromycin MICs (MIC ≥ 0.5 μg/mL) and 78% had elevated levofloxacin MICs (>4 μg/mL).[917] The species *A. urinaehominis* is based on a single urine isolate and has not been associated with other pathology to date. Isolates of *A. sanguinicola* are susceptible to penicillin, amoxicillin, cefotaxime, cefuroxime,

erythromycin, vancomycin, quinupristin-dalfopristin, rifampin, linezolid, and tetracyclines, and variably susceptible to the quinolones; some strains are resistant to clindamycin, meropenem, and trimethoprim-sulfamethoxazole.[322] Information on the antimicrobial susceptibility of *A. urinaehominis* and *A. christensenii* is not available.

Other *Aerococcus*-like isolates were first described among several isolates obtained

from cultures of foot and legs wounds and from breast abscesses.[127,212] These particular strains were facultative, gram-positive, catalase-negative cocci that resembled aerococci but produced variable growth in 6.5% NaCl broth. These isolates were lipophilic in that growth on agar media and in broth was enhanced by the presence of serum or Tween 80. These organisms were shown to belong a new genus and species by genetic and phenotypic criteria and were assigned to the new genus *Helcococcus* as *Helcococcus kunzii*.[212] Studies on the ecology of this organism suggest that it is part of the bacterial skin flora of the lower extremities and that it has an association with cellulitis or wound infections along with other, more virulent organisms, such as *S. aureus*.[412] *H. kunzii* has been isolated from wounds, infected sebaceous cysts, breast abscesses, postsurgical foot abscess, and infection of a total knee prosthesis.[167,631,821,862] *H. kunzii* was isolated from infections in two patients as a cause of primary bloodstream infection and thoracic empyema, respectively, and a *Helcococcus*-like isolate was recovered from blood cultures of a patient with endocarditis.[346,1139] *H. kunzii* infection of the tissue surrounding an implantable cardiac rhythm device was successfully treated without device removal as there was no evidence of endocarditis.[706] Isolates of *H. kunzii* are susceptible to penicillin, ampicillin, ciprofloxacin, trimethoprim-sulfamethoxazole, and vancomycin, but susceptibilities to clindamycin and erythromycin are variable.[167,821,1139] In 1999, a second *Helcococcus* species, *Helcococcus ovis,* was isolated from sheep, horses, and cattle; this organism caused purulent bronchopneumonia in sheep and goats and endocarditis in cattle.[214,366,586] In 2004, a new *Helcococcus* species, *H. sueciensis,* was recovered from a wound culture, and another new species, *Helcococcus pyogenes,* was isolated from an infection of a prosthetic knee joint.[213,796,797] The latter organism most closely resembled *Pediococcus* species phenotypically, but molecular studies confirmed its association with the helcococci. This isolate was also relatively resistant to vancomycin, with an MIC of 8µg/mL.[796,797]

Leuconostoc *Species*

Leuconostoc species are gram-positive, nonmotile, non–spore-forming, heterofermentative, facultative cocci that are found in the environment (i.e., on plants, soil). These organisms have economic importance because of their use in the dairy and pickling industries and in wine making.[778] They are also found in fermented sausages, vacuum-packed meat products, cereals, and dairy products (butter, cream, fresh/raw milk, cheese). Phenotypically, these organisms are catalase-negative coccobacilli or cocci that produce gas from glucose along with formation of D(-)-lactic acid and do not hydrolyze arginine. All *Leuconostic* species are intrinsically resistant to vancomycin. Over 27 species and subspecies of *Leuconostoc* have been described but most species

are divisible into three subclusters based on 16S rRNA gene sequences: the *L. mesenteroides* subcluster, the *L. fructosum* subcluster, and the *L. fallax* subcluster (includes *L. fallax* only).[310] The four species in the *L. fructosum* subcluster were recently reclassified in the genus *Fructobacillus,* while *L. fallax* remains as the sole member of *L. fallax* subcluster. The *L. mesenteroides* subcluster includes several species, including those that have been isolated from human clinical specimens.

Leuconostoc bacteremia has been documented predominantly in patients with underlying malignancies (acute myeloid leukemia, non-Hodgkin's lymphoma, hepatocellular carcinoma) and as a complication of solid-organ (e.g., liver) and stem cell transplantation.[273,497,627,925,1022,1155] These coccal organisms also colonize indwelling intravenous catheters, resulting in catheter-related bacteremias.[349,479] Other risk factors associated with *Leuconostoc* bacteremia include prior or current treatment with vancomycin, gastrointestinal disease, and possibly collagen-vascular disease and rheumatoid arthritis.[925] *Leuconostoc* infections have been reported in extremely low-birth-weight and premature neonates with various underlying intestinal conditions, such as short bowel syndrome.[349,510,1159] In some cases, these infants were being treated with vancomycin when bacteremia developed.[510] Nosocomial infections have occurred in pediatric populations due to *Leuconostoc*- contaminated infant formula and enteral and parenteral nutrition supplements.[105] Nosocomial UTIs may also develop, again, in those patients on long-term vancomycin therapy.[133,1002] As opportunistic pathogens, *Leuconostoc* species have been isolated from brain and liver abscesses, osteomyelitis, and pulmonary infections in compromised and debilitated patients (e.g., gastroenterology patients, burn patients, AIDS patients) and as agents of spontaneous bacterial peritonitis and peritonitis in CAPD patients.[18,339,381,518,572,1069] While endocarditis due to a vancomycin-susceptible *Leuconostoc* species has been reported, details of microbial identification and antimicrobial susceptibility were not available.[962] While intrinsically resistant to vancomycin, *Leuconostoc* species are usually susceptible to azithromycin, daptomycin, tigecycline, linezolid, clindamycin, and SXT; variable susceptibilities, tolerance and full resistance to β-lactams (i.e., penicillin, ampicillin) has been described in some case reports.[105,349,497,627] *Leuconostoc* species may be misidentified as pneumococci, viridans streptococci, aerococci, or lactobacilli. Manual (e.g., ID32 Strep) and automated (i.e., Vitek2, Phoenix system, Biolog) identification systems have difficulty with identification compared with genotypic approaches (i.e., 16S rRNA sequencing), however, these systems do provide correct identifications to genus-level in most cases, which, along with susceptibility testing, is usually adequate for patient management.[105,273,627,925] Characteristics of *Leuconostoc* species that differentiate them from other *Streptococcus*-like bacteria are their resistance to vancomycin and the formation of gas

from glucose during growth in MRS broth (discussed later).

Pediococcus *and* Tetragenococcus *Species*

Pediococcus species are gram-positive cocci that, like the streptococci, produce lactic acid as the sole product of glucose fermentation. These organisms are found naturally on plants and are important in the brewing and food industries.

778

Pediococci may be found in beers and ales and are also used in foods for processing and preservation. They are included as flavor enhancers in processed vegetables and soy products and are used in biotechnology as indicator strains for vitamin bioassays. As of 2013, the genus *Pediococcus* contains 14 species: *P. acidilactici*, *P. argentinicus*, *P. cellicola*, *P. claussenii*, *P. damnosus*, *P. dextrinicus*, *P. ethanolidurans*, *P. inopinatus*, *P. lolii*, *P. parvulus*, *P. pentosaceus*, *P. siamensis*, *P. solitarius,* and *P. stilesii*. *Pediococcus halophilus* represents a line of descent separate from both pediococci and aerococci so this species has been placed in genus *Tetragenococcus,* with the type species being *Tetragenococcus halophilus*.[234] The former species *P. urinaeequi* was transferred to the genus *Aerococcus* as *A. urinaeequi*.[333] The species *P. solitarius* was transferred to the genus *Pediococcus* from the genus *Enterococcus.*[311]

Pediococci have been isolated from several human clinical specimen types, including stool, urine, wounds, abscesses, and blood cultures. Patients infected with these organisms have underlying conditions, including hematologic malignancies, cardiovascular disease, chronic lung disease, gastroschisis (a birth defect in which there is a separation in the abdominal wall with a protrusion of an intestinal loop through this opening), pancreatitis, and diabetes.[59,441,893,940] Many patients with these infections had previous abdominal surgery or had nasogastric tubes or central venous catheters for total parenteral nutrition in place for prolonged periods. *P. acidilactici* endocarditis developed in a 32-year-old male following a small bowel transplant and he responded to daptomycin therapy.[501] Persistent bacteremia with pediococci in a 67-year-old female with a complicated clinical course following metastatic adenocarcinoma was also successfully treated with daptomycin.[974] Liver abscess due to *Pediococcus* species developed in a 27-year-old woman following a flare-up of Crohn's disease.[75] Blood cultures and specimens from an ultimately fatal necrotizing cellulitis following rupture of a retroperitoneal tumor grew *P. pentosaceus*.[710] Like *Leuconostoc* species, pediococci are intrinsically vancomycin-resistant, and many patients first manifest symptoms of infection while being treated with this agent. Isolates of pediococci from clinical specimens have been identified as either *P.*

acidilactici or *P. pentosaceus*.[57] Pediococci are generally susceptible to penicillin G, erythromycin, clindamycin, gentamicin, and imipenem.

Gemella *Species*

The genus *Gemella* includes seven species: *G. asaccharolytica*, *G. bergeriae, G. cuniculi, G. haemolysans*, *G. morbillorum*, *G. palaticanis,* and *G. sanguinis*.[218,219,226,475,558] *G. haemolysans*, type species of the genus, is an easily decolorized gram-positive coccus that characteristically appears as diplococci with adjacent sides flattened. Because of this, it was included with the gram-negative cocci in genus *Neisseria*. Cell wall analysis demonstrated that the organism had a thinner cell wall other gram-positive organisms, but was, nonetheless, gram-positive. Nucleic acid hybridization studies did not support any relatedness to the family *Neisseriaceae.* The negative catalase reaction initially relegated this species to family *Streptococcaceae*. But, unlike streptococci, growth is poor under anaerobic conditions. *G. morbillorum* was previously classified with the streptococci as *Streptococcus morbillorum* and was originally included among viridans streptococci. Genotypic studies of *S. morbillorum* demonstrated a closer relationship with *G. haemolysans* than to other streptococci and peptostreptococci.[558] Chromatography showed that these organisms produced acetic, formic, succinic, and pyruvic acids, plus traces of ethanol, along with lactic acid. These data supported transfer of *S. morbillorum* to genus *Gemella* as *Gemella morbillorum*. In 1998, two new *Gemella* species —*Gemella bergeriae* and *Gemella sanguinis*—were characterized and described.[218,219] Six strains of each species were recovered from blood and were distinct from the previously described *Gemella* species by biochemical and molecular characterization. Subsequently, two veterinary species—*Gemella palaticanis* and *Gemella cuniculi*—were described.[226,475] *G. palaticanis* was isolated from an oral vesicle of a Labrador retriever, and *G. cuniculi* was recovered from a submandibular abscess of a lop-eared pet rabbit. Th normal microbiome of *G. bergeriae* and *G. sanguinis* in humans is not known, and, other than recovery from blood cultures, no specific infections have been associated with them. The newest member, *G. asaccharolytica*, was isolated from an arm wound in an IV-drug user, a finger wound, and a labial abscess from a patient with a malignancy.[1064] Unlike the other *Gemella* species, *G asaccharolytica* is does not ferment any carbohydrates.

Gemella species are infrequently isolated from clinical specimens. Cultural similarity to viridans streptococci has likely resulted in misidentifications. *G. haemolysans* is part of the upper respiratory tract flora, whereas *G. morbillorum* is found in the respiratory and gastrointestinal tracts. Both organisms have been isolated as occasional causes of bacteremia and endocarditis involving both native and prosthetic heart valves in pediatric and adult patients.[20,329,482,597,989,1174] Interestingly, *Gemella* species have

also caused endocarditis following tongue piercing.[1161] As ophthalmic pathogens, *G. haemolysans* can cause infectious crystalline keratopathy and both *G. haemolysans* and *G. morbillorum* have caused postsurgical, cataract- and glaucoma-associated endophthalmitis.[530,732,747,863] Both species have also been isolated as causes of chronic ambulatory peritoneal dialysis-related peritonitis, and liver abscess.[406,672,1065] As with *S. gallolyticus* (former *S. bovis*), an association has been made between *G. haemolysans* and *G. morbillorum* bacteremia, endocarditis and presence of adenomatous polyps and possible colonic carcinoma.[443,657] Culture- and molecular-based approaches have shown that *G. morbillorum* is a consistently present and persistent pathogen in primary and secondary/persistent endodontic (i.e., root canal and periradicular abscesses) infections.[389] *G. haemolysans* has been isolated from cerebrospinal shunt fluid in a 16-year-old-boy, and recovery required antibiotic treatment and removal and replacement of the shunt.[654] *G. morbillorum*, the more commonly isolated species, is an uncommon cause of central nervous system infections, osteomyelitis and joint space infections, and pulmonary abscesses.[70,1079,1098]

The late 1990s and 2000s saw the discovery of several new *Gemella* species. The first six isolates of *G. bergeriae* were from blood cultures; three patients had clinical endocarditis.[218] Two subsequent reports of *G. bergeriae* endocarditis have appeared, including endocarditis in a 15-year-old boy with tetralogy of Fallot and pulmonary atresia.[308,656]

779

G. sanguinis has been isolated from blood cultures of patients with suspected or confirmed endocarditis, with the initial isolates being from Virginia, New York, Georgia, California, and Sweden.[219] All were identified initially as *G. morbillorum*, *G. haemolysans*, or "*Gemella* species". Another case of *G. sanguinis* endocarditis was described in a 69-year-old male with poor dentition and vegetations on both mitral leaflets; valve replacement was required.[928] In this case, the organism was identified by amplification of the 16S rRNA by PCR and sequencing of the PCR product. A third case of *G. sanguinis* endocarditis was reported in 2013.[166] *G. asaccharolytica* was isolated from wound specimens (arm wound in an IV-drug user, a finger wound, and a labial abscess) from three patients.[1064] *Gemella* species are usually susceptible to a wide variety of antimicrobial agents, including penicillin, ampicillin, rifampin, and vancomycin, but low-level resistance to aminoglycosides and trimethoprim may be observed in some isolates.

Vagococcus *Species*

The genus *Vagococcus* was proposed in 1989 to accommodate motile gram-positive, catalase-negative cocci recovered from chicken feces and river water. Phenotypically, they resembled lactococci, but 16S rRNA sequencing indicated that these motile strains formed a distinct line of descent within the lactic acid-producing bacteria and were separate from the streptococci, enterococci, and *Lactococcus* species *sensu stricto*. These isolates were also phenotypically distinct. Collins and associates[210] placed these organisms into the new genus *Vagococcus* ("wandering coccus"). The motile group N *Lactococcus*-like isolates in the genus *Vagococcus* are now named *Vagococcus fluvialis* ("belonging to a river"). Strains of *V. fluvialis* have also been recovered from cutaneous lesions and tonsils of pigs, cattle, horses, and domestic cats.[839] The CDC has reported receipt of two *V. fluvialis* strains, one from a blood culture and the other from peritoneal fluid of a renal dialysis patient.[319] Additional isolates of *V. fluvialis* have been recovered from human clinical sources (i.e., blood cultures, peritoneal fluid, wounds, infected root canal lesions), animals (i.e., pigs), and the environment (i.e., well water).[21,1012]

During a genetic study of atypical lactobacilli isolated from various meat products (members of the genus *Carnobacterium*), two isolates from adult rainbow trout were described that were distinct from the poultry isolates.[1103] These two strains showed the highest degree of 16S rRNA sequence homology with strains of *V. fluvialis*, forming a genetic cluster close to the carnobacteria, streptococci, lactococci, and enterococci. These salmonid isolates were assigned to genus *Vagococcus* as *Vagococcus salmoninarum*. Subsequently, this organism was shown to cause peritoneal infections in salmon and brown trout. In 1999, a third *Vagococcus* species —*V. lutrae*—was isolated from blood, liver, lung, and spleen specimens of a common otter (*Lutra lutra*).[613] A fourth *Vagococcus* species was isolated from autopsy specimens of seals and porpoises. This organism—dubbed *V. fessus*—was recovered in pure culture from liver, lung, kidney, brain, intestinal, and placental tissues.[476] *V. carniphilus* was characterized in 2004, and another species, *Vagococcus elongatus* was described in 2007.[609,920] *V. carniphilus* was recovered from ground beef, while *V. elongatus* was isolated from swine manure. Recently, two *Vagococcus* species were isolated from a bioreactor used for treating food wastewater (*V. acidifermentans*) and from the "spoilage microbiota" of cooked shrimp in France (*V. penai*).[505,1107] Only *V. fluvialis* has been isolated from clinical specimens obtained from humans.

Alloiococcus *Species*

In 1989, Faden and Dryja reported on the recovery of a slow-growing, large, gram-positive coccus from 10 children with chronic otitis media with effusion.[324,430] The

children ranged in age from 10 months to almost 3 years, and each child had histories of two to five previous episodes of otitis media. Middle ear aspirates from these children consisted of serous, mucoid, or frankly purulent fluid; inflammatory cells were observed in all specimens. In most cases, large, gram-positive, coccal organisms could also be seen on Gram-stained smears of these fluids. A novel organism was recovered in pure culture from 11 ear aspirates and in mixed culture with nontypeable *Haemophilus influenzae*, diphtheroids, micrococci, or coagulase-negative staphylococci in five specimens. One of the children examined in the study had the same organism isolated from three separate middle ear specimens collected over an 8-month period. On culture, the organisms grew extremely slowly, leading the authors to suggest that perhaps they had been missed in the past because culture plates had not been incubated long enough. Because of the association of this slow-growing gram-positive coccus with chronic otitis media, Faden and Dryja recommended that middle ear aspirates submitted for culture should be incubated for at least 5 days to facilitate detection of these bacteria.[324] Aguirre and Collins subsequently characterized this unusual coccus and named it *Alloiococcus otitis*.[12] A revision of the name of this organism from *A. otitis* to *A. otitidis* was subsequently suggested and approved in keeping with the rules of binomial nomenclature. In addition to isolates from middle ear fluids, the CDC has received strains of *A. otitidis* that were isolated from blood cultures and sputum.[319] With adequately collected tympanocentesis specimens, Gram's stains and cultures of the material are positive if plates are incubated under microaerophilic conditions or in the presence of increased CO_2 (7.5%) for 7 days and if enrichment in BHI broth with subculture is performed.[40,272] Because of its slow growth, several workers have developed molecular amplification methods for detection of this organism is middle ear effusions.[39,44,410,542,633] These molecular methods have also demonstrated that otitis media with effusion is more often polymicrobial than acute otitis media and that carriage of *A. otitidis* in the nasopharynx of at-risk children is rare.[463,509] These highly sensitive techniques have also enabled the detection of this organism in the outer ear canal, suggesting that this site is the natural habitat and reservoir of *A. otitidis*.[301,678,1007] Isolates of *A. otitidis* are susceptible or intermediately resistant to penicillin, ampicillin, and the expanded-spectrum cephalosporins (i.e., cefixime, ceftriaxone), and are resistant to erythromycin and trimethoprim-sulfamethoxazole.[104] Some of these agents (β-lactams, erythromycin) are frequently used to treat otitis media in children. Persistence of the organism in middle ear fluids in children who have received these agents has been

demonstrated by both cultural and molecular methods.[429] Western immunoblot

techniques have demonstrated the presence of IgG_2, IgA, and IgM against *A. otitidis* in middle ear effusion specimens.[430] Typing of *A. otitidis* isolates from children by PFGE has revealed at least 13 different PFGE types.[554]

Globicatella *Species*

In 1992, Collins et al.[209] described nine unique human clinical isolates (five from blood cultures, three from urine cultures, and one from CSF). Phenotypic traits excluded these strains from the *Streptococcus*, *Lactococcus*, *Enterococcus*, or *Aerococcus* groups and genetic investigations showed a distinct line of descent for them within the "lactic acid" bacteria. These strains have been assigned to the new genus *Globicatella* (meaning a short chain composed of spherical cells). All strains were phenotypically similar and have been given the species name *Globicatella sanguinis* (formerly *G. sanguis*) Isolates of *G. sanguinis* that have been submitted to the CDC have been from blood cultures, urine cultures, wound cultures, and a CSF specimen obtained during an autopsy.[319] In 2001, Shewmaker and colleagues[922] reported on 28 strains of *G. sanguinis* that had been isolated from urine cultures and from blood cultures of patients with diagnoses of endocarditis, sepsis, and bacteremia. Since its initial description, *G. sanguinis* has been particularly associated with bacteremia and meningitis, including one report of ventriculoperitoneal shunt-associated meningitis and one describing meningitis following a head injury.[4,506,600,913] In one case, the *G. sanguinis* isolate from the CSF of a 56-year-old woman with signs and symptoms of meningitis was found colonizing the rectum and the groin area of the patient.[448] In Japan, *G. sanguinis* was isolated along with *Corynebacterium riegelii* from blood and urine cultures of an elderly male with urolithiasis.[695] Vandamme and colleagues[1075] in Belgium characterized a second *Globicatella* species that was isolated from respiratory tract and septic joint infections in calves, sheep, and swine. This isolate was named *Globicatella sulfidifaciens* due to its ability to produce H_2S.

Facklamia *Species*

In 1997, Collins and associates[215] characterized five human isolates of catalase-negative, gram-positive cocci from urine, vaginal, blood, and abscess specimens. Comparative 16S rRNA gene sequencing demonstrated that these strains were genotypically homogeneous and constituted a new phylogenetic line closely related to the genus *Globicatella*. These isolates also differed from *G. sanguinis* in their peptidoglycan murein structure. Phenotypically these isolates were quite different. *G. sanguinis* produced acid from several carbohydrates, while the new isolates were totally asaccharolytic. Some characteristics resembled those of salt-tolerant *Gemella*-like organisms (like *D. pigrum,* below). These isolates were placed in the genus

Facklamia as *Facklamia hominis*.[215] Since its description, *F. hominis* has been associated with a case of chorioamnionitis, when it was isolated from blood and placental specimens of a 34-year-old woman following spontaneous rupture of membranes and delivery at 31 weeks gestation.[436] The same organism was isolated from a gastric aspirate from the premature neonate.

Several additional *Facklamia* species have been described in the taxonomy and microbiology literature in subsequent years. Collins and associates[221,231] characterized two human blood isolates as a second asaccharolytic species, *Facklamia ignava,* and the next year the same group described *Facklamia sourekii* in their characterization of another two isolates recovered from human blood cultures. These species differed from *F. hominis* and *F. ignava* in being active fermenters. *Facklamia languida* was proposed as a new *Facklamia* species to describe three human isolates from blood and cerebrospinal fluid specimens.[607] *F. languida* is asaccharolytic, but differs phenotypically from the other species in several enzymatic reactions. *Facklamia tabacinalis* was also described in 1999 and named to describe an isolate recovered as a contaminant from snuff.[221] Its 16S rRNA gene sequence most closely resembled *F. ignava*. *Facklamia miroungae* was described in 2001 and was isolated from a nasal swab of a juvenile elephant seal (*Mirounga leonina*).[474]

Facklamia species appear to have slightly different antimicrobial susceptibility profiles. LaClaire and Facklam determined the susceptibilities of *F. hominis* (four strains), *F. ignava* (five strains), *F. languida* (six strains), *F. sourekii* (three strains), and *F. tabacinalis* (one strain), and found that one *F. hominis* and two *F. ignava* strains had penicillin MICs that tested in the intermediate range, while all other strains were penicillin-susceptible.[590] One strain of *F. ignava*, one of *F. sourekii*, and all six *F. languida* strains were resistant to cefotaxime; 5 of the 6 latter strains were also resistant to cefuroxime. While most isolates were susceptible to erythromycin, three *F. ignava* strains and two *F. languida* strains were erythromycin-resistant. Five of the six *F. languida* strains and 1 of the 5 *F. ignava* strains were resistant to clindamycin. All isolates were either intermediate or resistant to trimethoprim-sulfamethoxazole, and none of the isolates were resistant to levofloxacin or vancomycin.

Dolosigranulum, Ignavigranum, Dolosicoccus, *and* Eremococcus *Species*

Dolosigranulum and *Ignavigranum* are *Gemella*-like genera that are able grow in 6.5% NaCl. *Dolosigranulum pigrum*, the sole species in the genus, was described in 1993, and the CDC Streptococcus Laboratory has characterized several isolates from blood cultures, eye specimens, nasopharyngeal swabs, sputum, urine, gastric and sinus aspirates, and autopsy spinal cord specimens.[13] *D. pigrum* has been isolated from

blood cultures of a 64-year-old male patient with synovitis and a 76-year-old man with acute cholecystitis.[418,648] This organism was recovered from respiratory secretions of a patient with ventilator-associated pneumonia and from bronchoalveolar lavage fluid and blood cultures of a 73-year-old man with COPD and chronic respiratory insufficiency.[460,622] This organism was isolated from blood cultures of a rheumatoid arthritis patient who developed synovitis in multiple joints associated with an infected hip replacement. The organism was seen on Gram's stains of the synovial fluid but the organims was not recovered because specimens were submitted after treatment had been started.[521] LaCaire and Facklam performed susceptibility tests on 27 clinical isolates of *D. pigrum* and found that all were susceptible to penicillin, amoxicillin, cephalosporins (i.e., cefotaxime, cefuroxime),

781

clindamycin, levofloxacin, meropenem, rifampin, tetracycline, and vancomycin; fifteen of the isolates were resistant to erythromycin.[589]

Ignavigranum ruoffiae is the name given to two strains of catalase-negative gram-positive cocci that were isolated from a wound and an ear abscess.[232] These salt-tolerant strains were phylogenetically related to *Globicatella* and *Facklamia* species and phenotypically resemble the asaccharolytic *Facklamia* species. Antimicrobial susceptibility data on these strains is not available.

The genus *Dolosicoccus* was created to accommodate another unique catalase-negative gram-positive coccus that was isolated from a blood culture.[228] This isolate was phylogenetically related to *G. sanguinis* and the *Facklamia* species cluster, and phenotypically resembles *F. hominis* and *F. ignava*. The sole species in the genus is *Dolosicoccus paucivorans*.

The genus *Eremococcus* was created to accommodate two phylogenetically and phenotypically unique cocci recovered from the genital tracts of thoroughbred mares.[229] Comparative 16S rRNA sequencing demonstrated that these strains were related to *A. defectiva* and *G. sanguinis* and more distantly related to *Facklamia* species and *I. ruoffiae*. The single species in the genus is *Eremococcus coleocola*.

Lactococcus *Species*

Genus *Lactococcus* contains the "lactic acid" or "milk" streptococci. About 80% of isolates carry the Lancefield group N antigen. Lactococci have important roles in the dairy industry as they are used as starter cultures for the production of various dairy products (including several types of cheese) from over 100 million metric tons of milk yearly.[335] Strains are cultivated for their different fermentative and flavor enhancement capabilities. As of 2012, 11 species and subspecies of *Lactococcus* have

been described, but those species recovered from human clinical specimens (and also the species and subspecies used most in dairy products) are *L. garvieae*, *L. lactis* subsp. *lactis*, and *L. lactis* subsp. *cremoris*. The latter two subspecies are separated by phenotypic criteria that are strain-variable and genotypic variation (i.e., subspecies *cremoris* phenotype with a *lactis* genotype, and vice versa) has been described *L. garveiae*, *L. lactis* subsp. *lactis,* and *L. lactis* subsp. *cremoris* have mostly been associated with native- and prosthetic valve endocarditis.[348,454,637,644,879,1170] Native disease most often involves the mitral valves. Most cases of endocarditis have occurred in elderly people with valve prostheses. Commonly reported complications include the formation of bulky vegetations and the propensity to cause cerebral infarction.[637,644] In a case of *L. garviae* native valve endocarditis in a 55-year-old woman, the clinical course was complicated by cerebral and renal infarcts and a mycotic aneurysm.[1108] *L. garvieae* endocarditis also occurred in a 63-year-old patient who had previously undergone two bouts of enterococcal endocarditis.[879] Transesophageal echocardiography revealed that the heart lesion was on the native valve and spared the prosthetic aortic valve. *L. garvieae* has also been isolated from a total hip arthroplasty- and joint-site infection and from bone biopsy specimens from the lumbar spine of a patient with spondylodiscitis.[43,169] *L. lactis* subspecies *lactis* and *cremoris* are rare causes of catheter-associated bacteremia, and late-onset bacteremia and meningitis due to *L. lactis* has been seen in neonates.[385,1059] A 2-cm temporal brain abscess due to *L. lactis* subsp. *cremoris* occurred in a 19 month old Turkish child that resolved after drainage along with ceftriaxone and meropenem therapy.[1035] Bacteremia with lactococci has also lead to liver abscess with empyema and ascending cholangitis in two previously healthy individuals.[262,560] Peritoneal dialysis-associated peritonitis due to *L. lactis* subsp. *cremoris* developed in a 63-year-old male who made and ate yogurt in his home while he made his dialysis exchanges.[592]

Isolation and Identification of Streptococci and the "*Streptococcus* -Like" Bacteria

Direct Gram-Stained Smears

Gram-stained smears of clinical specimens that yield streptococci on culture will generally show gram-positive or gram-variable cocci arranged in pairs and chains. Chains of cells in both specimens and broth cultures tend to appear as chains of pairs of cells rather than as chains of individual cells. Individual cell shapes range from those that resemble diplococci to those that appear coccobacillary or coryneform. This

morphology is often observed on smears from broth cultures and from solid media as well. Viridans streptococci, in particular, tend to have cells that appear more elongated. *S. pneumoniae* will most often appear as pairs of lanceolate-shaped cells. On smears of specimens yielding mucoid, heavily encapsulated strains, the capsule may appear as a pink halo or as a nonstaining area surrounding the cells in relief against a pink background surrounding the organism. If the cellular morphology is consistent with *S. pneumoniae*, this should be reflected in the Gram's stain report as "gram-positive diplococci resembling *S. pneumoniae* (or pneumococci)."

A rapid diagnosis of group B streptococcal and pneumococcal meningitis can be made by examination of a Gram-stained smear of CSF. If sufficient CSF is submitted (i.e., more than 1 to 2 mL), the specimen should be centrifuged to obtain a pellet for examination and culture. Cytocentrifugation of CSF specimens enhances the detection of small numbers of organisms and increases the sensitivity of the Gram's stain in comparison with conventionally centrifuged or uncentrifuged specimens. Use of cytocentrifugation circumvents the need for the performance of latex or coagglutination tests for detection of group B streptococcal or pneumococcal capsular antigens (see Direct Detection section below).

Culture Media

Specimens should be inoculated onto a suitable blood-containing medium that has a peptone base. The base medium should be a peptone infusion medium without added carbohydrates, such as tryptic-soy, proteose-peptone, or Todd–Hewitt medium. Sheep blood is added to the basal medium at a 5% concentration as the indicator cells for hemolysis. Lower concentrations of blood in the media make the hemolytic reaction difficult to discern, whereas higher concentrations may obscure hemolysis entirely. Although the colonies

will generally be larger on glucose-containing basal medium such as Columbia agar after 24 hours, utilization of glucose in the medium inactivates the SLS of group A β-hemolytic streptococci and makes interpretation of hemolytic reactions less clear. Streptococci belonging to groups A, B, C, F and G are β-hemolytic (to be described in the following), whereas the majority of *Enterococcus* species and group D streptococci are α-hemolytic or nonhemolytic. *Arcanobacterium haemolyticum*, another cause of pharyngitis, also grows well on SBA, is catalase-negative, but is clearly a gram-positive rod and not a coccal organism.

Selective agar may also enhance the recovery of group A streptococci from throat cultures. The formulations that are most often used and that are commercially available employ a tryptic soy agar base containing 5% sheep blood and

sulfamethoxazole (23.75 µg/mL)-trimethoprim (1.25 µg/mL). Much of the normal oropharyngeal flora (e.g., viridans streptococci, micrococci, staphylococci, and neisseriae) will be inhibited on this medium. Use of this selective medium enhances recovery of group A and B streptococci and allows visualization of β-hemolysis without the "background" of other organism growth. Commercially available selective media include Group A Selective Strep A with 5% sheep blood (ssA; BD Diagnostic Systems, Sparks, MD), and Strep A Isolation Agar (Remel Laboratories, Lenexa KS). Most laboratories incubate media for isolation of group A β-hemolytic streptococci for 48 hours in a CO_2-enriched environment, assuming that only cultures from patients with small numbers of organisms or from those who are group A streptococcal carriers will grow under anaerobic conditions. However, even patients with small numbers of organisms may have an immune response, suggesting that they are infected and not merely carrying the organism. Small numbers of organisms on a culture plate in a patient with clinical streptococcal pharyngitis may also reflect inadequate specimen collection.

Streptococci recovered from human clinical specimens are identified on the basis of their hemolytic qualities, serologic tests for the detection of cell wall or capsular antigens, and physiologic and biochemical tests. Some of the tests performed in the laboratory for identification of these organisms provide presumptive results, whereas others provide definitive results. Before proceeding with identification tests, however, one must be sure that the gram-positive cocci under consideration are **catalase-negative** using 3% H_2O_2, placing them in the *Streptococcus* and *Streptococcus*-like bacterial groups. The catalase test is discussed in detail in Chapter 12.

Hemolysis on Blood Agar

Four types of hemolysis may be produced by streptococci on SBA (Box 13-6) (Image Plate 13-1D, 13-1E and13-1F). Observation and correct interpretation of the hemolytic properties of streptococci is very important because the performance of subsequent tests is predicated on this initial evaluation. Hemolysis is best observed by examining colonies grown under anaerobic conditions or by inspecting subsurface colonies in pour plates or streak-stab plates because, for group A streptococci, maximal activity of both the oxygen-labile (SLO) and oxygen-stable (SLS) hemolysins is observed only under anaerobic conditions. Oxygen-labile hemolysins are also produced by group C and some group G strains, so detection of hemolysis by these organisms is also enhanced by anaerobic incubation. Although routine anaerobic incubation of specimens expected to yield streptococci is not recommended, steps can be taken to maximize detection of hemolysis under aerobic or capnophilic incubation. This is the point of the "streak-and-stab" technique that is used for inoculating throat swab specimens on blood agar for diagnosis of streptococcal pharyngitis (Fig. 13-2). This technique forces some of the inoculum under the agar, thereby creating a

relatively anaerobic environment. Areas of the plate not inoculated with specimen should also be stabbed. Plates should be incubated at 35°C in air or in 5% to 7% CO_2. Although some laboratorians advocate one incubation environment over the other for throat cultures, the recovery of β-hemolytic streptococci from patients with streptococcal pharyngitis will not generally be compromised under either environmental condition.

Nonculture, Direct Detection Techniques for Group A β-Hemolytic Streptococci in Pharyngeal Specimens

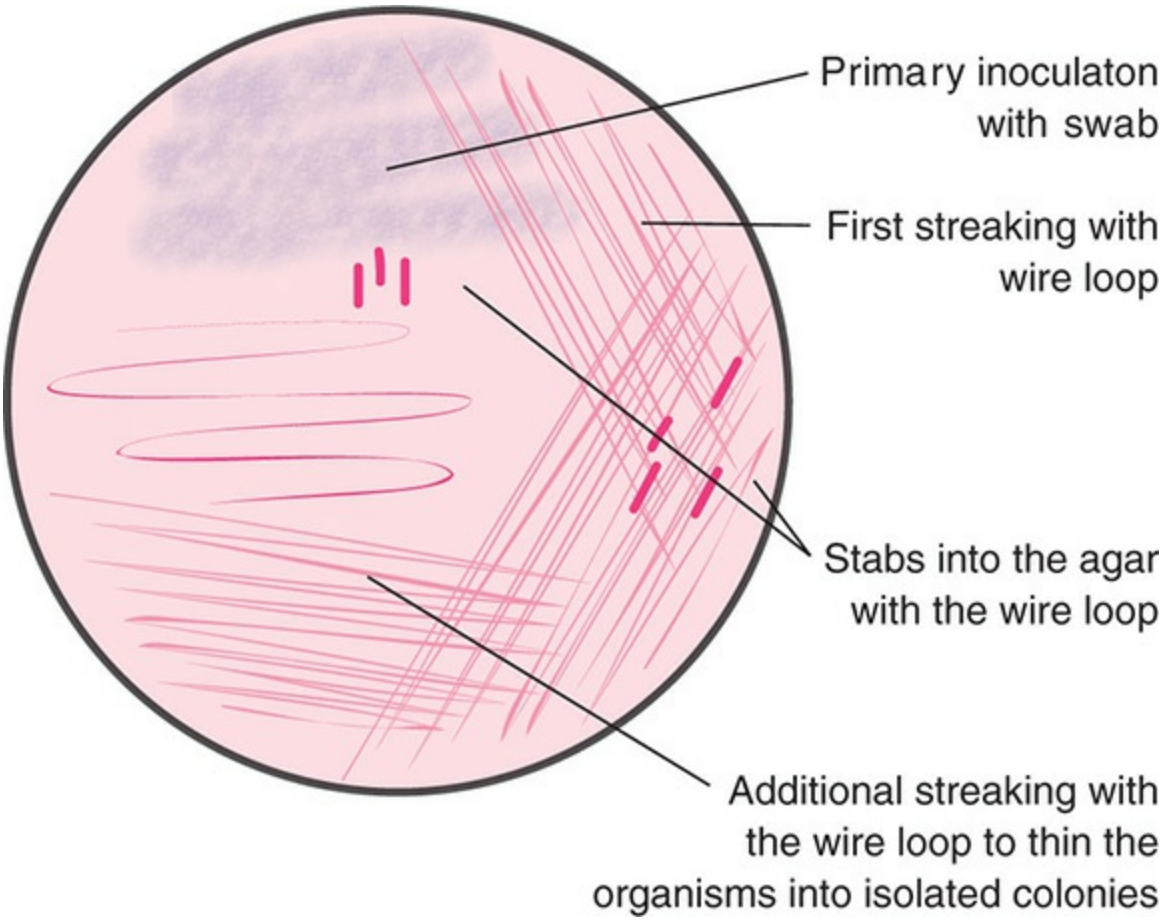
Nonculture techniques for direct detection of group A streptococci on throat swab specimens have been in wide use

BOX 13-6

Hemolytic Reactions of Streptococci and *Streptococcus* -Like Bacteria

Type of Hemolysis	Description
α	Partial lysis of the erythrocytes surrounding a colony, causing a greenish-gray or brownish discoloration of the media.
β	Complete lysis of the erythrocytes, causing a clearing of blood from the medium under and surrounding the colonies.
γ	No hemolysis and, consequently, no change in the medium under and surrounding the colonies; organisms showing no hemolysis are referred to asγ-hemolytic or "nonhemolytic."
α-Prime or "wide zone α"	A small zone of intact erythrocytes immediately adjacent to the colony, with a wider zone of complete hemolysis surrounding the zone of intact erythrocytes; may be confused withβ-hemolysis.

783



■ **FIGURE 13-2** Streak–stab technique for isolation of β-hemolytic streptococci.

in clinical laboratories since the early 1980s. In these rapid antigen detection tests (RADT's), the group A streptococcal antigen is extracted from the swab using nitrous acid or an enzymatic extraction step, followed by detection of the extracted antigen. The initially marketed kits used latex agglutination or enzyme immunoassay formats for detection, but most RADT's now use lateral flow immunoassays (e.g., Clearviw Strep Exact II cassette, Remel) or rapid immunochromatographic strip "dipstick" approaches (e.g., Clearview Strep A Exact II Dipstick, Remel; BD Chek Group A Strep, Becton-Dickinson, Sparks, MD; ImmunoCard STAT Strep A Test, Meridian Bioscience, Inc., Cincinnati, OH) for detection (Image Plate 13-1H). The sensitivities of these assays for detecting group A streptococcal antigen in throat swab specimens range from 62% up to 96%; specificities in most cases exceed 97%.[375,598,1008] While cultures and some RADTs have been deemed as moderately complex tests by CLIA, other RADT's that are easier to perform are classified as CLIA-waived and can be performed without certification.[1008] Direct DNA probe (e.g., the Gen-Probe Group A Streptococcus [GASDirect] Test, Gen-Probe, San Diego, CA) and amplified probe

(e.g., Illumagene, Meridian Bioscience, Cincinnati, OH) technologies have also been used for direct detection of group A streptococci in throat swab specimens. The Group A Streptococcus Direct Test (Gen-Probe) is a nonisotopic chemiluminescent method that uses a DNA probe to detect the complementary rRNA sequences of group A streptococci directly in an extract from a throat swab. Test sensitivities range from 88.6% to >95%, with specificities of greater than 98%.[107,108,176,442,836] The Illumigene Group A *Streptococcus* DNA amplification assay (Meridian Bioscience) uses novel loop-mediated amplification (LAMP) technology to target a highly conserved 206-base-pair region of the group A streptococcal pyrogenic exotoxin B (*speB*) gene. A 2013 multicenter clinical evaluation of the Illumigene Group A *Streptococcus* test reported a sensitivity and specificity following discrepancy analysis of 99.0% and 99.6%, respectively.[31] Other real-time PCR assays (e.g., LightCycler Strep A assay, Roche Applied Sciences, Indianapolis, IN) have also been developed that target other group A streptococcal genes (e.g., *dnaseB* gene) and have shown high sensitivity and specificity.[945,1062]

Although the specificity of RADTs is quite high, the sensitivities of the various kits for group A streptococcal antigen detection can vary widely (between 62% and 95%). As with most tests, the inoculum size on the throat swab depends on how well the specimen was collected, and swabs containing a lighter inoculum are more likely to produce negative RADT results.[206,583] While the American College of Physicians and the American Society of Internal Medicine recently proposed practice guidelines for management of adults with pharyngitis that relied on clinical criteria alone (without using rapid antigen tests or cultures) for diagnosis, this approach is considered to be controversial by other professional societies, including the Infectious Diseases Society of America, the American Heart Association, and the AAP.[88,238,379,650] A diagnostic strategy employing collection of two swabs, with a negative RADT being followed by repeat testing with the same RADT using the second swab specimen was not as sensitive as performing a culture following a negative RADT result (91.4% vs. 95.7%).[379] The American Heart Association, package inserts for many of the rapid antigen test kits, and most clinical microbiologists recommend that all specimens that yield negative rapid antigen results be confirmed by culture. Regardless of the method used or the claims of the manufacturer for a given test kit or technique, it is recommended that two throat swabs be collected. A standard throat culture should be performed with the second swab for those specimens that yield negative rapid antigen detection results with the first swab. Some laboratories have substituted the Gen-Probe Group A Strep Direct test in place of culture for confirmation of negative direct antigen results.

Nonculture, Direct Detection Techniques for Group B β-Hemolytic

Streptococci

Diagnosis of systemic group B streptococcal disease is best accomplished by culture of the organisms from appropriately collected specimens. Methods are also available for direct detection of group B streptococcal capsular antigen in cerebrospinal fluid, serum, and urine. Latex agglutination (LA) and coagglutination (COA) tests have been used in many laboratories for rapid diagnosis of systemic group B streptococcal infections, particularly meningitis in the newborn period. Currently available LA tests include the Directogen Meningitis Combo Test kit (BD Biosciences Microbiology Products, Sparks, MD), and the Wellcogen Bacterial Antigen kit (Murex Diagnostics Limited, Central Road, Temple Hill, Dartford, England) Research Triangle Park NC). The commercial COA test kit is the Phadebact CSF test (Boule Diagnostics AB, Huddinge, Sweden) Sensitivities of the LA products for detection of group B streptococcal antigens range from the mid-80% to 100%, although some studies have reported sensitivities as low as 27% to 54%. Many laboratories have discontinued offering these tests routinely. Aside from their relatively high cost, diagnostic and prognostic utility of these tests have not been borne out after years of experience. These tests may be most useful in cases of suspected meningitis where the Gram's stain is negative and/or when CSF cultures are negative after 48 hours; particularly if the patient had received antimicrobial therapy prior to specimen acquisition.

784

The recommended method for optimal direct detection of group B streptococci in CSF depends on careful inspection of a Gram-stained smear of a cytocentrifuged specimen. Direct detection methods for group B streptococci in rectovaginal specimens are insensitive compared with the broth amplification methods recommended by the CDC (Box 13-3). Real-time PCR techniques targeting various group B streptococcal genes, including *cylb* (hemolysin), *cfb* (CAMP factor gene), and *ssr* (serotype antigen gene) have been described for detection of group B streptococci in rectovaginal, blood, and other clinical specimens.[288,547,1115] Rapid LA- or EIA-format assays should not be used for screening of rectovaginal swab specimens for group B β-hemolytic streptococci (see section on Clinical Significance of Group B β-hemolytic streptococci for discussion of screening methods).

Nonculture, Direct Detection Techniques for Streptococcus pneumoniae

As an adjunct to cultural diagnosis of respiratory tract and central nervous system infections by *S. pneumoniae*, methods are now available for detection of pneumococcal antigen in urine of patients with pneumococcal pneumonia and in CSF

of patients with pneumococcal meningitis. The Binax NOW *Streptococcus pneumoniae* antigen card (Alere, Inc., Waltham, MA) is a rapid immunochromatographic assay that allows a presumptive diagnosis of pneumococcal pneumonia and meningitis by detection of specific soluble capsular antigens in urine and CSF specimens, respectively.[490] The pneumococcal antigens detected by this test account for more than 90% of invasive disease occurring in the United States and worldwide. In a study conducted in the United Kingdom, the NOW assay was positive in 82% of 107 urine specimens from patients with bacteremic pneumococcal pneumonia; 3 of 106 patients with pneumonia and bacteremia due to other organisms were also NOW test-positive, yielding a specificity of 97%.[950] A subsequent study by the same clinical group found the Binax NOW was positive in 88% of 58 bacteremic pneumococcal cases while a dual-PCR assay targeting pneumolysin and autolysin genes of *S. pneumoniae* had a sensitivity of only 53.5%.[951] In a prospective, population-based study of adults with pneumonia in Spain, the test was positive in 70.4% of 27 patients with culture-documented pneumococcal pneumonia; corresponding specificity of the test in this study was 89.7%.[409] In another study, the urinary antigen was detected in 80% of 20 patients with pneumococcal bacteremia and in 52% of 54 patients with *S. pneumoniae* isolated from sputum.[736] A 3-year prospective study of the Now assay conducted in Japan found that the test detected 75.9% of 83 patients with pneumococcal pneumonia that were confirmed by routine methods (i.e., transthoracic needle aspiration and/or positive blood cultures).[496] The predictive values for positive and negative urinary antigen tests were 91.3% and 82.6%, respectively. Of note was that the diagnostic yield for a pneumococcal pneumonia diagnosis was increased by 38.9% when the antigen test was combined with other diagnostic measures. In a study of 474 cases of community-acquired pneumonia in Spain, Sorde and colleagues[955] found that the NOW test was positive in 43.8% of 171 cases due to *S. pneumoniae*, and that the test specificity was 96%. An Italian study found that a positive urinary antigen test and recovery of *S. pneumoniae* from sputum was seen in only 8.7% of 46 patients for whom both results were available.[724] Positive urine antigen tests and negative sputum cultures were seen in 17.4%, and negative urine antigen tests were seen in 28.3% of patients with sputum cultures positive for *S. pneumoniae*. The NOW urinary antigen test has also been shown to be a useful adjunctive test for diagnosis of pneumococcal empyema in children, exacerbations of pneumococcal infections in patients with COPD, and as an indicator of complications associated with pneumococcal infection (e.g., vertebral osteomyelitis, psoas muscle abscess) in compromised hosts.[32,684,692] The time to development and the intensity of positive bands on the NOW immunochromatographic strip were also found to correlate with the severity of pneumococcal pneumonia in a study of 119 children with *S. pneumoniae* pneumonia.[918] Other workers have shown

that the NOW test may be useful for detection of *S. pneumoniae* in nasal and nasopharyngeal specimens for diagnosis and management of acute otitis media as well as community-acquired pneumococcal pneumonia.[42,1102] The test was also positive with pericardial fluid obtained from a patient with purulent pneumococcal pericarditis.[746] A meta-analysis of 27 evaluations of the NOW pneumococcal urinary antigen test found the test to have a sensitivity and specificity of 74% and 97.2%, respectively.[936]

Samra and coworkers[887] evaluated the NOW test with both CSF and urine specimens from 22 patients with culture-documented pneumococcal meningitis. For CSF specimens, 21 of 22 CSF specimens were positive (95.4% sensitivity) with the rapid test; only 12 of 21 urine specimens were positive (57.1% sensitivity). Testing of CSF specimens that were culture-negative for *S. pneumoniae* or positive for other organisms were all negative, for a specificity of 100% for CSF specimens. However, 5 (18.5%) of 27 urine specimens from patients with CSF cultures positive with other bacteria, and 63 (13.4%) of 470 urine specimens from patients with negative CSF cultures were positive with the NOW test. A multicenter study on bacterial meningitis surveillance conducted in five countries throughout Africa and Asia found that 99% of 69 culture-confirmed cases of pneumococcal meningitis were detected by the NOW urinary antigen assay and 99% of 125 meningitis cases due to other bacterial agents were negative with the NOW assay.[723] Positive CSF antigen results may persist for some time after appropriate therapy and can cloud the diagnosis of recurrent disease versus a sterile aseptic meningitis syndrome that has been observed in adequately treated patients.[33]

A potential drawback of the NOW urine test is that healthy nasopharyngeal carriers of *S. pneumoniae* may also have positive tests. A study conducted in the Gambia, where the carriage rate among evaluated children was 87%, reported that 55% of urine specimens from healthy children who were pneumococcal carriers were Binax NOW test-positive.[9] Another study conducted in Ecuador found that 21.7% of children who carried nasopharyngeal *S. pneumoniae* were NOW test-positive and 4.2% of noncarriers had false-positive urine antigen tests.[419] These workers postulated that the Binax NOW urine assay may be most useful for the diagnosis of pneumococcal pneumonia and bacteremia in populations with low rates of nasopharyngeal pneumococcal carriage.

785

However, in another study of 98 women in which 24 (25%) carried nasopharyngeal *S. pneumoniae*, only 3% had positive urinary antigen tests.[1056] False-positive NOW urinary antigen results have also been documented. In a retrospective cohort study

conducted at Northwestern University, 5 (9.6%) of 42 positive urinary antigen results were deemed to be falsely positive; interestingly, two of the five false-positive tests occurred in individuals who had received the 23-valent pneumococcal vaccine.[881] False-positive urinary antigen tests are, therefore, associated with nasopharyngeal pneumococcal carriage, invasive pneumococcal disease in the past, and receipt of pneumococcal vaccine.

Nonculture Techniques for the Detection of Enterococci in Blood Cultures

PNA FISH technology combines fluorescence in situ hybridization (FISH) with unique peptide nucleic acid (PNA) molecules wherein the negatively charged carbohydrate-phosphate moieties comprising the backbone of DNA and RNA are replaced with uncharged PNA probes containing the same nucleotide bases as DNA, allowing them to hybridize with complementary nucleic acid sequences. The uncharged, hydrophobic backbone of PNA probes allows the probes to penetrate the hydrophobic cell walls of bacteria and enables tighter and more specific hybridization to nucleic acid sequence targets. The PNA probes hybridize with rRNA sequences of specific enterococcal species. These PNA probes are labeled with molecules that fluoresce (i.e., fluorophores) under UV light. PNA FISH technology has found its greatest application in direct identification of pathogenic bacteria directly in positive blood cultures. The *Enterococcus faecalis*/Other Enterococci (OE) PNA FISH assay uses a mixture of a fluorescein-label *E. faecalis*-specific PNA probe and a rhodamine-labeled PNA probe specific for OE. This reagent is applied to a smear prepared from a positive blood culture. Hybridization is performed at 55°C for 30 minutes and is followed by a posthybridization wash for 30 minutes at 55°C with a stringent wash solution. The smear is mounted with a mounting medium supplied with the kit, and is then examined by fluorescence microscopy. *E. faecalis* is identified as multiple, bright green fluorescent cocci, while OE appear as multiple red fluorescent cocci. Nonenterococcal organisms do not fluoresce. A multicenter evaluation of the *E. faecalis/* OE PNA FISH was performed on 152 positive blood cultures showing gram-positive cocci in pairs and chains on Gram's stain.[728] Of these, 100% of 41 cultures positive for *E. faecalis* and 100% of 33 cultures positive for OE were correctly identified. None of the cultures growing nonenterococcal gram-positive cocci were misidentified as enterococci. In another study, the use of *Enterococcus*/OE PNA FISH resulted in earlier initiation of appropriate empirical antimicrobial therapy due to earlier recognition of *E. faecium* VRE bacteremia.[353]

Recently, the *Enterococcus* QuickFISH BC was approved for use. This test identifies *E. faecalis* and OE from blood cultures in less than 30 minutes by elimination of a wash step. This modification uses a drop from a positive blood culture

that is prepared on FISH slides with positive and negative controls already present on the slide. The slide is heat-fixed at 55°C for up to 5 minutes. Single drops of two PNA solutions—*Enterococcus* PNA blue and *Enterococcus* PNA Yellow—are mixed together on a coverslip that is placed inside a template. Mixture of the two reagents in the oval window of the template results in a uniform green color. The coverslip is then flipped over and applied to the dried/fixed blood culture drop on the specimen slide within the borders of the viewing area. The slide is incubated at 55°C for 15 to 20 minutes at the workstation. The slide is read on a fluorescence microscope by first inspecting the controls, then moving over to the specimen well in the same plane of focus. As with the longer procedure, *E. faecalis* appears as bright, apple-green fluorescent clusters of cocci, while OE appear as multiple, bright-red fluorescent cocci. This test has a turnaround time of less than 30 minutes with a hands-on time of less than 5 minutes.

Colony Morphology and Catalase Testing

After 18 to 24 hours' incubation on blood agar, colonies of group A β-hemolytic *Streptococcus* are about 0.5 mm in diameter, translucent or transparent, and have a smooth or matte surface. The zone of β-hemolysis is usually two to four times the diameter of the colony (see Image Plate 13-1D) The colonies are domed and have an entire edge. Occasional strains of group A streptococci will be mucoid due to the presence of large amounts of capsular material. Groups C and G also have a similar appearance, although colonies of some group G strains may have a golden cast on close inspection and the hemolytic zones are usually very large. Group B β-hemolytic streptococci form larger colonies on agar medium, the margin of hemolysis around the colony is comparatively smaller for group B streptococci than for the other β-hemolytic streptococci, and the hemolysis is generally "softer" and less obvious. A significant proportion of group B streptococci (up to 11%) may be nonhemolytic. Group D streptococcal colonies tend to be larger than those of group A streptococci, being 0.5 to 1.0 mm after overnight incubation. Group D isolates are α-hemolytic or nonhemolytic on SBA. The colonies are usually gray, smooth, and have an entire edge. Group F streptococci form very small, pinpoint colonies with a large zone of β-hemolysis. These extremely small colonies are called "minute colonies" and they are characteristic of the anginosus group of streptococci, *S. anginosus*, *S. constellatus*, and *S. intermedius*. Minute β-hemolytic colonies are generally pinpoint after 24 hours' incubation, yet will have a rather large, florid zone of β-hemolysis. The anginosus group organisms growing on solid media also have a distinct sweet, caramel ("butterscotch") or honeysuckle odor owing to the production of diacetyl. This characteristic may be noted with α-hemolytic, β-hemolytic, and nonhemolytic members of this group.

S. pneumoniae displays a spectrum of colony types, the appearance of which

depends on the degree of encapsulation. These colonies are generally surrounded by a large zone of intense green α-hemolysis. Colonies of heavily encapsulated strains may be several millimeters in diameter, are very mucoid, appear gray, and may resemble drops of oil on the agar surface. Colonies of the less heavily encapsulated strains are smaller. On prolonged incubation, the central portion of

the colony may collapse, giving the characteristic "checker piece" appearance. Some colonies may collapse altogether, giving the appearance of a flat nail-head on the surface of the agar.

Other species of viridans streptococci form colonies of various sizes and textures. Some may be smooth and have an entire edge, whereas others may appear rough, with the formation of scalloped edges on prolonged incubation. Colonies of *Aerococcus*, *Pediococcus*, *Gemella*, *Leuconostoc*, *Tetragenococcus*, *Vagococcus*, *Globicatella*, *Helcococcus*, *Facklamia*, *Dolosicoccus*, *Dolosigranulum*, *Ignavigranum*, and the facultative *Lactobacillus* species strongly resemble viridans streptococci or group D streptococci in their appearance, and they are either α-hemolytic or nonhemolytic.

Members of the streptococci and *Streptococcus*-like bacterial groups are catalase-negative, except for *A. otitidis*. This organism is *Streptococcus*-like in its colony morphology but is catalase-positive. Some enterococcal strains (particularly *E. faecalis* strains) produce a "pseudocatalase" that is responsible for the weak-positive catalase reaction that is seen with some strains, particularly on primary isolation. The strength of this reaction may diminish after a few serial subcultures.

Recognition and Preliminary Characterization of Streptococci and the "Streptococcus -Like" Bacteria

The determination of hemolysis and the performance of a catalase test were once the only tests that were required to preliminarily characterize streptococci. However, with the recognition of several groups of *Streptococcus*-like bacteria in human infections, it is also necessary to perform additional tests, particularly for those isolates recovered from sterile body fluids. Some of these organisms (i.e., *Leuconostoc* and *Pediococcus* species) are intrinsically resistant to vancomycin and related cyclic glycopeptide antibiotics (e.g., ristocetin, aracidin, and teicoplanin). The apparent increase in the recognition and isolation of these organisms may be partly related to the emergence of methicillin-resistant *S. aureus* and the consequent use of vancomycin as a first-line antibiotic, particularly in severely debilitated hosts. These and other "look-alike" organisms may be preliminarily differentiated from *Streptococcus* and *Enterococcus* species and from one another with the tests shown in Table 13-2.

On SBA, these organisms resemble viridans streptococci or enterococci; all of them are α-hemolytic or nonhemolytic. The characteristic streptococcal morphology—chains of cocci—is seen with the streptococci, enterococci, lactococci, *Leuconostoc/Weissella* species, *Vagococcus* species, *Abiotrophia/Granulicatella* species, *Dolosicoccus* species, *Ignavigranum* species, *Globicatella* species, and *Lactococcus* species on Gram-stained smears prepared from thioglycolate broth cultures. Gram-positive cocci arranged predominantly in pairs, tetrads, and or clusters are more characteristic of the aerococci, *Alloiococcus* species, *Gemella* species, *Pediococcus* species, and *Helcococcus* species and *Tetragenococcus* species. Some of the recently described *Streptococcus*-like bacteria (e.g., *Facklamia* species, *Tetragenococcus* species) often form pairs or short chains. Facultative lactobacilli will generally show the typical rod-shaped morphology, whereas other species will appear coccal. Observation of gram-positive cocci in short chains in blood culture media and growth of organisms on subculture to chocolate agar with no growth on a corresponding SBA subculture suggests *Abiotrophia/Granulicatella* species. On media containing blood, some isolates may produce a weak catalase reaction with 3% H_2O_2; therefore, strains showing this reaction should be subcultured onto blood-free medium and retested for catalase activity.

Viridans or nonhemolytic streptococci from sterile body fluids can be screened for susceptibility to vancomycin using the regular 30 mg disk on a SBA plate incubated at 35°C for 18 to 24 hours. Occasional isolates may require prolonged incubation (i.e., up to 72 hours) for test interpretation. Organisms that are resistant to vancomycin (i.e., *Pediococcus* species, *Leuconostoc* species) generally have MICs higher than 250 μg/mL and will grow right up to the edge of the disk. The presence of any zone around the disk indicates susceptibility to vancomycin. Production of gas from glucose, a helpful test for differentiation of *Leuconostoc* species from the other organisms, is best determined in *Lactobacillus* Mann–Rogosa–Sharpe (MRS) broth (Difco Laboratories, Detroit MI) overlaid with petrolatum (Deman–Rogosa–Sharpe, 1960). The formation of bubbles under the petrolatum seal indicates gas production and the heterofermentative nature of their metabolism. The MRS broth is incubated for up to 7 days. Other tests that are helpful for preliminary characterization of the *Streptococcus*-like organisms include pyrrolidonyl arylamidase (PYR), leucine aminopeptidase (LAP), and salt tolerance tests. The latter test is performed in heart infusion broth containing 6.5% NaCl. The presence of growth is the endpoint, as in the salt tolerance test for identification of enterococci. The PYR and LAP tests are available as rapid disk tests from several manufacturers (e.g., Remel, Carr-Scarborough) and are also on some of the kit systems (e.g., API Rapid Strep). The BactiCard *Streptococcus* test (Remel Laboratories) includes PYR, LAP, and an esculin hydrolysis test. This card, when used with vancomycin susceptibility results, can provide preliminary characterization of *Enterococcus*, *Lactococcus*, *Aerococcus*, *Gemella*, *Leuconostoc*, *Pediococcus*, and *Globicatella* species.

Occasionally, more uncommon tests may be helpful to augment traditional tests or to confirm identifications obtained with kit systems. For the growth temperature tests, a water bath set at 45°C and a 10°C refrigerator are recommended. Growth, if any, is observed after 24 to 48 hours of incubation. Motility is determined in regular semisolid motility agar medium, with or without the addition of tetrazolium. This test should be incubated for up to 48 hours at room temperature. The VP test for acetylmethyl carbinol that is used for streptococci is performed in heavily inoculated VP broth incubated overnight. After addition of α-naphthol and sodium hydroxide reagents, the tube is shaken or vortexed and incubated at room temperature for 30 minutes. Red, pink, and colorless reactions at this time correspond to positive, weakly positive, and negative reactions, respectively.

787

TABLE 13-2 Phenotypic Characteristics for Presumptive Identification of Catalase-Negative, Gram-Positive Cocci

Genus	Gram Stain Morphology in Thioglyollate Broth	Hemolysis, SBA	Catalase	Growth, 10°C	Growth, 45°C	Motility	LAP	PYR	Growth, 6.5% NaCl Broth	Gas, MRS Broth	Vancomycin
Streptococcus	Chains	α, β, γ	–	–	V	–	+	–	V	–	S
Enterococcus	Pairs, chains	α, γ	–	+	+	V	+	+	+	–	S/R
Abiotrophia	Chains	α, γ	–	–	V	–	+	+	–	–	S
Granulicatella	Chains	α, γ	–	–	V	–	+	+	–	–	S
Aerococcus	Tetrads, clusters	α	–	–	–	–	V	V	+	–	S
Helcococcus	Tetrads, clusters	γ	–	–	–	–	–	+	+	–	S
Leuconostoc	Chains	α, γ	–	+	+	–	–	–	V	+	R
Weissella	Chains	α, γ	–	V	V	–	–	–	+	+	R
Pediococcus	Tetrads, clusters	α	–	–	+	–	+	–	V	–	R
Tetragenococcus	Tetrads, clusters	α	–	–	+	–	+	–	+	–	S
Gemella	Tetrads, clusters, chains	α, γ	–	–	–	–	V	+	–	–	S
Vagococcus	Chains	α, γ	–	+	–	+	+	+	+	–	S
Alloiococcus	Clusters, tetrads	α	+	–	–	–	+	+	+	–	S
Globicatella	Chains	α	–	–	–	–	–	+	+	–	S
Facklamia	Clusters, chains	α	–	–	–	–	+	+	+	–	S
Dolosigranulum	Clusters, tetrads	α	–	–	–	–	+	+	+	–	S
Ignavigranum	Clusters, chains	α	–	–	–	–	+	+	+	–	S
Dolosicoccus	Chains	α	–	–	–	–	–	+	–	–	S
Eremococcus	Chains	α	–	–	+	–	–	NA	+[w]	–	S
Catellicoccus	Pairs, short chains	γ	–	–	NA	–	+	–	NA	–	S
Lactococcus	Chains	α, γ	–	+	V	–	+	+	V	–	S

+, positive reaction; –, negative reaction; V, variable reaction; +[w], weak-positive reaction; S, susceptible; R, resistant; NA, data not available; LAP, leucine aminopeptidase; PYR, pyrrolidonyl arylamidase; MRS broth, Mann-Sharpe-Rugosa broth.

788

Presumptive Identification of Streptococci and Enterococci

β-Hemolytic streptococci, pneumococci, group D streptococci, and enterococci are

definitively identified using serologic procedures (discussed later) that detect either the Lancefield group antigens (groups A, B, C, D, F, and G) or the capsular polysaccharide antigens (*S. pneumoniae*) of the organisms. Species identification of group D streptococci, *Enterococcus* species, and the viridans streptococci is accomplished primarily by biochemical, physiologic, and enzymatic tests. Laboratories use a handful of presumptive tests that correlate highly with the serologic methods, yet are less expensive to perform. Results of presumptive tests for the major streptococcal groups are summarized in Table 13-3. Detailed procedures for performance and interpretation of the more commonly used presumptive tests are described in Charts 13-1 to 13-4.

Susceptibility to Bacitracin. The bacitracin susceptibility test is used for the presumptive identification of group A β-hemolytic streptococci (Image Plate 13-2B). The test is performed on a blood agar medium with a bacitracin differential disk (e.g., TAXO A Bacitracin Disk, 0.04 units, BD Microbiology Systems, Cockeysville MD; Bacitracin Differentiation disks, 0.04 units, Remel). The procedure is described in detail in Chart 13-1. Any zone of inhibition around the disk is considered a positive test. Although this test is simple, inexpensive, and fairly accurate for presumptive identification of group A streptococci, it is not highly specific. Over 10% of group C and G streptococcal strains are also susceptible to bacitracin, as are about 5% of group B strains. Consequently, this test is often performed along with the sulfamethoxazole-trimethoprim (SXT) susceptibility test because groups C and G streptococci are usually susceptible to SXT, whereas groups A and B streptococci are resistant. Some workers have advocated the use of bacitracin disks directly on primary, nonselective blood agar for rapid detection and identification of group A streptococci in throat cultures. However, this method will identify only 50% to 60% of isolates. Placement of bacitracin disks on primary plates containing selective media is considerably more sensitive. The laboratory report should reflect the use of a presumptive method; "β-hemolytic streptococci, presumptively group A by bacitracin" or "β-hemolytic streptococci, presumptively not group A by bacitracin."

Susceptibility to Sulfamethoxazole-Trimethoprim (SXT). The SXT susceptibility test presumptively distinguishes groups A and B streptococci from other β-hemolytic streptococci (Image Plate 13-2C). When used in conjunction with the bacitracin test, the SXT susceptibility test helps screen out those non–A, non–B streptococci that may be susceptible to bacitracin because both group A and B strains are SXT-resistant, whereas groups C, F, and G are SXT-susceptible.. The test is performed the same as the bacitracin test, except that a commercial disk containing 1.25 µg trimethoprim and 23.75 µg of sulfamethoxazole is used. Any zone of inhibition indicates susceptibility to SXT (see Chart 13-1).

CAMP Test and Pigment Production. The CAMP test (named for Christie, Atkins, and Munch-Petersen) is used to presumptively identify group B streptococci (see Chart 8-1) and is performed using a β-hemolysin-producing strain of *S. aureus* (ATCC #25923 Group B streptococci secrete a protein called "CAMP factor" that interacts with the β-hemolysin produced and secreted by *S. aureus* to cause enhanced or synergistic hemolysis (Image Plate 13-2D). This appears as an arrowhead-shaped area of increased hemolysis in the area where the two streaks of growth are closest. This test is highly sensitive, and even nonhemolytic group B strains will be CAMP-positive. A small percentage of group A streptococci will also be CAMP-positive, as will *Listeria monocytogenes*; the shape of the CAMP reaction with *L. monocytogenes,* however, is rectangular rather than the arrowhead shape produced with group B streptococci. This test is frequently used in conjunction with the bacitracin and SXT tests on the same blood agar plate to presumptively identify these organisms (Table 13-3). Reports should state "presumptive β-hemolytic group B streptococci by CAMP test."

Hydrolysis of Sodium Hippurate. Group B streptococci are able to hydrolyze hippurate to its components, glycine and benzoic acid. To perform the test, broth containing sodium hippurate is inoculated with the organism and incubated overnight at 35°C. The cells are centrifuged and the supernatant is removed. Ferric chloride reagent (0.2 mL; $FeCl_3 \cdot 6H_2O$, 12 g, in 100 mL 2% aqueous HCl) is then added to the supernatant (0.8 mL), with the formation of a heavy precipitate. If the precipitate remains after 10 minutes, benzoic acid is present and the test is positive for hippurate hydrolysis. Alternatively, ninhydrin reagent may be added to the supernatant to detect free glycine. In this method, the formation of a deep blue color is positive. Hippurate-positive, β-hemolytic streptococci are reported as "presumptive group B streptococci by hippurate hydrolysis."

Bile Esculin Test. This test is used for the presumptive identification of *Enterococcus* species and group D streptococci (Image Plate 13-2F). It is generally performed on an agar slant or in a plate (Chart 13-2). Organisms that are bile esculin–positive are able to grow in the presence of 40% bile and to hydrolyze esculin. Most *Enterococcus* species and group D streptococci will blacken bile esculin medium within 24 hours; rare strains may require a 48-hour incubation before hydrolysis is apparent. Care should be taken to use bile esculin agar formulations that contain the requisite 40% bile; some manufacturers' products contain less bile than this amount, resulting in misidentification of some viridans streptococci as group D streptococci or enterococci.

Salt Tolerance Test (6.5% NaCl Broth). The salt tolerance test (6.5% NaCl broth) separates *Enterococcus* species from the group D nonenterococcal streptococci (*S. gallolyticus* subspecies) (see Chart 13-4). The organism to be identified is inoculated

into an infusion-based agar or broth containing 6.5% NaCl. After overnight incubation, the medium is observed for the presence of growth, indicating tolerance to 6.5% salt. *Enterococcus* species will be salt-tolerant. *S. gallolyticus* subspecies will not grow in 6.5% NaCl broth.

Leucine Aminopeptidase (LAP) Test. Production of leucine aminopeptidase (LAP), along with PYR, is helpful

789

TABLE 13-3 Phenotypic Criteria for Presumptive Identification of Clinically Significant Streptococci and Enterococci

Organism	Hemolysis, SBA	LAP	Bacitracin	SXT	CAMP Test	HIPP	Growth, BE Agar	PYR	Growth, 6.5% NaCl Broth	Optochin	Bile Solubility
Group A *Streptococcus*	β	+	S	R	–	–	–	+	–	R	–
Group B *Streptococcus*	β, γ	+	R	R	+	+	–	–	V	R	–
Groups C, F, and G streptococci	β, γ	+	V	S	–	–	–	–	–	R	–
Group D *Enterococcus*	α, β, γ	+	R	R	–	V	+	+	+	R	–
Group D *Streptococcus*	α, γ	+	R	S	–	–	+	–	–	R	–
Viridans streptococci	α, γ	+	V	S	–	V	V	–	–	R	–
Pneumococcus	α	+	V	S	–	–	–	–	–	S	+

+, positive reaction; –, negative reaction; V, variable reaction; S, Susceptible; R, Resistant; LAP, leucine aminopeptidase; SXT; trimethoprim-sulfamethoxazole; HIPP, hippurate hydrolysis; BE agar, bile esculin agar; PYR, pyrrolidonyl arylamidase.

790

for identifying streptococci, enterococci, and some of the *Streptococcus*-like organisms. This test is available as a disk spot test (Remel Laboratories; Carr-Scarborough Microbiologicals, Decatur, GA), as a part of a three-test presumptive identification system (Remel Bacti-Card Strep) or on 4-hour or overnight panels for streptococcal identification (the API Rapid Strep). Disks are moistened and heavily inoculated with colonial material from an agar plate (this may require that plates of very slow-growing isolates be incubated 2 to 3 days before sufficient inoculum is available for testing). After 10 minutes, a drop of the detection reagent is added to the disk. Development of a red color on the disk after 3 minutes indicates a positive LAP reaction; a yellow color is a negative test; and a pink color is coded as a weakly positive test. The LAP test is positive for all streptococci and enterococci, the latter also being PYR-positive.

Pyrrolidonyl Arylamidase (PYR) Test. The PYR hydrolysis test (Chart 1-6) is a presumptive test for both group A and group D enterococcal streptococci (Image Plate 13-2G). It replaces the bacitracin test and the salt tolerance test for group A streptococci and *Enterococcus* species, respectively. The enzyme that is detected is

called pyrrolidonyl arylamidase. Broth containing PYR (L-pyrrolidonyl-β-naphthylamide) is inoculated with the organism and incubated at 35°C for 4 hours. During this time, PYR is hydrolyzed. Free β-naphthylamide is then detected by addition of the diazo dye coupler, *N*, *N*-dimethylaminocinnamaldehyde. A red color develops if PYR has been hydrolyzed. This test is highly sensitive and specific for group A streptococci and most *Enterococcus* species. Several adaptations of the PYR hydrolysis test are commercially available and provide rapid results (15 minutes or less). Other organisms (e.g., most lactococci, *A. viridans, G. haemolysans*, the nutritionally variant streptococci, and some staphylococci) are also PYR-positive. This test is included along with esculin hydrolysis and leucone aminopeptidase on the Bacti-Card Strep system (Remel).

Commercial Presumptive Identification Tests. Commercially produced triplates are available for the presumptive identification of β-hemolytic streptococcal groups A and B, the group D streptococci, and *Enterococcus* species (Image Plate 13-2H). The Strep-ID II Tri-Plate (Remel) contains three compartments: an SBA quadrant for assessment of hemolysis and performance of the CAMP and SXT tests, a bile esculin agar quadrant, and a PYR medium quadrant. The Strep-ID II QUAD plate has four quadrants for the bacitracin susceptibility test, a CAMP test, growth on bile esculin agar, and growth in the presence of 6.5% NaCl, respectively. After inoculation and overnight incubation, the tests are interpreted as shown in Table 13-3.

Serologic Identification of β- Hemolytic Streptococci

The pioneering work of Rebecca Lancefield set the stage for the serologic classification of human streptococci. This classification is based on the detection of the group-specific carbohydrate antigen from the cell wall of the organism. Groupable streptococci that cause disease in humans belong to Lancefield groups A, B, C, D, F, and G. Only β-hemolytic streptococci and the α- or nonhemolytic group D organisms can be classified with this scheme. To detect the cell wall antigens of these organisms, the antigen must first be extracted from the cell wall and solubilized. This may be accomplished by acid extraction (e.g., nitrous acid), autoclave extraction (Rantz–Randall method), or by enzymatic extraction. Once extracted, the antigen may be detected by a variety of methods.

Capillary Precipitin Test. In this method used by Lancefield, the extracted antigen is layered over group-specific antisera in a capillary tube. The formation of a precipitin reaction at the extract-antiserum interface provides the group designation of the organism.

Coagglutination. In this technique, the antigen extract is reacted with *S. aureus* cells sensitized with group-specific antisera. Visible agglutination of the staphylococcal cells

coated with a specific antiserum provides the group designation of the organism. Commercial coagglutination test kits are available (Phadebact Streptococcus, MLK Diagnostics AB, Sollentuna, Sweden).

Latex Agglutination. The LA tests employ polystyrene latex beads as the carriers for the group-specific antisera that are reacted with the organism extract. Commercial kits for this method are widely used as well (Streptex, Remel; Patho-D_X Strep Grouping Kit, Diagnostic Products Corporation, Los Angeles CA; Slidex Plus Strep, bioMerieux, Inc., Hazelwood MO). LA procedures have replaced the Lancefield extraction–capillary precipitin technique as the reference method for serogrouping of β-hemolytic streptococci. The proper assessment of hemolysis is essential for test reliability, and cross-reactions with other organisms have been reported. This error may occur when organisms are tested directly from blood culture bottles without first determining the hemolytic character of the isolate. Thompson and Facklam also reported that the group B LA regent from several manufacturers cross-reacts with *S. porcinus* and *S. pseudoporcinus*.[1024] While these strains react with the group B latex reagents, the organisms form small colonies with very large, clear zones of β-hemolysis, which is very different from the soft, marginal β-hemolysis associated with group B streptococci.

Phenotypic Characteristics for Identification of Groupable Streptococci

The groupable streptococci can be identified to species on the basis of physiologic characteristics. Several of these reactions are used in the various kit systems for identifying the β-hemolytic streptococci. Biochemical identification methods may also enable detection of aberrant strains of β-hemolytic streptococci. For example, Brandt and colleagues[117] isolated three strains of β-hemolytic streptococci from blood cultures that possessed the group A antigen, but were identified as *S. dysgalactiae* subsp. *equisimilis* by phenotypic testing and 16S rDNA sequencing. These strains were acetoin-negative and PYR-negative, unlike group A streptococci. Although most clinical laboratories dealing with specimens from humans use serologic methods for

identification of these organisms, workers in veterinary microbiology may find these tests helpful because Lancefield antisera for groups other than A, B, C, F, and G are not readily available. Phenotypic characteristics for the identification of groupable streptococci are presented in Table 13-4. Molecular markers have also been identified to discriminate *S. pyogenes* from other members of the pyogenic cocci group (e.g., *S.*

dysgalactiae subsp. *equisimilis*).[705]

Identification of S. pneumoniae: Susceptibility to Optochin, the Bile Solubility Test, and AccuProbe Pneumococcus Test

The alpha-hemolytic dimpled colony morphology and Gram stain characteristics are often the first clues to recognizing pneumococcus (Image Plate 13-1C and13-2A). Susceptibility to optochin (ethyl hydrocupreine hydrochloride) is used to differentiate *S. pneumoniae* from the other viridans streptococci (see Chart 13-3). As with the bacitracin and SXT tests, the optochin susceptibility test is performed on blood agar media. Unlike the former tests, however, zones of inhibition must be measured before interpretation. A zone of 14 mm or wider around the 6-mm disk indicates susceptibility to optochin and identifies the organism as a pneumococcus (see Image Plate 13-2E). If the zone is smaller than 14 mm, an alternative identification test (e.g., serology or bile solubility) should be performed because some nonpneumococcal viridans streptococci and aerococci may show small zones of inhibition. Viridans streptococci and group D enterococci are generally optochin-resistant. The bile solubility test is another test for identification of *S. pneumoniae*. The test can be performed on a broth or saline suspension of the organism or directly on a plate. Both procedures are described in Chart 13-5. Deoxycholate, the "bile" reagent used in these procedures, activates the autolytic enzymes of the organism. Optochin-susceptible and -resistant, bile-insoluble isolates of *S. pneumoniae* and optochin-resistant, bile-soluble viridian streptococcal isolates have been reported.[36,493] Molecular assays for detection of the *ply* (pneumolysin) and the *psa* (pneumococcal surface antigen) are useful distinguishing unusual or atypical isolates of *S. pneumoniae* from other viridans streptococci that occasionally display bile solubility or susceptibility to optochin.[493]

An evaluation of the optochin test with 99 clinical isolates of *S. pneumoniae* and 101 viridans streptococci reported a sensitivity and specificity of 99% and 98%, respectively.[551] Characterization of optochin-susceptible strains of *S. mitis* revealed acquisition of genes from *S. pneumoniae* that encode subunits of the H+ ATPase, which is the target of optochin.[682] Strains of *S. pneumoniae* that are optochin-resistant have point mutations in either the a- or c-subunit of the H+ ATPase and have optochin MICs that are 4- to 30-fold higher than susceptible strains.[831] The AccuProbe DNA hybridization assay (Gen-Probe) reliably identifies typical optochin-susceptible, encapsulated pneumococci, but may not reliably identify optochin-susceptible, unencapsulated isolates.[529] The recently described species *S. pseudopneumoniae*, which is considered a member of the "mitis group" of viridans streptococci (see below), will demonstrate resistance (6 mm zone) or intermediate susceptibility (8 to 13 mm zones) to optochin when cultures are incubated in 5% CO_2 at 35°C to 37°C, but

the same isolates may test optochin-susceptible (zone of ≥14 mm) when cultures are incubated at 35°C to 37°C in ambient air.[36] While the Accuprobe hybridization test may reliably differentiate optochin-susceptible, bile-soluble *S. pneumoniae* from optochin-resistant viridans streptococci, the assay may produce equivocal or positive results with optochin susceptibility-variable, bile-solubility-negative isolates that correspond to *S. pseudopneumoniae*.[36] Wessels and colleagues[1118] studied 23 *S. pneumoniae*, 3 *S. pseudopneumoniae*, and 29 other mitis group isolates and found that optochin susceptibility testing with incubation in ambient atmosphere, bile solubility, MALDI-TOF, and sequencing of the *tuf* and *rpoB* genes resulted in false-positive, false-negative, and inconclusive results. Detection of and sequencing of the *cpsA* gene (a partial region of the capsular polysaccharide gene) and the *rpoA* (RNA polymerase α-subunit) gene, have been shown to specifically discriminate *S. pneumoniae* from other viridans streptococci.[803,804] PCR detection of the genes for pneumococcal polysaccharide antigen (*psa*) and pneumolysin (*ply*) have also proven to be helpful for the identification of atypical, nontypeable or optochin-resistant pneumococci.[493] A highly reliable molecular method for differentiation of these species involved a multiplex, real-time PCR assay targeting the *Spn9802* and *lytA* genes. The Spn9802 assay detected *S. pneumoniae* and *S. pseudopneumoniae* but not *S. mitis* or *S. oralis*, and the *lytA* PCR detected only *S. pneumoniae*, so a combination of the two PCRs could be used for rapid detection and differentiation of these organisms.[1118] MALDI-TOF MS has shown high sensitivity and specificity for identifying atypical *S. pneumoniae* isolates and for identification of *S. pseudopneumoniae*.[299]

Serologic Identification of Streptococcus pneumoniae

Definitive identification of *S. pneumoniae* involves the serologic detection of pneumococcal capsular polysaccharides using specific antisera. This is complicated because there are more than 92 different capsular serotypes, antisera for the more uncommon serotypes are not widely available, and the quality of the antisera may vary from lot to lot. Omniserum, a Scandinavian product, is capable of detecting all pneumococcal serotypes. Such antiserum pools have been used to develop commercial coagglutination (Phadebact Pneumococcus, MLK Diagnostics AB, Sollentuna, Sweden) and LA tests (Pneumoslide, BD Microbiology Systems; Slidex Pneumo, bioMerieux, Inc.) (Image Plate 13-3C) for rapid serologic identification of *S. pneumoniae*. Specific identification and assignment to an individual capsular serotype is accomplished with the Quellung test (Image Plate 13-3B). Nontypeable isolates may react if an expanded panel of high-quality antisera is used.[493] Nonencapsulated isolates of *S. pneumoniae* cannot be typed or identified by the Quellung test.

The Quellung test may employ a serum pool, as well as type-specific antisera (Pneumotest, Statens Serum Institute, Copenhagen, Denmark). A light suspension of

the organism is prepared in saline, and a loopful of this suspension is mixed with a loopful of antiserum and a loopful of methylene blue on a glass slide. A glass coverslip is applied, and the slide is incubated at room temperature for 10 minutes. The

slide is examined under the high dry objective and under oil immersion, with decreased light. Owing to a microprecipitin reaction occurring on the surface of the organism, the refractive index of the capsule changes and takes on a "swollen," more visible appearance as a halo around the blue-stained bacterial cells. Microscopic organism agglutination may also be observed, particularly with heavily encapsulated strains. Quellung results must be compared microscopically with a similar preparation made with saline instead of antisera.

Identification of the Viridans Streptococci

The viridans streptococci other than *S. pneumoniae* include several α-hemolytic and nonhemolytic species (Table 13-5, Table 13-6, and Box 13-2). Unlike the human β-hemolytic streptococci, these organisms, with the exception of members of the "*Bovis* group," lack specific Lancefield serologic group antigens, although some may carry antigens that cross-react with these antisera. Unlike pneumococci, viridian group streptococci are optochin-resistant and bile-insoluble. In cases of endocarditis and bacteremia in neutropenic patients, it may be clinically helpful to identify these organisms. Persons with preexisting valvular damage may have recurrent episodes of endocarditis or experience relapse following inadequate treatment. Knowledge of the identity and the antimicrobial susceptibility of these isolates help in differentiating treatment failures and reinfections.

Phenotypic tests were initially used to group the viridans streptococci based on their common features. In 1998, Whiley and coworkers[1124] in the Department of Oral Microbiology at London Hospital Medical College published comprehensive schemes for phenotypic identification of the viridans streptococci recognized at the time. This "conventional" approach used 24-hour carbohydrate fermentation tests and a panel of 4-methylumbelliferyl-linked substrates for the 3-hour determinations of various enzymes. The dichotomous key in Figure 13-3 incorporates the "grouping" tests from Table 13-4 and additional tests from Table 13-5 for identifying "typical" individual species within a group. The viridans streptococcal groups include the **Mitis/Sanguinis Group,** the **Mutans Group**, the **Salivarius Group**, the **Anginosus Group**, and the **Bovis Group.**[291] Organisms can be assigned to these groups based on arginine dihydrolase (ADH) production, esculin hydrolysis, acetoin production (VP), urease, and acid production from mannitol and sorbitol (Table 13-5). Box 13-2 provides details on the clinical significance of these species.

Manual and automated commercial systems do not adequately identify this difficult group of organisms, and the data bases for these systems are not updated frequently enough to provide reliable species-level identifications. Most laboratories that attempt to identify these organisms employ one or more commercial kits for this purpose.

Often, additional phenotypic tests need to be added. Commercial products use modified conventional test and chromogenic or fluorogenic substrates for detection of preformed enzymes; these approaches have become a standard part of test batteries used for streptococcal identification. Applications of molecular and chemotaxonomic methods have resulted in significant modifications in viridans streptococcal taxonomy and approaches to identification. Molecular methods proposed for identification of streptococci to the species level must have sufficient variability between different species, but little sequence variability within a species. Molecular techniques for identification of viridans streptococci and enterococci include PCR-mediated amplification/detection of 16S rRNA, 16S rDNA, and the 16S-23S rRNA intergenic spacer regions. For the most part, 16S rRNA gene sequencing does not adequately resolve species identifications among some viridans streptococci (e.g., the Mitis Group streptococci) because organisms within these groups (i.e., *S pneumoniae*, *S pseudopneumoniae*, and *S. mitis*) share >99% sequence homology among each other in the rRNA locus. Consequently, detection and sequencing of specific genes found in these organisms have been used to determine species identifications.[593,679,763] These genes include *ddl* (D-alanine:D-alanine ligase gene), *lytA* (autolysin gene), *dex* (dextranase gene),

groEL (genes encoding 10kDa and 60 kDa heat-shock proteins), *rnpB* (gene encoding the RNA subunit of endoribonuclease O), *sodA* (superoxide dismutase gene), *tuf* (gene encoding elongation factor Tu), *gyrA* (gene encoding quinolone-resistance-determining regions of DNA gyrase), *rpoB* (gene encoding RNase P), *parC* (topoisomerase subunit C gene), and *recN* (recombination/repair protein gene).[370,384,483,546,828,1009,1122] MALDI-TOF shows promise as a rapid and accurate method for species identification of the viridans streptococci. Identification by mass spectrometry is dependent on having an accurate database reflecting the spectral arrays found in these bacteria. The Bruker Daltronics and bioMerieux MALDI-TOF platforms contain a vast array of spectra based on species-specific PCR assays and 16S rRNA gene sequencing.

Specific applications of these methods for direct detection in clinical specimens and for identification of cultural isolates are described below and in the sections dealing with specific identification kits and methods.

Mitis/Sanguinis Group. The Mitis Group contains several closely related species, including *S. mitis, S. pneumoniae,* and *S. pseudopneumoniae*. Members of this group are more frequently isolated from blood cultures and are of some importance due to emerging resistance to penicillin and other β-lactam agents in this group. Original members of the Mitis Group did not hydrolyze esculin, did not produce ADH or aceteoin, and did not ferment mannitol or sorbitol. Some taxonomic schemes include members of the Sanguinis Group of viridans streptococci (*S. sanguinis*, *S. parasanguinis*, and *S. gordonii*) within the Mitis Group based on 16S rRNA sequencing. Isolates in the Sanguinis Group are ADH- and esculin-positive and, like members of the Mitis Group,

are negative for acetoin production and do not ferment mannitol or sorbitol. Analysis of *S. sanguinis*-like strains resulted in the descriptions of other Mitis and Sanguinis Group members (*S. gordonii* and *S. oralis*), and members of the Mitis Group genotypically (usually based on 16S rRNA sequencing) had phenotypic characteristics shared with Sanguinis Group members.[795] For example, *S. cristatus* shares features of *S. mitis*, but is ADH-positive. *S. parasanguinis* and *S. cristatus* have been isolated from the upper respiratory tract, dental plaque, urine, periodontal abscesses, and blood cultures.[422,694,882,1125] *S. peroris* and *S. infantis* are found on the teeth and in the nasopharynx.[545] *S. sinensis* is an α-hemolytic *streptococcus* that was isolated from the blood of a patient with endocarditis in 2002.[1142] Newer Mitis Group species that have been isolated from human clinical specimens (i.e., *S. australis*, *S. lactarius*, *S. massiliensis*, *S. oligofermentans*, and *S. tigurinus*) are described in Box 13-2. *S. pneumoniae* and *S. pseudopneumoniae* are discussed further below. MALDI-TOF MS has shown high sensitivity and specificity for identifying atypical *S. pneumoniae* isolates, for identification of *S. pseudopneumoniae,* and for differentiation of these organisms from other organisms in the Mitis Group.[299,1117]

Mutans Group. The Mutans Group includes oral streptococci found in humans and various animal species. (Box 13-2) Species in the Mutans Group were originally serotypes of *S. mutans* that were elevated to species status later. *S. mutans* and *S. sobrinus* are species isolated from humans. *S. hyovaginalis* is also included in the Mutans Group because of its biochemical consistency with other mutans group streptococci, but this species is found in the genital tract of swine and as part of its

normal flora. Several new Mutans Group species have been isolated from bats, rats, pigs, bears, and wild boars. *S. mutans* and *S. sobrinus* hydrolyze esculin, produce acteoin, and ferment sorbitol and mannitol, do not produce ADH, and can be differentiated by enzymatic and fermentation tests (Table 13-6).

Salivarius Group. Among species in this group, only *S. salivarius*, *S. vestibularis*, and *S. infantarius* have been recovered from human clinical specimens. *S. salivarius* and *S. vestibularis* are found in the human oral cavity, while *S. infantarius* has been isolated from humans and food products.[901,1128] *Salivarius* group organisms produce acetoin and hydrolyze esculin, but are ADH-negative and do not ferment mannitol or sorbitol. *S. infantarius* strains are also included in the Salivarius Group because some strains are bile esculin– and esculin hydrolysis–negative. *S. hyointestinalis* is a *Salivarius* group species found in the gut of swine, and *S. thermophilus* is isolated from dairy products. Strains of *S. vestibularis* and some *S. salivarius* produce urease.

Anginosus Group. The organisms that comprise the anginosus group of streptococci —*S. anginosus* subsp. *anginosus*, *S. anginosus* subsp. *whileyi*, *S. constellatus* subsp. *constellatus*, *S. constellatus* subsp. *pharyngis*, *S. constellatus* subsp. *viborgensis*, and *S. intermedius*—produce "pinpoint" colonies on blood agar and may be β-, α-, or nonhemolytic, depending on the species/subspecies. A greater proportion of *S. intermedius* strains are nonhemolytic, and *S. constellatus* strains are often β-hemolytic. For β-hemolytic strains, the size of the hemolytic zone is usually much larger than the pinpoint colony diameter. Another clue to growth of an anginosus group species is the presence of a sweet odor from the culture plate that resembles "caramel," "butterscotch," or "honeysuckle." This odor is due to production of the metabolite diacetyl.[184] Isolates may carry group A, C, F, or G antigens or may be nongroupable. *S. intermedius* rarely carries Lancefield-grouping antigens. Growth is enhanced by incubation in a CO_2-enriched environment, and some strains may require anaerobic incubation for optimal growth. Members of the Anginosus Group are positive in the esculin hydrolysis, ADH, VP, and sorbitol reactions. Individual species may be differentiated by the phenotypic tests shown in Table 13-6. These and other tests shown in Table 13-7 are found in the commercially available kit systems (e.g., API Rapid Strep, RapID STR, and the API RapidID32 kits, see discussion below).[174] These kits generally have difficulty in separating the species in this group from one another, although certain enzymatic tests on the Rapid ID32tests may prove useful for this purpose.[977] Real-time molecular tests targeting 16S rRNA genes, cpn10/60 (groES and groEL heat-shock proteins), *tuf* (elongation factor 2), *rnp* (RNase P RNA) genes, and rRNA gene intergenic spacer (ITS) regions have been developed for identification and differentiation of members of the Anginosus Group.[786,977,1117] Molecular methods (i.e., 16S rRNA gene detection and sequencing) have proved useful for direct

detection of *S. intermedius* win culture-negative clinical specimens (e.g., brain abscess aspirate).[883]

Bovis Group. As discussed previously, the Bovis Group has undergone significant taxonomic revision. Like the enterococci, the group D streptococci possess the group D antigen, hydrolyze esculin in the presence of 40% bile, and grow at 45°C (Image Plate 13-4C, 13-4D, and 13-4E). They do not grow in 6.5% NaCl broth, do not hydrolyze PYR, and do not grow at 10°C. Most isolates are LAP-positive, produce acetoin, do not produce ADH or urease, and acidify lactose but not sorbitol. *S. gallolyticus* subsp. *gallolyticus* (*S. bovis* I) strains are positive in the mannitol, raffinose, glycogen, amygdalin, and α-GAL reactions, but β-GUR-negative; most strains also ferment inulin.[64] *S. infantarius* subsp *infantarius* (S. bovis II.1) and *S. gallolyticus* subsp. *pasteurianus* (*S. bovis* II.2) are mannitol-negative, with *S. infantarius subsp infantarius* being β-GUR-negative and *S. gallolyticus* sussp. *pasteurianus* being β-GUR–positive. These phenotypic characteristics are presented in Table 13-8. *S. gallolyticus* and its subspecies are included in the data bases of automated (e.g., Vitek 2) and manual (API20 Strep; ID32 Strep) identification systems which provide reliable phenotypic identifications.[569,617,787,973] A molecular identification approach have generally used sequencing of the 16S rRNA and *sodA* (superoxide dismutase gene), with partial sequencing of the *sodA* gene being the most accurate.[350,742,787] Molecular techniques (e.g., 16S rDNA PCR) performed on resected valvular tissue have aided in the diagnosis of severe infections such as multivalve infective endocarditis caused by *S. gallolyticus* subsp. *macedonicus* and *S. gallolyticus* subsp. *gallolyticus* bacteremia.[563,674] MALDI-TOF using the Bruker Biotyper identified all of 27 *S. gallolyticus* isolates, but did not provide subspecies designations.[872] Because of the known

+, positive reaction; –, negative reaction; V, variable reaction; V+, variable reaction, but most strains positive; ESC, esculin hydrolysis; GAL, gallate hydrolysis; GLU, glucose; LAC, lactose; MNTL, mannitol; RAFF, raffinose; TRE, trehalose; INU, inulin; STA, starch; GLYG, glycogen; α-GAL, α-galactosidase; β-GAL, β-galactosidase; β-GLU, β-glucosidase; β-GUR, β-glucuronidase.

association of the former *S. bovis* II.1 with endocarditis and colonic carcinoma, the emergence of *S. gallolyticus* subsp. *pasteurianus* as a cause of bacteremia and meningitis, and the confusing changes that have occurred in the taxonomy of the Bovis Group, it, is incumbent on the laboratory to familiarize clinicians with changes in the taxonomy. Reports should include both the new name and the old name or the organisms in order to prevent the underdiagnosis of serious diseases related to this organism group.[1081]

Identification of Streptococcus suis *and Other Streptococci Isolated From Animals*

S. suis should be suspected in patients with systemic signs of sepsis and meningitis who have had contact with pigs or porcine products. The organism is a catalase-negative, nonmotile, gram-positive coccus that occurs singly, in pairs, or in short chains. *S. suis* is α-hemolytic on SBA (β-hemolytic on horse blood agar), resistant to optochin, and does not grow in 6.5% NaCl broth. Some strains will grow in the presence of 40% bile, and all strains are able to hydrolyze esculin. *S. suis* phenotypically resembles certain viridans streptococci, particularly *S. gordonii*, *S. sanguinis*, and *S. parasanguinis*. *S. suis* is in the databases of the API 20 Strep (bioMerieux) and the Vitek 2; identifications obtained with these systems usually have likelihoods in excess of 99.7%.[481,559,1028] Human isolates are usually capsular serotype 2 strains that react with Lancefield group R antisera (Statens Serum Institute, Copenhagen, Denmark) Molecular methods for identification include sequencing of 16S rRNA and housekeeping genes (e.g., *tuf* gene, *sodA* gene).[481,1028] Direct detection of *S. suis* serotype 2 in clinical specimens (e.g. CSF) and capsular typing may also be accomplished by molecular methods using sequence analysis of 16S rRNA and capsular *cps* (especially *csp2j*) genes as targets.[671,949] These genes encode part of the operon for the *S. suis* serotype 2 capsular polysaccharide. Multiplex PCR assays have also been developed for detection of other serotypes and virulence-associated genes that are pathogenic for swine.[1135]Additional characteristics that are helpful for identification of *S. suis* are presented in Table 13-9. Table 13-9 also presents the phenotypic characteristics of α- and nonhemolytic streptococci isolated from various animal species.

Detection of Vancomycin-Resistant Enterococci

Enterococcus species grow well on most bacteriological media, including 5% sheep blood CNA, and chocolate agars. On SBA, most strains are nonhemolytic or α-

hemolytic. Most strains are able to grow at 35°C to 37°C in ambient air, although incubation in a CO_2-enriched environment stimulates growth of most isolates. Specimens containing enterococci that are heavily contaminated with gram-negative bacilli may be easily isolated on media containing sodium azide (e.g., Pfizer selective enterococcus agar, bile esculin azide agar). Identification of enterococci to species level is often helpful and sometimes crucial for proper patient management and for epidemiologic and infection control purposes. Isolates of *E. faecium* tend to be more resistant to penicillin and ampicillin than *E. faecalis* isolates, and the vast majority of VRE are strains of *E. faecium*. Asymptomatic colonization of the gastrointestinal tract by VRE typically precedes infection, and colonization may persist and serve as a reservoir for colonization/infection of other patients.[725] Patients who are colonized by VRE become efficient vectors for environmental distribution and spread of VRE to healthcare workers. Patients who are colonized with VRE in the intestinal tract can remain carriers for months to years. Hospital outbreaks of VRE have been reported extensively in the United States and several other countries. The major consequences of VRE infections include increased morbidity and mortality, increased lengths of hospitalization, and increased costs related to longer hospital stays.[82,138,365,604,847,954,1112] Early detection of VRE in at-risk patients enables the timely institution of infection control practices that are known to limit the spread of these opportunistic agents. The Hospital Infection Control Practices Advisory Committee of the CDC has promulgated guidelines to prevent the spread of VRE and has recommended implementation of contact isolation precautions for patients who have gastrointestinal colonization with VRE.[154] The breakpoint for vancomycin resistance is ≥32 µg/mL, with intermediate susceptibility being 8 to 16 µg/mL. (CLSI) VREs from nosocomial outbreaks generally have vancomycin MIC's ≥32 µg/mL.

Several agar and broth media formulations have been used for detection of VRE in anatomic sites that harbor enterococci (i.e., stool specimens, rectal swabs) (Image Plate 13-3H). Broth for growth enrichment of VRE is made semi-selective by addition of vancomycin to the media; other selective agents (e.g., clindamycin, aztreonam) may also be added. Because some VRE strains may be inhibited by these combinations of antimicrobial agents, subculture from selective broth medium to both selective and nonselective agar media is suggested in order to optimize recovery of VRE. For example, VRE broth (Hardy Diagnostics, Santa Maria, CA) is a differential/selective medium for recovery of VRE from heavily contaminated specimens. The medium contains esculin and ferric citrate to detect esculin hydrolyzing organisms, bile salts to inhibit gram-positive bacteria other than enterococci, and sodium azide to inhibit gram-negative bacteria. VRE broth also contains 8 µg/mL of vancomycin for selective detection of vancomycin-resistant strains. Further testing must be performed on media such as BHI with vancomycin as per (CLSI). BEAV agar (bile esculin agar with azide and vancomycin, Remel, Lenexa, KA) is an agar medium for isolation of VRE from

contaminated specimens. As with the broth medium above, esculin, ferric citrate, bile salts, and azide are present for inhibition of other gram-positive and gram-negative bacteria, respectively. Bile tolerance and esculin hydrolysis provide presumptive identification of group D streptococci, and the presence of vancomycin in BEAV agar (8 μg/mL) selects for VRE. With 8 μg/mL of vancomycin, BEAV does not support growth of *E. casseliflavus* and *E. gallinarium* (low-level resistance). VREs must be confirmed using BHI with vancomycin according to CLSI recommendations.

Several chromogenic media formulations are available for detection of gastrointestinal VRE colonization and include Spectra VRE (Remel), BBL CHROMagar VanRE (Becton-Dickinson), VRE-BMX (bioMérieux, Marcy l'Étoile, France), chromID VRE (bioMerieux), and Brilliance VRE agar (Oxoid). These media contain chromogenic substrates having sufficient sensitivity and specificity to identify

802

VRE. Spectra VRE is designed to detect VRE in stool or rectal swab specimens after 24 hours' incubation. These media contain proprietary antimicrobial additives. On Spectra VRE agar, vancomycin-resistant *E. faecium* grow as pink, purple, or dark-blue colonies, while vancomycin-resistant *E. faecalis* appear as light-blue colonies. A 2010 evaluation of Spectra VRE compared with BEAV agar found that the sensitivity, specificity, and positive and negative predictive values for Spectra VRE medium were 98.2%, 99.3%, 98.2%, and 99.3% compared with 87.6%, 87.1%, 72.8%, and 94.7% for BEAV agar.[825] Similar results for Spectra VRE medium have been reported by other investigators.[514] On BBL CHROMagar VanRE, vancomycin-resistant *E. faecium* and vancomycin-resistant *E. faecalis* appear as mauve colonies and green colonies after 24 hours' incubation, respectively. In an evaluation of this medium by Kallstrom and coworkers,[532] the sensitivity, specificity, and positive and negative predictive values for CHROMagar VanRE were 98.6%, 99.1%, 95.9%, and 99.7%, respectively. On VRE-BMX and chromID VRE agars (bioMérieux), colonies of *E. faecium* and *E. faecalis* appear as purple or green, respectively. Ledeboer and colleagues[269,623,624] compared VRE-BMX agar with BEAV agar for detection of VRE in stool specimens and found that VRE-BMX detection 94.4% of 54 vancomycin-resistant *E. faecium* and 100% of 12 vancomycin-resistant *E. faecalis* after 24 hours' incubation. Evaluations of chromID agar have reported sensitivities ranging from 80% to 100% for detection of vancomycin-resistant *E. faecium* and *E. faecalis* with

specificities exceeding 99% when direct specimen inoculation methods were used.[624] Specimen preenrichment in broth medium containing vancomycin or incubation of chromID agar for an additional 24 hours resulted in sensitivities ranging from 93% to 100%.[254,289,581,624]

Molecular approaches are also available for the detection of VRE in stool and rectal swab specimens. Widely used tests include the BD GeneOhm VanR (Becton-Dickinson) and the Gene Xpert *vanA/vanB* (Cepheid). These assays detect the *vanA* and *vanB* responsible for moderate- to high-level vancomycin resistance. The sensitivities and specificities of these assays vary depending on the prevalence of enterococci carrying the *vanA* or the *vanB* resistance determinants. In one study, the GeneXpert assay showed sensitivities for *vanA* and *vanB* detection of 73.9% and 87.5%, respectively, while corresponding sensitivities for the GeneOhm assay were 43.5% and 100%, respectively.[372] Both assays have shown low specificities ranging from 14.7% to 20.6% for detection of these resistance determinants, and lower specificities for detection of *vanB* have been reported for the BD GeneOhm assay in other studies.[961,1067] An evaluation of the GeneXpert *vanA/vanB* assay during a VanA *E. faecium* outbreak showed sensitivity, specificity, and predictive values of positive and negative test results of 61.5%, 79.2%, 61.5%, and 79.2%, respectively.[1164] The authors of this study concluded that, while a rapid (i.e., less than 1 hour) positive test enabled early recognition of some colonized patients, culture on chromogenic agar medium (in this case, chromID VRE agar) was required to detect and confirm VRE colonization in other patients. A study conducted at Johns Hopkins found that the GeneOhm VanR assay detected 96.6% of 147 VRE isolates compared with chromogenic culture media, with a specificity of 87.0%.[961] The lower specificity was due to false-positive results occurring with the *vanB* portion of the assay. While these assays primarily detect *E. faecium* and *E. faecalis* carrying vancomycin-resistance genes, positive results may be obtained with other enterococcal species (e.g., *E. raffinosus*, *E. durans*, *E. gallinarum*) carrying *vanA* or *vanB* genes.[961] Both of these molecular assays are considerably faster than culture. Other highly sensitive and specific quantitative and real-time PCR assays for detection of VRE have also been described.[1043]

Identification of Enterococcus *Species*

Identification of *Enterococcus* species is accomplished by biochemical and physiologic tests (Table 13-10). Most (about 80%) *Enterococcus* species react with antiserum against Lancefield group D by capillary precipitin or LA; the group D antigen cannot be demonstrated in strains of *E. pseudoavium*, *E. dispar*, *E. cecorum*, *E. sulfureus*, *E. columbae*, and *E. saccharolyticus*. Most species of enterococci are able to grow within 48 hours in BHI broth incubated at both 10°C and 45°C. However *E. cecorum*

and *E. columbae* fail to grow at 10°C and *E. sulfureus*, *E. malodoratus*, and *E. dispar* do not grow at 45°C. Most *Enterococcus* species hydrolyze esculin in the presence of 40% bile (BE test), growth in broth containing 6.5% NaCl, and are PYR-positive, although some species are negative in these tests as well (Table 13-10). Although *E. faecalis* and *E. faecium* constitute those species that are most commonly recovered from clinical specimens, the incidence of the other species and their roles in specific disease processes are unknown. Isolates that fit the criteria listed above are inoculated into several phenotypic test media and are identified based on these reactions. For identification of enterococci by conventional procedures, carbohydrate fermentation tests and pyruvate utilization are determined in heart infusion broth base media containing bromcresol purple and 1% filter-sterilized carbohydrates or 1% pyruvate. Deamination of arginine is determined using Moeller's decarboxylase broth, and motility is determined in semisolid motility medium. Detection of the yellow pigment produced by *E. casseliflavus*, *E. gallinarum*, and *E. mundtii* is achieved by sweeping up some of the growth on a white Dacron swab and observing the colonial material on the swab for a yellow or yellow-orange color (Image Plate 13-4A). *E. casseliflavus* and *E. gallinarum* are also motile (Image Plate 13-4B). Acid production in methyl-α-D-glucopyranoside (MGP) is a helpful differential test for differentiation of *E. faecalis*, *E. faecium*, *E. gallinarum* and *E. casseliflavaus*. The former two species do not acidify MGP broth, while the latter two species do. A handful of phenotypic tests, including motility, pigmentation, arginine dihydrolase, and acid production from MGP, arabinose and raffinose may be used for phenotypic identification of *E. faecalis*, *E. faecium*, *E. casseliflavius*, *E. gallinarum*, and *E. raffinosus*. A flowchart for identifying the clinically significant *Enterococcus* species is presented in Figure 13-4. In addition, many laboratories rely on manual (e.g., API Strep) and automated (e.g., Vitek 2, Phoenix, Microscan) identification systems for identifying enterococci. These systems and their performance for identifying enterococci are described later in this chapter. PCR-based

808

molecular methods involving sequencing of specific genes (e.g., *tuf* gene, *rpoB* gene)

have also been useful for accurate identification of *Enterococcus* species.[638]

Identification of Abiotrophia *and* Granulicatella *Species*

A. defectiva and *Granulicatella* species should be suspected when direct Gram's stains of specimens or of positive blood cultures show streptococcal organisms that fail to grow on subsequent culture or subculture. Commercial blood culture media contain pyridoxal and will support the growth of these organisms. Subculture onto blood agar and the placement of a staphylococcal streak as is done in the satellite test for *Haemophilus* spp. will ensure growth of the nutritionally variant streptococci adjacent to the staphylococcal streak (Image Plate 13-3D). Alternatively, disks impregnated with pyridoxal may also be placed on the subculture plate, with subsequent growth of the organisms appearing as satellite colonies surrounding the disk. Commercially available chocolate agar contains pyridoxal, so these organisms will grow on chocolate agar.

When grown on pyridoxal-supplemented (10 mg pyridoxal hydrochloride per liter), cysteine-supplemented (100 mg L-cysteine/L) media, or chocolate agar, these organisms can be identified with the phenotypic tests shown in Table 13-11. Like the streptococci, these organisms are LAP-positive, but unlike the streptococci, *A. defectiva* and *Granulicatella* species are PYR-positive. Identification can be accomplished by automated (e.g., Vitek 2) or manual methods (e.g., API 20 Strep) or combinations of identification approaches.[6,23,24,270,823,873] Phenotypic testing by itself can result in incorrect identifications. For example, *G. elegans* has been misidentified as *S. acidominimus*, *G. morbillorum*, and *G. adiacens*, although the former two species grow well on unsupplemented blood agar.[6,23,137] Molecular methods for species identification include 16S rRNA, *rpoB* gene, *groES* and *groEL* heat-shock protein genes, 16S RNA, 23S RNA, and ribosomal 16S-23S intergenic spacer region sequencing performed on isolates or directly in excised valvular tissues.[84,297,484,779,1051] *Abiotrophia* and *Granulicatella* species are homofermentative (lactic acid being the end product of glucose fermentation), optochin-resistant, and vancomycin-susceptible. MALDI-TOF MS shows promise for identifying these organisms, and, in one study, *G. adiacens* was identified only to the genus-level for 33% of isolates tested.[758]

Identification of Aerococcus *and* Helcococcus *Species*

The genus *Aerococcus* contains five species: *A. viridans*, *A. urinae*, *A. sanguinicola*, *A. christensenii*, and *A. urinaehominis*. All species are α-hemolytic on SBA and grow in broth cultures as pairs, tetrads, and small clusters. Strains of *A. viridans* characteristically appear mostly as tetrads on Gram-stained smears, whereas *A. urinae* isolates occur mostly in clusters. On agar media, strains of *A. viridans* form large

colonies that resemble those of enterococci. All species except *A. christensenii* grow in 6.5% NaCl; *A. sanguinicola* and some *A. viridans* grow as black colonies on BE agar. Isolates of *A. viridans* are PYR-positive and LAP-negative, but *A. urinae* and *A. christensenii* strains are PYR-negative and LAP-positive. *A. sanguinicola* is positive for both LAP and PYR, while *A. urinaehominis* is negative in both tests. Table 13-12 provides additional phenotypic characteristics of these species.

Helcococcus kunzii, unlike most aerococci, produces variable growth in 6.5% NaCl, and growth is stimulated by

serum or Tween 80. On the API Rapid Strep system, *H. kunzii* produces a profile that corresponds to a "doubtful" identification of *A. viridans* (API profile 4100413). Isolates of *H. kunzii* are nonhemolytic and do not grow at either 10°C or 45°C. The organism is esculin- and PYR-positive, is LAP-negative, produces acid from glucose, maltose, lactose, trehalose, and glycogen, and does not produce β-galactosidase or β-glucuronidase. These organisms are commonly penicillin-, ampicillin-, and vancomycin-susceptible. *H. kunzii* and the other human isolates, *H. sueciensis* and *H. pyogenes*, are easily differentiated from the ovine species *H. ovis* by phenotypic tests (Table 13-12).

Identification of Leuconostoc, Pediococcus, *and* Tetragenococcus *Species*

Leuconostoc species are gram-positive, catalase-negative, lactic acid-producing cocci

that are resistant to vancomycin and produce CO_2 gas from glucose. These bacteria may be differentiated from the gas-producing lactobacilli by careful scrutiny of Gram-stained smears made from thioglycolate broth. *Leuconostoc* species do not grow at 45°C and are arginine dihydrolase-negative, PYR-negative, and LAP-negative. Production of gas from glucose is best determined in Lactobacillus MRS (Mann-Rogosa-Sharpe) broth (Difco Laboratories, Detroit MI) overlaid with sterile petrolatum. The formation of bubbles under the petrolatum seal indicates gas production and confirms their heterofermentative metabolism. *Leuconostoc* species are further identified by a battery of biochemical tests. Table 13-13 shows the phenotypic characteristics of *L. mesenteroides* subsp. *mesenteroides*, *L. mesenteroides* subsp. *dextranicum*, *L. mesenteroides* subsp.cremoris, *L. pseudomesenteroides*, *L. citreum*, *L. lactis*, and *Weissella paramesenteroides* (formerly *L. paramesenteroides*), which are the *Leuconostoc/Weissella* species that have been isolated from human clinical specimens.

Pediococcus species are also intrinsically vancomycin-resistant gram-positive cocci. However, they are generally homofermentative, similar to the streptococci and, unlike *Leuconostoc* species, they do not produce gas from glucose in MRS broth. The organisms appear as gram-positive cocci in pairs, clusters, and tetrads, and they are catalase-negative. Growth occurs over a temperature range of 25°C to 50°C. On plates, they resemble viridans streptococci in their colony morphology. They may be confused with group D streptococci or enterococci because they are bile esculin-positive, they possess the Lancefield group D antigen, and some strains grow in the presence of 6.5% NaCl. Pediococci are PYR-negative and LAP-positive. The species that have been recovered from human infections include *P. acidilactici* and *P. pentosaceus*. These organisms may be difficult to differentiate from one another, with maltose fermentation—positive for *P. pentosaceus* and negative for *P. acidilactici*—being the most reliable test for separation of the two. Both of these species are susceptible to β-lactams, clindamycin, rifampin, erythromycin, gentamicin, and imipenem and are resistant to vancomycin, teicoplanin, and the fluoroquinolones. As mentioned *P. halophilus* is phylogenetically closer to the enterococci and has been reclassified in the genus *Tetragenococcus* as *T. halophilus*. From data given in the original description of this species, *T. halophilus* characteristically grows as pairs or tetrads (hence, the name) and, occasionally, as clusters, does not grow at 10°C or at 45°C, is nonmotile, grows in 6.5% NaCl (actually will grow in up to 10% NaCl) and on BE agar, and is arginine dihydrolase-negative. Most strains produce acid from arabinose, glucose, glycerol, maltose, ribose, sucrose, and trehalose, and do not produce acid from lactose, mannose, mannitol, and sorbitol (Table 13-14). Unlike the other pediococci, *T. halophilus* is susceptible to vancomycin.

Identification of Gemella *Species*

Of the seven *Gemella* species that have been described, five—*G. haemolysans*, *G. morbillorum*, *G. bergeriae*, *G sanguinis,* and *G. asaccharolytica*—have been isolated from human clinical specimens. The two remaining species—*G. palaticanis* and *G. cuniculi*—are found in dogs and rabbits, respectively. *Gemella* species are catalase-negative, gram-positive cocci that characteristically grow as pinpoint colonies on SBA, often requiring 48 hours or more for distinct colonies to grow. Incubation in a CO_2-enriched atmosphere stimulates growth. They are α- or nonhemolytic, except for the animal species *G. cuniculi*, which is β-hemolytic. On Gram-stained smears from broth cultures, the organisms appear as single cells, pairs, or short chains. All *Gemella* species are PYR-positive, LAP-positive, nonmotile, and fail to grow at 10°C or 45°C. They do not grow on BE agar, do not hydrolyze esculin, urea, starch, or gelatin, and do not grow in 6.5% NaCl broth. *Gemella* species can be differentiated on the basis of acid formation from maltose, sucrose, lactose, mannitol, sorbitol, and trehalose. *G. haemolysans* and *G. morbillorum*, the most common clinical isolates, can also be differentiated by reduction of nitrite. Because of their thin cell walls, *G. haemolysans* and *G. morbillorum* easily decolorize on Gram's staining and may appear as gram-negative cocci in pairs, clusters, and short chains. Growth of some strains is enhanced by the presence of fermentable carbohydrates and by the addition of Tween 80 to the growth media. Because of limited numbers of clinical isolates, the performance of kit systems for identifying these bacteria cannot be assessed critically. Only *G. haemolysans* and *G. morbillorum* are included in the databases of the various kit systems at this time. Phenotypic characteristics for identification of *Gemella* species are found in Table 13-15.

Identification of Vagococcus *Species*

Of the seven species in the genus *Vagococcus*, only *V. fluvialis* has been encountered in human clinical specimens. *V. fluvialis* is *Streptococcus*-like in its colony morphology and is α- or nonhemolytic, facultative, and homofermentative in its metabolism, and is catalase-negative. On Gram's stains, the organisms appear as spherical to ovoid cells, arranged in pairs or chains. According to the original description by Collins and coauthors, *V. fluvialis* are motile cocci that produce peritrichous flagella.[210]Motility can be demonstrated with motility medium incubated at room temperature. *V. fluvialis* is PYR-positive, LAP-positive, and hydrolyzes esculin in the presence of 40% bile (Table 13-16).[1012] Most strains grow at 10°C, but growth at 45°C is variable. Most strains also grow in 6.5% NaCl and some strains produce acetoin.[319,1012]

V. fluvialis produces acid from glucose, maltose, mannitol, sorbitol, ribose and trehalose, but not from arabinose, inulin, melibiose, or raffinose (Table 13-16).[1012] Strains of *V. fluvialis* have been recovered from pigs, cats, and horses; these strains were positive for the VP, alkaline phosphatase and LAP reactions; some of the strains were nonmotile.[839] Members of the genus *Vagococcus* are not included in the data bases of any of the commercial identification systems. *V. fluvialis* produce positive reactions with the AccuProbe *Enterococcus* test (Gen-Probe, Inc.). Isolates of *V. fluvialis* recovered from human clinical specimens are susceptible to ampicillin, cefotaxime, trimethoprim-sulfamethoxazole, and vancomycin, and are resistant to clindamycin and oflaxacin.[1012] Since the other *Vagococcus* species are environmental or animal isolates, their recovery from clinical specimens is unlikely.

Identification of Alloiococcus *Species,* Globicatella *Species,* Facklamia *Species*, Dolosigranulum *Species,* Ignavigranum *Species, and* Dolosicoccus *Species*

The organisms included in the genus *Alloiococcus* and the genera *Globicatella*, *Facklamia, Dolosigranulum*, and *Ignavigranum* are *Gemella*-like species that are able to grow in 6.5% NaCl (Table 13-17). *A. otitidis*, the sole member of the genus *Alloiococcus*, and has been isolated from tympanocentesis specimens obtained from the middle ear of children with chronic otitis media, from blood cultures, and from sputum.[12,633] The organism grows slowly on agar media, with visible colonies apparent only after 2 to 3 days, and does not grow in thioglycolate broth. Gram-stained smears from agar media show cocci arranged in pairs, tetrads, and sometimes clusters. Optimal growth occurs at 35°C to 37°C, and no growth occurs at either 10°C or 45°C. Colonies appear off-white, pinpoint, and nonhemolytic, although α-hemolysis and slightly yellow pigmentation may be observed after several days of incubation. Fresh clinical isolates of *A. otitidis* will grow on blood agar but may not grow on chocolate agar. Luxuriant growth in broth containing 0.5% Tween or 0.07% lecithin suggests that the organism may require lipid for optimal growth. Unlike the other organisms considered in this chapter, *A. otitidis* is catalase-positive; this reaction may be quite weak or delayed. The organism is aerobic rather than facultative and does not produce acid from any carbohydrates. *A. otitidis* grows on bile esculin agar but does not hydrolyze esculin, and grows slowly in 6.5% NaCl broth. PYR, LAP, and β-galactosidase are produced, and hippurate is hydrolyzed by some isolates. Bosley and colleagues[104] performed antimicrobial susceptibility studies on 19 *A. otitidis* strains and found that all 19 strains were resistant to trimethoprim-sulfamethoxazole, and 18 were resistant to erythromycin. The MICs for penicillin and ampicillin ranged from susceptible to intermediately resistant (MIC range for penicillin, 0.06 to 0.12 μg/mL; ampicillin MIC range, 0.12 to 0.5 μg/mL), with the same degree of relative resistance

being seen for ceftriaxone and cefixime. None of the strains they examined produced β-lactamase enzymes.[104]

G. sanguinis has been recovered from human specimens, including blood, cerebrospinal fluid, and urine. On Gram-stained smears from broth cultures, these organisms appear as gram-positive cocci in pairs and short chains. Colonies on SBA are *Streptococcus*-like and are α-hemolytic. Like the enterococci, *G. sanguinis* is bile esculin–positive, grows in 6.5% NaCl, and produces PYR; unlike both the enterococci and the streptococci, LAP is not produced. *G. sanguinis* grows at 45°C but not at 10°C.[922] These reactions also differentiate *G. sanguinis* from other viridans streptococci in that the latter species are PYR-negative, LAP-positive, and do not grow in 6.5% NaCl broth. The BactiCard Strep (Remel Laboratories), which includes rapid PYR, LAP, and esculin hydrolysis tests in a card format, can be used for these determinations.

+, positive reaction; –, negative reaction; V, variable reaction; NA, data not available; SBA, sheep blood agar; LAP, leucine aminopeptidase; PYR, pyrrolidonyl arylamidase; ESC, esculin hydrolysis; ADH, arginine dihydrolase; KIA, Kligler's iron agar; VP, Voges–Proskauer (acetoin); α-GAL, α-galactosidase; β-GAL, β-galactosidase; β-GUR, β-glucuronidase; GLU, glucose; MAL, maltose; SUC, sucrose; LAC, lactose; MNTL, mannitol; SBTL, sorbitol; RIB, ribose; TRE, trehalose.

Unlike the aerococci, *G. sanguinis* produces distinct chains in broth media instead of tetrads. This growth characteristic must be determined to differentiate *G. sanguinis* from *A. viridans*, which, like *G. sanguinis*, is LAP-negative, PYR-positive, and hippurate hydrolysis-positive. *G. sanguinis* produces acid from several carbohydrates, including glucose, maltose, sucrose, lactose, mannitol, raffinose, and trehalose; acid production from arabinose, ribose, and sorbitol is variable (Table 13-17). *G. sanguinis* is in the database of the BBL Crystal Gram-Positive ID kit, but not in the data bases of the API Rapid Strep, the RapID STR, or the ID32 identification systems.[922]Using

NCCLS breakpoints for *Streptococcus* species other than *S. pneumoniae*, Shewmaker and colleagues[922] determined the antimicrobial susceptibility of 28 strains of *G. sanguinis* and found that all strains were susceptible to amoxicillin and vancomycin, and some strains had penicillin MICs that fell in the intermediate range. Variable susceptibility was observed for other agents, including cefotaxime (52% susceptible), cefuroxime (26% susceptible), meropenem (63% susceptible), erythromycin (52% susceptible), trimethoprim–sulfamethoxazole (48% susceptible), clindamycin (70% susceptible), and tetracycline (48% susceptible). The bovine/ovine pathogen, *G. sulfidifaciens*, can easily be differentiated from *G. sanguinis*.[1075] *G. sulfidifaciens* produces H_2S and β-glucuronidase, while *G. sanguinis* does not. *G. sanguinis* also produces β-galactosidase, ferments mannitol, and hydrolyzes hippurate; *G. sulfidifaciens* is negative with these tests.

Members of the genus *Facklamia* are catalase-negative, gram-positive cocci that are related to but phylogenetically distinct from *Globicatella* species. Species isolated from human clinical specimens are *F. hominis*, *F. sourekii*, *F. ignava*,

and *F. languida*. *F. miroungae* and *F. tabacinalis* have been isolated from elephant seals and powdered tobacco, respectively. On gram-strained smears from thioglycolate broth, *Facklamia* species appear as gram-positive cocci arranged in clusters, except for *F. languida*, which usually form pairs and short chains. On SBA, colonies are usually α-hemolytic and similar to viridans streptococci. *Facklamia* species are do not grow on bile esculin media, but do grow in 6.5% NaCl. *Facklamia* species do not grow at either 10°C or 45°C and are LAP-positive and PYR-positive (Table 13-17).

The genus *Ignavigranum*, with its single species, *I. ruoffiae*, was first described in 1999. This species grows primarily as chains in thioglycolate broth and is closely related phylogenetically to both *F. hominis* and *G. sanguinis*. *I. ruoffiae* is PYR-positive, LAP-positive, grows in 6.5% NaCl broth, and does not hydrolyze esculin. Some strains are arginine dihydrolase-positive. While most strains of *F. hominis* are also arginine dihydrolase-positive, this species is hippurate hydrolysis-positive, while *I. ruoffiae* is hippurate-negative (Table 13-17). A distinctive feature of *I. ruoffiae* is the "sauerkraut" odor produced by the organism when grown on SBA.

The genus *Dolosigranulum* contains a single species, *D. pigrum*. On SBA, this organism grows as small, grayish white, α-hemolytic colonies. On Gram's stains from broth (both thioglycolate, and, in one case report, Organon-Teknika BacT/Alert FAN blood culture medium), this organism appears in pairs, *Gemella*-like tetrads, and clusters. (Like *Facklamia* species, *D. pigrum* is PYR-positive, LAP-positive, and grows in 6.5% salt. This organism is esculin hydrolysis–positive, but this reaction may take several days to develop. No growth is observed at 10°C, 45°C, or on BE agar (Table 13-17).

The genus *Dolosicoccus*, with its single member, *Dolosicoccus paucivorans*, is a new group that is based on two isolates recovered from human blood cultures.[228] This organism is distinct from, but phylogenetically related to the *Facklamia* and *Globicatella* genera. Like, the organism discussed above, *D. paucivorans* is PYR-positive, but, unlike these others, it is LAP-negative, does not grow in 6.5% NaCl broth, and appears on broth Gram-stained smears as single cells, pairs, and short chains. Like *D. pigrum*, *D. paucivorans* does not grow on BE medium, and does not grow at 10°C or 45°C (Table 13-17).

Identification of Lactococcus *Species*

Because of the superficial resemblance to enterococci or the viridans streptococci, these organisms have been misidentified as atypical streptococci or enterococci in the clinical laboratory. The lactococci show many of the characteristics of both streptococci and enterococci; many strains are positive for the PYR, LAP, BE, and 6.5% NaCl reactions and are able to grow at 10°C. Lactococci, unlike enterococci, do

not grow at 45°C. A "tip off" to the possibility that an isolate is a possible *Lactococcus* species is the generation of a list of characteristics that do not fit either streptococci or enterococci.[319] Most clinical isolates of lactococci submitted to the CDC have been either *L. lactis* subsp. *lactis, L. lactis* subsp. *Cremoris,* or *L. garvieae.* These three species can be differentiated from common *Enterococcus* species in that these species produce acid from mannitol but do not produce acid from raffinose, sorbitol, or arabinose. *L. garvieae, L. lactis* subsp. *cremoris*, and *L. lactis* subsp. *lactis* are included in the database of the ID32 Strep (Table 13-17). API Rapid Strep, and BBL Crystal identification kits, respectively (see the following section). Genus-specific PCR methods for separating enterococci and lactococci have also been published.[265] In most case reports, both phenotypic methods and sequencing of 16S rRNA and/or the *sodA* gene have been used for species identification.[43,169,340] Phenotypic tests for differentiation of enterococci, lactococci, and similar organisms are shown in Table 13-19.

Commercial Systems for Identification of Streptococci, Enterococci, and Selected "*Streptococcus* -Like" Bacteria

Kit systems that incorporate physiologic and enzymatic tests for streptococcal identification have been of great help in species identification of the viridans streptococci, enterococci, and the group D streptococci. Biochemical test included in the kit systems are used to generate an organism biotype number that corresponds to the identity of the organism. Although these systems include the β-hemolytic streptococci in their databases, these organisms are best handled using other methods, such as the presumptive tests described earlier or the rapid streptococcal grouping kits that are available. However, caution should also be exercised with the commercial identification kits. For example, the API Rapid Strep will misidentify *Leuconostoc* organisms as species of viridans streptococci, so vancomycin resistance and other preliminary test results must be considered along with the biochemical reactions that are observed on the strip. Commercial systems for the identification of streptococci include the following.

Vitek 2

The Vitek 2 (bioMérieux) automated identification/susceptibility testing system uses a gram-positive identification card containing colorimetric substrates for organism identification. The GP card is a 64-well card containing 43 biochemical tests and the

database includes members of both the *Streptococcaceae* (streptococci, enterococci) and the *Micrococcaceae* (staphylococci, micrococci). The card is placed in a cassette of the Vitek 2 instrument and is inoculated using a vacuum-release method. The card is automatically sealed and incubated online at 35.5°C. Wells in the card are subjected to colorimetric scanning every 15 minutes for a total incubation period of 8 hours, although some isolates provide sufficient data for identification after 180 minutes incubation. Algorithms within the machine analyze the biopatterns of interpretable and noninterpreted tests and verify whether sufficient data have accumulated to provide an accurate identification. Ligozzi and colleagues[643] found that the Vitek 2 identified 96.5% of 29 *S. agalactiae*, 96.9% of 66 *S. pneumoniae*, and 83.1% of enterococci (*E. faecalis*, *E. faecium*, *E. durans*, *E. gallinarum*). In a 2005 evaluation, the Vitek-2

GP identification card identified 92% of 153 streptococcal species (including all of 38 *S. pyogenes* and all of 39 *S. pneumoniae* isolates) and 97% of 64 *Enterococcus* species. All 13 isolates of viridans group streptococci were correctly identified. Identifications were obtained within 7 hours of incubation for over 90% of isolates tested.[363] In another evaluation by Wallet and colleagues, the colorimetric GP card correctly identified 84.8% of 132 streptococcal and enterococcal isolates. This latter study included several strains of viridans group streptococci, enterococci, and "*Streptococcus*-like" isolates (e.g., *Gemella* species, *Helcococcus* species, *Pediococcus* species).[1104] A study of the Vitek-2 by Abele-Horne et al.[7] reported that 94.2% of 121 *Enterococcus* species were correctly identified. In a comparison of enterococcal identification with the Bruker and bioMerieux MALDI-TOF MS instruments, the Vitek 2 GP card identified 131 of 132 enterococci, including 31 of 32 *E. faecalis*, 63 *E. faecium*, 16 *E. casseliflavus*, and 21 *E. gallinarum*.[328] Haanpera et al.[411] identified a collection of α-hemolytic streptococci, (102 blood culture isolates, 39 isolates from oropharyngeal cultures, and 17 invasive *S. pneumoniae* isolates) by genotypic methods and Vitek 2 and found that 75.0% of the isolates were assigned to the same streptococcal species by both methods and 46.0% reached consistent results at the species level. Ten strains remained unidentified by Vitek 2 and 4 isolates could not be assigned to any streptococcal group.[411] When compared with genotypic and molecular identification methods, the Vitek 2 system cannot adequately identify some viridans streptococci. Among 251 viridans streptococci isolated from blood cultures, 220 (87.6%) were assigned to the same species group by both methods, and only 67 of the 150 strains in the Mitis Group resulted in the same species identification by both methods. Fifteen pyogenic cocci and 54 *E. faecalis* isolates were correctly identified by both methods.[5] Teles and colleagues[1014] found that the Vitek 2 identified only 55%

of 42 viridans streptococcal isolates when compared to genotypic identification methods (i.e., *sodA* gene sequencing, restriction fragment length polymorphism of the 16S rRNA genes, and multilocus sequence analysis of seven housekeeping genes). A study by Mittman and colleagues[719] with 311 isolates of *S. pneumoniae* found that the Vitek 2 and the Phoenix system (see the following subsection) were comparable in the ability to identify *S. pneumoniae* and were preferable to routine phenotypic tests with respect to accuracy and time savings. A meta-analysis of studies evaluating the Vitek 2 found that the overall correct identification rate for the instrument was 96.1% for the streptococci and 99.70% for the enterococci.[177]

Phoenix (Becton-Dickinson Diagnostic Systems, Sparks, MD)

The BD Phoenix system is an automated identification and susceptibility test system that uses an ID panel called PMIC/ID-13 for identification of gram-positive cocci.[325] The panel contains 45 wells containing 20 enzymatic substrates, 16 carbohydrates utilization tests, and 7 assimilation carbon sources, and susceptibility to colistin and polymyxin B. A standardized suspension of the bacterial isolate is prepared in broth and poured into the panel within 30 minutes of preparation. The panel is then loaded into the instrument where it is incubated and read by the optics of the instrument. Time to providing an identification ranges from 3 to 4 hours. In a study of 179 enterococcal isolates and 15 streptococcal isolates, the Phoenix system identified 98.9% of the enterococci and 100% of the 15 streptococci. With regard to pyogenic cocci in particular, Kanemitsu et al.[534] found that the Phoenix accurately identified 85.9% of 92 *S. pneumoniae*, 95.8% of 24 *S. pyogenes*, and 90% of 10 *S. agalactiae* isolates. A second evaluation of the BD Phoenix also conducted in Japan found results similar to Kanemitsu et al. for the pyogenic species, but found that the system identified only 58% of 12 *S. mitis* group organisms and 82% of 22 *S. anginosus* group isolates.[457] Brigante and colleagues[119] compared identifications obtained by a manual identification kit (API Strep) and sequencing of 16S rRNA and three housekeeping genes with those obtained with the Phoenix system. The Phoenix system correctly identified 93.8% of 129 streptococci, 90% of 70 enterococci, 100% of 45 *S. pneumoniae*, and 49 of 50 β-hemolytic streptococci. For the viridans streptococci, the Phoenix identified 83.9%, with accurate identification of the *S. sanguinis* and *S. anginosus* groups, and less accurate identifications of *S. mitis* group isolates. Carroll and coworkers[140] found that the Phoenix identified 100% of 90 *Enterococcus* species, including *E. faecalis*, *E. faecium*, *E. casseliflavus*, *E. gallinarum*, and *E. raffinosus*. The meta-analysis of these automated systems reported that the overall accuracies of the Phoenix system for identification of streptococci and enterococci were 96.70% and 98.27%, respectively.[177]

API Rapid Strep. This strip format system (bioMerieux, Inc.) includes 20 tests,

including physiologic tests, chromogenic enzyme substrate tests, and carbohydrate utilization tests. The unique thing about this system is that the strip can be read twice. If an identification is not obtained after 4 hours' incubation using the physiologic and chromogenic substrates, the strip is reincubated and read after overnight incubation to include acid production from 10 carbohydrates. The database includes groupableβ-hemolytic streptococci, viridans streptococci, *S. gallolyticus* strains, *Enterococcus* species (*E. faecalis*, *E. faecium*, *E. gallinarum*, *E. avium*, and *E. durans*), viridans streptococci, lactococci, aerococci, *Gemella* species, and *Listeria monocytogenes* (Image Plate 13-3F and13-3G). Identification of strains that have been completely characterized by conventional biochemical tests and genetic analysis (e.g., DNA relatedness, 16S rRNA sequencing) indicate that the API Rapid Strep system is reproducible and complements existing genetic studies. The phenotypic reactions for many organisms shown in the tables of this chapter reflect the recent studies during which genetic analysis and the description of new species were performed along with API Rapid Strep characterization. In a 2011 evaluation of the ID32 Strep compared with the Vitek 2 and genotypic methods, the ID32 identified 79% of 23 clinical and 19 type strains of viridans streptococci without the need for additional tests.[1014] In a 2013 study of 27 *S. anginosus* group isolates, the API Rapid Strep correctly identified only 40.7%.[174] A 2012 study comparing API 20 Strep with genotypic methods and MALDI-TOF MS found that the manual system identified only 60.5% of viridans streptococcal isolates.[658]Percentages of correct identifications varied from as low as 36.5% for the Anginosis Group to 75% for the Salivarium and Bovis Groups of streptococci. Davies and colleagues[261] compared

the API 20 Strep system with the Bruker MS and found that only 26% 49 viridans streptococcal isolates were correctly identified to species level by API 20 Strep. At this time, the database for this system has not been updated or expanded to include newer streptococcal and enterococcal species.

Rapid ID 32 Strep. This system (bioMerieux, La Balme les Grottes, France) is a 32-test strip format identification system for the streptococci and streptococci-like bacteria. The database of this system is extensive and includes the groupable streptococci, several *Enterococcus* species, and the viridans streptococci (including newly described species such as the "mutans group" oral streptococci, *S. oralis*, *S. gordonii*, and *S. vestibularis*). A suspension of the organism is prepared in sterile water to a turbidity equivalent to a McFarland 4 standard and 55 µL of the suspension is placed into each of the 32 cupules. The strip is incubated at 35°C to 37°C for 4 hours and either read manually using a code book or with the automated reader (ATB 1520 Reader linked with an ATB 1545 computer, bioMerieux). In an evaluation of the

Rapid ID 32 Strep system with 433 strains belonging to the genera *Streptococcus*, *Enterococcus*, *Lactococcus*, *Aerococcus*, *Gemella,* *Leuconostoc*, *Erysipelothrix*, *Gardnerella*, and *Listeria*, 95.3% of strains were correctly identified.[358] Additional tests were required for identification of 25.1% of the strains. Only 16 isolates (3.7%) were not identified, and only four isolates (1.0%) were misidentified. Another evaluation by Kikuchi and coworkers[555] reported that the ID32 Strep system identified 87% of 156 viridans streptococcal strains and that most misidentification involved strains of *S. oralis, S. mitis*, and *S. gordonii*. Chang and Lo found that the Rapid ID 32 Strep identified 77.8% of 27 isolates belonging to the Anginosus Group, outperforming both the API Strep and the Vitek 2 GP card.[173] The Rapid ID 32 Strep system does not include several genera of the *Streptococcus*-like bacteria in its database and correctly produces "unacceptable identifications" when strains belonging to these species are tested.[591]

BBL Crystal Gram-Positive Identification System. The Crystal Gram-Positive identification system contains 29 dried biochemical and enzymatic substrates plus a fluorescence negative control. The inoculum is prepared by suspending colonies of the pure isolate in the fluid provided with the kit to a turbidity equivalent to a 0.5 McFarland standard. The suspension is then poured into a specific area of the base of the panel, which is then manipulated to distribute the inoculum. The panel lid, which contains the test substrates, is then snapped onto the base, with consequent hydration of the substrates with the inoculum. After incubation, tests are read for fluorescence or for changes in the colors of pH indicators using a special panel viewer. The resulting pattern of the 29 reactions is converted into a 10-digit profile number that correlates with an identification provided by the Crystal Electronic Code book. The panel can be interpreted using a 4-hour or an 18- to 24-hour incubation database. In a 1998 evaluation of this system, the Crystal Gram-Positive identification system identified all strains of groupable β-hemolytic streptococci and *S. pneumoniae*, but only identified 25 of 37 strains of viridans streptococci to the species level. The system correctly identified all of 23 *E. faecalis*, 2 of 2 *E. avium*, and all of 14 *E. faecium*.[1100] Hudson and coworkers[480] challenged the system with genotypically defined veterinary strains of enterococci and found that repeated testing of the same strains resulted in different profile numbers, some of which resulted in different identifications. In fact, 19 of the 50 strains tested were identified at different times as both *E. faecalis* and *E. faecium*. This system cannot identify or misidentifies isolates belonging to the "*Streptococcus*-like" bacterial genera.[591]

RapID STR. The RapID STR system (Remel Laboratories) employs a small cuvette containing 10 wells, four of which are bifunctional, resulting in a total of 14 biochemical tests (used in conjunction with the hemolytic reaction of the isolate). Tests include physiologic determinations (arginine dihydrolase, esculin hydrolysis),

carbohydrate utilization tests, and chromogenic enzyme substrate hydrolysis. The system is inoculated with a suspension of the organism (McFarland 1 turbidity standard) prepared in a fluid purchased with the kit, and the tests are read after 4-hour incubation at 35°C in a non-CO_2 incubator. The database of this system includes the β-hemolytic streptococci group A, B, and C/G, group D streptococci, the Anginosus Group, *Enterococcus* species (*E. faecalis*, *E. faecium*, *E. avium*, *E. cassiliflavus/mundtii*, *E. durans/hirae*, *E. gallinarum*, *E. raffinosus*, and *E. malodoratus*), viridans streptococcal species (*S. mitis*, *S. mutans*, *S. salivarius/vestibularis*, *S. sanguinis/gordonii*), *S. pneumoniae*, *Aerococcus* species, *Gemella morbillorum*, *Leuconostoc* species, *Lactococcus* species (*L. lactis*, *L. mesenteroides* group) and *Pediococcus* species (*P. acidilactici*, *P. pentosaceus*). More recently described viridans streptococci, enterococci, and *Streptococcus*-like bacteria are not included in the database. In a study by Shewmaker et al.[922] on phenotypic characterization of 28 *G. sanguinis* strains, the RapID STR misidentified 7 strains as *S. mutans* (5 strains), *E. casseliflavus* (1 strain), or *E. malodoratus* (1 strain), while the remaining strains gave inadequate profiles for identification. Another evaluation found that this system was unable to identify isolates belonging to the "*Streptococcus*-like" bacterial genera (*D. pigrum*, *I. ruoffia, Facklamia* species), indicating the need for database revision and updating.[591]

Microscan Gram-Positive Breakpoint Combo Panel. This 18-hour system provides simultaneous identification and antimicrobial susceptibility results in a microtiter format. Tritz and colleagues[1044] evaluated this system for its ability to identify enterococci and found that both *E. faecalis* and *E. faecium* were reliably identified, but less common enterococcal species were misidentified.

Matrix-Assisted Laser-Desorption/Ionization Time-of-Flight Mass Spectrometry. MALDI-TOF has been evaluated in several studies for the identification of streptococci, enterococci, and *Streptococcus*-like bacteria. The Bruker Biotyper MS instrument correctly identified 61 of 65 *S. pyogenes* isolates when compared to phenotypic methods (API 20 Strep).[1106] In a study of 76 streptococcal and 50 enterococcal isolates from the routine microbiology laboratory, MALDI-TOF identified 88% and 79% of the isolates correctly.[69] A 2012 study compared the identifications obtained with the MALDI Biotyper (Bruker Daltronics, Bruker Daltronics GmbH, Bremen, Germany), the BD Phoenix system, and the API 20 Strep for 56 α-hemolytic streptococcal isolates.[261] Using 16S rRNA gene sequence analysis as the gold standard, MALDI-TOF, BD Phoenix, and API 20 Strep identified 46%, 35%, and 26% of the isolates, respectively. Fang

and colleagues[328] in Sweden compared identifications obtained with both the Bruker and Vitek MS, the Vitek 2, and multiplex PCR and found that 100% of 132 enterococci were identified correctly by both mass spectrometry instruments, while 121 of the 132 isolates were correctly identified to species by Vitek 2. The ability of the MALDI-TOF to differentiate *S. pneumoniae* from nonpneumococcal streptococci has been studied.[1116] Early studies of *S. pneumoniae* and other *S. mitis* group streptococci (i.e., *S. mitis*, *S. oralis,* and *S. pseudopnuemoniae*) found that discrimination of these species was difficult because of very high degree of similarities in the spectra generated using MALDI-TOF. Analysis of minor mass spectral peaks using the Bruker MS instrument and defining these peaks in the spectral database resulted in discriminatory sensitivity and specificity for these species of almost 100%.[491] A study performed in Spain compared MALDI-TOF identifications with those obtained with API 20 Strep for 124 α-hemolytic streptococcal isolates obtained from blood cultures.[658] Using *sodA* gene sequencing as a reference method the API 20 Strep and MALDI-TOF provided correct species-level identifications for 60.5% and 73.4% of the isolates, respectively. The turnaround times for identifications obtained by *sodA* sequencing, API 20S, and MALDI-TOF were 12 to 24 hours, 24 to 48 hours, and 15 minutes, respectively. In a large study conducted in France, the Vitek MS MALDI-TOF instrument was evaluated for the identification of 334 *S. pneumoniae* isolates, 166 other *S. mitis* group strains, 184 non- *S. mitis* group streptococci, and 19 other α- and nonhemolytic *Streptococcus*-like bacteria.[299] Reference identification methods include optochin susceptibility, bile solubility, serotyping, and the Rapid ID32 Strep kit. Discordant results were arbitrated with genotypic methods (i.e., 16S rRNA and *recA* gene sequencing). The Vitek MS system identified 99.1% of the pneumococci, with only three bile-insoluble isolates being misidentified as *S. mitis/oralis*. Of the nonpneumococcal isolates, 90.8% were correctly identified to the species or subspecies level. Interestingly, three *S. pseudopneumoniae* isolates were identified by the Vitek system. A collaborative, multicenter US study compared the Vitek MS with nucleic acid sequence-based identifications for 1,146 isolates representing 13 genera and 42 species of gram-positive aerobic and facultative cocci, including 134 enterococci and 218 streptococci.[880] The Vitek MS identified 97% of the enterococcal isolates and 82% of the streptococci to the species level. Among the streptococci, 2%, and 5% of the 218 isolates were misidentified or not identified by the Vitek MS, respectively. In this study, only 51% of 47 *S. dysgalactiae* isolates were correctly identified to the species level. The limitation for correct identification of *S. dysgalactiae* has been noted in other studies.[908]

Antimicrobial Susceptibility of *Lactobacillus* Species

***Weissella* Species**

The aerobic/facultative gram-positive bacilli include a wide variety of organisms that are responsible for "classical" diseases such as listeriosis, anthrax, and diphtheria, and also for newer disease syndromes, particularly in immunocompromised hosts. The aerobic/facultative gram-positive bacilli also include several newly recognized genera that are environmental or veterinary organisms not previously associated with humans or human infections. The use of molecular techniques for characterization of many new species has required reexamination of classical pathogens as well. For example, the recognition of several new facultative species in the genus *Actinomyces* has enabled recognition of the facultative nature of classical pathogens such as *A. israelii* that were previously considered to be obligately anaerobic organisms. These new techniques have also permitted the classification of previously unnamed bacteria, such as the Centers for Disease Control and Prevention (CDC) coryneform groups, into new or existing genera, and has led to the taxonomic dissection of genera known to contain many unrelated species (e.g., the genus *Bacillus*). The classification scheme presented in the new edition of *Bergey's Manual of Systematic Bacteriology* now reflects the genotypic relationships rather than phenotypic similarities among these organisms. Box 14-1 presents the classification of the organisms to be discussed in this chapter.

Listeria Species and *Listeria monocytogenes*

Taxonomy of the Genus Listeria

The genus *Listeria* consists of gram-positive, non–spore-forming, facultatively anaerobic, regular rod-shaped bacteria (see Image Plate 14-1A). The genus is defined by a G+C%

BOX 14-1

Classification of the Aerobic/Facultative Gram-Positive Bacilli in the Domain Bacteria

Phylum	Class/Subclass	Order/Suborder	Family	Genera
Firmicutes	Mollicutes	Incertae sedis	*"Erysipelotrichaceae"*	*Erysipelothrix*
	"Bacilli"	Bacillales	*Bacillaceae*	*Bacillus, Alkalibacillus, Amphibacillus, Anoxybacillus, Cerasibacillus, Filobacillus, Geobacillus, Gracilibacillus, Halobacillus, Halolactibacillus, Lentibacillus, Marinococcus, Oceanobacillus, Paraliobacillus, Pontibacillus, Saccharococcus, Tenuibacillus, Thalassobacillus, Virgibacillus*
			"Listeriaceae"	*Listeria, Brochothrix*
			"Sporolactobacillaceae"	*Sporolactobacillus, Sinobaca, Tuberibacillus*
			"Paenibacillaceae"	*Paenibacillus, Ammoniphilus, Aneurinibacillus, Brevibacillus, Cohnella, Oxalophagus, Thermobacillus*
			"Alicyclobacillaceae"	*Alicyclobacillus, Sulfobacillus*
		"Lactobacillales"	*Lactobacillaceae*	*Lactobacillus, Paralactobacillus, Pediococcus*
			Incertae sedis	*Exiguobacterium*
Actinobacteria	Actinobacteria/ Actinobacteridae	Actinomycetales/ Actinomycineae	*Actinomycetaceae*	*Actinomyces, Actinobaculum, Arcanobacterium, Trueperella, Mobiluncus*
		Actinomycetales/ Micrococcineae	*Micrococcaceae*	*Rothia*
			Brevibacteriaceae	*Brevibacterium*
			Cellulomonadaceae	*Cellulomonas, Cellulosimicrobium, Oerskovia*
			Dermabacteriaceae	*Dermabacter, Helcobacillus*
			Intrasporangiaceae	*Sanguibacter*
			Jonesiaceae	*Jonesia*
			Microbacteriaceae	*Microbacterium (Aureobacterium), Leifsonia*
		Actinomycetales/ Corynebacterineae	*Corynebacteriaceae*	*Corynebacterium*
		Bifidobacteriales	*Bifidobacteriaceae*	*Gardnerella*
			"Unknown affiliation"	*Turicella*

DNA content of 36% to 38%, a typical gram-positive cell wall with a peptidoglycan murein layer containing *meso*-DAP attached to the cell membrane by lipoteichoic acid, and membrane-associated polyribitol teichoic acids. Genetic studies indicate that *Listeria* organisms exhibit the closest phylogenetic relationship to the genus *Brochothrix* (an environmental organism) and are more distantly related to organisms in genus *Bacillus,* related spore-forming genera, and the genus *Lactobacillus*, rather than to organisms in the genera *Streptococcus*, *Enterococcus*, and *Lactococcus.* The relationship between *Listeria* and *Brochothrix* species is also supported by chemotaxonomic data. Although some taxonomists have favored the inclusion of *Listeria* species in the family *Lactobacillaceae*, Collins and other workers believe that

Listeria species merit inclusion in a new family. In the current edition of *Bergey's Manual of Systematic Bacteriology*, *Listeria* and *Brochothrix* species are included in the proposed family "*Listeriaceae*" in the order *Bacillales*, class "*Bacilli*" in the phylum *Firmicutes*.[695] The genus *Erysipelothrix* is included in the phylum *Firmicutes* along with *Listeria* species, but is currently classified as species incertae sedis (Box 14-1). Table 14-1 presents the major characteristics that differentiate *Listeria*, *Erysipelothrix, Lactobacillus*, and *Brochothrix* from one another.

Genus *Listeria* includes *L. monocytogenes*, *L. ivanovii* subsp. *ivanovii*, *L. ivanovii* subsp. *londoniensis*, *L. seeligeri*, *L. innocua*, *L. grayi*, *L. welshimeri*, *L. marthii*, *L. rocourtiae,* *L. fleischmannii,* and *L. weihenstephanensis*.[99,122,433,633,648,996] *L. rocourtiae* was initially isolated from precut lettuce in Salzburg, Austria, in 2002.[648] *L. marthii* was originally isolated from river water, soil, puddles, and run-off environmental samples collected in the Finger Lakes National Forest and the Connecticut Hill Wildlife Management Area in New York State.[433] The newest species in the genus, *L. fleischmannii* and *L. weihenstephanensis*, were isolated from Swiss cheese and from a water plant (*Lemna trisulca*) in a freshwater pond in Bavaria, Germany, respectively.[99,633] *L. monocytogenes* can be divided into 13 serotypes based on somatic (S) and flagellar (H) antigens. Among the 13 serotypes (1/2a, 1/2b, 1/2c, 3a, 3b, 3c, 4a, 4ab, 4b/4bX, 4c, 4d, 4e, and 7), most diseases are due to types 4b, 1/2a, and 1/2b. *L. monocytogenes* and *L. ivanovii* are closely related pathogenic species, while *L. innocua*, *L. welshimeri*, *L. seeligeri*, *and L. marthii* are regarded as nonpathogens. *L. grayi* is distantly related to the other *Listeria* species, and in 1974, a proposal of a new genus, *Murraya*, to accommodate *L. grayi* was made but never approved.[1063] *L. monocytogenes* can infect a wide range of hosts, while *L. ivanovii* is largely a pathogen of sheep.

Virulence of L. monocytogenes

L. monocytogenes is a facultative intracellular pathogen that is able to adhere to, invade, and survive within mammalian cells, including macrophages and several human tissue culture cell lines.[782] This organism employs several cellular proteins that belong to a family known as the **internalins.**[108] These proteins are members of the LRR (leucine-rich repeat) protein superfamily. The two major proteins that *L. monocytogenes* employs are internalin A and internalin B. The receptor for internalin A on human epithelial cells is **E-cadherin,** while the receptor for internalin B is the globular portion of the complement component C1q. These interactions result in induction of organism phagocytosis by cells that are not usually phagocytic cells.[741] Cadherins are 110-kDa transmembrane glycoproteins that are structurally related and

tissue specific. Experiments using several different cell lines have established that the internalin A/E-cadherin interaction promotes both specific binding and entry of *L. monocytogenes* into epithelial cells.[741] Recent work has established that other cellular proteins, such as clathrins (which function in the endocytosis of macromolecules) and septins (GTP-binding proteins involved in cell division), are also involved in the internalization of *L. monocytogenes*.[1151] Once sequestered within the phagosomes, the organisms produce **listeriolysin O** and several phospholipases that enable the organism to escape from the phagosome before lysosomal fusion, thereby avoiding intracellular killing. Listeriolysin O is encoded by the *hly* gene and is a pore-forming hemolysin that is similar to streptolysin O of group A streptococci.[987] Listeriolysin O acts by binding to membrane cholesterol and then inserting itself into the target membrane, resulting in the formation of transmembrane pores. These pores inhibit lysosome fusion by altering pH and intracellular calcium levels.[1005] Once within the cytosol, another listerial surface protein, **ActA**, promotes polymerization of actin to form actin "tails," which enable the organism to be actively motile and spread directly from cell to cell.[424] At this point, other mechanisms that promote intracellular survival also become

TABLE 14-1 Phenotypic Characteristics for Differentiation of *Listeria, Brochothrix, Erysipelothrix,* and *Lactobacillus*

Genus	Growth at 35°C–37°C	Catalase	H_2S in KIA	Motility	Acid From Glucose	Peptidoglycan Di-Amino Acid
Listeria	+	+	–	+[a]	+	meso-DAP
Brochothrix	–	+	–	–	+	meso-DAP
Erysipelothrix	+	–	+	–[b]	+	L-lysine
Lactobacillus	+	–	–	–	+	L-lysine or meso-DAP or L-ornithine

[a] All strains motile at 20°C–25°C; poorly motile or nonmotile at 35°C–37°C.
[b] Most species are nonmotile, although a few motile species have been described.
+, positive reaction; –, negative reaction; KIA, Kligler's iron agar.

involved. These include the production of peptidoglycan-modifying enzymes by the organism that deacetylate D-glucosamine residues in the bacterial cell wall, rendering them resistant to lysis by intracellular lysozyme, and ActA-mediated inhibition of the normal autophagic enzymes involved in normal turnover of cellular constituents.[126,783,1236] These mechanisms enable the organism to move directly from cell to cell without exposure to soluble immune factors such as antibodies and complement.

Epidemiology of L. monocytogenes

Although all *Listeria* species may be isolated from the environment and from a wide variety of animals, both as pathogens and as commensals, only *L. monocytogenes* is a well-recognized animal and human pathogen. This organism can be isolated from soil, water, sewage, and vegetation and as a part of the fecal flora of a wide variety of animals, including rodents, rabbits, sheep, and ruminants.[1074] Infections in these animals include sepsis, rhombencephalitis, prematurity, and abortion. Many foods are contaminated with *L. monocytogenes,* and the organism can be recovered from 15% to 70% of raw milk samples, cheese, raw vegetables, and meats, including processed chicken and beef products from delicatessen counters. *L. monocytogenes* is able to grow in biofilms on the surface of various foods, and refrigeration actually augments further organism growth because of the ability of the organisms to grow at 4°C. Because of their ubiquity in foods, humans probably have contact with these organisms on a daily basis, and as a result, some individuals become fecal carriers of *L. monocytogenes.* The organism is a transient constituent of the human intestinal flora and may be excreted in the feces by 3.5% to 5% of healthy humans.[438,1074] Human listeriosis occurs mostly on the spring and summer months, and sporadic cases (outside of food-borne outbreaks) occur at annualized rates of less than 1 case per 100,000 population. In the year 2000, listeriosis was made a nationally reportable illness. With the development and application of food industry regulations formulated to minimize risks of food-borne disease, incidence rates in the United States declined from 7.4 per million population in the mid-1980s to 4.4 cases per million by 1993.[207,1093]

Clinical Significance of L. monocytogenes

L. monocytogenes is associated with a spectrum of clinical syndromes.[24,736,788,789,879] The most common result of organism acquisition is a transient asymptomatic gastrointestinal carrier state that usually results from ingestion of contaminated food. During this time, the organism may be excreted in the feces. Acute symptomatic infection with this organism often occurs during pregnancy. *Listeria* infection is 18 times more common in pregnant than nonpregnant females, and 16% to 27% of all *L. monocytogenes* infections occur in pregnant women.[541,543] Pregnancy-associated infection usually occurs during the third trimester, although cases have occurred at earlier gestational ages.[631] About two-thirds of patients usually develop mild, influenza-like symptoms of fever, malaise, sore throat, myalgias, lower abdominal pain, and back pain.[788] Occasionally, a vaginal discharge, diarrhea, and urinary tract symptoms are noted. Peripheral leukocytosis may be present, and blood cultures collected during the acute phase of this transient illness may be positive. During

maternal infection, occult bacteremia and transplacental transmission of the organism may occur, leading to intrauterine infection of the fetus. Infection of the fetus in utero may induce labor, resulting in spontaneous abortion in 10% to 20% of cases. Over 50% of infants infected in utero are delivered preterm, and intrauterine fetal death may occur in about 11%.[736] Symptoms in the mother usually subside following the delivery of the infected infant and the placenta. Fetal survival is partly determined by the length of gestation, with spontaneous abortion occurring when the infection is acquired early in pregnancy, and neonatal infection resulting when the infection is acquired later.[788]

Neonates become infected either by inhalation and ingestion of infected amniotic fluid in utero, by transplacental infection via the maternal circulation, or by ascending infection from the vagina. The hematogenous route is probably the most common avenue of neonatal infection. Infection of the neonate occurs in about 8.6 cases of every 100,000 live births.[186] In more than half of the cases, the mother is likely to have had the antecedent flu-like syndrome, and in 44% to 89% of cases, *L. monocytogenes* may be isolated from blood or cervicovaginal cultures.[631,677,736] Like that of group B streptococci, there are two forms of the disease in infected neonates that are categorized as either "early onset" or "late onset." The symptoms of early-onset disease generally occur with 36 to 48 hours after birth. Newborns who are infected in utero generally present with acute sepsis with positive blood cultures in 80% to 90%, respiratory distress with pneumonia in about 38%, and meningitis in about 24% of cases.[788,789] Pustular skin lesions and inflammatory granulomas containing *L. monocytogenes* may be found in the brain, liver, kidneys, lung, and spleen ("granulomatosis infantisepticum"). Placental tissues from these infections usually show evidence of acute chorioamnionitis and the presence of microabscesses.[1112] The mortality rate of early-onset listeriosis may be as high as 20% to 60%, but fatal neonatal infections are more common among immunocompromised children.[726,736,788] Listeriosis in infants may also occur as "late-onset" infections. These infections become clinically apparent between 5 days and 2 or more weeks after delivery, and infants with this condition are usually born at term. Late-onset listeriosis usually presents as neonatal meningitis, with signs and symptoms of fever and irritability.[879] Gram's stains of cerebrospinal fluid (CSF) will show polymorphonuclear leukocytes along with high protein and low glucose indices; the gram-positive rods of *L. monocytogenes* will usually be seen in over 50% of cases. Neonatal blood cultures are positive in 17% to over 90% of cases of late-onset disease. Postpartum transmission or nosocomial acquisition is assumed to occur in infants with late-onset disease. Usually, the mother has had an uncomplicated pregnancy, with no signs of infection (e.g., fever) or sepsis (e.g., positive blood cultures) being present.

Nonpregnant adults may also become infected with *L. monocytogenes*, and those

individuals with compromised immune systems are at greater risk for severe, life-threatening listeriosis. Adults with acute listerial sepsis usually are greater than 60 years old and have underlying malignancies or are otherwise immunocompromised (e.g., lymphoma,

organ transplantation, diabetes, chronic liver/renal disease, collagen-vascular disease, alcoholism, HIV infection, and AIDS).[407,849] Persons who are receiving treatment with immunosuppressive agents such as tumor necrosis factor inhibitors and corticosteroids are also at increased risk.[467] Immunocompromised patients usually present with acute sepsis, subacute meningitis, meningoencephalitis, or, rarely, rhombencephalitis.[736] Positive blood cultures and clinical findings similar to sepsis associated with gram-negative bacteremia are usually observed. In some patients, the organisms cross the blood–brain barrier, resulting in infection of the meninges, the ventricles, and the brain.[88,788] Meningitis is usually seen in neonates, the elderly, and patients who are immunosuppressed. Oftentimes, central nervous system (CNS) infection is subacute, develops over several days, and is characterized by low-grade fever, headaches, and nuchal rigidity. The Gram's stain of the CSF is positive in less than 40% of patients. CSF cell counts are generally lower, and in 60% of cases, CSF glucose levels are normal. The protein levels in the CSF are usually elevated, with higher levels correlating with a poorer prognosis.[879] Meningoencephalitis caused by *L. monocytogenes* is associated with several unique features. Nuchal rigidity is less common, being found in 80% to 85% of adults. Motor disorders, such as ataxia, tremors, cranial nerve palsies, and seizure activity, are more common with listerial infection than with other etiologic agents of meningoencephalitis.[736,788,999] The development of ventriculitis may necessitate insertion of extraventricular drains to treat acute hydrocephalus and brain edema.[88] Fluctuating mental status is another clinical feature in these patients. In some cases, CNS listerial infection may progress to include brainstem involvement (i.e., rhombencephalitis), and imaging studies may show microabscesses in the diencephalon and cerebellum.[999] Rhombencephalitis usually occurs in previously healthy individuals without predisposing or underlying conditions, and presents with a prodrome of nonspecific CNS symptoms (e.g., nausea, vomiting, and fever) for 5 to 10 days, followed by development of brain stem involvement as evidenced by asymmetric cranial nerve palsies, sensory deficits, respiratory depression, impaired consciousness, and seizure activity.[811,1131] Brain abscesses, both solitary and multiple, may occur as complications of listerial meningoencephalitis and rhombencephalitis.[260,1161] Abscesses are usually found in subcortical regions of the brain parenchyma (i.e., the thalamus, pons, and medulla), while spinal cord abscesses

are rare.[788] Vertebral osteomyelitis due to *L. monocytogenes* may develop as a sequelae of spinal abscesses.[590] Diagnosis of meningoencephalitis and rhombencephalitis is established by culture of CSF and blood specimens. Listerial meningoencephalitis is rare in nonimmunocompromised patients, but has been reported.[652]

Hematogenous dissemination of *L. monocytogenes* may result in a variety of focal infection, including cutaneous infections, abscesses, arthritis, peritonitis, intra-abdominal, liver and splenic abscesses, endophthalmitis, prosthetic joint/vascular graft infections, osteomyelitis, pericarditis, myocarditis, and endocarditis.[983] Infection at sites other than the CNS and the bloodstream is usually seen in patients with underlying acute or chronic diseases and conditions (i.e., malignancies, systemic lupus erythematosus [SLE], rheumatoid arthritis, organ transplantation, ulcerative colitis, diabetes, renal disease, alcoholic cirrhosis, and HIV infection) or in individuals being treated with immunosuppressive or immunomodulating therapies (i.e., corticosteroids, cytotoxic chemotherapy, tumor necrosis factor [TNF]-α inhibitors). Cutaneous infections have been observed in previously healthy persons (i.e., veterinarians, animal handlers, laboratory workers) with histories of occupational contact with infected animals or animal tissues (i.e., placental tissues, amniotic fluids).[738] Cutaneous lesions may also be manifestations of early-onset disease in neonates.[1037] A positive culture of *L. monocytogenes* from a biopsy of a thigh lesion provided the diagnosis in a bone marrow transplant patient with cerebritis, since all other cultures were negative.[630] Cutaneous lesions may be papular or pustular, and disseminated infections have occurred following primary cutaneous inoculation.[151,1037] Intra-abdominal infections with *L. monocytogenes* are rare and include solitary and multiple liver abscesses, diffuse or granulomatous hepatitis, splenic rupture, and spontaneous bacterial peritonitis.[682,691,989,1017,1077] Patients with intra-abdominal complications usually have diabetes, renal disease, liver cirrhosis/hepatitis, or underlying carcinoma. *L. monocytogenes* is also capable of causing infections in continuous ambulatory peritoneal dialysis (CAPD) patients and in those with ventriculoperitoneal shunts.[107,1120,1199] Several reports have appeared describing *L. monocytogenes* as a cause of septic arthritis in patients receiving TNF-α inhibitors (e.g., methotrexate, etanercept, infliximab) for treatment of rheumatoid arthritis.[545,587,791] During bacteremia,*Listeria* organisms may seed implanted prostheses, such as knee joints and hip arthroplasties, causing subacute infection and eventual failure of the implanted device. Most patients with these infections are elderly, and the severity of infection usually requires replacement of the failed hardware.[194,235,603,731] In one report, 18 patients with infected hip arthroplasties who underwent replacement were cured, but 5 of 13 patients for whom the prostheses was not removed had protracted infection

despite chemotherapy.[194] Septic arthritis has been described in native joints and an unusual case of *L. monocytogenes* septic arthritis from Taiwan occurred following acupuncture, with inadequately sterilized needles being the suspected vehicle for transmission.[744,1107] *L. monocytogenes* is an uncommon cause of eye infections in humans, although ocular infections have been described in sheep, cattle, and horses. Case reports have been published documenting *L. monocytogenes* as a rare cause of keratitis, uveitis, hypopyon, and endogenous endophthalmitis in humans.[529,740,1096]

L. monocytogenes endocarditis results from bacteremia and usually involves damaged native aortic/mitral valves or prosthetic valves. A survey of all reported cases of *L. monocytogenes* endocarditis found that 60% of patients had some type of valvular compromise, and 23% had some type of cardiac prosthesis in place. The remainder of cases have occurred in patients with rheumatic valvular disease, mitral valve prolapse, and hypertrophic myocardiopathy.[39] Patients with endocarditis involving native valves have a lower mortality rate (about 31%) than those with prosthetic valve infection (about 41% mortality).[1052] Septic embolization to distant sites is relatively uncommon with *L. monocytogenes* endocarditis.[266,876,1068] Endocarditis involving prosthetic valves is associated with large vegetations, perivalvular leaks, dehiscence of the prosthesis, fistula formation, and

pericarditis.[334,570,876] Listerial pericarditis with pericardial effusion has also been reported without the presence of valvular lesions lesion or cardiac involvement.[277] Prosthetic valve endocarditis with *L. monocytogenes* may be complicated by paravalvular and aortic root abscesses.[707] Listerial infection of pacemaker leads is extremely rare, and, in the single case report available, pacemaker infection and vegetations were documented and the patient died due to hemodynamic instability, shock, requirement for chest tube placement due to a pleural effusion, and the development of renal failure requiring dialysis.[1068] Endocarditis with *L. monocytogenes* has also been reported in a patient with psoriatic arthritis who was being treated with infliximab.[578] Pleural fluid infections with *L. monocytogenes* have been documented in patients with malignancies, where pleural infection occurred by hematogenous seeding of malignant pleural effusions rather than secondary to a parapneumonic process.

L. monocytogenes is present as a contaminant in many kinds of foodstuffs, including raw milk, raw vegetables, fish, poultry, and both fresh and processed meats. The organism can be recovered from 15% to 70% of raw vegetables, raw milk, meats, and cheese.[320] In 1983, a widespread outbreak of *L. monocytogenes* was associated

with contaminated coleslaw, and since then, numerous outbreaks involving soft cheese, processed ready-to-eat delicatessen meats (pork, turkey), pates, butter, milk, and fish products have been documented.[1074] As a corollary to the recognition of food-borne outbreaks of listeriosis, a syndrome of febrile gastroenteritis caused by *L. monocytogenes* has also been described.[966] This syndrome includes noninvasive, nonbloody diarrhea, nausea, and vomiting accompanied by fever, fatigue, chills, and myalgias.[249,927,1074] Retrospective serologic analysis of patients with febrile gastroenteritis has been able to demonstrate immune responses to listeriolysin, a putative virulence factor of *L. monocytogenes*.[249] This acute illness usually occurs 6 hours to a few days after ingestion of foods with high listerial burdens and lasts 2 to 7 days. Individuals with this syndrome have fever, watery diarrhea, nausea, headache, and joint pain. Febrile gastroenteritis due to *L. monocytogenes* is usually self-limited, but invasive disease may occur in immunocompromised patients and those with other underlying bacterial or viral gastrointestinal infections.

With the recognition and documentation of food-borne outbreaks due to *L. monocytogenes*, the CDC has promulgated guidelines for the prevention of food-borne listeriosis.[179] Guidelines that apply to all individuals include thoroughly cooking raw food from animal sources, thoroughly washing raw vegetables before eating, keeping uncooked meats separate from vegetables, cooked foods, and "ready-to-eat foods," and avoidance of the consumption of raw (unpasteurized) milk or foods made from raw milk. Hands, knives, and cutting boards should be thoroughly washed after handling uncooked foods. For persons at high risk for listeriosis (i.e., immunocompromised persons, pregnant women, elderly individuals), soft cheeses (e.g., Mexican-style, feta, Brie, Camembert, and blue-veined cheese) should be avoided, although there is no need to avoid hard cheeses (e.g., Swiss cheese, Colby cheese), cream cheese, cottage cheese, or yogurt. Leftover foods or "ready-to-eat" foods (e.g., hot dogs) should be re-heated until steaming hot before eating. "Delicatessen counter" food (e.g., cold cuts, salami) should be avoided or thoroughly heated before eating. During the mid-1990s, the food industry introduced an initiative called Hazard Analysis at Critical Control Points (HACCP) to improve the surveillance and control of *L. monocytogenes* and other food-borne pathogens in the food processing plant environment, and the US Food and Drug Administration (FDA) has mandated a "zero tolerance" approach to the control of listeriosis, with increases in both the numbers of FDA inspections of food processing centers and recalls of foods suspected of harboring pathogens.

Isolation of L. monocytogenes *From Clinical Specimens*

L. monocytogenes may be isolated from the blood, cerebrospinal fluid, genital tract specimens, amniotic fluid, and biopsy specimens derived from maternal/fetal tissues.

Direct inoculation of both agar and broth media with overnight incubation will usually yield the organism. On Gram's stains of clinical specimens and from blood cultures, the organism may appear as regular, gram-positive bacilli or as short, plump coccobacilli. If polymorphonuclear or mononuclear cells are present, organisms are found both intra- and extracellularly. Because of variations in Gram's stain morphology that are observed with this organism, *L. monocytogenes* morphotypes may be mistaken for diphtheroids or for certain streptococci, particularly *Streptococcus pneumoniae*, enterococci, and some viridans streptococci.

Methods for the recovery of *L. monocytogenes* and other *Listeria* species from foods and environmental samples differ significantly from those used for isolation from human clinical specimens. Additional information regarding methods used for the detection and recovery of *L. monocytogenes* from food and environmental samples may be found in the indicated references.[25,26,165]

Identification of Listeria *Species*

L. monocytogenes grows well on sheep blood agar (SBA), producing gray-white colonies that closely resemble those of group B β-hemolytic streptococci. After 18 to 24 hours' incubation, colonies may show a narrow zone of β-hemolysis that does not extend very far beyond the edge of the colony (see Image Plates 14-1B and 14-1C). Before this time, β-hemolysis may only be noted directly under the colony after removal of the colonial growth from the agar surface with a swab. On longer incubation, or in areas of the plate that have been stab-inoculated, the β-hemolysis of the organism becomes more obvious. Among the other species, *L. ivanovii* subspecies produce wide zones or even multiple zones of β-hemolysis on sheep blood- or horse blood-containing media, while *L. seeligeri* produces hemolytic zones that are narrower than those of *L. monocytogenes*. Because of the resemblance of the colonies of *L. monocytogenes* to those of enterococci and group B β-hemolytic streptococci, short cuts in laboratory identification are to be discouraged. Gram stains and catalase tests should always be performed.

L. monocytogenes is a catalase-positive, facultative, gram-positive bacillus (Table 14-2). The organism is motile, showing "tumbling motility" particularly in hanging drop preparations prepared from overnight broth cultures

incubated at 25°C. This greater motility following room temperature incubation is also apparent in semisolid motility medium, where the organism displays a characteristic "umbrella" of motility near the surface of semisolid motility medium containing 0.2% to 0.4% agar after incubation at 25°C (Image Plate 14-1E). The organism also grows in the presence of 40% bile and hydrolyzes esculin; therefore, bile esculin agar slants used for presumptive identification of group D streptococci (i.e., *Streptococcus gallolyticus*) and enterococci may be used to demonstrate esculin hydrolysis (Image Plate 14-1D). The organism is fermentative, producing acid from glucose, and produces acetoin, resulting in a positive Voges–Proskauer reaction. All strains of *L. monocytogenes* ferment α-methyl-D-mannoside and do not ferment D-xylose. The β-hemolytic reaction, positive catalase test, lack of H_2S production in TSI agar, room temperature motility, and esculin hydrolysis differentiate *L. monocytogenes* from *Erysipelothrix rhusiopathiae*. Motility differentiates this organism from all *Corynebacterium* species. *Leifsonia aquatica*, the former "*Corynebacterium aquaticum,*" is also a motile, catalase-positive, gram-positive bacillus, but this organism is nonhemolytic, grows as yellow-pigmented colonies, and is Voges–Proskauer-negative (see section on *Leifsonia* species). While the biochemical characteristics of *L. monocytogenes* are usually uniform and unambiguous, aberrant strains lacking catalase activity have been isolated from patients with typical listerial sepsis and meningitis.[146,306] Phenotypic characteristics for identification of *Listeria* species are presented in Table 14-2.

The CAMP test has also been used to identify *L. monocytogenes*.[23] With *Listeria* species, the CAMP test is performed with a β-lysin-producing *S. aureus* strain and

with a strain of *Rhodococcus equi*. Synergistic hemolysis is seen between *S. aureus* and putative *L. monocytogenes* and *L. seeligeri* strains, whereas enhanced hemolysis is seen between *R. equi* and putative *L. ivanovii* strains. Other *Listeria* species (i.e., *L. innocua*, *L. welshimeri*, and *L. grayi*) are CAMP test-negative with both *S. aureus* and *R. equi*. With *L. monocytogenes*, a positive CAMP test with *S. aureus* is indicated by enhanced hemolysis in the region between the two nonintersecting streaks of growth at right angle to one another, while that seen between *R. equi* and *L. ivanovii* appears as an area of shovel-shaped enhanced hemolysis. The CAMP test for *Listeria* species may be difficult to interpret, as some investigators have reported synergistic hemolytic reactions between *L. monocytogenes* and *R. equi*.[23] Test performance is somewhat dependent on the basal media used to perform the test and the experience of the user in test interpretation.[737]

Kit systems are also available for identifying *Listeria* species. The API Coryne (bioMérieux, Inc., Marcy l'Étoile, France) and the RapID CB-Plus systems (Remel, Inc., Lenexa, KA) contain *Listeria* species in their data bases and have been shown to reliably identify these organisms to at least the genus level. In an evaluation of this system for identification of *Listeria* species, the API Coryne identified all 72 *L. monocytogenes* strains that were tested as *L. monocytogenes/innocua*, with definitive species identification being dependent on the presence of β-hemolysis and a positive CAMP reaction (Image Plate 14-1F).[584] Similar results have been reported by other investigators for both the API Coryne and the RapID CB-Plus.[379,384,528] The API *Listeria* (bioMérieux, Inc.) and the Micro-ID *Listeria* (Organon-Teknika, Durham, NC) are identification systems designed specifically for identification of *Listeria* species. The API *Listeria* is a 10-test, chromogenic enzyme substrate system that has been shown to reliably identify several species in the genus, including *L. monocytogenes*, within 24 hours.[737,853] This identification panel includes a test for glycyl arylamidase (DIM test) that differentiates *L. monocytogenes* (DIM test-negative) from *L. innocua* (DIM test-positive) without the need for assessing hemolytic activity on SBA. The other tests on the API *Listeria* include esculin hydrolysis, detection of α-mannosidase, acid production from D-arabitol, D-xylose, L-rhamnose, α-methyl-D-glucoside, D-ribose, glucose-1-phosphate, and D-tagatose. Stand-alone tests for detection of alanyl arylamidase using either DL-alanine-β-naphthylamide or DL-alanine-*p*-nitroanilide can also be used to identify *Listeria* species.[210] *L. monocytogenes* does not hydrolyze these compounds due to absence of specific arylamidases, while all other species, including *L. innocua*, are alanyl or glycyl arylamidase-positive. This test is particularly helpful in identifying *L. monocytogenes* strains that are poorly hemolytic or nonhemolytic. Some strains of *L. ivanovii* may be alanyl- or glycyl-arylamidase-negative as well.[737] The 15-test Micro-ID *Listeria* also identifies these organisms correctly, but, like the API Coryne, requires an assessment

of hemolysis for differentiation of *L. monocytogenes* and *L. innocua*.[68] Tests on the Micro-ID *Listeria* include MR/VP, nitrate reduction, phenylalanine deaminase, H_2S production, lysine and ornithine decarboxylase, malonate utilization, urea and esculin hydrolysis, β-galactosidase, and fermentation of xylose, rhamnose, mannitol, and sorbitol.[101] In an evaluation of the Micro-ID *Listeria*, this identification method agreed with conventional biochemical identification for 98% of *L. monocytogenes*, 77.1% of *L. seeligeri*, 90% of *L. ivanovii*, 96% of *L. grayi*, 73.9% of *L. welshimeri*, and 100% of *L. innocua* strains tested.[492] In a comparative evaluation with 207 *Listeria* species isolates, the API *Listeria* showed 95.2% agreement and the Micro-ID showed 93.2% agreement with conventional biochemical testing.[101] Certain substrates on the API 50CH (bioMérieux, Inc.) carbohydrate assimilation panel have also used for identification of *Listeria* species.[585]

Molecular approaches to the identification of *Listeria* species have also been developed. A highly sensitive and specific chemiluminescent DNA probe assay—the AccuPROBE *Listeria monocytogenes* Culture Identification kit (Gen-Probe, San Diego, CA)—and a spectrophotometric DNA probe assay—the GeneTrak DLP *Listeria* (GeneTrak Systems, Framingham, MA)—are also available for rapid identification of *L. monocytogenes* from colonies grown on primary isolation media.[804,818] The AccuPROBE *Listeria* hybridization assay has also been evaluated using broth media seeded with *L. monocytogenes* and showed variable results. Three nonselective broth media (BHI, tryptic soy, and Todd-Hewitt broth) gave positive AccuPROBE results, but media selective for *L. monocytogenes* gave negative reactions, even with organism loads as high as 10^8 to 10^9 cfu/ml.[804] Other workers have also noted false-negative results with AccuPROBE *Listeria* when testing is performed from certain *L. monocytogenes* enrichment broths.[842] The GeneTrak DLP (Direct Labeled Probe) *Listeria* was developed and is used primarily

for the detection of *L. monocytogenes* in foods and environmental samples following broth enrichment. The assay uses *L. monocytogenes*-specific probes directly labeled with horseradish peroxidase and a colorimetric detection system. The test takes 2 hours after a 40- to 48-hour broth enrichment step. In a side-by-side evaluation of the AccuPROBE and the Gene-Trak assays for identification of *L. monocytogenes* from plated media, all 86 *L. monocytogenes* were identified correctly, while 121 isolates of other *Listeria* species were negative with both hybridization assays.[101]

Kits are also available for the rapid detection of *L. monocytogenes* in foods and environmental samples. These tests are performed on aliquots of enrichment broth inoculated with food or environmental materials and incubated for 24 to 48 hours. The

Reveal *Listeria* (Neogen, Lansing, MI) is a lateral flow assay that is able to detect 10^6 cfu/mL of *Listeria* organisms after overnight incubation. An evaluation of the Reveal assay relative to reference methods found that the test has a sensitivity of 85.9% after 27 hours of enrichment and 97.1% sensitivity after 30 hours of enrichment.[26] The Reveal assay out-performed reference culture methods for detection of *Listeria* species on surfaces such as stainless steel, plastic, and cast iron, and was equivalent to reference culture procedures for ceramic tile and sealed concrete surfaces. NeoGen also manufactures GeneSequence, which uses molecular technology in a microtiter format for detection of *Listeria* and other pathogens present in foods. In this assay, an aliquot of the enrichment culture is placed into a test tube, lysis reagent is added, and a portion of the lysed sample is transferred to a microwell and the probe reagents are added. Probe reagents consist of an oligonucleotide capture probe specific to rRNA sequences of the target organism and labeled at the 3′ end with polydeoxyadenylic acid (poly dA) and an oligonucleotide detector probe, also specific to rRNA sequences of the target organism, that is labeled at the 5′ end with horseradish peroxidase (HRP). The tray is then incubated for 1 hour. If target rRNA is present in the sample, both probes hybridize to their complementary sequences on the target molecule and the resulting complex is captured onto the solid phase that is coated with polydeoxythymidylic acid (poly dT) (complementary to the poly dA portion of the capture probe). Unbound probe is then washed away, and a substrate of HRP is added. After another incubation, stop solution is added and results are determined spectrophotometrically. The sensitivity of this assay compared with reference USDA–FSIS (US Department of Agriculture–Food Safety and Inspection Service) procedures exceeds 90% with greater than 99% specificity.[25]

Antimicrobial Susceptibility and Treatment of Listeria *Infections*

Except for those women who deliver infants with early-onset disease, infection with *L. monocytogenes* is usually fatal if left untreated. *L. monocytogenes* is generally susceptible to penicillin, ampicillin, the aminoglycosides, erythromycin, tetracycline, trimethoprim-sulfamethoxazole, and imipenem.[721] Cephalosporins (first, second, and third generations) and the fluoroquinolones are not active against *L. monocytogenes*.[317,506] Ampicillin is considered the therapy of choice, but the standard of practice includes adding gentamicin to the ampicillin regimen for bacteremia, endocarditis, meningitis, and immunocompromised patients.[506,692] For those patients with penicillin allergy, trimethoprim-sulfamethoxazole with or without rifampin is believed to be the best alternative agent for treating *L. monocytogenes* infections.[747] Amoxicillin with trimethoprim-sulfamethoxazole was also found to be as effective as ampicillin with gentamicin in one retrospective study.[747] Patients should be treated for at least 3 weeks or longer, depending upon their immune status and clinical response.

Patients with advanced HIV disease may require lifelong therapy to prevent relapses. Interestingly, the use of trimethoprim-sulfamethoxazole as a prophylactic agent for *Pneumocystis jirovecii* infection in HIV-positive patients may be partially responsible for protecting these individuals from *Listeria* infections, although widely promulgated dietary guidelines may also have some impact on disease incidence in this population. Cephalosporins, erythromycin, and tetracyclines have no utility in the therapy of *L. monocytogenes* infections, and high rates of resistance to clindamycin have been reported in a large cancer center.[968] Vancomycin is an appropriate therapeutic agent for primary *L. monocytogenes* bacteremia, but it does not cross the blood–brain barrier sufficiently well to be useful in treating meningitis. Naturally occurring, high-level resistance to vancomycin among the listeriae has never been reported, but the *vanA* genes that code for vancomycin resistance in *Enterococcus faecium* (VRE) have been transferred to *L. monocytogenes* and four other *Listeria* species in the research laboratory.[106]

The Clinical and Laboratory Standards Institute (CLSI) has published a standard for microbroth dilution antimicrobial susceptibility testing of *L. monocytogenes*.[214] The medium used for testing is cation-adjusted Müeller–Hinton broth with lysed horse blood (2.5% to 5% v/v). The inoculum is a direct colony suspension equivalent to a 0.5 McFarland turbidity standard. Incubation is at 35°C in ambient air for 20 to 24 hours. Breakpoints are only available for penicillin, ampicillin, and trimethoprim-sulfamethoxazole. For penicillin and ampicillin, only a susceptible category is defined since resistance of *L. monocytogenes* to these agents has not been described, but breakpoints defining susceptible, intermediate, and resistant categories are available for trimethoprim-sulfamethoxazole. For penicillin and ampicillin, *L. monocytogenes* isolates will have minimum inhibitory concentrations (MICs) of ≤2 μg/mL. Isolates that are susceptible to trimethoprim-sulfamethoxazole have MICs of ≤0.5/9.5 μg/mL, while isolates that are resistant will have MICs of ≥4/76 μg/mL. Strains with MICs of 1/19 to 2/38 μg/mL are considered intermediate in susceptibility to trimethoprim-sulfamethoxazole.

Pathogenicity of Other Listeria *Species*

In both mouse and tissue culture models, only *L. monocytogenes* and *L. ivanovii* demonstrate pathogenic properties, while the other species in the genus are considered to be nonpathogenic. Gouin et al.[423] demonstrated that the gene cluster associated with virulence of *L. monocytogenes* is also found in *L. ivanovii* and *L. seeligeri*. While both *L. monocytogenes* and *L. ivanovii* are able to invade mammalian cells in tissue culture and to spread from cell to cell, the latter species lacks the cytotoxin associated with *L. monocytogenes*, suggesting

that lack of cytotoxin may account for the lower virulence of *L. ivanovii*.[571] In 1994, Cummins and colleagues[245] isolated *L. ivanovii* from blood cultures of a patient with AIDS complicated by non-Hodgkin's lymphoma. Lessing and coworkers[669] also recovered L. *ivanovii* from a blood culture of an alcoholic 26-year-old IV-drug user. In 2010, *L. ivanovii* was isolated from the blood of a 55-year-old man with a history of kidney transplantation and hepatitis C. The same organism was isolated from the patient's diarrheal stool specimen.[450] In 2003, *L. innocua* was reported for the first time as a cause of fatal bacteremia in a nonimmunocompromised 62-year-old patient with cholangitis and septic shock.[863] The organism was identified by conventional methods and confirmed by the API *Listeria* and sequencing of the 16S rDNA. *L. grayi* has also been isolated from human clinical specimens in two cases. In the first, *L. grayi* was isolated from two sets of blood cultures from a 20-year-old female with relapsed T-cell leukemia who was being conditioned for receipt of an allogeneic peripheral blood stem cell transplant.[970] The isolate was resistant to vancomycin (MIC, >32 µg/mL) and susceptible to ampicillin (MIC, 0.5 µg/mL). In the second case, *L. grayi* was isolated from one of two sets of blood cultures from a 57-year-old male heart transplant recipient.[899]

Erysipelothrix Species

Taxonomy of the Genus Erysipelothrix

The genus *Erysipelothrix* includes three species of catalase-negative, gram-positive bacilli and is classified in the Phylum Firmicutes in the Class Mollicutes (Box 14-1). Within this class, orders I through IV include the mycoplasmas and related organisms, while order V (incertae sedis) includes the genus *Erysipelothrix* and the genus *Holdemania* within the proposed family *Erysipelotrichaceae*.[1155] *Erysipelothrix* strains can be subdivided into serotypes, the most recently described being serotype 26. These are also some strains, termed "N strains", which do not produce any precipitating antibodies against homologous or heterologous heat-stable extracts in rabbits. DNA–DNA hybridization studies performed with these various serotypes indicated that the genus *Erysipelothrix* contained two species: *E. rhusiopathiae* (composed of serotypes 1, 2, 4 to 6, 8, 9, 11, 12, 15 to 17, 19, 21, and type N) and *E. tonsillarum* (composed of serotypes 3, 7, 10, 14, 20, 22, and 23).[1079,1080] Strains representing the first group of serotypes exhibited more than 73% hybridization with the type strain of *E. rhusiopathiae* but less than 24% hybridization with the type strain

of *E. tonsillarum*.[1080] Conversely, strains belonging to the second group of serotypes exhibited more than 66% hybridization with the *E. tonsillarum* type strain and less than 27% with the *E. rhusiopathiae* type strain.[1080] Isolates of *E. tonsillarum* are phenotypically identical to *E. rhusiopathiae*, except that the former species is able to ferment sucrose, and *E. tonsillarum* strains are not pathogenic for swine.[1081] (Table 14-3). Studies of the 16S rRNA genes of *E. rhusiopathiae* and *E. tonsillarum* have shown that the nucleotides sequences are 99.8% concordant, with only a three-nucleotide difference between the two sequences.[599] Two serotypes (13 and 18) are distinct from the others by DNA hybridization and may represent separate, unnamed genomic species. *E. tonsillarum* has been isolated from porcine tonsillar tissue and from the blood of dogs with endocarditis; it has not been isolated from human infections.[1079,1080,1082] Strains belonging to the same serotype are genetically diverse as demonstrated by ribotyping, randomly amplified polymorphic DNA (RAPD) analysis, amplified fragment-length polymorphism (AFLP) analysis, pulsed-field gel electrophoresis (PFGE), and nucleotide sequencing of a hypervariable region of the *spaA* gene.[17,241,242,792,815,816,826] PFGE appears to be more sensitive and discriminatory than RAPD or ribotyping and is considered the method of choice for epidemiological studies.[826] In 2004, a third *Erysipelothrix* species was isolated as a contaminant from a "sterile"-filtered vegetable broth medium prepared for pharmaceutical manufacturing. This new species was named *Erysipelothrix inopinata*.[1155]

Clinical Significance of E. rhusiopathiae

E. rhusiopathiae is widely distributed in nature, where it is found in various species of animals, mainly swine. It is also found in fish, birds, shellfish, and other wild and domestic mammals.[345,1081] The organism is also commonly found in decomposing organic matter and may be isolated from the soil. In swine, the organism causes the economically important disease known as **erysipelas**, but it may cause significant illness in other species of wild and domesticated animals. Swine erysipelas results from the ingestion of contaminated food and water. The organisms multiply in the tonsils and lymphoid tissues in the gut and gain access to the bloodstream. Swine erysipelas may have an acute, subacute, or chronic presentation. Acute infection presents with generalized septicemia within 24 hours of infection. Cutaneous lesions (e.g., erythema, vesicular lesions, necrosis) may also be present. Subacute infection presents as cutaneous lesions that develop over a few days. Swelling of tissues results in pink-to-red skin lesions that overlap and involve most of the skin surface. Lesions may go on to heal and desquamate, or may develop into septicemic lesions that eventually cause death. A live attenuated *E. rhusiopathiae* vaccine for swine immunization (Suvaxyn

E-Oral, Fort Dodge Animal Health, New Zealand) is available and appears to be safe and to afford protection against disease.[799] *E. rhusiopathiae* is also pathogenic for sheep, lambs, many species of wild and domestic birds, and, rarely, for cattle. In lambs, sheep, and cattle, this organism causes polyarthritis, but rarely causes death. Infections in birds occur most frequently in turkeys, but may occur in chickens, ducks, geese, hens, pigeons, parrots, and quail. In birds, *E. rhusiopathiae* causes hemorrhagic lesions in muscle tissue, with subsequent development of fatal diarrheal illness. Humans generally acquire the organism through contact with the tissues of infected animals or animal products and most infections occur via skin scratches or puncture wounds. Infection is usually, but not always, limited to individuals in certain occupations, such as butchers, veterinarians, abattoir workers, farmers, and fishermen.[1179]

In humans, *E. rhusiopathiae* may cause a mild, localized cutaneous infection, a generalized cutaneous infection, or a septicemic infection that is often associated with endocarditis.[944] **Erysipeloid**, the most common form of infection,

develops following cutaneous inoculation of the organism, and is usually found on the fingers or hands.[1154] Lesions appear 2 to 7 days after organism acquisition and are characterized by an elevated, violaceous, erythematous, advancing border and a faded central area. Localized throbbing pain, itching, swelling, and purplish erythema typically develop and may spread to the wrist and forearm. Lymphadenopathy, fever, and joint pain may be present. Erysipeloid usually resolves in a few weeks without systemic therapy. Erysipeloid may progress to a more generalized cutaneous infection with the appearance of lesions that are remote from the initial inoculation site. Fever, joint pain, frank arthritis, and the development of bullous lesions along with regional lymphadenitis or lymphangitis may also be a part of this generalized cutaneous infection. As the organism is located in the perivascular regions of the dermis, biopsy specimens of the advancing margin of the lesion are required to isolate the organism from localized infections.

Systemic infection occurs infrequently and is characterized by sepsis and

bacteremia.[10,471,1179] In these patients, *E. rhusiopathiae* endocarditis (particularly left-sided) is common, causes extensive damage to healthy heart valves and cardiac tissues, and has a high mortality rate.[1133] Both native valve endocarditis and prosthetic valve endocarditis (including both Starr–Edwards prosthetic valves and porcine xenograft valves) caused by *E. rhusiopathiae* have been reported.[481] Native valve endocarditis with *E. rhusiopathiae* usually requires valve replacement along with antimicrobial chemotherapy for treatment and cure. Individuals with systemic infections frequently have no prior history of primary cutaneous infection.[1133] Patients with systemic involvement are usually debilitated by immunosuppressive therapy (e.g.,

corticosteroid administration) or underlying conditions that result in immunocompromised states, such as cancer, diabetes, alcoholism, or systemic lupus erythematosus.[1007]Multisystem disease evidenced by shock and renal failure has also been reported, particularly among those with endocarditis.[408] Complications and unusual manifestations of *E. rhusiopathiae* bacteremia and endocarditis include prolonged hypertension, paravalvular and myocardial abscesses, septic arthritis, endogenous endophthalmitis, necrotizing fasciitis, and cerebral infarcts.[47,307,502,611,954,1019,1070] Recently, *E. rhusiopathiae* was isolated from infections of total hip and total knee arthroplasties that required total revision of both implants.[1114,1117] One patient worked in a tanning factory, where he worked with hides of pigs, cows, and deer and suffered frequents cuts and abrasions on his hands.[1114] The second patient had no direct exposure to wild animals, but she had a dog that was used for hunting and frequently carried wild animals in its mouth.[1117] In 2010, *E. rhusipathiae* was reported as the cause of an abdominal abscess in a patient with a recent history of a surgical duodenocephalopancreatectomy for distal bile duct adenocarcinoma.[326] This organism is rarely isolated from the CNS, but two reports, one in 2007 and the other in 2011, document meningitis in two patients, neither of whom had any overt animal exposures.[558,595] In one case, the patient presented with chronic headache that had lasted for 2 months, and subsequently developed hydrocephalus requiring placement of a ventriculoperitoneal shunt. *E rhusiopathiae* was isolated from the CSF.[595] In the second case, onset of meningeal signs and symptoms were acute.[558] Although the CSF failed to grow the organism, the cellularity of the CSF and magnetic resonance imaging (MRI) scans showed chronic ischemia in the cerebral white matter, with no indications of infarcts or hemorrhage. Echocardiography revealed severe mitral regurgitation compatible with infective endocarditis, and *E. rhusiopathiae* was isolated from blood cultures. In 2012, *E.*

rhusiopathiae pneumonia was diagnosed in an immunocompetent male stockyard worker who spent most of his time feeding cattle.[746] *E. rhusiopathiae* has also been documented as a rare cause of peritonitis in patients on CAPD.[160,472,1012]

Isolation and Identification of E. rhusiopathiae

E. rhusiopathiae may be isolated from biopsy specimens of erysipeloid lesions and from blood cultures. The specimen of choice for isolation of the organism from skin lesions is an aspirate obtained by injection and aspiration of sterile saline from the leading edge of the cellulitis or a punch biopsy from the same area. The organism grows well in commercially available blood culture media. On SBA, *E. rhusiopathiae* forms small (0.1 to 0.5 mm in diameter), circular, convex, smooth colonies. A weak α-hemolytic reaction may be noted in the media, particularly in areas where the growth is more confluent (Image Plate 14-1H). On Gram-stained smears, the organisms appear as slender rods; chains of nonbranching bacilli may also be observed and the individual bacterial cells may be straight or somewhat curved (Image Plate 14-1G). *E. rhusiopathiae* is catalase-negative and nonmotile (Table 14-3). The most useful property for identifying this organism is the production of H_2S in the butt of a TSI agar or Kligler's iron agar (KIA) slant (see Image Plate 14-2A). Failure to look for H_2S production by suspect isolates may result in the misidentification of these organisms as *Lactobacillus* species.[297] A properly streaked and stabbed KIA slant will show an acid slant and acid butt, due to acid production from glucose and lactose; H_2S may be noted throughout the butt or only along the streak line in the butt. This reaction helps to differentiate *E. rhusiopathiae* from other catalase-negative bacilli such as *Arcanobacterium haemolyticum*; this latter species is also β-hemolytic on SBA. The negative catalase reaction, lack of hemolysis or weak α-hemolysis on SBA, and production of H_2S in KIA or TSI agar also help to differentiate *E. rhusiopathiae* from *L. monocytogenes*. Stab inoculation of a tube of gelatin agar and incubation at 22°C results in the production of "bottle brush" or "pipe cleaner" growth, where the organisms grow out in straight lines perpendicular to the stab inoculation, giving the appearance of "bristles".

E. rhusiopathiae is weakly fermentative, producing acid from glucose, galactose, fructose, lactose, maltose, and *N*-acetyl-glucosamine. No acid is produced from glycerol, arabinose, xylose, adonitol, inositol, mannitol, sorbitol, amygdalin, malibiose, trehalose, cellobiose, inulin, melezitose, raffinose, and glycogen. Acetoin and indole are not produced and nitrate is not reduced to nitrite. *E. rhusiopathiae* is included in the data bases of both the API Coryne and the RapID CB-Plus identification systems. Isolates of *E. tonsillarum* are phenotypically identical to *E. rhusiopathiae*, except that the former species also produces acid from sucrose. Biochemical characteristics for identification of *Erysipelothrix* species are shown in Table 14-3. Rapid molecular

methods, including real-time polymerase chain reaction (PCR) approaches, have been developed for detection of *E. rhusiopathiae* and differentiation of *E. rhusiopathiae* and *E. tonsillarum* in animal specimens.[837,1221]

Antimicrobial Susceptibility of E. rhusiopathiae

E. rhusiopathiae strains are generally susceptible to penicillin, cephalosporins, imipenem, piperacillin, and ciprofloxacin.[343,345] Of considerable therapeutic importance is the fact that *E. rhusiopathiae* strains are intrinsically resistant to vancomycin, teicoplanin, and other glycopeptide drugs.[343] MICs for vancomycin are generally >64 μg/mL.[343] Penicillin, amoxicillin clavulanate, imipenem, and the fluoroquinolones have been found to be the most active agents against this organism.[746] In one study of 60 isolates from animal and human infections, the MIC50s and MIC90s were both 0.03 μg/mL for penicillin, both 0.06 μg/mL for ciprofloxacin, and 0.06 μg/mL and 0.125 μg/mL, respectively, for ceftriaxone.[343] Some isolates may have elevated MICs or may be resistant to clindamycin, erythromycin, tetracycline, trimethoprim–sulfamethoxazole, the fluoroquinolones, and gentamicin. In an antimicrobial susceptibility study of 149 *E. rhusiopathiae* strains isolated from pig tissues in Japan, 37.6% were resistant to erythromycin, 2.7% were resistant to lincomycin, 12.1% were resistant to ofloxacin, and 12.8% were resistant to enrofloxacin (a fluoroquinolone used in veterinary medicine).[206] Daptomycin and linezolid also have excellent activity against this organism.[826,871] Even with

appropriate antimicrobial therapy, the mortality associated with disseminated disease may be as high as 35% to 40%. This high mortality rate is largely attributable to complications resulting from endocarditis. Cases of human cutaneous infection may be effectively treated with oral penicillin, but severe disease requires penicillin G, 12 to 20 million units/day for 10 to 14 days.

In 2010, CLSI published an approved standard for microbroth dilution antimicrobial susceptibility testing of *E. rhusiopathiae*.[214] The interpretive criteria are based on a synthesis of previously/currently published standards for susceptibility testing of staphylococci and streptococci. The medium used is cation-supplemented Müeller–Hinton broth with lysed horse blood (2.5% to 5% v/v), with inoculum coming from a direct colony suspension equivalent to a 0.5 McFarland turbidity standard. Tests are incubated at 35°C in ambient air for 20 to 24 hours. Only susceptible breakpoints are available for the penicillins, cephalosporins, carbapenems, and fluoroquinolones, while susceptible and resistant breakpoints are published for clindamycin and erythromycin.

Vancomycin does not need to be tested because of intrinsic resistance. In the document, CLSI points out the importance of correct and rapid identification of the organism because of its association with complicated endocarditis and its resistance to vancomycin, which is often used as a frontline drug for empiric antimicrobial therapy.

Bacillus Species and Related Genera

Taxonomy and the Taxonomic Dissection of Genus Bacillus

The genus *Bacillus* is comprised of a large group of aerobic and facultative, catalase-positive, gram-positive rods that are characterized by the ability to form spores under aerobic conditions (see Image Plate 14-2B). Because the description of genus *Bacillus* placed particular emphasis on endospore formation as a taxonomic criterion, an extremely diverse collection of species was assigned to this genus over several decades. Within this criterion, endospore shape (i.e., spherical, oval, ellipsoidal, cylindrical), spore location within the cell (i.e., central, subterminal, terminal), and spore-induced changes in cell shape (i.e., cells swollen or not swollen by the intracellular spore) were also used as taxonomic descriptors. Until recently, members of genus *Bacillus* included aerobic and facultative organisms that were also acidophiles, alcaliphiles, psychrophiles, mesophiles, and thermophiles, reflecting growth and metabolism over wide temperature and pH ranges. Some species are able to metabolize a wide assortment of carbon sources, including methanol, cellulose, and chitin. Significant variation also is found in the amino acids comprising the cross-linkages within the cell wall peptidoglycan. At the genetic level, diversity within the genus is exemplified by G+C contents, which range from 33 mol% to 69 mol%. Such genetic heterogeneity is incompatible with inclusion in a single genus as defined by current bacterial taxonomic methods. Not surprisingly, 16S rRNA sequencing studies demonstrated that extant "genus *Bacillus*" was phylogenetically heterogeneous, with at least eight highly divergent phyletic lines being represented. Aerobic and facultative spore-forming bacilli are now included in three families: family *Bacillaceae*, family *Paenibacillaceae*, and family "*Alicyclobacillaceae*," all of which are in the order Bacillales, class "Bacilli" in the phylum Firmicutes.[695] The family *Bacillaceae* includes genus *Bacillus* and at least 18 other genera, most of which are environmental species. The family *Paenibacillaceae* includes the genus *Paenibacillus* and at least 6 other genera. Members of genus *Paenibacillus* are facultatively anaerobic spore-forming rods that produce swollen sporangia and have G+C contents ranging from 45 mol% to 54 mol%.[51,1008]Currently there are over 60 species in the genus *Paenibacillus* and some of these have been isolated from human clinical specimens. The family "*Alicyclobacillaceae"* includes species that are acidophilic thermophiles that contain unique cycloheptane/cyclohexane cell membrane fatty acids. The family

"*Sporolactobacillaceae"* is composed of three genera of anaerobic, motile, endospore-forming lactic acid-producing bacilli (*Sporolactobacillus*, *Sinobaca,* and *Tuberibacillus*) and is also classified in phylum Firmicutes.

The genus *Bacillus sensu stricto* is composed of aerobic gram-positive rods that produced endospores under aerobic conditions. At the present time, the genus contains more than 269 species. With rare exceptions, all species in the genus are mesophilic and aerobic or facultative. The primary pathogen in this group is *Bacillus anthracis*, the causative agent of anthrax. These organisms are catalase-positive, and, with the exception of *B. anthracis* and *B. mycoides*, many other species are motile via peritrichous flagella (H antigens). Most non-*anthracis Bacillus* species are ubiquitous in the environment (dust, soil, water, and materials of both plant and animal origin), and some species are recognized pathogens in animals and insects. *Bacillus* species are used in antibiotic and vitamin manufacturing and production, in bioassays, and as indicator organisms for monitoring the efficacy of disinfectants and sterilization procedures (e.g., autoclaving, heat, and radiation sterilization). Various species within this group, particularly *B. cereus*, are being increasingly recognized for their potential to cause significant human infections, particularly among immunocompromised hosts. *B. anthracis* belongs to the "*B. cereus* group," which includes eight very closely related species: *B. anthracis*, *B. cereus, B. thuringiensis, B. mycoides*, *B. pseudomycoides*, *B. weihenstephanensis*, *B. gaemokensis*, and *B. maliponensis*.[563,564,647,793] The *B. cereus* group can be divided into three distinct clades.[279] *B. anthracis* is restricted to clade 1 along with virulent emetic toxin-producing *B. cereus* strains.[1056] Other pathogenic *B. cereus* strains are placed in clade 2 along with most *B. thuringiensis,* and clade 3 includes *B. mycoides*, *B. pseudomycoides*, and *B. weihenstephanensis. B. anthracis, B. cereus, B. thuringiensis*, and *B. mycoides* share a high degree of genetic similarity by DNA–DNA hybridization and comparisons of rRNA and rDNA at the 16S, 23S, and the 16S-to-23S spacer region.[48–50] Some researchers have even suggested that these organisms should be considered as a single species based on gene sequence analysis and multilocus enzyme electrophoresis studies.[647] *B. cereus* is a mesophilic organism that is ubiquitous in the environment as a soil saprophyte in food of plant and animal origin. *B. cereus* is also a cause of food poisoning and, in this role, is a serious problem for the commercial

food industry. This organism can also cause localized and systemic opportunistic infections in immunocompromised hosts, intravenous drug users, and neonates, as well as keratitis (see section on *B. cereus* below). Genotypic analyses of *B. cereus* and *B. thuringiensis* strains from the environment, animals, and humans have

demonstrated a great deal of diversity within and between the species.[161] *B. thuringiensis* is a pathogen of insects and is a rare cause of opportunistic infections and food poisoning in animals and humans. During sporulation, this organism forms parasporal crystals composed of insecticidal proteins called Cry proteins. Cry proteins have molecular weights of 40 to 140 kDa and are toxic to several orders of insects, including members of the Coleoptera (beetles), Diptera (mosquitoes), and Lepidoptera (butterfly and moth larvae). The genes for these toxins are located on large transmissible plasmids. Several other extracellular products of *B. thuringiensis* such as Vip proteins and β-exotoxin are also potent insecticides. All of these insecticides are purified, manufactured, tested for safety and investigated for environmental impacts before they can be licensed and marketed. Products of *B. thuringiensis* account for about 90% of the world's microbial pest control agents market. *B. mycoides* is a nonmotile species that forms rhizoidal colonies on agar. For many years, *B. mycoides* was considered a variant of *B. cereus*, but they are genetically distinct taxa.[794] DNA studies and chemotaxonomic analysis of whole-cell fatty acids delineated a new species within "*B. mycoides,*" resulting in the species, *B. pseudomycoides*.[793] *B. weihenstephanensis* is closely related to *B. cereus* and includes primarily psychrotolerant strains that grow at 4°C to 7°C but not at 43°C.[647] *B. gaemokensis* and *B. manliponensis* are new members of the *B. cereus* group that were isolated from tidal flat sediment of Gaemok Harbor and Manlipo Beach, both of which are in the coastal region of the Yellow Sea in the Republic of Korea.[563,564]

Bacillus anthracis

Epidemiology of Anthrax. Anthrax, the classical disease caused by *B. anthracis*, is primarily a disease of wild and domestic herbivorous mammals, including cattle, sheep, goats, bison, antelope, and deer. The organisms exist as a spore and as a vegetative, actively replicating, large gram-positive bacillus. The spores are dormant forms that are found in the soil, particularly in warmer, wetter climates.[294] Animals ingest the spores while grazing on contaminated vegetation. Illness in animals usually appears within 3 to 7 days after exposure to the spores. Animals usually develop fulminant systemic disease with edema, hemorrhage, hemorrhagic discharges from body orifices, and necrosis.[531]In infected animals, the bacteria are shed in blood and other body fluids, and the organisms subsequently sporulate and contaminate the soil and water, where they can remain viable for decades. Because of this ability to persist, animals suspected of having anthrax should be incinerated after death to prevent dissemination of spores. Outbreaks of anthrax in North America usually occur in the hot, dry summer months. Disruption of the soil by winds or construction in regions where animals have died may result in further dissemination of spores and to additional cases of disease. Other animals feeding on the carcasses of dead animals

may help to disseminate both vegetative bacilli and spores, and biting insects can act as mechanical vectors by spreading spores to vegetation after feeding on infected carcasses.[1124] Anthrax is most common in South America, Central America, sub-Saharan Africa, Central and Southwestern Asia, and Southern and Eastern Europe.[530,1127] In the United States, this disease has been essentially eradicated because of the widespread use of effective human and animal vaccines since the late 1930s, improvements in hygienic procedures used in factories processing animal products, and increased use of synthetic fibers as alternatives to animal hides, fur, and hair. However, because the spores of *B. anthracis* are highly resistant to adverse environmental conditions and because it is exceedingly difficult to be sure that the organism has been truly eradicated from former endemic regions, a high index of suspicion should be maintained if a clinically compatible illness suddenly appears. Historically, anthrax is usually defined in terms of its mode of acquisition. **Industrial anthrax** refers to cutaneous inoculation or inhalation of anthrax spores by those individuals employed in the cleaning and industrial processing of contaminated leather hides, wool, hair, or bone from various animals.[63] **Nonindustrial anthrax** refers to the acquisition of the organisms from close contact with infected animals or with their carcasses and tissues.[63,182] At-risk individuals in this category would include slaughterhouse workers, veterinarians, butchers, and ranchers, with cutaneous anthrax being the most common clinical presentation.

B. anthracis has been exploited and developed as an agent of biologic warfare by several countries, including Japan, the former Soviet Union, the United Kingdom, Iraq, and the United States.[926] In 1992, the Soviets admitted their ongoing efforts in the weaponization of anthrax over the previous few decades, and divulged that, in 1979, an accidental release of anthrax spores from a Soviet military laboratory in Sverdlovsk resulted in over 77 cases of inhalational anthrax, with more than 66 human fatalities.[183,184,748] The potential for bioterrorism associated with *B. anthracis* was brought into sharp focus in the United States during the last 4 months of 2001, when spores of *B. anthracis* were delivered in mailed letters and packages via the US Postal Service to locales within the continental United States.[183,184] As a consequence of these exposures, 22 people developed anthrax, including 11 cases of cutaneous disease and 11 cases of inhalational anthrax. Five people with pulmonary disease died. Since these incidents occurred soon after the September 11 attack on the World Trade Center, the Pentagon, and United Airlines Flight 93, several laws were passed by Congress placing limitations on access to and possession of select agents—a CDC- and USDA-sanctioned listing of pathogens believed to be the most dangerous. Additional funding for research on these agents was also made available. These incidents also resulted in the passage of anti-terrorism legislation in the United States and the development the Bioterrorism Preparedness Initiative. Through this initiative, the

CDC, along with the Association of Public Health Laboratories (APHL), various federal agencies (i.e., the Federal Bureau of Investigation [FBI], and the Department of Defense [DOD]), and the various states' public health laboratories, established the Laboratory Response Network (LRN).[177,178] In the LRN, clinical microbiology laboratories throughout the country

858

are integrated into a four-tier network. Sentinel laboratories include clinical microbiology laboratories in hospitals; advanced-level sentinel laboratories must have class II biologic safety cabinets and establish and maintain compliance with biosafety level-2 laboratory practices. Through the LRN, technologists in laboratories perform basic tests to rule out potential biothreat agents and to refer possible agents to the next level—reference laboratories.[31,1168] These laboratories are usually the state public health laboratories, where confirmatory testing of referred isolates can be done in a timely manner. Referrals from this level are made to national laboratories that have biosafety level 4 facilities: the CDC and the US Army Medical Research Institute for Infectious Diseases (USAMRID). Most hospital-based clinical laboratories with microbiology capabilities are sentinel members of the LRN. Sentinel laboratory tests for detection of possible *B. anthracis* are found in Table 14-4 and will be addressed in the "Isolation and Identification" section.

Virulence Factors of *B. anthracis.* *B. anthracis* is highly monomorphic, shows little genetic variation, and produces toxins that are composed of three distinct proteins: protective antigen (PA), edema factor (EF), and lethal factor (LF).[614,866]Virulent strains also are encapsulated. *B. anthracis* harbors two large plasmids called pX01 (182 kb) and pX02 (95 kb).[765] The structural genes for PA, EF, LF—*pagA*, *cya*, and *lef*, respectively—are found on the pX01 plasmid. These genes reside noncontiguously in a 30-kb area on the pXO1 plasmid within a 44.8 kb "pathogenicity island".[817] Another gene in this region, *atxA*, encodes the trans-activating transcriptional regulator AtxA and the repressor PagR, which regulate expression of the toxin genes.[614] pX02 contains a five-gene operon consisting of *capB*, *cap C*, *capA*, *capD*, and *capE;* these genes function in the synthesis of the poly-γ-D-glutamic acid capsule, which enables vegetative cells of *B. anthracis* to evade phagocytosis and killing by macrophages. The five capsular genes and the genes for capsular transcriptional regulators AcpA (*acpA*) and AcpB (*acpB*) are located on a 35-kb "pathogenicity island" on pX02. Expression of the transcriptional regulators for the capsule are also under the control of AtxA from pX01.[860] PA is synthesized and secreted by the organism and binds to TEM8 (tumor endothelial marker 8) and CMG 2 (capillary morphogenesis protein 2)

sites on target cells, where it undergoes proteolytic cleavage.[134] A 20-kDa amino-terminal fragment is released, and the remaining 63-kDa PA fragment polymerizes with other similar fragments to form a ring-shaped heptamer, which forms a pore through the cell membrane.[321,1194] Each 63-kDa PA monomer in the heptamer acts as an "adhesion subunit" and binds one molecule of either EF or LF, and the PA-EF and PA-LF complexes enter the target cell by endocytosis. Acidification of the phagosome allows these complexes to be released from the phagosome and the complexes dissociate to free LF and EF. LF is a zinc metalloprotease and EF is a calmodulin-dependent adenylate cyclase. EF increases intracellular cAMP levels, which leads to inhibition of phagocytosis, and deregulation of cytokine production.[1092] In macrophages, LF inhibits macromolecular synthesis, promotes apoptosis, and hydrolyzes protein kinases involved in intracellular signal transduction. Interruption of signaling pathways results in the inactivation of transcriptional factors in the cell nucleus and induction of proinflammatory cytokines.[764] During infection, LF and EF are able to suppress the cellular immune response by all of these mechanisms. Toxin gene expression and toxin production are specifically enhanced at the genetic level by CO_2 and growth at 35°C to 37°C.[613] Organism growth under these conditions results in fourfold to sixfold enhancements in the transcription of toxin genes and in toxin synthesis.[765]

Interestingly, several *B. cereus* group strains carry plasmids that are related genotypically to pX01 and pX02, but these plasmids do not carry the anthrax toxin genes, capsular genes, the pathogenicity islands, or the regulatory genes found on the *B. anthracis* plasmids.[614,850,851] In addition, certain important phenotypic properties of *B. anthracis* (i.e., nonmotility, β-hemolysis, sensitivity to γ-bacteriophage, failure to produce phospholipase C) result from a unique single base mutation in a chromosomal gene called *plcR*, which encodes a global transcriptional regulatory protein called PlcR.[11,1033] This gene is functional in *B. cereus* and *B. thuringiensis*, but the single-point mutation in the *B. anthracis plcR* gene renders the gene product nonfunctional. In *B. cereus*, PlcR interacts with a second molecule in a quorum-sensing system that controls expression of genes encoding phospholipases, proteases, hemolysins, and collagenases.[412] In most cases, *B. anthracis* can be easily distinguished from *B. cereus* and *B. thuringiensis*, but there are strains of *B. cereus* that contain the toxin and capsular virulence genes and that also have the *plcR* mutation and, that may express a phenotype like *B. anthracis*. In fact, three recent clinical isolates of *B. cereus* were isolated from metal workers in Texas and Louisiana with pneumonias similar to inhalational anthrax.[507,508] These isolates contained the entire *B. anthracis* pX01 plasmid with the full complement of virulence and regulatory genes. In addition, two *B. cereus* group strains recovered from 10 great apes in the Ivory Coast and Cameroon contained both pX01 and pX02 plasmids, with all the required regulatory

genes and capsular biosynthesis genes.[602,658,659,1164] Further genotypic analysis, phenotypic studies, and MLST-based phylogenetic taxonomic studies established that these isolates were indeed, **not** *B. anthracis* in the classic sense. The nine chimpanzees and a single gorilla died from anthrax-like illnesses. Much work is now being done to further characterize these and other isolates among the "nonanthrax *B. cereus*" group organisms.

Clinical Presentations of Anthrax. Human anthrax may be divided into four clinical forms, depending upon the mode of organism acquisition. These forms include cutaneous anthrax, oropharyngeal/gastrointestinal anthrax, inhalational anthrax, and injectional anthrax.[1075] **Cutaneous anthrax** accounts for 95% to 99% of cases worldwide and most cases occur in Africa, Asia, and eastern Europe, where livestock and animal worker vaccinations are not readily available. Infection results from direct mucosal contact with infected animals, animal products (e.g., hair or animal hides), soil containing the organism, or exposure to spores.[288] Spores enter through small cuts or abrasions and germinate subcutaneously within local macrophages and in the regional lymph nodes.[1212] Lesions of cutaneous anthrax usually occur on exposed areas of the skin (e.g., hands, arms, neck, wrist,

and face). After an incubation period of 2 to 7 days (range of 1 to 19 days), a painless or pruritic initial papule develops at the site of inoculation.[287] Cutaneous lesions are generally single, but sometimes two or more lesions may be present. The lesion is surrounded by an area of edema and erythema due to growth of the organism and the elaboration of edema toxin locally. The lesion rapidly evolves into a vesicle or bullous lesion that is less than 4 cm in diameter, and the fluid within the vesicle becomes black

from hemorrhage into the lesion. This lesion eventually ulcerates and develops a black-bottomed, central eschar with surrounding edema. Frequently, small, pearl-like satellite lesions may appear surrounding the central

860

eschar. Eschars of cutaneous anthrax are characteristically painless, although the surrounding edematous reaction may be painful. The eschar usually dries up and sloughs over the next 10 to 14 days. On biopsies, eschars usually show massive edema with necrosis and lymphocytic infiltrates, with focal hemorrhage and no abscess formation.[710] Large, deep eschars may require surgical removal with subsequent skin grafting once the localized inflammation and edema subside 4 to 6 weeks later.[288] Localized or generalized painful lymphadenopathy may be observed, depending on the extent and severity of the initial infection, and constitutional symptoms (e.g., fever, malaise, headache) may also be present. In severe cases, a toxemic shock picture may present, with hypothermia, cutaneous inflammation with extensive edema, leukocytosis with a predominance of polymorphonuclear leukocytes, hypoalbuminemia, and elevated liver enzymes.[288] Rare complications of cutaneous anthrax include airway obstruction due to massive neck edema, bacteremia, meningitis, and deep-tissue necrosis with scar tissue formation.[286,574,1036,1095] Cutaneous anthrax may resolve spontaneously in some cases, but the mortality associated with untreated cutaneous anthrax may be as high as 10% to 20%. With treatment, mortality is less than 1%.[1193]

Oropharyngeal anthrax and **gastrointestinal anthrax** are acquired by ingestion of inadequately cooked foods (usually meats) containing either spores or vegetative bacilli.[77,998,1075] Both of these forms of infection may become systemic and, like the pulmonary form, have a high mortality if untreated. The incubation period of gastrointestinal anthrax is 2 to 7 days; in one large outbreak, the infection was associated with ingestion of contaminated beef, and the incubation period was 42 hours.[1027]Oropharyngeal anthrax usually presents as an oral or esophageal ulcer, with regional lymphadenopathy and edema.[1028] Eschars may be noted on the posterior pharynx, tonsillar areas, or the hard palate. Progression of the infection results in dysphagia and a severe sore throat. Gastrointestinal anthrax involves primarily the terminal ileum and cecum (Image Plate 14-2C). Symptoms begin with fever, nausea, malaise, and vomiting and progress rapidly to an acute abdomen, sepsis and bloody diarrhea. A few days after onset, cloudy or outright purulent ascites that is teeming with anthrax bacilli may develop.[22] The mucosal surfaces of the gastrointestinal tract show extensive necrosis, edema, and mesenteric lymphadenitis, and anthrax bacilli can be cultured from the gastrointestinal tissues and inflammatory infiltrates. Profound

illness due to loss of blood, electrolyte imbalance, and toxic shock may develop.[569] Mortality can be as high as 60% to 100% if not aggressively treated. Death usually results from overwhelming sepsis, and intestinal blockage with subsequent intestinal perforation.[1028] Gastrointestinal anthrax has been reported in the United States in a patient who presented with abdominal cramps, nausea, vomiting, and hypotension. The patient went on to develop massive ascites, nodular hemorrhagic mesenteric lesions, small bowel necrosis, and retroperitoneal abscesses and hematomas. Unfortunately, respiratory failure ensued that required intensive support, along with antimicrobial chemotherapy and administration of anthrax immune globulin.[187,605]

Pulmonary or inhalational anthrax results from inhalation of *B. anthracis* endospores.[998] In the past, this infection was seen in persons whose occupations involved handling animal hides contaminated with anthrax spores. Although this situation no longer obtains due to animal control guidelines and vaccinations, occasional reports of inhalational anthrax still appear now and then from endemic regions. Following inhalation, the spores reach the lungs, where they are phagocytosed and cleared by macrophages of the reticuloendothelial system. The macrophages migrate to the hilar and mediastinal lymph nodes, where the spores germinate and mature into vegetative bacilli.[514] The organisms multiply and produce toxins, causing edema and hemorrhagic necrosis of the mediastinum, which is evident on chest films as marked mediastinal widening. From the substernal area, the organisms invade the pleural space, resulting in hemorrhagic pleural effusions.[514,1210] The macrophages harboring the organisms are killed and the vegetative bacteria escape into the general circulation where they continue to multiply. Hematogenous dissemination seeds distant sites, leading to metastatic lesions throughout the body, including the gastrointestinal tract and CNS. Anthrax meningitis is a fulminant complication that can follow cutaneous, gastrointestinal, or inhalational anthrax. This complication may develop in up to 30% to 40% of patients with inhalational anthrax and has a mortality of 100%.[514,634] Most patients do not survive long enough to manifest signs and symptoms of meningitis; patients are usually lucid until systemic shock supervenes, resulting in coma and death. The incubation period of inhalational anthrax is 1 to 4 days, followed by the sudden onset of flu-like symptoms, such as fever, chills, myalgias, substernal pain and a nonproductive, dry cough, and nausea with vomiting. After 3 or 4 days of this prodromal illness, fulminant disease follows, with the development of dyspnea, hypotension, an elevated hematocrit, and mental status alterations reflecting overwhelming toxemia, often progressing to coma and death in 24 to 48 hours. On chest roentgenogram, infiltrates, pleural effusions, and widening of the mediastinum may be noted; histologic examination of lung tissues at autopsy usually show focal necrotizing, hemorrhagic pneumonitis and necrosis of peribronchial and mediastinal lymph nodes with no abscess formation or consolidation. Gastrointestinal

involvement results in abdominal pain, hematemesis, and melena. The mortality associated with this form of the disease exceeds 80% to 90% if left untreated.

Injectional Anthrax. This newly described clinical presentation of anthrax infection was first recognized in an injection drug user in Norway who skin-popped heroin into his right buttock.[941] Within 4 days, extensive swelling and erythema involved the entire right gluteal region. The patient was placed on anti-staphylococcal therapy and discharged until he returned 4 days later with meningitis and shock, swelling, edema, and erythema involving the gluteal region, the thighs, and lower abdomen. Unlike cutaneous inoculation anthrax, papules, vesicles, and classical eschars were not observed. Surgery revealed no abscesses but extensive tissue edema was present, and the CSF and intraoperative wound specimens all grew *B. anthracis*. The patient died within 3 days of admission while on high-dose penicillin plus chloramphenicol. This seemingly isolated scenario was not reported again until December of 2009, when two intravenous drug users were hospitalized in the United Kingdom with *B. anthracis* isolated from their blood

861

cultures. By the end of 2010, there were 47 confirmed cases with 13 deaths reported in Scotland, 5 cases with 4 deaths in the United Kingdom, and 2 cases with 1 death reported from Germany.[78,127,893,898] The clinical presentation of injectional anthrax is quite variable. In most patients, soft tissue infection is evidenced by swelling in the area of drug injection after 1 to 10 days. Surgical examinations of infected tissues show edema, necrosis of the fatty tissue, and diffuse bleeding; in some cases patients developed deep wounds requiring wide excisional debridement or, in the case of a groin infection, a fasciectomy due to fasciitis and peritonitis. Constitutional symptoms consisting of chills, fever, and nausea were also seen in some patients. Injectional anthrax has a mortality rate as high as 34%; this is partly due to the increased likelihood of recurrent shock with this form of disease and failure to consider this uncommon diagnosis. The heroin involved in these outbreaks was suspected of being contaminated because it was smuggled into Europe from anthrax-enzootic regions in Afghanistan, Iran, and Turkey.

Antimicrobial Susceptibility and Treatment of *B. anthracis* Infections. *B. anthracis* is susceptible to several antimicrobial agents, including tetracyclines, macrolides, clindamycin, aminoglycosides, fluoroquinolones, carbapenems, rifampin, and the first-generation cephalosporins (cephalothin, cefazolin). *B. anthracis* is resistant to the second- and third-generation cephalosporins (i.e., cefotaxime, ceftriaxone, ceftazidime), monobactams (i.e., aztreonam), and trimethoprim–sulfamethoxazole.[174,216,766,1128] Resistance to penicillin, ampicillin, and second-

generation cephalosporins was detected in 11.5% of 96 *B. anthracis* isolates from animals and the environment in France from 1994 through 2000.[174]

Treatment regimens for anthrax differ depending on the clinical presentation and the severity of disease.[183,184,1057] For naturally acquired (e.g., occupational) cutaneous infections, oral penicillin is the drug of choice. The recommended agent is amoxicillin (adults, 500 mg every 8 hours; children, 80 mg/kg/day every 8 hours). Unless there is clear evidence that the infection was naturally acquired, the possibility of anthrax infection being acquired by intentional release of spores must be kept in mind. The use of penicillin and ampicillin is controversial and these agents should not be used alone because of constitutive or inducible β-lactamase production by some strains of *B. anthracis*. The recommended treatment for gastrointestinal and inhalational anthrax is intravenous (IV) ciprofloxacin (400 mg every 12 hours) or IV doxycycline (100 mg every 12 hours), plus addition of another intravenous agent (i.e., ampicillin, imipenem, clindamycin, clarithromycin, rifampin, vancomycin). Once clinically indicated, oral therapy (ciprofloxacin, 500 mg twice daily; doxycycline 100 mg twice daily) can be substituted. Treatment of children uses the same agents with dosages adjusted for age and weight. In the event that the patient develops meningitis, the fluoroquinolone regimen should be used instead of doxycycline due to superior penetration into the CNS; in such instances, when the second IV agent is added, it should be able to penetrate into the CNS as well.[72] In most cases, 10 to 14 days of intravenous antimicrobial chemotherapy is sufficient, followed by oral therapy. Since the US anthrax mailings in 2001, it was recommended that treatment be continued for up to 60 days in case the patient harbored spores that may germinate into vegetative cells later.[189]

Patients being treated for anthrax also require intensive supportive care, and newer adjunctive treatment regimens are available to address these issues. Patients with inhalational and injectional anthrax often develop recurring pleural effusions that contain large numbers of anthrax bacilli. Frequent thoracentesis and drainage of accumulating pleural fluids is recommended and has been shown to increase survival.[514,546] Anthrax immune globulin (AIG) is also available as an adjunctive therapeutic agent. This material is made by plasmaphoresis of persons who were immunized with anthrax vaccine (see below) and is available from Cangene Corporation in Canada. AIG contains predominantly antibodies against the PA and should be used along with antimicrobial chemotherapy for treatment of severe disease (primarily inhalational anthrax).[1175] Human monoclonal antibodies against the PA of *B. anthracis* are also available through consultation with the CDC. These novel therapeutic agents were developed following passage of the Project Bioshield Act in 2004, which allows the FDA to approve anti-biothreat agents and drugs that show efficacy only in animal models and, based on these data, would have reasonable

benefit in humans.[327] This legislative measure also established the Strategic National Stockpile, which stores medical supplies and drugs as a protective measure in case of an attack. These agents may have utility as preexposure prophylactic agents and as postexposure therapy for inhalational anthrax.[732] Three anti-PA monoclonal antibodies have been developed and tested that have demonstrated protective efficacy in animal models of inhalational anthrax. These include Raxibacumab (human recombinant IgG monoclonal antibody [Human Genome Sciences]), Anthim (an affinity-enhanced monoclonal antibody [Elusys Therapeutics]), and Valortim (human monoclonal antibody [PharmAthene/Medarex]).

Prevention of Anthrax. The first-generation human vaccine to be licensed for use in the United States is BioThrax (formerly Anthrax Vaccine Adsorbed (AVA), Bioport, Lansing, MI), a cell-free formulation prepared from a culture filtrate of a toxigenic, nonencapsulated, avirulent strain of *B. anthracis* (strain V770-NP-1-R) adsorbed to aluminum salts as an adjuvant.[112,127] This culture filtrate contains PA, LF, and EF, with PA being the major component. Following the initial injection, five more doses are given over the next 18 months to complete a six-dose regimen. After receipt of the six-injection series, annual booster immunizations are given to maintain a protective level of antibodies.[874] The AVA vaccine is recommended for those who work directly with *B. anthracis* in the laboratory, those who work with animal products (e.g., hides and furs) imported from areas of anthrax endemicity, those who work with animals and animal products within endemic regions, and military personnel who are deployed to high-risk regions of the world. In addition, anthrax vaccine may be used as preexposure prophylaxis for those individuals with quantifiable risks of exposure to anthrax and, in conjunction with CDC, may be used along with antibiotics for postexposure prophylaxis of inhalational anthrax. The vaccine is well tolerated and appears to be

safe.[231,429] Work is proceeding on the development of new vaccines, with the most promising candidate antigen being highly purified, recombinant PA (rPA).[487,577] Two vaccines using rPA have been manufactured in the United States and the United Kingdom. The US product was tested and found to be immunogenic and safe, but the instability of the vaccine on storage precluded its ability to be stockpiled for future use. Work on third-generation rPA-based vaccines is proceeding, with the examination of different adjuvants, novel inoculation and administration strategies, and use of candidate vaccine antigens other than rPA.[60,137,548,581,1059]

Bacillus cereus

Virulence Factors of *B. cereus*. *B. cereus* produces several potential virulence factors in addition to the toxins associated with gastrointestinal infections (see below), and these factors are thought to play a role in nongastrointestinal infections.[130] Virulence factors include three hemolysins and three phospholipases. The hemolysins are called cereolysin, hemolysin II, and hemolysin III, respectively. Cereolysin is similar to streptolysin O (SLO) in being a heat-labile protein that is activated by thiols and inhibited by cholesterol. Hemolysin II is a hemolytic toxin that is also a lethal toxin in mice, and hemolysin III causes osmotic lysis of erythrocytes by transmembrane pore formation. Phospholipases include phosphatidylinositol hydrolase, phosphatidylcholine hydrolase, and a sphingomyelinase. The phospholipases cleave lipid moieties that serve to anchor cell-surface proteins, compromise cell membrane integrity, and abrogate regenerative capacities of injured cells. *B. cereus* strains also produce at least three different β-lactamases, extracellular collagenases, and membrane-bound proteases.

***B. cereus* Gastroenteritis.** *B. cereus* is found in the soil and contaminates many agricultural products. Several different food items may become contaminated with vegetative cells or spores of *B. cereus,* including pastas, rice, milk products, grains, spices, vegetables, meat, chicken, and seafoods.[988] Some *B. cereus* strains are able to grow at low temperatures, so even refrigerated food are subject to spoilage by this organism.[395] The presence of spores in food products is another issue, since spore germination occurs at 65°C to 75°C, which is similar to the range used for high temperature-short duration pasteurization methods for dairy products. The highly resistant spores can also withstand exposure to γ-radiation. Biofilm formation by some strains of *B. cereus* makes it difficult to eradicate these and other organisms from pipes, vats, and other containers used in food processing and manufacturing.[858] Contaminated foods, dairy products, and hospital- or pharmacy-prepared supplements and infant formulas represent potential risks for hospitalized patients, particularly children and immunosuppressed patients. Since food-borne illness due to this organism is not reportable, exact figures on incidence and prevalence are not available for most parts of the world. Between 1973 and 1985, *B. cereus* was responsible for 17.8% of the food-borne outbreaks in Finland, 11.5% in the Netherlands, 2.2% in Canada, 0.8% in Scotland, 0.7% in England and Wales, and 0.7% in Japan. The incidence in the United States is also quite low, with only 1.3% of bacterial food poisoning cases being attributable to *B. cereus* between 1972 and 1982. It is estimated that over 27,000 cases of food-borne illnesses in the United States were caused by *B. cereus*.[739,823]

Enterotoxin-producing strains of *B. cereus* are known to cause acute, self-limited gastroenteritis in humans, usually following ingestion of contaminated foods. This

syndrome follows two clinical forms, depending on the type of toxin produced by the organisms present in the suspect food. Short-incubation illness (or emetic food poisoning) is characterized by the onset of symptoms within 1 to 6 hours after ingestion of contaminated foods, with the predominant symptoms being nausea, vomiting and abdominal cramping. Symptoms generally abate within 10 to 24 hours of onset. Incriminated foods associated with the emetic type of illness include Asian fried rice dishes, cream and milk products, pastas, and reconstituted infant formula. The responsible heat-stable exotoxin produced by these *B. cereus* strains is a cyclic dodecadepsipeptide called **cereulide**, which has a molecular weight of about 1,165 Da and is very heat-stable.[12,13] With rice dishes, the rice is usually cooked, cooled, and then held at room temperature, during which time the vegetative cells outgrow and produce cereulide, which is not destroyed by reheating. This molecule is also stable in the presence of acids, alkalis, and proteases and is nonantigenic. Cereulide causes swelling of the mitochondria and uncoupling of oxidative phosphorylation.[755] In mice, cereulide causes liver pathology and in cell cultures, this toxin causes mitochondrial swelling and eventually apoptosis.[834] Cereulide poisoning causing fulminant liver failure was reported as a cause of death in a patient in 1997.[706] High levels of cereulide were found in the liver, bile, small intestine and blood of the patient, and on the cooking utensils and pan used to reheat the contaminated food. The gene for cereulide has been identified and a PCR assay was designed for its detection.[303]

Long-incubation *B. cereus* food poisoning occurs 8 to 16 hours following ingestion, and is characterized predominantly by the onset of profuse watery diarrhea, nausea, tenesmus, and lower abdominal cramps.[694] Symptoms usually abate after 12 to 14 hours. Foods associated with this type of illness include meat and vegetable dishes, cakes, sauces, and dairy products. Four different heat-labile enterotoxins are associated with this clinical presentation including two protein complexes (hemolysin BL [HBL] and nonhemolytic enterotoxin [NHE]), and two enterotoxic proteins (enterotoxin T and cytotoxin K).[988] HBL and NHE are composed of three proteins each, and the genetic loci encoding for either HBL or NHE are organized in discreet and separate operons located on the chromosome of *B. cereus* (and occasionally *B. thuringiensis*).[162] HBL is an exotoxin that has hemolytic activity ("H") and is composed of three proteins: a 37.8-kDa binding component ("B") and two proteins (L1, 38.5 kDa, and L2, 43.2 kDa) that have cytolytic and dermonecrotic properties.[81] Genes encoding the B component (*hblA*), L1, (*hblD*), and L2 (*hblC*) are arranged in a tandem operon adjacent to each other.[957] All three components of HBL are required for biologic activity. HBL causes hemolysis of the red blood cells from a variety of mammalian species, including guinea pig, swine, sheep, rabbit, human, and horse blood. HBL binds to the cell membrane of eukaryotic cells, forming pores that result in leakage of the cell contents. HBL is also dermonecrotic, causes increases in vascular

permeability,

863

and causes accumulation of fluids, villi necrosis, submucosal edema, and lymphocytic infiltration in the rabbit ileal loop assay.[82] HBL from different strains of *B. cereus* demonstrate a high degree of molecular heterogeneity, differ in the extent and species host range for hemolysis, and usually have similar biologic activities.[83] NHE is a 41-kDa antigenic protein that is associated with 39.8-kDa and 36.5-kDa proteins that are encoded by a three-gene operon.[432] This tripartite toxin is dermonecrotic, cytotoxic, and alters membrane permeability.[697] Other workers have characterized and reported on other enterotoxins from various *B. cereus* strains, but HBL and NHE are considered to be the toxins responsible for *B. cereus* diarrheal illness resulting from food poisoning. Some isolates of *B. cereus* may produce both the emetic toxin and the enterotoxin complexes. Intoxication associated with *B. cereus* and its toxins may be avoided by adequate cooking of foods, particularly meats, and proper refrigerated storage. *B. thuringiensis* has also been isolated in association with gastroenteritis outbreaks and has demonstrated cytotoxicity that is similar to that caused by enterotoxigenic *B. cereus*.[542] On rare occasions, other *Bacillus* species (e.g., *B. subtilis*, *B. licheniformis*) may also cause gastroenteritis and food poisoning.

Opportunistic Infections Caused by B. cereus, *Other* Bacillus *Species, and* Paenibacillus *Species*

Because of their ubiquity in the environment, the recovery of *Bacillus* species from clinical specimens has most frequently been considered as nuisance contamination. However, the increasing frequency of reports in the literature of *Bacillus* species as agents of disease in compromised hosts suggests that these organisms should not be dismissed as contaminants in all cases. Serious *Bacillus* and *Paenibacillus* species infections have been associated with operative procedures, immunosuppression, traumatic wounds, burns, hemodialysis, and parenteral drug abuse. Isolates recovered from nongastrointestinal infections produce a variety of putative virulence factors, including hemolysins, necrotizing exotoxins, and phospholipases. Analyses of large series of cases involving significant *Bacillus* infections indicate their involvement in the clinical syndromes discussed below. *B. cereus* is well recognized as an agent of gastroenteritis and is the *Bacillus* species that is most frequently recovered as an opportunistic agent from compromised hosts. Box 14-2 details infections caused by nonanthrax *Bacillus* species other than *B. cereus* plus infections caused by *Paenibacillus* species.

***B. cereus* Bacteremia and Endocarditis.** Bacteremia and endocarditis with *B. cereus* is usually seen in intravenous drug users, patients with valvular heart disease, those with prosthetic valves or cardiac implants (e.g., pacemakers), or patients who are immunosuppressed due to cancer or chemotherapy.[2,171,233,409,498] Endocarditis is a rare event, but in the setting of parenteral (usually heroin) drug abuse, it is a well-recognized complication. In these cases, organisms probably originate from contaminated injection paraphernalia or from the heroin. Endocardial infection usually involves the tricuspid valve, with septic emboli to the lungs being noted on chest films. Drug users with *B. cereus* endocarditis will have compatible clinical findings and multiple positive blood cultures a short time after parenteral drug administration. *Bacillus* bacteremia may also reflect nosocomial contamination of implanted intravascular catheters. In these cases, removal of catheter hardware often will result in clearance of the organisms from the bloodstream. Sometimes a source of *B. cereus* bacteremia cannot be pinpointed, and polymicrobial bacteremia with *B. cereus* and *S. epidermidis*, members of the *Enterobacteriaceae*, or *P. aeruginosa* is well documented.[65] Premature and very low birth weight infants are also at risk for serious infections with *B. cereus*; organisms in these cases are usually isolated from both blood and CSF cultures or from endotracheal aspirates.[498,668] *B. cereus* has also been a cause of catheter-related sepsis in children with various neoplastic disease receiving parenteral chemotherapy.[170]

***B. cereus* Infections in Compromised Hosts.** *B. cereus* infections in immunocompromised patients have included fulminant bacteremia and sepsis, CNS infections (meningitis, meningoencephalitis, brain abscess), lower respiratory tract infections with empyema, penetrating wound infections, postsurgical infections, and burn wound infections.[45,65,402,646,712,833,964] CNS infections occur as a result of spinal anesthesia, fistula repair, spread from a contiguous focus of infection, or from contaminated ventriculoperitoneal shunts.[204,402,716] *B. cereus* infection of premature and very low birth weight infants usually involves both the bloodstream and the CNS and outcomes in these babies are usually poor.[498,668,712] Pulmonary infections, including necrotizing pneumonitis, pseudomembranous tracheobronchitis, pneumonia, and acute respiratory failure with sepsis have occurred primarily in patients with leukemias, hepatocellular carcinoma, and in premature neonates.[353,757,1062] Reasons for immunosuppression in these patients have included severe alcohol abuse, leukemia, lymphoma, induction chemotherapy, meningioma, rheumatoid arthritis, systemic lupus erythematosus, severe burns, diabetes, severe combined immunodeficiency disease, and AIDS. Lee and colleagues[656] reported a fatal case of bacteremia, spontaneous bacterial peritonitis and necrotizing fasciitis due to *B. cereus* in a 47-year-old man whose underlying conditions included cirrhosis due to chronic

hepatitis B infection and esophageal varices. Fatal outcomes in many of these patients reflect generalized immunosuppression resulting from immunologic disease, cytotoxic chemotherapies used for treatment, and the use of indwelling devices used for life support (e.g., total parenteral nutrition) and receipt of therapies.

***B. cereus* Ocular Infections.** Endophthalmitis and other ocular infections with *B. cereus* ordinarily occur following penetrating eye injuries (exogenous infection) or as a consequence of bacterial seeding of the posterior segment of the eye during bacteremic episodes resulting from indwelling devices, transfusions. contaminated drug injection paraphernalia, or contaminated drugs (endogenous infection).[258,728,756,1003,1121] Penetrating eye injuries involving *B. cereus* often occur in association with specific occupations (metalworkers, construction crews) and settings (rural areas, farming accidents).[258,720] In penetrating injuries and/or

864

BOX 14-2

Members of the Genus *Bacillus* (Other Than the *B. anthracis* and *B. cereus*) and *Paenibacillus* Isolated From Human Infections

Species	Infections	References
Bacillus circulans	*B. circulans* has been isolated from blood cultures as a cause of endocarditis, pericarditis, catheter-related bacteremia, and fatal sepsis in immunocompromised patients (e.g., patients receiving anti-neoplastic chemotherapy, bone marrow and solid organ transplant recipients). This organism has also been isolated as a cause of peritonitis in a patient receiving chronic ambulatory peritoneal dialysis and as a cause of endogenous endophthalmitis and wound infections.	21, 65, 98, 170, 422, 452, 618, 1090
Bacillus coagulans	This organism is a rare cause of bacteremia in patients with cancer.	65
Bacllis hackensackii	This new species was isolated from a single blood culture from a 22-year-old woman with abdominal pain and tenderness.	516

Bacillus licheniformis	*B. licheniformis* has been isolated as a cause of Hickman, Broviac, and central venous catheter-related bacteremias. This organism was also isolated from a cluster of bloodstream infections in patients with hematological malignancies; the source of the organism was traced to contaminated cotton used during skin disinfection. *B. licheniformis* has also been associated with endophthalmitis and brain abscess following penetrating orbital injuries, and has been recovered from peritoneal fluid in patients receiving CAPD. *B. licheniformis* is also a rare cause of prosthetic valve endocarditis and has been isolated from a parotid gland abscess.	120, 469, 480, 556, 665, 689, 730, 833, 841, 1105
Bacillus megaterium	This *Bacillus* species has been isolated from a cutaneous anthrax-like ankle lesion and as a cause of delayed-onset lamellar keratitis in a male patient 2 weeks after LASIK surgery.	298, 897
Bacillus pantothenticus	*B. pantothenticus* was isolated from the blood and a liver abscess of a 44-year-old immunocompetent man.	790
Bacillus pumilis	*B. pumilis* has been isolated from blood cultures of septic neonates, as a cause of central venous catheter-related sepsis in a child on total pareneteral nutrition, and from primary cutaneous infections resembling cutaneous anthrax in three shepherds.	65, 89, 596, 1101
Bacillus sphaericus	*B. sphaericus* was isolated from a cancer patient with bacteremia.	65
Bacillus subtilis	*B. subtilis* is a rare cause of bacteremia in patients with cancer, head tauma, and pyelonephritis. In some cases, bacteremia was due to a *B. subtilis* strain that was administered to the patients as a probiotic. This organism was also associated with two cases of severe hepatotoxicity following consumption of Herbalife nutritional products contaminated with *B. subtilis*.	65, 812, 923, 1058
Bacillus thuringiensis	This member of the *B. cereus* group has industrial and commercial applications due to production of insecticidal proteins. Like *B. cereus*, this organism also produces hemolysins, proteases, and, occasionally, enterotoxins. *B. thuringiensis* has been isolated from blood cultures, soft tissue infection (periorbital cellulitis), burn wounds,	250, 403, 482, 622, 856

	periodontal and pulmonary infections.	
Paenibacillus alvei	This organism was isolated from blood cultures and from an infected hip arthroplasty of a 26-year-old woman with sickle cell disease.	902
Paenobacillus cineris	This species, originally isolated from soil in Antarctica, was isolated from a sputum specimen of a 25-year-old man during a acute exacerbation of his cystic fibrosis.	645, 685
Paenibacillus hongkongensis	This organism was isolated from one of four sets of blood cultures collected from a 9-year-old boy with neutropenic fever who had undergone surgery, radiation, and several cycles of chemotherapy for treatment of a medulloblastoma.	1102
Paenibacillus konsidensis	This organism was isolated from two sets of blood cultures collected from a 75-year-old man with persistent fevers, hematemesis, and hypotension.	609
Paenibacillus larvae	*P. larvae* is known to cause American foulbrood, a severe disease of honey bees, and this organism can be cultured from honey. Bacteremia with this organism occurred in five intravenous drug users who were injecting methadone opioid that was mixed with honey to be used as an oral medication. The clinical course of bacteremia with *P. larvae* was benign in three patients, but one patient developed spontaneous bacterial peritonitis, and another developed pulmonary emboli.	928

865

Paenibacillus macerans	*P. macerans* was isolated from blood cultures of eight neonates in the intensive care unit. None of these infants were infected, as evidenced by the absence of fever and leukocytosis. Infection control identified that the pseudobacteremia was due to contamination of the rubber stoppers of the blood culture bottles.	809
Paenibacillus massiliensis	This species was recovered from a blood culture of a 13-year-old boy with acute lymphoblastic leukemia who received chemotherapy and subsequently underwent a stem cell transplant. At the time the blood culture was collected, the patient was neutropenic and had cutaneous	950

	and hepatic graft-versus-host disease.	
Paenibacillus polymyxa	This species was isolated from a blood culture from a 93-year-old woman who suffered a cerebral infarction.	797
Paenibacillus provencensis	Isolated as a contaminant from the CSF of a 54-year-old man with Whipple's disease	949
Paenibacillus sanguinis	This species was isolated from a blood culture of a 49-year-old man who was receiving chemotherapy and radiation for epidermoid carcinoma of the oropharynx.	950
Paenibacillus sputi	Isolated from the sputum of a 60-year-old woman who was being screened for tuberculosis infection	594
Paenibacillus thiaminolyticus	*P. thaminolyticus* was isolated from blood cultures of an 80-year-old man with a history of subtotal colectomy with ileostomy for colon cancer. The patient also had hypertension, congestive heart failure, Parkinson's disease, and end-stage renal disease requiring hemodialysis. The patient had an indwelling Permacath, which was thought to be the source of the bacteremia.	832
Paenibacillus timonenesis	This organism was isolated from a blood culture collected from a 75-year-old woman who presented with chronic interstitial nephropathy requiring hemodialysis.	950
Paenibacillus urinalis	This organism has been isolated as a contaminant from a urine specimen of a 36-year-old woman with suspected tuberculosis.	949

retained foreign bodies within the orbit, periorbital edema and corneal inflammation lead to vitreal infection that spreads to the retina, resulting in loss of visual acuity within 12 to 24 hours after the injury. Diagnosis is made by immediate anterior-chamber paracentesis and collection of blood cultures.[728,756] Fever and leukocytosis are usually present. Endophthalmitis may be complicated by spread of the organisms to contiguous anatomic sites, including the brain and CNS. Rare cases of *B. cereus* keratitis and endophthalmitis have also been reported in association with contaminated contact lens care systems and following cataract surgery and LASIK procedures.[293,953] This syndrome follows a rapid clinical course and may result in loss of vision requiring enucleation of the eye.[258] Because these infections are rapidly

destructive, a high index of suspicion and aggressive therapy (e.g., vancomycin, ceftazidime, aminoglycosides) administered systemically and intraocularly is required.[756] In the clinical laboratory, Gram's stains of material aspirated from aqueous and vitreous humor specimens should be interpreted carefully, and the isolation of a *Bacillus* species from these specimen must be reported to the physician and not dismissed as a contaminant. The rapidly destructive course of intraocular *B. cereus* infections has been attributed to the production of toxins and destructive enzymes by the causative organism.

***B. cereus* Skin, Bone, and Soft Tissue Infections.** *B. cereus* may cause posttraumatic cutaneous and subcutaneous infections, necrotizing fasciitis, cellulitis, myonecrosis, and acute and chronic osteomyelitis.[442,743,990] These infections are often assumed to be due to clostridia, until culture results prove otherwise. Posttraumatic wound infection, soft tissue infection, necrotizing fascitis, and osteomyelitis caused by *B. cereus* have been documented in individuals who had sustained severe trauma such as automobile accidents or gunshot wounds.[552,779,1206] Intravenous drug use, underlying hematologic malignancies, or treatment with immunosuppressive therapies are risk factors for the development of these infections.[442,960] The presence of underlying disease (e.g., leukemia, sickle cell disease, myelodysplastic syndrome) in individuals suffering trauma also predisposes them to more complicated *B. cereus* infections and superinfections, including fasciitis and myonecrosis.[960] *B. cereus* wound infections may be highly destructive to tissues and may requiring wide excisional debridement or amputation of affected limbs to prevent spread of the infection.[743] In intravenous drug users, soft tissue infection with *B. cereus* can lead to bacteremic episodes that seed distant sites, and unusual infections such as acute vertebral osteomyelitis have been reported as a result of hematogenous spread. *Bacillus* species may also cause significant infections in burn patients. The tissue destruction that is seen with severe wound infections caused by *Bacillus* species is related to production of extracellular enzymes that have histolytic and histotoxic properties (e.g., hemolysins, phospholipases, proteases).

Nosocomial Infections. Outbreaks of *Bacillus* gastroenteritis have been reported in health care facilities

and in other institutional settings. In these cases, implicated foods have been beef stews, fried rice, chicken, and processed turkey. Other nosocomial outbreaks of *Bacillus* infections have involved common-source spread from contaminated reservoirs in the environment.[730] These sources have included contaminated

hemodialyzers, bronchoscopes, Ommaya reservoirs, manual ventilation balloons, multiple unit injectables, and contaminated diapers, gloves, and surgical bandages.[166,489,924,1143,1235] In 2001, pseudobacteremia in a neonatal intensive care unit caused by *Paenibacillus macerans* was traced to contaminated blood culture bottles.[809] *Bacillus* species have also been isolated from peritoneal fluids in cases of nosocomial peritoneal dialysis-associated peritonitis. Pseudo-bacteremias caused by *Bacillus* species have also been traced to contaminated stoppers of blood culture bottles and have been temporally related to environmental disruption, such as hospital construction.[683]

Laboratory Safety, Specimen Collection, and Processing

If anthrax is suspected, the states' public health laboratory and the CDC should be notified immediately. Specimens that may be collected include material from cutaneous lesions, blood cultures, and any other potentially infected tissues. Laboratory safety is of utmost importance when working with any materials thought to contain *B. anthracis*. All specimens and cultures must be examined and carefully processed in a class II biologic safety cabinet. All precautions should be taken to minimize the generation of aerosols from the potentially infected material. Laboratory personnel must wear protective coats, gowns, masks, and gloves when manipulating specimens. This apparel must be discarded or autoclaved before re-use. After completion of specimen processing and inoculation of plated and tubed media, all surfaces in the biologic safety cabinet and the open benchtops must be disinfected with 5% sodium hypochlorite and all instruments used for specimen processing must be autoclaved. In addition, laboratory personnel who work with spore suspensions or contaminated animals carcasses and tissues must be appropriately immunized.

Specimens for isolation of *B. anthracis* should reflect the mode of acquisition and the consequent pathology of the infection. For the diagnosis of cutaneous anthrax, specimens of serous fluids or a biopsy obtained from beneath the surface of the eschar should be collected along with blood cultures. Diagnosis of suspected inhalational anthrax necessitates collection of sputum specimens and blood cultures. Gastric aspirates and fecal specimens may be submitted to aide in the diagnosis of gastrointestinal anthrax along with blood cultures. For suspected *B. cereus* gastroenteritis, food that is epidemiologically linked to the illness should be collected. Since *B. cereus* may be present in the stool of healthy individuals and since there is no typing system for this organism readily available to clinical laboratories, the recovery of *B. cereus* from the stools of ill patients does not provide sufficient evidence to ascribe an etiologic role to the isolates. It may be worthwhile, however, to recover the organism from the feces of individuals in an outbreak situation provided similar specimens from appropriately matched controls are demonstrated not to contain the organism. Isolates from implicated foods and from the stool of patients can be sent to

a reference laboratory (e.g., the state health department laboratory or the CDC) for identity confirmation and strain typing. A stool specimen of sufficient volume (25 to 50 g) should be collected in a sterile, leak-proof container. Shipment of the food, stool specimens, and/or isolates to the state health department or the CDC should be undertaken after prior notification and discussion of the outbreak situation with these agencies.

Isolation and Identification of the "Bacillus cereus *Group"*

Members of the genus *Bacillus* that are recovered from clinical specimens usually grow well and sporulate on sheep blood and chocolate agars incubated at 37°C under aerobic conditions. Sporulation may be stimulated by subculture onto nutrient agar supplemented with $MnSO_4$ (5 μg/mL final concentration) and subsequent incubation. On Gram's stains from blood cultures, other broth media, and occasionally solid media, *Bacillus* and related species may appear as gram-negative bacilli, resulting in the mistaken impression that the organism is a gram-negative, nonfermentative bacillus. Inoculation of broth media and preparation of a Gram-stained smear after a few hours of growth may reveal the gram-positive nature of the organisms. Intracellular and cell-free spores do not stain by the Gram's technique but may be visualized with the malachite green stain. A smear of the organism is made on a slide, heat-fixed, and stained with 10% malachite green for 45 minutes. The smear is washed, counterstained with safranin for 30 seconds, and observed under oil immersion. The spores will appear green, while vegetative cells are stained pink to red. Unstained, spores appear as slightly refractile, clear, round-to-oval structures within and outside of vegetative cells (Image Plate 14-2D).

On SBA, colonies of *B. cereus* and *B. thuringiensis* are usually large with a matte or ground glass texture and most strains are β-hemolytic (Image Plate 14-2H). These colonies have a butyrous consistency with entire, crenate or fimbriate edges. In contrast, colonies of *B. anthracis* are usually smaller, gray-white, rough-surfaced, nonhemolytic, and have a tenacious consistency such that, when the colonies are touched with an inoculating loop, they form standing peaks resembling beaten egg whites (Image Plate 14-2E, 14-2F, and 14-2G). Under the dissecting microscope, numerous undulating, comma-shaped outgrowths consisting of filamentous chains of bacilli surround the *B. anthracis* colony, giving the appearance of a "Medusa head" from Greek mythology (Image Plate 14-2F). Colonies of *B. mycoides* are flat, nonhemolytic, and have a sinuous or rhizoid appearance that resembles some clostridia. On Gram-stained smears, cells of the *B. cereus* group (including *B. anthracis*) are 3 to 8 μm long and 1.2 to 1.4 μm wide gram-positive bacilli that occur singly or in chains. Individual cells have squared-off or concave ends. Oval spores may be observed centrally or subterminally and the cells are not swollen in the areas where the spore is located. Phase-contrast microscopy of smears of *B. thuringiensis*

may show crystals adjacent to the spore (parasporal crystals). These crystals, which consist of the naturally produced insecticidal toxin, may also be observed by staining a smear of the organism with malachite green.

867

All members of the *B. cereus* group produces lecithinase on egg-yolk agar and hydrolyze casein, starch, and gelatin. *B. thuringiensis* and some *B. cereus* and *B. mycoides* strains are arginine dihydrolase-positive; *B. anthracis* is arginine dihydrolase-negative. Indole is not produced by any of the *B. cereus* group, and most strains reduce nitrate to nitrite. *B. anthracis* is also nonmotile in hanging drop preparations or in semisolid motility medium, while *B. cereus*, *B. thuringiensis*, and *B. mycoides* are motile. In addition, *B. anthracis* strains are often encapsulated in infected tissues, as demonstrated with an India ink wet prep or with the M'Fadyean capsule stain.[1051] Formation of capsular material can be stimulated by subculture of the organism on nutrient agar containing 0.7% $NaHCO_3$ and incubation at 37°C overnight. The capsule of *B. anthracis* is composed of poly-D-γ-glutamic acid and it functions to prevent phagocytosis. *B. anthracis* may also be definitively identified and differentiated from the other *Bacillus* species by gas chromatographic whole-cell fatty acid analysis or by susceptibility to theγ-bacteriophage. Biochemical characteristics for identification of *B. anthracis*, *B. cereus*, *B. thuringiensis* and the other members of the *B. cereus* group are presented in Table 14-4.

B. anthracis is one of several potential agents of bioterrorism. The CDC and members of the LRN have determined that all *Bacillus* species recovered in the clinical laboratory be screened for detection of possible *B. anthracis*. Agents that fit the screening criteria are forwarded to state public health laboratories for definitive identification. In general, these characteristics include Gram's stain and colony morphology, presence or absence of hemolysis, production of catalase, and determination of motility. At the referral laboratories, the identity of presumptive *B. anthracis* strains is confirmed by whole-cell fatty acid analysis, susceptibility to γ-bacteriophage, or real-time PCR methods. The sentinel laboratory characteristics for screening of *Bacillus* isolates for possible *B. anthracis* are presented in Box 14-3. Additional characteristics that may be helpful include the capsule stain (performed directly on clinical material) and a β-lactamase test. Most nonanthrax *Bacillus* species are nonencapsulated and resistant to penicillin due to production of β-lactamase enzymes. The chromogenic cephalosporin disk test (Nitrocefin, BD Microbiology Systems) can be used for the latter test.

Identification of *Bacillus* species and related species can be accomplished by observation of cellular morphology, the shape, position, and appearance of endospores, and the determination of biochemical characteristics using conventional

tests.[920] Spore shapes and locations are usually determined by Gram's stain or a spore stain, and cell motility is determined by stab inoculation of semisolid motility medium. Carbohydrate acidification can be assessed with semisolid CTA medium containing 1% carbohydrates. Nitrate reduction and production of indole are detected by inoculation of indole nitrate broth and development with the appropriate reagents, respectively. Gelatin, casein, and starch hydrolysis are determined by inoculation of tubed or plated conventional media. Miniaturized kit systems like API 20E (includes cupules for arginine dihydrolase [ADH], indole, nitrate reduction, and gelatin hydrolysis) and the API 50 Carbohydrate (API 50CH) may also be helpful for differentiation of *B. anthracis* from other *B. cereus* group organisms, and for identifying other *Bacillus* and related species.[684] The Vitek system (bioMérieux, Inc.) has a stand-alone *Bacillus* identification card, and the Biolog system (Biolog, Inc., Hayward, CA) also has a robust database of *Bacillus* species.[61] Fatty acid methyl-ester analysis using the Microbial Identification System (MIDI) (Microbial Identification, Inc., Newark, DE) is also available for identification of these organisms. The aerobic

bacteria library of the MIDI system includes some members of the *B. cereus* group (i.e., *B. cereus*, *B. thuringiensis*, *B. mycoides*), several other environmental *Bacillus* species, and some members of the genus *Paenibacillus*. MIDI also has a Biodefense Library that includes *B. anthracis* and other potential agents of bioterrorism. *Bacillus* species have also been identified using a variety of chemotaxonomic methods, including pyrolysis mass spectroscopy, Fourier-transform infrared spectroscopy, and polyacrylamide gel electrophoresis. MALDI-TOF has also been used to identify *B. anthracis* and other members of the *B. cereus* group.[589,640]

BOX 14-3

Sentinel Laboratory Screening Tests for Presumptive Identification of Bacillus anthracis

Category	Characteristics
Safety	Biosafety level 2 for processing of clinical specimens; Biosafety level 3 laboratory practices for all culture manipulations that may produce aerosols (mincing, cutting, vortexing, etc.); Perform all work in a biologic safety cabinet
	Rapidly growing colonies, 2–5 mm in diameter after incubation for

Colonial characteristics	18–24 hours at 35°C–37°C Non-pigmented, dry, "ground glass" surface; flat or slightly convex; Irregular edges with "comma-shaped" projections ("Medusa's head" colony); Sticky, tenacious consistency such that, when colonies are touched with a loop, the colonial growth will stand up like beaten egg whites No hemolysis on SBA
Microscopic characteristics	Large, gram-positive bacilli, single and/or in chains; May become gram-variable after 72 hours; May be encapsulated in clinical material and in blood culture media; Terminal/subterminal spores do not swell the vegetative cell; Spores are not present in clinical material unless exposed to low CO_2levels, such as that found in ambient air; higher CO_2 levels will inhibit spore formation
Key characteristics	Nonhemolytic, nonmotile, catalase-positive; spores present when cultured aerobically without CO_2; β-lactamase-negative

Because of the potential role of *B. anthracis* in bioterrorism, much work has been done to develop methods for direct detection of the organism in both environmental and clinical specimens. While cultural methods are fairly reliable, isolation and identification of potential *B. anthracis* is time consuming. Various affinity-based methods, such as antibody-based enzyme immunoassays directed against the BclA surface glycoprotein, the poly-D-glutamic acid capsule, the *B. anthracis* S-layer, or extracellular antigen-1 (EA-1) have been developed.[620,1086,1087,1177] In addition to surface antigens of *B. anthracis*, assays for detection of the three toxin protein antigens—PA, EF, and LF—have also been exploited using antibodies against these antigens as ligands.[977] Unfortunately, these assays lack both sensitivity and specificity. EIAs for detection of *B. anthracis* spores have a detection limit of 10^5 to 10^6 spores, which was 100- to 1,000-fold less sensitive than that claimed by the manufacturer.[598] Molecular methods such as PCR have also been proposed for direct detection, but care must be taken to select gene targets and to design primer pairs and probes that are specific for *B. anthracis*. Gene targets for molecular assays have included the pXO1 and pXO2 plasmids of *B. anthracis*, but pXO1- and pXO2-like plasmids are found in various nonvirulent *B. cereus* strains and therefore affect the specificity of these real-time PCR assays. *B. cereus* strains that cause anthrax-like illness are also detected by

plasmid-specific PCR identification tests.[507,508,600,601] Several workers have examined *B. anthracis* chromosomal genes in order to design specific molecular assays, but, again, these efforts have been hampered by the presence of genes with similar nucleotide sequences in other *B. cereus* group organisms.[118] Certain chromosomal genes and "signature" nucleotide sequences, such as the BA-813 sequence, the BA-5449 sequence, and the *rpoB* gene, were initially thought to represent *B. anthracis*-specific genotypic markers and, therefore, useful for detection and identification.[608] However, subsequent studies have detected counterpart genes with similar nucleotide sequences in *B. cereus* strains. It has also been discovered that some *B. thuringiensis* strains share *rpoB* polymorphisms with *B. anthracis*.[1244] In 2008, Antwerpen and colleagues[42]identified a genomic marker that has not yet been found in *B. cereus* or other nonanthrax *Bacillus* species. The sensitivity and specificity of this sequence for detection and identification of *B. anthracis* is currently being evaluated.

Molecular methods have also been used for strain typing, and molecular epidemiology of *B. cereus* group isolates associated with food-borne outbreaks and clusters of apparent nosocomially transmitted infections.[680,729,920,1099] PFGE, AFLP, and multilocus sequence typing (MLST) have been shown to have insufficient discriminatory power to resolve *B. anthracis* of various origins.[483,575] Variable number tandem repeats (VNTRs) found in open reading frames of *B. anthracis* genes and intergenic areas on the *B. anthracis* chromosome and on the pX01 and pXO2 plasmids has been used to devise a VNTR typing method called multiple locus VNTR analysis or MLVA.[576,1137] Between 8 and 25 loci can be used to discriminate among *B. anthracis* isolates using this method.[678,1145]

Antimicrobial Susceptibility Testing of Bacillus *Species*

The CLSI M45-A2 approved guideline for susceptibility testing of infrequently isolated or fastidious bacteria includes a procedure for microbroth antimicrobial susceptibility testing of *Bacillus* species, not *B. anthracis*.[214] The method uses cation-adjusted Müeller–Hinton broth and an inoculum prepared from a direct colony suspension equivalent to a 0.5 McFarland turbidity standard. The tests are incubated at 35°C in ambient air for 16 to 20 hours. Clindamycin, the fluoroquinolones, and vancomycin are suggested for primary testing. Breakpoints are available for penicillin, ampicillin, first- and second-generation cephalosporins, imipenem, gentamicin, amikacin, erythromycin, tetracycline, ciprofloxacin, levofloxacin, trimethoprim–sulfamethoxazole, rifampin, and vancomycin.[214] Most *Bacillus* species are penicillin- and cephalosporin-resistant due to production of broad-pectrum β-lactamase enzymes.

Corynebacterium Species

Introduction and Taxonomy

The genus *Corynebacterium* contains many species and includes the classical pathogen, *C. diphtheriae*, the causative agent of diphtheria. While diphtheria is relatively uncommon in developed countries due to widespread vaccination, it is a cause of significant morbidity and mortality in resource-limited countries, and sporadic outbreaks are occasionally reported in the United States. Many of the organisms in the genus *Corynebacterium* constitute part of the normal flora of the skin and the upper respiratory tract.[1166] These same species, as well as other *Corynebacterium* species and related coryneform bacteria, have become recognized as significant agents of human disease, particularly in compromised hosts and patients with indwelling medical devices. Application of molecular (i.e., 16S rRNA and rDNA sequencing, nucleic acid hybridization), chemotaxonomic (i.e., peptidoglycan analysis, cellular fatty acid studies, menaquinone characterization) and expanded phenotypic methods (i.e., kit identification systems, organic compound assimilation tests, detection of preformed glycosidase or aminopeptidase enzymes) to the characterization of gram-positive bacilli has resulted in the description of many new *Corynebacterium* species isolated from human clinical specimens, from animals, and from the environment. Analysis of unnamed coryneform isolates has resulted in their assignment to previously described genera (e.g., the genera *Corynebacterium*, *Arcanobacterium*, and *Actinomyces*) and to new genera (e.g.,

Turicella, *Cellulosimicrobium, Dermabacter*). Some CDC coryneform group isolates belong to genera not previously associated with human infections (e.g., *Arthrobacter*, *Brevibacterium*, *Cellulomonas*, *Microbacterium*). Genera that are related to *Corynebacterium* species include the nocardioform organisms (*Nocardia*, *Streptomyces*, *Oerskovia*, *Rhodococcus*, *Gordona*, *Dietzia*, *Tsukamurella*), the facultative and anaerobic actinomycetes (*Actinobaculum*, *Actinotignum*, *Actinomyces*), anaerobic "diphtheroids" (*Propionibacterium*, *Propioniferax*), and the acid-fast bacilli (*Mycobacterium*). Chemotaxonomic and phenotypic descriptions of the genus *Corynebacterium* and related coryneform genera found in human clinical specimens are presented in Table 14-5. Some of these genera will be discussed in this chapter, while others (e.g., *Propionibacterium* species) are described in subsequent chapters.

Genus *Corynebacterium* include pleomorphic, club-shaped, gram-positive bacilli that are catalase-positive, nonmotile, non–spore-forming, and non–acid-fast. Most *Corynebacterium* species contain mycolic acids, arabinose, and galactose in their cell

walls.[1220] The peptidoglycan of *Corynebacterium* species contains ***meso*-diaminopimelic acid** (*meso*-DAP) as the constituent di-amino acid. Distinctive cellular fatty acids and menaquinones are also found in the cell membranes of these organisms (Table 14-5). Classical descriptions of this genus include their tendency to form "picket fence" and "Chinese letters" arrangements on Gram-stained smears (Image Plate 14-3A). Most species are facultative and fermentative in their metabolism of carbohydrates, although a few species are non-fermentative and/or utilize carbohydrates oxidatively. Some species also require lipids for optimal growth (lipophilism). This requirement is suggested by growth on lipid-containing media (e.g., SBA) and either poor or no growth on commercially available chocolate agar, which contains hemin powder instead of lysed erythrocytes. Lipophilism is best demonstrated by enhanced growth of these species on medium containing 0.1% to 1% Tween-80 in comparison with the same medium lacking Tween-80 (Image Plate 14-3B).

The application of "research" techniques to the characterization of coryneform organisms has also created problems for the clinical laboratory, where resources for genetic/chemotaxonomic identification methods are limited and phenotypic identification is the norm. Two clinical isolates may produce identical results on phenotypic testing (e.g., an API Coryne), but when genetic and chemotaxonomic methods are applied, these isolates may be different (e.g., different cellular fatty acids, different di-amino acids in the peptidoglycan, etc.) Because of limited phenotypic characterization of many environmental genera (e.g., *Microbacterium* species), the assignment of clinical isolates to these genera is more difficult and, unfortunately, less accurate. As a result of scientific progress, the interpretation of clinical case reports regarding individual *Corynebacterium* or coryneform species has become problematic because isolates described in these reports may not have been rigorously characterized.

Identification of Corynebacterium *Species and Coryneform Bacteria*

Identification of *Corynebacterium* species and other coryneform bacteria was originally performed with phenotypic tests like other organisms in the clinical laboratory. With the application of molecular methods, the number of species in the genus *Corynebacterium* and related genera has expanded so rapidly that, by necessity, the number of phenotypic tests required for identification has increased as well. Conventional tests are performed as for other organisms (e.g., enteric gram-negative bacilli) with some modifications. Requirements for lipid are determined by inoculating the organism as a lawn onto a non-lipid-containing medium (e.g., Müeller–Hinton agar, BHI agar, Tryptic soy agar) and placing a drop of 0.1% Tween-80 onto the inoculum. After incubation, lipophilic strains will show enhance growth in the area of Tween deposition and poor or no growth in areas away from the lipid (Image Plate 14-3B).

Nonlipophilic strains will grow over the entire agar surface. Conventional identification media (i.e., carbohydrate utilization tests) may also require supplementation with 3 to 4 drops of 0.1% to 1% Tween-80 (per 5 mL of broth media) for identification of lipophilic strains. Gas-liquid chromatography for detection of volatile and nonvolatile products of glucose fermentation is also helpful. All taxa produce small to moderate amounts of acetic, lactic, and succinic acids from glucose, but others may produce propionic acid. This characteristic is often helpful in separating strains that have very similar biochemical profiles (e.g., separation of *C. amycolatum* [propionate-positive] from *C. striatum* [propionate-negative]).[723] Box 14-4 lists the currently described *Corynebacterium* species and their clinical significance, and Table 14-6, which starts on page 885, presents the phenotypic characteristics for the identification of *Corynebacterium* species.

Commercial products that address identification of coryneform gram-positive bacilli are the **API Coryne** (bio Merieux, Inc.), the **RapID CB-Plus** (Remel Laboratories), and the **Vitek 2 Anaerobe/*Corynebacterium* card** (bioMérieux, Inc.).

API Coryne. The API Coryne is a microcupule gallery identification kit comprised of 11 enzymatic tests, 8 carbohydrate fermentation tests, and a fermentation control cupule. A heavy organism suspension (#6 or greater McFarland standard) is prepared in water and placed in the enzyme test cupules (NIT through GEL). A 0.5 mL aliquot of this suspension is then placed in the GP medium (enriched medium with phenol red indicator) provided; this is used to fill the carbohydrate control and test cupules (O through GLYG). Each of the latter cupules is overlaid with sterile mineral oil. The strip is incubated for 24 to 48 hours in a non-CO_2 incubator. Reagents A and B are added to the nitrate cupule (NIT) and ZYM A and ZYM B reagents are added to the enzyme cupules (PYZ through β-NAG); these reactions are read after 10 minutes. ESC, URE, GEL, and the carbohydrate tests are read directly without the addition of reagents. From the pattern of reactions on the strip, a biocode is generated and interpreted by consulting the online database. The API Coryne database has been updated to accommodate some newly described taxa and to reflect changes in taxonomy, but nomenclature continues to change. Funke et al.[384] evaluated version 2.0 with 390 strains representing all 49 taxa included in the new database, plus 17 strains belonging to taxa not included in the database. The kit identified 90.5% of the strains belonging to included taxa,

TABLE 14-5 Characteristics of the Genus *Corynebacterium* and Other Coryneform Gram-Positive Bacilli

Genus	Cell Morphology	Catalase	Motility	Pigment	Growth	CHO Metabolism	Mycolic Acids	Peptidoglycan Di-Amino Acid	Menaquinones	Cellular Fatty Acids	Comments
Actinobaculum	Straight to slightly curved slender rods; may show some branching	–	–	None	Fac/Ana	Ferm	Absent	L-Lysine, L-Ornithine	MK-10(H4)	C16:0, C18:1(9C, cycl), C18:0	Four species, including former *Actinomyces suis*
Actinomyces	Rods, filamentous, branching	V	–	None; occasionally pink/red	Fac	Ferm	Absent	L-Lysine, L-Ornithine	MK-10(H_4)	C16:0, C18:1(9C, cycl), C18:0	CDC group 1, group 2, "group 1-like", and group E strains, plus other previously described *Actinomyces* species
Arcanobacterium	Short, irregular rods	V	–	None	Fac	Ferm	Absent	L-Lysine	MK-9(H_4)	C16:0, C18:1(9C, cycl), C18:0	Five species, including former *Actinomyces bernardiae*
Arthrobacter	Rod-to-coccus cycle	+	V	Variable	Aer	Oxid	Absent	L-Lysine	MK-8, MK-9, MK-9(H_2)	C15:0ai, C17:0ai, C15:0i	Some CDC group B-1 and B-3 strains
Brevibacterium	Rod-to-coccus cycle	+	–	Dirty white, yellow, orange, purple	Aer	Oxid (inert)	Absent	*meso*-DAP	MK-8(H_2), MK-7(H_2)	C15:0ai, C17:0ai, C16:0i	Some CDC group B1 and B-3 strains
Cellulomonas	Irregular rods; coccal forms	+	V	Yellow	Fac	Ferm/Oxid	Absent	L-Ornithine	MK-9(H_4)	C15:0ai, C16:0	CDC group A-3 (*C. hominis*)
Cellulosimicrobium	Irregular rods; rod-to-coccus cycle	+	–	Yellowish white	Fac	Ferm	Absent	L-Lysine	MK-9(H_4)	C15:0ai, C16:0i, C16:0, C16:0i	Includes *Cellulosimicrobium cellulans* (formerly *Oerskovia xanthineolytica*) and *Cellulosimicrobium funkei* (formerly *Oerskovia turbata*)
Corynebacterium	Rods, club-shaped bacilli	+	–	None, gray/white	Fac	Ferm/inert	V(C22–C38)	*meso*-DAP	MK-9(H_2), MK-8(H_2)	C18:1, C16:0, C18:0	*Corynebacterium* species
Dermabacter	Short bacilli or coccobacilli	+	–	None	Fac	Ferm	Absent	*meso*-DAP	MK-9, MK-8, MK-7	C17:0ai, C15:0ai, C16:0i	CDC groups 3 and 5
Exiguobacterium	Short, irregular rods with rod-to-coccus cycle	+	+	Pale orange, yellow	Fac	Ferm	Absent	L-Lysine	MK-7	C17:0i, C15:0i, C16:0	Include *E. acetylicum* resembles some CDC group A-4 strains
Leifsonia	Pleomorphic rods that fragment into shorter rods and cocci; motile via peritrichous flagella	+	+	Yellowish to deep yellow with age	Aer	Oxid, ferm (so CHO's)	Absent	DL-Diaminobutyric acid	MK-11, MK-10	C15:0,ai, C17:0,ai, C16:0i	Includes *L. aquatica* (formerly "*Corynebacterium aquaticum*" and other environmental bacteria
Microbacterium	Irregular, thin rods; some coccal forms	+	V	None-to-yellow	Aer	Oxid/weakly ferm	Absent	L-Lysine	MK-12, MK-11, MK-10	C15:0ai, C17:0ai, C16:0i	Some CDC group A-4 and A-5 strains and former *Aureobacterium* species

871

Oerskovia	Coccoid to rudimentary filaments; vegetative but no aerial "hyphae"	+	V	Yellow	Fac/Aer	Ferm	Absent	L-Lysine	MK-9(H_4)	C15:0, C16:0, C15:0i, C17:0ai	Includes *O. jenensis* (from insects) and *O. paurometabola* (from soil)
Propionibacterium	Irregular rods with branching or "bifid" ends; some coccoid forms	V	–	White/gray-white	Ana/Fac	Ferm	Absent	LL-DAP	MK-9(H_4)	C15:0, C15:0ai, C17:0ai	Usually grow better under anaerobic conditions, especially on primary isolation; produce major amount of lactic acid from glucose
Propioniferax	Irregular rods	+	–	None	Aer	Ferm	Absent	LL-A_2pm	MK-9(H_4)	C15:0ai, C16:0i	Includes single species *Propioniferax innocua* (formerly *Propionibacterium innocuum*)
Rothia	Irregular rods with rudimentary branching	+	–	White, gray-white	Fac	Ferm	Absent	L-Lysine	MK-7	C15:0ai, C17:0ai, C16:0	Includes white and black colony variants and "*Rothia*-like" CDC fermentative coryneform group 4; other human isolate in the genus is *R. mucilaginosa*
Turicella	Irregular rods	+	–	None	Aer	Inert	Absent	*meso*-DAP	MK-10(H_2), MK-11(H_2)	C18:1, C16:0, C18:0	Single species (*T. otitidis*); phenotypically similar to *C. auris* and *C. afermentans*

Fac, facultative; Ana, anaerobic; Aer, aerobic.

872

BOX 14-4

Members of the Genus *Corynebacterium* Isolated From Human Clinical Specimens

Species	Clinical Significance and Identification
Corynebacterium accolens	*C. accolens* has been isolated from human clinical specimens, including wound drainage, endocervical specimens, sputum, and throat swabs.[798] Cases of native mitral and aortic valve endocarditis, breast abscess, and pelvic osteomyelitis caused by *C. accolens* have been reported.[37,209,1204] *C. accolens* is a lipophilic species that forms small (i.e., less than 0.5 mm in diameter), gray, smooth, transparent, nonhemolytic colonies on SBAafter 48 hours incubation. It reduces nitrate but does not hydrolyze esculin or produce urease. Like most other corynebacteria, most *C. accolens* strains are pyrizinamidase-positive; however, alkaline phosphatase is not produced. Glucose and ribose are fermented, and some strains will also produce acid from sucrose and/or mannitol. Isolates of this species are susceptible to penicillin, cephalosporins, erythromycin, clindamycin, tetracycline, and the aminoglycosides, and are resistant to sulfamethoxazole.[209,798]
Corynebacterium afermentans subsp. *afermentans, Corynebacterium afermentans* subsp. *lipophilum*	Organisms belonging to CDC group ANF-1 are pleomorphic gram-positive bacilli that do not produce acid from any carbohydrates, hence the name ANF, meaning "absolute nonfermenter." Riegel and coworkers[931] examined the genetic and biochemical characteristics of 11 ANF-1 strains and proposed a new species, *Corynebacterium afermentans*, containing two subspecies, *C. afermentans* subsp. *afermentans* and *C. afermentans* subsp. *lipophilum*.[931] The former subspecies grows equally well in both the absence or presence of 1% Tween-80, although the colonies acquire a beige pigmentation on Tween-containing media. The latter subspecies forms very small colonies on SBA after 24 hours, but produces large, beige colonies on Tween 80-supplemented SBA. These organisms are biochemically inert except for positive pyrazinamidase (PYZ) and alkaline phosphatase (PAL) reactions. Phenotypically, *C. afermentans* subsp. *afermentans* resembles *Corynebacterium auris* and *Turicella otitidis*, both of which are associated with otitis media. All produce the same biocode on the API Coryne (biocode 2100004). These three organisms are differentiated based on colony morphology, CAMP test, DNase and leucine arylamidase (LAP) activities. *C. afermentans* subsp. *lipophilum* also produces the same API biocode and is the only lipophilic species that is CAMP test-positive. The isolate was susceptible to ampicillin, vancomycin, cefazolin, ceftriaxone, gentamicin, erythromycin, ciprofloxacin, and imipenem, and was resistant to clindamycin, and trimethoprim-sulfamethoxazole. *C. afermentans* subsp. *lipophilum* also has been described as the cause of a brain and a liver abscess in a previously healthy 39-year-old man and lung abscess with empyema in a patient with AIDS.[299,762] *C. afermentans* subsp. *afementans* has also been documented as a cause of sepsis following neurosurgery.[621]
Corynebacterium amycolatum	In 1988, Collins and associates[218] reported a new species of *Corynebacterium* isolated from human skin. Although *meso*-DAP, arabinose, and galactose were present in the cell wall, corynemycolic acids found in most *Corynebacterium* species were absent. Despite this departure from an important chemotaxonomic genus characteristic, 16S rRNA sequencing supported inclusion of this organism in genus *Corynebacterium*. The organism was named *Corynebacterium amycolatum* ("without mycolic acids") and accepted as a valid *Corynebacterium* species in 1988. *C. amycolatum* is regarded as an emerging pathogen in immunocompromised patients. This organism has been documented as an agent of sepsis in patients with underlying hematological malignancies and neutropenic fever.[8,264] Native valve endocarditis involving *C. amycolatum* has occurred in patients with preexisting valvular disease or as a nosocomial complication from contaminated peripheral access devices (e.g., left subclavian hemodialysis catheters, IV catheters).[85,248,254,264,607,1234] Oteo and coworkers[829] described three cases of *C. amycolatum* bacteremia in three patients. All had underlying disease (e.g., laryngeal carcinoma, chronic bronchitis, diabetes, deep venous syndrome, adenocarcinoma of the stomach) and bacteremia developed as a complication of pneumonia, infection of a hip fracture following open reduction/internal fixation, empyema, and hemothorax. *C. amycolatum* has been involved in catheter-related and surgical wound infections, mastitis, cardioverter lead-electrode infection, and septic arthritis following vascular graft sepsis.[211,852,1144] *C. amycolatum* was reported as the cause of fatal sepsis in a premature infant and recurrent peritonitis associate with continuous ambulatory periotoneal dialysis.[97,200,1234] Isolates of *C. amycolatum* show a range of MICs for the β-lactams, macrolides, clindamycin, aminoglycosides, quinolones, and rifampin. *C. amycolatum* strains are susceptible to tigecycline, vancomycin, tetracycline, linezolid, and quinupristin-dalfopristin, but macrolides and clindamycin usually demonstrate poor activity against this organism.[338,418,967] About 40% of 101 *C. amycolatum* strains tested in a 1996 study were resistant to β-lactam antimicrobial agents (MICs > 64 μg/mL).[380] In addition, the

	MICs of ciprofloxacin, chloramphenicol, clindamycin, and erythromycin at which 50% of the isolates were inhibited were all greater than the susceptibility breakpoints for staphylococci. Resistance to gentamicin was also seen in some isolates. *C. amycolatum* strains that show high-level fluoroquinolone resistance have single or multiple mutations in the *gryA* gene, resulting in MICs of >32 μg/mL for these agents.[418,1016,1234] Macrolide resistance in *C. amycolatum* is associated with methylase enzymes encoded by the *erm(X)* gene.[828]
	C. amycolatum characteristically produces flat, dry, whitish-gray, matte or waxy colonies on SBA. Confluent areas of growth on agar media may become "wrinkled-looking" on prolonged incubation (see Image Plate 14-3C). This colony morphology is easily differentiated from those of *C. minutissimum* or *C. striatum*, which grow as gray-white, moist colonies. *C. amycolatum* is nonlipophilic, pyrazinamidase- and alkaline phosphatase-positive and most strains also reduce nitrate to nitrite. Acid is produced from glucose and ribose, and most strains also ferment maltose and sucrose. Some isolates may be urease-positive and PYR-positive. *C. amycolatum* strains produce propionic acid as the major end product of glucose metabolism. *C. amycolatum* has likely been misidentified as *C. striatum, C. xerosis, C. minutissimum*, and CDC group I-1 by clinical laboratories for many years.[372,1185,1247] Table 14-6 shows the additional tests that can be used to differentiate *C. amycolatum* from these other corynebacteria.[912,1185,1188,1247] Common API Coryne profile numbers for *C. amycolatum* (i.e., 3100325, 3100125, 7100125, 3100365, 4100325, 3040121) usually provide a cross-call of *C. amycolatum/C. striatum*, necessitating additional tests for definitive identification (see Image Plate 14-3D, and 14-3E). Letek and colleagues described a real-time PCR assay based on the use of various primer pairs for amplification of the cell division gene, *divIVA*, that was able to specifically differentiate *C. amycolatum* from *C. striatum, C. minutissimum*, and *C. xerosis*.[670]
Corynebacterium appendicis	*C. appendicis* is a recently described species that was isolated from a postsurgical wound in a patient with appendicitis.[1230] Genotypically, this new species is most closely related to *C. afermentans*, *C. coyleae*, and *C. lipophiloflavum*. *C. appendicis* is a lipophilic species that is pyrazinamidase-, alkaline phosphatase- and urease-positive and produces acid from glucose and maltose only within 7 days (API Coryne reactions). Lactic acid is the major product from glucose fermentation.
Corynebacterium argentoratense	*C. argentoratense* is the name assigned to four isolates that were recovered from throat cultures of patients with tonsillitis, but the role of these bacteria in disease is not known. *C. argentoratense* is closely related to members of the "*C. diphtheriae* group" (i.e., *C. diphtheriae, C. pseudotuberculosis,* and *C. ulcerans*) and to *C. kutscheri*. Because of the genetic similarity to the "*C. diphtheriae* group", these strains were examined for the presence of the *tox* gene of the β-corynephage, but this gene was not detected. *C. argentoratense* is nonlipophilic, forms creamy gray-white, nonhemolytic colonies on SBA, and rapidly produces acid from glucose, fructose, and occasionally ribose.[937] Nitrate is not reduced and urea, esculin, and gelatin are not hydrolyzed. Pyrazinamidase is produced, but most strains are alkaline phosphatase-negative. This organism resembles *C. coyleae* except that *C. coyleae* is strongly CAMP test-positive and acidifies ribose, while *C. argentoratense* is CAMP test-negative and is ribose fermentation-variable. Like *C. amycolatum*, *C. argentoratense* produces propionic acid from glucose fermentation.
Corynebacterium atypicum	The description of *C. atypicum* corresponds to a single isolate obtained from an undisclosed human source.[461] The isolate was nonlipophilic, nonhemolytic, and did not hydrolyze esculin, gelatin, or starch, and was LAP-positive. Unlike most *Corynebacterium* species, both pyrazinamidase and alkaline phosphatase tests are negative. Acid is produced from glucose, maltose, sucrose, and ribose. This new species, like *C. amycolatum* and *C. kroppenstedtii*, lacks cell wall mycolic acids. Like *C. glucuronolyticum*, this species produces β-glucuronidase, with other enzymatic tests on the API Coryne being negative. The unique API code for this atypical species is 0200365.
Corynebacterium aurimucosum	*C. aurimucosum* has been isolated from human clinical specimens, including blood cultures from a patient with bronchitis, bone and joint infections, and diabetic foot wounds.[414,948,1229] The organism grows as nonlipophilic, sticky, slightly yellow colonies on SBA. On the API Coryne, the pyrazinamidase and alkaline phosphatase tests are positive and acid is produced from glucose, maltose, and sucrose, resulting in API Coryne biocode 2100125. Lactic acid is the principal product of glucose fermentation. Genotypically and phenotypically, *C. aurimucosum* closely resembles *C. minutissimum*. The API Coryne profile, 2100125, is the same for both species, except that *C. aurimucosum* produces yellow colonies and is hippurate hydrolysis-positive, while *C. minutissimum* grows as moist, gray-white colonies and is hippurate-negative. In 2004, Daneshvar et al.[253] reported on several charcoal-black-pigmented isolates from female genital tract specimens that were provisionally designated as CDC fermentative coryneform

874

	group 4. These isolates were related at the species level to *C. aurimucosum* and *C. nigricans*, which was originally isolated from female genital tract specimens. Black-pigmented variants of *C. aurimucosum* appear to be specific to the female lower genital tract and are associated with complications during pregnancy (e.g., spontaneous abortion).[1118] Because of these isolates and their close relationship to *C. aurimucosum*, the description of this organism has been amended to include not only the original colony types ("sticky, slightly yellow") but also these charcoal-black pigmented variants. *C. nigicans* is a later synonym of *C. aurimucosum*.
Corynebacterium auris	In 1995, Funke and coworkers[373] reported isolation of 10 strains that were identified as CDC group "ANF-1-like", but were distinct from both *C. afermentans* subspecies and *T. otitidis* by cellular morphology and colonial appearance. Colonies of these isolates were dry, weakly adherent to the agar, and became slightly yellow with time, while colonies of both *C. afermentans* and *T. otitidis* were creamy, smooth, and gray-white. These strains were also phenotypically similar to both *C. afermentans* subsp. *afermentans* and *T. otitidis*, but could be differentiated by substrates in the Biolog identification system. Genetic analysis confirmed that the 10 strains were a new *Corynebacterium* species and the name *Corynebacterium auris* ("auris" referring to the ear) was proposed. *C. auris* grows as nonlipophilic, nonhemolytic, dry, adherent, yellowish colonies on SBA and, as mentioned, produces reactions in common phenotypic tests that are identical to *C. afermentans* subsp. *afermentans* and *T. otitidis*. However, both *C. auris* and *T. otitidis* are strongly CAMP test-positive, while *C. afermentans* is CAMP test-variable. In addition, *C. afermentans* subspecies and *C. auris* are DNase-negative, while *T. otitidis* is DNase-positive. LAP activity can be detected in *T. otitidis* and *C. auris*, while *C. afermentans* subsp. *afermentans* is LAP-negative.[913] On the API Coryne, the numerical biocode for *C. auris* is 2100004.
Corynebacterium bovis	This lipophilic species is associated mainly with cattle, although rare human infections have been documented.[4,95,247] *C. bovis* is a lipophilic species that is pyrazinamidase-negative, alkaline phosphatase- and urease-positive, and produces acid from glucose only. Rare strains are also weakly maltose-positive, although this reaction is negative on the API Coryne. The API Coryne profile for *C. bovis* is 0101104.
Corynebacterium canis	Like *C. freiburgense*, this organism was isolated from a dog bite wound along with *Bacteroides* species and *Prevotella* species, so this organism is likely found in the mouths of dogs.[363] This species forms dry, beige-white, adherent colonies with irregular, convoluted edges on SBA. The organism produces a variety of enzymes including pyrazinamidase, alkaline phosphatase, and α- and β-glucosidase. Urease, pyrrolidonyl arylamidase (PYR), α- and β-galactosidase, β-glucuronidase, and *N*-acetyl-β-d-glucosaminidase are not produced. *C. canis* produces acid from glucose, maltose, fructose, sucrose, trehalose, starch and glycogen, but not from lactose, ribose, xylose, mannitol, sorbitol, or amygdalin. The isolate was susceptible to all antimicrobial agents.
Corynebacterium confusum	*C. confusum* has been isolated from a plantar abscess, calcaneal osteomyelitis, and from blood.[377] The blood culture isolate was from a non-immunocompromised patient during a febrile episode following back surgery. This organism is nonlipophilic and produces a delayed acidic reaction from glucose (i.e., the GLU cupule on the API Coryne was positive only after 48–72 hours incubation). Failure to prolong incubation of the API Coryne strip past 24 hours resulted in identification of these strains as *C. propinquum* (see below), but these strains did not hydrolyze tyrosine (*C. propinquum* is tyrosine hydrolysis-positive). *C. confusum* reduces nitrate to nitrite, produces pyrazinamidase and alkaline phosphatase, does not hydrolyze esculin or urea, and is CAMP test-negative. All API enzymatic tests are negative. On the API Coryne, codes generated by this organism are 3100304 or 3100104, indicating that some strains are also ribose-positive. In the original report, strains of *C. confusum* were susceptibile to the penicillins, cephalosporins, aminoglycosides, tetracyclines, quinolones, and glycopeptides, and were variably susceptible to rifampin, and the macrolides.[377] All strains were resistant to aztreonam.
Corynebacterium coyleae	*C. coyleae* has been recovered from pleural fluid, pancreatic abscess, breast abscesses, genitourinary tract specimens, and blood cultures of patients with fevers of unknown origin secondary to underlying conditions (i.e., AIDS, surgery, diabetes, non-Hodgkin's lymphoma).[336,382,1078] Colonies of *C. coyleae* are nonlipophilic, nonhemolytic on SBA, creamy to sticky in consistency, and about 1 mm in diameter after 24 hours of incubation. The organism is pyrazinamidase-, alkaline phosphatase-, and CAMP test-positive, and produces acid from glucose, ribose, fructose, and mannose. Most strains produce API Coryne biocode numbers 2100304 or 6100304. The latter biocode is the same as that for *C. jeikeium*, but *C. coyleae* is nonlipophilic and does not display multiple resistance to antimicrobial agents. *C. coyleae* strains are susceptible to β-lactams, gentamicin, imipenem, rifampin, tetracycline, vancomycin, and linezolid. Many strains are resistant to clindamycin, erythromycin, and the fluoroquinolones.

875

Corynebacterium diphtheriae	See text
Corynebacterium durum	*C. durum* has been recovered from throat cultures of healthy individuals and from sputum and lavage specimens of immunocompromised hosts (i.e., neoplasms, leukemia, renal failure).[932,1166] On culture, this nonlipophilic organism produces small, beige colonies that are adherent to the agar, although not all isolates have this appearance. On Gram's stains, the cells are long, pleomorphic, and sometimes filamentous, somewhat resembling the cellular morphology of *C. matruchotii*, but lacking the characteristic "whip handle" of the latter species. Most strains of *C. durum* are negative for alkaline phosphatase and PYR. Esculin is hydrolyzed weakly and urea hydrolysis is slowly positive or negative. *C. durum* is also one of the few *Corynebacterium* species that strongly ferments both mannitol and galactose, which helps to differentiate this organisms from *C. matruchotii*, which does not ferment these carbohydrates. On the API Coryne strip, *C. durum* produces unique numerical profiles (i.e., 3000135, 3001135, 3040135, 3400115, 3400135, 3400305, 3400325, 3400335, 3040325, 3040335, 3440335, 3441335) even though this organism is not included in the data base of that system.[71] Data on the antimicrobial susceptibility of this species are not available.
Corynebacterium falsenii	*C. falsenii* was described in 1998 by Sjoden and colleagues[1031] at the University of Goteborg, Sweden.[1031] Isolates were obtained from blood, and CSF cultures. Two of the blood culture isolates were from patients with malignant lymphoma and lymphocytic leukemia, respectively. These isolates were nonlipophilic and developed a distinct yellow pigmentation after 72 hours; prolonged incubation beyond this time resulted in more intense pigmentation. The isolates did not reduce nitrate or hydrolyze esculin. All four strains fermented glucose slowly, while a single strain also produced a slow acidic reaction with maltose. Conventional urea was hydrolyzed after overnight incubation, and the urease cupule of the API Coryne became positive only after 48 hours incubation. These fermentative, nonlipophilic strains were genetically and chemotaxonomically distinct and the name *C. falsenii* was proposed. Since the description of *C. falsenii* from human clinical specimens, similar strains also have been isolated from the mouths of eagles along with a second nonlipophilic isolate (*C. aquilae*).[331] On the API Coryne, the biocodes for *C. falsenii* include 2101104 and 2101304. Some API Coryne biocodes for this organism are identical to those for *C. jeikeium* (2100304, 2100324), but *C. falsenii* strains will be yellowish and nonlipophilic. *C. falsenii* isolates are susceptible to cephalothin, ciprofloxacin, erythromycin, gentamicin, imipenem, rifampin, tetracycline, cefetamet, and ceftibuten and resistant to aztreonam. MICs for penicillin range from 0.25 to 0.50 μg/mL. In 2010, *C. falsensii* was isolated from the blood of a 13-month-old infant.[1085] This isolate was susceptible to penicillin, clindamycin, doxycycline, gentamicin, linezolid, meropenem, rifampin, and vancomycin and resistant to ceftriaxone, erythromycin, and trimethoprim-sulfamethoxazole.
Corynebacterium freiburgense	This species is probably found in the oral cavity of dogs, as the only isolate was obtained from a dog bite wound on the forearm of a 57-year-old female. This organism was isolated along with *Pasteurella multocida*, *Prevotella* species, and α-hemolytic streptococci.[367] Colonies are beige-white, dry, convoluted with irregular edges, and adherent to the agar surface. After 5 days, the colonies assume a "spoked wheel" morphology. Pyrazinamidase, urease, PYR, gelatinase, and α-glucosidase are not produced, while β-glucosidase and β-galactsidase are produced. Acid is produced from glucose, maltose, sucrose, lactose, and ribose, but not from mannitol, sorbitol, xylose, raffinose, trehalose, or starch. Acid production from lactose and the positive β-galatosidase reaction are unusual among *Corynebacterium* species. This isolate was susceptible to penicillin, cefotaxime, ciprofloxacin, doxycycline, erythromycin, gentamicin, linezolid, meropenem, rifampin, and vancomycin.
Corynebacterium freneyi	*C. freneyi* has been isolated from blood, wounds, abscesses, and a sperm specimen.[55,911] In 2008, Funke and Frodl reviewed 18 additional *C. freneyi* isolates;13 isolated from vaginal swab specimens, with the rest being from ear discharge, human skin, a nasal culture, a wound culture, and a varicose ulcer.[365] *C. freneyi* is genotypically related to *C. xerosis* and *C. amycolatum* and can be phenotypically differentiated from them by carbon source assimilations and certain biochemical characteristics. Colonies of this organism are white-gray or yellowish, dry, wrinkled, 0.5–1 mm in diameter after 24 hours growth, nonhemolytic, and nonlipophilic. Like *C. xerosis*, isolates of *C. freneyi* are α-glucosidase-positive. Pyrazinamidase and alkaline phosphatase are produced and reduction of nitrate to nitrite is variable. *C. freneyi* is able to grow at 20°C, ferments glucose at 42°C, and does not acidify ethylene glycol, while *C. xerosis* strains do not grow at 20°C and do not ferment glucose at 42°C; some strains acidify ethylene glycol. The ability of *C. freneyi* to grow at 20°C also aids in the differentiation of it from *C. amycolatum*, which is not able to grow at this temperature. *C. striatum* and *C. minutissimum* may also resemble *C. freneyi*, but *C. striatum* grows at 20°C, ferments glucose at 42°C, and acidifys ethylene glycol. *C. minutissimum* ferments glucose at 42°C, but does not grow at 20°C and does not acidify ethylene glycol.

876

	On the API Coryne, *C. freneyi* yields a biocode of 3110325, which corresponds to a *C. striatum/C. amycolatum* cross-call; these species can be separated by the tests described above. *C. freneyi* is susceptible to doxycycline, linezolid, gentamicin, meropenem, rifampin, vancomycin, and penicillin.[365]
Corynebacterium glucuronolyticum ("Corynebacterium seminale")	*C. glucuronolyticum* is a nonlipophilic coryneform that has been isolated from man with genitourinary tract infections and from semen specimens of patients with prostatitis.[359,393] In 2001, this organism was isolated as a cause of urethritis in an 18-year-old man.[393] This organism has also been found in the semen of boars and in uterine and vaginal secretions of sows.[271] This organism produces gray-white to slightly yellow, nonhemolytic colonies on SBA (see Image Plate 14-4G and 14-4H). While some phenotypic test results are variable (i.e., nitrate reduction, esculin hydrolysis, urease), most isolates are strongly CAMP test-positive and β-glucuronidase (β-GUR)-positive (see Image Plates 14-5A and 14-5B). On GLC of spent culture media, this species also produces propionic, lactic, and succinic acids from glucose. Strains of this organism are usually susceptible to β-lactams, aminoglycosides, rifampin, and vancomycin; some strains are resistant to tetracycline, doxycycline, erythromycin, clindamycin and certain quinolones (e.g., ciprofloxacin, norfloxacin). Another group of investigators also have described this organism and named it "*Corynebacterium seminale*," but the name *C. glucuronolyticum* has been given precedence.[935]
Corynebacterium hansenii	The description of *C. hansenii* is based on a single strain that was isolated from an aerobic culture of pus from surgical debridement of a liposarcoma.[914] Phenotypically, this species closely resembles *C. freneyi* and *C. xerosis*. This species is nonlipophilic and forms small, dry, rough, yellow-pigmented colonies on agar media. It is pyrazinamidase-positive, alkaline phosphatase-negative, and does not hydrolyze urea, gelatin, or esculin. Acid is produced from glucose, maltose, sucrose, and ribose. The API Coryne profile of this species was 2000325. Unlike *C. freneyi* and *C. xerosis*, the α-glucosidase reaction is negative. This isolate was susceptible to all antimicrobial agents except tetracycline.
Corynebacterium imitans	*C. imitans* has been recovered from pharyngeal cultures of patients with suspected diphtheria in Poland.[361] In addition to the index case, a 5-month-old boy, seven additional patients were subsequently reported, all of whom had contact with the index case. A "*C. diphtheriae*-like" organism was recovered from the index patient and three of the other patients. All strains were negative for diphtheria toxin by both animal challenge and the Elek method. Two independent PCR methods also failed to demonstrate the presence of any portion of the *tox* gene in any of the isolates. Because the isolates did not produce diphtheria toxin, the authors felt that they were not the cause of the patients' illness and that they had been misdiagnosed, although person-to-person transmission of the organisms had likely occurred.[361] *C. imitans* is a nonlipophilic species that can easily be distinguished from *C. diphtheriae*. Unlike *C. diphtheriae*, *C. imitans* is weakly pyrazinamidase-positive, α-glucosidase-negative, and CAMP test-positive, while *C. diphtheriae* strains are pyrazinamidase-negative, α-glucosidase-positive, and CAMP test-negative. All four isolates in the initial report produced identical profile numbers on the API Coryne (2100324). *C. imitans* could be differentiated from *C. striatum* and from *C. minutissimum/C. amycolatum* by maltose fermentation and the CAMP test, respectively. Lactate and succinate are produced as the sole products of glucose fermentation by *C. imitans*, while both *C. amycolatum* and *C. diphtheriae* produce mostly propionic acid. All four of the isolates described in the original report were susceptible to antimicrobial agents except aztreonam, clindamycin, erythromycin, and azithromycin.[361]
Corynebacterium jeikeium	*C. jeikeium* (formerly group JK) is one of the most commonly isolated *Corynebacterium* species from human infections.[540] This lipopophilic species colonize the axillar, groin, rectum, and perineum of hospitalized patients and may also be recovered from the hospital environment.[822,1048,1100] Infections with *C. jeikeium* are seen predominantly in immunocompromised hosts with hematologic and solid organ malignancies, other underlying diseases (including AIDS), indwelling medical devices, integumentary barrier breaks, neutropenia, and therapy with broad-spectrum antimicrobial agents.[282,1046,1050,1142,1176] *C. jeikeium* is a well documented cause of community- and nosocomially-acquired bacteremia and sepsis, native and prosthetic valve endocarditis.[85,771,947] Other less common clinical presentations described for *C. jeikeium* include, meningitis/ventriculitis, cardiovascular device-related infections, pneumonia, pyelonephritis, osteomyelitis, peritonitis, otitis media, and cutaneous/soft tissue infections.[79,121,265,434,550,827,1191,1231] After 24 hours of incubation, colonies of *C. jeikeium* on SBA are small (0.5–1 mm in diameter), nonhemolytic, and gray-white (Image Plate 14-4D). Growth on commercially available chocolate agar is usually scant due to the absence of lipids in current chocolate agar formulations. Unlike several other species, this organism is strictly aerobic. In the absence of supplementation of the growth media with Tween 80, acidification of the glucose and ribose test cupules in the API Coryne is often weak after 24 hours. The organism is pyrazinamidase- and alkaline phosphatase-positive, and acidifies glucose, ribose, galactose, and some strains also acidify maltose. All of the enzymatic tests on the API Coryne are negative for *C. jeikeium* (see Image Plate 14-4E and 14-4F).

877

	C. jeikeium was the first *Corynebacterium* species that was documented as being resistant to multiple antimicrobial agents. Isolates of this species often show resistance to β-lactams (penicillins, cephalosporins, imipenem) and aminoglycosides and variable susceptibility to the macrolides, tetracyclines, rifampin, and the fluoroquinolones.[551,722,773,974] *C. jeikeium* is susceptible to vancomycin, tigecycline, daptomycin, linezolid, and quinupristin/dalfopristin.[282,338,418,635] Multiple antibiotic resistance in *C. jeikeium* is believed to be chromosomal rather than plasmid-associated. However, inducible, transposon-associated macrolide-lincosamide-streptogramin (MLS) resistance has been demonstrated in *C. jeikeium*.[828,946]
Corynebacterium kroppenstedtii	The description of *C. kroppenstedtii* is based on a single human isolate that was recovered from the sputum of an 82-year-old woman with pulmonary disease.[219] Cell wall analysis revealed the presence of *meso*-DAP and arabinoglactan, and 16S rRNA sequence analysis supported the inclusion of this organism in the genus *Corynebacterium*. Recent studies suggest a role for this organism in the pathogenesis of granulomatous mastitis in women.[91,852,933,1097] *C. kroppenstedtii* is a lipophilic species that produces gray, non-pigmented, slightly dry or smooth colonies on blood agar. Colonies are usually less than 0.5 mm in diameter after 24 hours of incubation. This organism is esculin-positive, urease- and nitrate reductase-negative, and CAMP test-negative. Acid is produced from glucose, sucrose, and maltose (weak reaction). API Coryne biocodes for this strain are 2040105 or 2040125, depending upon the interpretation of the maltose reaction. *C. kroppenstedtii* does not grow at 42°C. In vitro testing of the single isolate demonstrated susceptibility to penicillin, cefuroxime, clindamycin, erythromycin, and vancomycin.[219]
Corynebacterium lipophiloflavum	During a search for microorganisms involved in the pathogenesis of BV, Funke and colleagues[371] isolated a previously undescribed coryneform organism from the vagina of a 32-year-old woman with this clinical diagnosis. This isolate fulfilled the initial criteria for being a member of the genus *Corynebacterium*, was intensely yellow-pigmented, and displayed a lipid requirement for growth. The organism was oxidative in its metabolism, did not produce acid from carbohydrates, and was urease-positive after 24 hours in urease broth. The API Coryne produced the same profile number as *C. urealyticum* (profile #2101004). However, *C. urealyticum* is rapidly urease-positive (i.e., Christianson's urea slants become noticeably positive within minutes) and is not pigmented. In addition, this new isolate was broadly susceptible to β-lactams, macrolides, clindamycin, and aminoglycosides, while *C. urealyticum* is usually resistant to many of these agents.
Corynebacterium macginleyi	This species was proposed following a genetic examination of 51 lipophilic coryneform isolates (13 reference strains and 38 clinical isolates) that exhibited heterogenous biochemical patterns.[936] Isolates of *C. macginleyi* have been recovered predominantly from ocular specimens of patients with conjunctivitis, corneal ulcers, or postoperative endophthalmitis.[29,341,405,555,1072,1158] *C. macginleyi* has also been isolated from a tracheostomy site of a patient with laryngeal carcinoma, the urine of a patient with a long-term indwelling catheter, and from blood cultures of patients with catheter-related sepsis.[276,285,781,1159] *C. macginleyi* is also a rare cause of endocarditis.[884] On SBA, the organism forms pinpoint colonies after 48 hours; on SBA supplemented with 0.1% Tween 80, large, reddish beige colonies are produced. Higher concentrations of Tween-80 (i.e., 1% vs. 0.1%) may be somewhat inhibitory to the growth of some strains. *C. macginleyi* is alkaline phosphatase-positive, but is pyrazinamidase-negative. Acid is produced from glucose, sucrose, and mannitol and propionic acid is not produced from glucose fermentation. *C. macginleyi* isolates are usually susceptible to a broad range of antimicrobial agents, although some isolates may be resistant to fluoroquinolones, clindamycin, erythromycin, and/or the aminoglycosides.[1158] Some isolates of *C. macginleyi* have demonstrated high-level resistance to the fluoroquinolones due to point mutations in the *gyrA* gene.[302]
Corynebacterium massiliense	This new *Corynebacterium* species was isolated from hip joint fluid from an 84-year-old man who had previously undergone arthroplasty.[745] After 48 hours growth on SBA, colonies are grayish, glistening, and 0.5–1 mm in diameter (lipophilic). Urea, esculin, and gelatin are not hydrolyzed and nitrate is not reduced to nitrite. This species is weakly pyrazinamidase-positve and does not form acid from glucose, maltose, sucrose, xylose, or ribose on the API Coryne. This isolate was susceptible to amoxicillin, doxycycline, gentamicin, ofloxacin, clindamycin, trimethoprim-siulfamethoxazole, erythromycin, and rifampin.
Corynebacterium matruchotii	*C. matruchotii* is part of the oral flora of humans and animals and has been isolated on rare occasions from cases of endophthalmitis and corneal ulcers in compromised patients. This organism is also a documented veterinary pathogen.[979] Although this organism may appear on Gram's stain as typical coryneform bacteria, they may also appear as a "whip and handle" form on staining and may also show

878

	rudimentary branching. Colonies of *C. matruchotii* are also atypical compared with other coryneforms, being small and flat. *C. matruchotii* is nonlipophilic, produces pyzazinamidase but not alkaline phosphatase, reduces nitrate to nitrite, and is usually esculin-positive. Acid is produced from glucose, maltose, sucrose, and ribose. Recent analysis of several ATCC strains of *C. matruchotii* revealed that some were actually members of the recently described species *C. durum*.[71] Although they are not included in the API Coryne data base, bona fide *C. matruchotii* strains produce API Coryne biocodes 7000325, 7010325, or 7050325. The original ATCC strain of *C. matruchotii* (ATCC #43833) has also been found to be distinct from true *C. matruchotii* strains by 16S rDNA sequence analysis. This strain is now called "*C. matruchotii*-like strain" and yields biocode 2140325 on the API Coryne.[71]
Corynebacterium minutissimum	*C. minutissimum* is a nonlipophilic species of uncertain clinical significance because most case reports do not contain sufficient phenotypic data to rule out other species, particularly *C. amycolatum*.[1185] Historically, *C. minutissimum* is associated with erythrasma, a superficial skin infection characterized by small, brownish-red macular patches, generally in the intertriginous areas. Case reports implicating "*C. minutissimum*" as an etiologic agent include endocarditis, meningitis, recurrent breast abscesses, costochondral abscess, bacteremia, postdiscectomy/vertebral fusion surgical wound infection, pyelonephritis with bacteremia, catheter-related sepsis, and CAPD-associated peritonitis.[15,43,64,175,246,333,955] Van-Bosterhaut and colleagues[1139] reported the isolation of multidrug-resistant strains of "*C. minutissimum*" from blood cultures in a 60-year-old man undergoing treatment for lymphocytic leukemia, a 50-year-old hemodialysis patient, and a 77-year-old woman on peritoneal dialysis for chronic renal failure. These isolates were probably *C. amycolatum*, since propionic acid was produced from glucose fermentation and the organism was multidrug-resistant. True *C. minutissimum* strains grow as smooth, moist, gray-white, nonhemolytic colonies on SBA, unlike the waxy colonies of *C. amycolatum*.[1247] Phenotypically, this organism closely resembles *C. aurimucosum*. Acid is produced from glucose and maltose; most strains also acidify sucrose. No acid is produced from glycogen, inulin, lactose, mannose, ribose, sorbitol, trehalose or xylose. Pyrazinamidase, alkaline phosphatase, and leucine arylamidase are positive. *C. minutissimum* strains also produce acetoin, are PYR-negative, and are rarely CAMP test-positive. *C. minutissimum* strains are DNase-positive and produce lactic and succinic acid from glucose, while *C. amycolatum* strains are DNase-negative and produces lactic and propionic acid from glucose.[1185,1247] Isolates of *C. minutissimum* may be multiresistant to antimicrobial agents, including β-lactams, macrolides, and fluroquinolones.[1125]
Corynebacterium mucifaciens	*C. mucifaciens* has been recovered from human blood, wound, ear and nasal specimens, and joint fluid specimens.[157,375,775] This organism was also isolated from blood cultures of a 50-year-old man with cavitary pneumonia.[284] Colonies of this species are unusual in that they are nonlipophilic, glistening, slightly yellowish, and very mucoid, a characteristic that is uncommon among the corynebacteria. On the API Coryne, this organism produces profile numbers that correspond to several lipophilic species (i.e., *C. jeikeium, C. bovis*, CDC group G) or the nonlipophilic fermentative species *C. striatum* (Table 14-10). *C. mucifaciens* produces pyrazinamidase and alkaline phosphatase and does not hydrolyze esculin, urea, or gelatin. The oxidative metabolism displayed by this species is likely responsible for failure to rapidly acidify carbohydrates present on the API Coryne gallery. *C. mucifaciens* produces acid oxidatively from glucose and occasionally from sucrose; acid production from fructose, mannose, and glycerol is useful to differentiate this species from *R. equi*. The eight strains of *C. mucifaciens* described in the original report were also examined for antimicrobial susceptibility; seven were susceptible to β-lactams (cefazolin, penicillin), and all were susceptible to the glycopeptides and aminoglycosides. The susceptibilities of these strains to the tetracyclines, the macrolides (erythromycin, azithromycin, clarithromycin), clindamycin, and the quinolones were variable. All eight strains were resistant to aztreonam, cefetamet, ceftibuten, and fosfomycin.
"Corynebacterium nigricans" (C. aurimucosum)	*"C. nigricans"* is an unusual black-pigmented *Corynebacterium* species that has been isolated from the human female genital tract. These isolates have been associated with complications of pregnancy, including spontaneous abortion and preterm labor.[1014,1015] Morphologically, colonies of *C. nigricans* are black, adherent and tend to "dig into" the agar. This organism must be differentiated from gray-black-pigmented strains of CDC group 4, which resemble *Rothia* species more closely than corynebacteria. Colonies of *"C. nigricans"* are about 2–3 mm in diameter after 48 hours incubation and are nonlipophilic. This species ferments glucose, maltose, and sucrose; glycogen and/or ribose are fermented by some strains. While pyrazinamidase and alkaline phasphatase reactions are variable, the reduction of nitrate and hydrolysis of esculin, urea, and gelatin are negative. On the API Coryne, *"C. nigricans"* produces biocodes 0000125, 2000125, and 2100327. These codes correspond to low-confidence identifications for *C. striatum, C. amycolatum, C. minutissimum,* and CDC groups G and F-1, but the colony

879

	morphology of *C. nigricans* is distinctive enough that identification is not a problem. Strains of CDC group 4 bacteria reduce nitrate and hydrolyze both esculin and gelatin.[996] "*C. nigricans*" is also related at the species level to black-pigmented variants of *C. aurimucosum*.[253]
Corynebacterium pilbarense	This nonlipophilic species is based on a single isolate obtained from an anaerobic BACTEC bottle that was inoculated with an ankle aspirate from a man with gout in Pilbara, West Australia (hence the organism name).[44] This organism is urease- and nitrate reduction-negative, and does not hydrolyze esculin, hippurate, or gelatin. Acid is produced from glucose, sucrose, and ribose, but not from maltose, lactose, mannitol, sorbitol, xylose, raffinose, trehalose, or glycogen. Pyrazinamidase and alkaline phosphatase reactions are positive.
Corynebacterium propinquum	*C. propinquum* includes strains formerly belonging to CDC group ANF-3.[930] This nonlipophilic species has been isolated from the respiratory tract, a traumatic elbow wound, and from blood cultures associated with native aortic valve endocarditis.[864,963] Colonies on SBA are 1–2 mm in diameter after 24 hours of incubation and are off-white and dry with entire edges. Esculin and urea are not hydrolyzed, and strains variably produce pyrazinamidase and alkaline phosphatase. Like *C. pseudodiphtheriticum, C. propinquum* is asaccharolytic, but the two may be differentiated by the production of urease by *C. pseudodiphtheriticum. C. propinquum* can be differentiated from *C. afermentans* subsp. *afermentans* by the ability of the former to reduce nitrate and from *C. afermentans* subsp. *lipophilum* by both nitrate reduction and the lack of a lipid requirement.
Corynebacterium pseudodiphtheriticum	Increasing numbers of case reports suggest that *C. pseudodiphtheriticum* is an important emerging pathogen, particularly among immunocompromised hosts. While considered a member of the normal human oropharyngeal flora, respiratory tract infections associated with this organism include exudative pharyngitis, bronchitis, bronchiolitis, necrotizing tracheitis, tracheobronchitis, pneumonia, and lung abscess.[16,148,199,354,454,717] In compromised hosts with these infections, underlying diseases or predisposing factors have included permanent tracheostomy secondary to laryngeal carcinoma, chronic obstructive pulmonary disease, diabetes mellitus, coronary artery disease, intubation and mechanical ventilation secondary to a motor vehicle accident, end-stage renal disease, cirrhosis, tuberculosis, and HIV infection.[153] In some cases, respiratory tract infection with *C. pseudodiphtheriticum* may mimic respiratory diphtheria.[539] In 2010, an outbreak of *C. pseudodiphtheriticum* infection was documented among 13 children with cystic fibrosis (CF) at two treatment centers in France.[114] The children presented with cough, rhinitis, and exacerbations of their chronic disease. Molecular techniques demonstrated that about 20% of CF patients at the centers were colonized with *C. pseudodiphtheriticum*. Native and prosthetic valve endocarditis caused by *C. pseudodiphtheriticum* have also been reported, and most native valve infection have occurred in the setting of preexisting valvular damage.[777,1197] Suppurative cervical lymphadenitis, vertebral discitis following nasal turbinate surgery, postarthroscopy arthritis, cutaneous and wound, and eye infections caused by *C. pseudodiphtheriticum* have also been reported.[314,484,637,672,1213] *C. pseudodiphtheriticum* is nonlipophilic and grows as smooth, white colonies on SBA (Image Plate 14-5C). Pyrazinamidase and nitrate reductase reactions are positive, and the alkaline phosphatase reaction is variable. This organism is urease-positive after 24 hours and does not ferment or oxidize carbohydrates (Image Plate 14-5D). Like *C. afermentans* subspecies and *C. auris, C. pseudodiphtheriticum* does not produce acid from carbohydrates, but is easily differentiated from these species by its positive urease and nitrate reductase reactions. *C. pseudodiphtheriticum* isolates are generally susceptible to β-lactam agents, vancomycin, and aminoglycosides, but strains that are resistant to clindamycin, erythromycin, tetracycline, and the quinolones have been found. In a study of 58 strains of *C. pseudodiphtheriticum*, 52 were erythromycin-resistant and 6 were susceptible. The macrolide, lincosamide, and streptogramin B (MLSB)-constitutive resistance phenotype was found in 89.7% of the strains. The presence of the *erm(X)* gene that is associated with the MLSB resistance phenotype was confirmed by PCR.[820]
Corynebacterium pseudotuberculosis	*C. pseudotuberculosis* causes caseous lymphadenitis (CLA or "cheesy gland") in sheep, cattle, and other small ruminants.[1198] Most human infections associated with *C. pseudotuberculosis* have been reported among rural sheep-herders in Australia or in butchers, and have presented with either acute or chronic lymphadenitis.[136,855] In human infections, surgical drainage and excision of the affected lymph node(s) was necessary, and most of the patients had persistent or recurrent drainage from the wound site for prolonged periods. *C. pseudotuberculosis* is a member of the "*C. diphtheriae* group" *C. pseudotuberculosis* can be experimentally transformed into a diphtheria toxin-producing species by infection and lysogenization with the β-corynephage, but naturally occurring lysogenized strains have not been isolated. *C. pseudotuberculosis* is pyrazinamidase-negative and produces cystinase, as evidenced by

880

	the production of brown halos around colonies on modified Tinsdale medium. *C. pseudotuberculosis* is urease-positive, nitrate reductase and alkaline phosphatase-variable and differs from *C. ulcerans* in that it does not produce acid from glycogen or trehalose and does not hydrolyze gelatin. Like *C. ulcerans* and *A. haemolyticum*, *C. pseudotuberculosis* is reverse CAMP test-positive. In the report on 10 patients with lymphadenitis due to *C. pseudotuberculosis* published by Peel and colleagues,[855] all isolates produced API Coryne profile #0111324, indicating positive reactions for alkaline phosphatase, α-glucosidase, urease, glucose, maltose, and ribose. *C. pseudotuberculosis* are generally susceptible to penicillins, macrolides, tetracyclines, cephalosporins, quinolones, and rifampin; most are resistant to aminoglycosides, nitrofurans, and polymyxin.[561]
Corynebacterium resistens	*C. resistans* was described in 2005 based on five isolates from blood, abscess, and bronchial aspirate specimens.[830] The organism derives its name from its antimicrobial susceptibility pattern. All isolates had MICs beyond clinically achieveable levels for penicillin (MIC > 64 μg/mL), cefazolin (MIC > 64 μg/mL), cefepime (MIC > 64 μg/mL), imipenem (MIC > 32 μg/mL for all but one isolate, MIC ≤ 0.13 μg/mL), amikacin (MIC ≥32 μg/mL), clindamycin (MIC > 16 μg/mL), ciprofloxacin (MIC > 16 μg/mL), and minocycline (two isolates, MIC 16 μg/mL; two isolates, MIC 8 μg/mL; one isolate, MIC 0.25 μg/mL). MICs for vancomycin and teicoplanin were 2 μg/mL and ≤0.5 μg/mL, respectively, for all five isolates. On the API Coryne, only the pyrrolidonyl arylamidase (PYR) and alkaline phosphatase reactions are positive, with negative reactions for nitrate reduction, pyrazinamidase, esculin, urease, gelatin, glucose, ribose, xylose, mannitol, maltose, lactose, sucrose, and glycogen (API Coryne profile number 4100004).
Corynebacterium riegelii	*C. riegelii* has been recovered in urine specimens from women with symptoms of urinary tract infection and from blood cultures.[374] Urine isolates were recovered from women of ages 21 to 62 years with no underlying diseases. The organisms were present in significant numbers (i.e., >100,000 cfu/mL). Isolates of *C. riegelii* are nonlipophilic and produce white, glistening sticky colonies on SBA (Image Plate 14-5E). Isolates are strongly urease-positive (like *C. urealyticum*), with positive reactions on Christensen's urea slants being noted within 5 minutes after inoculation (Image Plate 14-5F). An unusual characteristic of this species is that strains produce acid slowly from maltose, but no acid is formed from glucose. Atypical reactions occur with conventional media (e.g., CTA-based carbohydrates) and with the API Coryne strip (Image Plate 14-5G and 14-5H). API Coryne profile numbers for *C. riegelii* are 0101224, 2001224, and 2101224. Strains of *C. riegelii* are susceptible to penicillin, cephalothin, chloramphenicol, ciprofloxacin, gentamicin, rifampin, tetracycline, and vancomycin and resistant to cefetamet, ceftibuten, and fosfomycin.[374]
Coynebacterium sanguinis	*C. sanguinis* has only been recovered from blood cultures to date.[369] Colonies of this organism on SBA are 1–2 mm in diameter after 48 hours incubation, smooth, dry and yellowish. Pyrazinamidase, alkaline phosphatase, and PYR tests are positive, and the CAMP test is negative. The organism slowly ferments glucose and ribose (on the API Coryne) but no other carbohydrates. *C. sanguinis* is negative for nitrate, urease, esculin, and the CAMP test. On the API Coryne, all isolates produced the biocode number 6100304.
Corynebacterium simulans	*C. simulans* has been isolated from a foot abscess, a lymph node biopsy, a boil, and a prosthetic joint infection.[176,1181] This organism is a nonlipophilic fermentative species that is phenotypically similar to *C. minutissimum* and *C. striatum*, but phylogenetically distinct based on 16S rRNA sequences. *C. simulans* strains grow as nonlipophilic, gray-white, glistening, creamy colonies that are 1–2 mm in diameter after 48 hours. *C. simulans* is nitrate positive and maltose-negative (*C. minutissimum* is nitrate-negative and maltose-positive) and does not ferment ethylene glycol or grow at 20°C (*C. striatum* ferments ethylene glycol and grows at 20°C). This is the only *Corynebacterium* species that is able to reduce nitrate to nitrite and then further reduce nitrite to nitrogen gas, so a negative nitrate test must be challenged with zinc to confirm this reaction. In addition, some strains may be catalase-negative. On the API Coryne, *C. simulans* produces several biocodes. Data on the antimicrobial susceptibility of *C. simulans* are not available.
Corynebacterium singulare	The description of *C. singulare* is based on two human isolates (one from semen, the other from blood).[939] These two isolates possessed all the key chemotaxonomic characteristics of the genus *Corynebacterium* and resembled *C. minutissimum* by morphologic and biochemical characteristics. Colonies are convex, entire, creamy, and white-gray. Unlike *C. minutissimum*, however, the two isolates were urease-positive. Examination of other urease-positive taxa within the genus confirmed that the two isolates were indeed distinct from them by several characteristics, including increased fermentative ability, failure to reduce nitrate, and the absence of β-glucuronidase. The organism can be differentiated

881

	from *C. amycolatum* by its failure to produce propionic acid from glucose. On the API Coryne, the organism generates a unique octal code (biocode 6101125).
Corynebacterium sputi	This species encompasses a single isolate from the sputum of a patient with pneumonia.[1228] This organism is lipophilic and is genotypically most closely related to *C. hansenii*. *C. sputi* is urease-positive, but hippurate, esculin, and gelatin are not hydrolyzed and nitrate is not reduced. Acid is produced from glucose, but not from maltose, sucrose, lactose, mannitol, sorbitol, ribose, trehalose, xylose, or starch. The API Coryne biocode for this organism is 2011104.
Corynebacterium striatum	*C. striatum* has been found in cattle, as part of the normal flora of the human nasal passages, and on human skin. In 1980, the first case of human pleuropulmonary infection with *C. striatum* was reported in a 79-year-old man with chronic lymphocytic leukemia.[133] The organism was isolated from the sputum, two sets of blood cultures, and a pleural fluid culture. Since then, *C. striatum* had been associated with several human infections and has been isolated from several types of clinical specimens. In 1994, Wolde Rufael and Cohn reported the first patient with native valve endocarditis caused by *C. striatum*.[1202] Since then, *C. striatum* has been documented as a significant agent of both native valve and prosthetic valve endocarditis and pacemaker-associated endocarditis.[103,125,259,725,727,821,1001,1106,1115] *C. striatum* is an important agent of sepsis and bacteremia in immuncompromised patients, including those with lymphoblastic lymphoma with autologous bone marrow transplantation, myelodysplasia with allogeneic bone marrow transplantation, amyotrophic lateral sclerosis, chronic renal failure, colorectal cancer, diabetes, and HIV infection.[197,719,831,1123] *C. striatum* is also a significant cause of respiratory tract infections, including community-acquired and nosocomial pneumonia, bronchitis, and empyema, particularly in those with chronic obstructive pulmonary disease.[916,1094,1205] Isolates of *C. striatum* has been recovered from patients with vertebral osteomyelitis, septic arthritis and synovitis, breast abscess, meningitis, CSF shunt infections, pancreatic abscess, peritoneal dialysis catheter exit site infection, and CAPD-associated peritonitis.[75,102,105,125,232,243,1060,1189] Evidence from studies conducted in intensive care units indicate that that *C. striatum* may occasionally be transmitted nosocomially.[534,663,831,916] *C. striatum* isolates are nonlipophilic and grow as gray-white, moist, smooth, nonhemolytic colonies with entire edges on SBA (Image Plate 14-6A). Colonies are about 1–2 mm in diameter after 24 hours' incubation. Pyrazinamidase and alkaline phosphatase are produced, and urea, esculin, and gelatin are not hydrolyzed.[723] Most strains reduce nitrate and produce acid from glucose, sucrose, fructose, and galactose only (Image Plate 14-6B). *C. striatum* strains produce lactic and succinic acids from glucose, which is helpful in differentiating isolated from *C. amycolatum*. A 1995 examination of 31 clinical isolates found that all strains were susceptible to both imipenem and vancomycin; most strains were susceptible to ampicillin, cephalosporins, and aminoglycosides, and most were resistant to clindamycin, erythromycin, and tetracycline. However, this organism has demonstrated increasing resistance to antimicrobial agents since that time. Several case reports have described isolates of *C. striatum* that are multiresistant to β-lactams (including penicillin, ampicillin, ceftriaxone, cefotaxime, and cefipime), macrolides, tetracyclines, fluoroquinolones.[105,197,534,725,821,916,1094,1106] Susceptibility to the carbapenems (imipenem, meropenem) is variable.[831] The *C. striatum* isolate from the patient with endocarditis described by Mashavi and colleagues was susceptible only to vancomycin.[727] *C. striatum* isolates are usually susceptible to vancomycin, rifampin, linezolid, tigecycline, and daptomycin.[725,967,1001,1094] A *C. striatum* isolate from a a 56-year-old man with endocarditis, which was complicated by diabetes mellitus and end-stage renal disease, demonstrated the presence of a mixed daptomycin-susceptible and -resistant population by Etest.[1095] The susceptible subpopulation had a daptomcyin MIC of < 0.094 μg/mL, while the resistant subpopulation had a daptomycin MIC of >256 μg/mL by broth microdilution testing. The resistant subpopulation emerged after the patient had received daptomycin for two 6-week treatment courses.
Corynebacterium sundsvallense	*C. sundsvallense* has been recovered from blood cultures, a vaginal specimen, and a groin-wound culture.[217] The Gram's stain appearance of this organism is unique in that knobs or "bulges" may be noted on the ends of some of the bacilli. The organism is nonlipophilic, and produces buff-to-yellow, sticky, adherent colonies on SBA. The organism slowly ferments glucose, maltose, and sucrose, but not lactose, mannitol, ribose, xylose, or amygdalin. Nitrate is not reduced and esculin is not hydrolyzed, but urease is produced and the α-glucosidase reaction is positive. Lactic and succinic acids are the major products of glucose fermentation. Antimicrobial susceptibility data on this organism are not available.
Corynebacterium thomssenii	The species description of this organism is based on two similar isolates that were recovered from pleural fluid specimens of a 56-year-old man with chronic renal failure, stroke and pneumonia.[1246] *C. thomssenii* is a slow-growing, nonlipophilic organism that produces sticky, adherent colonies that

882

	are less than 0.5 mm in diameter even after 48 hours incubation. The organism is urease-positive, DNase-positive, and both nitrate and esculin hydrolysis-negative. Acid is slowly produced from glucose, maltose, and sucrose. Unlike all other *Corynebacterium* species, isolates of this species are strongly *N*-acetyl-β-glucosaminidase-positive, producing the API Coryne profile number 2121125. Isolates of *C. thomssenii* are susceptible to ampicillin, cefazolin, gentamicin, erythromycin, clindamycin, tetracycline, ciprofloxacin, rifampin, and vancomycin; isolates areresistant to aztreonam, cefetamet, ceftibuten, and fosfomycin.
Corynebacterium timonense	This species was isolated from five of six sets of blood cultures from a patient with pacemaker-associated endocarditis.[745] This species is nonlipophilic and forms shiny yellow colonies 1–2 mm in diameter after 24 hours' incubation. Esculin is weaky hydrolyzed, but gelatin and urea are not hydrolyzed. On the API Coryne, pyrazinamidase and alkaline phosphatase are positive, and acid is produced from glucose and ribose, but not from maltose, sucrose, lactose, mannitol, xylose, or glycogen. This isolate was susceptible to amoxicillin, doxycycline, gentamicin, ofloxacin, clindamycin, trimethoprim-siulfamethoxazole, and rifampin, and resistant to erythromycin. The organism is named for Hopital de la Timone, the hospital in Marseille, France where the type strain was isolated and characterized.
Corynebacterium tuberculostearicum	*C. tuberculostearicum* is a species that was described years ago, but never validly published. This organism was formally proposed as a new species in 2004 based on isolates from clinical specimens (e.g., bone marrow, lymph nodes, blood, urethral specimen, skin, peritoneal fluid), foods (canned tuna), and the environment.[342] This lipophilic species is urease-, esculin-, and gelatin hydrolysis-negative. Acid is produced from glucose and ribose, but not from mannitol, sorbitol, lactose, xylose, glycogen, starch, or inulin. Acid production from maltose, sucrose, trehalose, and *N*-acetyl-glucosamine is variable. API Coryne biocodes (6100324, 6100325, 7100325, 6100305, 2100325) correspond to *Corynebacterium* CDC group G in the API profile index.
Corynebacterium tuscaniae	This species is based on a single isolate recovered from six sets of blood culture from an 85-year-old woman with gastric carcinoma and endocarditis.[929] This species possesses mycolic acid in its cell walls and is pyrazinamidase- and alkaline phosphatase-positive. Urease is not produced and esculin, gelatin, and hippurate are not hydrolyzed. Acid is produced from glucose and maltose, but not from, ribose, lactose, xylose, mannitol, sucrose or glycogen. The API Coryne profile number for this speies is 2100124. The organism name refers to Tuscany, the Italian region where the strain was isolated.
Corynebacterium ulcerans	*C. ulcerans* is a nonlipophilic member of the "*C. diphtheriae* group," along with *C. diphtheriae* and *C. pseudotuberculosis*.[938] Most *C. ulcerans* isolates (and some isolates of *C. pseudotuberculosis*) produce diphtheria toxin. In one study, 25 of 37 *C. ulcerans* strains and 1 of 14 *C. pseudotuberculosis* strains produced positive Elek tests for diphtheria toxin.[441] In addition, all the Elek test-positive strains and two Elek test-negative strains produced positive signals when hybridized with a DNA probe for the tox structural gene for diphtheria toxin. Restriction endonuclease fragment analyses have shown that *C. diphtheriae* and *C. ulcerans* strains share considerable homology on Southern blots; these homologous fragments include the integration site for the β family of corynephages. Wong and Groman also demonstrated that the diphtheria toxins produced by strains of *C. ulcerans* and *C. pseudotuberculosis* were similar in molecular weight and immunological structure, in enzymatic ADP-ribosylating activity, and in the regulation of their synthesis by iron.[1207] In the United Kingdom, a survey of 102 patients with infections caused by toxigenic corynebacteria, 59 were due to toxigenic *C. ulcerans*.[1172] *C. ulcerans* causes mastitis in cattle, nonhuman primates, and other animals, and has been recovered from unpasteurized cows' milk and other dairy products.[128] *C. ulcerans* has also been isolated from cats and dogs, and the ribotypes of feline and canine isolates suggest that these animals may be reservoirs for human infections.[93,239,275,639] Human infections have generally occurred in rural areas in individuals with histories of animal exposure or ingestion of raw dairy products. *C. ulcerans* has been isolated from patients with illnesses indistinguishable from classical diphtheria, with and without the presence of both cardiac and neurologic sequelae.[477,572,889,1109] Severe pulmonary infections due to *C. ulcerans* have been reported in immunocompromised and immunocompetent hosts.[1098] In 1996, a case of respiratory diphtheria due to toxigenic *C. ulcerans* was reported in a 54-year-old woman from Terre Haute, Indiana.[181] The patient, who had never been immunized against diphtheria, was treated with ceftriaxone, erythromycin, and 40,000 international units (IU) of equine diphtheria antitoxin with a rapid clinical response. Culture of clinical specimens (throat swabs and fragments of diphtheritic pseudomembrane) confirmed the presence of *C. ulcerans* and toxigenicity of this isolate was demonstrated by both the Elek immunoprecipitation assay and by a PCR assay for diphtheria toxin. Toxin-producing isolates of *C. ulcerans* have also caused cases of cutaneous "diphtheria".[1171,1172] In 2002, Wellinghausen and colleagues[1192] described a fatal case of necrotizing sinusitis in an elderly man due to toxigenic *C. ulcerans*. *C. ulcerans* has also

883

	been documented as a cause of peritonitis related to continuous ambulatory peritoneal dialsysis.[597] Colonies of *C. ulcerans* are gray-white, dry, and waxy appearing with a slight diffusely β-hemolytic area under and surrounding individual colonies. The organism is nonlipophilic and colonies are 1–2 mm in diameter after 24 hours of incubation. *C. ulcerans* is pyrazinamidase-negative and positive for alkaline phosphatase and urease production. Acid is produced from glucose, maltose, mannose, arabinose, ribose, and glycogen. Like *C. pseudotuberculosis*, *C. ulcerans* is reverse CAMP test-positive and produces propionic acid as a product of glucose fermentation. *C. ulcerans* isolates are susceptible to penicillin, ampicillin, cephalothin, erythromycin, clindamycin, tetracycline, and gentamicin.
Corynebacterium urealyticum	*C. urealyticum* was formerly called CDC coryneform group D-2; in 1992, the name *Corynebacterium urealyticum* was formally proposed and adopted.[872] Normally a saprophytic organism found on the skin, this species has been associated with acute and chronic urinary tract infections, urolithiasis, renal cysts, and ureteral stenosis.[291,1021,1049] This organism causes similar infections in dogs and cats as well.[59,138] *C. urealyticum* is highly associated with a clinical condition called alkaline encrusted cystitis. The latter is a chronic condition seen in compromised hosts with preexisting bladder injury, where ulcerative inflammation results from the deposition of ammonium-magnesium phosphate crystals (struvite and apatite crystals) on the bladder wall.[261,554] This condition is caused by organisms that are able to rapidly split urea, such as *Proteus* species. Complicated urinary tract infections and pyelonephritis caused by *C. urealyticum* are seen primarily in immunocompromised patients and in kidney transplant patients with postsurgical complications.[14,291,349,690,835] In addition to its role as a urinary tract pathogen, *C. urealyticum* has also been isolated occasionally from blood cultures as a cause of bacteremia, and native and prosthetic valve endocarditis.[308,1049] Other infections associated with *C. urealyticum* include pericarditis, osteomyelitis, wound/soft tissue infections, and nosocomial infecti ons.[201,318,335,814,958,1046,1047] *C. urealyticum* is a lipophilic coryneform that grows slowly on SBA, producing small (<0.5 mm in diameter after 24 hours incubation) gray, nonhemolytic colonies on SBA. It is pyrazinamidase and alkaline phosphatase-positive, asaccharolytic, and rapidly urease-positive. Urea agar slants begin to turn positive immediately upon inoculation. Molecular approaches for detection and identification of *C. urealyticum* have also been described.[1021] *C. urealyticum* strains are usually multidrug-resistant to β-lactam, aminoglycoside, and macrolide antimicrobial agents; occasional strains may be β-lactam-susceptible.[337,418,974,1242] Fluoroquinolones show irregular activity against *C. urealyticum*. Isolates that are resistant to the quinolones and rifampin may be selected during therapy with these drugs. *C. urealyticum* strains are generally susceptible to tigecycline, linezolid, rifampin, quinupristin/dalfopristin and vancomycin.[337] *C. urealyticum* is known to produce biofilms, and studies on the antimicrobial susceptibility of *C. urealyticum* have shown that organisms grown in biofilms have higher MICs and MBCs to fluoroquinolones and vancomycin, than planktonic (free-floating) organisms.[1045] MICs of erythromycin for biofilm-trapped organisms were more than 8,000 times higher than those for planktonic organisms. This ability may contribute to the difficulties encountered in eradicating the organism from patients with chronic *C. urealyticum* urinary tract involvement.
Corynebacterium ureicelerivorans	The species description of this organism is based on a single isolate that was recovered from a blood culture.[1224] Subsequently, this organism was isolated from blood cultures of five patients with underlying diseases (e.g., colon cancer, diabetes, acute abdomen, leukemia, diverticulitis) and from ascites fluid of a patient with cirrhosis.[337] *C. ureicelerivorans* is a lipophilic species that is rapidly and strongly urease-positive (positive reaction in 60 seconds) and hippurate-positive. Esculin and gelation are not hydrolyzed and nitrate is not reduced. Acid is formed from glucose on the API Coryne after 72 hours, with weak acidic reactions being noted for ribose and xylose. For most isolates, the API biocode number is 6101104 after 72 hours, which fits the profile of *C. bovis*. *C. ureicelerivorans* is susceptible to β-lactams, gentamicin, rifampin, tetracycline, linezolid, and vancomycin and often resistant to the fluoroquinolones, erythromycin, clarithromycin, azithromycin, and clindamcyin.
Corynebacterium xerosis	Substantial data now indicate that most clinical isolates of "*C. xerosis*" are actually *C. amycolatum* (see discussion of this organism above).[372] True *C. xerosis* produce granular, yellowish colonies, contain mycolic acids in their cell walls, are LAP- and α-glucosidase-positive, and produce lactic acid from glucose fermentation, while strains of *C. amycolatum* produce dry waxy, whitish-gray colonies, lack mycolic acids, are negative or weakly positive for LAP, are α-glucosidase-negative and produce propionic acid from glucose fermentation.[372,1185] Unlike *C. striatum*, true *C. xerosis* isolates do not hydrolyze tyrosine and ferment sugars slowly (72–96 hours). The literature contains several case reports regarding *C. xerosis* as the etiologic agent in a variety of types of human infections. In these reports, the isolates were oftem found to be multiply-resistant to antimicrobial agents. These multiresistant strains were actually *C. amycolatum* and not *C. xerosis*, since bona fide strains of the latter species are quite rare and are

884

	known to be broadly susceptible. Because of its infrequent isolation in the clinical laboratory, *C. xerosis* was deleted from the version #2 of the API Coryne data base. However, certain biocodes—2110325 and 3110325—do correspond to true isolates of *C. xerosis*.[838] True human infections with *C. xerosis* are rare and the organism has been recovered from clinical specimens obtained from animals.[838,1152] *C. xerosis* strains are susceptible to most antimicrobial agents.
Corynebacterium Group F1	CDC coryneform group F1 is a lipophilic, fermentative coryneform that can be separated into two phenotypically indistinguishable DNA homology groups. As a urease-positive, lipid-requiring coryneform, CDC group F1 closely resembles the newly named lipid-requiring species *C. macginleyi*.[936] However, CDC group F1 strains are pyrazinamidase-positive, alkaline phosphatase-negative, and ferment glucose, maltose, and sucrose, while *C. macginleyi* strains are pyrazinamidase-negative, alkaline phosphatase-positive, and ferment glucose and sucrose but not maltose. CDC coryneform group F1 has been recovered most frequently from the urogenital tract. In 1992, an isolate of the CDC group F1 was reported from a 40-year-old man with struvite stone formation.[281] The organism was present in the urine in significant numbers ($>10^8$ cfu/mL) and was susceptible to tetracycline. Treatment of the patient with doxycycline resulted in resolution of the infection and cessation of stone formation.
Corynebacterium group G	CDC coryneform group G has been isolated from vitreous humor specimens, blood, cerebrospinal fluid, and the genitourinary tract.[936] Isolates belonging to group G are lipophilic, and growth is stimulated Tween-80 (Image Plate 14-6C and 14-6D). In 1983, Austin and Hill reported a 40-year-old man with prosthetic valve endocarditis, which unfortunately was fatal, caused by a CDC group G microorganism.[54] The isolate was susceptible to ampicillin, cephalothin, cefamandole, cefoxitin, gentamicin, and vancomycin. Group G coryneforms were also isolated from blood cultures of a 74-year-old man undergoing maintenance hemodialysis due to chronic renal failure.[583] This isolate was also uniformly susceptible to antimicrobial agents.
Corynebacterium groups F2 and I	CDC groups F2 and I have been shown to correspond to strains of *C. amycolatum*.[323,708,1185]

with additional tests being required for correct identification of 55.1% of all strains tested. Only 5.6% of isolates were not identified and 3.8% were misidentified. The current API Coryne database is found at apiweb.biomerieux.com is version 3. The API Coryne requires a heavy inoculum to prevent false-negative reactions and longer incubation may be necessary to detect carbohydrate fermentation reactions.[378] Reports on new *Corynebacterium* species often include API Coryne tests as part of the species description. Seven-digit API biocodes only provide identifications for species in the database, and new species may be misidentified unless additional tests are performed. However, some newer species do generate unique biocodes.

RapID CB-Plus. The RapID CB-Plus employs the cuvette format similar to other Remel identification kits and includes 18 single-test wells. To inoculate the system, a suspension of the organism grown on 5% SBA (tryptic soy, Columbia, or BHI base) equivalent to a #4 McFarland turbidity standard is prepared in 2 mL of RapID inoculation fluid. The suspension is poured or pipetted into the cuvette and all 18 wells are simultaneously inoculated by manual manipulations of the cuvette. The system is incubated for 4 to 6 hours at 35°C to 37°C in a non-CO_2 incubator. Nitrate reagents A and B are added to the NIT well, and a second reagent (RapID CB-Plus Reagent) is

added to the arylamidase test wells. Thirty seconds to 1 minute after reagent addition, the color reactions in the wells are read and a numeric microcode is generated. The RapID CB-Plus Code Compendium is consulted for the identification. Evaluations of RapID CB-Plus have reported that the kit correctly identifies 88.5% to 95% of *Corynebacterium* species, particularly those species commonly encountered in the clinical laboratory (i.e., *C. amycolatum, C. jeikeium*, *C. striatum*, *C. urealyticum*, *C. minutissimum*, *C. pseudodiphtheriticum,* and CDC group G).[379,528] Isolates of some newly described taxa (e.g., *Dermabacter hominis*, *Microbacterium* species, *Turicella otitidis*, *Cellulomonas* species, *Brevibacterium casei*, and *Arthrobacter cumminsii*) were also correctly identified. Difficulties with this system were related to the interpretation of some of the carbohydrate acidification and aminopeptidase reactions.

Vitek 2 Anaerobe/*Corynebacterium* Card. The ANC card is a 64-well biochemical test card that is used with the Vitek 2. The card is inoculated by the Vitek 2 instrument and incubation takes place within the machine. Identifications are usually available within 6 hours after inoculation of the card. The database of the ANC card includes corynebacteria, (*C. amycolatum*, *C. diphtheriae*, *C. jeikeium*, *C. pseudodiphtheriticum*, *C. striatum*, *C. ulcerans*, and *C. urealyticum*), some *Actinomyces* species (*A. israelii*, *A. meyeri*), and *Arcanobacterium* species (*A. haemolyticum*, *A. pyogenes*) in addition to clinically significant gram-positive and gram-negative anaerobic bacteria. Evaluations indicate that the Vitek 2 ANC card is able to adequately identify those corynebacteria that are included in the database.[915]

MS) has also been used to identify *Corynebacterium* species, including *C. diphtheriae*. Alatoom and colleagues[20] evaluated the Bruker Biotyper MALDI-TOF MS for identification of 92 clinical *Corynebacterium* species isolates in comparison with 16S rRNA and *rpoB* gene sequencing. Of these 92 isolates, 80 (87%) were correctly identified to species level, except for *C. aurimucosum* strains, which were misidentified as the closely related species, *C. minutissimum*. In another study,

MALDI-TOF MS was able to rapidly identify all 90 strains of *C. diphtheriae* tested; these investigators proposed a testing algorithm using MALDI-TOF MS for rapid identification, followed by real-time PCR for *tox* gene detection, and the Elek test for detecting production of diphtheria toxin.[616] MALDI-TOF MS has also been used in individual case reports to confirm the identity of isolates that were provided by conventional biochemical testing or by the API Coryne identification kit.[1201]

Antimicrobial Susceptibility Testing of Corynebacterium *Species and Coryneform Bacteria*

CLSI first addressed antimicrobial susceptibility testing of coryneform bacteria in their 2005 standard for testing of infrequently isolated or fastidious bacteria, which was published in its second edition in 2010.[214] The approved standard is a microbroth dilution procedure that uses cation-adjusted Müeller–Hinton broth with lysed horse blood (2.5% to 5% v/v). For testing of daptomycin, the medium must be supplemented with calcium (50 μg/mL). The inoculum is prepared from a direct colony suspension that is equivalent to a 0.5 McFarland turbidity standard. Microbroth dilution panels are incubated at 35°C in ambient air for 24 to 48 hours. Results for antimicrobial agents that demonstrate resistance can be reported after 24 hours, while isolates demonstrating susceptible results for the β-lactams should be incubated for an additional 24 hours before reporting the results. The agents recommended for primary testing include penicillin, erythromycin, gentamicin, and vancomycin, but breakpoints defining susceptible, intermediate, and resistant categories are available for certain cephalosporins, carbapenems, gentamicin, erythromycin, ciprofloxacin, tetracycline, doxycycline, clindamycin, trimethoprim-sulfamethoxazole, rifampin, quinupristin-dalfopristin, and linezolid. Isolates that should be tested include those from sterile body sites, deep-tissue specimens, and prostheses-associated infection.

Members of the Genus Corynebacterium *Isolated From Humans*

The genus *Corynebacterium* contains species that have been isolated from human clinical specimens, animals, and the environment. *C. diphtheriae*, a classical pathogen, is the cause of diphtheria. Other species, such as *C. jeikeium*, *C. striatum*, *C. pseudodiphtheriticum*, and *C. urealyticum* are isolated more frequently than the other *Corynebacterium* species and behave primarily as opportunistic agents in immunocompromised and/or debilitated patients.[318] *C. amycolatum* is the most commonly isolated species in the clinical laboratory and may represent a skin contaminant or a significant agent of infection (Image Plate 14-3C).[263,284,579] Box 14-4 describes the clinical significance of *Corynebacterium* species that have been isolated from human clinical specimens and includes additional information on cultural

characteristics of these organisms. Table 14-6 presents the phenotypic biochemical characteristics of *Corynebacterium* species isolated from human clinical specimens.

Corynebacterium diphtheriae

Epidemiology. *C. diphtheriae* is the cause of the classic disease diphtheria. This infection is relatively uncommon in the United States, although it is still seen in developing countries. The frequency of infection in the United States has decreased markedly since the introduction and widespread use of effective diphtheria toxoid vaccines and the introduction of universal childhood immunization in the late 1940s. During the late 1960s and into the 1970s, diphtheria was still endemic in the Pacific Northwest and in the southwestern United States, with the last major outbreak of diphtheria in the United States occurring in the Seattle, Washington area in the 1970s.[198] Between the early 1980s through 2010, only 55 cases of diphtheria were reported to the CDC.[113] The importation of toxigenic *C. diphtheriae* from certain regions of developing countries where diphtheria remains endemic poses a constant threat and has accounted for most cases of diphtheria in industrialized countries in recent years. In developing countries, implementation of the World Health Organization's Expanded Program on Immunization for children during the 1970s was successful in achieving high levels of vaccination. With the passage of time, however, large portions of the populations targeted in earlier vaccination efforts became susceptible to infection due to waning immunity. During the 1980s and 1990s, sporadic outbreaks of diphtheria were reported in Germany, Sweden, China, Thailand, the Sudan, Jordan, and Ecuador. Epidemic diphtheria re-appeared in the New Independent States (NIS) of the former Soviet Union beginning in 1990 in the Russian Federation.[1162] This event occurred in part from unnecessary vaccination contraindications in regions of the NIS that resulted in inadequate vaccination coverage for children. Large population movements during the dissolution of the former Soviet Union resulted in disruptions of health services, and inadequate resources to maintain supplies of vaccine and antitoxin set the stage for the emergence and spread of diphtheria.[180] By 1994, all NIS regions were involved in the emergent epidemic, and more than 90% of all diphtheria cases reported from 1990 through 1995 were from this part of the world.[181] By 1998, the Newly Independent States of the former Soviet Union reported more than 150,000 cases of diphtheria to the WHO in Geneva.[283,410,592,805] Intensive control measures, including mass vaccination campaigns targeting persons aged 23 years or more, plus efforts to administer a four-dose DTaP series by age 2 years to more than 95% of the eligible populations has succeeded in bringing the epidemic under control in most regions.[1173,1240] More recently, outbreaks of diphtheria have occurred in Haiti and the Dominican Republic, and recent cases diagnosed in the United States have occurred in travelers returning

from Haiti.[185] Despite the success of widespread immunization, diphtheria continues to be a

891

lethal, resurgent infectious agent in many parts of the world, including Africa (Algeria, Angola, Egypt, Ethiopia, Guinea, Niger, Nigeria, Sudan, Zambia, other sub-Saharan countries), Central and South America (Bolivia, Brazil, Columbia, Dominican Republic, Ecuador, Haiti, Paraguay), Europe (Albania, Armenia, Azerbaijan Belarus, Estonia, Georgia, Kazakhstan, Kyrgyzstan, Latvia, Lithuania, Moldova, Russia, Tajikistan, Turkmenistan, Ukraine, Uzbekistan), Asia/South Pacific (Bangladesh, Bhutan, Myanmar, Cambodia, China, India, Indonesia, Laos, Malaysia, Mongolia, Nepal, Pakistan, Papua New Guinea, the Philippines, Thailand, Vietnam), and the Middle East (Afghanistan, Iran, Iraq, Saudi Arabia, Syria, Turkey, and Yemen).

While historical evidence suggests that humans constitute the sole reservoir of *C. diphtheriae*, recent investigations have identified nontoxigenic *C. diphtheriae* as a cause of infections in animals. *C. diphtheriae* was isolated from both ears of a cat with bilateral otitis, ataxia, and anorexia.[457] An investigation of the cat's household and the veterinary staff caring for the animal yielded another isolate from the ear of a second cat. All the strains produced black colonies with brown halos on Tinsdale agar, produced the same identification code on the API Coryne, belonged to biotype belfanti, were sucrose fermentation-negative, and did not produce diphtheria toxin. PCR testing demonstrated the presence of the gene for the toxin A subunit, but not the gene for the toxin B subunit. The isolates were susceptible to all agents, including ampicillin, the cephalosporins, the fluoroquinolones, the carbapenems, erythromycin, clindamycin, gentamicin, daptomycin, linezolid, and vancomycin. Sequencing of the *rpoB* gene suggested that these feline strains may represent a novel *C. diphtheriae* subspecies.[457] *C. diphtheriae* biotype *belfanti* has been isolated from a bovine skin lesion and biotype *gravis* was isolated from a wound of a horse.[238,485]

Diphtheria Immunizations. Currently, the Immunization Practices Advisory Committee of the Public Health Service recommends immunization with DTaP (diphtheria toxoid, tetanus toxoid, and pertussis acellular vaccine) for all persons at least 6 weeks old but less than 7 years old. The vaccination series consists of three doses administered at 2, 4, and 6 months of age, with a minimum of 4 weeks between doses. The first booster dose is given at 15 to 18 months of age and should be administered at least 3 months after the third DTaP dose. A second booster dose is recommended for children ages 4 to 6 years, and adolescents ages 11 through 18 years should be given a single booster dose of TdaP if they have completed the primary immunization series. After this, boosters of Td vaccine should be given at 10-year

intervals.[188] Travelers to diphtheria-endemic areas should be up to date with all immunizations, and information on inoculations for travel can be found at http://www.cdc.gov/travel. In addition, persons convalescing from clinical diphtheria should also receive toxoid immunization since clinical infection does not necessarily induce protective levels of antitoxin. Because of the failure of most adults to receive booster injections, a susceptible adult population currently exists; 10% to 60% of individuals greater than 30 years of age have inadequate levels of circulating antibodies against diphtheria toxin. Because of this, outbreaks of diphtheria continue to be reported.

Diphtheria: Pathogenesis and Clinical Presentation. *C. diphtheriae* is the classical prototype of the toxigenic microorganism. Virulence of the organism is related almost entirely to the production of diphtheria toxin. Diphtheria toxin is a 58,342 Da polypeptide containing 535 amino acid residues. The toxin is composed of two fragments, fragment A (21,500 Da) and fragment B (37,200 Da). Fragment B, containing the receptor binding/translocation domains, allows the passage of the toxin molecule through the cell membrane of the target cells. Fragment A, the biologically active part of the molecule, catalyzes the transfer of the adenosine diphosphate ribose (ADPR) moiety from nicotinamide adenine dinucleotide (NAD) to elongation factor 2 (EF-2), a soluble protein that is required for the translocation of peptidyl-transfer RNA from the acceptor to the donor site on the eucaryotic ribosome. This adenoribosylation inactivates EF-2 and protein synthesis in the affected cell is inhibited. The structural gene (*tox* gene) that codes for diphtheria toxin resides on the DNA of a corynephage (bacteriophage) called the β-corynephage.[512] Upon infection of a *C. diphtheriae* strain with the *tox* + corynephage, the nucleic acid containing the *tox* gene becomes integrated into the bacterial chromosome (lysogeny) and replicates with chromosomal replication. Most nontoxigenic isolates of *C. diphtheriae* and most *tox*$^-$ corynephages do not contain any detectable *tox*-related DNA sequences. Only *C. diphtheriae* strains that are lysogenized by a β-phage containing the *tox* gene are capable of producing diphtheria toxin. *C. ulcerans* and *C. pseudotuberculosis* (the "*C. diphtheriae* group" organisms) are also capable of carrying the β corynephage and producing diphtheria toxin.

Respiratory tract diphtheria is primarily transmitted among humans via direct contact or by sneezing or coughing. Carriage of the organism on the skin and asymptomatic carriage of the organisms in the upper respiratory tract are common sources of transmission to other susceptible individuals. The onset of disease is insidious, and during an incubation period of 2 to 7 days, the organism multiples locally in the posterior naso- and oropharynx. Initial symptoms consisting of a sore throat, difficulty swallowing, malaise, and a low-grade fever may be present during this time. As infection progresses, there is an accumulation of organisms, fibrin, and

inflammatory cells to produce the characteristic grayish white **diphtheritic pseudomembrane**, which may eventually cover the tonsils, pharynx, larynx, and posterior nasal passages (Image Plate 14-3F).[455] Extension of the pseudomembrane anteriorly may lead to involvement of the soft palate and the uvula. In severe cases, the pseudomembrane may extend into the trachea and bronchi, resulting in airway obstruction. The pseudomembrane is strongly adherent to the oropharyngeal mucosa, and attempts to remove portions of pseudomembrane usually result in bleeding. Cervical and submandibular lymphadenopathy is also usually present. Further extension of the pseudomembrane into the posterior nasopharynx and nasal passages is associated with a serosanguinous or purulent discharge from the nose that is highly infectious. Middle ear involvement may result from contiguous extension of the infectious process. Extension of respiratory tract infections to the skin of the face (i.e., nose, ears, cheeks) and neck also occurs occasionally. Inoculation of the organisms into the eyes may lead to conjunctivitis with

892

or without involvement of the cornea. Satellite lesions may also occur in the esophagus, stomach, or lower airways.

Locally multiplying bacteria synthesize and release diphtheria toxin, which is absorbed systemically. The toxin has direct toxic effects on the heart, the central and peripheral nervous system, liver, and kidneys. A diffuse myocardiopathy may result in 20% to 70% of patients. These symptoms may appear insidiously or cataclysmically, resulting in circulatory collapse and acute congestive heart failure. Neurologic complications and neuropathies may appear in 20% to 75% of patients and usually correlate with the severity of the illness. These complications may initially include paralysis of the soft palate and posterior pharyngeal wall, followed by oculomotor and ciliary paralysis. The latter contributes to the risk of oropharyngeal aspiration and pneumonia. Fatty degenerative changes and focal necrosis in the kidneys, liver, and adrenals may also complicate severe infections. In general, the myocardiopathy and neuropathy occur later and are less severe following cutaneous diphtheritic infections than those following respiratory tract infection. Death may ensue from cardiac failure or paralysis of the diaphragm.

C. diphtheriae may also cause a primary cutaneous infection, where toxin is also absorbed systemically. Skin lesions may resemble several other skin conditions, including folliculitis, impetigo, pyoderma, abscess, or seborrheic dermatitis. Other pyogenic organisms, such as *Streptococcus pyogenes*, may be co-isolated with *C. diphtheriae*. Cutaneous diphtheria has also been reported following the bites of insects, such as spiders, infection of preexisting wounds (e.g., surgical wounds, pyoderma, eczema, impetigo, dermatitis) and following tattooing.[455,760,995] An

ulcerative lesion called **ecthyma diphtheriticum** is the initial lesion. This lesion begins as a vesicle or pustule containing a straw-colored or serosanguinous fluid. After this material drains, the lesion becomes a punched-out ulcer a few millimeters to a few centimeters in size. The margins of the lesion are elevated and undermined. Diphtheritic skin lesions are usually painful and subsequently become covered with a dark, adherent pseudomembranous eschar or scab. This pseudomembrane eventually falls off, leaving a beefy, hemorrhagic base that oozes serosanguinous fluid. As the initial lesion develops, the surrounding skin becomes red and edematous, with the formation of satellite bullae surrounding the ecthyma diphtheriticum lesion. Most of the cutaneous lesions are on the arms, hands, feet or lower legs. Although cutaneous lesions are much less likely to cause serious systemic toxicity, they do pose a significant risk of spread to the environment and to other individuals. Lesions are often co-infected by other pathogens (e.g., *S. aureus*, β-hemolytic streptococci).

Reports of severe infections caused by nontoxigenic *C. diphtheriae* have increased substantially since the late 1980s and into the present. This increase has been noted in Canada, throughout Europe (including England, Wales, Poland, France, Italy, Germany, Switzerland), and Australia.[357,448,693,848,901,945] Isolates involved in these infections are often clonal (i.e., have the same multilocus sequence type [MLST]) Infections include cutaneous and wound infections, bacteremia, and endocarditis. Cutaneous infection with nontoxigenic *C. diphtheriae* have been found particularly among homeless persons in urban areas, and are associated with homelessness, intravenous drug use and alcoholism.[448,693,848] Skin lesions are characterized by chronic, weeping, non-healing ulcers that are often co-infected with other skin and soft tissue pathogens. In a study of cutaneous infections performed in Australia, cultures from more than 50% of patients grew both *S. aureus* and β-hemolytic streptococci along with *C. diphtheriae*.[421] Nontoxigenic bloodstream isolates are usually biotype *gravis* or *mitis*, and, in regions where outbreaks have occurred, ribotyping and MLST have demonstrated different invasive clones residing in each outbreak region (e.g., ST130 in France, ST82 in New Caledonia, MLST8 in Poland).[322,1243] Bloodstream infection with a nontoxigenic *C. diphtheriae* was reported in a 23-year-old man from Ohio with acute myelogenous leukemia.[1201] The source was not documented, but the patient had pharyngitis on presentation and also had a triple-lumen Hickman catheter in place for chemotherapy. While *C. diphtheriae* endocarditis is rare, case reports documenting endocarditis due to nontoxigenic isolates have increased substantially since 1980. *C. diphtheriae* endocarditis occurs in those with underlying or preexisting cardiac disease (e.g., congenital heart disease, mitral regurgitation, rheumatic fever), or with prosthetic valves or other hardware (e.g., aortic homograft).[742,787,986] In 2011, Muttaiyah and colleagues[787] reported on 10 cases of endocarditis due to nontoxigenic strains that occurred in Auckland, New Zealand, over a 14-year period. The patients

ranged in age from 4 to 62 years, 8 of the 10 had preexisting cardiac abnormalities, and only 3 of the 10 patients required surgical intervention for valve manipulation. Destructive native pulmonary valve endocarditis with pericardial effusion was described in a 2-year-old French Guyanese infant in which the organism was detected by sequencing of 16S rRNA from the resected valve; the *tox* gene sequence was absent.[986] The patient initially presented with a febrile prodromal illness and may have had exudative pharyngitis. Echocardiography usually demonstrates large valvular vegetations that have a propensity to embolize to the small blood vessels in the brain, spleen, and kidneys. Mycotic aneurysms and septic arthritis may develop in the course of heart valve and bloodstream infection. Surgical intervention and valve placement or replacement may be required to effect cure in some cases. An association has also been made between the use of IV drugs and *C. diphtheriae* endocarditis.[448] In these cases, cutaneous colonization or infection with nontoxigenic *C. diphtheriae* may serve as the nidus for introduction in the bloodstream. The pathogenesis of severe infections due to nontoxigenic *C. diphtheriae* is not understood at the present time. The organism is able to actively invade tissue, causing a fulminant disease involving the cardiac, endothelial, and synovial tissues.

The capacity of *C. diphtheriae* to infect a wide variety of cell types may be responsible for some of the unusual presentations of diphtheria. Havaldar and Shanthala reported a case in an 11-year-old girl who presented with abdominal pain of 2 weeks duration.[479] The child subsequently developed bilateral, conjunctival pseudomembranes that were culture-positive for *C. diphtheriae*. Intestinal involvement became apparent with the passage of bloody stools and casts of sloughed intestinal tissue. Rare infections with nontoxigenic *C. diphtheriae* have included purulent pericarditis and percutaneous nephrostomy catheter insertion site infection in an elderly patient with bladder cancer.[415,617] In the latter

case, the isolate was demonstrated to form adherent biofilms on polystyrene, polyurethane, and glass surfaces. Other infections associated with *C. diphtheriae* (e.g., septic arthritis, osteomyelitis) have been reported but are rare.[69,877]

Treatment of Diphtheria. Treatment of diphtheria involves the administration of equine antitoxin to neutralize toxin not already bound to target cells. Antitoxin should be administered as soon as a presumptive diagnosis of diphtheria is made, since the antitoxin only inactivates extracellular toxin. The amount of intravenous antitoxin administered depends on the duration and extent of the disease. Hypersensitivity to horse protein must be evaluated by skin testing and, if an immediate type hypersensitivity reaction develops, desensitization with progressively higher antitoxin

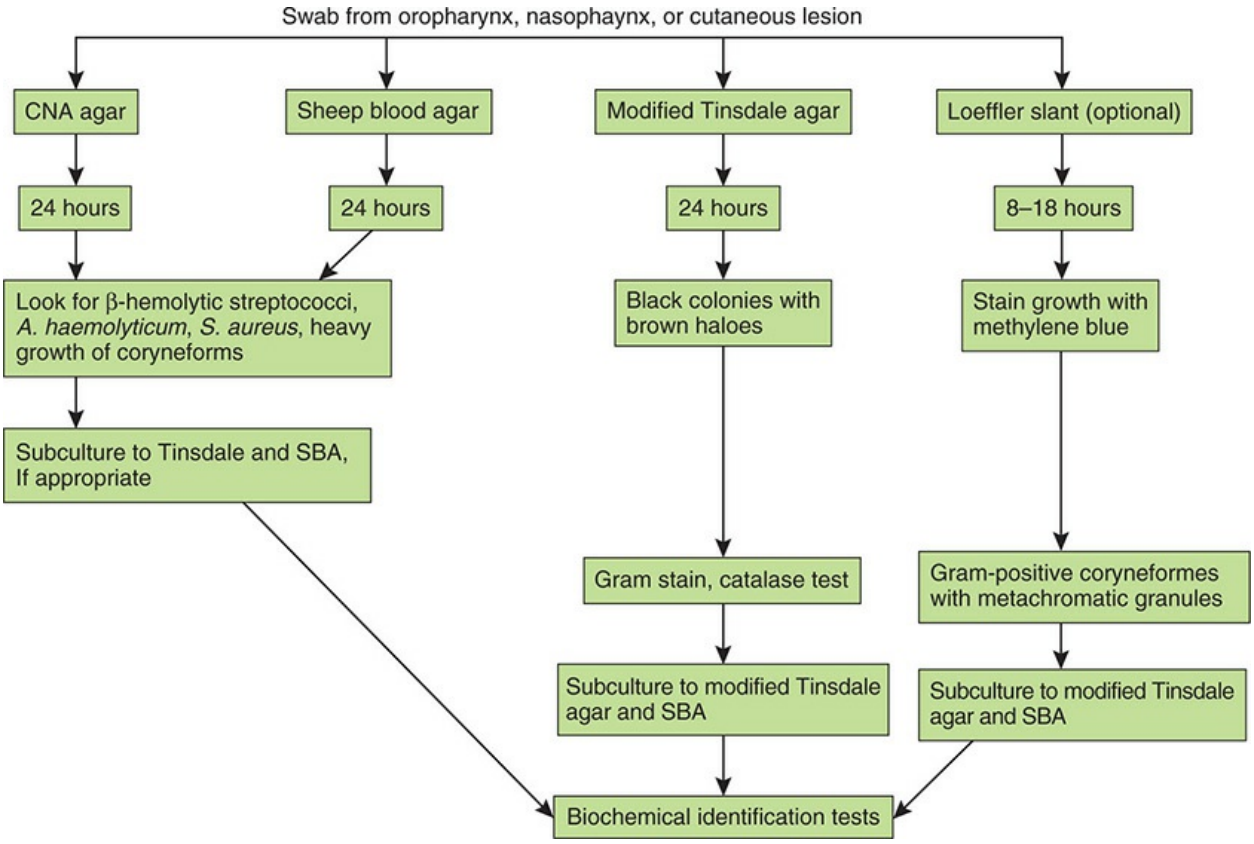
dose administration is warranted. Since diphtheria antitoxin is no longer licensed for production in the United States, the CDC must be notified to acquire the foreign product. No effective therapy is available for reversal of cardiac or neurologic involvement that might have occurred prior to specific diagnosis. Supportive care (i.e., tracheostomy or intubation, airway clearance, monitoring of cardiac function) is necessary and of extreme importance. Penicillin or erythromycin may also be administered to speed the eradication of the organisms from the respiratory tract of the patient, to decrease the toxin burden in the patient, and to prevent spread of the organism to others.[606] Procaine penicillin G (<20 lbs, 300,000 units; >600,000 units) is given intramuscularly every 12 hours, until the patient is able to swallow. Treatment is then switched to oral penicillin or erythromycin to complete a 14-day course. Both rifampin and erythromycin have been used to eradicate carriage of *C. diphtheriae* in exposed individuals.

Isolation and Identification of *Corynebacterium diphtheriae*. For the isolation of *C. diphtheriae*, swab specimens are obtained from the oropharynx, the nasopharynx, or from cutaneous lesions. Swabs should be made of Dacron and should be used to sample multiple, inflamed areas of the nasopharynx. If a pseudomembrane is present, swab specimens from beneath the membrane should be collected. Swab specimens may be sent to the laboratory in a routine semisolid transport medium such as Amies. Specimens are inoculated onto SBA and/or a Columbia CNA plate, and an agar medium containing cystine and potassium tellurite. For the cystine-tellurite medium, laboratories should use cystine-tellurite–blood agar or modified Tinsdale agar for the recovery of *C. diphtheriae* (Image Plate 14-3G).[1041] Although not routinely done, some laboratories will also inoculate a slant of Loeffler medium, which contains coagulated beef serum and egg. Methylene-blue staining of smears prepared from 8- to 18-hour growth on Loeffler medium may provide a preliminary diagnosis of diphtheria, since these organisms grow rapidly on this medium and produce distinctive, club-shaped, diphtheroidal cells containing metachromatic granules (Image Plate 14-3H) (Charts 14-1 and 14-2). However, since other coryneforms may also have this appearance on Loeffler medium, results should only be reported as presumptive and must be correlated with the clinical presentation of the patient. SBA and CNA are used to screen for β-hemolytic streptococci, *Staphylococcus aureus* and *Arcanobacterium haemolyticum*. *S. aureus* may be co-isolated with *C. diphtheriae* and will also grow as black colonies on Tinsdale medium, so the blood agar plate or CNA plate will help to assess the extent of staphylococcal growth on the tellurite-containing medium (Chart 14-3). Since some laboratories may not stock tellurite-containing medium because of infrequent requests, the inoculation of SBA and/or CNA agar will still enable the recovery of *C. diphtheriae* and other pathogenic organisms, enabling suspected coryneform isolates to be subcultured and examined further should the clinical

presentation and history of the patient (e.g., presence of a characteristic pseudomembranous oropharyngeal lesion, lack of immunizations, outbreak settings) strongly suggest *C. diphtheriae* infection.

C. diphtheriae, *C. ulcerans*, and *C. pseudotuberculosis* produce black colonies that are surrounded by brown halos on modified Tinsdale medium (Image Plate 14-3G). Black coloration of the colonies results from tellurite reductase activity, resulting in the reduction of tellurium, while the brown halos indicate cystinase activity. Other diphtheroids, staphylococci, and some streptococci may also reduce tellurite, although halos around the colonies are not generally present, so Gram's stains and catalase tests should be performed on all suspicious colonies. *C. diphtheriae* does not produce urease, so this test may be used to distinguish this organism from *C. ulcerans* and *C. pseudotuberculosis* (both urease-positive). The latter two organisms can be separated from one another by the production of acid from starch or glycogen. Deamidation of pyrazinamide to pyrazinoic acid by pyrazinamidase, a test used in mycobacteriology, is also a helpful test for distinguishing the "*C. diphtheriae*" organisms (pyrazinamidase-negative) from other *Corynebacterium* species (mostly pyrazinamidase-positive). A flow chart for detecting and presumptively identifying isolates recovered on Tinsdale medium is presented in Figure 14-1 and Figure 14-2.

C. diphtheriae may appear as four distinct colony types (biotypes) designated *gravis*, *mitis*, *intermedius*, and *belfanti*. These biotypes also differ slightly in Gram's stain morphology, certain biochemical reactions, and historically, in the severity of the disease processes they produce. *C. diphtheriae* biotype *gravis* and biotype *mitis* strains produce fairly large (1 to 2 mm in diameter at 24 hours), convex colonies with entire edges, while biotype *intermedius* strains produce small (less than 1 mm in diameter at 24 hours), blacker, dense colonies on tellurite-containing agar. Most *mitis* and some *gravis* strains are weakly β-hemolytic on SBA. All four biotypes grow as black colonies surrounded by brown halos on modified Tinsdale medium, all form gray-white, smooth, nonhemolytic colonies on SBA, and all are catalase-positive (Image Plate 14-4A). None of the biotypes have pyrazinamidase activity or produce alkaline phosphatase, and they do not hydrolyze esculin or urea. Acid is produced from glucose, maltose, fructose, galactose, mannose, and ribose, but not from sucrose, lactose, mannitol, xylose, raffinose, trehalose, glycerol, or glycogen; sucrose-fermenting strains have been reported (Table 14-6).[262] *C. diphtheriae* is included in the data bases of many manual and automated identification kits, including the API Coryne, the RapID CB-Plus, and the Vitek 2 *Anaerobe/Corynebacterium* card.[869,915] The API Coryne identification panel has been used as the primary phenotypic identification system for *C. diphtheriae* in many



■ **FIGURE 14-1** Flowchart for identification of *Corynebacterium diphtheriae*.

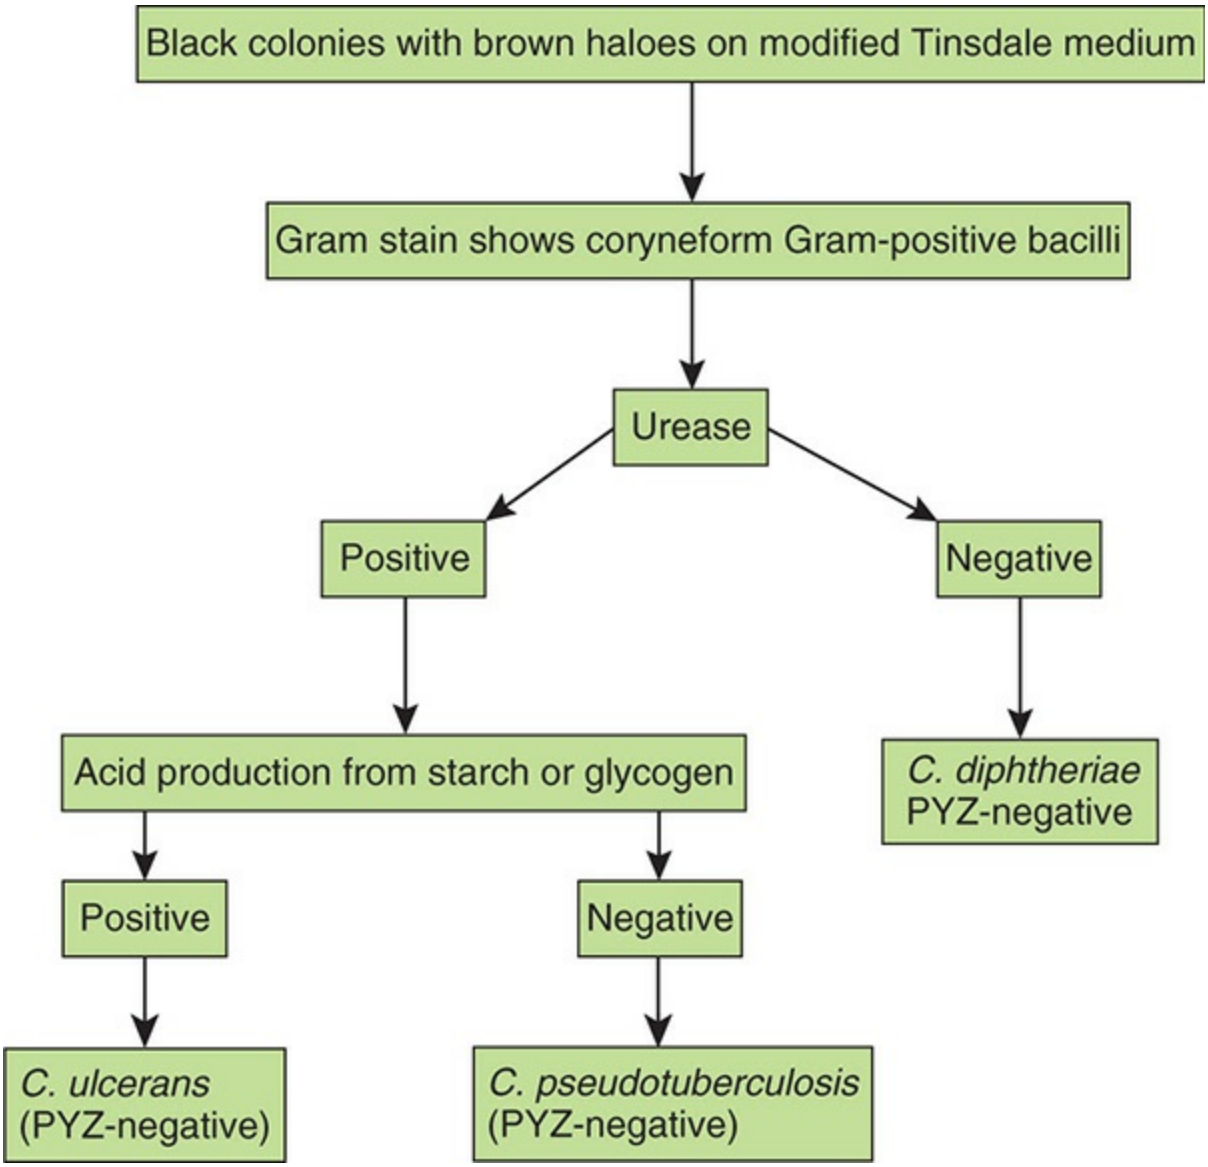
publications (see Image Plate 14-4B and 14-4C). Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) was also able to rapidly identify all 90 strains of *C. diphtheriae* tested, and these investigators proposed a testing algorithm using MALDI-TOF MS for rapid identification, followed by real-time PCR for *tox* gene detection, and the Elek test for detecting production of diphtheria toxin.[616]

Since isolation of *C. diphtheriae* is a rare event in developed countries, particularly in the United States, many laboratories do not keep the ingredients for modified Tinsdale medium or other cystine-tellurite-containing media on hand. Therefore, it is helpful to have a method to screen diphtheroidal colonies isolated on blood and chocolate agar for possible *C. diphtheriae,* particularly for those patients with compatible clinical presentations (e.g., severe pharyngitis or skin lesions) when immunization histories are not available. Pimenta and colleagues[869] evaluated the DNase test as an approach for screening. Of 91 *C. diphtheriae* isolates (37 toxigenic and 54 nontoxigenic), DNase activity was detected in 100% of the *C. diphtheriae* isolates regardless of biotype status (*mitis*, *interemdius*, *belfanti*, or *gravis*) and ability or inability to ferment sucrose. The DNase test was negative for 93.9% of 565 non-

diphtherial *Corynebacterium* species.

Once an organism is biochemically identified as a possible *C. diphtheriae*, the isolate must be tested for the ability to produce diphtheria toxin. The "gold standard" for detection of diphtheria toxin production is a Vero cell cytotoxicity assay.[301] Many laboratories that perform toxigenicity tests use the modified Elek immunoprecipitation procedure, which is an immunodiffusion method that is similar to the classical Ochterlony test. The test employs KL Virulence agar (Difco), a proteose peptone-based agar, supplemented with sterile rabbit serum or with KL Virulence enrichment (a non-serous enrichment designed for use with KL Virulence agar by Difco) and with 0.03% potassium tellurite (supplied as Bacto-Chapman tellurite solution, 1%; Difco) as the basal medium. This medium is poured into a sterile 150 mm petri plate. Before the medium solidifies, a 1 × 8 cm strip of filter paper that is saturated with diphtheria antitoxin (Bacto-KL antitoxin strips, Difco) is submerged in the medium and oriented across the diameter of the plate. After cooling, the isolate to be tested for toxin production is streaked perpendicular to the submerged antitoxin strip. Equidistant from either side of this streak, a known toxigenic *C. diphtheriae* strain and a known nontoxigenic *C. diphtheriae* strain are also streaked for control of the test. The plate is then incubated at 35°C and examined every 24 hours for 3 days. If the unknown strain is toxigenic, precipitin lines will form at 45° angles between the inoculum and the antitoxin strip. These lines will show identity with the toxigenic control *C. diphtheriae* strain. A modified Elek immunodiffusion procedures uses a centrally placed disk containing antitoxin with the test organisms being spot inoculated 7 to 9 mm away from the central antitoxin disk.[311] Such modifications enable simultaneous testing of multiple isolates and are adaptable to outbreak situations. High-quality antitoxin can be obtained from several sources (Pasteur-Merieux, Lyon, France; CNG, Peyrm, Russia; Wyeth Laboratories, Marietta, PA; Connaught Laboratories, Swiftwater, PA).

Several other methods, including enzyme immunoassays and reverse passive latex agglutination tests have also been



■ **FIGURE 14-2** Flowchart for isolation of *C. diphtheriae*.

developed for the detection of toxin production by *C. diphtheriae*.[309,310,311,1110] The rapid EIA developed by Engler and Efstratiou used equine polyclonal antitoxin as the capture antibody, and an alkaline phosphatase-labeled monoclonal antibody directed against fragment A of diphtheria toxin as the detection antibody. This method detected 87 toxigenic stains among 245 *C. diphtheriae* isolates and was completely concordant with the results from the modified Elek method.[309] In 2002, an immunochromatographic strip (ICS) assay was developed and marketed by the World Health Organization and the Program for Appropriate Technology in Health (Seattle, WA).[310] For this test, a suspension of the organism is prepared in an enrichment broth

and incubated for 3 hours. An ICS strip is placed in the tube. After 10 minutes, the strip is examined for the presence of a band that is parallel to an internal positive control present on the strip. This assay can detect as little as 0.5 ng/mL of diphtheria toxin and is 10 times more sensitive than EIA methods and 20 times more sensitive than agglutination assays.[310]

Molecular methods have also been developed for identification of *C. diphtheriae* and for the detection of the *tox* gene. For identification purposes, the most robust target is the *dtxR* gene, which is present in all toxigenic and nontoxigenic *C. diphtheriae* strains.[273,796,1117] The *dtxR* gene encodes a global regulator of metabolism in *C. diphtheriae*, and functions in the regulation of *tox* gene expression.[273,300,868] Pimenta and colleagues described a PCR assay for detection of *dtxR* in 91 *C. diphtheriae* isolates (54 nontoxigenic and 37 toxigenic) and 111 isolates of other *Corynebacterium* species. This assay was positive for all *C. diphtheriae*, and none of the 111 corynebacterial isolates, including one *C. ulcerans* and 2 *C. pseudotuberculosis* isolates that were *dtxR*-positive.[867] Most PCR assays for detection of *tox* gene sequences in *C. diphtheriae* use primers that flank sequences corresponding to the biologically active toxin fragment A.[754,795] These assays have been used for toxin detection in pure cultures of *C. diphtheriae* and directly in clinical specimens. Some studies have noted a 100% correlation between molecular-based techniques and phenotypic methods for detection of toxin production (e.g., the Elek test).[754]However, PCR methods may also detect toxin gene sequences in isolates that do not produce biologically active toxin. In one study, 6 of 55 *C. diphtheriae* isolates did not produce toxin but possessed the *tox* gene, in whole or in part.[300] Therefore, negative PCR tests on suspected isolates are helpful for excluding the diagnosis of diphtheria but may not predict phenotypic expression of toxin production. Pimenta et al.[867] designed a multiplex PCR assay that used three primer pairs for detection of the *dtxR* gene, toxin fragment A, and toxin fragment B, respectively. This approach correctly identified all 33 toxigenic and 51 nontoxigenic *C. diphtheriae*, and none of the other *Corynebacterium* isolates tested were positive for *dtxR* or tox A/tox B.[867] Complete correlation was also noted for positive PCR results for *toxA* and the Vero cell cytotoxicity assay, which is considered the "gold standard" in vitro assay for diphtheria toxin detection. In 2011, Sing et al.[1023] described a real-time PCR assay that detected the *tox* gene of toxigenic *C. diphtheriae* and the *tox* gene found in some *C. ulcerans* strains. This assay amplified the *tox* genes present in both species, and identification of the individual isolates was achieved by melting curve analysis.[1023] The CDC performs both the *dtxR* and *tox* gene PCR assays through consultation with state public health laboratories.

Many approaches have been used to develop a typing scheme for *C. diphtheriae*. Any typing scheme must be discriminatory, reproducible, and stable. Ribotyping has

been considered as the "gold standard" for molecular characterization of *C. diphtheriae*.[272,440] Ribotyping for *C. diphtheriae* was standardized in 1997 and, in 2004, ribotyping nomenclature was revised to construct a database with internationally recognized ribotype designations.[440,905] In 2008, a study was performed comparing ribotyping with three other methods for typing *C. diphtheriae* typing in order to address the global epidemiology of this important pathogen.[274] The study compared ribotyping with PFGE, random amplified polymorphic DNA (RAPD), and AFLP for their ability to discriminate between and among strains. This study found that ribotyping was still highly discriminatory and reproducible, followed by RAPD. AFLP and PFGE were less discriminatory than ribotyping and RAPD, even though the former tests were more rapid and less difficult to perform. However, a 2009 study examined 20 *C. diphtheriae* isolates from Belarus and found that all isolates belonged a single ribotype.[768,769] Application of a reverse-hybridization microassay that detected polymorphisms in two gene "spacer" sequences designated as DRA and DRB were able to subdivide these twenty isolates into three distinct clusters that were able to resolve links in organism transmission that were not explained by the ribotyping data.[769]In a 2010 study of 19 nontoxigenic isolates from Poland, ribotyping failed to show any differences among the isolates, whereas ERIC-PCR and PFGE were able to discriminate strains within different ribotypes.[1243] As more information becomes available on the molecular evolution of this bacterial agent, other typing methods or modifications to older methods are likely to be developed for global epidemiologic purposes.

C. ulcerans may cause diphtheria-like respiratory tract or cutaneous infections and, as mentioned above, can also

896

produce diphtheria toxin.[1172] Depending on the molecular test used, toxigenic *C. ulcerans* may be detected in *tox* gene PCR assays for *C. diphtheriae*. The *tox* genes from the two organisms differ in their nucleotide sequences and, consequently, the amino acid sequences of A and B toxin subunits.[1024,1025] In one study, a previously described real-time PCR assay for the A and B subunits of the *tox* gene was compared with the conventional *tox* PCR assay for the same gene.[169] These tests differed in the sets of primers and probes used in the real-time versus the conventional *tox* assay.[784,796] Elek tests were also performed with each isolate and amplification products for both PCR assays were sequenced. Of the 20 *C. ulcerans* strains examined, four were positive for both toxin subunits by both PCR assays and all four were Elek test-positive. Another eight strains were negative in all PCR assays and were Elek test-negative. Seven isolates were positive for both *tox* gene subunits by the

conventional PCR assay, but the *tox* sequences for the B subunit were not detected and results for toxin A sequence detection were atypical in the real-time PCR assay. Sequencing of the *tox* gene from the seven isolates revealed several nucleotide differences in the regions where the primers and probes annealed in the real-time PCR assay. For the real-time PCR assay for subunit A, three to four mismatches were noted, while eight mismatches were found for subunit B. Corresponding mismatch values for the conventional PCR assay were three to four for subunit A and no mismatches for subunit B.[169] Other real-time *tox* gene PCR assays have been described that are based on published *tox* gene sequences from *C. diphtheriae* and *C. ulcerans* and are sensitive and specific enough to differentiate the two organisms.[991] Because of the results generated by toxigenic strains of *C. ulcerans* in molecular tests for the *C. diphtheriae tox* gene, negative or atypical real-time PCR results should be confirmed with conventional *C. diphtheriae* molecular assays and toxin tests (i.e., the Vero cell cytotoxicity assay, Elek test) should be performed.

Antimicrobial Susceptibility of *Corynebacterium diphtheriae*. Most isolates of *C. diphtheriae*, the primary pathogen in the genus, remain susceptible to penicillin, ampicillin, and erythromycin, the drugs used for treatment of diphtheria. These same agents are also used for treatment of infections caused by nontoxigenic *C. diphtheriae* strains. Most isolates are also susceptible to ceftriaxone, clindamycin, gentamicin, vancomycin, daptomycin, and linezolid.[606,715] Isolates that are resistant to β-lactam agents and erythromycin have been described, as has multidrug-resistant *C. diphtheriae*.[606,847,861] Multidrug-resistant strains have been isolated from individuals returning from regions of endemicity. For example, a wound isolate from an unvaccinated male patient was resistant to clindamycin, erythromycin, tetracycline, and trimethoprim–sulfamethoxazole, and intermediate in susceptibility to ceftriaxone and cefotaxime.[760] The isolate remained susceptible to gentamicin, ciprofloxacin, daptomycin, linezolid, meropenem, quinupristin-dalfopristin, and vancomycin. In 2012, this organism was the cause of a bloodstream infection in a patient with AML and neutropenic fever; the organism was susceptible to penicillin, clindamycin, erythromycin, gentamicin, ciprofloxacin, trimethoprim–sulfamethoxazole, imipenem, meropenem, daptomycin, and vancomycin, but was resistant to ceftriaxone (MIC 4 μg/mL).[1201] In a study of 19 nontoxigenic isolates from nasopharyngeal, bloodstream, and wound infections in Poland, all isolates were susceptible to every agent tested, except that a single strain was intermediate for ciprofloxacin, and 47% were intermediate for cefotaxime.[1243] A study performed in Italy also noted elevated MICs for cefotaxime for all *C. diphtheriae* isolates tested.[1167]

Reporting of *Corynebacterium diphtheriae*. Epidemiologic investigations of possible

diphtheria cases require cooperation between public health and the laboratory. A confirmed case of diphtheria must have the compatible upper respiratory tract illness and (a) isolation of *C. diphtheriae* from the nose, throat, or a sampling of the pseudomembrane, (b) histopathologic evidence of diphtheria, or (c) epidemiologic linkage to a laboratory-confirmed case. Positive PCR assays are considered as supportive evidence, and cases that have positive *dtxR* and *tox* gene PCR results without organism isolation, histopathologic evidence, or linkage to a confirmed case are considered as probable cases. Attempts must be made to recover the organism from properly collected nose and throat specimens of suspect cases and their close contacts as soon as diphtheria is suspected, and the laboratory must be informed so that the appropriate culture media can be obtained or prepared. Once isolated and identified, tests must be performed to determine the biotype and the Elek test should be performed to detect toxin production. Isolates of *C. diphtheriae* should be sent to the CDC Diphtheria Laboratory for reference testing through arrangement with the state public health laboratory. In the event that other possible toxin-producing isolates are obtained (e.g., *C. ulcerans*, *C. pseudotuberculosis*), these should be forwarded to the CDC as well. Healthcare providers must notify both the state health department and the CDC regarding probable or confirmed cases of diphtheria as soon as possible so that investigations can be promptly initiated.

Corynebacterium *Species Associated With Animals and the Environment*

Corynebacterium species have also been isolated from a variety of animal species, and some of these are regarded as pathogens in their respective animal hosts. A few animal isolates (e.g., *C. falseni*) have also been isolated from humans. Box 14-5 lists these *Corynebacterium* species and the animals associated with them. Several *Corynebacterium* species have also been isolated from various food and environmental sources, and none of these are implicated in human infections.

Other Coryneform Bacteria

Other coryneform bacteria that have been isolated from human clinical specimens include pleomorphic gram-positive bacilli that form characteristic Chinese letters, V-forms and occasional coccoid forms on Gram's stain. These species differ from recognized *Corynebacterium* species in several

BOX 14-5

Corynebacterium Species Isolated From Animals

Species	Source of Isolation—Infection
C. aquilae[331]	Spanish Imperial Eagles (*Aquila adalberti*)—mouth/tracheal isolates
C. auriscanis[224]	Canines—otitis externa
C. bovis	Cattle, others (humans)
C. camporealensis[330]	Sheep—mastitis
C. canis[363]	Dog—bite wound isolate
C. capitovis[221]	Sheep—head wound isolate
C. caspium[220]	Caspian seals—penile wound isolate
C. ciconiae[332]	Black storks—trachel culture isolates
C. cystiditis[1222]	Cows—genitourinary tract isolate
C. epidermidicanis[355]	Dogs—skin isolate from dog with pruritis
C. falsenii[331]	Eagles—mouth/tracheal isolates
C. felinum[222]	Wild cat—respiratory tract isolate
C. kutscheri[144]	Rats, mice
C. mastiditis[329]	Sheep—subclinical mastitis
C. mustelae[366]	Ferret—lung, liver, kidney tissue, lethal sepsis
C. phocae[845]	Common seals
C. pilosum[1222]	Cows—genitourinary tract isolate
C. pseudotuberculosis	Sheep (humans)
C. sphenisci[426]	Wild penguins—cloacal isolates from healthy animals
C. spheniscorum[427]	Wild penguins—cloacal isolates from healthy animals

C. suicordis[1153]	Pigs—respiratory tract isolates, pericardial isolates
C. testudinoris[222]	Tortoise—necrotic oral lesion isolate
C. ulceribovis[1225]	Cows—udder ulceration
C. vitarumen	Cow rumen isolate

respects. Most of them lack *meso*-DAP as the di-amino acid comprising the cross-linkages in the peptidoglycan structure, but rather have other amino acids (e.g., L-lysine, L-ornithine) present (Table 14-5). Other components normally found in the corynebacterial cell wall, such as arabinose, galactose, and short chain mycolic acids may also be absent. The menaquinones present as part of the electron transport system also vary from group to group. In addition, some of the coryneform organisms are oxidative rather than fermentative with respect to carbohydrate metabolism. These bacteria have been recovered from several types of human clinical specimens, including blood, cerebrospinal fluid, urine, and other normally sterile body sites and fluids.

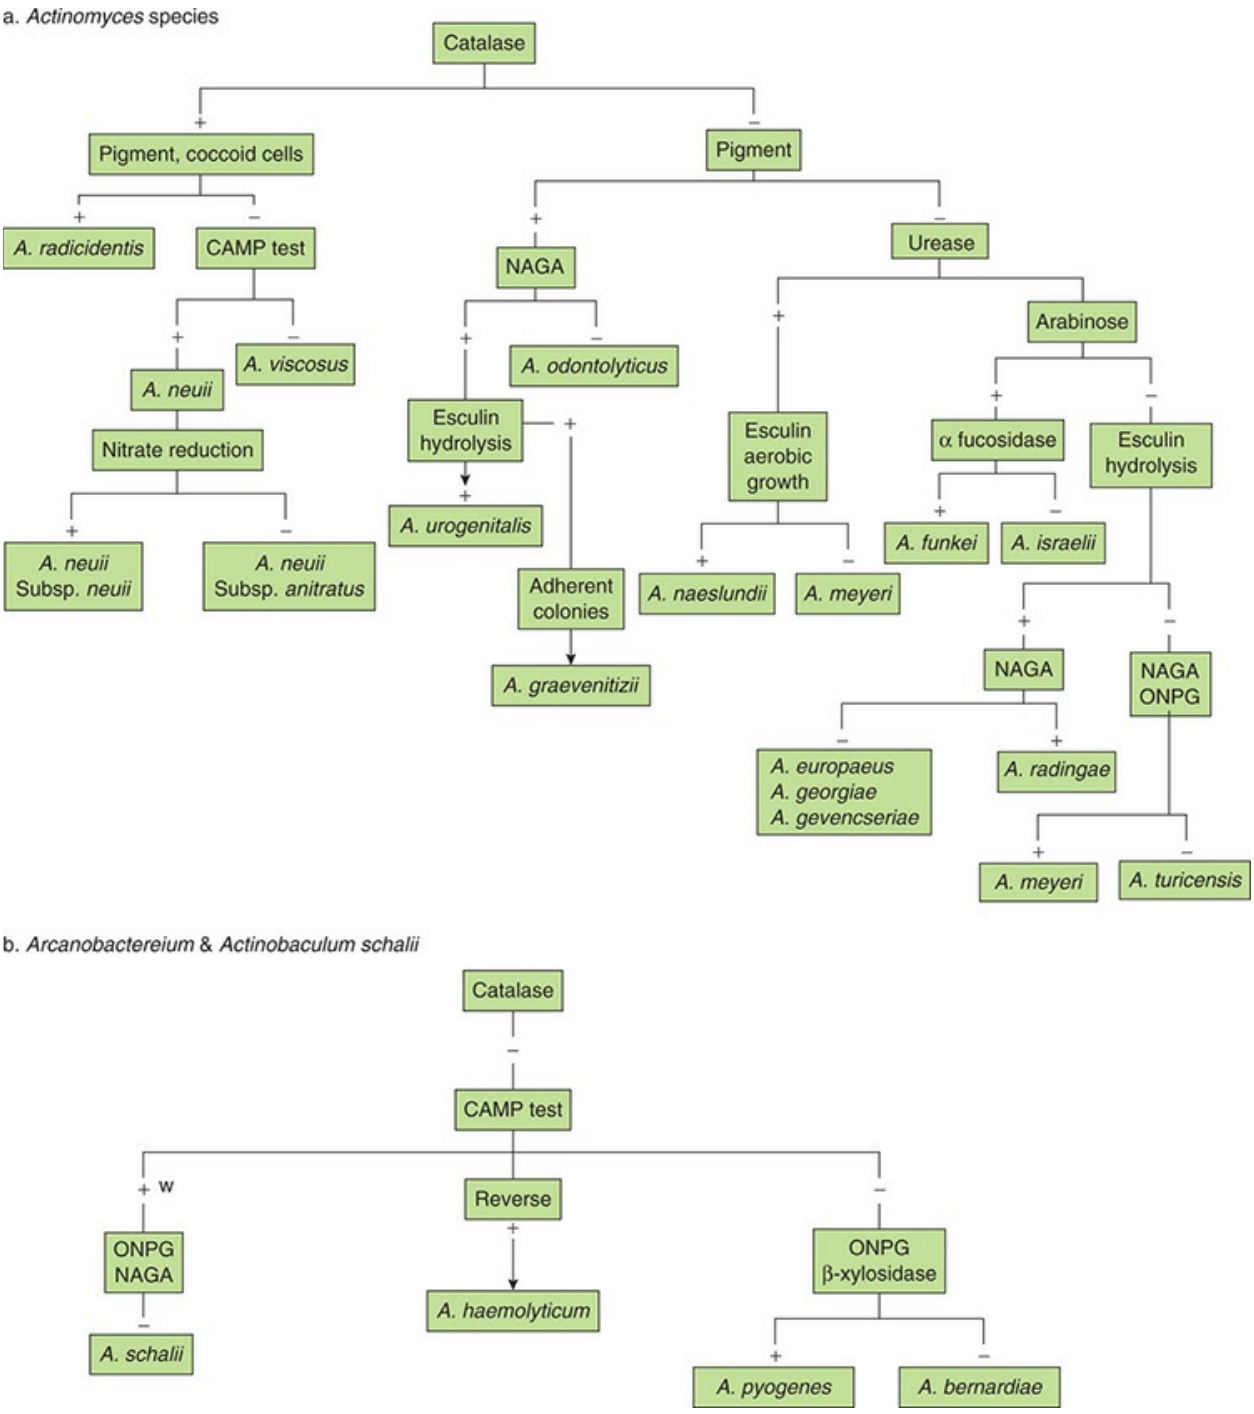
While some of the former CDC coryneform groups have been formally reclassified in the genus *Corynebacterium,* others have been found to belong to genera not previously associated with human pathology. Several research groups, particularly in Europe, are working to unravel the complex taxonomic relationships among these disparate organisms using both genetic (e.g., DNA–DNA hybridization, 16S and 5S ribosomal RNA [rRNA] sequencing) and chemotaxonomic (e.g., cell wall, cellular fatty acid, cellular menaquinone analyses) approaches. These methods have established that reliance on phenotypic characteristics alone may not be sufficient for identification of these organisms, and that molecular and chemotaxonomic analyses of subcellular components may be necessary to differentiate among organisms that have identical or similar phenotypic characteristics. Although these organisms are relatively uncommon isolates in the clinical laboratory, they are increasingly being recovered as nosocomial colonizers and occasional pathogens, particularly in immunocompromised patients.

Actinotignum *and* Actinobaculum *Species*

Intensive genotypic examination of other "*Actinomyces*-like" strains from human clinical specimens has resulted in descriptions of totally new genera and reclassification of existing *Actinomyces* species. Lawson and associates[642] examined five strains of an unknown *Actinomyces*-like organism that were recovered from human specimens (including blood) and found that they were distinct from previously described *Actinomyces* species. The most closely related organism to these unknown strains was

the obligately anaerobic species

898



■ **FIGURE 14-3** Flowchart for identification of *Actinomyces, Actinobaculum,* and *Arcanobacterium* species from human clinical specimens.

Actinomyces suis, and even this organism was phylogenetically divergent from other *Actinomyces* species that were examined. Based on genetic, chemotaxonomic, and biochemical data, a new genus, *Actinobaculum*, and species,*Actinobaculum schaalii*, was proposed for the five previously undescribed human isolates from blood and urinary tract specimens and *Actinomyces suis* was also reclassified as *Actinobaculum suis*.[642] Since the description of *A. schaalii* and the reclassification of *A. suis*, two additional *Actinobaculum* species—*A. massiliae* and *A. urinale*—have been isolated from urine specimens from patients with chronic/recurrent urinary tract infections.[437,459] *A. massiliae* has also been isolated from superficial cutaneous infections.[1170] Figure 14-3 provides a flow chart for identification of the more common *Actinomyces* (Figure 14-3a), *Actinotignum, Actinobaculum,* and *Arcanobacterium* species (Figure 14-3b).

899

Recent taxonomic dissection of *Actinobaculum* species using chemotaxonomic and molecular approaches has resulted in the reclassification of *A. schaalii* and *A. urinale* to the new genus *Actinotignum* as *Actinotignum schaalii* and *Actinotignum urinale*, respectively. These workers also found that the type strain of *A. massiliense* was actually a strain of *A. schallii*.[1228a]

Since its initial description, *A schaalii* has emerged as a significant urinary tract pathogen, causing urosepsis, acute and chronic cystitis, asymptomatic bacteriuria, and sepsis.[172,490,801] Reinhard et al.[909] reported on 10 patients in Denmark with urosepsis due to *A. schaalii*. Nine of the patients were elderly and had predisposing conditions, including prostatic hyperplasia, diabetes mellitus, rheumatoid arthritis, dementia, colon carcinoma, kidney stones, paraplegia, and pyelonephritis, and all patients had *A. schaalii* isolated from urine, blood, or both. A 2010 retrospective study of all cases identified in Switzerland since 2004 yielded 21 *A. schaalii* isolates from 19 patients.[84] Ten of the isolates were cultured from urine, six were from blood, three were from pus, and one was from both blood and urine cultures. Thirteen (76%) of the 17 patients with positive blood or urine cultures had underlying urinary tract disease, and, when urine cultures were positive, all these patients had pyuria and negative nitrite tests. Urosepsis with *A. schaalii* along with other uropathogens, including *Aerococcus urinae* and *Actinobaculum urinale*, have also been reported.[328,1064] Pediatric infection with *A. schaalii* was documented in 2003, with a case of pyelonephritis that occurred in a 5-year-old boy with hemiplegia secondary to a hemispheric tissue lesion and pyeloureteral obstruction.[836] Bank and colleagues[67] developed a real-time quantitative PCR assay for *A. schaalii* and tested urine specimens from 177 hospitalized patients and 75 out-patients in Denmark. PCR detected *A. schaalii* in

22% of specimens from individuals greater than 60 years old. In 9 of 10 PCR-positive specimens, other common urinary tract pathogens were also present, suggesting that *A. schaalii* may be present as an undetected urinary co-pathogen in many urinary tract infections. A subsequent study by the same group used quantitative PCR to screen urine samples from 76 patients with kidney stones, 29 childen, and 37 patients with indwelling catheters. Urine specimens from 7 (29%) of patients with kidney stones, 5 (14%) of 14 children less than 3 years old, none of 15 children 3 to 15 years old, and 8 (22%) of the catheterized patients were positive for *A. schaalii*.[66] Andersen and colleagues[34] documented *A. schaalii* in quantities of $>10^4$ to 10^5 cfu/mL by real-time PCR in 5 of 29 screened urine specimens from children less than 4 years of age. Two other children had urine specimens with colony counts of $\geq 10^6$ cfu/mL that were positive by both PCR and culture.

Other infections associated with *A. schaalii* and other members of the genus are rare. Gomez and coworkers[417] described 12 patients with *Actinobaculum* bacteremia. Blood cultures turned positive in from 1 to 3 days and only the anaerobic bottle was positive. *A. schaalii* was recovered from 10 patients, with *A. urinale* and *A. massiliense* being isolated from two patients, respectively. All patients were older than 65 years, 66% were male, and 10 of the 12 had underlying urogenital pathology (e.g., benign prostatic hypertrophy, prostate cancer, urinary retention, urethral stricture, prior urological instrumentation). Interestingly only 40% of the positive blood cultures were considered as significant by the physicians Vertebral osteomyelitis of the lumbar spine due was reported in a 71-year-old Swiss man with a past history significant for hepatitis B and tuberculosis requiring lung and rib resection.[466] In 2010, the first case of *A. schaalii* aortic prosthetic valve endocarditis was reported in a 52-year-old man in Austria.[505] This patient had no symptoms referrable to the urinary tract and urine cultures incubated both aerobically and anaerobically were negative after incubation for 5 days. *A. schaalii* was also isolated in pure culture from necrotic tissues of a 33-year-old obese male diagnosed with Fournier's gangrene, a type of necrotizing fasciitis affecting the genital, perineal, and perianal body sites.[1141] *A. schaalii* infection in North America was first reported in 2010 in a case report describing a chronic urinary tract infection in a 76-year-old Canadian woman.[636]

Actinobaculum species are anaerobic or facultatively anaerobic, catalase-negative, nonmotile gram-positive bacilli. *Actinobaculum* species may grow well or poorly at 37°C in a CO_2-enriched atmosphere and grow poorly at 37°C in air. Individual cells may be slightly curved or may exhibit branching. The principal product of glucose or maltose fermentation are lactic and acetic acids; *A. schaalii* produces succinate as well and *A. suis* produces acetic and formic acid plus some ethanol from maltose fermentation (glucose is not fermented). All members of the genus hydrolyze hippurate, but do not reduce nitrate to nitrite and esculin and gelatin are not

hydrolyzed. *A. suis* strains may ferment maltose but do not ferment sucrose. On the API Coryne system, *A. schaalii* is pyrazinamidase-negative, pyrrolidonyl arylamidase (PYR)-positive, alkaline phosphatase-variable, and α-glucosidase-positive, while *A. massiliae* is pyrazinamidase-positive, PYR-negative, alkaline phosphate-negative, and α-glucosidase-positive. *A. urinale* is pyrazinamidase, PYR and α-glucosidasenegative, but β-glucuronidasepositive.[909] Additional phenotypic characteristics for identification of *Actinobaculum* species are included in Table 14-7. *A. schaalii* isolates are susceptible to amoxicillin, mecillinam, ceftriaxone, gentamicin, vancomycin, linezolid, and nitrofurantoin and resistant to ciprofloxacin, metronidazole, and trimethoprim-sulfamethoxazole.[35,173] Isolates from patients with bacteremia reported by Gomez et al.[417] were all susceptible to penicillin (MIC, <0.5 μg/mL), resistant to metronidazole (MIC, >256 μg/mL), 10 were susceptible to clindamycin (MIC, <0.5 μg/mL), whereas two were clindamycin-resistant (MIC, >256 μg/mL). More than 90% of strains may be susceptible to other fluoroquinolones such as levofloxacin and moxifloxacin, and, in isolates that were ciprofloxacin- or levofloxacin-resistant, a mutation was noted in the *gyrA* but not in the *parC* gene, which are the quinolone-resistance-determining regions.[173]

Actinomyces *Species*

The genus *Actinomyces* is composed of a heterogeneous group of gram-positive, facultatively anaerobic or microaerophilic, non–spore-forming, non–acid-fast nonmotile bacilli, some of which display rudimentary branching. Many *Actinomyces* species are part of the oral microflora of humans and various animals.[992] *A. israelii*, *A gerencseriae*, *A. georgiae*, *A. odontolyticus*, and *A. naeslundii* are prevalent in both supra- and sub-gingival plaque specimens in patients with adult periodontitis and gingivitis.*Actinomyces* species may cause classical actinomycosis, wound infections, abscesses, genital tract infections, and urinary tract

infections.[362,890,1043] Rarely, an *Actinomyces* species has been reported to cause sepsis.[997] Genus *Actinomyces* is classified in the phylum *Actinobacteria*, class *Actinobacteria*, order *Actinomycetales*, family *Actinomycetaceae.* Other genera in the family are *Actinobaculum, Arcanobacterium, Trueperella*, and *Mobiluncus.* (Box 14-1).

The genus *Actinomyces* has undergone rapid expansion over the last several years, with the description of many new species from both humans and animals. The plethora of new agents has created problems for the clinical laboratory as far as accurate identification of these organisms is concerned. Years ago, microbiology laboratories relied on conventional anaerobic bacteriology methods for phenotypic identification. Reference identifications were determined with anaerobic bacteriology techniques promulgated in the *Virginia Polytechnic Institute (VPI) Anaerobe Manual* and the *Wadsworth Anaerobic Bacteriology Manual.*[510,560,976] Unfortunately, the *VPI Anaerobe Manual* is no longer available and the *Wadsworth Anaerobic Bacteriology Manual* has not been updated since 2002. In the VPI approach to the identification of anaerobes, gas-liquid chromatography (GLC) for detection of volatile and nonvolatile products of glucose fermentation was very helpful for identification, since gram-positive, non–spore-forming bacilli that produce major amounts of succinic acid could be placed in the genus *Actinomyces* without further testing. Since new species are now validated by genotypic, molecular approaches, GLC data as well as phenotypic data on new species are often limited or unavailable. Several commercial vendors have marketed rapid enzymatic kits for identification of anaerobic bacteria, but these systems do not perform well for identifying *Actinomyces* species.[758] Santala and colleagues[975]evaluated the RapID ANA II (Remel), the RapID CB-Plus (Remel), the BBL Crystal ANR ID (BD Microbiology Systems) and the RapID 32A (bioMérieux, Inc.) for their ability to identify "classical" and newly described *Actinomyces* species. These kits correctly identified only 26% to 65% of the "classical" *Actinomyces* strains to the species level, and only 13% to 49% of the newer species to the genus level. A 2005 study evaluated the RapID ANA II, RapID32, RapID CB-Plus and BBL Crystal ANR ID systems for the identification of *Actinomyces* species.[586] Of 54 isolates tested, 46% were identified to the genus/group level by BBL Crystal, 30% by the RapID32A, 20% by the RapID CB-Plus, and 13% by the RapID ANA II. One of the newer systems for identification of anaerobic bacteria is the Vitek 2 Anaerobe/*Corynebacterium* (ANC) card. In the multicenter evaluation of the ANC card, two of two *A. meyeri* strains and one of two *A. isrealii* strains were correctly identified, and, in another study of the ANC card, along with RapID ANA II, and BBL Crystal ANR, only two *Actinomyces* isolates were included, so the performance of

these kits for *Actinomyces* identification was difficult to assess.[119,915] In another evaluation of the Vitek 2 ANC card, five *Actinomyces* isolates were tested; three were identified to the species level, while one isolate each was misidentified or gave no identification.[651] In another evaluation of the ANC card by Mory and colleagues,[780] six of six *Actinomyces* species were correctly identified to the species level, suggesting that this kit may have great potential for assisting in phenotypic identification of *Actinomyces* species. The phenotypic characteristics of new *Actinomyces* species as determined by these kits are often included as part of the original species descriptions. Because of the difficulties with phenotypic identification, genus- and species-specific DNA probes have been developed for investigating the role of *Actinomyces* species in periodontal disease and in the initiation of dental caries.[116,1091,1217] *Actinomyces* species can also be identified by molecular methods such as 16S rDNA sequencing and restriction fragment-length polymorphism analysis.[465,978] None of these techniques are available to the routine clinical laboratory. Box 14-6 includes descriptions of *Actinomyces* species from humans and animals. Phenotypic data presented in Table 14-8, which begins on page 908, includes both human and animal isolates and represents a synthesis of phenotypic characteristics and descriptions from several sources.[510,560]

Actinomycosis is a chronic infection that is characterized by localized swelling with suppuration, abscess and granuloma formation, draining sinus tracts, and tissue fibrosis and is caused primarily by members of the genus *Actinomyces*.[140] *A. israelii* is the most common cause of actinomycosis in humans, although other species (i.e., *A. meyeri*, *A. naeslundii*, *A. odontolyticus*, *A. gerencseriae*, and *A. viscosus*) may also occasionally cause this infection. Although the classic association of *Actinomyces* with intrauterine devices is well known, *Actinomyces* species may be associated with infections of other prosthetic material.[145] Because of their chronic nature, actinomycotic infections frequently mimic carcinomas. The clinical course of the infections are also affected by the immune competence of the host and other predisposing, comorbid conditions, such as alcoholism, radiation, debilitation, diabetes, malignancies, immunosuppression, and HIV infection. Actinomycosis can be divided into several clinical forms, including cervicofacial actinomycosis, primary cutaneous actinomycosis, thoracic actinomycosis, abdominal/pelvic actinomycosis, and CNS actinomycosis. Most actinomycotic infections are polymicrobial, and other facultative (e.g.,*Aggregatibacter actinomycetemcomitans*, *Eikenella corrodens*, streptococci, staphylococci, *Enterobacteriaceae*) and anaerobic bacteria (e.g., *Bacteroides* species, *Fusobacterium* species) are involved in pathogenesis and disease.[140]

Cervicofacial actinomycosis is the most common clinical presentations of actinomycosis and a rare complication of dental manipulations, oral surgery, maxillofacial trauma, and other head and neck infections (e.g., otitis,

mastoiditis).[18,413,825] At least nine different *Actinomyces* species can cause this infection, although *A. israelii* and *A. gerencseriae* predominate.[886] In most cases, endogenous oral *Actinomyces* are introduced by trauma and begin to grow in the head and neck tissues to form an acute, pyogenic abscess that may evolve into an indurated submandibular mass.[632] Spontaneous sinus tracts discharging purulent material may be seen in up to 40% of cases.[413] Lymph node involvement is often present and the patient often present with lymphadenopathy. Co-infecting organisms present in the tissues along with the actinomycete help determine the clinical evolution of the infection as subacute, acute, or chronic. Microcolonies of the organisms called "sulfur granules' may be discharged from draining sinus tracts in some cases. These sulfur granules are matted collections of the organism and show basophilic organism masses with distinct eosinophilic clubs radiating from the border of the granule. These granules provide excellent material for culture and organism detection. Cervicofacial actinomycosis may involve the submandibular space, parotid glands, teeth, tongue, nasal cavity, epiglottal area, and pharynx. Osteomyelitis may occur due to extension of infection

902

BOX 14-6

Members of the Genus *Actinomyces*

Species	Clinical Significance and Identification
Actinomyces bovis	*A. bovis* causes actinomycosis in cattle and other animals.[714] This organism was confirmed with phenotypic, chemotaxonomic, and genotypic approaches. On the API Coryne, this isolate produced biocode number 0101104, indicating positive reactions for alkaline phosphatase, urease, glucose and catalase.
Actinomyces bowdenii	This species was originally isolated from clinical specimens obtained from dogs and cats and has not yet been recovered from clinical specimens obtained from human sources.[846]
Actinomyces canis	This species, described in 2000, is a catalase-positive species isolated from dogs.[519] *A. canis* is closely related to *A. hyovaginalis*, *A. georgiae*, *A. meyeri*, *A. odontolyticus*, *A. radingae,* and *A. turicensis*.
Actinomyces cardiffensis	*A. cardiffensis* has been isolated from human pleural fluid, a paracolonic abscess, a jaw abscess, a post-mastoidectomy ear abscess, a sinus washout, and intrauterine devices.[458] On Gram's stain, the organisms appear as slender, slightly curved rods with beaded, branching filaments. After 48 hours incubation, colonies are small, convex, entire, and may be creamy to pinkish. *A. cardiffensis* is a facultative anaerobe that is catalase-negative and produces major amounts of succinic and lactic acids and small amounts of acetic acid from glucose fermentation. Esculin, urea, and gelatin are not hydrolyzed.
Actinomyces catulii	*A. catuli* has been isolated from dogs.[522]
Actinomyces coleocanis	*A. coleocanis* was isolated from the vagina of a dog.[518]
Actinomyces dentalis	*A. dentalis* was described in 2005, when it was isolated from pus aspirated from a dental abscess.[464] This organism is obligately anaerobic and forms filamentous, beaded, branching gram-positive rods. It is catalase-negative and the major end product of glucose metabolism is lactic acid, with minor amounts of acetic acid; it does not form succinic acid from glucose.
Actinomyces denticolens	This species was originally isolated from dental plaque specimens from cattle.[268]
Actinomyces europaeus	This species was described in 1997, when it was isolated as the sole organism or as the only aerobic organism recovered from human abscess material.[358] This organism has also been recovered from skin-related infections (e.g., pilonidal sinus infection, perianal abscesses, decubitus ulcers) and urinary tract infections.[959] *A. europaeus* was co-isolated with *A. turicensis* from a subcutaneous fistula associated with severe congenital hypoplasia of the right leg in a 23-year-old male and from a breast abscess.[1018,1245] On Gram-stained smears, this organism appears as short, gram-positive rods arranged in small clusters with no discernable branching. Colonies on SBA are small (less than 0.5 mm after 48 hours incubation in CO2), gray, and translucent. This organism is catalase-negative, nonmotile, and ferments glucose and maltose, but not mannitol or xylose. Some strains of this organism also hydrolyze esculin and gelatin, but these reactions are delayed. Nitrate is not reduced to nitrite and urease is not produced. As with other *Actinomyces* species, succinic acid is produced as the major product of glucose fermentation.
Actinomcyes funkei	This recently described species was originally recovered from blood cultures, a sternal wound culture, n abdominal incision, and was reported as a cause of native tricuspid valve endocarditis.[644,1195] These isolates were orginally identified as strains of *A. turicensis*, but certain phenotypic traits and 16S rRNA sequencing showed that this organism was closely related to but not identical with *A. turicensis*. Cells of *A. funkei* are gram-positive, slender, slightly curved, and exhibit some branching. Growth occurs under both aerobic and anaerobic conditions. On SBA, colonies are small, nonhemolytic, and gray after 24 hours incubation. Acid is produced from glucose, sucrose, and xylose, but not from arabinose, mannitol, glycogen, raffinose, sorbitol or trehalose. Hippurate is hydrolyzed, but esculin and gelatin are not. On the API Coryne system, the original isolated produced biocode numbers 0130761 or 3530761, indicating the variability of the pyrazinamidase, nitrate reductase, and β-galatosidase reactions on the test strip.
Actinomyces georgiae	*A. georgiae* was described in 1990 and is found as a part of the normal microbiota of the gingival crevices of adults and children. In 2008, this organism was isolated from blood cultures of a patient with endocarditis in Thailand.[549] Strains of this species are facultatively anaerobic. On Gram's stain, this species appears as rods that occurring in pairs or short chains; cells may also have swellings along their length and branching is seldom seen.[553] In older broth cultures, cells may have a coccoid appearance. After 48 hours of anaerobic incubation, colonies are 1 mm in diameter, circular, entire, shiny, and smooth with entire adges. Colonies may be white, tan, or beige. The organism is catalase-negative, and succinic, acetic, formic, and small amounts of lactic acid are produced from glucose fermentation. Acid is produced from a variety of carbohydrates, including glucose, maltose, sucrose, xylose, trehalose and glycogen. The majority of strains hydrolyze esculin, but do not reduce nitrate to nitrite.

Actinomyces gerencseriae	This species was described in 1990 and was formerly called *A. israelii* serotype II.[553] However, it is genetically unrelated to the type strains of *A. israelii*. *A. gerencseriae* is found in the human oral cavity and in the gingival crevices. About 12% of isolates are obligately anaerobic, while the remainder produce scant to moderate growth on blood agar incubated in 5%–7% CO_2. On Gram's stain, the organisms appear as filamentous cells with occasional swellings and branching. After 48 hours incubation under anaerobic conditions, colonies are about 0.2 mm in diameter, white, opaque, nonhemolytic, and may have a "lumpy" topography. This species is catalase-negative, esculin hydrolysis-positive, gelatin-hydrolysis-negative, and produces acid from a variety of carbohydrates, including glucose, maltose, mannose, sucrose and trehalose. Lactic, succinic, formic, and acetic acids are produced by glucose fermentation. In 2010, *A. gerencseriae* was isolated from a case of thoracic actinomycosis presenting as empyema necessitatis, which is an extension of purulent pleural fluid through the tissues forming an abscess on the thoracic wall.[681]
Actinomcyes graevenitzii	The original report of this new species described four human isolates, three of which were from respiratory tract specimens, while the fourth was isolated from the jaw of a patient with osteitis.[895] These isolates were gram-positive, nonmotile, slightly curved rods with some branching and occasional swollen ends. Colonies on SBA are very small (0.2 mm in diameter after 24 hours' incubation) and are adherent to the agar, particular on primary isolation. This species is catalase-negative, does not hydrolyze esculin, urea or hippurate, and does not reduce nitrate to nitrite. This species is also strongly *N*-acetyl-β-d-glucosaminidase positive on the API Coryne strip, which helps to differentiate it from the other closely related *Actinomyces* species. Succinic and lactic acids constitute the end-products of glucose fermentation. Since its initial description, *A. graevenitzii* has been isolated from a patient with disseminated co-infection with this organism and *M. tuberculosis*, and from a patient with bacteremia and alcoholic liver cirrhosis.[533,1108]
Actinomyces hominis	*A. hominis* was described in 2010, when a wound swab collected from a 89-year-old German women grew a pure culture of a catalase-positive coryneform bacterium after 72 hours of aerobic incubation.[363] The isolate was confirmed as an *Actinomyces* species by 16S rRNA gene sequencing and was closely related to *A. europaeus*. *A. hominis* is catalase-positive (one of the 10 *Actinomyces* species that is catalase-positive), CAMP test-positive, produces acid from raffinose and is *N*-acetyl-β-d-glucosaminidase positive.
Actinomyces hongkongensis	This novel species, described in 2003, was isolated from purulent material of a patient with pelvic actinomycosis.[1208] This species is strictly anaerobic, grows on SBA as pinpoint, nonhemolytic colonies and is catalase-negative. By 16S rRNA gene sequencing, this species is most closely related to *A. maramammalium*, which has been isolated from seals and porpoises.
Actinomyces hordeovulneris	*A. hordeovulneris*, along with *A. viscosus* and *A. bovis*, are the three species that cause actinomycosis in dogs.[147,857] *A. hordeovulneris* has been isolated from patients with pleuritis, septic arthritis, peritonitis and abscesses.
Actinomyces houstonensis	This human species originated with three isolates from serious subcutaneous abscesses that required drainage.[212] *A. houstonensis* is a facultative anaerobe, producing α-hemolytic, gray colonies that are about 0.2 mm in diameter after 48 hours of incubation at 35°C–37°C. The cells are pleomorphic gram-positive rods that tend to form half-circles. The organism is catalase-negative and does not hydrolyze esculin, urea or gelatin. Nitrate is reduced to nitrite and acid is produced from glucose and sucrose, but not from xylose.
Actinomyces howellii	*A. howellii* is found in dental plaque of dairy cattle.[269] This organism is antigenically related to *A. naeslundii* and *A. viscosus*.[888]
Actinomyces hyovaginalis	Described in 1993, *A. hyovaginalis* was originally isolated from purulent vaginal lesions of pigs.[228] Subsequent genotypic studies of isolates from porcine necropsy specimens identified a new biotype of *A hyovaginalis* from kidney, lung, brain, bladder and joint tissue that was termed the "general" biotype to distinguish these from the "vaginal" biotype described previously.[1061] Vaginal biotypes are associated with porcine abortion.[509] *A. hyovaginalis* is also a cause of lymphadenitis in goats.[974] More recent sequencing and expanded phenotypic studies have documented that certain strains of *A. hyovaginalis* cause disease in sheep similar to *C. pseudotuberculosis*, *A. pluranimalium* and *T. pyogenes*.[351]
Actinomyces israelii	*A. israelii* is the agent most frequently associated with the various presentations of actinomycosis, including cervicofacial, thoracic, pulmonary, and pelvic actinomycosis (often associated with the presence of intrauterine devices) (see text).[515,882] *A. israelii* has been recovered from cases of head and neck actinomycosis with CNS, spinal cord, vertebral, ocular, and periocular involvement, including endophthalmitis and osteomyelitis.[392,511,759,807,1239] *A. israelii* has also been isolated from rare cases of indolent breast

904

	abscess, primary sternal actinomycosis and endocarditis.[6,653,870,882,971] Pulmonary actinomycosis may manifest due to *A. israelii* may present as pleural, chest wall and splenic abscesses with empyema.[451] Abdominal actinomycosis involving *A. israelii* include abdominal wall masses, and intrabdominal, liver and pancreatic abscesses, intestinal actinomycosis with bowel obstruction and retroperitoneal involvement with obstructive uropathy.[5,401,653,1129,1135,1219] Infections of prosthetic joints following bacteremia with *A. israelii* have also been reported.[1241] This organism is primarily anaerobic, with facultative growth in a CO_2-enriched atmosphere only occurring after repeated subcultures. Colonies of *A. israelii* may resemble a molar tooth, are nonhemolytic on SBA and are not pigmented. This species is catalase-negative, esculin hydrolysis-positive and most strains reduce nitrate to nitrite. Acid is produced from glucose, maltose, sucrose, raffinose, xylose, lactose and trehalose.
Actinomyces johnsonii	During an examination of 115 type/reference strains, clinical isolates, and oral isolates of *A. naeslundii*, the partial gene sequences of several housekeeping genes were determined. These sequences identified three distinct genospecies. *A naeslundii* genospecies 1 and genospecies 2 formed two distinct clusters that were well separated from the third cluster, designated genospecies WVA 963. Genospecies 1 clustered with the type strains of *A. naeslundii sensu stricto*, so this genospecies 1 strains remained as *A. naeslundii*. The name *Actinomyces oris* was proposed for the *A. naeslundii* genospecies 2 isolates, while the name *Actinomyces johnsonii* was proposed for *A. naeslundii* genospecies WVA 963.[486]
Actinomyces marimammalium	*A. marimammalium* was originally isolated from multiple internal organs of a dead hooded seal, lung tissues of a dead harbor porpoise, and small intestinal tissue of a dead gray seal.[523]
Actinomyces massiliensis	This species was isolated in 2009 from a blood culture of a 38-year-old man with pleuropneumonia.[918] This obligately anaerobic organism is catalase-negative, oxidase-negative, and produces acid from glucose, fructose, and lactose, but not from mannitol, xylose, raffinose or amygdalin. This species is most closely related to *A. gerencseriae*, *A. israelii*, *A. oricola*, *A. ruminicola* and *A. dentalis*.
Actinomyces meyeri	*A. meyeri* is an obligately anaerobic species that has been associated with a variety of human infections, including cervicofacial, thoracic and pulmonary actinomycosis.[240,325,674,1136] Primary cutaneous actinomycosis due to *A. meyeri* has been reported in persons with minor cutaneous trauma, and usually presents as indolent ulcerated lesions draining purulent material.[416,488] In one instance, this infection was the first manifestaion of HIV infection in a 23 year-old man.[416] This organism is an uncommon cause of postoperative endophthalmitis, brain abscess, cutaneous and intra-abdominal abscesses, endocarditis and osteomyelitis.[526,688,859,1148] Intra-abdominal *A. meyeri* infections have included splenic abscesses.[399] *A. meyeri* has a propensity to disseminate from localized infection, and, in one patient, the infection was mistaken for lung cancer with metastases to the brain.[230,1148] *A. meyeri* has also been isolated from synovial fluid from a patient with metastatic squamous cell carcinoma.[190] Colonies on blood agar are white and non-pigmented. Strains of *A. meyeri* are catalase-negative, do not hydrolyze esculin and do not reduce nitrate. The CAMP test is positive, and some strains also produce urease. Acid is produced from glucose, maltose, sucrose, and xylose, and some strains will also ferment glycerol and glycogen. Mannitol, trehalose, raffinose, and mannose are not fermented.
Actinomyces naeslundii	*A. naeslundii* is found in the human oropharnyx and is a rare cause of cervicofacial actinomycosis, IUD-associated endocervical actinomycosis, septic arthritis, and periodontal disease.[465,667,1216] *A. naeslundii* may cause bacteremia following dental procedures in patients with periodontal disease.[104] *A. naeslundii* strains were divided into genospecies 1 and 2; genospecies 1 is now recognized a *A. naeslundii* sensu stricto, and genospecies 2 has been reclassified as *Actinomyces oris*.
Actinomyces nasicola	This species was originally isolated from pus that was aspirated from the antrum of a patient undergoing a routine nasal polypectomy.[463] On Gram's stain, this organism appears as coryneform gram-positive bacilli with some branching and coccoid forms being evident as well. The organism is facultatively anaerobic and catalase-negative; acetic, lactic and succinic acid are produced as products of glucose fermentation. Esculin, gelatin and starch are not hydrolyzed and urease is not produced. Acid is produced from fructose and cellobiose, but not from glucose, maltose, sucrose, ribose, xylose, lactose, mannitol or amygdalin.
Actinomyces neuii subsp. *neuii and Actinomyces neuii* subsp. *anitratus*	These *Actinomyces* species were described in 1994 and encompass former members of CDC coryneform group 1 and "group 1-like" strains that were recovered from a variety of clinical specimens, including cerebrospinal shunt fluid, ear cultures, vitreous fluids, mammary gland abscesses, furuncles and blood.[376] Group 1 strains were α-hemolytic on human blood agar, reduced nitrate to nitrite, were unable to ferment adonitol, and were alkaline phosphatase-negative, while the "group 1-like" strains were nonhemolytic, failed to reduce nitrate to nitrite, fermented adonitol and were alkaline phosphatase-positive. Both groups of organisms grew under both aerobic and strictly anaerobic conditions.

905

	Cell wall analysis showed that these isolates lacked *meso*-DAP and mycolic acids in their cell walls. Analysis of volatile and nonvolatile fatty acids showed that succinic acid was the major end product of glucose fermentation for both groups of organisms, and examination of fatty acid methyl esters revealed that the cell walls contained C16:0, C18:1*cis*-9, and C18:0 fatty acid methyl esters as their major cell wall constituents. These data suggested a phylogenetic relationship between CDC group 1 and "group 1-like" strains and *Actinomyces* species.[376] Subsequently, 16S rRNA gene sequences of these organisms were determined and found to support the inclusion of CDC group 1 and "group 1-like" isolates in the genus *Actinomyces*. In 1994, CDC group 1 and "group 1-like" strains were formally proposed as *Actinomyces neuii* subsp. *neuii* and *Actinomyces neuii* subsp. *anitratus*, respectively.[388] Since the deposition of this coryneform in the genus *Actinomyces*, this species has been associated with abscesses, infected skin lesions, bacteremia and both native valve and prosthetic valve endocarditis.[215,387,419,444,623,713,1165] Bacteremias have been associated with urinary tract infections, joint infections, and chorioamnionitis.[388,470,713] Other infections have included pericarditis, osteomyelitis, ventriculo-peritoneal shunt infections, endophthalmitis and infection of a mammary and a total hip prostheses.[145,400,430,862,894,925,1138,1165,1180] Both *A. neuii* subsp. *neuii* and *A. neuii* subsp. *nitratus* are catalase-positive, nonhemolytic gram-positive bacilli. Colonies are circular, smooth, convex, and white with entire edges; subsp. *neuii* is α-hemolytic on SBA, while subsp. *anitratus* is nonhemolytic. These organisms are very active fermenters and produce acid from glucose, maltose, sucrose, mannitol, lactose, mannose, trehalose and xylose. Both species produce leucine arylamidase, α-galactosidase, β-galactosidase, and α-glucosidase and both are CAMP test-positive. *A. neuii* subsp. *neuii* reduces nitrate to nitrite, while subsp. *anitratus* is negative for this characteristic. Rare strains of *A. neuii* may be catalase-negative.[144] *A. neuii* isolates are susceptible to penicillin, ampicillin, cephalosporins, imipenem, erythromycin, clindamycin and vancomycin. Suceptibility to the aminoglycosides and fluoroquinolones is variable.[388]
Actinomyces odontolyticus	*A. odontolyticus* is found in the human oropharnyx in association with the gingival crevices and deep carious lesions. This species, along with *A. naeslundii* and *A. viscosus*, has been documented as a cause of bacteremia after dental procedures.[104] This organism is also a rare cause of bacteremia, thoracopulmonary infections, empyema thoracis, lung and liver abscesses, soft tissue infections and IUD-associated pelvic actinomycosis.[72,73,193,196,234,679,767,1084] *A. odontolyticus* has also been isolated from an abscess adjacent to the exit site of a Tenckhoff catheter for chronic ambulatory peritoneal dialysis.[1029] This species is catalase-negative, produces pinkish colonies on SBA, and forms red colonies on brain heart infusion agar. Nitrate is reduced to nitrite and urease is not produced. Acid is produced from glucose, maltose, and sucrose and some strains also ferment glycerol, glycogen, and xylose.
Actinomyces oricola	*A. oricola*, like *A. radicidentis* (see below), was isolated originally from a dental abscess.[462] This species includes gram-positive rods that display both branching and filament formation. The organism is facultatively anaerobic, catalase-negative and produces pinpoint colonies on SBA after 48 hours incubation. GLC analysis of glucose broth cultures reveals the formation of acetic, lactic, and succinic acids. On the API Coryne strip, acid is produced from glucose, maltose and sucrose only. Other positive tests (i.e., pyrazinamidase, alkaline phosphatase, esculin hydrolysis, α-glucosidase, and β-galactosidase) produces a biocode of 2550121.
Actinomyces oris	During an examination of 115 type/reference strains, clinical isolates, and oral isolates of *A. naeslundii*, the partial gene sequences of several housekeeping genes were determined. These sequences identified three distinct genospecies. *A. naeslundii* genospecies 1 and genospecies 2 formed two distinct clusters that were well separated from the third cluster, designated genospecies WVA 963. Genospecies 1 clustered with the type strains of *A. naeslundii sensu stricto*, so this genospecies 1 strains remained as *A. naeslundii*. The name *Actinomyces oris* was proposed for the *A. naeslundii* genospecies 2 isolates, while the name *Actinomyces johnsonii* was proposed for *A. naeslundii* genospecies WVA 963.[486]
Actinomcyes radicidentis	*A. radicidentis* has been isolated in pure cultures from infected root canals in humans.[223,568] These isolates were gram-positive, catalase-positive, coccoid to coccobacillary in morphology, and grew under both aerobic and anaerobic conditions. Colonies on SBA may produce a pink pigment. This species is fermentatively active, producing acid from glucose, maltose, mannitol, lactose, ribose, and sucrose on the API Coryne. The organism hydrolysisof esculin, reduction of nitrate and production of urease are variable characteristics. A PCR assay for *A. radicidentis* was developed and applied to dental root canal specimens obtained from patients with primary (root canal infections) and persisting (i.e., posttreatment) endodontic infections.[1026] *A. radicidentis* was detected in 2 (4%) of 50 samples collected from primary infections and in 1 (8%) of 12 root canal samples from patients who failed therapy. This organism is probably a previously unrecognized member of the normal indigenous oral microbiota of humans.

906

Actinomyces radingae	CDC coryneform group E organisms were originally described as "*A. pyogenes*-like" bacteria that were recovered from several clinical sources. These organisms were believed to be aerotolerant strains of the anaerobe *Bifidobacterium adolescentis* that differed in the volatile and nonvolatile end-products produced from glucose fermentation.[449] Using genetic and chemotaxonomic approaches, Wust and colleagues[1214,1215] found that these strains were closely related to *Actinomyces* species and proposed two new species: *Actinomyces radingae* and *Actinomyces turicensis*. VanDamme and associates subsequently used whole-cell protein electrophoresis, fatty acid analysis, phenotypic tests (i.e., API Coryne and the IDS Rapid ANA panel) and species-specific oligonucleotide probes to characterize a group of unidentified, catalase-negative coryneform bacteria.[1215] These workers found that the organisms formed two clusters that corresponded to *A. turicensis* and *A. radingae*, respectively. These analyses enabled the publication of emended descriptions of these "*Actinomyces pyogenes*"-like isolates from human clinical specimens.[1140] Using species-specific oligonucleotide probes for *A. turicensis* and *A. radingae*, Sabbe and colleagues examined 294 "*Actinomyces*-like" isolates from human clinical specimens collected over a 7-year period and found that *A. radingae* is primarily associated with skin-related infections (e.g., skin abscesses, pilonidal cysts, perianal abscesses).[52,959] Isolates of *A. radingae* are facultative, catalase-negative, gram-positive bacilli. After 48 hours incubation, colonies on SBA are small, gray, convex and circular with a butyrous consistency. Most strains are α-hemolytic. Esculin is hydrolyzed, but gelatin and urea are not. Nitrate is not reduced to nitrite and the CAMP test is negative. Acid is produced from glucose, maltose, sucrose, lactose, xylose and ribose, but not from mannitol or glycogen. With enzymatic tests on the API Coryne, *A. radingae* produces α-glucosidase, β-glucosidase, α-galactosidase, β-galactosidase, and *N*-acetyl-β-d-glucosaminidase, but does not produce leucine arylamidase, pyrrolidonyl arylamidase, alkaline phosphatase or β-glucuronidase. *A. radingae* isolates are susceptible to penicillin, cephalosporins, erythromycin, and tetracyclines.[1140]
Actinomyces ruminicola	*A. ruminicola* is an obligately anaerobic species that has been isolated from the bovine rumen.[33]
Actinomyces slackii	*A. slackii* is found in the dental plaque of dairy cattle.[270]
Actinomyces suimastidis	This species was isolated from a sow with chronic granulomatous mastitis.[521]
Actinomyces timonensis	*A. timonensis* was described in 2010, when an unusual isolate was recovered from an osteo-articular specimen obtained from the sacral area of a 13-year-old girl with chronic lower back pain. This organism is most closely related to the type strain of *A. denticolens*.[919] This organism is an obligately anaerobic catalase-negative, gram-positive rod.
Actinomyces turicensis	*A. turicensis* is found mainly in genital tract infections, skin-related infections, urinary tract infections and some isolates have been recovered from appendiceal tissue, hepatic abscess, head/neck infections and blood.[940,959] Since its initial description, *A. turicensis* has been isolated from pilonidal cysts, cutaneous and peri-rectal abscesses, gas gangrene-associated scrotal exudates, liver abscess, an ovarian cyst infection, subcutaneous fistulae, furuncles, and carbuncles.[205,824,940,1245] *A. turicensis* has also been isolated as a cause of mitral valve endocarditis in a Labrador Retriever.[565] On Gram's stain, cells of *A. turicensis* are straight, slightly curved, or club-shaped. Colonies on SBA are small, gray, convex, and entire after 48 hours' incubation in a CO_2 atmosphere. The organism is catalase-negative, does not hydrolyze esculin, urea or gelatin, does not reduce nitrate to nitrite and is CAMP test-negative. Acid is produced from glucose, maltose, sucrose, xylose, ribose and trehalose, but lactose and mannitol are not fermented. On the API Coryne, α-glucosidase is detected, but the other enzymatic tests are negative. *A. turicensis* is broadly susceptible to a variety of agents, including pencillin, cephalosporins, erythromycin and doxycycline.[1140]
Actinomcyes urogenitalis	Isolates of this species were originally recovered from urine, vaginal discharge and urethral cultures.[803] In 2006, a previously healthy 38-year-old woman, with IUD-associated pelvic actinomycosis due to *A. urogenitalis* was reported.[305] She presented with a 2-week history of fever, a heavy malodorous vaginal discharge, and lower back pain that appeared 8 months after insertion of the IUD. These organisms are facultative, regular gram-positive, catalase-negative rods. This species produces acid from glucose, maltose, sucrose, lactose, xylose, and some strains also ferment mannitol and ribose. Nitrate is reduced to nitrite and esculin is hydrolyzed, but gelatin, urea and hippurate are not.
Actinomyces vaccimaxillae	This isolate was recovered from pus exuding from a jaw lesion of an adult cow.[460]
Actinomyces viscosus	*A. viscosus* is found in the oral cavity of human and animals. This species, along with *A. naeslundii* and *A. viscosus*, has been documented as a cause of bacteremia after dental procedures.[104] In 2005, *A. viscosus* was recovered as a cause of endocarditis that required aortic valve replacement.[562] This organism was isolated from multiple draining sinus tracts on the back of a patient with an unusual presentation of chronic cutaneous actinomycosis and from a loculated pleural effusion in a patient with acute

907

	lymphoblastic leukemia.[290,750] *A. viscosus* was also co-isolated with *Streptococcus constellatus* from a subdural empyema in a previously healthy 8-year-old girl, which unfortunately was fatal.[132] This species is a catalase-positive, gram-positive rod. Colonies on SBA are small and nonhemolytic after growth for 48 hours. Esculin and urea are hydrolyzed and nitrate is reduced to nitrite. Acid is produced from glucose and sucrose and some strains produce acid from xylose.
Actinomyces weissii	This species is based on two isolates from the mouths of two dogs.[493] The first was isolated from an oral wound infection caused by a foreign body in a 4-year-old male Labrador Retriever, while the second was isolated from a gingival specimen from a 13-year-old West Highland White Terrier. Both were recovered in mixed culture with other flora. This organism was noted to be reverse CAMP test-positive.

from perimandibular areas of infection.[1004] Crossman and Herold reported a case of actinomycosis of the maxillary and nasal bones requiring debridement in an 85-year-old male.[244] CT scans initially were suggestive of a diffuse malignant process, but histological staining made the diagnosis. In some cases, other maxillofacial dysplasia or neoplasia may mimic actinomycotic infection or may co-exist in the same infected site.[1038] Mucocutaneous actinomycosis involving the mucosa of the lips and mouth has also been reported.[657]

Thoracic actinomycosis occurs as an extension of cervicofacial infection into the chest and mediastinal region, as a result of aspiration of oropharyngeal contents, or as an extenision of abdominal/pelvic infection that has spread retroperitoneally or transdiaphragmatically.[140] Infection may also result from contiguous extension into the mediastinum from the neck, or may reach the lung parenchyma via the bloodstream.[700] This infection presents initially as an aspiration pneumonitis with the eventual development of lung mass or cavitations. Chest roentgenogram (i.e., X-ray) may reveal masses, fibronodular lesions, or cavitary lesions with accompanying pleural effusions and/or empyema.[761] Pulmonary infection may also extend to involve the bones (i.e., ribs, sternum, thoracic vertebrae, shoulder girdle), chest wall muscles, and soft tissues, including the pericardium and myocardium, and mediastinum.[73] Symptoms include cough, hemoptysis, chest pain, and low-grade fever, and weight loss. The differential diagnosis of thoracic and thoracopulmonary actinomycosis in broad and includes tuberculosis, fungal infection (e.g., blastomycosis, cryptococcosis), nocardiosis, and carcinoma.[761] Up to 25% of cases of thoracic actinomycosis may be initially thought to represent a malignancy.[700]

Abdominal actinomycosis develops when the gastrointestinal mucosa is compromised by surgical procedures, lower gastrointestinal tract trauma, immunosuppression, presence of a foreign body, or as a complication of colonic diverticulitis.[140,1069]Postsurgical actinomycosis develops sometime months to years

after procedures such as appendectomy, with extension from the intestine and involvement of adjacent tissues and organs. Usually, the ileocecal region of the colon is involved, and the infection may remain localized or can spread hematogenously or by direct extension to the liver, abdominal wall, spleen, stomach, gallbladder, pancreas, kidneys, and retroperitoneal tissue.[5,280,1103] The colon may be involved at multiple discrete sites, and infection of the sigmoid colon and rectum has also been described.[883,1040] As with craniofacial infection, mass lesions that develop in the abdomen may be misdiagnosed as solid tumors.[5,887] Mass abdominal lesions may cause large bowel obstruction and can result in intestinal perforation as well.[808,883] Radiological methods are not very helpful for diagnosing abdominal actinomycosis, but Computerized tomography (i.e., CT) can delineate the site and size of intra-abdominal masses and the relation of the mass to adjacent tissues and organs.[525] Anorectal actinomycosis may originate in an infected anal crypt, fissure, or abscess or by direct extension from an intra-abdominal location. Omental actinomycosis that presented as an inflammatory tumor with fistula formation between the transverse colon and the jejunal region of the small intestine has also been described.[675] Isolated hepatic and hepatosplenic actinomycosis are rare clinical entities that may present as a palpable tender mass in the left mid-abdomen as with constitutional symptoms such as fever, night sweats, bloating, anorexia, and weight loss.[629,1178] Abdominal actinomycosis may also develop as an extension and complication of pelvic actinomycosis associated with intrauterine contraceptive devices.[159] Pusiol and colleagues[887] described a patient with abdominal-pelvic actinomycosis that consisted of a retroperitoneal mass lesion extending from the lower pole of the right kidney to the lower pelvis. This mass involved the ascending colon, cecum, the distal ileum, the right Fallopian tube and ovary, ureter, and the psoas muscle. The patient had an intrauterine contraceptive device (IUD) in place for the prior 3 years. Symptoms of abdominal actinomycosis include fever, weight loss, nausea, vomiting, abdominal pain, and changes in bowel function and habits.[1169] Abdominal actinomycosis may mimic colon cancer, particularly in immunocompromised patients (e.g., liver transplant recipients).[628] A diagnosis can be made if sulfur granules are present and microscopic examination reveals, branching gram-positive bacilli. Both surgical and medical interventions may be necessary to diagnose and treat these infections.[1069] Surgery enables the removal of necrotic tissue and persistent sinus tracts and may shorten the time required for parenteral therapy so a switch to oral agents can be made more quickly.

Pelvic actinomycosis may result from contiguous spread of abdominal actinomycosis or may originate in the pelvis itself. This infection is often associated with IUDs that become colonized with *Actinomyces* organisms.[140,1208] Pelvic actinomycosis is more common in women who have had an IUD in place for more

than 4 years. The clinical presentation ranges from asymptomatic endocervical colonization to tubo-ovarian infection. Pelvic actinomycotic infection may cause endometritis, salpingitis, salpingo-oophoritis, and tubo-ovarian abscess. Adnexal masses may become large enough to palpate and suggest the presence of a pelvic neoplasm.[1022] Pelvic actinomycosis may extend into adjacent

organs, including the intestine, bladder, liver, and peritoneum.[129,593] Imaging studies, particular CT scans, may be particular useful for defining size of pelvic lesions and the extent of involvement of adjacent organs.[57] Symptoms can include fever, chronic vaginal discharge, abnormal vaginal bleeding, pelvic pain, and weight loss. Kim and colleagues[593] described a patient with multiple, large ovarian and hepatic masses, plus peritoneal metastases for which the working diagnosis was metastatic ovarian cancer. Pathology established that the cause was actinomycosis. Pelvic actinomycosis mimicking ovarian malignancy may also occur in female patients without a history of IUD placement or use.[786]

CNS actinomycosis occurs as a result of hematogenous dissemination or by direct extension from actinomycotic infections in the cervicofacial or neck areas.[456,1034] Patients usually present with a chronic meningitis or meningoencephalitis complicated by the development of subdural empyema, epidural and spinal abscesses, and cranial osteomyelitis. In 75% of cases, CNS actinomycosis presents with single or multiple encapsulated brain abscesses, usually in the temporal or frontal lobes.[1035] Patients may have the signs and symptoms of a chronic meningitis that resembles tuberculous

meningitis or another chronic CNS infections. CSF usually shows a mononuclear pleocytosis, elevated protein, and normal or low glucose concentrations. On CT scans, the lesions are ring enhancing and resemble the CNS lesions of nocardiosis. Interestingly, headache and focal neurological signs are usually present but fever is found in only about half of patients with CNS actinomycosis.

Actinomycosis may have unusual presentations because of the propensity of the organism to spread contiguously. Acevedo and colleagues[3] described a 37-year-old man with a previous history of pectoral actinomycosis who presented with lower back pain, multiple nodules with purulent discharge on the lumbar region, and genital and abdominal wall edema resulting in swelling of his legs. CT scans showed retroperitoneal and paravertebral masses compressing the inferior cava and ureters, hydronephrosis, and osteolytic lesions in the lumbar vertebrae. Another patient, a 41-year-old woman, had actinomycotic cholecystitis involving the gallbladder with adhesions and extension to the stomach and right colon.[3] Other unusual clinical presentations have included actinomycotic pericarditis with tamponade.[3] Primary cutaneous actinomycosis is rare. In one instance, an 18-year-old male with common variable immunodeficiency developed large, tumor-like masses on two of his fingers several days after receiving a lamb bite.[714] *A. bovis* was cultured from purulent material oozing from the lesions. Finally, a 35-year-old woman presented with a 7-year history of back wounds that discharged purulent material on occasion.[750] Gram's stain of the sinus tract discharge showed branching, filamentous gram-positive bacilli and *A. viscosus* grew from the cultured specimen.

Arcanobacterium *and* Trueperella *Species*

Arcanobacterium species are facultative, gram-positive, nonmotile bacilli that may be slightly curved and show rudimentary branching along with "Chinese letters" and V-forms. Unlike *Corynebacterium* species, these organisms are mostly catalase-negative, do not possess cell wall mycolic acids, and contain L-lysine and L-ornithine rather than *meso*-DAP as the peptidoglycan di-amino acid. The genus *Arcanobacterium* formerly included nine species: *A. haemolyticum*, *A. pyogenes*, *A. bernardiae*, *A. phocae*, *A. pluranimalium*, *A. hippocoleae*, *A. bialowiezense*, *A. bonsai* and *A. abortisuis*.[56,226,520,643,661,896] *A. haemolyticum*, *A. pyogenes*, and *A. bernardiae* were formerly members of the genus *Corynebacterium* and subsequently the genus *Actinomyces* before 16S rRNA sequence studies established the genus *Arcanobacterium*.[226,896,903] *A. phocae* was isolated from seals and other marine animals, while *A. pluranimalium* was recovered from a harbor porpoise, and ovine material.[350,643,896] *A. hippocoleae* has been isolated from vaginal secretions of a horse and from cases of equine placentitis and stillbirth, and *A. bialowiezense* and *A. bonasi*

were isolated from prepuce cultures from bison bulls.[475,520,661] *A. abortisuis* is an obligately anaerobic species that was isolated from the placenta of a sow who had experienced an abortion, and, subsequently, isolates of this species have been obtained from vaginal, urine, kidney, and cervical cultures from pigs.[56,87,1130] In 2006, Lehnen and coworkers[661] examined the menaquinones of *A. pyogenes* and found they were similar to those found in *A. bialowiezense* and *A. bonasi*, but divergent from those of *A. haemolyticum*. The suggestion was made that genus *Arcanobacterium* should be restricted to *A. haemolyticum*, *A. phocae*, *A. pluranimalium*, and *A. hippocoleae*, whereas *A. pyogenes*,*A. bernardiae*, *A. bialowiezense*, and *A. bonasi* should be reclassified in a new genus.[661] Yassin and colleagues then undertook an polyphasic investigation of the structure of the genus *Arcanobacterium*, examining 16S rRNA gene sequences, peptidoglycan structure, fatty acid and whole cell wall carbohydrate analysis, and polar lipid and menaquinone composition. On the basis of these studies, it was formally proposed that the genus *Arcanobacterium* be restricted to *A. haemolyticum*, *A. hippocoleae*, *A. phocae*, and *A. pluranimalium*, and that *A. abortisuis*, *A. bernardiae*, *A. bialowiezense*, *A. bonasi*, and *A. pyogenes* be reclassified in the new genus *Trueperella* as *Trueperella abortisuis*, *Trueperella, bernardiae*, *Trueperella bialowiezense*, *Trueperella bonasi*, and *Trueperella pyogenes,* respectively.[1227] In 2012, the new *Arcanobacterium* species, *A. canis,* was described. This species was isolated from an otitis externa of a 7-year-old English Bulldog.[496]

A. haemolyticum is associated with acute pharyngitis in humans, with the highest incidence in individuals between 15 and 18 years old.[701] Cervical lymphadenopathy, tonsillitis, and rash frequently may accompany the infection. Because of the rash, patients may be thought to have scarlet fever. *A. haemolyticum* may also cause other types of head and neck infections, including sinusitis and peri-orbital cellulitis.[676,1163] *A. haemolyticum* has also been recovered from chronic skin ulcers, soft tissue cellulitis, postoperative wound infections, and deep-tissue abscesses, including brain, peritonsillar, paravertebral, pelvic, and intra-abdominal abscesses.[709,1032,1147,1149] *A. haemolyticum* may occasionally cause bacteremia and sepsis in both immunocompetent and immunocompromised hosts. Bacteremia usually results from spread of the organism from local sites, including abscesses, pneumonia, and cellulitis.[1088,1104] *A. haemolyticum* has also been associated on three two occasions with Lemierre's disease, which is characterized by peritonsillar infection followed by unilateral swelling and tenderness along the sternocleidomastoid muscle due to

sole isolate from blood cultures, while, in the two other cases, the organism was co-isolated with *F. necrophorum*, the typical agent involved in Lemierre's disease.[339,698,1238] *A. haemolyticum* is a rare cause of endocarditis, osteoarticular infections, thyroid abscess, pelvic abscess, septic arthritis, chorioamnionitis, and urinary tract infections.[28,208,428,981,982,1988,1104,1147] *A. haemolyticum* may also cause infections in horses and rabbits.[476] *A. haemolyticum* is usually susceptible to all classes of antimicrobial agents, including penicillins, cephalosporins, macrolides, and vancomycin, with resistance to trimethoprim-sulfamethoxazole being a consistent finding.[163,164] Occasional isolates may be resistant to tetracyclines, the macrolides, clindamycin, and ciprofloxacin.[164]

Trueperella bernardiae includes isolates that were formerly called CDC coryneform group 2 and, subsequently *Actinomyces bernardiae*.[383] Sequence analysis of the 16S rRNA of these isolates resulted in the transfer of this species to the genus *Arcanobacterium* as *Arcanobacterium bernardiae* and recent polyphasic taxonomy studies resulted in transfer of this species to the new genus *Trueperella* as *Trueperella bernardiae*.[896,1227] *T. bernardiae* was isolated from a blood cultures of a 72-year-old woman who had large sacral decubiti; the organism was not recovered from the ulcers, but was isolated from the blood.[1190] Two patients with complicated urinary tract infections by this organisms have been described in individuals with chronic bladder dysfunction and structural urinary tract abnormalities.[535,664] One of these patients developed bacteremia and perirenal abscesses.[535] *T. bernardiae* has also been associated with osteoarticular infections, including septic arthritis, osteitis of the knee, and infection of a left total hip prosthesis.[9,86,686,891] *T. bernardiae* has also been isolated from an anal swab from a piglet.[495] *T. bernardiae* is susceptible to amoxicillin, cephalothin, cefotaxime, imipenem, aminoglycosides, erythromycin, clindamycin, linezolid, levofloxacin, and vancomycin.[86,686]

T. pyogenes is an inhabitant of the upper respiratory, gastrointestinal, and urogenital tracts of many domesticated animals and is also recognized as a veterinary pathogen, causing infections in pigs, cattle, sheep, goats, and domesticated companion animals (i.e., dogs and cats).[109,497] In this regard, the organism and the infections is causes have significant economic importance. It may also be recovered from milk and other dairy products produced from infected animals. While human infections caused by this organism have been reported since 1940, the validity of these reports is questionable due to lack of microbiological data ensuring a definite distinction of this agent from closely related bacteria like *A. haemolyticum*. Bacteriologically confirmed infections have occurred mostly in persons living in rural areas who have close contact with animals and have included bacteremia in a patient with colon cancer, five patients with intra-abdominal infections (including one patient with cervical cancer), two patients

with otitis media, one with mastoiditis, two with cystitis (including one with prostatic carcinoma), two patients with skin abscesses, and one diabetic patient with a mixed wound infection and positive blood cultures containing *T. pyogenes*.[70,295,391,699] In 2007, Plamondon et al.[875] reported the first instance of ultimately fatal *T. pyogenes* endocarditis in a 57-year-old Canadian man. This patient had several underlying conditions, including alcoholic cirrhosis, poorly controlled type II diabetes, peripheral neuropathy, and chronic leg ulcers.[875] In 2009, *T. pyogenes* sepsis was reported in a immunocompetent farmer from Brazil, and in 2010, three patients with skin and soft tissue infections were reported from India.[573,671] These patients had diabetes, Hansen's disease (leprosy), or scabies as underlying conditions that were likely involved in the pathogenesis of the infections. *T. pyogenes* is susceptible to ampicillin, third- and fourth-generation cephalosporins, aminoglycosides, macrolides, linezolid, rifampin, and vancomycin; some strains are resistant to tetracyclines and trimethoprim-sulfamethoxazole.[1116,1237]

A. haemolyticum, *T. bernardiae*, and *T. pyogenes* are the species that may be encountered in clinical specimens from humans. On SBA, *A. haemolyticum* grows as small, dull, matte colonies that are β-hemolytic (Image Plate 14-6E). Hemolysis may first be noted in areas of confluent growth after 24 hours incubation; isolated colonies will be β-hemolytic after 48 hours incubation. Use of horse blood (5%) instead of sheep blood allows recognition of β-hemolysis surrounding isolated colonies up to 24 hours earlier than sheep blood.[396] All three species are negative for arginine dihydrolase, β-glucosidase, reduction of nitrate, and urease, and none of them produce acid from arabinose, raffinose, sorbitol, or sucrose. *A. haemolyticum* is catalase-negative and does not hydrolyze esculin or urea. Most strains are pyrazinamidase, alkaline phosphatase, β-galactosidase, α-glucosidase and *N*-acetyl-β-D-glucosaminidase positive, but gelatin hydrolysis and β-glucuronidase negative. Most isolates ferment glucose, maltose, lactose, and ribose, and do not ferment mannitol, xylose, glycerol, or glycogen (Image Plate 14-6F). *A. haemolyticum* is reverse CAMP test-positive (or CAMP test inhibition-positive). In this test, the effect of the β-hemolysin of *S. aureus* on sheep red blood cells is inhibited by the phospholipase of *A. haemolyticum*. This appears on the SBA plate as a dark "arrowhead-shaped" non-hemolyzed area between *S. aureus* and the *A. haemolyticum* that has been streaked at right angles to the streak of *S. aureus*. *T. bernardiae* forms small, smooth, glassy colonies on SBA that may or may not be β-hemolytic on SBA. This organism is catalase-negative, and produces acid from glucose, maltose, ribose, and glycogen, but not from sucrose, mannitol, xylose, and lactose. Unlike *A. haemolyticum*, glucose is more readily fermented than maltose. *T. pyogenes*, the most infrequently isolated species from animals, is also β-hemolytic and catalase-negative. This species is easily differentiated from *A. haemolyticum* and *T. bernardiae* because it is obviously β-hemolytic at 24 hours, is

gelatin hydrolysis-positive, ferments xylose, and is β-glucuronidase (β-GUR)-positive. All three species are readily identified with the API Coryne. In a study of 56 *A. haemolyticum* isolates, 7 API Coryne profiles were obtained. The profiles and the percentage of strains with the indicated profile were 6530361 (12.5%), 6730161 (3.6%), 6530360 (7.2%), 6730360 (39.2%), 2730160 (17.8%), 2530360 (7.2%), and 2730260 (12.5%).[397] MALDI-TOF has also been shown to be a reliable and rapid tool for identifying *Arcanobacterium* and *Trueperella* species.[494,1157] A method for typing of *A. haemolyticum* isolates using PFGE has been developed.[348] The phenotypic characteristics of *Arcanobacterium* and *Trueperella* species are found in Table 14-9.

Arthrobacter *and Related Species*

Members of the genus *Arthrobacter* are gram-positive cornyneform bacilli that occupy several ecologic niches in the environment. For example, some species are psychrophilic and have been isolated from extreme environments (e.g., Antarctic snow) and some species have been isolated from veterinary specimens. One species described in 2004 was isolated from filtered air samples from the Mir Russian Space Laboratory![673,1226] These organisms have a marked rod-to-coccus cycle, where bacilli predominate in younger cultures and cells become more coccobacillary and coccoid with age. The cellular fatty acid content is consistent among all *Arthrobacter* species as well. In the cell wall, *meso*-DAP is absent, lysine is the predominant amino acid, and alanine and glutamic acid comprise the interpeptide (A3α-type) linkages. During their examination of various CDC group B-1 and B-3 strains, Funke and colleagues[370] encountered 11 human clinical isolates (from urine, skin infection, blood cultures, endophthalmitis) that had characteristics consistent with genus *Arthrobacter*. Newer *Arthrobacter* species—*A. cumminsii* and *A. woluwensis*—were proposed for these CDC group B-1 and B-3 strains. A 1998 analysis of 15 clinical isolates of *A. cumminsii* from the urinary tract, middle ear, amniotic fluid, vagina, calcaneal osteomyelitis, deep-tissue cellulitis, cervix, blood, and wounds revealed unique cellular fatty acid patterns, with the consistent presence of C14:0i and C14:0, and unusually high amounts of C16:0 and C16:0i fatty acids, which are not found in other *Arthrobacter* species.[378] *Arthrobacter* species were also reported in a patient with endophthalmitis following intraocular lens implantation and from a neutropenic patient with acute lymphoblastic lymphoma who developed septicemia.[313,524]

Since 1998, several new *Arthrobacter* species associated with serious infections have been isolated and characterized phenotypically, chemotaxonomically, and

genetically. Clinically relevant species and their sources of isolation include *A. creatinolyticus* (from urine specimens), *A. oxydans*, *A. luteolus* (from surgical wounds), *A. albus* (from multiple blood culture from patient with severe phlebitis), and *A. scleromae* (exudates from multiple dorsal dermal scleromata).[517,527,1183] In 2004, *A. woluwensis* was reported as the cause of endocarditis in an injection drug user.[96] Mages and colleagues performed an exhaustive examination of 50 *Arthrobacter* strains from several types of clinical specimens, including 12 strains each from blood and wounds, 8 from urine samples, 5 from sterile sites, and the remainder from miscellaneous sites. Thirty-eight strains were true *Arthobacter* species, and more than half of these were either *A. cumminsii* (14 isolates) or *A. oxydans* (11 isolates). The third most common isolate was *A. aurescens*, which had never before been isolated from human specimens. This work also revealed a new species, *A. sanguinis*, from blood cultures.[703] As had been reported earlier for *A. woluwensis* and *A. cumminsii*, all 38 bona fide *Arthrobacter* species were susceptible to β-lactams, doxycycline, gentamicin, linezolid, rifampin, and vancomycin. A 2012 report documented another new species, *A. mysorens*, from a soil-contaminated erythrasma-like skin lesion; the same organism was isolated from the soil.[536] Molecular techniques were used to detect an *Arthrobacter* species in blood and placental tissue associated with fetal death and maternal disseminated intravascular coagulation.[1009] These organisms have also been isolated from semen specimens from patients with inflammatory prostatitis.[1126]

Arthrobacter species demonstrate a rod-to-coccus cycle, with cocci predominating in older cultures. Colonies may be creamy white, gray/white, or yellow, and are smooth, glistening, and circular with entire edges. Some environmental *Arthrobacter* species may have red to blue/green colonies. Nitrate reduction and hydrolysis of urea and esculin are variable characteristics. Acid is produced oxidatively from a variety of carbohydrates, as determined by assimilation. In most reports on these organisms, the API CHO (bioMérieux, Inc.), a carbohydrate assimilation, not fermentation, panel was used for characterization, but this system is not usually used in clinical laboratories. *A. cumminsii,* the most frequently isolated *Arthrobacter* species from human clinical specimens, is LAP-positive, and negative for both nitrate reductase and esculin hydrolysis. Some strains produce urease, and both DNase and gelatinase activity are produced by most isolates. While most strains produce acid from ribose, acid production from glucose is variable, and no acid is produced from maltose, sucrose, mannitol, xylose, lactose, or glycogen. *A. woluwensis* hydrolyzes esculin, urea, gelatin and DNA, and, unlike *A. cumminsii*, produces several enzymatic activities, including β-galactosidase (β-GAL), α-glucosidase (α-GLU), β-glucosidase (β-GLU), and *N*-acetyl-β-D-glucosaminidase (NAGA). *Arthrobacter* species are included in the API Coryne database; however, the carbohydrate fermentation cupules will usually be negative after 24 hours. Prolonged incubation of the identification panels (up to 5 to 7

days) may result in slow oxidative utilization of some carbohydrates. When *A. cumminsii* isolates were tested on the API Coryne, numerous different biotype numbers were generated after 24 hours, 48 hours, and 7 days incubation.[370,378] Molecular methods (e.g., sequencing studies) and chemotaxonomic methods are necessary for definitive identification of *Arthrobacter* species. Phenotypic and biochemical characteristics of *Arthrobacter* species isolated from clinical species are presented in Table 14-10.

The antimicrobial susceptibility of *Arthrobacter* species may be quite variable. In a study of 10 *A. cumminsii* strains, the β-lactams, rifampin, and vancomycin showed good activity against most isolates.[378] All strains were susceptible to the macrolides, and most were tetracycline susceptible. MICs for the aminoglycosides were surprisingly high, with the MIC_{50} being 8 μg/mL for gentamicin and 64 μg/mL for tobramycin. Similarly, the fluoroquinolones showed elevated MICs for most strains tested. The *A. woluwensis* endocarditis isolate reported by Bernasconi et al.[96] was resistant to penicillin and ciprofloxacin, and susceptible to tetracycline and vancomycin by disk diffusion.[96] *Arthrobacter* strains examined by others have exhibited susceptibility to theβ-lactams, doxycycline, gentamicin, rifampin, linezolid, and vancomycin, with less susceptibility seen for ciprofloxacin.[370,378,703] These studies also noted the multiresistant nature of *A. woluwensis*. The single *A. scleromae* isolate reported by Huang and colleagues[527] was susceptible to ceftriaxone, rifampin, and tetracycline, intermediate in susceptibility to cefazolin, cefotaxime, doxycycline, erythromycin, and vancomycin, and resistant to penicillin, ampicillin, oxacillin, and all aminoglycosides (gentamicin, tobramycin, amikacin, streptomycin, kanamycin) by the CLSI criteria established for

917

staphylococci. Reports of infections with uncharacterized *Arthrobacter* species have also noted isolates with elevated MIC against β-lactams, macrolides, and tetracyclines, and susceptibility to vancomycin.[517]

During their examination of the 50 *Arthrobacter* isolates, 7 isolates were found to be other species. While three belonged to genus *Brevibacterium*, and two were *Microbacterium* species, single isolates belonged to the genera *Pseudoclavibacter*,*Leucobacter*, or *Brachybacterium*.[703] All of these genera include various environmental organisms. The *Pseudoclavibacter* species in this study was isolated from an aortic valve of a 74-year-old male. Lemaitre et al.[662] isolated a gram-positive rod from a chronic subcutaneous infection of the right leg. The isolate was sequenced and determined to have 99% sequence similarity with genus *Pseudoclavibacter*.[662] *Brachybacterium* species have been recovered from clinical material before, but *Leucobacter* had never been previously reported in human clinical samples.[1044]

Brevibacterium *Species*

Brevibacterium species are irregular, slender, rod-shaped bacteria that also display a marked rod-to-coccus cycle. Fresh subcultures (<3 days) stain as bacilli, but as the culture ages (4 to 7 days), the cells may appear coccal in morphology. Cells are gram-positive, but may be easily decolorized. The rod-shaped cells show diphtheroidal morphology and are non–acid-fast. *Brevibacterium* species are obligately aerobic and are oxidative in their metabolism. They are nonmotile, salt-tolerant (>6.5% NaCl), produce catalase and proteinases, do not possess urease, and do not produce acid from glucose or other carbohydrates in peptone media. Brevibacteria also characteristically produce methanethiol (CH_3SH) from L-methionine. The peptidoglycan contains *meso*-DAP as the principal di-amino acid, but does not contain arabinose, lysine, or mycolic acids (galactose may or may not be present).[150]

Genus *Brevibacterium* contains more than 45 species, most of which are environmental bacteria. Colonies are grayish white, yellowish white, yellow, or tan and have an intense "cheesy" odor. The habitat of the many brevibacteria is primarily milk products, where the organisms contribute to the aroma (e.g., Limberger cheese) and the color (e.g., orange-pigmented *B. linens*) of surface-ripened cheeses. They are also found on human skin surfaces; under moist, macerating conditions (e.g., between the toes and other intertriginous areas), these organisms are believed to contribute to body odor. Brevibacteria are rare causes of human infections and examination of strains previously classified as CDC groups B-1 and B-3 established that some were *Brevibacterium* species. Gruner, Pfyffer, and von Graevenitz isolated nine *Brevibacterium* strains from dialysate fluids, blood cultures, sputum, CSF, pleural fluid, and a miscellaneous body fluid.[445] Comparison of their biochemical characteristics with reference *Brevibacterium* strains indicated that these organisms were either *B. casei* or *B. epidermidis*. These researchers suggested that aerobic, gram-positive and catalase-positive bacilli that are nonmotile and fail to ferment sugars may be identified as presumptive *Brevibacterium* species based on colony pigmentation and morphology (gray-white to yellow, opaque, convex and smooth) and an intensive "cheesy" or "stinky feet" odor. A subsequent examination of 41 clinical strains of CDC groups B-1 and B-3 found that 22 were identical to *B. casei*, with 5 additional isolates forming another phenotypic cluster within the genus *Brevibacterium*.[446] Funke and Carlotti also examined 43 *Brevibacterium* strains recovered from clinical specimens over the last 20 years and compared them to reference *Brevibacterium* strains.[360] Using chemotaxonomic analysis and carbohydrate assimilation tests with the API 50CH assimilation panel, 41 were identified as *B. casei* and 2 were identified as *B. epidermidis*.

Brevibacterium species have been isolated from several human infections since their initial characterization, and 10 species have been isolated from human clinical

specimens: *B. casei*, *B. epidermidis*, *B. iodinum*, *B. mcbrellneri*, *B. otitidis*, *B. lutescens*, *B. paucivorans*, *B. sanguinis*, *B. massiliensis,* and *B. ravenspurgense*. *B. casei* has been isolated from blood cultures as a cause of catheter-related bacteremia in AIDS patients, bacteremia in a patient with choriocarcinoma, central venous catheter infections, and as a cause of brain abscess, corneal ulcers, and pericardial infection.[38,135,156,404,544,908,1132,1186] *B. sanguinis* has been isolated from skin and from dialysate fluids and is phenotypically similar to, but genotypically distinct from *B. casei*.[1186] *B. epidermidis* has caused central venous line infection and native valve endocarditis in an immunocompetent 52-year-old man.[711,734] *B. otitidis* has been isolated from ear drainage of patients with bilateral otorhea, from blood cultures as a cause of prosthetic valve endocarditis in an elderly woman, and from peritoneal fluid of a patient on CAPD.[257,844,1187] *B. lutescens* is a *B. otitidis*-like species that was also isolated from human peritoneal dialysis fluid and infected ear drainage in 2003.[1182] *B. iodinum* peritonitis in a CAPD patient was reported in Greece in 1997.[40] *B. mcbrellneri* was originally isolated from human genital hairs that were co-infected with *Trichosporon beigelii* and *B. paucivorans*, which was described in 2001, has been isolated from CSF, abscesses, wounds, blood, ear discharge, and intravascular catheters.[733,1184] *B. massiliensis* was isolated from discharge from an ankle wound resulting from a car accident.[951] *B. avium* has only been isolated from granulomatous lesions of poultry.[843] In their survey of *Arthrobacter* species, Mages et al.[703] identified a new *Brevibacterium* species, *B. ravenspurgense*, that was isolated from a wound.

All brevibacteria are aerobic, gram-positive, non–spore-forming bacilli that are catalase-positive. They are nonhemolytic on SBA, nonmotile, and asaccharolytic. Colonies of *B. casei* are usually whitish-gray, while *B. epidermidis* strains develop yellowish colonies with time (Image Plate 14-6G). Detection of methanthiol and cellular fatty acid analysis can be used to confirm the assignment of the isolate to the genus *Brevibacterium*, and carbohydrate assimilations can also be useful for identification of these organisms.[360] Some *Brevibacterium* species are included in the data bases of the API Coryne and the RapID CB-Plus (Image Plate 14-6H). Molecular characterization most accurately identifies these organisms. Biochemical characteristics of *Brevibacterium* species are shown in Table 14-11.

The antimicrobial susceptibility of *Brevibacterium* species may be quite variable. Funke, Punter, and von Graevenitz examined 50 *B. casei* strains, which are the the most frequently isolated species, and found that all isolates showed decreased susceptibility to all β-lactam agents, with half of

the 50 isolates tested having β-lactam MICs of >1 μg/mL.[380] Troxler and colleagues[1119] also found that *B. casei* strains tended to have higher β-lactam MICs, with some isolates having cephalosporin MIC's of >8 μg/mL. Both research groups found that *B. casei* displayed elevated MICs to other drug classes, including the macrolides, lincosamides, and fluoroquinolones. Others have found that *B. casei* strains are susceptible to β-lactams, aminoglycosides, tetracyclines, rifampin, linezolid, vancomycin, teicoplanin, imipenem, meropenem, and linezolid.[38] The clinically significant isolates of *B. otitidis* (from blood and peritoneal fluid) were susceptible to all agents tested, including penicillin, ampicillin, cephalosporins, fluoroquinolones, macrolides, gentamicin, ciprofloxacin, linezolid, and vancomycin.[257,1187] The *B. iodinum* isolate reported by Antoniou et al.[40] was resistant to ampicillin, the cephalosporins, and vancomycin, but susceptible to fluoroquinolones and amikacin.

Cellulomonas, Cellulosimicrobium, *and* Oerskovia *Species*

Cellulomonas species are principally environmental organisms that appear as small, slender, irregular coryneform rods that become more coccoid in older cultures. They are gram-positive (although easily decolorized), non–acid-fast, and may be nonmotile or motile due to single polar or sparse lateral flagella. Colonies of these organisms are usually opaque, convex, and yellow-pigmented. The cell wall peptidoglycan contains L-ornithine and does not contain *meso*-DAP, glycine, lysine, or homoserine. These organisms are either oxidative or fermentative in their metabolism; most strains produce acid from glucose both aerobically and anaerobically. *Cellulomonas* species are catalase-positive, hydrolyze cellulose, starch, and gelatin (weak reaction), reduce nitrate to nitrite, and produce DNase. The genus *Cellulomonas* includes several valid species that are isolated from various environments (e.g., soil, compost, water).[381] The genus *Cellulomonas* (and *Cellulosimicrobium*) are in the phylum *Actinobacteria*, class *Actinobacteria*, in the *Micrococciniae* suborder of the order *Actinomycetales*, family *Cellulomonadaceae.*

Some strains of former CDC coryneform groups A-3 and A-4 have been reclassified as *Cellulomonas* species that have been isolated from human clinical specimens.[381,389,478] Funke, Ramos, and Collins examined clinical isolates from CSF (two isolates) and blood (two isolates); both of the CSF isolates had been phenotypically identified as CDC group A-3, while the blood culture isolates were identified as CDC group A-4.[381] These isolates were compared to type strains of the characterized environmental *Cellulomonas* species using peptidoglycan and cellular fatty acid analysis in addition to the phenotypic tests used for characterization of coryneforms. Phenotypic test results for these isolates did not correspond to any of the extant *Cellulomonas* species. The four clinical isolates contained L-ornithine as the peptidoglycan di-amino acid, thereby reinforcing affinity with *Cellulomonas* species. Partial sequencing of the 16S rRNAs of these organisms further validated the similarities with *Cellulomonas* species, and Funke and coworkers[389] formally proposed that CDC group A-3 and some group A-4 strains be assigned to a new genus, *Cellulomonas hominis*. These organisms have been isolated from vitreous humor specimens following penetrating injuries or intraocular lens transplants, blood cultures associated with catheter-related sepsis, native valve endocarditis, and cerebrospinal fluid.[115,389,478] In 2005, the remaining six coryneform A-3 isolates strains (i.e., two blood isolates, one CSF isolate, one each from a homograft valve, a pilonidal cyst, and a lip wound) were placed in the new species *Cellulomonas denverensis.*[142] *C. denverensis* has also been isolated from the blood and bile cultures of an 82-year-old woman with acute cholecystitis.[813] In 2009, an uncharacterized *Cellulomonas* species was isolated from several sets of blood cultures from a 78-year-old female with endocarditis complicated by osteomyelitis of the lumbar spine.[626]

C. hominis and *C. denverensis* are both small, thin, motile gram-positive rods. Colonies of both organisms on SBA are smooth, circular, convex, and white; a pale yellow to yellow pigmentation develops after 2 to 3 days. Both species are catalase-positive, hydrolyze esculin, reduce nitrate to nitrite, and are urease-negative. Both species produce acid from several carbohydrates including, glucose, maltose, sucrose, xylose, and lactose. Mannitol is not fermented by either species. The two species can be differentiated by sorbitol fermentation; *C. denverensis* produces acid from sorbitol, while *C. hominis* does not.[142,381] Unlike environmental *Cellulomonas* species, *C. hominis* does not hydrolyze cellulose. *Cellulomonas* species are included in the API Coryne database, but these organisms will usually give a cross-call with *Microbacterium* species.

The genus *Cellulosimicrobium* includes the organisms formerly included in the genus *Oerskovia* (*O. xanthineolytica* and *O. turbata*) that were subsequently transferred to the genus *Cellulomonas* as *C. cellulans* and *C. turbata,* respectively. Analysis of 16S rDNA dendrograms provided evidence that "*C. cellulans"* branched outside of the phylogenetic confines of the genus *Cellulomonas* and was a phylogenetic "nearest neighbor" of the genus *Promicromonospora*. In addition, chemotaxonomic analysis of the cell wall of "*C. cellulans*" showed that the type strain and other strains of this species possess a "type A4α" peptidoglycan, a characteristic not found among members of the genus *Cellulomonas*, including "*C. turbata*". L-lysine was found to be the principal cell wall di-amino acid of "*C. cellulans*", while other *Cellulomonas* species contain L-ornithine. The agreement between the phylogenetically distinct position of this organism in the 16S rDNA dendrogram, and the different chemotaxonomic properties exhibited by this organism justified the assigment of "*C. cellulans*" to the new genus *Cellulosimicrobium,* with the type species being *Cellulosimicrobium cellulans* ("*Oerskovia xanthineolytica*").[993] In 2006, Brown and colleagues[143] proposed that some clinical isolates of "*C. turbata*" be included in the genus *Cellulsosimicrobium* based on 16S rRNA sequence and chemotaxonomic data; this species is named *Cellulosimicrobium funkei*. In 2007, a third *Cellulosimicrobium* species, *Cellulosimicrobium terreum*, was isolated from soil samples from Dokdo, South Korea.[1233] This latter species description is based on a single environmental isolate, and this species does not grow at or above 35°C. In 2002, another *Cellulosimicrobium* species, *C. variabile*, was isolated from the hindgut of a termite, but this species was reclassified in as *Isoptericola variabilis* in 2004.[62,1055]

C. cellulans is found in the environment (soil, water, grass cuttings), as a cause of infection in animals (e.g., horses)

921

and as a rare cause of opportunistic infections primarily in in immunocompromised hosts, with *C. cellulans* being isolated much more frequently than *C. funkei*.[41,124] *C. cellulans* has been reported as a rare cause of keratitis, endophthalmitis, pneumonia, prosthetic joint-related infection, catheter-related bacteremia, ventriculoperitoneal shunt-associated meningitis, and peritonitis in patients receiving chronic ambulatory peritoneal dialysis.[474,567,696,735,800,1000] *C. cellulans* bacteremia has also been documented in bone marrow transplant recipients, in AIDS patients, and in patients with underlying liver disease.[304,705] These organisms may contaminate total parenteral nutrition solutions; this was only discovered after a patient developed signs and symptoms of bacteremia immediately following parenteral infusion, with recovery of the organisms from blood cultures, from the associated central venous catheter, and from a sampling of the nutritional supplement.[453] More recently. *C. cellulans* has been isolated as the cause of neonatal sepsis with negative CSF and urine cultures and as the agent of central venous catheter-related bacteremia in a 13-year-old male with midgut volvulus and short bowel syndrome.[167,952] Pyogenic flexor tenosynovitis of the right middle finger and septic arthritis of the knee due to *C. cellulans* were described in two patients, both of whom had had penetrating injuries to the involved site with retained foreign bodies serving as the nidus of infection.[704,1122] Molecular methods using universal primers based on conserved sequences of the *rrn* gene (encoding 16S rRNA) were used to amplify a 479-base-pair fragment from a biopsy specimen of a tongue lesion from a patient with AIDS. On sequencing, the fragment was identical to the 16S rRNA gene of the *C. cellulans* type strain.[491] *C. cellulans* was also identified as the causative agent of postoperative endophthalmis following cataract surgery in three patients.[19]

C. funkei is isolated less frequently than *C. cellulans* and has been documented as the cause of Broviac catheter-related bacteremia in a 3-year-old male and as a cause of endocarditis in a 68-year-old man whose aortic valve had been replaced with a homograft heart valve because of severe aortic insufficiency related to ankylosing spondylitis.[666,910] In 1996, this organism was reported as a cause of bacteremia (along with *Comomonas acidovorans*) in a patient with AIDS.[627] More recently, *C. funkei* bacteremia and possibly prosthetic valve endocarditis was reported in an 81-year-old male who had received a tissue aortic valve replacement 7 months previously due to aortic stenosis and from a patient with peritonitis.[100,865]

C. cellulans produces smooth, glistening, entire colonies that are strongly yellow-pigmented (Image Plate 14-7C). The organism's actinomycetous affinities are manifested by the production of a substrate "mycelium" that fragments into irregular, curved and club-shaped rods arranged in V-forms and "Chinese letters." After exhaustion of fermentable carbohydrate from broth media, these rod-shaped organisms are transformed into even shorter rods or coccal forms. These organisms

are biochemically active and are included in the databases of both the API Coryne and the IDS RapID CB-plus systems for the identification of coryneform bacteria. The common API Coryne biocodes for *C. cellulans* are 3552727, 7552727, 3572727, or 7572727 (Image Plate 14-7D).[952] Both *C. cellulans* and *C. funkei* hydrolyze casein, but only *C. cellulans* hydrolyzes xanthine. In addition, *C. cellulans* grows at 42°C, while *C. funkei* does not. MALDI-TOF MS has been used successfully for identification of *C. cellulans*.[704]

C. cellulans and *C. funkei* are variable in their susceptibility to antimicrobial agents. While many isolates have been reported as susceptible to penicillin, ampicillin, cephalothin, tetracycline, clindamycin, erythromycin, gentamicin, trimethoprim-sulfamethoxazole, ciprofloxacin and vancomycin, strains that are resistant to these agents have also been reported.[735,1122] The isolate from the neonatal sepsis case reported in 2010 was resistant to penicillin, ampicillin, cefotaxime, clindamycin, ciprofloxacin, and erythromycin, and susceptible to linezolid, rifampin, sulfamethoxazole-trimethoprim, and vancomycin using the CLSI standards for *Corynebacterium* species.[167,214] In the species description of *C. funkei*, all 13 isolates evaluated were susceptible to ampicillin, amoxicillin clavulanate, ceftriaxone, clarithromycin, minocycline, and vancomycin.[143] The *C. funkei* blood isolate described by Petkar et al.[865] was resistant to penicillin, erythromycin, tetracycline ciprofloxacin, rifampin, sulfamethoxazole-trimethoprim, and imipenem, and susceptible to vancomycin and gentamicin. Linezolid and vancomycin may be considered the drugs of choice for *C. cellulans* and *C. funkei* infections.[704] High-level vancomycin and teicoplanin resistance has been reported in a clinical isolate of *C. funkei*.[881] This glycopeptide resistance was shown to be due to modified cell wall peptidoglycan structure related to the presence of *vanA* gene sequences similar to those found in vancomycin-resistant strains of *Enterococcus faecium*. Treatment of some *C. cellulans* infections required removal of foreign bodies in order to effect cure with the appropriate agents.[1122]

Members of the emended genus *Oerskovia* demonstrate branching vegetative hyphae that penetrate into the agar and fragment into motile rod-like elements.[1054] On smears, the organisms appear as coryneform bacilli. Organisms may or may not be motile. They are catalase- and oxidase-positive and facultative with respect to oxygen, although some strains may be strictly aerobic. Major fatty acids, isoprenoid quinone composition, and other characteristics of the genus are shown in Table 14-5. *O. enterophila* is recovered from insects and was formerly a *Promicromonospora* species, while *O. jenensis* and *O. paurometabola* are soil isolates.

Dermabacter *and* Helcobacillus *Species*

In 1988, Jones and Collins described four strains of coryneform bacteria that were isolated exclusively from human skin.[557] The cell walls of these isolates contained *meso*-DAP, alanine, and glutamic acid, but lacked cell wall mycolic acids.[150] These bacteria also contained predominantly branched-carbon cellular fatty acids, a characteristic found only in *Brevibacterium* species and the environmental organism *Brachybacterium faecium*. The organisms were fermentative (not oxidative like *Brevibacterium* and *Brachybacterium* species) and produced acid from several carbohydrates. The name *Dermabacter hominis* was proposed for these strains. Subsequent examination of CDC group 3 and group 5 isolates recovered human clinical established that these two CDC groups were identical to the type strain of *Dermabacter hominis* described by Jones and Collins.[94,386,557] *D. hominis* has been recovered from a variety of clinical specimens

including blood, lung tissue, abscesses, CSF, peritoneal fluid, conjunctivae, calcaneal osteomyelitis, and infected vascular grafts.[420,447,1138] In 1998, Bavbek and colleagues[76] described a renal transplant recipient that presented as a contrast-enhancing brain mass, which was found to be a cerebral abscess caused by *D. hominis*. *D. hominis* has also been recovered as a cause of peritonitis from a patient on CAPD and was co-isolated with *S. aureus* and *Finegoldia magna* from a recurrent abscess.[718,892] A *Dermabacter*-like organism was isolated by Renvoise and colleagues[917] from an erythrasma-like lesion from a 58-year-old man. The organisms showed 95.1% similarity with *D. hominis* and represented a new genus and species. This organism was named *Helcobacillus massiliensis*. Both of these species are classified in the family *Dermatobacteriaceae,* suborder *Micrococcineae*, order *Actinomycetales*, class *Actinobacteria*, in the phylum *Actinobacteria*.

D. hominis and *H. massiliensis* are catalase-positive, nonhemolytic, nonmotile coryneform rods. On Gram's stain, both organisms appear coccobacillary or coccoid. Colonies of *D. hominis* are usually white, convex, and have a creamy or slightly sticky consistency. After 48 hours of incubation, colonies are usually about 1.5 mm in diameter. *H. massiliensis* also forms shiny, white, smooth, nonhemolytic colonies on SBA. *D. hominis* does not reduce nitrate or produce pyrazinamidase and is PYR-positive, while *H. massiliensis* reduces nitrate to nitrite, is pyrazinamidase-positive, and is PYR-negative. These species also produce acid from different carbohydrates as well. *D. hominis* is included in the API Coryne database. Additional phenotypic characteristics of this organism and *H. massiliensis* are presented in Table 14-12.

Exiguobacterium *Species*

Exiguobacterium species are short, irregular coryneform bacilli that demonstrate a marked rod-coccus cycle in their growth. They characteristically produce yellow or pale orange colonies on agar media and are facultative and fermentative in their metabolism.[227] Mycolic acids are absent and L-lysine is the peptidoglycan di-amino acid. *Exiguobacterium* species are catalase-positive, motile, and resemble *Microbacterium* and *Oerskovia* species, although they differ in their cell wall fatty acids. More than fourteen species of *Exiguobacterium* have been described and they are all alkaliphilic, halotolerant, and found in environmental sources. *E. aurantiacum* and *E. acetylicum* are the two species that have been previously isolated from human clinical specimens (e.g., skin, wound, cerebrospinal fluid).[389] *E. aurantiacum* was isolated from blood cultures of six patients in London over a 10-year period; three of these patients had myeloma and one had endocarditis.[873] *E. acetylicum* was isolated from blood cultures as a cause of catheter-related bacteremia in an elderly woman.[588] In 2006, an unnamed *Exiguobacterium* species was isolated from a blood culture of a patient in Belfast. This isolate was misidentified as *C. cellulans* by the API Coryne, and confirmed as an *Exiguobacterium* species by 16S rRNA sequencing.[582] These bacteria produce light yellow, intense yellow, or orange colonies on SBA. Both organisms are catalase-positive and produce acid from variety of carbohydrates. Phenotypic properties of *E. acetylicum* and *E. aurantiacum* are shown in Table 14-13.

Leifsonia *Species*

During a taxonomic investigation of microbes isolated from grassroot galls induced by a free-living nematode, Evtushenko and colleagues[315] recognized a group of coryneform bacteria that were phenotypically similar to the motile coryneform that has historically been called "*C. aquaticum*." Although long considered a *Corynebacterium* species, certain properties (e.g., motility and oxidative carbohydrate metabolism) serve to exclude this organism from this genus. Strains previously called "*C. aquaticum*" also contained DL-2, 4-diaminobutyric acid in the cell wall, as did the grassroot gall isolates. This unusual di-amino acid is also found in the cell walls of *Clavibacter* species. Further analysis of the grassroot gall isolates, reference strains of "*C. aquaticum*," and existing *Clavibacter* species isolates established that these organisms were chemotaxonomically and phylogenetically related. The genus *Leifsonia* was created to accommodate previously described *Clavibacter* species, the isolate from grassroot galls, and "*C. aquaticum*." Therefore, the genus *Leifsonia* is comprised of *L. xyli* subsp. *xyli* and *L. xyli* subsp. *cynodontis* (former *Clavibacter* species), *L. poae* (the isolate from *Poa annua* root galls induced by the nematode *Subanguina radicola*), and *L. aquatica* ("*C. aquaticum*").[1071]

L. aquatica has been described as a rare cause of infections in humans, including

bacteremia, endocarditis, access device infection, meningitis, chronic ambulatory peritoneal dialysis-associated peritonitis, wound infections, and urinary tract infections.[80,168,346,638,772] Two patients with central venous catheter (CVC)-related bacteremias due to *L. aquatica* have been described in immunocompromised men.[878,1067] In Italy, *C. aquaticum* was isolated from blood cultures of 10 patients in a cluster of CVC-related bacteremias in a hemodialysis unit.[251] Colonies of *L. aquatica* are opaque, butyrous, and yellow-pigmented; pigmentation increases with the age of the culture. Some isolates may appear mucoid and, on Gram's stain, the organisms may appear as curved, gram-positive bacilli in tangled masses.[878] The cells are motile at both 35°C to 37°C and at room temperature via long, peritrichous flagella. The organism demonstrates a rod-coccus cycle, so in older cultures, coccoid cells predominate. *L. aquatica* is aerobic, catalase-positive and oxidase-positive (most other corynebacteria are oxidase-negative) (Table 14-13). Acid is produced oxidatively from glucose, sucrose, fructose, arabinose, galactose, and mannose. The organism is urease-negative and esculin is not hydrolyzed. In the past, some *Microbacterium* species recovered from human clinical specimens have been misidentified as "C. *aquaticum*."[390,443] *L. aquatiam* is in the database of the API Coryne, but some biocodes yield cross-calls with *Microbacterium* species (i.e., biocode 247004). In one report, the API Coryne identified this organism as "*Microbacterium/Leifsonia aquatica*, with 98.7% probability."[878] Because of their oxidative metabolism, carbohydrate acidification tests may be negative or uninterpretable after 24 hours' incubation. Hydrolysis of casein and gelatin are helpful for separating possible *Microbacterium s*pecies (gelatin hydrolysis- and casein hydrolysis-positive) from "*C. aquaticum*" (gelatin hydrolysis- and casein hydrolysis-negative). *L. aquatica* also produces strong DNase activity. Other *Leifsonia* species (i.e., *L. cynodontis*, *L. rubra*, *L. aurea*, *L. shinshuensis*, *L. naganoensis*) are environmental

isolates and have not been isolated from human clinical specimens.[904,1071] The blood culture isolate described by Porte et al.[878] was tested on the MALDI-TOF mass spectrometry instrument (Bruker Daltronics, Bremen, Germany) and gave an identification of *Leifsonia,* genus level only; retesting provided no identification. However, at the time of testing, the Bruker database contained only the type strain of

L. aquatica. Isolates of *L. aquatica* tend to have intermediate susceptibility to vancomycin.[389] Historically, this organism has had vancomycin MIC_{90}s of 8 μg/mL, and recent isolates have had MICs of 4 μg/mL.[878,1067] Resistance to penicillin and other β-lactams is also common.

Microbacterium *Species*

Microbacterium species are small, irregularly-shaped, gram-positive, catalase-positive obligately aerobic bacilli that grow with typical "diphtheroid" morphology. They may be nonmotile or motile via one to three flagella and are oxidative and aerobic in their metabolism, although some species may be fermentative. Unlike *Cellulomonas* species, *Microbacterium* do not hydrolyze cellulose. Instead of *meso*-DAP, these organisms contain D-ornithine or lysine as the di-amino acid in their cell walls and have "glycine-glycine-lysine" or "glycine-lysine" as the interpeptide cross-linkage in the cell wall peptidoglycan. In addition to D-ornithine and glycine, the cell wall also contains alanine, glutamic acid, and homoserine. Unlike *Corynebacterium* species, arabinose, galactose, and mycolic acids are not components of the cell wall. In 1998, Takeuchi and Hitano analyzed extant *Microbacterium* and *Aureobacterium* species using 16S rRNA sequencing and found that the species in these two genera formed a monophyletic intermixed association.[980] This and additional physiological and chemotaxonomic features resulted in the unification of these genera in a re-defined genus *Microbacterium.*[1083] All of the *Microbacterium* species (and former *Aureobacterium* species) are widely distributed in the environment (i.e., food, plants, soil, sewage, insects).

Microbacterium species have been isolated from human clinical specimens and some former CDC coryneform group A-4 and group A-5 isolates have been assigned to the genus *Microbacterium* based on phenotypic, chemotaxonomic, and genotypic analyses. Funke and colleagues[364] examined 22 strains of yellow- and orange-pigmented, gram-positive bacilli by a variety of chemotaxonomic and phenotypic techniques. Strains included *Microbacterium* type strains, environmental isolates, and 13 (10 from blood) All were *Microbacterium* species by cell wall analysis; three clinical isolates were phenotypically identical to *M. imperiale* and two others were identical to the *M. arborescens* type strain. The remaining clinical isolates did not phenotypically resemble any other recognized *Microbacterium* species, although they were *Microbacterium* species based on chemotaxonomic analysis. In 2010, an isolate with 96% rDNA sequence homology with *M. arborescens* was isolated from the peritoneal fluid of a 57-year-old woman with end-stage renal disease on continuously cycling peritoneal dialysis.[7] The isolate was resistant to clindamycin and erythromycin, and susceptible to β-lactams, ciprofloxacin, linezolid, rifampin, and vancomycin.

Microbacterium species have been associated with severe human infections,

including a fatal disseminated infection in a 75-year-old man and persistent bacteremia from cellulitis in a 39-year-old man with acute myelogenous leukemia and porphyria cutanea tarda.[806,989] In the latter instance, the isolate was vancomycin-resistant. These organisms have also been associated with nosocomial and catheter-related bacteremias in patients with leukemia, and with contamination of peripheral blood stem cell products infused into transplant recipients.[8,27,154,501,641] Laffineur et al.[624] described a yellow-pigmented coryneform isolate that was recovered from blood cultures of a child with leukemia. Genetic and chemotaxonomic comparisons with existing *Microbacterium* species resulted in the characterization of *Microbacterium paraoxydans*, another new *Microbacterium* species. *M. paraoxydans* has also been associated with central venous catheter-related bacteremia.[312] Funke and colleagues[368] in Switzerland and Germany reported a patient with endophthalmitis due to a *Microbacterium* species following a penetrating eye injury. Phylogenetically, the organism clustered with recognized *Microbacterium* species, suggesting that the isolate may actually represent yet another new *Microbacterium* species.[368] The isolate was susceptible to cefazolin, cefotetan, ciprofloxacin, clindamycin, imipenem, piperacillin, teicoplanin, and vancomycin and was resistant to gentamicin and tobramycin. In 2006, a novel *Microbacterium* species was isolated from the sputum of a heart transplant recipient and was thought to be the cause of insterstitial pulmonary inflammation and pleural effusion. This isolate showed more than 98% 16S rRNA sequence similarity with eight other *Microbacterium* species, including *M. oxydans* and *M. paraoxydans*.[406] Two novel gram-positive rods recovered from blood cultures in 1976, 1977, and 2007 were analyzed by genotypic and chemotaxonomic approaches and were determined to represent two new *Microbacterium* species; the 1976/1977 strains were named *Microbacterium binotii*, while the 2007 isolate was named *Microbacterium pyrexiae*.[213,610] In 2008, Gneiding, Frodl, and Funke characterized 50 *Microbacterium* species that had been recovered from a variety human clinical specimens over the previous 5-year period using molecular genetic and phenotypic methods.[411] In their study, the 50 isolates represented 18 different species, with 3 species (*M. oxydans*, *M. paraoxydans*, and *M. foliorum*) representing more than half of the isolates. Four isolates belonged to species never recovered from humans before, and two isolates represented undescribed species.

Microbacterium species form whitish-yellow, yellow- or orange-pigmented colonies on SBA (Image Plate 14-7E). All species are catalase-positive, and some species (*M. arborescens*, *M. imperiale*, *M paraoxydans*) are motile. Most species hydrolyze esculin and do not hydrolyze urea. Acid is produced oxidatively or fermentatively from a variety of carbohydrates. Original members of genus *Microbacterium* tend to be fermentative, while former *Aureobacterium* species are more oxidative in their utilization of carbohydrates. *Microbacterium* species are included in the API Coryne

database, but additional tests are required to separate them from *Cellulomonas* species and *L. aquatica.* Acidification of carbohydrates may not be apparent after 24 hours incubation. API Coryne biocodes (0470004, 0452004, 0472004, 0570004, 0572004) included in the database usually give cross-calls

928

with "*L. aquaticum*" (Image Plate 14-7F). Incubation beyond 24 hours may be necessary to determine acidification of carbohydrates. Additional phenotypic data is found in Table 14-13. *Microbacterium* species may vary in their susceptibility to various antimicrobial agents. Among the 50 isolates examined by Gneiding and coworkers,[411] 100% were susceptible to meropenem and linezolid, 98% were susceptible to vancomycin and doxycyline found, and 56% were susceptible to ciprofloxacin. For the β-lactams, 78% were susceptible to penicillin and 72% were susceptible to cefotaxime. Individual clinical isolates from case reports have generally been pan-susceptible, although resistance to aminoglycosides, macrolides, and erythromycin has been encountered in several clinical isolates.[7,312,368,406]

Turicella *Species*

In 1993, Simonet and colleagues[1020] in France reported the recovery of a coryneform isolate in pure culture from middle ear fluids collected by tympanocentesis from children with acute otitis media. These isolates contained *meso*-DAP, arabinose, and galactose in their cell walls, but corynemycolic acids were absent. The isolate grew as convex, whitish, creamy, nonhemolytic colonies on blood agar that became yellowish with age. This colonial morphology was distinctly different from the flat, gray-white, nonhemolytic colonies produced by *C. afermentans* subspecies or the convex dry, adherent, slightly yellowish colonies of *C. auris*, coryneforms that have both been associated with acute and chronic otitis media.[373,931] On chemotaxonomic analysis, the cellular menaquinone patterns of this middle ear isolate were also different from the two *Corynebacterium* species. Even though these organisms displayed markedly different colony morphologies, the two *Corynebacterium* species and the third isolate had identical phenotypic characteristics. These middle ear isolates have now been assigned to the new genus *Turicella*, (referring to Turicum, the Latin name for Zurich, Switzerland, where the first isolates were collected) as *Turicella otitidis*.[385] Since its description, *T. otitidis* has been recovered from other head and neck infections (e.g., posterior auricular abscess) and from blood cultures as well.[252,687,921]

On Gram's stains, *T. otitidis* appear as long rods, and in culture, colonies of the organism are white-gray, are convex, and have entire edges. Colonies on SBA are 1.5 to 2 mm in diameter after 48 hours' incubation. *T. otitidis* does not have a lipid

requirement for growth. All *T. otitidis* isolates produce the biocode number 2100004 on the API Coryne system, indicating positive test results for pyrazinamidase, alkaline phosphatase, and catalase, and negative tests for glucose, ribose, xylose, mannitol, maltose, lactose, sucrose, and glycogen fermentation, nitrate reductase, urease, esculin hydrolysis, β-glucuronidase, β-galactosidase, α-glucosidase, esculin hydrolysis, urease, and gelatin hydrolysis (Table 14-13). These phenotypic characteristics are similar to those of both *C. afermentans* subsp. *afermentans* and *C. auris*. *T. otitidis*, *C. afermentans* subsp. *afermentans* and *C. auris* can be differentiated most efficiently by genetic and chemotaxonomic analyses. However, Renaud et al.[913] have shown that colony morphology, the CAMP test, certain enzymatic activities (e.g., LAP, DNase), and carbon substrate assimilations are useful for separating these species. Colonies of *T. otitidis* are creamy and pale yellow, while colonies of *C. auris* and *C. afermentans* are slightly yellowish and adherent (*C. auris*) or flat, smooth, and grayish white (*C. afermentans*). *T. otitidis* is DNase-positive, while *C. afermentans* subsp. *afermentans* and *C. auris* are DNase-negative. Both *T. otitidis* and *C. auris* are LAP-positive, while *C. afermentans* is LAP-negative. Lastly, *T. otitidis* and *C. auris* are CAMP test-positive, while this characteristic is variable for *C. afermentans*. Isolates of *T. otitidis* are susceptible to ampicillin, cephalosporins, ciprofloxacin, gentamicin, rifampin, tetracyclines, vancomycin, and linezolid; some strains are resistant to clindamycin, erythromycin, and azithromycin.[380,418,934]

Rothia *Species*

Rothia species are members of the phylum *Actinobacteria*, class *Actinobacteria*, subclass *Actinobacteridae*, order *Actinomycetale*s, suborder *Micrococcineae,* in the family *Micrococcaceae.* This family also includes the *Micrococcus*, *Arthrobacter*, *Kocuria*,*Stomatococcus*, and *Nesterenkonia* genera. Prior to 2000, the genus *Rothia* included a single species, *Rothia dentocariosa*. Based on 16S rDNA sequencing and chemotaxonomic data, *Stomatococcus mucilaginosus*, the catalase-variable gram-positive coccus found in the human oropharynx, was transferred to genus *Rothia* as *Rothia mucilaginosa*.[92,225] A third species in the genus called *Rothia nasimurium* was described at the same time and is found in the anterior nares of mice. In 2004, a novel gram-positive coccobacillary organism was isolated from air and condensation water samples from the Russian space station Mir and this organism was named *Rothia aeria*.[673] Two additional environmental species were characterized in 2002 and 2008, respectively.*Rothia amarae* was isolated from sewer sludge in China, and *Rothia terrae* was isolated from soil sample from Taiwan.[202,319] While *R. mucilaginosa, R. nasimurium, R. aeria* and *R. terrae* are gram-positive cocci, *R. dentocariosa* is a gram-positive coryneform bacillus that shows rudimentary branching, although, in older broth cultures, coccoid cells may predominate. *R. dentocariosa* does not

produce major amounts of succinic acid from glucose, a characteristic that distinguishes this organism from facultative *Actinomyces* species. Like the corynebacteria and aerobic actinomycetes, these organisms are catalase-positive and tend to grow better under aerobic conditions. However, unlike *Nocardia* species, these organisms are fermentative, which facilitates identification by phenotypic tests routinely used for *Corynebacterium* species and the coryneform groups described above.

Rothia dentocariosa is part of the normal human oropharyngeal and gingival flora and may be isolated from saliva and supragingival plaque. During the 1950s and 1960s, the Special Bacteriology Branch at the CDC collected several isolates, most of which were from abscesses, respiratory tract specimens, pilonidal cysts, cerebrospinal fluids, urine, and blood. *R. dentocariosa* has most frequently been associated with endocarditis involving both native and prosthetic valves.[111,131,615,1002] In several cases, this infection was associated with severe, life-threatening complications, including the multi-valve infections and development of aortic root and paravalvular abscesses.[340,615,1066] Valvular infections may result in the formation of large vegetations, which may lead to the development of pulmonary infarcts, intracranial

hemorrhages, and brain abscesses.[538,922,961] Bacteremia without endocarditis has also been reported in adults, children, and neonates.[965,1010,1223] Shin and colleagues[1010] reported a neonate with meconium aspiration syndrome who developed bacteremia with this organism in 2004; then, in 2007 this same species was isolated from a fetal blood culture that also involved meconium aspiration. Immunocompromised children and adults on cytotoxic chemotherapy are at increased risk for sepsis and bacteremia with this organism, particularly if there is mucositis or poor dentition.[1196] Septic arthritis due to *R. dentocariosa* was diagnosed in a patient with rheumatoid arthritis who was on etanercept, which is known to place patients at increased risk of infection.[324] Other case reports have documented *R. dentocariosa* as a cause of endophthalmitis, corneal ulcer, vertebral osteomyelitis with paraspinal abscess, and peritonitis associated with chronic ambulatory peritoneal dialysis.[580,702,776,778] Although rare, *R. dentocariosa* has also been recognized as a cause of pneumonia in patients with severe underlying diseases, including acute myelocytic leukemia and adenocarcinoma of the lung.[984,1174]

R mucilaginosa and *R. aeria* are also rare causes of infection. Surprisingly, *R. mucilaginosa* has been isolated from several cases of meningitis in patients with ALL, AML, multiple myeloma, and non-Hodgkin's lymphoma.[650] *R. mucilaginosa* was isolated as the cause of meningitis in two pediatric stem cell transplant patients and as

a cause of bacteremia associated with infectious granulomatous dermatitis in a man with acute myeloid leukemia.[650,774] Bacteremia with this organism was also documented in a child with Shwachman–Diamond syndrome, a rare autosomal-recessive multisystem disorder that causes bone marrow dysfunction, immune deficiency, and neutrophil deficiencies that lead to recurrent infections.[1134]Septic arthritis and late prosthetic hip arthroplasty infection due to *R. mucilaginosa* have been reported in two elderly patients with histories of diabetes mellitus and arterial hypertension.[566,751] This organism has also been isolated from peritoneal fluid of a patient on CAPD.[504] *R. mucilaginosa* are usually susceptible to most antimicrobial agents including vancomycin, rifampin, and linezolid, although occasional isolates may be resistant to penicillin or clindamycin. The first isolation of *R. aeria* from a human was from a blood culture of a neonate delivered to a mother who had a tooth extraction without antimicrobial prophylaxis 4 days prior to delivery.[770] *R. aeria* was subsequently isolated from a sputum specimen obtained from a diabetic patient with acute bronchitis who was being treated with etanercept for rheumatoid arthritis and from the joint fluid of an elderly female with abscessed teeth who was also being treated with methotrexate and prednisone for rheumatoid arthritis.[752,1156] All three isolates were susceptible to all agents tested including vancomycin and linezolid, except one isolate was resistant to ofloxacin and a second isolate was clindamycin-resistant.

CDC fermentative coryneform group 4 organisms are closely related to *R. dentocariosa*. These organisms have been recovered mostly from female genitourinary tract specimens, although no specific human infections with CDC group 4 isolates have been reported. Daneshvar and colleagues[253] at the CDC investigated several black colony-forming isolates that were provisionally categorized as group 4 bacteria. These organism segregated into two groups by molecular genetic analysis. One group (including only one genital tract isolate) was most closely related to *R. dentocariosa*, while the other group, which included isolates that were mainly recovered from female genital tract specimens, were most closely related to *C. aurimucosum*, a more recently described *Corynebacterium* species isolated predominantly from the female genital tract (Box 14-4). This work resulted in emendations of the species descriptions of both *R. dentocariosa* and *C. aurimucosum* to include variants that formed charcoal-black colonies on agar media. Consequently, the colony morphologies of *R. dentocariosa* include bone-white, off-white, or charcoal-black colonies that are dry, rough, and adherent, or smooth and entire. *C. aurimucosum* colonies are sticky, white-to-yellow, or charcoal black Table 14-14 presents the phenotypic characteristics of *R. dentocariosa* and *C. aurimucosum* for comparison to aid in the identification of coryneforms that produce charcoal-black pigmented colonies. "*C. nigricans*" is identical to *C. aurimucosum* and is a later synonym for the same organism.[253]

The similarities of *R. dentocariosa* with other aerobic actinomycetes are apparent upon examination of colony morphology. After 72 hours incubation at 35°C to 37°C in CO_2, colonies are usually dry, rough, and bone-white (Image Plate 14-7A). Rare isolates may be black-pigmented and may correspond to pigmented *R. dentocariosa* or *C. aurimucosum*. Pigmented *R. dentocariosa* strains are more likely to be isolated from blood cultures or the respiratory tract, and not the female genital tract, while *C. aurimucosum* is isolated from the latter site. The colonies often appear heaped and cerebriform, particularly in areas of confluent growth. Inspection of the edges of colonies reveals that the colonies tend to "dig into" the agar surface like those of *Nocardia* species. Strains of *R. dentocariosa* also have relatively uniform phenotypic characteristics and are quite biochemically active. *R. dentocariosa* is catalase-positive (although catalase-negative strains may be encountered), reduces nitrate to nitrite and produces pyrazinamidase and pyrrolidonyl arylamidase (Table 14-14). The organism hydrolyzes esculin but does not hydrolyze urea or gelatin, and acid is produced fermentatively from glucose, maltose and sucrose. *R. dentocariosa* is included in the data bases of both the API Coryne and the RapID CB-Plus. On the API Coryne, most strains produce the biocodes 7050125, 7052125, 7050165, or 7052165 (Image Plate 14-7B). While these organisms are usually uniformly susceptible to all classes of antimicrobial agents, strains that are resistant to β-lactams because of β-lactamase production have been isolated.[253] The latter strains contain plasmids bearing the β-lactamase structural genes.

Gardnerella vaginalis

Taxonomy and Cellular Morphology

Gardnerella vaginalis was first described in 1953 and has been known by various names, including *Haemophilus vaginalis* and *Corynebacterium vaginale*. In 1980, this organism was formally placed in the new genus *Gardnerella* by Greenwood, Pickett, and others based on electron microscopic, biochemical and chemotaxonomic data, and DNA–DNA

hybridization studies.[435] Ultrastructural studies of *G. vaginalis* indicate that this organism has a gram-positive type of cell wall, but the peptidoglycan layer is much thinner than that found in the cell walls of *Corynebacterium*, *Lactobacillus*, or *Staphylococcus* species. The peptidoglycan content of the *G. vaginalis* cell wall constitutes about 20% of the total cell wall weight, which is similar to that found in *Enterobacteriaceae,* such as *Escherichia coli*, where the peptidoglycan constitutes about 23% of the cell wall weight. Consequently, different strains of *G. vaginalis* may appear predominantly gram-positive, gram-negative, or gram-variable. Cell wall extracts of *G. vaginalis* do not contain compounds normally present in gram-negative cell wall lipopolysaccharides (e.g., *meso*-DAP, 2-keto-3-deoxy-D-manno-2-octonoic acid, hydroxy fatty acids). The absence of *meso*-DAP, arabinogalactans, and mycolic acids confirms that the *G. vaginalis* cell wall is distinct from the gram-positive cell wall type found in *Corynebacterium* species.

Molecular studies on *G. vaginalis* have shown that this organism is closely related to the bifidobacteria. Miyake and colleagues[763] used 16s rRNA gene sequence analysis to examine the type strains of 21 *Bifidobacterium* species and showed that *G. vaginalis* clustered with 19 of the 21 *Bifidobacterium* species. Another study used phenotypic, chemotaxonomic (e.g., whole-cell protein and fatty acid analysis), and 16S rRNA sequence analysis to characterize *G. vaginalis* and "*G. vaginalis*-like" strains.[1146]Chemotaxonomic methods resulted in recognition of two "clusters" that were shown to represent different genera by sequencing, and these different genera could be distinguished by phenotypic methods. Cluster I strains represented *G. vaginalis*, with its closest relative being members of the genus *Bifidobacterium*. *G. vaginalis* strains demonstrated a level of similarity of 93.1% to *Bifidobacterium bifidum*.[1146] These investigators felt that the G+C contents of *G. vaginalis* and *Bifidobacterium* species were different enough that *G. vaginalis* could not be considered a member of the *Bifidobacterium*. Analysis of heat-shock protein gene sequences also suggested a phylogenetic relationship between *G. vaginalis* and bifidobacteria, but this relationship was more distant than suggested by 16S rRNA analysis and confirmed the genus status of *Gardnerella.*[547] Amplified ribosomal DNA restriction analysis has shown that *G. vaginalis* strains are fairly heterogeneous and may be divided into at least three or four genotypes depending upon the restriction enzymes used.[537] In culture, it may be difficult to differentiate some *G. vaginalis* strains from "look-alike" organisms, which are termed "unclassified, catalase-negative coryneform" bacteria. *G. vaginalis* is the only member of the genus *Gardnerella*, which is classified in the phylum *Actinobacteria*, class *Actinobacteria*, order *Bifidobacteriales*, in the family *Bifidobacteriaceae*.

Clinical Significance of Gardnerella vaginalis

G. vaginalis is a member of the normal vaginal microbiota. In the past, this organism was closely associated with the clinical syndrome called **bacterial vaginosis (BV)**. This condition is termed BV because no single organism is solely responsible for the condition and inflammatory cells (seen with both *Candida* and *Trichomonas* vaginal infections) are not observed on Gram-stained smears of the vaginal discharge. BV is characterized clinically by a malodorous vaginal discharge associated with a significant overgrowth in the numbers of *G. vaginalis* and various obligate anaerobes, including *Prevotella bivia*, *Prevotella disiens*, *Mycoplasma* species, peptostreptococci, and *Mobiluncus* species, with a concomitant decrease in the numbers of normal vaginal lactobacilli.[292] Several case-control and cohort-based studies have established that BV has a significant impact on adverse pregnancy outcomes and is a risk factor for preterm birth.[840] BV is also a risk factor for obstetrical infections and pelvic inflammatory disease. When this condition was originally described, *G. vaginalis* was hypothesized to be the etiologic agent.[398] Subsequent studies determined that other organisms were involved, and that, while *G. vaginalis* was invariably present in the vaginas of women with BV, it was also present in greater than 50% of women without bacterial vaginosis.[753] Using semiselective media, *G. vaginalis* may be found in from 14% to 70% of healthy women without BV.[1113] It appears, however, that the presence of large numbers of *G. vaginalis* in the vagina are indicative of BV. Using a radiolabelled oligonucleotide probe specific for *G. vaginalis* 16S rRNA, Sheiness and coworkers[1006] in Seattle showed that the presence of these bacteria at concentrations of $\geq 2 \times 10^7$cfu/mL of vaginal fluid, along with a vaginal pH greater than 4.5, had a sensitivity and specificity of 95% and 99%, respectively, in classifying women with and without BV when compared with strictly clinical diagnostic criteria. *G. vaginalis* may also be found in the male urethra. Using molecular methods, Schwebke and coworkers[994] found an overall prevalence of *G. vaginalis* of 25% in males and found no difference in the prevalence rates between male sexual partners of women with or without BV.

Diagnosis of BV is accomplished with clinical criteria along with either a wet mount or a Gram's stain of the vaginal discharge ("Diagnosis of Bacterial Vaginosis and Culture Characteristics of *G. vaginalis*" below). Routine culture of vaginal specimens for *G. vaginalis* for diagnosis of BV is not recommended since culture does not provide decisive evidence of infection due to the presence of *G. vaginalis* as part of the resident vaginal microbiota. *G. vaginalis* has been isolated from rectal specimens of 56% of 148 women with BV, 12% of 69 healthy women, 9% of 83 male sexual partners of women with BV, and 6% of 49 male sexual partners of healthy women.[513] These latter data suggest that *G. vaginalis* is not sexually transmitted, but probably

colonizes the vagina endogenously from the intestinal tract. Villegas and colleagues[1160] performed an ultrastructural study of the vaginal secretions from 10 women with BV and semen samples from their asymptomatic sexual partners using optical and electron microscopy. *G. vaginalis* was isolated from semen specimens of 50% of the men. Electron microscopy showed that the organisms adhered to the cell membranes and penetrated into the cytoplasm of both vaginal and male urethral epithelial cells. Asymptomatic colonization of the male lower genital tract by *G. vaginalis* may have some relevance regarding the role of the male partner in "recolonization" ("reinfection") of the female vagina.

G. vaginalis has also been isolated from female genitourinary tract infections associated with complications of pregnancy and from infants born to mothers with such

complications, particularly during and after delivery. These may include intrauterine infections and intra-amniotic infections, chorioamnionitis, postabortal pelvic inflammatory disease, and postpartum endometritis after cesarean delivery.[500,655] Surgically obtained tissues from these infections have yielded *G. vaginalis* in pure or mixed culture with other facultative and/or obligately anaerobic organisms. Postpartum and postabortal bacteremia with *G. vaginalis* and other genital tract microorganisms may also occur in these clinical settings.[123,906] Bacteremia with genital tract microflora occurs when organisms gain access to venous channels of the placental bed, which is disrupted before and during vaginal/cesarean deliveries. Systemic and localized *G. vaginalis* neonatal infections may occur in those involved with such complications and may include amnionitis, episiotomy wound infection, bacteremias, meningitis, cellulitis, conjunctivitis, and osteomyelitis (often involving fetal scalp monitors).[30,90,802] Oropharyngeal cultures, gastric aspirates, and tracheal suction specimens from neonates have also yielded *G. vaginalis*, presumably acquired during passage through a heavily colonized birth canal. *G. vaginalis* has been isolated from Bartholin's gland abscesses, postcesarean section and postsurgical wound infections, abdominal surgeries, hysterectomies, and episiotomies.[203,619]

G. vaginalis has also been a cause of rare infections in males and occasionally other infections not generally associated with the genitourinary tract. Bacteremia with *G. vaginalis* in men has been reported following transurethral prostatectomy, urogenital surgical procedures, and in association with renal calculi, and urinary retention secondary to obstruction.[74,267,625] Extragenital infections with *G. vaginalis* have included a pyogenic postcesarean liver abscess in a 23-year-old woman, bacteremia with lung abscess/empyema in an alcoholic man with aspiration pneumonia, and

vertebral disk and joint space infections and septic hip arthritis in a woman who was a renal transplant recipient.[316,431,503,660,1030] Yoon et al.[1232] reported a case of *G. vaginalis* bacteremia complicated by endocarditis and pyelonephritis is a previously healthy 39-year-old man, and Calvert and colleagues[152] reported a empyema and perinephric abscess in 50-year-old man.

G. vaginalis may also play a role in urinary tract infections in both men and women.[559,785] Given its normal ecosystem as part of the normal vaginal microbiota, it is not surprising that *G. vaginalis* has been recovered from the urinary tract specimens from women more frequently than from men. *G. vaginalis* has been isolated from both the upper (i.e., ureters, renal pelvis, and calyx) and the lower urinary tracts (i.e., bladder) of both symptomatic and asymptomatic patients. A treatment study performed in Mexico with 45 women with *G. vaginalis* UTI most frequently had symptoms of dysuria and frequency, lower back pain, suprapubic discomfort, and abdominal pain.[854] Isolation rates from urine specimens are greater among pregnant women than among nonpregnant women, and many of these patients are asymptomatic. Pyuria appears to be infrequently associated with *G. vaginalis* urinary tract infection and may be absent even in the presence of serious upper urinary tract disease. In a study of the role of *G. vaginalis* in urinary tract infections in men, two-thirds of 15 men with significant numbers of *G. vaginalis* in the urine had signs and symptoms referable to the urinary tract (i.e., urgency, frequency, hematuria).[1039] Most of these patients also had underlying diseases, including diabetes, hypertension, spinal cord injuries, prior UTIs, and cardiovascular disease. As in previous studies of *G. vaginalis* and the urinary tract, pyuria was present only in 7 of the 15 males evaluated. Significant numbers (i.e., $>10^4$ cfu/mL) of *G. vaginalis* in urine specimen from men are difficult to evaluate because such numbers may be seen in cultures from asymptomatic males and from men with underlying renal diseases such as ureteral obstruction, chronic prostatitis, and end-stage renal disease.[559] Rarely, *G. vaginalis* may cause complicated ascending urinary tract infection in healthy males, although such scenarios are more likely in compromised hosts, such as renal transplant recipients.[344] The consensus is that *G. vaginalis* may play an important role in complicated and uncomplicated urinary tract infections in both men and women and, if present in significant numbers, the organism should be identified and reported.

Diagnosis of BV and Cultural Characteristics of Gardnerella vaginalis

Diagnosis of BV usually involves a patient with a malodorous vaginal discharge; there may be with minimal irritation, particularly after sexual contact. Exposure to the alkaline pH of vaginal secretions after sexual contact and during the menses is responsible for volatization of amines that contribute to the "fishy" odor often noted by patients. This is also the basis for the whiff test, where KOH is mixed with the discharge to reproduce the fishy odor. The vaginal discharge of BV is characteristically homogeneous, white-gray, and may be frothy. Besides the clinical complaint and presentation, the vaginal pH will usually be >4.6, with the specificity of diagnosis being even greater when the vaginal pH is ≥5. Microscopically, wet mounts will usually show moderate-to-many vaginal epithelial cells with large numbers of adherent bacteria of various morphologies (the "clue" cell); in many cases, the sheer numbers of adherent microorganisms may completely obscure the margins of the epithelial cells (Image Plate 14-8B and C). Many labs use the Gram's stain criteria published by Nugent and colleagues to evaluate relative amounts of lactobacilli, *Gardnerella* morphotypes, and *Mobiluncus* morphotypes to arrive at a score that correlates with the absence, possible presence, or diagnosis of BV. In these smears, vaginal epithelial "clue" cells will be covered with the bacterial morphotypes described above, with the benefit of distinguishing their Gram reactions and morphologies, and having a permanent record for review and training/teaching purposes.

As BV is known to have a polymicrobial etiology and because *G. vaginalis* can also be isolated from vaginal cultures of more than 50% of asymptomatic women, culture of vaginal specimens for *G. vaginalis* should be discouraged. Routine use of semiselective media such as Human Blood Tween (HBT) and V agars for culture of vaginal specimens represents an unnecessary expense that contributes little useful information, given that the laboratory diagnosis of BV rests on careful examination and interpretation of properly collected wet preps or Gram-stained smears of vaginal discharge.[499,810] *G. vaginalis* can be recovered on regular CNA agar medium after prolonged incubation, and presumptive identification will usually suffice in these circumstances.

933

G. vaginalis can be isolated from clinical specimens using routine SBA, CNA, and chocolate agar media (Image Plate 14-8D). Semiselective media include HBT agar or V agar.[1113] HBT agar has a bottom layer of Columbia colistin–nalidixic acid agar base supplemented with Proteose Peptone no. 3 (BD Microbiology Systems, Sparks, MD),

amphotericin B (2.0 µg/mL), and 0.0075% Tween 80, overlaid with a similar layer to which 5% human blood is added. Tween 80 improves the growth and enhances β-hemolysis produced by *G. vaginalis*. V agar contains Columbia agar base with 1% proteose peptone and 5% human blood. On HBT agar, *G. vaginalis* forms small, clear zones of β-hemolytic colonies surrounding colonies with diffuse edges after 48 hours incubation (Image Plate 14-8E). For "routine media", *G. vaginalis* grows better on Columbia agar-based media (i.e., CNA agar) than on blood agar made with a tryptic soy base. On CNA, *G. vaginalis* shows a subtle, "diffuse" hemolysis surrounding the colonies that is noted initially in confluent areas of growth or after incubation for >72 hours. Growth is best at 35°C to 37°C in a 5% to 7% CO_2 atmosphere. Most isolates are recovered after 48 to 72 hours' incubation. *G. vaginalis* will also grow in most blood culture media; however, the anticoagulant additive sodium polyanethol sulfonate (SPS) is inhibitory to some *G. vaginalis* and may compromise the recovery of this organism from blood cultures.[907] As with the pathogenic *Neisseria*, this growth inhibition by SPS may be overcome by adding gelatin (1% v/v) to blood culture bottles.

Suspect *G. vaginalis* from systemic body sites (e.g., blood, joint fluid, etc.) should be confirmed by additional testing. Presumptive identification of *G. vaginalis* includes typical cellular morphology on Gram-stained smears (small gram-positive, gram-negative, or gram-variable coccobacilli), characteristic growth on CNA agar with "diffuse" weak β-hemolysis, and negative oxidase and catalase tests. Definitive identification of *G. vaginalis* can be made based on the reactions shown in Table 14-15 Other characteristics that confirm the identification of *G. vaginalis* and help to separate it from the other so-called "unclassified, catalase-negative coryneform" (UCNC) organisms include the presence of α-glucosidase, the absence of β-glucosidase, and positive starch and hippurate hydrolysis reactions. Carbohydrate utilization tests are performed in medium containing Proteose Peptone no. 3, phenol red indicator, and 1% filter-sterilized carbohydrate. Acid is produced from glucose, maltose, sucrose, and starch, but not from mannitol, sorbitol, raffinose, rhamnose, or salicin (Image Plate 14-8F). The organism hydrolyzes hippurate, but does not possess lysine or ornithine decarboxylases or arginine dihydrolase, does not reduce nitrate, and does not produce indole, urease, or acetoin. *G. vaginalis* strains will show zones of inhibition around disks containing metronidazole (50 µg) and trimethoprim (5 µg). *G. vaginalis* is included in the database of the API Coryne system (bioMérieux, Inc., Hazelwood, MO) for the identification of gram-positive bacilli and in the databases of the *Haemophilus-Neisseria* Identification (HNID) Panel (Siemens-American MicroScan, West Sacramento, CA), the API Coryne (bioMérieux, Inc.), RapID CB-Plus (Remel), and the Vitek 2 *Neisseria-Haemophilus* (NH) identification card (bioMérieux, Inc.) for identification of fastidious gram-negative bacilli.

TABLE 14-15 Biochemical Characteristics for the Identification of *Gardnerella vaginalis*

Sulfonamide	+

+, positive reaction; −, negative reaction.

Direct nucleic acid probe and amplification technology have also been used to detect and identify *G. vaginalis* in clinical specimens, but, given the high prevalence of *G. vaginalis* in vaginal specimens, specific molecular tests solely for this organism are not particularly useful in most cases. The Affirm VP III Microbial Identification Test (Becton-Dickinson, Sparks, MD) is a commercially available, semi-automated system that uses synthetic, oligonucleotide hybridization probes for the simultaneous detection of *G. vaginalis*, *Trichomonas vaginalis* and *Candida* species from a single vaginal swab. This assay has a total hands-on time of about 5 minutes and test results are available in less than 1 hour. The test is performed on the BD MicroProbe Processor

instrument. The first product, Affirm VP, detected only *G. vaginalis* and *Trichomonas vaginalis*, but the newer Affirm VP III assay also detects *Candida albicans*. Briselden and Hillier evaluated the first assay and found that the Affirm VP test for *G. vaginalis* was positive for 97% of women who had BV based on clinical criteria and had a specificity of 71%.[139] Since the probe was more sensitive than culture on HBT medium, increased specificity could be attained by evaluating Affirm VP test results along with other diagnostic criteria (i.e., vaginal pH, presence of amine odor with KOH ["whiff test"]) for BV. Witt and colleagues[1200] found that the Affirm VP III had a specificity of more than 97% when compared to Gram-stained smears. The sensitivity of the assay varied depending on the score given the Gram-stained smear by established scoring criteria and ranged from 73.2% to 89.5%.[810] More recent evaluations have examined the currently available Affirm VP III Microbial Identification Test.

934

Brown and colleagues[141] compared the Affirm VP III to wet preparations for diagnosis of BV in 425 women and found that 190 patients (45%) were positive for *G. vaginalis* with the Affirm VP III assay, while only 58 patients (14%) were positive by wet mount detection of clue cells. Symptomatic women were more likely to be positive by Affirm VP III alone or by both AffirmVP IIII and wet mount than by wet mount alone, and asymptomatic women were more likely to be negative by both Affirm VP III and wet mount. In 2008, Pappas et al.[839] evaluated the Affirm VP III assay for detection of BV in 291 consecutive female patients (193 were symptomatic and 98 were asymptomatic). *G. vaginalis* was detected in 108 of 193 symptomatic patients and in 40 of 98 asymptomatic patients when compared to clinical diagnostic criteria of Amsel et al.[32] (i.e., vaginal discharge, pruritis and irritation, foul-smelling vaginal discharge). The sensitivity of the Affirm VP III assay compared with the clinical diagnosis was 97.2% for the whole sample of women; the test had a sensitivity of 96.4% for detection of BV in symptomatic women and 100% in asymptomatic women. Specificities of the assay were 71.4%, 72.2%, and 64.4% for all women tested, for symptomatic women, and for asymptomatic women, respectively.[839]

Antimicrobial Susceptibility of Gardnerella vaginalis

Strains of *G. vaginalis* are generally susceptible to penicillin, ampicillin, erythromycin, clindamycin, trimethoprim, and vancomycin.[591] Ciprofloxacin and imipenem show variable activity against *G. vaginalis*. Some strains may be resistant to tetracycline and minocycline, and marked resistance to amikacin, aztreonam, and sulfamethoxazole is seen in most strains. Some clinical isolates may be pan-susceptible, including

susceptibility to daptomycin and linezolid.[625] Because of resistance to sulfamethoxazole, no synergistic activity against *G. vaginalis* is seen with cotrimoxazole (i.e., sulfamethoxazole and trimethoprim in a 19:1 ratio).

Lactobacillus Species

Taxonomy and Epidemiology

Lactobacilli are gram-positive bacilli that are part of the normal microbiota of the human vagina, gastrointestinal tract, and oropharynx. They are widely distributed in nature (i.e., water, sewage, milk products, and silage), and comprise part of the normal flora of many other animal species. Lactobacilli are also found in various foods (e.g., dairy products, grains, meats, fish, sauerkraut) largely because of their wide range of fermentative capabilities. Certain *Lactobacillus* species are now commonly added to foods as probiotics, presumably for their beneficial health effects. Individual cells of *Lactobacillus* species are often long and slender, although smaller "coryneform" bacilli or "coccobacilli" may be observed (Image Plates 14-8A and 14-7G). Some *Lactobacillus* species may form long chains. Most species are nonmotile, with rare motile species having peritrichous flagella. Most species are facultative, although certain species grow best under either anaerobic or microaerophilic conditions, particularly on primary isolation. Lactobacilli are so named because the major end product from glucose fermentation is lactic acid; some species may also produce acetic, formic, and succinic acids, along with CO_2. Lactobacilli are uniformly catalase-negative, oxidase-negative, do not reduce nitrate, do not produce indole or H_2S, do not liquefy gelatin, and do not form spores. The cell walls of *Lactobacillus* species contain a thick peptidoglycan and membrane-bound teichoic acids. Lysine, *meso*-diaminopimelic acid (*meso*-DAP), and ornithine are the di-amino acids comprising the peptidoglycan cross-linkages. Electron transport menaquinones are absent. Lactobacilli are classified in phylum *Firmicutes* in the class "Bacilli," proposed order "Lactobacillales." In this order, genus *Lactobacillus* and genus *Pediococcus* are included in the family *Lactobacillaceae*.

Clinical Significance of Lactobacillus *Species*

While inherently of low virulence, lactobacilli cause opportunistic infections in compromised hosts. The most common clinical presentations include bacteremia and endocarditis. *Lactobacillus* bacteremia occurs primarily in patients with underlying conditions, including immunosuppressive therapy, cancer with chemotherapy, bone marrow and solid organ (particularly liver) transplantation, diabetes, kidney disease, and prior surgical interventions.[46,155,425] *L. rhamnosus* is the most frequently isolated

species causing bacteremia; other species have included *L. gasseri*, *L. acidophilus*, *L. casei*, *L. paracasei*, *L. delbrueckii*, *L. fermentum, L. minitus*, *L. plantarum*, *L. zeae*, and *L. reuteri*.[155,425,649] Portals of entry for septic episodes with lactobacilli reflect the normal habitats of these organisms within the oropharynx, the genitourinary tract, and the gastrointestinal tract. Risk factors for the development of *Lactobacillus* bacteremia include persistent neutropenia, use of broad-spectrum antibiotics, allograft transplantation with immunosuppressive therapy, chemotherapy for cancer, and invasive gastrointestinal, gynecologic, or respiratory tract instrumentation and procedures.[155,237,356] *Lactobacillus* bacteremia has also been associated with HIV infection and AIDS.[1,943] In profoundly immunosuppressed patients, bacteremia with vancomycin-resistant *Lactobacillus* strains may occur during or shortly after administration of vancomycin (and other broad-spectrum agents). A 2010 case report described *L. casei* bacteremia in a 75-year-old woman with prostheses in the thoracic aorta and abdomen for aortic dissection 8 years before.[956] During her continuous bacteremia, the patient developed another aortic dissection despite absence of prosthetic vegetations. The authors suggested that *L. casei* may have directly infected aortic lesions that triggered the dissection. *Lactobacillus* bacteremia is also associated with gynecologic infections; women with lactobacillemia usually have underlying genital pathology (e.g., endometritis), have undergone invasive gynecological or obstetrical procedures (e.g., dilatation and curettage procedures, drainage of pelvic abscesses), or have neoplasms of the female genitourinary tract (e.g., ovarian cancer with large bowel invasion, choriocarcinoma).[36,236,1065] In these cases, the source of the organism is usually the patients' own vaginal microbiota. Lactobacilli are not part of the resident skin flora and have not been associated with intravenous catheter-related infections.

935

Despite the increasing and widespread use of lactobacilli in various foods as probiotics (i.e., *L. acidophilus, L. rhamnosus* GG), the incidence of *Lactobacillus* infections or the proportion of bacteremic *Lactobacillus* infections have not increased.[972,973]However, in several reports, ingestion of probiotic lactobacilli by patients with various underlying conditions has been temporally associated with the development of lactobacillemia. In some cases of *Lactobacillus* bacteremia, heavy dairy consumption was posited as a "possible risk factor."[155,612,956,1111] LeDoux and colleagues[649] in New York described persistent *L. acidophilus* bacteremia in a 38-year-old man with AIDS and stage IV Hodgkin's disease. In addition to his antiretroviral therapy, the patient had been taking acidophilus probiotic three times a day for the previous 3 weeks. In another instance, a 24-year-old woman with a

prosthetic aortic valve developed *L. rhamnosus* sepsis from peri-operative administration of a probiotic containing three strains of *L. rhamnosus*.[612] One of these was identical to the *L. rhamnosus* strain recovered from the blood cultures by PFGE. The authors suggested that the organisms may have directly translocated across the intestinal barrier and avoided entrapment in mesenteric lymph nodes due to the patient's mesenteric ischemia resulting from heart failure. At the present time, three *Lactobacillus*-containing probiotics have received "GRAS" ("generally recognized as safe") status from the FDA, despite the absence of clinical efficacy data. These are *Lactobacillus reuteri* strain DSM 17938, *Lactobacillus casei* subsp. *rhamnosus* GG (known as *L. rhamnosus* GG), and *Lactobacillus acidophilus*/*Lactobacillus lactis*/*Pediococcus acidilactici* complex. Concerns have been raised about the administration of such probiotics in certain populations, including immunocompromised hosts, the very young, the elderly, patients with multiple comorbidities, patients with intravenous catheters or prostheses, and patients with valvular defects or short bowel syndrome.[1042]

Lactobacillus species are infrequent causes of endocarditis primarily in patients with congenital heart defects (e.g., ventral septal defect, bicuspid aortic valve defects), acquired native valve defects (e.g., prior endocarditis, rheumatic heart disease), vascular grafts, and prosthetic valves.[155,394,532,885,1218] Transient bacteremia originating from localized abscesses (e.g., periapical tooth abscesses), dental manipulations (e.g., extractions, root canals), gynecologic surgery or instrumentation, neonatal peri-omphalitis, and gastrointestinal endoscopy can seed the abnormal valves and initiate endocardial lesions.[1065] In those with native valve disease, large vegetations containing the lactobacilli may be noted by echocardiograms of aortic, mitral, tricuspid, and pulmonic valves.[885] These cardiac vegetations have a marked propensity to embolize to the brain and other organs. In the series of patients reviewed by Gallemore and colleagues,[394] 14 of 35 patients developed septic emboli to the brain; 5 of these patients died and 9 required surgery. Fradiani reported a case of *L. jensenii* endocarditis in a previously healthy 47-year-old woman who presented as a 10 mm mobile mass in the left atrium and a large vegetation on the mitral valve. The clinical course was complicated by thromboembolic complications, and the patient required replacement of the mitral valve.[352] For patients with endocarditis due to *Lactobacillus* species, synergistic therapy with a β-lactam agent plus an aminoglycoside for at least 4 to 6 weeks appears to be the optimal therapy. However, effecting a medical cure alone without relapse or the necessity for valve replacement is often difficult. In one series, cure with antimicrobials alone was achieved in only 39% of patients.[439]

Pleuropulmonary infections due to *Lactobacillus* species have been reported in systemically immunocompromised patients and those with impaired pulmonary status

(e.g., COPD) or localized underlying disease. Infections have included necrotizing pneumonia secondary to esophageal cancer, pleural empyema in a patient with esophageal squamous cell carcinoma, and community-acquired lung abscess.[943] Sriskanden, Lacey, and Fisher documented pneumonia due to *Lactobacillus* species in three patients with profound neutropenia secondary to immunosuppression from HIV infection, and from cytotoxic chemotherapy for vasculitis and subsequent bone marrow transplantation.[1053] In 2002, Wood and colleagues[1211] reported the first case of ventilator-associated pneumonia in a critically ill immunocompetent patient. Lung abscess due to *L. rhamnosus* was described in a 79-year-old man with COPD and emphysema.[1013] While the patient was being treated with a carbapenem, the abscess enlarged and ruptured into the pleural space, and the organism was isolated from the pleural effusion specimen.

Lactobacilli have been isolated from a variety of other infectious processes. Meningitis due to lactobacilli has been described as a complication of endocarditis, where septic emboli have lodged in the brain causing embolic brainstem infarction.[1203]Relapsing *L. rhamnosus* bacteremia and meningitis developed in a 10-year-old boy undergoing allogeneic hematopoietic stem cell transplantation, and a fatal meningitis caused by *L. rhamnosus* developed on an elderly female as a complication of prolapsed cervical disc surgery and cervical spine plate grafting 6 years earlier.[942,985] Lactobacilli have also been a cause of epidural abscess and vertebral osteomyelitis due to a spontaneous esophageal rupture and postresection surgical site abscesses in patients with cancer receiving radiation therapy.[749,1209] Hepatic and splenic abscesses involving *L. rhamnosus*, *L. paracasei*, and other species have occurred in patients with underlying disease (e.g., tonsillar carcinoma, uncontrolled type II diabetes, pancreatitis) and in clinically well individuals.[149,191,289,962] Lactobacilli are rare causes of septic arthritis and protheses infections.[53,192] Lactobacilli are uncommon causes of uncomplicated and complicated urinary tract infections, and have been associated with both urolithiasis and pyelonephitis.[195,256] Uncommon clinical presentations have included endophthalmitis following penetrating eye injuries, chrondritis following ear piercing, bacteremic cholecystitis, and primary peritonitis.[278,436,900,1209] Like many other opportunistic agents, lactobacilli have also been recovered from peritoneal infections in patients on CAPD.[604]

Isolation and Identification of Lactobacillus *Species*

After growth for 24 hours on SBA, colonies of *Lactobacillus* species are usually small (2 to 5 mm), convex, and smooth with entire edges; some α-hemolysis or "graying" of the media may also be observed (Image Plate 14-7H). Because of the large number of *Lactobacillus* species that have been described, isolates are not generally identified to

the species level. For species-level identification, workers have used the

phenotypic methods described by Holdeman and Moore in the *VPI Anaerobe Manual*, cross-referenced with species descriptions in *Bergey's Manual of Systematic Bacteriology*. In many publications, the API CH, a carbohydrate assimilation panel, has been used to assist in identification of lactobacilli. Highly standardized whole-cell protein patterns obtained by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) have proved helpful for identifying *Lactobacillus* species.[880] Oligonucleotide hybridization and molecular taxonomic methods (PCR, 16S rRNA sequencing) have also been developed for both genus- and species-level identification of lactobacilli.[58,296]

Recognition and confirmation of lactobacilli in the clinical microbiology laboratory can be accurately obtained with a handful of phenotypic tests. Some species of *Lactobacillus* are intrinsically resistant to vancomycin, and this characteristic is often helpful in identifying these organisms. Resistant isolates will grow up to the edge of a vancomycin test in a disk diffusion test. Vancomycin-resistant isolates must be differentiated from *Leuconostoc* and *Pediococcus* species, which are both vancomycin-resistant and can appear coccobacillary on Gram's stains. *Leuconostoc* species produce gas from glucose in Mann–Rugosa–Sharp (MRS) broth, while the majority of *Lactobacillus* species isolated in the clinical laboratory do not produce gas. Lactobacilli are also PYR-positive, while both *Leuconostoc* and *Pediococcus* species are PYR-negative. Lactobacilli are also LAP-negative, while *Streptococcus, Enterococcus*, *Pediococcus*, and *Lactococcus* species are LAP-positive. GLC from glucose broth cultures can be used to obtain a genus-level identification of isolates, due to the formation of large amount of lactic acid by these organisms. *Lactobacillus* species that have been identified in association with human infections include *L. rhamnosus*, *L. plantarum*, *L. leichmanii*, *L. fermentum*, *L. casei* subsp. *casei*, *L. paracasei*, *L. confusus*, and the *L. acidophilus* group. Strains of *L. rhamnosus*, *L. casei*, and *L. plantarum*, in particular, may be intrinsically resistant to vancomycin and teicoplanin (Image Plate 14-8A).

Antimicrobial Susceptibility of Lactobacillus *Species*

Recent surveys on the antimicrobial susceptibility of lactobacilli have shown a wide variation in susceptibility for several antimicrobial agents.[155,255,1076,1150] Danielsen and colleagues[255] in Denmark determined the susceptibility of 23 significant blood culture isolates belonging to seven different species. No differences were seen among the isolates regarding susceptibility to ampicillin (0.125 to 4 μg/mL), clindamycin

(0.032 to 1 µg/mL), erythromycin (0.032 to 2 µg/mL, and linezolid (0.5 to 4 µg/mL). High or intrinsic resistance related to individual species was observed against vancomycin, ciprofloxacin, cefotaxime, and meropenem. Vancomycin MICs were either <2 µg/mL or >256 µg/mL. In a retrospective review of over 200 cases (including reports of bacteremia, endocarditis, and localized infections), most lactobacilli were susceptible to clindamycin (90.9%) and erythromycin (94.3%), while only 22.5% of the isolates were susceptible to vancomycin.[155] In this survey, the percentage of susceptible isolates were 54.9% for penicillin, 63.6% for ampicillin, 47.8% for cefazolin, 64.3% for ciprofloxacin, and 70% for gentamicin. Individual case reports have also documented multi-resistance among *Lactobacillus* strains. For example, a *L. rhamnosus* isolate that was recovered from CSF of a stem cell transplant patient was resistant to penicillin, cefotaxime, all aminoglycosides, trimethoprim-sulfamethoxazole, all fluoroquinolones, tetracycline, and vancomycin.[942]Resistance of lactobacilli to vancomycin and teicoplanin is related to their cell wall structure. Analysis of the cell walls of vancomycin-resistant strains (e.g., *L. rhamnosus*) reveals that the peptidoglycan precursors for these species have a terminal depsipeptide "D-alanine-D-lactate," while species that are vancomycin-susceptible (e.g., the *L. acidophilus* group) have a terminal "D-alanine-D-alanine" structure.[110,468] This single amino acid difference effectively alters the target site for vancomycin, allowing peptidoglycan synthesis to occur in the presence of vancomycin.

Weissella Species

Weissella species are catalase-negative, gram-positive bacilli that were formerly members of the genus *Lactobacillus* (*L. confusus*) and *Leuconostoc* (i.e., *Leuconostoc paramesenteroides*).[229] Two additional *Weissella* species—*W. hellenica* and *W. thailandensis*—have also been described, and four former *Lactobacillus* species have also been transferred to the genus *Weissella* as *W. halotolerans*, *W. kandleri*, *W. minor*, and *W. viridescens*.[724,1089] These bacteria constitute a distinct phylogenetic group separate from the genera *Lactobacillus*, *Leuconostoc*, and *Streptococcus*. The cell wall of these organisms contains lysine and alanine joined with an intra-peptide bond and gas is produced from glucose. These properties differentiate *Weissella* species from the homofermentative lactobacilli, which contain lysine and *meso*-DAP in their cell walls. Two species—*W. confusa* (formerly *L. confusus*) and *W. cibaria*—have been associated with human infections, and these organisms are usually resistant to vancomycin.[117] *W. confusa* has been isolated as a cause of bacteremia in immunocompromised hosts, including a liver transplant patient with a history of hepatocellular carcinoma, a patient with abdominal aortic dissection and repair, and a

allogeneic stem cell transplant recipient.[473,819,969] Two patients with native valve endocarditis due to *W. confusa* have been reported. One case was detected as an incidental finding in a 65-year-old man with angina pectoris and aortic insufficiency, while the second patient had a transthoracic echocardiography that showed severe mitral insufficiency and a nodular vegetation on the mitral valve.[347,1011] In the latter instance, the patient refused antimicrobial therapy and further care, resulting in his death 4 days after discharge. Lee and colleagues in Taiwan described 10 patients with *W. confusa* bacteremia. Underlying diseases in these patients included non-Hodgkin's lymphoma, B-cell lymphoma, chronic renal failure, ischemic bowel disease, malignant peritonitis, esophageal cancer, ileus, and subarachnoid hemorrhage.[654] *W. confusa* has also been isolated from foods, clinical specimens from dogs, and human feces.[117] *W. cibaria* has been isolated from fermented food products ("chili-bo") in Malaysia, sugar cane and cheese whey in Germany, and clinical specimens from animals (i.e., otitis isolates from dogs' ears) and humans (i.e., feces).[117]

937

Weissella species are nonmotile, catalase-negative, heterofermentative bacilli that produce CO_2 from glucose along with lactic acid. Both *W. confusa* and *W. cibarica* are arginine dihydrolase-positive. *W. confusa* ferments galactose and xylose, but not arabinose, while *W. cibarica* ferments arabinose but does not ferment either galactose or xylose.[117] *W. confusa* strains have been misidentified as *Leuconostoc mesenteroides*, *Leuconostoc lactis*, *Staphylococcus hominis*, and *Streptococcus bovis* II by the Phoenix Automated Microbiology System (Becton-Dickinson) and as *Pediococcus pentosaceus*, *Leuconostoc pseudomesenteroides*, *Leuconostoc citreum*, and *Leuconostoc lactis* by the Vitek 2 system (bioMérieux, Inc.).[654] Some strains of *W. confusa* are susceptible to penicillin, ampicillin, imipenem, erythromycin, clindamycin, and ciprofloxacin; high-level resistance to trimethoprim-sulfamethoxazole, metronidazole, and vancomycin is commonly found, as is high-level resistance to ceftazidime (MIC >256 μg/mL).[654,1073] Ampicillin-sulbactam, amoxicillin clavulanate, daptomycin, doripenem, and tigecycline are active against most isolates of *W. confusa*, but they vary in their susceptibility to linezolid.[654]

Concluding Comments

Introduction, Classification, and Taxonomy

The aerobic actinomycetes are gram-positive bacteria that are characteristically more filamentous and branched than the bacteria discussed in other chapters. These bacteria commonly produce fungal mycelium-like growth that fragments into rod-shaped and short coccoid forms. These organisms, when isolated in many clinical laboratories, are most often initially isolated in the mycology or mycobacteriology sections of the laboratory and/or are referred for identification to mycology or to mycobacteriology

rather than remaining in the routine bacteriology section of the laboratory. The reasons are that most aerobic actinomycetes grow more slowly than other aerobic and facultatively anaerobic bacteria; hence, the routine bacterial media may not be incubated long enough for their isolation. They are more often seen on commonly used fungal media (e.g., Sabouraud dextrose agar [SAB] or potato dextrose agar [PDA]) or on mycobacteria isolation media (e.g., Middlebrook agar or Löwenstein–Jensen [LJ] media), which are incubated for weeks rather than a few days. These aerobic, branching, filamentous gram-positive rods are, nonetheless, bacteria, not fungi. True fungi have a eukaryotic cellular organization. In contrast to the fungi, the prokaryotic aerobic actinomycetes do not have a membrane-enclosed nucleus; they lack the intracellular organelles possessed by eukaryotic organisms (e.g., mitochondria); their cell walls contain muramic acid, diaminopimelic acid (DAP), or lysine (which fungi lack); they are inhibited by antibacterial antibiotics, but not by antifungal agents. Lastly, they do not produce hyphae although the term *branching hyphae* is often used to describe the aerobic actinomycetes; the branching filaments are narrower than fungal hyphae, measuring 0.5 to 1.2 μm in diameter (Box 15-1). Modern chemical and genetic techniques have established the great diversity of this group, and although the phenotypic characteristics described above remain an important part of the microbiologic definition, these alone are insufficient for species identification of most members of the group (Table 15-1).[41] The aerobic actinomycetes as a whole are placed taxonomically in the class *Actinobacteria*, order *Actinomycetales*, and divided among six suborders, including *Corynebacteriaceae, Streptosporangineae, Pseudonocardineae, Streptomycineae, Micrococcineae,* and *Thermoactinomcetaceae*. The flowchart in Figure 15-1depicts the relationships among these bacteria. Although the taxonomy and nomenclature of these bacteria are still being determined, a provisional, ad hoc phenotypic characterization of the group may remain useful, although in the future, more reliance will be placed on molecular taxonomy.[19,30,41,58]

BOX 15-1

Terms Used to Differentiate and Classify the Aerobic Actinomycetes

1. Aerobic actinomycetes are prokaryotes unlike the eukaryotic fungi; hyphae are used to describe the “filaments” of fungi that make up a matt of mycelia among the fungal molds; however,*branching* and *aerial hyphae* (and at times mycelia)

are terms used to describe some of the aerobic actinomycetes, especially the *Nocardia* spp. Here are some differences between fungi and the aerobic actinomycetes.

A. *Nocardia* filaments (and those of other aerobic actinomycetes), are 0.5–1.0μm in diameter as compared to the diameter of the hyphae of fungi which varies, but has a range of 1.5 to≥15μm.
B. *Nocardia* and other aerobic actinomycetes reproduce by fission (like other bacteria) as compared to the way in which fungi reproduce asexually by mitosis-derived conidia, as well as in some instances, sexually by means of more elaborate reproductive structures and meiotically-derived spores.
C. Many of the aerobic actinomycetes possess mycolic acid in their cell wall; fungi possess chitin in their cell wall along with glucans and mannans and other fungal-specific proteins.
D. Treatment of the aerobic actinomycetes is with antibacterial agents as compared to the antifungal agents used to treat yeasts and molds.

Having listed these differences, the term "hyphae" is still used throughout the literature to describe the filaments of many of the aerobic actinomycetes.

2. Strain description of the aerobic actinomycetes:
   A. "Type strain" denotes the exact strain of the bacterium for which the original description of the species was based.
   B. "Reference strains" is name given to other strains in a collection that are thought to belong to the same species as a given type strain.
   C. *Sensu stricto* means "in the strict sense" and when used with a species name, refers to organisms belonging to that particular species. So,*N. asteroidessensu stricto* should mean isolates that by gene sequencing are identical to the type strain *N. asteroides* ATCC 19247.
3. *N. asteroides* complex: This term is used in this chapter to refer to the 8–10 *Nocardia* species, such as *N. farcinica, N. nova,* and *N. transvalensis*, that are all partially acid-fast, contain *meso*-DAP with short-chain mycolic acids in cell wall (44–64 carbon atoms), and are usually negative for hydrolysis of casein, xanthine, and tyrosine.

The scheme outlined in Figure 15-1 uses tests that had been commonly performed in clinical microbiology laboratories and in some cases are still being performed. The non–acid-fast genera present the greatest problem, because the cell wall analyses required for their identification are beyond the capacity of most clinical laboratories. Molecular techniques or mass spectrometry will probably replace the phenotypic and cell wall analyses for species-level differentiation, although cell wall analysis will remain as a tool for research and epidemiologic studies. Most of the aerobic actinomycetes are environmental bacteria that can occasionally produce infections in

humans, especially in an immunocompromised host. If an aerobic actinomycete is isolated from a patient who has a clinically compatible illness, it should be referred to a reference laboratory for complete identification, especially if your laboratory does not have the capacity to perform sequencing or employ other advanced methods for identification. Even within the group that consists of partially acid-fast organisms, increasing complex tests are required for identification. The distinction of aerobic actinomycetes from a rapidly growing *Mycobacterium* species should always be done; this is usually accomplished by performance of full and partial acid-fast stains. *Mycobacterium* spp. should be fully acid-fast positive as compared to the partial or weakly acid-fast nature of some of the aerobic actinomycetes, such as *Nocardia* spp. *Mycobacterium* spp. are usually devoid of filamentous bacillary structures seen with the aerobic actinomycetes. Both rapidly growing *Mycobacterium* spp., *Nocardia,* and other aerobic actinomycetes can cause similar diseases (see Chapter 19).

Kiska and colleagues have presented a simplified battery of tests for the identification of *Nocardia* spp.[99] This biochemical algorithm may be useful initially to determine if one has indeed isolated an aerobic actinomycetes, but are not sufficient for complete identification to the species level and at times, not even to the genus level when used alone. This edition of the text will migrate from traditional biochemical testing and will emphasize molecular and mass spectrometric means of identification, which are becoming the gold standard for identification of these organisms.

The aerobic actinomycetes are widely distributed in nature, where they participate in the decomposition of organic plant material.[75,167] Isolates of various species are made regularly from soil and marine sediments, as well as from the feces of a variety of animals. They should be considered

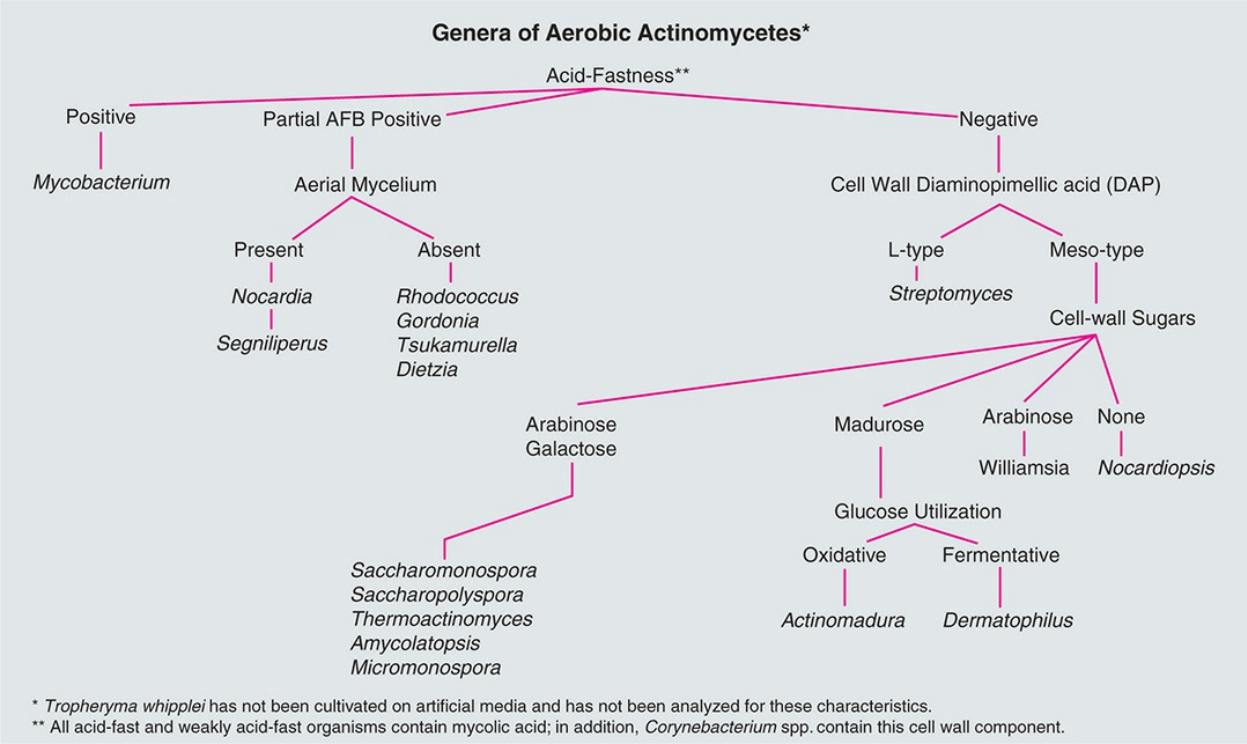
[a] Table has been modified from reference 41, Figure 1, page 444. This list does not contain all the members of Actinomycetales, but rather the ones most commonly isolated from human disease and clinical specimens.
[b] Also in suborder *Corynebacterineae* are the *Mycobacterium* spp. and *Corynebacterium* spp.

opportunistic pathogens, causing infection primarily in individuals whose defense mechanisms have been compromised. In addition, however, these bacteria have provided some of our most important antibiotics: streptomycin (*Streptomyces* spp.), vancomycin (*Amycolatopsis orientalis*), macrolides (*Micromonospora* spp.), and aminoglycosides (*Micromonospora* spp.). By far the most important pathogens are in the genus *Nocardia*, which will be considered in detail. The detail of discussion of the other genera will be proportional to their clinical relevance.

From a practical standpoint, the aerobic actinomycetes can be recognized in the laboratory because they form glabrous, tough, adherent, waxy, or dry chalky colonies that grow after 3 days to 2 weeks of incubation. Tan, pink, orange, or gray pigments may be observed. The odor of a musty basement or freshly turned soil is an important clue by which they can be recognized, although caution should always be used in working with these isolates to minimize aerosolization and "sniffing" of any bacterial or fungal colonies. The odor from these organisms is usually evident, without sniffing the plate. The optimal temperature for growth is 30°C to 36°C, both in the CO_2 incubator (as for the culture of mycobacteria) or in ambient air (as in the incubator

used for fungal cultures). They grow well on culture media such as sheep's blood agar, chocolate agar, LJ egg-based medium, Middlebrook synthetic agar, and on most fungal recovery media that are free of cycloheximide. All species are gram-positive, although *Nocardia* spp., in particular, tend to stain with a beaded, gram-variable pattern. Thus, the finding of gram-positive or gram-variable, beaded, delicate (1 μm in diameter), branching organisms should alert one to the possibility of an aerobic actinomycete; cultures for *Nocardia* should be held for 2 to 4 weeks. As mentioned above, the most common characteristic by which *Nocardia* spp. are separated from rapidly growing *Mycobacterium* species in clinical laboratories is their "partial" acid-fastness. The acid-fast reaction for *Nocardia* is positive only when a low concentration of an inorganic acid such as sulfuric acid (H_2SO_4) is used instead of the stronger hydrochloric acid (HCl) as the decolorizer. One can have a high suspicion for an isolate being a *Nocardia* spp. if the isolate is partially acid-fast, demonstrates branching filaments, and produces the musty, dirt-like odor or appropriate colony morphology. These properties are variable, however, and not always reliable. In problem cases, analysis of the cell wall or genome analysis has been required, which necessitated sending the isolate to a specialized reference laboratory. Today, however, methods such as mass spectrometry and sequencing are becoming more available, and knowing which laboratories provide these services is very important if your laboratory cannot.[35,143,167,193,194] For completeness and during this transition period, the cell wall composition of the aerobic actinomycetes, still potentially useful both taxonomically and diagnostically, is detailed in Table 15-2.



■ **FIGURE 15-1** Classification of aerobic actinomycetes associated with human disease.

The Nocardioform Group

Nocardia *spp.*

The taxonomy of *Nocardia*, the most important genus among the aerobic actinomycetes, is ever-changing. The definition of a nocardiae species is based on molecular data, usually obtained from 16S rDNA sequencing. The *Nocardia* spp. possess tuberculostearic acid, like *Mycobacterium* spp., but also contain short-chain mycolic acids (40 to 60 carbon units); their cell wall contains peptidoglycan as do all gram-positive bacteria, but it is composed of *meso*-DAP, arabinose, and galactose. The presence of these cell wall components is fairly universal among the aerobic actinomycetes; however, the length of the mycolic acid chains may differ among the genera.[19,167] In addition, some of the aerobic actinomycetes, as shown in Table 15-2, do not contain mycolic acids.

The original isolate from infected animals with granulomatous disease (bovine farcy) was made by Nocard in 1888 on Guadeloupe Island. This isolate was subsequently named *Nocardia farcinica*, and this isolate was made the type species of the genus in

1954.[41]Interestingly, the original isolate of Nocard actually consisted of two strains that were thought to be identical, but in actuality one of the strains had mycolic acids that are characteristic of nocardiae, while the mycolic acids of the other were more typical of a mycobacteria.[19] The strain that had characteristics of a *Nocardia* sp. (American Type Culture Collection [ATCC] strain 3318) was found in 1962 to be phenotypically identical to what was then being called *N. asteroides* and since the latter nomenclature had become more commonly used in clinical laboratories, *N. asteroides* (ATCC strain 19247) replaced *N. farcinica* as the type species for the genus and continued to be used in most clinical laboratories as the name for the most commonly isolated *Nocardia* species.[41] *N. asteroides* proved to be very diverse as more genetic studies were performed and these differences led to formation of subgroups within the *N. asteroides* species. Microbiologists were eventually able to demonstrate that many of these subgroups of isolates actually were biochemically and immunologically identical to the original ATCC strain of *N. farcinica*, 3318, and interestingly not to *N. asteroides* type species 19247. The term *N. asteroides* "complex" was coined to demonstrate this diversity, and thus designations appeared like *N. asteroides* subsp. *farcinica* or *N. asteroides* subsp. *nova*, etc. to define these differences within the complex. More sophisticated molecular studies soon verified the homology of the subgroup referred to as *N. farcinica* with the ATCC-type strain 3318.[32]

As the use of polymerase chain reaction (PCR), nucleic acid sequencing, and other molecular tools continued to be applied to the *Nocardia* isolates, it became apparent that many of what had been called *N. asteroides* or even *N. asteroides* complex were not related to the type species at all.

N. asteroides complex isolates are relatively inert biochemically, and hence differentiation using phenotypic means was impossible and many infections that were reported to be due to *N. asteroides* were really not caused by this organism, when the infecting agent was identified using modern molecular tools. In addition, Wallace et al.[199] and others began to notice differences in drug susceptibility patterns among the species of the *N. asteroides* complex, and in 1988, he and his colleagues reported six different drug patterns for 12 antimicrobials (Table 15-3). This group defined as drug patterns I to VI for the 78 clinical isolates of what were referred to at the time as *Nocardia asteroides*. Steingrube and associates

TABLE 15-2 Cell Wall Composition of Aerobic Actinomycetes

Cell Wall Chemotype[a]	Composition	Nocardomycolic Acids	Genera
I	L-DAP; no diagnostic sugars	No	*Streptomyces*
II	*meso*-DAP; no diagnostic sugars	No	*Thermoactinomyces, Nocardiopsis*
III	*meso*-DAP; madurose	No	*Actinomadura, Dermatophilus*
IV	*meso*-DAP; arabinose and galactose	Yes	*Nocardia, Rhodococcus, Gordonia, Tsukamurella, Dietzia*
VI	No DAP; aspartic acid and galactose	No	*Oerskovia*[b]
NA	No DAP; madurose	No	*Actinomadura*

[a]Cell wall of all genera contain major amounts of alanine, glutamic acid, glucosamine, and muramic acid.
No significant human pathogens have the characteristics of II, V, VII, or VIII cell walls.
[b]*Oerskovia* has been found to be more closely related to the general *Cellulomonas* than to the genus *Nocardia* or other aerobic actinomycetes.
Data from references 19 and 199.

TABLE 15-3 Antimicrobial Susceptibility Profiles of 78 Isolates of the *Nocardiaasteroides* Complex

Type	Percentage (%) Isolates	Susceptible	Resistant	Species Correlation
I	20	Ampicillin, carbenicillin, broad-spectrum cephalosporins, imipenem (50%)	Imipenem (50%)	*Nocardia abscessus*
II	0	Same as type I, but kanamycin- and ciprofloxacin-susceptible	Gentamicin and Clarithromycin	*N. brevicatena/ N. paucivorans*
III	18	Ampicillin, erythromycin	Carbenicillin	*Nocardia nova*
IV	5	Ciprofloxacin	All aminoglycosides, including amikacin	*N. transvalensis* complex
V	17	Ciprofloxacin, imipenem	All penicillins and broad-spectrum cephalosporins, all aminoglycosides except amikacin	*Nocardia farcinica*
VI	35	Broad-spectrum cephalosporins	Penicillins	*Nocardia asteroides* sensu stricto, *Nocardia cyriacigeorgica*

Data from reference 199.

later defined four separate unnamed groups, designated type I, type II, type IV, and type VI, using DNA amplification and restriction fragment length polymorphism (RFLP) to characterize products derived from the 65-kDa heat-shock protein gene.[179] These groups likewise showed differences in antimicrobial susceptibility profiles, as Wallace had previously shown. Strains that match the classical description of the type species (ATCC 19247) were designated *Nocardia asteroides* sensu stricto type VI. It should be noted that "type VI" in this context is not the type VI classification of the components of the cell wall. It was later proposed that the isolates with a type VI susceptibility pattern should be named *N. cyriacigeorgica* and not *N. asteroides*.[163,219]

Roth and colleagues in 2003 redefined the phylogeny of the genus *Nocardia* based on 16S rDNA sequencing. They determined 30 established species and 10 unclassified

taxa in the genus and proposed methods for future taxonomic decisions as new species are recognized. Brown-Elliott in 2006 reviewed all of the data regarding taxonomy of *Nocardia* spp., including the work of Wallace (1988), Steingrube, and Roth, clarifying the status of the genus at that time. Many earlier reports of clinical disease did not distinguish these pathogens using currently acceptable techniques; so it is at times difficult to determine what the true identity of the infecting species.[19,163]

It turns out that the drug pattern VI isolates referred to as *N. asteroides* sensu stricto represents approximately 35% of clinical isolates of *Nocardia* spp.[19,199] It has been suggested that perhaps sometime in the future the name *N. asteroides* will return to designate this group of *Nocardia* sp. since this drug pattern represents one-third of the isolates seen clinically. Currently, *N. cyriacigeorgica* and *N. asteroides* complex both share that designation. The following lists the species that correspond to each of the six drug patterns listed in Table 15-3, which will increase as new species are being identified regularly:

I. *N. abscessus*[217];
II. *N. brevicatena*[99,163]/*N. paucivorans*[53,215] complex and an unnamed group;
III. *N. nova* complex, which is composed of *N. nova*,[196] *N. veteran,*[7,36,152] *N. africana,*[78] and *N. kruczakiae*[38];
IV. *N. transvalensis* complex (including *N. wallacei*)[39,126,222];
V. *N. farcinica*[204];
VI. *N. asteroides* complex (or sensu stricto) and *N. asteroides* Type VI (unnamed)/*N. cyriacigeorgica*.[219]

Non-N. asteroides Complex Species

Among the non-"*N. asteroides* complex" (not members of the antimicrobial susceptibility patterns I to VI), *N. brasiliensis*,[167,176] *N. pseudobrasiliensis,*[90,165,195] and *N. otitidiscavarium*[34,148] (formerly *N. caviae*) are the most commonly isolated species in human disease. Additionally, other species of *Nocardia* that have been found to be involved in clinical disease include *N. arthritidis*,[91] *N. punis*,[221] *N. asiatica*,[89] *N. beijingensis*,[142] *N mexicana,*[161] and many other named and unnamed species.[19,60,99]

Epidemiology, Pathology, and Pathogenesis. Members of what was once referred to as the *N. asteroides* complex are the most frequently isolated human aerobic actinomycetes pathogens and are distributed widely throughout the United States.[167] *N. farcinica*, *N. cyriacigeorgica,* and *N. nova* are the species most often identified;

however, some of this is geographically determined. Beaman et al.[12] estimated that 500 to 1,000 cases of nocardiosis occur in the United States each year, but that figure is likely to be an underestimate because nocardiosis is not a reportable disease. Unfortunately, this survey was done in the 1970s and there have been no other more recent surveys of the incidence of *Nocardia* in the United States, although with increasing immunosuppressed populations, the number of infections is most likely higher today.

Nocardiae are opportunistic pathogens, more often producing infections in patients who are immunocompromised or have debilitating diseases. A combination of long-term corticosteroid therapy and chronic lung disease has been suggested as a particularly important combination of risk factors.[167] Patients with nocardiosis may have no

demonstrable underlying immunologic defect, but these are not the usual hosts for *Nocardia* spp. other than in cases of traumatic introduction of the organism into the skin and soft tissues. Nocardiae may colonize the skin and respiratory tract; so isolation of a *Nocardia* sp. could potentially represent colonization rather than infection in any nonsterile site. In one Australian study, only about 20% of the isolates were not associated with clinical disease.[64]Even the recovery of *Nocardia* species from blood cultures can be insignificant. Of eight patients with *Nocardia* bacteremia reported by Esteban and associates, *N. asteroides* was thought to be clinically relevant in only two; the remaining isolates were considered clinically insignificant or of uncertain significance.[55] However, there have been many reports more recently about positive blood cultures, especially in catheter-related bacteremia cases in which the *Nocardia* spp. were indeed significant. Clinical correlation with laboratory results is always needed so that isolates are not dismissed as merely laboratory contaminants or "diphtheroids."[147,168]

The most common clinical presentation of nocardial disease, especially when caused by members of the *N. asteroides* complex, is that of pulmonary disease in the immunocompromised host; the portal of entry of the organisms is via inhalation of airborne fragments of the bacteria from the environment. Extrapulmonary disease, as a result of dissemination from primary pulmonary disease or localized infection, can occur anywhere in the body, but predominantly occur in the skin, subcutaneous tissue, and the central nervous system. Approximately 20% of patients with disseminated disease present solely with extrapulmonary disease.[19] The second most common form of nocardiosis, cutaneous and soft tissue infections, is more commonly caused by nonasteroides complex *Nocardia* spp. *N. brasiliensis* is a common cause of

subcutaneous infections and mycetoma in South America, much of Central America. In the 1960s, 85% to 95% of reported mycetomas in Mexico were caused by *N. brasiliensis*.[71] Castro and associates noted that *N. brasiliensis* was by far the most common actinomycete isolated from 41 patients seen in Sao Paulo, Brazil, between 1978 and 1989.[28]Most patients were from rural areas in the northeast regions of the country, and the majority were field laborers. Significant infection of skin and soft tissues with *N. brasiliensis* was also found in patients from Queensland, Australia, who had nocardiosis.[64] Although primarily found in tropical countries, *N. brasiliensis* is, nonetheless, among the most common of the *Nocardia* sp. isolated in the United States, where it is most prevalent in southwestern and southeastern states.[176] As mentioned above, many of the reports of *N. brasiliensis* infection are actually due to a newly described species, *N. pseudobrasiliensis*.[90,165,195] *N. brasiliensis* and *N. pseudobrasiliensis* can also cause pulmonary disease in immunocompetent and immunocompromised hosts.[103]

N. otitidiscaviarum (formerly *N. caviae*) has been isolated from soil throughout the world. It is a less common cause of disease and is less frequently recovered than other *Nocardia* spp. The distribution and clinical relevance of other rarely isolated species of *Nocardia* is less clear although molecular and mass spectrometry methods for identification may change this in the future.[57,193,202]

One of the most serious forms of nocardiosis is chronic pulmonary infection, with or without dissemination to other organs. The pathogenesis of infection with the *Nocardia* spp. is inhalation of airborne bacteria, which perhaps explains the frequency of infection in the dry southwestern states, analogous to infections by *Coccidioides* spp.[19,167] Cutaneous disease, including actinomycotic mycetoma, can result from direct introduction of bacteria after trauma, including gardening, walking barefoot, after surgical or cosmetic procedures, or as a result of disseminated disease.[45,51,167]

Nocardia spp. are facultative intracellular pathogens. Their ability to grow in macrophages and also polymorphonuclear nuclear leukocytes is undoubtedly important for their ability to produce infection. The organisms are capable of living inside macrophages by inhibiting phagosome–lysosome fusion and by their ability to produce catalase and superoxide dismutase, which inactivates products of the myeloperoxidase system of these phagocytic cells. In particular, patients with chronic granulomatous disease are at risk of serious nocardial infection, as they are for other bacteria that produce catalase.[46] The cellular immune response is critical for control of the infection, as suggested by experimental studies and the occurrence of disease in patients with compromise of cellular immunity.[11,69] Initially, nocardial infection appeared to be underrepresented in patients who are infected with HIV; however, Beaman and others note the accumulating number of case reports and unreported infections, and that the geographic variations in environmental nocardiae, which do not

match centers of HIV infection, may partially explain any of the discrepancies in incidence.[11]

The bacterial cells of *Nocardia* spp. are not usually seen in hematoxylin- and eosin-stained sections, and may not be seen in periodic acid–Schiff (PAS) stains. They are quite readily observed in Gomori methenamine–silver, Gram–Weigert, Giemsa, or tissue Gram's stains (e.g., Brown and Brenn, or Brown–Hopps stains). In a tissue Gram's stain, the organisms are usually thin, beaded, branched filamentous rods. The modified Kinyoun acid-fast stain (i.e., the partial acid-fast stain wherein destaining is done with 1% aqueous H_2SO_4 instead of the usual 3% HCl that is used in the Ziehl–Neelsen method) is useful for direct smears and frozen sections, whereas the Fite–Ferraco acid-fast stain (i.e., also a partial acid-fast stain) is recommended for paraffin sections.[209,210] When both full and partial acid-fast staining is used,*Nocardia* spp. are partially acid-fast positive/full acid-fast negative, *Mycobacterium* spp. in both the full and partial acid-fast positive, and *Actinomyces israelii* and the other anaerobic actinomycetes are negative with both the full and partial acid-fast stains. Other members of the aerobic actinomycetes, such as *Rhodococcus*, *Gordonia*, and *Tsukamurella*, for example, stain partially acid-fast positive or not at all. For all of the aerobic actinomycetes, use of the partial acid-fast stain in tissue and clinical samples directly often gives a true indication of their acid-fastness as compared to applying the stain to the in vitro colonies of the isolate when the property of acid-fastness can wane. Box 15-2 describes the method for performing the partial acid-fast stain.

Clinical Disease. The clinical disease produced by all species of the genus *Nocardia* is similar. Pulmonary disease can present as a subacute, or indolent disease lasting from days to weeks before a patient seeks medical care.[19,125] Manifestations include fever, a cough productive of thick mucopurulent sputum, sometimes accompanied by weight loss and fatigue mimicking nontuberculous mycobacterial disease. There is usually chest roentgenogram evidence of nonresolving infiltrates with or without smooth, round nodules in one or more locations. Cavitation of the infiltrate or nodule can develop.[19] There may be progressive bronchopneumonia, extensive consolidation, single or multiple abscesses, pleural effusions, empyema, and sinus tracts with involvement of the chest wall. The primary inflammatory response is neutrophilic, but in rare instances granulomas have been described.

BOX 15-2

Modified Acid-Fast Stain for *Nocardia* Species

1. Make a smear of the organism from growth media and heat-fix.
2. Flood the slide with Kinyoun carbolfuchsin for 5 minutes.
3. Pour off the excess stain.
4. Decolorize with a 1% aqueous solution of H_2SO_4.
5. Wash with tap water.
6. Counterstain with methylene blue for 1 minute.
7. Rinse with water and dry. Examine under oil-immersion optics.

Disseminated infection usually originates from a pulmonary focus, but it may also occur after a primary infection elsewhere. Bacteremic spread results in multiorgan infection, especially in the brain and skin.[19,41,80] Approximately 45% of patients with disseminated nocardiosis have infections of the central nervous system, usually in the form of one or more brain abscesses.[7,19,60,113] The prognosis for these patients is poor with a fatality rate of 7% to 44% overall and up to 85% in severely immunosuppressed patients.[125] Serious infection with *Nocardia* spp. has been documented in patients who have neoplastic disease[188] or acquired immunodeficiency syndrome[85] and in recipients of renal transplants,[207] among others. Metastatic brain abscesses, which develop in about one-third of patients, produce headaches, nausea, vomiting, changing mental status and depressed consciousness. Seizures, focal neurologic deficits or other neurologic abnormalities can also occur. Blood cultures (in spite of hematogenous spread of the organism) and cerebrospinal fluid (CSF) cultures almost invariably fail to demonstrate the bacteria.[53]

Cutaneous infections are probably underdiagnosed because they are often self-limited and adequate microbiologic studies may not be done on superficial infections.[113] Primary cutaneous infections usually present as lymphocutaneous, superficial cellulitis or localized infections on the face when presenting in children or on the lower extremities in adults.[19]When there is lymphangitic spread to the regional lymph nodes, possibly with fistula formation, it clinically resembles sporotrichosis and has been referred to as sporotrichoid nocardiosis.[175] Secondary cutaneous infection can also occur as a result of disseminated disease. Unlike pulmonary disease, the patient who develops primary cutaneous disease is most often an immunocompetent host. As previously mentioned, *N. brasiliensis* and *N. pseudobrasiliensis* are more commonly associated in cutaneous nocardiosis than members of the *N. asteroides* complex and can occur in immunocompetent as well as immunocompromised individuals.[62] A more recently recognized species in *Nocardia asteroides* complex, *N. neocaldoneniensis* was isolated from an abscess of the jaw of a 68-year-old man

receiving prednisone and methotrexate for his rheumatoid arthritis.[124] In addition, a classical cutaneous lesion, the mycetoma, may be caused by true fungi (eumycotic mycetoma) or by aerobic actinomycetes, including *Nocardia* spp. (actinomycotic mycetoma). (See discussion in the section on "*Actinomadura*," below.)

Bacteremia can occur with *Nocardia*, although not commonly, in patients with and without catheters.[2,31] *N. nova* has been the organism most often isolated in patients with cancer and was the cause of a catheter-related bacteremia; the presence of a biofilm may suggest the mechanism of its pathogenicity.[2]

Ocular nocardiosis can occur in an immunocompetent individual subsequent to trauma or as a postoperative complication. Alternatively, the eye may be infected as a result of disseminated disease in an immunocompromised host. *Nocardia* infections of the eye include keratitis,[51] uveitis, retinal abscesses, or endophthalmitis.

A variety of other infections may be caused by *Nocardia* spp. Peritonitis can occur in patients who are undergoing continuous ambulatory peritoneal dialysis, the presentation of which is indistinguishable from that of other bacteria. *N. veterana* was recently recovered from ascitic fluid in an infection in a HIV-positive individual.[36,69] *Nocardia synovitis* has also been reported, but is rare. There have been healthcare-related *Nocardia* infections, as well as rarely reported outbreaks of infections in the community. One such outbreak has involved *N. cyriacigeorgica* in which eight individuals developed soft tissue infection subsequent to an unlicensed cosmetic procedure for enhancement. All eight patients required hospitalization, surgical debridement, and prolonged antimicrobial therapy.[6]

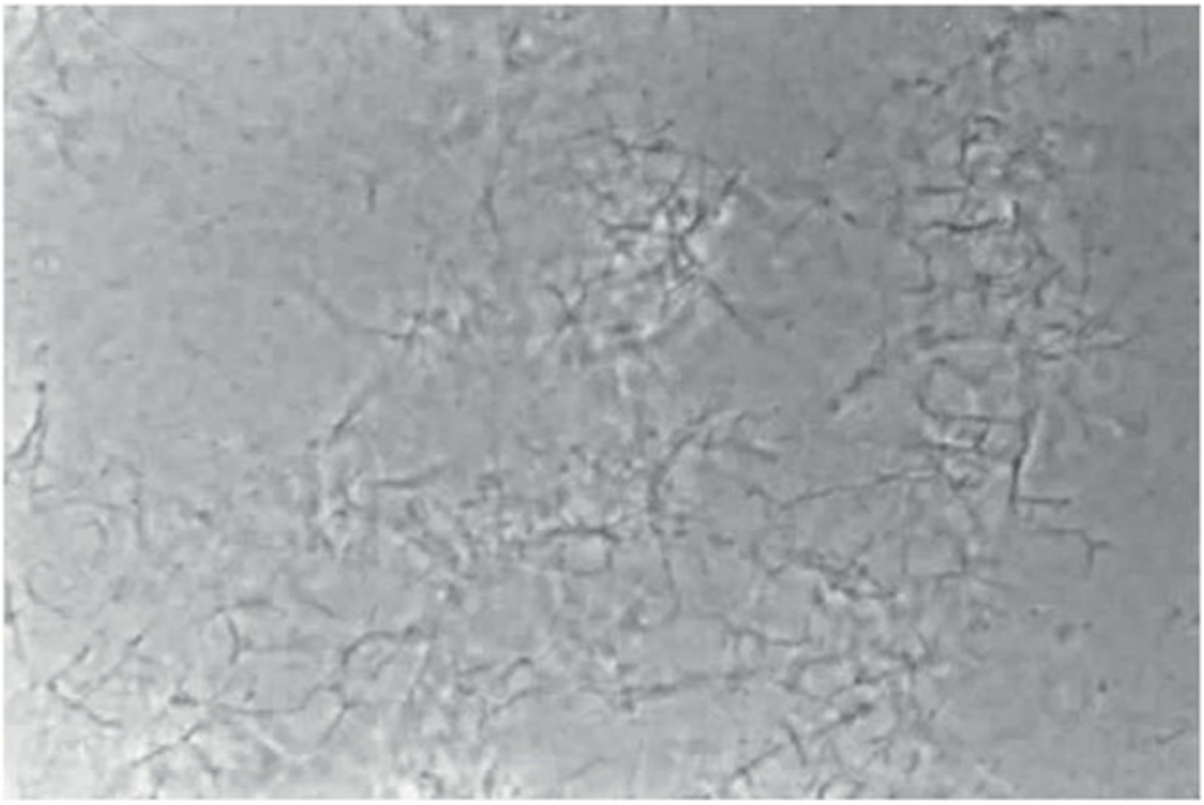
The frequency of *Nocardia* infections in organ transplant patients varies between 0.7% and 3%. A review of 5,126 transplants in the United States revealed 0.6% *Nocardia* infections. Most patients presented with pulmonary disease, although 20% had disseminated nocardial infections. The incidence of nocardiosis in transplant recipients was reported as follows: lung, 3.5%; heart, 2.5%; intestine, 1.3%; kidney, 0.2%; and, liver, 0.1%. *N. nova* was the most common species involved, followed by *N. farcinica*, *N. asteroides,* and *N. brasiliensis*. Sixty-nine percent of the patients were on prophylaxis with sulfamethoxazole–trimethoprim (SXT) and 89% were successfully treated and cured of their nocardial infection.[144] Another review of lung transplant recipients in Pittsburgh reported that 2.1% of 473 patients had *Nocardia* infection, and the major species involved was *N. farcinica*; the overall mortality was much higher than the Peleg study at 40%.[83] Of the *N. asteroides* complex species, *N. farcinica* is often the most resistant to antimicrobials, which might explain the difference in prevalence.

Rhodococcus *spp.*

Taxonomy and Classification. The genus *Rhodococcus* is a heterogeneous group of bacteria that are closely related to the *Nocardia*, although these lack the aerial "hyphae" (Fig. 15-2) that are characteristic of the *Nocardia* spp. (Fig. 15-3). Members of this group of aerobic actinomycetes are gram-positive, nonsporulating, and are usually partially acid-fast. As the name implies, the appearance of any of the members under specific environmental conditions or staining properties, may be coccoid or rod-like. The species are widely distributed in the environment, in soil, on plants, or in the gastrointestinal tract of a variety of insects or animals. There have been many changes to the taxonomy of the *Rhodococcus* genus, and many former species have been reassigned to other genera, such as *Gordonia*, *Dietzia*, *Tsukamurella,* and others.

The term *Rhodococcus* was first used by a German botanist, Zopf, in 1891 as he was classifying pigment producing bacteria and fungi; these particular bacteria produced a salmon-pink to red colony after 4 days of growth on solid media and their colonies were often mucoid. The genus name *Rhodococcus* was redefined in 1977 to include members of the "rhodochrous" complex of bacteria that contained organisms that were evolutionarily placed somewhere between the nocardioform and mycobacterial species.[214] Many of the *Rhodococcus* spp. have never been shown to cause infections.[125]

FIGURE 15-2 *Rhodococcus* on tap water agar. No aerial hyphae are produced.



■ **FIGURE 15-3** *Nocardia* on tap water agar produces aerial hyphae.

Rhodococcus equi (at one time referred to as *Corynebacterium equi* and *Mycobacteriumrhodochrous*) is the most important human pathogen in the genus. The other human pathogens, *R. erythropolis*, *R. rhodnii,* and *R. rhodochrous,* are rarely recovered from clinical specimens.[74] The biochemical characteristics of *R. equi* include production of catalase, urease, lipase, and phosphatase, but not DNase, elastase, or lecithinase. These bacteria are partially acid-fast and may demonstrate gram-positive coccoid and bacillary forms, or short branching chains; this group does not produce aerial hyphae (Fig. 15-2). *R. equi* does not grow in lysozyme, which is another differentiating feature from *Nocardia* spp. However, like most *Nocardia* complex isolates, it does not hydrolyze casein, tyrosine, or xanthine.[214] Chart 15-1addresses these hydrolysis assays and Chart 15-2 addresses the lysozyme test. Table 15-4 gives a summary of the characteristics of many of the aerobic actinomycetes.

Epidemiology, Pathology, and Pathogenesis. *Rhodococcus equi* is the cause of pulmonary disease in foals and other domestic animals. Between 1967 and the early 1980s, only a limited number of human infections were reported. Rhodococcosis is a zoonotic disease, with human infections resulting from contact with animal carriers (e.g., cattle, pig, horses, cattle, or manure), presumably by a respiratory route.[190] *R.*

equi causes a rare and often fatal, primarily pulmonary disease. Human infections most commonly occur in immunocompromised individuals, primarily those with defects in cell-mediated immunity—for example, patients with lymphoma, Hodgkin's disease, leukemia, AIDS, and following transplantation.[190,214] McNeil and Brown cited over 100 cases of *R. equi* infections in patients with AIDS in 1994 and patients with infections continue to be reported annually.[59,125,187]

The histopathology of *Rhodococcus* is unique. Although neutrophils are a component of the inflammatory response, there is also a prominent chronic inflammatory component, consisting predominantly of macrophages. These collections of histiocytes may be interspersed with microabscesses.[125] Well-formed caseating granulomas, as seen in tuberculosis, are not present. Malacoplakia, a distinctive histologic reaction in which laminated basophilic concretions (Michaelis–Gutmann bodies) are found amid the macrophages, has been described in patients with pulmonary *Rhodococcus equi* infection.[137,214] Although there may be other rare causes of pulmonary malakoplakia, this histologic finding has become almost pathognomonic for pulmonary rhodococcosis.

The pathogenesis of infections with *R. equi* is thought to be due to the ability of the organism to persist in and eventually destroy macrophages, by prevention of phagosome–lysosome fusion and the nonspecific degranulation of lysosomes in vivo.[153] In addition, the production of a biofilm has been implicated as a factor in catheter-related bacteremia, in particular in association with central lines. Removal

TABLE 15-4 Principal Features of the Major Aerobic Actinomycetes

Genus	Colony	Gram/AFB	Lysozyme	Aerial Hyphae
Nocardia spp.	Chalky or velvety, musty or soil odor; white initially, then may be any color, but often orange or salmon or tan	Beaded, branching, and filamentous; modified acid-fast positive	Growth	Present
Rhodococcus equi	Rough, smooth, although often mucoid; pigment may be delayed, but often pink, red, or orange	Coccoid and bacillary forms; often modified acid-fast positive	No growth	Considered negative; however, rudimentary aerial hyphae may be seen microscopically
Gordonia spp.	Rough and wrinkled; brown, pink, orange, red pigments	Short coryneform (diphtheroidal) without branching; usually weakly modified acid-fast positive, if at all	No growth	No aerial hyphae
Tsukamurella spp.	Small colonies, dry; may be white or pigmented orange	Straight to slightly curved long rods, singly or in pairs; no branching; some may demonstrate shorter bacilli and appear diphtheroidal; stains very weakly with the modified acid-fast stain	Growth	No aerial hyphae
Dietzia spp.	Smooth yellow colonies	Coccobacillus to bacillus without branching; modified acid-fast stain negative	No growth	No aerial hyphae
Nocardiopsis	Coarsely wrinkled or folded surface; greenish yellow or brown pigment	Aerial hyphae usually coccoid forms; best seen in slide cultures; modified acid-fast stain negative	No growth	Positive, usually abundant aerial hyphae
Actinomadura spp.	Wrinkled and often leathery colonies; may be almost any pigment	Thin, short, branching filaments; modified acid-fast stain negative	No growth	Variable; some strains may have aerial hyphae
Streptomyces spp.	Discrete, lichenoid, leathery, or butyrous; may be pigmented, sometimes gray but other colors as well depending upon species	Filamentous rods that may bead at times; can look like *Nocardia* on Gram's stains; modified acid-fast stain negative	No growth	Positive, present
Dermatophilus	Rough, heaped, opaque, or may be granular; may adhere to agar; some β-hemolysis may appear	Branching filaments and coccoid cells arranged longitudinally and parallel with other chains; modified acid-fast stain negative	Unknown	Present
Segnilaparus	Smooth and domed or rough and wrinkled; usually nonpigmented	Bacillary with V forms; no branching; modified acid-fast positive	Unknown	No aerial hyphae
Williamsia	Smooth colonies; orange to red colonies	Short bacillus or coccobacillus; modified acid-fast stain negative	Unknown	No aerial hyphae

of the catheter is important in the treatment of these patients, as well as appropriate antibiotic therapy.[1] Box 15-3 addresses treatment options.

Clinical Disease. Pulmonary infections with *Rhodococcus* may clinically mimic tuberculosis, as these are slowly progressive and may cavitate.[110,170,190] Invasive pneumonia with cavity formation is noted particularly in patients with HIV and a low CD4 count, in whom there is a high propensity for the infection to disseminate to the brain, liver, spleen, and other organs.[125,187] Clinical disease develops insidiously, with fever over several days to weeks, malaise, dyspnea, a nonproductive cough and chest pain. Hemoptysis has been reported in some patients. Chest roentgenogram examination demonstrates an infiltrative process with opaque lesions, usually in one upper lung lobe. Cavitation will occur if untreated and in rare instances a pleural effusion can occur.[170] Blood and sputum were the specimens most commonly found

positive in a review of 272 cases of HIV-associated *R. equi* disease.[187]

A 37-year-old HIV-positive patient with *Pneumocystis* pneumonia developed prostatic and scrotal abscesses with *R. equi* that required 6 weeks of antimicrobial therapy for resolution.[121] Non–HIV-positive immunosuppressed patients should also be considered at risk of *R. equi* pulmonary infections, including children with leukemia, transplant recipients—especially kidney and lung transplant recipients—and patients on immunosuppressive therapy, including treatment with alemtuzumab or corticosteroids or anti-metabolites given to patients with connective tissue disorders.[129,131,214] *R. equi* has also been reported to cause bacteremia, endophthalmitis, osteomyelitis, pleurisy with effusion and wound infections.[153,155,166,187,214] *R. equi* infection has rarely been seen in immunocompetent hosts, who have much lower mortality rates. Immunocompetent patients with rhodococcosis had a mortality rate of 11%, whereas patients with HIV had 50%

969

BOX 15-3

Usual Susceptibility Patterns of the More Common Non-*Nocardia* Species of Aerobic Actinomycetes

Rhodococcus equi

Usually susceptible to erythromycin, aminoglycosides (gentamicin, tobramycin, and amikacin), rifampin, vancomycin, imipenem, and minocycline

Resistant to penicillin, ampicillin, and cephalosporins

Variable susceptibility to fluoroquinolones

There are clinical reports of success with the use of linezolid.

Gordonia spp.

There are no recommended standards for treatment of *Gordonia* spp. However, the CLSI document M-24-A2recommends that these agents can be considered for primary susceptibility testing: amikacin, amoxicillin clavulanic acid, ceftriaxone, ciprofloxacin, clarithromycin, imipenem, linezolid, minocycline, SXT, and tobramycin.

There are some data from case reports that fluoroquinolones may be adequate.

Tsukamurella

There is variability to the response of different species of *Tsukamurella* and if treatment information is needed, a susceptibility test should be done on each

isolate.

In general, the following can be suggested before specific susceptibility results are known:

Susceptible to amikacin, imipenem, SXT, and ciprofloxacin

Resistant to amoxicillin/clavulanate, ampicillin, erythromycin, and minocycline

Streptomyces

Usually susceptible to amikacin, linezolid, imipenem, clarithromycin, and minocycline

Variable susceptibility to SXT

Often resistant to ciprofloxacin and ampicillin and cephalosporins

Actinomadura

Susceptible to SXT, erythromycin, linezolid, minocycline, fluoroquinolones, and imipenem

Resistant to ampicillin

to 55% mortality and non-HIV immunosuppressed patients had a mortality of 20% to 25%.[214]

Gordonia *spp.*

Taxonomy and Classification. *Gordonia* spp. (originally *Gordona* spp.) consists of aerobic actimomycetes species that were originally described by Tsukamura and revived by Stackebrandt et al. in 1988.[41] Members of this genus are difficult to identify and to separate from one another and from related genera without the use of newer molecular or mass spectrometric methods.[41] These organisms may have been dismissed in older literature as contaminating "diphtheroids" or misidentified as members of the *Nocardia* or *Rhodococcus* genera.[16]

Gordonia spp. are usually partially acid-fast, do not grow in lysozyme and possess 48 to 66 carbon atoms in their mycolic acids. Use of DNA sequencing or mass spectrometry for identification may aid in identification of the *Gordonia* spp. in the future and help clarify their role in clinical disease. There are 29 validly named species in the genus, but *Gordoniabronchialis,*[177,205] *G. sputii,*[21] *G. terrae,*[47,68,149] *G. otitidis,*[156] and *G. polyisoprenivorans*[96,192] are the species most often associated with human infections or isolated from clinical specimens.[68,96,149,174]

Epidemiology, Clinical Disease, and Pathogenesis. Infection, most often catheter-related bacteremia, and skin and soft tissue infections in immunocompromised and

immunocompetent individuals, are being reported more frequently with use of newer identification methods. Table 15-4 lists some of the main differentiating characteristics of *Gordonia* among the aerobic actinomycetes. Ramanan et al.[156] has reviewed a patient with *G. otitidis* bacteremia and reviewed additional patients with catheter-related *Gordonia* bacteremia. The patient was a 4-year-old boy with multiple medical issues, including Hirschsprung disease, who had a broviac catheter in place for TPN. Fever developed and the patient failed to thrive. He was initially treated with amoxicillin but when *Gordonia* sp., identified initially as "gram-positive diphtheroids," was isolated from multiple blood cultures on two separate episodes of fever, appropriate antibiotics were successfully instituted for *Gordonia* and cultures became negative and a clinical cure achieved.[211] Johnson et al.[86] reported a patient recently who developed a pleural infection and bacteremia; this patient did not have any intravascular catheters. This emphasizes the need for clinicians and laboratories to maintain awareness of this organism from any blood culture, but especially in immunocompromised hosts. In addition, pneumonia, osteomyelitis and central nervous system infections have been reported.[47,174,177] Catheter-related bacteremia in five pediatric patients were reviewed in Utah; three were due to *G. terrae* and one each due to *G. otitidis* and *G. bronchialis*. Fifteen other instances of invasive *Gordonia* infections in adults and pediatric patients were reviewed, 12 of which

were catheter-related. Twelve of the 15 reviewed infection occurred in immunocompromised patients as did 3 of the 5 instances reviewed in the Blaschke report.[16,68,149] *Gordoniabronchialis* has been reported to cause a recurrent breast abscess in an immunocompetent 43 year old woman. Microscopic examination of the biopsy initially revealed acute inflammatory changes and intra- and extracellular gram-positive bacteria without abscess. Within 2 weeks of inadequate antibiotic therapy, abscesses formed from which 10 mL of purulent material was drained. Despite doxycycline treatment and repeated drainage, the abscesses recurred, which appears to be consistent with other reported cases of *Gordonia* abscesses.[205] *G. terrae* has been documented as a cause of granulomatous mastitis following nipple piercing. *G. bronchialis* and *G. terrae* are indistinguishable with phenotypic identification methods, but can be differentiated by use of sequencing.[86,223] A more recently described species, *G. araii*, has been associated with infection of medical devices, which may suggest that like *R. equi*, *Gordonia* can produce a biofilm that leads to its pathogenicity in the appropriate patient and setting.[84] Box 15-3 addresses treatment options.

Tsukamurella *spp.*

Taxonomy and Classification. *Tsukamurella* are another group of aerobic actinomycetes that are being identified more often in clinical laboratories especially with newer molecular tools or mass spectrometry. These were originally named for the Japanese microbiologist Tsukamura to describe a group of actinomycetes that contained long-chain and unsaturated mycolic acids (68 to 70 carbons). Initially the organism was isolated from sputum of a patient with tuberculosis-like pulmonary disease in 1971, and was called *Gordona aurantiaca.* This same organism was later called *Rhodococcus aurantiacus*, but after 16S rDNA sequencing was employed in 1988, it was found to be homologous with an organism referred to as *C. paurometabola* and the two were combined into a new name, *Tsukamurella paurometabola,* which is now the type species of the genus.[169] Other species that have been associated with clinical disease include *T. inchonensis, T. pulmonis, T. tyrosinosolvens* and a recently described species, *T. strandjordae*.[95,216,218]

Tsukamurella are slightly acid-fast when a partial stain is applied; aerial hyphae are usually not found; rod and coccal forms, as is seen with *R. equi,* may occur with *Tsukamurella*. The bacilli of *Tsukamurella* spp. tend to be longer than most other actinomycetes.[95]

Epidemiology and Clinical Disease. Infections have been reported rarely as opportunistic disease in patients who are immunocompromised or have foreign bodies. Like *Gordonia* spp., *Tsukamurella* spp. are most often associated with catheter-related bacteremia and osteomyelitis.[17,108,169,171,173] *Tsukamurella* has been demonstrated as a cause of keratitis in a patient following corneal grafts; this mimicked infection with rapidly growing mycobacterial species and was reported by Tam et al.[184] in 2010. These authors (and others) reminded readers that correct identification of organisms in keratitis is essential to appropriate therapy.[178,184] In a review of infections caused by *Tsukamurella* spp. from 1997 to 2008, eight infections and two instances of colonization were found, all of which had been incorrectly identified as being caused by *Rhodococcus* spp. until sequencing corrected the identifications. *T. tyrosinosolvens* was the most frequent species and keratitis, followed by bacteremia, were the most common infections produced.[114] Box 15-3 addresses treatment options.

A pseudo-outbreak of *Tsukamurella* was described in Hong Kong in 2013 wherein the organism was found at the same time in four patients; it was concluded that this was the result of laboratory contamination of scissors that were used for tissue processing.[186] A combination of 16S rDNA sequencing, pulsed-field gel electrophoresis, phenotypic and metabolic tests were used to prove that all isolates were identical. When a cluster of infrequently isolated bacteria occur within a short period of time in a laboratory, then an investigation of the possibility of an outbreak or

pseudo-outbreak should be considered and investigated.

Dietzia *spp.*

Dietzia spp. are aerobic actinomycetes and like the others described above are gram-positive rods. These are usually shorter than those of *Tsukamurella*, usually non–acid-fast positive and possess short-chain mycolic acids (34 to 38 carbons); they do not grow in lysozyme. *Dietzia* are normally present in the canine intestinal tract and oral cavity as well as in environmental sources like soil and plants. Colonies may be butyrous and orange pigmented. The name *Dietzia* was given to these organism in honor of Alma Dietz, an American microbiologist.[154]The type species, *D. maris* (formerly *Rhodococcus maris*), has been isolated from the bloodstream of an immunosuppressed patient who had an indwelling intravascular catheter,[14]a pacemaker pocket infection,[146] a hip prosthesis infection,[150] papillomatosis skin lesions in an immunocompetent individual,[87] and a dog bite wound.[81] A new species of *Dietzia*, *D. aurantiaca*, was recently proposed for an isolate from CSF of a young woman.[93] In the past, most *Dietzia* spp. were probably misidentified as a member of the *Rhodococcus* genus; with molecular methods, recognition of this genus has increased.[100,141,151]

Other Nocardioform Bacteria

Segniliparus spp. are aerobic actinomycetes that are rod-shaped without branching or aerial hyphae; they are strongly partially acid-fast positive and contain very long-chain mycolic acids (70 to 90 carbon atoms). The first isolations of *S. rugosus* from cystic fibrosis patients were published in 2007.[24] In 2001, pneumonia due to *S. rotundus* was reported in a patient with bronchiectasis not associated with cystic fibrosis. Treatment with clarithromycin and ciprofloxacin was successful in eliminating the organism and resolving the clinical symptoms.[102]

Williamsia spp. are aerobic actinomycetes that appear as short, gram-positive rods to coccobacilli that are not acid-fast. These do not produce aerial hyphae and do not grow in lysozyme. Their cell walls contain mycolic acids with from 50 to 56 carbon atoms. *W. muralis* is the species most often

described from environmental sources, including surfaces in a day care centers.[92] These aerobic actinomycetes were assumed to be nonpathogens until recently.*W.*

muralis was isolated from a protected bronchial brush specimen of an 80-year-old woman with pneumonia from which she died and no other significant pathogens were recovered.[44]With the increased use of molecular techniques and mass spectrometry, laboratories may recognize more isolates of *W. muralis*.

The *Streptosporangineae*

Actinomadura *spp.*

Taxonomy and Classification. The genus *Actinomadura* is genetically diverse, and is separated into two suprageneric groups.[72,125] Once again, the terminology is confusing and in transition. Goodfellow suggests that *Actinomadura* spp. should be reserved for *A. madurae* and related species (including *A. pelletieri*), which are genetically most closely related to the *Thermomonospora* group.[73] In contrast, "maduromycetes" is reserved for a natural group of bacteria that includes *A. pusilla* and related organisms.[73] From a practical standpoint, the major human pathogens, *A. madurae* and *A. pelletieri* are categorized with the former group. Members of the genus *Actinomadura* contain *meso*-DAP in their cell walls like the aerobic actinomycetes described thus far; however, madurose is the major carbohydrate component and they do not possess mycolic acids in their cell wall.[41,73] A more recently described species in the genus, *A. sputii* sp. nov., has been isolated from the sputum of a 64-year-old man.[220] *Actinomadura* spp. are not acid-fast positive, but may produce short branching filaments. Growth in lysozyme is variable.

Epidemiology, Clinical Disease, and Pathology. *Actinomadura* spp. are soil organisms that are introduced through the skin by trauma. The infections are found primarily in tropical and subtropical countries, which may, in part, reflect the greater propensity for people who live in warmer climates to spend majority of time outdoors and walk barefoot.[125]

Mycetomas are chronic, penetrating, progressively destructive lesions that destroy skin, subcutaneous tissue, and underlying structures, such as bone, muscle, and fascia. Not surprisingly for infections caused by soil organisms, they tend to occur on the extremities, with the foot being a particularly common site. The chronic, granulomatous inflammation often results in multiple draining sinuses, from which granules (or grains) are extruded. These granules, which usually measure less than 1 mm in diameter, represent colonies of the infectious agent. The granules vary in color depending on the nature of the infecting agent—for example, white grain mycetoma. Microscopically, granules consist of masses of filamentous bacteria or fungal hyphae embedded in a cement-like matrix, which imparts the color that is seen

macroscopically. An immunologic reaction of deposited proteins and immunoglobulins surrounding the organism, known as the Splendore–Hoeppli phenomenon, may be present histopathologically. Fibrosis is often the end result of mycetoma, although not to the extent seen in actinomycosis caused by *Actinomyces israelii*. Bone is commonly involved in *Actinomadura* mycetoma infections.

Mycetomas are caused by true fungi (eumycotic mycetoma) or by aerobic actinomycetes (actinomycotic mycetoma). Colloquially, actinomycotic mycetoma is sometimes called "Madura foot." The most common etiologic agents and their associated characteristics are summarized in Table 15-4. In a study of 366 isolates of aerobic actinomycetes from mycetomas submitted to the Centers for Disease Control and Prevention (CDC) in the late 1980s, *A. madurae* was second in incidence only to *N. asteroides* (11.5% vs. 26%).[127] Most infections occur in tropical countries, particularly in India and Tunisia (*A. madurae*) or in Senegal, Chad, and Somalia (*A. pelletieri*). As noted above, *Nocardia asteroides* causes infections worldwide, whereas *N. brasiliensis* is limited to the southern United States and Central and South America. An uncommon nocardial species, *N. harenae*, was reported as a cause of mycetoma in two patients from Mexico in 2012. Before the isolate was sequenced, it was assumed to be *N. brasiliensis*, but the isolate was susceptible to imipenem and treatment was successful after a combination of amikacin and imipenem was used followed by SXT, minocycline, and dapsone for 2 years.[104]

The vast majority of *A. madurae* infections are superficial, and can be found on any part of the host, depending on where the organisms have entered the host, most commonly the foot,[185] but mycetomas have occurred on the tongue,[133] on the neck, back, and chest of two family members in West Bengal[119] and perianally in another reported patient.[30] An unusual scenario involved a man who had experienced "Madura foot" 10 years prior to its appearance on his spine, abdominal wall, and retroperitoneal space.[27] Systemic infections have been reported in patients with compromised host defenses. *A. madurae* peritonitis has been reported in a patient undergoing continuous peritoneal dialysis.[212] Disseminated *A. madurae* infection has occurred in a patient with AIDS who was also a habitual user of heroin.[128] The diagnosis of mycetoma may be challenging at times because of the difficulty to grow the organism involved; discussion of these challenges can be found in the article by Liu et al.[115] in 2008. Box 15-3 addresses treatment options.

Nocardiopsis *spp.*

Nocardiopsis dassonvillei, the most important species in the genus, forms zigzag chains of spores within a sheath-like structure and has a type III cell wall (*meso*-DAP) with no diagnostic sugars present. The members of the genus *Nocardiopsis* were

removed from the genus *Actinomadura* to accommodate related organisms that lack the unique cell wall carbohydrate madurose. These organisms lack mycolic acids in their cell wall, are non–acid-fast but can produce aerial hyphae. They do not grow in lysozyme.[41] *N. dassonvillei*, ordinarily a soil saprophyte, has been recovered from animals and rarely from human infections. When it has been recovered, the infection has been primarily a mycetoma.[70] Nasal vestibulitis due to *N. dassonvillei* was described recently in an adult diabetic patient.[164] In 1997, Yassin and colleagues reported the isolation of a new species, *N. synnemataformans* from the sputum of a renal transplant recipient[216]; the role of this new species in human disease is unclear.

972

The Streptomycetes

Streptomyces *spp.*

Streptomyces spp. are soil organisms that have considerable importance in the industrial and pharmaceutical fields and are responsible for production of two-thirds of the world's naturally occurring antibiotics, including streptomycin. Clinically, *Streptomyces* species, of which there are over 500, are chiefly responsible for actinomycotic mycetoma. In a study of 366 aerobic actinomyces isolates from clinical mycetomas submitted for study at the CDC in the late 1980s, only *N. asteroides* and *A. madurae* were recovered more frequently than *Streptomyces* species.[127] *S. somaliensis*, which can cause actinomycotic mycetoma, has essentially a worldwide distribution, having been recovered from patients with mycetoma in Saudi Arabia, Nigeria, Niger, Sudan, Somalia, South Africa, Venezuela, India, and Mexico.[125] A high proportion of these infections involved the head and neck, producing what is known as "Madura skull." One woman with actinomycotic scalp abscesses due to *Streptomyces* spp. also had blood cultures positive for the same *Streptomyces* spp. for which she was successfully treated with SXT and penicillin.[88] Grains from streptomycete mycetomas are large (2 to 4 mm) and yellow-brown. *Streptomyces anulatus,* also referred to as *S. griseus*, is an organism that causes subcutaneous mycetomas in felines and dolphin, also has been recovered from human mycetomas.[29]

Streptomyces spp. are most often saprophytes, and when isolated in clinical laboratories, they are usually considered as contaminants in clinical specimens. However, a number of nonactinomycotic human infections have been described especially in immunocompromised individuals.[94] Invasive pulmonary disease has been described in HIV patients, in a splenectomized patient with sarcoidosis and in

otherwise immunocompetent hosts.[48,101,160]This organism was found to cause peritonitis, probably contracted from multiple paracenteses, in a chronic alcoholic patient who presented with fever and abdominal pain; no other pathogens were found to explain his symptoms.[43] A brain abscess was found due to *Streptomyces* sp. in a patient who experienced penetrating cerebral trauma with an object heavily contaminated with soil.[162] Rare instances of bacteremia, with and without the presence of an indwelling catheter, have been reported due to *Streptomyces* spp.[25,54,65,134] In one of these patients, the use of a holistic preparation as treatment for breast cancer was implicated as the source of the infection; although the catheter tip was negative for the organism, no other pathogens were isolated and the patient's systemic symptoms disappeared with treatment for the *Streptomyces* sp.[25] A Saudi Arabian patient was reported with endocarditis that followed a Carpentier–Edwards valve replacement for aortic stenosis. Multiple blood cultures were positive for *Streptomyces* and treatment was successful with a combination of antibiotics directed to the isolate in conjunction with valve replacement.[135]Repeated isolation of any aerobic actinomycetes from sterile specimens such as blood cultures needs to be further investigated before being considered as merely a contaminant or saprophyte. Box 15-3 addresses treatment options. With the increased use of molecular techniques and mass spectrometry for microbial identification, and with increasing immunocompromised patient populations, more of these infections may be recognized and reported correctly.[94,122]

Thermophilic Actinomycetes

Thermophilic actinomycetes cause human disease, but they are rarely encountered in the clinical microbiology laboratory. They are more commonly a cause of allergic reactions rather than productive infections. In 1963, Pepys and colleagues defined the antigen present in moldy hay as *Saccharopolyspora rectivirgula*.[145] Subsequently, *Thermoactinomyces vulgaris* was recognized as an additional allergen. The clinical disease, farmer's lung, is an example of hypersensitivity pneumonitis or extrinsic allergic pneumonitis caused by these organisms. The illness can be chronic and disabling, with deterioration of lung function until the offending antigen is removed or avoided. Other similar situations occur after exposure to moldy compost, sugar cane (bagassosis), air conditioners or ventilation ducts. There are a few recent review articles describing the presentation, epidemiology and pathology of hypersensitivity pneumonitis.[76,80,106] Various members of the *Saccharopolyspora*,*Micropolyspora* (*Faenia*) and *Thermoactinomyces* genera are responsible. The taxonomy of these organisms has undergone multiple changes over the years. The use of molecular

techniques for identification may enable more of these isolates to be recognized and classified to further assist in proper diagnosis and treatment.[213]

Miscellaneous Actinomycetes

Dermatophilus

Dermatophilus congolensis is an interesting actinomycete that causes a pustular, exudative dermatitis known as dermatophilosis. This disease is also known as foot rot, pitted keratolysis, or streptotrichosis in many species of animals, including cattle, sheep, horses, goats, deer, swine, squirrels, and domestic cats. A similar presentation has been found in human infections, however, it infrequently produces disease in humans.[67] *D. congolensis* has been associated with hairy leukoplakia on the tongue.[22] The exact mode of transmission is unknown, although most infections occur following direct contact with infected materials, and possibly from the bites of ectoparasites and flying insects. Occupations and avocations that appear at particular risk are primarily those that involve extensive contact with animals, such as veterinarians, abattoir workers and hunters.[5,41] Recently, a 15-year-old girl returning from horseback riding camp developed pustular dermatitis which was due to *Dermatophilus*.[23] Pathologists may encounter these organisms within hair follicles or keratin layers of the soles of the feet in the forms of masses of non–acid-fast, branching, filaments.

Tropheryma whipplei

History and Taxonomy. This bacterium is the latest addition to the aerobic actinomycetes, but the associated disease, intestinal lipodystrophy (Whipple's disease), was first described in 1907 by George Whipple. The bacteria had been identified in affected tissues by light and electron microscopy, but the nature of the etiologic agent remained a mystery until 1991, when Wilson and colleagues used

nucleic acid amplification and sequencing of 16S rDNA in a duodenal biopsy from a patient with Whipple's disease to delineate the nature of the etiologic agent.[123] The morphologic appearance of the bacteria in tissue was not considered typical for either gram-positive or gram-negative bacilli, perhaps because of the intracellular location of the organisms.[123] By molecular analysis, however, the organism aligns best with the gram-positive family. It is most closely related to *Rothia*,[123] *Rhodococcus*, *Arthrobacter,* and *Streptomyces*, and less closely related to the mycobacteria.[208] Less

than a decade later the bacterium was cultivated in human fibroblasts[158] and named *Tropheryma whipplei* (an emended designation from the original *T. whippelii*).[109] The genome of *T. whipplei* has now been sequenced completely, providing useful insights into its nature.[15] It has a surprisingly small genome, demonstrating characteristics of other intracellular bacteria that require external amino acids and are deficient in energy metabolism. The amount of genetic material devoted to coding surface structures is, nonetheless, relatively large, suggesting that interactions between the external aspect of the bacteria and the host are critical to its survival. Finally, there is considerable genetic variability, including phase variation, which may be advantageous for adapting to changing intracellular environments.[15]

Ecology. The ecologic niche of *T. whipplei* remains unknown. It has been detected in human feces and in sewage. It is unclear whether human excrement is a source of infection for humans or these findings simply are the result of excretion by infected individuals.[123] This organism has been detected in human saliva[182] and gastric secretions[52] by nucleic acid amplification methods. It has been detected in duodenal biopsy specimens from patients who do not have Whipple's disease,[52] although other investigators have found *Tropheryma* DNA only rarely in the absence of clinical evidence of the disease.[50,98,120] It is possible, therefore, that humans are reservoirs for the bacteria, but much remains to be determined. Potential problems with the specificity of amplification procedures and the presence of extraintestinal Whipple's disease without overt involvement of the bowel[77] complicate the analysis.

Clinical Disease and Pathology. Whipple's disease is a rare, chronic, multisystem disease.[49,123] The classical triad of infection consists of diarrhea, weight loss, and malabsorption, which reflects the frequency with which the gastrointestinal tract is affected. Other organ systems are also involved, particularly joints and the central nervous system (Box 15-4). The heart may also be affected, as *T. whipplei* is a documented cause of culture-negative bacterial endocarditis.[58,77]

The pathogenesis of Whipple's disease is poorly understood. It is likely that defects in cellular immunity and/or macrophage function are important, but they appear to be specific to this agent, as patients are not usually infected with other opportunistic pathogens. *T. whipplei* is a facultative intracellular pathogen. As is true for such bacteria, the pathologic hallmark of infection is the macrophage. Foamy macrophages, which contain numerous bacteria within vacuoles, were responsible for the yellow lacteals that George Whipple observed in the small bowel. The bacteria in these cells can be stained by the PAS method, but this technique is not specific. Other bacteria, particularly *Mycobacterium avium* complex, are PAS-positive and occur within macrophages, particularly in patients with advanced HIV infection. *Tropheryma* and

M. avium may be differentiated with an acid-fast stain, as *Tropheryma* is not acid-fast. *Rhodococcus equi*, present in macrophages, may also be considered in the differential diagnosis usually outside of the intestinal tract. Ultimately, immunologic staining of tissues, culture, or nucleic acid amplification is required for diagnostic resolution. A recent review of Whipple's disease by Mendolara et al.[4] includes an unusual scenario wherein a young girl was recognized during emergency surgery for gastrointestinal obstruction and perforation. In extraintestinal tissues, noncaseating, sarcoid-like granulomas may be observed.[123] There appears to be an increase in the reports of patients with cardiac infection with *T. whipplei* without any evidence of gastrointestinal involvement.[117,206] With the use of molecular techniques, including quantitative PCR applied to gastrointestinal tissue biopsies to delineate the degree of otherwise undiagnosed disease and also as a result of the many microbiome projects, the scope of Whipple's disease and infection with *T. whipplei* may increase and be more fully understood.[50,118]

BOX 15-4

Extraintestinal Sites of Whipple's Disease: An Analysis of 52 Cases[a]

Extraintestinal Site	No. (%) of Cases
Joints	43 (83)
Nervous system	11 (21)
Skin and mucous membranes	9 (17)
Heart and blood vessels	9 (17)
Lung and pleura	7 (13)
Eye	5 (10)

[a] Multiple sites affected in some patients.

Laboratory Diagnosis of Infections Caused by Aerobic Actinomycetes

Primary Isolation

N. asteroides and other aerobic actinomycetes are aerobic organisms that grow on a variety of bacteriologic media, including sheep's blood agar, brain–heart infusion agar, or SAB without antibiotics. They can be inhibited, however, by chloramphenicol, penicillin and streptomycin present in selective media. They also grow on media designed for the recovery of mycobacteria. *N. asteroides* grows well at 25°C, 35°C to 37°C, and at 42°C to 45°C. Incubation at the higher temperature permits growth of *N. asteroides* complex, whereas many other bacteria will be inhibited. Growth may take from 2 days to 4 weeks of incubation. However, in many instances of true infection, *Nocardia* can be isolated in ≤5 days. Growth is enhanced by incubation in 10% CO_2. *Nocardia* species can

be recovered from contaminated specimens using modified Thayer–Martin (MTM) medium.[139] Shawar and associates took advantage of the peculiar ability of these bacteria to grow with paraffin as a sole source of carbon to develop a selective, chemically defined medium that contained paraffin on a coated glass rod placed into a carbon-free broth.[172] If *Nocardia* is present in this system, then growth appears on the rod just above the surface of the broth. Similarly, Ayyar and colleagues found paraffin agar an inexpensive selective medium for *Nocardia* spp., being superior to either MTM or the paraffin bait technique of Shawar.[9]

Selective buffered charcoal-yeast extract agar (BCYE), commonly used for the recovery of *Legionella* spp. from respiratory specimens, also facilitates the recovery of *Nocardia* spp. from sputum and other specimens that may be contaminated with mixed bacteria.[63,97] The use of selective BCYE agar, to which polymyxin B, anisomycin, and vancomycin have been added, and pretreatment of the specimen by an acid wash (Chart 10-1) improved recovery of *Nocardia* spp. from 8% to 33% for the former and to 67% for the latter.[97]

N. asteroides may survive the usual *N*-acetyl-L-cysteine digestion procedure (without NaOH) that is used for recovery of mycobacteria from sputum or bronchial washings.[138] It has been recommended that cultures of sputum and bronchoalveolavage specimens submitted for *Nocardia* culture be done both before and after the digestion procedure, although this approach doubles the work.

Colonies on LJ media often develop within 1 to 2 weeks. They may be similar in appearance to atypical mycobacteria (see Chapter 19). *Mycobacterium* spp., however, do not produce aerial hyphae, are fully acid-fast, and differ biochemically from nocardiae. The branched filaments of *Nocardia* that may not always be seen in smears prepared from growth on solid media can sometimes be demonstrated from growth in

broth cultures, whereas mycobacteria do not usually branch, although some rods may be elongated.

Differentiation of Nocardia *From Other Genera of Aerobic Actinomycetes*

Infections of humans with the genera *Streptomyces*, *Nocardiopsis*, *Rhodococcus*, *Actinomadura*,*Gordonia*, *Tsukamurella,* and *Dermatophilus* are far less common than infections caused by *Nocardia* spp. Some characteristics that may aid in differentiating among and within genera of aerobic actinomycetes and other related bacteria are given in Table 15-4. The presence of *Nocardia* and *Streptomyces* spp. can be suspected on the basis of a few simple characteristics. The typical colonies of *Nocardia* and *Streptomyces* spp. are dry to chalky in consistency, and usually heaped or folded. *Nocardia* spp. are commonly some shade of yellow or light orange, whereas *Streptomyces* spp. are most frequently gray-white. (Image Plate 15-1A) Both groups produce colonies with a pungent musty basement odor. The colonies of *Rhodococcus equi* lack the musty odor and often have a pink or salmon color on agar media (Image Plate 15-1B). *Gordonia* spp. produce rough and wrinkled colonies with some pigment, whereas *Tsukamurella* often produces smaller colonies that are dry, wrinkled, and without pigment.

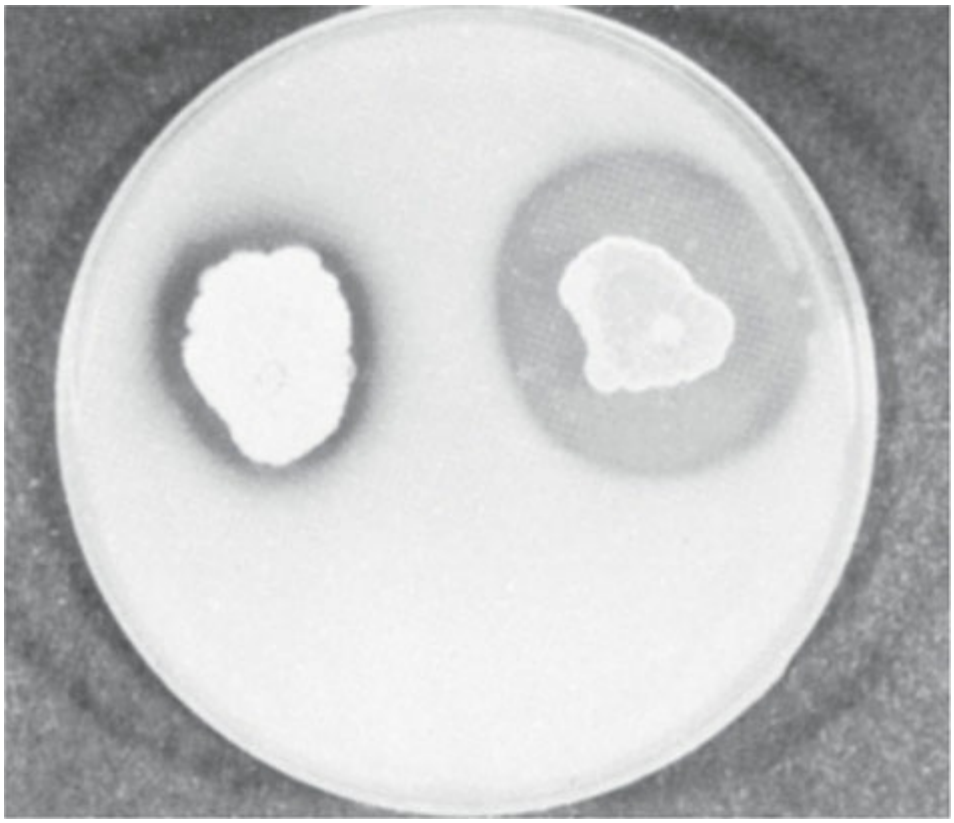
Typically, Gram's stain of material from a colony of *Nocardia* or *Streptomyces* will show delicate, branching filaments no more than 1 μm in diameter (Image Plate 15-1C). *Nocardia* spp. are partially acid-fast (i.e., they do not decolorize when treated with 1% H_2SO_4, but will decolorize when the more active HCl decolorizer used in the Ziehl–Neelsen or Kinyoun stains is applied) (Box 15-2). *Streptomyces* spp., in contrast, are not partially acid-fast. The acid-fastness property of *Nocardia* may be enhanced by growing the organism on certain media, such as Middlebrook 7H11 agar or casein agar (see discussion of identification techniques below). If the unknown organism is not acid-fast, a report of "non–acid-fast aerobic actinomycete" can be made, but such a report should be delayed until adequate attempts to improve the acid-fastness have been made.

Rhodococcus equi do not form the long filaments seen in isolates of *Nocardia* and *Streptomyces*. They are gram-positive coccobacilli that may cluster like Chinese characters, reflecting their former taxonomic home in the genus *Corynebacterium* (Image Plate 15-1D). Isolates can be partially acid-fast, but this depends on the media and age of the colony (Image Plate 15-1E). If *R. equi* is grown in broth cultures, the coccoid appearance of the bacteria may be more apparent.

Growth in the presence of lysozyme is useful for identifying *Nocardia* spp. (Table 15-4; Chart 15-2), particularly for those strains that are weakly acid-fast. All *Nocardia* species are resistant to lysozyme and will grow in the presence of lysozyme within 5 to 10 days. A control tube of glycerol broth without lysozyme should always be

simultaneously inoculated and included in addition to positive and negative controls. For specific directions about preparation of lysozyme and how to perform the test, refer to the Manual of Clinical Microbiology, 2011.[8]

The differential ability of the various nocardiae and related aerobic actinomyces to hydrolyze casein, tyrosine, xanthine, and hypoxanthine is one of the mainstays of conventional phenotypic identification protocols in clinical laboratories. The procedure is described in Chart 15-1. The differential plates are inoculated with the unknown organism and incubated for up to 3 weeks at 30°C and observed for hydrolysis. This appears as clearing of the medium around the colonies. An example of casein hydrolysis by a colony of *Streptomyces* spp. is shown in Figure 15-4. Differentiation of certain species cannot be accomplished solely with the analysis of



■ **FIGURE 15-4** Casein agar plate illustrating the hydrolytic action of two species of *Streptomyces*.

975

hydrolysis. Characterization of the ability to decompose carbohydrates or use them as a sole carbon source may be necessary.[132]Differentiation of some members of the

Nocardia complex is facilitated by analysis of the temperature of growth,[12] by the ability to opacify Middlebrook 7H10 or 7H11 media (Table 15-5),[26,61,99] and by the antimicrobial susceptibility profile (Table 15-6).[33]

Molecular tools for specific identification of the aerobic gram-positive rods, including the aerobic actinomycetes, are becoming more widely available as is the use of mass spectromety.[20,143,193,194] Mishra and colleagues have devised a key for more detailed differentiation of the nocardiae and the streptomycetes than has been modified and presented in Table 15-5.[132] The use of carbohydrate utilization in test

tubes or with a kit system has been assessed for the identification of species of *Nocardia,* but as more and more species of *Nocardia* are identified, it will be more difficult to identify *Nocardia* to the species level with phenotypic means alone.

Thin-layer chromatography has been helpful alone or in conjunction with phenotypic or molecular methods for identification. Differences in the cell wall composition are used in some research laboratories or reference laboratories for taxonomic purposes. The primary constituents of the cell walls are summarized in Table 15-2 (Fig. 15-1). Most of the nocardioform organisms, including *Nocardia* and *Rhodococcus*, have a type IV cell wall composition (i.e., the significant constituents are *meso*-DAP, arabinose, and galactose, with mycolic acids present). *Streptomyces* species have type I cell walls (i.e., no L-DAP and no diagnostic carbohydrates). Other chemotaxonomic tests, in addition to determining cell wall type, include analyses of menaquinones, long-chain fatty acids, phospholipids, and mycolic acids. These studies are not practical, nor are they necessary for differentiation of most isolates of *Nocardia* and *Rhodococcus* in the clinical microbiology laboratory. If definitive identification is necessary, microbiologists may wish to refer isolates to a reference laboratory.

Nucleic acid amplification techniques and DNA sequencing are useful both for direct detection of aerobic actinomycetes in clinical specimens and for identification of isolated bacteria.[13,42,100,107,111,143,163,181,201–203] Cloud and colleagues have suggested that sequencing of 16S rDNA is more accurate than a combination of conventional biochemical tests and antimicrobial susceptibility profiles for identification of *Nocardia*

spp.[35] Patel et al. used partial 16S rDNA gene sequencing as compared to biochemicals, fatty acid analysis, drug susceptibility testing, and PCR-restriction analysis of the 65 *hsp* gene for the identification of 74 *Nocardia* isolates; some species could not be entirely differentiated and hence the introduction of the "complex" identification that many laboratories used.[143] Partial rRNA sequencing was used to successfully identify *R. equi*, to distinguish among species of *Gordonia* and *Streptomyces* and identify *Actinomadura* to the genus level. Some difficulty was found with *Tsukamurella* strains.[143] Molecular methods have been used to identify *Gordonia,*[16] *Dietzia,*[150,151] *Tsukamurella,*[173,186] and *Nocardiopsis dansonvillei*.[13] As with any molecular sequencing methods, the validity of the database used is essential to obtaining the most appropriate identifications.[40,130]

All clinical microbiologists are becoming very familiar with the use of matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry for the identification of aerobic and anaerobic bacteria; so it is not surprising that identification of aerobic actinomycetes would also benefit from use of this new technique. Farfour et al. used Bruker MS with Andromas software to identify 659 aerobic gram-positive bacilli. Over 98% of the strains, which included 46 *Nocardia* spp. and two *R. equi,* were identified correctly to the species level.[57] Verroken et al. demonstrated that MALDI-TOF could be used successfully to identify *Nocardia* sp. in <1 hour with an inexpensive method[193]; Vila et al. reported the use of MALDI-TOF for identification of *R. equi* as well as relevant *Corynebacterium* spp. and *Arcanobacterium hemolyticum*.[194]

It is important that clinical microbiologists keep abreast of these advanced methods of identification, since they will provide often species-level identification of difficult-to-identify microorganisms. The appropriate identification, in turn, affords more targeted decision-making by clinicians, which

should translate into and the prompt administration of appropriate therapeutics. It will be increasingly difficult if not impossible for laboratories to rely on phenotypic methods alone for the identification of the ever-increasing aerobic actinomycetes.

Identification of Thermophilic Actinomycetes

The thermophilic actinomycetes are rarely encountered in the clinical laboratory because they are environmental organisms that produce disease in humans by an allergic reaction, rather than productive infection.[145] Their ability to grow at elevated temperatures provides a useful means by which to evaluate their presence in

environmental specimens, if desired. Protocols for identification of these bacteria have been suggested.[82,105] As mentioned above, use of 16S rRNA sequencing and other molecular techniques for identification of these unusual organisms will increase in the future.[140,213]

Identification of Tropheryma whipplei

This actinomycete can be cultured, but only with difficulty.[159] In most instances, the diagnosis will be made by clinical and histologic criteria, and through the use of molecular methods. Immunohistochemical identification of the organism in sectioned tissue has been demonstrated.[10,112,159] Alternatively, the organism can be recognized by nucleic acid amplification techniques.[157] Although experience is limited, it has been suggested that molecular methods may be more useful than histology for monitoring the course of patients with Whipple's disease.[157] Although PCR-based methods are important diagnostic tools, it is important to recognize that *T. whipplei* DNA can be detected in the absence of overt clinical disease.[52,182] The significance of these results is unclear, but the diagnosis of Whipple's disease should not be based solely on molecular detection of bacterial DNA. The results of molecular studies should be correlated with clinical and, if available, histopathologic findings. These techniques are currently used primarily in research or large reference laboratories; microbiologists must remain alert to the future availability of commercial products.

In Vitro Susceptibility of Nocardia *and Related Bacteria to Antimicrobial Agents and Therapy for Infections*

The antimicrobial susceptibility patterns of aerobic actinomycetes are useful for taxonomists, clinical microbiologists (as a clue to the identification of an isolate), and clinicians for treatment of infected patients. The pattern of susceptibility for various *Nocardia* species is summarized in Table 15-6. Standardization of susceptibility testing for clinical use has been published by the Clinical and Laboratory Standards Institute (CLSI) and includes methods for performing the susceptibility test via a broth microdilution and breakpoints for interpretation of the results.[33] These are the guidelines recommended for use.

If the results of sulfonamide testing are difficult to interpret in broth microdilution and a disk diffusion test, then an Etest is recommended. The inocula for performing a susceptibility test with the aerobic actinomycetes should be prepared from a blood agar or trypticase soy agar plate that contains sufficient growth. The final organism concentration should approximate 1.0×10^4 to 5.0×10^4 colony-forming units (CFU)/well. For many of the *Nocardia* spp., which tend to clump, care must be taken to emulsify the inoculum as well as possible. The broth microdilution panels should be

incubated in ambient air at 35°C ± 2°C for 3 days; some species such as *N. nova* may require up to 5 days. However, *R. equi* and some *Tsukamurella* spp. can be read within 24 to 48 hours. Examples of interpretation of the wells of the microtiter plates are given in the CLSI document and should be referred to frequently, especially when first beginning to perform susceptibility testing for the aerobic actinomycetes. Table 9 in the CLSI document provides breakpoints for *Nocardia* spp. For *R. equi* it is recommended that breakpoints for *S. aureus* should be used but should be considered tentative until more data is generated. The footnote in Table 9 of the CLSI M24-A2 document states that the breakpoints provided are to be reported as "tentative" for other aerobic actinomycetes pending accumulation of further information in the future.[33]

A multisite study demonstrating the reproducibility of the CLSI broth microdilution method for susceptibility testing of *Nocardia* sp. was published in 2012. In addition, it provided isolates that could be used as reference isolates for laboratories to use in order to successfully perform the test.[37] For laboratories that perform these tests rarely, it is judicious to send isolates to a reference laboratory that has considerable experience with aerobic actinomycetes, however it behooves all laboratorians to understand the methods and how to interpret the results.

Many β-lactamases have been characterized in various *Nocardia* spp. and these are mainly penicillinases with less activity against cephalosporins.[200] Clavulanic acid can inhibit many of the β-lactamase enzymes and combination of β-lactam antibiotics plus β-lactamase inhibitors do demonstrate activity against some *Nocardia* spp. The enzymes found in *N. farcinica* are distinct from those found in other species of *Nocardia* and are homogeneous as compared to the diversity of β-lactamases found in *N. brasiliensis*.[180,197] The drugs of choice for treatment of nocardiosis, even in immunosuppressed patients, remains the sulfonamides (e.g., sulfadiazine, sulfisoxazole, and triple-sulfonamide combinations). The combination of SXT is preferred by most clinicians,[19,198] but the question of whether the combination is more effective than a sulfa drug alone remains open.[198] In vitro studies may be needed to aid in the selection of antimicrobial agents for patients who are allergic to sulfonamides or who are infected with *N. otitidiscaviarum* and some species of the *Nocardia* complex that demonstrate inconsistent susceptibility to sulfonamides. Imipenem, minocycline, amikacin and linezolid are potential choices, based on in vitro studies and some clinical trials along with clinical experiences in the literature.[136]

Alternatively, desensitization to sulfonamides may be considered. There has been a recent report from the CDC[189] that data from 10 years of testing demonstrated as much as 61% sulfamethoxazole resistance among strains of *Nocardia* spp.; however, a subsequent article by Brown–Elliott et al. suggested that those results could be due to a misinterpretation

of in vitro testing results, since their review of testing by six large laboratories in the United States demonstrated only a 2% resistance. Inclusion of quality control strains to assist in correct reading of microtiter trays will be very useful.[18] Resistance to amikacin was recently described in a new species of *Nocardia*, *N. amikacinitolerans*.[56] Resistance to imipenem is common among strains of *N. brasiliensis*.

For mycetomas, a combination of surgical and pharmacologic approaches, often empirical, is indicated. To prevent antibiotic resistance and cover all clinical isolates of *Nocardia* spp., a combination of SXT, amikacin, and ceftriaxone or imipenem is preferred for patients with local or disseminated disease.[19] A recent article tested strains of *Streptomyces* from patients with a mycetoma and found that all were resistant to sulfamethoxazole, but were susceptible to novobiocin, doxycycline, and gentamicin.[79] Other articles have suggested use of oxalidinones such as linezolid based on in vitro data.[162]

Rhodococcus equi is susceptible to vancomycin, which is considered by some to be the therapy of choice; most isolates are susceptible to erythromycin, aminoglycosides, rifampin, and imipenem; there are data available about the successful use of linezolid in management of *R. equi* infections.[3,116,214] Experience with treatment is limited. However, recent review articles suggest that a combination of surgical debridement and antibiotics is appropriate. In vitro synergy testing was reported recently with many drug combinations including macrolides and rifampin; no clinical relevance was made to correlate with in vivo results, however.[66]There are no treatment recommendations for *Gordonia* infections. CLSI does recommend that breakpoints for *Nocardia* can be used for other aerobic actinomycetes such as *Gordonia* and recommends that testing for the latter should include amikacin, amoxicillin clavulanic, ceftriaxone, ciprofloxacin, clarithromycin, imipenem, linezolid, minocycline, SXT, and tobramycin.[33,211] In a recent article from China, three species of *Tsukamurella*, responsible for eight infections, had different drug susceptibility patterns; *T. pulmonis* was the most resistant pathogen, with higher minimum inhibitory concentrations of clindamycin (>2 mg/L), erythromycin (2 mg/L), and tetracycline (8 mg/L) than those for *T. tyrosinolvens* or *T. spumae*.[114] The in vitro susceptibility of 24 strains of *Actinomadura madurae* to a new oxazolidinone (DA-7867), gatifloxacin, moxifloxacin, and garenoxacin by using a broth microdilution method was determined; the most active was DA-7867.[191] An article about a rare instance of brain abscess caused by *Streptomyces* sp. includes information from the CDC on successful use of linezolid and amikacin based on in vitro susceptibility data.[162] A review article of invasive

*Streptomyces i*nfections found that isolates were consistently susceptible to amikacin; frequently susceptible to imipenem, clarithromycin or erythromycin, minocycline, and SXT; and infrequently susceptible to ciprofloxacin and ampicillin.[94] Less information is available for treatment and susceptibility testing of other aerobic actinomycetes.

The recommended therapy for Whipple's disease is prolonged (at least 1 year) treatment with SXT.[123] Tetracycline therapy, previously used commonly, is associated with an unacceptably high frequency of relapses. Especially in seriously ill patients, an initial course of parenteral therapy with ceftriaxone or a combination of penicillin and streptomycin is administered before long-term oral SXT therapy is begun.[123]

Concluding Comments

Although uncommonly isolated in clinical laboratories and rarely encountered in clinical practice as compared to other aerobic bacteria, the aerobic actinomycetes are a very diverse group of bacteria that have traditionally been difficult to identify and consequently may have been misidentified, signed out as "unknown" or discarded as contaminants.[168,183]Unfortunately, conventional phenotypic methods will not be sufficient to allow for species-level and sometimes not even for genus-level identification of many of these. Susceptibility testing is not performed in all laboratories for these isolates, so in addition, the appropriate agents might not be recognized to assist the clinician in making appropriate therapeutic decisions. There is good evidence, however, to believe that the newer molecular and mass spectrometry methods will be very helpful in overcoming these difficulties. At the moment, only some reference laboratories are capable of performing these tests, but that will hopefully change in the future.

Summary

This chapter includes information about the present taxonomy and clinical relevance of anaerobes in human infections; traditional methods for isolation and identification of anaerobic bacteria; nontraditional methods for identification of anaerobes, including DNA sequencing and matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometery; in vitro susceptibility testing; and management of infections involving anaerobes. An Appendix has been added to the chapter that contains some of the more conventional phenotypic procedures for identification of anaerobes that have been included in past chapters of this text. Greater emphasis is placed on the nonphenotypic classification and identification of anaerobes, but we have kept the traditional methods as much as possible or provided references for presumptive identification of anaerobes. Updates on anaerobic diseases such as Lemierre's disease, botulism, tetanus, bacterial vaginosis, and *C. difficile* enterocolitis are included. A summary of recent changes in the susceptibility testing of selected anaerobes concludes the chapter.

Introduction to Anaerobic Bacteria

Classification of Bacteria Based on Their Response to Oxygen

Although defined in various ways by different authors, a practical working definition is that *obligately anaerobic bacteria* are those bacteria that grow in the absence of free oxygen but fail to multiply in the presence of oxygen on the surface of nutritionally adequate solid media incubated in room air or in a CO_2 incubator (i.e., 5% to 10% CO_2 in air). The amount of O_2 in a CO_2 incubator, or in a candle extinction jar, is considerable (i.e., about 18% to 19%). In practice, anaerobic bacteria are most often recognized in the clinical laboratory following aerotolerance tests of colonies that grew on primary isolation plates incubated anaerobically (see below). Thus, most anaerobes identified in the clinical laboratory grow initially on anaerobic blood agar, or on one of

the selective anaerobic media, or in an enrichment broth incubated anaerobically, but not on blood agar or chocolate agar plates incubated aerobically or in a CO_2 incubator.

It is an oversimplification to discuss the anaerobes as if they fit uniformly in one large group, just as it is an oversimplification to refer to all bacteria that grow in room air as aerobes. Thus, several terms, including *obligate aerobe, facultative anaerobe, microaerophile, aerotolerant anaerobe,* and *obligate anaerobe* (strict and moderate), have been used to subdivide bacteria based on their relationships to oxygen. These terms reflect a continuous spectrum of bacteria that cannot tolerate oxygen to those that require it for growth.

Obligate aerobes, including species of *Mycobacterium* and *Pseudomonas*, require molecular oxygen as a terminal electron acceptor, resulting in the formation of water, and do not obtain energy by fermentative pathways. However, it is not uncommon to find *P. aeruginosa* growing scantily on anaerobically incubated media in the clinical laboratory, since these bacteria can use nitrate in the medium as a terminal electron acceptor, through anaerobic respiration, in place of O_2. In contrast, molecular oxygen varies in its toxicity to different species of anaerobic bacteria and is not a terminal electron acceptor for the anaerobic bacteria. In general, the clinically important anaerobes obtain their energy through fermentative pathways, in which organic compounds such as organic acids, alcohols, and other molecules serve as final electron acceptors.

Anaerobes are divided into two major groups: the obligate anaerobes and the aerotolerant anaerobes. The obligate anaerobes have been further subdivided into two groups based on their ability to grow in the presence of or to tolerate small amounts of oxygen. Strict obligate anaerobes are not capable of growth on agar surfaces exposed to O_2 levels above 0.5%. Atmospheric oxygen is highly toxic for these microorganisms for reasons that are not entirely known. Examples of these bacteria include *Clostridium haemolyticum, C. novyi* type B, *Selenomonas ruminatium,* and *Treponema denticola.* The second group of obligate anaerobes, the moderate obligate anaerobes, is bacteria that can grow when exposed to oxygen levels ranging from about 2% to 8% (average, 3%). Examples of these bacteria include members of the *Bacteroides fragilis* and the pigmented *Prevotella-Porphyromonas* groups (i.e., formerly the pigmented *Bacteroides* group), *Fusobacterium nucleatum, and C. perfringens*.[299]

The term *aerotolerant anaerobe* is used by some microbiologists to describe anaerobic bacteria that will show limited or scant growth on agar in room air or in a 5% to 10% CO_2 incubator, but show significantly better growth under anaerobic conditions. Examples of these bacteria include *Clostridium carnis, C. histolyticum,* and *C. tertium*. Most of the anaerobes isolated from properly selected and collected specimens in the clinical laboratory fit into the moderate

obligate anaerobe or aerotolerant category. These organisms are more tolerant to the toxic effects of oxygen than the strict obligate anaerobes, but are still killed by oxygen unless anaerobic conditions are maintained properly during specimen collection and transport to the laboratory and during the steps required for processing of specimens and isolation and identification, as discussed in later sections of the chapter. Strict obligate anaerobes are rare in infections of humans, but both the moderate and the strict obligate anaerobes are found in a variety of nonpathogenic habitats (e.g., the gastrointestinal [GI] tract from and the oropharynx to large intestine), as part of the normal microbiota.

The facultative anaerobes (e.g., *Escherichia coli* and *Staphylococcus aureus*) grow under either aerobic or anaerobic conditions. They use oxygen as a terminal electron acceptor or, less efficiently, can obtain their energy through fermentation reactions under anaerobic conditions. Grown aerobically, facultative anaerobes obtain much more energy when they completely catabolize a molecule of glucose to CO_2 and H_2O, than when grown anaerobically. The microaerophiles require oxygen as a terminal electron acceptor, yet these bacteria do not grow on the surface of solid media in an aerobic incubator (i.e., 21% O_2) and grow minimally, if at all, under anaerobic conditions. An example of a microaerophile is *Campylobacter jejuni*, which grows optimally in 5% O_2; the gas mixture of the incubation environment commonly used for recovering this organism in clinical laboratories is 5% O_2, 10% CO_2, and 85% N_2. *Campylobacter* spp. are discussed in another chapter as are *Capnocytophaga* spp. For this edition, they have been removed from tables in this chapter, although you will find them listed in older editions.

Reasons for Anaerobiosis

Through the years, bacteriologists working on the development of improved media and systems for cultivation of anaerobes have focused on two fundamental limiting factors that may affect the growth of anaerobes. The first and most important of these are the inhibitory effects of atmospheric oxygen and its toxic derivatives. The second limiting factor of concern is the oxidation–reduction potential of the culture medium. Some of the strictest obligate anaerobes (e.g., *Clostridium haemolyticum* and *C. novyi* type B) are killed when exposed to atmospheric oxygen on the open laboratory bench for 10 minutes or longer. Conversely, most of the moderate obligate anaerobes encountered in human infections tolerate exposure to oxygen for longer times, from 25 minutes to a few hours. There are likely multiple reasons why anaerobes vary in their tolerance to oxygen, but one idea is that the oxygen tolerance of many moderate obligate anaerobes depends on their production of superoxide dismutase (SOD),

catalases, and possibly peroxidase enzymes, which are protective against toxic oxygen reduction products.[238,470]

A popular notion is that exposure to atmospheric O_2 results in a series of reactions within the bacterial cells, possibly reactions mediated by flavoproteins, results in production of the negatively charged superoxide radical (O_2-), hydrogen peroxide (H_2O_2), and other toxic oxygen reduction products.[325] The superoxide anion and H_2O_2 may react together to produce free hydroxyl radicals (OH.), the most powerful biologic oxidants known, and there may also be the production of toxic singlet oxygen ($1O_2$) through the reaction of superoxide anions with free hydroxyl radicals. SOD catalyzes the conversion of superoxide radicals to less toxic hydrogen peroxide and molecular oxygen. Catalase catalyzes the conversion of hydrogen peroxide to form water and oxygen. Several species of oxygen-tolerant moderate obligate anaerobes were shown to produce SOD and the level of SOD produced correlated with the level of oxygen tolerance and virulence of the organism.[470] Other studies have not shown such correlations. Several species of anaerobes have been shown to produce catalase (e.g., members of the *Bacteroides fragilis* group, *Propionibacterium acnes,* and others), as well as SOD, and some anaerobes that are relatively oxygen-tolerant or aerotolerant (e.g., *Clostridium tertium*) produce neither SOD nor catalase. Rolfe et al. observed that the degree of oxygen tolerance of anaerobic bacteria is related to the proportion of the bacterial cells in the population that survive following exposure to oxygen.[398]

The oxidation–reduction potential (abbreviated "redox" potential or Eh) of a culture medium, expressed in volts or millivolts, is affected by pH (i.e., the hydrogen ion concentration); thus, redox potential is commonly expressed at neutral pH (pH 7) as Eh. Reducing agents, such as thioglycolate and L-cysteine, may be added to anaerobic transport media and to certain culture media to help maintain reduced conditions (i.e., a low Eh) in the medium. A positive Eh (e.g., as indicated by pink color of resazurin indicator in certain media, or a blue color of methylene blue indicator in other media) means that the medium is oxidized. In nature, the upper limit of Eh is +820 mV, which might be found in some environments that have considerable oxygenation. Oxidizing conditions prevail in healthy human tissue that is well-oxygenated and has an intact blood supply (e.g., the Eh is about +150 mV). In contrast, the lower limit of Eh in nature is about −420 mV. An anaerobic environment (e.g., an abscess or necrotic tissue) or a culture medium rich in hydrogen might have such a low Eh. The large bowel of humans, containing enormous numbers of strict obligate anaerobes, has an Eh of about −250 mV. In an excellent study reported by Walden and Hentges,[500] some of the misconceptions about Eh effects on anaerobic bacteria were dispelled. They determined that oxygen inhibited multiplication of *C. perfringens, B. fragilis,* and *P. magnus* whether the medium was at a negative redox potential (Eh =−50 mV) or at a

positive redox potential (Eh near +500 mV). In the absence of O_2, these organisms were able to multiply even when the Eh was maintained at +325 mV, by the addition of potassium ferricyanide (an oxidizing agent). From their work, a practical conclusion was drawn that the purging of oxygen from the cultural environment, to avoid oxygen toxicity, is probably more important than the establishment of a low Eh.[500] Thus, the rapid achievement and maintenance of a low oxygen tension, or the absence of oxygen, is an essential requirement for the successful cultivation of anaerobes in modern anaerobic systems (e.g., anaerobic jars and glove boxes used for incubation of anaerobes in the clinical laboratory).

Habitats for Anaerobes

Anaerobic bacteria are widespread in soil, marshes, lake and river sediments, the oceans, sewage, foods, and animals.

986

In humans, anaerobic bacteria normally are prevalent in the oral cavity around the teeth, in the GI tract, especially in the colon, where they outnumber coliforms by at least 1,000:1, and in the orifices of the genitourinary (GU) tract, and on the skin.[160,217] Most of these anaerobic habitats have both a low oxygen tension and reduced Eh resulting from the metabolic activity of microorganisms that consume oxygen through respiration. If the oxygen is not replaced, anaerobic conditions are maintained in the environment. A brief summary of commonly encountered anaerobes in the normal microbiota of the human body is given in Box 16-1.

Taxonomic Classification and Nomenclature

The anaerobes include essentially all morphologic forms of bacteria: gram-negative rods; curved, spiral-shaped, and spirochete forms; gram-positive and gram-negative cocci; gram-positive non–spore-forming (NSF) rods; and spore-formers. Based on their morphologic features as observed in Gram-stained preparations and the absence or presence of spores, the anaerobic bacteria are broadly classified as shown in Table 16-1. Several of the genera in this list have been found only in nonpathogenic habitats (e.g., sites harboring normal microbiota such as the oral cavity, lower intestinal tract [as evidenced in feces], GU tract, and skin of humans or various animals) and have not been reported to occur in diseases of humans. Many of these genera will not be discussed further.

There have been many recent developments in the taxonomic classification and

nomenclature of anaerobes since the sixth edition[519] of this book was published. Genetic studies utilizing polymerase chain reaction (PCR) and 16S ribosomal (r) RNA, 16S rDNA sequencing, 16S–23S rRNA spacer-region (SR)-PCR, and other molecular methods have more definitively classified anaerobes than was possible using phenotypic characterization and the older, less sophisticated genetic methods available in the past.[449,450] These studies have resulted in the descriptions of many new species and other taxa; at times, the genera into which an organism is then placed may not relate to Gram reaction, rod or coccus morphology, the ability to form spores, relationships to oxygen, or other phenotypic characteristics traditionally used to classify anaerobes. Fortunately, some excellent taxonomic updates have simplified the task of keeping up with ongoing changes in nomenclature.[158,162,236,237] Table 16-2 provides a compendium of taxonomic changes, compiled over the past several decades, for clinically significant anaerobic bacteria. The most clinically important anaerobes and/or those that are most commonly encountered in properly selected and collected specimens are listed in Table 16-3. Up-to-date, correct species identifications can have important implications related to prognosis, treatment, and clinical outcomes of patients with anaerobic infectious diseases.[158,160,162]

Taxonomy of the Anaerobic Gram-Negative Bacilli

The anaerobic gram-negative bacilli include some of the most commonly isolated and pathogenic anaerobes from clinical specimens. Tables 16-1 and 16-2 provide a summary of the latest taxonomy of this group of anaerobes, although not all anaerobic bacteria are listed because many are not known to be clinically relevant or part of the human microbiota. Members of the *Bacteroides fragilis* group make up a significant proportion of the normal microbiota of the GI tract in which the number of bacteria can be as high as 10^{11} to 10^{12} colony-forming units (CFU)/g feces; anaerobes far outnumber the aerobes >1,000:1. *B. thetaiotaomicron* and *B. ovatus* are the most common members of the *B. fragilis* group in the GI tract. *B. fragilis*, although only comprising about 0.5% of the human colonic microbiota, is the most common species involved in clinical disease because of its known virulence factors.[238] It is the most common cause of

BOX 16-1

Anaerobes Found in Normal Human Microbiota

Oral Cavity and Upper Respiratory Passages

Pigmented *Prevotella* species; *Porphyromonas* species

Nonpigmented *Prevotella* species (e.g., *P. oralis*)

Bacteroides species (e.g., *B. ureolyticus*)

Fusobacterium species (e.g., *F. nucleatum*)

Anaerobic gram-positive cocci

Veillonella species

Actinomyces species and *Propionibacterium* species

Stomach (During Fasting)

Lactobacilli

Small Intestine (Proximal Portion)

Microaerophilic streptococci

Lactobacilli

Large Bowel (and Terminal Ileum)

Bacteroides fragilis group

Porphyromonas species

Fusobacterium species

Anaerobic gram-positive and gram-negative cocci—many species

Clostridium species

Eubacterium species

Eggerthella species

Bifidobacterium species and related genera

Propionibacterium species

Other anaerobic gram-positive bacilli

Genitourinary Tract; Vagina and Cervix

Pigmented *Prevotella* species; *Porphyromonas* species

Nonpigmented *Prevotella*

Bacteroides species

Anaerobic gram-positive cocci

Eubacterium species

Eggerthella species

Clostridium species

*Veillonell*a species

Lactobacillus species

Propionibacterium species

Mobiluncus species

Atopobium species

Urethra (Male and Female)

Propionibacterium species

Anaerobic gram-positive and gram-negative cocci

Bacteroides species

Prevotella species

Fusobacterium species

Skin

Propionibacterium species

Anaerobic cocci

987

TABLE 16-1 Classification of the Genera of Anaerobic Bacteria

Gram-Negative Bacilli (Include Curved, Spiral, and Spirochete Forms)	Gram-Positive Cocci	Gram-Negative Cocci	Gram-Positive Bacilli (Non–Spore-Forming)	Gram-Positive Spore-Forming Bacilli
Alistipes	*Anaerococcus*[a]	*Acidominococcus*	*Alderreutzia*	*Clostridium*[a,b]
Anaerobiospirillum[a]	*Atopobium*[a]	*Anaeroglobus*	*Alloscardovia*	*Desulfomaculum*
Bacteroides[a]	*Coprococcus*	*Megasphaera*	*Anaerofustis*	*Desulfosporosinus*
Barnesiella	*Finegoldia*[a]	*Negativococcus*	*Anaerostipes*	*Caloramator*[b]
Bilophila[a]	*Gallicola*[1]	*Veillonella*[a]	*Anaerotruncus*	*Filifactor*[b]
Butyrivibrio[c]	*Gemmiger*		*Actinobaculum*	*Moorella*[b]
Catonella[a]	*Murdochiella*		*Actinomyces*[a]	*Oxobacter*[b]
Desulfuromonas	*Peptococcus*		*Atopobium*[a]	*Oxalophagus*[b]
Desulfovibrio	*Peptostreptococcus*[a]		*Bifidobacterium*[a]	
Dialister[a]	*Ruminococcus*		*Bulleidia*	
Faecalibacterium	*Sarcina*		*Catabacter*	
Fusobacterium[a]	*Peptoniphilus*[a]		*Catenibacterium*	
Johnsonella[a]	*Staphylococcus*[a]		*Cryptobacterium*	
Jonquetella	*Streptococcus*[a]		*Collinsella*	
Leptotrichia	*Gemella*[a]		*Eggerthella*[a]	
Megamonas			*Eubacterium*[a]	
Mitsuokella			*Faecalibacterium*	
Odoribacter			*Gordonibacter*	
Parabacteroides[a]			*Holdemania*	
Paraprevotella[a]			*Lachnospira*	
Parasutterella[a]			*Lactobacillus*[a]	
Phocaeicola			*Marvinbryantia*	
Porphyromonas[a]			*Methanobacterium*	
Prevotella[a]			*Mobiluncus*[a]	
Pyramidobacter			*Mogibacterium*	
Selenomonas			*Olsenella*	
Sneathia			*Oribacterium*	
Spirochaeta			*Paraeggerthella*	
Succinomonas			*Parascardovia*	
Succinivibrio			*Propionibacterium*[a]	
Sutterella[a]			*Propionimicrobium*[a]	
Tannerella[a]			*Pseudoramibacter*	
Tissierella			*Roseburia*	
Treponema[d]			*Scardovia*	
			Shuttleworthia	
			Slackia[a]	
			Solobacterium	
			Turicibacter	
			Varibaculum	

[a] In the majority of properly collected clinical specimens, only these genera will need to be considered by the clinical microbiologist. However, on rare occasions, serious illness may involve *Anaerobiospirillum*,[208] *Leptotrichia*,[156] *Selenomonas*,[2778] *Desulfovibrio*[93] or one of the other genera that is not listed above.
[b] The genus *Clostridium* continues to be under major taxonomic revision. Thus, in 1994, five new genera of spore-forming anaerobes were proposed by Collins et al.[49] With a single exception, none of these is known to be pathogenic for humans. *Filifactor alocis* has been isolated from patients with endodontic infections.[236]
[c] *Butyrivibrio* is discussed with the gram-negative bacilli in Vol. 1 and with the irregular non–spore-forming, gram-positive anaerobic rods in Vol. 2 of Bergey's Manual.[153,241] Although they are gram-negative with the Gram's stain, some strains have atypical gram-positive cell wall features by electron microscopy.
[d] *Treponema* spp. will not be discussed in this chapter, but is included here because they are a strict anaerobe.
Adapted and modified from *Bergey's Manual of Systematic Bacteriology*[153,241] and from very recent volumes of the International Journal of Systematic and Evolutionary Microbiology that contain numerous publications related to recent changes in anaerobe taxonomy.

TABLE 16-2 Present and Former Names of Anaerobic Bacteria

Present Name	Former Name/Comments
Anaerobic Gram-Negative Rods	
Genus Bacteroides—*Bacteroides fragilis* Group[507,a]	
Bacteroides caccae	Fecal microbiota
B. eggerthii	Fecal microbiota—not common in infections
B. fragilis	Most common anaerobe in infections
B. ovatus[370]	Human fecal microbiota; occasional infections
B. stercoris	Human fecal microbiota
B. thetaiotaomicron	Second to *B. fragilis* in causing infections
B. uniformis	Occasional clinical isolate
B. vulgates[370]	Common fecal microbiota; occasional fecal isolate
B. dorei[22,370]	New species; rarely isolated from blood
B. finegoldii[21]	New species; occasional clinical infection
B. massiliensis[156]	New species; isolated rarely from blood
Also Considered *B. fragilis* Group Members, but in *Parabacteroides* Genus	
Parabacteroides distasonis[403]	Human infections; formerly *B. distasonis*
P. goldsteinii[403]	Formerly *B. goldsteinii;* bacteremia
P. gordonii[19,408]	New species; blood culture isolate
P. johnsonii[405]	New species; fecal microbiota
P. merdae[403]	"T4-1," formerly *B. merdae;* human fecal microbiota
Other Species Remaining in the Genus *Bacteroides*, but Not a Member of the *Bacteroides fragilis* Group	
B. coagulans	Rare in clinical specimens
B. galacturonicus	Human fecal microbiota
B. pectinophilus	Human fecal microbiota
B. ureolyticus[485,511]	Human oral cavity; oral infections, head and neck infections
Genus *Prevotella*	
P. amni	New species; genitourinary (GU) infections
P. baroniae[131,397]	New species; oral cavity; infected root canal and dental abscess infections
P. bergensis[130]	New species; skin and soft tissue infections
P. bivia[372]	*Bacteroides bivia*; vaginal microbiota; GU infections
P. buccae	*Bacteroides buccae;* oral cavity; head, neck and chest infections; human bite wound
P. buccalis	*Bacteroides buccalis;* oral cavity
P. copri[213]	New species; fecal isolates
P. corporis	*Bacteroides corporis*; oral cavity; GU infections; pigmented
P. dentalis[514]	*Mitsuokella dentalis; Hallela seregens*; oral cavity

P. denticola[263]	*Bacteroides denticola*; oral cavity; carious lesions sputum of CF patients; some are pigmented
P. disiens[372]	*Bacteroides disiens;* vaginal microbiota and oral microbiota; GU infections
P. enoeca[337]	Oral cavity
P. heparinolytica[6]	*Bacteroides heparinolytica;* animal bite wounds
P. histicola	New species; some are pigmented
P. intermedia[427,428]	*Bacteroides intermedius*; head, neck, and abdominal infections; many oral infections; human bite wounds; pigmented
P. loescheii[461]	*Bacteroides loescheii*; oral cavity; pigmented; wounds
P. maculosa	New species
P. marshii[131]	New species; oral cavity
P. melaninogenica[263]	*Bacteroides melaninogenica;* pigmented; oral, pulmonary, skin and soft tissue infections; sputum of patients with cystic fibrosis
P. micans[124]	New species; oral cavity; pigmented
P. multiformis[404]	New species; nonpigmented; gingival plaque
P. multisaccharivorax[397]	New species; endodontic infections
P. nanceiensis[4]	New species; nonpigmented; many clinical specimens
P. nigrescens[428,529]	Indistinguishable from *P. intermedia*; oral cavity; many oral infections; pigmented
P. oralis[6]	*Bacteroides oralis*; oral cavity; abscesses; osteomyelitis
P. oris	*Bacteroides oris;* oral cavity; odontogenic infections
P. oulorum	*Bacteroides oulorum;* oral cavity; *P. oulora*
P. pallens[262]	New species; pigmented
P. pleuritidis[406]	New species; isolated from pleural fluid
P. saccharolytica[132]	New species; oral cavity
P. salivae[407]	New species; oral cavity; sputum of patients with cystic fibrosis
P. shahii[407]	New species; oral cavity; pigmented
P. stercorea[213]	New species; fecal isolates
P. tannerae[337]	New species; oral cavity; carious lesions; some strains pigmented
P. timonensis[183]	New species; breast abscess
P. veroralis	*Bacteroides veroralis;* oral cavity
P. zoogleoformans[337]	*Bacteroides zoogleoformans*
Genus *Porphyromonas*	
P. asaccharolytica[469]	*Bacteroides asaccharolyticus*; many nonoral clinical specimens
P. bennonis[466]	New species; nonoral infections; wounds and abscesses

989

***Porphyomonas* spp.**	
Porphyromonas catoniae[263]	*Oribaculum catoniae*; oral cavity; not pigmented; abdominal abscess
P. endodontalis[165]	*Bacteroides endodontalis*; dental infections
P. gingivalis[47]	*Bacteroides gingivalis*; periodontitis and dental abscesses and nonoral infections
P. somerae[467]	Lower extremity skin and soft tissue infections related to human-like *P. levii* strains
P. uenonis[165]	New species; appendicitis, peritonitis; decubitus ulcer
The following are species that are normal microbiota or pathogens in animals; any could potentially be involved in human bite wound infections.[1,6]	
P. cangingivalis	Dogs
P. canoris	Dogs
P. cansulci	Dogs
P. circumdentaria	Cats
P. crevivoricanis	Dogs
P. gingivicanis	Dogs
P. gulae	Cat, coyote, dogs, bear, wolf
P. levii	Cattle
P. macacae	*Bacteroides macacae;* monkeys and cats
***Fusobacterium* spp.**[263]	
F. gonidiaformans	Human infections
F. mortiferum[98,238]	Human infections
F. naviforme	Human infections
F. necrogenes	Human fecal microbiota; also from oral cavity
F. necrophorum subsp. *fundiliforme*[24,376,394]	Human microbiota; virulent species; Lemierre's and other oral and many other nonoral infections
F. necrophorum subsp. *necrophorum*[394]	More commonly isolated from animals; less virulent of the two subspecies
F. nucleatum[376,465]	Most common clinical *Fusobacterium* sp.; normal microbiota in oral cavity and GI tract
F. periodonticum[465]	Oral cavity; also found in GI tract
F. russii	Human fecal microbiota
F. ulcerans[98]	New species; tropical ulcers
F. varium[98,376]	Various human infections
Other Genera of Anaerobic Gram-Negative Bacilli	
Alistipes finegoldii[157,388]	New species; human appendicitis, bacteremia
A. onderdonkii[447]	New species; pigmented; intra-abdominal specimens
A. putredinis[388]	*Bacteroides putredinis*; rarely found in intra-abdominal infections

Alistipes.shahii[447]	New species; pigmented; intra-abdominal infections
Anaerobiospirillum succiniciproducens[250,377,472]	Human fecal microbiota; bacteremia
Anaerobiospirillum thomasii[263]	New species; human fecal microbiota
Anaerostipes caccae	New species; human fecal microbiota
Anaerorhabdus furcosa	*Bacteroides furcosus; Anaerohabdus furcosus*
Barnesiella intestinihominis[341]	New genus and species
Bilophila wadsworthia[30,484]	Peritonitis, appendicitis, brain abscess
Catonella morbi[329,340]	New species; prosthetic valve endocarditis
Centipeda periodontii[415]	Oral isolates
Cetobacterium somerae[164]	New species; human feces
Desulfovibrio piger[303]	*Desulfomonas pigra;* human feces
D. desulfuricans[192,495]	Fecal microbiota
D. vaginalis[228]	Vaginal microbiota
Dialister pneumosintes[135,340]	*Bacteroides pneumosintes*; oral isolate; odontogenic infection
Faecalibacterium prausnitzii[333]	*Fusobacterium prausnitzii*; normal GI microbiota; may help to balance immunity in GI tract
Filifactor alocis[193]	*Fusobacterium alocis;* oral cavity; endodontic disease
Jonquetella anthropi[241]	New genus and species
Johnsonella ignava[340]	New genus and species; human gingival crevice
Genus *Leptotrichia*	
L. amnionii	New species; amniotic fluid
L. buccalis[40,198]	*Leptothrix buccalis;* oral microbiota; bacteremia
L. goodfellowii[69,146]	New species; blood isolates
L. hofstadii[146]	New species; oral cavity
L. shahii[146]	New species; gingivitis
L. trevisanii[270]	New species; oral isolate; bacteremia
L. wadeii[146]	New species; oral cavity
Other Genera	
Megamonas fumiformis[409]	New genus and species; related to *Sutterella*; human feces
Odoribacter splanchnicus[210]	Formerly *Bacteroides splanchnicus*
Oxalobacter formigenes[251]	Colon colonizer; reduces calcium oxalate stones
Paraprevotella spp.[342]	New Genus; human feces

990

Parasutterella secunda[343]	New genus; human feces
Phocaeicola abscessus[11]	New genus and species; isolated from brain abscess
Pyramidobacter piscolens[133]	New genus; oral cavity
Pseudoflavonifractor capillosus[70]	Formerly *Bacteroides capillosus*; rarely in clinical specimens
Genus *Selenomonas*[415]	
S. artemidis	Oral microbiota
S. dianae	Human gingival crevice
S. flueggei	Human oral microbiota
S. infelix	Human gingival crevice
S. noxia	Human gingival crevice
S. sputigena[415]	Oral microbiota
Sneathia sanguinegens[103]	*Leptotrichia sanguinegens*; bacteremia; bacterial vaginosis-associated
Sutterella wadsworthensis[336,346,508]	Formerly, strains of *Campylobacter (Bacteroides) gracilis;* GI microbiota
Tannerella forsythensis[193,396]	*Bacteroides forsythus*; oral cavity; periodontitis
Tissierella praeacuta[151]	*Bacteroides praecutus*
Anaerobic Cocci	
Gram-Positive Cocci	
Peptococcus niger	Only species in genus
Peptostreptococcus anaerobius[108,350]	Only species in genus; many clinical specimens; endocarditis
Anaerococcus prevotii[230,351]	*Peptostreptococcus prevotii*; GU infections
A.tetradius[351]	*Peptostreptococcus tetradius;* GU infections
A. hydrogenalis[351]	*Peptostreptococcus hydrogenalis*
A. vaginalis[351]	*Peptostreptococcus vaginalis;* GU infections
A. lactolyticus[351]	*Peptostreptococcus lactolyticus;* GU infections
A. murdochii[448]	New species
A. octavius[351]	*Peptostreptococcus octavius;* GU microbiota; skin microbiota
Finegoldia magna[170,291,349]	*Peptostreptococcus magnus;* most common anaerobic coccus in specimens; bacteremia; endocarditis
Gallicola barnesae[148]	*Peptostreptococcus barnesae*
Parvimonas micra[351,396,446]	*Micromonas micros; Peptrostreptococcus micros;* many clinical specimens; oral cavity
Peptoniphilus asaccharolyticus[351]	*Peptostreptococcus asaccharolyticus;* many clinical specimens
P. gorbachii[448]	New species

P. harei[351]	*Peptostreptococcus harei;* rare clinical specimens
P. indolicus[351]	*Peptostreptococcus indolicus*
P. ivorii[351]	*Peptostreptococcus ivorii*; leg ulcer
P. lacrimalis[351]	*Peptostreptococcus lacrimalis*; lacrimal gland abscess
P. olsenii[448]	New species
Other Anaerobic Gram-Positive Cocci	
Atopobium parvulum[128]	*Streptococcus parvulus;* oral cavity; dental abscesses
Coprococcus catus	Human feces
Coprococcus comes	Human feces
Coprococcus eutactus	Human feces
Murdochiella asaccharolyticus[351,483]	New species
Sarcina ventriculi	GI microbiota
Staphylococcus saccharolyticus[8,187,256]	*Peptococcus saccharolyticus*; bacteremia; contaminated platelets
Staphylococcus aureus subsp. *anaerobius*[141,368]	Abscesses
Gram-Negative Cocci	
Acidaminococcus fermentans[312]	Human feces; rare clinical specimens
Anaeroglobus geminatus[72]	New species; oral and GI microbiota
Megasphaera elsdenii[50]	Human feces; endocarditis
Megasphaera micronuciformis	New species
Negativicoccus succinicivorans[94,312]	New species
Veillonella atypica	Human oral microbiota; rare clinical isolates; prosthetic joint infections
V. dispar	Human microbiota; rare human specimens
V. parvula[41,45,166]	Human microbiota; most common species
V. montpellierensis[240]	New species; rare clinical specimens
Anaerobic Gram-Positive, Non–Spore-Forming Bacilli	
***Actinomyces* spp.**	
A. cardiffensis[203]	New species; abscesses
A. dentalis[208]	Oral cavity; dental abscess
A. europaeus[174,402]	New species; breast abscesses
A. funkei[283]	New species; clinical samples
A. georgiae[235]	Human gingival crevice
A. gerencseriae[235]	Human periodontal microbiota
A. graevenitzii[274]	New species; clinical specimens
A. hongkongensis[521]	New species; clinical specimens
A. israelii[222,365,383,499]	Cause of actinomycosis
A. johnsonii[216]	New species; related to *A. naeslundii*
A. massiliensis[392]	New species; blood culture isolate

991

A. meyeri[153,200,238]	Head and neck infections; brain abscess
A. naeslundii[216,235,499]	Can cause actinomycosis; oral microbiota
A. nasicola[206]	New species
A. neuii subsp. *neuii*[175,176,310,497]	CDC Coryneform group 1
A. neuii subsp. *anitratus*[175]	CDC coryneform 1-like
A. odontolyticus[238,499]	Human oral cavity; rare actinomycosis
A. oricola[205]	New species; dental abscesses
A. oris[216]	New species; related to *A. naeslundii*
A. radicidentis[102,247,402,438]	New species; infected root canals
A. radingae[402,526]	New species; clinical specimens
A. turicensis[402,486,526]	New species; many clinical specimens
A. urogenitalis[144,357]	New species; urogenital microbiota
A. viscosus[235,499]	Human oral cavity; occasional actinomycosis
Genera Related to *Actinomyces* spp.	
Actinobaculum massiliense[356]	New species; isolated from urine
Actinobaculum schaalii[282,356]	New species; blood and urine isolates
Actinobaculum urinale[204]	New species; urine isolates
Varibaculum cambriense[93,207]	New genera and species
Genus *Bifidobacterium* spp.[499]	
B. adolescentis	Oral cavity
B. breve[307]	Oral cavity
B. dentium[307]	Oral cavity; involved in dental infections
B. gallicum[307]	Human feces
B. longum[307]	Dental caries
B. scardovii[221]	New species; oral cavity; dental caries
Genus *Eubacterium*[238,499]	
E. brachy	Periodontitis
E. infirmum	New species; oral microbiota
E. limosum[145]	GI microbiota; skin & soft tissue and GI infections
E. minutum	*Eubacterium tardum*
E. nodatum	Oral microbiota; periodontitis
E. saphenum	Dental infections
E. sulci	*Fusobacterium sulci*
E. tenue[281]	Oral microbiota; bacteremia
E. yurii	Dental plaque

Genus *Lactobacillus*	
L. casei[68,195]	Normal microbiota mouth, vagina, GI tract; many clinical specimens
L. coleohominis	New species; facultative anaerobe
L. oris	Saliva
L. paraplantarum	New species; fecal microbiota
L. rhamnosus[68,195]	Normal microbiota of mouth, vagina and GI tract; many clinical specimens
Genus *Propionibacterium* spp.	
P. acidifaciens[134]	Oral microbiota; associated with dental infections
P. acnes[295,328,371]	Most common species; skin microbiota; involved in many infections
P. avidum[39,331]	Skin microbiota; rare but increasing reports of clinical infections
P. granulosum[91,360]	
P. propionicum[89,438,499,524]	
New Genera Related to *Propionibacterium* sp.	
Propionimicrobium lymphophilum[457]	
Other Anaerobic Gram-Positive, Non–Spore-Forming Bacilli	
Alloscardovia omnicolens[227,307]	New genus and species; related to *Bifidobacterium* spp. Isolated from many clinical sites
Anaerofustis stercorihominis[499]	New genus and species; fecal microbiota
Anaerotruncus colihominis[499]	New genus and species; fecal microbiota; bacteremia
Atopobium minutum[105,319]	*Lactobacillus minutus*
Atopobium rimae[13,105,128]	*Lactobacillus rimae*;oral microbiota; periodontitis; bacteremia
Atopobium vaginae[85,479]	New species; association with bacterial vaginosis
Blautia wexlerae[296]	New species
Bulleidia extructa[129,260]	New genus and species; oral cavity
Catabacter hongkongensis[278,442]	New genus and species; bacteremia
Catenibacterium mitsuokai	New genus and species; fecal microbiota
Collinsella aerofaciens[245]	*Eubacterium aerofaciens*; fecal microbiota most abundant bacterium in intestine
Collinsella stercoris[244]	New species; fecal microbiota
Collinsella intestinalis[244]	New species; fecal microbiota
Cryptobacterium curtum[353]	*Eubacterium curtum;* Oral cavity; periodontitis
Dorea formicigenerans[471]	*Eubacterium formicigerans*; fecal microbiota

992

Dorea longicatena	New species; fecal microbiota
Eggerthella lenta[238,493,498,499]	*Eubacterium lentum;* bacteremia; the most commonly isolated species of *Eubacterium/Eggerthella* from nonoral sites
Eggerthella sinensis[280]	New species; bacteremia
Flavonifractor plautii[70]	*Clostridium orbiscindens* and *Eubacterium plautii*; fecal microbiota; blood, abdominal wounds
Holdemania filiformis[517]	New genus and species; fecal microbiota
Mobiluncus curtisii[120,185,218,456]	Vaginal microbiota; associated with bacterial vaginosis
Mogibacterium vescum	New genus and species; oral cavity
Mogibacterium diversum	New species; oral cavity
Mogibacterium neglectum	New species; oral cavity
Mogibacterium timidum[211]	*Eubacterium timidum*
Moryella indoligenes[71]	New genus and species; probably GI microbiota; isolated from abdominal abscess
Olsenella profusa[118]	New species oral cavity; periodontitis; gingivitis
Olsenella uli[118,281]	*Lactobacillus uli;* gingival crevice; periodontitis; gingivitis; bacteremia
Paraeggerthella hongkongensis[280,525]	*Eggerthella hongkongensis*; bacteremia
Parascardovia denticolens[233]	*Bifidobacterium denticolens*
Pseudoramibacter alactolyticus[439,516]	*Eubacterium alactolyticum*
Roseburia intestinali[137]	New species; fecal microbiota
Scardovia inopinata[126,233]	*Bifidobacterium inopinatum;* oral cavity; dental caries
Scardovia wiggsiae[126]	New species; oral cavity; isolated from wound
Shuttleworthia satelles[127,430,508]	New genus and species; oral cavity; endocarditis
Slackia exigua[211,257,498]	*Eubacterium exiguum*
Slackia heliontrinireducens[381,498]	*Peptostreptococcus helionitrinireducens*
Solobacterium moorei[37,246]	Fecal isolate; bacteremia
Turicibacter sanguinis[46]	New species; bacteremia
Gram-Positive, Spore-Forming Bacilli[464]	
Clostridium aldenense[502]	New species; one of *C. clostridioforme* group
C. argentinense[181]	*C. botulinum* Type G
C. baratii[181]	*C. paraperfringens, C. perenne;* can produce *C. botulinum* Type G toxin

C. bartlettii[452]	New species; fecal microbiota
C. bolteae[451]	New species; one of the *C. clostridioforme* group; bacteremia
C. botulinum[181]	Cause of food, infant, and wound botulism; toxin-producer
C. butyricum[238,464]	*C. pseudotetanicum;* can produce *C. botulinum* Type G toxin
Clostridium celerecrescens[48]	
C. citroniae[502]	New species; one of the *C. clostridioforme* group
C. clostridioforme[163]	One of many species in *C. clostridioforme* group; bacteremia
C. hathewayi[293,461]	New species; fecal microbiota; one of the *C. clostridioforme* group; bacteremia and liver abscess proposal to change name to *Hungatella hathewayi*
C. hiranonis	New species; fecal microbiota
C. hylemonae	New species; fecal microbiota
C. innocuum[424]	Common clostridia species in clinical specimens; bacteremia
C. lavalense[121]	New species; one of the *C. clostridioforme* group
C. methylpentosum	Fecal microbiota
C. neonatale[7]	New species; isolated from patient with necrotizing enterocolitis
C. perfringens[334,463,498]	*C. welchii;* gas gangrene; food poisoning; bacteremia
C. ramosum[167]	*Eubacterium filamentosum, Ramibacterium ramosum, Actinomyces ramosus, Eubacterium ramosus*
C. scindens[143]	New species; fecal microbiota; intra-abdominal abscess
C. septicum[253,416]	Bacteremia; necrotizing fasciitis
C. sordellii[15,258,463]	Bacteremia; necrotizing fasciitis
C. symbiosum[478]	*Fusobacterium symbiosum;* bacteremia
C. tertium[173,330]	Bacteremia and other infections; aerotolerant

[a] There are now >23 species of the *B. fragilis* group, for example. Most of those not in this table have been recently named and/or have not as yet been found in clinical specimens nor associated with human infections.
This is not intended to be an all-inclusive list. A number of species of no or doubtful clinical relevance have not been included, especially in the genera *Bacteroides, Eubacterium, Lactobacillus* and *Clostridium.*
Some species that might have been in past editions may have been removed from this edition, such as *Propioniferax*, which is an aerobe, although related to *Propionibacterium* spp.
This table is based on information compiled predominantly from many references 238, 263, 446, 464, and 499 and the International Journal of Systematic and Evolutionary Microbiology.

TABLE 16-3 The Most Clinically Important Anaerobes and/or Those Most Frequently Encountered in Clinical Specimens

Gram-Negative Rods
Bacteroides fragilis group (especially *B. fragilis, B. thetaiotaomicron, B. vulgatus,* and *B. ovatus*)
Parabacteroides distasonis
Other *Bacteroides* (*B. ureolyticus*)
Porphyromonas (especially *P. asaccharolytica, P. gingivalis* and *P. endodontalis*)
Pigmented *Prevotella* (*P. melaninogenica, P. loescheii, P. denticola, P. tannerae, P. intermedia, P. nigrescens* and *P. corporis*)
Nonpigmented *Prevotella* (*P. oralis* group, *P. oris/buccae, P. bivia* and *P. disiens*)
Fusobacterium (especially *F. nucleatum, F. necrophorum, F. mortiferum* and *F. varium)*
Bilophila wadsworthia
Anaerobic Cocci
Gram-positive cocci (especially *Peptostreptococcus anaerobius, Finegoldia magna, Parvimonas micra, Peptoniphilus asaccharolyticus, Anaerococcus prevotii*, *Staphylococcus saccharolyticus,* and *Atopobium parvulum*)
Gram-negative cocci (*Veillonella* spp.)
Anaerobic Gram-Positive, Non–Spore-Forming Rods
Actinomyces (especially *A. israelii, A. meyeri, A. naeslundii, A. odontolyticus*, *A. turicensis, A. graevenitzii* and *A. viscosus*)
Atopobium vaginae
Propionibacterium (*P. acnes* and *P. propionicum*)
Bifidobacterium dentium
Eubacterium limosum

Eggerthella lenta
Paraeggerthella spp.
Lactobacillus sp.
Gram-Positive, Spore-Forming Rods (*Clostridium* spp.)
C. perfringens
C. clostridioforme group (especially *C. clostridioforme, C. hathewayi,* and *C. bolteae, C. citroniae, C. aldenense* and *C. lavalense*)
C. innocuum
C. ramosum
C. difficile
C. bifermentans
C. sporogenes
C. septicum
C. sordellii
C. novyi
C. histolyticum
C. botulinum
C. tetani
C. tertium

anaerobic bacteremia.[58,238,420] There are over 20 species in the *B. fragilis* group that are related genetically, as well as by their phenotypic characteristics: 20% bile resistance, Gram's stain morphology, and innate and increasing resistance to a wide variety of antibiotics. Table 16-2 lists the members of the *B. fragilis* group species. One group of *B. fragilis* complex (*B. merdae, B. goldsteinii,* and *B. distasonis*) has been reclassified into the genus *Parabacteroides*.[263,403] Most of the non-*B. fragilis* group *Bacteroides* spp. have also been reclassified, although *B. ureolyticus* presently

remains in the *Bacteroides* genus; however, there is a proposal to reclassify it as *Campylobacter ureolyticus*.[485] Many of the other one-time *Bacteroides* spp. members are listed with their new genera in the Table. *B. splanchnicus,* for example, has been placed in the genus *Odoribacter* and *B. capillosus* in a new genus, *Pseudoflavonifractor*, as *P. capillosus*.[70,210]

Since 1992, the genus *Porphyromonas* has changed markedly with a total now of at least 16 species (Table 16-2). Many have been isolated from the oral cavity and may be responsible for endodontic infections. Five of the *Porphyromonas s*pp. have been isolated from oral cavities of dogs only (*P. cangingivalis, P. canoris, P. cansulci, P. crevioricanis,* and *P. gingivicanis*); one has been isolated from the oral cavities of cats only (*P. circumdentaria*); another has been isolated from both monkeys and cats (*P. macacae*, which includes those previously classified as *P. salivosa*); another is from cattle (*P. levii*); one species was isolated from the human oral cavity *(P. catoniae*), and *P. gulae*, described in 2001, was isolated from various animals, including bear, cat, coyote, dog, wolf, and monkey.[169,515] Presumably, although their clinical importance in humans is unknown, the species isolated from the mouths of animals could be encountered in bite wound infections.[1] In 1995, not only did Willems and Collins reclassify *Oribaculum catoniae* as *Porphyromonas catoniae*, but they emended the genus *Porphyromonas* as well. In accordance with their emended description, some species are now included that are saccharolytic (*P. levii, P. macacae,* and *P. catoniae*); *P. catoniae* alone does not form pigment.[467,515]

There are over 37 species of the genus *Prevotella,* which consists of pigmented and nonpigmented strains. They make up the bulk of the gram-negative anaerobic normal microbiota of the oral cavity, but are also involved in many oral as well as nonoral infections.[263] Table 16-2 lists the most common species of *Prevotella*.

Fusobacterium spp. are another common genera of gram-negative bacilli, and many of them have retained their genus and species names; a number of newly named *Fusobacterium* are also shown in Table 16-2.[95] *Fusobacterium nucleatum* has the characteristic Gram's stain morphology of long, thin pointed rods (i.e., a fusiform shape) and a few other species also demonstrate this trait, but many of the species produce shorter rods, and some rather bizarre morphologies that are quite distinctive for their identification. The virulence of the *Fusobacterium* spp. has been recognized and reported on with increasing frequency in the literature as will be discussed in the sections on human infections.[95,395]

Faecalibacterium prausnitzii is a very common bacterium in the normal GI microbiota and often identified in fecal material.[238,333] *Leptotrichia* is an unusual gram-negative bacillus, the cells of which are much longer than other anaerobic gram-negative bacilli; this will be included for discussion later as well.[40,198] *Bilophila wadsworthia* is very similar to the *B. fragilis* group in its resistance to bile and

susceptibility to antibiotics, and has become increasingly recognized as a pathogen as methods of isolation and identification improve. *B. wadsworthia* will be discussed further in this chapter.[30,484] Some of the other genera of anaerobic gram-negative bacilli will not be further covered, but if references are available, these will be provided in text or tables so readers can obtain more information, if desired.

Taxonomy of the Anaerobic Gram-Positive Non–Spore-Forming Bacilli

The gram-positive NSF bacilli are a very heterogeneous group of anaerobes, often difficult to specifically identify and characterize. One of the most commonly isolated anaerobes, *Propionibacterium acnes*, belongs to this group, as do members of the *Actinomyces* genus that include the well-known pathogen *A. israelii*. Members of both of these genera share a trait of "aerotolerance" in that, although often isolated in primary cultures only under strict anaerobe conditions, they often grow quite well in the presence of oxygen upon transfers from the primary plates. *Propioniferax* spp., a genus related to *Propionibacterium* spp., is actually an aerobe, and will not be included in this chapter. *Propionibacterium propionicum*, *P. acidifaciens,* and *Propionimicrobium lymphophilum* (related to the *Propionibacterium* spp.) are not aerotolerant. For the aerotolerant species of *Actinomyces* and *Propionibacterium*, drugs such as metronidazole, which are only active against anaerobes, have no effect on their growth; the nonaerotolerant strains vary in their response to metronidazole.[100,238,263]

P. acnes is very common as a part of the normal skin microbiota, but can be a pathogen in infections in which the entry of the organisms from the skin is enhanced by placement of foreign devices through or near the skin. *Propionibacterium propionicum* (formerly referred to as *Arachnia propionica*) has been implicated in actinomycosis and other infections, as will be discussed in the next section.[55]

A. israelii is an anaerobic gram-positive, branching bacillus that has long been associated with the condition "actinomycosis," a chronic granulomatous infection that can affect the cervicofacial, thoracic, abdominal, or pelvic regions of the body. Disease is most commonly caused by *A. israelii, A. gerencseriae,* and *A. gravenitzii*. The presence of "sulfur granules" (masses of branching bacilli), seen in histopathology or on Gram's stains of clinical specimens in the microbiology laboratory, are regarded as the hallmark of such *Actinomyces* infections; in fact, actinomycosis in most instances is actually a polymicrobial infection.[55,238,263] In recent years, extensive taxonomic revisions have been made within the genus *Actinomyces* (Table 16-2). These changes have included the designation of several new or additional species including *A. cardiffensis,*[203] *A. europaeus*,[402] *A. funkei*,[283] *A. georgiae*,[235] *A. gerencseriae*,[235] *A. graevenitzii,*[385] *A. hongkongensis*,[521] *A. nasicola,* [206] *A. neuii*,[175,176,310] *A.*

oricola,[205] *A. radicidentis*,[102,247] *A. radingae*,[402,486,526] *A. turicensis,*[402,486,526] and *A. urogenitalis*.[357] Other more recently described genera that are closely related to the genus *Actinomyces* are *Actinobaculam* (e.g., *Actinobaculam schaalii* and *A. urinale*),[204,282] *Arcanobacterium* (e.g.,*Arcanobacterium bernardiae* and *A. pyogenes*),[386] and *Varibaculum cambriense*.[93,207] There will

be no further discussion of *Arcanobacterium* in this chapter because it is not an anaerobe.

Table 16-2 lists the most recent taxonomy of the anaerobic, gram-positive NSF bacilli. Using newer molecular tools for identification, many of the once *Eubacterium, Bifidobacterium,* and *Lactobacillus* have been reclassified into new genera. A very common anaerobe, *Eubacterium lentum*, has been renamed *Eggerthella lenta*; there are now at least four or five other species of clinically significant *Eggerthella* spp. or the related *Paraeggerthella* spp.[292,493,498,499] Most of the other *Eubacterium* have been reclassified into over 11 new genus/species, as can be seen in Table 16-2. Most of these have been isolated from fecal or oral microbiota, as well as, from many clinical specimens, and in some instances have been implicated in diseases either as the sole cause of disease or as part of a polymicrobial infection.[128]

Many of the once *Bifidobacterium* spp. have been reclassified into the genera *Scardovia, Alloscardovia* or *Parascardovia*; *B. breve, B. longum, B. scardovia,* and *B. dentium* remain in the *Bifidobacterium* genus. All are part of the normal oral or GI microbiota, and may contribute to the normal oral or GI health, rarely playing a pathogenic role in dental caries and periodontitis.[482,499]

The lactobacilli are common inhabitants of the human mouth, GI tract, and female genital tract. They are used as a marker of "normal" vaginal microbiota when seen in scored Gram's stains of vaginal specimens from women who are being screened for bacterial vaginosis. Some of the lactobacilli are strict anaerobes, but others are facultative and this trait can make it difficult in their recognition and identification, unless newer molecular methods of identification are utilized. The most common species involved in clinical specimens are *L. rhamnosus* and *L. casei*.[68,195] Because lactobacilli are often incorporated in probiotic treatments, the possibility of their pathogenicity in nonimmunocompromised patients is often questioned. Some of the one-time *Lactobacillus* spp. have been reclassified and placed in the genera *Atopobium*, for example, *A. rimae* (formerly *L. rimae*) and *A. minutum* (formerly *L. minutus*).[13,105,319] Two other members of the genus are *A. parvulum* (formerly *Streptococcus parvulus*) and *A. vaginae*, a newly described species which has been associated with GU tract infections including bacterial vaginosis.[85,479] *Lactobacillus*

uli has been reclassified as *Olsenella uli*; another member of this genus is *O. profusa.* Both are microaerotolerant anaerobes found in the oral cavity and have been associated with dental plaque and endodontic disease.[118]

There are also many other new genera of anaerobic gram-positive NSF bacilli as seen in Table 16-2. Some of these have only been isolated from feces, suggesting they may play a role as normal microbiota of the GI tract. These include *Anaerofustis, Anaerostipes*, *Anaerotruncus, Catenibacterium, Colinsella, Dorea, Holdemanii,* and *Roseburia*. *Mogibacterium* is new genera with species primarily found in oral cavity; *M. timidum* is the new name for *Eubacterium timidum.*[211] The other newer genera that might have some clinical relevance will be discussed further below in the section on Human Infections.

Taxonomy of the Clostridium *spp.*

Clostridium spp. are a group of anaerobic spore-forming bacilli that can be part of the normal microbiota primarily of the GI tract; these are clinically relevant as the cause of both endogenous and exogenous infections. *Clostridium tetani* is the causative agent of tetanus; *C. botulinum*, the cause of many different forms of botulism; *C. perfringens*, one of the causes of gas gangrene, a cause of necrotizing skin infections, as well as a cause of food poisoning; and *C. difficile,* the cause of a syndrome of diarrheal conditions ranging from antibiotic-associated diarrhea (AAD) to pseudomembranous colitis (PMC) and associated complications. All of these are strict anaerobes, with the exception of *C. perfringens*. These produce spores readily in cultures from clinical specimens so that identification as a *Clostridium* spp. is usually not difficult. There are many other species of *Clostridium*, as seen in Table 16-2, and probably more will be identified with increased use of molecular and mass spectrometry techniques in clinical laboratories. One of the more commonly isolated species, *C. clostridiofome*, is now considered a complex of organisms, including *C. clostridioforme,*[163,518] *C. hathewayi,*[293,461] *C. bolteae,*[451] *C. aldenense,*[502] *C. citroniae,*[502] and *C. lavalense*.[121,518] The aerotolerant *Clostridium* sp., which includes *C. tertium, C. histolyticum,* and *C. carnis,* can easily be mistaken for aerobes.[173,330,464] There are species of *Clostridium* that have been newly designated and/or newly recognized as human pathogens, such as *C. disporicum*, an unusual *Clostridium* that produces a double spore, and *C. celerescrescens*, which is sometimes mistaken as a *C. clostridioforme* group isolate.[48,379] A few of the *Clostridium* spp. appear in Gram's stains only as gram-negative bacilli, such as *C. ramosum*[167] and *C. symbiosum*[478]; others that stain gram-negative have been reclassified in non-*Clostridium* genera. *Clostridium* spp. and related genera are a complex group of organisms responsible for a diverse group of infections, some of which have yet to be elucidated. In addition, as is shown in Table 16-1, there are other genera of spore-

forming anaerobic gram-positive bacilli, but thus far none of these has been demonstrated to be pathogenic nor related to any human infections, with the exception of *Filofactor alocis*, which has been isolated in endodontic infections.[437]

Taxonomy of the Anaerobic Gram-Positive and Gram-Negative Cocci

The anaerobic cocci are part of the normal microbiota of the oral cavity, GI tract, GU tract, and skin. As can be seen in Table 16-2, the more commonly isolated anaerobic cocci have undergone significant taxonomic changes.[351] The only remaining members of the genus *Peptostreptococcus*, once the predominant genus of anaerobic gram-positive cocci, are *P. anaerobius* and *P. stomatis*.[350] *P. anaerobius*, along with *Parvimonas micra* (once called *P. micros* and *Micromonas micros*) and *Finegoldia magna* (once called *Peptostreptococcus magnus*), are the most commonly isolated anaerobic gram-positive cocci today.[291,349,351] Four species that were once members of the genus *Peptostreptococcus* have now been placed in the *Peptoniphilus* genus and six in the *Anaerococcus* genus. The commonly isolated members of these genera include *Peptoniphilus assacharolyticus* (formerly *Peptostreptococcus assacharolyticus*), which is isolated from the oral cavity along with *F. magna,*[348,351] and *Anaerococcus prevotii* (formerly *Peptostreptococcus prevotii*), which is a common inhabitant of the GI and GU tracts.[230,351,446] Other new

genera that now contain former *Peptostreptococcus* spp. include *Gallicola, Slackia,* and *Blautia*. A few newly named species of anaerobic gram-positive cocci can be found in Table 16-2 and include *Blautia wexlerae, Ruminococcus gauvreauii, Anaerococcus murdochii,* [448] *Peptoniphilus* pathogen *Murdochiella assacharolytica*.[483] *Atopobium parvulum* is the new name of what was once referred to as *Streptococcus parvulum*, an anaerobic gram-positive coccus that is part of the normal microbiota of the oral cavity.[128] It should be noted that members of the genus *Atopobium* which are morphologically bacilli and not cocci will be discussed in the section on gram-positive rods. Lastly, two *Staphylococcus* spp., are considered to be anaerobes. They appear initially as strict anaerobes, but upon transfer can become aerotolerant. These are *Staphylococcus saccharolyticus* (once called *Peptotreptococcus saccharolyticus*) and *Staphylococcus anaerobius* subsp. *anaerobius.*[446] The former can be isolated quite frequently from anaerobic cultures, although clinical relevance is not always easy to determine. The genus *Peptococcus* contains only one species, *P. niger*, which is infrequently isolated from human clinical

specimens and will not be further discussed in this chapter.

The anaerobic gram-negative cocci, although not infrequently isolated in clinical specimens, are usually not associated with clinical disease. When these are associated with disease, it is usually as a component of a polymicrobial infection. There are now six genera (Table 16-2) of these anaerobes that are part of the normal human microbiota, with *Veillonella* spp. being the most commonly isolated.[72,312,446]

Human Infections Involving Anaerobes

Overview

Anaerobic bacteria have been demonstrated to cause infections in virtually every organ and anatomic region of the body. Some of the more commonly involved sites are illustrated in Figure 16-1.[519] Based on other reports in the literature, the relative incidence of anaerobes in infections is summarized in Table 16-4.[56–60,160,161,238]

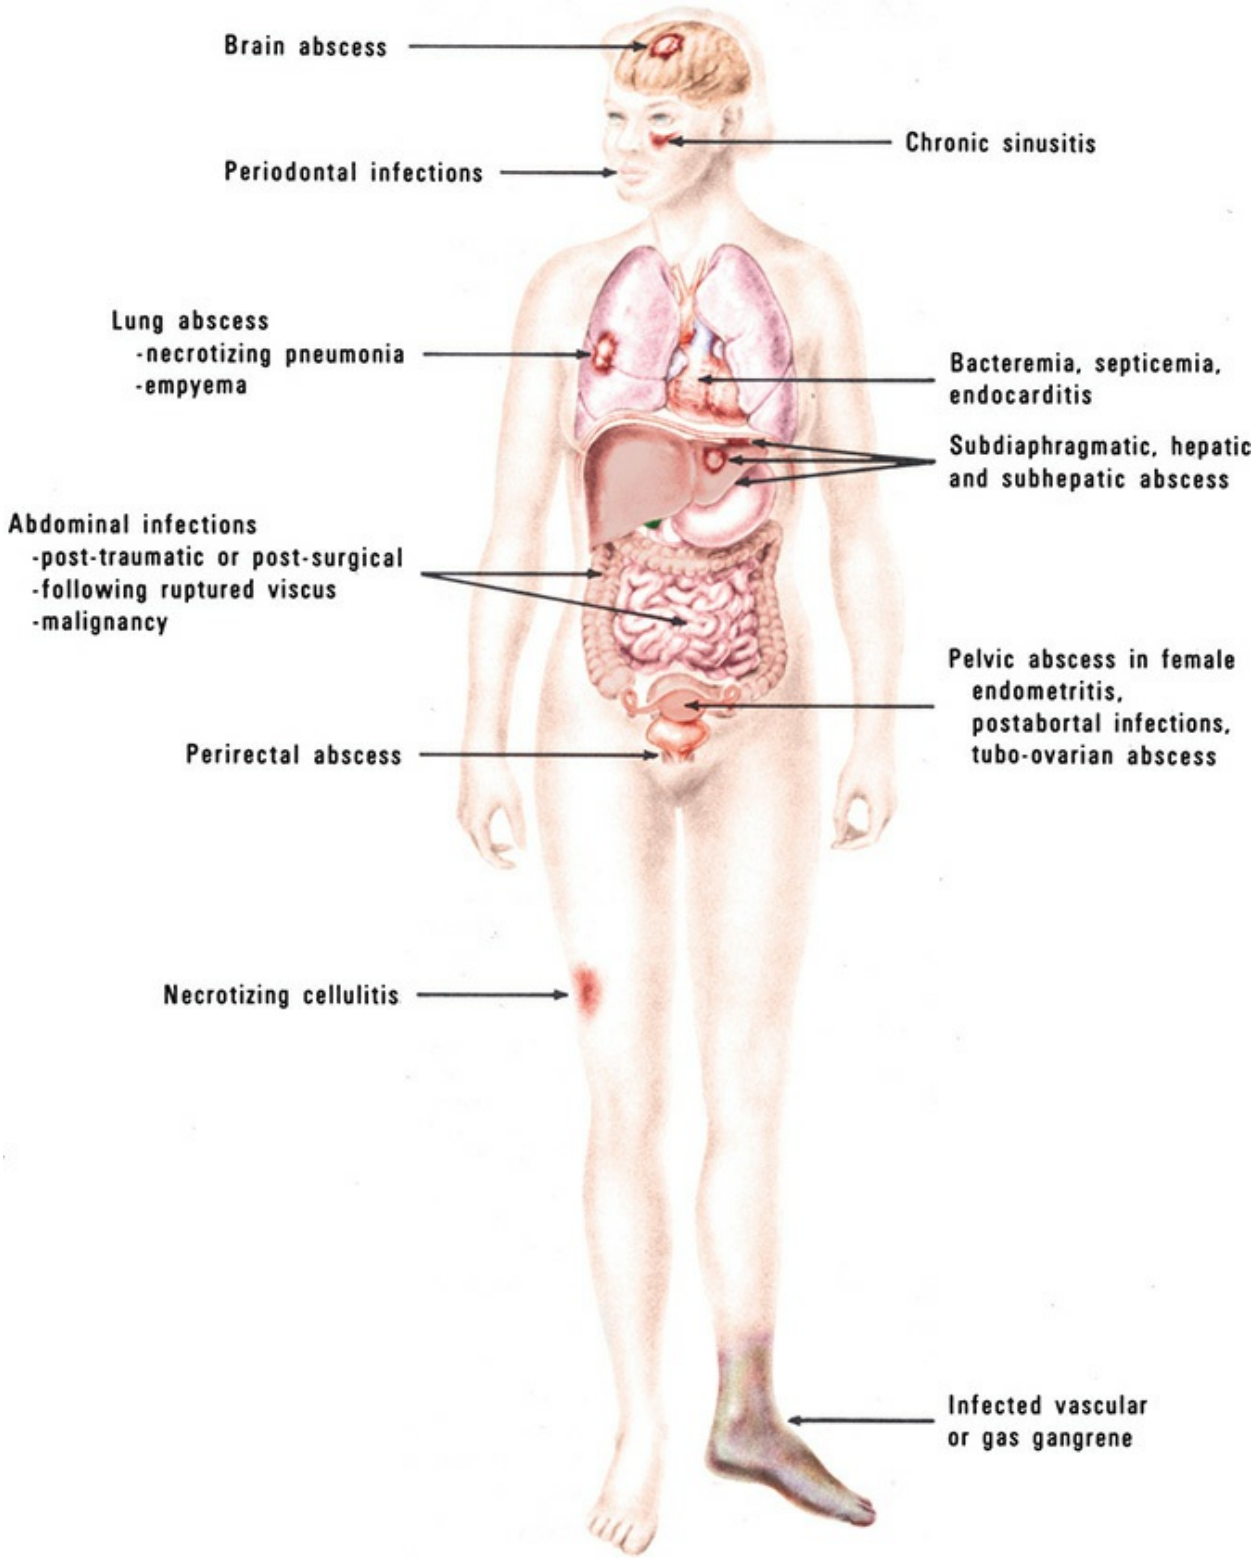
Most deep-seated abscesses and necrotizing lesions involving anaerobes are polymicrobial; these may include obligate aerobes, facultative anaerobes or microaerophiles as concomitant microorganisms.[160,161,238] These microorganisms, acting in concert with trauma, vascular stasis, and/or tissue necrosis, lower the oxygen tension and the Eh in tissues, and provide favorable conditions for the propagation of obligate anaerobes. Historically, infections and diseases involving anaerobes from exogenous sources are the ones that have been best known (Box 16-2). Within the past few decades, however, endogenous anaerobic infections have become far more common. There are two probable explanations. One is that the laboratory recovery of anaerobic bacteria has improved so that endogenous infections are no longer misdiagnosed or overlooked as they were in the past. The other is that a larger proportion of the patient population is receiving immunosuppressive drugs for malignancy and other disorders, resulting in populations of compromised hosts in which members of the normal microbiota, including anaerobes, can become opportunistic pathogens.[160,161] Primary anaerobic infections easily become established in areas of tissue damage. Bacteremia may ensue, with metastatic spread of bacteria and the formation of distant abscesses. This progressive chain of events sometimes results in a fatal outcome. The more common causes of endogenous anaerobic infections are listed in Box 16-3.

Not surprisingly, the most common anaerobic infections involve intra-abdominal abscesses, because of the predominance of anaerobes in the GI tract as normal microbiota; *B. fragilis* is the most common anaerobe in these infections, in particular due to the role of its capsule in abscess formation.[507] Most of the abscesses are polymicrobial, involving aerobes and anaerobes. Peritonitis, due to a break in the

barriers of the GI tract (often referred to as secondary peritonitis) is most often due to a mixture of aerobes (most commonly *E. coli*) and anaerobes (most commonly *B. fragilis*). A study of children whose peritonitis results from a perforated appendix determined that 81% of the peritoneal cultures were positive for *E. coli*, which were nearly always susceptible to amoxicillin/clavulanate, and 54% for anaerobes, all of which were found susceptible to metronidazole. Their study corroborated the use of these two agents for treatment.[361] In contrast, spontaneous bacterial peritonitis is rarely an anaerobic infection; likewise, peritonitis associated with peritoneal dialysis is rarely an anaerobic infection, however, when it does occur, it is due to contamination of the catheter, is most often polymicrobial and carries a good prognosis.[87] Pyogenic liver abscesses, most of which have a cryptogenic source, can be due to a mixture of aerobes and anaerobes. One study showed a predominance of *K. pneumoniae* (45%) and *E. coli* (32%); however, anaerobes were found in only 9% of positive cultures.[309]

Anaerobes are a significant component of the oral cavity and contribute greatly to periodontitis and other oral/dental infections. However, anaerobic bacteria are infrequent pulmonary pathogens, except in selected infections such as aspiration pneumonia, lung abscess, necrotizing pneumonia and empyema. Because laboratories do not process most specimens for anaerobes that are sent to the laboratory for diagnosis of pneumonia, ie sputum, bronchoalveolar lavage and endotracheal aspirates, due to the contamination of the specimen by the upper airway microbiota, which includes anaerobes. Recognition of the probable presence of anaerobes on direct Gram's stains of sputum can be very helpful to the clinicians who might not otherwise suspect aspiration pneumonia; if aspiration or necrotizing pneumonia is expected and identification of the anaerobes is requested, collection of appropriate specimens for anaerobic cultures, using a protected fiberoptic collection device or sending lung tissue aspirates is needed.[37] Bartlett's review of anaerobic infection of the lung in 2012 suggested that pleural fluid and transthoracic needle aspiration are the best specimens for the meaningful recovery of anaerobes since transtracheal aspirates are no longer performed, and fiberoptic bronchoscopy specimens are not often handled appropriately.[36] The most common anaerobes involved in these usual polymicrobic pulmonary infections, are *F. nucleatum*, the pigmented *Porphyromonas* spp. (<10%),*Prevotella* spp. (30% to 50% and these are often β-lactamase positive) and the anaerobic streptococci. The *B. fragilis* group is involved in <10% of pulmonary infections.[238] Antibiotics that cover these anaerobes and drainage of the area is necessary for treatment.[36,37]

997



■ **FIGURE 16-1** Common locations of infections involving anaerobic bacteria.

Skin and soft tissue infections are often caused by aerobic gram-positive cocci that

predominate as normal microbiota; however, complicated skin and soft tissue infection may involve anaerobes, and result from endogenous or exogenous sources.*Clostridium* spp. such as *C. perfringens* predominate in exogenous infections; animal and human bite wounds often involve anaerobes. A review of the microbiology of dog and cat bite wounds, as well as bites from other more exotic animals demonstrated that 48% of dog bite wounds resulted in a polymicrobial infection that often included anaerobes, but anaerobes alone were responsible for disease in only one patient with a mixed infection caused by *Porphyromonas/Bacteroides* (Image Plate 16-2B). The most common anaerobe isolated from dog bite wounds was *F. nucleatum*, followed by species of *Bacteroides, Porphyromonas, Prevotella*, *Peptostreptococcus,* and *P. acnes*. From cat bite wounds, 78% were found to be mixed anaerobic/aerobic infections and again *F. nucleatum* was the most common isolate. Other organisms recovered included other species of *Fusobacterium*, *Bacteroides* spp., *Porphyromonas, Prevotella* and a wide variety of other anaerobic species.[1]

998

TABLE 16-4 Percent of Positive Cultures That Yielded Anaerobes in Infections

Type of Infection	Percentage (%) of Positive Cultures With Anaerobes
Pulmonary	
Aspiration pneumonia	62–93
Lung abscess	58–100
Empyema (thoracic)	22–36
Bacteremia	1–17[a]
Brain abscess	62–83
Sinusitis	
Chronic sinusitis	48–100
Acute sinusitis	<10
Dental, oral, facial	67–100
Abdominal[b]	

Intra-abdominal	60–100
Liver abscess	<60
Pelvic[c]	50–100
Soft tissue infections	
Bite wounds	50–70[d]
Nonclostridial crepitant cellulitis	75
Gas gangrene (clostridial)	100
Diabetic foot ulcers	50–90[e]
Miscellaneous infections	
Urinary tract infection	<5[f]
Meningitis	<10

[a] From a review of anaerobic bacteremia by Brook, 2010.[58] Others have reported incidence of 7%–9% in 2008 and 2013.[155,354]

[b] Varies depending upon whether the patients are postsurgical or not.

[c] Varies considerably; pelvic inflammatory disease, <50%; pelvic or vaginal cuff abscess, 98%; postpartum endometritis, 66%.

[d] Depends on whether animal or human.

[e] Depends on methods of culture collection.

[f] May change using molecular or other new methods of direct specimen detection.

Modified from Jousimies-Somer et al.[238]

Anaerobes are responsible for 1% to 17% of bacteremia as reported in a review by Brook in 2010. The most common anaerobes were *B. fragilis*, followed in lesser incidence by anaerobic gram-positive cocci, *Clostridium* spp. and *Fusobacterium.*[58] A Canadian population-based surveillance study of anaerobic bacteremia between 2000 and 2008 found an incidence of 8.7/100,000 per year, with the predominant organisms as follows: *B. fragilis, Clostridium* (non-*perfringens*), *Peptostreptococcus* (includes *F. magna*), and *C. perfringens*. Male sex, increasing age, and a host of underlying illnesses and malignancies were predisposing factors; 30 day mortality was 20%.[354] In literature from the 1980s and 1990s, anaerobes were reported to cause 1% to 11% of

cases of endocarditis.[413,505] In a more recent review of the still infrequent anaerobic causes of endocarditis, the most common anaerobes were microaerophilic streptococci, *P. acnes, B. fragilis* group and *Clostridium* spp; mortality was high ranging from 21% to 43%.[57]

BOX 16-2

Anaerobic Infections of Exogenous Origin

Clostridium difficile hospital-acquired (nosocomial) diarrhea

Food-borne botulism

Infant botulism

Wound botulism

Clostridium perfringens gastroenteritis

Myonecrosis (gas gangrene)

Tetanus

Crepitant (anaerobic) cellulitis

Benign superficial infections

Infections following animal or human bites

Infections of injection drug abusers

Septic abortion

BOX 16-3

Anaerobic Infections of Endogenous Origin

Abscess of any organ

Actinomycosis

Aspiration pneumonia

Bacteremia

Bacterial vaginosis

Complications of appendicitis or cholecystitis

Crepitant and noncrepitant cellulitis

Dental and periodontal infections

Endocarditis

Endophthalmitis, usually following cataract surgery

Lemierre's syndrome (*Fusobacterium necrophorum*): also known as necrobacillosis

Meningitis, usually a complication of a communicating brain abscess

Necrotizing fasciitis

Necrotizing pneumonia

Osteomyelitis

Chronic otitis media

Peritonitis

Septic arthritis

Chronic sinusitis

Subdural empyema

Thoracic empyema

999

It is essential to isolate and identify anaerobic bacteria because these infections are associated with high morbidity and mortality, and the treatment of the infection varies with the bacterial species involved. Antibiotic therapy for certain anaerobic infections

is different from that used for many infections caused by aerobic or facultatively anaerobic bacteria.[160,443,444] Prompt surgical intervention, including debridement of necrotic tissue or amputation of a limb, may be of extreme importance, particularly for patients with clostridial gas gangrene or in loculated abscesses into which antibiotics penetrate poorly until the exudate is drained.

Infections Involving Anaerobic Gram-Negative Bacilli

Prior to the mid-1960s, clostridial infections predominated. In recent years, however, <15% of all anaerobes were species of *Clostridium.*[159] Currently, more than three-fourths of anaerobes isolated from properly selected clinical specimens are accounted for by the *Bacteroides fragilis* group, *Prevotella, Porphyromonas, Fusobacterium*, the anaerobic cocci, and the anaerobic gram-positive NSF rods (Table 16-3).

The most common disease-producing, anaerobic gram-negative NSF rods isolated from clinical specimens are members of the *Bacteroides fragilis* group (including *Parabacteroides* spp.), the *Prevotella-Porphyromonas* (formerly members of the pigmented *Bacteroides*) groups and *Fusobacterium nucleatum*. *B. fragilis, B. thetaiotaomicron* and other species of the *B. fragilis* group are especially common. They are particularly important not only because they may be isolated from a variety of life-threatening infections, but also because of their resistance to the action of penicillin and its analogs and their resistance to many cephalosporins (including the third-generation cephalosporins) and the tetracyclines; the emergence of resistance to several of the newer quinolones; and increasing resistance to clindamycin.[149,188,190,355,364,443,444,507] Lorber has recently reviewed the role of anaerobes, especially *Bacteroides*, in the maintenance of health and their role in clinical disease.[301]

As mentioned above, members of the *Bacteroides fragilis* group are responsible for a variety of clinical infections, but the species *B. fragilis* has the highest incidence. A number of virulence factors have been demonstrated to explain the enhanced virulence and pathogenicity of this particular species: the presence of agglutinins and fimbriae that provide adhesion ability; protection against the host immune response due to the presence of a capsule to evade phagocytosis; mechanisms to ameliorate oxygen toxicity; and, destruction of host tissue via production of histiocytic enzymes. *B. fragilis* is most commonly responsible for intra-abdominal abscesses and sepsis, but is also involved in gynecological abscesses, skin and soft tissue infections, pericarditis (as a result of hematogenous spread to the heart), bacteremia often associated with malignancies or in postsurgical infections and rare instances of endocarditis, meningitis and septic arthritis.[420,507] At one time, the incidence of bacteremia following post-GI and post-GU surgery was high and carried a very high mortality (up to 60%), but with prophylaxis directed toward anaerobes and aerobes, that incidence has decreased. The

mortality associated with *B. fragilis* infection, however, can be as high as 19% and even higher when the patient has endocarditis, for example.[507] *B. thetaiotaomicron* and *B. ovatus* are two other members of the *B. fragilis* group that are more commonly involved in anaerobic infections than other members of the group (other than *B. fragilis*); they constitute a significant proportion of the microbiota of the GI tract, much more so than *B. fragilis*. Therefore, it is not surprising that breaks in the GI mucosa afford entry for these bacteria and consequent intra-abdominal infections. Many times in clinical laboratories, anaerobic gram-negative bacilli that grow on *Bacteroides fragilis* selective media (like *Bacteroides* bile esculin) may be reported out as "*B. fragilis* group"; so it is difficult to know how common some of the other members are in infections. With increased use of molecular methods and MALDI-TOF in the future, we should expect to be able to better determine what species really are involved in clinical infections; two of the more recently identified species using molecular techniques, *B. dorei* and *B. finegoldii*, have been specifically identified in blood cultures.[21,22,263]

Bacteroides ureolyticus, the corroding anaerobic gram-negative bacillus that remains as one of the few members of the non-*Bacteroides fragilis* group at least presently, has been associated with periodontal disease and has been isolated from a patient with sinusitis, but the relevance in this instance was unknown; rarely, it has been implicated in nonoral infections. There is at least one report of bacteremia and meningitis.[60,511]

Many of the pigmented *Bacteroides* are now in the *Porphyromonas* genus. Three are members of the oral microbiota, but may also be pathogens there, causing infections, such as periodontitis, dental abscesses and infected root canal. The oral species are *P. gingivalis*, the most significant and frequently isolated, *P. endodontalis* and *P. catoniae*, a recently named species.[263] *P. catoniae* has not been involved in oral infections, but has been isolated from an abdominal abscess.[263] Skin and soft tissue infections, including diabetic foot infections, have been caused by *P. asaccharolytica*[469] and *P. somerae.*[467] A new *Porphyromonas* sp., *P. uenonis,* has been found in appendicitis, peritonitis, sacral decubitus ulcers, pilonidal abscesses and other wounds of buttocks and groin.[165,466] Another oral pathogen closely related to the genus *Porphyromonas* is *Tannerella forsythia* (formerly *Bacteroides forsythus*). It plays a substantial role in periodontal disease. It has also been isolated from vaginal specimens from women suspected of having bacterial vaginosis and synovial specimens from patients with arthritis.[193,263,396]

The genus *Prevotella* has over 37 species of what were once *Bacteroides* spp. or have been newly named. About one-third of the strains are pigmented and the remaining are nonpigmented. Most members of the genus are found in the oral cavity as commensals (Table 16-2); however, many have also been associated with oral and

even nonoral infections. *P. intermedia* and *P. nigrescens*, related oral species which are difficult to distinguish phenotypically, are commonly detected in cases of gingivitis, root canal infections, dental abscesses, and other oral and dental infections. *P. intermedia* has a large role in periodontitis.[263]*P. nigrescens* has also been isolated

1000

from a patient with cellulitis.[529] *Prevotella bivia* and *P. disiens* have been isolated from blood, head and neck infections, GU tract infections in both males and females, and other sites of infection.[263] One recent study found higher bacterial counts of *P. bivia* and *P.disiens* in patients with bacterial vaginosis and gingivitis as compared to patients with bacterial vaginosis without gingivitis.[372] *P. melaninogenica* (formerly *B. melaninogenica*, and a very commonly identified pigmented oral anaerobe) has been found in the sputum of patients with cystic fibrosis, as have *P. denticola, P. oris,* and *P. salivae*.[238,263] Isolates of *P. bivia, P. disiens, P. buccae, P. denticola*, and *P. nigrescens* have been found in bloodstream infections.[263,436] An observational study of the incidence and characteristics of gram-negative bacilli from many tertiary hospitals in Greece (2005 to 2006) found that the majority of infections were intra-abdominal, skin and soft tissue, or pelvic; the majority were polymicrobial. *Prevotella* spp. were more frequently isolated from respiratory tract infections, superficial wounds and patients with diabetes as compared to *Bacteroides* spp. (primarily *B. fragilis* group), which were predominant in intra-abdominal infections and bacteremia. Many more of the patients with infections with *Prevotella* spp. were treated as outpatients, with most being skin and soft tissue infections, possibly indicating less serious diseases. Clindamycin was used more successfully for *Prevotella* spp. than when infections included members of the *B. fragilis* group in the intra-abdominal infections. *Prevotella* spp. did demonstrate more resistance to metronidazole (16%) than did *Bacteroides* spp. or *Fusobacterium* spp. (both less than 1%).[367] One of the non-*B. fragilis* group, *B. ureolyticus,* is a significant component of the normal oral microbiota, but has been involved in oral infections, infected sinuses, and head and neck space infections.[511]

F. nucleatum and *F. necrophorum* are the most commonly isolated species of the *Fusobacterium* genus. *F. nucleatum* is part of the microbiota of the oral cavity, along with *F. periodonticum* and *F. simiae*, but is responsible for production of biofilms in periodontal pockets and hence involved in periodontal disease. *F. nucleatum* is the species most commonly found in clinical specimens. Recent attention has been called to severe systemic infections caused by *F. nucleatum* in patients with neutropenia and mucositis following chemotherapy.[67,150] *F. nucleatum* along with members of the *Prevotella-Porphyromonas* group are the organisms most frequently involved in

anaerobic pleuropulmonary infections (e.g., aspiration pneumonia, lung abscess, necrotizing pneumonia, and thoracic empyema). In addition, *F. nucleatum* can cause bacteremia, abscesses, and infections of the GI tract, joints, brain, and GU tract.[263] The second most commonly isolated species, *F. necrophorum,* is divided into two subspecies,*fundiliforme* and *necrophorum*, but only *F. necrophorum* subsp. *fundiliforme* is recognized as a cause of human infection. *F. necrophorum* subsp. *fundiliforme* has been shown to be the cause of as many as 20% of acute pharyngitis cases especially in adolescents and young adults, and up to 20% of cases of recurrent or persistent, chronic sore throats. It can cause abscesses in adolescents, otitis media and mastoiditis in children, peritonsillar abscesses in adolescents and young adults and sinusitis in adults aged 30 to 50 years.[289,530] Perhaps more significantly, it is the primary cause of the severe and possibly life-threatening condition, Lemierre's syndrome, which has a greater incidence, morbidity and mortality than even rheumatic fever in adolescents and young adults in the Western Hemisphere.[51,56,384,393,394,474]

Lemierre's syndrome (anaerobic postanginal septicemia or necrobacillosis) usually begins with pharyngotonsillitis, followed by unilateral swelling and tenderness along the sternocleidomastoid muscle due to septic thrombophlebitis of the jugular vein. This proceeds to high fevers and metastatic lung abscesses. If recognized early and treated appropriately, it is responds to therapy, but it remains a challenging clinical and laboratory diagnosis.[51,92] Lemierre's and other disseminated *F. necrophorum* infections were prospectively investigated from 1998 to 2001 in Denmark. Fifty cases were found with an incidence of 14.4 cases per million annually in patients that ranged in age from 15 to 24 year olds. The infection originated mainly from an oropharyngeal infection but there were other instances originating from ear, sinus or teeth. The overall mortality was 9%. In older patients, Lemierres was found to have originated from foci in lower parts of body and patients often had predisposing diseases, leading to a mortality of 26%.[268] An immunocompetent patient with fulminant meningitis that developed subsequent to *F. necrophorum* otitis media has been reported, as well as a young adult patient with endocarditis.[12,339] Lastly, an epidural abscess in an elderly gentleman was found to contain *F. necrophorum* using molecular methods.[412]

Fusobacterium prausnitzii, a gram-negative anaerobe that makes up to 5% of the human GI tract normal microbiota and appears to be responsible for balancing the immune responses in the gut, has been reclassified as *Faecalibacterium prausnitzii*.[333]There is a recent review article about the significance of *Fusobacterium* spp. in serious infections. The incidence of *Fusobacterium* was 0.76 cases/100,000 in this study, and *F. necrophorum* was the most common pathogen. *F. nucleatum* and *F. varium* were described in this study as well.[376] This reference should be referred to for more information about the relevance of *Fusobacterium* spp.

Among the more recently described genera of anaerobic gram-negative bacilli, some

references are included in Tables 16-1 and 16-2, but only a few of these organisms are considered further here. The bile-resistant and pigmented *Allistipes* spp., for example, have been recently linked to appendicitis in children and species of the genus have been isolated from blood, intra-abdominal fluid, abscesses, and urine.[263] *Bilophila wadsworthia,* a non-*B. fragilis* group organism that is bile-resistant and a strict anaerobe, has become recognized as a significant human pathogen. The fastidious nature of this organism, however, may limit our ability to recover it from clinical samples and hence decrease its routine recognition. It is also an isolate found in normal fecal microbiota. Baron brought this organism to our attention in 1997 describing its involvement in polymicrobial intra-abdominal infections, especially appendicitis, and more recently, two patients in Hungary. One of these patients had mastoiditis, whereas the other had a brain abscess.[29,484] With the use of better collection procedures and culture methods for the isolation of anaerobes, as well as the use of molecular methods or mass spectrometry, laboratories may begin to more frequently detect this often antimicrobial resistant pathogen. Box 16-4 describes cultural and clinical characteristics of *B. wadsworthia*.

1001

BOX 16-4

Characteristics and Clinical Significance ofBilophilaspp.

Gram-negative, non–spore-forming, nonmotile, pleomorphic rods; 0.7–1.1μm in width by 1–10 μm in length

Growth enhanced by 20% bile and by 1% pyruvate; grows slowly on BBE medium; colonies on BBE after 4 days of incubation were described as 1–2 mm (diameter), either as circular, erose, umbonate, and translucent with dark black centers, or as irregular, low convex, and opaque black colonies

Colonies on Brucella agar formed slowly (4–7 days), were punctate, less than 1 mm in diameter, circular, erose, translucent, and gray

Strongly catalase-positive (using 15% H_2O_2)

Asaccharolytic

Urease-positive

β-lactamase-negative (nitrocefin test), but nonetheless, resistant to β-lactam antibiotics

Clinical Relevance: GI microbiota; common isolate in human specimens if culture conditions are optimal; perforated and gangrenous appendicitis, surgical abdominal infections; bacteremia.[30,263,484]

Desulfovibrio, a curved, often motile, gram-negative bacillus is in the same family as *B. wadsworthia*. It is a human fecal isolate, but *D. desulfuricans* and *D. fairfieldensis* have also been isolated from clinical specimens, including blood cultures.[263,495] Like *B. wadsworthia*, species of *Desulfovibrio* are often difficult to recover in laboratories without special media and the capability of molecular methods for identification, but they should be kept in mind when a curved gram-negative anaerobe is isolated from a blood culture.[292]

Leptotrichia spp. are large gram-negative "fusiform-shaped" nonmotile bacilli that are part of the normal oral microbiota. It is infrequently isolated in clinical specimens, but can cause disease in patients with underlying malignancies who have neutropenia and may have some form of mucositis/gingivitis. It has been isolated from blood and peritoneal fluid; at least one instance of endocarditis has been attributed to *L. buccalis* as well.[40,198] A few newly named species of *Leptotrichia, L. trevisanii,* and *L. goodfellowei* have also been reported to cause bacteremia and endocarditis, respectively, in immunocompromised hosts.[69,270] In addition, *Sneathia sanguinegens* (formerly *Leptotrichia sanguinegens*) has been associated with bacteremia, as well as, bacterial vaginosis.[103,120] Lastly, a long spiral-shaped gram-negative rod, *Anaerospirillum* spp., has been reported from patients with bacteremia and diarrhea; these patients had underlying disorders, including alcoholism, malignancy, diabetes, and poor dentition.[377,472] The pathogenicity and clinical relevance of this organism was recently reviewed by Kelesidis.[250]

Box 16-5 provides information on the clinical relevance of some species of anaerobic gram-negative bacilli that were not discussed above.

BOX 16-5

Clinical Relevance of Selected Anaerobic Gram-Negative Bacilli

Species	Clinical Relevance
Alistipes spp.	GI flora; isolated from abdominal infections and urine[157,447]
Anaerobiospirrilum succiniproducens	Bacteremia[250]
Catonella morbi	Endocarditis[329]
Dialister pneumosintes	Endodontogenic infections and sinusitis[135]

Filifactor alocis	Endodontic infections[193]
Leptotrichia spp.	Bacteremia[270]; peritonitis[198]; endocarditis[69]
Sneathia sanguinegens	Bacteremia[103]; associated with bacterial vaginosis
Sutterella wadsworthensis	Peritonitis; intra-abdominal abscesses; bacteremia[336]
Tannerella forsythensis	Endodontic infections[193,396]
Centipeda sp.,*Johnsonella* sp.; many *Leptotrichia* sp., *Pyramidobacter* sp., *Selenomonas* spp.	Oral flora; occasional case reports of infection
Anaerostipes sp.,*Barnesiella* sp., *Cetobacterium* sp., *Desulfovibrio* spp., *Faecalibacteriumprausnitzii, Megamonas* sp.,*Oxalobacter* sp.,*Paraprevotella* sp., *Parasutterell* sp.	Fecal flora; occasional case reports of infection

Information from reference 263 and other references as noted in table.

1002

Infections Involving Anaerobic Gram-Positive NSF Bacilli

Actinomycosis is an acute and chronic infectious disease characterized by suppurative lesions, abscesses and draining sinus tracts. The disease most often presents as cervicofacial, thoracic, abdominal or pelvic actinomycosis, but it can occur in other regions of the body.[109,186,378,382,401,499] *Actinomyces israelii* is the major cause of all forms of actinomycosis. Other species that are established causes of actinomycosis, though less frequently encountered in this condition than *A. israelii*, are *A. naeslundii, A. odontolyticus, A. meyeri, A. viscosus, A. gerencseriae,* and *Propionibacterium propionicum* (formerly *Arachnia propionica*). Although encountered in relatively low frequency in routine specimens, all of these species are well-documented pathogens. Members of the genus were first described in the 19th century; *A. bovis* was isolated from purulent drainage of a condition referred to as "lumpy jaw" in cattle. The association of actinomycosis and the use of an intrauterine device (IUD) have been recognized for many years. Although there has been controversy about how the diagnosis is made, the presence of abdominal pain in a

patient with an IUD should raise suspicion of pelvic actinomycosis.[383] There have been a number of reports in which actinomycosis cases are mistaken for tumors, sometimes leading to difficult and unnecessary surgical resections.[365] Many of the species of *Actinomyces*, such as *A. odontolyticus* and *A. naeslundii,* are part of the normal oral microbiota, and although they can be associated with human disease, their isolation from the respiratory tract may not always indicate that they are involved in any infectious processes. Correlation with the clinical picture, finding of *Actinomyces*-like organisms on Gram's stain, and isolation of the organism from sterile sites increase the likelihood of their role in the disease.

A. meyeri, although an uncommon cause of actinomycosis, can be associated with pulmonary disease more often than other species of *Actinomyces* and appears to have a predilection for dissemination. A series that reviewed 32 patients, disclosed poor dental hygiene and alcoholism as predisposing factors. The patients did respond well to a combination of penicillin therapy and surgical debridement.[153] An elderly patient with poor oral hygiene who developed meningitis caused by *A. meyeri* has also been reported; no anaerobic cultures of cerebrospinal fluid (CSF) were performed, although gram-positive rods were seen on Gram's stain; a blood culture was positive for *A. meyeri* in this patient.[200] More recently described *Actinomyces* species, using sequencing or mass spectrometry, have been associated with a variety of infection. *A. europaeus* has been associated with breast abscess, *A. cardiffensis* with septicemia in conjunction with lung and hepatic abscesses and *A. funkei* with endocarditis.[203,423,435,506] A report by Clarridge and colleagues aids in assessing the significance of several recently described species.[99] *A. turicensis* and *A. neuii* are two more recently described species that are responsible for a wide variety of clinical infections including breast abscess, endophthalmitis, bacteremia, and endocarditis.[310,402,497] Although the new species listed in Table 16-2 have been isolated from various human clinical sources, information still is lacking for many of them as to their clinical importance, but where reports were found, the references are included in the table. Two new genera, *Actinobaculum* and *Varibaculum*, are related to *Actinomyces* spp. Isolates *Actinobaculum* have been associated with urinary tract infections and also have been isolated from blood.[204,282,356]

Propionibacterium acnes, at one time often considered a contaminant when isolated from clinical specimens, has proven to be a pathogen when recovered from sterile sites such as ocular fluid in patients with postsurgical endophthalmitis, from blood in patients with endocarditis and in infections associated with surgically implanted prosthetic devices.[295,324,328,501] The latter includes infections following shoulder, hip and knee replacement, as well as and shunt-related infections of the central nervous system.[290,324,501] The association of *P. acnes* in lumbar disc herniation and infection has been reported when *P. acnes* was found in the excised herniated disc

tissue of 38% of the 64 patients in the study.[399] It can be difficult to determine the significance of the isolated *P. acnes*, but in true infections, the organism is repeatedly isolated, often seen on direct Gram stains of the specimens, and is the only isolate from the source of infection. Response to appropriate antibiotics can also play a role in determination of its significance.[371] *P. propionicum* (formerly *Arachnia propionicus*) is part of the normal oral cavity microbiota, but has been associated with infections of the lacrimal ducts and has been reported to cause actinomycosis-like infections in the pelvis.[499,524]*P. acidifaciens* is a member of normal oral microbiota but also has been associated with dental caries.[134,499] *P. granulosum* has been associated with infections following arthroplasty along with *P. acnes* and other *Propionibacterium* spp.[331,360] A related gram-positive bacillus, *Propionimicrobium lymphophilum*, has been isolated from lymph node of a patient with Hodgkin's disease.[457]

Eubacterium spp. are part of the normal GU and GI tracts. Many of the species are rarely isolated from clinical specimens as significant pathogens. This, however, may change with advances in molecular and mass spectrometry methods for identification. Tables 16-2 and 16-20 list the few remaining members of the genus *Eubacterium* as well as the newer genera. One of the more common clinical isolates, *Eggerthella lenta* (formerly *Eubacterium lentum)* has been associated with numerous patients with bacteremia, both as the sole pathogen and as part of a polymicrobial infection.[287,292,493] In a review of 25 patients with bacteremia caused by *E. lenta* wherein this was the only organism isolated in blood culture, 52% of the patients had fever, hypotension or leukocytosis during the bacteremia and in 44% an abdominal source was found. Mortality was high with 39% of the patients dying within 30 days of the diagnosis.[493] In addition, *Paraeggerthella hongkongensis* (formerly *Eggerthella hongkongensis)* and *Eggerthella sinensis* have recently been described as responsible for bacteremia, and like *E. lenta*, associated with significant morbidity and mortality.[280] *E. lenta* has also been described to cause multiple brain abscesses, liver abscesses, necrotizing pneumonia and osteomyelitis in an immunocompetent young man.[410] *Eubacterium limosum* made up 6% and *E. lenta* 24% of all anaerobes isolated in infections in patients with leukemia and solid tumors in a study from Egypt; in this study, anaerobes overall were responsible for 5% of the infections in this population.[145] It may be that the fastidious nature of these anaerobic gram-positive NSF bacilli has been overcome with newer isolation techniques and better

methods for identification; their relevance may continue to increase and laboratories should not dismiss their isolation especially from sterile sites.[281] *Solobacterium*

moorei, another *Eubacterium*-like gram-positive NSF bacillus, has been found responsible for oral infections and is associated with halitosis. It is not often found outside the oral cavity, but has been isolated from a few patients with bacteremia.[246,369] The taxonomy and phenotypic characteristics of other members of *Eubacterium*-related genera of anaerobic gram-positive NSF are given in Tables 16-2 and 16-20.

The genus *Bifidobacterium* has undergone taxonomic changes and now includes many species in the newly named genera or genera of *Bifidobacterium*-like anaerobes. They are normal microbiota in the human GI tract and are functionally important to the health. They can, however, be found in polymicrobial infections in which their significance may be greater than previously appreciated. *Bifidobacterium dentium* (previously *Bifidobacterium eriksonii)* is primarily associated with dental caries,[161,307] and like other bifidobacteria (e.g., *B. longum, B. adolescentis,* and *B. breve*) is isolated rarely from clinical specimens; it can, however, be involved in infections of immunocompromised hosts.[499] Many of the *Bifidobacterium* spp, along with *Lactobacillus* spp, are important in development of probiotics used for health nutrition and maintenance. *B. scardovia* has caused recurrent urinary tract infections in the elderly and has also been isolated from blood and other sites.[25,499] *Bifidobacterium*-like gram-positive anaerobic bacilli, now in other genera, such as *Parascardovia denticolens, Scardovia inopinata,* and other *Scardovia* spp., have been reported as potential pathogens when isolated from clinical material, especially in association with dental caries. Their significance in other infections has not been delineated.[126,233,499] The related *Alloscardovia omnicolens* has been isolated from a variety of sites, including urine, the GU tract, blood, lung, and the aorta, where it produced abscesses; it is felt to have pathogenic potential.[227,307]

Lactobacilli are commensals of the human microbiota, but are not regularly associated with clinical disease. *Lactobacillus* spp. rarely may cause endocarditis, but their pathogenicity when isolated from blood cultures not in association with endocarditis, or when isolated from other sites is not well defined.[68] Analysis of *Lactobacillus* spp, isolated from many sites over a 5-year period of time in a French hospital, demonstrated that *L. rhamnosus* was the most commonly isolated species and was isolated from blood cultures of 16 patients. The majority of these patients were immunosuppressed and/or had a catheter-related bacteremia. A review of 45 additional patients from the literature supported these findings.[195] The pathogenic potential of over 200 patients with *Lactobacillus* bacteremia, endocarditis and localized infection was reviewed in 2005. A 30% overall mortality was reported, although this was not deemed attributable mortality. Therefore *Lactobacillus* bacteremia may be an indicator of a serious underlying illness and/or a marker of poor long-term prognosis. In this study, the mortality rate for *Lactobacillus* endocarditis

was 23%. The localized infections in which *Lactobacillus* spp. were isolated included pulmonary infection, abscesses, endophthalmitis, meningitis, and vascular graft infections, among others.[68]

Some of the lactobacilli have been reclassified. For example, *L. uli*, which resides in gingival crevices, is now in genus *Olsenella. O. uli* has been associated with periodontitis and necrotizing gingivitis.[118] One instance of bacteremia due to this organism has been described.[274] *O. profusa* is a newly recognized species which has is also found in gingival crevices.[118] Another *Lactobacillus*-related group of organisms are now in the genus *Atopobium*. *A. minutum* (formerly *L. minutus*) and *A. rimae* (formerly *L. rimae*) are both found in gingival crevices.[105] *A. vaginae*, a new species, has been found in the vagina in association with GU infections.[85,479]

In 1984, Spiegel and Roberts proposed the name *Mobiluncus* for a new genus of gram-variable or gram-negative, motile, curved, NSF anaerobic rods, which occur singly or in pairs and have a "gull wing" appearance.[456] Electron micrographs revealed multilayered cell walls lacking an outer membrane that were more typical of gram-positive than gram-negative cell walls; nonetheless, the organisms tend to stain gram-variable in young culture and gram-negative in older culture. The name *Mobiluncus* was derived from the Latin words *mobilis* (meaning capable of movement) and *uncus* (which means hook).[456] The pathogenic potential of *Mobiluncus* spp., if any, is still not clear. It has been isolated from patients with extragenital infections on a few occasions, and there is a report of the isolation of this organism from a patient with severe sepsis.[185,218] The organism is one of many genera of anaerobes that colonizes the vagina in both health and disease.[499] *Mobiluncus,* along with other anaerobes, can be present in vaginal samples of women with bacterial vaginosis.[219,455]

Bacterial Vaginosis. Bacterial vaginosis involves an overgrowth of multiple bacteria, including *Gardnerella vaginalis, Mycoplasma hominis, Mobiluncus spp., Prevotella bivia, Prevotella disiens* and other *Prevotella* spp., *Peptostreptococcus anaerobius, P. asaccharolyticus, P. magnus* and other anaerobic cocci and anaerobic gram-positive rods including *Propionibacterium spp*.[219,455] Therefore, vaginosis is a synergistic infection in which many organisms play a role. As reviewed elsewhere,[445,531] the diagnosis of bacterial vaginosis is based on demonstrating consistent clinical, as well as, microbiologic criteria. In the laboratory, the scored Gram's stain has become the gold standard for diagnosis, evaluating the predominating presence and quantity of normal lactobacilli versus gram-negative and gram-variable short rods. The presence of typical "clue cells" continues to be utilized at point of care testing and can be visualized on the Gram's stain as well.[359] In the future, use of molecular methods to identify specific anaerobes that are responsible for syndrome and/or the presence or

absence of specific metabolic biomarkers may become the gold standard for diagnosis.[78,531] Newer molecular assays are being used for the assessment of specimens from patients suspected to have bacterial vaginosis. Among the more recently named genera of anaerobic gram-positive NSF, *Catabacter hongkongensis*, has been isolated from patients with bacteremia and is associated with high rates of mortality, especially in patients with underlying malignancies. The source of the bacteremia is usually the GI tract.[278,442] The clinical significance of other newer genera of anaerobic gram-positive NSF bacilli can be reviewed in the references given in Table 16-2, Box 16-6 and other tables throughout this chapter.

BOX 16-6

Selected Infections Caused by Anaerobic Gram-Positive Non–Spore-Forming Rods

Species	Clinical Relevance
***Actinomyces* spp.**	
A. israelii, A. meyeri, A. naeslundii, A. odontolyticus, A. viscous, and A. gerencseriae	Thoracic,[109,186] cervicofacial,[382] abdominal,[378] and pelvic actinomycosis[401]
A. meyeri, A. funkeii, and *A. cardiffensis*	Bacteremia[153,203,506]
A. europaeus	Breast absscess[435]
A. neui	Neonatal sepsis[310]; abscesses, endophthalmitis. Bacteremia and endocarditis[497]
A. turicensis	Breast abscess, bacteremia[402]
Actinobaculum spp.	Urinary tract infections[204]
***Propionibacterium* spp.**	
P. acnes	Shunt-associated infections[501]; endophthalmitis following cataract surgery[328]; prosthetic joint infections[290,324]; endocarditis[295]
P. propionicum	Actinomycosis-like infection[524]; lacrimal

P. propionicum	canaliculitis[238]
Propionimicrobium lymphophilum	Isolated from lymph node in patient with Hodgkin's disease[457]
P. granulosum	Arthroplasty infection[360]
***Bifidobacterium* spp. and related genera**	Oral/dental infections; mainly involved as normal flora in maintenance of health; used in probiotics; some species involved in urinary tract infections and isolated in blood cultures[307]
Alloscardovia spp., *Scardovia* spp.	Isolated in blood cultures,[307] dental caries[126]
***Eubacterium* spp. and related genera**	Bacteremia[287]; dental infections
Eggerthella spp. and *Paraeggerthella* spp.	Bacteremia[280,287,310,493,498]
Catenibacterium sp., *Colinsella* spp., *Dorea* spp., *Flavonifractor plautii*, *Holdemania*	Fecal flora
Cryptobacterium sp., *Bulleidia* sp., *Mogibacterium* spp.	Oral flora
Pseudoramibacter alactolyticus	Oral flora; involved in endodontic infections[439]
Slackia exigua	Oral flora; wound infections/abscesses[257]
Shuttleworthia satelles	Oral flora; endocarditis[430]
Solobacterium moorei	Fecal flora; bacteremia[369]
Turicibacter sanguinis	Fecal flora; bacteremia[46]
***Lactobacillus* spp. and related genera**	Normal vaginal flora; bacteremia[68,195]
Atopobium vaginae	Association with bacterial vaginosis[479]
Atopobium rimae	Oral infection[128]; bacteremia[13]
Olsenella spp.	Oral cavity; gingivitis and periodontitis[118]
Miscellaneous new genera	
Anaerofustis sp., *Blautia wexlerae*; *Rosburia* sp.	Fecal flora
Anaerotruncus colihominis	Fecal flora; bacteremia[499]

Catabacter hongkingensis	Bacteremia[278,442]
Mobiluncus sp.	Association with bacterial vaginosis[120]; bacteremia[185,218]
Slackia heliotrinireducens	Abscesses[381]

This is not a comprehensive list of all infections published by these organisms; refer to text and Table 16-2 for references to individual organisms or infections, if not given in table.
Adapted from reference 499 and other references as noted in table.

Infections Involving Clostridium *spp.*

Clostridium spp. are responsible for long recognized exogenous, toxigenic infections, including tetanus (*C. tetani*), botulism (*C. botulinum*) and trauma-associated myonecrosis or gas gangrene (*C. perfringens, C. septicum, C. histolyticum* and occasionally *C. sordellii*). *C. tetani* and *C. botulinum* infections are described in a separate section below. *C. difficile* colitis is also a now well-described toxigenic infection, resulting after colonization of the GI tract, either in the hospital or community; it, too, will be described in detail below).[463] Species of *Clostridium* can also cause endogenously acquired infections from species that are part of the normal GI or GU tract microbiota, including such species as *C. perfringens,* members of the *C. clostridioforme* group, *C. ramosum, C. difficile, C. innocuum, C. septicum, C. sordellii,* and *C. bifermentans* (Tables 16-2 and 16-23). Many other *Clostridium* species are found in human feces; in most instances, the significance of any species varies with the clinical setting. Box 16-7provides information on clinical relevance of selected *Clostridium* species.

Isolation of a *Clostridium* species from a wound, blood culture or other body fluid does not necessarily have clinical significance. *C. perfringens*, the most frequently isolated *Clostridium* species, is a common inhabitant of the large bowel; it and other clostridia transiently contaminate the skin of the perianal area and other skin surfaces. However, when *C. perfringens* or other species of *Clostridium* are isolated from multiple blood cultures in patients with signs of bacteremia, they are likely clinical relevant. Most commonly, *C. septicum, C. tertium, C. sordellii* and members of the *C. clostridioforme* group (*C. bolteae, C. citroniae, C. clostridioforme, C. aldenense,* and *C. hathewayi*) have been associated with bacteremia, including septic shock in patients with malignancies or other underlying diseases.[163,463,464,502,518] In a study of

Clostridium from 138 patients with clostridial bacteremia were *Clostridium perfringens* (42%) followed by *Clostridium septicum* (14%), *Clostridium ramosum* (9%), *Clostridium clostridiiforme* (6%), and *Clostridium difficile* (5%).[284] Thirty percent of the patients died, and most were on hemodialysis or were patients with malignancy. It will be interesting if these findings change as more molecular methods, like 16S rRNA sequencing, are used for identification of bloodstream isolates.[436,522]

C. perfringens and Related _Clostridium_ spp. Involved in Skin and Soft Tissue Infections. *C. perfringens* is encountered in myonecrosis (gas gangrene), gangrenous cholecystitis, septicemia, and intravascular hemolysis following abortion and anaerobic pleuropulmonary infections. It is also a major cause of food poisoning in the United States. The other clostridia most often involved in gas gangrene are *C. sordelli, C. septicum,* and occasionally *C. histolyticum*.[463] Clostridial myonecrosis (gas gangrene) is a clinical entity that involves rapid invasion and liquefactive necrosis of muscle with gas formation and clinical signs of toxicity. It is a serious condition requiring close cooperation between the microbiology laboratory and clinical staff for confirmation of the clinical diagnosis. Gram-stained smears of aspirated material from myonecrosis reveal a necrotic background with a lack of inflammatory cells and presence of gram-positive bacilli with a morphology resembling *C. perfringens* or other clostridia. In other conditions, such as simple wound infection or anaerobic cellulitis, in which there may also be gas in tissue, muscle cell outlines and/or the presence of granulocytes and mixed morphologic forms of bacteria in Gram-stained smears of lesions would be evidence against clostridial myonecrosis.[463,464]

BOX 16-7

Clinical Relevance of Selected *Clostridium* spp.

Species	Clinical Syndromes/Infections
C. botulinum A,B,E,F	Botulism: Food-borne, wound, infant, adult colonization (toxemia), iatrogenic (inhalation)[79,464]
C. argentinense	Produces *C. botulinum* G Toxin and can cause botulism[181]
C. baratii and *C. butyricum*	Can produce botulism toxin and cause the disease[181]
C. clostridioforme group: *C. aldensense, C.*	Bacteremia, abscesses,

bolteae, C. citroniae, C. clostridioforme, C. hathewayi and *C. lavalense*	Bacteremia, abscesses, peritonitis[121,163,463,502]
C. perfringens	Gas gangrene, necrotizing fasciitis, food poisoning, many other skin and soft tissue infections[332,463,464]
C. ramosum	Bacteremia[167]
C. septicum	Bacteremia[253,311]; necrotizing fasciitis[416]
C. sordelli	Bacteremia[15]; postabortion infections[463,464] necrotizing fasciitis[258]
C. tertium	Bacteremia[330]
C. tetani	Tetanus[88,463,464]

Adapted from reference 464 and other references as shown in table.

1006

Myonecrosis due to *C. perfringens* usually results from a crushing type injury, with laceration of large arteries and open fractures of long bones that become contaminated with the spores of the bacterium. It can also occur in the abdomen or flanks after traumatic injury, for example from knife or gunshot wounds. There have also been patients with gas gangrene due to *C. perfringens, C. novyi* type A and *C. sordellii* following intravenous drug abuse among the users of black tar heroin.[258,463] *C. perfringens* produces an alpha toxin and theta toxin (perfringinolysin) that are responsible for the pathogenesis of myonecrosis. Alpha toxin has phospholipase C and sphingomyelinase activity and is a potent platelet agonist. The formation of thrombi occludes capillaries, venules, and arterioles, which decreases tissue perfusion and further enhances an anaerobic environment, resulting in rapid destruction of the tissue and producing the symptoms of myonecrosis. Theta toxin is a cytolysin that causes the lysis of human cells, and in addition modulates the inflammatory response to infection.[380,463,464]

C. septicum also produces alpha toxin, but the toxin it produces lacks phospholipase activity. In addition, three other toxins are produced: beta toxin (DNase), gamma toxin (hyaluronidae), and delta toxin (septicolysin, a hemolysin).[380] All of these may contribute to myonecrosis, which usually occurs without preceding trauma. *C.*

contribute to myonecrosis, which usually occurs without preceding trauma. *C. septicum* can proliferate in normal tissue, often following bacteremia. *C. sordellii* can produce up to seven exotoxins, of which lethal toxin and hemorrhagic toxin are the most virulent.[380] Gas gangrene can follow medically induced or self-induced abortions, as well as cesarean sections. The onset of shock and multi-organ failure in these gynecologic infections is very rapid and fatalities are high. Recognition of the infection early on is extremely important.[463]

Crepitant cellulitis (anaerobic cellulitis) seen in diabetic patients, involves subcutaneous tissue or retroperitoneal tissue and can progress to fulminant disease rapidly. Unlike myonecrosis, muscle and fascia are not involved. Several references are available for further details on the histotoxic clostridia and anaerobic cellulitis.[59,161,300,463]

Intestinal Diseases Involving *C. perfringens*. *C. perfringens* has become the second most common bacterial agent of food-borne disease in the United States causing one million illnesses each year. Most of the *C. perfringens* food-borne outbreaks in the United States have involved strains that produce toxin type A.[197,463] *C. perfringens* food poisoning results from the consumption of contaminated beef, turkey, chicken, pork, gravy, and other foods containing large numbers of the organism; outbreaks are often associated with consumption of these products at restaurants or catering facilities.[197] Crampy abdominal pain usually develops, within 7 to 15 hours after eating the suspected food. In most patients, there is foamy, "foul-smelling" diarrhea, usually without vomiting or fever. Illness occurs after viable vegetative *C. perfringens* cells reach the small intestine and undergo sporulation. A potent enterotoxin, produced in the gut while the spores are being formed, causes the diarrhea. The illness tends to be mild and self-limited, and patients usually recover in 2 to 3 days from the onset; at greater risk for more severe disease are the very young and the very old.[463,464] Laboratories can diagnose *C. perfringens* food poisoning by detecting the bacterial toxin in feces or by tests to determine the number of bacteria in the feces. Quantitative anaerobic cultures on selective media, demonstrating at least 10^5 *C. perfringens* organisms in the epidemiologically implicated food, or spore counts showing 10^6 or more *C. perfringens* spores per gram of feces collected within 48 hours of onset of symptoms, are done to confirm the diagnosis in an outbreak investigation.[81] In addition, serotyping of the isolates is done to determine if the same serotype of *C. perfringens* is present in the epidemiologically implicated food and in the feces of ill persons, but not in controls. Serologic typing must be done in established laboratories that are satisfactorily equipped to perform this service, such as at the Centers for Disease Control and Prevention (CDC).[464] The CDC website contains more information about *C. perfringens* and food safety

Necrotizing enteritis (enteritis necroticans, NEC), caused by *Clostridium perfringens*, is much more serious than the food-borne illness described above. NEC is characterized by the sudden onset of abdominal cramps and abdominal distention, vomiting, bloody diarrhea, shock related to fluid and electrolyte problems and acute inflammation with focal to widespread necrosis of the intestinal mucosa. The disease, recognized in post-war Germany, called "Darmbrand" (meaning "fire bowels") was a severe form of necrotizing enterocolitis with an associated mortality of approximately 40%. "Pig bel," a form of necrotizing enteritis seen mainly in children in the highlands of Papua New Guinea, has been associated with a mortality rate of about 30% to 60%.[463] Factors believed to be important predisposing conditions to NEC include the consumption of excessive amounts of rich food or foods containing trypsin inhibitors (e.g., sweet potatoes, peanuts) by malnourished individuals. As reviewed elsewhere, *C. perfringens* type C and type A have been implicated in this disease. *C. perfringens* NEC have been reported from many countries around the world, including Europe and the United States in adults who are malnourished or suffer from diabetes, alcoholic liver disease, or neutropenia.[463] In low birth rate infants who are in intensive care, NEC due to *C. perfringens* (alpha toxin A) can be very serious with high mortality rates, up to 44%.[119,172] There is both a clinical and pathologic spectrum in the severity of NEC. Some patients may survive with supportive care and decompression of the bowel; others may require resection of the involved intestinal segment; still others are inoperable and die with extensive gangrenous necrosis of the small and large bowel. The differential diagnosis includes PMC (whether or not associated with *Clostridium difficile*), acute shigellosis, food-borne illness caused by various agents (including *Escherichia coli*, *Campylobacter jejuni,* and others), acute ulcerative colitis, and obstruction of the bowel (due to adhesions, volvulus, etc.). In suspected cases, efforts to culture *C. perfringens* type A and C (e.g., blood cultures, peritoneal cultures if there is peritonitis, and intestinal contents of surgically removed or necropsy specimens) should be made. A reference laboratory (such as the state health laboratories or CDC), where typing of isolates can be accomplished, should be consulted.

As mentioned above, *C. perfringens* is the primary cause of clostridial bacteremia often in older patients and/or

1007

patients with liver disease.[284,463] Central nervous system infections are rare, but the organism has been responsible for meningitis, meningoencephalitis, and subdural empyema.[225]

Infections Involving Miscellaneous *Clostridium* spp.

Clostridium ramosum. *Clostridium ramosum* is a prominent member of the large

in particular, in intra-abdominal specimens following trauma. A review of clinical cases showed that although *C. ramosum* is a very common GI commensal, and is often isolated from clinical specimens, the association with human infections is still quite rare. It has caused ear infections in young children and bacteremia in the immunocompromised patients.[167] *C. ramosum* can, however, be easily be misidentified or overlooked, since it usually stains as a gram-negative rod and its terminal spores are frequently hard to demonstrate.

Clostridium septicum. Although *Clostridium septicum* is not nearly as commonly encountered as *C. perfringens*, it is especially important to recognize in the clinical laboratory. *C. septicum* can be isolated from serious, often fatal infections. It can be a cause of myonecrosis, with a 67% to 100% mortality. The predisposing factors for this condition include colonic carcinoma, diverticulitis, GI surgery, leukemia, cancer chemotherapy, radiation therapy, and AIDS.[463] *C. septicum* bacteremia is associated with underlying malignancy, particularly carcinoma of the colon or cecum, carcinoma of the breast, and hematologic malignancies (e.g., leukemia-lymphoma); laboratories should not dismiss even a single blood culture positive for *Clostridium* sp, and should always notify clinicians when *C. septicum* is identified in a blood culture, since aggressive diagnostic studies should be done to rule out GI abnormalities in these patients, if it has not already been performed.[265,311]

***C. clostridioforme* Group.** The members of the *C. clostridioforme* group are commonly isolated *Clostridium* spp. in the clinical laboratory. As mentioned in the section on taxonomy, there are at least 5 to 6 species included in the group Table 16-2, many of which require molecular methods for definitive identification. The species differ in their virulence and antimicrobial susceptibility patterns. These organisms can be found as part of the microbiota of the GI tract, and occasionally found in GU tract and as part of oral microbiota.[163] The most common clinical finding associated with this group is bacteremia and most of the species in the group have been described in the literature to cause BSI, along with intra-abdominal abscesses, necrotizing fasciitis and peritonitis.[11,34,48,163,451,463,502,518]

Other *Clostridium* spp. *C. inocuum* is a common clostridial isolate in clinical laboratories. It can cause bacteremia; patients in one review of clostridial bacteremia fared much worse when it was the infecting species, as compared to bacteremia with *C. septicum* or *C. perfringens*.[424] *C. sordellii* has been found in patients with bacteremia and, as mentioned above, can cause skin and soft tissue infections such as gas gangrene and necrotizing fasciitis; some infections have been associated with injection heroin use.[15,463,464] *C. tertium*, one of the aerotolerant *Clostridium* spp., is one of the *Clostridium* spp. found in blood cultures and has been implicated in bacteremia, especially in the neutropenic patient.[330] It has also been isolated in a patient with gas gangrene in which it had initially been identified as a *Lactobacillus,*

patient with gas gangrene in which it had initially been identified as a *Lactobacillus,* because of its good growth on aerobic plates.[173]

Infections With *C. botulinum* and Related *Clostridium* spp. Botulism is a life-threatening neuroparalytic disease caused by antigenically distinct, heat-labile, protein toxins of *C. botulinum*.[294] Although seven toxin types (A to G) are produced by different strains of *C. botulinum*, most cases of botulism in humans are caused by types A, B, E, and F. Of these, type F is the least common. Types C and D are associated with botulism in birds and mammals, but not in humans. *Clostridium* that produces the type G toxin, now reclassified *Clostridium argentinense*, has been isolated from autopsy samples of a few individuals who died suddenly; it is not clear to what extent type G organisms cause botulism in humans.[294,380,464] Some strains of *C. butyricum* and *C. baratii* also carry botulinum toxins and produce disease.[464] Regardless of which antigenic type, botulinum toxin acts by binding to synaptic vesicles of cholinergic nerves, thereby preventing the release of acetylcholine at the peripheral nerve endings, including neuromuscular junctions. Acute, flaccid, descending paralysis eventually develops without supportive treatment.[122] The paralysis begins with bilateral impairment of cranial nerves resulting in paralysis of muscles of the face, head, and throat. The paralysis then descends symmetrically to involve the muscles of the thorax, diaphragm, and extremities. Patients may die of respiratory paralysis unless they have proper respiratory intensive care, including mechanical ventilation; death may also result from secondary pneumonia, caused by nonbotulinum organisms.[159,294,464]

There are about 145 cases of botulism in the US each year according to the CDC, representing five different categories of infection. The first of these is classical food-borne botulism, typically seen in adults, resulting from the ingestion of preformed toxin in contaminated food; this form accounts for 13% of reported patients with botulism. The second category, wound botulism results from production of botulinum toxin in vivo after *C. botulinum* has multiplied in an infected wound; this accounts for about 20% of patients. The third category, infant botulism, is the most common, accounting for ~65% of reported cases in the United States. It results from in vivo multiplication of *C. botulinum* with the production of the neurotoxin within the infant gut. Adult intestinal colonization or adult toxemia is the fourth category and is very rare; it mimics infant botulinum. The fifth category as defined by the CDC is iatrogenic botulism, caused by an overdose of botulinum toxin and is also very rare.[80,464] Included in this latter category is "inhalation botulism" resulting from aerosolization and inhalation of botulinum toxin. This type can be considered as a bioterrorism threat and *C. botulinum* toxin is categorized as a potential bioterrorism agent.[80,464] Home-processed foods, rather than commercially processed foods, have been involved in

processed foods, rather than commercially processed foods, have been involved in most of the outbreaks of food-borne botulism. The foods most often implicated have been vegetables (e.g., home-canned tomatoes, tomato juice, green beans, greens, peppers, corn, beets, and spinach), fish (e.g., home-processed tuna fish, smoked salmon, fish eggs, commercially processed tuna, smoked whitefish, etc.), fruits (home-canned apple butter, blackberries, etc.), and miscellaneous foods (e.g., beef stew, chili, spaghetti sauce, luncheon

1008

meats, etc.). Symptoms of food-borne botulism include double and/or blurred vision, droopy eyelids, slurred speech, difficulty in swallowing, dry mouth, and muscle weakness.[80]

Infant botulism was recognized as a distinct clinical entity in 1976. From 1976 to 1988, 760 patients were diagnosed with this disease.[14,294] Infant botulism has been reported from many different states, with the greatest number of cases in California. Most cases reported west of the Mississippi River have been type A; the majority of those east of it have been type B. Affected infants have ranged from 6 days to 11.7 months in age, and both sexes have been affected equally. The infants ingest spores, not preformed toxin, from soil, household dust, honey, or another source. Within the gut, *C. botulinum* multiplies and elaborates toxin. Clinical features include constipation (usually the first sign), listlessness, difficulty in sucking and swallowing, an altered cry, hypotonia, and muscle weakness. Eventually the baby appears "floppy" and loses head control. Ptosis, ophthalmoplegia, flaccid facial expression, dysphagia, and other neurologic signs may develop. Respiratory arrest or respiratory insufficiency necessitating respiratory therapy occurs. A small number of infants with laboratory-confirmed infant botulism have died. Infant botulism has accounted for a small number of sudden infant death syndrome.[44]

The diagnosis of classical food-borne botulism is confirmed in reference laboratories, such as the CDC, by demonstrating botulinum toxin in serum, feces, gastric contents or vomitus. Also, the organism may be isolated from the feces.[80,294,464] The detection of botulinum toxin in epidemiologically implicated food, with or without isolating the organism, is useful for ascertaining what food was involved in the outbreak. About 15 to 20 mL of serum and 25 to 50 g of feces should be collected for shipment to the appropriate reference laboratory, as directed by the appropriate state or federal public health official who is capable of providing epidemiologic and laboratory aid in the investigation. In suspected wound botulism, serum, exudate or swab samples from the wound should be collected, along with tissue (e.g., at autopsy), and feces.

When infant botulism is suspected, serum (2 to 3 mL) and as much stool as possible

refrigerated or placed on ice for shipment. However, many, if not most, of these infants are constipated early in the illness, and stool may not be available. Therefore, the clinician must decide whether the risk of obtaining an anorectal swab specimen is clinically warranted for the laboratory to isolate *C. botulinum* from this source. Wound botulism is caused by the infection of a wound with *C. botulinum*. A specific type of wound botulism has developed due to injection of black tar heroin. Most of the patients with this type of disease have been seen in California.[532]

Some, but not all, state health department laboratories provide diagnostic services for botulism. With prior approval of the CDC and/or the local state health department laboratory, specimens may be submitted to the CDC for laboratory diagnosis. Confirmation of the clinical diagnosis of botulism requires demonstration of botulinum toxin (mouse neutralization test) in serum or feces, and/or *C. botulinum* in feces.[80,464] Isolation and identification of the organism is performed by conventional cultural biochemical procedures and the confirmed with the toxin neutralization test. Toxin has only rarely been detected in serum from an affected infant. It is recommended that culture and toxin testing for *C. botulinum* be done only by properly equipped reference laboratories for this specialized testing. During investigations of possible terrorism, sera, gastric aspirates, feces, environmental samples or nasal swabs could be useful and should be refrigerated until they can be transported to a reference laboratory for testing. For further details, the interested reader is referred to the following references.[80,464]

Infections With *C. tetani*. Tetanus is an infectious disease caused by *C. tetani*. There is an effective immunization available. In resource-rich countries with effective immunization strategies, disease is most commonly seen with injection drug users. The incidence of *C. tetani* in the United States was reported to be 233 patients from 2001 to 2008, averaging approximately 29 cases per year. The case fatality rate (in those with known outcomes) was 13.2%, but in those ≥65 years of age it rose to 31.3%.[82] Tetanus is a dramatic illness characterized by spastic contractions of voluntary muscles and hyperreflexia. It is caused by the actions of two toxins, tetanolysin and tetanospasmin elaborated by *C. tetani*.[88,159,464] Tetanus shares some similarity with diphtheria, in that the infection, and the organism, remains localized (usually a minor penetrating wound), whereas the toxin is absorbed, producing major systemic effects. The spores of *C. tetani*, like those of *C. botulinum*, are widely distributed in the soil, as well as in aquatic environments. Tetanus usually results from spore contamination of puncture wounds, lacerations, or even crush injuries.[15,88,464] Fecal contamination of the umbilical cord has been the source of *C. tetani* in some instances of neonatal tetanus.[90] The incubation period ranges from 3 to 21 days. Following a localized penetrating injury, there may be a deep-seated mixed infection involving anaerobes

providing favorable conditions for *C. tetani* spores to germinate, for the vegetative cells to multiply and release the tetanospasmin on autolysis of the bacterial cells.[15] Tetanospasmin attaches to peripheral motor nerve endings, and travels along nerves to the central nervous system (CNS). The toxin binds to gangliosides in the CNS, and blocks inhibitory impulses to the motor neurons. Patients have prolonged muscle spasms of both flexor and extensor muscles. Tetanospasmin attaches to binding sites at myoneural junctions, thus inhibiting the release of acetylcholine. This is like the attachment of botulinum toxin to myoneural junctions, except that the binding sites for tetanospasmin and for botulinum toxin are different.[15,122] As indicated previously, patients with tetanus have spastic muscle contractions, difficulty opening the jaw (called lockjaw, "trismus"), a characteristic smile called "risus sardonicus" and contractions of back muscles resulting in backward arching. Patients are extremely irritable, and tetanic seizures develop, brought about by violent, painful muscle contractions following some minor stimulus, such as a noise.[15]

The regular use of vaccines and tetanus antitoxin for wound management, and improved childbirth practices have greatly assisted in decreasing the incidence of disease, and improving outcomes when infection does occur. Today,

1009

50% of infections are secondary to contaminated wounds, traumatic or surgical, and abscesses, as well as the association with intravenous drug abuse.[59] *C. tetani* is a reportable disease in the United States, and there have been reports of infections following laparoscopic hernia repair surgery and a rare instance of bacteremia in an 87-year-old wherein an endogenous source of the bacterium was suspected to be responsible for the disease.[209]

Tetanus is a medical emergency requiring hospitalization, immediate treatment with human tetanus immune globulin (TIG) (or equine antitoxin), tetanus vaccination, and drugs to control muscle spasms. In addition, aggressive wound care, and antibiotics are part of the appropriate treatment plan. Diagnosis is based on clinical findings rather than laboratory studies.[88]

The antecedent wound is often minor or trivial. Direct Gram-stained smears and anaerobic cultures of the wound site often fail to reveal the organism. When it is recovered in culture, *C. tetani* forms round, terminal spores, produces spreading or swarming growth on anaerobe blood agar, produces major amounts of acetate and butyrate with only a minor amount of propionate, is lipase and lecithinase-negative on egg yolk agar (EYA), and is asaccharolytic (Image Plate 16-4A and 16-4B).

Infections Involving Anaerobic Gram-Positive and Gram-Negative Cocci. The anaerobic cocci most commonly encountered in clinical specimens include *Finegoldia*

anaerobic cocci most commonly encountered in clinical specimens include *Finegoldia magna* (formerly *Peptostreptococcus magnus*), *Peptostreptococcus anaerobius*,*Peptoniphilus asaccharolyticus* (formerly *Peptostreptococcus asaccharolyticus), Anaerococcus prevotii* (formerly *Peptostreptococcus prevotii*), *Parvimonas micra* (formerly *Peptostreptococcus micros and Micromonas micros)* and *Streptococcus intermedius.*[446]Nomenclature changes for the anaerobic cocci are listed in Table 16-2. There is little doubt that anaerobic cocci can be pathogenic for humans in certain clinical settings. They can be isolated from approximately 25% of all anaerobic infections.[348] In pulmonary diseases, up to 40% of the anaerobic infections may contain a gram-positive anaerobic coccus, especially *F. magna, P. micra* or *P. anaerobius*.[348,351,446] With the exception of *F. magna,* most infections involving anaerobic gram-positive cocci are polymicrobial[446] and associated with abscesses from common skin abscesses to more life-threatening brain abscesses. In addition they have been involved in patients with bacteremia, meningitis, necrotizing pneumonia septic abortion, and decubitus ulcer infections and other skin and soft tissue infections. *F. magna* is the single most common pathogenic anaerobic gram-positive coccus. It possesses many pathogenic factors including adhesion factors, a capsule and various enzymes; it has been reported to cause endocarditis, mediastinitis, septic joint infections, prosthetic implant infections, respiratory tract infections and diabetic foot infections.[170,252,487]*P. micra* is predominantly an oral pathogen, most commonly involved in periodontal disease. It has, however, been associated in polymicrobial infections of bone and joints, brain abscesses, septicemia and human bite wounds, among others.[348] *P. anaerobius* has been isolated in polymicrobial infections involving the abdominal, urogenital and respiratory tract. Like *P. micra,* it has also been associated with oral infections, including peritonsillar abscesses and periapical abscesses in root canals.[396]

Atopobium parvulum (formerly *Streptococcus parvulus*) has been isolated from oral cultures in patients with odontogenic infection, although the specific contribution of this organism to the overall infection is unknown.[128]

Staphylococcus saccharolyticus is an anaerobic coagulase-negative *Staphylococcus* species that is part of the normal microbiota of the skin. It has been found to be responsible for native and prosthetic valve endocarditis. In addition, the organism has been isolated from a patient with spondylodiscitis, and has been recovered from stored platelet concentrates.[8,187,267] *S. aureus* subsp. *anaerobius* is an anaerobic *S. aureus* that can cause disease in animals and humans. It has been isolated from abscesses and shown to cause bacteremia.[141,368]

Anaerobic gram-negative cocci are much less involved in infections than other anaerobic or microaerophilic cocci.[238,446] There are rare reports of meningitis, osteomyelitis, prosthetic joint infections, discitis, endocarditis, and bacteremia, mainly

osteomyelitis, prosthetic joint infections, discitis, endocarditis, and bacteremia, mainly involving *V. parvula*.[41,45,94,298,312,316] In many of these instances, the patient had an underlying disease, including a primary periodontal infection, or the infection followed surgery or other invasive procedures such as endoscopy.

Box 16-8 provides information on the clinical relevance of anaerobic cocci. Tables 16-27 and 16-28 describe the identification characteristics of anaerobic gram-positive cocci and gram-negative cocci, respectively.

Isolation of Anaerobic Bacteria

The steps involved in the laboratory diagnosis of anaerobic bacterial infections are similar in many ways to those for aerobic bacteria, as described in Chapters 1 and 2. Particularly attention must be paid to the proper selection, collection, and transport of clinical specimens for recovering anaerobic bacteria. The processing of specimens, selection of media, inoculation and incubation methods, and inspection of positive cultures are laboratory procedures that must be carefully quality-controlled. Performing any one step incorrectly may lead to erroneous results, thus creating the potential to supply misinformation to the physician.

Selection of Specimens for Culture

With few exceptions, all materials collected from sites not harboring an indigenous microbiota, such as body fluids other than urine, exudates from deep abscesses, fine-needle aspirates and tissue biopsies, should be cultured for anaerobic bacteria. However, since anaerobes normally inhabit the skin and mucous membranes as part of the normal indigenous microbiota, the specimens presented in Table 16-5 are unacceptable for anaerobic culture, because the results cannot be interpreted.

Collection and Transport of Specimens

When collecting specimens through the skin or mucous membranes, stringent precautions must be taken to decontaminate the surface properly. A surgical soap scrub should be used, followed by application of 70% ethyl or isopropyl alcohol, then tincture of iodine for 1 minute (or 10% povidone-iodine, Betadine for 2 minutes, or more recently, use of chlorhexidine). This should be applied in concentric circles starting from the center. Because some patients are sensitive or allergic to tincture of iodine, it is important to remove the iodine with alcohol after collecting the specimen.

BOX 16-8

Clinical Findings Associated With Selected Anaerobic Gram-Positive Cocci

Species	Clinical Infections
Finegoldia magna	Bacteremia and endocarditis[170,487];soft tissue infections[252]; prosthetic joint infections[291]
Parvimonas micra	Predominantly an oral pathogen[348,351,396]; human bite wounds[446]; Osteomyelitis and prosthetic joint infections[446]
Peptostreptococcus anaerobius	Bacteremia and endocarditis[108]; recovered from many other clinical specimens[446]
Peptoniphilus spp.	Varies among the species and often isolated in polymicrobial infections, and in many different clinical specimens.[351,446]
Anaerococcus spp.	Varies among the species and often isolated in polymicrobial infetctions, and in many different clinical specimens.[351,448]
A. prevotii	Septic arthritis[230]
Atopobium parvulum	Dental abscesses[128]
Staphylococcus saccharolyticus	Bacteremia; prosthetic valve endocarditis[267]; contaminated platelets[8]

Adapted from reference 243 and other references as noted in table.

TABLE 16-5 Specimens That Should Not Be Cultured for Anaerobic Bacteria

Throat or nasopharyngeal swabs
Gingival swabs
Sputum or bronchoscopic specimens[a]

Gastric contents, small-bowel contents, feces, rectal swabs, enterocutaneous fistulae, colostomy stomata[b]
Surfaces of decubitus ulcers, swab samples of encrusted walls of abscesses, mucosal linings, and eschars
Material adjacent to skin or mucous membranes other than the above that have not been properly decontaminated
Voided urine
Vaginal or cervical swabs

[a] Collection of bronchoscopic specimens using sterile fiberoptic bronchoscopic may be acceptable for anaerobe cultures.

[b] When indicated clinically, specimens from these sources can aid in the diagnosis of botulism and for intestinal disease caused by *Clostridium difficile* and *C. perfringens*.

In general, swabs other than those already listed in this table, should not be processed for anaerobes from wounds without discussion with the healthcare team as to the need for aspirates, body fluids or tissue samples if at all possible. Swabs sent from the operating room for anaerobes should not be processed.

A needle and syringe should be used whenever possible for collecting specimens for anaerobic culture. Collection of swab specimens should be discouraged because they do not allow for collection of large enough specimens and also because they expose anaerobes, if present, to ambient oxygen. Some studies have shown that if there is abundant purulent material in the specimen, survival on swabs is sufficient and recovery enhanced provided the swabs are transported in appropriate anaerobic transport devices. Regardless, the collection of fluids, aspirates or tissue biopsies are preferred for the optimal recovery of anaerobic bacteria.[96] Once any specimen is collected, particular precautions should be taken to protect them from oxygen exposure and most importantly to deliver them to the laboratory promptly.

Anaerobic Blood Cultures

Blood culture techniques should permit optimal recovery of obligate anaerobes, as well as, aerobes and facultative anaerobes. Before the 1980s, anaerobes were encountered in about 9% to 20% of all positive blood culture sets at a number of medical centers.[159] During the past two to three decades, because of surgical prophylaxis

protocols for GI and GU surgeries in particular, anaerobes have accounted for about ≤5% to 10% of bacteremias, dependent on varying patient populations.[58,155,229,354] A study at the Mayo clinic in 2007 suggested a possible reemergence of anaerobic bacteremia, making the point that blood cultures should always include inoculation into aerobic and anaerobic media. There may be differences between incidence of anaerobes in different hospital settings (e.g., community hospitals vs. tertiary care medical centers), but culturing for anaerobes should be performed with all blood cultures as a matter of routine; this will ensure the optimal assessment of the patient suspected to have bacteremia.[155,277] A recent report documented adverse outcomes in patients with antibiotic-resistant *Bacteroides* bacteremia, stimulating renewed interest in the laboratory diagnosis of anaerobic bacteremia and the need for antimicrobial susceptibility testing of these bacteria.[214,355] In a study of on bone marrow transplant recipients, 17% of all bloodstream infections were due to anaerobes, with *F. nucleatum* being the most common, followed by *Leptotrichia buccalis,*

1011

C. septicum and *C. tertium*. Risk factors among this group included neutropenia and mucositis.[274]

The decontamination of the skin at the venipuncture site cannot be overemphasized for optimal recovery of significant anaerobes. Chlorhexidine appears to be comparable or superior to alcohol and povidone-iodine or alcohol and tincture of iodine, and is now being used for skin antisepsis in a number of medical centers.[26,332] To optimize the recovery of microorganisms from patients with bloodstream infections, the blood specimen volume from adult patients should be 20 to 30 mL per venipuncture.[503] For neonates and older children, smaller volumes are usually collected (e.g., 0.5 mL for an infant; 2 to 5 mL for an older child), based on the weight of the child. Collection of more than three blood specimens per 24-hour period to diagnose a suspected episode of bacteremia is not required and is not recommended for any patient.[389]

For instrumented blood culture systems, bottles currently available that support growth of obligately anaerobic bacteria, as well as facultatively anaerobic bacteria, are listed below.

Bactec Plus Anaerobic/F (resin, anaerobic; up to 10 mL of blood)
Bactec Lytic/10 Anaerobic F (lytic agent, anaerobic; up to 10 mL of blood)
Bactec Anaerobic F (standard anaerobic; up to 7 mL of blood)
BacT/Alert FN (FAN, anaerobic with activated charcoal; up to 10 mL of blood)
BacT/Alert (standard anaerobic; up to 10 mL of blood)
VersaTrek REDOX 2 Anaerobic Broth (standard anaerobic; up to 10 mL of blood)

Instrumented blood culture systems have a special head space that contains an anaerobic atmosphere, containing nitrogen and carbon dioxide without oxygen. Both the aerobic and anaerobic bottles should be shaken during incubation and should be incubated at 35°C for 5 days. When either the aerobic or anaerobic bottles demonstrate evidence of growth, aerobic and anaerobic subcultures should be performed; anaerobe blood agar may be used for subculture, followed by anaerobic incubation. The use of selective plating media for anaerobic subculture (such as phenylethyl alcohol [PEA] anaerobe blood agar or kanamycin–vancomycin blood agar), in addition to nonselective anaerobe blood agar, is recommended to aid in recovery of anaerobes in the setting of polymicrobial bacteremia. Anaerobes can be isolated on occasion from the aerobic blood culture bottles. The lysis/centrifugation (Isolator; Wampole, Cranbury, NJ) system and the Septichek (Roche, Indianapolis, IN) blood culture system (discussed in Chapters 1 and 2) have performed suboptimally compared with the traditional and Bactec broth systems for anaerobic blood culture. It is recommended that laboratories using either of these systems also use a traditional method or an additional instrumented broth culture system for anaerobic blood cultures.[238]

Direct Examination of Clinical Material

Gross examination of specimens is particularly valuable in the assessment for the possible presence of anaerobes. Although unpleasant, a foul odor, the purulent appearance of fluid specimens, and the presence of necrotic tissue and gas or sulfur granules are all valuable clues (Image Plate 16-2C).

The importance of the microscopic examination of clinical specimens has been emphasized by several authors, and the information derived may give immediate presumptive evidence that anaerobes are present.[238,313] In preparing slides for Gram's staining, methanol fixation is much better than traditional heat fixation. The background and cellular characteristics of the smear should be observed; and the Gram reaction; the size, shape, and arrangement of bacteria; and the relative number of organisms present should be recorded. The presence of spores, their shape and position in the bacterial cell, and other distinctive morphologic features such as branching, filaments with spherical bodies, pointed ends, and granular forms should be noted. Although the Gram's stain is ordinarily satisfactory for determining cellular characteristics, acridine orange stains can be helpful for detecting bacteria in blood cultures, CSF, pleural fluid, joint fluid, and exudates.[269] The morphology of several anaerobes in stained preparations examined microscopically is illustrated in Image Plates 16-1, 16-2, 16-3 and 16-4, as well as in the Image Plates of Chapter 1.

The presence of numerous squamous epithelial cells without inflammatory cells in the Gram's stain preparations from skin wounds and in respiratory and urogenital tract specimens usually indicates poor quality, superficially collected specimens that usually

yield mixtures of insignificant organisms from the normal microbiota or surface contaminants. It is worthwhile to limit the extent of identifications when the direct microscopic examinations reveal samples of poor quality specimens, because the predictive value of such tests is limited. Of course, clinicians should be notified of the direct examination results and the problem of specimen quality in a timely manner, prior to discarding the primary culture plates. Microbiologists should work closely with clinicians in an effort to enhance the quality and the clinical relevance of the specimens processed and the results reported.

Selection and Use of Media

The media used for recovering anaerobes from specimens should include nonselective, selective and enrichment media, as illustrated in Tables 16-6 and 16-7. Other media may also be included or substituted for those listed in Table 16-6. For example, chopped-meat glucose medium is commonly used instead of enriched thioglycolate medium; colistin nalidixic acid (CNA) agar may be used instead of PEA agar. Either paromomycin–vancomycin blood agar or kanamycin–vancomycin blood agar can be used for the selective isolation of the gram-negative NSF anaerobes. *Bacteroides* bile esculin (BBE) agar is recommended for the selection and presumptive identification of the *Bacteroides fragilis* group and has also been found useful as a selective medium for *Bilophila wadsworthia*.[29,238] Results obtained with plating media formulations such as Schaedler, Columbia, Brucella, or other media may not be entirely comparable to the morphology and growth characteristics of anaerobes seen on the CDC anaerobe blood-agar–based media formulations (Image Plates 16-1 through 16-4).

1012

TABLE 16-6 Representative Media for Primary Isolation of Anaerobes From Clinical Specimens

Medium	Major Ingredients and Comments	Purpose
CDC anaerobe blood agar (AnBAP)	Trypticase soy agar base with 5% sheep blood; supplemented with yeast extract, hemin, vitamin K_1 and L-cystine for anaerobes requiring additional growth factors (e.g., *Prevotella melaninogenica, Fusobacterium necrophorum*, and others). Additional media bases, including Brucella, brain-heart infusion, Schaedler, and Columbia blood agar support excellent growth of many anaerobes, but morphology and other characteristics tend to differ on these media.	Nonselective blood agar-plating medium for the primary isolation of all types of anaerobes found in clinical materials (see text and Image Plates 16-1 through 16-4).
Anaerobe phenylethyl alcohol blood agar (PEA)	In addition to containing the same ingredients as the CDC anaerobe blood agar formulation above, this medium has phenylethyl alcohol (2.5 g/L). PEA inhibits the swarming of *Proteus* spp. and inhibits the growth of many other gram-negative facultatively anaerobic bacteria, including most *Enterobacteriaceae*. PEA is volatile. Plates should be tightly sealed in cellophane or plastic bags and stored at 4°C. A batch of plates that no longer inhibits the swarming of *Proteus* should be discarded, regardless of the expiration date.	PEA medium aids in selective isolation of anaerobes from infected materials containing a mixture of bacteria. It supports good growth of most gram-positive and gram-negative obligate anaerobes. Facultatively anaerobic gram-positive bacteria such as staphylococci, streptococci, *Bacillus* spp., and coryneform bacteria also grow well on this medium.
Anaerobe laked kanamycin-vancomycin blood agar (KV)	Contains the same CDC anaerobe blood agar formulation as AnBAP above, but in addition, contains 100 mg/L of kanamycin and 7.5 mg/L of vancomycin. The kanamycin inhibits many (but not all) facultatively anaerobic gram-negative rods and the vancomycin inhibits gram-positive bacteria in general (including most gram-positive anaerobes and aerobes). Vancomycin in this concentration can also inhibit the growth of *Porphyromonas* spp.	KV medium is useful for selective isolation of most *Bacteroides* spp., *Prevotella* spp., *Fusobacterium* spp. and *Veillonella* spp. from clinical specimens containing mixed aerobic and anaerobic bacteria.
Anaerobe paromomycin-vancomycin blood agar (PV)	Laked PV medium is similar to the formulation above, except that 100 mg/L of paromomycin is substituted for the kanamycin. Also in PV, the blood is laked before it is added (by freezing and thawing the blood). Performance is similar to KV, except that the paromomycin may inhibit some additional facultative anaerobes that are resistant to kanamycin, such as some strains of *Klebsiella* sp. Similar to KV agar, laked PV should inhibit growth of gram-positive organisms. The laked blood may aid in early recognition of pigmented *Prevotella*.	Laked PV is an excellent medium for selective primary isolation of organisms in the *Bacteroides fragilis* group, the pigmented and nonpigmented *Prevotella* spp., *Fusobacterium nucleatum, F. necrophorum, F. mortiferum, Veillonella*, and other obligately anaerobic gram-negative, non–spore-forming anaerobes. It is not necessary to use both KV and PV; rather, it is reasonable to select one or the other of these media, based on preferences of the microbiologist.
Cycloserine-cefoxitin fructose agar (CCFA)	Trypticase soy or proteose peptone base containing fructose and neutral red indicator. In addition, cycloserine (500 mg/L) and cefoxitin (16 mg/L) are added to inhibit intestinal microbiota. *C. difficile*, at 48 hours of incubation, forms 4 mm or larger yellowish rhizoid colonies that have birefringent crystalline internal structures ("speckled opalescence") (Image Plate 16-4F). *C. difficile* colonies show yellow-green fluorescence under long-wave UV light. In addition, their odor is reminiscent of horse manure. *C. difficile* is negative for both lipase and lecithinase activity.	CCFA is for selective isolation of *C. difficile* from stool specimens or other intestinal materials. However, growth on CCFA is not specific for only *C. difficile*; therefore, identification of pure culture isolates is still required. It is common to find breakthrough growth on the medium of *Enterobacteriaceae, Bacillus* spp., staphylococci, and other clostridia.
Bacteroides Bile Esculin Agar (BBE)	BBE agar contains digest of casein and soybeans. Hemin, vitamin K_1, oxgall and gentamicin are included in the agar as selective factors. The bile (oxgall) is inhibitory to most bacteria other than the *B. fragilis* group. Hydrolysis of esculin helps differentiate among the species; there will be a blackened zone around positive colonies.	BBE agar is used for the selection and presumptive identification of the members of the *Bacteroides fragilis* group, including *Parabacteroides* spp. and *Bilophila wadsworthia*. Organisms that grow will appear as gray, circular, raised colonies of >10 mm. There will be a blackening of the agar around colonies capable of hydrolyzing the esculin. Most gram-positive aerobes and anaerobes will be inhibited as will members of the *Enterobacteriaceae* and other gram-negative aerobic bacteria.
Enriched thioglycolate medium (THIO)	THIO is an enriched liquid medium prepared by supplementing the BBL-0135C formula thioglycolate medium (without indicator) with hemin and vitamin K_1	This is a noninhibitory broth that is especially useful for primary isolation of actinomycetes. THIO is also an excellent supplement to semisolid (i.e., agar) media for isolation of slow-growing or fastidious organisms. It supports good growth of essentially all anaerobes commonly found in clinical materials.

All the media in this table are available in prepared form from several manufacturers.

TABLE 16-7 Additional Media for Use in Cultivating or Selecting for Specific Anaerobes

Medium	Composition	Purpose
Anaerobe Blood Agar with neomycin	TSA supplemented with yeast extract, vitamin K_1, hemin, cystine, and 5% sheep blood agar plus neomycin	Inhibitory to most strains of *S. aureus* and many of the *Enterobacteriaceae*
Forget–Fredette Agar	Digest of casein and soybean milk, glucose, and sodium azide	Used for cultivation of *Clostridium* spp.
Hartley's digest broth	Ox heart, pancreatin, sodium carbonate, and HCl	Used for cultivation of *Actinomyces* spp.
Lombard Dowell Agar	Digest of casein, yeast extract, cystine, tryptophan, sodium sulfite, hemin, and vitamin K_1	Used for isolation of most anaerobes
McClung–Toabe agar base with egg yolk	Peptone, glucose, and egg yolk emulsion	For isolation and cultivation of *C. perfringens*
Shaidi–Ferguson Perfringens Agar	Tryptose, digest of soybean meal, yeast extract, ferric ammonium citrate, sodium sulfite, egg yolk emulsion, kanamycin, and polymyxin sulfate	For isolation and enumeration of *C. perfringens*; they appear as black colonies surrounded by a precipitate.
Tryptose–sulfite–cycloserine agar	Tryptose, beef extract, digest of soybean meal, yeast extract, ferric ammonium sulfate, ferric ammonium citrate, cycloserine, polymyxin B, and kanamycin	For isolation and enumeration of *C. perfringens*
Wilkens–Chalgren anaerobe Broth	Digest of casein, gelatin, peptone, yeast extract, glucose, sodium pyruvate, arginine, hemin, and vitamin K_1	For cultivation of most anaerobes; also used for antimicrobial susceptibility testing
Fusobacterium selective agar	Sheep blood agar with josamycin, neomycin, and vancomycin	Inhibit most gram-positive aerobes and anaerobes as well as most other gram-negative anaerobes, except

		Fusobacterium spp.
Fusobacterium necrophorum selective media[24]	Horse Blood agar with nalidixic acid and vancomycin	Inhibits most gram-positive bacteria and many gram-negative aerobes and anaerobes; β-hemolysis on horse blood helps to specifically identify *F. necrophorum* from throat swabs or other respiratory specimens when Lemierre's disease is suspected.

The use of a nonselective anaerobic blood agar such as Brucella or CDC blood agars that contain hemin, L-cystine and vitamin K_1 is recommended for the primary isolation and subculture of most anaerobes including certain thiol-dependent or sulfur-containing amino-acid–requiring bacteria such as *Fusobacterium necrophorum* and fastidious, thiol-dependent streptococci that have been isolated from patients with endocarditis. This medium also supports excellent growth of the strict anaerobes *Clostridium novyi* type B and *Clostridium haemolyticum*. These can be purchased from the major media vendors. The formula for CDC anaerobe blood agar can be found in Chart 16-1. Prereduced anaerobically sterilized (PRAS) media can be purchased from Anaerobe Systems, CA. Many of the commercially prepared anaerobe blood agar plates can be stored in the refrigerator in cellophane bags for at least 6 weeks provided precautions to prevent drying out are utilized. Prior to use, the plates can be prereduced by holding them for 4 to 16 hours in an anaerobic jar or an anaerobic glove box in an atmosphere of 85% N_2, 10% H_2, and 5% CO_2. The enriched thioglycolate medium (BBL-135C with hemin and vitamin K_1 supplement) is recommended as a backup to the plating media. This medium is particularly helpful for cultivating slow-growing species of *Actinomyces* and *P. acnes*. Chopped-meat glucose broth, a good alternative to enriched thioglycolate medium, is useful for the isolation of *Clostridium* species by the spore selection technique and as a holding medium for anaerobic cultures in general.

Other special purpose selective media for primary isolation of anaerobes of the normal microbiota studies have been described in many texts and references.[18,238] Many scientists have developed media specific for various fastidious anaerobes. Smith and Moore described selective media and a cold enrichment technique to aid in isolation of *Mobiluncus* species from vaginal specimens.[441] Eley et al. reported on a selective and differential medium for isolation of *Bacteroides ureolyticus*.[142] Lee and coworkers developed a new selective medium for *Bacteroides gracilis*.[285] Malnick and associates formulated a new selective medium for isolating *Anaerobiospirillum*

spp. from feces.[308] There have been a few selected media described for the isolation of *Fusobacterium necrophorum*, in particular from throat swabs and other respiratory specimens for the determination of pharyngitis and the more severe Lemeirre's syndrome. *F. necrophorum* can be a component of normal oral microbiota, so the mere isolation of this organism from the oropharynx does not always indicate clinical significance; a selective media can assist in enabling isolation of the organism from amid other normal microbiota in instances of suspected infection. The addition of horse blood for detection of hemolysis and the addition of vancomycin and nalidixic to inhibit the growth of many other gram-positive and gram-negative normal microbiota has been shown to enable detection of *F. necrophorum* from throat swabs.[24,84] Some of the newer anaerobic selective media are provided in Table 16-7.

The OxyPlate is a commercially available medium that can be used for isolation of anaerobes without the need for anaerobic jars, chambers, or pouches. It consists of plastic plates that are manufactured and used as seals so that

anaerobic conditions are maintained inside. An enzyme, Oxyrase, (Oxyrase, Inc., Mansfield, OH), which is in the media, removes oxygen from the PRAS blood agar and the space above the media as well. Once inoculated with specimens or colonies, the plates are stored in a routine aerobic incubator. There have been a few studies to date comparing the use of OxyPlate to conventional anaerobic incubation approaches. One evaluation with eye specimens found that it was equivalent to the recovery of anaerobes in a GasPak jar and although it did not necessarily recover more anaerobes, it could be an alternative in the laboratory so that chambers and jars might not be required.[117,512]

Systems for the Cultivation of Anaerobic Bacteria

Comparative studies have shown that the following systems, when used properly, are satisfactory for the cultivation of anaerobic bacteria commonly associated with human disease[255,400]: evacuation-replacement jars; anaerobic jars with disposable gas generators; anaerobic glove box techniques; and, roll tube and roll-streak tube with PRAS media. To ensure optimal results, the general principles listed in Box 16-9 must be followed. Bacic and Smith describe the proper methods for cultivation and storage of *Bacteroide*s spp. and in the article provide useful information about some of the various methods used for incubation of anaerobes and denote the advantages and disadvantages of these techniques.[20]

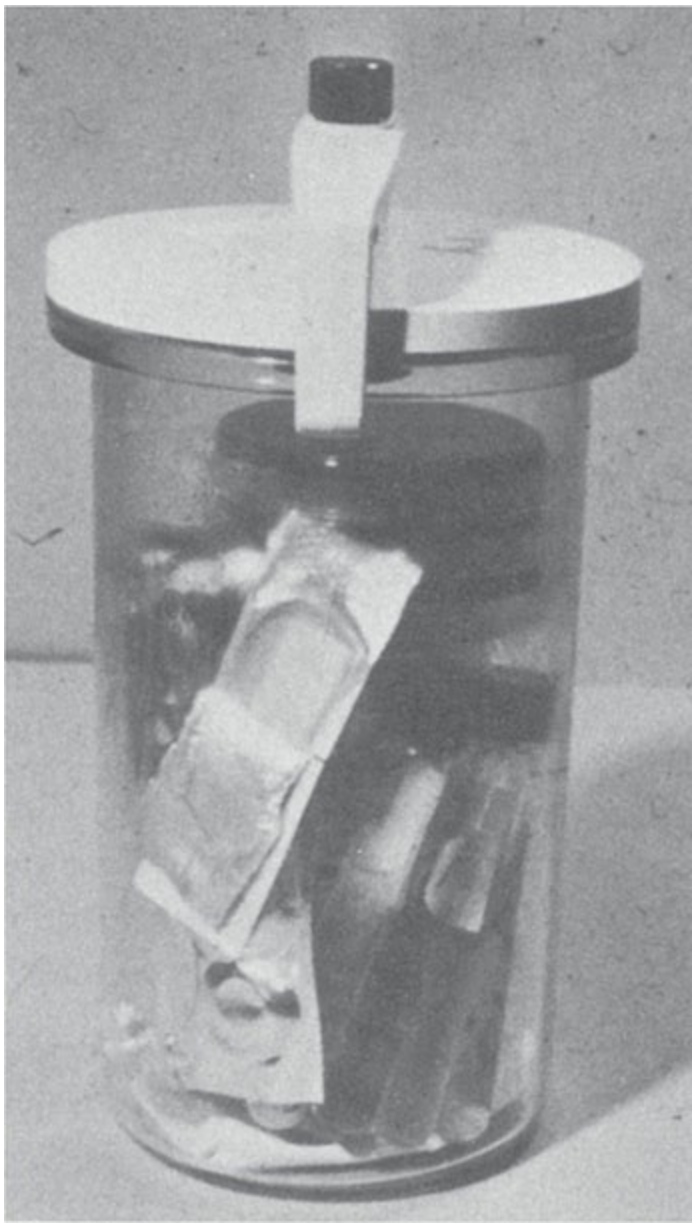
Use of the Anaerobic Jar

Anaerobic jars are commonly used for cultivating anaerobic bacteria on primary plating media or on subculture plates. The GasPak jar (Becton Dickinson), illustrated in Figure 16-2, has long been used in clinical laboratories in the United States.[317] The Oxoid anaerobic jar (Fig. 16-3) has a metal lid, Schrader valves, and a pressure gauge. Like the GasPak jar, the Oxoid jar can be used either as an evacuation-replacement jar or it can be used with a disposable gas generator. Other commercially available sources of anaerobic jars include Hardy Diagnostics, Santa Maria, CA and Thermo Fisher Scientific, Waltham, MA, among others. The basic principle of the jars that require catalyst (e.g., GasPak) is the removal of oxygen from the chamber by reaction with hydrogen added to the system in the presence of the catalyst. Oxygen is reduced to water as follows: $2H_2 + O_2 + \text{catalyst} = 2H_2O$.

BOX 16-9

Principles for Optimal Recovery of Anaerobes

1. Proper collection of the clinical specimens with guidelines provided by the laboratory
2. Appropriate and timely transfer of the clinical specimens to the laboratory
3. Appropriate labeling, including specimen type and site of collection
4. Published rejection criteria that are adhered to by the laboratory
5. Processing of specimens with minimal exposure to atmospheric oxygen
6. Use of fresh or prereduced media
7. Use of a combination of selective and nonselective media
8. Proper use of an anaerobic incubation system



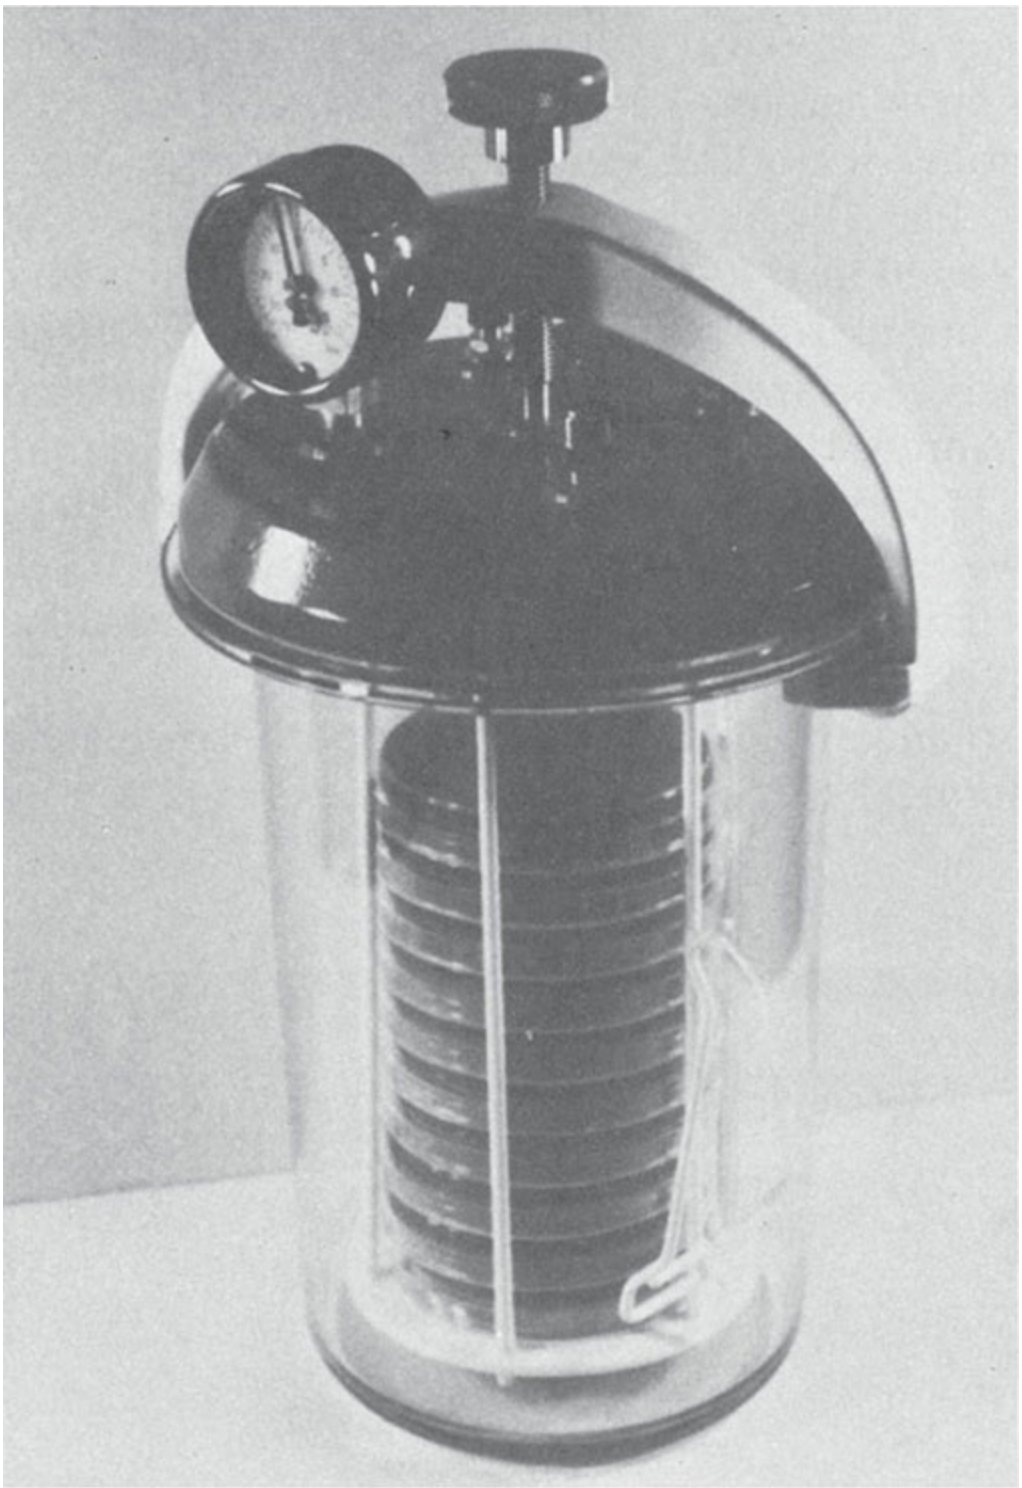
■ **FIGURE 16-2** The GasPak (Becton Dickinson Microbiology Systems, Cockeysville, MD) anaerobic system: The jar contains inoculated plates, broth tubes, a GasPak hydrogen and carbon dioxide generator envelope, a disposable methylene blue indicator strip, and a catalyst basket in the lid.

Anaerobic conditions can be produced in jar systems with either the disposable hydrogen–carbon dioxide generator (GasPak, Oxoid) or by the evacuation/replacement procedure. The evacuation/replacement procedure, in which the air in the jar is removed and replaced with a mixture of 85% N_2, 10% H_2, and 5% CO_2 is more economical than gas generators and allows anaerobic conditions to be established more rapidly. Any airtight container can be used, including a GasPak jar with a vented lid, a

Brewer jar, an Oxoid jar, or even a modified pressure cooker.

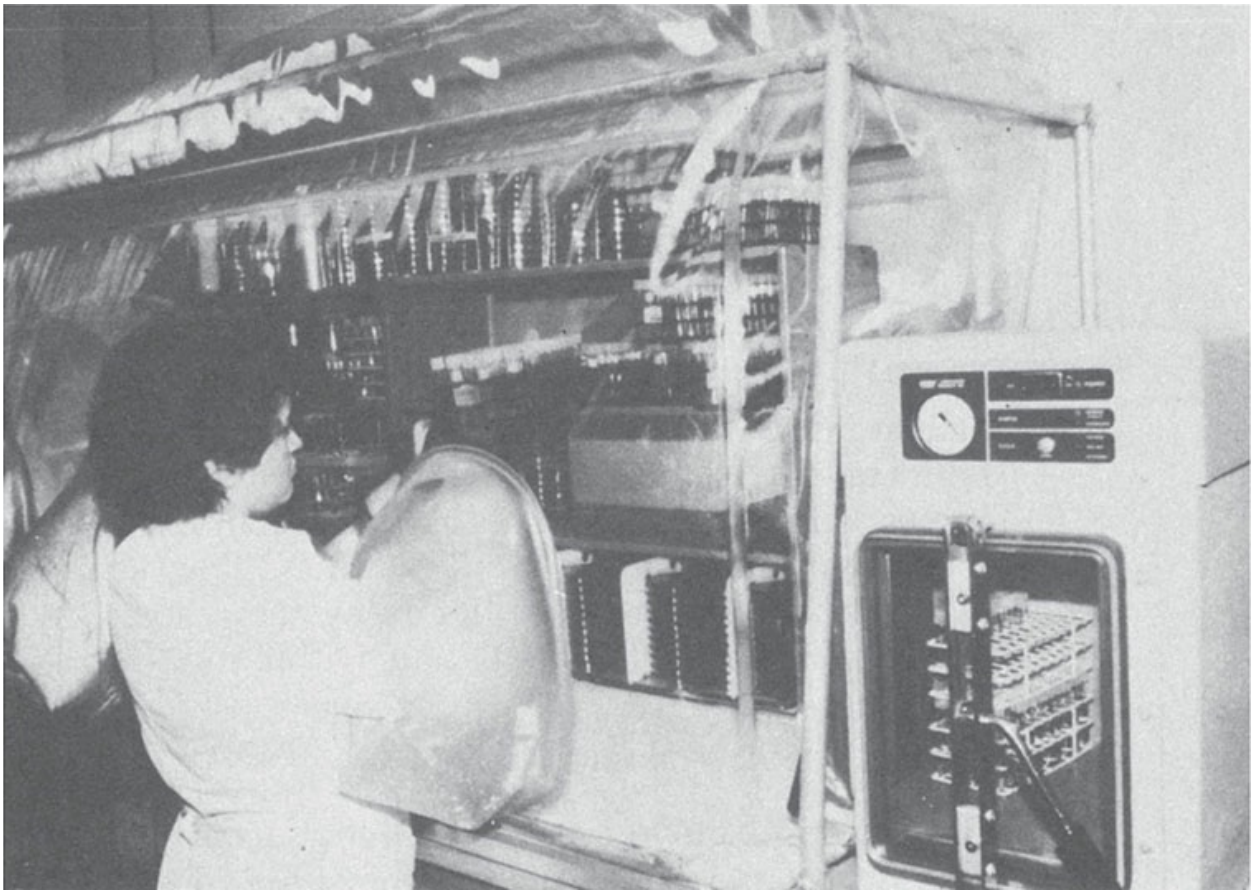
Anaerobic conditions should always be monitored when using either of the two jar techniques by including an oxidation–reduction indicator. Methylene blue strips are available commercially for this purpose. Alternatively, a 13-mm × 100-mm test tube containing a few milliliters of methylene blue–$NaHCO_3$–glucose mixture can be placed in the jar. Methylene blue is blue when oxidized and clear when reduced. The color changes at about +11.0 mV. Thus, if anaerobic conditions are achieved, the methylene blue indicator solution will gradually turn colorless and will remain that way if there are no leaks that allow additional oxygen to enter the system. If the solution turns blue after being colorless, this indicates that anaerobic conditions were not maintained and that the culture results may not be valid.

1015



■ **FIGURE 16-3** The Oxoid anaerobic jar (Oxoid USA, Columbia, MD) contains a 3.5-L polycarbonate jar closed by a heavy-duty metal lid and metal clamp. The lid center has two Schrader valves and a plus-or-minus pressure gauge, with two valves to facilitate the evacuation/replacement (E/R) technique. There is also a safety valve in the lid to prevent extra gas pressure caused by incorrect use of the E/R technique. A sachet containing a low-

temperature catalyst is clipped to the undersurface of the lid. In lieu of using the E/R technique, the jar can be used with the Oxoid generating kit available from the manufacturer.



■ **FIGURE 16-4** The anaerobic glove box (Coy Laboratory Products, Ann Arbor, MI). Materials are passed in and out of the large, flexible plastic chamber through an automatic entry lock. Anaerobic conditions are maintained by constant recirculation of the atmosphere within the plastic chamber (85% N_2, 10% H_2 and 5% CO_2) through a palladium catalyst. Cultures are incubated either within a separate incubator inside the glove box, or by maintaining the entire chamber at 35°C through use of heated catalyst boxes.

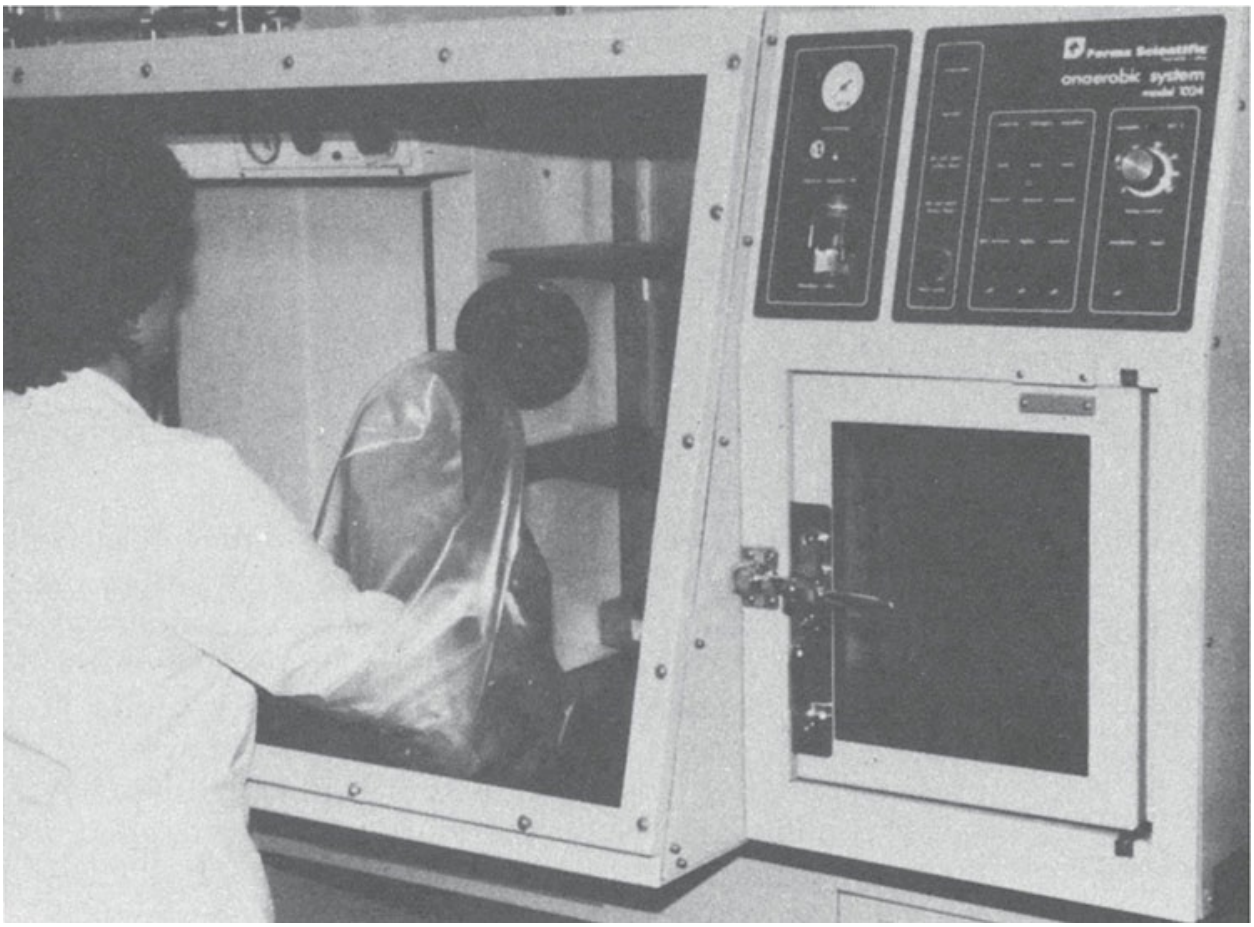
More recently, anaerobic gas-generating systems have been introduced that do not require either catalyst or the addition of water to activate these systems. The AnaeroPack (Mitsubishi Gas Chemical America, New York, NY), for example, absorbs oxygen and generates carbon dioxide, but does not generate hydrogen. It appears to be an excellent alternative to the GasPak and other established anaerobic incubation systems.[114] Becton Dickinson continues to distribute their traditional BBL GasPak system, but has also introduced the GasPak EZ gas-generating container and GasPak Generating Pouch Systems, both of which use a sachet or pouch,

respectively, without the need for addition of water to generate the anaerobic environment. Another type of commercially available catalyst-free system makes use of iron filings in a sachet to which water is added (Anaerocult, Merck, Darmstadt, Germany), producing an oxygen-free, carbon dioxide-rich atmosphere.[238] Manufacturers' websites can be used for more information on any of these products.

Use of the Anaerobic Glove Box

An anaerobic glove box (or anaerobic chamber) is a self-contained anaerobic system that allows the microbiologist to process specimens and perform most bacteriologic techniques for isolation and identification of anaerobic bacteria without exposure to air. Glove boxes suitable for cultivation of anaerobes can be constructed from various materials, including steel, acrylic plastic or fiberglass (Fig. 16-4). The flexible vinyl plastic anaerobic chamber and its modifications are available in varying sizes from many manufacturers including: Coy Manufacturing (Ann Arbor, MI), A Forma Scientific (Marietta, OH) and Toucan Technologies (Cincinnati, OH), among others. Rigid, "gloveless," glove boxes are marketed by Anaerobe Systems (Bactron Anaerobe Chamber and Sheldon Manufacturing (CorneOR), among others. An example of a glove box is shown in Figure 16-5.

1016



■ **FIGURE 16-5** The Forma Model 1024 anaerobic glove box (Forma Scientific, Marietta, OH). This system has an automatic entry lock. During routine daily operation, atmospheric air is bubbled through a methylene blue–glucose–HEPES buffer solution, which aids in monitoring O_2 leaks or determining if the catalyst is not working properly.

A certified anaerobic glove box is economical to operate because it permits the use of conventional plating media and the cost of gases for operation of the system is minimal. Once set up, the major expense is for the 85% nitrogen, 10% hydrogen, 5% carbon dioxide gas mixture used to replace the air in the entry lock when materials are passed into the glove box chamber. The referenced review on the principles behind and proper use of an anaerobic chamber is available, if more information is needed.[454]

Use of the Roll-Streak System

The roll-streak system, developed by W.E.C. Moore and associates of the Virginia Polytechnic Institute (VPI) Anaerobe Laboratory,[238] is a modification of the roll tube technique developed by Hungate and associates for culturing anaerobic bacteria from the rumen of cows and other herbivorous animals. Equipment for the VPI anaerobic

culture system, including the Hungate tubes, is available commercially from CEB Tech Services (Aberdeen, SD). The roll-streak system uses PRAS media prepared in tubes with rubber stoppers. This method is no longer widely used in clinical laboratories, and hence not discussed further; for those interested, more information is provided in earlier editions of this text and on the website for CEB Tech Services (www.CEBtechservices.com).

Use of Anaerobic Bags or Pouches
