This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based on healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data, and other factors unique to the patient. The publisher does not provide medical advice or guidance, and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work, including all medical judgments, and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made, and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things, conditions of use, warnings, and side effects and to identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used, or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Foreword

viii

ix

The diagnostic process for infectious diseases is complex. An astute clinician may be able to make a clinical diagnosis based on the history, presenting features, physical examination, and epidemiologic exposures, including relevant travel. For example, pneumonia is a clinical diagnosis albeit with radiographic confirmation. Establishing an etiologic diagnosis may be much more difficult and is dependent on obtaining a relevant specimen of interpretable quality, swift reliable transport, and the testing repertoire of the supporting clinical microbiology laboratory. Moreover, presenting features of different causative agents often overlap and an infectious process may involve multiple organ systems, thereby adding further complexity to the task of establishing an etiologic diagnosis on which specific antimicrobial therapy depends. Indeed without an accurate and timely etiologic diagnosis, empirical treatment ensues or is prolonged, which may consist of multiple antimicrobial agents, those with unnecessarily broad activity, or both. This increases the risk of adverse drug reactions, alters the patient's microbiome, and promotes selection of resistant mutants that indirectly put other patients at risk. Such collateral damage emphasizes only the need for rapid and accurate tests wisely deployed for the optimal outcome of patient care.

Thus, the founding objective of Koneman's *Color Atlas and Textbook of Diagnostic Microbiology* was to provide a clear exposition of procedures routinely employed in the laboratory identification of microbial agents causing infectious diseases. Since its first edition in 1979, the recognition and emergence of new infectious agents; better tools for their microbiologic diagnosis; more immunocompromised patients due to organ and stem cell transplantation, chemotherapy of malignancies, and immune-modulating agents; and a changing environment both of care and exposures have vastly complicated the quest for an etiologic diagnosis. These transformative developments have only accelerated since the sixth edition in 2006.

Fortunately, the tools available for the challenges at hand have also expanded and improved. Quantitative viral load determinations have become essential for care of

Downloaded From Vet-eBooks.com

patients with HIV and hepatitis C virus infections. Many other molecular test procedures are now commonplace in diagnostic microbiology laboratories large and small. The identification of microorganisms has been transformed by the introduction of matrix-assisted laser desorption/ionization time-of-flight mass spectrometry. Increasing advanced next-generation sequencing strategies are being deployed for microbial agents that have eluded diagnosis in the past or remain difficult to identify. Concurrently, traditional growth and isolation techniques remain important for many, if not most, bacterial, fungal, and mycobacterial agents and are required for reliable antimicrobial susceptibility testing given the growing threat of multidrug-resistant microorganisms. Recovery and testing is also crucial for infection control measures and for public health surveillance. As a result, now more than ever, the invaluable contribution of medical microbiology lies in providing, fostering, and promoting a proper balance between the science of the possible with the art of the appropriate. This is a professional team endeavor incumbent upon all entrusted with the stewardship of finite resources.

Therefore, it is fortuitous that Dr. Gary W. Procop now assumes the role of editor-in-chief for the seventh edition of *Koneman's Color Atlas and Textbook of Diagnostic Microbiology*, owing to his many contributions to the field in molecular microbiology, medical mycology, the histopathology of infectious diseases, and his leadership in advancing appropriate testing strategies for improved patient outcomes wherein true value lies. He and his fellow cadre of contributors are admirably positioned by virtue of knowledge, training, and experience in the field to not only maintain but also to augment the usefulness of this edition for all those who might benefit from its content: medical microbiologists, infectious disease specialists, pathologists, and clinical laboratory scientists.

L. Barth Reller, MD, DTM&H

Preface

x

xi

The seventh edition of this text represents a comprehensive update to our audience of the increasingly complex and challenging realm of diagnostic microbiology. *Koneman's Color Atlas and Textbook of Diagnostic Microbiology* is in recognition of Elmer W. Koneman as one of the founding authors of this classic text and a driving force behind publication of the first six editions. Dr. Koneman has continued to provide guidance and editorial support, so his expertise remains an important part of this seventh edition.

The seventh edition welcomes back long-time authors Drs. Paul C. Schreckenberger and William (Bill) M. Janda, who share their in-depth expertise of bacteriology. Dr. Gail Woods also returns to share her world-renowned expertise in mycobacteriology. This edition welcomes Dr. Deirdre Church, a premiere clinical microbiologist and infectious diseases clinician, and Dr. Gerri Hall, who shares her in-depth expertise in anaerobic bacteriology, mycoplasmas, and aerobic actinomycetes. It is a pleasure to join this august company in the production of this next edition of *Koneman's Color Atlas and Textbook of Diagnostic Microbiology.*

There have been substantial advances in clinical microbiology since the last edition of this textbook, with which the authors were challenged to incorporate in clinically meaningful ways. Mass spectrometry, commercially available highly multiplexed syndrome-based PCR assays, and next-generation sequencing were research tools at best when the last edition was published. Some of these, such as MALDI-TOF mass spectrometry and user-friendly nucleic acid amplification tests, are becoming commonplace in even smaller clinical laboratories. It is clear, however, that all laboratories have not adopted these technologies, and even if they desire to do so, the implementation rate is not uniform. Therefore, we were also challenged to retain traditional methods of organisms' detection and identification that are still used in many laboratories, while also including new and advanced methods. This edition attempts to bridge the divide between the traditional and the newer advanced methods that are being employed. It is for this reason that some traditional tests, which will likely become entirely replaced by newer methods, are in part retained. We have

Downloaded From Vet-eBooks.com

recommended previous editions for those assays and methods that are more universally considered antiquated.

The general organization of the text remains similar to the previous edition, but all sections have been significantly updated. The first two chapters are an introduction to clinical microbiology. Associated image plates for these chapters include artifacts in Gram-stained smears, emphasizing the importance of knowing what is not real, as well as the morphology of microorganisms. The expanded discussion of management, quality, compliance, and regulatory issues in the diagnostic microbiology laboratory confers necessary knowledge for those in the modern medical practice. Additionally, we have attempted to provide guidance to questions that clinical microbiologists face daily, such as: What do we work up, when do we work it up, and how extensively do we work it up? These challenges have become as important as the more traditional scientific issues confronted in the clinical laboratory, given the ever-dwindling financial and personnel resources.

The traditional techniques that are still important for clinical laboratories receive appropriate attention in this edition, but the increasing importance of immunologic methods (Chapter 3) and particularly molecular techniques (Chapter 4) justifies explicit discussion of principles, as well as expanded coverage in individual chapters as appropriate. Where immunologic and/or molecular approaches have become the norm in diagnostic laboratories, the text has been updated to reflect these changes. Discussions of methods that are obsolete or rapidly becoming archaic have been eliminated or significantly condensed.

The introduction to bacteriology, still the lynchpin of clinical laboratories, follows as Chapter 5 and sets the stage for the subsequent chapters in this vast field. These chapters are followed by those addressing mycobacteria fungi, parasites, and viruses and other intracellular pathogens. The increasing frequency with which ectoparasites are submitted to diagnostic laboratories for identification has been acknowledged with an expanded discussion of tick identification in an appendix, including several image plates to aid in the appropriate identification of these organisms.

In an era of rapid changes in diagnostic methods, the goal of the text remains the same: to provide an extensive but practical discussion of the science and art of diagnostic microbiology. We strongly believe that it is essential to integrate the clinical issues with the practice of laboratory medicine, so as to provide the information that our clinical colleagues need to best serve the patients. This integration expands the role of the microbiologists and removes them from a position in a basement somewhere and from behind a microscope. Although our skills as expert microbiologists must be retained and sharpened, additional value is gained at the health system level when microbiologists and other laboratorians participate on clinical practice committees and help to determine the optimal use of laboratory resources. We are of immense value to our institutions, but too often remain an unrecognized and untapped resource of the healthcare delivery team. Emerge from the laboratory and let your value be known,

Downloaded From Vet-eBooks.com

with service to the patient being the driver of all these efforts.

There are two intended audiences for this text. The first group consists of students and instructors of microbiology and medicine, particularly those interested in infectious diseases. The book provides a comprehensive review for graduate students, residents in pathology, and fellows in medical microbiology and infectious diseases. For undergraduate students, the volume of material may appear overwhelming, but this denotes the depth and complexity of our field. It is hoped that this depth and complexity will inspire rather than deter, providing a view into a career option that will remain ever evolving, challenging, and interesting. It is hoped that

the dedicated teachers of our craft will find ample and updated material to guide the beginning student, who will then have a resource to carry on into the graduate environment or the workplace, rather than a superficial and outmoded introduction for the bookshelf. The second, equally important audience, is laboratory professionals for whom the text can represent the initial resource for updating competency or troubleshooting problems in clinical practice. To facilitate understanding of the subject matter, we continue to employ tables, detailed charts, summary text boxes, and extensive color illustrations. Each chapter begins with a detailed outline, which represents the chapter at a glance. Charts can be found online at http://thepoint.lww.com/

We are all greatly indebted to a variety of mentors, colleagues, and students who have challenged and inspired us. We are particularly indebted to Drs. L. Barth Reller and Glenn D. Roberts, who generously collaborated to contribute a Foreword for this edition. We also thank Dr. Glenn D. Roberts for contributing many of the images for the mycology chapter. Two of our former co-authors, the late Dr. Washington C. Winn Jr and the late Dr. Stephen D. Allen, and one of the current authors, the late Dr. Gerri Hall, are very much in our memory as we carry the torch forward that they have borne. We could not have done this without the contributions of Dr. Hall to the current edition and the fundamental work of Drs. Winn and Allen in the previous editions. To recognize their contributions, we dedicate this edition to their memory.

Acknowledgments

We are, first of all, indebted to our colleagues in the microbiology laboratories at our respective institutions for their important roles in our professional life. They have challenged us, inspired us, and educated us. We hope this book serves to repay their

Downloaded From Vet-eBooks.com

contributions in some small part. Additionally, we are grateful to the members of our families for their forbearance while we struggled to meet deadlines. Their support and encouragement at home are integral to our activities at work.

CHAPTER 1 **Introduction to Microbiology**

Part I The Role of the Microbiology Laboratory in the Diagnosis of Infectious Diseases: Guidelines to Practice and Management

Introduction
- Outline of the Book
- The World of Infectious Disease

The Triad of Infectious Disease
- The Infectious Agent
  - Classes of Infectious Agents
  - Interactions Between Hosts and Infectious Agents
  - Virulence
- The Environment
- The Infected Host
  - Innate, Noncellular Defenses
  - Innate, Cellular Defenses
  - Types of Inflammation
  - Adaptive Immunologic Cellular Defenses
  - Adaptive Immunologic Noncellular (Humoral) Defenses
  - Clinical Signs and Symptoms of Infection
  - Indirect Effects of Infectious Agents on Humans

Phases of the Diagnostic Cycle
- Preanalytic Phase
  - Specimen Collection
  - Specimen Transport
  - Specimen Receipt and Preliminary Observations
  - Criteria for Rejection of Specimens

Downloaded From Vet-eBooks.com

Cost-Effective Approaches in the Preanalytic Phase
Analytic Phase
Microscopic Examination
Processing Specimens
Interpretation of Cultures
Procedures for Preliminary Identification of Bacterial Isolates
Identification of Organisms Other Than Bacteria
Testing of Susceptibility to Antimicrobial Agents
Cost-Effective Approaches in the Analytic Phase
Postanalytic Phase
Reporting Results
Interactions With Epidemiologists
Analysis of Results
Maintenance of Samples and Records
Administrative Aspects of the Microbiology Laboratory
Government Regulations
Accreditation and Laboratory Inspection
Risk Management and Patient Safety
Laboratory Safety
General Safety Rules and Regulations
Routine Safety Precautions
Biologic Agents
Universal Precautions
Shipping of Specimens and Etiologic Agents
Nonbiologic Hazards
Biodefense
Quality Assurance
Quality Control
Components of a Quality Control Program
Monitoring Laboratory Equipment
Monitoring Culture Media, Reagents, and Supplies

CHAPTER 2 **Introduction to Microbiology**

Part II Guidelines for the Collection, Transport, Processing, Analysis, and Reporting of Cultures From Specific Specimen Sources

Introduction

CHAPTER 8 Curved Gram-Negative Bacilli and Oxidase-Positive Fermenters

Historical Background
Classification of *Campylobacter* and Related Taxa
Genus *Campylobacter*
Campylobacter jejuni subsp *jejuni*
Other *Campylobacter* Species
Genus *Arcobacter*
Arcobacter butzleri
Arcobacter cryaerophilus
Arcobacter skirrowii
Genus *Helicobacter*

Helicobacter pylori
Culture and Isolation of *H. pylori*
Identification of *H. pylori*
Other Medically Important *Helicobacter* Species
Other Microaerophilic Gram-Negative Bacilli
Sutterella wadsworthensis
Definitive Identification of Campylobacters and Related Bacteria
Rapid Identification of Campylobacters From Colonies Grown in Culture

Downloaded From Vet-eBooks.com

Morphologic Identification
Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry
Commercial Kit Systems
Methods for Direct Detection of Campylobacters From Stool
Direct Immunofluorescence
Enzyme Immunoassay
PCR
Phylogeny of the *Vibrionaceae*
Genus *Vibrio*
Taxonomy
Description and Associated Clinical Syndromes of *Vibrio* Species of Human Importance
Methods for Laboratory Isolation of *Vibrios*
Biochemical Characterization and Laboratory Identification of *Vibrio* Species
Listonella, Photobacterium*, and *Shewanella
Aeromonas* and *Plesiomonas
Genus *Aeromonas*
Taxonomy
Clinical Significance
Aeromonas Species in Medicinal Leeches
Laboratory Recovery of *Aeromonas* Species From Clinical Specimens
Laboratory Identification of *Aeromonas* Species
Genus *Plesiomonas*
Clinical Significance
Laboratory Isolation and Identification
Genus *Chromobacterium*

CHAPTER 9 Miscellaneous Fastidious Gram-Negative Bacilli

Introduction to the Family *Pasteurellaceae*
***Haemophilus* Species**
Taxonomy
Haemophilus influenzae
Haemophilus Influenzae Type b Vaccines and Immunity
Other *Haemophilus* Species
Haemophilus ducreyi
Laboratory Diagnosis of *Haemophilus* Infections
Direct Examination of Clinical Specimens
Recovery of *Haemophilus* Species in Culture

Downloaded From Vet-eBooks.com

Identification of *Haemophilus* Species
Haemophilus ducreyi: Laboratory Diagnosis of Chancroid
Specimen Collection and Direct Examination
Culture
Antimicrobial Susceptibility of *Haemophilus* Species
Genus *Aggregatibacter*
Taxonomy
Clinical Significance
Aggregatibacter aphrophilus
Aggregatibacter segnis
Aggregatibacter actinomycetemcomitans
Cultural Characteristics and Identification of *Aggregatibacter* Species
Antimicrobial Susceptibility of *Aggregatibacter* Species
***Cardiobacterium* Species**
Taxonomy
Clinical Significance
Cultural Characteristics and Identification
Antimicrobial Susceptibility
Eikenella corrodens
Taxonomy
Clinical Significance
Cultural Characteristics and Identification
Antimicrobial Susceptibility
***Kingella* Species**
Taxonomy
Clinical Significance
Cultural Characteristics and Identification
Antimicrobial Susceptibility
***Capnocytophaga* Species**
Taxonomy
Clinical Significance
Cultural Characteristics and Identification
Antimicrobial Susceptibility
***Dysgonomonas* Species**
Taxonomy
Clinical Significance
Cultural Characteristics and Identification
Antimicrobial Susceptibility
Streptobacillus moniliformis
Taxonomy
Epidemiology

Downloaded From Vet-eBooks.com

Clinical Significance
Cultural Characteristics and Identification
Antimicrobial Susceptibility
***Simonsiella* Species**
***Pasteurella* and *Mannheimia* Species**
Taxonomy and Characteristics of the Genus *Pasteurella*
Reclassification of Other *[Pasteurella]* Species
Pasteurella Species: Clinical Significance, Identification, and Antimicrobial Susceptibility
Pasteurella multocida
Pasteurella dagmatis, Pasteurella canis, and *Pasteurella stomatis*
[Pasteurella] Species Incertae Sedis: Clinical Significance, Identification, and Antimicrobial Susceptibility
[Pasteurella] aerogenes
[*Pasteurella*] *pneumotropica*
[*Pasteurella*] *bettyae*
[*Pasteurella*] *caballi*
Avibacterium ([*Pasteurella*]) *gallinarum*
Mannheimia Species (Formerly the "*Pasteurella haemolytica/Pasteurella granulomatis*" Complex)

xxi

Genus *Actinobacillus*
Taxonomy
Clinical Significance of *Actinobacillus* Species
Actinobacillus ureae
Actinobacillus hominis
Other *Actinobacillus* Species
Cultural Characteristics of *Actinobacillus* Species
***Brucella* Species**
Introduction
Taxonomy and Epidemiology
Virulence of *Brucella* Species
Clinical Spectrum of Brucellosis
Serologic Diagnosis of *Brucella* Infections
Isolation and Cultural Characteristics
Identification of *Brucella* Species
Treatment of Brucellosis
***Francisella* Species**
Epidemiology of Tularemia

Downloaded From Vet-eBooks.com

History and Taxonomy
Clinical Spectrum of Tularemia
Detection, Isolation, and Cultural Characteristics
Treatment of Tularemia
Virulence of *F. tularensis*
Afipia* Species, *Bosea* Species, and Other α-*Proteobacteria
***Bartonella* Species**
Taxonomy
Epidemiology of *Bartonella* Species
Human Infections Associated With *Bartonella* Species
Oroya Fever and Verruga Peruana
"Classical" and "Urban" Trench Fever
Bacillary Angiomatosis
Peliosis
Fever and Bacteremia
Endocarditis
Cat Scratch Disease
Miscellaneous Infections
Emerging Pathogens in the Genus *Bartonella*
Detection, Isolation, and Identification of *Bartonella* Species
Specimen Types
Microscopic Examination of Clinical Specimens
Culture
Gram's Stain and Colony Morphology
Identification Methods
Serologic Diagnosis
In Vitro Antimicrobial Susceptibility
***Bordetella* Species**
Background and Taxonomy of *Bordetella* Species
Epidemiology of Pertussis
Clinical Significance of *Bordetella pertussis*
Pertussis Vaccines
Clinical Significance of Other *Bordetella* Species
Bordetella parapertussis
Bordetella bronchiseptica
Bordetella avium
Bordetella hinzii
Bordetella holmesii
Bordetella trematum
Bordetella petrii
Bordetella ansorpii

Downloaded From Vet-eBooks.com

Culture and Isolation of *Bordetella pertussis*
Direct FA Test
Cultural Characteristics and Identification of *Bordetella* Species
Molecular Methods for Detection and Identification of *Bordetella* Species
Serologic Tests for Diagnosis of Pertussis
Treatment of *Pertussis*
Antimicrobial Susceptibility Testing of *Bordetella* Species

CHAPTER 10 *Legionella*

Introduction
Taxonomy and Characteristics of the Genus *Legionella*
Clinical and Pathologic Spectrum of Legionellosis
Predisposing Factors
Pathology and Pathogenesis
Epidemiologic and Ecologic Aspects of Legionellosis
Incidence
Legionellaceae in the Environment
Natural Habitats
Aquatic Habitats Made by Humans (Artificial)
Legionellosis in Travelers
Nosocomial Outbreaks of Legionellosis
Laboratory Diagnosis
Selection, Collection, and Transport of Clinical Specimens
Direct Examination of Clinical Specimens
Gross Examination
Microscopic Examination
Legionella PCR and Other Molecular Methods
Direct Fluorescent Antibody Testing
Legionella Antigen Detection
Detection of *Legionella* in Clinical Specimens
Isolation of *Legionella* Species From Clinical Specimens
Tissue Specimens
Pleural Fluid and Transtracheal Aspirates
Acid-Wash Decontamination Procedure
Blood Cultures
Identification of *Legionella* Species
Antimicrobial Susceptibility and Treatment
Serologic Studies for *Legionella*

Downloaded From Vet-eBooks.com

Environmental Microbiology Studies
Molecular Detection of *Legionella* in Environmental Samples
Isolation and/or Detection of *Legionella* in Environmental Samples
Typing of *Legionella* Isolates

xxii

CHAPTER 11 *Neisseria* Species and *Moraxella catarrhalis*

Introduction
Taxonomy of the Family *Neisseriaceae* and the Family *Moraxellaceae*
General Characteristics of the Genus *Neisseria*
Clinical Significance of *Neisseria* Species
Neisseria gonorrhoeae
Epidemiology
Infections Caused by *N gonorrhoeae*
Neisseria meningitidis
Meningococcal Epidemiology: Serogroups, Serotypes, and Serosubtypes
Carriage of *N. meningitidis*
Infections Caused by *N. meningitidis*
Meningococcal Prophylaxis and Meningococcal Vaccines
Other *Neisseria* Species
Clinical Significance of *Moraxella catarrhalis*
Isolation of *Neisseria* Species
Neisseria gonorrhoeae
Direct Gram-Stained Smears
Specimen Collection and Transport
Selective Culture Media: Inoculation and Incubation
Neisseria meningitidis
Specimen Collection and Transport
Laboratory Safety
Direct Gram-Stained Smears and Direct Capsular Antigen Tests
Isolation and Incubation
Identification of *Neisseria* Species
Colony Morphology
Gram Stain and Oxidase Test
Superoxol Test
Differentiation of Other Organisms on Selective Media
Presumptive Criteria for Identification of *N. gonorrhoeae*

Downloaded From Vet-eBooks.com

Identification Tests for *Neisseria* Species
Carbohydrate Utilization Tests
Conventional CTA Carbohydrates
Rapid Carbohydrate Utilization Test
CarboFerm *Neisseria* Test
Other Carbohydrate Utilization Methods
Chromogenic Enzyme Substrate Tests
Gonochek II
BactiCard *Neisseria*
Immunologic Methods for Culture Confirmation of *N. gonorrhoeae*
Coagglutination Test
GonoGen II Test
Multitest Identification Systems
DNA Probe Test for Culture Confirmation of *N. gonorrhoeae*
Nucleic Acid Hybridization Tests for *N. gonorrhoeae*
Nucleic Acid Amplification Tests for *N. gonorrhoeae*
MALDI-TOF for Identification of *Neisseria* Species
Sexual Abuse/Assault and *N. gonorrhoeae*
Typing Methods for *N. gonorrhoeae*
Molecular Methods for Detection of *N. meningitidis*
Serogrouping and Typing of *N. meningitidis*
Cultural Characteristics of Other *Neisseria* Species
N. lactamica
N. cinerea
Neisseria subflava biovars, *N. mucosa*, and *N. sicca*
N. polysaccharea
N. flavescens
N. elongata Subspecies
N. weaveri
N. bacilliformis
N. animaloris and *N. zoodegmatis*
N. wadsworthii
N. shayeganii
Cultural Characteristics and Identification of *Moraxella catarrhalis*
Antimicrobial Susceptibility of *Neisseria* Species
N. gonorrhoeae
N. meningitidis
Antimicrobial Susceptibility of *Moraxella catarrhalis*

CHAPTER 12 Gram-Positive Cocci

Downloaded From Vet-eBooks.com

Part I Staphylococci and Related Gram-Positive Cocci

Taxonomy of Staphylococci and Related Gram-Positive Cocci
Clinical Significance of Staphylococci and Related Gram-Positive Cocci
Staphylococcus aureus subsp. *aureus* (Herein Called *S. aureus*)
Staphylococcus aureus subsp. *anaerobius*
Coagulase-Negative Staphylococci
Staphylococcus epidermidis
Staphylococcus saprophyticus subsp. *saprophyticus*
Other Coagulase-Negative Staphylococci
Micrococcus Species and Related Genera
Rothia mucilaginosa
Isolation and Preliminary Differentiation of Staphylococci and Related Gram-Positive Cocci
Direct Gram-Stained Smears
Isolation From Clinical Specimens
Colony Morphology
The Catalase Test
Methods for Differentiating Micrococci and Staphylococci
Fermentation of Glucose
Susceptibility to Lysostaphin
Production of Acid From Glycerol in the Presence of Erythromycin

Susceptibility to Furazolidone
Modified Oxidase Test
Susceptibility to Bacitracin
Coverslip Growth Method
Methods for Direct Detection of MRSA in Clinical Specimens
Chromogenic Media for Surveillance of MRSA Colonization
Molecular Methods for Surveillance of MRSA Colonization
Molecular Methods for Detection of MRSA and MSSA in Blood Cultures and Skin/Soft Tissue Infections
Identification of *Staphylococcus aureus*
Slide Coagulase Test
Tube Coagulase Test
Alternative Coagulase Test Procedures
Agglutination Tests
Additional Confirmatory/Identification Tests for *Staphylococcus aureus*

Downloaded From Vet-eBooks.com

Deoxyribonuclease Test
Thermostable Endonuclease Test
Mannitol Fermentation
AccuProbe *Staphylococcus aureus*
Rapid Tests for Detection of Methicillin Resistance
Genotype MRSA
Identification of Coagulase-Negative Staphylococci
Conventional Identification Methods
Pyrrolidonyl Arylamidase Activity
Susceptibility to Polymyxin B
Ornithine Decarboxylase Test
Urease Production
Acetoin Production
Susceptibility to Novobiocin for Presumptive Identification of *Staphylococcus saprophyticus*
Commercial Identification Systems
Automated Identification Systems
Manual Identification Systems
Staphylococcus aureus/Coagulase-Negative Staphylococci PNA FISH Culture Confirmation Kit (AdvanDx, Woburn, MA)
Molecular Identification and Typing Methods for Staphylococci
Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry
Identification of *Micrococcus* and Related Species
Identification of *Rothia mucilaginosa*
Laboratory Approach to the Identification of Staphylococci

CHAPTER 13 Gram-Positive Cocci

Part II Streptococci, Enterococci, and the "*Streptococcus*-Like" Bacteria

General Characteristics of the Streptococci
Group A β-Hemolytic Streptococci (*Streptococcus pyogenes*)
Virulence Factors
Clinical Spectrum of Group A Streptococcal Disease
Group B β-Hemolytic Streptococci (*Streptococcus agalactiae*)
Virulence Factors
Clinical Spectrum of Group B Streptococcal Disease
Prevention of Group B Streptococcal Disease

Downloaded From Vet-eBooks.com

Other Infections Caused by Group B Streptococci
Antimicrobial Susceptibility of Group B Streptococci
Group C and Group G β-Hemolytic Streptococci
Group F β-Hemolytic Streptococci
Emerging Pathogens Among the Streptococci
Streptococcus suis
Streptococcus porcinus and *Streptococcus pseudoporcinus*
Streptococcus iniae
Streptococcus pneumoniae
Virulence Factors
Pneumococcal Vaccines
Clinical Spectrum of *S. pneumoniae*
Antimicrobial Susceptibility of *S. pneumoniae*
Viridans Streptococci
The Anginosus Group: *Streptococcus anginosus, Streptococcus constellatus*, and *Streptococcus intermedius*
Group D Streptococci: The "*Streptococcus bovis*" Group
***Enterococcus* Species**
Taxonomy
Virulence Factors
Clinical Spectrum of Enterococcal Infections
Antimicrobial Susceptibility of Enterococci
Genus *Melissococcus* and Genus *Catellicoccus*
The "*Streptococcus*-Like" Bacteria
Abiotrophia and *Granulicatella* Species
Aerococcus and *Helcococcus* Species
Leuconostoc Species
Pediococcus and *Tetragenococcus* Species
Gemella Species
Vagococcus Species
Alloiococcus Species
Globicatella Species
Facklamia Species
Dolosigranulum, *Ignavigranum*, *Dolosicoccus*, and *Eremococcus* Species
Lactococcus Species
Isolation and Identification of Streptococci and the "*Streptococcus*-Like" Bacteria
Direct Gram-Stained Smears
Culture Media
Hemolysis on Blood Agar
Nonculture, Direct Detection Techniques for Group A *β*-Hemolytic Streptococci in

Downloaded From Vet-eBooks.com

Pharyngeal Specimens
Nonculture, Direct Detection Techniques for Group B β-Hemolytic Streptococci

xxiv

Nonculture, Direct Detection Techniques for *Streptococcus pneumoniae*
Nonculture Techniques for the Detection of Enterococci in Blood Cultures
Colony Morphology and Catalase Testing
Recognition and Preliminary Characterization of Streptococci and the "*Streptococcus*-Like" Bacteria
Presumptive Identification of Streptococci and Enterococci
Susceptibility to Bacitracin
Susceptibility to Sulfamethoxazole-Trimethoprim (SXT)
CAMP Test and Pigment Production
Hydrolysis of Sodium Hippurate
Bile Esculin Test
Salt Tolerance Test (65% NaCl Broth)
Leucine Aminopeptidase (LAP) Test
Pyrrolidonyl Arylamidase (PYR) Test
Commercial Presumptive Identification Tests
Serologic Identification of β-Hemolytic Streptococci
Capillary Precipitin Test
Coagglutination
Latex Agglutination
Phenotypic Characteristics for Identification of Groupable Streptococci
Identification of *S. pneumoniae*: Susceptibility to Optochin, the Bile Solubility Test, and AccuProbe *Pneumococcus* Test
Serologic Identification of *Streptococcus pneumoniae*
Identification of the Viridans Streptococci
Mitis/Sanguinis Group
Mutans Group
Salivarius Group
Anginosus Group
Bovis Group
Identification of *Streptococcus suis* and Other Streptococci Isolated From Animals
Detection of Vancomycin-Resistant Enterococci
Identification of *Enterococcus* Species
Identification of *Abiotrophia* and *Granulicatella* Species
Identification of *Aerococcus* and *Helcococcus* Species
Identification of *Leuconostoc*, *Pediococcus*, and *Tetragenococcus* Species
Identification of *Gemella* Species

Downloaded From Vet-eBooks.com

Identification of *Vagococcus* Species
Identification of *Alloiococcus* Species, *Globicatella* Species, *Facklamia* Species, *Dolosigranulum* Species, *Ignavigranum* Species, and *Dolosicoccus* Species
Identification of *Lactococcus* Species
Commercial Systems for Identification of Streptococci, Enterococci, and Selected "*Streptococcus*-Like" Bacteria
Vitek 2
Phoenix (Becton-Dickinson Diagnostic Systems, Sparks, MD)

CHAPTER 14 Aerobic and Facultative Gram-Positive Bacilli

Listeria* Species and *Listeria monocytogenes
Taxonomy of the Genus *Listeria*
Virulence of *L. monocytogenes*
Epidemiology of *L. monocytogenes*
Clinical Significance of *L. monocytogenes*
Isolation of *L. monocytogenes* From Clinical Specimens
Identification of *Listeria* Species
Antimicrobial Susceptibility and Treatment of *Listeria* Infections
Pathogenicity of Other *Listeria* Species
***Erysipelothrix* Species**
Taxonomy of the Genus *Erysipelothrix*
Clinical Significance of *E. rhusiopathiae*
Isolation and Identification of *E. rhusiopathiae*
Antimicrobial Susceptibility of *E. rhusiopathiae*
***Bacillus* Species and Related Genera**
Taxonomy and the Taxonomic Dissection of Genus *Bacillus*
Bacillus anthracis
Epidemiology of Anthrax
Virulence Factors of *B. anthracis*
Clinical Presentations of Anthrax
Antimicrobial Susceptibility and Treatment of *B. anthracis* Infections
Prevention of Anthrax
Bacillus cereus
Virulence Factors of *B. cereus*
B. cereus Gastroenteritis
Opportunistic Infections Caused by *B. cereus*, Other *Bacillus* Species, and *Paenibacillus* Species
B. cereus Bacteremia and Endocarditis

Downloaded From Vet-eBooks.com

B. cereus Infections in Compromised Hosts
B. cereus Ocular Infections
B. cereus Skin, Bone, and Soft Tissue Infections
Nosocomial Infections
Laboratory Safety, Specimen Collection, and Processing
Isolation and Identification of the "*Bacillus cereus* Group"
Antimicrobial Susceptibility Testing of *Bacillus* Species
***Corynebacterium* Species**
Introduction and Taxonomy
Identification of *Corynebacterium* Species and Coryneform Bacteria
API Coryne
RapID CB-Plus

Clinical Significance of *Lactobacillus* Species
Isolation and Identification of *Lactobacillus* Species
Antimicrobial Susceptibility of *Lactobacillus* Species
***Weissella* Species**

CHAPTER 15 Aerobic Actinomycetes

Introduction, Classification, and Taxonomy
The Nocardioform Group
Nocardia spp.
Non- *N. asteroides* Complex Species
Epidemiology, Pathology, and Pathogenesis
Clinical Disease
Rhodococcus spp.
Taxonomy and Classification
Epidemiology, Pathology, and Pathogenesis
Clinical Disease
Gordonia spp.
Taxonomy and Classification
Epidemiology, Clinical Disease, and Pathogenesis
Tsukamurella spp.
Taxonomy and Classification
Epidemiology and Clinical Disease
Dietzia spp.
Other Nocardioform Bacteria
The *Streptosporangineae*
Actinomadura spp.
Taxonomy and Classification
Epidemiology, Clinical Disease, and Pathology
Nocardiopsis spp.
The Streptomycetes

Downloaded From Vet-eBooks.com

Streptomyces spp.
Thermophilic Actinomycetes
Miscellaneous Actinomycetes
Dermatophilus
Tropheryma whipplei
History and Taxonomy
Ecology
Clinical Disease and Pathology
Laboratory Diagnosis of Infections Caused by Aerobic Actinomycetes
Primary Isolation
Differentiation of *Nocardia* From Other Genera of Aerobic Actinomycetes
Identification of Thermophilic Actinomycetes
Identification of *Tropheryma whipplei*
In Vitro Susceptibility of *Nocardia* and Related Bacteria to Antimicrobial Agents and Therapy for Infections
Concluding Comments

CHAPTER 16 The Anaerobic Bacteria

Introduction to Anaerobic Bacteria
Classification of Bacteria Based on Their Response to Oxygen
Reasons for Anaerobiosis
Habitats for Anaerobes
Taxonomic Classification and Nomenclature
Taxonomy of the Anaerobic Gram-Negative Bacilli
Taxonomy of the Anaerobic Gram-Positive Non–Spore-Forming Bacilli
Taxonomy of the *Clostridium* spp.
Taxonomy of the Anaerobic Gram-Positive and Gram-Negative Cocci
Human Infections Involving Anaerobes
Overview
Infections Involving Anaerobic Gram-Negative Bacilli
Infections Involving Anaerobic Gram-Positive NSF Bacilli
Bacterial Vaginosis
Infections Involving *Clostridium* spp.
C. perfringens and Related *Clostridium* spp. Involved in Skin and Soft Tissue Infections
Intestinal Diseases Involving *C. perfringens*
Infections Involving Miscellaneous *Clostridium* spp.
Infections With *C. botulinum* and Related *Clostridium* spp.

Downloaded From Vet-eBooks.com

Infections With *C. tetani*
Infections Involving Anaerobic Gram-Positive and Gram-Negative Cocci
Isolation of Anaerobic Bacteria
Selection of Specimens for Culture

Collection and Transport of Specimens
Anaerobic Blood Cultures
Direct Examination of Clinical Material
Selection and Use of Media
Systems for the Cultivation of Anaerobic Bacteria
Use of the Anaerobe Jar
Use of the Anaerobic Glove Box
Use of the Roll-Streak System
Use of Anaerobic Bags or Pouches
Use of the Anaerobic Holding Jar
Anoxomat
Incubation of Anaerobic Cultures
Procedures for Handling Anaerobic Cultures
Inspection and Subculture of Colonies
Aerotolerance Tests
Preliminary Reporting of Results
Identification of Anaerobic Isolates
Determination of Cultural and Biochemical Characteristics
Presumptive Identification
Use of Differential Agar Media and Spot Tests
Antibiotic Special Potency Disk Tests
Use of SPS and Nitrate Disk Tests
Identification of Anaerobes Using Phenotypic Characteristics
Conventional Approaches
Commercial Microsystems for the Identification of Anaerobes
Determination of Metabolic Products by Gas-Liquid Chromatography
Use of Molecular and Mass Spectrometric Methods (MALDI-TOF) for Identification of Anaerobic Bacteria
Identification of Specific Groups of Anaerobic Bacteria
Levels of Identification in Different Laboratories
Identification of Anaerobic Gram-Negative Bacilli

Introduction

Outline of the Book

There are almost as many ways to look at the world of infectious disease as there are infectious agents. In this book, we will concentrate on the detection and identification of infectious agents in the clinical laboratory, followed by determination of susceptibility to antimicrobial agents if appropriate. Conceptually, the book is divided into three sections. The first section, which consists of two chapters, covers general principles of infectious diseases and laboratory diagnosis. In the second section, immunologic and molecular techniques that have virtually universal applicability are presented. Finally, the third and largest section consists of extensive discussion of groups of infectious agents and the diseases that they produce. The general principles of bacteriology are illuminated in a separate chapter because of the diversity of organisms in this large group of human pathogens.

The World of Infectious Disease

Throughout human existence, infectious diseases have been the predominant cause of illness and death, not only limiting improvements in personal comfort but also thwarting the societal development. The improvements in living conditions, sanitation, and medical intervention of the 20th century significantly diminished many infectious diseases. Unfortunately, these challenges remain in resource-limited countries throughout much of the world. The challenge remains for the world community to extend these achievements around the globe.

2

By the 1950s, the successes of modern medicine and public health seemed so impressive that many prominent scientists were prompted to predict the conquest of infectious disease and the eradication of pestilence as a cause of misery from the face of the earth. William H. Stewart, the then Surgeon General of the United States, famously stated in 1969 “It is time to close the book on infectious diseases.” It is the misfortune of us all that those men greatly underestimated the adaptability of the multitudinous life forms that share Earth with us—both infectious agents and

Downloaded From Vet-eBooks.com

predatory ectoparasites, such as arthropods. Likewise, they could not foresee the unanticipated consequences of major medical advances that prolonged human life, including the effects on host defense mechanisms. Nor did they appreciate the effects of human incursion farther into the environment or the consequences of free movement of plants and animals, including humans, around the globe. As a result, the list of new or newly rejuvenated infectious diseases that have plagued us since those erroneous predictions is long and still growing. A partial accounting is given in Table 1-1.

The Triad of Infectious Disease

In order to understand infectious diseases, the student must appreciate the interactions among three entities:

1. **The affected host**. From our anthropomorphic point of view, this host will usually be a human. The veterinarian will be concerned with animal hosts, while a botanist will focus on plants. The affected host may even itself be an infectious agent, for example, when a bacterium is infected by a bacteriophage.
2. **An infectious agent**. This designation is the broadest description for a variety of life forms that interact intimately with a host (i.e., another life form), usually to the detriment of the latter. Infectious agents often enter (i.e., infect) the host in some manner.
3. **The environment**. The natural environment, both animate and inanimate, is essential for maintenance of most infectious agents and important for transmission of infectious agents from one host to another.

TABLE 1-1 Newly Recognized Infectious Diseases and Newly Identified Pathogens Since the "Conquest of Infectious Diseases"

Year	Agent	Disease(s)
1977	Ebola virus	Ebola hemorrhagic fever
	Legionella spp.	Legionnaires' disease
	Hantaan virus	Hemorrhagic fever with renal symptoms
	Campylobacter jejuni	Gastroenteritis
	Escherichia coli 0157	Hemorrhagic colitis; hemolytic

Downloaded From Vet-eBooks.com

	(verotoxin-producing)	uremic syndrome
	Borrelia burgdorferi	Lyme disease
1983	*Helicobacter pylori*	Gastric/duodenal ulcer
	Human immunodeficiency virus	Acquired immunodeficiency syndrome
1989	Hepatitis C virus	Non-A, non-B hepatitis
1991	*Ehrlichia chaffeensis*	Human monocytic ehrlichiosis
	Guanarito virus	Venezuelan hemorrhagic fever
1991	*Cryptococcus gattii*	Meningitis and pulmonary infection
1993	Sin nombre virus	Hantavirus pulmonary syndrome
	Bartonella henselae	Cat scratch disease; bacillary angiomatosis
1994	Human herpesvirus 8	Kaposi's sarcoma
	Anaplasma (*Ehrlichia*) *phagocytophilum*	Human granulocytic anaplasmosis (ehrlichiosis)
1995	Hendra virus	Respiratory disease; meningoencephalitis
1996	Australian lyssavirus	Human rabies
1997	Influenza virus H5N1	Avian influenza in humans
1999	Nipah virus	Respiratory illness; meningoencephalitis
	Influenza virus H9N2	New variant of avian influenza in humans
2001	Human metapneumovirus	Respiratory illness
2003	SARS coronavirus	Severe acute respiratory syndrome
2009	Influenza A virus H1N1	Influenza in humans
2012	MERS coronavirus	Respiratory illness

Downloaded From Vet-eBooks.com

2012	MERS coronavirus	Respiratory illness
2013	Chikungunya virus	Fever, joint and muscle pain, headache

3

An amusing and readable but highly educational view of these relationships has been presented as a fantastical assembly of bacteria that have come together to voice their complaints about the "spin" humans have placed on their relationships. *The Other End of the Microscope: The Bacteria Tell Their Story* by E.W. Koneman takes a nontraditional view of the interactions between humans, their microbiome, and infectious agents.[68]

A more traditional, but also eminently readable, elucidation of the complex interconnections between humans and infectious agents was prepared by Cedric Mims, the distinguished British microbiologist. It has been maintained by colleagues and is an outstanding way to explore the fascinating subject of pathogenesis further.[83]

The Infectious Agent

Classes of Infectious Agents. Infectious agents can be divided into a finite number of types. Most are free-living and contain all the machinery necessary for the maintenance and replication of their kind; they are generally referred to as **microbes**. Bacteria, fungi, parasites, and viruses are the traditional groups of infectious agents.

1. **Bacteria** contain the largest number of species that are pathogenic for humans. They are single-celled and contain both DNA and RNA. Their DNA, however, is not contained within a nucleus; they are prokaryotic. Bacteria reproduce by binary fission. Although most are autonomous and free-living, there are a few families of bacteria, most notably the *Rickettsiaceae*, *Anaplasmataceae*, and *Chlamydiaceae* that lack all the necessary biochemical processes for replication and must interact with a host cell to reproduce.
2. **Fungi** are single and multicellular organisms that contain a defined nucleus and cytoplasm; they are eukaryotic microorganisms. **Yeasts** are single-celled fungi most of which reproduce by budding, although some reproduce by binary fission. **Molds** or **moulds** are more complex multicellular organisms that reproduce by both sexual and asexual means. Some fungi have both yeast and mold phases; these are referred to as dimorphic fungi. **Microsporidia** are a unique group of fungi that are intracellular pathogens, which were originally thought to be parasites.

Downloaded From Vet-eBooks.com

celled animals, such as the protozoa, and very complex, multi-celled organisms that have well-defined organs and tissues, such as gastrointestinal tracts and genital systems. These organisms, whether macroscopic or microscopic, derive some benefit from the infectious state, often nutrition, at the expense of the host.

4. **Viruses** comprise a large number of infectious agents that do not have the complete biochemical organelles or processes to sustain their own propagation. They must, therefore, infect another life form, including humans, animals, plants, bacteria, and even other viruses. They represent the simplest form of infectious agent. With rare exceptions, viruses contain either DNA or RNA, but not both. In contrast to other microbes, which reproduce by replication and subsequent division of their genetic material, viruses reproduce by extensive replication of their genetic material, which is packaged individually into new virions, all within the confines of an infected cell.

In addition to the traditional infectious agents, more evolved members of the animal kingdom, such as insects, may be considered a kind of parasitic agent (i.e., an ectoparasite) if their existence is intimately related to a host. At the other extreme, the entirely unconventional **prions** contain no nucleic acid and, therefore, cannot replicate in the traditional sense. Yet, their abnormal protein structure results in a process that leads to a replicative cycle.

Interactions Between Hosts and Infectious Agents. If two or more organisms exist together and each is neither rewarded nor damaged, the process is called **commensalism.** Such an agent is referred to as a **commensal**.

If the infectious agent derives benefit from the host, but causes no harm to the host, the microbe is designated a **saprobe**. If both organisms are saprophytic and benefit from one another, then the process is called **symbiosis** or **mutualism**.

Conversely, if the host is damaged by the infectious agent with or without benefit to the infectious agent, the process is called **parasitism** and the infectious agent is designated a **parasite** (a more general use of the term than the class of infectious agents known as parasites). Infectious agents of all types may be parasites.

When microbes exist on body surfaces, either external (skin or hair) or internal (upper respiratory and gastrointestinal tracts), they are described as microbiota or **colonizing flora**. The relationship of the microbiota to the host may be commensal, saprobic, or parasitic. These relationships may change over time, if there is an alteration in the virulence of the microbe or a diminution in the ability of the host to resist infection.

An organism that has demonstrated the ability to cause infections regularly is referred to as a **pathogen**. If the microbe produces disease on occasion, it is often termed a **potential pathogen**. A potential pathogen is described as an **opportunistic**

Downloaded From Vet-eBooks.com

termed a **potential pathogen**. A potential pathogen is described as an **opportunistic agent** if it produces infection only in individuals who have compromised defense mechanisms.

Infectious agents also have several types of relationships to their hosts at the cellular level. Free-living microbes (some bacteria, fungi, and parasites) exist extracellularly and can grow in vitro in the absence of cells. Facultatively intracellular microbes can grow in the absence of cells in vitro; in vivo they grow either intracellularly or extracellularly. Obligately intracellular infectious agents lack one or more of the biochemical processes necessary for an extracellular existence; they must utilize a host cell to supply the needed process or substance(s). These relationships are summarized in Table 1-2.

Virulence. Virulence is the sum of characteristics of a microorganism that increase the ability of that organism to cause disease. It is not an all-or-none phenomenon; there are widely varying degrees of virulence. Most discussions of virulence focus on microbial factors, but it is actually the balance of all three members of the triad discussed above that is most important.[12]

4

TABLE 1-2 Relationships of Infectious Agents and Their Hosts at the Cellular Level

Relationship	Infectious Agents	Examples
Free-living	Most bacteria, fungi, and parasites	Staphylococcus, Enterobacteriaceae, Candida, Aspergillus, Protozoa, Helminths
Facultatively intracellular	Certain bacteria, mycobacteria, certain fungi	Legionella, Brucella, Mycobacterium tuberculosis, Dimorphic fungi
Obligately intracellular	Certain bacteria, fungi, and protozoa, viruses	Rickettsia, Ehrlichia, Anaplasma, Toxoplasma gondii; influenza virus

The most virulent organism will not cause disease if it does not have access to a susceptible host, for one of two reasons:

Downloaded From Vet-eBooks.com

hosts. For example, after the yellow fever virus cycle in urban mosquitoes was interrupted, transmission of disease stopped until humans entered a previously unrecognized cycle of yellow fever in species of mosquitoes that existed in the jungle.

2. All of the available hosts have developed protective immunity. For instance, many viral infections that elicit protective immunity, such as measles virus, "burn out" after all the susceptible persons have been infected. Only after the birth of a new generation of individuals, who are previously uninfected and therefore susceptible, can there be a new epidemic.

In contrast, an organism that produces mild or no disease in immunocompetent individuals (i.e., an organism of intrinsically low virulence) may produce devastating disease in an individual whose immune system has been compromised. For example, the spores of *Aspergillus* species are encountered on a daily basis and immunocompetent individuals, who constitute most of the population, do not become infected. However, patients with severe compromises in their immune system may develop severe to life-threatening disease (i.e., invasive aspergillosis).

The most successful infectious agents are those that are highly adapted to their hosts and cause only minimal damage. As an example, it has been hypothesized that Epstein–Barr virus, which infects long-lived memory lymphocytes, has developed a strategy for minimizing negative effects on its host.[113]

Host factors also play an important role. An organism may be particularly virulent in a human host, but continue to exist in nature because it has evolved a permissive relationship with other hosts. For instance, humans may be lethally infected with *Trypanosoma brucei*, whereas a milder form of the disease is seen in other vertebrate hosts.

Virulence may result from factors that are operative at virtually any stage of the infectious process. Some examples are summarized in Table 1-3. A number of excellent references are available for readers who desire more detailed information.[50,55,67,69,76,100,101]

TABLE 1-3 Selected Virulence Factors

Category	Virulence Factor	Example
Survival in environment	Intracellular replication in free-living amoebae	Legionella spp.
	Resistance to desiccation	Variola virus
Effective	Motile forms that can seek out a	

Downloaded From Vet-eBooks.com

Effective transfer/transmission	Motile forms that can seek out a susceptible host	Cercariae of schistosomes
	Adaptation to a vector that can transmit infection	Rickettsia rickettsii in ticks
Evasion of host defenses	Lysis of polymorphonuclear inflammatory cells	Streptococcus pyogenes leukocidins
	Destruction of tissue	Proteases of Pseudomonas aeruginosa
	Destruction of tissue	Invasion of blood vessels by Aspergillus fumigatus
	Destruction of immune lymphocytes	Human immunodeficiency virus
	Antigenic modulation to subvert humoral immunity (antibodies)	Antigenic shift and drift of influenza virus; antigenic variation of Borrelia recurrentis or Trypanosoma brucei
Sequestration in an inaccessible site	Intracellular location in macrophages	*Mycobacterium tuberculosis*
	Intracellular location in neurons of spinal ganglia	Varicella zoster virus or herpes simplex virus
Resistance to antimicrobial agents	Resistance to disinfectants	Pseudomonas aeruginosa and antiseptics
	Resistance to fixatives	Prions and formaldehyde
	Resistance to anti-infective agents	Staphylococcus aureus and methicillin
	Resistance to antiviral agents	Human immunodeficiency virus; cytomegalovirus

TABLE 1-4 Common Routes of Transmission and Portals of Entry for Infectious Agents

Source of Agent	Mechanism for Entry	Portal of Entry	Example
Infected human	Aerosol	Respiratory	Influenza virus
Infected human	Direct contact	Cutaneous	Herpes simplex in wrestlers
Infected human	Sexual intercourse	Genital	Syphilis; Gonorrhea
Infected human or patient	Oral or nasopharyngeal secretions to eye	Ocular	Bacterial or viral conjunctivitis
Infected human	Transfusion of blood products	Intravascular	Hepatitis viruses
Contaminated environment	Food or water	Gastrointestinal	Enteric bacterial and viral pathogens
Contaminated environment	Cooling tower drift	Respiratory	Legionnaires' disease
Infected animal	Animal bite	Cutaneous	Rabies
Infected tick	Tick bite	Cutaneous	Lyme disease
Patient	Aspiration of endogenous flora	Respiratory	Bacterial pneumonia
Patient	Spillage of intestinal flora through a damaged bowel wall	Gastrointestinal	Bacterial peritonitis
Patient	Migration of bacteria from oropharynx to middle ear through eustachian tube	Ear	Bacterial otitis media

The Environment

The host range of some infectious agents is limited to humans. Maintenance of such organisms requires access to a new susceptible host and the ability to survive environmental factors during the transfer. In some instances, the transmission is quickly achieved, such as through a cough or a sneeze, and environmental factors are of less importance. However, in some instances, obligate human infectious agents, such as the bacteria responsible for typhoid or enteric fever, may spend extended time in the environment. In such instances, transmission may be interrupted. This is how the advances in wastewater treatment and drinking water treatment have led to the substantial reduction of infectious diarrheal illnesses in resource-advantaged countries. The environmental aspect of the cycle was interrupted.

Many infectious agents, however, have a phase wherein they live free in the environment, and commensals or infectious agents in nonhuman hosts, and/or pass through a vector, usually an arthropod, between various vertebrate hosts. Some of the interactions may become extremely complex; for instance, the developmental stages of several parasites involve a series of animal hosts.

The link between the infectious agent and the ultimate host is the environment. The transfer to a new host requires a portal of entry. The most common routes of transmission and portals of entry are summarized in Table 1-4. Some of the terms used to describe infectious diseases in populations are defined in Box 1-1.

The Infected Host

The host is the organism that harbors the infection. It may be human, animal, or even

Downloaded From Vet-eBooks.com

another microbe, but this text will concentrate on human hosts. Once an individual has been infected, a variety of host responses are usually elicited. The response may be localized at the site of infection or may be generalized (systemic). The local reaction to infection takes the form of inflammation. *Inflammation* is a general term that refers to the response of the body to tissue damage, which may be secondary to infection or other causes (e.g., trauma). Inflammation has both immunologic and nonimmunologic components. In each case, the defense may be cellular or noncellular (humoral). The suffix "-itis" is used to indicate inflammation; when attached to an anatomic site,

it describes a disease process. For instance, appendicitis is an inflammatory process that affects the appendix, whereas hepatitis is inflammation of the liver (hepar), and endocarditis is inflammation of the endocardium (lining of the chambers of the heart).

BOX 1-1

Categories of Infectious Diseases

Communicable disease: An illness that can be transmitted from an external source, animate or inanimate, to a person.
Contagious disease: An illness that can be transmitted from person to person.
Iatrogenic infection: An infection that is produced by medical interventions
Infectious disease: An illness caused by a replicating or multiplying external agent
Nosocomial infection: An infection that is acquired in a healthcare facility
Opportunistic infection: An infection in a patient with compromised defenses by an agent of low virulence that would not produce infection in a patient with a fully functioning immune system.
Subclinical infection: An infection that produces an immunologic response, but minimal-to-no clinical symptoms.

Innate and adaptive immunity are the two major components of the immune response.[42,77,104] The innate immune response is the more primitive of the two. It provides an immediate response against invading microbes, regardless of the particular nature of the microbe. Some of the molecules (i.e., the receptors) that make contact between the microorganism and the cellular defender are compounds called lectins, which are widely distributed in nature. The innate response is limited and does not directly result in the production of defenses specific for the invading microorganism.

Rather, portions of the innate immune response send signals that activate the second arm, which is called adaptive immunity.

The adaptive immune response is immunologically specific to the invading pathogen. Once protein from the invading microorganisms is "processed" by certain cells and "presented" to other cells in the immune system, then an immune response specific to that particular protein of the microorganisms is generated. This is the basis of vaccination.

Innate, Noncellular Defenses. The physical barriers, such as the skin and the epithelium that lines the respiratory, the gastrointestinal, and the genitourinary tracts, may not initially be considered part of the immune defense system, but these physical barriers are highly effective in keeping microorganisms outside our bodies. The disastrous infectious consequences of burn wounds are testimony to the effectiveness of the skin. In addition, patients undergoing chemotherapy will lose some of the epithelium lining their mouths and other mucous membranes. They may develop mucositis and bacteremia with bacteria that are common microbiota in the mouth.

The most basic defense in this category is the mucus that lines all mucosal surfaces of the body. The mucociliary escalator of the lungs is an innate defense. The mucus produced by goblet cells in the tracheobronchial tree is propelled upward by the uniform beating of the cilia of epithelial cells. Microorganisms become entrapped in the mucus, and are thereby prevented from reaching the critical, distal aspects of the lungs. The gastric acid of the stomach is also an innate defense and serves as a barrier to microorganisms and prevents many potential pathogens from reaching the small intestine. In addition, certain antibacterial compounds, such as lysozyme, are present in extracellular fluids and help to diminish the quantity of bacteria. Finally, some "primitive" or "preimmunologic" humoral defenses play an important role in host defense. These compounds, as a group, are referred to as acute-phase reactants.[50] The first to be identified, in 1930, was C-reactive protein, which was found to react with pneumococcal C-polysaccharide. Components of the hemostasis or clotting system also fall into this category. Importantly, the alternate pathway of the complement system is an early defense against some bacterial infections before specific antibodies develop (see below). Finally, the innate cellular defenses produce a variety of inflammatory modulators that include chemoattractants for other inflammatory cells. These compounds are the means by which inflammatory cells are activated and recruited to the point of infection; they are called **cytokines** (sometimes referred to as chemokines or lymphokines).[40] The first recognized cytokine (Interleukin 1 or IL-1), which is the main mediator responsible for the febrile response, is produced by monocytes and macrophages.[44] Cytokines also play a prominent role in the adaptive immune response, as described below.

Innate, Cellular Defenses. The primary inflammatory cells, which are not part of the adaptive or specific immune response, are the fixed tissue macrophages (histiocytes), their circulating counterparts (monocytes), and polymorphonuclear neutrophils (PMNs). The tissue macrophages are the primary defenses against certain infectious agents. For instance, the alveolar macrophages are very effective in phagocytosis and killing of certain bacteria and fungi. There are, however, some microorganisms that can survive in macrophages (e.g., mycobacteria or *Legionella* spp.), which can overcome this immune response and cause infection. Tissue macrophages are present in high concentrations in the liver, spleen, and lymph nodes, which together make up the reticuloendothelial system; this system is critical for monitoring and removing circulating particles, including infectious agents, from the blood and lymph. Patients whose spleens have been removed or whose livers have been damaged are at increased risk of many serious bacterial infections.

The polymorphonuclear (PMN) leukocyte is one of the most important acute inflammatory cells (see below). This cell, which has a segmented nucleus, is often the first to respond to inflammatory mediators and to arrive at the site of infection. It is able to phagocytose and kill a variety of microorganisms through a number of biochemical actions, including the production of small molecules, such as defensins, and reactive oxygen molecules, among other mechanisms, all of which aid in killing the invading microbe.

Types of Inflammation[121]

Acute Suppurative (or Purulent) Inflammation. An acute suppurative infection is the inflammatory response in which pus is formed. Pus is a liquid material that contains large numbers of inflammatory cells and has a specific gravity exceeding 1.013. The initial and dominant inflammatory cell present is the PMN.[75] Macrophages enter the former site of infection, once the neutrophils have eradicated the invading microorganism, to phagocytose, digest, and remove the debris from the infection. This is followed by the ingrowth of fibroblasts and new epithelium, as the final aspect of the healing process, which may include scar formation.

Cellulitis is often used to describe an infection that involves the loose subcutaneous connective tissue. Microorganisms and the purulent exudate spread between layers of the involved tissues. **Necrosis** refers to cell death or dissolution of tissue, which may be caused by destructive enzymes or by restriction of nutrients from the site, usually by blockage of blood flow. **Abscess** is the term used when segmented neutrophils become localized in a walled-off area of suppurative inflammation, with resultant destruction of tissue.

Purulent inflammation is a hallmark of infections caused by certain bacteria and some fungi. For example, *Staphylococcus* and *Streptococcus* are sometimes referred to as suppurative bacteria, because they elicit a neutrophilic response. In fact, the vast

majority of bacteria encountered in the clinical

7

microbiology laboratory will elicit a neutrophilic response, if they are the cause of an infection. Fungi, such as *Candida* and *Aspergillus* species, most commonly elicit a neutrophilic response, although exceptions exist.

Granulomatous Inflammation. Granulomatous infection is a subtype of chronic infection in which granulomas are formed. A **granuloma** can be most simply defined as focal collections of activated macrophages or histiocytes that have an increased capacity for phagocytosis and digestion of foreign particles. These cells are also called "epithelioid" cells because they occasionally line up in a manner similar to that seen with squamous epithelium. Macrophages often aggregate and coalesce to form multinucleated giant cells. The other cellular components of granulomas include lymphocytes and eventually fibroblasts. Activation of the macrophages is produced by products of immunologically specific lymphocytes.

Certain granulomas contain a particular type of necrosis, called caseous necrosis, in which the tissue has a homogeneous, cheese-like consistency. These are also sometimes referred to as necrotizing granulomas. The presence of granulomas with multinucleated giant cells and caseous necrosis are characteristic of tuberculosis, but they may also be seen in certain other infections, particularly dimorphic fungal infections. If the granuloma is solid and the cells are intact and no necrosis is present, then it is described as a nonnecrotizing or noncaseous granuloma. Nonnecrotizing granulomas are found in infections by many of the nontuberculous mycobacteria, although *Mycobacterium kansasii* may produce necrotizing granulomas indistinguishable from *Mycobacterium tuberculosis.* Less commonly encountered bacteria, such as *Brucella,* may produce granulomas. Certain parasitic infections, most commonly those involving helminthic parasites, produce granulomas.

Lymphohistiocytic Inflammation. Some infections, particularly those caused by viruses, elicit an inflammatory response composed of lymphocytes, macrophages, and sometimes plasma cells. Both humoral and cellular immune responses are involved in this type of inflammatory response. *Treponema pallidum,* the agent of syphilis, elicits this type of response, which is rich in plasma cells during certain phases of infection. Lymphohistiocytic inflammation is often the residual inflammation, once an acute or granulomatous response has subsided.

Atopic Inflammation. Allergic reactions are mediated by a different group of cells —eosinophils, basophils, and mast cells (fixed tissue basophils). The inciting allergen may be chemical, such as the familiar grasses and pollens, or microorganisms.[66]Helminthic parasites elicit an eosinophilic inflammatory response. This type of response is usually not seen with protozoal parasites, but has been

reported with *Cystoisospora* (*Isospora*) infections. Allergic mucous (i.e., mucus rich in eosinophils that contains Charcot–Leiden crystals) is seen in patients with allergic fungal sinusitis. Allergic inflammatory cells are also seen in patients with bronchopulmonary aspergillosis. The list of microorganisms to consider is relatively short, when eosinophils are the primary inflammatory cells present.

Adaptive Immunologic Cellular Defenses. The lymphocyte is the principal cell of the adaptive immune system, of which there are two primary classes, B and T lymphocytes.[43] The B lymphocyte and plasma cell, which is derived from B lymphocytes, are responsible for producing immunologically specific antibodies, which comprise the humoral immune system.

The T lymphocyte coordinates much of the activity of the adaptive immune response. It is also responsible for specific cellular immunity. T lymphocytes are divided into helper lymphocytes ($CD4^+$ phenotype) and suppressor lymphocytes ($CD8^+$phenotype). $CD4^+$ cells are responsible for immunologic memory and secretion of cytokines to modulate the immune response. $CD4^+$ lymphocytes are further subdivided into type 1 (T_H1) cells and type 2 (T_H1) cells based on the types of cytokines they secrete. $CD8^+$ cells are cytotoxic and responsible for eliminating foreign cellular material, including cells infected with viruses. A variety of different subtypes of lymphocytes exist, each with particular functions, but further discussion is beyond the scope of this text.

Adaptive Immunologic Noncellular (Humoral) Defenses. Humoral immune defenses are driven and produced by the immunologically specific cells. This sophisticated communication system coordinates activity of a large complement of the host defenses. The signaling molecules produced by lymphocytes that coordinate this response are called cytokines.[40] In addition to coordinating the humoral response, cytokines also function as effector molecules for the cytotoxic lymphocytes.

The end product of the humoral response is the production of antibodies (see Chapter 3). In brief, antibodies, also known as immunoglobulins, are proteins produced by plasma cells that are secreted into the lymph and blood and can penetrate into tissues. These are Y-shaped molecules and may form complexes depending on class. The "top" of the Y consists of two Fab regions that recognize and specifically bind with particular antigens, such as those found on invading microorganisms. The "bottom" portion of the Y is the Fc region and it functions to provide signals to other portions of the immune defense system, such as signals for phagocytosis or complement activation.

The complement system consists of a cascade of enzymes that eventually result in the formation of compounds (C7-8-9) that are known collectively as the attack

complex.[116,117] These are effector molecules that damage certain pathogens, such as meningococci. The complement system functions in a manner similar to the clotting system. Additionally, intermediate components of the system, particularly C3a and C5a, are extremely important as chemoattractants (i.e., they recruit the various inflammatory cells to the site of an infection).

The complement system has two arms, which converge at C3; beyond that point the pathway is the same. The classical arm is immunologically specific; it is triggered by complexes of antigen and corresponding antibodies. The alternate arm (formerly called the properdin system) and the more recently recognized lectin-binding system are not immunologically specific and form part of the innate immune response.

On occasion, the immune response can fail to differentiate "self" from "nonself," which results in an autoimmune disease.[65] Although most autoimmune diseases are not associated with infections, there are some instances wherein the immune response initially directed against a pathogen will subsequently be directed against self.[41,71] Rheumatic

fever is the classic example of such a response, wherein the immune response mistakes myosin of the cardiac muscle fibers for the very similar M protein of *Streptococcus pyogenes*.[93] In addition to immunologic damage caused by specific antibodies reacting with human antigens that are molecularly similar to microbial antigens, there may also be nonspecific damage caused by the inflammatory response. For example, the enzymes and toxic molecules (e.g., oxygen free radicals) that are produced within neutrophils to destroy an invading bacterium are release with the death of the neutrophil and can cause tissue damage. The immune system evolved to control of infectious agents and to undertake the surveillance and destruction of neoplastic cells. We cannot survive without it and are at great risk when it is diminished either by naturally occurring (i.e., genetic) defects, environmental (e.g., radiation), infections (e.g., HIV infection) or by therapies (e.g., immunosuppressants used to modulate organ rejection in transplant recipients). The immunocompromised patients most commonly encountered in practice are either those with HIV infection, those with bone marrow suppression due to an underlying malignancy, such as acute leukemia, or those iatrogenically suppressed with therapeutic agents for a variety of reasons. The classic example is the recipient of an organ transplant. In order to prevent the body from rejecting the foreign transplant, the immune system must be suppressed to a certain degree. In so doing, the process of defense against invading microbes and tumor cells is compromised, sometimes with disastrous consequences.[88]

The complexity of the immune system is amazing. Its intricacies are staggering and they are still not completely understood. The interested reader is referred to several

excellent reviews of the subject.[42,77,104]

Clinical Signs and Symptoms of Infection. Signs and symptoms of infection may be generalized (i.e., systemic) or they may be focal or localized to a particular organ or organ system. Early Greek and Roman physicians recognized four cardinal signs of inflammation: These were Dolor (pain); Calor (heat); Rubor (redness); and Tumor (swelling).

The underlying mechanisms predisposing to these signs are complex and even today incompletely understood. The initiating pathophysiologic mechanism is the dilation of blood vessels caused by a complex cascade of vasoactive amines and other chemical mediators.[38] The local release of chemical mediators results in an increased blood flow to the site of injury or infection, with venous and capillary congestion; this, in part is responsible for the calor and rubor that is experienced. The increased permeability of vessels allows for the escape of fluid, blood, and proteins from the vascular system into the extracellular spaces; this, in part, resulted in the dolor and tumor that is experienced. Polymorphonuclear leukocytes (i.e., neutrophils) are attracted to the area of injury by chemotactic substances that are released when injury occurs; these leukocytes escape through the permeable vasculature into the extracellular spaces. Collection of these leukocytes and the extracellular fluids is referred to as pus formation.

General or Systemic Signs and Symptoms of Infection. In the acute phase of an infection, the patient may experience fever (often high-grade and spiking), chills, flushing (vasodilation), and an increase in pulse rate. Patients with subacute or chronic infections may present with minimal or vague symptoms—intermittent low-grade fever, weight loss or fatigue, and lassitude. Toxic reactions to bacterial products may produce eczematous or hemorrhagic skin reactions or a variety of neuromuscular, cardiorespiratory, or gastrointestinal signs and symptoms—initial indicators of an underlying infectious disease.

Local Signs of Infection. The cardinal signs of inflammation are unmistakable at the site of a local infection. Imagine an infection that will result from a thorn injury to the hand. There is localized redness and heat at the site of injury, the production of a swelling as the fluid and inflammatory cells fill the subcutaneous tissues. Finally, there will clearly be pain with and often even with palpation of and around the lesion. The presence of a draining sinus and the secretion of a purulent exudate are also indications of a local inflammatory or infectious process. Any of these signs and symptoms should direct the physician to collect material for direct microscopic examination and culture.

The specific signs and symptoms of infections that manifest in the several organ systems (respiratory, gastrointestinal, urinary tract, genital, or other) will be presented in detail in Chapter 2.

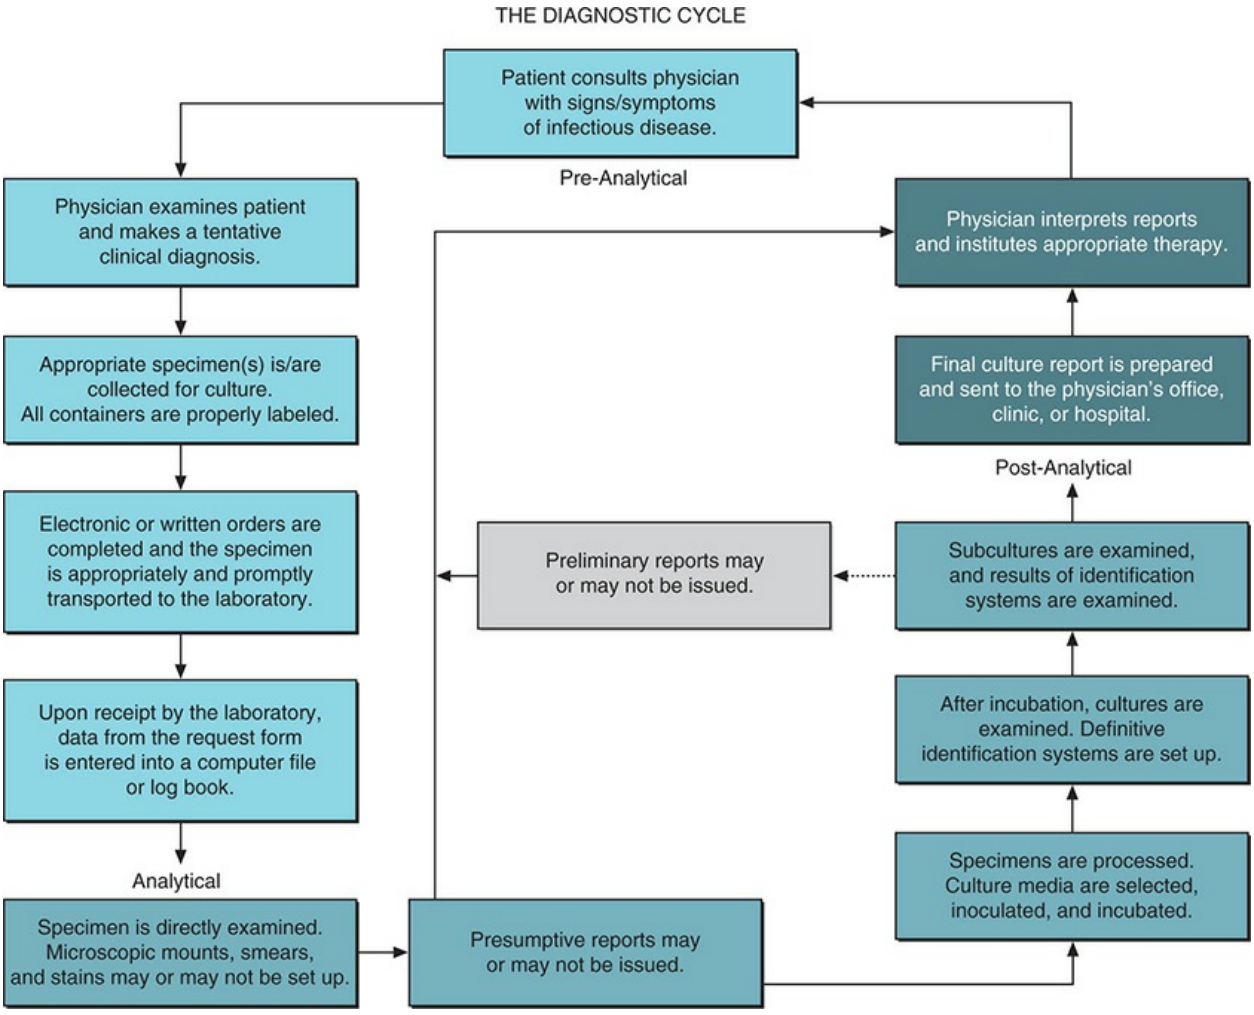
Indirect Effects of Infectious Agents on Humans. As humans have responded to

infectious agents over millennia, many changes in our genetic makeup have resulted. The development of the immune system is the most dramatic and important, but other examples can be found. Malaria is one of the most prevalent and devastating infections in the world, although not common in the United States. The appearance of hemoglobin S, which results in less severe infections by *Plasmodium falciparum*, probably was an adaptive change.[72] Unfortunately, when the infectious challenge no longer exists (i.e., areas wherein malaria has been eradicated), the untoward consequences of this hemoglobin, which manifests as sickle cell disease, are preeminent. Similarly, the Duffy blood group antigen is required for entry of *Plasmodium vivax* merozoites into red blood cells. Although it is a highly prevalent antigen, the recognition of this biologic phenomenon has provided clues that could be used for construction of vaccines to block entry of malarial parasites into their target cells.[79]

Phases of the Diagnostic Cycle

It is useful to categorize the laboratory assessment of clinical specimen into three phases: the preanalytic, the analytic, and the postanalytic (Fig. 1-1). Traditionally, microbiologists and other laboratorians have concentrated most of their efforts on the scientific measurement or assessment (i.e., the analytic phase). It is now very clear that what occurs prior to measurement (i.e., the preanalytic phase) and what occurs after the scientific determination is complete (i.e., the postanalytic phase) are just as important as the accuracy of the measurement. Monitoring of performance throughout the whole cycle is part of quality assurance for the laboratory, and is discussed later in this chapter.[32]

9



■ **FIGURE 1-1** The clinical and laboratory diagnosis of infectious diseases: a schematic overview of the diagnostic cycle.

Preanalytic Phase

Specimen Collection. Once an infectious disease is suspected, appropriate tests must be ordered. Culture, serologic studies, and/or molecular detection of nucleic acids are all possible diagnostic approaches. As discussed in Chapters 3 and 4, direct detection of antigen and nucleic acid in clinical specimens and use of these approaches for identification of isolated organisms are being utilized with increasing frequency. Pathologists, microbiologists, and medical technologists are available in most institutions and communities to assist physicians in selecting the proper specimens for culture and in ordering the appropriate tests to achieve the maximum recovery or detection of microorganisms.

The proper collection and transport to the laboratory of a specimen for examination is a critically important step in the ultimate confirmation of the etiologic agent that is

responsible for the infectious disease process.[82] A poorly collected specimen not only may result in failure to recover important agents, but may also lead to incorrect or even harmful therapy if treatment is directed toward a commensal or contaminating organism. For example, assume that *Klebsiella pneumoniae*, a recognized cause of human pneumonia, was recovered from the sputum of a patient with the clinical features of pneumonia. It would be considered the etiologic agent of disease. However, *K. pneumoniae* is also known to colonize the tonsils and nasopharynx. If the sputum in this theoretical case was improperly collected and consisted primarily of saliva, then the recovery of *Streptococcus pneumoniae* might not reflect the true cause of the pneumonia, but merely nasopharyngeal colonization. Furthermore, the treatment directed against *K. pneumoniae* would be improper, if the disease were actually caused by an agent unresponsive to such therapy, such as *Legionella pneumophila.* A scenario similar to that given above actually happened in Pennsylvania in 1976. Attendees at the annual convention of the Pennsylvania American Legion were infected at the convention hotel in Philadelphia, but became ill after they returned to their homes. They were treated with ineffective antibiotics directed against enteric bacilli that were colonizing the upper respiratory tract. The actual pathogen, *L. pneumophila*, was not known at the time and unfortunately the wrong therapeutic approach was employed based on the misleading laboratory results.[47]

10

The following are fundamentals to be considered when collecting specimens:

1. The material must be from the actual site of infection, collected with a minimum of contamination from adjacent tissues, organs, or secretions. For example, throat swabs for streptococcal screening should be taken from the peritonsillar fossae and posterior pharyngeal wall, avoiding contact of the swab with other areas in the mouth. Contamination of sputum or lower respiratory specimens with oropharyngeal secretions must also be minimized. Other situations where an improperly collected specimen may produce misleading results include the following:

- **a.** Failure to culture the depths of a wound or draining sinus without touching the adjacent skin
- **b.** Inadequate cleansing of the periurethral tissue and perineum before collecting a clean-catch urine sample from a woman
- **c.** Contamination of an endometrial sample with vaginal secretions
- **d.** Failure to reach deep abscesses with aspirating needles or cannulas

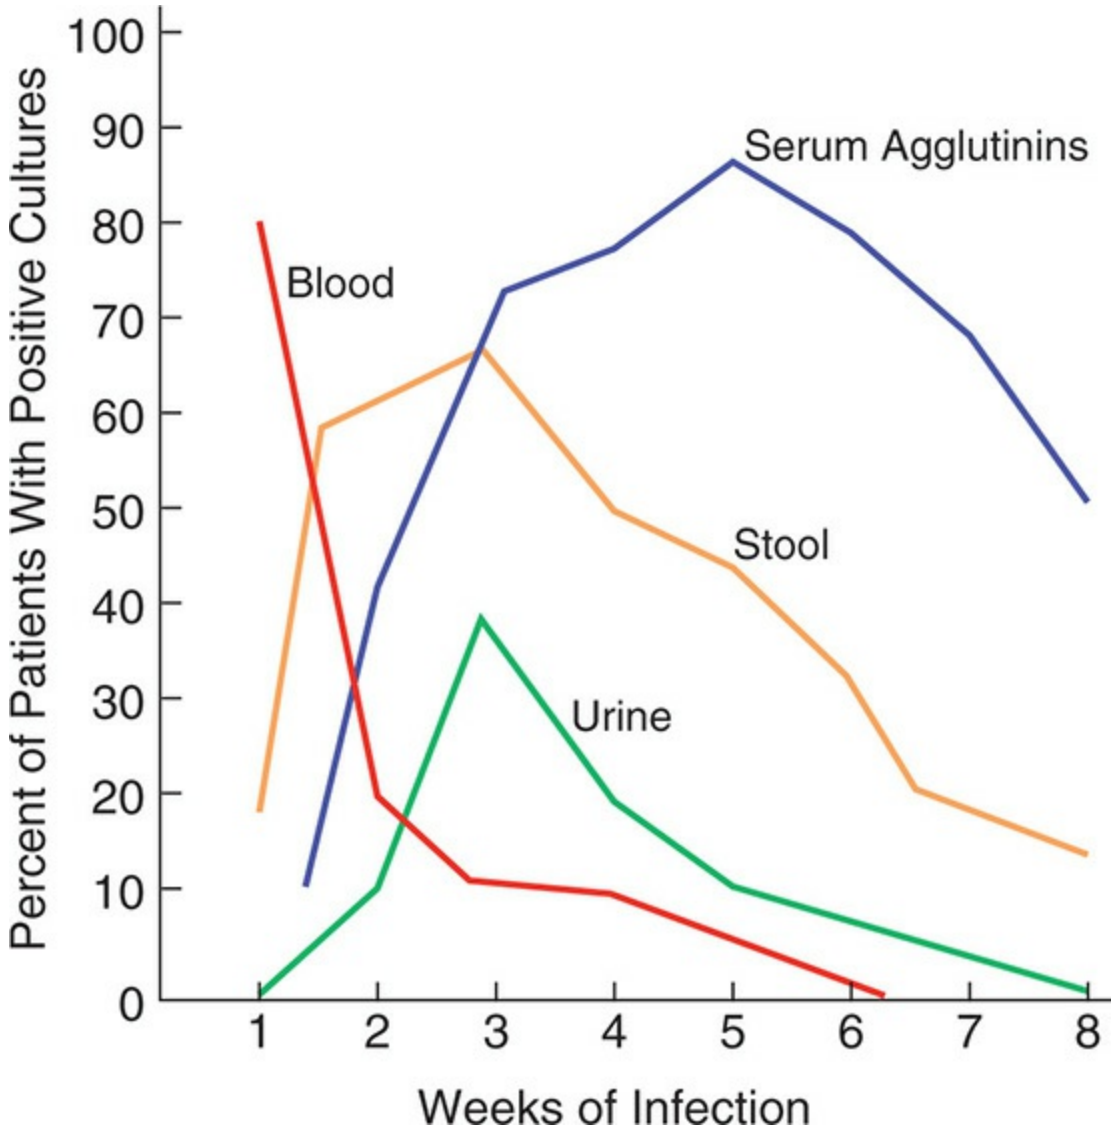
Swabs are, by and large, inferior in the collection of most specimens; the use of

aspiration needles and catheters should be encouraged whenever there are local accumulations of pus. Protected discard containers for collection of "sharps" should be readily accessible and appropriate devices used to minimizing injury when removing needles must be provided at the site of specimen acquisition. Syringes with needles attached should not be submitted to the laboratory, as they represent a hazard.

2. Optimal times for collection of specimens must be established to provide the best chance of recovering causative microorganisms. Knowledge of the natural history and pathophysiology of the infectious disease is important for some infections for determining the optimal time to collect the specimen. Although typhoid fever is now a rare disease in the United States, the progression of the infectious process in this disease is a prime example of the importance of proper timing of specimens (Fig. 1-2). The causative bacterium can be recovered optimally from the blood during the first week of illness. Culture of the feces or urine is usually positive during the second and third weeks of illness. Serum agglutinins begin to rise during the second week of illness, reaching a peak during the fifth week; they remain detectable for many weeks after clinical remission of the disease, but are infrequently used diagnostically in modern laboratories.

Twenty-four-hour collections of clinical materials for culture, particularly of sputum and urine, should not be done, because the risk of contamination or overgrowth of rapidly growing commensal bacteria is greater than if one well-collected specimen is promptly submitted to the laboratory.

3. A sufficient quantity of specimen must be obtained to perform the tests requested. Guidelines should be established to define a sufficient volume of material for testing. In most active bacterial infections, sufficient quantities of pus or purulent secretions are produced that volume should not be a problem. All too often, however, an unknowing clinician may submit a tiny sample, while discarding the remainder of a voluminous specimen.



■ **FIGURE 1-2** Diagnosis of typhoid fever by culture and serology.

In chronic or mild forms of infection, it may be difficult to procure sufficient material. Submission of a dry swab or scant secretions to the laboratory with the hope that something will grow is frequently an exercise in futility and, possibly, of considerable cost to the patient. Furthermore, the lesion may be incorrectly considered to be uninfected on the basis of a falsely negative culture, because of an inadequate specimen was obtained and submitted for study. For these reasons, it is a standard of practice to add disclaimer language to blood culture reports wherein a substandard amount of blood was collected for culture. All too frequently, 0.5 mL or less of material labeled "sputum" or "bronchial washings" is delivered to the laboratory with a request for routine, acid-fast bacilli (AFB), and fungal cultures. Such specimens may not represent pulmonary secretions from the site of infection, and the low volume may

be insufficient to enable performance of all the procedures requested. Tubes containing holding broth such as physiologic saline (nonnutrient) or phosphate yeast glucose (PYG) (nutrient) can be provided. The physician can directly inoculate whatever amount of material that can be collected. In this way, the specimen can be divided in the laboratory for inoculation to a variety of primary isolation media. In some institutions, several tubes are provided, each containing culture media optimal for the recovery of mycobacteria, fungi, and viruses. If the secretions obtained are minimal, the physician must choose which tube to inoculate based on clinical considerations.

When the sample size is too small to fulfill all of the requests adequately, it is worth a telephone call to the clinician so that priorities for culture may be established. If the specimen will be exhausted before all testing can be performed, then it is important to communicate which tests were not performed because of a lack of specimen. The report should indicate that the material submitted for examination was scanty.

4. Appropriate collection devices, specimen containers, and culture media must be used to ensure optimal recovery of microorganisms. Sterile containers should be used for

collection of most specimens. It is also important that containers be constructed for ease of collection, particularly if the patients are required to obtain their own specimens. Narrow-mouthed bottles are poorly designed for collection of sputum or urine samples. The containers should also be provided with tightly fitted caps or lids to prevent leakage or contamination during transport.

Swabs are commonly used for obtaining many types of cultures; however, they are generally inferior to other methods for collecting specimens, and their use should be discouraged as much as possible if aspirate or tissue is available as an alternative.

If swabs are used, certain precautions should be taken. Cotton swabs may contain residual fatty acids, and calcium alginate may emit toxic products that may inhibit certain fastidious bacteria. Swabs tipped with Dacron or Rayon polyester are often better choices. The newer flocked swabs represent a significant advance in swab technology and deliver significantly more specimen than former swab types. Specimens should not be allowed to remain in contact with the swab any longer than necessary. In addition to toxicity, the ability of swabs to absorb and then release specimens varies with the material used to construct the swabs.

Swabs should be placed in a transport medium or moist container to prevent drying and death of bacteria. Good recovery of most bacterial species from these tubes has been demonstrated for up to 48 hours or longer. The use of culture tubes containing semisolid Stuart's or Amies' transport medium, with or without charcoal, also serves

as an adequate means for holding swab cultures during transport. There are a few exceptions to this guideline. Skin scrapings and nail clippings for recovery of dermatophytic fungi should be submitted dry in a clean container to prevent the overgrowth of bacteria. Throat swabs are acceptable for the detection and/or recovery of *S. pyogenes* from patient with streptococcal pharyngitis. Similarly, swabs are acceptable specimens for the detection of most causes of vaginitis.

The ability to collect a specimen of virtually anything with a swab is an even larger problem than toxicity and retention of material. The likelihood is much higher with an aspirate or biopsy that the specimen that will yield meaningful results (i.e., detect the etiologic agent of infection). In contrast, a swab may have been used to sample either an inflammatory process (e.g., the tonsillar exudate) or colonizing microbiota (e.g., the side of the mouth). Whenever a potential pathogen (e.g., *Haemophilus influenzae*) is admixed with normal microbiota, it is often impossible to differentiate pathogen from flora. This is particularly true when the potential pathogen may be part of the normal microbiota in the anatomic location sampled. Figure 1-3 compares the results of culturing an aspirate and a swab from the same site.

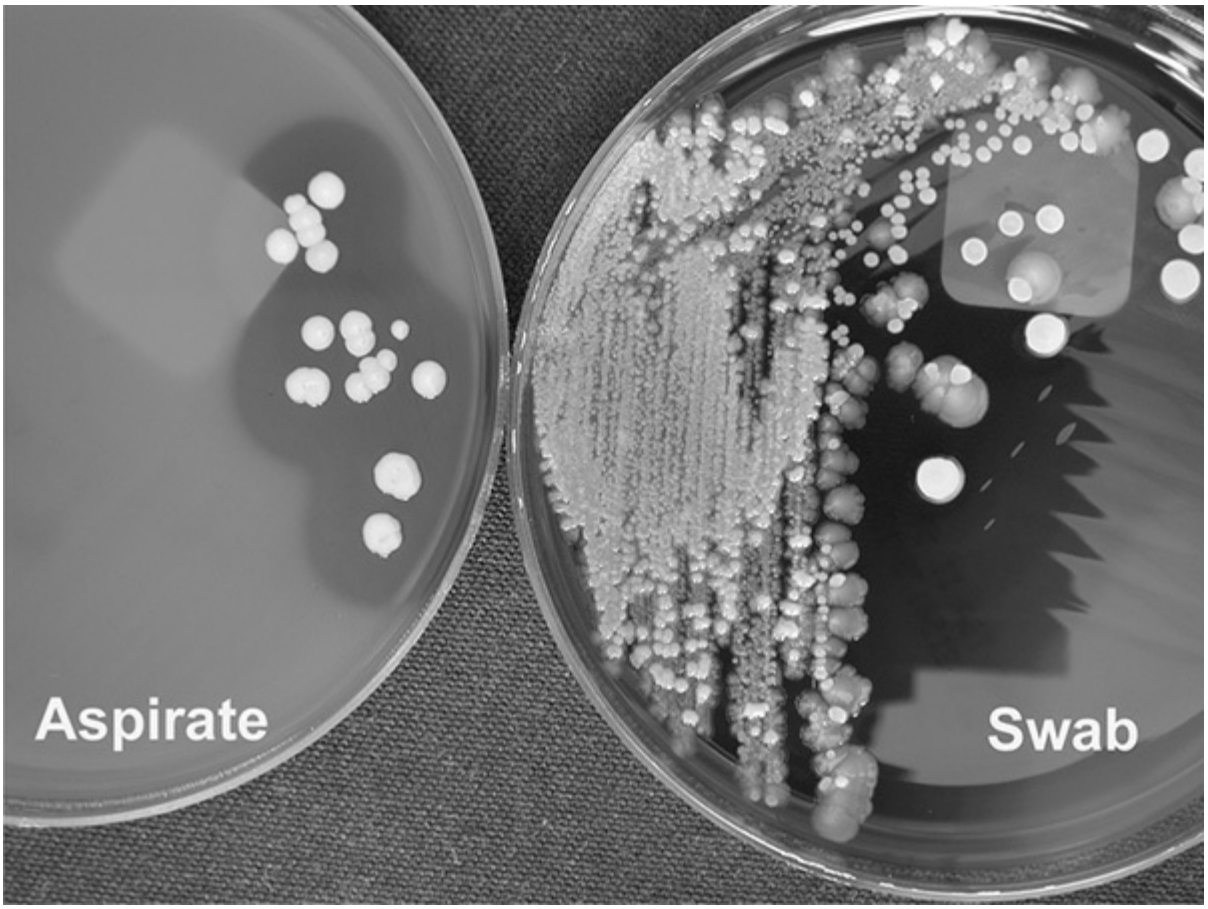


FIGURE 1-3 Comparison of aspirated pus and swab specimens. An infected joint site

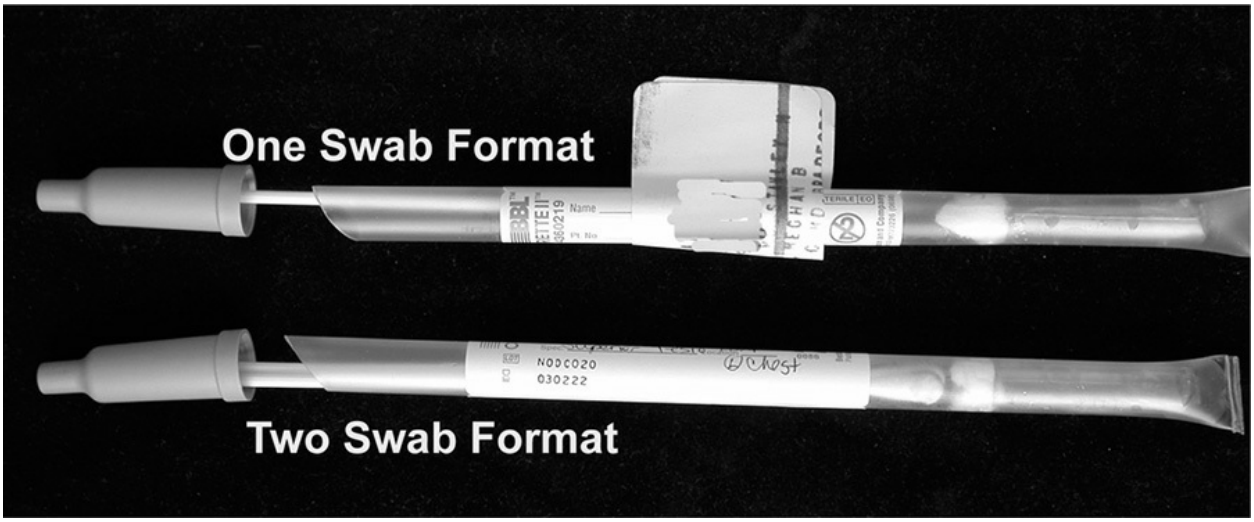
was sampled with a swab and with aspirated material. The aspirate yielded a pure culture of *S. aureus*. The *Staphylococcus* was also recovered in the specimen collected by swabbing, but it was mixed in with other contaminating flora. Interpretation of the aspirate was straightforward; determining the significance of the swab culture is problematic, even with the presence of a likely pathogen.

Although it is possible to perform a smear and a culture from a single swab if the glass slide is flamed to sterilize it before the smear is prepared, it is not optimal because of the possibility of contaminating the culture. Many swab devices contain dual swabs that are both to be used in specimen collection and then submitted for smear and culture, so to assure adequate material for both tests. In that case, it is wise to provide two-swab transport systems to caregivers in order to minimize the instances where a single swab accompanies a request for smear and culture (Fig. 1-4).



■ **FIGURE 1-4** Swab transport systems. The simplest system contains a single swab in a transport tube that contains a nonnutrient medium to maintain moisture (**top**). A similar system is available with two swabs in a single transport tube (**bottom**); in this case, one swab can be used for culture and the second swab for a direct smear.

12

TABLE 1-5 Transport Containers for Anaerobic Specimens

Container	Rationale or Description
	Fresh exudate or liquid specimens can be transported to the

Syringe and needle for aspiration	laboratory after bubbles are carefully expelled from the syringe and the needle is removed using an approved safety device; syringes with needles in place should not be submitted, as these represent a safety hazard. This procedure is valid only if the specimen can be transported to the laboratory without delay.
Tube or vial	Tube or vial contains semisolid holding medium, an atmosphere of 5% CO_2, a reducing agent, and resazurin indicator to give visual indication of anaerobiosis. The tube is used primarily for insertion of swab specimens; the vials are used for inoculation of liquid specimens. High-quality anaerobic transport vials are commercially available and are commonly used for the transport of specimens that will require anaerobic culture.
Swab/plastic jacket system	Plastic tube or jacket is fitted with a swab and contains either Cary–Blair, Amies transport, or prereduced (PRAS) medium. The culturette system also includes a vial or chamber separated by a membrane that contains chemicals resulting in generation of CO_2 catalysts, and desiccants to "scavenge" any residual O_2 that may get into the system. This approach is rarely used.
Bio-bag or plastic pouch	Transparent plastic bag containing a CO_2-generating system, palladium catalyst cups, and an anaerobic indicator. The bag is sufficiently large to enclose an inoculated Petri dish containing prereduced media, or a biochemical identification microtube tray such as for performing Minitek tests. Bag or pouch is sealed after inoculated plates have been inserted and the CO_2-generating system is activated. The advantage of these systems is that the plates can be directly observed through the thin, clear plastic of the bag for visualization of early growth of colonies.

The use of swabs for collection of specimens for recovery of anaerobic bacteria is discouraged; rather, aspiration with a needle and syringe is recommended. The collected specimens must be protected from exposure to ambient oxygen and kept from drying until they can be processed in the laboratory. Selected transport systems suitable for anaerobic specimens are listed in Table 1-5.

Constant education is required to discourage inappropriate use of swabs. The education can be as instructions for collection of specimens in a laboratory services directory, as newsletters, and as comments on reports for specimens that were submitted on swabs.

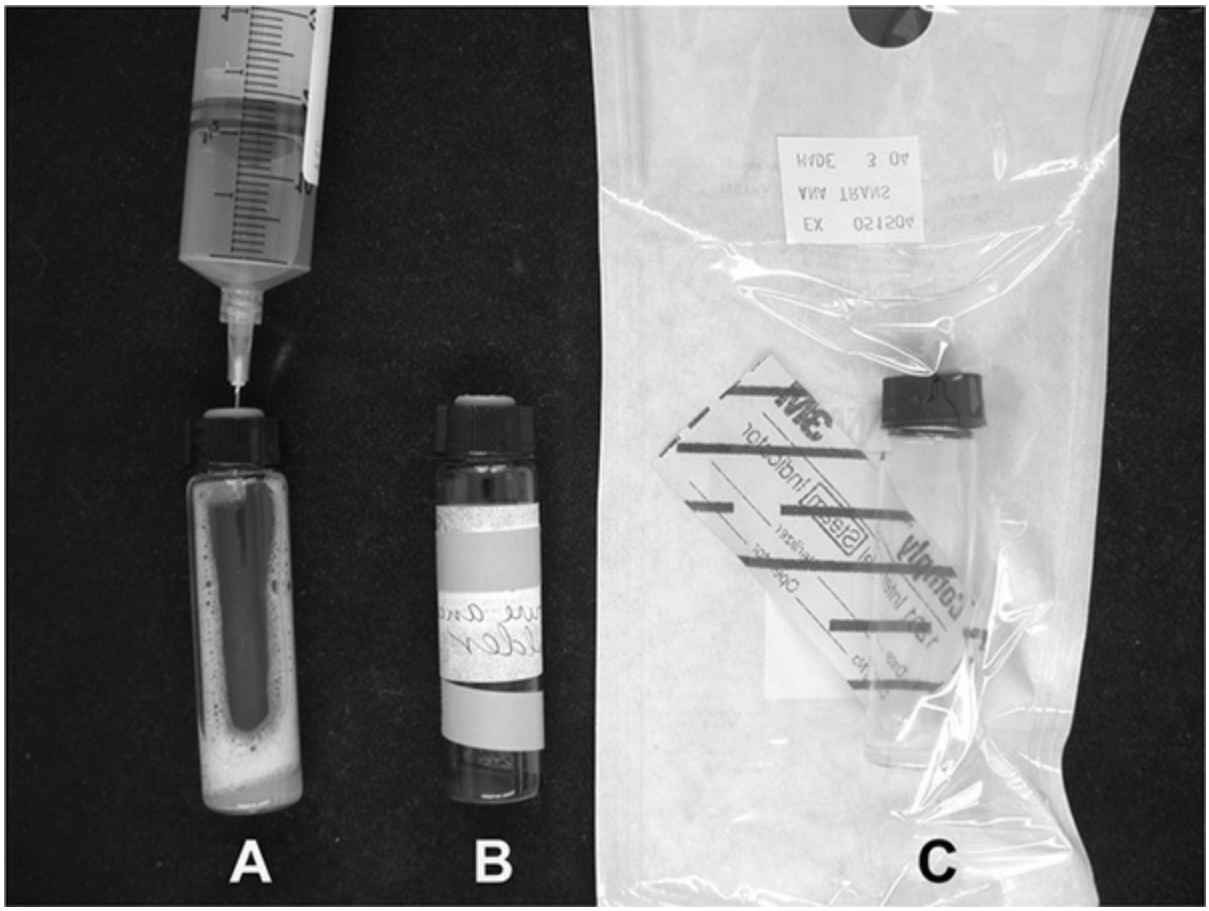
Although fluid or tissue is the preferred specimen type, in contrast to swabs, there have been advances in swab technology. Flocked swabs are swabs that have numerous microscopic folds which significantly increases the surface area of the swab, so that more clinical specimen can be obtained on the swab surface. These types of swabs are commercially available, and are often preferred to standard swabs. They have been validated for use in a variety of assay and are compatible with instruments of automation.

The operating room is one place where there is virtually no excuse for collection of a specimen with a swab. A campaign should be undertaken to remove swabs from the operating room and prevent their reintroduction. Communication with the operating room nurses is a useful means for accomplishing that goal. Appropriate sterile contains and collection tubes should be readily available in every operating room. Excellent commercially available transport tubes, such as the BBL Port-A-Cul transport vials and similar products are designed to protect both anaerobic and aerobic microorganisms prior to inoculation (Fig. 1-5).

Regardless of the transport system used, the major task is to reduce to a minimum the time delay between collection of specimens and inoculation of media. For example, if rectal swabs are used for the recovery of *Shigella* species from patients with bacillary dysentery, the material collected should optimally be inoculated directly onto the surface of MacConkey medium or into gram-negative enrichment broth. Even the use of a holding or transport medium may diminish the recovery of certain strains. Urethral or cervical secretions obtained for the recovery of *Neisseria gonorrhoeae* also should be inoculated directly onto the surface of chocolate agar and one of several selective culture media (see Chapter 11). Alternatively, a commercially available transport system that includes a tablet for generation of CO_2 can be employed (BD BBL Jembec system; BD, Franklin Lakes, NJ) for the recovery of *N. gonorrhoeae*. If a culture-based approach is taken for the detection of *Bordetella pertussis* from

13

upper respiratory specimens, then fresh Bordet–Gengou, Regan–Lowe charcoal agar, or an equivalent should be used at the bedside or in the clinic, unless an appropriate transport system (such as Regan–Lowe medium) is used.[94]



■ **FIGURE 1-5** Transport system for aerobic and/or anaerobic culture. A vial is closed with a screw cap that contains a rubber diaphragm. A layer of agar in the bottom of the vial maintains moisture; a redox indicator in the agar visually displays the oxygenation of the atmosphere. Vial A contains aspirated fluid that has been inoculated through the rubber diaphragm. Vial B contains a resected graft segment that has been placed into the uncapped vial at surgery. Vial C has been sterilized in an envelope made for surgical instruments; it is ready for use in a sterile field.

5. Whenever possible, obtain cultures before the administration of antibiotics. Obtaining cultures before the use of antibiotics is particularly recommended for recovery of organisms that are usually highly susceptible to antibiotics, such as β-hemolytic streptococci from throat specimens, *N. gonorrhoeae* from genitourinary samples, or *H. influenzae* or *Neisseria meningitidis* from cerebrospinal fluid. It is also particularly important that a full complement of blood cultures are drawn on patient suspected of having endocarditis prior to the administration of antibiotics. The administration of antibiotics does not necessarily preclude recovery of microorganisms from clinical specimens, and even a compromised specimen is better than none at all, as long as clinicians understand that the results must be viewed with circumspection.

6. Smears should be performed in addition to cultures in most instances. Smears provide extremely useful information that supplements the culture. There are occasions when the smear is arguably more useful than the culture, as in examination of expectorated sputum. Smears allow assessment of the inflammatory nature of the specimen and provide an indication as to whether the results of culture are meaningful clinically. For example, sputum specimens contaminated with oral microbiota, as evidenced by excessive squamous epithelial cells, should not be cultured. If a culture were performed in the absence of a smear, which would have disclosed excessive squamous epithelium, then normal microbiota, such as *S. pneumoniae, Moraxella catarrhalis,* and *H. influenzae* could be reported and basis of the treatment would be completely erroneous. Similarly, a typical wound specimen that does not contain PMNs and yields mixed bacterial flora on culture should be recognized as a superficial sampling and not a valid representation of the organism(s) causing the infection.

In addition, a review of Gram's smear may serve as a quality indicator. A smear that contains many gram-negative bacilli that fail to grow in a conventional aerobic and anaerobic culture may indicate that the culture conditions were not optimal or the organisms were nonviable. Suboptimal culture conditions include an inappropriate atmosphere of incubation (anaerobes) or inappropriate media selection (fastidious organisms, such as *Legionella* or *Bordetella*). Investigation into increase transport times may disclose possible reasons for nonviability. Alternatively, the microbes could be nonviable because of appropriate antimicrobial therapy or because of an effective inflammatory response.

The federal fraud and abuse regulations require that a laboratory perform only the tests that have been requested. Therefore, it is necessary to convey the importance of the direct examination (i.e., a smear), as an accompaniment to the culture, to the ordering physicians. Mechanisms for enhancing appropriate use of the laboratory in the preanalytical phase are discussed below.

7. The specimen container must be properly labeled. Each specimen container must have a legible label, with the following minimum information:

Patient name
Patient identification number
Source of specimen
Clinician
Date/hour collected

The full name of the patient should be used; avoid initials. The identification number may be the hospital number, clinic or office number, home address, or social security number, depending on local policy. The name of the submitting physician or office contact is necessary should consultation or early reporting be required. The

specimen source should be noted so that the optimal culture media selection can be made. The date and time of collection should be recorded to assess the timeliness of specimen transport and processing. The tracking of specimens with timestamps at important points, such as collection, receipt, and processing completion, is invaluable to performing root-cause analysis should problems arise. Other potentially useful information includes the clinical diagnosis and the antibiotic treatment history of the patient, but the latter is rarely provided.

Specimen Transport. The primary objective in the transport of diagnostic specimens, whether within the hospital, from the clinic, or externally by courier to a distant reference laboratory, is to maintain the specimen as near its original state as possible. Quality control guidelines for manufacturers of devices used for collection and transport of specimens have been developed by the Clinical and Laboratory Standards Institute (CLSI).[36] Potential hazards to specimen handlers are minimized by using tightly fitting collection devices that are confined within proper protective containers. To maintain the integrity of the specimen, adverse environmental conditions, such as exposure to extremes of heat and cold, rapid changes in pressure (during air transport), or excessive drying should be avoided. The use of freezing specimens at −70°C is considered if there will be an extended transport time, but this is highly dependent on the microorganism suspected. Guidelines are available from quality reference laboratory providers, and should be followed to achieve optimal recovery of the organisms sought. Sputum samples that have been collected primarily for recovery of mycobacteria and fungi may be shipped without further treatment if collected in sterile propylene or polyethylene containers. To avoid breakage during transport, do not use glass containers.

Most fluid specimens should be transported to the laboratory as quickly as possible. In a hospital setting, a maximum 2-hour time limit between collection and delivery of specimens to the laboratory is recommended.[6,63] This time limit poses a problem for specimens collected in physicians' offices. Urine transport containers containing a small amount of boric acid may be used if rapid transport is not possible. Alternatively, urine specimens may be refrigerated for up to 24 hours before they are cultured. A holding or transport medium can be used for most other specimens, following the manufacturer's instructions. Stuart, Amies, and Carey–Blair transport media are most frequently used and are commercially available; instructions exist, however, for those interested in preparing media (Box 1-2).

14

BOX 1-2

Stuart's Transport Medium

Sodium chloride	3 g
Potassium chloride	0.2 g
Disodium phosphate	1.25 g
Monopotassium phosphate	0.2 g
Sodium thioglycolate	1.0 g
Calcium chloride, 1% aqueous	10.0 g
Magnesium chloride, 1% aqueous	10.0 g
Agar	4.0 g
Distilled water to equal pH = 7.3	1.0 L

These media are essentially solutions of buffers with carbohydrates, peptones and other nutrients and growth factors excluded, designed to preserve the viability of bacteria during transport without allowing their multiplication. Sodium thioglycolate is added as a reducing agent to improve recovery of anaerobic bacteria, and the small amount of agar provides a semisolid consistency to prevent oxygenation and spillage during transport. Sodium borate solution can be recommended as a preservative for shipping specimens suspected of containing mycobacteria to distant laboratories.[98] Sucrose–phosphate–glutamate is a good transport buffer medium for recovery of certain viruses, such as herpesvirus. Universal transport media and M4 are common transport solutions for viral culture, and may also be used in conjunction with many of the molecular assays that are rapidly replacing viral culture. Culturette swabs have also been used successfully for viral specimens in some facilities.[107] New and updated joint guidelines from the Infectious Diseases Society of America (IDSA) and the American Society for Microbiology (ASM) have been published; these extensive and well-done guidelines should be thoroughly reviewed and maintained in every microbiology laboratory.[4] These are available electronically online and free of charge.

Rather than recreate an excellent document, the reader is directed to *A Guide to Utilization of the Microbiology Laboratory for the Diagnosis of Infectious Diseases: 2013 Recommendations by the Infectious Diseases Society of America (IDSA) and the American Society for Microbiology (ASM).* This 100-page document provides guidelines on the recommended diagnostic procedures to secure an adequate specimen to achieve a diagnosis, as well as the optimum type of specimen and specimen transport.

Specimen Receipt and Preliminary Observations. There is an area is designated for the receipt of specimens in most clinical laboratories. Initial observations and handling should be performed in a biologic safety cabinet (BSC) (see below) because of the increasing possibility that laboratory personnel may incur a laboratory-acquired infection from specimens that contain pathogens. Personnel should wear protective clothing as appropriate—laboratory coats, rubber gloves and, in some instances, custom-fitted masks. In the distant past, these precautions were taken only for specimens carrying hazard labels. It is not possible, however, to determine if a patient may be harboring a transmissible agent or if a given sample contains a highly contagious pathogen. In addition, blood or body fluids that are submitted for bacterial culture may also contain HIV, HCV, or other blood-borne pathogens. Therefore, all clinical specimens should be handled in a safe and uniform way, which has been termed *universal precautions*. Following these guidelines helps protect the technologist performing the processing from the unsuspected pathogen, as well as the suspected ones.

The processing of specimens includes the following: (1) the entry of essential data into a log, which today is usually a computer database that is part of the laboratory information system (LIS); (2) visual examination and determination of whether all criteria for acceptance are met (see section on criteria for specimen rejection immediately below); and (3) for certain specimens, the microscopic examination of direct mounts or stained smears to establish a presumptive diagnosis.

Criteria for Rejection of Specimens. Criteria for rejection of unsuitable specimens for culture must be established in all laboratories.[112] Although general guidelines exist and accrediting agencies have established standards, each laboratory director must decide which parameters to utilize, depending on local conditions. Request slips and specimen labels must be checked upon specimen receipt to see that all essential information is included. Should there be a problem, collection of a fresh sample is the best course of action. If the specimen cannot be re-collected, a responsible person should be contacted to make corrections. A comment should be entered on the final report that the specimen was received with a (specified) problem, and the name of the person who corrected the problem should be appended. If the type of specimen can be ascertained, it may be acceptable in certain cases to issue a report: "specimen appears to be ----------." If not, the specimen should be rejected. Whenever discrepancies occur, a written record of how the situation was handled and names of the individual contacted should be entered on the back of the requisition, in a log, or in the computer database.

A list of specimen types or culture requests that should appear on the rejection list and should not be processed further appears in Box 1-3.

When a specimen is to be rejected, the person who submitted the specimen should be contacted and made aware of the problem. Every effort should be made not to

reject specimens that are difficult to re-collect, such as cerebrospinal fluid or bronchial washings. If a problem cannot be resolved expeditiously, cultures should be set up to avoid losing the integrity of the specimen. The decision can be made afterward whether to report the results. If appropriate, the condition of the specimen should be indicated on the report. The clinician will then have the responsibility for interpreting the report in light of the qualifying information.

Rejection criteria should be clearly communicated in the laboratory service directory. Instruction of hospital personnel on the importance of submitting relevant specimens for culture should be conducted when possible. Recurring problems and their solutions should be published in laboratory newsletters or other publications that may reach hospital personnel and staff physicians. Targeted re-education of particular groups that consistently breach protocol or submit substandard specimens is sometimes necessary. When this is needed, collegially approaching the group to establish "best practices" in patient care is a method to begin the dialogue in a nonconfrontational manner.

15

BOX 1-3

Specimen Types or Culture Requests That Should Be Rejected

1. Any specimen received in formalin. The only exception might be large specimens in which the time of exposure to formalin is short (less than 1 hour). In these instances, the tissue should be bisected with a sterile knife or scissors and an innermost portion sampled for culture.
2. Twenty-four-hour sputum collections. It is difficult to prevent contamination, and individual collections containing a high concentration of microorganisms will be diluted out by subsequent, less-concentrated samples.
3. Smears of secretions from uterine cervix, vaginal canal, or anus for Gram's stain detection of *Neisseria gonorrhoeae*.
4. A single swab submitted for multiple requests; for example, "aerobes, anaerobes, fungus, and tuberculosis."
5. Submission in an improper, nonsterile, or obviously contaminated container in which portions of the specimen have leaked out. Any leaking container that contains a clinical specimen should be handled with extreme care.
6. Culture plates that are overgrown or dried out.
7. Specimens that are obviously contaminated, as evidenced by the presence of foreign materials, such as barium, colored dyes, or oily chemicals.
8. The following specimens are not acceptable for anaerobic culture: gastric washings, midstream urine, prostatic secretions collected transurethrally, feces

(except for the recovery of *Clostridium difficile* in the rare instance that toxigenic culture is needed), ileostomy or colostomy swabs, throat, nose, or other oropharyngeal specimens (except specimens obtained from deep tissue during oral surgery), superficial skin, and environmental cultures.

Cost-Effective Approaches in the Preanalytic Phase. Discussing cost-effectiveness in clinical microbiology has been unpopular for many years and associated with "cutting corners" and providing suboptimal testing. It was considered antiacademic, impure, or even dangerous by traditional microbiologists. Another way to view the issue, however, is the application of clinical relevance to diagnostic microbiology. The point is not to identify every organism that might be recovered or to perform susceptibility tests on every organism that will grow in the laboratory. The point is to provide clinicians with information that will allow them to provide the best care for their patients. In the process, the work can usually be done more economically than if everything possible is done. Thus, clinical relevance usually equals cost-effectiveness. Cost-effectiveness does not mean cheap; it means the best value for money.

These concepts are not new. Dr. Bartlett, a distinguished pathologist and the director of the microbiology laboratory at Hartford Hospital in Connecticut for many years, wrote meaningfully on the subject in the mid-1970s. His seminal book on the subject is still worthwhile reading for clinical microbiologists.[6,7] Many others have followed his lead, and importantly, led with best practices for best patient care, rather than seeking yet another means to cut costs.

Clinical relevance and cost-effectiveness should inform laboratory practice at every stage in the process. Some suggestions for the preanalytical phase are detailed in Table 1-6. Newer concepts, some of them imported from industry and streamline processes, decrease variability and contribute to improved outcomes. The investigation and time investment to explore these strategies may result in substantial savings in materials and time.[84] The clever laboratory director will then reuse the saved time and money to justify new clinical services or insourcing tests that will provide even better service to their patients and providers. Conditions vary in every institution, so each laboratory director must decide which possibilities are appropriate and investigate these with the local leadership. Most importantly, the director should ensure that there is professional leadership driving the change, in contrast to purely cost-saving initiatives from administration.

Analytic Phase

Microscopic Examination. The reasons for performing microscopic examination of clinical materials have been emphasized.[6,8]

1. The number and percentage of segmented neutrophils that are present indicate the magnitude and type of inflammatory response. The quality of the specimens can be validated.
2. The observation of bacteria, hyphae and/or yeast forms, parasitic structures, or viral inclusions may provide sufficient information to render an immediate presumptive diagnosis.
3. Direct microscopic examination may also give immediate presumptive evidence that species of anaerobic

16

TABLE 1-6 Cost-Effective Approaches in the Preanalytical Phase of Testing

Action	Rationale	Comments
Selective culturing of CSF for fungi[70]	Low yield in immunocompetent patients who have normal CSF chemistry and cell count values	*Cryptococcus neoformans* may produce chronic infection without pleocytosis in the CSF.
Selective culturing of CSF for mycobacteria[70]	Low yield in immunocompetent patients who have normal CSF chemistry and cell count values	In populations with a low risk of tuberculosis, the yield will be even less.
Selective culturing of feces for bacterial pathogens or examination for O&P[70,105]	Low yield in patients who have been hospitalized more than 3 days	Exceptions exist, which include immunocompromised patients and the elderly.
Selective culturing of endotracheal suction aspirates or expectorated sputum[70]	Recovery of contaminating oropharyngeal flora increased if more than 10 squamous epithelial cells per low power field observed.	Several different criteria have been applied by investigators.
Selective use of broth back-up for bacterial cultures	Questionable usefulness except for cultures wherein there may be biofilm formation (e.g., CSF shunt cultures) or delayed growth (e.g., Actinomyces, P. acnes, and possibly valves from patients with endocarditis)	Broth cultures may be used in other situations if they are examined only when an organism seen in smears is not recovered on plates. They should never be performed on specimens from mucosal surfaces.

Nonuse of bacterial antigen tests on CSF[70,111]	Poor sensitivity and specificity limit usefulness	
Selective culturing of peritoneal fluid	Pattern of organisms recovered and susceptibility profiles predictable in patients with secondary peritonitis (community-acquired)	Cultures indicated in primary peritonitis (spontaneous bacterial peritonitis) and in peritonitis acquired in the hospital
Selective culturing of throat specimens	Streptococcus pyogenes is the major cause of pharyngitis: "routine culture" with multiple media will likely provide misleading information.	Culture for Corynebacterium diphtheriae, Neisseria, or herpes simplex virus should be requested specifically if appropriate Arcanobacterium hemolyticum causes pharyngitis in older children and adolescents, but is isolated on media for recovery of Streptococcus pyogenes.
Selective culturing for anaerobic bacteria	Anaerobic cultures should be performed routinely only on tissues or aspirated fluid/pus.	Never perform anaerobic cultures on specimens from sites that may be contaminated with mucosal flora or feces
Limits on frequency of culture	Throat, urine, wound limited to one per 24 hours; blood limited to two to three cultures for exclusion of bacteremia (10 mL/bottle, 2 bottles/set and two sets used per blood culture order with the sets drawn approximately 15 minutes apart)	Results of the first cultures should be evaluated prior to ordering additional cultures, unless the patient is critically ill and/or the clinical condition has changed in a way that suggests a new infection.
Limits on frequency of O&P exams	Yield from exams for Giardia minimal after three specimens, which should be collected every other day	Less than three exams probably adequate for other intestinal parasites.
	Repeat testing is not warranted within at least 7 days following	There is no value in repeat testing

Limits on frequency of testing for C. difficile[96]	a negative result from a PCR-based assay, because of the high negative predictive value. Repeat testing should only be performed if there is a clinical change suggestive of new-onset C. difficile enterocolitis.	following a positive PCR result; there is no "test of cure" for this disease and C. difficile may remain as part of the microbiota of the patient without causing disease.
Limits on testing of CSF for herpes simplex DNA[106,110]	Yield minimal if CSF cell counts normal and no evidence of focal lesions by MRI exam	Exceptions have been described, especially in children.
Limits on duplicate specimens submitted from the same site on the same day	Either pool the specimens or select the best specimen (based on Gram's stain and/or transport time)	If there is any uncertainty as to the equivalence of the specimens, consult the clinician before processing; when in doubt, process separately immediately and consult at leisure; preserve specimens for at least 24 hours
Limits on repeat specimens from a nonsterile site within a defined time period	Refer subsequent specimens to the previous evaluation; if the subsequent specimen has been inoculated to media and substantial differences from the original specimen are present, consult clinician about further action	Preserve specimen for at least 24 hours; preserve inoculated plates that are incompletely evaluated for a defined period (e.g., 7 days)
Elimination of culture of indwelling urinary catheter tips[114]	Reject the specimen for culture	Inform the clinician that urine should be submitted

CSF, cerebrospinal fluid; O&P, ova and parasites; MRI, magnetic resonance imaging. For more information, the reader should consult references 4, 62, and 81.

17

bacteria are present. With these clues in hand, the clinician can make more rational decisions about initial antimicrobial therapy.

In the past, the examination of wet mounts of unstained materials by phase contrast or darkfield microscopy was used for demonstrating motility, spirochetes and endospores, but this in uncommon performed today. Giemsa's, Wright's, or acridine orange (AO) stains may be helpful in observing bacterial forms that stain poorly or that have little contrast with background material.

Direct Gram's stains of clinical material may also be used to determine whether a specimen is representative of the site of infection. This technique has been applied to the evaluation of sputum samples. Bartlett has devised a grading system for evaluating sputum samples for the relative number of squamous epithelial cells and segmented neutrophils in direct Gram-stained sputum samples, (Box 1-4).[6] Using this system, negative numbers are assigned to a smear when squamous epithelial cells are observed, indicating contamination with oropharyngeal secretions (saliva). Positive numbers are assigned for the presence of segmented neutrophils, indicating the presence of active inflammation. The magnitude of these negative and positive determinations depends on the relative numbers of epithelial cells and segmented neutrophils as shown in the outline of Bartlett's grading system. A final score of 0 or less indicates either lack of inflammatory response or presence of significant salivary contamination, thus invalidating the specimen. Representative photomicrographs of Gram-stained sputum preparations illustrating this grading system are shown in Image Plate 1-1.

BOX 1-4

Bartlett's Grading System for Assessing the Quality of Sputum Samples

No. of Neutrophils per 10× Low-Power Field	Grade
<10	0
10–25	+1
>25	+2
Presence of mucus	+1
No. of Epithelial Cells per 10× Low-Power Field	
10–25	−1

>25	−2
Total[a]	

[a]Average for the number of epithelial cells and neutrophils in about 20 or 30 separate 10×microscopic fields is determined; then a total is calculated. A final score of 0 or less indicates lack of active inflammation or contamination with saliva. Unsatisfactory specimens should be rejected, the provider should be notified and a repeat sputum specimen should be requested, if clinically indicated. The denotation of "if clinically indicated" is important, because if a message such as "Repeat sputum culture" is given, then this may be performed, even if the clinically findings of the patient do not warrant repeat testing.

BOX 1-5

Murray and Washington's Grading System for Assessing the Quality of Sputum Samples

	Epithelial Cells Per Low-Power Field	Leukocytes Per Low-Power Field
Group 1	25	10
Group 2	25	10–25
Group 3	25	25
Group 4	10–25	25
Group 5	<10	25

A similar grading system has been proposed by Murray and Washington[86] (Box 1-5). The large number of epithelial cells in groups 1 to 4 of this system indicates contamination with oropharyngeal secretions and invalidates the samples (i.e., the specimen should be rejected). Only group 5 specimens are considered clinically relevant. In a clinical study, Van Scoy[115] recommended that sputum samples containing more than 25 neutrophils be accepted for culture even if more than 10 epithelial cells are present (group 4). These suggested criteria for evaluation of sputum have been evaluated by applying them to matched pairs of respiratory secretion obtained by expectoration and by transtracheal aspiration, a technique that bypasses

the oropharyngeal flora.[53]

The sputum grading system cannot be employed if pulmonary infections caused by mycobacteria, fungi, *Legionella* spp., and viruses are suspected. Additionally, the significance of PMNs is altered in a few situations: (1) when the patient is neutropenic from disease or therapy, (2) when the patient does not mount an effective inflammatory response, and (3) where a foreign body causes irritation to a mucosal surface. Neutropenia can result from an inherited deficiency or because the inflammatory cells or their precursors are destroyed, either by a disease process or by chemotherapy for a disease. In some conditions, the ability of neutrophils to migrate to the site of an infection is impaired. From the information ordinarily supplied by clinicians, it is rarely possible for the clinical microbiologist to determine whether a patient is neutropenic. One of the exceptions is the incompletely understood deficiency in mobilization of neutrophils that is found in infancy.[39] The exact age at which a full neutrophilic response can be mounted is not clearly defined, but in the very youngest children (less than 2 months of age) decisions to reject specimens or evaluate isolates incompletely should not be based on the absence of neutrophils in the specimen.

The two situations in which foreign bodies modify the interpretations associated with the presence of neutrophils. These are when an endotracheal catheter is in place the lower respiratory tract and when there is an indwelling catheter in the lower urinary tract, such as a Foley catheter. In each of these situations, the presence of neutrophils in a specimen may reflect irritation from the catheter rather than from an

infectious agent, although both factors may be present. In the respiratory tract, the inflammation may come from local infection (tracheitis) rather than from pneumonia, even if there is an infectious element. If the respiratory tract neutrophils cannot be used as an indication of pneumonia, then the diagnosis of pneumonia must be made clinically and radiographically, as discussed in Chapter 2. In the lower urinary tract, the presence of leukocytes cannot be used as an indication of a clinically important infection if a catheter is in place[108] or even if repeated intermittent catheterization is performed.[54] The critical determinant for therapy of urinary tract infections in the chronically catheterized patient is whether the patient is symptomatic (see Chapter 2).

Microscopic Techniques. A number of techniques may be used in the direct microscopic examination of clinical specimens, either to demonstrate the presence of microorganisms or to observe certain biochemical, physiologic, or serologic characteristics. The techniques commonly used in clinical microbiology laboratories are outlined in Table 1-7. Because the refractive index of bacteria and other

TABLE 1-7 Techniques for Direct Examination of Unstained Specimens

Methods and Materials	Purpose	Techniques
Saline mount Sodium chloride, 0.85% (aqueous) Glass microscope slides, 3 × 1-inch Coverslips Paraffin–petrolatum mixture (Vaspar)	To determine biologic activity of microorganisms, including motility or reactions to certain chemicals, or serologic reactivity in specific antisera. The latter includes the quellung (capsular swelling) reaction used to identify different capsular types of Streptococcus pneumoniae and Haemophilus influenzae.	Disperse a small quantity of the specimen to be examined into a drop of saline on a microscope slide. Overlay a coverslip and examine directly with a 40× or 100× (oil immersion) objective of the microscope, closing the iris diaphragm to reduce the amount of transmitted light. To prevent drying, ring the coverslip with a small amount of paraffin–petrolatum before overlaying the specimen drop on the slide.
Hanging-drop procedure Hanging-drop glass side (This is a thick glass slide with a central concave well.) Coverslip Physiologic saline or water Paraffin–petrolatum mixture	The hanging-drop mount serves the same purpose as the saline mount, except that there is less distortion from the weight of the coverslip and a deeper field of focus into the drop can be achieved. This technique is generally used for studying the motility of bacteria.	A small amount of paraffin–petrolatum mixture is placed around the lip of the well on the undersurface of the hanging-drop slide. Cells from a bacterial colony to be examined are placed in the center of the coverslip, into a small drop of saline or water. The slide is inverted and pressed over the coverslip, guiding the drop of bacterial suspension into the center of the well. The slide is carefully brought to an upright position for direct examination under the microscope.
Iodine mount Lugol's iodine solution: Iodine crystals, 5 g Potassium iodide, 10 g Distilled water, 100 mL	Iodine mounts are usually used in parallel with saline mounts when examining feces or other materials for intestinal protozoa	A small amount of fecal matter or other material is mixed in a drop of the iodine solution on a microscope slide. This is mixed to form an even suspension, and a coverslip is placed over

Dissolve KI in water and add iodine crystals slowly until dissolved. Filter and store in tightly stoppered bottle. Dilute 1:5 with water before use. Microscope slides, 3 × 1-inch Coverslips	stains the nuclei and intracytoplasmic organelles so that they are more easily seen. Iodine mounts cannot be used to the exclusion of saline mounts because iodine paralyzes the motility of bacteria and protozoan trophozoites.	and a coverslip is placed over the drop. The mount is then examined directly under a microscope. If this is to be delayed or if a semipermanent preparation for future study is desired, the edges of the coverslip can be sealed with the paraffin–petrolatum mixture.
Potassium hydroxide (KOH) mount Potassium hydroxide, 10% (aqueous) Microscope slides, 3 × 1-inch Coverslips	The KOH mount is used to aid in detecting fungal elements in thick mucoid material or in specimens containing keratinous material, such as skin scales, nails, or hair. The KOH dissolves the background keratin, unmasking the fungal elements to make them more apparent.	Suspend fragments of skin scales, nails, or hair in a drop of 10% KOH. Add coverslip over the drop and let sit at room temperature for about half an hour. The mount may be gently heated to accelerate the clearing process. Do not boil. Examine under a microscope for fungal hyphae or spores.
India Ink preparation India Ink (Pelikan brand) or Nigrosin (granular) Microscope slides, 3 × 1-inch Coverslips	India ink or nigrosin preparations are used for the direct microscopic examination of the capsules of many microorganisms. The fine granules of the India ink or nigrosin give a semiopaque background against which the clear capsules can easily be seen. This technique is particularly useful in visualizing the large capsules of Cryptococcus neoformansin cerebrospinal fluid, sputum, and other secretions.	Centrifuge the cerebrospinal fluid or other fluid specimens lightly to concentrate any microorganisms in the sediment. Emulsify a small quantity of the sediment into a drop of India ink or nigrosin on a microscope slide and overlay with a coverslip. Do not make the contrast emulsion too thick, or the transmitted light may be completely blocked. Examine the mount directly under a microscope, using the 10× objective for screening and the 40× objective for confirmation of suspicious encapsulated microorganisms.
		The secretion to be examined is obtained from the patient. In

Darkfield exam Compound microscope equipped with a darkfield condenser Microscope slides, 3 × 1-inch Coverslips Physiologic saline Applicator sticks or curet Paraffin–petrolatum mixture	Darkfield examinations are used to visualize certain delicate microorganisms that are invisible by brightfield optics and stain only with great difficulty. This method is particularly useful in demonstrating spirochetes from suspicious syphilitic chancres for Treponema pallidum.	the case of a chancre, the top crust is scraped away with a scalpel blade and a small quantity of serous material is placed on a microscope slide. Ring a coverslip with paraffin–petrolatum mixture and place over the drop of material. Examine the mount directly under a microscope fitted with a darkfield condenser with a 40× or 100× objective. Spirochetes will appear as motile, bright "corkscrews" against a black background.

microorganisms is similar to that of the mounting medium, they are not visible when examined by brightfield illumination. Therefore, microorganisms are most commonly stained prior to attempts at visualization. However, sometime, an unstained assessment is made and can be enhanced with certain manipulations of the light source. Often, it is helpful to reduce the amount of light entering the field by closing the iris diaphragm, thereby increasing the contrast between the object being observed and the background. The common practice of lowering the condenser to achieve this effect should be discouraged.

Direct Stains. Biologic stains are generally required to visualize bacteria adequately and sometimes demonstrate the fine detail of internal structures. The introduction of stains in the mid-19th century was, in large part, responsible for the major advances that have occurred in clinical microbiology and in other fields of diagnostic microscopy during the past 100 years. Today, we are so dependent on biologic stains that it is difficult to imagine how the study of bacteria would have progressed without their introduction. The chemical formulas, components, and purposes of the stains commonly used in the microbiology laboratory are shown in Table 1-8.

Stains consist of aqueous or organic preparations of dyes or groups of dyes that impart a variety of colors to microorganisms, plant and animal tissues, or other substances of biologic importance. Dyes may be used as direct stains of biologic materials, as indicators of pH shifts in culture media, as oxidation–reduction indicators to demonstrate the presence or lack of anaerobic conditions, or to demonstrate physiologic functions of microorganisms using so-called supravital techniques.

Almost all biologically useful dyes are derivatives of coal tar. The fundamental chemical structure of most dyes is the benzene ring. Dyes are generally composed of two or more benzene rings connected by well-defined chemical bonds that are associated with color production (chromophores).

TABLE 1-8 Common Biologic Stains Used in Bacteriology

Stain	Chemical Formula	Ingredients		Purpose
Loeffler's methylene blue	 Tetramethyl thionin	Methylene blue Ethyl alcohol, 95% Distilled water	0.3 g 30 mL 100 mL	This is a simple direct stain used to a variety of microorganisms, specifically used to detect bacteria in cerebrospinal fluid smears in suspected cases of bacterial meningitis.
Gram's stain	 Crystal Violet (Hexamethylpararosanilin)  Dimethyl Phenosafranin	Crystal violet Crystal violet Ethyl alcohol, 95% NH_4 oxalate Distilled water Gram's iodine Potassium iodide Iodine crystals Distilled water Decolorizer Acetone Ethyl alcohol, 95% Counterstain Safranin O Ethyl alcohol, 95% Add 100 mL to distilled water	 2 g 20 mL 0.8 g 100 mL 2 g 1 g 100 mL 50 mL 50 mL 2.5 g 100 mL 100 mL	This is a stain used to demonstrate the staining properties of bacteria of all types. Gram-positive bacteria retain the crystal violet dye after decolorization and appear deep blue. Gram-negative bacteria are not capable of retaining the crystal violet dye after decolorization and are counterstained red by the safranin dye. Gram-staining characteristics may be atypical in very young, old, dead, or degenerating cultures.

20

Ziehl–Neelsen acid-fast	 Carbolfuchsin (Triaminotriphenylmethane)	Carbolfuchsin Phenol crystals Alcohol, 95% Basic fuchsin Distilled water Acid alcohol, 3% HCl, concentrated Alcohol, 70% Methylene blue Methylene blue Glacial acetic Distilled water	 2.5 mL 5 mL 0.5 g 100 mL 3 mL 100 mL 0.5 g 0.5 mL 100 mL	Acid-fast bacilli are so called because they are surrounded by a waxy envelope that is resistant to staining. Either heat or a detergent (Tergitol) is required to allow the stain to penetrate the capsule. Once stained, acid-fast bacteria resist decolorization, whereas other bacteria are destained with the acid alcohol.
Fluorochrome	 Auramine O  Rhodamine B  Acridine orange (AO)	Auramine O Rhodamine B Glycerol Phenol Distilled water AO powder Sodium acetate buffer (pH 3.5) (Add about 90 mL 1 M HCl to 100 mL 1 M Na acetate)	1.5 g 0.75 g 75 mL 10 mL 50 mL 20 mg 190 mL	This fluorochrome dye stains mycobacteria selectively by binding to the mycolic acid in the cell wall. This stain demonstrates mycobacteria better than conventional acid-fast stains and permits screening of smears at lower magnification because organisms are more easily seen. Acridine orange is a stain particularly well adapted for the demonstration of bacteria in blood culture broth, cerebro-spinal fluid, urethral smears, or other exudates where they may be present in relatively small numbers, as low as 10^4 CFU mL, or when they are obscured by a heavy background of polymorphonuclear leukocytes or other debris. At pH below 4.0, bacteria and yeast cells stain brilliant orange against a black, light green, or yellow background.
Wright—Giemsa's	Polychrome methylene blue Methylene blue Methylene azure Eosin  Methylene azure B	Powdered Wright's stain Powdered Giemsa's stain Glycerin Absolute methyl alcohol Mix in brown bottle and let stand for 1 month before using.	9 g 1 g 90 mL 2910 mL	Wright—Giemsa's is commonly used for staining the cellular elements of the peripheral blood smear. It is useful in microbiology for the demonstration of intracellular organisms such as *Histoplasma capsulatum* and *Leishmania* species (Image Plate 1G). The stain is also useful in demonstrating intracellular inclusions in direct smears of skin or mucous membranes, such as corneal scrapings for trachoma.
Lactophenol	 Aniline blue	Phenol crystals Lactic acid Glycerol Distilled water Dissolve ingredients, then add: Aniline blue	20 g 20 g 40 mL 20 mL 0.05 g	Because of the sulfonic groups, aniline blue the dye is strongly acidic and has been used as a counter stain for unfixed tissues, bacteria, and protozoa, in combination with other dyes. Currently used for the direct staining of fungal mycelium and fruiting structures which take on a delicate light blue color.

Although the underlying mechanism of the color development is not totally understood, it is theorized that certain chemical radicals have the property of absorbing light of different wavelengths, acting as chemical prisms. Some of the more common chromophore groupings found in dyes are: C=C, C=O, C=S, C=N, N=N, N=O, and NO_2. (Note the presence of these groups in the chemical formulas of the stains shown in Table 1-8.) The depth of color of a dye is proportional to the number of chromophore radicals in the compound.

Dyes differ from one another in the number and arrangement of these rings and in

the substitution of hydrogen atoms with other molecules. For example, there are three key single substitutions for one hydrogen atom of benzene that constitute the basic structure of most dyes: (1) substitution of a methyl group to form toluene (methylbenzene),

21

(2) substitution of a hydroxyl group to form phenol (carbolic acid), and (3) the substitution of an amine group to form aniline (phenylamine). Most stains used in microbiology are derived from aniline and are called aniline dyes.

All biologic dyes have a high affinity for hydrogen. When all the molecular sites that can bind hydrogen are filled, the dye is in its reduced state and is generally colorless. In the colorless state, the dye is called a leuko compound. Looking at this concept from the opposite view, a dye retains its color only as long as its affinities for hydrogen are not completely satisfied. Because oxygen generally has a higher affinity for hydrogen than many dyes, color is retained in the presence of air. This allows certain dyes, such as methylene blue, to be used as an oxidation–reduction indicator in an anaerobic environment, because the indicator becomes colorless in the absence of oxygen.

In broad terms, dyes are referred to as acidic or basic. These designations do not necessarily indicate their pH reactions in solution, but rather, whether a significant part of the molecule is anionic or cationic. From a practical standpoint, basic dyes stain structures that are acidic, such as the nuclear chromatin in cells; acidic dyes react with basic substances, such as cytoplasmic structures. If both nuclear and cytoplasmic structures are to be stained in a given preparation, combinations of acidic and basic dyes may be used. A common example is the hematoxylin (basic) and eosin (acidic), the characteristic H&E, stain used in the examination of tissue sections.

The Use of Stains in Microbiology. Microbiologists commonly perform direct microscopic examination on specimens submitted for culture. Not only may it be possible to provide the physician with a rapid presumptive diagnosis, but also the detection of specific microorganisms may serve as a guide for selecting appropriate culture media and provide a valuable quality control comparison with isolates recovered. The positive findings for various staining procedures and diseases in selected specimens that are submitted to microbiology laboratories are listed in Table 1-9. The following is a brief description of the stains most commonly used.

Gram's Stain. Gram's stain, discovered over 100 years ago by Hans Christian Gram, is most commonly used for direct microscopic examination of specimens and subcultures (Table 1-8). The staining procedure is explained in Box 1-6.

Crystal violet (gentian violet) serves as the primary stain, binding to the bacterial cell wall after treatment with a weak solution of iodine, which serves as the mordant to bind the dye. Some bacterial species, because of the chemical nature of their cell

walls, have the ability to retain the crystal violet even after treatment with an organic decolorizer, such as a mixture of equal parts of acetone and 95% ethyl alcohol. Dye-retaining bacteria appear blue-black when observed under the microscope and are called gram positive. Certain bacteria lose the crystal violet primary stain when treated with the decolorizer, presumably because of the high lipid content of their cell wall and less abundant peptidoglycan.

TABLE 1-9 Diagnosis of Infectious Disease by Direct Examination of Culture Specimens

Specimen	Suspected Disease	Laboratory Procedure	Positive Findings
Throat culture	Diphtheria	Gram's stain	Delicate pleomorphic gram-positive bacilli in Chinese letter arrangement
		Methylene blue stain	Light-blue-staining bacilli; with prominent metachromatic granules
	Acute streptococcal pharyngitis	Direct fluorescent antibody technique (after 4–6 hours incubation in Todd–Hewitt broth)	Fluorescent cocci in chains; use positive and negative controls with each stain
Oropharyngeal ulcers	Vincent's disease	Gram's stain	Presence of gram-negative bacilli and thin, spiral-shaped bacilli
Sputum Transtracheal aspirates Bronchial washings	Bacterial pneumonia	Gram's stain	Variety of bacterial types; *Streptococcus pneumoniae* (i.e., gram-positive lancet-shaped diplococci) are particularly diagnostic
	Tuberculosis Pulmonary mycosis	Acid-fast stain Gram's stain, Wright–Giemsa's stain, or Calcofluor white Gram–Weigert's stain	Acid-fast bacilli Budding yeasts, pseudohyphae, true hyphae, or fruiting bodies
Cutaneous wounds or purulent drainage from subcutaneous sinuses	Bacterial cellulitis	Gram's stain	Variety of bacterial types; suspect anaerobic species
	Gas gangrene (myonecrosis)	Gram's stain	Gram-positive bacilli suggesting *Clostridium perfringens* (i.e., gram-positive, boxcar-shaped bacilli); spores usually not seen
	Actinomycotic mycetoma	Direct saline mount Gram's stain or modified acid-fast stain	"Sulfur granules" Delicate, branching gram-positive filaments; *Nocardia* species may be weakly acid-fast
	Eumycotic mycetoma	Direct saline mount Gram's stain or lactophenol cotton blue mount	White, grayish, or black grains True hyphae with focal swellings or chlamydospores

22

Cerebrospinal fluid	Bacterial meningitis	Gram's stain	Small gram-negative coccobacilli (*Haemophilus* species) Gram-negative diplococci (*Neisseria meningitidis*) Gram-positive diplococcic (*Streptococcus pneumoniae*)
		Methylene blue stain	Bacterial forms that stain blue-black
		Acridine orange stain	Bacterial forms that glow brilliant orange under ultraviolet illumination
	Cryptococcal meningitis	India ink or nigrosin mount	Encapsulated yeast cells with narrow-necked budding
	Listeriosis	Gram's stain Hanging-drop mount	Delicate gram-positive bacilli Bacteria with tumbling motility
Urine	Yeast infection	Gram's stain or Wright–Giemsa's stain	Pseudohyphae or budding yeasts
	Bacterial infection	Gram's stain	Variety of bacterial types
	Leptospirosis	Darkfield examination	Tightly coiled motile spirochetes
Purulent urethral discharge	Gonorrhea	Gram's stain	Intracellular gram-negative diplococcic
	Chlamydial infection	Direct fluorescent antibody stain of smear	Elementary bodies
Purulent vaginal discharge	Yeast infection	Direct mount or Gram's stain	Pseudohyphae or budding yeasts
	Trichomonas infection	Direct mount	Flagellates with darting motility
	Gardnerella vaginalis	Pap stain or Gram's stain Measure pH of vaginal secretions	"Clue cells" or pH of vaginal secretions >5.5
Penile or vulvar ulcer (chancre)	Primary syphilis	Darkfield mount of chancre secretion	Tightly coiled motile spirochetes
	Chancroid	Gram's stain of ulcer secretion or aspirate of inguinal bubo	Intracellular and extracellular small gram-negative bacilli
Eye	Purulent conjunctivitis	Gram's stain	Variety of bacterial species
	Trachoma	Giemsa stain of corneal scrapings	Intracellular perinuclear inclusion clusters
Feces	Purulent enterocolitis	Gram's stain	Neutrophils and aggregates of staphylococci
	Cholera	Direct mount of alkaline peptone water enrichment	Bacilli with characteristic darting motility; no neutrophils
	Parasitic disease	Direct saline or iodine mounts. Examine purged specimens.	Adult parasites or parasite fragments; protozoa or ova
Skin scrapings, nail fragments, or plucked hairs	Dermatophytosis	10% KOH mount	Delicate hyphae or clusters of arthroconidia
	Tinea versicolor	10% KOH mount or lactophenol cotton blue mount	Hyphae and spores resembling spaghetti and meatballs
Blood	Relapsing fever (*Borrelia*)	Wright's or Giemsa stain Darkfield examination	Loosely coiled spirochetes
	Blood parasites: malaria, trypanosomiasis, filariasis	Wright's or Giemsa stain	Intracellular parasites (malaria, babesia) Extracellular forms: trypanosomes or microfilaria
		Direct examination of anticoagulated blood for the presence of microfilaria	

These decolorized bacteria are then stained with the safranin counterstain and appear pink or red when observed under the microscope; they are called gram negative (Image Plate 1-2A). The visualization of certain fastidious gram-negative bacilli, such as *Legionella* species, can be improved by adding 0.05% carbolfuchsin to the safranin counterstain. These Gram reactions, when observed in conjunction with the morphologic form (cocci and bacilli) and arrangement of bacterial cells, can be used to make presumptive identifications.

Common applications of Gram's stain have been reviewed by Friedly.[48] Gram-positive cocci in clusters suggest staphylococci, whereas cocci in chains suggest streptococci.

23

BOX 1-6

Gram's Stain Technique

1. Make a thin smear of the material for study and allow to air-dry.
2. Fix the material to the slide by passing the slide three or four times through the flame of a Bunsen burner or dry on a slide warmer. This is done so that the material does not wash off during the staining procedure. Some workers now recommend the use of alcohol for the fixation of material to be Gram-stained, wherein the slide is flooded with methanol or ethanol for a few minutes)
3. Place the smear on a staining rack and overlay the surface with crystal violet solution.
4. After 1 minute of exposure to the crystal violet stain, wash thoroughly with distilled water or buffer.
5. Overlay the smear with Gram's iodine solution for 1 minute. Wash again with water.
6. Hold the smear between the thumb and forefinger and flood the surface with a few drops of the acetone–alcohol decolorizer, until no violet color washes off. This usually takes 10 seconds or less.
7. Wash with running water and again place the smear on the staining rack. Overlay the surface with safranin counterstain for 1 minute. Wash with running water.
8. Place the smear in an upright position in a staining rack, allowing the excess water to drain off and the smear to dry. Alternatively, one may blot dry.
9. Examine the stained smear under the 100× (oil) immersion objective of the microscope. Gram-positive bacteria stain dark blue; gram-negative bacteria appear pink-red.

Gram-positive, lancet-shaped diplococci, when seen in smears made from respiratory and CSF specimens are highly suggestive of *S. pneumoniae*; these characteristics have a lower positive predictive value in other specimens, because *Acinetobacter,* which sometimes retains the crystal violet in Gram's stain and occasionally enterococci are similar in appearance. Gram-negative, kidney-shaped diplococci are characteristic of *Neisseria* species or *M. catarrhalis*. Large, "boxy" gram-positive bacilli suggest

Bacillus or *Clostridium* species, whereas small gram-positive bacilli suggest *Listeria* species. The coryneforms (diphtheroids) are suspected, if small gram-positive bacilli in "Chinese-letter" or "picket fence" arrangements are observed. Curved, gram-negative bacilli in diarrheal stool specimens suggest *Vibrio* species, whereas very small, helical or corkscrew forms are supportive of a *Campylobacter* species. Gram-negative bacilli are some of the bacteria most commonly encountered in clinical laboratories and include the *Enterobacteriaceae,* which are plump, the nonfermentative bacilli, which are thinner in diameter than *Enterobacteriaceae*, *Haemophilus* species, which are coccobacillary, and a variety of fastidious species. Selected Gram-stained images are included in Image Plate 1-3, which are discussed in more detail in a later section of this chapter.

Gram's stain is a deceptively simple procedure, but the appropriate performance, which includes interpretation, is highly complex. Considerable experience, careful training, and correlation with culture results are essential to achieve a high level of proficiency. The intermittent performer of Gram's stain will not usually do as well as someone who views them regularly, particularly with respect to the subtleties that really only come with experience and correlation with culture. For example, an interesting study examined the performance of medical house staff and experienced microbiologists in the diagnosis of community-acquired pneumonia.[45] The house staff were better than the nursing personnel at obtaining a purulent sputum specimen, but their preparation and interpretation of the Gram-stained smears was inferior to that of the microbiologists.

There are some microbiologic and technical reasons for the importance of experience. Most of the time bacterial morphology matches the classical descriptions. Occasionally, this is not the case. With good training, practice, and a willingness to learn from mistakes, the microbiologist will learn the pitfalls. Some of the classical challenges that may be encountered in Gram's stain interpretations are summarized in Table 1-10. A cardinal rule is that the final interpretation must be made on the basis of staining color, bacterial morphology, and known variants. To complicate matters still further, a variety of artifacts can resemble infectious agents and be reported mistakenly as a microbe. Some of these potential sources of error are illustrated in Image Plate 1-4. If the possibility of an artifact is considered, a useful maneuver is to stain another smear with AO (see below); with this stain it can be established whether the structure contains DNA and is, therefore, biologic. Although the staining procedure is simple, the decolorization step can cause problems if not performed properly. If acetone, rather than acetone–alcohol is used as the decolorizer, particular care must be taken because it acts very quickly. Under-decolorization can be monitored by observing the nuclei of inflammatory cells; if they are not completely gram negative, then the smear has not been adequately decolorized. The only recipe for detecting over-decolorization is cross-checking the Gram reaction and the morphology of the

bacteria with known staining characteristics. If the quality assurance program (see below) includes a review of smears that do not correlate with cultures, improper decolorization and nonbacterial artifacts that have been reported erroneously can be detected and the reader of the smear can learn from the mistake.

Gram's stain can also be used to identify nonbacterial forms such as fungi, trichomonads, *Strongyloides* larvae, *Pneumocystis jiroveci* cysts, and *Toxoplasma gondii* trophozoites, although it is not as sensitive as other special stains used for visualizing these organisms. These various applications demonstrate the versatility of Gram's stain.

Acid-Fast Stains. The cell walls of mycobacteria essentially coats them with a thick, waxy material that resists

TABLE 1-10 Pitfalls in the Interpretation of Gram's Stains

Organism	Classic Presentation	Variant Presentation	Comments
Streptococcus pneumoniae	Gram-positive, lancet-shaped, diplococci	Elongated cocci, resembling short bacilli	May be misinterpreted as mixed organisms; over-decolorized cells may be mistaken for gram-negative coccobacilli.
Acinetobacter spp.	Gram-negative coccobacilli	Gram-negative cocci; gram-variable staining is common	May be mistaken for *Neisseria* spp. and reported as gram-negative cocci; search the smear to find some organisms that demonstrate elongated forms, which are not seen in *Neisseria*
Clostridium perfringens	Boxcar-shaped gram-positive bacilli	Gram-positive cocci	May be mistaken for *Streptococcus pneumoniae* and reported as gram-positive cocci; in addition to a coccal form, cells retain crystal violet tenaciously during decolorization.
		Gram-variable or gram-negative bacilli	May be mistaken for gram-negative bacilli; the boxcar shape is a clue that the organism is gram-positive; other *Clostridia* and *Bacillus* spp. may also appear similar.
Yeast, especially *Cryptococcus neoformans*	Gram-positive round or oval cells with budding	Gram-variable cells	May be mistaken for artifacts; size and shape distinguish them from bacteria.

staining; once stained, however, the bacterial cells resist decolorization by strong organic solvents such as acid–alcohol. Consequently, these bacteria are known as acid-fast, a phenomenon first discovered in 1881 by Ziehl and Neelsen.

Special treatment is required for the primary stain, carbolfuchsin, to penetrate the waxy material of the acid-fast bacilli. Heat is used in the conventional Ziehl–Neelsen technique. After the carbolfuchsin is overlaid on the surface of the smear to be stained, traditionally the flame of a Bunsen burner is passed back and forth beneath the slide. The smear is heated to steaming, stopping short of boiling. The Kinyoun modification of the acid-fast stain is called the "cold method" because a surface-active detergent, such as Tergitol, is used rather than heat treatment.

With either of these stains, the acid-fast bacilli appear red against either a green or

blue background depending on the counterstain used (Image Plate 1-2B). Although this method is satisfactory for most mycobacteria, certain weakly acid-fast strains of rapidly growing species (e.g., *Mycobacterium fortuitum* or *M. chelonae*) may stain better with the Ziehl–Neelsen method (see Chapter 19). In addition, certain bacteria, such as *Nocardia* spp., characteristically exhibit partial or weak acid-fastness.

Fluorescent Stains. Fluorescein isothiocyanate (FITC) and tetramethylrhodamine isothiocyanate (TMRI) are two commonly used fluorochromes that, on excitation with ultraviolet or short-wavelength visible light, emit light waves in the visible range, with absorption maxima of 490 nm and 555 nm, respectively. These fluorochromes bind chemically with a variety of proteins, including antigens and antibodies, providing a fluorescent signal that can be visualized in direct smears of biological materials. Fluorochrome/protein ratios vary with different reagents for optimal staining of the desired objects with a minimum of nonspecific background distraction. The current development of monoclonal antibodies, which are specific for their respective antigens, has led to the preparation of fluorescent reagents for direct and indirect detection of several pathogens including *Legionella* species, *T. pallidum*, *T. gondii*, and several viruses, including varicella zoster, herpes simplex, influenza, cytomegalovirus, and respiratory syncytial viruses, among others.

Fluorescence microscopy is an exacting technique that requires a microscope of high quality, the proper combination of microscope objectives, bright and darkfield condensers, a mercury arc or halogen ultraviolet light source, and appropriate combinations of exciter and barrier or suppression filters.[22] Achromatic objectives are satisfactory for most applications, except in research applications where expensive apochromatic lenses may be needed to achieve maximum illumination and resolution. The selection of microscope slides and coverslips of proper thickness and the use of low-fluorescing immersion oils and mounting fluids are critical for optimal performance.

The choice of filters in fluorescence microscopy is also critical to successful work. Four filters are required in sequence: (1) one to absorb heat (to prevent damage to the exciter filter), (2) an exciter filter with a wave bandwidth appropriate for the wavelength of light produced by the excited fluorochrome, (3) a red-absorbing filter to block any red light emitted by the blue excitation filters, and (4) a barrier filter to absorb any of the residual short-wavelength incident excitation light (which would damage the eyes of the microscopist), allowing only the longer-wavelength visible light to pass. Suboptimal performance of a fluorescence microscope system is often due to poor selection of filter combinations. Manufacturers of fluorescence equipment provide information and consultation so that users can achieve optimal performance. Fluorescence systems that employ (1) epi-illumination, (2) blue light halogen lamps that do not require expensive transformers, and (3) interference filters with maximum absorption peaks at the longer visible wavelengths are now available within a price

range acceptable to most clinical laboratory directors.

Fluorochrome Stains for Mycobacteria. The fluorochrome dyes auramine and rhodamine can be used to demonstrate acid-fast bacilli. Viewed by fluorescence microscopy,

25

the bacterial cells appear yellow, red, or orange (depending on the filter combination and dyes used); the background is dark when potassium permanganate is used as the counterstain (Image Plate 1-2C). Use of the fluorescence procedure facilitates the screening of smears, particularly when a 25× objective is utilized. This objective provides magnification low enough to scan wide microscopic fields, yet sufficiently high to see the yellow light points of light emanating from the fluorescing bacterial cells (Image Plate 1-2C). Higher magnification can be used to confirm suspicious objects observed with the 25× lens. It is also a common practice in some laboratories to confirm mycobacteria detected by this method with a traditional acid-fast stain, as described above.

The acid-fast stains can also be used to identify nonbacterial microorganisms. The oocysts of *Cryptosporidium* species and *Cystoisospora* (formerly *Isospora*) *belli*, two coccidian organisms that are known etiologic agents of gastroenteritis, are acid-fast and can be readily detected in appropriately stained preparations of stool (Image Plate 22-4BJ).

Acridine Orange. The AO stain is used with increasing frequency in microbiology laboratories to detect bacteria in smears prepared from fluids and exudates in which bacteria are expected to be in low concentration (10^3 to 10^4 colony-forming units [CFU]/mL) or are trapped within a heavy aggregate of background debris, making them difficult to visualize by conventional staining procedures. The AO stain was originally used by microbiologists to demonstrate bacteria in soil samples. As in the application of fluorochrome dyes for studying acid-fast bacilli, smears stained with AO and examined under ultraviolet light can be more rapidly and efficiently screened at low-power magnifications (100×), reserving magnifications of 450× or higher when suspicious forms are visualized. The stain detects both living and dead bacteria, but does not indicate whether they are gram negative or gram positive. Once bacteria have been detected using the AO stain, a Gram's stain must be used to determine their differential-staining characteristics (Image Plate 1-2D).

Lauer and associates have found the AO stain to be more sensitive than Gram's stain in detecting bacteria in CSF sediments, particularly when gram-negative bacteria are present.[70] The AO stain has also been useful to screen urine specimens for significant bacteriuria.[59] In Box 1-7 preparation of an AO stain is outlined.

Toluidine Blue and Methylene Blue. Toluidine blue, a dye closely related to azure

A and methylene blue, is used for staining lung biopsy imprints and respiratory secretions to detect *P. jiroveci*. Methylene blue stains may be performed on spinal fluid sediments along with Gram's stains. This may be useful to detect the gram-negative bacterial cells of *H. influenzae* and *N. meningitidis* that often do not stand out against the red-staining background in Gram's stains. With methylene blue, polymorphonuclear leukocytes stain blue; the bacterial cells are also deep blue and easier to detect against the light gray-staining background (Image Plate 1-2E). Methylene blue stains should be considered as an adjunct to Gram's stains in laboratories where the inaccessibility to a fluorescence microscope precludes the use of the AO procedure.

Calcofluor White. Calcofluor white, a colorless dye used in industry to whiten textiles and paper, has two properties that make it useful in microbiology: (1) binding to beta 1-3, beta 1-4-polysaccharides (specifically cellulose and chitin); and (2) fluorescence when exposed to long-wavelength ultraviolet and short-wavelength visible light. Calcofluor white is a valuable fluorochrome stain for the rapid detection of fungi in wet mounts, smears, and tissues, because the cell walls of fungi and plants are rich in chitin. The stain has been most useful in detecting yeast cells, hyphae, and pseudohyphae in skin and mucous membrane scrapings. When mixed with 10% potassium hydroxide, mounts of skin scrapings can be screened for dermatophytes rapidly. Viewed microscopically under ultraviolet light, fungal structures display a brilliant apple-green or a blue-white color (Image Plate 1-2F), depending on the wavelength of the exciter light and the filter combinations used. The fungi are readily differentiated from background debris, cells, and tissue fragments based on their morphologic features, which are well highlighted. Calcofluor white has the added advantage that tissue sections can be stained subsequently with periodic acid–Schiff stain (PAS), Gomori methenamine silver (GMS), or other special stains without interference, should confirmation of findings or the availability of permanent slides be desired. The calcofluor white-staining technique is rapid and provides good definition of fungal fine structures and better contrast from the background than the widely used lactophenol aniline blue stain.[56]

BOX 1-7

Preparation of an AO Stain

Ingredients: AO powder 20 mg, sodium acetate buffer 290 mL, HCl 1M

Reagent preparation: Add 20 mg AO powder (JT Baker Chemical Co., Phillipsburg, NJ) to 290 mL of sodium acetate buffer (stock solution of 100 mL of 2 molar [M]$CH_2COONa.3H_2O$ and 90 mL of 1M HCl); 1M HCl should be added as necessary to maintain the differential staining of the bacteria against the

background debris.[84]The staining solution should be stored in a brown bottle at room temperature.

Procedure: The stain is performed by flooding air-dried and methanol-fixed smears of the material to be examined with the AO stain for 2 minutes, followed by a washing with tap water. The stained slides are dried and examined with a microscope equipped with an ultraviolet light source.

Silver Impregnation Stains. Certain bacteria, for example, spirochetes (including the etiologic agent of Lyme disease, *Borrelia burgdorferi*) and the small bacillary organisms associated with cat scratch disease (*Bartonella henselae*), are not readily stained by conventional methods. These organisms are either too slender to be visualized by brightfield microscopy, they are not present in sufficient concentrations to be detected, or their chemical composition does not interact with the stains. Darkfield microscopy has been used to identify *T. pallidum*, the etiologic agent of syphilis, and

other nontreponemal spirochetes, such as *Leptospira interrogans*, the cause of leptospirosis. One limitation of the darkfield procedure is the necessity to examine wet, moist specimens containing living organisms very quickly, because visualization of the moving bacteria is essential to detection. The silver stain has been used to observe these organisms in tissue sections and immunofluorescent or immunohistochemical reagents are available for some pathogens, such as *T. pallidum*.

The Warthin–Starry, Dieterle, and Steiner silver impregnation stains have been used for years to demonstrate spirochetes in formalin-fixed tissue sections. They perform equivalently. However, we (author GWP) have demonstrated that the detection of *T. pallidum* by silver precipitation stains is inferior to detection using an immunohistochemical method.

Wright–Giemsa's Stain. The Wright–Giemsa's stain is commonly used for staining the cellular elements of the peripheral blood smear. This stain has little use for staining bacteria, but is used primarily to detect the intracellular yeast forms of *Histoplasma capsulatum* or the intracellular amastigotes of *Leishmania* species or *Trypanosoma cruzi* (Image Plate 1-2G). The stain is also helpful for demonstrating certain intracellular viral inclusions (Table 1-8).

Periodic Acid–Schiff. The PAS stain is based on the oxidation of hexoses and hexosamines by periodic acid, which cleaves the pyranose rings in these molecules, producing dialdehydes that react with Schiff reagent. Schiff reagent is a triphenylmethane dye prepared from basic fuchsin or *p*-rosaniline by reduction with

sulfuric acid. Most substances that contain hexoses or hexosamines are PAS-positive, staining red against a green or blue background, depending on the counterstain used. The stain is most frequently used for staining tissue sections to demonstrate fungi (Image Plate 1-2H). The PAS stain highlights glycogen, which is a limitation of the stain in glycogen-rich tissues, such as the liver. Pretreatment of glycogen-rich tissues with diastase, which substantially reduces the amount of glycogen in such tissues, is needed prior to PAS staining.

Processing Specimens. After a specimen for culture has been received in the microbiology laboratory, the following decisions must be made:

1. Selection of primary culture media appropriate for the particular specimen.
2. Determine the temperature, atmosphere, and length of incubation to recover organisms of potential significance.
3. Determine which of the isolates recovered on primary media require further characterization.
4. Determine whether antimicrobial susceptibility tests are required.

No single approach can be expected to serve the needs of all laboratories and clinical settings. The protocol in a 50-bed rural community hospital will differ from that used in a large, tertiary care medical center. Everyone recognizes, however, the difficulties in maintaining quality services in an environment of more and more stringent demands for containment of costs. Laboratory directors and supervisors must identify and eliminate the clinically irrelevant work to optimize the limited resources. In addition, the establishment of evidence-based, cost-effective strategies will hopefully help to eliminate the "pan-culture" of every clinical specimen (i.e., the indiscriminate ordering of cultures from all accessible body sites in the hope of recovering a pathogen). For the past several decades, many microbiologists have been attempting to practice what Bartlett calls "processing control," "restricting the processing and reporting of culture specimens to the production of predictably useful information."

Selection of Primary Culture Media. Only a few media are required for daily use in the diagnostic laboratory. Agar plates are commonly used. Inoculation of broth media for primary recovery of organisms should be limited to those few specimens for which supplemental broth media have proven useful (Table 1-6). The past practice of inoculating thioglycolate broth routinely to recover pathogens has been abandoned in most laboratories. In almost all instances, the recovery of an organism in broth culture after 4 or 5 days of incubation will have little clinical relevance. Incubation of broths for prolonged periods also leads to the frequent recovery of contaminants.[85] Bacterial isolates in very low concentrations are rarely significant, and the prolonged time for recovery will usually render the information irrelevant for effective management. In

some laboratories, broth media are inoculated for certain types of specimens, but they are examined only if growth is not detected on agar plates or if bacterial morphotypes observed in a direct smear of patient material are not recovered on agar.

There are situations in which broth cultures are useful or even essential. The most obvious one is in the culture of blood, where a single pathogen is expected in most situations and commensal flora are not expected. A few other clinical situations meet these guidelines and broth cultures may be useful: spontaneous bacterial (primary) peritonitis (as opposed to peritonitis after disruption of an abdominal viscus),[10] peritoneal infections in patients who are receiving peritoneal dialysis,[2] cultures from prosthetic material that may harbor organisms in a biofilm state, cardiac valves from patients with endocarditis who have been extensively treated with antibiotics and septic arthritis.[60]

The media used may be selective or nonselective. Nonselective media are free of inhibitors and support the growth of most microorganisms encountered in clinical laboratories. Five percent sheep blood agar is the most commonly used nonselective medium and is included in the battery of primary isolation media for virtually every clinical specimen. Horse blood agar, sheep blood agar supplemented with additives such as IsoVitaleX (or a similar supplement that includes nicotinamide adenine dinucleotide [NAD] and a heme product), or chocolate agar (agar to which partially hemolyzed blood or hemoglobin powder has been added) is necessary for the recovery of *H. influenzae* because it has no inhibitory effects on bacterial growth and is a rich source of Factor X. Chocolate agar is also important for recovery of *N. gonorrhoeae* and other fastidious bacteria.

Blood agar can be made selective by adding antibiotics or inhibitory chemicals. It is a general rule that inhibitory agars should not be used alone, because they usually inhibit the organisms of interest—just less so than other microbiota. Often the inhibition is only partial, so growth on a selective agar should not be taken as proof that the targeted organism has been isolated. For instance, enterococci and yeast often break through and produce small colonies on MacConkey agar, especially if the formulation does not include crystal violet.

27

Media can also be made differential by addition of certain dyes, sugars, or other chemicals, thus providing some clues to the identity of the isolated microbes. Some of the commonly used selective and differential agars are summarized in Table 1-11.

Techniques for Transfer and Culturing of Clinical Specimens. Once a specimen is found acceptable for culture (i.e., did not demonstrate any of the various criteria for rejection), appropriate portions must be transferred to the culture media described previously. Media inoculation is

TABLE 1-11 Commonly Used Differential and Inhibitory Agars

Inhibitory (I) or Differential (D) Agar	Added Compounds (I or D)	Organisms Inhibited	Organisms Enriched	Comments/Chapter Reference
Bacteroides bile esculin (BBE) (I, D)	Bile salts (I); esculin (D)	Most bacteria	*Bacteroides fragilis* group	Bile stimulatory for *B. fragilis*
Campy-BAP (I)	Bacitracin, novobiocin, colistin, cephalothin, polymyxin B (I)	Most bacteria	*Campylobacter jejuni*	Incubation at 42°C also selects for *C. jejuni*
CCFA (I, D)	Cycloserine, Cefoxitin (I); Fructose (D)	Most bacteria	*Clostridium difficile*	Yellow colonies; very inhibitory
CHROMagar (D)	Various (D)	NA	Various	Identification of colonies suggested by color
CIN (I)	Cefsulodin, Irgasan, novobiocin (I)	Most bacteria	*Yersinia* spp., *Aeromonas* spp.	Several formulations available
CNA (I)	Colistin, nalidixic acid (I)	Gram-negative bacteria	Gram-positive bacteria	Most strains of *Staphylococcus saprophyticus*[48] and some strains of *S. aureus* are inhibited.
EMB (I, D)	Eosin (I); eosin, methylene blue, lactose, sucrose (D)	Gram-positive bacteria	Gram-negative bacteria	Slightly selective (inhibitory);[49] lactose or sucrose fermenting organisms produce blue-black colonies (sucrose fermenters, such as *Yersinia enterocolitica*, appear identical to lactose fermenters); strong lactose fermenters (such as *Escherichia coli* or *Candida kefyr*) produce a characteristic green sheen.
Hektoen enteric (HE) (I, D)	Bile salts (I); lactose, sucrose, salicin, bromthymol blue, acid fuchsin (D); sodium thiosulfate, ferric ammonium citrate for hydrogen sulfide production (D)	Gram-positive bacteria	Enteric pathogens[a]	Moderately inhibitory; lactose (sucrose, salicin) fermenters produce green colonies; hydrogen sulfide producers form black colonies.
LKV (I)	Kanamycin, vancomycin (I)	Aerobic bacteria; anaerobic gram-positive bacteria	Anaerobic gram-negative bacilli, particularly *Bacteroides*	Laked blood added as a source of nutrients; vancomycin-resistant enterococci may be selected on this medium.
MacConkey (I, D)	Bile salts, crystal violet (I); lactose, neutral red (D)	Gram-positive bacteria	Enteric pathogens[a]	Moderately inhibitory (selective); lactose fermenters produce red colonies; formulations without crystal violet available
Mannitol-salt (I, D)	NaCl (I); Mannitol, phenol red (D)	Gram-negative bacteria; gram-positive bacteria other than *Staphylococcus*	*Staphylococcus aureus*	Coagulase-negative staphylococci grow on salt agar, but do not ferment mannitol.
Mycobiotic/Mycosel (I)	Chloramphenicol, cycloheximide (I)	Bacteria; saprophytic fungi (and a few fungal pathogens)	Dermatophytes, dimorphic fungi	
PC (*Pseudomonas* [*Burkholderia*] *cepacia*) (I, D)	Crystal violet, bile salts for gram-positive bacteria (I); polymyxin B, ticar cillin for gram-negative bacteria (I); pyruvate (D)	Gram-positive bacteria; most gram-negative bacteria	*Burkholderia cepacia*	Highly selective; pink colonies not completely specific for *B. cepacia*

PEA (I)	Phenylethyl alcohol (I)	Gram-negative bacteria	Gram-positive bacteria	
Salmonella–Shigella (SS) (I, D)	Bile salts, brilliant green (I); lactose, neutral red (D); sodium thiosulfate, ferric ammonium citrate for hydrogen sulfide (D)	Gram-positive bacteria	Enteric pathogens[a]	More inhibitory (selective) than MacConkey and EMB agars; *Shigella* spp. may be inhibited.
Sorbitol–MacConkey (I, D)	Bile salts, crystal violet (I); sorbitol, neutral red (D)	Gram-positive bacteria	*Escherichia coli* O157 (sorbitol negative)	Screening agar for shigatoxin-producing *E. coli*
TCBS (I, D)	Sodium thiosulfate, sodium citrate, NaCl for gram-negative bacteria (I); bile salts, NaCl for gram-positive bacteria (I); sucrose, thymol blue–bromthymol blue (D)	Gram-positive bacteria; most gram-negative bacteria	*Vibrio* spp.	Sucrose fermenting species appear yellow; species that utilize citrate appear blue.
GC selective media (Modified Thayer–Martin, Martin–Lewis, etc.) (I)	Vancomycin for gram-positive bacteria (I); colistin for gram-negative bacteria (I); trimethoprim for swarming *Proteus* (I); nystatin, amphotericin B, or anisomycin for yeast (I); supplements for growth	Gram-positive bacteria; gram- negative bacilli	*Neisseria gonorrhoeae, N. meningitidis*	Multiple formulations available. Some strains of *N. gonorrhoeae* are inhibited by vancomycin. Optimally, chocolate agar should also be inoculated.
XLD (I, D)	Bile salts, NaCl (I); lactose, sucrose, xylose, phenol red (D); sodium thiosulfate, ferric ammonium citrate for hydrogen sulfide production (D)	Gram-positive bacteria	Enteric pathogens[a]	Performs similar to Hektoen enteric agar

[a]Enteric pathogens: *Salmonella* spp., *Shigella* spp., and *Yersinia* spp.

usually carried out in a designated part of the laboratory and should be carried out in a BSC (see below). The best policy is to handle all specimens as if they were highly infectious (i.e., universal precautions). Personnel should be required to wear rubber gloves and other personal protective equipment when handling clinical specimens. The wearing of a surgical mask is optional, but is unnecessary for most operations in the diagnostic microbiology laboratory, with the exception of some of the worked necessary in mycobacteriology.

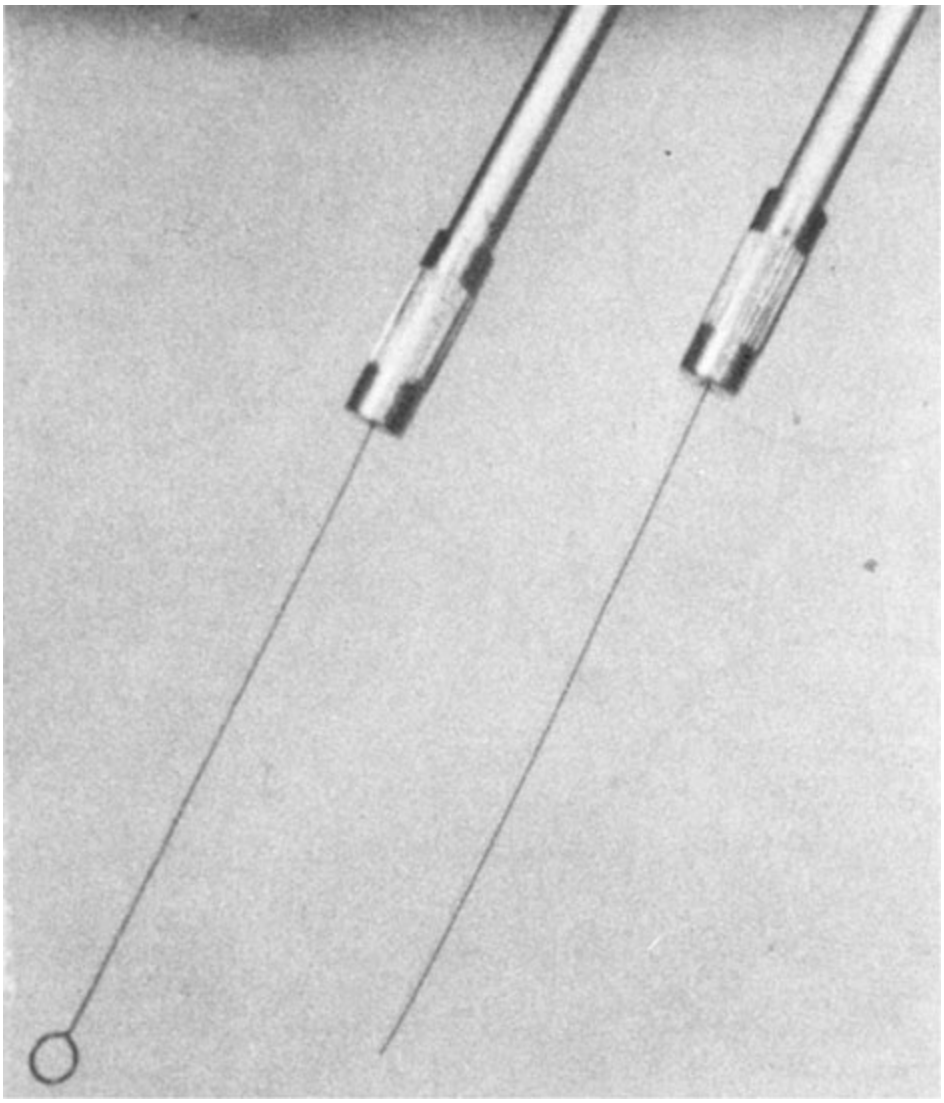
The inoculation area should be equipped with all of the necessary implements and stocked with appropriate culture media. Most media must be refrigerated for prolonged storage, but must be allowed to warm to room temperature before inoculation.

Although full-time personnel working in the setup area may have memorized the culture media required for each specimen type, it is essential to have appropriate charts and instructions readily available, and included in a bench manual for use by those who perform the tasks infrequently. Every attempt should be made to use well-trained personnel, under close supervision, for the processing of specimens. Errors or

misjudgments made during this phase of the diagnostic cycle can negate all the expertise one may apply in the assessment and interpretation of cultures. Expert microbiologists and technologists have occasionally been deterred in making a definitive diagnosis because inadequate or incorrect media were selected for a specimen.

Techniques for Culturing Specimens. The equipment required for the primary inoculation of specimens is relatively simple. A Nichrome or platinum inoculating wire or loop is recommended (Fig. 1-6), with one end inserted into a cylindrical handle for easy use. Disposable, sterile plastic loops are an acceptable alternative. The surface of agar media in Petri plates may be inoculated with the specimen by several methods, one of which is shown in Figure 1-7. The primary inoculation can be made with a loop, swab, or other

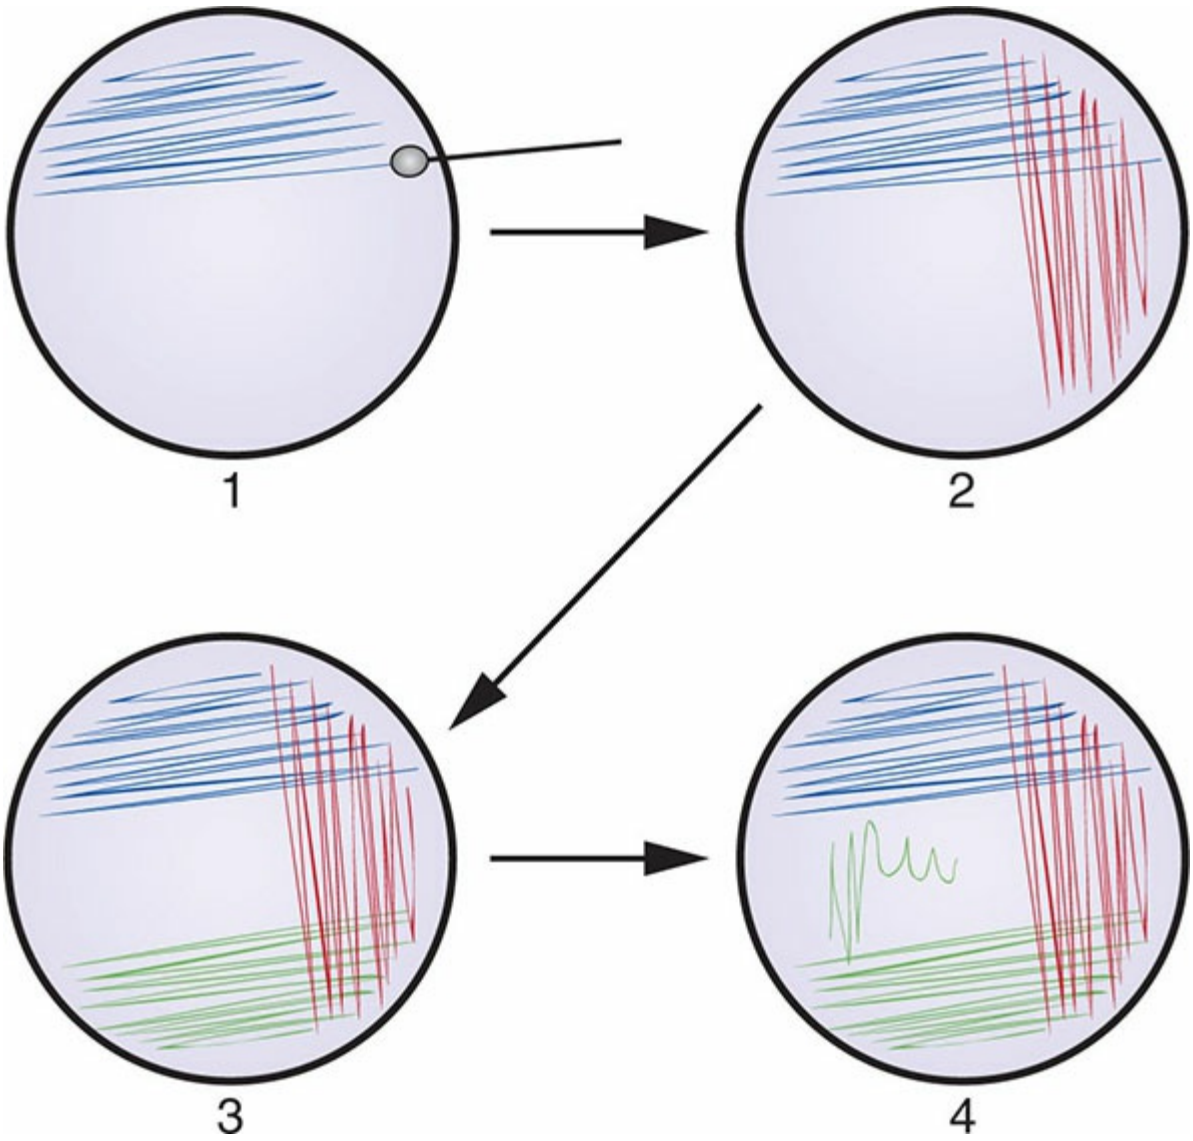
29



■ **FIGURE 1-6** Loop and straight wires commonly used for the transfer of isolates and subculturing. Although these may also be used for the inoculation of specimens, disposable loops are also commercially available.

■ **FIGURE 1-7** The surface of an agar plate being inoculated with a specimen contained within an inoculating loop. Inoculation is accomplished by first touching the surface of the

agar in one small area, then streaking the surface with a back-and-forth motion in a pattern shown in F igure 1-8.



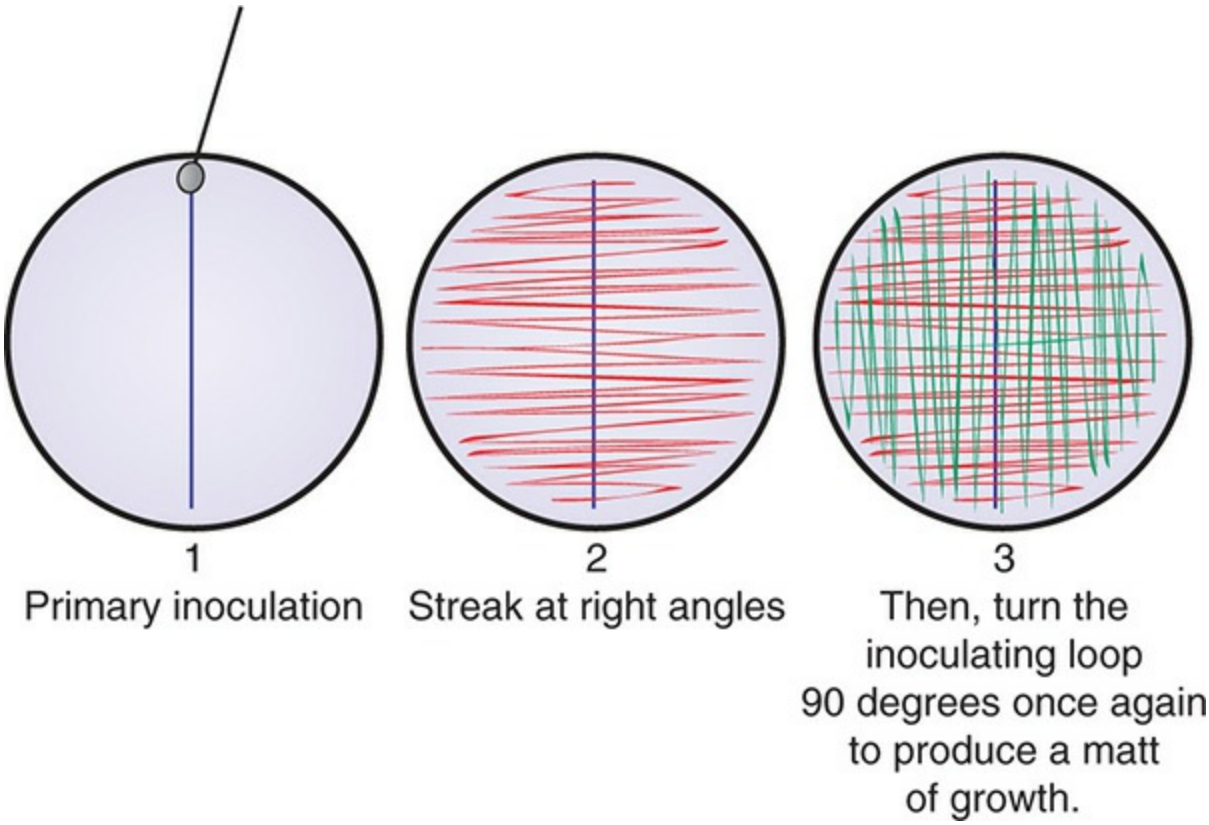
■ **FIGURE 1-8** Streaking pattern for the inoculation of specimens onto culture plates to obtain isolated bacterial colonies.

suitable device. Once the primary inoculum is made, a loop or straight wire can be used to spread the material into the four quadrants of the plate, as illustrated in Figure 1-8. The inoculum is successively streaked with a back-and-forth motion into each quadrant by turning the plate at 90-degree angles. The loop or wire should be sterilized between each successive quadrant streak. The purpose of this process is to dilute the inoculum sufficiently on the surface of the agar medium so that well-isolated colonies

of bacteria are obtained. The isolated colonies can then be subcultured individually to other media to obtain pure populations for further study. When streaking blood agar plates with throat swabs submitted for streptococcal screens, multiple stabs should be made in the areas of inoculation to disclose the oxygen-labile hemolysins, enhancing the detection of β-hemolytic streptococci. Also, bits of tissue that have been submitted for the recovery of fungi should be submerged beneath the surface of the agar (i.e., pushed into the agar). The initial growth of many species of fungi is enhanced in the microaerophilic atmosphere just beneath the agar surface. In addition, the filamentous fungi are frequently not disassociated from the tissue in which they are invasive and may not be recovered, if portions of tissue are not added to the agar plates.

The streaking technique used to inoculate agar media for semiquantitative colony counts is illustrated in Figure 1-9. This is most commonly performed for urine cultures. Nonferrous (Nichrome or platinum) or disposable plastic inoculating loops, calibrated to contain either 0.01 or 0.001 mL of fluid, are immersed into an uncentrifuged urine sample.[1] The loop is then carefully removed and the entire volume within the loop is delivered to the surface of an agar plate by making a single streak across the center. The inoculum is spread evenly at right angles to the primary streak; then the plate is turned 90 degrees and the inoculum is spread to

30



■ **FIGURE 1-9** Culture plates demonstrating streaking patterns of specimens for which a semiquantitative bacterial count is to be performed.

cover the entire surface. In some laboratories, two plates are inoculated, one with the 0.01-mL loop and the other with the 0.001-mL loop, serving as a quality control check. Although the inoculating loops are calibrated to deliver the volume of urine prescribed, accuracy has an error rate of as much as ±50%, particularly when using the 0.001-mL loop. Vertical sampling from a small container may deliver only 50% of the prescribed volume; horizontal sampling at a 45-degree angle from a large container may deliver 150% of volume. Microbiologists should be aware of these potential errors and derive a standard angle for sampling in their laboratory, based on the volume of containers being used.

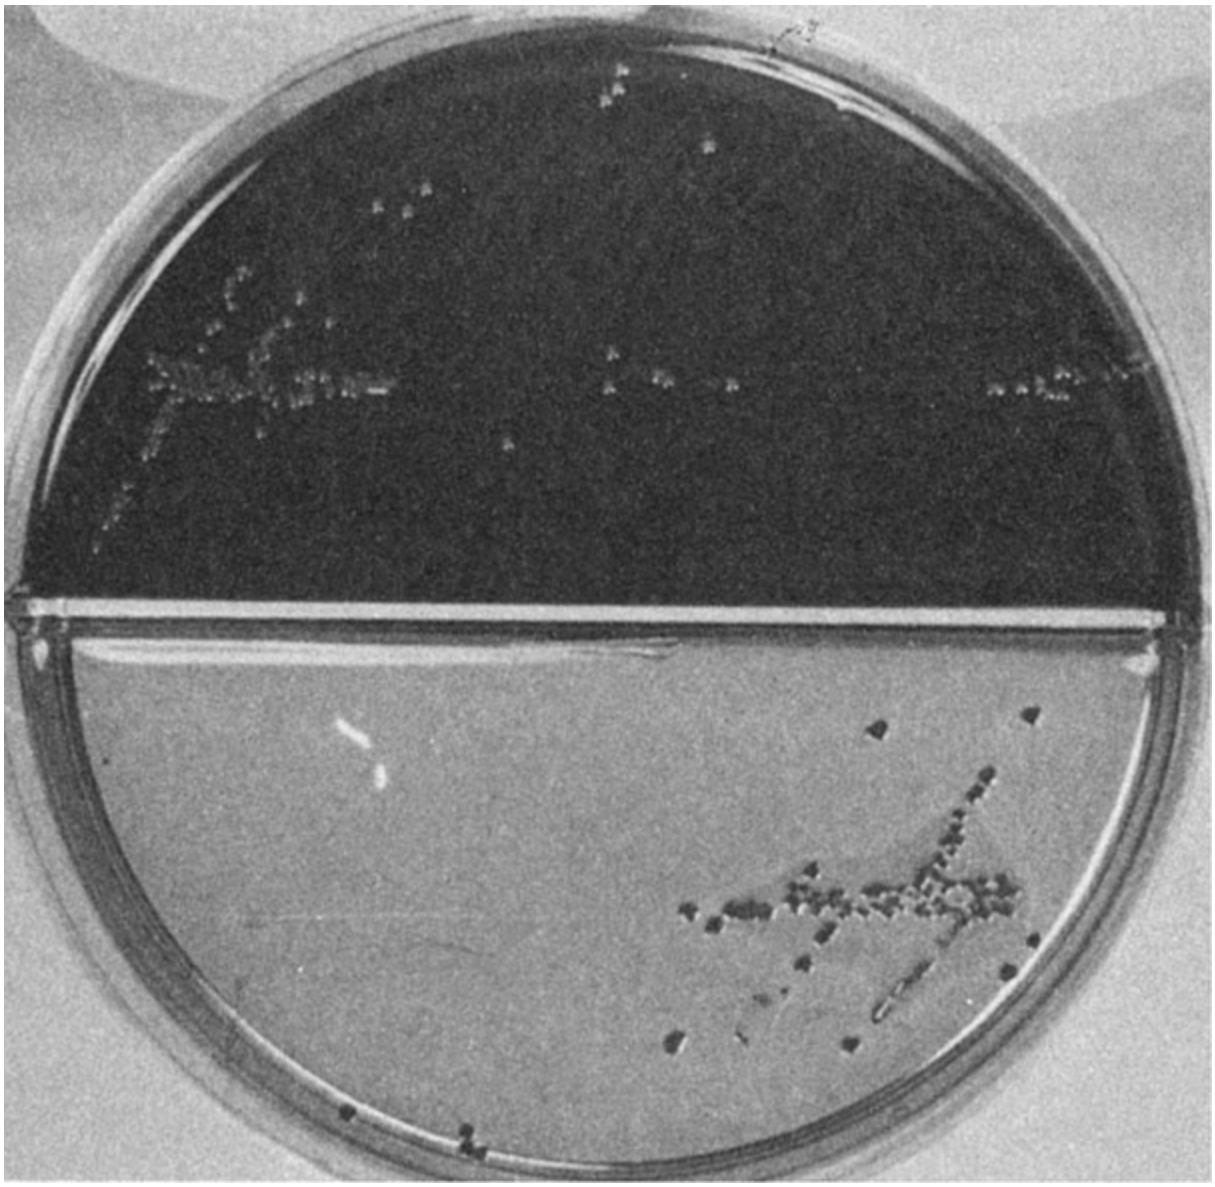
Accuracy and precision studies on the volume of inoculum can be done (1) photometrically, by adding a loop of gentian violet sampled from a 60-mL reservoir of dye to 2 mL of water in a cuvette and reading it in a spectrophotometer set at 590 nm, or (2) manometrically, by noting the change in weight when a loop of water is delivered to a filter paper disk placed in the pan of a highly sensitive analytical balance. Devices are available to deliver a standard inoculum from fluid samples.[73]

After 18 to 24 hours of incubation, the number of bacteria in urine samples is estimated by counting the number of colonies on the surface of the agar. As illustrated

in Figure 1-10, approximately 50 colonies are present. If a 0.001-mL loop had been used to inoculate the medium, the number of colonies would be multiplied by 1,000. Therefore, the count in this illustration is 50,000 CFU/mL.

Although semiquantitative techniques are used most commonly with urine, they have been employed in other situations also. Quantitating the bacteria recovered from the lower respiratory tract by bronchoscopic techniques may help in interpretation of these cultures.[21] When bacteria were present at a concentration greater than 10^3 to 10^4 CFU, the probability that they were causing pneumonia was greater than when lesser quantities were present. Considerable work can be avoided by not evaluating small quantities of contaminating nasopharyngeal, throat, and oral microbiota.

Semiquantitative cultures are commonly employed to evaluate the likelihood that intravascular catheters are the source of a bacteremia. Although a variety of techniques have been employed, the most prevalent approach is to roll the resected segment of catheter on the surface of agar.[74] There is a statistical association of isolated bacteria with catheter-related bacteremia if more than 15 colonies of the bacterium are present. In this approach, the catheter is removed in order to perform the test. Quantitation of bacteria in blood drawn through an intravascular catheter, which is left in place, has also been used to assess the role of the catheter in an infectious process.[46]



■ **FIGURE 1-10** Blood agar–MacConkey agar biplate previously streaked for a semiquantitative colony count demonstrates approximately 50 colonies on each side of the plate. If a 0.001-mL calibrated semiquantitative urine inoculating loop had been used for streaking each medium, the colony count would be 50,000 colony-forming units (CFU) per mL.

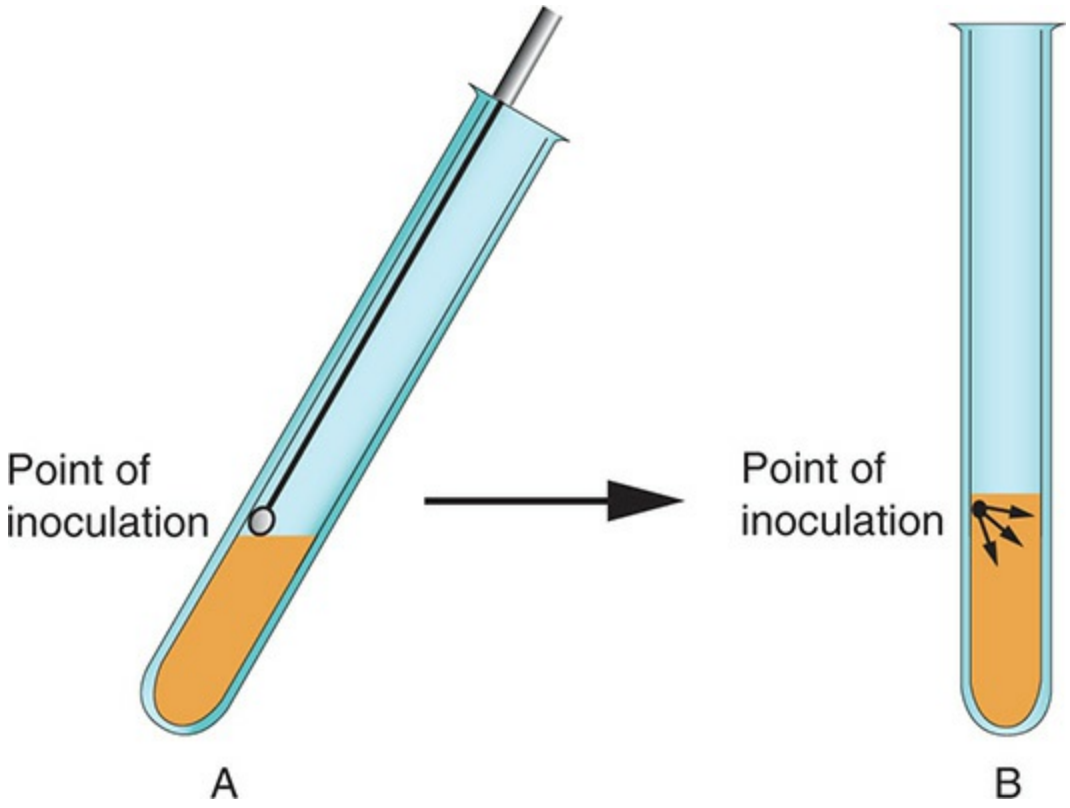
Quantitation may also be useful in virology for determining the significance of a virus, such as cytomegalovirus, that can produce persistent or latent infection.[11] In addition, the effectiveness of antiviral chemotherapy can be monitored by following the quantity of virus present.[61] Many of the quantitative tests for viral disease (viral load testing) employ molecular detection and measurement of viral nucleic acid rather

than culture.

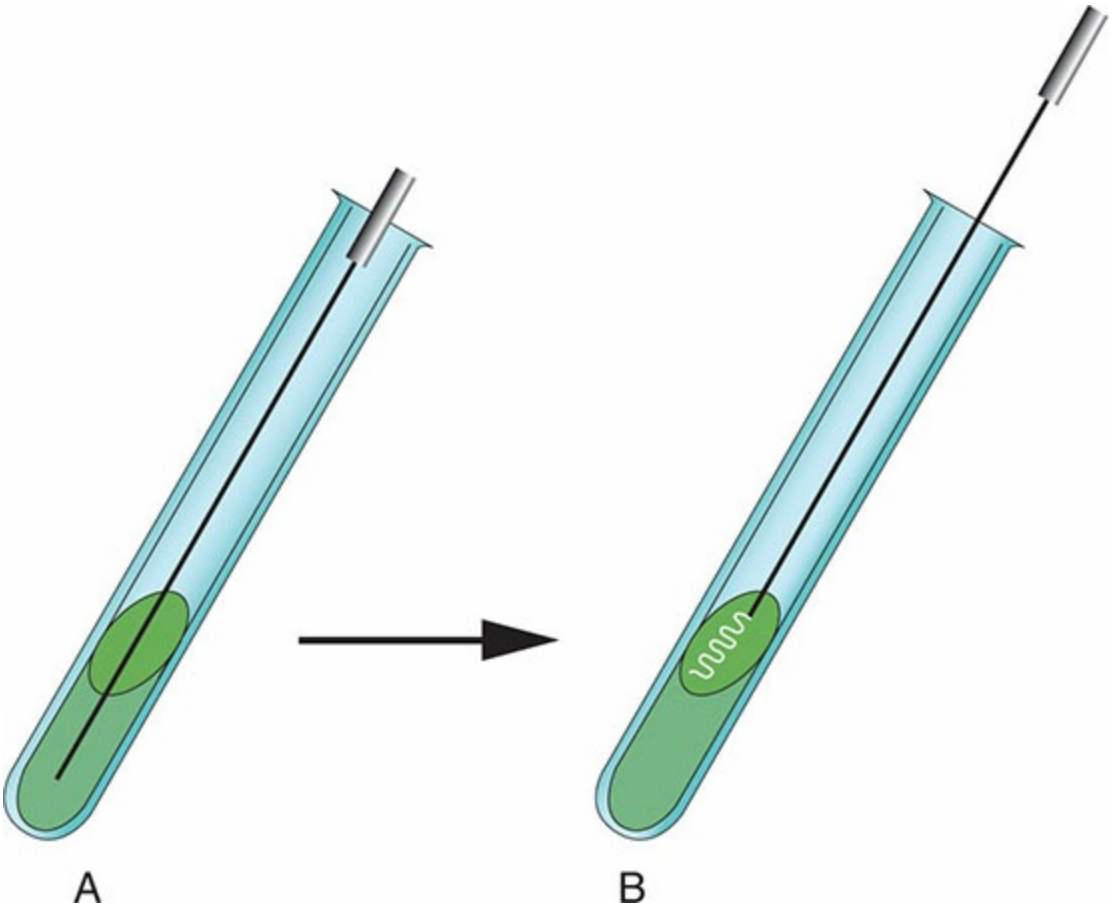
Media in tubes may be liquid, semisolid (0.3% to 0.5% agar), or solid (1% to 2% agar). Semisolid agar is most commonly used for motility testing. Broth medium in a tube can be inoculated by the method shown in Figure 1-11. The tube should be tipped at an angle of approximately 30 degrees and an inoculating loop touched to the inner surface of the glass, just above the point where the surface of the broth makes an acute angle. When the culture tube is returned to its upright position, the area of inoculation is submerged beneath the surface. Laboratory directors and microbiology supervisors, in an evidence-based manner, must determine which specimens should be transferred to broth cultures routinely (Table 1-6).

Slants of agar medium are inoculated by first stabbing the depth of the agar, followed by streaking the slant from bottom to top with an S-motion as the inoculating wire is removed (Figs. 1-12 and 1-13). When inoculating semisolid

31



■ **FIGURE 1-11** Technique for inoculating a tube of broth medium. **A.** Slant the tube and inoculate the tube by touching the moist inner surface of the glass tube at the acute angle of the meniscus. **B.** Return the tube to an upright position, which has the effect of submerging the point of inoculation under the surface.



■ **FIGURE 1-12** The technique for inoculating an agar slant with a straight inoculating wire: **A.** Stab the deep of the agar slant to within 2 to 3 mm of the bottom of the glass. If the bottom of the glass is touched, atmospheric air may enter, negating the anaerobic conditions. **B.** Slowly remove the wire and streak the agar surface with a back-and-forth "S" motion.

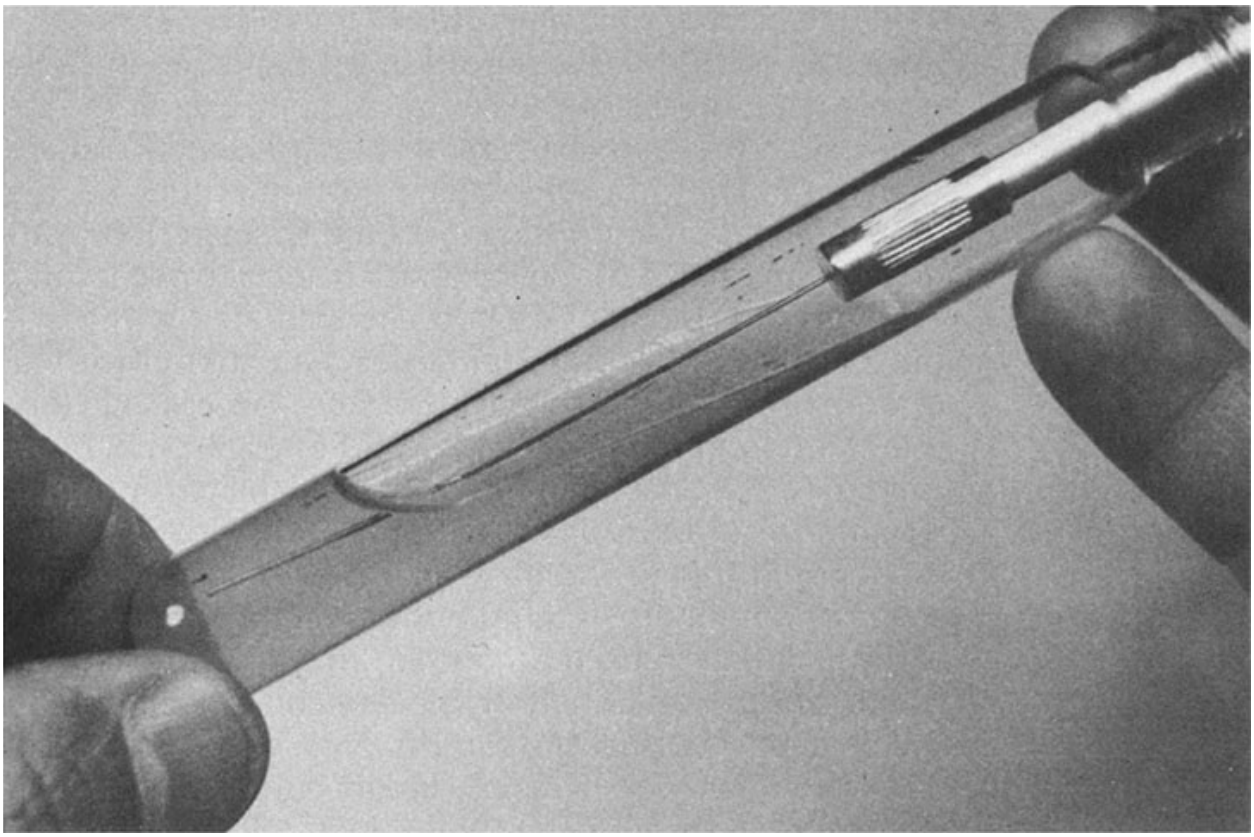
tubed agar for motility testing, it is important that the inoculating wire be removed along the exact track used to stab the medium. A fanning motion can result in a growth pattern along the stab line that may be falsely interpreted as bacterial motility.

Certain specimens may require centrifugation or filtering to concentrate any microbes present. Tenacious, mucoid sputum samples can be liquefied with *N*-acetylcysteine (Mucomyst, WellSpring Pharmaceutical Corp., Neptune, NJ) to facilitate even streaking of the agar surface. Sputum samples to be processed for the recovery of *Mycobacterium* spp. must also be treated with sodium hydroxide to minimize the overgrowth of bacterial contaminants. Other specimens, such as urine and stool suspensions submitted for the recovery of mycobacteria, can also be briefly treated with NaOH to eliminate colonizing bacteria. Similarly, antibiotic-containing media can be used to control bacterial overgrowth.

Body fluids, such as those obtained by thoracentesis and paracentesis, should first be allowed to settle, after which aliquots of the sediment are centrifuged to concentrate further any bacteria that are present. Requests may be made to provide blood culture bottles for the direct inoculation of certain specimens, as previously discussed. This practice is appropriate in those few situations where small numbers of a single pathogen are expected. It should be discouraged in other situations for several reasons:

1. If mixed bacterial species are present, bacteria that grow more rapidly will overgrow the slower growing bacteria in the broth.
2. The semiquantitative relationships of isolated bacterial types that may be seen on agar plates are lost in a broth culture.
3. The direct smear that is so important to assessment of the inflammatory nature of the specimen and the types of bacteria present are lost if the entire specimen is inoculated into a broth.

Cerebrospinal fluid specimens should be centrifuged and portions of the sediment transferred to appropriate culture media; or preferably, the fluid should be passed through a 0.45-mm microbiologic filter to trap and concentrate any bacteria or yeast that may be present. The challenge with filtration is



■ **FIGURE 1-13** The technique for inoculating an agar deep with a straight wire, as illustrated in F igure 1-12A. The deep of the medium is stabbed with the wire to within 2 to 3 mm of the bottom of the tube; then, after slowly removing the needle, the agar surface is streaked with a back-and-forth "S" motion, as illustrated in F igure 1-12B.

that contamination may occur when the filter is manipulated either upon inoculation of the medium initially or when the position of the filter is moved to examine for growth.

Microorganisms differ in their optimal temperatures of incubation. In small laboratories, where resources may be limited, it may not be possible to provide all of the incubation temperatures optimal for growth of all clinical isolates. Most microorganisms grow at 35°C; thus, if only one incubator is provided, it should be set at 35°C. Even organisms such as *Campylobacter jejuni*, which grows optimally at 42°C, will grow at 35°C if an additional 24 or 48 hours of incubation are allowed. In this case, however, the differential effect of incubation at higher temperatures where other bacteria do not grow is lost. The growth of most organisms is enhanced by an atmosphere of 5% to 10% CO_2. If only an ambient air, non-CO_2 incubator is available, the culture tubes and plates can be placed in a candle extinction jar and the entire assembly placed in the incubator. Conversely, an ambient air environment can be maintained in a CO_2 incubator by placing the cultures into a holding jar with a tightly fitted lid (an anaerobic jar or chamber is suitable). It should be realized, however, that organisms such as *C. jejuni*, which requires a reduced oxygen tension of 5% or below (i.e., are microaerophilic), will have difficulty growing in a candle jar, in which the oxygen concentration is in the range of 10%.

Many microorganisms grow optimally within a narrow temperature range; others have a relatively wide spectrum within which they can be recovered. The optimum temperature for growth of *C. jejuni* is 42°C, as just mentioned. Most fungi grow best at 30°C; however, most can be recovered at room temperature or 35°C on appropriate media. *Yersinia enterocolitica* grows optimally at a temperature slightly above room temperature. Most strains will also grow, however, at 35°C, even though colonies may appear small or require an additional 24-hour incubation period. Thus, only infrequently will access to a single incubator compromise the ability of a microbiologist to recover most clinically important bacteria. In large laboratories where several incubation temperatures can be provided, recovery of organisms will often be more rapid, and the appearance of colonies more characteristic. Occasionally, incubation at room temperature for an extended time may be necessary to demonstrate certain biochemical or physical characteristics, such as pigment production and motility. These various adjustments will be learned through experience and by trial and error.

Probably more important than the specific temperature of incubation is prevention

of wide fluctuations in temperature. Incubators should be carefully controlled for temperature, with no more than ±1 to 2°C fluctuations from day to day. Incubators should be located so that the control dials are protected and cannot be easily disturbed by cleaning personnel during off hours.

Humidity control within the incubator is also important. Most organisms grow maximally when the humidity is 70% or higher, and culture media tend to deteriorate more rapidly when undue drying occurs. The recovery of *H. pylori*, in particular, and to a lesser extent, *N. gonorrhoeae* requires an atmosphere with high humidity. Most incubators purchased during recent years have built-in water reservoirs by which humidity in the chamber can be regulated. If not, open pans of water can be placed on shelves to provide moisture through evaporation. Incubators must also be checked periodically for inadvertent spills that can cause contamination or a buildup of chemicals from reagents that may be inhibitory to bacterial growth.

Interpretation of Cultures. Interpretation of primary cultures after 24 to 48 hours of incubation requires considerable skill. From initial observations, the microbiologist must assess the nature of isolated colonies and decide whether additional procedures are required. The relevant parameters include the characteristics and relative number of each type of colony recovered on agar media; the purity, the Gram-stain features of each type of colony; and changes in the media, which reflect the metabolic activities of the bacteria within the colony (e.g., pink colonies on MacConkey due to lactose fermentation).

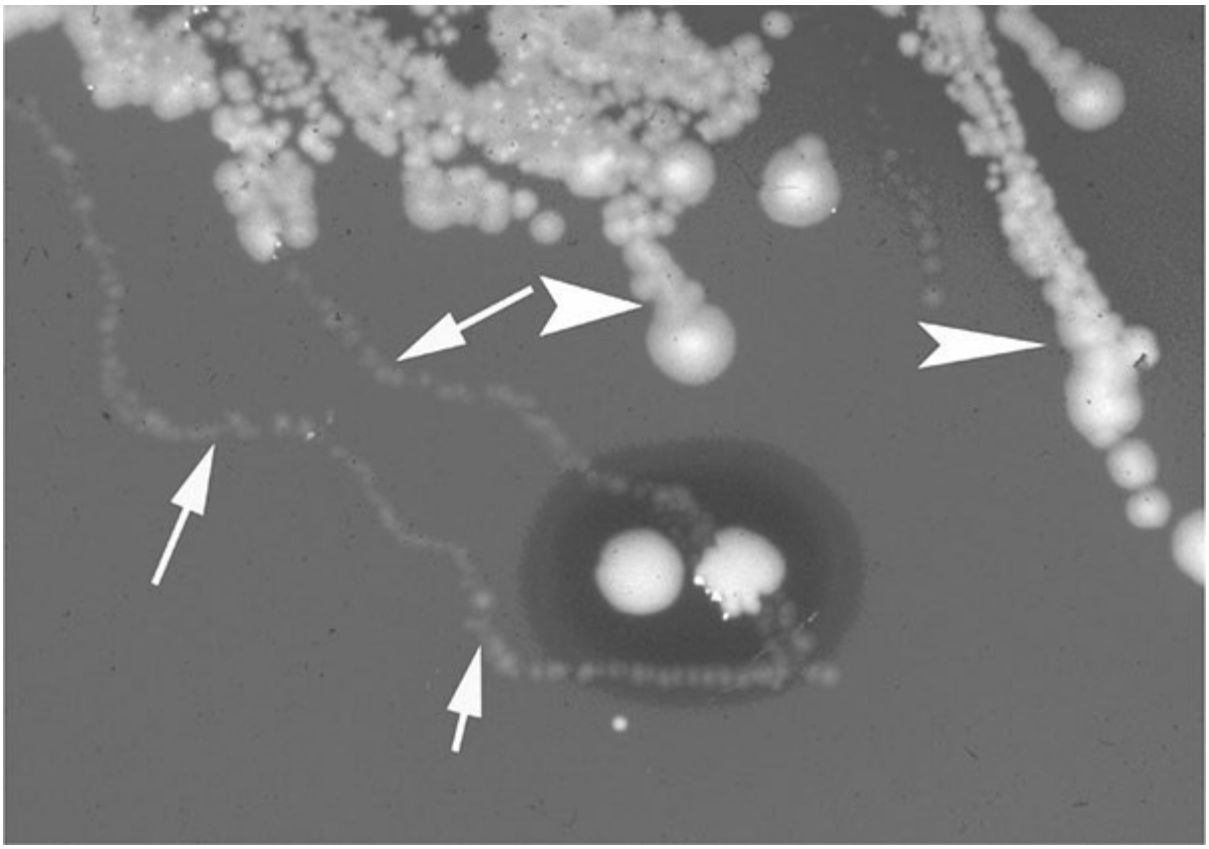
In the process of collecting specimens from patients or in handling those specimens in the laboratory extraneous organisms may be introduced from the environment or from the indigenous flora of the individuals who handle the culture. In blood cultures, for instance, resident skin flora is frequently encountered and must be interpreted carefully. In addition, "contaminants" may be introduced in the process of manufacturing or handling microbiologic products, such as agar plates. It may be apparent that a colony is extraneous if it is present on the second or third streak area of a plate—with no growth on the initial inoculation zone. These colonies can usually be ignored, although special attention must be given to important pathogens that are unusual "contaminants." A more difficult challenge arises when a single colony of a typical skin organism, such as coagulase-negative *Staphylococcus*, is found in the primary inoculation zone. There is, of course, a one-third or one-fourth probability of a plate contaminant ending up in the first zone. If the specimen is a critical one, such as cerebrospinal fluid and has been retained in the laboratory, it can be reinoculated on to the surface of a new agar. Individual laboratory directors need to assess how apparent contaminants should be handled in the local setting. If the decision is made to report an isolate wherein there is a high likelihood that it is a contaminant, some will append a comment such as "… ., probable contaminant." The clinician can then integrate this laboratory information with the clinical findings to make a final

interpretation of the significance.

Unusual situations present themselves on occasion. For instance, mixed organisms that resemble indigenous upper respiratory tract flora may be recovered from a normally sterile site. It is hard to avoid the suspicion that someone "sneezed" on the plate, but further evaluation must depend on evaluation of all factors, perhaps in consultation with the clinician. A most unusual laboratory phenomenon is illustrated in Figure 1-14.

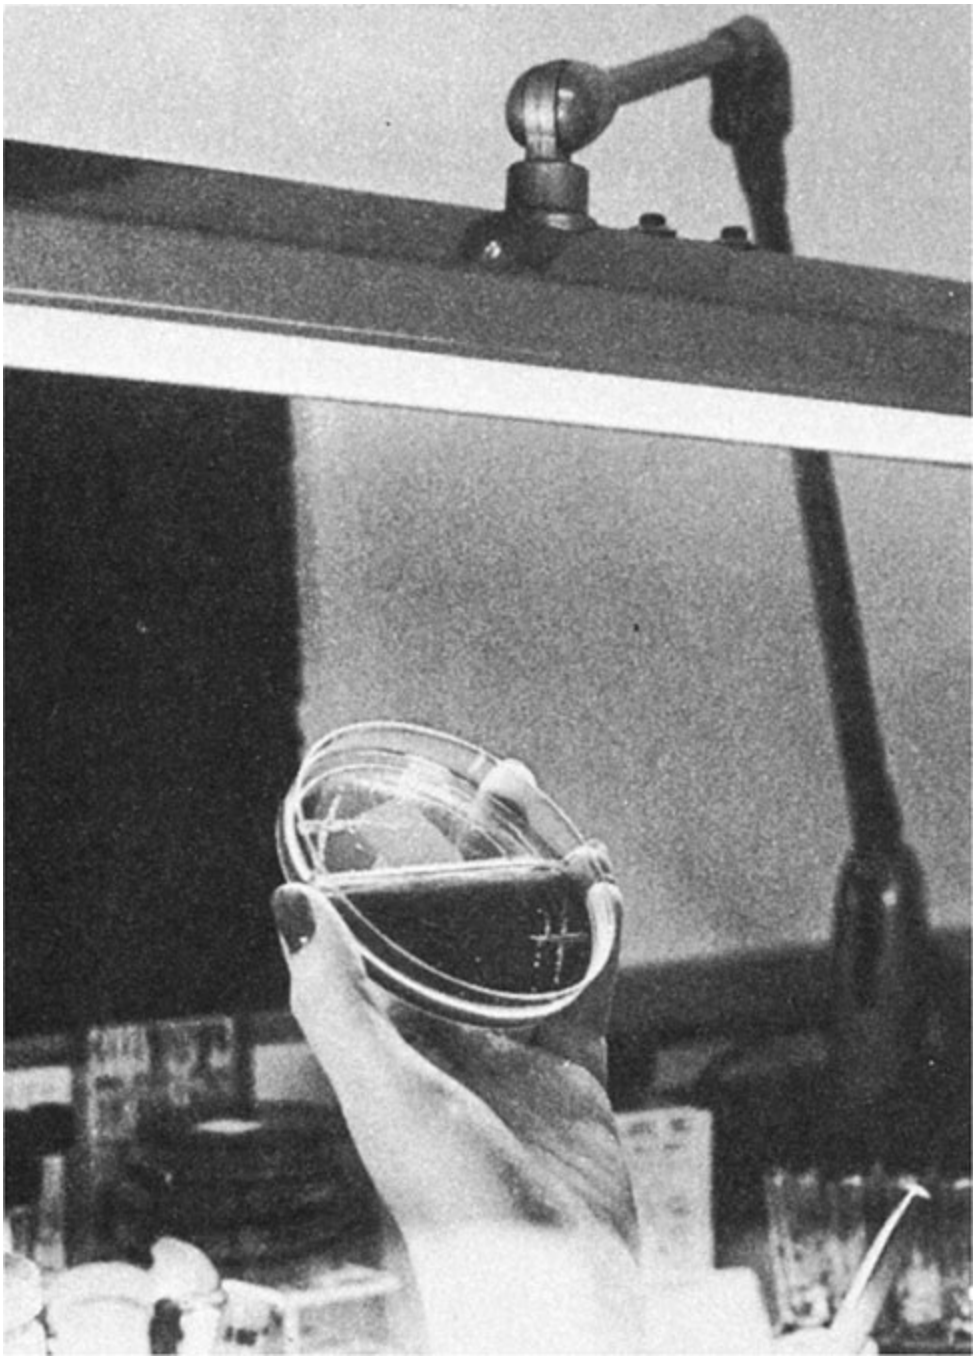
Characteristics of Macroscopic Colonies. The gross assessment of colony characteristics is usually performed by inspecting growth on the surface of agar plates. This examination is carried out by holding the plate in one hand and observing the surface of the agar for the presence of bacterial growth (Fig. 1-15). Standard culture plates are 100 mm in diameter and are convenient to hold in one hand. Each plate must be studied carefully, because the bacteria initially recovered from specimens are often in mixed culture and a variety of colonial types may be present. Pinpoint colonies

33



■ **FIGURE 1-14** An agar plate, which had been inoculated with a skin specimen, contains

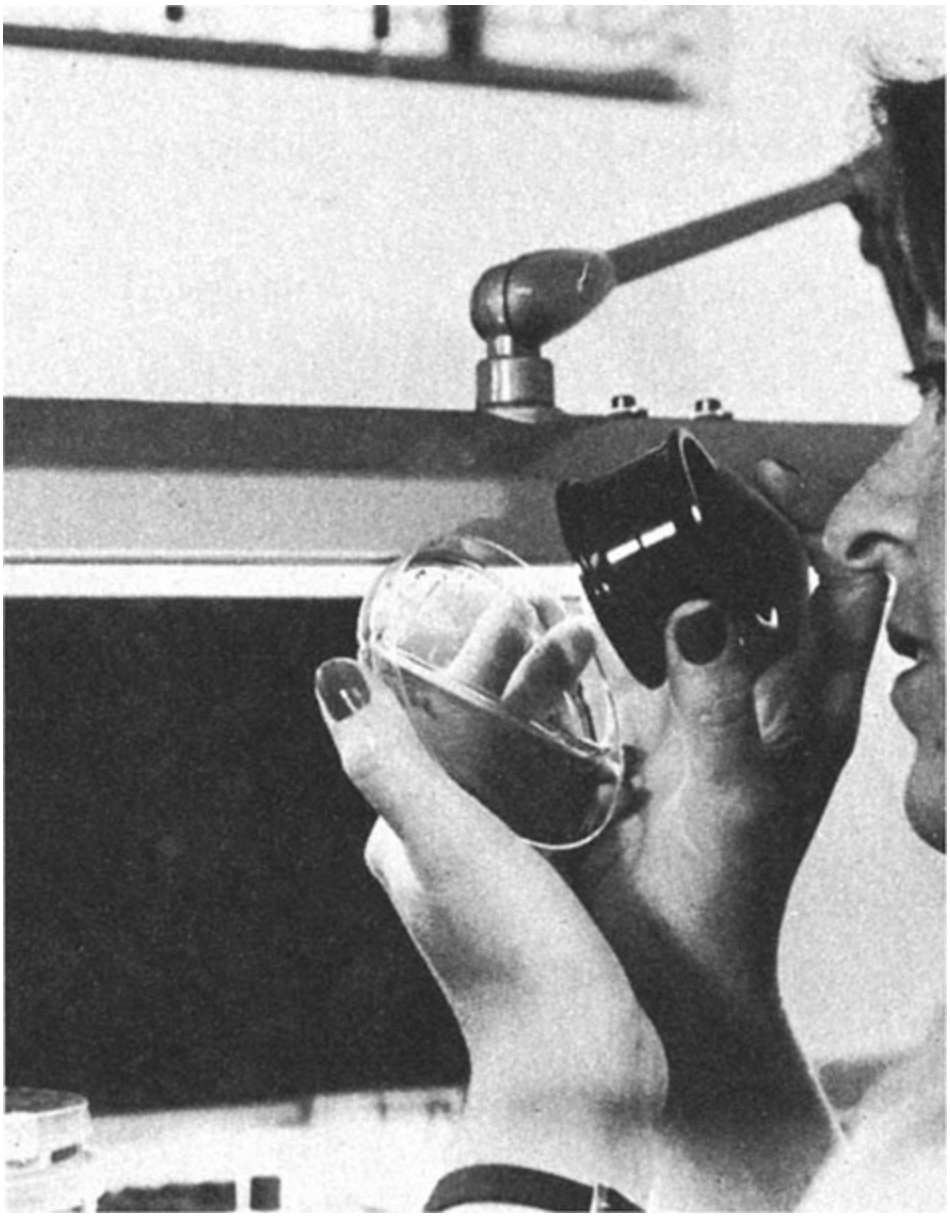
mixed bacterial microbiota from the skin. An irregular, meandering track of bacteria can be seen among the isolated colonies (*arrow*). In addition, unusual linear patterns of mature colonies may represent the same process (*arrowheads*). The most likely explanation is that a mite was present in the specimen that carried bacterial cells around the plate. This has also been seen in fungal cultures. Free-living amoebae have also been described to produce this phenomenon.



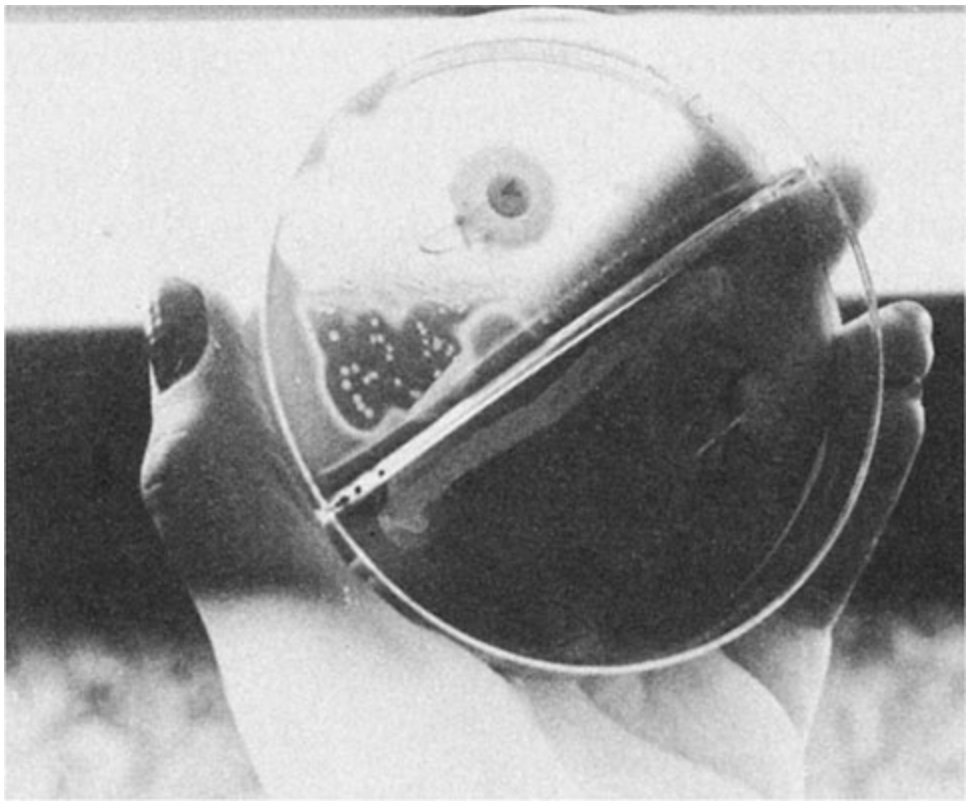
■ **FIGURE 1-15** The technique for examining the surface of an agar plate by direct, oblique-reflected light.

of slow-growing bacteria may be overlooked among larger colonies, particularly if there is any tendency for growth to spread over the surface of the plate.

During examination, plates should be tilted in various directions, under bright, direct illumination, so that light is reflected from various angles. This aids in the detection of small colonies. We highly recommend use of a hand lens, mounted magnifying lens or a dissecting microscope to assist in the detection of tiny or immature colonies and to observe their characteristics better (Fig. 1-16). Blood agar plates should also be examined with transilluminating bright light from behind the plate to detect hemolytic reactions in the agar (Fig. 1-17).



■ **FIGURE 1-16** The technique, using a hand lens, for examning colonies growing on the surface of an agar plate.



■ **FIGURE 1-17** The technique for examining colonies growing on the surface of an agar plate using transmitted light is helpful in assessing the hemolytic properties of colonies growing on blood agar.

Figure 1-18 provides terms and illustrations helpful when describing bacterial colonies. Additional guidelines are outlined in Boxes 1-8 through 1-10.

Although difficult to describe specifically, odors produced by the action of certain bacteria in plating media and in liquid media can be very helpful in the tentative identification of the microorganisms involved). Sniffing of plates is not recommended, but it does occur. The odors associated with certain bacteria are presented (Table 1-12). If performed against recommendations, it should always be performed

BOX 1-8

Characteristics of Colonies Used in the Identification of Bacteria

Size: diameter in millimeters
Form: punctiform, circular, filamentous, irregular, rhizoid, spindle-like
Elevation: flat, raised, convex, pulvinate, umbonate, umbilicate
Margin (edge of colony): entire, undulant, lobate, erose, filamentous, curled
Color: white, yellow, black, buff, orange, other
Surface: glistening, dull, other
Density: opaque, translucent, transparent, other
Consistency: butyrous, viscid, membranous, brittle, other

See also Figure 1-18 and Image Plate 1-5.

BOX 1-9

Reactions in Agar Media Used in the Identification of Bacteria

Hemolysis on blood agar

Alpha: partial clearing of blood around colonies with green discoloration of the medium; outline of red blood cells intact
Beta: zone of complete clearing of blood around colonies owing to lysis of the red blood cells
Gamma: no change in the medium around the colony; no lysis or discoloration of the red blood cells

Pigment production in agar medium

Water-soluble pigments discoloring the medium
Pyocyanin
Fluorescent pigments
Nondiffusable pigments confined to the colonies

Reaction in egg yolk agar

Lecithinase: zone of precipitate in medium surrounding colonies
Lipase: "pearly layer," an iridescent film in and immediately surrounding colonies, visible by reflected light
Proteolysis: clear zone surrounding colonies

BOX 1-10

Changes in Differential Media

Various dyes, pH indicators, and other ingredients are included in differential plating media to serve as indicators of enzymatic activities and aid in identifying bacterial isolates.

Examples:

MacConkey agar: Lactose nonfermenting colonies appear clear, whereas lactose-fermenters appear pink because of the production of acid, subsequent change in pH and in some instances precipitation of dyes.
Hektoen-Enteric agar: Lactose and sucrose nonfermenting colonies appear green, whereas lactose or sucrose-fermenters appear yellow because of the production of acid, subsequent change in pH.

Bacteria that have the ability to produce hydrogen sulfide (H_2S) are black or have black precipitant in the center of the colony, whereas those without this ability do not.

35

TABLE 1-12 Characteristic Odors of Selected Microbes[a]

Microbe	Odor
Alkaligenes faecalis	Freshly cut apples
CDC EF-4 (N. animaloris/N. zoodegmatis)	Popcorn-like
Candida spp.	Yeast
Citrobacter spp.	Dirty sneakers

Clostridium difficile	Putrid, fecal
Corynebacterium spp., DF-3	Fruity
Eikenella corrodens	Bleach
Haemophilus spp.	Wet fur
Nocardia spp.	Musty basement
Pasteurella multocida	Pungent (indole)
Peptostreptococcus anaerobius	Fecal
Pigmented Bacteroides group	Acrid
Proteus spp.	Burnt chocolate
Pseudomonas aeruginosa	Grape juice
Staphylococcus spp.	Dirty sneakers
Certain viridans group Streptococcus spp.	Butter/butterscotch
Streptomyces spp.	Musty basement

[a]Foremost, the smelling of plates is discouraged. It should be noted that certain organisms (not listed here) pose a hazard if smelled. Therefore, if the microbiologist intends to smell the plate, he or she should be sure that the colonial features and other characteristics, such as Gram's stain morphology, exclude the possibility of these hazardous bacteria. See text for discussion.

with caution, by raising the lid of the Petri dish slightly to detect the odor. Some odors, such as those of *Nocardia* and *Streptomyces*, are so strong that they can be smelled even without removing the lid of the Petri dish. Laboratory workers are cautioned that a few species have demonstrated the ability to infect laboratory workers and isolates with even the remotest possibility of resembling these bacteria should never be sniffed. If there is any suspicion that *Bacillus anthracis*, *Francisella tularensis*, *Burkholderia pseudomallei*, *Brucella* spp., or *N. meningitidis* might be present, the culture should be removed to a BSC, where all subsequent work can be done without danger of transmission to the worker. Of course, plates and tubes should never be opened in the

mycobacteriology laboratory, until appropriate precautions are taken. Similarly, plates and tubed media that grow molds should be handled in a BSC with appropriate personal protective apparel.

By assessing the described colonial characteristics and action on media, the microbiologist can make a preliminary identification of the bacteria isolated by primary culture. These characteristics are helpful in selecting other appropriate differential media and tests to complete the identification of the isolates. Table 1-13 lists some of the commonly encountered colonial types, along with the groups of bacteria associated with each, additional tests required for definitive identification and reference to the relevant frame in Image Plate 1-5.

The initial inspection of colonies for preliminary identification of bacteria is one of the cornerstones of diagnostic microbiology and is discussed in detail in later chapters devoted to specific groups of pathogenic bacteria and other microorganisms.

Separation of Bacterial Morphotypes in Mixed Cultures. When agar plates are struck for isolation, it will be a simple matter to select isolated colonies for subculture. On

TABLE 1-13 Preliminary Bacterial Identification by Colonial Types

Colonial Type	Bacterial Group	Additional Tests	Frame of Plates Illustrating Type
Convex, entire edge, 2–3 mm, creamy, yellowish, zone of β-hemolysis	*Staphylococcus*	Catalase Coagulase DNase Mannitol utilization Tellurite reduction Novobiocin resistance Furazolidone resistance	1-5A
Convex or pulvinate, translucent, pinpoint in size, butyrous, wide zone of β-hemolysis	*Streptococcus*	Catalase Bacitracin "A" disk 6.5% NaCl tolerance Bile–esculin CAMP test Hippurate hydrolysis L-Pyrrolidonyl-β-naphthylamide (PYR)	1-5B, C
Umbilicate or flat, translucent, butyrous or mucoid, broad zone of α-hemolysis	*Pneumococcus*	"P" disk Bile solubility	1-5G

Pulvinate, semiopaque, gray, moist to somewhat dry, β-hemolysis may or may not be present	*Escherichia coli* and other *Enterobacteriaceae*	Multiple tests Indole Methyl red Voges–Proskauer reaction Citrate Decarboxylases Urease Phenylalanine Carbohydrate fermentations	1-5D
Flat, gray; spreading as thin film over agar surface; burned chocolate odor	*Proteus*	Phenylalanine deaminase Urease Lysine deaminase	
Flat, opaque, gray to greenish, margins erose or spreading, green-blue pigment, grapelike odor	*Pseudomonas*	Cytochrome oxidase Fluorescence of carbohydrate assimilations Denitrification DNase Hydrolysis of acetamide Growth at 42°C	

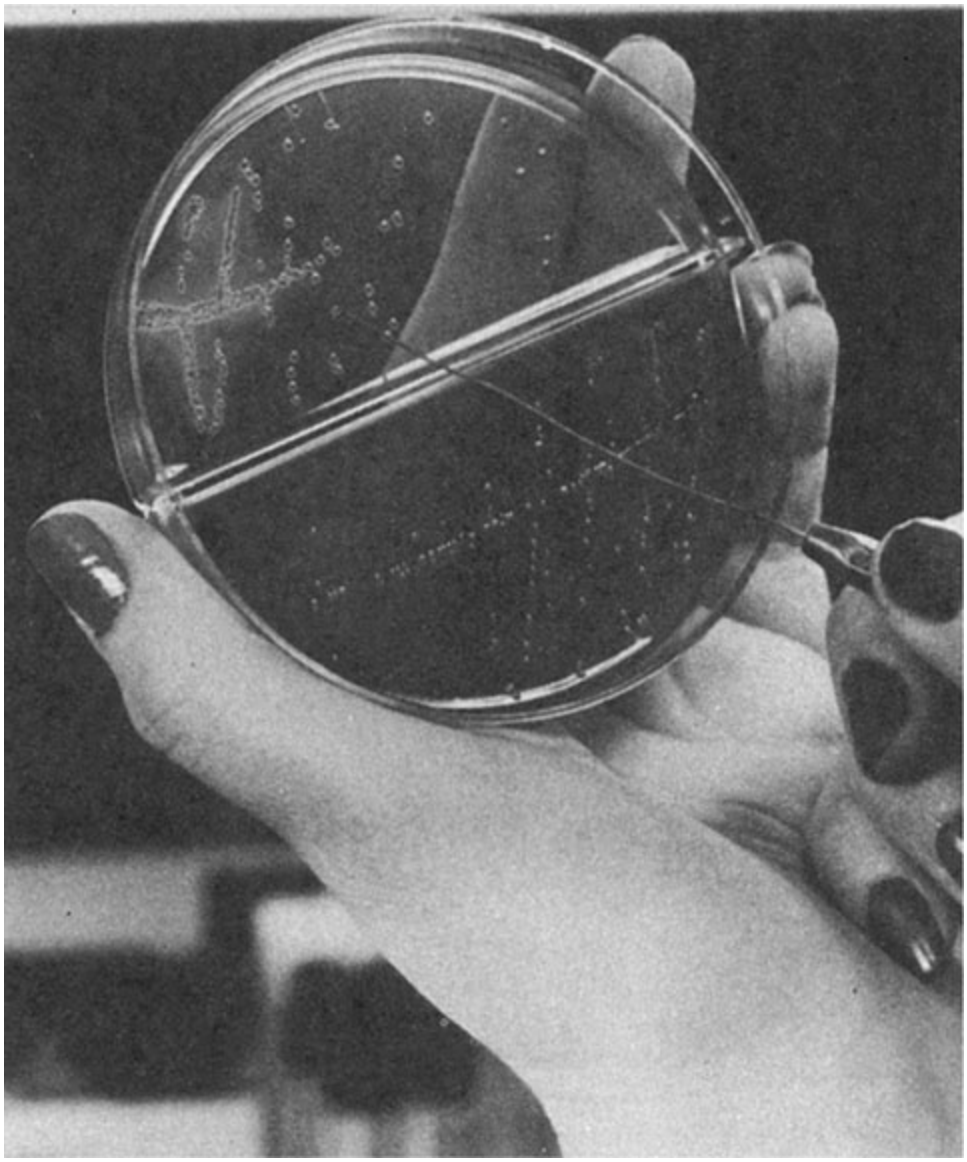
occasion, however, growth may be so crowded that it is difficult to pick individual isolated colonies. Several manipulations are available to the microbiologist in this eventuality (Table 1-14).

Gram's Stain Examination of Cultures. Preliminary impressions, based on observation of colony characteristics, can be further confirmed by studying Gram-stained smears, a technique that is relatively simple to perform. The top and center of the colony to be studied is first touched with the end of a straight inoculating wire, taking care not to touch the adjacent agar or nearby colonies (Fig. 1-19). The portion of the colony to be sampled is emulsified in a small drop of water or physiologic saline on a microscope slide to disperse the individual bacterial cells (Fig. 1-20). After the slide has air dried, the film is fixed to the glass surface either by using heat, quickly passing the slide four or five times through the flame of a Bunsen burner, or by flooding with methanol or ethanol for a few minutes. The fixed smear is then placed on a staining rack and Gram's stain is performed as described in Box 1-6.

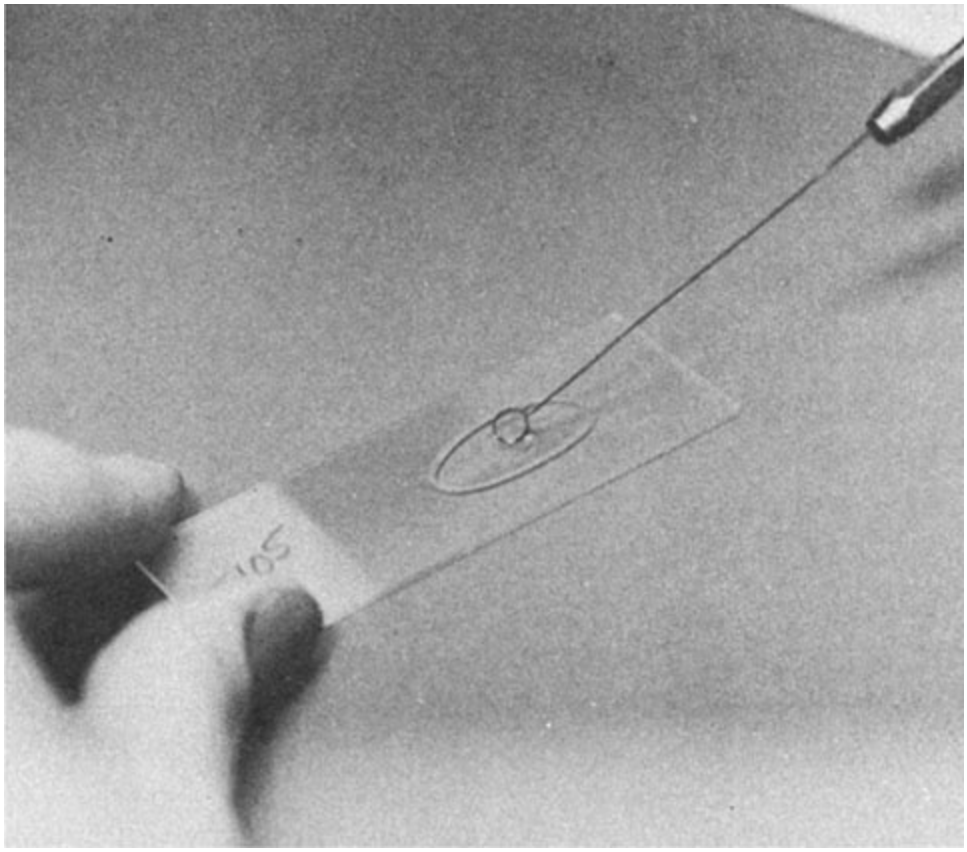
TABLE 1-14 Techniques for Preparation of Pure Isolates From Mixed Cultures

Technique	Description
Straight subculture	Carefully touch the surface of the desired colony with the tip of an inoculating needle (not a loop); streak a new plate for isolation
Use of selective media	Subculture the colony of interest onto an agar that will inhibit growth of the unwanted colonies; e.g., subculture of a gram-negative bacillus onto MacConkey agar to separate it from gram-positive cocci

Use of inhibitory chemicals incorporated into agar (analogous to selective media)	Subculture the colony of interest onto an agar that contains antibiotics or chemicals that will inhibit growth of the unwanted colonies
Use of antibiotic disks (analogous to an agar plate containing antibiotics but more flexible)	Subculture the colony of interest onto the surface of an agar plate and position an antibiotic-impregnated disk that is designed to inhibit the unwanted bacteria



■ **FIGURE 1-19** The technique for picking an isolated bacterial colony with a straight wire for subculture to another medium.



■ **FIGURE 1-20** The technique for preparing a smear for Gram's stain. The top portion of an isolated bacterial colony, as illustrated in F igure 1-19, is touched with an inoculating wire or loop, and then the tip of the loop is submerged in a drop of water or physiologic saline on a glass slide. The inoculum is then emulsified and the preparation is left to air-dry before heat fixation and staining.

The stained smear should be examined microscopically using an oil immersion objective. In addition to the Gram's stain reaction of the bacterial cells (gram-positive bacteria appear blue; gram-negative bacteria appear red or pink), three other characteristics are helpful in making a preliminary identification of isolates: (1) size and shape of the bacterial cells, (2) arrangement of the bacterial cells, and (3) presence or lack of specific structures (e.g., spores, metachromatic granules, capsule, or other features).

In making a preliminary identification of bacterial isolates, the microbiologist should evaluate each of these characteristics. A series of photomicrographs of several stains illustrating a number of the morphologic cells types and spatial arrangements of bacteria commonly encountered in clinical laboratories is shown in Image Plate 1-3.

With the information derived from the examination of bacterial colonies and the Gram's stain, the microbiologist now can be guided to the particular tests most likely to provide the correct identification. For example, a raised, creamy, hemolytic colony on blood agar that consists of gram-positive cocci in clusters is most likely *Staphylococcus* (Image Plate 1-3C). A pinpoint translucent β-hemolytic colony on blood agar that consists of gram-positive cocci in chains is most probably a *Streptococcus* species (Image Plate 1-3D).

The microbiologist soon learns, however, not to rely solely on the examination of Gram-stained smears because the staining reactions may be variable, particularly with very young or older colonies. Gram's stain morphology of bacteria is most characteristic when smears are prepared from a young broth subculture (4 to 6 hours), a time when the bacterial cells are in log phase of growth. Often the Gram's stain morphology is less characteristic when smears are prepared from colonies growing on agar surfaces.

Microbiologists should provide as much preliminary information to the physician as possible. In selected cases, such as when observing bacteria in a blood culture broth or directly in infected CSF, this type of preliminary information can be quite useful in directing specific antibiotic therapy before the final identification or antimicrobial susceptibility test results are available.

Procedures for Preliminary Identification of Bacterial Isolates. The initial observation and interpretation of microbial growth on culture media should be used to determine whether the microorganism(s) recovered merit further identification and whether antibiotic susceptibility tests should be performed. Subsequent tests are then used for the purpose of identifying an isolate, by assessing the biochemical or metabolic activity of the organism. This has traditionally been done by inoculating the primary isolate onto a series of differential test media or into solutions. Today, many of these will not be performed and the isolate may be submitted directly for identification by mass spectrometry. Although mass spectrometry is time and cost-effective, it is not perfect. Therefore, the retention of the knowledge and ability to identify of bacteria by traditional methods is warranted, particularly for isolates wherein the morphologic or other features are inconsistent with the identification by mass spectrometry. Furthermore, the use of colony morphology with key reactions (i.e., spot tests) is a recognized method for the identification of bacteria in certain culture settings, as described in the CLSI M32A and below, and in these settings even obviate the need for mass spectrometry.

Direct Biochemical Procedures for Making Preliminary Bacterial Identifications. Certain preliminary observations or a direct rapid test can be performed on select colonies. Frequently, an isolate can be identified to a level that is clinically useful based on these assessments alone. For example, the lactose-utilizing properties of gram-negative bacilli can be directly evaluated from MacConkey agar by

observing the red pigmentation of the colonies; H_2S production may be detected on Hektoen and xylose lysine deoxycholate (XLD) agars by observing colonies with black centers. The decarboxylation of lysine can also be suspected when observing colonies growing on XLD agar. A red halo around the colony, indicating an alkaline pH shift, indicates the decarboxylation of lysine.

The following are direct tests that can be performed on isolated colonies recovered on primary culture plates:

The Catalase Test. A few drops of 3% hydrogen peroxide are placed directly on a colony. Rapid effervescence indicates production of molecular oxygen and a positive test (Chart 1-1). Accurate results may be difficult to obtain if the test is performed on colonies growing on blood agar because of the presence of peroxidase in erythrocytes. The peroxidase reaction produced by erythrocytes is delayed and weak, however, and can usually be readily differentiated from the immediate and highly active reactions produced by catalase-positive bacteria. The catalase test is most often used to differentiate staphylococci (positive) from streptococci (negative) or *Bacillus* spp. (positive) from aerotolerant *Clostridium* species (negative).

The Bile Solubility Test. Two methods for determining bile solubility are commonly used. As an initial screen, a few drops of a 10% solution of sodium deoxycholate solution are placed on colonies of possible *S. pneumoniae*. Pneumococcal colonies lyse completely and disappear after about 30 minutes (Chart 1-2). This test is sometimes difficult to interpret

and the tube bile solubility test may be performed. An inoculum from the unknown bacterial colony can be suspended in a 10% solution of deoxycholate (bile salts) until turbidity is achieved. The clearing of the turbidity within 30 to 60 minutes after incubation at 35°C indicates bile solubility (Chart 1-2). A control viridans group *Streptococcus*, which does not dissolve in bile, should be tested concurrently.

The Slide Coagulase Test. A colony suspected of being *Staphylococcus* species is emulsified in a drop of rabbit plasma on a glass slide. Bacterial clumping within 2 minutes indicates the presence of bound coagulase and constitutes a positive test result (Chart 1-3). A negative slide coagulase test should be followed with a conventional tube coagulase test, if the colonial morphology is suggestive of *Staphylococcus aureus* in any way. Agglutination tests for detection of staphylococcal protein A can also be used as a marker for *S. aureus*. Bacteria with the appropriate morphology of *S. aureus* that are coagulase-positive may be reported as *S. aureus*. If this is done, technologists need to be aware of slide coagulase-positive isolates that may mimic *S. aureus,* so that additional testing may be performed. Coagulase-negative staphylococci are often reported as such, unless there is a clinical reason to identify these to the species level.

The Direct Spot Indole Test. A small portion of the colony to be tested is transferred from a nonselective medium, such as blood or chocolate agar, to a strip of filter paper that has been or will be saturated with Kovac's reagent or *p*-dimethylamino cinnamaldehyde (PACA) solution. The immediate development of a red color with Kovac's reagent indicates the presence of indole and a positive test (Chart 1-4). PACA is more sensitive than Kovac's reagent, and a positive test reaction is indicated by the rapid development of a blue color. In many laboratories, dry-appearing, lactose-positive, spot indole-positive colonies appearing after 24 hours of incubation on MacConkey agar, particularly on isolates from the urinary tract, are identified as *E. coli*, and further tests are usually not performed. In these cases the spot indole must be performed on colonies growing on parallel blood agar plates, because the pigmentation of the lactose-positive colonies on MacConkey agar will make interpretation of the color reaction difficult and indole is a derivative of tryptophan, which is present in blood containing media.

Cytochrome Oxidase Test. A portion of the colony to be tested is smeared on the reagent-impregnated area of an oxidase test strip. The immediate development of a blue color indicates cytochrome oxidase activity and a positive test result (Chart 1-5). Cytochrome oxidase tests are useful for the initial categorization of many bacterial species that have a distinctive colonial morphology. Bacterial species that produce cytochrome oxidase include *Aeromonas* spp., *Plesiomonas* spp., and *Pseudomonas* spp. Dimethyl oxidase is the reagent typically used in this test. Tetramethyl oxidase is a reagent that is useful for the identification of *Pasteurella* spp., which are dimethyl oxidase negative, tetramethyl oxidase positive. All members of the *Enterobacteriaceae* are oxidase negative.

MUG Test. The MUG (4-methylumbelliferyl-β-D-glucuronidase) test is based on the detection of the production of β-glucuronidase. This test can be used as a screen for *E. coli* as an alternative to the spot indole test. A heavy suspension of the unknown organism is inoculated into the MUG reagent, which has been suspended in tubes or impregnated in dehydrated disks. The reagent will fluoresce from release of 4-methylumbelliferone, if glucuronidase is present. Indole can also be detected by adding Kovac's indole reagent to the MUG tube, making this combination test a valuable method for screening lactose-fermenting enteric bacilli.

PYR Test. L-pyrrolidonyl-b-naphthylamide (PYR) substrate provides a simple method for the rapid identification of enterococci. The production of a red color after adding N, N-methylamino cinnamaldehyde reagent is indicative of PYR positivity. This is used predominantly for the identification of the genus *Enterococcus,* but other bacteria, such as *S. pyogenes,* are also positive (Chart 1-6).

Identification of Bacteria to the Level of Species and Selection of Differential Characteristics. The final characterization of an unknown bacterial isolate is usually accomplished by testing for enzyme systems that are characteristic of each species. These enzyme systems are detected by inoculating a small portion of a well-isolated

bacterial colony into a series of culture media that contain specific substrates and chemical indicators. By this means, the microbiologist can detect changes in pH produced by utilization of chemical substrates or color changes produced by specific by-products. The clinical microbiologist must select appropriate sets of differential characteristics that will permit the identification of each group of bacteria. One of the major advances in diagnostic microbiology has been the miniaturization of biochemical systems, so that multiple characteristics can be examined expeditiously and relatively inexpensively. Before these advances a small number of tests were performed in macroscopic tubes or plates, followed by subsequent testing based on the initial results. This process was slow, expensive, and more prone to error than modern approaches.[87]

Identification of Microorganisms Using Mass Spectrometry. The commercialization and Food and Drug Administration (FDA)-approval of mass spectrometry instruments with associated microbial libraries has changed the ways microbiologists identify microorganisms. It is not an exaggeration to state that the identification of some bacteria (e.g., *Listeria monocytogenes*) that took days and cost dollars can now be completed in minutes and for pennies. There are a variety of types and modifications of mass spectrometry. The matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) method and instrumentation is used for the identification of microorganisms in the two commercially available, FDA-approved systems.

In brief, the microorganisms are placed in a matrix material and ionized by a laser. Biomolecules, largely proteins, are accelerated and separated and the "time of flight" for each molecule is recorded. The composite of the time of flight signals for the molecules of the organism creates a spectrum, which remarkably correlates with the identification of the microbe. It is also reliable, reproducible and the manufacturers have made these instruments simple to use. There are well recognized limitations, which must be considered in laboratory procedures and utilize these instrument, but this is no different than any other technology. Numerous manuscripts and presentations have documented the ability of this technology correctly identify a wide array of microorganisms and to be meaningfully integrated into the clinical laboratory.

39

Identification of Organisms Other Than Bacteria

Fungi. Yeast share many characteristics with bacteria and similar approaches are used for identification. A few screening tests are commonly used on yeast isolates to identify or exclude commonly recovered and/or particularly important organisms. The germ-tube test has been the primary screening tests for *Candida albicans* for many years, although it is recognized that *Candida dubliniensis* is also germ-tube positive.

Urease testing, including a rapid version, is the other commonly used screening test. It is commonly used to examine respiratory isolates, because the most frequent pathogen (*Cryptococcus neoformans*) produces urease, whereas the most frequent commensal yeast isolate (*Candida* spp.) does not contain this enzyme with rare exceptions. Traditionally, the morphologic characteristics of the yeast isolated are examined (i.e., the cornmeal agar morphology) in conjunction with the assimilation and/or fermentation profile to achieve a final identification. The use of mass spectrometry in the clinical laboratory is changing the approach to routine identification, largely obviating the need for many biochemical reactions and cornmeal agar assessment. The evidence-based approach to the identification of yeast using this technology will be developed over the next few years.

The mainstay of identification of mold isolates, however, is the morphologic study of largely asexual reproductive characteristics. Biochemical testing and temperature studies play subsidiary roles, but occasionally are needed to achieve species-level identification. The feasibility of mass spectrometry for the identification of filamentous fungi is being explored, but is likely to be limited, since the morphologic assessment is also quick and inexpensive for those with the appropriate skill set.

Mycobacteria. As specialized bacteria, the traditional approaches to identification have been similar for these organisms. The biochemical testing, however, is considerably more difficult with mycobacteria than with conventional bacteria predominantly because of the extended incubation time needed for adequate growth for testing. Most laboratory directors choose to either refer these specimens to specialized laboratories for identification and/or susceptibility testing, or to use molecular methods. DNA probes are commercially available for several of the more commonly encountered mycobacteria. These are particularly useful for the rapid identification or exclusion of *M. tuberculosis* following the detection of mycobacterial growth. Broad-range polymerase chain reaction (PCR) followed by DNA sequencing has been the standard for identification of mycobacteria in many larger or reference laboratories. Mass spectrometry has also been evaluated and may be used for the identification of mycobacteria in some instances. The definitive role of this technology in the routine mycobacteriology laboratory remains to be determined.

Parasites. The screen for some parasites (e.g., *Giardia* and Cryptosporidium) may be performed effectively with commercially available immunoassays. Otherwise, characterization of parasites is by morphologic study. Culture of parasites is uncommonly performed.

Viruses. As obligate intracellular pathogens, viruses require a very different diagnostic approach. Although traditionally cell culture techniques were used to detect viruses, these are being replaced by more sensitive molecular methods. Characterization of antigens and nucleic acids are the predominant techniques used for viral diagnosis.

BOX 1-11

Factors Involved in Susceptibility Testing

Factor	Criteria
Isolate	Potential pathogen from a valid specimen (i.e., not likely to represent colonizing microbiota)
Susceptibility	Not predictable for infectious agent and antimicrobial
Clinical situation	Antimicrobial therapy indicated
Interpretive standards	Validated criteria available for determining the clinical significance of the result

Testing of Susceptibility to Antimicrobial Agents. In many respects, determining the susceptibility of pathogens to appropriate antimicrobial agents is the most important task performed in diagnostic microbiology laboratories. Some of the factors that must be evaluated when susceptibility testing is considered are summarized in Box 1-11.

Antimicrobial susceptibility testing is most often used for guidance in therapy of bacterial and mycobacterial infections (Chapters 17 and 19). The clinical microbiologists must ensure that testing is done on appropriate isolates by valid methods. The easiest course of action is to give in to an insistent clinician who demands testing of an isolate for which there are no interpretive standards, but the microbiologist must resist that temptation, using evidence-based approaches and recruiting knowledgeable colleagues for support, if necessary.

Testing of anaerobic bacteria, fungi, and viruses may be required in certain situations, but is not necessary routinely. If these agents are tested, it is important that a sophisticated clinician, who will be able to interpret the results properly, be involved in care of the patient.

Use of Antimicrobial Susceptibility Results for Quality Control of Identification Results. Some bacteria have predictable susceptibility to certain agents and need not be tested. Many more have characteristic susceptibility patterns that are not sufficiently absolute to obviate testing. These patterns can be used, however, as a check on the taxonomic characterization. For instance, *K. pneumoniae* is typically resistant to ampicillin, but susceptible to first-generation cephalosporins. In contrast,

Enterobacter spp. are usually resistant to both groups of antibiotics. If an isolate is identified as *Enterobacter*, but is susceptible to these agents, the results should be questioned. Tests both for identification and for susceptibility should be repeated, as something is likely in error. Optimally, a different method should be used for the repeat test from that used initially.

40

Cost-Effective Approaches in the Analytic Phase. In the analytical phase resources can be utilized efficiently by concentrating on several areas. It is possible to use abbreviated protocols for identifying certain organisms (Table 1-15). The CLSI has provided consensus recommendations for certain approaches.[26] Other means for optimizing resources are summarized in Table 1-16. The philosophical underpinning of these approaches is the focus on results that can be interpreted

TABLE 1-15 Abbreviated Identification of Bacteria and Yeast

Situation	Abbreviated Test Protocol	Identification
Gram-negative, nonswarming, oxidase-negative, β-hemolytic on sheep blood agar[a]	No additional tests	*Escherichia coli*
Gram-negative, nonswarming, oxidase-negative, nonhemolytic on sheep blood agar, lactose-fermenter[a]	PYR negative	*Escherichia coli*
Gram-negative, nonswarming, oxidase-negative, nonhemolytic on sheep blood agar, lactose-nonfermenter[a]	MUG positive	*Escherichia coli*
Small gram-negative bacilli or coccobacilli from respiratory or cerebrospinal fluid specimens; growth in 5% CO_2 on chocolate agar, but not sheep blood agar[a]	Rapid test for porphyrin synthesis negative	Haemophilus influenzae (cannot differentiate fromHaemophilus hemolyticus, an uncommon human pathogen)
Gram-negative diplococci, oxidase-positive, growth on	Rapid butyrate esterase or	*Moraxella*

both chocolate and sheep blood agars[a]	DNAse positive	*catarrhalis*
Gram-negative bacilli, oxidase-negative, lactose-nonfermenter, swarming growth on chocolate or sheep blood agar[a]	Indole positive	*Proteus vulgaris*
Gram-negative bacilli, oxidase-negative, lactose-nonfermenter, swarming growth on chocolate or sheep blood agar[a]	Indole negative; ampicillin susceptible	*Proteus mirabilis*
Gram-negative bacilli, oxidase-negative, lactose-nonfermenter, swarming growth on chocolate or sheep blood agar[a]	Indole negative; ampicillin resistant; maltose negative; ornithine positive	*Proteus mirabilis*
Gram-negative bacilli, oxidase-negative, lactose-nonfermenter, swarming growth on chocolate or sheep blood agar[a]	Indole negative; ampicillin resistant; maltose positive; ornithine negative	*Proteus penneri*
Gram-negative bacilli, oxidase-positive, typical smell of Concord grapes, typical colonial morphology (metallic sheen, green/reddish/black, mucoid)[a]	No additional tests	Pseudomonas aeruginosa (rare isolates of Aeromonas may be similar but are spot indole positive)
Gram-positive cocci in clusters; catalase positive; creamy, opaque, yellowish colonies on sheep blood agar (color accentuated on chocolate agar)[a]	Slide coagulase and/or 4-hour tube coagulase positive	Staphylococcus aureus (coagulase-positive Staphylococcus); rarely other staphylococci may be slide

		coagulase positive.
Gram-positive cocci in pairs and short chains, catalase negative or occasionally weakly positive; non-β-hemolytic on sheep blood agar[a]	PYR positive	Enterococcus spp.; failure to grow well for susceptibility tests suggests that the isolate may be another genus.
Gram-positive cocci in pairs and chains; catalase negative; usually narrow zone of β-hemolysis[a]	Rapid hippurate hydrolysis positive; spot CAMP test positive; or latex agglutination positive with specific antiserum	Streptococcus agalactiae (group B); β-hemolytic enterococci may be hippurate positive, but are also PYR positive.
Gram-positive cocci in pairs and short chains; catalase negative;α-hemolytic on sheep blood agar; colonies typically either mucoid or "checker" shaped	Spot bile or tube bile solubility positive	*Streptococcus pneumoniae*
Gram-positive cocci in pairs and chains; catalase negative; β-hemolytic on sheep blood agar with a wide zone of hemolysis; colonies usually dry and small relative to hemolysis[a]	PYR positive or latex agglutination positive with specific antiserum	Streptococcus pyogenes (group A); occasional strains of β-hemolytic enterococci have different colony morphology and are agglutination negative.
Small gram-negative bacilli; oxidase-positive; a "dew-drop" colony morphology on sheep blood agar with pitting of the agar; odor of bleach	No additional tests	*Eikenella corrodens*
	No additional	

Gram-negative regular bacilli or coccobacilli with large (>1 mm) colonies on anaerobic blood agar and similar size on LKV and BBE agars; no growth on chocolate agar in 5% CO_2[a]	tests essential; disk pattern may be used (penicillin resistant; kanamycin resistant; rifampin susceptible) as additional evidence.	Bacterioides fragilis group

41

Gram-negative, thin, pointed, fusiform bacilli; breadcrumb or opalescent colonies on anaerobic blood agar; no growth on BBE agar; no growth on chocolate agar in 5% CO_2[a]	Spot indole positive	*Fusobacterium nucleatum*
Gram-negative bacilli; small (<1 mm) colonies on anaerobic blood agar and BBE agar after at least 48 hours incubation; no growth on chocolate agar in 5% CO_2; black dot in colony center from H_2S production[a]	Catalase strongly positive	*Bilophila wadsworthia*
Small coccobacillary gram-negative bacilli; black colonies (or brick-red fluorescence under long-wavelength UV light) on LKV agar; small translucent or opaque colonies on anaerobic BAP agar; no growth on chocolate agar in 5% CO_2[a]	No additional tests needed	Prevotella spp.; Prevotella interme dia if spot indole positive
Small coccobacillary gram-negative bacilli; small translucent or opaque colonies on anaerobic BAP agar with brick-red fluorescence under long-wavelength UV light; no growth on chocolate agar in 5% CO_2[a]	Spot indole positive	Porphyromonas spp.
Thin gram-negative bacilli; flat, transparent colonies that pit the agar on anaerobic BAP agar; no growth on LKV agar; no growth on chocolate agar incubated in	No additional tests needed	*Bacteroides ureolyticus*

5% CO2; catalase negative; urease positive[a]		
Tiny gram-negative diplococci; small (<1 mm) transparent-to-opaque colonies on anaerobic BAP agar with red fluorescence under long-wavelength UV light; no growth on BBE agar; no growth on chocolate agar in 5% CO_2[a]	No additional tests needed	Veillonella spp.
Large, boxcar-shaped, blunt-ended gram-positive or gram-variable bacteria; large (>2 mm) irregular colonies with a double zone of β-hemolysis on anaerobic BAP; no growth on LKV or BBE agars; no growth on chocolate agar in 5% CO2; catalase negative[a]	No additional tests needed	*Clostridium perfringens*
Thin gram-positive bacilli with swollen, subterminal spores; smoothly swarming growth on anaerobic BAP agar; no growth on LKV or BBE agars; no growth on chocolate agar in 5% CO2; catalase negative; spot indole negative[a]	No additional tests needed	*Clostridium septicum*
Thin gram-positive bacilli with subterminal spores; equivalent growth on anaerobic BAP agar and on chocolate agar in 5% CO2; catalase negative	No additional tests needed	*Clostridium tertium*
Pleomorphic, coryneform gram-positive bacilli; small (1–2 mm) enamel-white opaque colonies on anaerobic BAP agar; catalase positive; spot indole positive[a]	No additional tests needed	*Propionibacterium acnes*
Budding yeast cells[a]	Germ-tube test positive in <3 hours; or mycelial projections from colonies on blood-containing media at <24 hours incubation (*C. dubliniensis* is	*Candida albicans*

	another germ-tube positive yeast).	
Spherical budding yeast cells; often mucoid colonies[a]	Rapid phenol oxidase test positive	Cryptococcus neoformans (Cryptococcus can be excluded on rapid urease-negative colonies)

[a]From consensus recommendations in reference 26.

correctly and that will lead to the best treatment for the patient. One conceptual principle is to think about specimens in two broad categories: (1) those from which isolated agents are highly likely to be pathogens and (2) those from which isolated agents cannot be interpreted with confidence. If a microbiologist gives equal attention to these two categories, it is entirely possible that so many resources will have been squandered on specimens of questionable significance that the most important specimens will be shortchanged.

Each clinical microbiologist must make decisions for the local laboratory, depending on the local environment. A prime consideration is to avoid providing results that may

TABLE 1-16 Some Suggested Approaches to Optimizing Laboratory Identifications

Category	Proposed Policy[a]
Repeat specimens from a nonsterile site within a defined time period	Refer subsequent specimens to the previous evaluation; if the subsequent specimen has been inoculated to media and substantial differences from the original specimen are present, consult clinician about further action
Cultures that contain mixed microbiota (i.e., mixed flora) from a nonsterile site, especially if submitted on a swab; inflammation minimal or no Gram's smear available	Report as mixed gram-positive/gram-negative microbiota (or flora)

Cultures that contain mixed microbiota from a nonsterile site, especially if submitted on a swab; moderate to heavy inflammation present	Report as mixed gram-positive/gram-negative microbiota (or flora); append a comment to consult the laboratory within X days for further processing
Cultures that contain mixed microbiota from a nonsterile site, especially if submitted on a swab; moderate to heavy inflammation present; single predominant potential pathogen present	Report identification of predominant pathogen and presence of mixed microbiota (or flora); either perform antimicrobial susceptibility tests on predominant pathogen or append a comment to consult the laboratory for susceptibility testing
Yeast isolated in mixed culture with bacteria from a nonsterile or potentially contaminated site, such as a wound or peritoneal fluid	Report presence of yeast; consider appending a comment to consult the laboratory for further processing
Mixed microbiota from urine specimens obtained by clean catch or indwelling catheter	Report as mixed gram-positive/gram-negative microbiota (or flora); append comment suggesting (1) repeat collection with an in-and-out catheter if clinically indicated and the patient does not have an indwelling catheter or (2) notifying the laboratory if the patient has an indwelling catheter and requires antimicrobial therapy
Mixed microbiota with a single predominant pathogen from urine specimens obtained by clean catch or indwelling catheter	Evaluate predominant pathogen; append a comment indicating presence of mixed microbiota (or flora)
Mixed vaginal microbiota present	Report only presence or absence of documented vaginal pathogens that are best documented by culture; i.e., Listeria monocytogenes, Streptococcus agalactiae (in women of childbearing age), Streptococcus pyogenes, Staphylococcus aureus (if toxic-shock syndrome suspected), and yeast. Susceptibility testing rarely indicated.
Mixed microbiota from an intravascular catheter	Report mixed gram-positive/gram-negative microbiota (or flora) and consider appending a comment to consult the laboratory for further processing

Recovery of bacteria that resemble Haemophilus influenzae or Moraxella catarrhalisfrom expectorated sputum	Proceed with identification and report the result only if the organism is found in a concomitant Gram's stain associated with polymorphonuclear neutrophils or is the predominant organism present.

[a] It is good policy to preserve specimens that are not evaluated completely for at least 24 hours. If possible, retain the residual specimen for at least 7 days. Preserve agar plates that have not been evaluated completely for a period of time. Seven days is a convenient period to preserve the plates, because all plates from a day can be stored together and discarded 1 week later.

be misinterpreted. A report of "Mixed microbiota (or flora); no definitive pathogen identified" is likely to stimulate collection of an additional, and hopefully better, specimen or treatment of the patient based on the pathogens that are likely causes of the particular infection. Putting a name on an isolated organism that is, in fact, colonizing or contaminating microbiota gives that organism more apparent credibility than it deserves. This will often result in a request for susceptibility testing. The adding of antimicrobial susceptibility results compounds the difficulty, and implies the need for therapy.

The question becomes "What is mixed bacterial microbiota or flora?" Knowledge of the types of bacteria that colonize human body surfaces and a solid grounding in the principles of diagnostic microbiology are essential to this decision. For instance, *S. pyogenes* is important to recognize and is a possible pathogen, no matter how many other species are present; any β-hemolytic colonies should be evaluated for the presence of the group A streptococcal antigen. As a guideline, Schreckenberger and Miller have suggested the "Rule of Three."[81,103] They suggest that one or two potential pathogens should be evaluated even in the presence of commensal flora, but three or more potential pathogens should not be evaluated.

The "Rule of Three" guideline is a useful aid, but sound judgment should be used. For instance, the rule should not be applied automatically to biopsied tissue or aspirated fluids and pus. In the urinary tract, a mixture of three or more organisms of any variety suggests contamination with vaginal or perineal flora; even if a potential pathogen is a part of the mixture and does not predominate, it is difficult to be confident that the analysis will provide valid information. Sometimes, the quantitative relationship of the organisms in the mixture can provide a clue. If one or possibly two organisms clearly

predominate, it is often reasonable to evaluate those organisms and report these, as well as the presence of mixed microbiota.

It should be noted that when a microbiologist examines an agar plate and determines that mixed bacterial types are present, it is actually mixed bacterial colonial types (morphotypes) that are being observed. These visually distinctive colonies often represent different species (or even genera), but they may also represent phenotypic variants of a single genotypic organism. The only way to be sure that multiple bacterial species have been isolated is to identify all of them, by which time, of course, all the work will have been done. In practice, we must use judgment as to whether the colonies are sufficiently different to justify characterizing the growth as mixed and recognize that we may be wrong on occasion.

One practical approach to these situations is to offer the clinician a chance to request that the isolates be evaluated or to initiate a dialogue preemptively, either through a verbal phone report or a written communication on the laboratory record. It is a simple matter to store plates, rather that identifying all the bacteria in a mixture, in the event that a request will be made to identify a particular subset. If the plates are taped together each day and stored for 7 days, the outdated specimens can be discarded easily. Should a dispute arise as to further evaluation of a specimen, it is a better position for the microbiologist if the specimen has been retained than if it has been discarded.

The techniques and interpretations of the foregoing procedures are discussed in greater detail in subsequent chapters. In an era of stringent cost containment, it is imperative that microbiologists apply their skills of observation and use a few select characteristics to identify bacterial species presumptively whenever possible. Developing this microbiologic "sixth sense" can also be helpful in verifying the results obtained from packaged kit systems or from automated instruments. On occasion, the biotype numbers issued by these systems may be in conflict with colonial characteristics, Gram-stain morphology, and/or biochemical "spot tests." In such instances, additional studies may be in order to prevent issuing an erroneous report.

Postanalytic Phase

Reporting Results. Reports of microbiology culture results should be issued as soon as useful information becomes available. Each laboratory director must establish those results that will be considered "urgent values." The reporting of these and the action taken by clinicians needs to be monitored, as these will be reviewed during a Joint Commission inspection for hospital accreditation. The next tier consists of results that are considered "important," but not necessarily "urgent." There is not always agreement regarding what should be characterized as urgent versus important; this is a local healthcare delivery decision. Some examples of "urgent" and "important" results are listed in Table 1-17. The construction of such a list will vary greatly, depending on

the patient population served, the capability of the institutional information system and the practice patterns of clinicians who use the laboratory. In addition to the defined categories, the clinician should have the opportunity to request a telephoned result on any culture at the time the examination is requested.

"Urgent" results must always be telephoned to the caregiver. Having the person receiving this information repeat back (i.e., read back) the reported information and documenting to whom it was reported should be part of the standard procedure for reporting urgent results. "Important" results are often also telephoned to the healthcare team, but occasionally may be delivered by an electronic means. The danger of the latter approach in assuring that someone who can act on the information actually received it. The most important consideration is that all parties understand the communication policy and the responsibility of each participant. Confidentiality of patient data must be assured anytime a report might be viewed by unauthorized personnel (e.g., faxing reports only to office machines). It is good practice to have a protocol for telephone reports that specifies backup recipients if the primary caregiver is not available; this protocol should be acceptable to both clinicians and laboratory workers.

TABLE 1-17 Suggested List of "Urgent" and "Important" Reports[a]

"Urgent" Reports	"Important" Reports
Positive blood cultures	Positive tissues and fluids other than blood and cerebrospinal fluid
Positive cerebrospinal fluid cultures	Stool pathogens
Positive acid-fast smears	Positive parasites other than Plasmodium spp.
Mycobacterium tuberculosis	Positive sexually transmitted pathogens
Plasmodium spp., especially P. falciparum	Streptococcus agalactiae if recovered via predelivery culture protocol
Streptococcus pyogenes from a normally sterile site or genital site	Streptococcus pyogenes from throat cultures
Streptococcus agalactiae from a genital site of a woman at term	Positive viral pathogens
Herpes simplex virus from a genital site of a woman at term	Positive dimorphic fungi

	Positive antigen or nucleic acid tests performed directly on clinical specimens
	Results that are likely clinically unsuspected, but may be medically important (e.g., the recovery of an unusual or unexpected pathogen that may not be covered by empiric therapy)

[a] These are recommendations; this list should be modified as appropriate for local conditions.

44

Timely preliminary and interim reports should be issued as a matter of policy. For example, preliminary reports on negative bacterial cultures should be issued within 24 to 48 hours. The timing of initial reports on other types of agents will vary with the speed of growth (e.g., weekly for mycobacteria and twice the first week followed by weekly for fungi). An interim report of "negative culture" may be helpful, because the physician may wish to reevaluate the patient pending the final report. Final reports should be issued as soon as possible; for most bacterial cultures, 48 hours is a reasonable goal. In most instances, the preliminary and final results are maintained in the LIS, which is interfaced with the hospital information system (HIS). As results are updated or finalized in the LIS, they should near-instantly appear in the HIS and be available for the provider. It is important to assure that the results successfully cross this interface and that the expected format has remained intact. This assurance can be incorporated in the checklist that is used when introducing new tests or validating a new computer system.

Interactions With Epidemiologists. Microbiologists play an important role in safeguarding the health of patients and the public at large.[52,89] Certain infectious agents must be reported to public health authorities by law; the list of such agents varies by state and should be available in the laboratory. The reports are now mainly electronic. Within the institution, similar relationships must be cultivated with hospital or healthcare system epidemiologists. These individuals are often called Infection Control or Infection Prevention specialists. The epidemiologists will review certain laboratory results on a regular basis. In addition, microbiologists should remain alert for unusual patterns of isolates that deserve mention to the epidemiologists for consideration of further investigation. For example, if a particular bacterium (e.g., *Serratia marcescens*) is isolated at an increased frequency from a particularly location (e.g., the neonatal intensive care unit), then the microbiologist should alert the

epidemiologist to this fact, as an outbreak is suspected and an intervention is likely needed. On occasion, molecular strain typing may be used to increase the quality of epidemiologic investigations. The additional testing may be performed locally or in a referral laboratory, depending on available expertise.

Analysis of Results. It is incumbent on the laboratory director to provide feedback to clinicians on some important parameters of laboratory performance (Box 1-12). If local information systems have the capability, feedback should be made optimally to individual clinicians or groups of clinicians (such as practice groups). The ultimate quality control tool for caregivers is to receive a report card on their use of the laboratory and results on their patients (such as frequency and rate of positive examinations) compared to other clinicians. Such reports are challenging to design because of the difficulty in being sure that the practitioners being compared serve patient groups that are truly equivalent. Studies of turnaround time (TAT) are more problematic in microbiology than in other areas of the laboratory because of the delays inherent in generating microbiologic results. However, certain examinations, such as direct examinations of clinical specimens, do lend themselves to TAT analysis. Summaries of antimicrobial susceptibility results should be provided on a yearly basis. Knowledge of the frequency of antimicrobial resistance in commonly recovered bacteria at a local level is important for guiding empiric therapy.

BOX 1-12

Parameters of Laboratory Performance and Clinical Results

Activity	Parameters
Blood cultures	Frequency and rate of recovery of "skin organisms"/"contaminants"
	Frequency and rate of submission of single cultures
Direct examination of clinical specimens	Analysis of TAT
Antimicrobial susceptibility testing	Summaries of % susceptibility of important bacterial pathogens
Mycobacterial cultures	Frequency of the recovery of *Mycobacterium gordonae.*
	Correlation of positive cultures with AFB smear results and review of the smears from

positive cultures

Maintenance of Samples and Records. Local and national guidelines for storage of requisitions and reports must be followed. They differ by specimen type and clinical situation.

After specimen processing and media inoculation, the residual specimen should refrigerated at least until the bacterial culture is complete. Often specimens are maintained for a set number of days after submission, in the event that the clinician would like to have additional tests performed. Although this is useful in that another specimen is not required, it should be noted that refrigeration diminishes the recovery of some microorganisms (e.g., *N. meningitidis* recovery is diminished at 4°C). Ideally, tissue should be frozen at −70°C for potential future use, but this is impractical for most laboratories. The retention of clinical specimens is importance, since subsequent analysis (e.g., histologic examination) may disclose the presence of an unsuspected pathogen (e.g., mycobacteria, viruses, or fungi) and a culture for that pathogen can be attempted. If successful, the retention of the specimen prevented the need for obtaining another specimen, which may be from an invasive procedure.

Blood culture isolates should be maintained for at least 30 days. Ideally, all positive cultures should be retained for a period (e.g., 7 days) to allow further evaluation, such as additional susceptibility tests, if clinically indicated. Some institutions stock clinically-significant blood culture isolates at −70°C for extended periods. A variety of methods have been described for storage of microbial isolates.[95] We have found the simple expedient of a loopful of bacteria into trypticase soy broth with 15% to 20% glycerol to be an effective

method of preserving most bacterial and yeast isolates. Fungi can be maintained as "water cultures" at room temperature or on slants under glycerol. Viruses must be frozen at −70°C.

Administrative Aspects of the Microbiology Laboratory

The focus of this book is on the science of microbiology as applied to diagnosis and treatment of infectious diseases. In daily practice, however, it is impossible to separate the business of microbiology from the science. One of the strengths of clinical microbiology laboratories is the sophistication of support systems for the scientific process. Research laboratories have much to learn from the planned maintenance and rigorous quality control of their diagnostic counterparts. The reader is referred to an

extensive exploration of laboratory management in theory and action.[51]

Government Regulations

In the United States, the government is involved in virtually every aspect of laboratory testing. Although some issues are directly related to specific sets of regulations, all aspects of laboratory management derive from governmental imperatives in some manner. In many cases, leaders in the private and academic laboratory industry developed the framework and defined the standards, which were then adopted by the government and made applicable to all laboratories. The federal agencies and other groups involved in laboratory and medical regulation are summarized in Box 1-13.

The authority for regulatory involvement in laboratory medicine derives from the Clinical Laboratory Improvement Act of 1967 (CLIA '67). This legislation authorized the regulation of hospital and commercial clinical laboratories. For 20 years, laboratories in other settings were exempt. The Clinical Laboratory Improvement Amendments of 1988 (CLIA '88) extended the mandate to include governmental laboratories, public health laboratories, and physicians' office laboratories that perform laboratory testing for human disease. Testing for research purposes (results not used in the care of patients) and veterinary medicine do not fall under governmental purview.

Several categories of testing were established in the CLIA '88 regulations (Table 1-18), and many other regulations depend on the category in which a test is placed. The Centers for Disease Control and Prevention (CDC) is charged with the task of assigning each test to a complexity category. An advisory group, the Clinical Laboratory Improvement Advisory Committee (CLIAC), composed of individuals from government, industry, medical groups, clinical and public health laboratories, and consumers advises the government on these decisions.

BOX 1-13

Agencies Involved in Laboratory and Medical Practice

Agency	Area of Responsibility
Center for Medicare and Medicaid Services (CMS)	Establishes the rules for accreditation, licensure, and inspection of laboratories; sets reimbursement rates for services to Medicare
Centers for Disease Control and Prevention (CDC)	Participates in categorization of test complexity; provides recommendations on a variety of issues, including laboratory techniques and bioterrorism preparedness
National Institute of Occupational	Responsible for regulations on protection from chemical

Health and Safety (NIOSH); a division of CDC	Responsible for regulations on protection from chemical and biologic hazards
Occupational Health and Safety Administration (OSHA)	Responsible for regulations on workplace safety
Food and Drug Administration (FDA)	Responsible for approving medicines and medical devices; FDA "clears" medical devices, but does not "approve" them; and is determining how to regulate laboratory-developed tests.
Veterans Affairs Department	Responsible for the health and welfare of eligible veterans, including a national network of hospitals and clinics
International Air Transport Association (IATA)	An international organization of air carriers; involved in promulgation of rules on safe shipment of infectious agents by air
Clinical and Laboratory Standards Institute (CLSI)	A voluntary organization of academia, industry, and government; its goal is to improve laboratory performance; although advisory, the recommendations often become standards of laboratory practice
American Medical Association (AMA)	Largest organization of physicians in the United States; responsible for developing coding of laboratory tests and medical procedures, which serve as the basis for reimbursement
The Joint Commission	Inspects and accredits hospitals and hospital laboratories, home healthcare agencies, long-term healthcare facilities, among others.
College of American Pathologists (CAP)	Provides laboratory accreditation and proficiency testing services.

46

TABLE 1-18 Complexity Categories of Laboratory Testing Under CLIA '88

Category	Description	Personnel Requirements	Proficiency Testing	Quality Control	Comments
High complexity	Tests requiring the greatest analytical skill and judgment	Most stringent; requires equivalent of Associates Degree	Required	Required	High and moderate complexity testing are jointly considered nonwaived testing.
Moderate complexity	Tests requiring analytical skill and judgment but at a somewhat lower level	Less stringent; requires training which may be on the job	Required	Required	There is a complex formula for categorizing tests as to level of complexity.
Provider performed microscopy	Microscopic examinations by certain groups of clinicians	Defined provider groups; cannot be delegated to other personnel	Required if applicable	Required if applicable	This is a subcategory of moderate complexity testing.
Waived testing	Simple tests that are not likely to have adverse consequences if performed incorrectly	None	Not required	Must follow manufacturer's instructions	Most laboratory workers have a hard time understanding how a test could be worth doing if a wrong answer causes no harm.

For more detailed information, see the CMS website: http://www.cms.hhs.gov/clia/appendc.asp

Detailed specifications for personnel qualifications, proficiency testing, and quality control are delineated in the regulations for all laboratories that perform nonwaived testing. Several consequences of the CLIA '88 regulations have devolved.

1. Most physicians have stopped performing all but the most basic testing because the regulatory requirements are considered too burdensome.
2. There is constant pressure from physician groups (other than pathologists) to loosen the regulations and allow performance of more complex tests without stringent controls.
3. Manufacturers strive to have their instruments and products placed into the waived category, so they can market them to physicians as simple tests without rigorous requirements for control and documentation.

Accreditation and Laboratory Inspection. The CLIA '88 regulations provide for licensure of laboratories after inspection by state inspectors or by another organization that has been "deemed" by Centers for Medicare and Medicaid Services (CMS) to provide equivalent—or stricter—standards. The two organizations that are most commonly used by clinical laboratories for accreditation and inspection are Joint Commission on Accreditation of Healthcare Organizations (JCAHO) and College of American Pathologists (CAP). In every case, the laboratory must be evaluated biennially. Laboratories that utilize JCAHO are usually located in hospitals, and the inspection of the laboratory is performed at the same time as the hospital inspection. In this case, the inspectors are "professional inspectors," usually with a medical or nursing background rather than training in laboratory medicine specifically. CAP was the first organization to evaluate laboratories; before the entry of the government into the process. Initially, accreditation was voluntary and viewed as an educational means

to self-improvement. The CAP philosophy is based on peer evaluation. Each laboratory that is inspected must provide a team to inspect another similar laboratory in turn. The inspectors are, therefore, "volunteers" who are practicing laboratory professionals.

Each organization that inspects laboratories has a set of standards for evaluation; these standards must be submitted to CMS for approval. In some states, accreditation by a state agency must also be performed if a laboratory does business in that state (e.g., New York State).

Proficiency Testing. An integral part of continuing accreditation is participation in proficiency testing. Specimens are sent to participating laboratories as unknowns on a periodic basis. The laboratory evaluates the specimens and returns the answers to the accrediting agency, after which the results are evaluated and a grade provided. Once again, CAP initiated this protocol many years before CLIA '67. The rules are now set by the government, although there is some freedom to work within them. The best programs provide an educational experience as part of the exercises. CLSI has provided guidance for improving laboratory performance through proficiency testing.[25] If an external source for proficiency testing samples is not available for an analyte, then another method for assessing performance must be developed in the laboratory. A variety of methods exists, including exchanging samples between laboratories and constructing a panel of "unknown" challenges within the laboratory.[27]

In CLIA '88, some seemingly obvious rules were codified: the protocol for proficiency tests must be as close to that used for clinical specimens as feasible (including the use of the same testing personnel) and laboratory personnel cannot

compare results before submitting the answers—in other words, no cheating!

Personnel Qualifications. Detailed specifications for personnel at all levels are provided in the CLIA '88 regulations for laboratories that perform nonwaived testing.

Procedure Manuals. Although there is not a rigid prescription for preparation of written policies and procedures, some general principles must be followed.[34] Policies must be clearly stated—and followed. Procedures should include the principle of the test, instructions for performance, and references. The best procedures are so well written that a qualified individual who has never before performed the test could read the detailed procedure, follow it and perform the test. Manuals must be available to all workers who will need to refer to them.

Space Requirements. The regulations do not specify detailed space requirements. Rather they indicate that the space must be adequate to perform the work satisfactorily. Informal guidelines for general laboratories[24] and for microbiology laboratories[120]have been described, however; they can serve as a useful guide when

constructing a new facility or evaluating the adequacy of an existing laboratory.

Reference or Referral Laboratories. It is a rare laboratory that will be able to fulfill all the requests made by clinicians. Some specimens must be sent to a specialized laboratory for further testing.[33] Selection of the referral laboratory or laboratories should not be done casually. The available choices should be evaluated carefully in conjunction with the medical staff, as appropriate. Price is not the only determinant, or even the most important factor. The selection should be reviewed on a regular basis.

Patient Confidentiality. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) provides safeguards for the confidentiality of information and allows patients to have access to their medical records. This now includes laboratory test results. Upon request, the test results must be provided to the patient within a reasonable timeframe. Safeguards must be in place to assure the identity of the patient is accurate. In most institutions, there will be similar policies regarding the release of medical records to patients upon request. It may be preferred to simply use these same policies and procedures for laboratory derived test results.

The FDA and Laboratory-Developed Tests. The FDA has oversight of the production of medically-important manufactured products. This agency has declared that this oversight responsibility extends to include laboratory-developed tests. This poses great concern to the medical community, given the number of laboratory-developed tests that are in daily operation throughout this country, and have become the standard of care in medical practice. To immediately "cease and desist" using such test, which fortunately has not been mandated to date, would be detrimental to patient care and would set medical practice back decades. The challenge of "how" the FDA will implement oversight, given an already strained infrastructure remains to be determined.

Risk Management and Patient Safety

Most healthcare facilities are currently involved in risk management. In fact, many hospitals and clinics have established formal risk management offices, fully funded and staffed, to help reduce to a minimum the chances for accidents and high-risk practices that might cause harm to patients and employees. The accreditation of hospitals has emphasized the need for continuous improvement in the area of safety. It is expected that patients should receive the latest from medical care without being harmed.[97] These initiatives also emphasize a safe work environment for employees. In addition to improving the healthcare environment for altruistic reasons, these initiatives also reduce costly workers' compensation claims and malpractice suits.

Working in conjunction with the quality assurance committee, a risk manager is assigned to investigate cases in which quality management is below the established thresholds or situations wherein employees or patients may be at undue risk. After

reviewing the details of the situation with the appropriate representatives of the department involved and after gathering the necessary data, the risk manager submits a condensed report to the quality assurance committee along with recommendations for corrective actions. A dialogue continues between the risk manager and the committee chairman until an appropriate plan of action is agreed upon. The compliance of the departmental personnel with the corrective action plans is then monitored.

Although the major focus of risk management is directed toward patient care, the clinical laboratory participates in seeing that all laboratory operations are in compliance with the overall practices and policies of the institution. If equipment or instruments are damaged because of fire or electrical accidents, if personnel are injured or if workers contract serious laboratory-acquired infections, then work flow may be disrupted and laboratory reports may be delayed. Thus, for the most part, laboratory risk management is related to implementing and monitoring laboratory safety practices, directed more to employees than to patients. Liability for injury clearly rests with the employer, even though the negligence leading to the injury may be that of a fellow worker.[64] For this reason, risk managers are insistent on conducting safety-oriented education courses and assuring that all rules and regulations pertaining to laboratory safety are both implemented and followed.

The other major area that is of increasing concern to risk managers is financial. There are strict regulations covering conflicts of interest, fraudulent billing, and unlawful enticements for business (i.e., kickbacks). Billing of government programs (Medicare and Medicaid) must utilize a set of test codes, called Current Procedural Terminology (CPT) codes. Most other insurers also utilize these codes. They are revised and published yearly by the American Medical Association (AMA), which has been charged by the government with this task. Input into the construction of the codes can be provided by any person or organization, but the operative committee of the AMA is drawn from its constituent societies. In the field of laboratory medicine, these are CAP and American Society for Clinical Pathology (ASCP).

Laboratory Safety

Although it is the legal responsibility of hospital and laboratory managers to provide for a safe working environment, employees must also bear the responsibility for adhering to safety

48

standards outlined in the Laboratory Safety Manual, to bring to the attention of the supervisor any hazards or potential hazards that may be encountered during work activities and to seek immediate medical attention for any job-related injury.[64]

There should be a designed safety officer in every laboratory or department, whose duties are to assure that safety standards and guidelines are written and published and that employees are informed of these standards through regularly scheduled laboratory safety courses and meetings. They also work to maintain a system to monitor compliance. The safety officer will work closely with the hospital risk manager to reconcile and correct any breaches of conduct or any irregularities discovered.

General Safety Rules and Regulations. Laboratory workers are advised not to take unnecessary risks. Carelessness, negligence, and unsafe practices may result in serious injuries, not only to the individual, but to coworkers and patients as well. The following are general considerations that will make working in microbiology laboratories less of a risk.[31] Each laboratory director is responsible for ensuring that laboratory policies and procedures follow current legal requirements (federal, state, and local) and standards of good laboratory practice.

1. Each employee should be instructed on the location and operation of all safety equipment and facilities, such as fire blankets, fire extinguishers, showers and eye wash fountains. Each of these must be readily accessible in the laboratory.
2. Personal protective equipment (surgical gloves, lab coats, etc.) should be worn when indicated. Laboratory coats should be worn (with buttons closed) at all times while in the laboratory, and removed when leaving the laboratory. Masks that are individually fitted for each individual must be used for some manipulations that might result in the generation of infectious aerosols with important pathogens, such as *M. tuberculosis*.
3. Personal habits and grooming must be put in perspective. Long hair must be tied such that it will not interfere with equipment or reagents. Application of cosmetics in the work area is prohibited. Sandals and open-style shoes do not afford proper foot protection and are not acceptable. Fingers, pencils, and other implements should not be placed in the mouth. Horseplay and practical jokes are inappropriate in this environment and should not be tolerated.
4. Contact lenses, especially the soft type, absorb certain solvents and may be a hazard after splashes and spills. Employees are strongly advised not to wear contact lenses in the laboratory, or to wear safety glasses when working with caustic or infective materials.
5. Eating or storing food and beverages in the laboratory or in refrigerators used for specimens or laboratory materials is not permitted. A refrigerator physically located outside of the laboratory should be designated specifically to store food and drink.
6. Pipetting by mouth of any material is absolutely prohibited. A variety of suitable pipetting aids are available.
7. Laboratory personnel with current skin infections, acute respiratory infections, or other contagious diseases should avoid patient contact. If such infections

(e.g., influenza) place coworkers at risk, then the affected employee should not come to work.

8. It is important that laboratory workers know the characteristics of all materials in use, so appropriate precautions can be taken during use and disposal. The manufacturer is required to provide this information in material safety data sheets (MSDS). These sheets should be maintained in one location in the laboratory and readily available to everyone in the laboratory.
9. Appropriate labels and signs must be placed on all specimens or instruments and in all areas of the laboratory where they are necessary for maintenance of a safe work environment.
10. Types and levels of decontamination are summarized in Table 1-19. It is important to match the type of disinfection or sterilization to the biohazard.[19,20,119]

Routine Safety Precautions

Centrifugation

1. Before centrifuging any item, check tubes, vials, or bottles for cracks. Periodically replace the rubber cushions in the bottoms of the trunnions and remove any material that should not be present (e.g., broken glass).
2. Make sure that the centrifuge is properly balanced before use. Check the trunnion rings and tube carriers to be sure the weights match.
3. Wait for the centrifuge to come to a complete stop before opening the lid to remove samples. Use only the braking device to bring the rotation to a more rapid and complete stop.
4. Should breakage of a tube occur in the centrifuge, first turn off the instrument, wait at least 20 minutes before opening the lid, and, after donning mask and gloves, thoroughly clean and disinfect the inside of the centrifuge.
5. As part of the routine maintenance program, each centrifuge should be thoroughly cleaned with a suitable disinfectant on each day of use. Preventive maintenance of all working parts should be on a regular schedule as appropriate.
6. If potentially infectious material is centrifuged, which is always the case with biologic specimens, the specimen must be placed in a closed carrier (sealed dome centrifuge tubes).

Needles and Glassware

1. Discard all chipped or cracked glassware in appropriate containers.
2. Pick up broken glass with a brush and pan; do not use hands.
3. Glass articles should not be discarded in the sink or loosely in a wastebasket where paper articles are being discarded. They can cut the fingers and hands of individuals removing the refuge. They should be placed in a container designed

for sharp objects.

49

TABLE 1-19 Types of Decontamination, Disinfection, and Sterilization[a]

Level[a]	EPA/FDA Category	CDC Category	Example	Type of Organisms	Examples
1	Hospital disinfectant	Low-level disinfectant	Quaternary ammonium compounds	Vegetative bacteria	*Staphylococcus* spp. *Pseudomonas* spp.
				Enveloped or midsized viruses	Human immunodeficiency virus Herpes simplex virus Hepatitis viruses B and C Coronavirus
2	Hospital disinfectant with tuberculocidal claim	Intermediate-level disinfectant	Quaternary ammonium compounds with alcohol; phenolics; iodophors; chlorine-containing products	Fungi	*Aspergillus* spp. *Candida* spp.
				Nonlipid or small viruses	Enteroviruses Rhinoviruses
				Mycobacteria	*Mycobacterium tuberculosis*
3	Sterilant/high-level disinfectant	High-level disinfectant	Glutaraldehyde; hydrogen peroxide	Bacterial spores	*Bacillus* spp.
4	Sterilization	Sterilization	Ethylene oxide; autoclave	All agents	

[a]Agents at each level are also effective against organisms killed by agents at higher levels. Prions require separate consideration; consult reference 99. Adapted from references 19 and 20.

4. Used needles and lancets (sharps) must be placed into appropriate used-needle containers for safe disposal. These sharps containers should be replaced periodically, when approximately three-fourths full; they should be monitored to prevent overfilling.
5. Avoid removing needles or exchanging needles on syringes as much as possible. There are devices that may be used to help protect employees if needles need to be removed. The practice of changing needles before discharging venepuncture blood into blood culture bottles has been abandoned in most hospitals.

Electrical Safety

1. All personnel should know the location of master switches and circuit breaker boards. Do not attempt to repair any instrument while it is still plugged in.
2. Plugs or cords that are broken, frayed, or worn should not be used.
3. Outlets must not be overloaded. Never use gang-type plugs.
4. All cord and plug-type electrical equipment should have grounded power cords and plugs. All shocks, including small tingles, must be immediately investigated.
5. Extension cords should be used only in compliance with the overall hospital

policies and procedures.

Corridor Cautions

1. Open doors into corridors with caution. Watch out for swinging doors. If there is a window in the door, look out to be certain the way is clear before opening the doors.
2. Keep to the right when approaching corridor intersections and when using stairways. Walk, never run, in halls, rooms, and stairwells. Appropriately placed mirrors provide images of potential traffic on crossing corridors.
3. Watch for hall hazards such as beds, carts, or tables. Watch out for articles on the floor, such as paper clips, electrical cords, loose tiles, and spilled liquids. Corridors should not be used for the storage of equipment, as this represents a hazard, particularly to egress in the event of a fire.

Lifting

1. Back injuries are among the most frequent causes of debilitating illness among hospital personnel. Avoid lifting heavy objects when possible. Always get help.
2. If you must lift objects alone, exercise the following precautions:

a. Have a good footing. Keep feet about 10 inches apart.
b. Bend at the knees to grasp the object.
c. Keep the object close to you and get a firm hold.
d. Keep the arms and back as straight as possible and lift gradually upward by straightening the legs.

Handling Specimens and Spills

1. Specimens should be collected in approved, sturdy containers with adequate closure to prevent spillage or leakage. All specimens must be considered a potential hazard.
2. Cuts on hands should be adequately covered with adhesive bandages. Wear disposable gloves if the

50

work activity involves contact with any body fluid or tissues.
3. If a sample shows evidence of breakage, leakage, or soiling biohazard bag that contains the specimen, then follow the institutional guidelines regarding specimen leakage. This may necessitate containing the physician for the procurement of another specimen.
4. Blood-contaminated specimen requisitions should be rejected. Handle such a requisition only with gloves, if processing is necessary in an emergency. Notify

the requestor that such contaminated materials present a health hazard. Fortunately, the widespread use of electronic order entry is making this less of an issue.

5. Wash hands thoroughly with soap and water several times a day and, particularly, after handling specimens before leaving for a coffee or lunch break.
6. Spills must be handled according to the nature of the material involved and should follow local policy.

Handling of Wastes and Hazardous Material

1. Set aside certain sinks in the laboratory to dispose urine and other body fluid specimens. Hand washing should not be allowed in these sinks.
2. Biohazard bags (so-labeled) must be used to dispose of all potentially contaminated samples—blood tubes, specimen containers, pipettes, pipette tips, and reaction vessels, among others. Leave sufficient room at the top so that the bag can be easily closed and secured. It is good practice to double bag hazardous waste.
3. Dispose of glassware and sharps in appropriate hard-walled containers. When three-fourths filled, such containers should be placed in the appropriate labeled waste boxes for proper disposal.
4. Remove filled biohazard bags to designated waste areas as frequently during the day as necessary to avoid buildup.
5. Immerse contaminated reusable glassware into disinfectant solution. Thoroughly rinse with water and autoclave before reusing.
6. At the end of each day or after a spill, all work surfaces must be disinfected with an agent that is effective against the agents expected at that site. All equipment that is removed from the laboratory should be decontaminated first. In addition, laminar flow safety cabinets must be decontaminated (preferably by a technician certified in care of this equipment) before any maintenance is done or filters changed.

Biologic Agents

Classification of Biologic Agents. The CDC and National Institutes of Health have categorized infectious organisms into risk groups,[99] which are summarized in Table 1-20 The document can be ordered from the government printing office or downloaded free of charge from the Internet: (http://www.cdc.gov/biosafety/publications/bmbl5/BMBL.pdf).

Physical Containment of Biohazards. The physical barriers to infection in the laboratory are either personal or institutional. The personal barriers include good hygiene (e.g., separate facilities for food and for hand washing) and protective equipment (e.g., splash shields, goggles, gloves, gowns, and masks). Institutional barriers are structural (e.g., isolated facilities, doors, and locks) and technological (e.g.,

air handling and filtration). BSCs are a critical component of protection for workers. It is important to recognize that BSC and chemical hoods serve very different purposes. It is possible to construct a BSC that can be used as a chemical hood, but only certain types of BSC should be used for chemicals and chemical hoods should not be used for infectious agents.

The classification of BSCs is summarized in Table 1-21 and depicted in Figures 1-21 through 1-25. Most clinical laboratories use Type II A BSCs for processing of specimens and for work with isolates, especially those that present an aerosol hazard. Type I hoods are rarely used today; Type III hoods are not commonly employed in diagnostic laboratories. In the class II and III cabinets, air is directed across the work surface from the top of the cabinet in a laminar fashion, minimizing contamination of the samples from aerosolized agents. These devices are sometimes referred to as laminar flow safety cabinets. The downward laminar flow also protects the work from unfiltered air that is drawn in through the front portal in the class II cabinets; the front intake air is directed by the laminar flow into the sump below the work surface where it is filtered before eventually joining the downward laminar flow.

The velocity of the airflow in Class I and II BSCs must be validated by a certified technician at least yearly or whenever repair work is done. The cabinet must be decontaminated by a certified technician before any manipulations that require compromise of the contaminated area are undertaken (e.g., changing filters, replacing or repairing motors, or moving the cabinet).

Common infectious hazards in diagnostic laboratories: Although most agents encountered in a clinical laboratory have the potential for causing diseases in laboratory workers, a relatively small number fulfill that potential. Miller and associates[80]describe a 25-year experience of laboratory-acquired human infections at the National Animal Disease Center (NADC) in Ames, Iowa, an institution where research on domestic diseases of livestock and poultry is conducted. The level of risk among workers is probably somewhat greater than in the average clinical laboratory. From 1960 to 1985, 128 laboratory exposures to zoonotic organisms were reported at NADC. Thirty-four laboratory-associated infections resulted. Brucellosis accounted for 47% of the cases, leptospirosis for 27%, and mycobacteriosis for 9%. *Salmonella* spp. and *Chlamydophila* spp., Newcastle disease virus (not a human pathogen) and *Trichophyton* spp. accounted for the other laboratory-acquired infections at NADC.

The 10 most frequent laboratory-acquired infections from accumulated studies are (1) brucellosis, (2) Q-fever, (3) typhoid fever, (4) tularemia, (5) tuberculosis, (6) typhus, (7) viral hepatitis, (8) Venezuelan equine encephalitis, (9) coccidioidomycosis, and (10) psittacosis.[90–92,118] Some of these infections are difficult to prevent, although zero infections should always be the goal. In some circumstances, however, a means to prevent the infection is obvious, at least in retrospect. For instance, a 22-year-old medical technology student contracted typhoid fever with complications after working

with *Salmonella typhi* as an unknown organism.[58]

51

TABLE 1-20 Classification of Biologic Agents by Risk[a]

Biosafety Level (BSL)	Class of Agents	Examples of Agents	Practices	Safety Equipment (Primary Barriers)	Facilities (Secondary Barriers)
1	Not known to cause disease consistently in healthy adults		Standard microbiologic practices	None required	Open bench top sink required
2	Associated with human disease Hazard = percutaneous injury, ingestion, or mucous membrane exposure	*Enterobacteriaceae* *Candida* spp. *Mycobacterium avium* complex Herpes simplex virus	BSL-1 practice plus: • Limited access • Biohazard warning signs • "Sharps" precautions • Biosafety manual defining any waste decontamination or medical surveillance practices	Class I or II BSCs or other physical containment devices used for all manipulations of agents that cause splashes or aerosols of infectious materials PPEs: laboratory coats, gloves, face protection as needed	BSL-1 plus: • Autoclave available
3	Indigenous or exotic agents with potential for aerosol transmission Disease may have serious or lethal consequences	*Mycobacterium tuberculosis* *Franciscella tularensis* West Nile virus	BSL-2 practices plus: • Controlled access • Decontamination of all waste • Decontamination of lab clothing before laundering • Baseline serum	Class I or II BSCs or other physical containment devices used for all manipulations of agents that cause splashes or aerosols of infectious materials PPEs: laboratory coats, gloves, face protection as needed	BSL-2 plus: • Physical separation from access corridors • Self-closing, double-door access • Exhausted air not recirculated • Negative airflow into laboratory
4	Dangerous or exotic agents which pose high risk of life-threatening diseases, aerosol-transmitted laboratory infections, or related agents with unknown risk of transmission	Arenaviruses that produce hemorrhagic fever (e.g., Lassa, Junin, Machupo) Filoviruses that produce hemorrhagic fever (e.g., Marburg, Ebola)	BSL-3 practices plus: • Clothing change on entering • Shower on exit • All material decontaminated on exit from facility	All procedures conducted in Class III BSCs or Class I or II BSCs in combination with full-body, air-supplied, positive-pressure personnel suit	BSL-3 plus: • Separate building or isolated zone • Dedicated supply and exhaust, vacuum, and decontamination systems • Other requirements listed in Reference[99]

[a]The safety level of many agents is increased when manipulations that might reasonably be expected to generate aerosols are performed or when large volumes of materials are employed. For some Level 2 agents, a higher level is indicated when cultures known to contain the agent are manipulated. A separate classification is used for agents in naturally or experimentally infected animals.
BSL, Biosafety level; BSC, Biologic safety cabinet; PPE, Personal protective equipment.

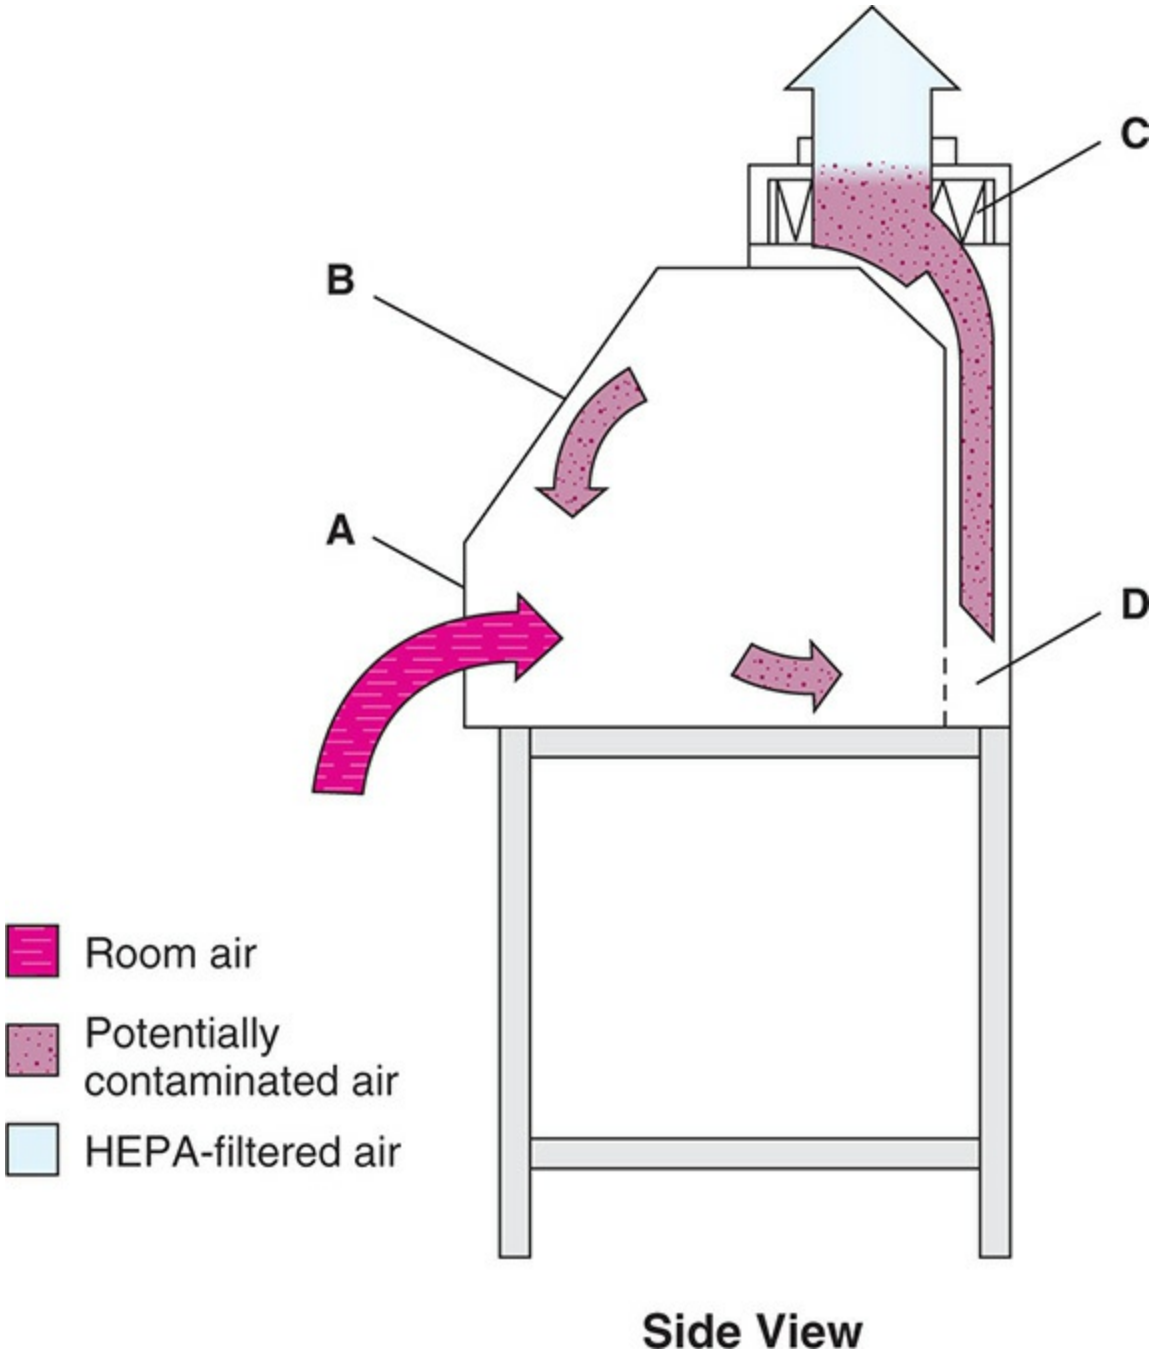
TABLE 1-21 Comparison of Biologic Safety Cabinets

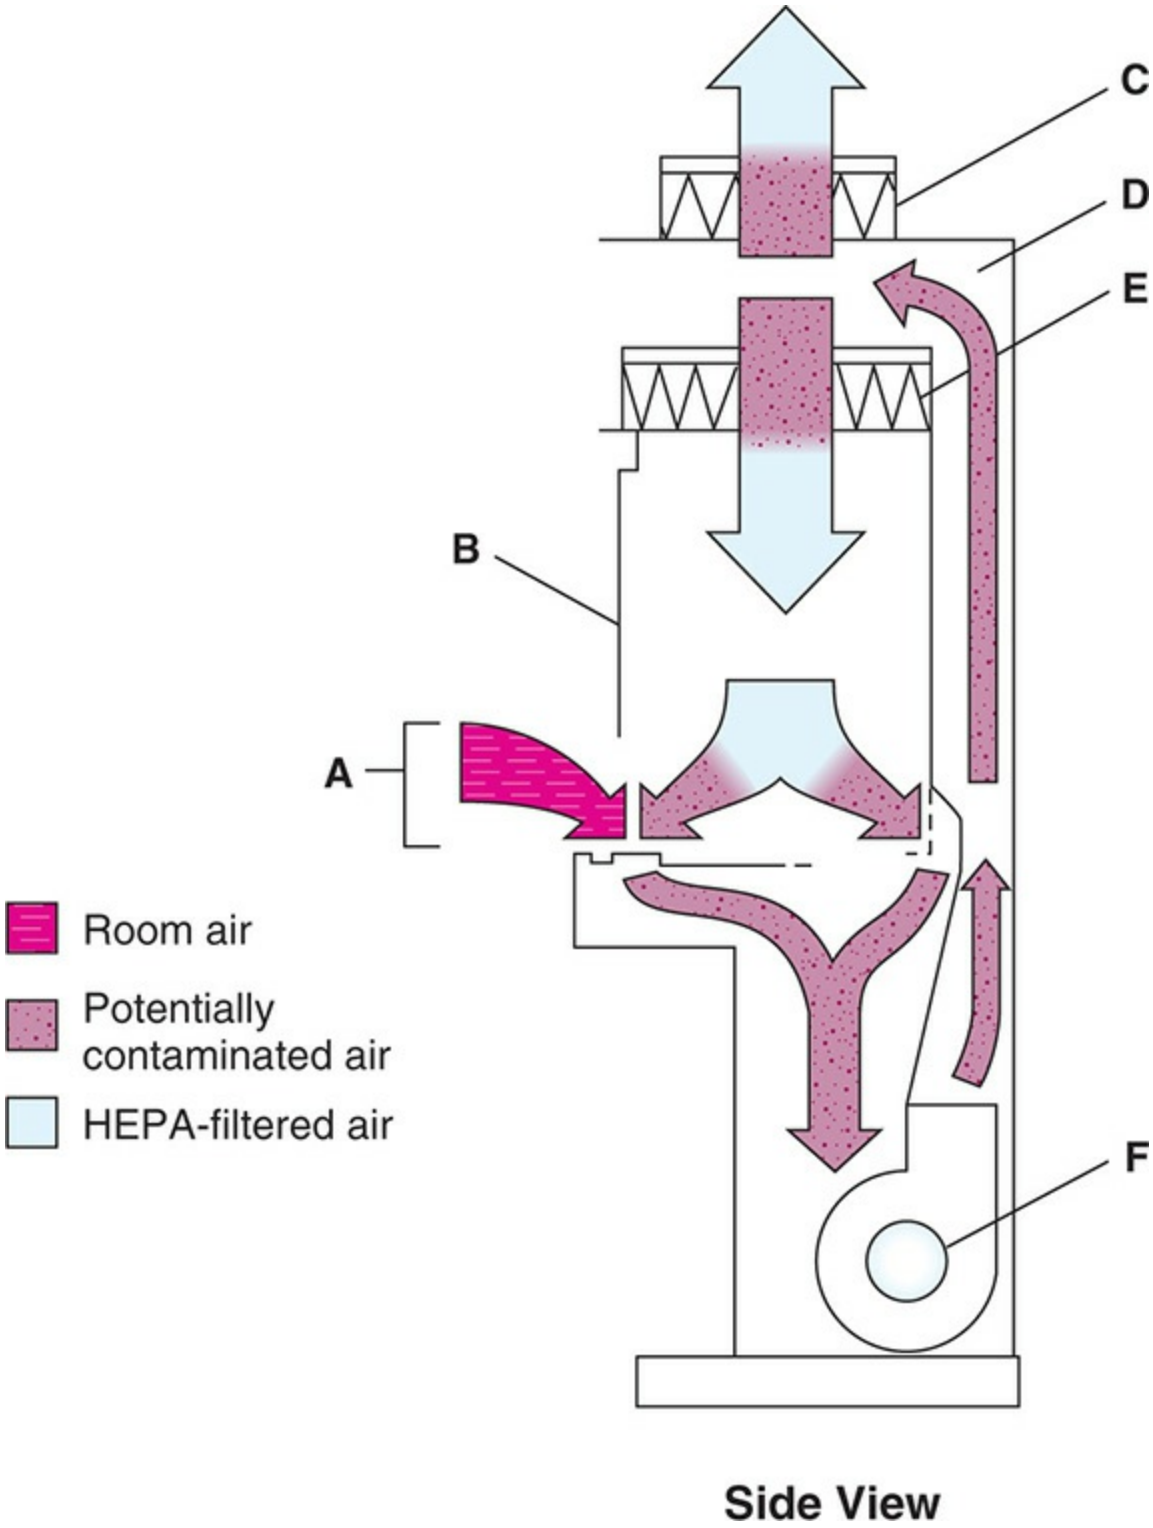
Type	Face Velocity (Lfpm)	Airflow Pattern	Radionuclides/ Toxic Chemicals	Biosafety Levels	Product (Specimen) Protection
Class 1 Open front	75	In at front; rear and top through HEPA filter (see Fig. 1-21)	No	2, 3	No
Class II Type A	75	70% recirculated through HEPA filter; exhaust through HEPA filter (see Fig. 1-22)	No	2, 3	Yes
Class II Type B1	100	40% recirculated through HEPA filter; exhaust via HEPA filter and hard ducted (see Fig. 1-23)	Yes (low levels/ volatility)	2, 3	Yes
Class II Type B2	100	No recirculation; total exhaust via HEPA filter and hard ducted (see Fig. 1-24)	Yes	2, 3	Yes
Class II Type B3	100	Same as IIA, but plena under negative pressure to room and exhaust air is ducted	Yes	2, 3	Yes
Class III	NA	Supply air inlets and exhaust through 2 HEPA filters (see Fig. 1-25)	Yes	3, 4	Yes

Lfpm, linear feet per minute; HEPA, high-energy particulate.
From reference 99.

52

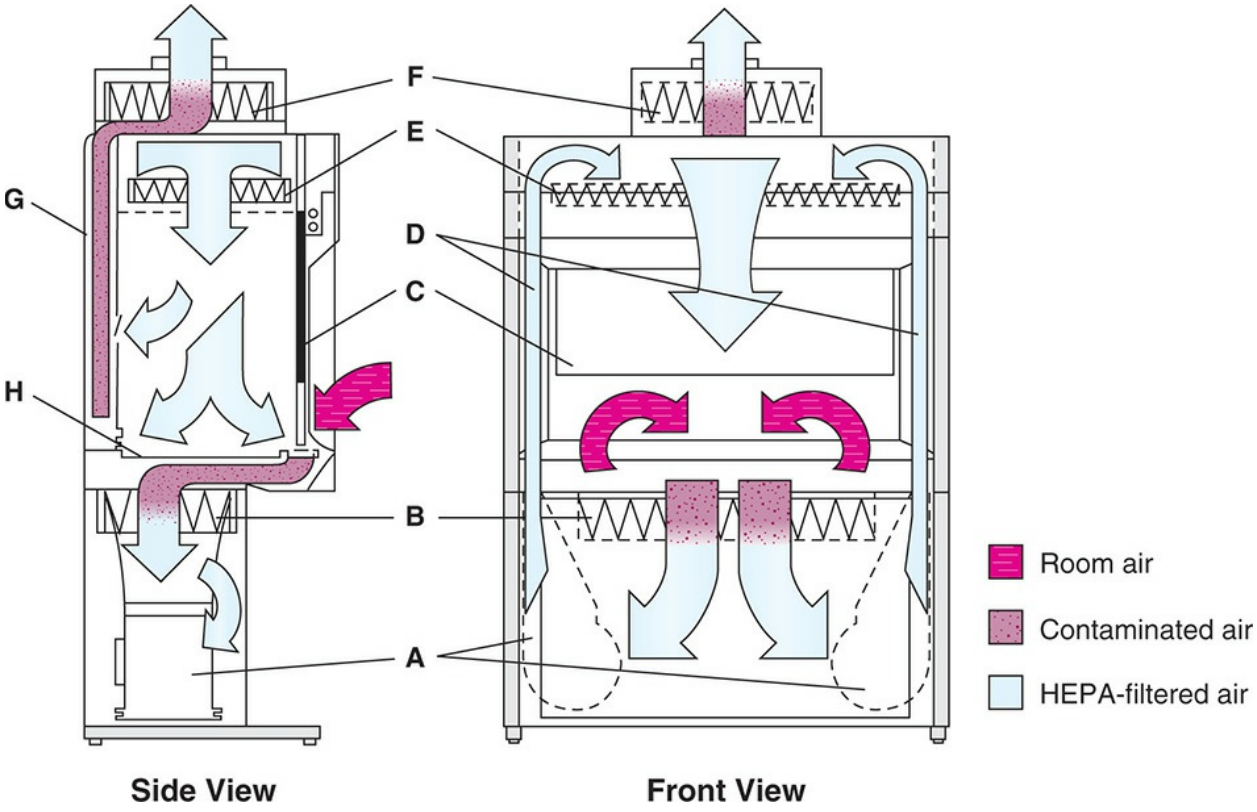


■ **FIGURE 1-21** Design of class I biologic safety cabinet (BSC). (**A**) These negative-pressure cabinets draw air from the room into the cabinet at a velocity of 75 fpm and exhaust it through a HEPA filter to the room or to the outside through a duct. It does not protect the specimen or sample from contamination with material present in room air. Because the specimen is not protected, these are uncommonly used in clinical microbiology, and have largely been replaced by class II units. (Adapted from reference 99.)



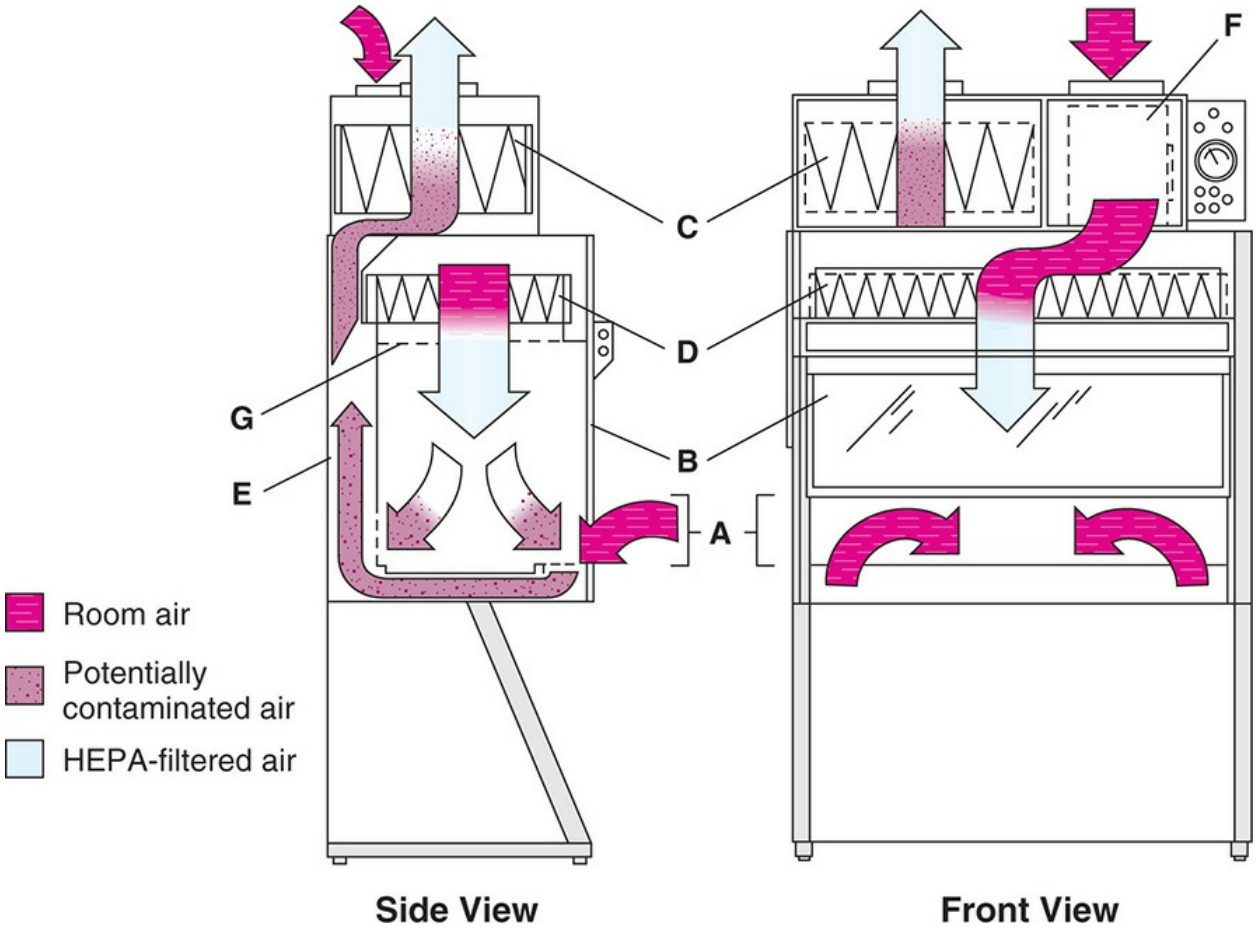
■ **FIGURE 1-22** Design of class II A biologic safety cabinet. Air is drawn from the room into the cabinet through the front opening (**A**), typically at a velocity of 75 fpm. It is then recirculated through a plenum (**D**) and a HEPA filter (**E**); a portion of the air, typically 70%, is recirculated into the workspace; the remainder is exhausted through the HEPA filter (**C**)

to the room. If the remainder is exhausted through a negative pressure plenum to the outside of the building, the cabinet is classified as class III B3. The work can be viewed through a glass sash (**B**). The blower is designated by (**F**). (Adapted from reference 99.)

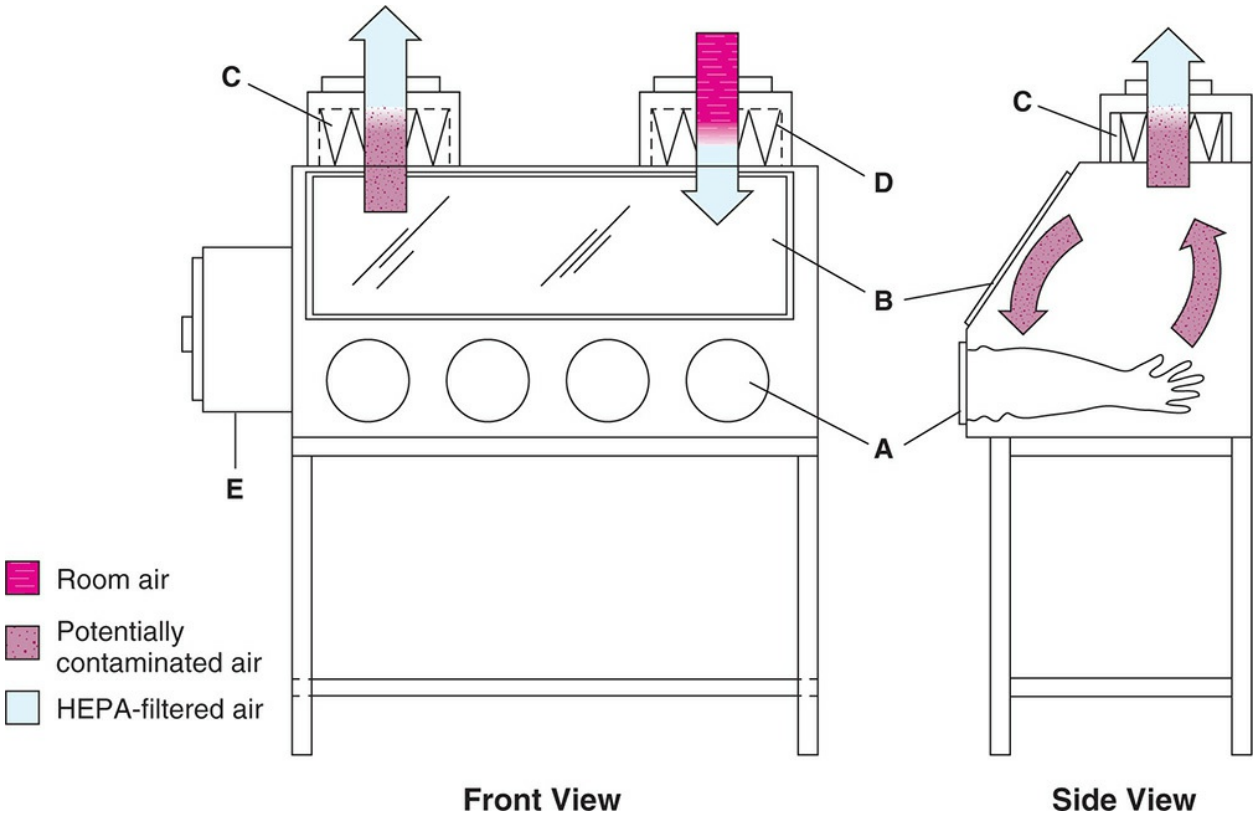


■ **FIGURE 1-23** Design of Class II B1 biologic safety cabinet. Air enters the cabinet from the room through the front opening at a velocity of 100 fpm. It is then recirculated (typically 40%) through a sump (**A**) and recirculating plenum (**D**), passing through HEPA filters (**B** and **E**) before being exhausted (**G**) through a HEPA filter (**F**) into negative pressure ducts to the outside. Because of minimal recirculation, limited quantities of low-level chemicals can be used in addition to biologic agents, but this should not be considered a chemical fume hood. The work space (**H**) can be viewed through a glass sash (**C**). (Adapted from reference 99.)

53



■ **FIGURE 1-24** Design of Class II B2 biologic safety cabinet. Air enters the cabinet from the room through the front opening (**A**) and is drawn into a cabinet plenum (**E**) before being exhausted to the outside through a HEPA filter (**C**) and a negative pressure duct system. Simultaneously, room air enters the cabinet through a second portal (**F**) and a HEPA filter (**D**), after which it passes down across the work area and then joins the outflow stream in the cabinet plenum (**E**). The work can be viewed through a glass sash (**B**). Toxic chemicals can be used in this cabinet that recirculates no air. (Adapted from reference 99.)



■ **FIGURE 1-25** Design of Class III biologic safety cabinet. This cabinet functions as a totally enclosed glove box with recirculating air. The hazardous agents are totally contained within the box, so the worker is not exposed. The same effect can be achieved if a Class II cabinet is used in conjunction with a biologic suit connected to an air supply for the worker, essentially isolating the worker and their air supply. Air enters through a portal and HEPA filter (**D**) before exhausting out through a HEPA filter (**C**) into a negative pressure duct system and the outside environment. The worker manipulates the samples through sealed gloves (**A**) and views the work through a glass shield (**B**). Samples are passed into the box through an interlock (**E**). The disadvantages of this approach include the difficulty of performing fine manipulations through thick rubber gloves. (Adapted from reference 99.)

54

Even worse, 22% of the technologists in a laboratory-developed gastroenteritis from *Shigella sonnei*. Typing of the isolates from the infected technologists revealed that these were all identical to one that had been given to a student as an unknown.[78] Some agents that would not be encountered in a clinical laboratory may cause infection in research workers,[5,37,57] sometimes when manipulations that produce aerosols are performed without adequate containment.

Universal Precautions. Ironically, laboratory workers are at considerably less risk of

acquiring infections than are their clinical colleagues. There are several reasons for this phenomenon. Patients sneeze and cough, whereas culture plates and clinical specimens can be handled in a safe, standardized manner that prevents infection. Unless procedures that produce large aerosols are performed in the laboratory, the risk for laboratory workers is relatively low. Physicians and nurses are much more likely to use sharp objects, such as scalpels and needles than are laboratory personnel. In modern medicine the greatest infectious risks are blood-borne pathogens. Technologists who work in microbiology are at lower risk than colleagues in other areas of the laboratory, such as chemistry and hematology, where large numbers of blood specimens are handled daily. The most serious laboratory-acquired infections are HIV, hepatitis B virus, and hepatitis C virus. Of these agents, hepatitis C virus is the most prevalent in most hospitals, because an effective vaccine is available for hepatitis B virus and the incidence of HIV in the general population is not as high as HCV. It is fortunate that an effective vaccine for hepatitis B virus exists, because the risk of an unimmunized worker contracting this infection is far greater than infection with hepatitis C virus or HIV.

Recommendations for minimizing blood-borne infections have been promulgated by CDC,[15–18] by the CLSI,[35] and by laboratory workers.[9]

The risks of contracting the major blood-borne pathogens are summarized in Table 1-22.[18]

It is usually not possible to predict those individuals who may harbor blood-borne pathogens, so the concept of **universal precautions** has arisen. That is, every specimen is considered a risk. Specifying some specimens as risky increases the possibility that a false sense of security will be engendered when dealing with the other specimens, which may in fact contain blood-borne pathogens.

The CDC and Occupational Health and Safety Administration (OSHA) have established the following universal precautions[13]:

1. Blood and body fluids from all patients must be handled as infectious material. These specimens from all patients should be assumed to be infectious (i.e., contain blood-borne pathogens).
2. All specimens of blood and body fluids should be put in a well-constructed container, with a secure lid, to prevent leaking during transport.
3. All persons who process blood and body fluid specimens (e.g., removing tops from vacuum tubes) should wear gloves—plus a face shield (or a mask with glasses or goggles); alternatively, they may work in a BSC that has adequate protection against splashes (i.e., a glass barrier between the specimen and the technologist).
4. Workers must change gloves and wash hands when finished processing specimens.

5. Workers should never pipette by mouth; they must use mechanical devices.
6. The use of needles and syringes should be limited to situations in which there is no alternative; needle-handling safety devices should be used.
7. Laboratory work surfaces should be decontaminated with an appropriate chemical germicide after a spill of blood or other body fluids and when work activities are completed.
8. Contaminated materials used in laboratory tests should be decontaminated before reprocessing, or, if disposable, these should be placed in bags and disposed of in accordance with institutional policies.
9. All persons should wash their hands after completing laboratory activities and should remove protective clothing before leaving the laboratory.

The recommendations for dealing with exposures vary by agent; recommendations are reviewed regularly by CDC and altered as necessary. In general, the source patient should be tested to determine if a risk exists and the injured worker should be followed to determine if infection has resulted. Postexposure immunization and/or prophylactic antiviral chemotherapy are appropriate in certain situations. These should be guided by infectious diseases physicians or other experienced clinicians. It must be emphasized strongly that primary attention should be given to prevention, so that the

problem of an accident never presents itself. Prevention can take the form of immunizing at-risk personnel and minimizing the exposure to "sharps" (needles, scalpel blades, broken glass, etc.), which are the most common sources of injury.

TABLE 1-22 Risks of Contracting Certain Blood-Borne Viral Infections After Needlestick Exposure to Blood[a]

Virus	Status of Source Patient	Outcome	Risk (%)
Hepatitis B	Positive for HBsAg and HBeAg	Clinical hepatitis	22–31
	Positive for HBsAg and negative for HBeAg	Clinical hepatitis	1–6
		Seroconversion	23–37
Hepatitis C	Seropositive	Seroconversion	0–7
HIV	Seropositive	Seroconversion	0.30

[a]The risk after contact of blood with mucous membranes is less well defined, but less than after needlestick exposure.
Data from reference 18.

Cleaning Spills of Infectious Materials. The recommended protocol for cleaning up skills of infectious material is[35]:

1. Wear gloves (preferably heavy-weight, puncture-resistant utility gloves), gowns, and masks.
2. If there are fragments of glass or other objects, they should be removed without touching them directly before proceeding.
3. Wear shoe covers that are impermeable to water if the spill is large.
4. Cover the spill with absorbent material and add concentrated disinfectant. After waiting 10 minutes, proceed with cleanup.
5. If aerosols may have been generated, as in a broken centrifuge tube, turn the centrifuge off but leave it closed for at least 30 minutes to allow any aerosols to settle.
6. Absorb the bulk of the spill with disposable materials before proceeding with disinfection.
7. Clean the spill site of all visible contaminating material with an aqueous detergent solution or a 10% solution of household bleach.
8. Decontaminate the site with an appropriate disinfectant (Table 1-19).
9. Absorb the disinfectant material and rinse the site with water. Dry the site a final time to prevent slipping.
10. Dispose of all materials in a biohazard container.

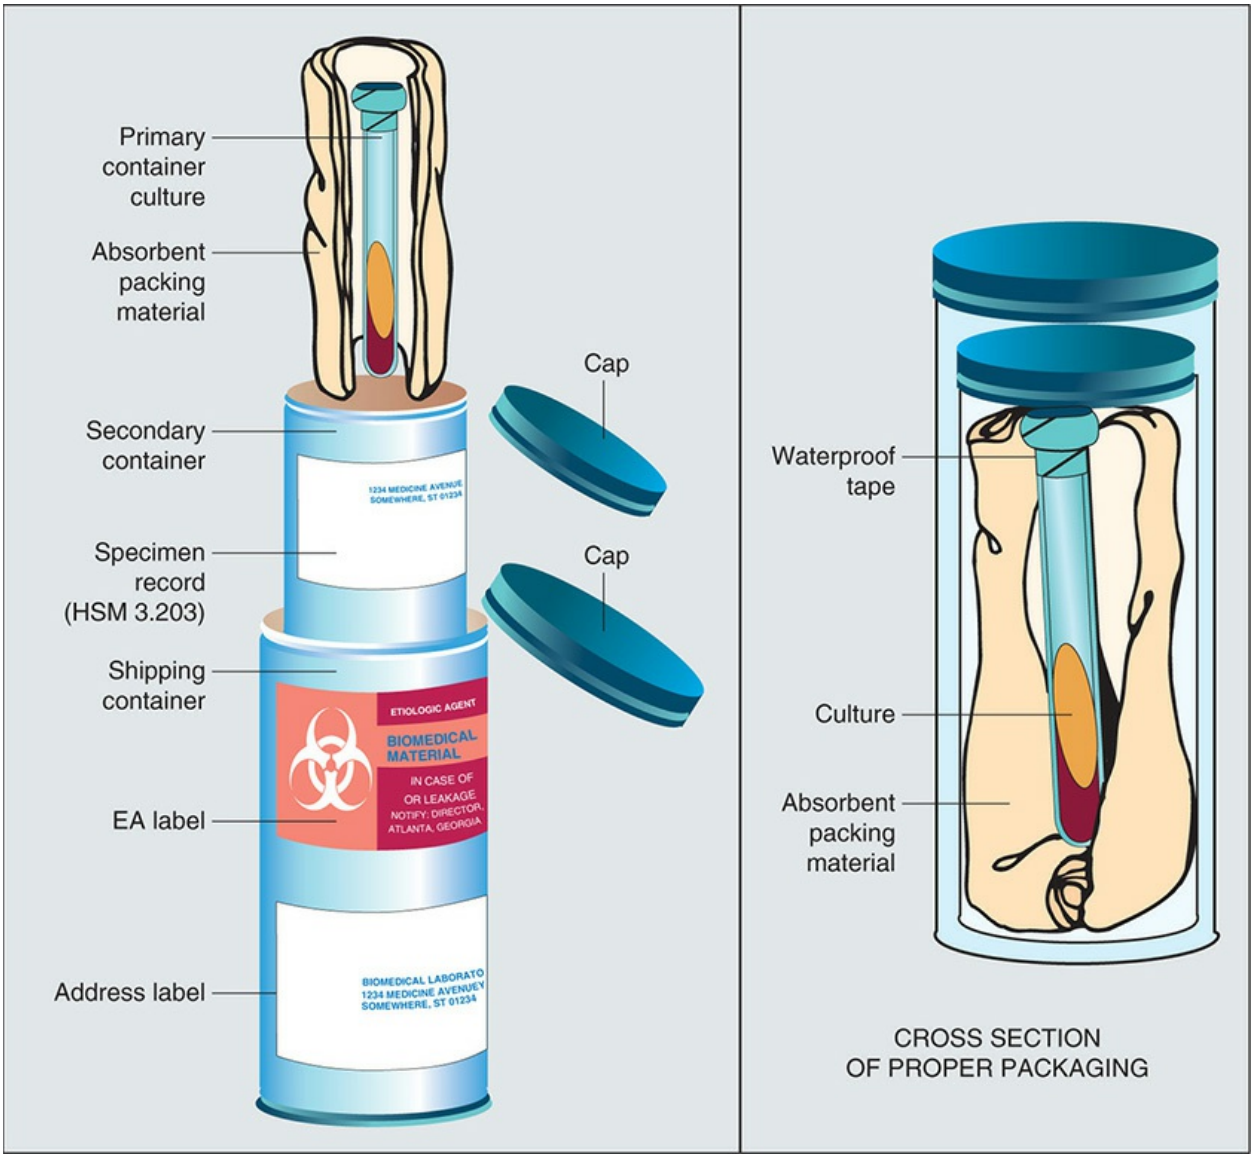
If a BSL-3 agent is spilled outside of a BSC, evacuate the area for at least 60 minutes, and notify the appropriate authorities according to your local policies.

Shipping of Specimens and Etiologic Agents. All microbiology specimens to be transported through the United States mail or commercial carriers must be packaged under strict regulations specified by the Department of Transportation (DOT) and the International Air Transport Association (IATA). Isolated organisms (etiologic agents) other than biosafety level 1 (Table 1-20) and diagnostic specimens reasonably expected to contain those etiologic agents must be appropriately packaged and labeled.

Specimens must be prepared to withstand shocks or pressure changes that may occur during handling and cause the contents to leak. A leaking container not only predisposes the specimen to potential contamination, but may also expose handlers or personnel at the receiving site to pathogenic agents. Figure 1-26 illustrates the proper packaging and labeling of etiologic agents. The primary container (test tube, vial) must be fitted with a watertight cap and surrounded by sufficient packing material to absorb the fluid contents should a leak occur. This container is then placed

in a watertight secondary container, preferably constructed of metal or rigid plastic, fitted with a screw-cap lid. The primary and secondary containers are then enclosed in an outer shipping carton constructed of corrugated fiberboard, cardboard or

Styrofoam.



■ **FIGURE 1-26** Proper technique for packaging of biologically hazardous materials.

Dry ice is considered a hazardous material. A shipping carton containing dry ice as a refrigerant for a specimen must be marked **"DRY ICE FROZEN MEDICAL SPECIMEN."** The packaging should be such that carbon dioxide gas can escape, preventing a buildup of pressure that could rupture the container. The dry ice should be placed outside the secondary container along with shock-absorbent material in such a manner that the secondary container does not become loose inside the outer container as the dry ice sublimates.

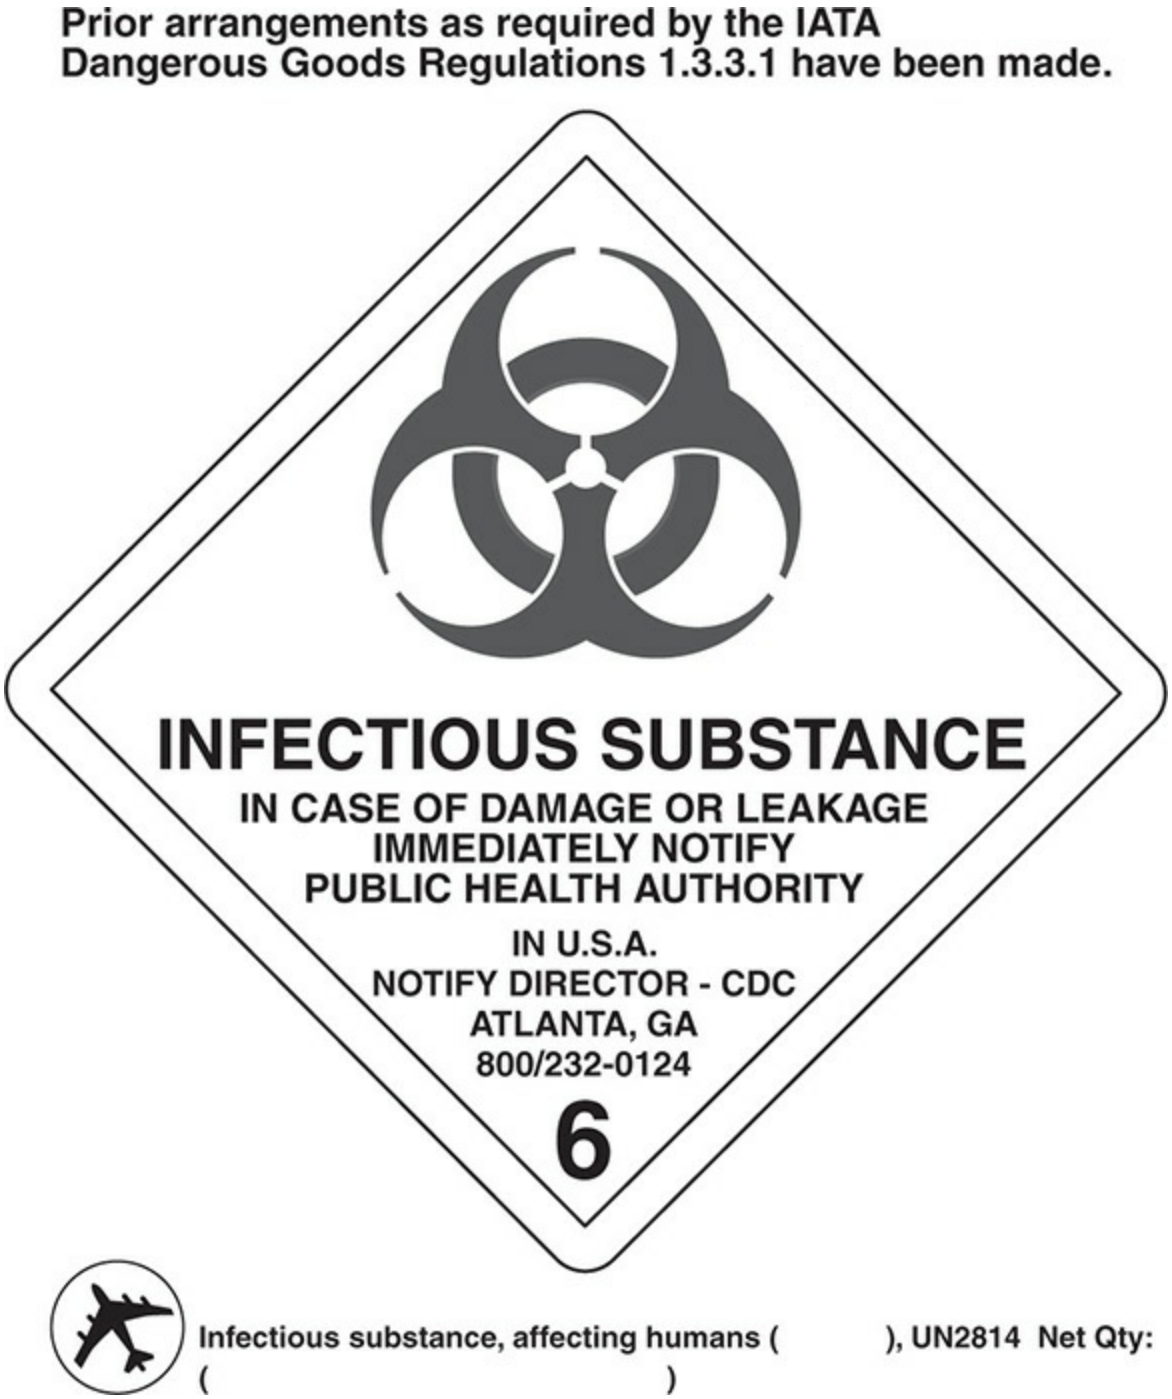
In addition to the address label, the outer container must also have the etiologic agents/biomedical material label (with its red logo against a white background) affixed as well as a notice to the carrier, as illustrated in Figure 1-27.

Individuals who package isolates and clinical specimen should have specialized training with respect to current regulations. The record of their certification should be maintained in their personnel files. Noncertified individuals should not ship microbial isolates or clinical specimens.

Nonbiologic Hazards

Chemicals

1. A chemical hygiene plan should be constructed for the laboratory.[31] Guidelines for managing laboratory waste are available.[29]



■ **FIGURE 1-27** Etiologic agents logo and "notice to carrier" that must be affixed to the outside of any package containing potentially hazardous or infectious materials.

2. Volatile combustible substances give off vapors along the surface of the liquid. The flash point is the lowest possible temperature at which a sufficient concentration of vapors is produced for a flame to occur. Volatile substances are collectively referred to as ignitables. The classification based on flash points and

boiling points is:

a. Flammables
   1) Class IA: Flash point, <73°F (22°C); boiling point, <100°F (38°C)
   2) Class IB: Flash point, <73°F (22°C); boiling point, >100°F (38°C)
   3) Class IC: Flash point, >72°F (21°C) and <100°F (38°C)

b. Combustibles:
   1) Class IIIA: Flash point, >140°F (60°C) and <200°F (94°C)
   2) Class IIIB: Flash point, >200°F (94°C)

A number of combustible materials may be found in the microbiology laboratory, although not in the quantities that are used in some other areas. A particular hazard is diethyl ether, which can form explosive peroxides after exposure to air. Ether has been used in some parasitology concentration procedures. Other alternatives that eliminate this hazard are now available and should be considered. If it is necessary to use ether, the smallest quantity possible should be stored appropriately.

3. Corrosive chemicals are defined as agents that have a pH <2.1 or >12.5 or that can corrode steel (SAE 1020) more than 0.25 inches per year at a temperature of 130°F. In the laboratory, the most common corrosives are strong acids, such as hydrochloric acid. Acid bottle carriers must be used for concentrated acids in quantities greater than 500 mL.

4. Incompatible chemicals (identified from MSDS) must not be used or stored together.

5. Storage safety cans and cabinets must be located away from sources of heat, flame, sparks, and exits. Storage areas should be adequately ventilated and of limited access to personnel. All flammable and corrosive chemicals should be stored in a fire-proof chemical storage cabinet according to local and national regulations.

6. All containers should be clearly labeled with

a. Content
b. Hazard warnings
c. Special precautions
d. Date received/prepared
e. Date opened/put in use
f. Expiration date
g. Manufacturer

7. In case of a liquid chemical spill[29,31]:

a. Determine the nature of the hazard by consulting the MSDS, if necessary. If the spill is an emergency, evacuate the area. If the material is a fire hazard,

eliminate all sources of ignition and take step to neutralize the chemical.

b. Notify the appropriate personnel and obtain additional help, if necessary. Identify any need for personal protective devices.

57

c. Confine the spill to as small an area as possible.

d. Neutralize acids with disodium carbonate. Neutralize alkalis with 1% boric acid. For larger amounts of acids or bases, flush with large amounts of water after neutralization.

e. Clean any areas that have been splashed by the spill.

f. For flammable and toxic liquid spills, use an absorbent to reduce the vapor pressure and prevent possible ignition of the liquid.

8. Disposal of chemicals:

a. Wear rubber gloves, a rubber apron, and goggles.

b. Remove all items from the sink designated for disposal. Start a nonsplashing stream of cold water into the sink.

c. Slowly pour the liquid as close to the drain as possible without splashing. Only quantities less than 500 mL can be disposed of in the sink drain.

d. Continue to run cold water for several minutes after completion.

e. Dispose of water-soluble organic solvents (methanol, acetone) as described in the foregoing. For water-insoluble organic liquids, only quantities less than 100 mL can be disposed of as just described. For quantities over 100 mL, consult with the hospital safety officer or the local Environmental Health and Safety Office.

9. Radiologic hazards: Formerly, clinical laboratories used radiochemicals, primarily for immunoassays. These procedures have been replaced by enzyme immunoassays or molecular methods. However, if any radioactive materials are used in the laboratory, appropriate regulations must be strictly followed. There is usually an institutional safety officer for radioactive materials, often in the Department of Radiology.

10. Carcinogens: Careful attention to safety issues is necessary for those chemicals that have been shown to have some neoplastic potential. In the microbiology laboratory, the most likely compound to be encountered in this category is formaldehyde. Formalin is a commercial stabilized solution of formaldehyde, usually used as a 10% buffered solution (4% formaldehyde). Formaldehyde is combustible as well as a potential carcinogen. Local regulations for storage, use, and disposal differ. In general, if formaldehyde is used, then the work area should be well ventilated, preferably a chemical exhaust hood should be used.

CAP requires monitoring of formaldehyde vapors in the workspace.

11. Mercury: Elemental mercury is a significant health hazard. In the microbiology laboratory, it is most often encountered in nonelectronic thermometers and in some fixatives in parasitology. Although only small quantities are involved, many institutions have elected, either voluntarily or because of local laws, to eliminate mercury entirely.

Fire

1. Every hospital employee is responsible for preventing fires and assisting in minimizing losses should fire occur.
2. Keep work areas free of trash accumulation and excess flammable materials. Corridors, passageways, aisles, and stairs must be kept free of obstructions that may inhibit exit or add fuel to a fire.
3. Be aware of ignition sources, open flames, heating elements, and spark gaps (motors, light switches, friction, and static). More than 22% of hospital fires are caused by faulty wiring.
4. Personnel should be instructed on the differences in, and use of, fire extinguishers for the four classes of fire:

a. Class A: Fires involving ordinary combustible materials such as wood, paper, cloth, and plastics. The use of a pressurized water extinguisher (type A) is acceptable.
b. Class B: Fires involving flammable liquids, such as alcohol, gasoline, kerosene, and grease; use a carbon dioxide extinguisher (type B).
c. Class C: Fires involving energized electrical equipment in which a resulting shock hazard owing to electrical conductivity may exist. De-energize the circuit and use a nonconductive extinguishing agent (i.e., never use a water extinguisher; use a dry chemical type extinguisher [type C]).
d. Class D: Fires involving combustible metals, such as magnesium and potassium. Special techniques are required. Never use water; use a dry power agent. Immediately call the local fire station.

5. Fire blankets are used to smother clothing by wrapping the victim in the blanket. If clothing should catch fire, drop to the ground and roll to smother the flame against the floor. Do not run for the blanket—airflow will only fan the flames and result in more serious injury. Similarly, a fire blanket should be used on the floor; wrapping the blanket around a standing person only creates a chimney for the flames.
6. Comply with all local fire regulations. Participate in periodic fire drills as conducted by the hospital. Each employee should know the fire drill procedure and the evacuation route for their area of the laboratory.

Biodefense

The possibility of terrorists using chemical, biologic, or radiologic agents has been real for many years, but the possibility took on new significance after (1) the tragedy at the World Trade Center and (2) the discovery of letters that contained anthrax spores and had been sent through the postal service soon thereafter. All laboratories are now required to limit certain agents to absolutely essential use and to provide the government with an inventory of those agents. In addition, each laboratory must prepare a biodefense plan for dealing with bioterrorism. Very few diagnostic laboratories will have one of the select agents on their premises (Table 1-23). The primary responsibility for dealing with most of these organisms falls to reference laboratories, public health laboratories, and other government laboratories. The primary responsibility of the diagnostic laboratory is to recognize the possibility of one of the listed agents in the normal course of doing assessing clinical specimens. Once the possibility of a select agent is recognized, then the agent is referred to a designated support facility, the proper authorities are notified, and residual specimens from which the agent was isolated must be destroyed. If terrorism is suspected, the investigation will quickly assume a criminal component. The categories of potential bioterrorism agents are summarized in Table 1-23.[14]

58

TABLE 1-23 Classification of Biologic and Chemical Agents With Potential for Terrorism

Category of Agent	Description of Category	Examples
Category A	• Easily disseminated or transmitted person-to-person • Cause high mortality with potential for major public health impact • Might cause public panic and social disruption AND • Require special action for public health preparedness	• Variola major (smallpox virus) • Bacillus anthracis (anthrax) • Yersinia pestis (plague) • Clostridium botulinum toxin (botulism) • Francisella tularensis (tularemia) • Filoviruses (Marburg and Ebola viruses) • Arenaviruses causing hemorrhagic fever
		• Coxiella burnetii (Q fever) • Brucella spp. (brucellosis) • Burkholderia mallei (glanders)

Category B	• Moderately easy to disseminate • Moderate morbidity and low mortality • Require enhanced disease surveillance	• Alphaviruses (e.g., eastern and western encephalomyelitis viruses) • Ricin toxin from Ricinus communis (castor beans) • ε-toxin of Clostridium perfringens • Staphylococcal enterotoxin B • Salmonella spp. • Shigella dysenteriae • Escherichia coli (O157:H7) • Vibrio cholerae • Cryptosporidium parvum
Category C	Emerging agents with: • Availability • Ease of production and dissemination • Potential for high morbidity, mortality, and public health impact	• Nipah virus • Hantaviruses • Tick-borne hemorrhagic fever viruses • Tick-borne encephalitis viruses • Yellow fever virus • Multidrug-resistant Mycobacterium tuberculosis

Adapted from reference 14.

The national preparedness plan for terrorism envisions a multilevel categorization of laboratories with a graded responsibility for evaluating potential threats. The classification of laboratories is detailed in Table 1-24. The original four categories have been compressed to three.[14]

Quality Assurance

Constant attention to the quality of work is a hallmark of good clinical laboratories. Quality assurance is the broad umbrella that covers several activities. These activities are sometimes known by slightly different terms at different institutions. Quality improvement or total quality improvement has given way to quality assurance, which now may be giving way to "continuous improvement." The basic message, however, is that microbiologists must constantly examine their methods and processes in an effort to improve performance, accuracy, and quality. Quality control is a traditional element that will be discussed separately.

Quality assurance can be accomplished entirely internally or may be done as part of

an external program. National consensus guidelines are available.[32,30] These programs should encompass all phases of the diagnostic cycle.[32]

Many of the features of a quality assurance program were discussed in the section on laboratory accreditation, which includes quality programs as a critical feature. Internal activities include documentation of the validation/verification for each new test introduced into the laboratory. The documentation of the utilization of the laboratory by clinicians is important, and may be part of a broader test utilization program. The performance of technical personnel in each task for which they are responsible must be documented. The comparability of morphologic observations among technologists performing the same tasks must be evaluated. Formal evaluation of the competencies of all personnel who perform laboratory tests (including nurses and physicians) is an accreditation requirement for all nonwaived tests. National consensus guidelines for setting up the program have been published.[28]

Evaluating laboratory performance can be improved by comparing your performance to that of your peers, using an external quality assurance program. CAP offers two such programs.[122,102] A parameter that is chosen for evaluation is referred to as an indicator.

The first program, called Q-Probes, consists of a one-time study on a single issue, such as the frequency of skin organisms in blood cultures (i.e., blood culture contamination rates). Each participating laboratory submits the results of a study that has been performed according to a defined protocol. The results of all participants are analyzed carefully and a critique is provided to all who have submitted results.

59

TABLE 1-24 Classification of Laboratories Involved in Investigation of Biologic or Chemical Terrorism

Level	Description	Examples
A	• Early detection of intentional dissemination of biologic or chemical agents • Initial processing of clinical specimens	• Hospital or public health laboratories • Low-level biosafety facilities
	• Core capacity for isolation and characterization of select bioterrorism agents • Serve to minimize higher-level laboratories from being	• Local and state public health

B (originally B and C)	overwhelmed with specimens • Advanced capacity for rapid identification of select agents, using culture and molecular techniques • Participate in test development and evaluation	laboratories • High-level federal laboratories • Academic medical centers
C (originally D)	• Highest level of containment and sophistication • Ability to detect engineered agents	• Select group of federal laboratories • Academic laboratories operating at highest containment level under federal contract

Adapted from reference 14.

In contrast, the Q-tracks program is a repetitive monitor of a limited number of indicators that have been judged to be particularly useful for assessment of laboratory performance. For instance, laboratory TAT for a particular analyte might be studied over time. It is then possible to plot performance over time in relation to peers.

A laboratory can also judge its performance against peers by participating in proficiency testing, as discussed previously.[25,109] Proficiency testing was initially provided by CAP as an educational tool for improving laboratory performance. After the introduction of the two CLIA laws, proficiency testing became a mandated part of doing business in laboratory medicine.

Quality Control

Quality control in the narrow sense has consisted of an ongoing, systematic assessment of work to ensure that the final product conforms to previously established tolerance limits of precision and accuracy.[3] Laboratory directors and supervisors must now realize that quality control is only one facet in the larger arena of quality assurance. Interested readers can access the current requirements of CAP for quality control (as well as safety and other important management issues) by downloading the Laboratory General Checklist from the College Web site (http://www.cap.org).

In a broad sense, quality control in microbiology is as much an art as it is a science. It involves intangible items such as common sense, good judgment, and constant attention to detail. Quality control programs should be organized, with well-defined objectives in mind and metrics should be documented to monitor, and if necessary improve, performance.

Components of a Quality Control Program. A basic microbiology quality control program contains several specific items that must be considered when implementing the various phases of the program. Bartlett[6] developed a quality control program and discusses different levels of activity ranging from basic to most advanced. Using his outline, a supervisor can select the level of activity that is appropriate for the personnel and volume of work in any given laboratory. These have been used and improved upon in the CLSI documents referenced throughout this text.

CAP has established standards for accreditation of medical laboratories, including an inspection checklist for microbiology laboratories. This checklist provides microbiology supervisors with valuable guidelines for making a point-by-point assessment of the quality control needs in their laboratories. Many of the requirements are embedded in the federal regulations of CLIA '88.

Regulations are constantly under review and may be revised. Some of the changes are more stringent than those of some deemed accreditation agencies, such as CAP; others are less stringent. By law, the deemed agencies must have standards that are at least as stringent as CMS, but their standards may be more stringent.

A significant and ongoing change is occurring during the writing of this chapter. This is the mandating of a new quality control plan by the CMS called the Individualized Quality Control Plan (IQCP). Guidance regarding this plan is available on the CMS website, www.cms.gov. Also look for guidance from CAP, CLSI, and the American Society for Microbiology.

At the onset, a quality control coordinator must be selected. The duties of the coordinator must be clearly established and appropriate authority conferred to the extent that problems can be efficiently handled when they arise. It is the responsibility of this coordinator to establish the minimal standards for quality control that are to be met by the laboratory and to outline the several steps to be taken for daily monitoring and surveillance of all facets of the program.

The coordinator should see that all activities are clearly described in a quality control manual. The quality control manual should also clearly outline the following:

1. The details of all quality control practices, such as the procedures and schedules for monitoring equipment function

2. The process for monitoring of all media and reagents for reactivity, expiration dates, and reaction patterns of appropriate challenge organisms
3. All proficiency testing results

Appropriate forms must be designed to collect data in the form of columns of numbers, graphs, or diagrams so that any item that is out of control can be detected

quickly. The coordinator also must review all control records and verify that all measurements that are out of control. There must be documentation of the corrective actions for all measurements that were out of control. A brief review of the several components of a quality control program follows.

Monitoring Laboratory Equipment. A preventive maintenance program should be established in all microbiology laboratories to ensure proper functioning of all electrical and mechanical equipment. Equipment should be checked at prescribed time intervals; certain working parts should be replaced after a specified period of use, even though they may not appear worn-out. A brief list of some of the equipment, the monitoring procedures to be carried out, and the frequency and tolerance limits is shown in Table 1-25. Assignments should be made among laboratory personnel to ensure that all inspections are carried out and all data are recorded accurately onto charts or in maintenance manuals. It is important to detect upward or downward trends immediately, so appropriate corrective action can be taken before serious errors result. The temperature of incubators, refrigerators, freezers, water baths, and heating blocks must be determined and recorded daily with a thermometer calibrated by the Bureau of Standards or with one that has been checked against a calibrated thermometer. The concentration of CO_2 in all CO_2 incubators must also be determined daily. For any reading that is outside of the established quality control range, the cause must be determined and the defect quickly corrected.

Monitoring Culture Media, Reagents, and Supplies. All media and reagents must be checked against appropriate controls for the proper reactivity. It has been recognized that many modern commercial media perform with a high degree or reliability. Consensus recommendations have been developed for the necessity of local quality control.[23] The few media with occasional quality control problems (e.g., chocolate agar, media for *C. jejuni,* and Thayer–Martin agar) should be subjected to control tests in each laboratory. Many others need not be tested if the manufacturer of the media provides documentation that the appropriate reactivity has been observed.

TABLE 1-25 Quality Control Surveillance Procedures of Commonly Used Microbiology Equipment

Equipment	Procedure	Schedule	Tolerance Limits
Refrigerators Freezers	Recording of temperature[a] Recording of temperature[a]	Daily or continuous Daily or continuous	2°C to –8°C –8°C to –20°C –60°C to –75°C
Incubators	Recording of temperature[a]	Daily or continuous	35.5°C ± 1°C
Incubators (CO_2)	Measuring of CO_2 content Use blood–gas analyzer or Fyrite[b] device	Daily or twice daily	5%–10%
Water baths	Recording of temperature[a]	Daily	36°C–38°C 55°C–57°C
Heating blocks	Recording of temperature[a]	Daily	±1°C of setting
Autoclaves	Test with spore strip *(Bacillus stearothermophilus)*	At least weekly	No growth of spores in subculture indicates sterile run
pH meter	Test with pH-calibrating solutions	With each use	±0.1 pH units of standard being used
Anaerobic jars	Methylene blue indicator strip	With each use	Conversion of strip from blue to white indicates low O_2 tension
Anaerobic glove box	*Clostridium novyi* type B culture	Run periodically	Growth indicates very low O_2 tension. It is used only where extremely low O_2 tension is required.
	Methylene blue indicator solution	Continuously or daily	Solution remains colorless if O_2 tension is low.
Serology rotator	Count revolutions per minute	With each use	180 rpm ± 10 rpm
Centrifuges	Check revolutions with tachometer	Monthly	Within 5% of dial indicator setting
Safety hoods	Measure air velocity[c] across face opening	Semiannually or quarterly	50 ft of airflow per minute ± 5 ft/min

[a]Each monitoring thermometer must be calibrated against a standard thermometer.

61

A list of suggested organisms and acceptable results for the culture media most commonly used in clinical laboratories is found in Table 1-26. Quality control stock organisms may be maintained in the laboratory by subculturing bacterial isolates recovered as part of the routine work. Alternatively, and more conveniently but also more costly, dried stock organisms may be purchased from culture collections, such as ATCC (American Type Culture Collection, 12301 Parklawn Dr., Rockville MD) or from commercial vendors. Each batch of media should be checked for reactivity and for appropriate support of microbial growth, either by the manufacturer or in the local laboratory.

Culture tubes, plates of media, and reagents must bear a label that clearly indicates the content and the dates of preparation and expiration. “Coded” culture tubes, plated media, and reagents should be referenced in such a way that even nonlaboratory personnel would be able to interpret the code. Clearly defined quality control rules apply to antimicrobial susceptibility testing.

Each batch of tubed or plated media must also undergo sterility testing, particularly media in which components are added after sterilization. Sterility checks must be done

both visually and by subculture. Certain selective media, for example, may sufficiently suppress the visible growth of bacteria; however, viable organisms may appear on subculture. Prepared media should also be observed for other signs of deterioration, such as discoloration, turbidity, color changes, evidence of freeze/thawing, and status of hydration.

The frequency with which quality control testing of media and reagents (including serologic reagents) is performed is clearly defined by various accrediting agencies. Some of the rules for quality control of media and reagents are displayed in Table 1-27. Recommendations for quality control are not static. It is important to follow current recommendations, at least in part, because changes are as likely to result in less work as in more work.

TABLE 1-26 Quality Control of Commonly Used Media: Suggested Control Organisms and Expected Reactions

Medium	Control Organisms	Expected Reactions
Blood agar	Group A Streptococcus	Good growth, β-hemolysis
	S. pneumoniae	Good growth, α-hemolysis
Bile–esculin agar	Enterococcus species	Good growth, black
	α-Hemolytic	No growth; no discoloration of media
	Streptococcus, not group D	
Chocolate agar	*Haemophilus influenzae*	Good growth
	Neisseria gonorrhoeae	Good growth
Christensen urea agar	*Proteus mirabilis*	Pink throughout (positive)
	Klebsiella pneumoniae	Pink slant (partial positive)
	Escherichia coli	Yellow (negative)
Simmons citrate agar	*K. pneumoniae*	Growth or blue color (positive)
	E. coli	No growth, remains green (negative)
Cystine trypticase (CTA) agar Dextrose	*N. gonorrhoeae* *Moraxella catarrhalis*	Yellow (positive) No color change (negative)

Sucrose	*E. coli*	Yellow (positive)
	N. gonorrhoeae	No color change (negative)
Maltose	Salmonella species, or N. meningitidis	Yellow (positive)
	N. gonorrhoeae	No color change (negative)
Lactose	*N. lactamicus*	Yellow (positive)
	N. gonorrhoeae	No color change (negative)
Decarboxylases Lysine	*K. pneumoniae*	Bluish (positive)
	Cronobacter sakazakii	Yellow (negative)
Arginine (dihydrolase)	*E. cloacae*	Bluish (positive)
	Proteus mirabilis	Yellow (negative)
Ornithine	*P. mirabilis*	Bluish (positive)
	K. pneumoniae	Yellow (negative)
Deoxyribonuclease (DNase)	*Serratia marcescens*	Zone of clearing (add 1 N HCl)
	E. cloacae	No zone of clearing

62

Eosin–methylene blue agar	*E. coli*	Good growth, green metallic sheen
	K. pneumoniae	Good growth, purple colonies, no sheen
	Shigella flexneri	Good growth, transparent colonies (lactose negative)
Hektoen enteric agar	*Salmonella typhimurium*	Green colonies with black centers
	S. flexneri	Green transparent colonies
	E. coli	Growth slightly inhibited, orange colonies

Indole (Kovac's)	*E. coli*	Red (positive)
	K. pneumoniae	No red color (negative)
Kligler iron agar	*E. coli*	Acid slant/acid deep
	Shigella flexneri	Alkaline slant/acid deep
	Pseudomonas aeruginosa	Alkaline slant/alkaline deep
	Salmonella typhimurium	Alkaline slant/black deep
Lysine iron agar	*S. typhimurium*	Purple deep and slant, + H^2S
	Shigella flexneri	Purple slant, yellow deep
	P. mirabilis	Red slant, yellow deep
MacConkey agar	*E. coli*	Pink colonies (lactose positive)
	P. mirabilis	Colorless colonies, no spreading
	Enterococcus species	No growth
Malonate	*E. coli*	No growth
	K. pneumoniae	Good growth, blue (positive)
Motility (semisolid agar)	*P. mirabilis*	Media cloudy (positive)
	K. pneumoniae	No feather edge on streak line (negative)
Nitrate broth or agar	*E. coli*	Red on adding reagents
	Acinetobacter lwoffi	No red (negative)
Phenylethyl alcohol blood agar	Streptococcus species	Good growth
	E. coli	No growth
o-Nitrophenol-β-D-galactopyranoside (ONPG)	*Serratia marcescens*	Yellow (positive)
	Salmonella typhimurium	Colorless (negative)
Phenylalanine deaminase	*P. mirabilis*	Green (add 10% FeCl3)

	E. coli	No green (negative)
Salmonella–Shigella (SS) agar	*S. typhimurium*	Colorless colonies, black centers
	E. coli	No growth
Voges–Proskauer	*K. pneumoniae*	Red (add reagents)
	E. coli	No development (negative)
Xylose–lysine–dextrose (XLD) agar	Salmonella species	Red colonies (positive lysine)
	E. coli	Yellow colonies (positive sugars)
	Shigella species	Transparent colonies (negative)

63

TABLE 1-27 Quality Control of Selected Reagents and Media[a]

Media or Reagents	Frequency	Controls
Gram's stain	Each new batch of stains and at least weekly	Gram-positive and gram-negative organism
Other nonimmunologic, nonfluorescent stains	Each day of use and each new batch, lot number, and shipment	Appropriate reactivity
Fluorescent stains	Each time of use	Appropriate reactivity
Catalase, coagulase, oxidase, bacitracin, optochin, ONPG, X or V or XV disks, identification systems	Each new batch, lot number, or shipment	Positive and negative controls
Antisera (Salmonella and	Each new batch, lot number, and shipment when prepared or	Positive and negative controls

Shigella)	opened and once every 6 months thereafter	Positive and negative controls
β-Lactamase (other than Cefinase)	Each day of use	Positive and negative controls
β-Lactamase (Cefinase)	Each new batch, lot number, or shipment	Positive and negative controls
Nucleic acid probes	Each day of use	Positive and negative controls
AFB stains	Each day of use	Positive and negative controls
Antimicrobial susceptibility tests	Daily or weekly if criteria met (see Chapter 17)	Appropriate organisms

Note: This will change with the implementation of IQCP in the future, but functions as a guide for quality control.

Introduction

67

In this chapter, we focus on the steps necessary for the diagnosis of infections. In each of the sections that follow, signs and symptoms of patients with infections that involve the major organ systems will be presented. Procedures for collection, transport, and processing of specimens are described. This information is summarized in Table 2-1. Otherwise stated, this chapter will predominantly consider the preanalytical phase of the diagnostic cycle. Later phases will be considered only briefly because they are the subject of most of the succeeding chapters. Joint guidelines concerning the utilization of the microbiology

TABLE 2-1 The Diagnosis of Bacterial Infections at Different Body Sites

Site of Infection	Presenting Signs and Symptoms	Specimens to Culture	Bacterial Species Potentially Associated with Infections
Respiratory tract	Upper tract—nose sinuses: Headache Pain and redness over malar area Rhinitis Radiograph: Sinus consolidation, fluid levels, or membrane thickening	Acute: Nasopharyngeal swab Sinus washings Chronic: Sinus washings Surgical biopsy specimen	*Streptococcus pneumoniae* *Streptococcus*, β-hemolytic group A *Staphylococcus aureus* *Haemophilus influenzae* *Klebsiella* spp. and other *Enterobacteriaceae* *Bacteroides* spp. and other anaerobes (sinus)
	Upper tract—throat and pharynx: Redness and edema of mucosa Exudation of tonsils Pseudomembrane formation Edema of uvula Gray coating of tongue/"strawberry tongue" Enlargement of cervical nodes	Swab of posterior pharynx Swab of tonsils (abscess) Nasopharyngeal swab	*Streptococcus*, β-hemolytic group A *Corynebacterium diphtheriae* *Neisseria gonorrhoeae* *Bordetella pertussis*
	Lower tract—lungs and bronchi: Cough: bloody or profuse Chest pain Dyspnea Consolidation of lungs: Rales and rhonchi Diminished breath sounds Dullness to percussion Radiographic infiltrates Cavity lesions Empyema	Sputum (poor return) Blood Bronchoscopy secretions Transtracheal aspirate Lung aspirate or biopsy	*Streptococcus pneumoniae* *Haemophilus influenzae* *Staphylococcus aureus* *Klebsiella pneumoniae* and other *Enterobacteriaceae* *Moraxella catarrhalis* *Legionella* spp. *Mycobacterium* spp. *Fusobacterium nucleatum, Prevotella melaninogenicus* and other anaerobes *Bordetella* species
Middle ear	Serous or purulent drainage Deep pain in ear and jaw Throbbing headache Red bulging tympanic membrane	Acute: No culture Nasopharyngeal swab Tympanic membrane aspirate Chronic: Drainage of external meatus	Acute: *Streptococcus pneumoniae* and other streptococci *Haemophilus influenzae* Chronic: *Pseudomonas aeruginosa* *Proteus* spp. Anaerobic bacteria
Gastrointestinal tract	Upper—stomach and duodenum: Gastritis and peptic ulcer disease	Gastric or duodenal biopsy	*Helicobacter pylori*
	Lower—small and large intestine: Diarrhea Dysentery Purulent Mucous Bloody Cramping abdominal pain	Stool specimen Rectal swab or rectal mucus Blood culture (typhoid fever)	*Campylobacter jejuni* and other *Campylobacter* spp. *Salmonella* spp. *Shigella* spp. *Escherichia coli* (toxigenic strains) *Vibrio cholerae* and other *Vibrio* spp. *Yersinia* species *Clostridium difficile* (demonstration of toxin)
Urinary tract	Urinary bladder infection: Pyuria Dysuria Hematuria Pain and tenderness; suprapubic or lower abdomen Kidney infection: Back pain Tenderness: costovertebral angle (CVA)	Clean-catch midstream urine Catheterized urine Suprapubic aspiration of urine	*Enterobacteriaceae* *Escherichia coli* *Klebsiella* spp. *Proteus* spp. *Enterococcus* spp. *Pseudomonas aeruginosa* *Staphylococcus aureus, S. epidermidis,* and *S. saprophyticus*

Genital tract	Males: Urethral discharge: serous or purulent Burning on urination Terminal hematuria	Urethral discharge Prostatic secretions	*Neisseria gonorrhoeae* *Haemophilus ducreyi* *Treponema pallidum* (syphilis) *Mobiluncus* spp. and other anaerobes *Gardnerella vaginalis*
	Females: Purulent vaginal discharge Burning on urination Lower abdominal pain, spasm, and tenderness Mucous membrane chancre or chancroid	Uterine cervix Rectum (anal sphincter swab) Urethral swab Darkfield examination	Nonbacterial: *Trichomonas vaginalis* *Candida albicans* *Mycoplasma* spp. *Chlamydia trachomatis* Herpes simplex virus
Central nervous system	Headache Pain in neck and back Stiff neck Straight-leg raising: positive Kernig sign Nausea and vomiting Stupor to coma Petechial rash	Spinal fluid Subdural aspirate Blood culture Throat or sputum culture	*Neisseria meningitidis* *Haemophilus influenzae* *Streptococcus pneumoniae* Streptococcus, β-hemolytic groups A and B (group B in infants) *Enterobacteriaceae:* debilitated patients, infants, and postcraniotomy *Listeria monocytogenes*
Eye	Conjunctival discharge: serous or purulent Conjunctival redness (hyperemia): pink eye Ocular pain and tenderness	Purulent discharge Lower cul-de-sac Inner canthus	*Haemophilus* spp. *Moraxella* supp. *Neisseria gonorrhoeae* *Staphylococcus aureus* *Streptococcus pneumoniae* *Streptococcus pyogenes* *Pseudomonas aeruginosa* (report immediately)
Blood	Spiking fever Chills Cardiac murmur (endocarditis) Petechiae: skin and mucous membranes "Splinter hemorrhages" of nails Malaise	Blood: two to three cultures; repeat as needed Any suspected primary site of infection: Cerebrospinal fluid Respiratory tract Skin—umbilicus Skin—ear Wounds Urinary tract	*Streptococcus* spp. Group A—all ages Viridans group streptococci (endocarditis) Groups A, B, D—neonates *S. pneumoniae* *Staphylococcus aureus* *Listeria monocytogenes* *Corynebacterium jeikeium* *Haemophilus influenzae* "HACEK" (*Haemophilus* species, *Aggergatibacter aphrophilus, Aggregatibacter actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens*, and *Kingella* species) Group *Escherichia coli* and other "coliforms" *Salmonella enterica* serogroup Typhi *Pseudomonas aeruginosa* *Bacteroides fragilis* and other anaerobic bacteria
Wounds	Discharge: serous or purulent Abscess: subcutaneous or sub-mucosal Redness and edema Crepitation (gas formation) Pain Ulceration or sinus formation	Aspirate of drainage Deep swab of purulent drainage Tissue biopsy	*Staphylococcus aureus* *Streptococcus pyogenes* *Clostridium* spp., *Bacteroides* spp., and other anaerobic bacteria *Enterobacteriaceae* *Pseudomonas aeruginosa* *Enterococcus* species
Bones and joints	Joint swelling Redness and heat Pain on motion Tenderness on palpation Radiograph: synovitis or osteomyelitis	Joint aspirate Synovial biopsy Bone spicules or bone marrow aspirate	*Staphylococcus aureus* *Haemophilus influenzae* *Streptococcus pyogenes* *Neisseria gonorrhoeae* *Streptococcus pneumoniae* *Enterobacteriaceae* *Mycobacterium* species

laboratory were published in 2013 from the American Society for Microbiology (ASM) and Infectious Diseases Society of America (IDSA).[7]This is a guideline to which every student of clinical microbiology should have ready access.

Infections of the Respiratory Tract

The respiratory tract is divided into the upper and lower respiratory tract. The upper respiratory tract consists of the nose, throat, oropharynx, and nasopharynx. The lower tract includes the larynx, trachea, bronchi, bronchioles, and the terminal airways or alveoli of the lungs. The middle ear, which is connected to the posterior pharynx through the eustachian tube, the salivary glands, which are connected to the oral cavity by ducts, and the paranasal sinuses, which are connected to the nasal cavity by ostea, will also be considered here.

Infections of the Upper Respiratory Tract

Indigenous Microbiota. Diagnosis of upper respiratory infections is complicated in that microorganisms that may be pathogens are also often present in the uninfected individual as part of their normal microbiota. Even *Streptococcus pyogenes* may be found, usually in small numbers, in the throats of asymptomatic individuals, which is the reason that following a streptococcal pharyngitis culture or other testing is not recommended as a "test of cure." There are certain organisms, such as *Neisseria gonorrhoeae*, that are never considered part of the normal microbiota.

The oropharyngeal microbiota of normal individuals is composed mainly of viridans streptococci, β-hemolytic streptococci, *Staphylococcus aureus*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, many anaerobic bacteria including *Fusobacterium* spp. and *Actinomyces israelii*, and yeast including *Candida albicans.* These microorganisms inhabit the upper respiratory tract without causing disease. In patients who are sick and have been admitted to the hospital, the indigenous microbiota switches from predominantly gram-positive (mostly streptococci) to predominantly gram-negative (*Enterobacteriaceae* and *Pseudomonas* spp.).[134] The reason for this alteration may be related to the loss of fibronectin, which enhances binding of gram-positive bacteria, from the surfaces of oropharyngeal epithelial cells.[286,338] This increased quantity of gram-negative bacteria in the nasopharynx of hospitalized patients is problematic for these patients should an aspiration event occur, as once these bacteria are displaced from the mucosal surface to the lung, pneumonia and/or lung abscess often ensues.

Pharyngitis. Acute pharyngitis is the most common infection of the upper respiratory

tract. By far the most important pathogen is *S. pyogenes* (group A β-hemolytic *Streptococcus*). Viral infection is the other common cause of pharyngitis.[25]

Streptococcal Pharyngitis. *S. pyogenes* pharyngitis may be suggested clinically by observing an inflamed and edematous pharyngeal mucosa in a patient who reports throat pain, difficulty swallowing, and secondary symptoms such as fever, headache, and tender anterior cervical lymph nodes. Occasionally, these patients may develop a scarlatiniform rash. Purulent exudates over the posterior pharynx and tonsillar area are commonly observed. The clinical presentations of streptococcal and nonstreptococcal pharyngitis overlap broadly.[26] Although diagnosis by clinical criteria alone has been advocated, the prevailing opinion is that it is impossible to determine the cause from clinical observations and that diagnostic support from the laboratory is required.[27]

The presence of a tough, fibrinous, gray membrane ("pseudomembrane"), pus exuding from abscesses or from draining sinuses, and mucosal ulcerations suggests an infectious disease other than acute streptococcal pharyngitis or advanced, invasive disease. In such instances, a diagnostic approach that addresses other pathogens, in addition to group A *Streptococcus*, is necessary.

β-Hemolytic streptococci other than group A (groups C and G) produce symptoms similar to, but milder than, those of group A strains.[25] They are not associated with rheumatic fever as a noninfectious sequela. Although group A strains may be found in the oropharynx occasionally in small numbers, groups C and G strains are regular colonizers. It is, therefore, more difficult to interpret isolation of small quantities of these organisms. If they are recovered in pure culture or as the predominant organism, it is reasonable to report their presence with a note about their clinical significance and interpretation.

The traditional standard for diagnosis of streptococcal pharyngitis has been bacterial culture on sheep blood agar, which remains an acceptable method for detection. Rapid methods for detection of group A streptococcal antigen are widely used in laboratories and at the point of care in offices and clinics. Most of the assays have high specificity, but the sensitivity is not good enough to depend on a negative result.[25] Newer methods that employ automated readers, and in some instances immunofluorescence, have increased the sensitivity of these assays. It has been the common practice that a negative rapid test should be followed by a bacterial culture, given the limited sensitivity of these assays. However, practice guidelines from the IDSA no longer recommend the routine use of throat culture as a backup for adults with usual pharyngitis and a negative antigen-detection test.[267] There have been no changes with respect to backup throat cultures for children with pharyngitis. Additionally, it is important to review the package insert of the rapid antigen-detection test used, as backup testing may be necessary for accreditation compliance purposes.

The primary advantages of antigen-detection tests are that they allow expedited treatment of patients who are detected, thus reducing the period of discomfort and

allowing the patient to return to school or work sooner. The frequency of noninfectious sequelae (rheumatic fever and glomerulonephritis) is not increased by using conventional culture for diagnosis. The rapid antigen tests add expense, and although many are waived, many of them are classified as moderately complex (see Chapter 1)—with attendant investment of time and effort by clinical staff. There is little justification for performing "rapid" tests in a central laboratory, because the patient will already have gone home by the time the result is available. Each clinician must make a determination as to the utility of performing the antigen tests.

There are molecular alternatives to culture for the detection of group A *Streptococcus.* A genetic probe for group A *Streptococcus* is available (GASDirect, Hologic, San Diego, CA) as an acceptable alternative to culture, although some have demonstrated it to be slightly less sensitive than

70

enhanced culture.[50] In contrast, there have been a large number of studies that demonstrate the improved sensitivity of polymerase chain reaction (PCR) for group A *Streptococcus* over culture. Although the detection rates are improved with PCR, one must always consider the possibility of detecting *S. pyogenes* that is part of the normal microbiota in some individuals. A highly sensitive assay, such as a PCR assay, could give a positive result for group A *Streptococcus* in a setting wherein this organism was part of the normal microbiota of the patient, but the pharyngitis was due to a viral etiology. Currently, there is no way to determine whether the positive group A *Streptococcus* result is from an etiologic agent or bystander microbiota; quantitative information available from real-time PCR assays could be potentially useful in this regard. There are at least two rapid molecular diagnostic assays that have or are seeking "waived" status for use in the point-of-care setting at the time of this writing. Group A *Streptococcus* assays may be detected by these methods in the future, which would obviate the need for the reflex testing.

Diphtheria. Diphtheria is now extremely rare in the United States.[25] It is primarily an infection of children, in whom it occurs in sporadic outbreaks, but adults may become infected, particularly those in lower socioeconomic groups.[115] The thick blue-white or gray membrane that covers the posterior pharynx, with marked edema of the underlying and surrounding tissues, can usually be differentiated from the bright-red throat of acute streptococcal pharyngitis.

The diagnosis is made by culture of the membrane on Loeffler's medium or tellurite selective medium. This organism can be differentiated from other *Corynebacterium* species by matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry. Once *Corynebacterium diphtheriae* is detected, it must be determined if the organism produces toxin. Specimens for culture of *C. diphtheriae*

are best referred to a reference or public health laboratory (see Chapter 14). These laboratories may also offer PCR-based assays for this organism and/or the lysogenic-bacteriophage that encodes the toxin.

***Arcanobacterium haemolyticum* Pharyngitis.** This bacterium causes acute pharyngitis that closely mimics streptococcal pharyngitis, including a scarlatiniform rash in many patients. In fact, this organism is more likely to produce a scarlatiniform rash than group A *Streptococcus.* It usually affects adolescents and young adults, in contrast to β-hemolytic streptococci, which typically cause disease in young children.[25] *A. haemolyticum* is better isolated on human blood agar than on sheep blood agar, but can be recovered in the clinical laboratory. It may inadvertently be dismissed as a non–group A *Streptococcus*, if Gram's stain and/or a catalase test are not performed (see Chapter 14).

Gonococcal Pharyngitis. Oropharyngeal infection by *N. gonorrhoeae* may be asymptomatic, produce pharyngitis that is indistinguishable from group A *Streptococcus*, or may be associated with disseminated disease.[25] It should be suspected in women and homosexual men who practice fellatio. Clinicians must indicate this possibility so that media for recovery of gonococcus can be inoculated. Culture on media that support the growth of *N. gonorrhoeae* is recommended, but some have validated oropharyngeal swabs for nucleic acid amplification tests.

Viral Pharyngitis. A variety of viruses may cause pharyngitis, including adenovirus, rhinovirus, coronavirus, parainfluenza virus, influenza virus, and the Epstein–Barr virus (EBV). Infection with EBV deserves special mention. After a nonspecific, febrile prodromal phase of infection by EBV, an acute pharyngitis with tonsillar enlargement, white exudates and cervical lymphadenopathy ensues. Palatal petechiae may be present.[25] Subsequently, systemic signs and symptoms of infectious mononucleosis, including hematologic abnormalities, hepatosplenomegaly, and generalized lymphadenopathy, make the diagnosis more obvious. In the early stages, the pharyngitis may suggest streptococcal disease, but adolescents and young adults are most commonly symptomatically infected. The diagnosis is made on a serologic basis. A similar illness may occur as part of the acute retroviral syndrome, caused by human immunodeficiency virus, but the onset is more acute and exudates are not seen. A disseminated maculopapular rash is common in the acute retroviral syndrome, but it is rarely seen in infectious mononucleosis unless ampicillin has been administered.

Adenoviruses produce an acute pharyngitis that resembles streptococcal pharyngitis closely. Conjunctivitis often is present in addition, a clue to the etiology (pharyngoconjunctival fever). Some enteroviruses, (e.g., serotypes of Coxsackie A) virus produce acute pharyngitis with vesicles in the posterior pharynx as part of hand, foot, and mouth disease. The infection typically occurs in children and is readily diagnosed clinically by the occurrence of cutaneous and mucosal vesicles. Herpes

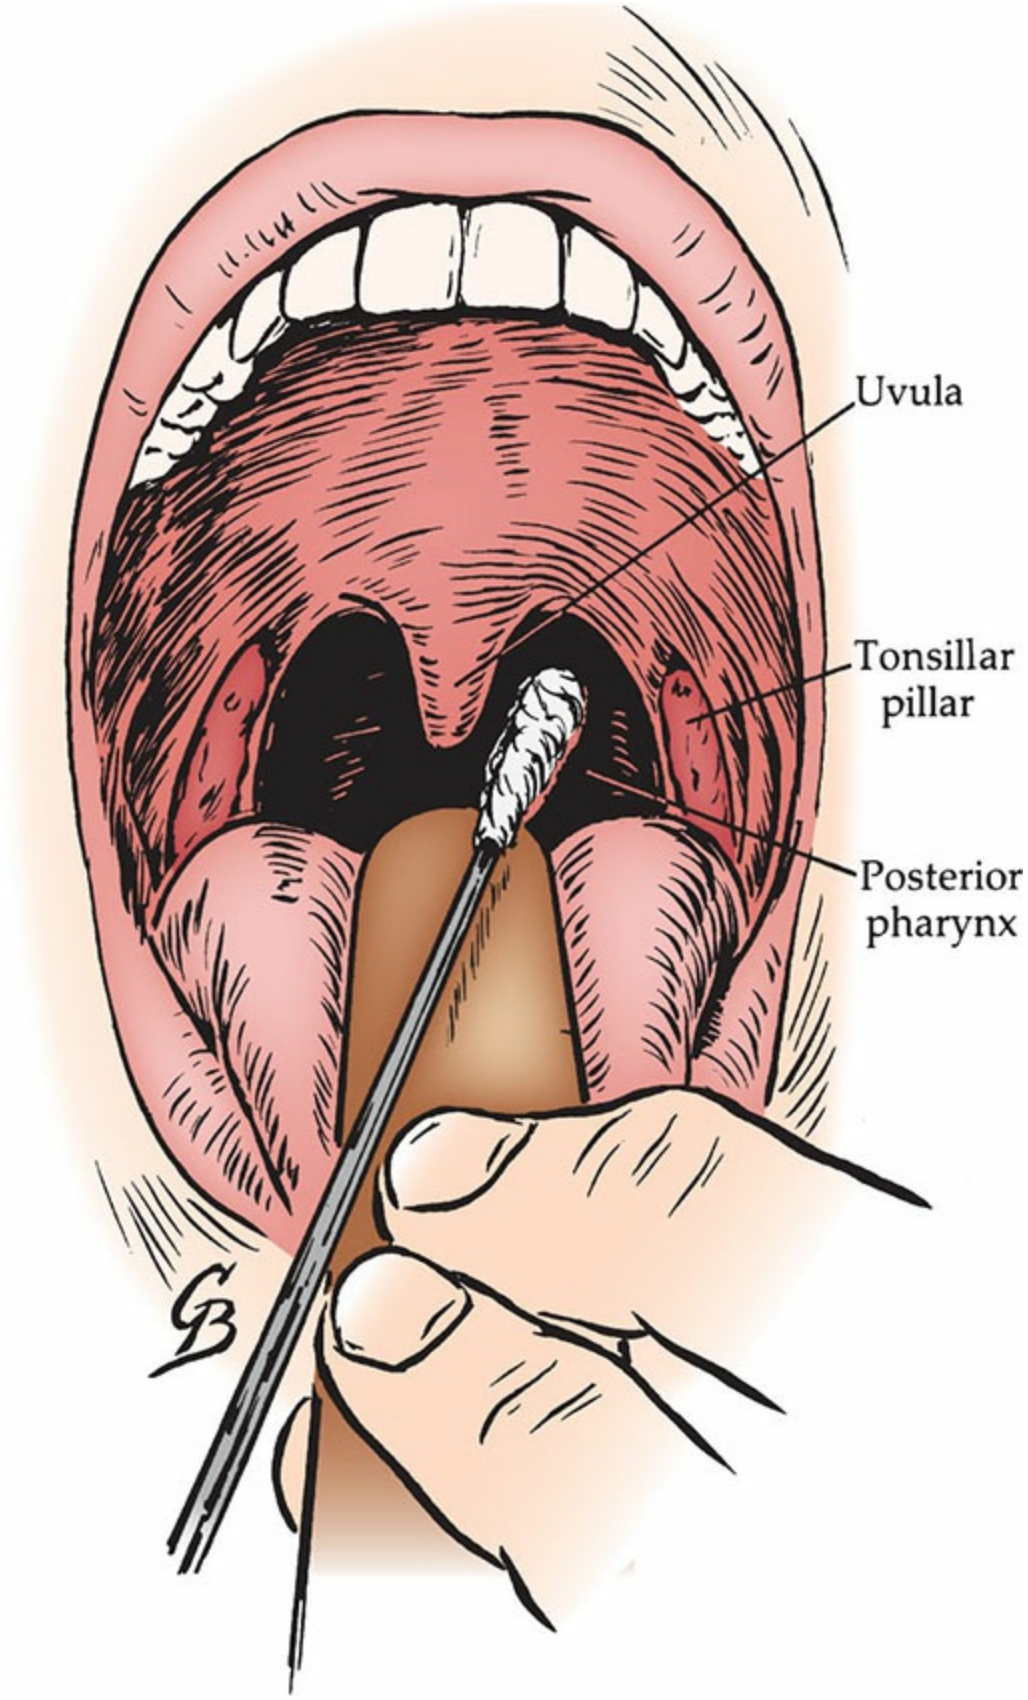
simplex virus pharyngitis has been described in young adults, but this virus is found in asymptomatic individuals, as is adenovirus. More details about the viral infections are found in Chapter 23.

Other Infectious Causes of Pharyngitis. *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae* have been described as causes of pharyngitis, but more commonly cause disease in the lower respiratory tract. *Candida* spp., especially *C. albicans*, produces a tenacious, creamy exudate when it infects the oropharynx (i.e., thrush), but does not produce prominent pharyngitis. Cytomegalovirus may cause the infectious mononucleosis syndrome, as part of the primary infection with this virus. As noted, a number of respiratory viruses may cause pharyngeal discomfort as part of an acute respiratory illness.

The joint IDSA and ASM guidelines state that *H. influenzae, S. aureus, Neisseria meningitidis,* and *S. pneumoniae* are not etiologic agents of pharyngitis and should not be sought in throat cultures.[7] For this reason the request of "Full Throat Culture," wherein every bacterium that grows is identified, should be discouraged. The default test should be a "Streptococcal Culture" or "Streptococcal Screen."

Collection of Throat Cultures. The proper method for obtaining a throat swab specimen is shown in Figure 2-1. A bright light from over the shoulder of the specimen collector should be focused into the oral cavity so that the swab can be guided to the posterior pharynx. The patient is instructed to tilt the head back and breathe deeply. The tongue is gently depressed with a tongue blade to visualize the tonsillar fossae and posterior pharynx. The swab is extended between the tonsillar pillars and behind the uvula. Care should be taken not to touch the lateral walls of the buccal cavity or the tongue to minimize contamination with commensal bacteria. Having the patient phonate a long "ah" serves to lift the uvula and helps prevent gagging. The tonsillar areas and the posterior pharynx should be firmly rubbed with the swab. Any purulent exudate should also be sampled.

71



Uvula
Tonsillar pillar
Posterior pharynx
GB

■ **FIGURE 2-1** Throat culture technique. The patient is asked to open the mouth widely and phonate an "ah." The tongue is gently depressed with a tongue blade and a swab is guided over the tongue into the posterior pharynx. The mucosa behind the uvula and between the tonsillar pillars is swabbed with a gentle sweeping motion.

After collection, the swab should be placed immediately into a sterile tube or other suitable container for transport to the laboratory. If the recovery of only group A β-hemolytic streptococci is desired (i.e., a "strep screen"), swabs may be allowed to dry during transport without compromising the recovery of viable organisms. Some reference laboratories recommend that swab tips be placed in a desiccant, such as silica gel, to suppress survival of commensal organisms and improve the recovery of *S. pyogenes*. Swabs for the recovery of viral agents should be placed in a special transport medium (see Chapter 23), although some microbiologists have found swabs in transport medium designed for bacteria to be acceptable for viral culture.[274]

Infections of the Oral Cavity Other Than Pharyngitis. Gingivitis and dental caries are caused by bacteria, but are primarily a concern for dentists, rather than physicians. In actuality, bacteria cause very few infections of the nasal and oral cavities, other than pharyngitis. Given the impossibility of collecting a surface culture of these spaces without including the abundant indigenous microbiota, cultures of lesions for bacteria will not produce interpretable results.

Necrotizing, ulcerative gingivostomatitis (Vincent's infection, Vincent's angina, or "trench mouth") is a synergistic infection caused by multiple oral anaerobic bacteria. It is rarely encountered today. Culture is not indicated. The condition may be accompanied by sepsis and metastatic infection, however, so blood cultures should be obtained in patients with this disease. Observing gram-negative fusiform bacilli and spirochetes in Gram-stained smears prepared from an ulcerative buccal or gingival ulcer is helpful for presumptive diagnosis of Vincent's angina. Cultures of the mouth and oral cavity are rarely helpful because of the presence of many species of commensal anaerobes.

Capnocytophaga spp., fusiform bacteria that are normally present in the oropharynx, have also been associated with ulcerations of the oral mucosa and positive blood cultures, particularly in patients with severe neutropenia.[318] These organisms may be recovered on selective media for pathogenic *Neisseria* because of their resistance to vancomycin, colistin, and trimethoprim. By using a selective medium similar in formulation to selective *Neisseria* medium, Rummens and associates[244] recovered *Capnocytophaga* spp. from 96% of oropharyngeal cultures compared with only a 6% recovery on chocolate agar plates inoculated in parallel.

Fungi may also cause infections of the oral cavity. The most common fungal infection in this location is thrush. White patches on the oral mucosa or the more

extensive involvement of the oral cavity with production of a thick, curd-like exudate is caused by *Candida* spp., especially *C. albicans*. A diagnosis that can be made by observing pseudohyphae and budding blastoconidia in a Gram-stained smear of the exudate. If the clinical history reveals a long-standing, nonhealing mucosal ulcer in the oral cavity, the possibility of the cutaneous extension of a systemic fungal disease must be considered. A biopsy of tissue for histologic study and direct examination of exudative material and culture should be performed in such instances. A black eschar on the hard palate in a neutropenic patient suggests the possibility of invasive zygomycosis, which is a medical emergency. In this scenario, an emergent frozen section should be performed, as well as a direct examination and culture. The differentiation of the mucoraceous hyphae of a zygomycete from the hyaline septate hyphae of *Aspergillus* or a similarly appearing mold is of critical importance since voriconazole, a commonly used antifungal drug, is of no use in the treatment of zygomycosis.

Herpes simplex virus, predominantly serotype 1, may produce an acute gingivostomatitis as a part of primary infection. Most individuals are exposed as children and young adults. The vesicular lesions occur on the skin of the face and the mucosa of the lips, but they may extend into the anterior portions of the mouth. Traditionally the diagnosis may be made by demonstrating infected cells in a stained smear (Tzanck preparation), but this is no longer the preferred method. More commonly, the detection of the virus is made by direct fluorescent antibody (DFA) testing or culture. Nucleic acid amplification assays could also be used in this setting following appropriate validation.

Infections of the Nasopharynx and Nasopharyngeal Cultures. The most frequent infection of the nasopharynx is the "common cold," usually caused by one of more than 100 serotypes of rhinovirus. This infection is rarely life-threatening, although we now recognize that the lower respiratory tract and even other organ systems may be affected.[79] The common cold is, however, a major cause of

72

morbidity and the large numbers of lost workdays makes it a potent economic force. The ubiquity of this infection is illustrated by the fact that, although very few of us will have had tuberculosis or hemorrhagic fever, we will all have experienced the discomfort of the common cold. The predominant symptom is coryza (i.e., runny nose). Fever is not a part of the infection. Laboratory studies are not necessary, because the illness is self-limited and specific therapy is not yet available. However, the detection of rhinovirus and/or coronaviruses is now possible using some of the commercially available multiplex respiratory viral panels. The detection of one of these viruses as the etiologic agent may be useful, particularly when conjoined with the

exclusion of other respiratory viral pathogens, such as influenza and respiratory syncytial virus (RSV).

Obtaining nasopharyngeal specimens is of little practical value, except in a few defined situations. Nasopharyngeal swabs are of limited value for establishing the diagnosis of acute otitis media[256] or bacterial sinusitis,[85] but they are the specimen of choice for the isolation of *Bordetella pertussis*, the etiologic agent of whooping cough.[124] These specimens are also useful for molecular testing for *M. pneumoniae* and *C. pnuemoniae.* Nasopharyngeal swabs and aspirates are equally effective for the diagnosis of viral respiratory infections,[95] although some virologists prefer aspirates for recovery of RSV.

Nasopharyngeal specimens are obtained under direct vision using over-the-shoulder illumination. With the thumb of one hand, gently elevate the tip of the nose. Moisten the tip of a small flexible nasopharyngeal wire swab with sterile water or saline and gently insert it into one of the nares. Guide the swab backward and upward along the nasal septum until a distinct feel of resistance indicates that the posterior pharynx has been reached. Gently remove the swab. If while guiding the swab undue resistance is met, attempt the procedure through the opposite nares. Leave the swab in contact with the posterior nasopharynx for 15 to 30 seconds if the patient can tolerate the discomfort. Newer flocked swabs with a higher surface area are becoming favored for the delivery of a higher quality specimen.

Otitis Media and Sinusitis. The middle ear and the paranasal sinuses are connected to the upper airway by ducts. Infections, primarily caused by viruses and bacteria, result when pathogens that populate the nose and throat make their way into the normally sterile middle ear and sinus.[89,109,314] Acute infections are caused by respiratory viruses and by certain bacteria—*S. pneumoniae*, *M. catarrhalis* and *H. influenzae*.[118] When the infection becomes chronic, facultatively aerobic gram-negative bacilli, anaerobic bacteria and fungi assume a prominent role in a polymicrobial infection.[70,89] It is virtually impossible to obtain an interpretable specimen by sampling the airway.

Sampling these structures for culture is difficult. Fortunately, the pathogens in acute disease are predictable, so antimicrobial therapy can be initiated without the necessity of invasive procedures. In chronic diseases, invasive procedures and surgical approaches may be required.

Epiglottitis. Acute bacterial epiglottitis, which was most commonly caused by *H. influenzae* type B,[186] is a life-threatening infection, but fortunately the incidence of this disease has been substantially reduced by immunization. Acute epiglottitis is a medical emergency. Swelling of the epiglottis can block the airway unless relieved by tracheostomy or expert directly visualized intubation. Most historians believe that

George Washington died from acute epiglottitis, which was treated by repeated bleeding.[198] The youngest of his three consulting physicians wanted to try the newly developed technique of tracheostomy on our first President, but he was overruled by his "wiser" superiors. The diagnosis of epiglottitis must be made clinically, because touching the epiglottis to obtain a sample can aggravate the obstruction. In *Haemophilus,* epiglottitis blood cultures were frequently positive.

Laryngitis. Acute laryngitis and (more commonly) laryngotracheobronchitis (croup) are most commonly caused by respiratory viruses. The parainfluenza viruses are likely the most common of laryngotracheobronchitis, but it may be a component of disease caused by a variety of respiratory viruses. *M. pneumoniae* is another common cause.[69] Rarely, the herpes simplex virus may cause tracheitis.

Other Infections of the Upper Respiratory Tract. Infection of the soft tissues of the head and neck usually originate in the oral cavity and are caused by organisms that reside there normally. Retropharyngeal abscesses and infection of the retropharyngeal space (quinsy) are infectious complications of streptococcal tonsillitis and pharyngitis. Compression of the airway can result; this also represents a medical emergency.[106] Sampling of peritonsillar abscesses must be done by percutaneous aspiration to avoid contamination with oropharyngeal microbiota.

Similarly, dental infections can extend into the adjacent soft tissues, resulting in abscesses, or into bone, causing osteomyelitis. Chronic draining infections of the neck may be caused by *A. israelii* (actinomycosis),[35,321] a component of the oropharyngeal microbiota in a minority of individuals. Material from the draining sinus must be collected by aspiration or curetting; a swab is not adequate to recover the concretions (sulfur granules) in which the bacteria are concentrated. Alternatively, gauze may be placed over the draining sinus to collect the granules that become enmeshed in the interstices of the cloth. Draining material can be placed in a Petri dish, diluted with sterile water, and examined for the concretions. If the granules are crushed, demonstration of branching gram-positive bacilli establishes the diagnosis. The crushed granule can then be cultured anaerobically to determine the specific cause.

Historically, mycobacterial infection also caused cervical lymphadenopathy, and the lymph nodes often drained to the surface of the skin (scrofula). It was commonly caused by *Mycobacterium bovis*, which entered the body through the oropharynx after being ingested in contaminated milk. Pasteurization eradicated this form of infection. Tuberculous lymphadenopathy usually follows primary pulmonary disease. Today, in resource-rich countries with a low incidence of tuberculosis, the most common mycobacterial infection of cervical lymph nodes is caused by members of the *Mycobacterium avium* complex (MAC) and primarily affects young children.[21] Lemierre's syndrome is a life-threatening infection of the oropharynx with extension

into the cavernous sinus and other important anatomic structures in the head and neck. It is characteristically associated with *Fusobacterium necrophorum,* but other bacteria may also be

73

involved. This commonly presents as a sore throat followed by neck pain and a neck mass. The extension of this infection causes into the cavernous sinus results in internal jugular vein thrombosis. Overall, 5% of the patients with this disease will die.[140]

The most common infection of the salivary glands in past years was mumps, but effective immunization has essentially eliminated the infection. Bacterial infection of the parotid glands is uncommon, but when it occurs is often caused by *S. aureus*.

Infections of the Lower Respiratory Tract

The lower respiratory tract consists of all structures below the larynx. The structures and infections considered here include the trachea (tracheitis), bronchi and bronchioles (bronchitis and bronchiolitis) and the distal air spaces (pneumonia).

Tracheobronchitis. Acute infections can be caused by bacteria or viruses. In children, viral and mycoplasmal agents predominate.[69] Symptoms include cough, fever, and varying degrees of sputum production. A distinctive illness, characterized by an inspiratory whoop and peripheral lymphocytosis, is caused by *B. pertussis* or *B. parapertussis*, which usually produces a milder illness.[31] The characteristic whoop of whooping cough is not present in the initial phases of illness, however. Apneic spells (absence of breathing) are common, but not lethal. Adenoviruses may produce a similar syndrome, although their etiologic role is controversial. Herpes simplex virus may cause disease, particularly in the infected neonate and those with other underlying severe illness. *C. pneumonia* is a recognized pathogen that causes acute bronchitis as well as pneumonia.

Chronic tracheobronchitis is symptomatically similar to acute disease, but more prolonged and less intense. Bacteria causes predominate, particularly *S. pneumoniae*, nonencapsulated *H. influenzae* and *M. catarrhalis*.

Prolonged acute disease may overlap with chronic bronchitis. *M. pneumoniae* has classically been associated with a lingering cough, but it is now recognized that *B. pertussis* can produce chronic illness in older children, adolescents, and adults[260] and *C. pneumoniae* may result in a lingering illness.[112]

Viral infections are usually not diagnosed with laboratory support unless the illness is sufficiently severe to require hospitalization. Whooping cough, *M. pneumoniae,* and *Chlamydophila* infection are diagnosed by culture or, increasingly, by molecular

methods. Serologic studies, consisting of either the detection of immunoglobulin M (IgM) or a rise in the immunoglobulin G (IgG) titer are often sought in patients suspected to be infected by *M. pneumoniae* and *C. pneumophila.* There are now Food and Drug Administration (FDA)-approved molecular assays for the detection of *Bordetella,* the sensitivity of which exceeds that of culture. Chronic bronchitis is usually evaluated by sputum culture if the illness is sufficiently severe. Special requests must be made if *Bordetella*, *Mycoplasma,* or *Chlamydophila* is considered.

Bronchiolitis. Infection of the smallest airways before the distal air spaces is dominated by viruses and *M. pneumoniae*.[117,336] Bronchiolitis affects infants and young children primarily and it occurs most commonly during the winter months. After a prodromal period of upper respiratory infections, primarily coryza, the predominant symptoms are cough, wheezing, and stridor (i.e., difficulty breathing). The differential diagnosis may include asthma and physical obstructions, such as foreign bodies. The illness is self-limited and laboratory diagnosis is required only if the patient is sufficiently ill to require hospitalization.

Pneumonia. The most serious infection of the respiratory tract is pneumonia, which is centered on the distal air spaces from the alveolar ducts to the alveolar sacs. The symptoms of pneumonia include fever, cough, varying degrees of sputum production, dyspnea (i.e., shortness of breath; difficulty breathing), and chest pain. Chest pain may be diffuse, vague and constant, or localized and intermittent, accentuated by deep respiration, if pleuritis is present. Shortness of breath and dyspnea usually indicate involvement of the terminal bronchioles and alveoli in a more diffuse pneumonic process. Physical signs supportive of a lower respiratory tract infection include rales and rhonchi, diminished breath sounds, and localized dullness to percussion in patients with lobar pneumonia.[73]

Pneumonia has been categorized several ways. For simplicity, we will consider: atypical pneumonia, acute pneumonia and chronic pneumonia. In addition, aspiration pneumonia, lung abscess and empyema require special consideration. Finally, from a management perspective pneumonia may be classified epidemiologically: outpatient pneumonia ("walking pneumonia") and pneumonia requiring hospitalization; community-acquired pneumonia versus hospital-acquired (i.e., nosocomial) pneumonia; pneumonia in immunosuppressed patients; pneumonia in cystic fibrosis; and pneumonia at the extremes of life. The distinction between lobar pneumonia, classically caused by *S. pneumoniae* (pneumococcus) and *Klebsiella pneumoniae* serotype 1 (Friedlander's pneumonia), and multifocal pneumonia, caused by other bacteria, is less useful clinically, because there is extensive overlap between the two patterns.

The type of pneumonia produced is a combination of microbial factors and the status of host defense mechanisms. Most pneumonia results from inhalation of

respiratory pathogens or aspiration, which may be microscopic and subclinical, of contents of the upper respiratory tract. As the colonizing microbiota of the oropharynx change, for example during prolonged hospitalization, so will the nature of organisms that infect the lung.

Atypical Pneumonia. Atypical pneumonia was defined in the 1930s as lower respiratory infection that did not resemble the classic lesions that had been described. The major difference is that sputum production is minimal in atypical pneumonia. Infection is often milder than in classic pneumonia, but not necessarily so. The primary pathogens responsible for atypical pneumonia are *M. pneumoniae*, *C. pneumoniae*, and *Legionella* spp.

Acute Pneumonia. Acute pneumonia in the outpatient setting (i.e., community-acquired pneumonia) is a combination of atypical pneumonia and classic pneumonia caused by oropharyngeal bacteria. The most important "classic" pathogen remains pneumococcus; other contributors are *H. influenzae* (now predominantly nontypeable strains), and *M. catarrhalis*.[11,177,191]

74

Viral pneumonia is rare in immunocompetent adults, or may be under recognized. Viral pneumonia will develop in a small percentage of previously healthy adults with influenza. In this situation, secondary bacterial infection (superinfection) is the major threat. Acute viral pneumonia is a more important consideration in young children, in whom it overlaps with bronchiolitis, caused by RSV and parainfluenza virus type 3. The most common cause of viral pneumonia in the immunosuppressed population is cytomegalovirus.

Acute pneumonia in the hospital is caused most commonly by *Enterobacteriaceae*, *Pseudomonas* spp., and *S. aureus*.[38] The shift in etiologic agents reflects changes in the nature of colonizing microbiota in the upper airways (see Chapter 1).

Aspiration Pneumonia. Although most pneumonia is caused by aspiration of oropharyngeal contents, massive aspiration causes a distinctive picture of focal pneumonia, affecting the dependent portions of the lung when standing or lying down (i.e., lower lobes and superior segment of the upper lobe). The infecting organisms in the outpatient are a mixture of aerobic (primarily gram-positive) and anaerobic bacteria.[8] In the hospitalized patient, aspiration pneumonia reflects the newly acquired gram-negative microbiota of the upper airways.

Chronic Pneumonia. As the name implies, the course of chronic pneumonia is prolonged. Symptoms are usually less dramatic than in acute pneumonia. As a result, diagnosis may be delayed for weeks or months, because nonspecific signs and symptoms such as low-grade fever, malaise (i.e., feeling "poorly"), and weight loss may be the only manifestations of infection. The etiologic agents in chronic pneumonia

are mycobacterial and fungal, but smoldering bacterial infection is also be a cause. *Candida* spp. are notably absent from the list of pulmonary pathogens, except for rare exceptions, most of which are part of disseminated candidiasis in immunosuppressed patients.

Lung Abscess. Closely related to aspiration pneumonia is lung abscess, sometimes called putrid lung abscess, because of the fecal odor of the infecting anaerobic bacteria.[8,9] The formation of abscesses is also a function of microbial virulence factors. *S. aureus*, *Enterobacteriaceae,* and *Pseudomonas* spp. often cause destructive lesions that destroy the architecture of the lung. In contrast, classic pneumococcal pneumonia preserves the architecture of the lungs. Certain fungi, primarily *Aspergillus* spp. and Zygomycetes, characteristically invade blood vessels. Thrombosis ensues and tissue death results when oxygenation is blocked, a process called infarction. *Pseudomonas aeruginosa* also has the capacity to produce vasculitis. When an infectious agent and thrombosis are present together, the process is called a septic infarct and is particularly destructive. The thrombosis can occur in situ or can result from a blood clot that travels through the bloodstream to the lung (i.e., an embolus).

Granulomas are another type of destructive lesion (see Chapter 1). They are typically produced by mycobacteria, especially *Mycobacterium tuberculosis* and by dimorphic fungi, particularly *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides* spp. These are considered further in the chapters covering mycobacteriology and mycology.

Empyema. Inflammation of the pleura (i.e., the mesothelial membrane that lines the lung and the chest wall) is common in pneumonia (pleurisy) and may produce an exudation of fluid (i.e., pleural effusion).[1] If the pleural effusion itself becomes infected, the filling of this fluid with a thick pus (i.e., polymorphonuclear leukocytes) results in empyema. The causes are those of bacterial pneumonia. A tuberculous empyema also occurs. Healing may result in obliteration of the pleural cavity. In many instances, the restrictive fibrous layer that results from the inflammation constricts the lung and must be surgically removed (i.e., decortication).

Pneumonia in Special Populations. Pneumonia in the elderly is more of a threat than in younger adults, but the list of pathogens is similar. *S. pneumoniae* is the most frequent agent.[168,206] This is why it is critically important for adults 65 years of age or older and certain higher risk individuals receive the pneumococcal vaccines. These same individuals should also receive the vaccination for influenza each year. It is now recognized that some agents such as RSV, originally thought to be etiologic agents in children, also infect adults and the elderly. Similarly, *C. pneumoniae* may also cause infections in this patient population.

Immunosuppressed patients are at risk for many pathogens that do not cause disease regularly in immunocompetent individuals. Among these opportunistic

pathogens are parasites, including *Toxoplasma gondii;* viruses, including cytomegalovirus; fungi, including *Aspergillus* spp., Zygomycetes, *Cryptococcus neoformans*, and *Pneumocystis jirovecii*; and mycobacteria, such as MAC.[261] Additionally, immunocompromised patients are less able to clear infections caused by more commonly encountered pathogens. Infections with adenovirus and even parainfluenza virus may result in serious, life-threatening infections.

A special category of compromised individuals is those with cystic fibrosis.[99] A progression of pathogens follows these patients throughout the course of their illness: *S. aureus*, *H. influenzae,* and *P. aeruginosa*. Strains of *P. aeruginosa* in cystic fibrosis have a characteristic mucoid character that is seen much less frequently in other patients. *Burkholderia cepacia* and *Stenotrophomonas maltophilia*, both previously categorized as species of *Pseudomonas*, and *Alcaligenes* spp. are also major concerns in cystic fibrosis because the infections are difficult to treat and the pathogens are often multidrug resistant and easily spread from one individual to another.

Allergic bronchopulmonary disease may be caused by *Aspergillus fumigatus*, other fungi and aerobic actinomycetes.[102] *A. fumigatus* is a versatile opportunistic pathogen that can produce invasive disease in immunosuppressed patients, a fungus ball in preexisting cavities of immunocompetent hosts, as well as an immunologic reaction in individuals with an atopic (allergic) predisposition.[94,97] In allergic aspergillosis, hyphae are found in the air spaces, where they produce an inflammatory reaction but do not invade tissue as in allergic aspergillosis.

Specimen Collection for the Diagnosis of Lower Respiratory Infection

Expectorated Sputum. The simplest and least expensive specimen for the diagnosis of lower respiratory infections is

expectorated sputum. The utility of this approach is the subject of considerable argument, because of the difficulty some patients have mobilizing lower respiratory secretions and the frequency with which the specimen is contaminated by oropharyngeal microbiota as it passes through the mouth.[233] When the specimen is collected carefully, however, it can provide useful information for initial therapy for the patient with pneumonia.[243]

The patient should be instructed carefully on the proper collection of sputum, rather than saliva. Having patients brush their teeth and gargle with water immediately before obtaining the specimen reduces the number of contaminating oropharyngeal bacteria. Spada and colleagues[278] showed a 1-log decrease in the mean concentration of contaminating bacteria from $3.6 \pm 7.5 \times 10^8$ to $3.7 \pm 7.2 \times 10^7$ in sputum samples

obtained from patients immediately following a simple mouth wash. Avoid using proprietary mouthwashes or gargles that may contain antibacterial substances. Once the specimen is collected, it should be submitted to the laboratory promptly rather than sitting at the bedside.

Early-morning sputum samples should be obtained because they contain pooled overnight secretions in which pathogenic bacteria are more likely to be concentrated. Twenty-four-hour collections should not be accepted because of the overgrowth of contaminating microbiota. When sputum production is scant, induction with nebulized saline may be effective in producing a specimen that is more representative of the lower respiratory tract. Avoid the use of "saline for injection," many preparations of which contain antibacterial substances.[235]

Special sputum collection devices are commercially available through laboratory supply companies, or a sterile wide-mouth jar with a tightly fit screw-cap lid can be used. To prevent contamination of the outside of the container, the patient should be instructed to press the rim of the container under the lower lip to catch all of the expectorated sputum specimen.[2]

Endotracheal Aspirate. The lower respiratory tract may be sampled by introducing a catheter through the larynx into the trachea. If an endotracheal tube is in place or there is a tracheotomy, aspirating tracheal secretions is simple. It is often assumed that endotracheal aspirates avoid some of the contamination problems of expectorated sputum. In fact, intubation introduces the possibility of contamination because oral secretions can seep down the endotracheal tube. These specimens must, therefore, be interpreted with the same care as that taken with expectorated sputum. It has been suggested that quantitative cultures of tracheal aspirates may provide better data (see the discussion of bronchoalveolar lavage below).[22] The quantitative technique involved performing a dilution of sputum that had been liquefied enzymatically before plating onto agar. A simpler semiquantitative approach, in which the sputum was washed twice with saline and struck onto agar as usual (see Chapter 1), correlated closely with the quantitative technique. This technique has not been widely adopted, as most laboratories use the semiquantitative technique.

Translaryngeal (Transtracheal) Aspiration. Translaryngeal aspiration is an invasive technique that was introduced to avoid contamination problems. Technical difficulties with proper performance and too frequent complications have nearly eliminated this approach to specimen collection.

Rigid Bronchoscopy. The rigid bronchoscope was capable of sampling only the central airways. Although it is adequate for mycobacterial cultures, it is not appropriate for organisms that colonize the oropharynx and infect the distal tract. It is seldom used today.

Flexible Bronchoscopy. Fiberoptic bronchoscopy is the technique frequently used for obtaining transbronchial biopsies, bronchial washings, bronchoalveolar lavage and

brushings, particularly in patients with lung abscesses or other suspected deep pulmonary infections. These techniques are also used in cancer diagnostics. The bronchial brush technique uses a telescoping double catheter plugged with polyethylene glycol at the distal end to protect a small bronchial brush. This technique has been recommended for the optimal recovery of aerobic and anaerobic bacteria, both facultative and obligate anaerobes, from deep-seated pulmonary lesions.[10] Discrete sampling of focal lesions may be accomplished after fluoroscopic localization of the tip of the bronchoscope. Although initially popularized, the rate of contamination of these specimens has limited the usefulness of cultures obtained by these methods. Protected brush specimens are not significantly better than those obtained by bronchoalveolar lavage.

Specimens that cannot be cultured immediately should be refrigerated. The success of this procedure depends on the following: (1) obtaining ample brush material from the distal bronchioles and alveoli to make several slides, (2) preparing a full set of special stains and multiple cultures, and (3) searching for more than one type of microorganism.

Bronchoalveolar Lavage. Bronchoalveolar lavage involves the injection of 30 to 50 mL of physiologic saline through a fiberoptic bronchoscope that has been threaded into the peripheral bronchiolar ramifications. The saline is then aspirated and submitted for smear preparation and culture. Semiquantitative or quantitative cultures of respiratory secretions obtained by protected bronchial brush and alveolar lavage techniques have been recommended for diagnosis of pneumonia in intubated patients undergoing ventilation.[52] Organisms that are present in concentrations greater than 10^3 to 10^4 colony-forming units (CFU)/mL and specimens that demonstrate intracellular bacteria in more than 25% of the inflammatory cells present are indicators of pneumonia that requires specific treatment. Unfortunately, the experience with quantitative microbiology of respiratory secretions has been highly variable.[300] One group of investigators found high specificity if a cutoff of 10^5 CFU/mL was used for fluid obtained by bronchoalveolar lavage, but the sensitivity was only 33%, largely because of prior antimicrobial therapy.[279] They concluded that at this bacterial concentration, pneumonia could be diagnosed reliably, but a negative result did not exclude the diagnosis.

Fine Needle Aspiration and Lung Biopsy. Fine needle aspiration is usually performed under radiologic guidance, particularly if a localized lesion is present.[301] This is an excellent means of obtaining material for cytology and culture; on-site cytologic assessment is useful to guide culture. For

example, the presence of granulomas would make one prioritize mycobacterial and fungal cultures, whereas all neutrophils would suggest a bacterial etiology. The transbronchial biopsy is a way of obtaining smaller amounts of intact tissue at the time of bronchoscopy. Although these biopsies are often diagnostic, they are subject to sampling error. When the diagnosis has not been achieved by the aforementioned techniques, then an open lung biopsy may be necessary. This is the most invasive approach and is reserved for situations in which other measures have failed. A small wedge is resected from the lung in which the disease process may be studied histopathologically and microbiologically.

Additional procedures may be helpful in determining the etiology of respiratory infections. Blood cultures should always be obtained during the acute phases of pneumonia. *S. pneumoniae* may be recovered from the blood in 25% to 30% of patients with pneumococcal pneumonia, often when sputum cultures are negative.[200] Although the blood culture is not sensitive for detecting the etiologic agent of pneumonia, it is highly specific.

The detection of antigens secreted in the urine is another important means of determining the etiologic agent of infection. The *Legionella pneumophila* serogroup 1 urinary antigen test and *S. pneumoniae* urinary antigen are ancillary diagnostics important for the diagnosis of pneumonia caused by these pathogens.[20,201] The antigen may be excreted for days, weeks, or even months, so a positive test does not absolutely document a recent or ongoing infection. Careful correlation with clinical information and culture and/or molecular diagnostic studies is required. The *Histoplasma* urinary antigen is also commonly ordered for patients with suspected fungal pneumonia due to the organism. This test is highly sensitive in disseminated disease, only moderately sensitive in infections limited to the lungs and insensitive for remote infections.

Laboratory Diagnosis of Pneumonia. The etiologic diagnosis of pneumonia is a cooperative enterprise that requires microbiologists, pathologists, radiologists and clinicians. The diagnosis of pneumonia is a clinical one, using history, the stethoscope, and chest radiographs. With a few important exceptions, such as recovery of *M. tuberculosis*, pneumonia is not diagnosed in the microbiology laboratory. Clinicians who send a sputum specimen to the laboratory without having a clinical diagnosis of pneumonia may receive confusing or even misleading test results. Once a diagnosis of pneumonia has been made, the laboratory can help a clinician define the etiology, through culture and other testing, and select appropriate therapy, through antimicrobial susceptibility testing.[43]

Sputum samples should be processed as soon after collection as possible. A significant decrease in recoverable organisms from sputum samples after 20 hours of refrigeration has been found,[218] although there was no compromise in the number or

quality of epithelial cells and segmented neutrophils. A decline in the number of viable tubercle bacilli that could be recovered from sputum after storage at room temperature for several days has also been found,[216] although the concentration of acid-fast bacilli seen in acid-fast stains was not reduced after 20 days.

The quality of sputum samples should also be assessed using one of the grading systems described in Chapter 1. There is controversy about the value of providing presumptive bacterial identifications based on morphologic criteria. Bartlett and coworkers[13] first suggested that categories of bacteria could be defined accurately by morphology in Gram-stained smears of sputum. For example, the morphologic identification of staphylococci, "*Bacteroides- Haemophilus*," and bacteria of mixed morphology were made with 75% accuracy if the sputum specimens were of high quality. It has been demonstrated[305] that semiquantitative enumeration of the bacteria in Gram-stained sputum cannot be reproduced from one technologist to another (or even with the same technologist examining smears on repeated occasions) and that such estimations should not be reported. One possible explanation for this observation is the variability of smears from one area to the next. Conversely, a more optimistic report[101] suggests that Gram's stains of high-quality sputum specimens, performed in a select population of adults with community-acquired pneumonia, may provide clinicians with enough information to initiate empiric antibiotic therapy. In either event, considerable experience on the part of the observers and regular correlation of laboratory results with clinical indicators is necessary before Gram's stain interpretations of sputum samples will be of value.

A useful quality assurance tool is the retrospective comparison of Gram's stain results and culture results. If organisms seen in the smears do not grow in culture or if organisms that grow in moderate to heavy quantities are not seen in the smear, the smear should be reviewed. Gram's stain is relatively insensitive (approximately 10^5 CFU/mL must be present to be visualized), so small numbers of bacteria in the culture may well not be seen in the smear. If the smear has been misinterpreted, it should be reviewed with the reader as an educational and process improvement tool. If the smear was correctly interpreted, this may be a clue that additional approaches to culture should be considered.

The grading systems for sputum samples do not apply in lower respiratory tract infections caused by *Legionella* spp., mycobacteria, fungi, *Mycoplasma, Chlamydophila,* and viruses. Purulent inflammatory cell responses are not necessarily elicited in these infections.

The semiquantitation of stainable tubercle bacilli in sequential examinations of sputum by acid-fast smears is of value for determining the efficacy of antituberculous drug therapy. A decrease from 4+ to 1+ to rare or even to an absence of bacilli over a 4- to 6-week course of therapy indicates good drug response and may be used to determine when it may be safe to remove the patient from respiratory isolation.

The importance of the microorganisms recovered from respiratory samples must always be evaluated in the context of the clinical information, as well as with the results from other studies. Interpretation of sputum cultures is particularly difficult because they are neither specific nor sensitive in the evaluation of lower respiratory infections. Lentino and Lucks[162] have succinctly stated the problem based on their experience in a study of 249 patients with suspected pneumonia (Box 2-1).

77

BOX 2-1

Interpretation of Sputum Cultures: Observations of Lentino and Lucks[162]

1. Using the sputum quality-grading system of Bartlett and of Murray and Washington as outlined in Chapter 1, 48% of the sputum cultures submitted to their laboratory did not pass the quality grade and were more reflective of oral secretions.
2. In the above case, 26.5% of purulent sputum samples were from patients showing no radiologic or clinical evidence for pneumonia.
3. Overall, 40% of sputum samples obtained from patients with evidence of pneumonia were not deeply expectorated, again more reflective of oral secretions.
4. Only 10.8% of patients producing nonpurulent sputa had pneumonia.
5. Only 56.8% of patients with pneumonia produced purulent sputum.

Infections of the Gastrointestinal Tract

Establishing the bacterial etiology of acute and chronic bronchitis can also be difficult, because so many species of bacteria can be found as normal microbiota or commensals in the respiratory tract (Table 2-2). The recovery of *S. pneumoniae*, *K. pneumoniae*, *H. influenzae*, and *Moraxella* (*Branhamella*) *catarrhalis* as the predominant microorganism from respiratory secretions, particularly when Gram-stained smears support their presence and/or the organisms are also recovered from concomitant blood cultures, supports their role in the development of acute pneumonia.[73,343] Induced sputum samples, collected after inhalation of nebulized saline, may be required to increase the yield of detection of certain organisms,

particularly *P. jirovecii*.

If pulmonary infections caused by mycobacteria, fungi, human parasites, or viruses are suspected, special techniques must be used to recover the etiologic agents, as outlined in the chapters devoted to each of these groups of microbes. Although the recovery of certain fungi, such as the dimorphic pathogens, usually indicates disease, other fungi, such as *Aspergillus* species, must be recovered repeatedly from successive samples before the diagnosis can be confirmed. The presence of fungal hyphae is less likely to represent environmental contamination. Diagnosis of viral pneumonia will be attempted most frequently in immunosuppressed patients and in children who are sufficiently ill to require admission to the hospital.

The use of blood culture, urinary antigen detection, and quantitative culture techniques has been discussed above. Modern molecular techniques are now available for expedited diagnosis of viral and mycobacterial infections; the number of situations in which these approaches will be applicable is unlikely to expand in the future. Measurement of a soluble triggering receptor that is found on myeloid cells has been proposed as a useful approach,[98] but the promising results require confirmation.

TABLE 2-2 Selected Commensal Microbiota and Potential Pathogens in the Respiratory Tract

Commensal Microbiota	Potential Pathogens
α/γ-Hemolytic streptococci β-Hemolytic streptococci, other than group A *Candida* spp. Coagulase-negative staphylococci *Corynebacterium* spp. (diphtheroids) *Haemophilus parainfluenzae* *Neisseria* spp.	Adenovirus Anaerobes (as part of mixed infection) *Bordetella pertussis* *Chlamydophila pneumoniae* *Chlamydophila psittaci* *Corynebacterium diphtheriae* *Cryptococcus neoformans* Cytomegalovirus *Enterobacteriaceae* *Haemophilus influenzae* Herpes simplex virus *Legionella* spp. *Moraxella catarrhalis* *Mycobacterium* spp. Myxoviruses and paramyxoviruses *Neisseria gonorrhoeae* *Neisseria meningitidis* *Pneumocystis jirovecii* *Pseudomonas aeruginosa*

	Staphylococcus aureus *Streptococcus pneumoniae* *Streptococcus pyogenes* (group A)

Lower Intestinal Infections

Clinical Symptoms. The most common presenting symptom of lower intestinal tract infections is diarrhea.[297] Although diarrhea is difficult to define quantitatively, patients usually know when they have bowel movements in excess of normal and when the stool takes on a form that is softer or more liquid than usual. The diarrhea may be accompanied by cramping abdominal pain of varying severity. "Enterocolitis" is a term used to describe the several types of lower gastrointestinal infection.

"Dysentery" is a term used to describe the condition in which diarrhea is accompanied by cramping abdominal pain, tenesmus (painful straining when passing a stool) and purulence of the stool. Dysentery results from "enteroinvasive" microorganisms that penetrate the mucosa and cause inflammation of the intestinal wall. These stools contain inflammatory cells and often may be grossly visible blood. *Shigella* and *Entamoeba histolytica* are classically associated with dysentery, but both of these actually cause a spectrum of disease wherein the diarrhea ranges from watery to dysenteric.

At the opposite end of the spectrum are the nonpainful, profusely watery diarrheal syndromes caused by viruses, certain parasites and some bacteria. Most acute, watery diarrheal syndromes resolve spontaneously within a week. If symptoms persist without explanation, parasites, such as

78

Giardia intestinalis (formerly *G. lamblia*), and noninfectious etiologies should be considered. The stools produced by *Giardia* are often foul-smelling, greasy, and float in the toilet bowl.

A unique, and fortunately uncommon category of enteritis in resource-rich countries, is enteric fever. This syndrome is classically caused by *Salmonella enterica* serotype Typhi, although it may also be caused by Serotype Paratyphi and rarely by other serotypes. Although there may be a diarrheal component to enteric fever, it is actually a systemic disease. Enteric fever is characterized by fever—first remitting and later constant, headache, abdominal pain, splenomegaly, relative bradycardia (low pulse rate), and leukopenia. Diarrhea is not prominent; in fact, constipation may be more common at the outset. This organism, after invading the intestine, becomes disseminated throughout the reticuloendothelial, such as the liver, spleen, and bone marrow. As demonstrated by the historically significant "Typhoid Mary," the

gallbladder may be colonized, particularly if calculi are present, and the organism may be shed into the environment for extended periods of time after the initial infection.

Certain infectious agents are associated with discrete risk factors or clinical features. Some agents, such as microsporidia, occur almost exclusively in severely immunosuppressed patients. *Clostridium difficile* produces disease predominantly in patients who have been treated with antimicrobial agents that alter the normal gastrointestinal microbiota. Many of the agents are transmitted through contaminated food and water.[49] The major syndromes of lower gastrointestinal disease are summarized in Table 2-3.

In many communities the most commonly identified agents of gastroenteritis are *Campylobacter jejuni*, *Salmonella* spp., *Giardia intestinalis*, rotaviruses and noroviruses.[66] Unfortunately, the diagnostic yield from stool cultures in most clinical laboratories is a disappointing 1.5% to 5.6%.[297] It is possible that this will be substantially improved with the implementation of commercially available molecular gastrointestinal panels, which include agents like norovirus and astrovirus, which have heretofore gone undetected in most laboratories.

Some agents of gastroenteritis require prompt treatment (e.g., *Shigella* spp.); for others specific therapy is not available (e.g., viruses); for still others therapy is indicated only if the patient is very young, immunosuppressed, or has complicated disease; enteric fever always requires antimicrobial therapy. Physicians are most likely to order stool cultures if one of the following conditions is present.[119]

1. The patient is immunocompromised.
2. The patient has traveled recently to a resource-poor country.
3. Presence of bloody stools.
4. Diarrhea has been present for more than 3 days.
5. Diarrhea has required intravenous rehydration.
6. Fever is present.

Laboratories differ greatly in the sophistication of their evaluation of fecal specimens. In a survey of 388 clinical laboratories during 1999 most microbiologists examined feces for the presence of *Salmonella* spp., *Shigella* spp., and *Campylobacter* spp. In contrast, approximately 50% of sites included *Escherichia coli* O157:H7, *Vibrio* spp., and *Yersinia* spp. in their diagnostic protocol.[308] Examination of stools for parasites was performed in only 59% of 455 laboratories surveyed; the remaining laboratories sent specimens to a reference laboratory for testing.[137] Examination of feces for *Cryptosporidium* spp., *Cyclospora cayetanensis*, and microsporidia was performed only on specific request in 89% of these laboratories. It is very important for each laboratory to indicate the pathogens sought when the results are reported to the clinician. A report of "No enteric pathogens isolated" is no longer

acceptable, but rather a listing of what was sought and not found must be given (e.g., Negative for *Salmonella, Shigella* and *Campylobacter*). In a survey of almost 3,000 physicians in five states 28% of physicians did not know whether the laboratory tested for *E. coli* O157:H7 and 40% did not know whether cultures had been performed for *Yersinia* spp. or *Vibrio* spp.[119]

TABLE 2-3 The Major Gastroenteritis Syndromes and Most Common Etiologic Agents

Syndrome	Bacteria	Viruses	Parasites	Comments
Inflammatory diarrhea, including dysentery	*Shigella* spp., Enteroinvasive *E. coli*, Enterohemorrhagic *E. coli, Salmonella enterica* various serotypes (e.g., Typhimurium, Enteriditis) , *Campylobacter jejuni* and other *Campylobacter* species, *Vibrio parahaemolyticus, Clostridium difficile*	None	*Entamoeba histolytica*	Involves colon; fecal leukocytes often present
Noninflammatory diarrhea	Enterotoxigenic *E. coli*, Enteroaggregative *E. coli* and *Vibrio cholerae*. Secondary to preformed toxins: *Clostridium perfringens, Bacillus cereus, Staphylococcus aureus*	Norovirus, rotavirus, enteric adenovirus, astrovirus, etc.	*Giardia intestinalis, Cryptosporidium* spp., *Cystoisospora belli, Cyclospora cayetensis,* microsporidia- (fungi)	Involves proximal small bowel; fecal leukocytes usually absent
Diarrhea with systemic disease, including enteric fever	*Salmonella enterica* serotype Typhi, other *Salmonella* spp., *Yersinia enterocolitica, Campylobacter* spp.	None	None	Involves distal small bowel; fecal mononuclear leukocytes may be present

Adapted from reference 108.

79

Collection of Fecal Specimens. The collection of diarrheal stools is not difficult. Specimens for detection of all pathogens should be collected in clean (not necessarily sterile), wide-mouthed containers that can be covered with a tight-fitting lid. Screw-top lids are most commonly used, as these are most secure in transit. The containers used for culture should be free of preservatives, detergents, and metal ions. Contamination with urine should also be avoided. If an intestinal parasite such as *E. histolytica*, *G. intestinalis,* or *Cryptosporidium* spp. is suspected, a small portion of stool sample should be placed in preservatives, such as polyvinyl alcohol, or a mercury-free alternative, and 10% formalin. Stool specimens for detection of viruses should follow the manufacturer's recommendations for transport.

In some instances, the collection of a rectal swab rather than feces may be necessary, particularly in newborns or in severely debilitated adults. Rectal swabs may be more effective than feces for recovery of certain strains of *Shigella*, because these organisms are susceptible to cooling and drying. Swabs have also been reported to be more effective than stool specimens[189] for recovery of *Clostridium difficile* in hospitalized patients. The rectal swab should be inserted just beyond the anal

sphincter, avoiding direct contact with fecal material in the rectum. The swabs should be inoculated immediately onto culture media or placed in a suitable transport system to prevent drying. Rectal swabs have also been used for diagnosis of rectal gonococcal infection.

Epidemiologic Considerations in the Evaluation of Patients With Gastroenteritis. A detailed medical history should be taken, including recent travel, exposure to potentially contaminated food or water and the presence of similar disease in friends or family. In particular, travel to countries outside the United States, where certain diarrheal diseases may be endemic, should be solicited. The most common cause of "traveler's diarrhea" (also called "Montezuma's revenge," "Delhi belly," and other colorful names) is enterotoxigenic *E. coli*,[213] but there are a variety of diarrheagenic *E. coli* (e.g., Enteropathogenic, Enteroaggregative, etc.) that may also cause disease in the traveler. Other important pathogens, such as *E. histolytica*, are also more common outside the United States. Poor-quality water and food supplies, marginal cold-storage facilities, and contamination from people preparing foods in countries outside the United States put travelers at risk. In these days of global commerce, however, staying at home is not free of risk either. Epidemics of gastroenteritis have been reported as a result of contaminated food,[49] usually vegetables or fruit that are not cooked before eating, that has been imported from other countries. For instance, a multistate outbreak of *Cyclospora* infection was traced to raspberries imported from Central America only after reports accumulated at national reference centers.[120] It is important to remember that bacteria commonly found on poultry, which will be killed during cooking, may cause disease if uncooked food, such as vegetables, come in contact with the contaminated chopping boards or counters that were used for preparation of the poultry.

Certain locales, foods, and clinical settings are particularly associated with specific pathogens (Table 2-4). A variety of factors may place the individual at risk for infectious enterocolitis, emphasizing the importance of the careful clinical history and reporting of cases to public health authorities.

Upper Intestinal Infections

The upper gastrointestinal tract consists of the esophagus, stomach, and proximal duodenum (i.e., from the oropharynx to the intestine).

Clinical Symptoms. Esophagitis is associated with difficulty swallowing and pain on swallowing (i.e., dysphagia) and by pain that radiates to the back. The gastroesophageal mucosa is at particular risk of ulceration. The most common infectious agents in this site are *C. albicans* and herpes simplex virus, both of which produce erosive disease.

When the stomach and gastroesophageal junction are involved, symptoms include anorexia, a feeling of nausea (occasionally with overt vomiting) and upper abdominal pain. Because of the very low pH of the gastric acid, 99.9% of ingested bacteria are killed within 30 minutes of exposure; therefore, gastritis from direct invasion of the stomach wall is rare. Upper gastrointestinal infection, therefore, is most commonly caused by viruses and preformed bacterial toxins.

80

Gastric acid also has an important role to play in protecting the lower gastrointestinal tract from bacterial infection. Antacid therapy, which neutralizes the low gastric pH and gastrectomy, in which most of the acid-forming mucosa is removed, predispose individuals to enteric infections from a variety of bacterial species. Guerrant[107] reports that the dose of *Vibrio cholerae* required to cause infection in normal people (10^8 organisms per milliliter) was reduced to only 10^4/mL in volunteers who were given bicarbonate to neutralize gastric acidity.

TABLE 2-4 Epidemiologic Associations of Gastrointestinal Infectious Agents

Factors	Infectious Agent(s)
Backpacking and drinking from mountain streams	*Giardia intestinalis*
Dairy products	*Salmonella* spp., *Campylobacter* spp., *Yersinia* spp., *Listeria monocytogenes*
East Coast and Gulf Coast	Halophilic vibrios; e.g., *Vibrio parahaemolyticus*, *Vibrio vulnificus*
Egg and potato salads, pastries	*Staphylococcus aureus*
Eggs	*Salmonella* spp.
Fresh fruit	*Cryptosporidium* spp. and *Cyclospora* spp.
Fried rice	*Bacillus cereus*
Hamburger	*Escherichia coli* O157:H7 and other Enterohemorrhagic *E. coli*
	Cryptosporidium spp., *Cystoisospora belli*, *Mycobacterium avium*

patients	complex, *Strongyloides stercoralis* hyperinfection, cytomegalovirus, *Candida* spp.
Shellfish	*Vibrio* spp., noroviruses, hepatitis A virus

Helicobacter pylori is recognized as the most important cause of gastritis and gastric ulcer.[158,180,294] The organism has the unique biochemical property of rapidly and avidly hydrolyzing urea and releasing ammonium ions. The bacterial cells can presumably surround themselves with an alkaline microenvironment, thereby making it possible to survive the highly acid environment of the gastric mucosa. The infectious etiology of peptic ulcer eluded detection for so long because it does not have the classic signs and symptoms of an "acute" infectious disease. The knowledge of this chronic infectious disease has opened new vistas on the spectrum of illness that microbes can produce.

A major factor in upper gastrointestinal infection is ingestion of microbes and/or preformed microbial toxins in food and drink, commonly known as food poisoning. The acute and often fulminant gastritis, accompanied by generalized weakness and vomiting, that may be experienced after ingesting food heavily contaminated with the toxins produced by organisms such as *S. aureus*, *Clostridium perfringens,* and *Bacillus cereus*, does not result from direct bacterial invasion of the stomach wall; rather, it results from the direct emetic action of preformed toxins. These toxins vary in their mechanisms of action. In most instances, although the emesis may be fulminant, it is brief in duration. The diagnosis is solely made on a clinical basis, as toxins are not detected in the clinical laboratory. Public health microbiologists may sample retained food specimens in an effort to detect the pathogen involved and the means of spread, but this is not the task of the clinical microbiologist.

Obtaining Specimens From the Upper Gastrointestinal Tract. Gastric specimens for culture are only rarely obtained and are limited to those few situations for which a diagnosis may not be possible by other means. The bacterial agents of acute toxic food poisoning may be recovered from vomitus material, but this is usually not requested.

Gastric biopsies are performed to detect *H. pylori*.[290,307] Biopsy specimens may be cultured for the recovery of *H. pylori*, a procedure rarely performed in clinical laboratories. Biopsies may be tested for the presence of urease activity, a presumptive test for the presence of *H. pylori*. More commonly biopsies are examined histologically for the presence of gastritis and spiral bacteria in the mucin layer. There is a stool antigen test available for the detection of *H. pylori,* as well as a urea-breath test, both of which have good performance characteristics. Conversely, serologic studies should be discouraged because of suboptimal performance compared with the other diagnostic tests noted.[7,53]

Aspirations of duodenal contents may be helpful in making the diagnosis of giardiasis and strongyloidiasis if repeated stool examinations have failed to detect a pathogen. The use of the commercial "string test" (e.g., Enterotest) is an alternative to endoscopy and biopsy. The Enterotest is a capsule containing a tightly wound string. The string is unraveled for a short distance and the end taped to the patient's cheek; then the capsule is swallowed. In about 30 to 60 minutes, when the capsule has reached the upper duodenum, the string is carefully removed and any mucus adhering to the strand is scraped onto the surface of a glass slide for direct microscopic examination. As noted gastric and/or small intestinal biopsy remains a diagnostic alternative.

Urinary Tract Infections

The urinary tract is divided into the upper urinary tract, composed of the kidneys, renal pelves, and ureters, and the lower urinary tract that consists of the urinary bladder and the urethra. Upper urinary tract infections are most commonly ascending (i.e., infections originate in the urinary bladder and ascend through the ureters to the kidneys). Normally, the vesicourethral valve prevents reflux of urine from the urinary bladder into the ureters. Individuals with urogenital anomalies or with overdistention of the urinary bladder from outflow obstruction, neurogenic malfunctions, or pressure from an enlarged uterus during pregnancy are particularly susceptible to ascending urinary tract infections. Infections of the renal pelvis (pyelitis) and kidney (pyelonephritis) are the most common complications. The infections can be acute or can be recurrent with chronic inflammatory damage.

Upper urinary tract infections less commonly result from hematogenous spread of bacteria into the renal cortex in patients with septicemia. Multifocal abscesses or acute suppurative pyelonephritis are common manifestations.

Urinary tract infections are sometimes divided into uncomplicated and complicated categories.[283,317] Uncomplicated infection is acute cystitis or pyelonephritis in a young woman without underlying urinary tract or systemic disease. If the diagnosis is cystitis, empiric antimicrobial therapy can be instituted without resorting to a culture, because *E. coli* is responsible for the vast majority of these infections. A urinalysis or test for leukocyte esterase (LE) should be performed to demonstrate that the process is inflammatory; if polymorphonuclear neutrophils are absent, a culture should be performed before initiating therapy. A follow-up culture ("test of cure") is not necessary unless symptoms persist.

Cystitis or pyelonephritis in males, children, chronically catheterized patients, and women with recurrent infection, urologic abnormalities or underlying disease is considered a complicated infection. Both urinalysis and urine culture are required for

complicated cystitis and for all patients with pyelonephritis.[283,317]

Clinical Signs and Symptoms

The cardinal clinical manifestations of upper urinary tract infections are flank pain and fever, which is often associated with chills. Frequency, urgency, and dysuria are more suggestive of infections of the urinary bladder and urethra. However, in some patients with pyelonephritis or other upper

81

urinary tract infections, particularly those with ascending infections, symptoms consistent with lower tract infections develop first. The differentiation is important because the approach to antimicrobial chemotherapy differs for the two conditions.[283,317]

Lower urinary tract infections typically involve the urinary bladder and/or the urethra. The symptoms are similar for infections in the two sites, so the process is sometimes called the acute urethral syndrome.[285] Frequent and painful urination of small amounts of turbid urine (i.e., symptoms of frequency and dysuria) and suprapubic pain are the usual clinical manifestations. Vaginitis in women and prostatitis in men can produce similar symptoms, but can usually be differentiated clinically. Diagnosis is particularly difficult in elderly persons, in whom fever or leukocytosis may not develop during an infection.

There has been much discussion about the significance of asymptomatic bacteriuria. Although this phenomenon has been documented in many types of patients and clinical scenarios, serious medical problems that necessitate treatment of the bacteriuria occur in only a few situations: pregnant women, women who are undergoing invasive genitourinary procedures, and recipients of renal transplants during the early posttransplantation period.[209]

Host Factors

The prevalence of urinary tract infections varies with the gender and age of the patient. In neonates and infants, urinary tract infections are more common in boys, with an overall prevalence of about 1%. Most of these infections are associated with congenital anomalies. By the time children attend school, there is a higher prevalence in girls compared with boys.[289] This ratio remains consistent into adulthood. High rates of incidence occur in certain conditions, such as diabetes or pregnancy. In the elderly, higher rates of occurrence can be expected for both women (20%) and men (10%) in whom predisposing conditions exist, such as obstructive uropathy from the prostate in men, poor emptying of the bladder from uterine prolapse in women, and

prostate in men, poor emptying of the bladder from uterine prolapse in women, and procedures that require instrumentation in both men and women.

By far the most common population at risk for both symptomatic urinary tract infection and asymptomatic bacteriuria, however, is sexually active women.[288] Although asymptomatic infection in this group does not clearly produce serious medical problems, it may be a predictor of future symptomatic infection.[209] Women are more susceptible to infection than men because of the shorter length of the female urethra. Perineal bacterial microbiota that originate in the gastrointestinal tract are the usual pathogens, especially if the bacteria possess factors that facilitate their binding to the uroepithelium.[246] Sexual intercourse facilitates entry of the bacteria into the female urethra.

A second population that is at increased risk of infection is the chronically catheterized patient.[281] A foreign body, such as an indwelling urinary catheter, guarantees colonization of the catheter within 5 days of placement. The presence of a colonized catheter results in asymptomatic bacteriuria and puts the patient at risk for developing symptomatic infection, including pyelonephritis and urosepsis. When the patient is also afflicted with dementia, as many elderly individuals are, it may be difficult to ascertain whether the infection is symptomatic. Without fever and leukocytosis the only indicators may be subtle changes in personality or mentation. The best person to assess these characteristics may be the primary caregivers, rather than the physician who sees the patient intermittently.

TABLE 2-5 Some Commensal Microbiota and Potential Pathogens in the Urinary Tract

Commensal Microbiota	Potential Pathogens
α/α-Hemolytic streptococci *Bacillus* spp. Coagulase-negative staphylococci Diphtheroids *Lactobacillus* spp.	*Corynebacterium urealyticum*[a] *Enterococcus* spp. *Enterobacteriaceae*[a] *Pseudomonas* spp. *Staphylococcus aureus* *Staphylococcus epidermidis* (elderly men) *Staphylococcus saprophyticus* (young women)

[a]Proteae and *Corynebacterium urealyticum* are urea splitters, alkalinizing the urine and predisposing to stone formation.

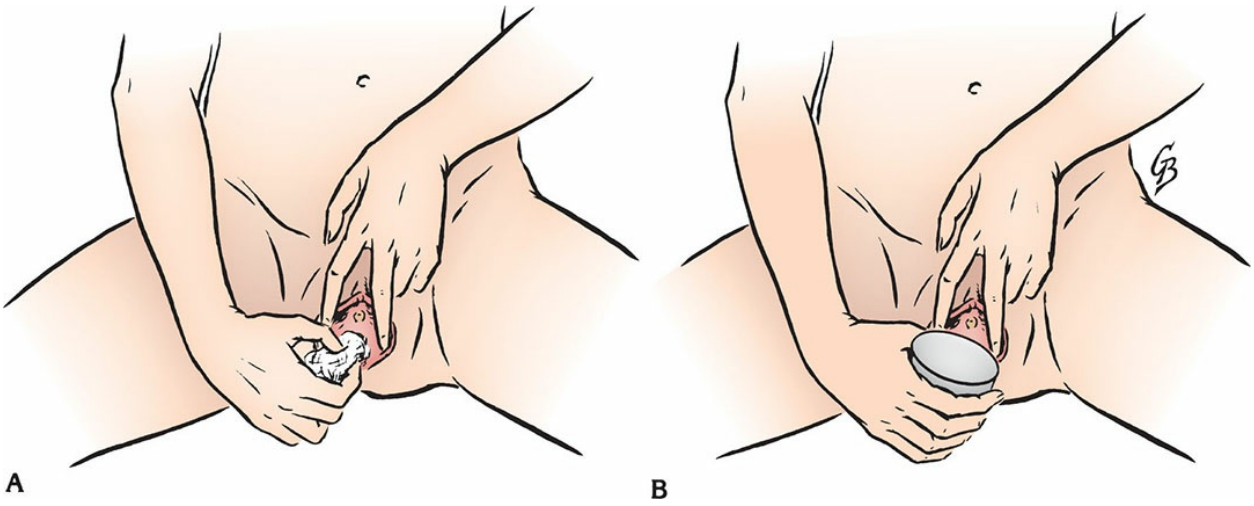
Except for the urethral mucosa, which supports the growth of microbiota, the normal urinary tract is usually devoid of bacteria.[141] Urine can easily become contaminated with bacteria from the vaginal canal, the perineum, or indigenous bacterial microbiota in the urethra. Table 2-5 lists selected microorganisms that are considered contaminants and those considered potential pathogens in the urinary tract.

Midstream Urine Specimens. Urine samples are most commonly collected by sampling the midstream flow by the clean-catch technique. Urine collection from women by this technique requires personal education and, in some instances, supervision for best results.[29] The periurethral area and perineum are first cleansed with two or three gauze pads saturated with soapy water, using a forward-to-back motion, followed by a rinse with sterile saline or water.

The labia should be held apart during voiding, and the first few milliliters of urine passed into a bedpan or toilet bowl to remove bacteria from the urethra (Fig. 2-2). The midstream portion of urine is then collected in a sterile, wide-mouthed container that can be covered with a tightly fitted lid. The use of a urine transport tube with a preservative is recommended to prevent overgrowth of contaminating microbiota during transport and processing. The soapy water preparation is usually not required for men; rather, simple cleansing of the urethral meatus immediately before voiding and then collection of the midstream sample is usually sufficient.

Patients seen in a clinician's office or in a clinic are frequently asked to obtain their own urine sample. This practice is acceptable if the patient is given precise instructions for properly collecting the specimen. It is recommended that these instructions be printed on a card that the patient can retain after receiving the verbal description. When the patient does not seem to comprehend or when language is a barrier, the nurse or office assistant should read through the instructions point by point or provide direct assistance in collecting the sample. An example of an instruction card is given in Box 2-2.

82



■ **FIGURE 2-2** Midstream clean-catch urine collection. **A.** The labia are separated with the fingers and cleansed with a 4 × 4-inch gauze pad saturated with soap. **B.** The midstream portion of the urine is collected in a sterile container.

The accuracy of the urine collection procedure can be monitored over time by noting the frequency with which urine colony counts range between 10,000 and 100,000 CFU/mL. Most patients will have colony counts outside this range. Those free of infection will have no bacteria or fewer than 10^2 CFU/mL. Infected patients will have 100,000 CFU/mL or more. The frequency of intermediate counts should not exceed 5% to 10% if the urine collection procedures have been performed properly. Specimens should be processed within 2 hours after collection to achieve accurate colony counts.

The BD Urine Collection Kit (Becton-Dickinson, Cockeysville, MD), designed to maintain the bacterial population in urine at room temperature for 24 hours, has been equally as effective as overnight refrigeration of specimens.[126] Although some decrease in colony count may be noted after prolonged storage, the system is recommended for transport of urine samples for which processing will be delayed up to 24 hours. Transport systems using boric acid, which is in included in the BD Urine Collection Kit additives, may offer an alternative method for home or remote collection of urine samples. Jewkes and associates[133] conclude from a study of 84 children that urine collection in boric acid minimizes contamination, although growth of potential bacterial pathogens may also be inhibited in a small number of instances.

Collection of valid clean-catch urine specimens for culture from incontinent elderly men residing in nursing homes also poses a problem. Nicolle and colleagues[210] reported success in diagnosing urinary tract infections in this population of patients by using an external collection device consisting of a sterile condom and leg bag. Before applying the condom, the glans penis was cleaned with soap and water and rinsed with

sterile saline. The leg bag was examined every 10 to 15 minutes until a specimen was obtained. Because contamination with low counts of bacteria occurred in almost 50% of the patients, rapid transport of the specimens to the laboratory and immediate transfer to culture media were required. Bacterial counts greater than 10^5CFU/mL, particularly if obtained on two successive collections, had a high correlation with other indicators of urinary tract infection.

Other Voided Urine Specimens. The purpose of the midstream technique is to collect urine that has been in the bladder after discarding the initial portion that has been in contact with the urethra—and presumably contaminated

83

with urethral microbiota. If one is investigating urethritis, however, it is actually the initial portion of voided urine that is of interest. Traditionally, a swab may be inserted into the distal urethra to collect the specimen. The primary application of initial voided urine specimens is the diagnosis of urethritis caused by *N. gonorrhoeae* and *Chlamydia trachomatis*.[135] More commonly, molecular methods are used on urine for the detection of these pathogens.

BOX 2-2

Instructions for Obtaining Clean-Catch Urine Specimens (Females)

1. Remove underclothing completely and sit comfortably on the toilet seat, swinging one knee to the side as far as you can.
2. Spread yourself with one hand, and continue to hold yourself spread while you clean yourself and collect the specimen.
3. Wash. Be sure to wash well and rinse well before you collect the urine sample. Using each of four separate 4× 4-inch sterile sponges soaked in 10% green soap or the equivalent, wipe from the front of your body toward the back. Wash between the folds of the skin as carefully as possible.
4. Rinse. After you have washed with each soap pad, rinse with a moistened pad with the same front-to-back motion. Do not use any pad more than once.
5. Hold yourself apart and allow the first few drops of urine to pass into the toilet bowl. Hold the cup on the outside and pass the remaining urine into the cup.
6. Place the lid on the container or ask the nurse to do so for you.

If one is considering the diagnosis of acute prostatitis, however, prostatic secretions are the specimen of choice. The most common technique is differential culturing of urine before and after prostatic massage. A 10-fold increase in bacterial numbers after massage of the prostate suggests the diagnosis.[72]

Catheter Collections. Catheterization for the express purpose of obtaining a urine specimen should be avoided if possible because of the risk of introducing bacterial pathogens. In a study of 105 women with suspected urinary tract infection,[315] the culture results obtained from midstream, clean-catch urine samples did not differ in sensitivity, specificity, or positive or negative predictive values from parallel straight catheter specimens collected immediately after the midstream samples. Catheterization should be restricted to patients who are unable to produce an adequate midstream sample, and it should be performed with meticulous attention to aseptic technique. The first several milliliters of urine from the catheter should be discarded to wash out any organisms that may have lodged in the catheter tip during transit through the urethra.

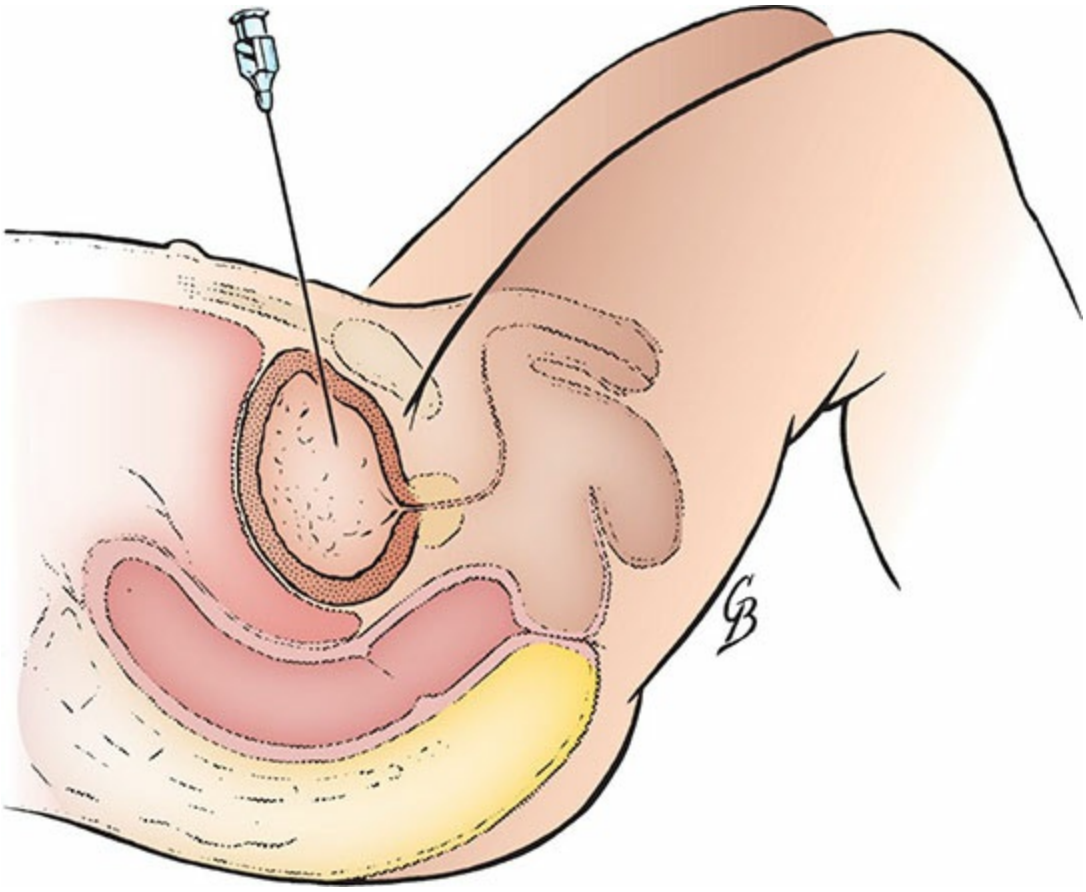
Urine samples from indwelling catheters (i.e., foley catheters) are not recommended, since it is not possible to differentiate the bacteria that have colonized the catheter from potential pathogens. Urine samples should not be obtained from catheter bags. Although it is tempting to use wet diapers or bags as a source of urine in infants, obtaining an interpretable specimen by these means is a major challenge. Foley catheter tips are unsuitable for culture because they are invariably contaminated with urethral or colonizing organisms.[304]

Suprapubic Aspiration. Suprapubic aspirations are reserved almost exclusively for neonates and small children. This technique is illustrated in Figure 2-3. The procedure is best performed when the bladder is full. The suprapubic skin overlying the urinary bladder is disinfected and sterile drapes are put in place. In the immediate site where the aspiration is to be made, an anesthetic solution, such as 1% lidocaine HCl, is injected subcutaneously. An 18-gauge, short-bevel spinal needle is extended into the urinary bladder and 10 mL of urine is aspirated into the syringe. Given the invasive nature of this technique, it is rarely used.

Culture of Urine Specimens

Both selective and nonselective media are required. A combination of 5% sheep blood agar and MacConkey agar is usually sufficient for the recovery of the organisms listed in Table 2-5. Some microbiologists whose laboratories serve primarily ambulatory patients, in whom *E. coli* is the most common pathogen expected, prefer to use eosin methylene-blue (EMB) agar because of the distinctive morphology of *E. coli* on that media. Although some microbiologists incorporate a medium selective for gram-

positive bacteria as well (e.g., colistin–nalidixic acid [CNA] blood agar or phenylethyl alcohol [PEA] agar), the yield from this addition is probably not worth the expense.[44] In many laboratories, inoculation of duplicate plates with both 0.01-mL- and 0.001-mL-calibrated loops is performed for comparison of counts as a quality control check and to facilitate counting colonies.



■ **FIGURE 2-3** Suprapubic urinary bladder aspiration. A needle is directed percutaneously into the urinary bladder just above the symphysis pubis. Urine can be removed with a syringe.

After delivering the inoculum from the calibrated loop, the surface of each agar plate should be completely streaked over all quadrants as demonstrated in Chapter 1 so that semiquantitative colony counts can be performed after incubation. A colony count of 10^5 CFU/mL or greater is the criterion most commonly used to determine whether identification and susceptibility testing of an isolate should be performed. When the colony count is between 10^4 and 10^5 CFU/mL, or when multiple species are recovered, the decision to make identifications and perform susceptibility tests must be

made by each laboratory director, often on a patient-by-patient basis. Some microbiologists use 10^4 CFU/mL as the decision point, because the calibrated loops tend to underestimate the colony count. Similarly, a pure culture is required in some laboratories, while a culture with two pathogens will be evaluated in others. (see Chapter 1 for further discussion of evaluating mixed cultures.)

Cultures of catheterized or suprapubic urine specimens are usually analyzed in detail, even with low colony counts or with the recovery of multiple organism types. Colony counts as low as 10^2 CFU/mL of enteric gram-negative bacilli may be significant in female patients with the acute urethral syndrome[284,285]; however, the physician must alert the laboratory in suspected cases, because semiquantitative urine culture techniques are not designed to detect such low colony counts. The significance of these "low-colony-count" infections has been documented only in women infected with enteric bacilli. Contamination is even more of an issue when evaluating small numbers of organisms. In one study, contaminated specimens were increased by 19% when a 0.01-mL loop was

used.[44] Discussion with the clinician about the significance of such isolates and the need for further work up is appropriate in these situations.

Screening Tests for Urinary Tract Infection

The literature on screening tests for urinary tract infection is voluminous, contradictory and sometimes confusing. It is useful to consider that screening for bacteriuria is a very different task than screening for inflammation.[334] The two will be considered separately.

With the exception of the few situations in which asymptomatic bacteriuria is clinically important, the function of the clinical microbiology laboratory is to test for symptomatic urinary tract infection. Many studies use the presence of 10^5 bacteria as a surrogate end point, but this approach is flawed. It is perhaps useful to think of the problem in the terms used to describe the approach to pneumonia. The diagnosis of urinary tract infection is made by evaluating clinical symptoms and/or testing for the presence of an inflammatory response. Once an infection has been documented, microbiologic culture is useful to determine the etiology of that infection.

Screening Tests for Bacteriuria. The presence of bacteriuria at concentrations that suggest urinary tract infection can be assessed by microscopic examination of the urine, by tests for bacterial products and by cultures. None of the tests detect low

colony counts in urine with adequate sensitivity.

Microscopic Examination. Gram's stain is an inexpensive method to estimate bacteriuria. In one study the presence of at least one organism per oil-immersion field in uncentrifuged urine had a sensitivity of 94% and a specificity of 90% for detecting colony counts of at least 10^5 CFU/mL.[319] This approach has the advantage that the Gram reactivity of the organisms can be characterized. Gram's stain of urine is not used in most clinical laboratories as a screening test, however, because methodically reviewing the smears is too labor-intensive. Examining unstained centrifuged urine as part of the urinalysis has been reported to have a sensitivity similar to Gram's stain on uncentrifuged urine,[44] but this experience has not been universal, and most clinicians do not depend on urinalysis for detection of bacteriuria. Differentiating bacteria from other particles in unstained preparations at moderate magnifications can be a challenge. A useful quality assurance tool is comparison of the results of culture and urinalysis.

Tests for Bacterial Products. One common approach is the use of a reagent-impregnated dipstick, designed to detect the presence of urine nitrite (Griess test) and indirectly to estimate the number of segmented neutrophils by detecting LE activity.[222]The rationale for the nitrite test is that most urinary tract infections are caused by nitrate-reducing members of the family *Enterobacteriaceae*, particularly *E. coli*. This test lacks accuracy when used alone.[136,197] False-positive results may occur if the specimen has been delayed in transit and overgrown with nitrate-reducing bacteria or from drug interference; false-negative results are encountered if the organism causing the infection does not reduce nitrates (e.g., *Enterococcus* spp.) or if the patient is on a vegetable-free diet (loss of an important source of nitrate).

The sensitivity of the combination nitrite–LE strip with bacteriuria at a level of 10^5 CFU/mL is in the range of 79% to 93%, with a specificity of approximately 82% to 98%.[136,222] In a multicenter study of 298 urine specimens with colony counts of fewer than 10^5 CFU/mL,[220] the strip detected 81% of infected patients. In a subset of 204 specimens with pyuria in addition to colony counts fewer than 10^5 CFU/mL (i.e., both inflammation and bacteria), however, the detection rate was increased to 95%.

An alternative approach is detection of catalase, which is produced by most uropathogens, marketed as Uriscreen (Savyon Diagnostics, Ashdod, Israel). It appears to function similarly to nitrite and suffers from the same defects. If the pathogens in a particular population of patients produce catalase, a negative catalase test effectively excludes high colony-count bacteriuria; it offers no advantage over a test for leukocyte esterase.[220,311]

Detection of Bacteriuria by Culture. Conventional culture is a simple and economic approach to screening. Although it does require 18- to 24-hour incubation, the decision to treat is rarely urgent. Some clinicians prefer to inoculate a urine dip slide in the office, rather than send the urine to a laboratory for culture. The dip slide

(SOLAR-CULT; Solar Biologicals, Ogdensburg, NY; Uricult, Orion Diagnostica, Espoo, Finland) is a paddle coated on each side with an agar intended to recover gram-positive and gram-negative bacteria. The paddle is dipped into the urine, drained, replaced in its container, and incubated. The quantity of growth is assessed by comparison to a chart. The dip slides are not waived tests; a clinician who uses them must meet the requirements for nonwaived tests, even if the bacteria are not identified and tested for susceptibility. The advantage of this approach is simplicity and economy for negative specimens. The disadvantage is the difficulty obtaining subcultures for subsequent evaluation of colonies. In the post-Clinical Laboratory Improvement Amendments (CLIA) 1988 era (see Chapter 1), many clinicians prefer the most straightforward approach of sending the original specimen to a diagnostic laboratory.

Screening Tests for Pyuria. LE is produced by polymorphonuclear leukocytes. A reagent strip, impregnated with buffered indoxyl carboxylic acid ester and a diazonium salt, can be used to detect LE activity in the urine. One advantage of this test is that leukocytes need not be viable for LE activity to be detected. When performed alone, this test correlated with 10 or more white blood cells per high-power field (WBC/HPF) in the urine, with a sensitivity in the range of 88% and a specificity of 94%.[155] False-positive LE test findings may result from high urinary levels of ascorbic acid or albumin (>300 mg/dL) or from the effects of preservatives and detergents. Most false-negative results occur when urine WBC counts are in the marginal range of 5 to 10/HPF. Kierkegaard and associates[145] report that 35% of urine samples in their study turned from positive (30 WBC/HPF) to negative (10 WBC/HPF or fewer) by microscopic exam when the urine was delayed in transit for 3 hours. Thus, the LE test may better reflect pyuria than does microscopic enumeration of neutrophils when the interval between collection and processing cannot be controlled.

A useful option to offer clinicians is that of performing a urine culture only if the LE test is positive (i.e., if an

inflammatory process is present). This approach is obviously not appropriate in the few situations in which asymptomatic bacteriuria is of concern or if the patient has neutropenia. The option to order a urine culture regardless of documented pyuria should be offered if the patient has the symptoms of an acute urinary tract infection.

Infections of the Genital Tract

The genital tract consists of external and internal genitalia in both sexes. In males, the

internal genitalia include the testes, epididymis, seminal vesicles and urethra (the prostate was discussed above). In the female, the internal genitalia are ovaries, fallopian tubes, uterus (primarily endometrium), uterine cervix, and the vagina with its accessory glands. The external genitalia consist of the penis and the labia.

Infections, for simplicity, can be divided conceptually into sexually transmitted infections, peripartum infections and vaginitis. The commensal microbiota and common pathogens of the genital tract are summarized in Table 2-6.

Sexually Transmitted Infections[47]

Urethritis and Cervicitis. The one of the most common sexually transmitted infection is caused by *C. trachomatis*, which causes urethritis and cervicitis. In men the symptoms primarily relate to urethritis (i.e., pain on urination and urethral discharge). Asymptomatic infections occur in men, but are less common than in women. In women, a distinctive mucopurulent cervicitis is a common manifestation of infection, in addition to acute urethritis.[36] The most serious complications of these infections is pelvic inflammatory disease, which can produce inflammatory scarring of the fallopian tubes that leads to infertility and ectopic pregnancies. This is especially problematic with *C. trachomatis* infection, which may be asymptomatic; therefore, screening of sexually active women is necessary to prevent these serious complications.[46] *N. gonorrhoeae* produces an infection that is similar to that caused by *C. trachomatis* in both men and women. Therefore many of the molecular diagnostic tests simultaneously detect and differentiate both these pathogens. It is recommended that when one of these infections is considered that tests for both are performed.

Mycoplasma hominis and *Ureaplasma urealyticum* are two causes of nongonococcal urethritis. Other *Mycoplasma* species may also cause disease. These organisms require special culture conditions. Newer diagnostic assays, including nucleic acid amplification assays that target these organisms, are now available through reference laboratories.

Genital Ulcer Disease

Herpes Simplex Virus. Several infectious agents, most sexually transmitted, produce ulcerated lesions in the external and/or internal genitalia.[194] By far the most common is

herpes simplex virus. The initial infection is frequently asymptomatic,[91] and asymptomatic shedding of virus occurs in a small percentage of both women and men.[312] In fact, the rate of viral shedding is very similar, whether a clinically evident

or an asymptomatic infection has occurred.[313] Clinical disease is most frequently accompanied by vesicular lesions with an erythematous base on the glans penis, vulva, perineum, buttocks, or cervix. The vesicles are painful, may ulcerate, and may be accompanied by systemic symptoms—fever, malaise, anorexia, and tender bilateral inguinal adenopathy.

TABLE 2-6 Commensal Microbiota and Selected Etiologic Agents in the Genital Tract

Anatomic Site	Commensal Microbiota	Sexually Transmitted Disease (STD) Etiologies	Non-STD Etiologies
Urethra	*Enterobacteriaceae*, α/γ-streptococci, Enterococcus spp., diphtheroids, coagulase-negative *Staphylococcus*, anaerobes (distal 1–2 cm)	*Chlamydia trachomatis* *Neisseria gonorrhoeae*	
External genitalia and perineal skin	Diphtheroids, coagulase-negative staphylococci, *Micrococcus* and *Kocuria* spp., yeast, *Acinetobacter* spp., *Enterobacteriaceae*	Herpes simplex virus, type 1; human papillomavirus; *Treponema pallidum; Haemophilus ducreyi; Klebsiella granulomatis* (granuloma inguinale); *Chlamydia trachomatis*, serotypes L1–L3 (lymphogranuloma venereum)	*Candida* spp.; *Streptococcus pyogenes*
Vagina	*Lactobacillus* spp., anaerobes, *Enterobacteriaceae*, α/γ-streptococci, *Enterococcus* spp., diphtheroids, coagulase-negative *Staphylococcus* (varies with age)	Human papillomavirus; *Trichomonas vaginalis*	*Candida* spp., bacterial vaginosis; *Staphylococcus aureus* (toxic-shock syndrome)
Endocervix	Normally sterile or minimally contaminated with vaginal flora	Human papillomavirus; herpes simplex virus, type 2; *Neisseria gonorrhoeae, Chlamydia trachomatis*	Cytomegalovirus
Endometrium, fallopian tube, ovaries	Normally sterile	*Neisseria gonorrhoeae, Chlamydia trachomatis*	Mixed aerobic-anaerobic infection (ascending); *Streptococcus pyogenes, Listeria monocytogenes, Streptococcus agalactiae; Actinomyces israelii* (in patients with intrauterine contraceptive devices)
Systemic infections with genital portal of entry		Human immunodeficiency virus (HIV), hepatitis B virus, hepatitis C virus	

Herpes simplex virus has two serotypes, which produce infections that differ both epidemiologically and clinically. Type 1 virus more commonly produces initial infections in infants, children and adolescents. Although traditionally infections caused by this virus are primarily in the upper half of the body, approximately one-third of genital infections are caused by this serotype. Conversely, type 2 virus is more commonly associated with sexual activity and with genital lesion, but infection of the oral and nasal mucosa may occur. The relative prevalence of the two serotypes varies geographically.[273] Infection with type 2 virus is increasing in the United States.[148] The presence or absence of symptoms after infection with type 2 virus is modified by preexisting antibody to type 1 virus[340] and may be influenced by characteristics of the infecting strain.

Herpesvirus establishes latency in the spinal ganglia after a primary infection.

Reactivation of genital herpes infection is more common and illness is more severe if the infecting strain is type 2 than if it is type 1. Recurrences decrease in frequency over time with both types of viruses.[19]

Other Genital Ulcers. In addition to herpes simplex, other genital ulcer syndromes include syphilis, chancroid (caused by *Haemophilus ducreyi*)[240]; lymphogranuloma venereum (caused by L1, L2, and L3 serotypes of *C. trachomatis*)[257]; granuloma inguinale (caused by *Klebsiella granulomatis*) and trauma.[240] The chancres of syphilis differ from those of herpes in that they are painless and have indurated margins with a clean base.[269] Chancroid ulcers, in contrast to syphilitic chancres, are painful and, in contrast to herpetic ulcers, do not have indurated margins. The primary pustule of lymphogranuloma venereum may resemble herpes simplex; however, this condition is usually recognizable by the massive bilateral necrotizing inguinal adenopathy. The primary lesion of granuloma inguinale is a subcutaneous nodule that erodes the surface, from which a beefy red, painless, elevated granulomatous lesion develops.

Although these other agents of genital ulcers are relatively uncommon in most areas of the United States, they are unfortunately increasing in frequency. In particular, syphilis[48] and chancroid[194,195] must be considered in the differential diagnosis in certain geographic areas and in certain patient populations. Chancroid, in particular, may be underreported.[254]

Interactions Between Genital Ulcers and Human Immunodeficiency Virus (HIV) Infection. Patients with genital ulcers of several etiologies are at increased risk for acquiring HIV. In fact, even nonulcerative sexually transmitted diseases, such as trichomoniasis, alter the mucosa and render the infected individual at increased risk for contracting HIV. Additionally, men who are infected with HIV shed type 2 herpes simplex virus more frequently than non–HIV-infected men (even if they have sex with men)[251] and are also quite likely more efficient at shedding HIV in the genital tract if they have ulcerative herpetic lesions.[250]

Venereal Warts. Human papilloma viruses (HPVs) produce exophytic excrescences in squamous epithelium of the skin (i.e., common warts and plantar warts) and mucosal surfaces of the respiratory and genital tracts.[114] Symptomatic anogenital warts (i.e., condyloma acuminata) are usually caused by genotypes 6 and 11. Condyloma acuminata are cauliflower-like excrescences that occur on moist mucosal surfaces, most commonly the vulva, vagina, penis, and anus. Keratotic and smooth pustular lesions occur on dry skin, while asymptomatic "flat warts" may be found in either smooth or dry areas. Untreated infections usually regress spontaneously, but latent or subclinical infection is probably common. The more serious manifestation of HPV infection is the cellular dysplasia and neoplasia that is produced by certain high-risk genotypes, particularly types 16 and 18.[23] Molecular testing for the detection of high-

risk HPV genotypes is now routine, with several excellent FDA-approved methods from which to choose. In addition, two HPV vaccines have been released that target certain high-risk HPV subtypes and are recommended for preteens.

Trichomonas vaginalis. *T. vaginalis* is a sexually transmitted protozoan parasite that infects both men and women. Many men and a substantial number of infected women are asymptomatic. Infection with this parasite classically produces a copious, frothy yellow or yellow-green discharge that collects in the posterior vaginal fornix. Traditionally, the direct microscopic examination to demonstrate the motile organisms has been performed in the physician's office. However, given the need for documentation concerning compliance standards surrounding provider performed microscopy, many physicians choose to submit the specimen to the laboratory. Because motility is lost relatively rapidly, enzyme immunoassays and, more recently, nucleic acid amplification assays have been approved for the detection of this parasite. The latter is particularly important in high-risk individual who are asymptomatic, as it can detect subclinical infections.

Genital Infections Transmitted by Nonsexual Means

Vaginitis and Vaginosis. Vaginitis is caused by a limited number of infectious agents, but noninfectious irritants can also cause inflammation, especially if the vaginal mucosa is atrophic.[276] The disease often involves the vulva (vulvovaginitis). Mixed infections may also occur. Classic presentations for candidiasis and bacterial vaginosis are described below, whereas trichomoniasis was described above. Unfortunately, the symptoms overlap sufficiently that it may not be possible to make a definitive diagnosis clinically.[249] In such instances, it is necessary to document the etiologic agent microbiologically. As many as half of vaginal infections have been reported as not having a demonstrable etiology; this, however, may change as more sensitive methods are employed.[249]

Candidiasis. The discharge in candidiasis is typically more thick and curd-like, and the vaginal mucosa tends to be erythematous. The most common agent is *C. albicans*, but

87

other species of *Candida* and even other genera can infect the vagina on occasion.

Bacterial Vaginosis. *Gardnerella vaginalis*, initially thought to be associated with bacterial vaginosis, actually works synergistically with anaerobic bacteria, such as *Mobiluncus* to produce the characteristic malodorous discharge.[280] The recovery of *G. vaginalis* in the absence of mixed anaerobic microbiota and symptoms of bacterial

vaginosis probably constitutes normal vaginal microbiota. It has been reported[78] that bacterial vaginosis (defined by clinical criteria) was not present in 55% of women from whom *G. vaginalis* was isolated. Therefore, culturing for *G. vaginalis* is not recommended because of the poor predictive value of this test. The importance of recognizing bacterial vaginosis clinically and establishing a laboratory diagnosis is emphasized.[122] In a study of 49 women with preterm labor, out of a subset of 12 who had concomitant bacterial vaginosis, 8 (67%) had a 2.1-fold increased risk for preterm birth before 37 weeks of gestation. Bacterial vaginosis was also associated with low birth weight. In the laboratory, bacterial vaginosis is best assessed through the use of the "scored Gram's stain," although newer, molecular methods are now available.

Infections of the Upper Female Genital Tract. These infections result from entry of vaginal microbiota into the upper genital tract.[45,121] The etiologic agents are, therefore, a mixture of aerobic and anaerobic bacteria. *A. israelii,* for example, has been shown to cause endometritis in women using intrauterine contraceptive devices.[75] The etiology is thought to involve the formation of a calcium carbonate nidus on the device, in which the *Actinomyces* species grow. In these infections, if *A. israelii* is present, the infections are more chronic and recalcitrant than if this particular organism is absent.

In the postpartum period, infection is a common cause of fever and even sepsis (i.e., puerperal infections).[84] The most devastating of these infections are caused by *C. perfringens*, typically after an illegal abortion with nonsterile instruments, and *S. pyogenes*, the classic cause of puerperal fever. One of the milestones of epidemiology and infection control was the study of puerperal fever by Semmelweis, who proved that the infection was carried to pregnant patients from the autopsy room by physicians who did not wash their hands.[132] The medical staff responded by ostracizing him; over a hundred years later, adequate handwashing remains a challenge for infection prevention.

Systemic Complications of Genital Infections

Infections in many organ systems result in organisms entering the bloodstream, resulting in disseminated infection and distant metastatic disease. In women, genital infectious agents may also be spread through the peritoneal cavity via the fallopian tubes, and toxins may produce extragenital effects after being absorbed through the mucosa. Dissemination of pathogens through the bloodstream occurs with *N. gonorrhoeae*, *Treponema pallidum*, and any of the agents of upper genital tract infection. *C. trachomatis* and *N. gonorrhoeae* produce a perihepatitis, known as Fitz–Hugh–Curtis syndrome.[146,337] *H. ducreyi*[239] and the lymphogranuloma venereum serotypes of *C. trachomatis*[138] spread to regional lymph nodes, where they produce

swollen, painful suppurative lesions. In addition, the granulomas of lymphogranuloma venereum may also be found in the rectal mucosa in individuals who practice receptive anal intercourse.[227] Granuloma inguinale, also known as donovanosis, does not produce regional lymphadenopathy,[14] but some variants of the infection may produce scarring that can result in lymphatic blockage, lymphedema and even elephantiasis of the external genitals.[259] Rarely, extragenital donovanosis can occur in any part of the body.[229] Finally, herpes simplex virus migrates through the peripheral nerves to the sacral ganglia, as mentioned previously. Reactivation of the virus can result in aseptic meningitis as well as recurrent genital disease.

Genital infections can also affect the fetus and the newborn infant. Some infections, primarily viral, will cross the placenta and infect the developing fetus.[225] These congenital infections include the rubella virus, cytomegalovirus, parvovirus, varicella zoster virus, and HIV, as well as *T. gondii* and *T. pallidum*. Other agents infect the neonate as it traverses the vagina (or in utero if an ascending infection causes chorioamnionitis). These infectious agents, mainly bacterial, include *N. gonorrhoeae* (conjunctivitis); *C. trachomatis* (conjunctivitis and neonatal pneumonia); and agents of neonatal sepsis, prominently herpes simplex virus,[147] *Streptococcus agalactiae*, *E. coli,* and *Listeria monocytogenes*.[123]

Diagnosis of Genital Tract Infections

Diagnosis of Urethritis, Cervicitis, and Vaginitis

Urethritis and Cervicitis. The traditional approach to diagnosis of gonococcal urethritis in men is to examine a Gram-stained preparation of the smear for the presence of intracellular gram-negative, biscuit-shaped diplococci. This finding alone in the discharge from women is insufficient for diagnosis, as nongonococcal *Neisseria* species are part of the normal vaginal microbiota. Although the presenting symptom in females may be a urethral discharge, clinical manifestations are usually more complex, and varying degrees of exudative cervicitis, vaginitis, salpingitis, and pelvic inflammatory disease may be present. Gram's stain is, therefore, recommended only for males with urethral discharge.[135]

Definitive diagnosis requires either the recovery of the etiologic agent in culture or demonstration of specific bacterial nucleic acid. The latter is the current reference standard as the molecular detection of *N. gonorrhoeae* and *C. trachomatis* is more sensitive than culture.[135] If sexual abuse is under consideration or if medicolegal questions are likely to arise, culture (with chain-of-custody documentation of the specimen) may be necessary; consultation with local authorities in such instances is recommended. Detection of antigen has been superseded by molecular approaches and should no longer be used.

Vaginitis. The quickest and least expensive method for diagnosis of vaginal infections is a wet preparation of vaginal secretions. It is possible to detect yeast of *Candida* spp., motile *T. vaginalis* (only if the specimen is examined promptly), and the clue cells of bacterial vaginosis by examining a drop of unstained secretions microscopically.

88

Bacterial vaginosis has been diagnosed by several means. Elevated levels of vaginal fluid sialidase activity, probably derived from enzymatic activity of *Bacteroides* species and *Prevotella* species,[30] and an elevation of vaginal fluid pH above 4.5 in conjunction with high levels of *G. vaginalis* (as determined by a specific DNA probe)[57,264] were other markers useful in confirming the diagnosis of bacterial vaginosis. Cook and associates[57] found that a persistent elevated pH and high polyamine and fatty acid levels in vaginal secretions along with clue cells in small numbers were valuable residual abnormalities predicting recurrence of bacterial vaginosis. Clue cells are vaginal epithelial cells that are covered with non-*Lactobacillus* bacteria, causing a change in the refractile index of the cells; they are a result of the altered bacterial microbiota in bacterial vaginosis. False-positive rates as high as 18.5% have been reported because other bacteria can also attach to epithelial cells. A 10% false-negative rate has been reported owing to inhibition of bacterial attachment by IgA. However, when the clue cell test is combined with the amine production or "whiff" test, the predictive negative value of 99% provides a good screen for the absence of bacterial vaginosis. Amine production is detected by mixing equal volumes of genital fluid and 10% KOH; perception of a fishy odor is a positive result.[179]

Microscopic examination for clue cells can be performed with a wet mount or a stained preparation, using the Papanicolaou (Pap) or Gram's stains. With Gram's stain the characteristic shift from predominantly gram-positive bacilli (*Lactobacillus* spp.) to mixed microbiota is also useful for making the diagnosis.[187] The Nugent scoring method is the most widely adopted means of scoring the Gram's stain for bacterial vaginosis.[212]As discussed previously, culture is not useful for diagnosis of vaginosis. There are newer molecular methods for bacterial vaginosis that have been or are soon to be released that warrant review.

If it is not possible to promptly examine a specimen from a symptomatic patient for the presence of *T. vaginalis*, there is a convenient and sensitive method for the transport of *T. vaginalis*. The InPouch TV Test (Biomed Diagnostics, White City, OR) consists of nutrient medium in a plastic pouch. After introduction of vaginal secretions, the pouch is resealed. It can then be examined immediately as a wet

preparation and/or incubated for subsequent periodic observation of motile trophozoites. Although less sensitive than culture or a wet preparation (in which the motility of the parasites facilitates detection), trichomonads can be visualized with Gram's stain or the Pap stain.

T. vaginalis may be submitted in Diamond's medium for culture, but this is not commonly performed and usually reserved for patients with refractory disease wherein an isolate will be needed to send for susceptibility testing. More recently, an capillary flow enzyme immunoassay (i.e., OSOM, Sekisui Diagnostics, Framingham, MA) became available, which is FDA cleared and CLIA waived for use in physician's offices; it reportedly has 82% to 95% sensitivity and a 97% to 100% specificity.[42,128]Additionally, molecular methods are now currently available and FDA cleared for use in the laboratory. Of these, the APTIMA *T. vaginalis* assay (Hologic, San Diego, CA) has the highest sensitivity and specificity, which are both between 95% and 100%. Laboratory-developed assays, with similarly high sensitivities and specificities are available through commercial reference laboratories. The high sensitivities of these nucleic acid amplification assays afford the detection of subclinical disease, which is important for early treatment and the prevention of disease transmission in high-risk individuals.

The direct examination (i.e., KOH/calcofluor white or Gram's stain) is usually sufficient to demonstrate the overabundance of yeast in women with *Candida* vulvovaginitis. Culture for yeasts has a limited role in diagnosis. In patients with recalcitrant or recurrent infections, fungal culture may be used to identify the type of yeast present and perform susceptibility testing.

Diagnosis of Genital Ulcer Disease and Venereal Warts. Diagnosis of genital ulcer disease may be by direct microscopy, immunofluorescence microscopy, molecular methods or culture, depending on the organism and the clinical situation. Herpetic ulcers may be sampled for viral culture or for demonstration of characteristic viral cytopathology. Herpes simplex virus produces multinucleated giant cells with intranuclear inclusions. They can be visualized after staining with Wright's stain (or Wright–Giemsa stain), hematoxylin–eosin stain, or the Pap stain. Alternatively, immunofluorescence or immunoperoxidase reagents can be used to stain viral antigen in epithelial cells or demonstrate the antigen in an enzyme immunoassay.[287] More recently has been the release of several FDA-approved nucleic acid amplification assays, most of which both detect and differentiate herpes simplex virus 1 and 2 from lesions.

The Donovan bodies of granuloma inguinale can be visualized (with difficulty) by staining the intracellular bacteria in mononuclear cells, using Wright's stain (or an equivalent stain), hematoxylin–eosin (used for primary histologic study of biopsies), or the Pap stain.[65,241] The classic culture technique for the diagnosis of chancroid used

rabbit blood agar, which is not available in most microbiology laboratories.[113] Fortunately, *H. ducreyi* can be cultivated on a variant of the enriched chocolate agar used for *N. gonorrhoeae*.[63,113] If the modified media are not available, enriched chocolate agar may be substituted. The presence of hemin (i.e., X factor) is needed for the growth of this organism. *H. ducreyi* is labile and does not survive well in transport. If standard transport media, such as Amies media, are used and the specimen is refrigerated, the bacteria can be recovered with acceptable accuracy.[64] Lymphogranuloma venereum is usually diagnosed serologically, but the agent can be cultivated if material from a suppurative regional lymph node is cultured for *C. trachomatis*.[257] None of the FDA-approved assays are cleared for this specimen type, so validation studies would be necessary to offer this type of testing, which is difficult given the low prevalence of infection in most settings.

The diagnosis of primary syphilis was classically made by darkfield microscopy of scrapings from the ulcer base.[157] The scrapings must be examined immediately, because visualization depends on having live, motile treponemes. This, however, is not commonly performed. Immunofluorescence reagents that react with *T. pallidum* have been available from the Centers for Disease Control and Prevention, but their continued availability is unsure. With these reagents a dried smear can be stained after transport to the laboratory.[130] Serologic diagnosis is the mainstay of diagnosis, the algorithm

of which has undergone significant changes. In brief, these changes allow for initial testing to be performed using treponemal assay (i.e., screening for *T. pallidum* IgG) followed by the use of the nontreponemal test (i.e., rapid plasma reagin [RPR]) on positive specimens. This change in the order of testing (i.e., traditionally nontreponemal tests have been performed first) affords higher throughput testing on automated instrument, which allows for the "screening out" of many specimens in a highly efficient manner.

Diagnosis of venereal warts must be made by molecular means because human papillomaviruses do not grow in cell culture and serologic responses are not dependable. The test for "low-risk" subtypes, which was performed in the past, is no longer recommended.[114] There are now three FDA-approved platforms for the detection of high-risk subtypes. One utilizes signal amplification technology, whereas the other two employ nucleic acid amplification. One of the latter has been cleared by the FDA as a "primary screen," which may represent a substantial change in the use of this test in women's health. Although it has been cleared for this purpose, at the time of this writing the major medical societies have not yet endorsed this approach.

Collection of Urethral Specimens From Males

When urethral discharge is scant and intracellular diplococci are not seen in a random sample, collecting an early-morning specimen before urination may be helpful. Exudate may be expressed from the urethral orifice by gently applying circumferential pressure to the penis; if material is not readily obtained, the tip of a narrow-diameter cotton, rayon, or Dacron swab on a plastic or aluminum shaft may be inserted 3 to 4 cm into the anterior urethra. The swab should be left in place for a few seconds to allow the fibers to become saturated with the exudate. If a culture for *C. trachomatis* is being obtained, the swab should be rotated 360 degrees to dislodge some of the epithelial cells. Urine specimens for nucleic acid amplification tests, which offer superior sensitivity, are now most commonly performed. Occasionally, however, culture may be needed, so the specimen collection portion above has been retained. Collection kits designed for each commercial assay are supplied by the manufacturer. The first portion of the urine, which contains urethral cells and bacteria that have been washed out, is collected, in contrast to the midstream urine that is obtained for the diagnosis of cystitis. The manufacturers of kits vary in the specifics of their recommendations for culture.

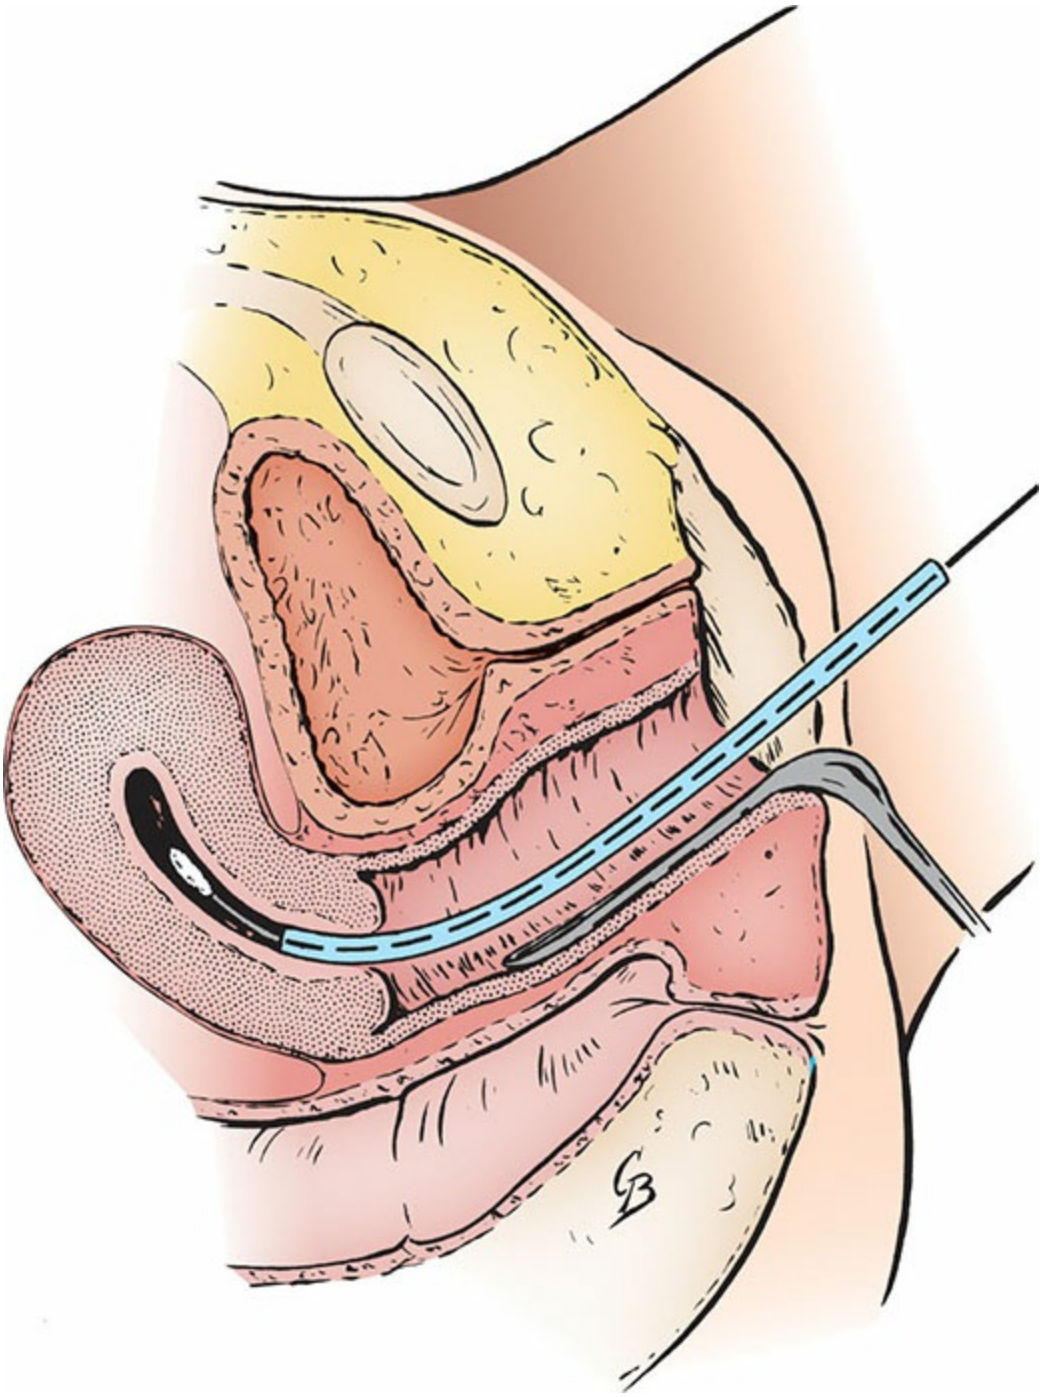
Collection of Genital Specimens From Females

In females with signs and symptoms of acute genital infection, samples are most commonly obtained from the uterine cervix. Cervical specimens are collected with the aid of a speculum after removal of the cervical mucus with a large swab. A smaller swab with a plastic shaft and a Dacron or polyester tip is recommended for obtaining the specimen.[174] The tip of the swab is inserted a few millimeters past the cervical os, rotated firmly to obtain both exudate and cervical cells, and removed, taking care not to touch the lateral walls of the vaginal canal. Urethral samples are more commonly obtained when screening asymptomatic women, and are obtained as a urine specimen. As it is for males, urine is a satisfactory specimen for diagnosis of infection in women. Although slightly less sensitive than cervical specimens, it is less invasive and may obviate the need for a speculum exam. Specific recommendations vary by manufacturer.

Vaginal secretions can be aspirated or collected with a swab. Specimens from the upper genital tract are difficult to obtain from below without contaminating the specimen with vaginal microbiota. Endometrial specimens are best obtained by inserting the swab through a narrow-bore catheter that has been introduced into the cervical canal, as illustrated in Figure 2-4. By using this technique, there is less chance of contaminating the specimen from secretions of the cervical os or the vaginal canal.[181] For specimens from the fallopian tubes and ovaries, laparoscopy or surgical approaches are necessary.

Collection of Specimens From Genital Ulcers

Ulcers should be cleaned to remove surface debris and contaminating bacteria. For darkfield examination or preparation of smears, a scalpel blade should be used to abrade the base of the ulcer and transfer the material onto a glass slide. For culture, either a washing of the base or a cotton swab may be used.[113] If intact vesicles are present, a swab may be used to collect fluid for Tzanck preparations or herpes culture. Swabs for bacterial culture may be placed in Amies' or Stuart's transport media.



■ **FIGURE 2-4** Endometrial culture technique. Through a speculum, a catheter is introduced into the cervical os and a swab extended through the catheter into the endometrial cavity. This helps prevent contamination of the swab by contact with the vaginal wall or the cervical os.

Infections of the Bones and Joints

Clinical Presentation and Diagnosis

Infections of the bones and joints may develop after bacteremic spread of the pathogen from a distant site, by direct extension from an adjacent infection or by introduction from the environment through trauma. The most common pathogenic organism in bacteremic spread is *S. aureus*, but other microbes may also reach the skeletal system by this route, including *Borrelia burgdorferi* (Lyme disease) and agents of systemic mycosis, such as *B. dermatitidis* and *Coccidioides* spp. Infections that originate in adjacent tissue are often polymicrobial and commonly include anaerobic bacteria. Traumatic lesions reflect the environmental microbiota introduced at the time of injury.

The symptoms of septic arthritis are fever, pain, and swelling of the affected joint(s).[266] Osteomyelitis may be associated with local pain and tenderness and with restriction of movement.[163] Systemic symptoms may be present in both types of disease. If the affected bone is in the extremity, the problem is usually evident. In acute vertebral osteomyelitis, there is often point tenderness over the affected vertebra. If however, the infection is subacute, there may be nonlocalized back pain or no local symptoms at all, especially in the elderly.[61] Osteomyelitis may become chronic, whereas septic arthritis is less likely to enter a chronic phase.

The diagnosis of osteomyelitis must be accomplished by surgical biopsy of the affected bone. Multiple specimens are often submitted from these surgeries. In addition to culture, it is important to have correlative histopathology. The fluid in a septic joint may be aspirated for microscopic examination and culture. Joint fluid clots readily, so special approaches are necessary. The fluid may be inoculated directly into blood culture bottles[127,153] or into the Isolator system,[342] an effective method for recovering single pathogens. Alternatively, the fluid may be inoculated into a sterile tube that contains sodium polyanethol sulfonate (SPS), the anticoagulant commonly added to blood culture bottles; after transport to the laboratory, the unclotted fluid can be processed as usual for any other normally sterile body fluid. If clotted joint fluid is received in the laboratory, cell counts cannot be performed, but the clot can be homogenized for Gram's stain and culture. It is essential to include chocolate agar when joint fluid is cultured, because fastidious bacteria are prominent pathogens. For infections that are thought to have originated with a bacteremia, blood cultures may yield the pathogen.[61] On occasion, recovery of *S. aureus* from blood in the absence of a clear source may be the first clue to vertebral osteomyelitis.

Infections of the Central Nervous System

The most common infections of the central nervous system (CNS) are encephalitis (brain), myelitis (spinal cord), meningitis (membranous covering of the brain and spinal cord) and meningoencephalitis. When meningitis and encephalitis (meningoencephalitis) occur together, they are most commonly part of the same infectious process. Infections of the soft tissue (e.g., epidural abscess) and bone (osteomyelitis) may impinge on the nervous system. Infections of the peripheral nervous system, which include neuroborreliosis (a variant of Lyme disease), leprosy and tuberculosis, are infrequent.

Meningitis

Patients with early acute meningitis may experience an influenza-like syndrome—sore and stiff neck, headache, low-grade fever, and lethargy. In elderly, debilitated, or immunosuppressed patients, an unexpected alteration in mental status may be the only clue to infection. Various degrees of confusion, agitation, disorientation, or coma may be observed. A positive Brudzinski's sign (i.e., resistance to passive neck flexion) and Kernig's sign (i.e., inability to extend the leg when the thigh is flexed at a 90-degree angle with the trunk) are signs of meningeal irritation. Subacute or chronic meningitis caused by tuberculosis or fungal infections may present with signs of increased intracranial pressure (e.g., papilledema, nausea, and vomiting) and mental changes, such as disorientation, confusion, personality change, and stupor.[190]

The cerebrospinal fluid (CSF) is normally water-clear, has no more than five lymphocytes per milliliter, has a glucose concentration between 45 and 100 mg/dL depending on the level of blood glucose, a protein concentration between 14 and 45 mg/dL and is sterile. The classic alterations attributable to meningitis are summarized in Table 2-7. Bacterial infections, which typically are accompanied by large numbers of polymorphonuclear leukocytes, are often called septic or purulent meningitis, whereas infections without a pronounced neutrophilic response (mycobacterial, viral, and most fungal infections) are called aseptic meningitis.[56] The common lay term "spinal meningitis" is not inaccurate, but it is not informative because it is rare for only one segment of the meninges to be infected; the term is often used for meningococcal meningitis, but obviously any agent can affect the spinal membranes.

Infectious agents can get to the CNS through the bloodstream or by direct extension from adjacent structures.

TABLE 2-7 Cerebrospinal Fluid Abnormalities in Meningitis

Parameter	Bacteria	Mycobacteria	Fungi	Viruses	Exceptions
Polymorphonuclear neutrophils	High to very high	High	High	Absent to elevated early; usually absent late	May be absent in *Cryptococcus neoformans*, in the profoundly immunocompromised host
Monocytes	Variable	Variable	Variable	Usually present	
Glucose	Low	Low	Low	Normal	May be low in herpes simplex infections
Protein	High	High	High	Elevated	

91

Herpesviruses and rabies virus reach the CNS by retrograde extension up peripheral nerves from spinal ganglia, but this route is unusual for other agents.

Meningitis is most prevalent in certain age groups or in patients with various underlying diseases. Meningitis in the neonate most commonly results from infection that is acquired from the mother in utero or during vaginal delivery.[6,344] *S. agalactiae* and *E. coli* are the organisms most often recovered; *L. monocytogenes*, various members of the *Enterobacteriaceae*, *Pseudomonas* spp., *Elizabethkingia meningosepticum*, *S. aureus*, and miscellaneous anaerobic bacteria are recovered less frequently. For reasons that are unknown, *Citrobacter koseri* (*diversus*) can cause a devastating meningoencephalitis in the neonate.[104] Herpes simplex virus type 2 produces meningitis in neonates after acquisition during vaginal delivery, which may progress to fully disseminated disease.[296]

N. meningitidis causes infections in all age groups. *H. influenzae* type B was the most common cause of acute bacterial meningitis in the 6-month to 5-year age group, but this infection has been virtually eradicated by an effective vaccine. Similarly, *S. pneumoniae* meningitis, which may result from bacteremia or extension of infection from adjacent sinuses or the middle ear, has been substantially reduced because of vaccination.

In adults, *S. pneumoniae* remains an important cause of bacterial meningitis. In young adults, *N. meningitidis* is also common pathogen for which a vaccine exists; this vaccine is highly recommended, but not mandated. *Listeria* is an important food-borne cause of meningitis, which preferential infection of individuals with underlying disease, such as malignancy. In the elderly, meningitis follows Shakespeare's ages of man, with the pathogens of the neonatal period making a reappearance. *E. coli* and other gram-negative bacilli are high in prevalence[190] and *S. agalactiae* is also a factor.[76]

Viral meningitis in all age groups is caused primarily by enteroviruses.[231] A large number of viruses that are transmitted by ticks and mosquitoes (arthropod-borne viruses or arboviruses) cause CNS disease uncommonly.[41] The West Nile virus has appeared in the United States since the last edition of this text and has subsequently

become endemic.[207]

C. neoformans, *M. tuberculosis* and the dimorphic fungi *H. capsulatum* and *Coccidioides* species cause indolent or chronic forms of meningitis in both intact hosts and in those with altered defenses. Recurrent aseptic meningitis (Mollaret's meningitis) is typically caused by herpes simplex virus,[295] but the diagnosis must be made by molecular means. *E. coli*, *K. pneumoniae*, and staphylococci are most commonly recovered from patients with posttraumatic or postsurgical meningitis. Approximately 50% of acute meningitis associated with ventricular shunts is caused by coagulase-negative staphylococci; other skin microbiota, such as *Corynebacterium* spp. and *Propionibacterium acnes* are also important causes.[190]

Naegleria fowleri, a free-living amoeba, produces a necrotizing meningoencephalitis termed primary amoebic meningoencephalitis, particularly in patients who swim in warm, brackish water.[172] *Acanthamoeba* spp. and *Balamuthia mandrillaris* are causes of chronic granulomatous meningoencephalitis. These parasites are addressed more fully in Appendix II.

Encephalitis and Brain Abscess

Brain abscess and encephalitis are the most serious infections of the CNS.[182,232,331] Encephalitis is most commonly caused by viruses, although it can also be produced by other agents, such as *M. pneumoniae*. The etiologic agent of most encephalitis syndromes is unknown.[100] Herpes simplex virus type 1 is the most frequently documented cause of sporadic encephalitis. The reactivated virus travels up the olfactory nerve to the temporal lobe of the brain, where it produces a necrotizing encephalitis that is distinctive because of the anatomic location. The diagnosis is unlikely in the absence of evidence of temporal lobe disease or a pleocytosis (inflammatory response) in the CSF, although exceptions have been described, particularly in children.[151] In the past, temporal lobe biopsy was required to achieve a definitive diagnosis. This practice is now very infrequent, with the diagnosis largely be achieved by herpes simplex virus PCR of the CSF.

Varicella-zoster virus also produces a localized encephalitis, but less commonly. This usually occurs in the setting of a patient with ophthalmic zoster (a recrudescent infection, usually years after chickenpox). The virus travels up the fifth cranial nerve and produces a necrotizing infection, often with vasculitis and presumably small vascular infarcts.[149] The clinical presentation can even mimic that of noninfectious stroke. This, too, is largely diagnosed by varicella zoster virus PCR of the CSF.

Other types of sporadic or epidemic encephalitis affect the brain diffusely; clinical and radiographic data are not diagnostic of a particular etiology, which must be made with serologic, microbiologic or molecular techniques. Rabies, fortunately extremely rare, is uniformly fatal if untreated; if associated with an animal bite, the diagnosis is

obvious, but contact with an animal is not always obvious and the diagnosis may not be made until autopsy.[211] Unfortunately, the rabies virus is now listed amongst the agents that can be transmitted by organ transplantation.

Anaerobic bacteria are frequently recovered from brain abscesses; anaerobic streptococci, *Prevotella melaninogenica*, *Bacteroides* spp., *Fusobacterium nucleatum*, *Eubacterium* spp., and *P. acnes* are the most commonly encountered species. The aerobic bacteria most commonly recovered include α and β-hemolytic streptococci, *S. aureus*, *S. pneumoniae* and gram-negative bacilli, both *Enterobacteriaceae* and nonfermentative organisms. *Nocardia* spp. and the certain dematiaceous fungus such as *Cladophialophora bantianum* (formerly *Xylohypha bantiana*) are particularly neurotrophic and may also produce brain abscesses.[258] A necrotizing encephalitis can result from extension of a zygomycetes fungus from a sinus into the eye and brain (i.e., rhinocerebral zygomycosis), particularly in patients with neoplastic or immunosuppressive disease and in diabetic patients who are experiencing ketoacidosis.[178]

Brain abscess may result from bacteremic spread, particularly in patients with bacterial endocarditis, wherein a single organism is usually recovered.[205] Conversely, there may be direct extension from an infection in an adjacent sinus or in the middle ear; in these instances the infection is often polymicrobial.[242] Most viridans streptococci are recovered as part of a polymicrobial infection, but one particular *Streptococcus*, known colloquially as "*Streptococcus* Milleri group," causes abscesses in several organs, including the brain, often as a sole pathogen.[54]

92

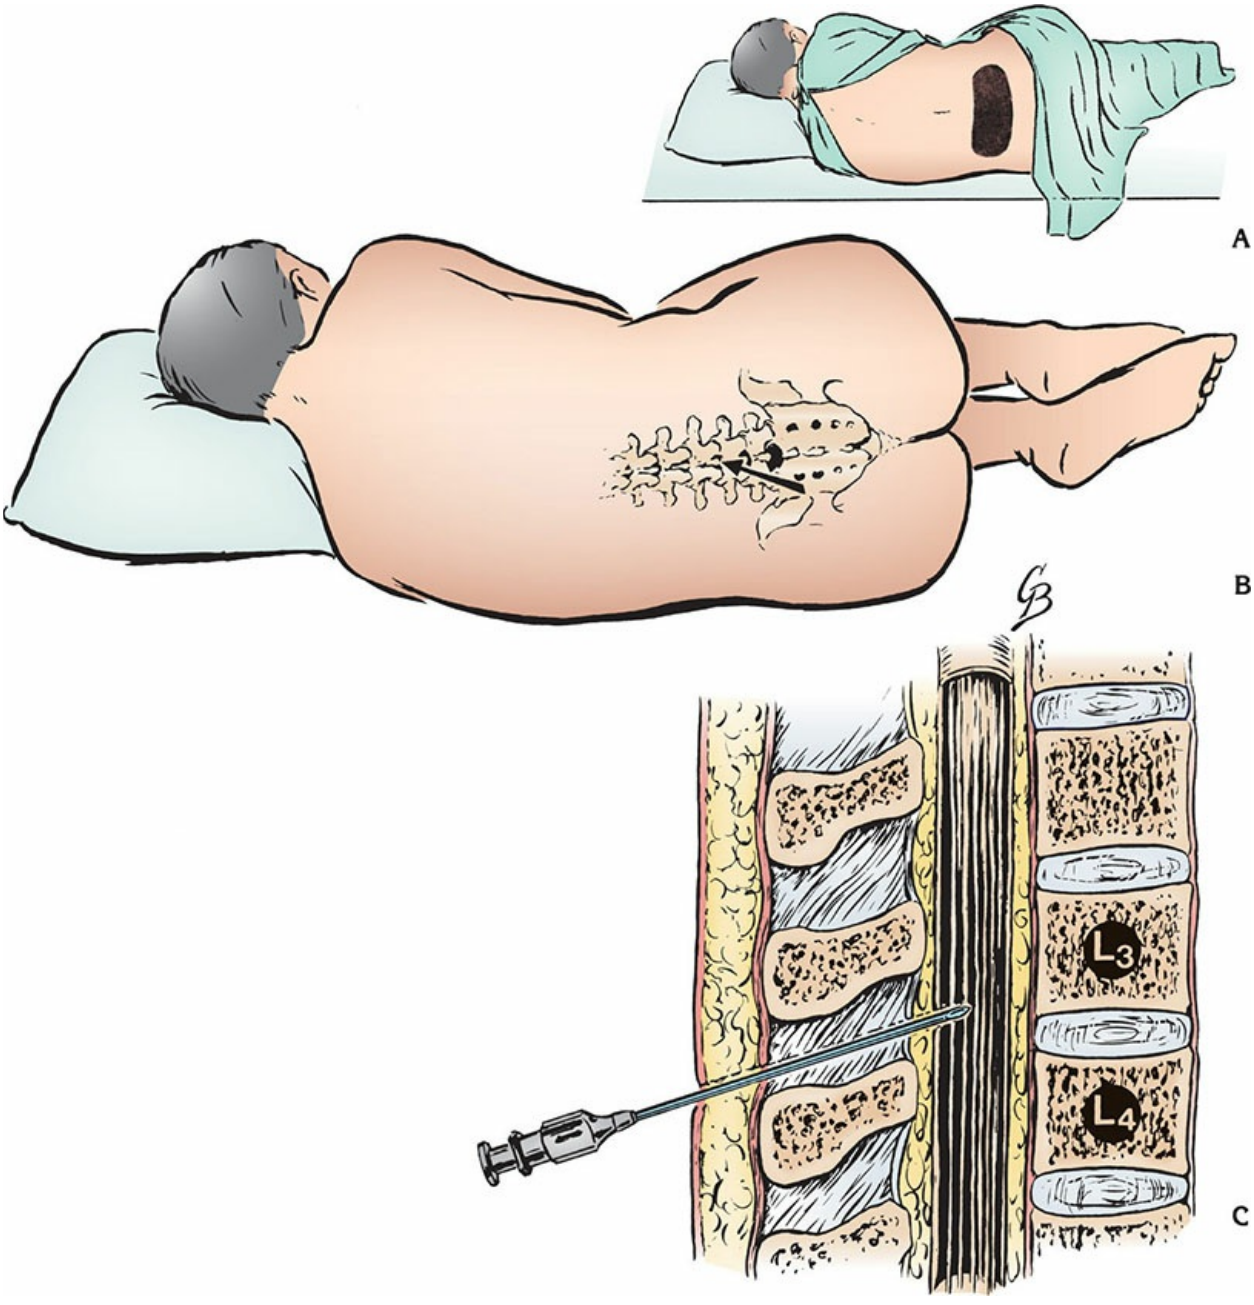
Several parasitic infections can cause necrotizing infection or a mass lesion in the brain. These include *Acanthamoeba* spp. and related free-living amoebae,[172] *Taenia solium* causing cysticerci[262] and *T. gondii*.[87] Cerebral malaria, caused by *Plasmodium falciparum*, is an often fatal complication in which the cerebral capillaries are occluded and the brain becomes hypoxemic.[116,275]

Diagnosis of Central Nervous System Infections

Collection of Specimens. CNS specimens for culture include CSF (obtained either by subdural or ventricular aspiration, or lumbar puncture), brain abscess (obtained by aspirate) and brain tissue (obtained by surgical biopsy). The spinal tap technique is illustrated in Figure 2-5.

CSF obtained from lumbar spinal puncture is the most common CNS specimen received in the laboratory. Optimally, three separate tubes of CSF fluid are submitted:

Tube 1 for cell counts and differential stains
Tube 2 for Gram's stain and culture
Tube 3 for protein and glucose, or for special studies, such as Venereal Disease Research Laboratory (VDRL; a serologic test for syphilis), cryptococcal antigen testing, or cytology, depending on the clinical situation.



■ **FIGURE 2-5** Spinal tap technique: The patient lies on his or her side, with knees flexed and back arched to separate the lumbar vertebrae. **A.** The patient is surgically draped, and an area overlying the lumbar spine is disinfected. **B.** The space between lumbar vertebrae L3

and L4 is palpated with the sterilely gloved forefinger. **C.** The spinal needle is carefully directed between the spinous processes, through the intraspinous ligaments into the spinal canal.

93

Assessing the Inflammatory Response and Microscopic Techniques. An orderly approach to the processing and culture of CSF specimens should be implemented. The time from when a specimen is obtained to when it is received in the laboratory should be monitored, as should the time from receipt to result. Prolonged transport time and process-to-result time may have deleterious effects on patient care. Examining stained smears of CSF sediment is helpful both in establishing a presumptive diagnosis and in providing guidelines for the selection of culture media. Microorganisms can often be detected in Gram-stained or methylene-blue-stained CSF smears if they are present in concentrations of at least 10^4 to 10^5/mL. Some suggest that gram-negative organisms are often better observed in the methylene-blue-stained smear because the deep blue-staining cells are easier to differentiate from the background debris.[62] Safranin stains the background pink-to-red in Gram's stain, tending to obscure any pink-staining bacteria. The addition of 0.05% basic fuchsin to the safranin counterstain improves the staining of gram-negative organisms. Smalley and Bradley[271] suggest that the LE test may substitute for the performance of cell counts on body fluids suspected of harboring bacteria, but this has not become a common practice. In a study of 63 culture-positive peritoneal fluids, 85.7% also had positive LE reactions. Six of the nine culture-positive and LE-negative fluids grew only a few colonies of coagulase-negative staphylococci, isolates of questionable clinical significance. DeLozier and Auerbach[68]reported an overall sensitivity of 84.4% and a specificity of 98.1% using the dipstick LE test on spinal fluids collected from 800 patients with suspected meningitis. The sensitivity of LE in culture-proven cases of bacterial meningitis was only 73%. They concluded that the LE is an adjunct to, but not a substitute for, CSF cell count and chemistry determination in the initial laboratory assessment of bacterial meningitis. The use of antigen testing of CSF specimens for bacterial pathogens has largely been abandoned and is often discouraged. Soon to be released multiplex molecular diagnostic assays hold great promise in the more rapid detection of the agents of meningitis.

Direct Detection of Antigen and Nucleic Acid. The initial enthusiasm for the rapid diagnosis of bacterial meningitis by antigen detection has been tempered by more recent experiences.[237] When latex particle agglutination tests for *H. influenzae* type B, *S. agalactiae*, *N. meningitidis,* and *S. pneumoniae* were performed on 1,540 CSF

specimens obtained from patients with suspected acute bacterial meningitis, antigen was detected in only 27 samples.[230] The positive antigen results were helpful only in the treatment of neonates with group B streptococcal infections. These authors considered the latex test not to be cost-effective. In addition, occasional false-positive agglutination results in an unacceptably poor predictive value of a positive result. Use of these tests has declined dramatically and cannot be recommended.

In contrast, direct detection of cryptococcal antigen in the spinal fluid is almost as sensitive as culture and has often replaced the less sensitive India ink test in most laboratories. Latex agglutination and enzyme immunoassay kits have been developed. In a study of 218 CSF specimens, which included 16 retrospective and 6 prospective patients with proven cryptococcosis, 2 latex antigen kits performed with 100% sensitivity compared to culture.[339] False-positive tests occur occasionally, caused at least in part by the presence of rheumatoid-like factors in specimens or inappropriate specimen transport.[333] Although infections with *Trichosporon* are very infrequent, specimens from such patients have produced false-positive cryptococcal antigen-detection results. Treatment of the specimens with pronase decreases spurious reactions, but does not completely eliminate them.[245] The sensitivity of latex tests on serum, but not on CSF, is increased by treating the specimen with pronase.[111]

Molecular techniques have been developed for diagnosis of selected infections, primarily those caused by herpes simplex virus and enteroviruses.[248,306] These application by far exceed the sensitivity of culture-based methods for the detection of these viruses from these specimens and have become the standard of care for the detection of these pathogens from CSF. Although not yet commercially available at the time of this writing, there are multiplex PCR assays in development that target the causative agents of meningitis and meningoencephalitis. These will use platforms that are currently FDA-approved and in use for the detection of respiratory viruses and gastrointestinal pathogens.

Serologic Diagnosis. Serology is a useful diagnostic tool for confirmation of infections by many of the arboviruses, such as the West Nile virus. These are important as the period of viremia is transient and serologic results may exceed reverse transcription-polymerase chain reaction (RT-PCR) of CSF specimens in sensitivity. Detection of IgM in CSF is currently the method of choice in selected laboratories where the performance of the test is carefully controlled and monitored.[176,224] The ratio of CSF immunoglobulin to measles virus compared to serum antibody levels has been used for the diagnosis of subacute sclerosis pan encephalitis (SSPE).

Diagnosis by Culture. Culture is the diagnostic standard for bacteria and fungi. The CSF specimens from patients with chronic, often basilar, meningitis caused by *M. tuberculosis* and the dimorphic fungi, *H. capsulatum* and *Coccidioides* are often

negative. The diagnosis in these instances often relies upon the assessment of a meningeal biopsy by both culture and histopathology. Culture of viruses from these specimens is largely not performed, given the superiority of molecular methods. The most important question in meningitis is whether a bacterial agent that could be treated with antibiotics is present, so Gram's stain and bacterial culture are essential.

In preparing CSF specimens for culture, the fluid should be centrifuged to concentrate any bacteria that may be present. Centrifugation is also recommended for the recovery of *M. tuberculosis* in patients suspected of having tuberculous meningitis. A total volume of at least 6 mL, which need not be collected all at once, should be processed to increase the likelihood of recovering mycobacteria.[298] As an alternative to centrifugation, the CSF can be passed through a 0.45-γm filter (Millipore, Bedford, MA) to concentrate the microbial cells. The filters should be placed face down on the surface of the agar and moved to a new location after 24 hours of incubation. An excellent review of the approach to the laboratory diagnosis of meningitis has been published by Gray and Fedorko.[105]

94

Wounds, Abscesses, and Cellulitis

Clinical Presentation

The accumulation of pus, either within an abscess, exuding from a sinus tract or from a mucocutaneous surface, is one of the cardinal indicators of a suppurative infection. Varying degrees of redness, pain, and swelling may also be present. Exogenous wound infections include those associated with traumatic injury or decubitus pressure ulcers (bedsores),[166] animal or human bites,[90,293] burns,[67,185] or foreign bodies in the skin or mucous membranes.

Endogenous wounds and abscesses may be associated with appendicitis, cholecystitis, cellulitis, dental infections, osteomyelitis, empyema, septic arthritis, sinusitis, or other internal infections. Many of these processes are nosocomial (i.e., acquired in healthcare institutions), contracted after invasive procedures, surgical manipulations or the placement of prostheses. Conversely, these may be derived from hematogenous spread of microorganisms from a primary site of infection to distant (i.e., metastatic) sites. Finally, there may be direct extension of bacteria from an adjacent site of infection or from ruptured viscera, particularly the large intestine. Anaerobic bacteria are commonly present when the infectious site is adjacent to the intestine or when the wound is contaminated with fecal microbiota.[208]

Certain bacteria are associated with particular clinical situations. For example,

Pasteurella multocida is commonly found in wounds that result from animal bites.[90,293] *P. aeruginosa* is a common pathogen when a penetrating injury of the foot occurs in patients who are wearing sneakers.[131] *P. aeruginosa*, *Candida* spp., and a variety of filamentous fungi are common causes of burn wound infections,[170] but herpes simplex virus has also been noted in this population patients.[93] Aerobic gram-positive bacteria, such as *Staphylococcus aureus* and *Streptococcus pyogenes*, strict anaerobic bacteria, and aerobic gram-negative bacilli frequently cause infections in patients with diabetes.[139]

Many wound infections and abscesses are polymicrobial, particularly those that result from fecal spillage, bedsores, and infections in diabetic patients. There is considerable dispute about the value of identifying and testing the antimicrobial susceptibility of multiple isolates, even if the specimen is a biopsy of tissue. Problems of sampling make it difficult to ensure that all pathogenic species have been recovered. A particularly instructive example of this phenomenon is a study of abscesses, in which multiple cultures of each specimen were performed over a 24-hour period; 11 of 37 total anaerobic strains were not recovered in the initial plating.[12] A case can be made, therefore, for empiric therapy based on the likely pathogens expected in a particular clinical situation, particularly in instances of polymicrobial infection.[28]

Cellulitis is a soft tissue infection that spreads through the planes of the superficial connective tissue rather than producing a mass lesion, which is what occurs when an abscess is produced. It is often possible to see the redness and feel the heat and swelling of the process by palpation of the overlying skin.[291] Cellulitis is most commonly caused by staphylococci and streptococci, but in certain situations, gram-negative bacilli and anaerobic bacteria are implicated. A deeper infection that spreads through the connective tissue (i.e., the fascia) is termed necrotizing fasciitis. This is characteristically caused by organisms such as *S. pyogenes* and *C. perfringens,* but may be caused by other bacteria. It is a rapidly progressive disease that must be treated as a medical and surgical emergency.

Diagnosis of Wound Infections, Abscesses, and Cellulitis

Collection of Specimens. Surface wounds are rapidly colonized with environmental bacteria. Therefore, if there is an underlying wound infection or associated cellulitis, a superficial specimen collected on a swab is more likely to reflect this colonizing microbiota than the true cause of the infectious process. Even if the true pathogen is recovered among the denizens of colonizing microbes, it is not possible to determine which of the many organisms recovered is the cause of disease. Therefore, a deep biopsy of tissue following curettage of the superficial aspects of the wound, or aspiration of loculated fluid/pus from the depths of wound or underlying abscesses using an approach through nearby decontaminated skin, are the most desirable

methods for collecting material to examine. The skin through which the aspiration will occur should first be decontaminated with surgical soap and 70% ethyl or isopropyl alcohol, chlorohexidine, or a similar disinfectant. In the past, the aspirating syringe was often used as the transport container, provided the needle was capped. This procedure is no longer acceptable because of the risk that a blood-borne virus will be transmitted by a needlestick. The aspirated material should be discharged into an anaerobic transport vial and promptly sent to the laboratory for processing. The syringe with the needle should not be recapped, as this also represents a needlestick hazard; rather, following the discharge of the specimen into a transport container, the needle and syringe should be discarded into an approved "sharps" container.

Aspiration of material from an area of cellulitis, with or without first injecting sterile normal saline may be attempted, but the results are usually unsatisfactory. Punch biopsies may provide more satisfactory results.[291] Regardless of whether aspiration or biopsy is attempted, these should be performed at the leading edge of the cellulitis. Blood cultures are usually not useful in this clinical situation.[219] Commonly, the therapeutic approach is defined by empiric knowledge of the pathogens expected in a given clinical situation.

Microscopic Examination of Specimens. Gram's stain should be performed on all specimens (see Chapter 1). There are several scoring systems for wound specimens that all work toward the same end (i.e., identifying those specimens wherein the culture workup will most likely demonstrate the agent of a wound infection rather than colonizing microbiota).[263] Morphologic clues to the etiology may suggest additional diagnostic procedures beyond those requested by the clinician; (e.g., anaerobic or fungal cultures). If a biopsy of tissue is received, histologic examination of hematoxylin-eosin–stained sections will disclose the type of inflammatory response, which should direct the ordering of subsequent histochemical stains for bacteria and fungi,

95

and possibly immunohistochemical stains for the assessment of potential viral inclusions.

Culture. Nonselective, selective/differential and enriched nonselective media should be used to recover both eugonic and fastidious bacterial species. Anaerobic culture is appropriate if tissue or aspirated material has been obtained, but is inappropriate for surface cultures and swabs.

Quantitative microbial cultures have been advocated for culture of wounds, by some, to determine the significance of isolates, predict the likelihood of burn wound

sepsis, and determine the probability that wound healing will proceed smoothly. Quantitative culture of biopsied tissue is complex, expensive, and time-consuming; tissue must be weighed on an analytic balance, homogenized in a measured amount of broth, diluted serially, and inoculated onto multiple agar plates. These maneuvers are difficult for most laboratories to accomplish. It is clear that infections by *S. pyogenes* are clinically important, no matter what the quantity of bacteria present.[238] Currently this approach is not endorsed, with the exception of perhaps uncommon circumstances, such as burn wound infections. The problem is complicated still further by the evidence that a single biopsy of a wound will not give an accurate picture of the entire microbiota of chronic wounds.[253]

There are data that support the use of surface cultures rather than biopsies[28]; although sometimes these are unavoidable, the difficulty in the interpretation of the findings from these versus a deeper, surgically obtained biopsy remains a fact. Similarly, semiquantitative cultures (i.e., performed routinely by serial streaking of quadrants on agar plates) have provided information that is equivalent to the more difficult quantitative approaches.[40] Obviously, if no microbes are recovered, a qualitative culture provides the same information as a quantitative one.

Eye Infections

Clinical Presentation

Infectious agents may become introduced to any part of the eye, either externally or from an endogenous source. External infections usually involve the superficial structures—the conjunctiva and the cornea—unless there has been a penetrating injury that introduces microbes into the globe. Infections from endogenous sources often include seeding of the eye from microorganisms present in the blood (e.g., endocarditis) or reactivation of latent viruses or parasites (e.g., cytomegalovirus or toxoplasmosis).

Conjunctivitis. The conjunctiva is a thin membrane that covers the eyelid (palpebral conjunctiva) and reflects onto the outer surface of the eyeball, the sclera (bulbar conjunctiva). The central cornea is not covered. The conjunctiva may be infected by a variety of many microbes, most of which inhabit the upper respiratory tract. Inflammation (conjunctivitis) produces redness (pink eye), itching and a discharge, which may be mucous or purulent.[161,292] The exudates in bacterial infection are particularly thick, sticky and encrusted, so the eyelids may stick together. Acute noninfectious inflammation may also develop in patients with seasonal allergies. Conjunctivitis is highly contagious; the infection can be transferred easily to the other

eye or to other individuals by contact (e.g., rubbing the infected eye and then the normal eye).

The most common bacterial pathogens are *Staphylococcus aureus*, *H. influenzae*, *Streptococcus pneumoniae* and *P. aeruginosa*. Acute conjunctivitis can result from two sexually transmitted pathogens, *C. trachomatis* and *N. gonorrhoeae*, which can affect sexually active adults or neonates who acquire the infection during vaginal delivery. The most common viral etiology is adenovirus, which can cause epidemic disease, with or without associated pharyngitis (i.e., epidemic pharyngoconjunctival fever).

Keratitis. Keratitis, inflammation of the cornea, is a much more serious infection than conjunctivitis. Rather than the temporary discomfort of conjunctivitis, keratitis can result in scarring and blindness. It is caused by infectious agents in every class. The most common bacterial agent is *S. aureus*.[164] Filamentous molds, especially *Fusarium* spp. and *Aspergillus* spp., and yeast, most commonly *Candida* spp. produce a lesion that may resemble bacterial infection, delaying diagnosis and appropriate treatment.[150] Herpes simplex virus can cause an ulcerative lesion called dendritic keratitis because of the branching pattern of the lesions.[173] Reactivated varicella-zoster virus (shingles) can produce a similar keratitis, if it affects the ocular branch of the trigeminal (i.e., fifth cranial) nerve.[287] In people who wear contact lenses, *Acanthamoeba* spp. (a free-living amoeba) can produce ulcerative lesions that are frequently very painful (Appendix II).[172]

Interstitial keratitis, produced when blood vessels grow into the cornea from the conjunctiva, is the most common cause of blindness in the world. Trachoma is a form of chronic keratoconjunctivitis that is produced by *C. trachomatis*.[138] The scarring that can result from recurrent disease has six million people worldwide. The World Trachoma Initiative aims to eliminate this treatable infection by 2020. In parts of Africa, a filarial parasite, *Onchocerca volvulus*, which is transmitted by black flies (*Simulium* spp.), produces an intense inflammatory response when migrating worms die, resulting in river blindness.[110] Other causes of interstitial keratitis include *T. pallidum* (syphilis),[159] *Mycobacterium leprae* (leprosy), and *M. tuberculosis* (tuberculosis).

Keratitis (and blindness) can also be produced by noninfectious injury, such as trauma, ultraviolet radiation (i.e., the reason for not looking directly at the sun, particularly during an eclipse) and conditions that diminish the tears that lubricate the cornea.

Uveitis and Endophthalmitis. The most serious infections are those that affect the interior of the eye. Endogenous infections reach the eye through the bloodstream. A

variety of bacteria, fungi, and viruses may be responsible. Likely the most common cause is endocarditis, wherein the eyes, as well as various other organs, are seeded by the continuous bacteremia. Other endogenous infections include reactivation of latent viruses and parasites, such as cytomegalovirus and *T. gondii,* respectively. Exogenous infections are usually associated with penetrating trauma to the eye. A special category is postsurgical infection. An exogenous parasitic source is the infection with animal helminthic parasites, such as *Toxocara canis, T. cati,*

96

or *Baylisascaris.* The infection of humans by these parasites results in visceral larva migrans, wherein the immature larvae wander since they are in the wrong host; these infections commonly involve the eyes and the CNS.

Diagnosis of Eye Infections

Collection of Specimens. Conjunctivitis is usually diagnosed with a swab of the affected conjunctiva, which can be placed in an appropriate transport medium. All other infections are appropriately collected by an ophthalmologist. Keratitis is addressed by scrapings of the affected lesion; if a bacterial or fungal etiology is suspected, material is often inoculated directly onto appropriate media by the clinician. Specimens for the diagnosis of endophthalmitis must be collected surgically.

Microscopic Examination. Depending on the pathogen suspected and quantity of specimen, Gram's stain, calcofluor white or Wright's stain (or equivalent) should be performed. If tissue is obtained surgically, appropriate stains for infectious agents should be done.

Culture. The appropriate media to inoculate depends on the clinical assessment of the most likely etiologies. Most of the commonly encountered bacterial and fungal pathogens can be cultivated on routine media. For certain pathogens, such as the agents of syphilis, leprosy, and parasitic infection, the diagnosis must be made microscopically or serologically.

Infections of the Blood

Clinical Presentation and Pathogenesis

Bacteremia and Septicemia. The suffix "-emia" refers to the circulatory system. Bacteremia, fungemia and viremia are states in which bacteria, fungi, and viruses, respectively, circulate through the vascular system. Signs and symptoms may be

present, but are not invariable. If the patient is not aware of the illness (i.e., the circulating microbes), then the condition is termed "silent" or "subclinical." In contrast, septicemia (sepsis) is a clinical syndrome characterized by fever, chills, malaise, tachycardia, hyperventilation and toxicity or prostration. Septicemia results when circulating bacteria multiply at a rate that exceeds their removal by phagocytes. The symptoms are produced by microbial toxins and/or cytokines produced by inflammatory cells.[217] It now appears that the immunostimulation of cytokines is followed by a series of important immunosuppressive events.[125] Failure of multiple organs is an important component of fatal sepsis, but the pathogenetic mechanisms that lead to death remain unclear.

Sepsis is traditionally associated with gram-negative bacteria, which contain endotoxin.[184] It is now well appreciated, however, that gram-positive bacteria and fungi can also cause the sepsis syndrome.[5,82]

Types of Bacteremia. Bacteremia may be transient, intermittent or continuous, reflecting several mechanisms by which bacteria enter the bloodstream. Transient bacteremia occurs when organisms, often members of the normal microbiota, are introduced into the blood by minimal trauma to membranes (e.g., brushing of teeth, straining during bowel movements or medical procedures[160]). Intermittent bacteremia occurs when bacteria from an infected site are periodically released into the blood from extravascular abscesses, spreading cellulitis or infections of body cavities, such as empyema, peritonitis or septic arthritis. Continuous bacteremia usually occurs when the infection is intravascular, such as infected endothelium (bacterial endocarditis or aneurysms) or infected hardware (arteriovenous fistulas, intraarterial catheters, or indwelling cannulas). The source of organisms may not be determined, however, in up to one-third of bacteremias.

Bacteremia may result from an infection in an organ or tissue (secondary bacteremia). Often, however, the primary site is not evident (primary bacteremia). In this situation it is possible that a transient bacteremia was not efficiently cleared by host defense mechanisms. At least in the case of *S. aureus,* it has been shown that colonizing bacteria in the nose may be the source of the systemic infection.[309] The factors that trigger dissemination from the anterior nares remain unclear, but simple mechanical spread to the skin and subsequent infection of wounds or intravascular devices is one possibility.

When an infection in an organ spills over into the blood (e.g., bacteremic pneumococcal pneumonia), the severity of the infection is often increased and the prognosis for the patient worsened.[204] Conversely, bacteremia can result in disseminated infection in distant organisms, a phenomenon that is termed "metastatic infection."

Bacteremia can also be classified as community-acquired or nosocomial. It can occur in immunocompetent or immunosuppressed hosts. The types of organisms and the prognosis of the resulting infection vary greatly depending on these factors, as well as on the age of the patient.[88,168,191,268]

A variety of bacteria have been recovered from the bloodstream, both gram-positive[221] and gram-negative.[71] Over the past several decades, there has been a clear shift in the nature of the infecting microbiota. The number of anaerobic isolates has decreased over that time, whereas the number of isolates of yeast and clinically significant coagulase-negative staphylococci has increased.[329] For reasons that are unclear, bacteremias with nonfermenting gram-negative bacilli are more often polyclonal (more than one molecular type) than are bacteremias with other gram-negative bacilli.[330] Changes in presurgical prophylaxis protocols and the use of intravascular access lines have likely had an impact in this area.

Some specific microbes have distinct clinical significance. *Clostridium septicum* is frequently associated with neoplastic disease, particularly carcinoma of the colon,[152] and may result in distant metastatic abscesses. Similarly, bacteremic *Streptococcus bovis* is commonly associated with endocarditis and with colonic disease, including carcinoma of the colon.[17] Rarely, episodes of *C. perfringens* bacteremia result in sudden, dramatic hemolysis, which can be rapidly fatal[302]; the hemolysis is caused by clostridial toxins, but it is unclear why the fatal hemolysis occurs only in a small proportion of clostridial bacteremias.

Risk Factors and Prognosis. Several mechanisms play a role in the removal of microorganisms from the bloodstream.

97

In healthy and immunocompetent hosts, a sudden influx of bacteria is usually cleared from the blood within 30 to 45 minutes. The liver and spleen play the primary role in clearing bacteria; intravascular neutrophils play only a minor role. Encapsulated bacteria are more difficult to eliminate, but specific antibodies (opsonins) enhance clearance.[34] Not surprisingly patients that have been splenectomized are at increased risk for infections by these encapsulated bacteria. Patients who are debilitated, immunodeficient or immunocompromised are at increased risk because circulating bacteria may not be cleared from the blood for hours.

Other risk factors have been investigated by Weinstein and associates.[326] In their study of 500 episodes of bacteremia and fungemia, the overall mortality rate was 42%, with approximately half of these deaths attributed directly to septicemia. Risk factors and the relative mortality rates for each are shown in Table 2-8. Bryan[37] also emphasizes how positive blood cultures identify a population of patients at high risk of

death; patients with positive blood cultures were 12 times more likely to die during hospitalization than those with negative blood cultures. From these experiences, it is imperative that the laboratory perform blood cultures correctly and report accurate results as soon as possible.

The timely detection of bacteremia and fungemia, followed by expeditious identification of pathogens and determination of susceptibility to antimicrobial agents can have great diagnostic and prognostic importance. The mortality rate from septicemia may be 40% or higher in certain populations of hospitalized patients.[326] Although underlying diseases are important determinants of fatal outcomes, approximately half of the deaths can be attributed directly to the infection.[37] Prompt initiation of appropriate antimicrobial therapy is demonstrably important for preventing morbidity and mortality.[167] Initial therapy must be empirically based on likely pathogens and typical patterns of antimicrobial susceptibility. The microbiology laboratory plays its most important role when the actual pathogen and/or the antimicrobial susceptibility deviate from that predicted by the clinician (i.e., the organism is not covered by empiric therapy). The fatality rate for patients who are treated appropriately is significantly less than that for patients who receive ineffective antibiotics.[329] Prompt correction of the empirically chosen course of action is dependent on speedy provision of data by the laboratory. This is more appropriate than ever with the introduction of FDA-cleared molecular diagnostic products that can rapidly and accurately achieve both a genus- and species-level identification, as well as detect key genetic determinants of resistance. Additionally, the application of MALDI-TOF affords the rapid and accurate identification of most bacterial pathogens. In addition to all the important patient care reasons for implementing these technologies, a financial case can also be made for expeditious provision of results.[18] Any activity that reduces complications and shortens hospital stay will result in major financial savings for the institution as well as improved care for the patient.

Intravascular Infection. The most common intravascular infection is endocarditis, infection of the endothelial lining of the heart.[16,247,320] The earlier division of illness into acute and subacute forms is no longer considered particularly useful. Although almost any organism can produce endocarditis on occasion, the majority of infecting organisms are gram positive. Most important among these are the viridans streptococci of the oral cavity and *S. aureus*. Patients are most at risk if they have endocardial abnormalities or previous valve surgery.[77] Endocardial damage was formerly most commonly the result of rheumatic fever. With the virtual disappearance of that disease, congenital or developmental abnormalities, such as bicuspid aortic valves and prolapsed mitral valves, have assumed greater importance. Fibrin-platelet thrombi on the surface of abraded endocardium serve as site for bacterial

adherence for those organisms that transiently circulate in all of us (e.g., after brushing our teeth). It has been shown that certain microbes, particularly streptococci and enterococci, have an enhanced ability to adhere to these thrombi.[60] The thrombi and associated bacteria form excrescences (i.e., vegetations), which can be visualized by radiographic or echographic techniques. Uninfected and infected thrombi cause marantic and infective endocarditis, respectively.

TABLE 2-8 Mortality Rates and Risk Factors Associated With Bacteremia[326]

Condition	Mortality (%)	Relative Risk of Death
Age of Patient		
20	13.8	1.00
21–40	32.8	2.33
41–50	42.9	3.06
>50	49.8	3.55
Type of Organism		
Nonfermenters (*Pseudomonas aeruginosa*)	27.7	6.84
Enterobacteriaceae		
Escherichia coli	35.5	3.3
Klebsiella pneumoniae	48.0	4.52
Gram-positive cocci		
Staphylococcus aureus	32.7	3.08
Streptococcus pneumoniae	22.0	2.08
Enterococci	45.5	4.28
Unimicrobial bacteremia	37.7	
Polymicrobial bacteremia	63.0	5.96

Fungi	67.7	
Source of Infection		
Intravenous catheter	1.1	1.00
Genitourinary	14.9	1.35
Foley catheter	37.8	3.38
Surgical wound (and burns)	42.9	3.88
Abscess	51.2	4.65
Respiratory infection	52.3	4.73
Predisposing Conditions		
Surgery	16.3	0.78
Trauma	27.3	1.30
Diabetes mellitus	30.0	1.43
Corticosteroids	33.3	1.59
Renal failure	37.5	1.79
Neoplasm	42.1	2.01
Cirrhosis	71.5	3.40

Although gram-positive bacteria are the most common etiologic agents of endocarditis, some fastidious gram-negative bacilli[33,81] and some fungi[4,192] can produce the infection. Somewhat more fastidious gram-negative bacteria, such as *Aggregatibacter aphrophilus*, *Aggregatibacter actinomycetemcomitans*, *Eikenella corrodens*, *Cardiobacterium* spp. and *Kingella kingae*, are known to cause endocarditis. In the past, special culture techniques were needed for these, but the advanced blood culture systems currently in use are adequate for recovery of these bacteria. The detection of endocarditis caused by *P. acnes* may require extended incubation. Fungi and some of these gram-negative bacilli are notable for their propensity to form large vegetations that can break off and travel through the bloodstream to distant sites (septic emboli). Most instances of endocarditis involve the left side of the heart, which is the high-pressure side of the system. If, however, bacteria are directly injected into the venous system, as occurs with illicit intravenous

injection of drugs, right-sided endocarditis, often caused by a *Bacillus* spp. *Candida* spp. or *P. aeruginosa*, may result.[332]

In a minority of patients with signs and symptoms of endocarditis, it is difficult or impossible to isolate an etiologic agent (i.e., culture-negative endocarditis). Diseases that cause marantic endocarditis may be responsible, but certain microbes are not readily recovered by conventional blood culture techniques. Prominent among these agents are *C. pneumoniae*, *Coxiella burnetii* (Q fever), and *Bartonella* spp.[32,96,183,303] The identity of the etiologic agent is usually achieved using serologic or molecular methods.

Patients who have recently implanted intravascular hardware are usually infected with bacteria that are indigenous to the skin, most commonly coagulase-negative staphylococci and diphtheroids, or, less commonly, microorganisms that cause wound infection, such as gram-negative bacilli, *S. aureus* or fungi.[223] Prosthetic-valve endocarditis occurs in 3% to 6% of patients who receive either mechanical or bioprosthetic (i.e., valves made from animal tissues) grafts[310]; the infections can be divided conceptually into early (<60 days after surgery) and late stages. In the early stage, the skin and wound microbes predominate. In late stages, the organisms that infect native valves are found.

The most serious complications of endocarditis are rupture of a cardiac valve with resultant heart failure and metastatic disease caused by embolization of pieces of the infected vegetation. Sudden cardiac decompensation is a particular problem in endocarditis caused by *S. aureus*, which may represent a surgical emergency. Renal failure and strokes can result from septic emboli to the kidney and brain, respectively.

Catheter-Associated Bacteremia and Sepsis. A special kind of intravascular infection has been the result of technologic advances that allow the life-saving use of indwelling vascular catheters. Catheters may simply be the portal of entry for bacteria that colonize the skin adjacent to the entry point or they may serve as a foreign body that harbors microbial microcolonies. Sepsis and serious metastatic disease may result from catheter-related infections.[228] In patients with neoplastic disease, intravascular catheters may be in place for prolonged periods; this group of patients, who may have profound neutropenia, are at great risk for serious and life-threatening infection.[80] In addition to the effects on quality of care and quality of life, catheter-related infections put a major financial burden on institutions.[3] Although central venous catheters are most commonly used and are most commonly the route of infection, intraarterial catheters may also present a risk.[282]

The most common organism found in catheter-related infections is coagulase-negative *Staphylococcus*, which is a common indigenous bacterium on the skin and possesses characteristics, such as the presence of a biofilm, that facilitates colonization

of catheters.[129] The most serious infections, however, are caused by *S. aureus* and gram-negative bacilli. There are now standardized methods that should be employed under observation to insert and change central venous catheters help to diminish, albeit not eliminate, the central venous catheter infections. Catheter-related bloodstream infections are quality metrics that are monitored by hospital leadership.

Collection of Blood Cultures

The critical factors that must be decided by laboratory directors include the type of collection, number and timing of blood cultures, the volume of blood to be cultured, the amount and composition of the culture medium, when and how frequently to subculture and the interpretation of results.[234,236,329]

Contamination With Skin Microbiota. Every precaution should be taken to minimize the percentage of contaminated blood cultures.[323] Isolates of *Corynebacterium* spp., *P. acnes,* and *Bacillus* spp. other than *B. anthracis* are usually contaminants, albeit line-related infections may also be caused by these bacteria. Most isolates of gram-negative bacilli, yeast, β-hemolytic streptococci, *Streptococcus pneumoniae*, *Enterococcus* spp., and *Staphylococcus aureus* are clinically significant. The most problematic isolates are coagulase-negative staphylococci, because although these species are increasingly causes of true bacteremia, they are also indigenous microbiota of the skin.

A quality assurance monitor tracing the incidence of contaminated samples should be performed regularly in all microbiology laboratories. Less than 3% of blood cultures should be contaminated. Bates and associates[15] estimate that a contaminant blood culture can lead to an increase of as much as 20% to 39% in a patient's hospital bill from an extended stay for intravenous antibiotic therapy and additional tests. They also emphasized the need for paired blood culture sets to indicate likely contamination if only one turns positive. If collection technique is good and contamination minimized, the cost of contaminants becomes acceptable.[316] Inappropriate antibiotic use can be discouraged by a laboratory policy wherein single isolates of coagulase-negative staphylococci not be tested for antimicrobial susceptibility

99

routinely. Several approaches to this determination are provided by Weinstein.[323]

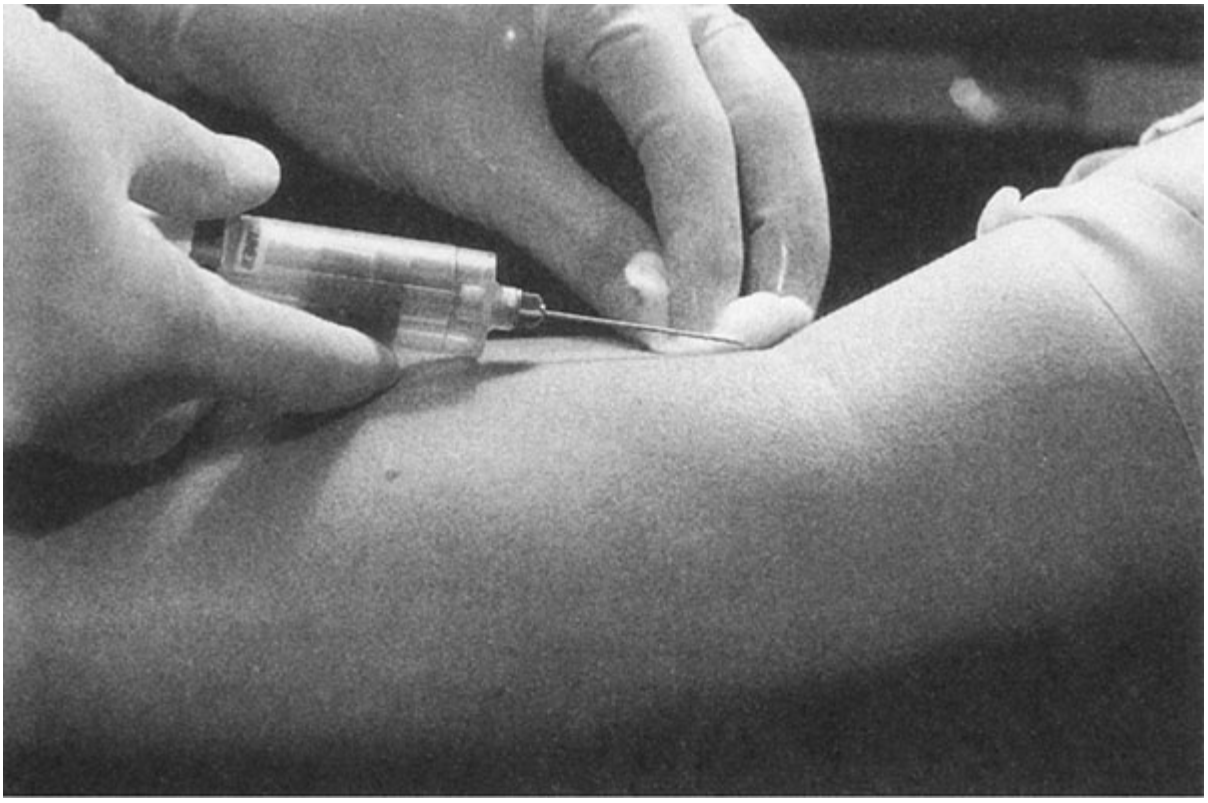
A variety of techniques have been proposed for determining whether an isolate of coagulase-negative *Staphylococcus* represents contamination. Unfortunately, none works well. Neither the number of positive bottles,[196] identification of the isolate to the level of species,[325] time to initial positivity[143] or the number of other negative

sets[143] distinguished clinically significant from insignificant isolates. Species of coagulase staphylococci other than *S. epidermidis*, *S. capitis*, and *S. haemolyticus* were almost always clinically insignificant, but these three species accounted for 98% of the significant isolates and 89% of the insignificant isolates.[325] The only way to determine with certainty whether two or more isolates represent the same strain is to perform molecular typing, a technique that is not available in most laboratories. Use of clinical data in combination with the antibiogram of the strains[143] or a combination of antibiogram and biochemical pattern (as opposed to identification)[323] have been proposed as means for determining whether multiple isolates represent multiple contaminants or a single infecting strain. The expanded use of MALDI-TOF now affords the ability to identify *Staphylococcus* to the species level in a rapid and inexpensive manner. This, at least, allows the laboratory the opportunity to assess if two coagulase-negative *Staphylococcus* species are members of the same species or not. If not, both may be contaminants and it is not possible to determine which, if any, is associated with a bloodstream infection. If, however, both are of the same species, then the likelihood of that organism representing a true infection is increased.

To reduce the chance of introducing contaminating organisms from the skin, the venipuncture site should ideally be prepared as follows: (1) wash with soap, (2) rinse with sterile water, (3) apply 1% to 2% tincture of iodine or povidone–iodine and allow to dry for 1 to 2 minutes (povidone–iodine) or 30 seconds (tincture of iodine), and (4) remove the tincture of iodine with a 70% alcohol wash. In practice, the soap wash is usually omitted; however, the combined use of iodine compound and alcohol to disinfect the venipuncture site is essential. If the site must again be palpated after the iodine–alcohol preparation, the finger of the glove must be disinfected or a sterile glove worn. If povidone–iodine is used, step 4 must be omitted. Be sure, however, that the povidone–alcohol solution is dry before making the venipuncture. A packaged skin preparation kit performed similarly to individual iodophor and alcohol pledgets.[335] There are increasing demands on the time of healthcare personnel, so there is a strong temptation not to allow the prolonged contact required for povidone–iodine solutions. Tincture of iodine, which is effective after contact with the skin for 30 seconds, has obvious advantages and has been reported to be more effective than povidone–iodine,[165] but is less acceptable to personnel. Other disinfectants have been suggested for preparation of venipuncture sites,[323] with variable acceptance. There are other acceptable alternatives, such as decontamination with chlorohexidine that may be explored.

Blood cultures may be obtained either by using a needle and syringe (Fig. 2-6) or by a closed system, consisting of a vacuum bottle and double-needle collection tube. Obtaining blood for culture from indwelling intravenous or intraarterial catheters should be discouraged. Although some authors have found a good correlation between

cultures drawn through a catheter or by venipuncture, most investigators have found a significantly increased risk of recovering skin organisms if an intravascular catheter is used.[39,86] The hope is that a patient will be saved the discomfort of a venipuncture, but recovery of a coagulase-negative *Staphylococcus* may actually result in more discomfort from additional venipunctures undertaken to address the questionable isolate.[323] If an intravascular catheter is used, a second culture should be drawn by venipuncture for comparison.



■ **FIGURE 2-6** Venipuncture technique for blood culture using a sterile needle and syringe. A tourniquet is applied to the upper arm above the venipuncture site to distend the antecubital veins. The site has previously been prepared with tincture of iodine and alcohol. The blood is removed with the syringe and needle and injected into an appropriate blood culture bottle. Rubber gloves must be worn during this procedure.

The practice of changing needles after the venipuncture and before injecting the blood into culture bottles has been replaced by direct injection with the original phlebotomy needle, because hepatitis or HIV infections can be acquired from accidental needlesticks. The majority of investigators who have studied this issue have concluded that there is no significant difference in blood culture contamination rates between patients for whom needles were switched between phlebotomy and injection

of the bottles and those for whom needles were not switched.[51,154,272] A meta-analysis of the issue did reveal more frequent contamination when needles were not changed, but the risk of acquiring a blood-borne viral infection greatly outweighs the benefits gained from changing needles.

One important factor in the quality of blood culture collection that is often overlooked is the training of the collectors. Multiple investigators have demonstrated that a trained phlebotomy team can obtain blood cultures with fewer instances of contamination than random individuals, no matter what their educational level.[322,323] It is recommended that phlebotomists are thoroughly trained and that the contamination rates for each phlebotomist is maintained and monitored by the phlebotomy supervisor. In this manner, lapses in technique can be readily uncovered and retraining instituted.

Number and Timing of Cultures. The number of specimens collected is less important than the total volume of blood cultured. Multiple studies have documented the

importance of volume; most are consonant with the finding that the yield increases to approximately 30 mL of blood in adults.[328] If a set of two bottles, each containing 10 mL of blood is submitted, two sets will satisfy the volume criterion. If the bottles only hold 5 mL each, or if a full complement of blood is not inoculated by the clinician, a correspondingly greater number of sets must be collected to satisfy the volume requirement. A lower total volume of blood is usually needed to document endocarditis, because the bacteremia is continuous. Some have suggested that a single aerobic culture may be adequate for patients with community-acquired pneumonia.[215] Organizing a blood culture order so that it consists of the phlebotomist filling of two sets of blood culture bottles approximately 15 minutes apart, with each set (i.e., a set contains one aerobic and one anaerobic bottle) representing a 20 mL assessment of blood (i.e., 10 mL per bottle) is a practical approach that covers all scenarios.

In a study of hospital blood culture practices, Schifman and associates[252] discovered that the incidence of solitary blood cultures ranged from 1% to 99%, with a median of 26%. They estimated that as many as 18,000 episodes of bacteremia might be missed annually because an inadequate volume of blood was collected. Between 20% and 30% of the solitary blood cultures they reviewed were not clinically indicated; most of the others were ordered by physicians who were unaware that one culture was not sufficient. Focused intervention and global education reduced solitary blood cultures from 40% to 24% in one hospital, and unnecessary collections were reduced from 38% to 12.5% in another institution. Unfortunately, the improvement of

performance after education has a short half-life; constant monitoring (e.g., as part of an ongoing quality assurance program), and/or electronic interventions are required. Solitary blood cultures present the additional problem that single isolates of coagulase-negative staphylococcus are difficult to interpret, as described above.

Blood cultures should be drawn before the use of systemic antimicrobials if possible. If therapy has been started, cultures should still be obtained, but negative results must be interpreted with circumspection.

Traditional guidelines were that multiple cultures should be taken at different times if intravascular infection and continuous bacteremia was suspected. Most authorities now believe that there is little to be gained by spacing cultures over time. Fever is often a somewhat delayed response to the entry of bacteria into the blood system, so collection of the specimens as soon as possible after a fever spike is recommended. As noted above, at least two venipunctures should be performed, but all necessary specimens (usually two to three sets, each containing two bottles) can be collected either at one time or approximately 15 minutes apart.[156]

After collecting an adequate volume of blood and initiating antimicrobial therapy, there is nothing to be gained by collecting additional specimens until the results of the initial sets are known.[103] The practice of a standing order for daily cultures should not be condoned. Most bacterial isolates are recovered by continuous-monitoring systems within 72 hours, so it is reasonable to wait at least 3 days before collecting additional specimens. A good rule is that it is preferable to consider the possibility of another cause rather than blindly repeating a nonproductive diagnostic approach. If clinical conditions change, however, additional specimens are indicated. "Breakthrough bacteremia" (positive cultures and new or persistent symptoms in the face of antimicrobial therapy) suggest the possibility of antimicrobial resistance and are a poor prognostic sign.[327] It should be remembered, however, that newer blood culture media that contain resins for removal of antimicrobial agents may result in the apparent persistence of pathogens; an assessment of the symptomatic status of the patient is of critical importance.

Culture Media. The media used in blood culture bottles are multipurpose and nutritionally enriched: tryptic or trypticase soy, supplemented peptone, brain–heart infusion, Columbia CNA agar, and brucella broths are commonly used. All are commercially available; however, variations in the composition of the same type of medium by different manufacturers makes comparisons and conclusions about the comparative yields of bacteria from each difficult to assess.

Most commercially available blood culture media contain the anticoagulant SPS in concentrations varying from 0.025% to 0.05%. In addition to anticoagulant properties (anticoagulation is a desired effect because certain bacteria do not survive well within the clot, where phagocytosis by neutrophils and macrophages remains active), SPS

also inactivates neutrophils and certain antibiotics, including streptomycin, kanamycin, gentamicin, and polymyxin, and precipitates fibrinogen, β-lipoproteins, β_{1C}-globulin, and other components of serum complement. SPS may also inhibit the growth of certain bacteria—*Peptostreptococcus anaerobius*, *N. gonorrhoeae,* and *N. meningitidis*. The inhibitory effect of SPS can be neutralized by adding gelatin to the medium, to a final concentration of 1%.

Many current blood culture bottles incorporate synthetic antibiotic-removing resins. Recovery of pathogens, and, unfortunately also skin contaminants, is clearly improved by these additions.[323] In a study of 6,839 paired blood cultures,[142] the use of resin media significantly improved the recovery of members of the family *Enterobacteriaceae*, *Enterococcus* spp., *S. pneumoniae* and viridans streptococci.

Traditionally, blood culture sets consisted of a bottle designed to recover aerobic bacteria and one engineered for anaerobic bacteria. In actuality, the majority of all types of bacteria are recovered in both bottles. The change in the pattern of bacteremias over time described above has led some investigators to suggest that an "anaerobic" bottle be limited to situations in which anaerobes might be expected (e.g., in patients with abdominal disease processes).[199] Recovery rates from three different paired bottle systems were compared: (1) one aerobic and one anaerobic bottle (5 mL of blood each); (2) two aerobic bottles (5 mL each); and (3) two aerobic bottles plus an extra anaerobic bottle when anaerobic infection was clinically suspected. The third approach had the largest yield of isolates. From their data, these investigators concluded that the use of two aerobic bottles with selective culturing for anaerobes will potentially increase the number of clinically important isolates by at least 6%.[199] The policy of substituting a second "aerobic" bottle for the "anaerobic" bottle is not a common practice, probably in part because of the difficulty of deciding which patients would benefit from the practice and the impossibility of leaving the decision to the clinical staff. Another reason is likely that others have demonstrated that anaerobic bacteremias are not predictable, so an anaerobic bottle should be included in every blood culture set.[59] It has been shown that many facultatively anaerobic bacteria (the majority of human pathogens) grow well in the "anaerobic" bottle.[55] It should be noted that the policy at one institution, where a decreasing incidence of anaerobic bacteremias had also been documented,[74] included two aerobic components in addition to the nonvented "anaerobic" bottle.

101

BOX 2-3

Guidelines for Obtaining Blood Cultures[a]

Ideally, a trained phlebotomy team should collect all blood cultures according to established protocols. The frequency of likely contaminants in cultures collected by each member of the team should be monitored so that team members can improve their performance.

Blood cultures are indicated when a serious febrile illness that will require antimicrobial therapy is present or when an infection in an organ system might be elucidated by isolating a pathogen from the blood (e.g., meningitis or pneumonia).

Compare the name and medical record number on the requisition with that of the stated identity of the patient. Two patient identifiers should be used. Establish the site(s) for venipuncture and clean the site with an iodine compound followed by alcohol (preceded by surgical soap and water if possible).

Two blood culture sets, each with an aerobic and an anaerobic bottle within the set, is recommended. The second set should be drawn in the manner described above from a second phlebotomy site. There should be at least two venipuncture sites. All venipunctures may be collected at one session, but some recommend temporally separating the phlebotomies by about 15 minutes. For adults, each blood culture bottle should be filled with 15 mL of blood. Therefore, upon completion there should be two aerobic and two anaerobic blood culture bottles, each filled with 10 mL of blood, for a total blood culture assessment of 40 mL.

Variations on this theme may occur from institution to institution, and there are different guidelines for pediatric patients which often employ body mass to guide the amount of blood drawn.

Use all available safety devices, such as needles with safety features, a safety transfer device for inoculating blood into bottles, and a tube holder adapter, when a winged collection device is used. Dispose of all sharps in a protected container.

Do not force blood into the bottles.

Transmit the inoculated bottles to the laboratory as quickly as possible.

[a]Adapted from reference 83.

Blood cultures for mycobacteria and fungi should be considered in appropriate clinical situations. Dimorphic fungi, particularly *H. capsulatum,* and filamentous molds require special attention.[171] *Candida* spp. are effectively recovered by the current, automated blood culture systems.[188]

A summary of recommendations for collecting blood cultures is presented in Box 2-3.

Systems for Processing Blood Cultures[214]

Manual Blood Culture Systems. Two of the manual commercial systems are variations on the classic agar–broth combination bottles, known as Castañeda bottles. For laboratories that do not have the resources for a more automated system that monitors bacterial growth continuously, they represent a reasonable choice.

The Oxoid Signal Blood Culture System. The *Oxoid Signal Blood Culture System* (Thermofisher) is a single-bottle blood culture system that uses the production of CO_2 to detect early bacterial growth. The main blood culture bottle is similar to those used in other broth systems; however, the system uses a second plastic chamber, known as the signal chamber, which is fitted at the bottom with a long needle. After the blood sample to be cultured has been inoculated into the main bottle, the signal chamber is connected by inserting the needle through the rubber stopper and positioning it below the surface of the culture medium. Growing and metabolizing bacteria produce CO_2. The resulting in increased pressure, which forces liquid into the signal chamber; this can be directly visualized and used to prepare Gram's stain and subculture. This system has been evaluated favorably.[203,255] A higher than normal number of false-positive results and a lower than normal yield of anaerobes remain problems. Weinstein and coworkers[324] found an improved yield of organisms with improved bottles that have an increased head–gas space and are subjected to agitation.

BBL Septi-Chek Blood Culture System. The Septi-Chek biphasic agar-slide system (BD Diagnostic Systems, Sparks, MD) is also widely used. The system uses a standard blood culture bottle that contains either brain–heart infusion broth or trypticase soy broth. The bottle is designed for connection to a second plastic chamber that contains a paddle with agar surfaces. After the primary bottle is inoculated with the blood specimen to be cultured, the plastic-contained "slide" is screwed on. This slide contains a trisurface paddle faced with chocolate, MacConkey, and malt agar strips. The first "subculture" is made after 4 to 6 hours of incubation at 35°C by inverting the bottle and allowing broth to enter the slide's chamber, thereby flooding the agar surfaces. The bottle is then again placed upright for continued incubation. The bottle can be inverted again at regular intervals to reinoculate the agar media on the paddle.

102

Lysis-Centrifugation Blood Culture System

Wampole Isostat/Isolator Microbial System. The Isolator system (Alere, Waltham, MA) is widely accepted as an alternative blood culture method that is particularly useful for recovery of fastidious or slow-growing organisms. It is the method of choice for dimorphic fungi, *Malassezia furfur* and *Legionella* spp.[24] There

was a reduction of mean recovery time for yeasts from 4.9 days using a conventional biphasic broth–agar system to 2.12 days with the Isolator. The mean recovery time of 8.0 days for *H. capsulatum* compared with 24.14 days for the biphasic system. The recovery of *H. capsulatum* using the Isolator system has not been surpassed by the automated systems. An overall 36.6% increase in the recovery rate of fungi from blood cultures was documented when the Isolator system was used. This method should be considered when other fastidious organisms, such as *Bartonella henselae*,[169,270] are suspected, if attempts at culture are being considered. The Wampole Isolator Microbial System (Alere) is a special tube that contains saponin, a chemical that lyses both the red and the white blood cells. Approximately 7.5 to 10 mL of blood are added to the tube, which is then thoroughly mixed by inverting the tube several times, so that the lysis reaction can go to completion. The tube is then placed into an angle centrifuge and spun at 3,000 rpm for 15 minutes to concentrate any microorganisms that may be present. After centrifugation, the sediment is aspirated and subcultured to appropriate media. A smaller version that does not require centrifugation is available for use in infants and young children; the use of the pediatric version for adults should be discouraged or prohibited because an insufficient volume of blood is cultured.

The Isolator system is also the method of choice when quantitative cultures of blood are desired. The CFU/mL can be calculated from the volume of blood processed and the number of colonies present on the agar surfaces.[341]

A twofold-to-eightfold increase in contamination rates over conventional systems is the major problem with the use of the Isolator. It has been suggested that contamination can be reduced by using dry agar plates, disinfecting the work area and processing samples in a vertical laminar air hood.[144] Another drawback is the labor needed to process each individual blood culture, each of which requires centrifugation and agar plate inoculation; this is substantially more labor intense than simply determining the quantity of blood present in a bottle of an automated system and placing it onto the instrument.

Examination of Manual Systems. Blood culture bottles should be incubated at 35°C and examined visually for evidence of growth (i.e., hemolysis, gas production, or turbidity) during the first 6 to 18 hours after collection. For those using conventional broth media, bottles should be examined against bright fluorescent bulbs or with incandescent transmitted light. The surface of the sedimented blood layer should be examined because discrete colonies may be detected. Blind subcultures to chocolate agar plates should be made from all nonagar broth and continuous blood culture bottles within 12 to 24 hours after collection, after which the plates are incubated aerobically in 5% to 10% CO_2 at 35°C. Blind anaerobic subcultures are usually not done in most laboratories. It is generally agreed, however, that both aerobic and anaerobic subcultures of all visually positive blood culture bottles should be set up. In

a study of 20,155 blood culture bottles (trypticase soy broth and thiol broth),[202] only 32 trypticase soy bottles and 10 thiol bottles turned positive after 7 days of incubation. Fifteen of the 32 trypticase isolates and all of the thiol isolates were either recovered in other cultures or were not considered clinically significant, indicating that holding manual blood cultures beyond 7 days is unnecessary. Most institutions have gone to holding blood cultures for only 5 days.

The routine microscopic examination of macroscopically negative blood culture bottles after 24 hours of incubation is not indicated because the number of organisms that can be detected by Gram's stain (about 10^5 CFU) is not appreciably less than the 10^6 to 10^7 CFUs required to produce visible turbidity of the broth.[236] Acridine orange stains are more sensitive, detecting 10^3 to 10^4 CFU/mL. Tierney and associates reported a 16.8% increase in the early detection of septicemia by examining macroscopically negative blood culture broths with the acridine orange stain.[299]

Automated and Computerized Blood Culture Systems. The introduction of continuous-reading, automated, and computerized blood culture systems represented an important advance in clinical microbiology practice. The use of manual blood culture systems has decreased with the introduction of these systems. Three such systems, the BacT/ALERT 3D (bioMérieux, Durham, NC), the BD BACTEC (BD Diagnostic Systems), and the VersaTREK (ThermoScientific, Cleveland, OH) are commonly used in the United States. Each of these systems alerts the microbiologist that a culture is positive, after which the relevant bottles can be removed for Gram's stain and subculture. More recently, FDA-approved multiplex molecular diagnostic assays are available for use on blood cultures that signal positive, which affords a more rapid species-level identification and, in some instances, the detection of genetic determinants of resistance. The media selected for subculture, as well as some of the molecular assays, can be chosen based on the Gram reaction and morphology of the microbes. If organisms are not visualized, a blind subculture should be performed and the bottle returned to the instrument for continued incubation. Multiple studies have demonstrated that bottles need be incubated only for 5 days when the continuous monitoring systems are used. In the future it may be possible to reduce the incubation time even further.[58]

The BacT/ALERT 3D Blood Culture System. As the first continuous-monitoring blood culture system developed and marketed in the United States, the BacT/ALERT3D (formerly BacT/Alert) system has been implemented in many clinical laboratories. Each blood culture bottle has the capacity to receive 10 mL of blood. As microorganisms grow in the blood–broth mixture, CO_2 is liberated. A CO_2-sensitive chemical sensor that is separated from the blood–broth mixture by a unidirectional CO_2-permeable membrane is bonded to the bottom of each bottle. In

the presence of CO_2, the color of the sensor turns from green to yellow, although the light-sensitive detector built into the instrument reacts before a color change is apparent.

Each bottle is placed bottom-side into a receiving well in the data unit, directed by a barcode on the bottle label, which is integrated in the computer to match the patient identification data for each. Each data unit is a cabinet about the size

of a small refrigerator which serves as a self-contained incubator, shaker and detection device, with a capacity to hold either 240 or 120 bottles, depending on the model. Multiple modules are through the same computer controls, yielding a total of 1,440 bottles that can be monitored. The wells are arranged in two rows within a horizontal rack that gently rocks back and forth when the door to the data unit is closed. At 10-minute intervals, a light beam from emitting diodes (one for each well) is projected through an excitation filter to reflect off the CO_2-sensitive sensor in the bottom of each bottle. The reflecting light is directed through an emission filter to a photosensitive detector that, in turn, is connected to a computer compiler. As soon as the accumulation of CO_2 is sufficient in the bottle to alter the sensor, an audible or visible "alert" is generated, and the position of the positive bottle is immediately flagged by the computer. Positive bottles can be immediately removed and further processed.

*The **BD BACTEC** Blood Culture Systems.* The BACTEC system consists of a self-contained incubator, agitator and detection device, similar in appearance to the BacT/ALERT 3D system. There are three sizes: model 9240 holds 240 bottles, model 9120 holds 120 bottles and model 9050 accommodates 50 bottles. Multiple modules can be linked to the same computer control unit. Similar to the BacT/Alert, each bottle has a sensor disk bonded to the inner surface of the bottom. The one operational difference between the BacT/Alert and the BACTEC systems is that the latter uses fluorescent, rather than spectral light to detect changes in the concentration of CO_2 in the broth–blood mixture. As CO_2 is produced in each bottle, its sensor emits a fluorescent light that passes an emission filter on the pathway to a light-sensitive diode. Bottles are placed bottom down into receiving wells that are monitored once every 10 minutes. The voltage of the current reading of the diode is compared with the previous reading. If the voltage change exceeds a preset delta value, the microcomputer flags the bottle as positive. The position of the positive bottle is indicated on the computer screen so that bottle can be pulled for further processing. A graph illustrating the progress of CO_2 production can be brought up on the computer screen at any time.

The VersaTREKBlood Culture System. The VersaTREK blood culture system (ThermoScientific (previously TREK Diagnostic Systems), Cleveland, OH) differs from the BacT/ALERT3D and the BD BACTEC systems in the following ways: (1)

the production of CO_2 is monitored manometrically, (2) both gas consumption and production are monitored, and (3) changes in the concentrations of H_2 and O_2 in addition to CO_2 are detected.

The data unit is also a cabinet that serves as a self-contained incubator, agitator and detector. Units with a capacity of 96-to-240 or up to 528 bottles are currently available. After inoculation of up to 10 mL of venous blood, each bottle is fitted with a disposable connector, which includes a recessed needle that penetrates the septum of the blood culture bottle. Each bottle is then placed in a defined position on a carrying rack that is aligned such that the connector attaches directly to a sensing probe located at the top of each position. Once the bottle is properly aligned, the pressure of the head–gas is continuously monitored. A reading is taken every 12 minutes. When the change in reading exceeds a delta value, lights are illuminated that indicate the position of any positive bottle.

A reading may occur during a phase of consumption of H_2 and O_2. Oxygen consumption is accelerated at the time replicating organisms enter the log phase of growth. A reading may be possible, therefore, early in the incubation period before a detectable amount of CO_2 is produced. Testing multiple gases is a theoretical advantage for the electrostatic precipitator (ESP) system, especially for the detection of asaccharolytic microorganisms that may not produce sufficient CO_2 for detection by the indicator.

Comparative Studies

The comparative performance of these blood culture systems has been extensively studied. Depending on the design of the study, the spectrum of microorganisms being recovered from clinical specimens, the volume of blood being cultured and the exact types of bottles and media formulations being compared, one system may emerge as slightly superior or inferior to another. Improvements in formulations of media, sensitivity of detectors, and design of instruments continue to be made; the results of a study performed some months ago may not necessarily reflect the current technology. Therefore, each laboratory director and supervisor must weigh published and verbal comments from individuals who have used the system and the needs of the local laboratory when determining whether a new system should be implemented. These are all FDA-approved, excellent instruments; the decision to be made is which is the best fit for the individual laboratory.

The advantages of continuous-monitoring blood culture systems include a decrease in laboratory workload, a decrease in the number of false-positive results and pseudobacteremia (because of decreased handling and sampling of the bottles), and a significant increase in the speed of detection and in the rate of microbial recovery. Disadvantages include a limited selection of media, the large size of the instruments

(this is less of a problem currently, as smaller platforms exist), and expense. The decrease in laboratory workload is primarily because a technologist's time can be dedicated to processing only the positive cultures instead of loading and unloading instruments or subculturing and observing predominantly negative specimens. An adjustment in staffing during off hours must be made because cultures may become positive at any time of day.

Special Considerations

Fastidious Organisms and Endocarditis. Although most pathogens are detected in a few days, some fastidious microbes grow slowly. Some of these organisms produce endocarditis. It is, therefore, appropriate to prolong incubation beyond the routine cutoff period when requested by the clinician. A discussion with the clinician is warranted to determine if they have a clinical suspicious for a particular fastidious microorganism. This is useful in several ways. In some instances, the clinician may be unaware of advances in blood culture instrumentation and may be interested in extended incubation for an organism that is readily recovered by the current systems (e.g., *Cardiobacterium* spp.). Alternatively, they may be interested in extended incubation for bacteria that will not grow in culture (e.g., *Coxiella burnetti*) or are highly unlikely to grow in culture (e.g., *Bartonella* spp.). In such instances, directing them to serologic and/or molecular solutions would

be appropriate. Finally, they may be interested in organisms, such as *P. acnes,* that may require extended incubation, in which case it should be performed. A problem with some rare, fastidious pathogens is that they do not generate sufficient CO_2 to trigger the detector. A useful maneuver, if this is suspected, is blind staining of bottles with acridine orange after incubation for 7 days and/or the total period of incubation. Acridine orange is preferred to Gram's stain because it is more sensitive and the smear can be examined more quickly.

Intravascular Catheter Cultures. Two basic approaches have been taken to the diagnosis of catheter-associated bacteremia. One requires removal of the catheter; the other does not.[193]

The initial suggestion for diagnosis—and probably the most common approach even today—was a semiquantitative procedure.[175] The tip of the catheter is rolled across the surface of an agar plate and the resulting colonies are counted after overnight incubation. A statistical association of >15 CFU with catheter-associated sepsis was established and subsequently confirmed by other investigators. Variations on this procedure have included culturing multiple segments, sonication of the catheter tip,

and washing the interior of the catheter,[265] but the simplicity of the original procedure has appealed to most microbiologists.

The second approach is performance of quantitative blood cultures, simultaneously collected through the catheter and by venipuncture.[92,226] The theory is that if the catheter is secondarily infected by a bacteremia from another source, fewer CFUs will be detected in the blood drawn through the catheter than in that collected by venipuncture. If the catheter was the source of the bacteremia, the reverse will obtain. The simplest method for performing the quantitative cultures is to use the Isolator blood collection system.[92] Similarly, some have examined time-to-detect in catheter-drawn and peripherally-drawn blood cultures as surrogates for quantitative blood cultures. The use of quantitative cultures and time to detection has not been widely deployed in clinical laboratories.

The advantage of the quantitative culture technique is that the catheter can be left in place if it is not implicated in the bacteremia. It should be noted, however, that it is possible to change a catheter over a wire, so that it is not necessary to perform a new procedure to maintain vascular access; in that case, a decision about removing the new catheter can be made after the results of culturing the first catheter are known.[193] In either case, an intravascular catheter is left in place if the catheter is determined not to be the cause of the sepsis. The usefulness of catheter-associated cultures is of great debate, because of the increased possibility of contamination and limited-to-no additional benefit compared with peripheral blood cultures. The approach to catheter-associated cultures should be made after thorough literature review and consultation with the ordering physicians regarding usage.

Tissues and Biopsies. Tissue samples for culture should be delivered promptly to the laboratory in a suitably capped, sterile container. If the sample is very small, it may be placed on a piece of sterile, moistened filter paper. Gauze is sometimes used, but it may be very difficult to recover small specimens from the interstices of the gauze. Specimens that have been placed in formalin are not suitable for culture.

Bone marrow cultures may be helpful in establishing the diagnosis of granulomatous diseases such as brucellosis, histoplasmosis, and tuberculosis. Using the Isolator system or other lytic systems to process the bone marrow samples may improve the recovery of bacteria, particularly if the infections are caused by intracellular organisms.

Immunofluorescence Techniques

Immunofluorescence Techniques for Antigen Detection
Immunofluorescence Techniques for Antibody Detection

In clinical microbiology laboratories, culture of microorganisms from patient specimens remains the principal method for the diagnosis of infectious diseases. During the 1940s and 1950s, serologic techniques, such as Oudin and Ouchterlony immunodiffusion, that were developed in research settings were introduced into clinical laboratories. Subsequently, other methods that exploited basic immunologic concepts, such as complement fixation (CF), were introduced as methods for retrospectively documenting the host immune response to infection. The development of enzyme immunoassay (EIA) and hybridoma technology has completely altered the role of serology in the diagnosis of infectious diseases. Methods that were originally developed for antibody detection were subsequently reconfigured for direct detection of microbial antigens in patient specimens. Newer immunoserologic techniques have expanded the role of the laboratory in patient care and have gained widespread acceptance as helpful diagnostic tools. All of these techniques have their foundations in basic immunologic concepts. After a brief review of these concepts, the newer applications of immunoserology to patient care will be discussed.

Antigens and Antibodies: Basic Definitions

An **antigen** is a substance that evokes the formation of antibodies in an animal that is immunized with that particular antigen. An antigen is generally immunogenic, that is, it has the capability to stimulate antibody formation and to specifically combine with the antibodies that are formed against it. Not all molecular structures composing an antigen are equally immunogenic; those molecular structures that are immunogenic and that are recognized by antibodies are called **immunodominant antigenic determinants** or **epitopes**. The unique characteristics of each antigenic epitope depend on the types and sequences of amino acids in proteins, the chemical and structural compositions of polysaccharides, glycoproteins, and nucleic acids, and their secondary, tertiary, and quaternary structures. Different molecules may share antigenic determinants and will be recognized by antibodies directed against these determinants. For example, the C1 portions of the light chains of the various immunoglobulin classes (discussed below) contain common antigenic determinants that allow them to be recognized by the same antibodies. These antigen/antibody combinations are termed **cross-reactive**. Cross-reactions of antibodies with common or closely related antigens may be clinically important in some disease states. For example, studies with monoclonal antibodies have shown that certain streptococcal M protein antigens and the group A streptococcal carbohydrate antigen *N*-acetyl-β-D-glucosamine cross-react with cardiac

myosin and several other proteins (e.g., tropomyosin, vimentin) found in heart muscle and heart valve tissue.[46,62,100] In this model, antibodies developed during acute streptococcal pharyngitis subsequently bind to these cross-reactive epitopes in heart tissue, thereby activating the complement cascade and resulting in immunologically mediated damage to cardiac muscle and adjacent tissues and the development of acute rheumatic fever (ARF).[104] A similar mechanism is believed to operate in the pathogenesis of poststreptococcal glomerulonephritis. Antibodies elicited against various non-M protein antigens of "nephritogenic" group A streptococci (e.g., cytoplasmic endostreptosin, extracellular "nephritis strain–associated protein [NSAP]," streptococcal pyrogenic

exotoxin B [speB]) may react with renal tissues to produce glomerular injury.[44,154]

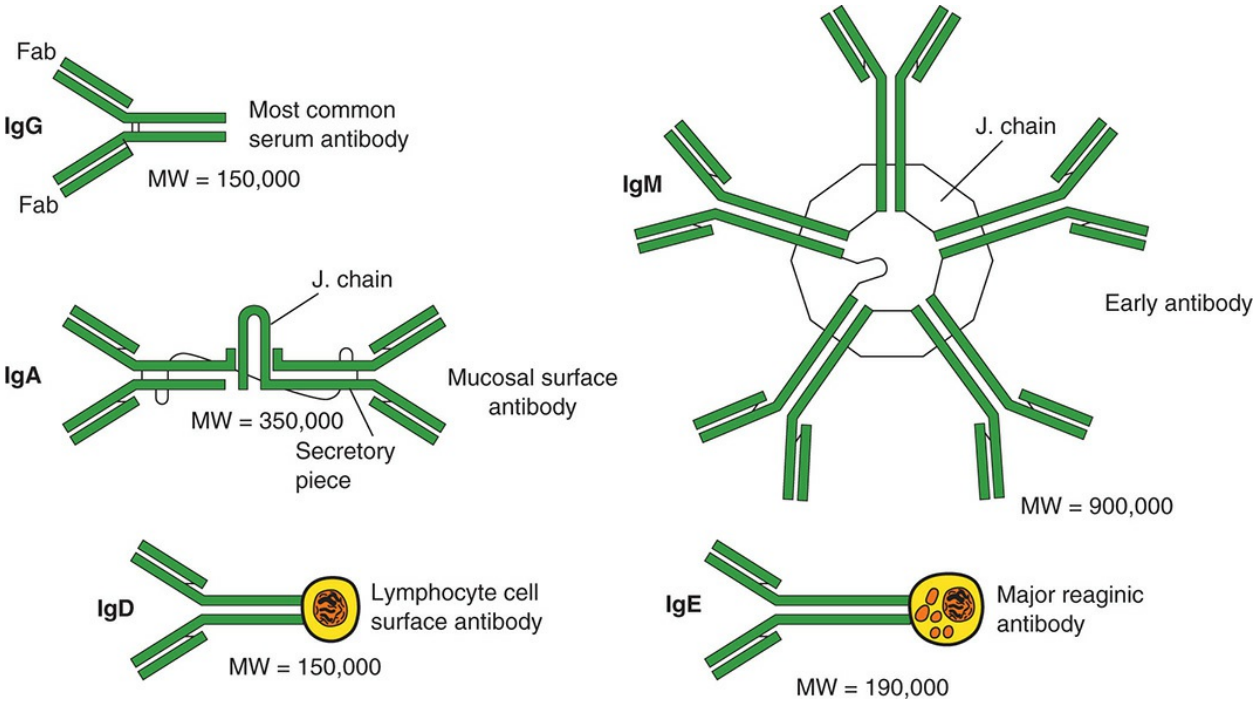
Antibodies belong to a group of structurally related glycoprotein molecules found in the blood and extracellular fluids and are known collectively as **immunoglobulins (Igs)**. These molecules are produced by B lymphocytes that express surface-bound Igs of a single specificity. When the antigen receptors on these cells encounter the appropriate binding ligand, the B cells proliferate and secrete soluble antibodies against the target antigen. Individual plasma cells produce quantities of single antibody molecules that have the same antigen-binding specificities. In addition, some B cells function as antigen-processing cells that subsequently present the antigen to T lymphocytes, stimulating additional antibody production and the induction of cellular immune responses.[27] The genesis of cellular and humoral immune responses and the cellular interactions that result in production of specific antibodies is beyond the scope of this text and may be found in other resources devoted to immunology and immunogenetics.[27]

Immunoglobulins can be divided into five classes based on their structure: IgG, IgM, IgA, IgD, and IgE (Fig. 3-1). IgG molecules have a molecular weight of about 150 kDa, are composed of two light chains and two heavy chains, and have two sites for binding to specific antigen (Fab sites). The non–antigen-binding site, composed of portions of the two heavy chains, is called the Fc region. Molecules of the IgG class are actively transported across the placenta and provide passive immunity to the newborn infant at a time when the immune mechanisms of the infant are in development. IgGs are divided into four subclasses, termed *IgG_1, IgG_2, IgG_3,* and *IgG_4*. IgG_1 is the major Ig in serum and is able to fix and activate complement. IgG_2 and IgG_4 are the major Igs produced in response to polysaccharide antigens and, therefore, to encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* type b. IgG_3 is produced in greater quantities during the

secondary immune response and is particularly important for viral neutralization. IgM molecules have a molecular weight of about 950 kDa and are composed of five monomers, each of which resembles a single IgG molecule. The five monomeric structures are joined to each other by disulfide bonds on the Fc region of each monomer and by a 15-kDa molecule called the J chain, which is necessary for aggregation of the pentameric structure. IgM is the first Ig class produced by the fetus and is the first Ig to appear in the circulation following immunization or infection. IgM is also helpful in complement fixation. The appearance of IgM in the serum is transient, and its presence usually indicates recent infection. However, IgM responses may be noted during reactivation of latent viral infections and during reinfection with the same or closely related agents. In addition, IgM antibodies may persist for weeks to months, depending on the agent and the host's immune competence. Unlike serum IgG, IgM does not cross the placenta; so demonstration of IgM against an infectious agent (e.g., rubella) in fetal or cord blood indicates a congenitally or perinatally acquired infection. Serum IgG appears 4 to 6 weeks after infection and usually persists for life. IgA antibodies occur either as monomers (160 kDa) or dimers (400 kDa) and account for about 15% of the total serum Ig. IgA is the principal antibody class found on mucosal surfaces and in extracellular secretions (e.g., colostrum, saliva, tears, mucin, intestinal, respiratory, and genital tract secretions). IgD is similar in structure to IgG, has a molecular weight of 175 kDa, and comprises only about 0.2% of the total serum Ig. This antibody class is found primarily on the surfaces of immature B lymphocytes and

113

acts as a cellular antigen receptor. IgE is a 190-kDa Ig that is present only in trace amounts in serum. This Ig is noncovalently bound by the Fc region to mast cells and basophils.[50] Binding of antigen to IgE activates the degranulation of these cells, leading to the synthesis of peptide mediators of hypersensitivity. Therefore, IgE antibodies play major roles in allergic reactions (e.g., anaphylaxis). These antibodies may also be transiently or persistently elevated in serum during intestinal helminth infections.[63,134]



■ **FIGURE 3-1** Classes of human Igs. Antibodies belong to five structural and functional classes, designated IgG, IgM, IgA, IgD, and IgE. The basic structural unit of members in each class consists of two pairs of polypeptides (two heavy chains and two light chains) joined by disulfide bonds, and each unit has two antigen-combining sites. Some Ig types have other structural components (J chain in IgM, secretory piece in IgA).

Serologic diagnosis of infections with bacterial, viral, fungal, or parasitic agents in the clinical laboratory is accomplished by detection of specific antibodies in patient serum specimens. As mentioned, IgM is the first antibody to appear after infection; so a serologic diagnosis of recent infection may be obtained by performing an IgM-specific test on a single serum specimen collected early in the clinical course. Diagnosis of recent infection can also be made by the detection of IgG antibodies in paired specimens. The first specimen is collected within 5 to 7 days after the onset of symptoms; the second is collected during convalescence 2 to 4 weeks later. A fourfold or greater rise in the antibody titer between the acute and the convalescent specimen suggests a recent or intercurrent infection. The antibody titer is defined as the reciprocal of the dilution of serum that still gives a positive test for the presence of antibodies. For example, if an acute-phase serum specimen is reactive at the highest dilution of 1:8 (titer of 8), and the convalescent specimen is reactive up to a dilution of 1:64 (titer of 64), the titer of the second specimen is greater than fourfold the titer of the first specimen ($8 \times 4 = 32$ and $64 > 32$). This fourfold rise in titer suggests infection with the agent within the recent past. Use of a fourfold titer increase to delineate recent infection is based on normal test variation and is predicated on testing

of both acute and convalescent specimens in the same procedure at the same time. Single serum specimens may be tested to determine the immune status of individuals to certain agents (e.g., rubella, varicella zoster, etc.); in these cases, test performance must include not only positive and negative controls, but also additional sera of known reactivity to serve as calibrators for the interpretation of test results.

Serologic diagnosis of infectious diseases is retrospective, as some time must elapse between infection with an agent and the detection of an immune response. However, serologic procedures have broadened in scope to include not only the detection of antibodies in serum, but also the detection of antigens in a variety of specimen types. For the rest of this chapter, methods for serologic detection of both antibodies and antigens will be addressed in general terms, with specific applications of these methods being addressed in subsequent chapters.

Monoclonal Antibodies

Antigens, by their nature as macromolecules having primary, secondary, tertiary, and quaternary structures, constitute a "mosaic" of antigenic determinants. An outgrowth of basic serologic principles and techniques has been the attempt to "purify" antigens to reduce the heterogeneity of antibodies developed against them. Antigen molecules with only a single epitope are rarely encountered; rather, hundreds or even thousands of potential antigenic determinants may exist on a cell surface or within the mix of other substances. When these mixed antigens are injected into an animal, an equal number of lymphocyte clones are stimulated. Even though each clone produces a specific antibody, the final result is a highly heterogeneous mixture of antibody molecules, the specificity and affinity of which are often unknown and difficult to control from batch to batch. When these **polyclonal antisera** are used in immunologic test systems involving infectious agents, cross-reactivity may be noted either because antigenic determinants are shared by different species or because mutations may have led to the evolution of epitopes sufficiently close in specificity to produce detectable cross-reactions. Attempts to produce pure antibodies through absorption with cross-reacting antigens or to prepare "clonal" from "polyclonal" antisera via techniques such as affinity column chromatography have only been partially successful.

As the science of serologic testing evolved, the view was held that the availability of an antibody having a high degree of molecular homogeneity and with specificity for a single, antigenic epitope without cross-reactivity would solve many of the problems encountered in the use of polyclonal antibodies. Highly specific **monoclonal antibodies**, the product of a single clone of lymphoid cells, gradually emerged as a by-product of the investigations in cell fusion and hybridoma technology conducted by Kohler and Milstein.[85,175] Because of their discovery, it is now possible to isolate

cloned lines of individual lymphocytes that produce unique, monospecific antibody molecules. Monoclonal antibodies refer to a uniform, homogeneous, molecular species of Ig, rather than to a heterogeneous array of Igs as is produced during the usual immune response. The principal feature of this technology was not that a single line of monoclonal antibody (MAB)-producing cells could be isolated, but rather that these mouse lymphocytes could be "fused" with mouse myeloma cells to produce hybrid cells having two inherent properties: (1) the capability of producing monospecific antibodies (acquired from the parent lymphocytes) and (2) the ability to grow permanently in culture (the characteristic "immortality" acquired from the transformed myeloma cells). Thus, individual monoclonal antibodies can be produced in a continuous and almost endless supply (Box 3-1).

Monoclonal antibodies have been developed against clinically relevant antigens of many bacterial, viral, fungal, and parasitic agents, and reagents prepared with these antibodies are used in many commercially available EIA and immunofluorescence test kits. In addition to the direct detection of microbial structural antigens (e.g., capsular polysaccharides, outer membrane protein antigens), monoclonal antibodies have also been developed for the detection of microbial virulence factors, such as toxins produced by enterohemorrhagic *E. coli* (e.g., Shiga and Shiga-like toxins).[80,102] This approach introduces a new way of evaluating the relationship of microorganisms and infectious diseases. Instead of the conventional focus on detection and identification of the organisms themselves, these reagents allow specific detection of microbial virulence factors that may be shared by several bacterial species associated with a given symptom complex. For example, it may be more important to know that an enteric toxin is the cause of hyperosmotic diarrhea, rather than to receive the information that the patient is infected with *Shigella* species or an enterotoxigenic *E. coli* strain.

BOX 3-1

Procedure for Production of Monoclonal Antibodies[85,175]

1. **Selection of Antigen**
   Monoclonal antibodies can be produced against any substance recognized as an antigen by the immune system of the animal being injected. Using a pure antigen is ideal. In fact, certain antigens, such as chemically purified drugs used for assays (e.g., digoxin), may be homogeneous. Even so, one can never guarantee that an antigenic determinant will consist of only one epitope. The fact that impure antigens can be used in MAB production is a chief advantage over

conventional methods used to produce polyclonal antibodies.

2. Animal Immunization

The chief objectives in the immunization procedure are to prime the immune system of the animal to avidly recognize all antigens injected, to maximally stimulate B-lymphocyte clones, and to have the spleen cells divide at a high rate. In the production of monoclonal antibodies, the BALB/c mouse strain is most commonly used. The antigen is injected subcutaneously or intraperitoneally, with the simultaneous injection of Freund's adjuvant. Injections are repeated at weekly intervals, and a final "booster" injection is given intravenously approximately 3 days prior to harvesting the spleen cells. At the end of the injection schedule, the animal is killed and the spleen is aseptically removed.

3. Fusion of Splenic Lymphocytes and Myeloma Cells

The animal spleen is placed in sterile culture medium containing antibiotics. The splenic tissue is teased to release cells and to form a slurry. This material is passed through a mesh to obtain single cells. Ficoll is added, and the slurry is centrifuged to remove RBCs. Polyethylene glycol (PEG) is added to the slurry to reduce cell-to-cell surface tension; this brings the cells into close proximity to one another, allowing their membranes to fuse. Dimethylsulfoxide (DMSO) is added to the fusion mixture to maximize cell contact even more. Finally, the cells are packed into a pellet by gently centrifuging the mixture for 5 minutes. Thus, at the end of these steps, the preparation consists of unfused myeloma cells, unfused lymphocytes, and a few fused hybrid lymphocyte-myeloma cells (It should be recognized that splenic lymphocytes and myeloma cells fuse with a frequency of only about 1 per 10^5 or 10^6 cells.).

4. Selection of Hybrid Lymphocyte-Myeloma Cells

Unfused myeloma cells rapidly outgrow the hybrids and must be removed in some manner. The myeloma cells used for fusion are grown in the presence of 8-azaguanine, a drug that causes the cells to permanently switch off the production of hypoxanthine phosphoribosyl transferase (HPRT), an enzyme that is needed to continue growth. If these HPRT-negative cells are suspended in a medium containing hypoxanthine, aminopterin, and thymidine (HAT medium), only the hybridoma cells will grow successfully. The hybridoma cells inherit HRPT from the splenic lymphocytes with which they have fused and will survive. The unfused myeloma cells, unable to synthesize DNA because of inability to produce HPRT, will be killed by the aminopterin in the selective HAT medium. It should also be remembered that unfused splenic lymphocytes do not survive beyond a few days in culture medium; therefore, the fused hybrid lymphocyte-myeloma cells alone survive in the HAT medium.

5. Cloning the Hybridoma Cells

The single hybrid cells producing the desired antibody must be isolated and grown as a clone. Two techniques can be used: (1) limiting dilution and (2) growth in an agar gel medium. In the limiting or doubling dilution technique, the suspension of hybrids (after maximum growth) is diluted and distributed into a series of sterile

wells in a microtiter plate. The dilutions are so calculated that each well contains an average of only one cell that can then be replaced as a single antibody-producing clone. In the alternative method, using agarose gel supplemented with serum, amino acids, and antibiotics, the dividing hybrid cells form tiny, sphere-like clusters. These spheres can be selected with a Pasteur pipette and transferred to microtube wells for further culture and ultimately for assay to determine whether the desired antibody is being produced.

6. Screening for Desired Antibodies
In the fusion step of the procedure of producing monoclonal antibodies, many lymphocytes other than those producing the desired monoclonal antibodies may have fused. In fact, less than 5% of the hybrid cells out of those selected actually produce the desired specific antibodies. Thus, assays of the selected cell lines are required to determine if the desired antibody is being produced. Radioimmunoassays, enzyme-linked immunosorbent assay (ELISA), precipitin techniques, and blotting techniques can be used for this phase of the procedure.

115

7. Mass Production of Monoclonal Antibodies
Once the desired clone of hybrid cells has been selected, the next step is the production of large quantities of monoclonal antibodies. The peritoneal cavity of mice, preferably the same strain that was used for the initial immunization step, can be used to grow the selected hybrid cell clone. First, the peritoneal cavity is injected with an organic irritant, such as pristane, to produce a chemical peritonitis. Next, the selected hybrid cell line is injected into the peritoneal cavity. Within days, a tumor known as a hybridoma develops. This tumor produces large quantities of monoclonal antibodies that can be harvested by aspirating the ascitic fluid from the mouse's peritoneal cavity. A tumor-bearing mouse will survive for 4 to 6 weeks, during which time large quantities of antibody can be harvested. Hybridomas can also be grown in tissue cultures in which highly purified antibodies are produced without the potential for contamination from serum, nonspecific interference from ascites proteins, or cross-reactivity of histoincompatibility antibodies derived from the mouse tissues.

Types of Antigen: Antibody Reactions Used in Diagnostic Serology

Precipitin Reactions

The basic type of antigen:antibody reaction is the precipitin reaction. This reaction is found in test systems that allow the free diffusion of antigen and antibody fronts toward one another. At a critical point of interface, where the concentrations are optimal, a visible precipitate composed of combined antigens and antibodies forms. In a **single-diffusion** system, antibody is incorporated into an agar gel into which antigen is allowed to diffuse. In the tube (Oudin) immunodiffusion method, antigen is overlaid onto agar-containing antisera, and one or more precipitin lines form at zones of equivalence. In **radial immunodiffusion**, antibody is incorporated into agar that is coated onto a glass slide. Material containing antigen is then placed into a circular well cut into the agar. During incubation, the antigen diffuses into the agar and a ring of precipitate forms. The square of the radius of the ring is directly proportional to the amount of antigen present in the material. Using a constant dilution of antiserum, semiquantitative antigen concentrations may be determined by comparing the diameters of the precipitin reaction produced by solutions of known antigen concentrations with that of the ring produced by an unknown solution. The most commonly used conventional immunodiffusion procedure is **double diffusion**. In this technique, both antigen and antibody are placed in wells adjacent to one another, and the materials diffuse out and toward one another. A line of precipitate then forms between the lines when concentrations of equivalence are reached. Double diffusion may require incubation for up to 48 hours before an interpretable result is obtained. **Countercurrent immunoelectrophoresis (CIE)** employs double diffusion technology, but uses an electric current running through the agarose support matrix to speed up the migration of the antigen and antibody toward one another. These methods may be used for the detection of either antibody or antigen in body fluids.

One precaution in performing precipitin procedures is to recognize the possibility of false-negative reactions due to prozone or postzone phenomena. If antibody is in excess (i.e., in concentrations far in excess of available antigen), a false-negative (prozone) reaction occurs, because molecular lattices, which make up the visible precipitate, do not form. In contrast, postzone reactions occur when antigen is in excess and binding sites on the antibody become saturated with antigen such that lattice formation characteristic of precipitin reactions does not occur. In cases wherein high concentrations of antigen or antibody are anticipated, false-negative prozone or postzone phenomena, respectively, can be avoided by repeating the tests using serial dilutions of the specimen. The zone of equivalence is defined as the range of reactant ratios that results in maximum precipitation of both antigens and antibodies.

Double diffusion methods are still used as an aid in the diagnosis of systemic fungal infections, including blastomycosis, histoplasmosis, coccidioidomycosis, paracoccidioidomycosis, and penicilliosis due to *Penicillium marneffei* (i.e., fungal immunodiffusion testing).[64,95,192] In fungal immunodiffusion, purified antigens from

these systemic fungal pathogens are reacted with patient and control sera containing antibodies in double diffusion tests. The development of precipitin lines of identity with the positive control sera and with the serum of the patient indicates the presence of antifungal antibodies. The presence or absence of certain precipitin bands (e.g., the H and M bands seen in *Histoplasma capsulatum* infection, anti-BAD1 [formerly WI-1] antigen bands in *Blastomyces dermatitidis* infection) may have diagnostic and prognostic significance for patient management.[83] Although specific, these tests suffer from inadequate sensitivity, and their use has been eclipsed by newer serologic (e.g., antigen detection, EIAs) and molecular diagnostic methods (e.g., gene amplification).[192]

Immunodiffusion is also the basis of the exoantigen test for identification of systemic fungal pathogens. In this method, an agar slant growing a mycelial culture of the organism to be identified is extracted with water:merthiolate overnight. This aqueous extract is concentrated and reacted in a double diffusion test with antisera against *H. capsulatum*, *B. dermatitidis*, *C. immitis*, and *Aspergillus* species along with appropriate antigen controls. After 24 hours incubation, the immunodiffusion plate is examined for lines of identity between the mycelial extract, the fungal antisera, and control antigens for each organism.[78] Although this method is still used for

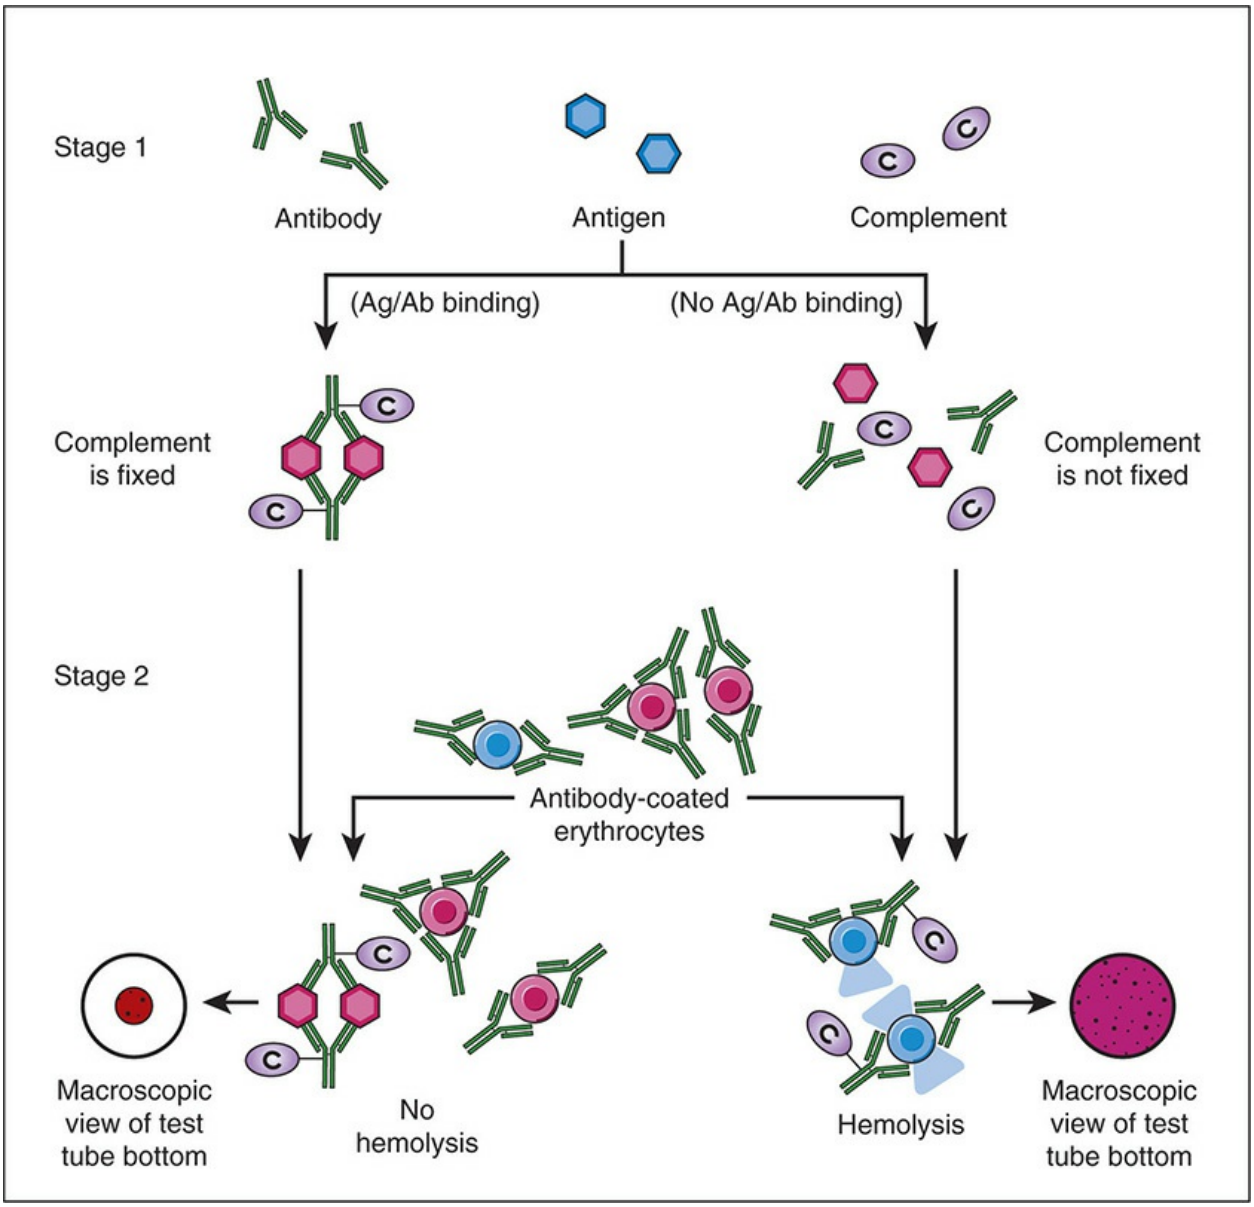
identification of systemic fungal pathogens, the availability of acridinium ester–labeled chemiluminescent nucleic acid probes for these agents offers certain advantages, including the use of younger, less mature colonies, clear-cut results, rapid turnaround time, and specific identification.[168,192]

Complement Fixation and Hemagglutination Inhibition

Over the last three decades, serologic methods for the diagnosis of infectious diseases have changed significantly. Older methods include **complement fixation** (**CF**) and **hemagglutination inhibition (HAI**). CF and HAI can be used either to identify viral antigens (i.e., usually for identification of viruses in tissue cultures) or to detect antibodies in patient serum and certain other specimen types (e.g., cerebrospinal fluid [CSF]). These tests have been widely used to retrospectively document infections, particularly those caused by microbes that are not easily detected by culture methods. In clinical laboratories, these methods have been largely superseded by other serologic methods (e.g., EIAs) and by nucleic acid–based methods of pathogen detection (e.g., polymerase chain reaction [PCR]).

In order to detect antibodies in patient serum, the serum specimen is first heated at 56°C for 30 minutes to inactivate endogenous complement, and an aliquot is placed in

the well of a microtiter plate. A titered amount of complement and antigen (specific for the antibody to be detected) are added to the microwell, mixed, and incubated overnight. If antibody in the patient serum complexes with (i.e., recognizes) the antigen, the two molecules combine and complement becomes "fixed' to this antigen–antibody complex. If antibody against that antigen is not present, no immune complexes form and complement remains free or "unfixed." In the next step, red blood cells (RBCs, generally from sheep) that are "sensitized" with anti-RBC antibodies are added to the microtiter well. If the complement was bound to immune complexes during the first step, it is not available to bind to the antibody-coated erythrocytes; so the sensitized RBCs are not lysed and settle to the bottom of the well as a "button." Conversely, if immune complexes were not formed during the first step, complement is free to bind to the antibody-coated RBCs, resulting in lysis of the erythrocytes. Lysis of the cells produces a diffuse reddish discoloration of the reactants within the microtiter well. The CF procedure is outlined in Figure 3-2 and presented in Chart 3-1.

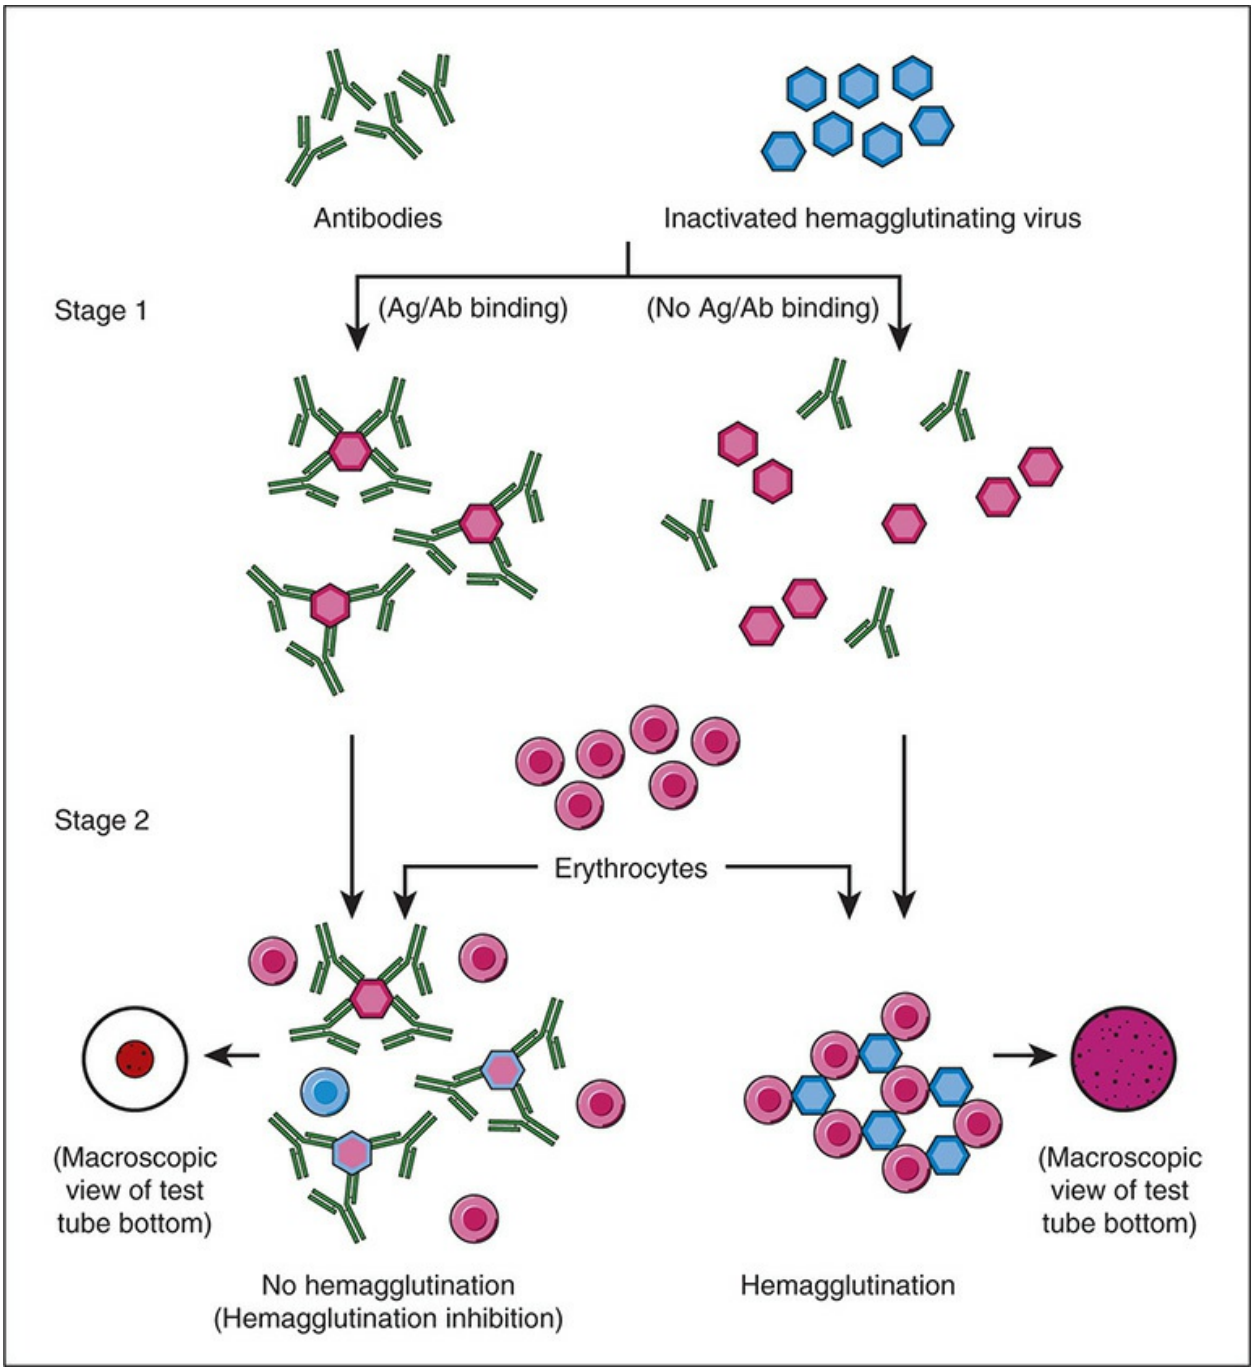


■ **FIGURE 3-2** CF testing. Antigen, antibody, and complement are mixed in stage 1. If the antigen and antibody bind, complement is fixed and will be unable to act on antibody-coated erythrocytes added in stage 2. The final reaction appears as an absence of hemolysis. If the antigen and antibody do not bind in stage 1, complement is not fixed and remains free to act on the antibody-coated erythrocytes added in stage 2. The final result appears as hemolysis of the erythrocytes. Unhemolyzed cells settle into a button in the center of the bottom of the test tube, whereas hemolyzed cells produce a reddish discoloration of fluid, with very few, if any, cells settled in the center of the bottom of the tube. Ag/Ab, antigen-antibody. (Redrawn from Leland DS. Clinical Virology. Philadelphia, PA: Saunders, 1996.)

117

The CF test continues to be useful for the diagnosis of certain infections, particularly histoplasmosis and coccidioidomycosis. For histoplasmosis, complement-fixing antibodies appear 4 to 8 weeks after infection and persist for years.[192] A fourfold rise in the CF titers or a single titer of 1:32 or greater suggests active infection. The CF test is less sensitive for diagnosis of histoplasmosis in immunocompromised hosts who may not mount an adequate immune response. In one study, the antibody response in patients with AIDS and disseminated histoplasmosis ranged from 67% to 80% compared with 86% in patients without underlying immunosuppression.[195] In coccidioidomycosis, elevated levels of antibodies can be detected by CF in over 90% of cases; CF titers decline with effective therapy and rise in cases of relapsing disease or treatment failure.[6,192] As with histoplasmosis, the sensitivity of the CF test is lower in immunocompromised patients (e.g., AIDS, transplant recipients).[5,19,166] The CF test is also useful for the diagnosis of coccidioidal meningitis. Complement-fixing antibodies can be detected in the CSF in more than 80% of cases.[73] CF antibody titers in the CSF decline with adequate therapy and increase with central nervous system disease progression.

Certain viruses (e.g., rubella, influenza/parainfluenza viruses, respiratory syncytial virus [RSV], measles, mumps) have surface antigens that are hemagglutinins; that is, they are able to bind to the *N*-acetylneuraminic acid on RBCs and form cross-linkages that result in macroscopic agglutination. Antibodies directed against a specific virus bind to these hemagglutinins, thereby inhibiting macroscopic agglutination of the RBCs. This reaction is the basis of the HAI assay for detection of viral antibodies (Fig. 3-3).[42,130] Patients with infections caused by hemagglutinating viruses can be diagnosed retrospectively by detecting a fourfold or greater rise in the titer of antibodies that inhibit the ability of the virus to agglutinate erythrocytes. Although antibody detection for rubella and other viral agents is now done by EIA or indirect



■ **FIGURE 3-3** HAI testing is performed in two stages. In stage 1, hemagglutinating viruses and antibodies are mixed. In stage 2, erythrocytes are added. If the antibodies bind to the virus in stage 1, the virus is inhibited and fails to hemagglutinate the erythrocytes. If the antibodies do not bind to the virus in stage 1, the virus remains active and hemagglutinates the erythrocytes in stage 2. Hemagglutination appears as a layer or "shield" of tiny aggregates in the bottom of the tube. Unagglutinated cells settle into a button in the center of the bottom of the tube. Ag/Ab, antigen-antibody. (Redrawn from Leland DS. Clinical Virology. Philadelphia, PA: Saunders, 1996.)

immunofluorescence in most clinical laboratories, HAI is still performed for standardization and validation of new assays (e.g., EIAs for viral serology) and in public health and reference laboratories for surveillance and diagnosis (e.g., serology for *Flaviviridae*, *Bunyaviridae*, *Togaviridae*).[42,68,72,122,130] The HAI procedure is presented in Chart 3-2.

Agglutination Reactions

Agglutination reactions can be defined as the specific immunochemical aggregation of particles (erythrocytes, latex particles, staphylococcal cells) coated with antigen or antibody that can be used to detect either soluble antibodies or antigens, respectively. Antigens or antibodies are attached to these particles either by intramolecular electrical forces or by covalent bonds. Clumping of the carrier particles occurs as an indicator of antigen–antibody interactions occurring on the surface of the carriers. Initially, erythrocytes were used as carriers. These erythrocytes had to be treated with tannic acid or other agents to stabilize the cell membrane, and then formalinized to increase the nonspecific absorption of peptides, proteins, and polysaccharides. For some proteins, chemical coupling agents were used to covalently link the proteins to the red cells; these agents worked for some proteins, but not for others. In 1955, uniformly sized (i.e., 0.81 nm diameter) polystyrene latex beads were demonstrated to be the ideal carrier for antibody molecules, since the hydrophobic surfaces of the beads specifically and irreversibly bind to the Fc region of IgG molecules. Antigens such as complex polysaccharides and proteins could also be linked to latex beads via sulfate groups that are present on the surface of the beads as a result of the manufacturing process. At present, latex beads are the most commonly used carriers in agglutination assays. Latex agglutination tests are usually performed on slides or plastic-coated cardboard cards. Latex beads coated with specific antibodies are the basis for cryptococcal antigen (capsular galactoxylomannan) latex agglutination tests (e.g., Cryptococcal Antigen Latex Agglutination System [CALAS], Meridian Bioscience, Inc., Cincinnati, OH; Crypto LA, International Biological Laboratories, Inc., Cranbury, NJ), latex particle agglutination assays for direct detection of group A streptococci in throat swab specimens, and commercial products for serologic grouping of β-hemolytic streptococci (e.g., Slidex Strepto-Kit, bioMérieux, Inc., Marcy l'Étoile, France; Streptex Streptococcal Grouping kit, Remel, Lenexa, KS).[9,33,93,163,174] Latex agglutination tests were the first-generation rapid tests for direct detection of group A streptococcal antigen in throat swabs specimens. The sensitivities of these antigen-detection latex agglutination tests ranged from 62% to 96%; specificities in most cases exceeded 97%.[57,93,164] These tests have largely been replaced by lateral flow

immunoassays or other nonculture molecular assays. Latex agglutination is still used for streptococcal grouping from positive cultures and for cryptococcal antigen detection. The cryptococcal antigen test is performed on CSF and serum specimens, but it has also been used for antigen detection in bronchoalveolar lavage (BAL) and other specimen types.[14,143,199] The sensitivities of the commercial cryptococcal latex tests vary from 83% to 97%, with specificities of 93% to 100%, depending on the manufacturer.[174] These tests generally provide a rapid diagnosis of cryptococcal meningitis in over 90% of cases.[192] Latex particles can also be conjugated to antigens, thereby allowing latex agglutination to be used for the qualitative and semiquantitative detection of antibodies (e.g., rubella). These tests were convenient, rapid, easy to perform, detected both IgG and IgM antibodies, and were fairly specific. However, latex agglutination tests were less sensitive for detecting low titers of antibody or seroconversions.[87,92,159] Latex agglutination tests for determining immune status to rubella, cytomegalovirus (CMV), and varicella zoster virus (VZV) are no longer commercially available.

Staphylococci may also be used as carrier agents. Strains of *Staphylococcus aureus* (e.g., ATCC 12498) have a high content of protein A in their cell wall. This protein is able to specifically bind the Fc region of IgG, leaving the Fab regions available for binding of antigen.[48] Because of the nature of protein A and its specific interaction with IgG molecules as a functional carrier, staphylococcal coagglutination is used primarily for antigen detection and is the method used in some commercial kits for serologic grouping of β-hemolytic streptococci (e.g., Phadebact Streptococcus Test, Bactus AB, Huddinge, Sweden). Following extraction of antigen from the organisms by chemical or physical means, the antibody-coated staphylococci are mixed with the extract. Visible agglutination of the staphylococcal cells is a positive test. Commercial coagglutination tests are also available for culture confirmation of *Neisseria gonorrhoeae* and *S. aureus* (i.e., Phadebact Monoclonal GC test, Phadebact Staph Aureus test, Bactus AB, Huddinge, Sweden).

Another type of agglutination reaction is the basis of a technique called **immune electron microscopy** (**IEM**). This technique is used for visual detection of viral agents that are noncultivable, such as hepatitis A, some of the newer agents of hepatitis, and noncultivable gastroenteritis viruses (e.g., Norwalk and Norwalk-like viruses, noroviruses) in stool filtrates.[94,137,148] Specific antiviral antibodies are used to cause aggregation of the viral particles; these aggregates are detected by the electron microscope more easily than individual, dispersed virions. The immunospecific aggregation of viral particles increases electron microscopic detection of viruses by 100- to 1,000-fold, thereby enabling detection of as few as 10^5 to 10^6 virus particles/mL of stool filtrate.

Solid-Phase Immunoassay Methods

EIAs for Antibody Detection

Solid-phase immunoassay refers to the binding of either antigen or antibody to a variety of solid materials, such as polystyrene microtube wells or plastic/latex beads. Solid-phase immunoassays designed for the detection of antibody in an unknown sample have antigen bound to the solid phase. The initial reaction occurs when the specimen to be tested is incubated for a prescribed time in contact with the solid phase. Specific antibody binds to the immobilized antigen. After the reaction mixture is washed to remove extraneous material, an antiglobulin is conjugated with a "tag" and incubated in the reaction vessel. In commercially available EIA systems for detecting human antibodies, the conjugate is frequently

119

alkaline phosphatase–or horseradish peroxidase–labeled antihuman Ig raised in goats or manufactured as monoclonal antibodies. If the initial antigen–antibody reaction has occurred, the antiglobulin (with its enzyme tag) binds to the antibody. The final step in these assays is the addition of the enzyme substrate, yielding a colored end product that is detected visually or spectrophotometrically. A positive reaction indicates that antibody was present in the original sample, and the intensity of the reaction is proportional to the concentration of antibody in the specimen. A representative EIA procedure for detection of rubella antibodies is shown in Figure 3-4. Commercially available EIA kits for detection of various antibodies in sera are widely available and have supplanted, in many cases, time-consuming and labor-intensive procedures such as CF and HAI for viral serology.

The chemistry of antibody conjugates used in EIA techniques is not limited to antigen/antibody interactions, as exemplified by avidin, streptavidin, and biotin. Avidin and streptavidin are glycoproteins that are purified from egg white and from *Streptomyces avidinii*, respectively. Biotin is a component of the B_2 vitamin complex and is a cofactor involved in CO_2 transfer in a number of carboxylase reactions. Avidin molecules are able to stoichiometrically bind biotin residues in much the same way as an antibody/antigen interaction.[194] In EIA formats, goat antihuman globulin attached to biotin molecules can be used as the conjugate to detect human antibodies that have bound to an antigen fixed to the solid phase. After a wash step, enzyme-labeled avidin (or streptavidin) is added. After incubation and washing, addition of the enzyme substrate yields a colored end product. Alternatively, biotinylated antiglobulin may be detected by adding unlabeled avidin, and, after a wash step, biotinylated enzyme is added. The biotinylated enzyme binds to the avidin, and, after washing,

addition of the enzyme substrate yields a colored end product.

Serologic procedures for antibody detection that are based on EIA technology were designed to increase their utility as specific diagnostic or confirmatory test methods. The Western immunoblot procedure grew out of a need to determine antigenic specificities of antisera and involved the electrophoretic separation of antigens on polyacrylamide gels, followed by electrophoretic transference and replication of the gel pattern on nitrocellulose paper.[103] Probing the transblotted antigens with antisera was then used to detect and characterize the specificities of polyclonal and MAB preparations. The Western immunoblot procedure for HIV-1 antibodies is the best known application of this technique (Fig. 3-5). In the original HIV-1 Western immunoblot procedure, HIV-1 grown in tissue culture is partially purified away from the cell culture and solubilized by detergent treatment (sodium dodecyl sulfate) and a reducing agent (2-mercaptoethanol). Using polyacrylamide gel electrophoresis, the HIV-1 proteins are fractionated based on molecular weight, with low-molecular-weight proteins migrating further than high-molecular-weight proteins and glycoproteins. A sheet of nitrocellulose paper is placed on the gel, and the proteins are electrophoretically "transblotted" onto the nitrocellulose sheet. The sheet is cut into strips for use as "solid phase" in the assay. Serum that is repeatedly reactive in the HIV-1 EIA is diluted and incubated with the nitrocellulose strip. If present, HIV-1 antibodies bind to specific viral antigens on the strip. After washing, the strips are incubated with goat antihuman antibodies conjugated with horseradish peroxidase or alkaline phosphatase. After another wash step, enzyme substrate is added to the strip. ■ **FIGURE 3-5** Western blot technique for detection of anti-HIV-1 antibodies. In step 1, virus that is grown in tissue culture is solubilized, partially purified, and subjected to electrophoresis in a polyacrylamide slab gel. This separates the viral proteins and glycoproteins by their molecular weights. In step 2, the antigens in the gel are electrophoretically "transblotted" onto a nitrocellulose sheet, which is then cut into strips. The strips are then incubated (step 3) with the test sample (serum). After washing away unbound material, an enzyme-labeled conjugate is added (step 4). This material binds to antibodies from the serum sample that have bound to the strip. After another wash step, the enzyme's chromogen substrate is added (step 5), and colored bands appear on the strip at the sites of initial antibody reactivity. In this diagram, reactivity is shown with gp41, p24, and p31, confirming that the serum sample contains anti-HIV-1 antibodies. (Reprinted, with permission, from Sandler SG. Xxxxx. In: DeVita VI Jr, Hellman S, Rosenberg SA, eds. AIDS Etiology, Diagnosis, Treatment, and Prevention. 2nd Ed. Philadelphia, PA: Lippincott, 1988:128.)

appear on the strip in areas where an initial antibody–antigen reaction has occurred. The position of the bands and comparison of the patterns with positive control samples enable reactivity of a specimen with specific viral antigens to be assessed and interpreted.[128] The HIV-1 Western blot remains the "gold standard" confirmatory test for HIV-1 infection and has a specificity of over 99%.

Immunoblot techniques can also be used to assess specificities of antibodies against other agents. For example, many EIAs that are used to detect antibodies against herpes simplex viruses (HSVs) are not able to differentiate HSV-1- or HSV-2-specific antibodies. Newer, second-generation microtiter-based EIAs were introduced that used purified gG1 and gG2, HSV-1- and HSV-2-specific glycoproteins, to capture virus type–specific antibodies in serum specimens.[38,203] Current immunoblot methods that detect antibodies against several virus type–specific antigens have greater than 98% sensitivity and specificity in differentiating antibodies against HSV-1 and HSV-2.[109,176] Immunoblot technology has also been evaluated as a test format for syphilis diagnosis. Antibodies directed against immunodeterminant *Treponema pallidum* antigens with molecular weights of 15.5, 17, 44.5, and 47 kDa are diagnostic of acquired syphilis when an anti-IgG conjugate is used.[123] When developed with anti-IgM conjugate, the immunoblot procedure is a sensitive and specific assay for the diagnosis of congenital syphilis.[67] Because of the relative insensitivity of EIA and immunofluorescence techniques, immunoblot procedures have also emerged as a sensitive and specific method for serodiagnosis of Lyme disease caused by *Borrelia burgdorferi*, and diagnostic criteria based on immunoblot banding patterns have been established by the Centers for Disease Control and Prevention.[25] Immunoblot methods have contributed to the diagnosis of cat scratch disease by identifying immunodominant antigens of

Bartonella henselae, the agent of cat scratch disease, that are most useful for diagnosis. These antigens could be used for development of EIA or indirect fluorescent antibody (IFA) tests that would provide a sensitive and specific serologic diagnosis.[97,112,187]

Both EIA and immunoblot test systems for the detection of HIV-1 antibodies have undergone several modifications since their introduction in 1984.[135] Initially, test kit manufacturers used lysates prepared from HIV-1-infected cultured T-lymphocyte cell lines as the source for antigens in both the first-generation EIA and immunoblot procedures. Biological false-positive reactions were seen because of the reactivity of antibodies directed against HLA (human leukocyte antigen) proteins expressed by the lymphoid cell lines used to grow the virus. Subsequently, recombinant antigens were obtained by cloning viral genes into bacteria or yeast expression systems using plasmid vectors. Use of these antigens resulted in the development of second-generation EIAs with even greater sensitivity and specificity than the first-generation assays.[35] In these assays, cross-reactions with contaminating bacterial or yeast antigens, however, may be a cause of false-positive reactions. Purification and amino acid synthesis of retroviral antigens then led to the use of synthetic peptides as antigens in the EIA procedure (third-generation assays). These antigens can be produced in large quantities and show little lot-to-lot variability. Because of their purity, indeterminate or atypical reactions due to contaminating components in lysate- and recombinant-based tests are minimized. Although the first- and second-generation assays detected primarily

121

IgG, the third-generation assays detect all classes of antibody (i.e., IgG, IgM, and IgA) to HIV-1 present in serum or saliva.[16] Third-generation HIV-1 EIAs also differ from earlier assays in their methodology; synthetic viral antigens fixed to the solid phase initially "capture" anti-HIV-1 antibodies, and the bound antibodies are detected by adding enzyme-labeled HIV-1 antigen instead of an enzyme-labeled antiglobulin. Fourth-generation HIV-1 EIAs, which are now approved by Food and Drug Administration (FDA), not only detect antibodies against HIV-1, but also have the ability to detect p24 antigen, which is present in blood during acute HIV-1 infection before the formation of antibodies.[141,142,181,189,190,191] These assays will help detect HIV-infected patients who present in the window period, the time between infection and the production of HIV-1-specific antibodies by 4 to 5 days. Western immunoblot–like assays have also been designed that use recombinant or synthetic peptides bound to nitrocellulose strips instead of transblotted viral lysate antigens.[110,116,140,183,201,202] These assays, termed *line immunoassays*, generally have fewer false-positive reactions than the standard HIV-1 Western blot because of the absence of cellular

proteins that are usually found associated with viral lysate–based immunoblot procedures. These novel immunoassays also include recombinant/synthetic peptides for serologic confirmation of HIV-2 infections (RIBA HIV-1/HIV-2 SIA, Chiron Corp., Emeryville, CA; Innolia HIV-1/HIV-2, Innogenetics, Antwerp, Belgium; Lia-Tek HIV III immunoblot assay, Organon Teknika, Turnhout, Belgium)

EIA Antibody-Capture Methods for IgM Detection

EIA methods for antibodies detect primarily IgG. However, specific IgM detection can be used to help differentiate recent from past infections because only IgM is present early in the course of most infections. Methods specific for IgM detection obviate the need for testing of acute and convalescent specimens for specific IgG. In congenital infections, detection of specific IgM in the fetal/neonatal blood indicates active infection rather than transplacental antibodies. Initially, EIA formats for IgM detection used an enzyme-labeled anti-IgM antibody as the conjugate. However, if IgG and IgM are present together in the same specimen, the smaller, more numerous IgG molecules effectively compete for binding sites on the antigen fixed to the solid phase, resulting in no binding of the anti-IgM conjugate and a false-negative IgM test result. In addition, rheumatoid factor in the specimen may interfere with the assay as well. Rheumatoid factors are antibodies primarily of the IgM class that are directed against IgGs of any specificity. If serum contains both IgG and rheumatoid factor, the smaller, specific IgG molecules bind to the antigen on the solid phase, and the rheumatoid factors, in turn, bind to the IgG. Addition of a labeled anti-IgM conjugate results in its binding to the rheumatoid factor, with the subsequent generation of a false-positive result on addition of the enzyme substrate.

In order to detect IgM in patient sera, several methods have been developed to separate IgM from IgG. Ion exchange column chromatography and gel filtration separate Ig classes based on molecular size and charge. Using buffers of varying ionic strength, IgM can be eluted from these columns and separated from IgG. Sucrose gradient density centrifugation also separates the molecules based on size, with IgM molecules traversing further in the sucrose gradient than the lighter, smaller IgG molecules. Serum specimens may also be treated with anti-IgG antibodies, resulting in binding of IgG into immune complexes and effectively preventing these antibodies from reacting in IgM assays. Staphylococcal protein A, either mixed directly with the serum specimen or incorporated into a gel filtration column, may also be used to “bind up” IgG molecules in patient specimens. However, these separation methods pose other technical problems. None of the methods are totally effective in separating IgM from IgG; so IgG interference with IgM detection may still be a problem even after specimen pretreatment. In addition, all of these techniques result in dilution of the serum specimen. Because IgM may be present in very low levels, specimen dilution may result in false-negative IgM test results even when agent-specific IgM actually is

present. Accurate and reliable laboratory testing for IgM is of considerable importance for the diagnosis of congenital rubella syndrome, because the risk of serious damage to the fetus is substantial. Termination of pregnancy is the recommended approach if congenital rubella syndrome is diagnosed antepartum.

The IgM detection method of choice is an "antibody-capture" method (Fig. 3-6). In this modification, IgG directed against IgM is bound to the solid phase. Incubation of the specimen results in binding of all IgM in the specimen aliquot to the immobilized IgG. After a wash step, the specific antigen is added to the microtiter well and becomes bound to IgM antibody molecules having that particular antigenic specificity. Subsequent addition of an enzyme-labeled IgG antibody conjugate directed against another epitope of the antigen results in indirect, enzymatic labeling of the antigen-specific IgM, yielding a colored end product after the addition of enzyme substrate. Captured rheumatoid factor or IgM antibodies of other antigenic specificities do not bind the conjugate to produce a colored end product. In recent years, IgM-capture EIAs have become commercially available for a variety of viral infections.[1,153,198]

EIAs for Antigen Detection

EIA formats may be modified for detection of antigens rather than antibodies. In this case, a "capture" antibody is fixed to the solid phase (Fig. 3-7); in most EIA formats, the solid phase is a well of a microtiter tray. Incubation with a specimen containing the antigen results in binding of the antigen to antibody. After a wash step, incubation with enzyme-labeled (or biotinylated) antibodies against a second epitope of the antigen results in binding of that antibody. After washing, enzyme substrate (or enzyme conjugated to avidin) is added, and subsequent addition of enzyme substrate yields a colored end product. Detection of this end product is usually determined spectrophotometrically; cut-off values for positive and negative results are determined by positive and negative controls or calibrators run simultaneously. Antigen-capture EIAs are available for the detection of diverse microbial pathogens or virulence factors in several specimen types such as diarrheal stool (e.g., EIAs for Shiga-like toxins of enterohemorrhagic *E. coli,* organism-specific antigens of *Giardia*, *Cryptosporidium*, and *Helicobacter pylori,* rotavirus antigen, and *Clostridium difficile* antigens and toxins), urine (EIAs for *L. pneumophila* serogroup 1 antigen), and serum (*Aspergillus* galactomannan [GM] and HIV-1 p24 antigen). A diagram of a typical antigen-capture assay for detection of antigen is presented in Figure 3-7.

■ **FIGURE 3-6** IgM-capture EIA. Patient's serum possibly containing IgM is exposed to antihuman IgM attached to a solid phase. Any IgM in the serum is "captured" or bound by the antihuman IgM. Subsequent steps in the assay (addition of known viral antigen, enzyme-labeled antiviral antibodies, and substrate) are performed to determine the specificity of the captured IgM. Captured IgM of the proper specificity will produce a final result of color change. Captured IgM of other specificity, including rheumatoid factor, will not produce an end result of color change. ■ **FIGURE 3-7** EIA antigen-capture technique for *H. pylori*. In this technique, antibody directed against the antigen to be detected is bound to the solid phase. A stool specimen is added to the well (step 1). Antigens present in the urogenital sample are "captured" by the solid-phase antibody. After a wash step, anti -*H. pylori* antibody that is conjugated to an enzyme is added (step 2) and reacts with the solid-phase antibody-bound antigen. After another wash step, enzyme substrate is added (step 3), and a visible color is detected.

Gastroenteritis is associated with bacterial, parasitic, and viral infections, and antigen-detection EIAs have been developed that address common agents in all of these organism groups. Food-borne enterocolitis and hemolytic-uremic syndrome in children are associated with *E. coli* O157:H7, but these syndromes can also be caused by non-O157:H7 *E. coli* that produce Shiga-like toxins. Sensitive and specific EIAs are available that detect *E. coli* O157:H7 (Premier *E. coli* O157 EIA, Meridian Bioscience, Inc.) or Shiga toxins 1 and 2 (Premier EHEC EIA, Meridian Bioscience, Inc.; ProSpecT Shiga Toxin *E. coli* (STEC), Alexon-Trend, Ramsey, MN) directly in stool specimens.[56,66,80,102] These EIAs can be performed directly on diarrheal stool, or on MacConkey broth enrichment cultures. The Premier EHEC EIA uses monoclonal antibodies directed against Shiga toxins 1 and 2 as capture antibodies, and polyclonal antibodies tagged with horseradish peroxidase for detection of bound toxins. The ProSpeCT STEC test uses polyclonal antibodies against Shiga toxins 1 and 2 as capture antibodies, and horseradish peroxidase–labeled monoclonal antibodies to detect the bound toxins. These assays have sensitivities of 79% to 87% when stools are tested directly and sensitivities of greater than 98% when stools are tested after overnight broth enrichment. Specificities of these assays with either specimen type exceed 97%. A microplate EIA is also available for detection of *Giardia lamblia*- and *Cryptosporidium*-specific antigens in stool specimens. The ProSpecT *Giardia* and *Cryptosporidium* microplate assays (Remel) have sensitivities of 70% to 80% for *Cryptosporidium* and over 90% for *Giardia,* with specificities of greater than 99% when compared with microscopy.[52,74,167,205] EIAs for these agents may not be positive if the numbers of parasites in the specimen are small. EIAs for detection of rotavirus in diarrheal stool have been in use in clinical laboratories for many years. When compared with IEM and reverse transcription PCR (RT-PCR) assays for rotavirus, the Premier Rotaclone assay (Meridian Bioscience, Inc.) has sensitivities and specificities of 95% to 100% and 99%, respectively.[39,96]

H. pylori is a common human pathogen that is associated with gastroduodenal syndromes, including dyspepsia, chronic gastritis, peptic ulcer disease, gastric cancer, mucosa-associated lymphoid tissue lymphoma, and gastric adenocarcinoma.[170]Diagnosis of *H. pylori* infection is accomplished by invasive measures involving endoscopy and gastric biopsy, or noninvasive methods such as

the ^{13}C-urea breath test and stool antigen tests. These tests are used for diagnosis, and have also been assessed for their ability to detect persistent infections following eradication therapy. Although serology for antibody detection is often used to determine whether an individual has been infected with *H. pylori*, serology cannot be used to determine eradication following treatment, because declines in antibody titers vary from person to person depending on the intervals between follow-up visits.[179] EIAs detect antigens of *H. pylori* in fecal specimens and use either immunoaffinity-purified polyclonal anti- *H. pylori* rabbit antibodies (Premier Platinum HpSA, Meridian Bioscience, Inc.) or monoclonal antibodies (Amplified IDEIA Hp StAR, DakoCytomation/Oxoid Ltd., Cambridge, UK; FemtoLab *H. pylori*, Connex, Martinsried, Germany) adsorbed to the microtiter well solid phase. In evaluations, the Premier Platinum HpSA assay has demonstrated sensitivities ranging from around 80% to over 95%, with corresponding specificities ranging from 79% to 99%, when compared with the ^{13}C-urea breath test.[59,91,146,177,178] EIAs that use monoclonal antibodies for antigen capture are comparable or slightly more sensitive and specific than the polyclonal antibody

124

assays.[23,107] In the United States, the Premier assay is more widely used than other microtiter EIA methods, and even this test is being replaced by lateral flow immunoassays for *H. pylori* antigen in many laboratories (see below).

Legionella infections are diagnostic dilemmas for the clinician and the laboratory. *Legionella* species are increasingly being recognized as agents of community-acquired, travel-associated, and nosocomial pneumonias in the United States and other countries.[18,24,119] *Legionella* species are responsible for 2% to 5% of all community-acquired pneumonias, and more than 90% of these cases worldwide are due to *L. pneumophila*. Of these infections, 70% to 80% are caused by *L. pneumophila* serogroup 1.[24,41,47] Immunosuppressed patients (i.e., organ transplantation, corticosteroids, hematological malignancies, bone marrow transplants) are also at risk. Many laboratories do not offer *Legionella* culture, as culture methods are laborious, requiring preanalytical specimen processing, inoculation of selective/nonselective media, and technical expertise for recognition and identification. Serologic diagnosis is retrospective and not clinically useful in the acute setting. Development and availability of EIAs that detect soluble antigens of *L. pneumophila* serogroup 1 in urine has changed the clinical and laboratory approaches to diagnosing *Legionella* infections. Urine EIA tests detect Pontiac MAB type 2 of *L. pneumophila* serogroup 1, but are less sensitive for other *L. pneumophila* serogroup 1 MAB types, and are insensitive for the detection of nonserogroup 1 *L. pneumophila* and other *Legionella* species. *L.*

pneumophila urine antigen EIAs use either microtiter (Biotest *Legionella* urinary antigen EIA [Biotest AG, Dreieich, Germany]; Binax *Legionella* urinary antigen EIA [Binax, Portland, ME]; Bartels ELISA *Legionella* urinary antigen EIA [Intracel, Frederick, MD]) or an immunochromatographic strip (Binax NOW *Legionella* urinary antigen ICT) formats. In a side-by-side comparison, the Binax assay demonstrated sensitivities of 63.7% and 88.9% when unconcentrated and concentrated (25-fold by ultrafiltration) specimens were tested, respectively.[43] Corresponding sensitivities for the Biotest EIA were 66.7% and 86.7%, respectively. Both assays were 100% specific. An evaluation of the Bartels EIA reported similar sensitivity and specificity consistent with the other two commercial EIAs.[61] A meta-analysis of all *Legionella* urinary antigen assay evaluations found a pooled sensitivity of 74% (range, 68% to 80%) and a specificity of 99.1% (range, 98.0% to 99.7%) for detection of *L. pneumophila* serogroup 1 antigen, with no statistically significant differences among the various brands.[162] These assays are best used to rule in rather than rule out *Legionella* infections.

The detection of *C. difficile* toxins A and B in stool specimens by antigen-capture EIA has been used in clinical laboratories for several years. These tests originally were validated against the cell-culture cytotoxin assay, which has sensitivities ranging from 80% to 100% and specificities of 98% to 99%, depending on the reference method employed.[118,136,152] *C. difficile* toxin microwell EIAs include the Meridian Premier Toxin A and B (Meridian Bioscience, Inc., Cincinnati, OH), TechLab Tox A/B (TechLab, Blacksburg, VA), and the VIDAS EIA (bioMérieux, Inc., Marcy l' Étoile, France), with the former two assays being most widely used. The sensitivities and specificities of the Premier assay range from 80% to 99% and 94% to 99%, respectively, when compared with the cell-culture cytotoxicity assay.[118,127] Similar sensitivities of 75% to 86% and specificities of 92% to 100% have been reported for the TechLab A/B assay.[111,155] Recent increased morbidity and mortality due to *C. difficile* infection and recognition of emergent strains of *C. difficile* that demonstrate significantly greater cytotoxin production (the NAP1/BI/027 *C. difficile* strain known by its restriction endonuclease pattern [BI], its pulsed-field gel electrophoresis pattern [North American PFGE type 1], and its PCR ribotype [027]) stimulated the development of more rapid and sensitive diagnostic approaches, including the use of toxigenic culture.[12,98,113,188] Toxigenic culture refers to isolation and identification of *C. difficile* from diarrheal stool specimens followed by in vitro detection of toxin production by the isolate using either EIA or the cell-culture cytotoxicity assay. Comparisons of EIA methods with toxigenic culture showed that the toxin EIAs were not as sensitive as once thought.[30,31,139] In order to optimize detection, the use of another EIA, the glutamate dehydrogenase (GDH) assay, was introduced. GDH is a cell wall enzyme that is found in both toxigenic and nontoxigenic *C. difficile* isolates.

This test was introduced as a screening test, so that only GDH-positive specimens would be tested by either toxin EIA or cytotoxicity assays. Unfortunately, GDH tests from different manufacturers vary in their sensitivity as well. The development, availability, and FDA clearance of commercial, highly sensitive molecular assays for *C. difficile* toxin gene detection have eclipsed the diagnostic utility of many *C. difficile* toxin A/toxin B EIAs.[136] Laboratories that lack molecular testing capabilities have formulated stepwise algorithms using EIAs for GDH followed by toxin A/toxin B EIAs to increase the sensitivity, specificity, predictive values, and accuracy of *C. difficile* disease diagnosis.[86,124,147,152,156,160]

In mycology, several EIA assays are now available to assist in the diagnosis of endemic and opportunistic fungal infections. These tests include a cryptococcal antigen EIA, *Histoplasma* antigen EIA, and the GM EIA for detection of invasive *Aspergillus* infection. The Premier cryptococcal antigen EIA (Meridian Bioscience, Inc.) uses a polyclonal-capture Ig and a monoclonal detection antibody and can be performed on both CSF and serum specimens with no pretreatment steps. This assay has demonstrated comparable performance with the cryptococcal antigen latex agglutination assays.[10,45,49,174] The cryptococcal antigen EIA is not affected by rheumatoid factor, syneresis fluid, or serum macroglobulins, and quantitative titers tend to be higher than those obtained with the latex agglutination test. The GM EIA (Platelia *Aspergillus* EIA, Bio-Rad, Redmond, WA) is a microtiter EIA for detection of GM of *Aspergillus* species in serum specimens of at-risk patients. The test uses a galactofuranose-specific rat MAB that recognizes the 1→5-β-D-galactofuranose side chains of the *Aspergillus* GM to capture and detect GM in serum specimens. This test was FDA cleared for use in the United States in 2003. When initially released, centers in Europe were using the cut-off value suggested by the manufacturer (positive: OD values >= 1.5); in the United States, the FDA approved an OD cut-off value of 0.5 for test interpretation. With lower cut-off values, test sensitivity was increased, but specificity was decreased.[138] In a European study of adult hematology patients, lowering the cut-off value increased the test sensitivity from 76.3% to 97.4%, but decreased the overall specificity from 97.5% to 90.5%.[105] Testing of two consecutive serum specimens using the lower cut-off value resulted in improved test specificity (97.5%) and predictive value of

125

positive test results (87.5%). In general, sensitivity of the GM EIA ranges from 57% to 100%, with specificity ranging from 66% to 100%; both of these parameters are influenced by the use of prophylactic and empirical antifungal therapies in patients at risk for invasive aspergillosis.[70,108,114] Sensitivities and specificities exceeding 85% to

90% have been reported for the GM EIA among patients with hematological malignancies and recipients of allogeneic hematopoietic stem cell transplants.[79,106,138,171]

The Platelia GM EIA has also been applied to other clinical specimens, such as BAL fluid. In one study of 333 BAL specimens from 116 lung transplant patients (including 9 BALs from patients with proven invasive aspergillosis), the sensitivity and specificity of the GM assay were 60% and 95%, respectively.[70,71] The EIA also compared well with molecular assays for detecting evidence of *Aspergillus* in BAL fluids. In a study of 49 hematopoietic stem cell transplant patients with proven/probable invasive pulmonary aspergillosis and 50 patients without the disease, the sensitivity of the GM EIA was 76% (using an index cut-off of 0.5) and the specificity was 94%, while the sensitivity and specificity of PCR were 67% and 100%, respectively.[117] In the same study, the sensitivities of GM EIA and PCR with 22 culture-negative BAL specimens from patients with invasive aspergillosis were 59% and 36%, respectively. The GM EIA has some documented limitations that are a matter of concern. Several other filamentous fungi have been demonstrated to produce antigens that cross-react with *Aspergillus* GM. Giacchino and colleagues described three cases of invasive *Geotrichum capitatum* infections in leukemic patients where the GM EIA was positive.[58] Subsequently, Wheat and colleagues found false-positive GM EIA results with serum specimens obtained from patients with disseminated histoplasmosis.[193] In vitro studies using culture filtrates have demonstrated additional test cross-reactivity with antigens derived from cultures of *B. dermatitidis*, *Nigrospora oryzae*, *Paecilomyces lilacinus*, *Penicillium chrysogenum*, and *Trichothecium roseum*.[32] Kitasato and colleagues reported a false-positive GM immunoassay result in a patient with pulmonary actinomycosis, and lipoteichoic antigens from *Bifidobacterium* may cause false-positive GM EIA results.[82,115] In addition, false-positive GM EIA results have been reported because of cross-reactivity of mold-derived antimicrobial agents such as amoxicillin, amoxicillin-clavulanate, ampicillin, ampicillin-sulbactam, piperacillin, and piperacillin-tazobactam.[2,8,13,172,186] These cross-reactivities may have significant clinical implications for patients who are at risk for invasive aspergillosis and are receiving broad-spectrum therapy, particularly piperacillin-tazobactam.

HIV-1 p24 antigen-detection methods have been available since the mid-1980s and have demonstrated some clinical utility. During acute HIV-1 infection, p24 antigen is present in high levels prior to the development of anti-p24 antibodies. When antibodies appear, much of the p24 antigen is present as immune complexes, and so free p24 antigen levels decrease.[60] Heat treatment or other methods to dissociate and remove anti-p24 antibodies have been used to enable detection of antigenemia beyond the period immediately following acute infection.[65,157] Commercial tests for detecting p24 antigen use polyclonal or monoclonal antibodies fixed to microtiter wells for antigen

capture from dilutions of patient sera, and detection is accomplished by addition of a second anti-p24 antibody conjugated with an enzyme. In 2010, Parpia and colleagues reported a dipstick, lateral flow p24 antigen-detection assay that used heat shock to disrupt immune complexes attributable to maternal anti-p24 antibodies. Using blinded specimens archived from the NIH-sponsored Women-Infants Transmission Study (WITS), this assay demonstrated an overall sensitivity and specificity of 90% and 100%, respectively, for detection of p24. In a field study of 389 specimens from South African infants at risk for HIV, 24 (6.8%) of the 389 specimens were HIV RNA positive by RT-PCR. The dipstick p24 test demonstrated a sensitivity of 95.8% and a specificity of 99.4% in detecting p24 in these heat-dissociated specimens.[131]

Immunoconcentration and Immunochromatographic Immunoassays

The basic technology that underlies immunoconcentration and immunochromatographic test systems was described in the 1960s, and the first commercial applications were actually home pregnancy tests, which became available in 1988. Since then, this technology has been applied to a wide array of tests for clinical, veterinary, and industrial applications. Immunoconcentration or "flow-through" assays use a nitrocellulose membrane fixed in a cartridge device.[180] Depending on the assay, either antigen (for detection of antibody) or antibodies (for detection of antigen) are immobilized on the membrane in discreet spots. Following antibody or antigen capture from the clinical specimen and a flow-through wash step, sequential addition of an enzyme-labeled conjugate and substrate results in the appearance of a colored reaction product directly on the membrane. These assays also contain internal positive and negative control spots on the membrane along with the test area; these controls determine if the test was performed correctly, and expected control results must be observed on the membrane for the test to be considered valid.

An example of an immunoconcentration assay for antibody detection is the ImmunoCard *Mycoplasma* (Meridian Biosciences, Cincinnati, OH), which detects *Mycoplasma pneumoniae*– specific IgM in serum samples.[3,17,173] In this assay, patient serum (two drops) is added to each of the two sample ports of the test cartridge. The samples then migrate along the membrane into the two reaction ports. One reaction port (Control port) serves as a procedural control and has human IgM bound to the membrane. In the other reaction port (Test port), the detergent-extracted antigens of *M. pneumoniae* are bound to the nitrocellulose membrane. Three drops of antihuman IgM conjugated to alkaline phosphatase are then added to each of the two sample ports, and this conjugate then migrates into the two reaction ports. Alkaline phosphatase enzyme substrate is then added to the Control and Test ports. The anti-IgM conjugate binds to the IgM bound to the membrane in the Control port. The

patient specimen is added to the Test port. Next, the enzyme-labeled antihuman IgM conjugate is added, followed by substrate. A blue color in both the Control and Test ports indicates a valid reaction and the presence of anti- *M. pneumoniae* IgM in the patient specimen, respectively. If anti- *M. pneumoniae* IgM antibodies are not present in the specimen, no color will be seen in the Test port, but the Control port should still be blue. However, if anti- *M. pneumoniae* antibodies are present in the specimen, the IgM in the specimen reacts with the

126

M. pneumoniae antigens on the membrane of the Test port. In one comparative evaluation of several serologic methods for detection of *M. pneumoniae* antibodies, including ImmunoCard *Mycoplasma*, the consensus sensitivity and specificity were 90% and 93%, respectively, and the test outperformed a microplate EIA, IFA testing, and CF.[3] This test has its greatest utility in the diagnosis of pediatric infections, since adults with *M. pneumoniae* infection may elaborate only an IgG response on primary infection and reinfection.[36,165]

Immunoconcentration assays for antigen detection have also been marketed and used in clinical laboratories. Second-generation rapid antigen tests for detection of group A streptococci in throat swab specimens utilized immunoconcentration flow-through technology when they were first introduced. An example of one of these was the TestPack Plus Strep A test (Abbott Laboratories, North Chicago, IL). Following extraction of a throat swab with nitrous acid, the extract is placed on a membrane and allowed to soak through. Anti–group A streptococcal antibody conjugated to alkaline phosphatase is then added to the membrane. Following a wash step, the alkaline phosphatase substrate is added, and the result is indicated by the appearance of a blue "+" or "–" sign, indicating the presence or absence of streptococcal antigen in the specimen, respectively. Immunoconcentration assays for group A streptococci have sensitivities ranging from 64% to 89.9%.[22,88,93,158,200] Most commercially available immunoconcentration assays have been replaced by immunochromatographic techniques.

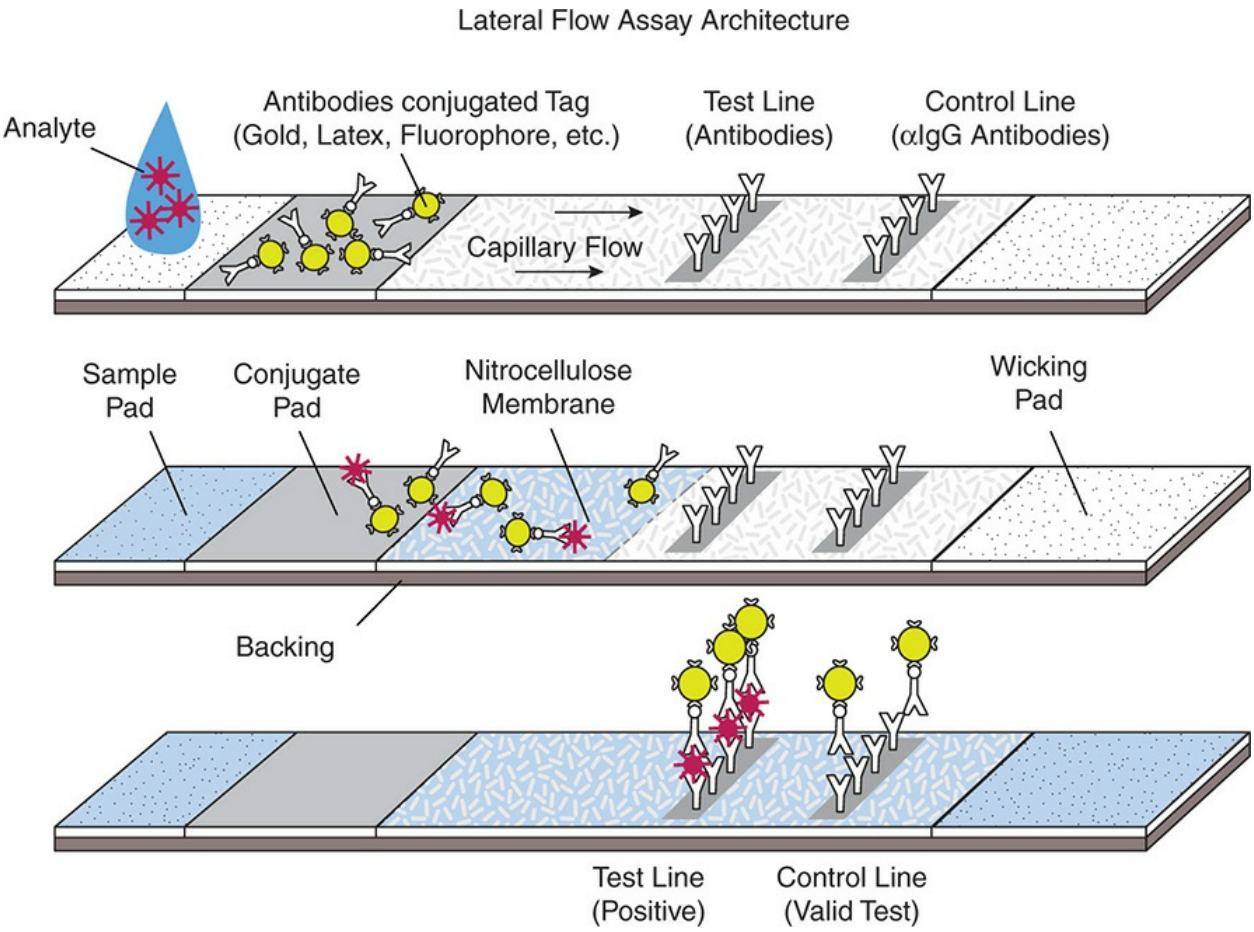
Immunochromatographic or lateral flow immunoassays are essentially immunoassays that have been adapted to the test strip format (Fig. 3-8). A number of variations of the technology have been developed into commercial products, but they all operate according to the same basic principles. A typical test strip consists of an absorbent pad onto which specimen is applied, a conjugate or reagent pad that contains antibodies specific to the target analyte conjugated to colored particles (i.e., colloidal gold particles or latex microspheres), a reaction membrane onto which antitarget analyte antibodies are immobilized in a line across the membrane as a capture zone or test line, a control zone containing antibodies specific for the

conjugate antibodies, and a waste reservoir composed of another absorbent pad (wick assembly) designed to draw the sample across the reaction membrane by capillary action. The components of the strip are fixed to an inert backing material and may be formatted as a simple dipstick or inside a plastic casing with a sample port and a reaction window showing the capture (test) and control zones.

Lateral flow immunoassays used in clinical microbiology laboratories are usually double-antibody sandwich assays. For detection of antigens, the capture zone on the membrane contains immobilized antibodies. The specimen applied to the sample pad migrates from the sample pad through the conjugate pad where the antigen target binds to the conjugate. The sample then continues to migrate across the membrane until it reaches the capture zone where the target/conjugate complex will bind to immobilized antibodies,

127

producing a visible line on the membrane. The sample then migrates further along the strip until it reaches the control zone where excess conjugate binds and produces a second visible line on the membrane. This control line indicates that the sample has migrated across the membrane as intended. A clear line in the control zone and in the test area on the membrane constitutes a positive result. A single line in the control zone is a negative result. Examples of commercially available lateral flow assays for antigen detection include tests for RSV in nasopharyngeal wash specimens (Binax NOW RSV, Inverness Professional Medical Diagnostics, Princeton, NJ; Remel Xpect RSV, Remel Laboratories) and for the detection of rotavirus (ImmunoCardSTAT! Rotavirus, Meridian Bioscience, Inc.), *G. lamblia* and *Cryptosporidium parvum* (ImmunoCardSTAT! *Cryptosporidium/Giardia*, Meridian Bioscience, Inc.), and *H. pylori* antigens (ImmunoCardSTAT SpSA, Meridian Bioscience, Inc.) in stool filtrates. The basic construction and principle of a lateral flow immunoassay are depicted in Figure 3-8.



■ **FIGURE 3-8** Lateral Flow Immunoassay. This figure shows a lateral flow immunoassay for detection of antigen. The specimen (e.g., serum, urine) containing the analyte to be detected is placed on the sample pad, which soaks up the specimen fluid. The fluid then migrates to the conjugate pad, which contains antibodies directed against the analyte. These antibodies are conjugated with gold, colored latex, or a chromophore. The analyte is captured by the antibodies on the conjugate pad and then migrates across a nitrocellulose membrane toward the "test" line. As more and more analyte–antibody complexes are captured at the "test" line, the line becomes visible on the membrane. Antibodies that are not analyte-specific are not captured and continue to migrate toward the "control line." The control line is composed of immobilized antibodies directed against immunoglobulin. As more and more uncomplexed antibody passes over the "control" line, the uncomplexed antibodies are captured and become visible at the "control" line. The presence of a "control" line only indicates that the test was performed properly and that the analyte is absent from the specimen. Lines at both the test and control areas indicate a positive test. A single line in the test area without a corresponding control line is an invalid test.

These rapid lateral flow antigen-detection immunoassays have shown generally good performance in clinical use. The Binax Now RSV and the Xpect RSV tests have

sensitivities ranging from 33% to over 80% and specificities exceeding 97%, resulting in positive predictive values of 57% to 100%, depending on the population and the specimen type being tested (i.e., nasopharyngeal washes or aspirates, BALs).[21,75] A 1999 evaluation of the ImmunoCardSTAT Rotavirus test demonstrated a sensitivity of 94% and a specificity of 100%.[39] Garcia and coworkers evaluated the ImmunoCardSTAT! *Cryptosporidium/Giardia* immunoassay and reported sensitivities of 98.8% and 93.5% for detection of *Cryptosporidium* and *Giardia,* respectively, with 100% specificity for both parasites.[54] Slightly lower sensitivities for detection of *G. lamblia* (81%) and *Cryptosporidium* (68%) were reported for the ImmunoCardSTAT! by Johnston and coworkers.[74] Evaluations of the ImmunoCardSTAT! HpSA (*H. pylori* stool antigen) assay have shown performance equivalent to or exceeding that of the *H. pylori* antigen microplate EIA.[76,77,197] Lateral flow immunoassays for antigen can also be "multiplexed" by configuring multiple capture zones on the detection pad so that multiple antigens in the same specimen can be detected simultaneously. For example, the Triage Micro Parasite Panel (Biosite Diagnostics, Inc., San Diego, CA) is a lateral flow immunoassay that is performed on fecal specimens and has immobilized antibodies directed against *G. lamblia*, *E. histolytica/E. dispar*, and *C. parvum*.[53,161] In an evaluation of this product by Garcia et al., the sensitivity of the Triage assay for detection of *G. lamblia*, *E. histolytica/E. dispar*, and *C. parvum* was 95.9%, 96.0%, and 98.3%, respectively, with over 97% specificity for each of the three parasites.[53]

However, not all lateral flow EIA tests have demonstrated the accuracy necessary for clinical use. For example, initial evaluations of the Clearview *Chlamydia* assay (Wampole Laboratories, Cranbury, NJ) compared this lateral flow EIA to culture and reported a sensitivity of 72.9% for the device.[20,84] Subsequent evaluations in which the Clearview assay was compared with nonamplified probe and then NAATs for *Chlamydia trachomatis* reported sensitivities ranging from 50% to 95%, depending on the tests being compared, the specimen types being evaluated, and the prevalence of *C. trachomatis* infection in the study population.[29,69,89] Similar poor performance owing to the lack of sufficient sensitivity for detection of *C. trachomatis* has been reported for the Quickview Chlamydia Test (Quidel Corp., San Diego, CA).[149,182]

The availability of recombinant and synthetic antigens with sensitive and specific reactivity in regular microtiter EIA formats has led to the development of rapid, immunoconcentration and immunochromatographic tests for the detection of HIV-1 and HIV-2 antibodies. FDA-cleared rapid HIV tests include the OraQuick Advance Rapid HIV-1/2 antibody test (Orasure Technologies, Inc., Bethlehem, PA), the Reveal G3 Rapid HIV-1 antibody test (MedMira, Inc., Halifax, Nova Scotia, Canada), Uni-Gold Recombigen HIV (Trinity Biotech, Bray, County Wicklow, Ireland), the Multispot HIV-1/HIV-2 Rapid Test (Bio-Rad Laboratories, Hercules, CA), the

Clearview HIV-1/HIV-2 STAT-PAK, the Clearview Complete HIV-1/HIV-2 (Inverness Medical Professional Diagnostics, Princeton, NJ), and the INSTI HIV-1 Antibody Test (bioLytical Laboratories, Inc., Richmond, BC, Canada). The OraQuick Advance assay can be performed on whole blood, plasma, and oral fluid, which is collected by swabbing completely around the upper and lower outer gums with a small absorbent pad. The Reveal G3 and the Multispot tests can be performed on either serum or plasma, whereas the Uni-Gold test, both Clearview tests, and the INSTI test can be performed on whole blood, serum, or plasma. Whole blood for these latter tests is collected by finger stick using test kit–specific devices (e.g., lancets, specimen collection "loops").

The Reveal G3 Rapid HIV-1 Antibody Test, the Multispot HIV-1/HIV-2 Rapid, and the INSTI HIV-1 Antibody Test use membrane immunoconcentration "flow-through" technology, whereas the OraQuick Advance Rapid HIV-1/HIV-2 Antibody Test, the Trinity-Biotech Recombigen HIV, and the Clearview HIV-1/2 STAT-PAK and Complete HIV-1/HIV-2 antibody tests employ lateral flow immunochromatographic technology. The Reveal G3 Rapid HIV-1, the Multispot HIV-1/HIV-2, and the INSTI tests are configured as single-use cube-shaped cartridges containing an immunoreactive membrane. In the Reveal G3 assay, the membrane contains a spot composed of synthetic peptides corresponding to conserved regions of HIV-1 structural proteins and a procedural/reagent control line composed of protein A. A small aliquot of specimen (serum or plasma) is placed in the center of the reaction membrane and is absorbed. A cap containing a protein A/colloidal gold conjugate is placed on the reaction cartridge, and 12 drops of buffer are applied to the center of the cap. Once all the fluid is absorbed, the cap is removed and the test is read. A reactive test results when the protein A portion of the conjugate binds to the captured HIV-1 antibodies, producing a red "dot" in the test zone and a vertical, red line in the control zone of the membrane. A negative test, resulting from absence of the HIV-1 antigen/antibody complex, is indicated by the presence of only the red vertical line in the control area of the membrane.

In the Multispot HIV-1/HIV-2 Rapid Test, the cartridge membrane contains a procedural control spot, an HIV-1 peptide (immunodominant HIV-1 gp41 envelope glycoprotein) spot, a recombinant HIV-1 antigen (recombinant HIV-1 gp41 envelope glycoprotein) spot, and HIV-2 peptide (immunodominant epitope of the HIV-2 gp36 envelope glycoprotein). These spots are composed of microparticles coated with these antigens. A dilution of the specimen (serum or

128

plasma) is applied to a prefilter covering the cartridge, and, after specimen absorption onto the membrane, the prefilter is removed. If antibodies against HIV-1 or HIV-2 are present, these antibodies bind to the antigens on the microparticles. A conjugate

(alkaline phosphatase–labeled goat antihuman IgG) is dropped onto the reaction membrane and binds to the human antibody/antigen complexes immobilized on the reaction spots of the cartridge membrane. After a wash step to remove unbound conjugate, color development reagent (i.e., a colorimetric alkaline phosphatase substrate) is added to the cartridge. A purple color appears on the test spots for HIV-1 or HIV-2 if antibodies to these agents were present in the specimen. A purple color develops at the procedural control spot on the membrane if the assay was performed correctly, regardless of the presence or absence of HIV antibodies. The INSTI HIV-1 Antibody Test membrane contains both HIV-1 and HIV-2 antigens, but the test has only been validated for detection of HIV-1 antibodies.

The OraQuick Advance Rapid HIV-1/HIV-2 Antibody Test, the Uni-Gold Recombigen HIV, and the Clearview HIV-1/HIV-2 STAT-PAK and Complete HIV-1/HIV-2 tests use lateral flow immunochromatographic technology. In these rapid (10 to 20 minutes) assays, a small aliquot of the specimen (oral fluids, whole blood, serum, or plasma, depending on the kit) is added to a specimen/sample well of the lateral flow cartridge. A running buffer is then added to facilitate the lateral migration of the specimen through the reaction cartridge by capillary action and to reconstitute the conjugate fixed to the membrane. If present, the anti-HIV antibodies bind to a colloidal gold dye-conjugated antibody binding protein. The dye-conjugated immune complex migrates further along the nitrocellulose membrane and is captured by the HIV antigens that are immobilized in the "test" area, producing a pink-to-purple-colored line and indicating the presence of antibodies to HIV-1 and/or HIV-2. The sample continues to migrate along the membrane and produces a pink-to-purple line in the control area, which contains IgG antigens. This internal procedural control verifies that the specimen and buffer have been properly applied to the cartridge and establishes the validity of the test.

The development of these rapid HIV antibody assays has provided the medical community with essential tools for the efficient detection of HIV infection in both developed and developing countries.[7,28,135] Depending on the Clinical Laboratory Improvement Amendments requirements of the various tests (waived vs. nonwaived), these point-of-care tests enable HIV testing to be offered in hospital emergency departments and clinics, physicians' offices, community-based clinics, outreach programs, and in field work and serosurveys. Evaluations of these rapid HIV tests generally have shown exquisite sensitivity and specificity in diverse populations worldwide.[37,90,101,125,126,129,132] Since IgG is the antibody detected, these tests are not suitable for the diagnosis of neonatal infections, because of the presence of maternal antibodies up to about 12 months of age. A recent Australian prospective evaluation of five of the rapid HIV antibody test kits licensed in Europe with a cohort of 200 known HIV-positive individuals showed reduced sensitivity of three of the FDA-cleared tests when result obtained with whole blood obtained with finger stick

was compared with matched serum specimens.[132] The sensitivities of finger-stick blood versus serum were 94.5% versus 97.5% for the OraQuick Advance Rapid HIV-1/HIV-2 antibody test and 94.7% versus 100% for the Uni-Path HIV-1/HIV-2 assay. Only the INSTI HIV-1 Antibody Test showed equivalent performance with whole blood and serum, with a sensitivity of 99%.[132] In this study, use of oral fluid specimens produced the lowest sensitivity (86.5%) compared to 94.5% and 97.5% for finger-stick whole blood and serum, respectively. The rapid HIV antibody tests also vary in their ability to identify recently infected persons.[99] Just as the fourth-generation EIAs for HIV-1 and HIV-2 detect both specific antibodies as well as HIV-1 p24 antigen, a lateral flow immunoassay for simultaneous detection of antibodies and HIV-1 p24 antigen is also available (Alere Determine HIV-1/HIV-2, Alere San Diego, CA) and is FDA cleared. An evaluation of this assay demonstrated 100% sensitivity and specificity for detection of HIV-1 and HIV-2 antibodies, and a sensitivity of 86.6% for detection of p24 antigen, as documented by testing 10 different seroconversion panels.[15]

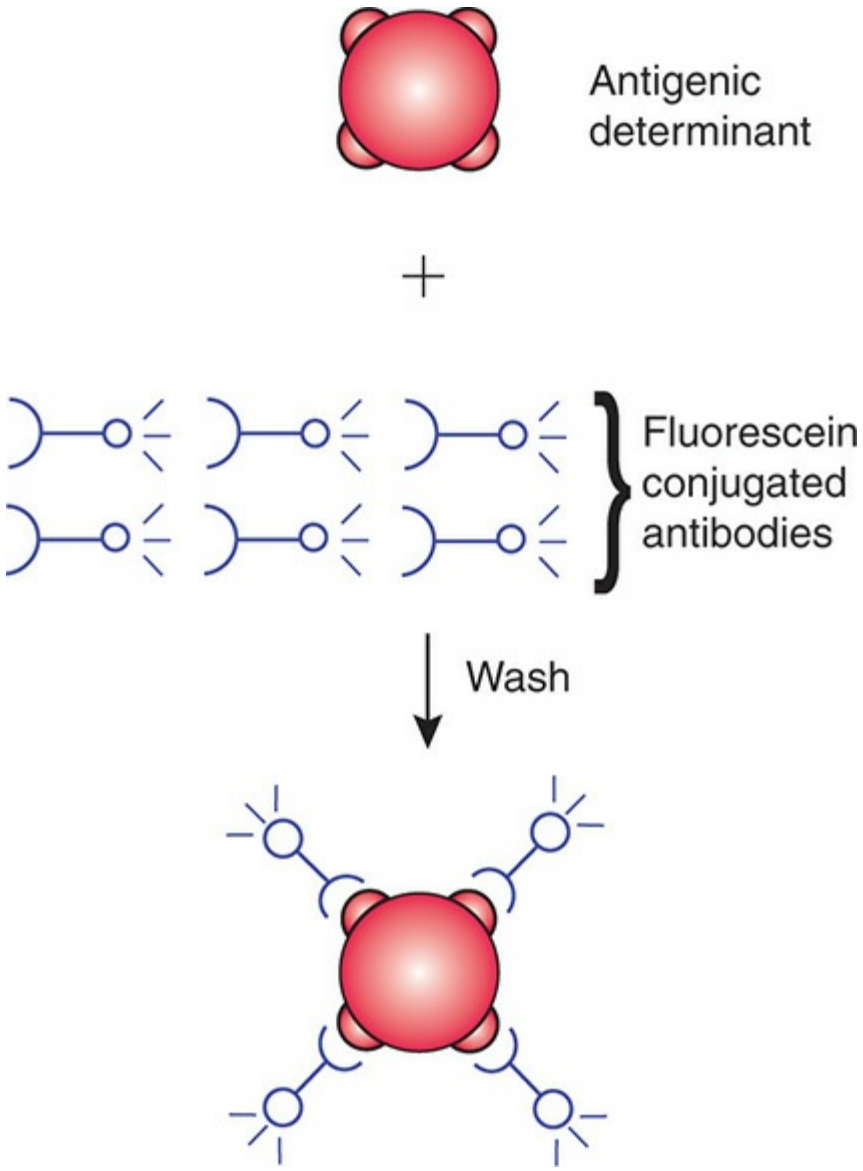
Immunofluorescence Techniques

Immunofluorescence provides an alternative to EIA as a means for detecting and localizing antigens in making the diagnosis of bacterial, fungal, parasitic, and viral diseases. This technique may also be used to detect antibodies for retrospective diagnosis of infectious diseases. Fluorescence is defined as the radiation of energy when light of a shorter wavelength (the "excitation" wavelength) incites the electrons of a molecule to a higher energy state for a very short time. As the electrons return to the preexcitation or ground state, the energy is released as light of a longer wavelength. In fluorescence immunoassays, specific antibody is conjugated to a compound capable of photoexcitation and subsequent fluorescence (usually fluorescein isothiocyanate [FITC] or rhodamine derivatives), resulting in a sensitive tracer with unaltered immunologic reactivity. The conjugated antiserum is added to cells or tissues on a slide and becomes fixed to antigens, forming a stable immune complex. Nonreacting materials are removed by washing, and the preparation is then dried and observed with a fluorescence microscope equipped with an appropriate light source and barrier filters. Antigens bound specifically to a fluorescent antibody (IF) can be detected as bright apple-green or orange-yellow objects against a dark background depending on the fluorochrome being used. Immunofluorescence techniques may be direct or indirect. Direct immunofluorescence tests are usually used for antigen detection; the indirect method can be used for both antigen and antibody detection (i.e., serology).

Immunofluorescence Techniques for Antigen Detection

Direct immunofluorescence techniques (also called **direct fluorescent antibody** [**DFA**] techniques) (Fig. 3-9) involve application of the labeled conjugate to the material being examined, followed by a 15- to 30-minute period of incubation in a humid environment at 35° to 37°C to allow the

129



■ **FIGURE 3-9** Schematic diagram of a direct immunofluorescence assay (DFA). In the DFA method, the antigen (e.g., respiratory specimens for RSV) is placed in the well of an FA slide and reacted directly with a fluorescein-conjugated monoclonal antibody directed

against the antigen. After incubation and washing, the slide is examined for characteristic fluorescence.

antigen–antibody reaction to occur. After a wash step to remove unbound conjugate, the preparation is air dried and mounted for observation under a microscope fit with an appropriate fluorescent light source and barrier filters. In the **IFA** procedure (Fig. 3-10), the material to be examined is first overlaid with an excess of unlabeled immune serum directed at the antigen and allowed to react for 30 to 45 minutes at 35° to 37°C. The specimen is washed with phosphate-buffered saline solution and then reacted with tagged antiserum against the species of Ig used in the initial reaction (e.g., fluorescein-conjugated antihuman antibody raised in goats). After washing the background free of extraneous material, the presence of microscopic fluorescence indicates the presence of antigen. DFA tests are simple and rapid to perform with fewer nonspecific reactions; however, they may be less sensitive than indirect procedures. IFA methods are more sensitive and produce brighter fluorescence; however, they may be less specific and are subject to increased cross-reactivity.

Reagents for either DFA or IFA detection of antigens are commercially available for a variety of agents, including HSVs, VZV, respiratory viruses (i.e., influenza, RSV, parainfluenza viruses), *Pneumocystis jirovecii*, *G. lamblia*, and *C. parvum.* Chan and colleagues evaluated the SimulFluor DFA for HSV-1, HSV-2, and VZV and found the assay to be slightly less sensitive than immunoperoxidase staining of shell-vial cultures for HSV detection (80% sensitivity versus 87% sensitivity) and cytospin DFA staining for VZV (87.1% sensitivity). However, the SimulFluor assay provided same-day results for HSV detection, and no difference in turnaround time for detection of VZV compared with cytospin DFA detection.[26] The Merifluor *Pneumocystis* DFA test (Meridian Diagnostics) is more sensitive than other

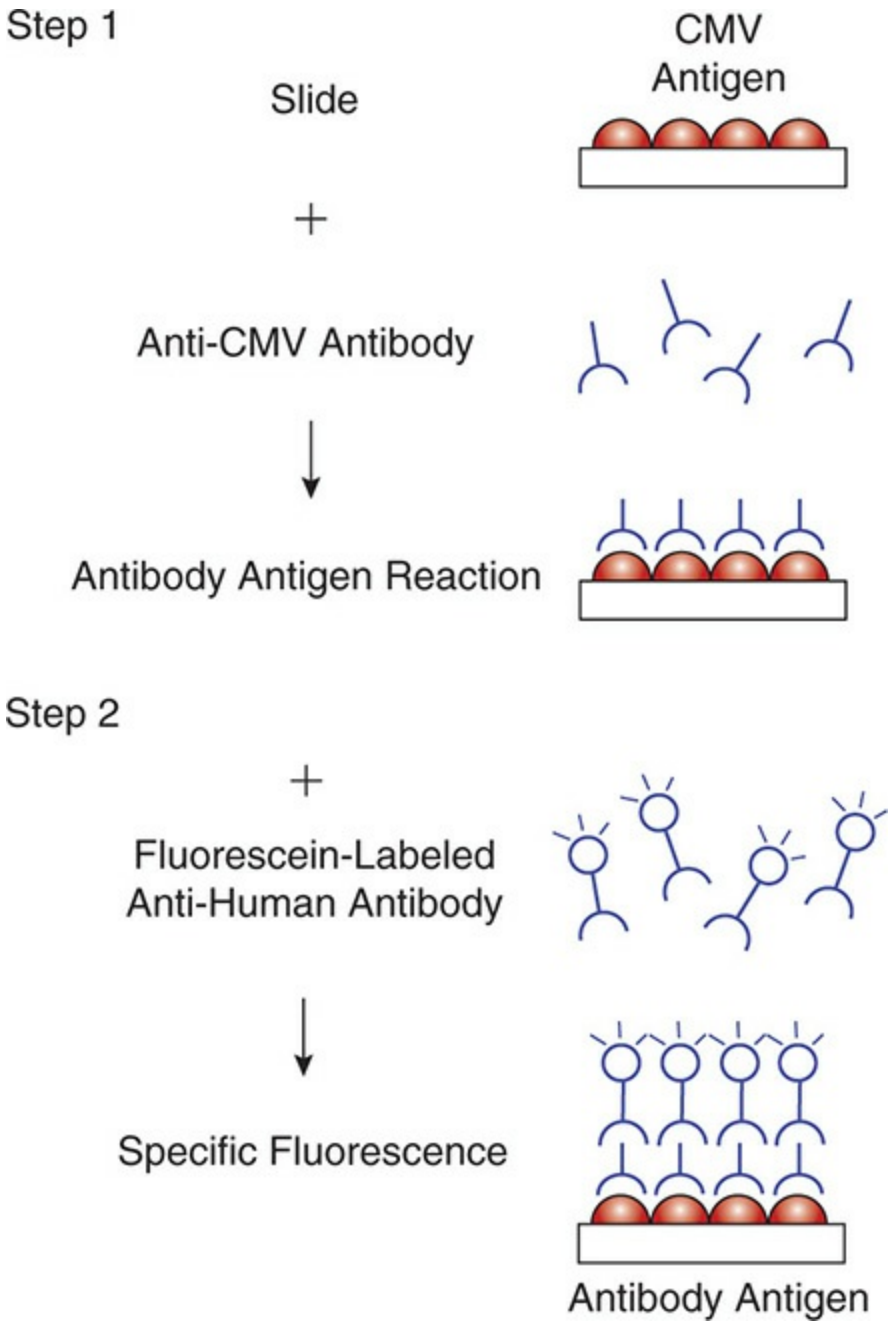
■ **FIGURE 3-10** Schematic diagram of an indirect immunofluorescence assay (IFA) for antigen detection. In this method, the specimen (e.g., sputum for *Legionella*) is reacted with an excess of unlabeled antibodies directed against the antigen. After a wash step, fluorescein-conjugated antibodies directed against the species of antibody used in the initial reaction (e.g., fluorescein-labeled antirabbit IgG raised in goats) are overlaid on the FA slide. After washing, the slide is examined for specific fluorescence. With *Legionella*, for example, unlabeled rabbit antibodies against a large number of serotypes can be used for the first step in the procedure, but only a single fluorescein-conjugated goat antirabbit Ig is required for the second step. If *Legionella* organisms were to be detected by a DFA method, separate fluorescein-labeled conjugates for each serotype would be required.

staining methods for *P. jiroveci*, (i.e., calcofluor white, GMS, Diff-Quik), but it appears to be less specific (i.e., more false-positives); some evaluations have suggested that positive immunofluorescent results be confirmed with another method to increase the specificity and positive predictive value of the DFA.[120,121,145,169] The Merifluor *Cryptosporidium/Giardia* DFA test (Meridian Diagnostics, Inc.) detects both organisms and is very sensitive and specific; in some studies, this DFA test outperformed other detection methods, including reference parsitologic methods and EIAs.[4,55,74,205] Some immunofluorescent reagents, particular for viruses such as HSV-1, HSV-2, and VZV, can be used for both direct detection of organisms in clinical specimens (e.g., cells scraped from the base of vesicular lesions, sputum, BAL) and for confirmation of isolates recovered in culture (e.g., respiratory viruses, HSVs, VZV).

Immunofluorescence Techniques for Antibody Detection

IFA assays can be used for detection of antibodies in much the same way as the CF or HAI tests. IFA test is often used for retrospective diagnosis of viral infections by looking for seroconversion or for a fourfold increase in antibody titer between acute and convalescent specimens. In the IFA procedure for viral antibodies, slides with virus-infected tissue culture cells fixed in discrete FA test slide wells are overlaid with serial dilutions of patient serum. After incubation and washing, a fluorescein-labeled goat or rabbit antibody directed against human Ig (conjugate) is added to each of the slide areas containing the viral antigens. After washing, the slides are inspected with a fluorescence microscope and an endpoint, that is, the highest dilution of serum producing positive immunofluorescence, is determined. Changes in titer may be determined by inspection of slides reacted with serial dilutions of acute- and convalescent-phase sera that are performed together in the same test. Indirect assays

can also be performed using enzyme-labeled conjugates (e.g., horseradish peroxidase) instead of fluorochrome-tagged reagents. Enzyme conjugate tests produce a colored precipitate that is read with a light microscope instead of a fluorescence microscope. Most laboratories that use IFA for serology will screen sera at a dilution of 1:8 or 1:10. If a positive reaction is obtained at this dilution, further twofold dilutions are prepared and each dilution is tested by IFA until an endpoint dilution is reached. The reciprocal of the highest serum dilution showing fluorescence is the titer of that specimen for the antibody in question. IFA can be used to document infections with bacterial agents that are difficult to culture in vitro, such as *B. henselae*, the major cause of cat scratch disease.[34,151,184,185,204] Figure 3-11 shows an IFA procedure for detection of antibodies to CMV.

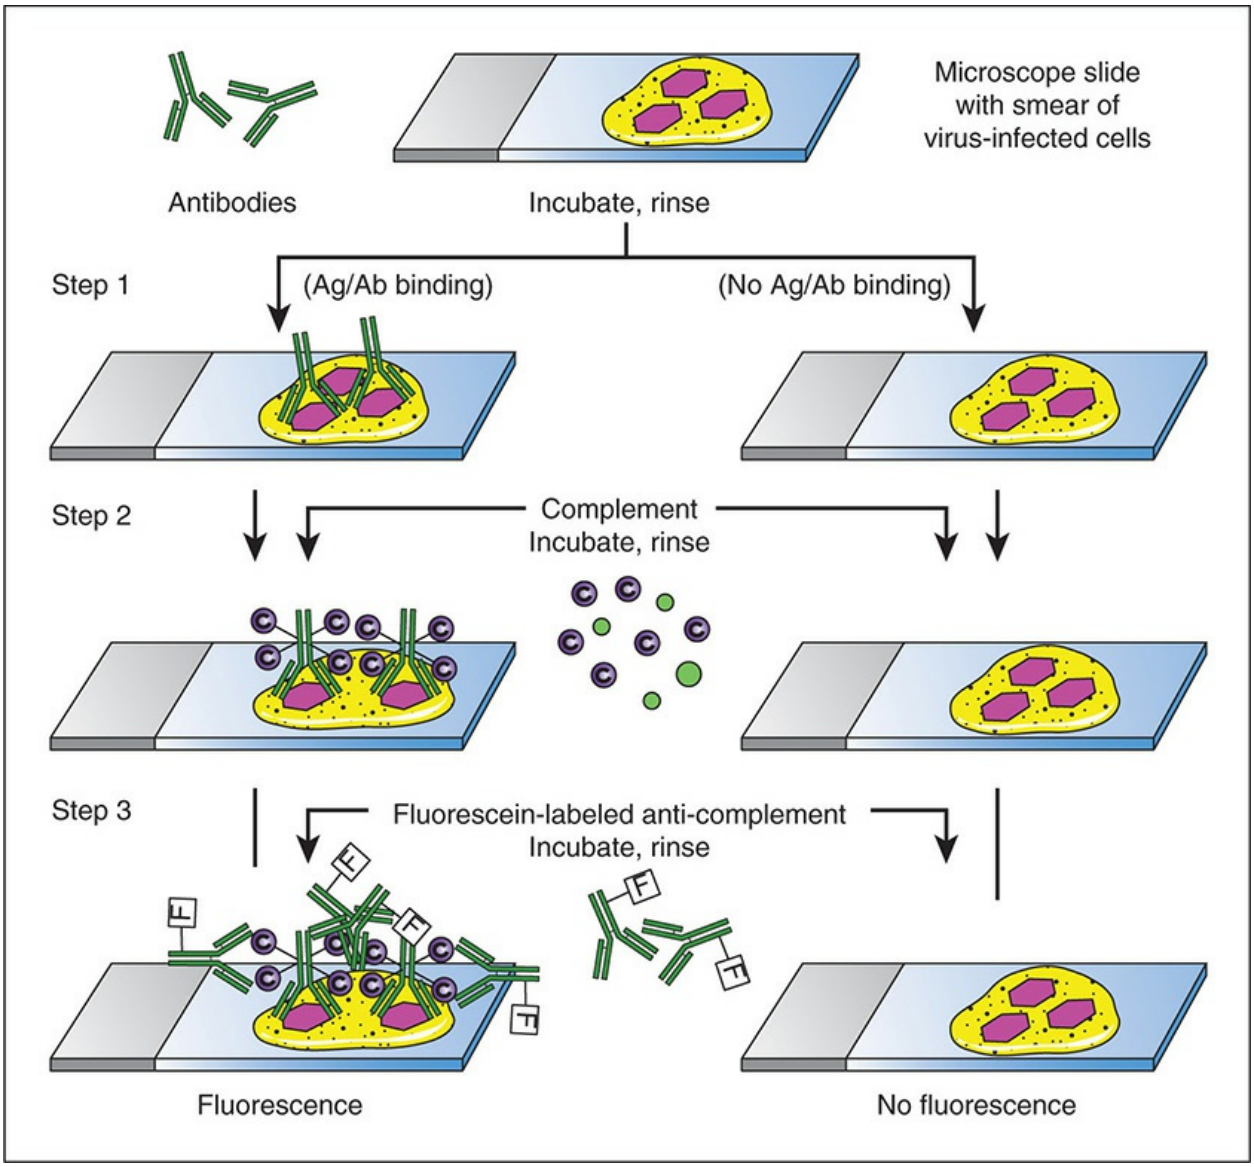


■ **FIGURE 3-11** IFA method for antibody detection. In this method, antigen (e.g., CMV-infected tissue culture cells) is fixed onto a FA slide and reacted with patient serum. If anti-CMV antibodies are present, they bind to the antigens on the slide. After a washing step, a fluorescein-conjugated goat antihuman antibody is overlaid on the slide. This results in labeling of the CMV-infected cells on the slide and indicates the presence of anti-CMV antibodies in the initial serum specimen. Titers can be determined by performing the assay with twofold dilutions of serum and reading for the highest serum dilution, resulting in a proscribed degree of fluorescence.

The diagnoses of certain viral infections such as Epstein–Barr virus (EBV) infection rely totally on serologic detection of antigens or antibodies because these agents do not grow in cell-culture lines used in routine clinical microbiology laboratories. EBV is a member of the family *Herpesviridae* and causes infectious mononucleosis. The specific immune response to EBV infection is characterized by the sequential appearance of certain antibodies, such as anti-VCA (viral capsid antigen) IgM and IgG, and antibodies against Epstein–Barr nuclear antigen (EBNA) and early antigen (EA) (see Chapter 23). Although anti-VCA IgM and then IgG appear during acute infection, anti-EBNA antibodies are absent during acute infection, appear during convalescence, and are maintained for life. Therefore, the presence of anti-EBNA in serum is indicative of past rather than current infection. Because EBNA is present in low levels in EBV-infected cells, the sensitive **anticomplement immunofluorescence (ACIF) test** is a reference method used for its detection (Fig. 3-12).[40,133] In ACIF, an EBV-infected lymphoblastic cell line is used as the source of antigen. Raji cells are usually used for this purpose because these cells express only EBNA antigens; VCA is not expressed and EA is rarely detectable in this cell line. These cells are fixed to a slide and reacted with patient serum. Specific anti-EBNA antibodies, if present, bind to the nuclear antigen. After a wash step, complement is overlaid on the cells. If specific anti-EBNA antibodies have reacted in the first step, complement binds to the immune complexes. After another wash step, fluorescein-conjugated anticomplement antibodies are overlaid on the cells. After incubation, the slide is again washed and then observed under a fluorescence microscope. The presence of

131

nuclear fluorescence indicates the presence of EBNA and indicates past infection with EBV. ACIF has also been used for determining immune status (e.g., presence of protective antibodies to VZV), detection of antibodies to CMV, and for demonstrating seroconversion following immunization with viral vaccines (e.g., varicella zoster vaccine).[11,51,81,144,150]



■ **FIGURE 3-12** Anticomplement immunofluorescence. In step 1, antibodies are exposed to virus-infected cells fixed on a microscope slide. In step 2, complement is added and binds to antigen–antibody (Ag/Ab) complexes formed in step 1. In step 3, fluorescein-labeled anticomplement is added and binds to complement that bound in step 2, and fluorescence is seen. If antibodies do not bind in step 1, complement cannot bind in step 2, fluorescein-labeled anticomplement cannot bind in step 3, and no fluorescence is seen. (Redrawn from Leland DS. Clinical Virology. Philadelphia, PA: Saunders, 1996.)

Another immunofluorescence assay called the **fluorescent antibody to membrane antigen (FAMA) test** is the test of choice for determining immune status for certain viruses such as VZV largely because of its exquisite sensitivity.[51,196] In this assay, patient serum is serially diluted in microtiter wells, and cultured cells infected with

VZV are added to the diluted serum. After incubation, the microtiter tray is centrifuged to force the cells to the bottom of the wells and washed twice, with intervening centrifugation steps. A working dilution of fluorescein-conjugated antihuman IgG is added to the wells and incubated. After a few wash/centrifugation steps, the cells are harvested, fixed to the wells of an FA slide, and examined with a fluorescence microscope. The FAMA test is more sensitive than CF or EIA, but it requires live, virus-infected cells for its performance.

Immunofluorescence and EIA approaches each have their own advantages and disadvantages. EIA methods for antigen detection are advantageous in high-volume laboratories where many samples are examined daily for a single determinant (e.g., rotavirus, RSV). Although DFA techniques are more labor intensive, the ability to directly observe the background cellular elements in certain direct antigen procedures to determine the adequacy of the specimen is a distinct advantage. For example, since *C. trachomatis* preferentially infects cervical columnar epithelial cells, the presence of squamous epithelial cells and/or segmented neutrophils, erythrocytes, and mucus indicates that the specimen is inadequate for diagnostic purposes. Adequate specimens show a preponderance of intact cuboidal and columnar epithelial cells. This assessment can be made with the direct FA test and incorporated into the laboratory report, allowing the physician to weigh clinical evidence of chlamydial infection along with the possibility that a negative report may actually reflect an inadequately collected endocervical specimen. These determinations cannot be made with nonvisual tests such as EIA and most molecular assays.

Mass Spectrometry
Conclusion

Introduction

Microbiologists have always searched for and continue to search for more rapid and efficient ways to detect and characterize microorganisms. The molecular techniques are some of the most powerful tools that may be used to this end. More recently, the widespread adoption of mass spectrometry has changed the way we practice clinical microbiology. These assays have revolutionized the microbiology laboratory and have changed the way we detect, characterize, and quantify microorganisms directly in clinical specimens and from cultures. Over the past 20 years, these techniques have progressed from once cumbersome, highly technical, labor-intensive assays to user-friendly tests that are so rapid that it is, in some instances, possible to achieve test results within an hour from the start of the assay, directly from the clinical specimen.

The molecular assays used by the early molecular microbiologist were often used for the detection of only fastidious or uncultivable microorganisms or to determine the cause of significant outbreaks. However, as these assays became easier to use and less expensive, they have been exploited for the detection and characterization of more common microorganisms.

Molecular microbiology may be separated into three categories. The first is the detection of microorganisms without the use of nucleic acid amplification. These applications rely on the amplification of a signal generated, usually light or a color, which is the result of the successful hybridization of a nucleic acid probe with the target nucleic acid molecule. Second, nucleic acid amplification methods are used for the detection, characterization, and, in some instances, quantitation of microorganisms. Finally, molecular methods have also been used extensively to determine the relatedness among microorganisms (i.e., strain typing), which are critical tools for the hospital and public health epidemiologist. These technologies, in one way or another, all use nucleic acid chemistry. Therefore, we will begin this chapter with a review of the basics of nucleic acids.

It would be impractical and beyond the scope of this book to review all the molecular assays that have been used in the assessment of microorganisms. Therefore, tests that

have proven most useful in the clinical laboratory, tests that are commercially

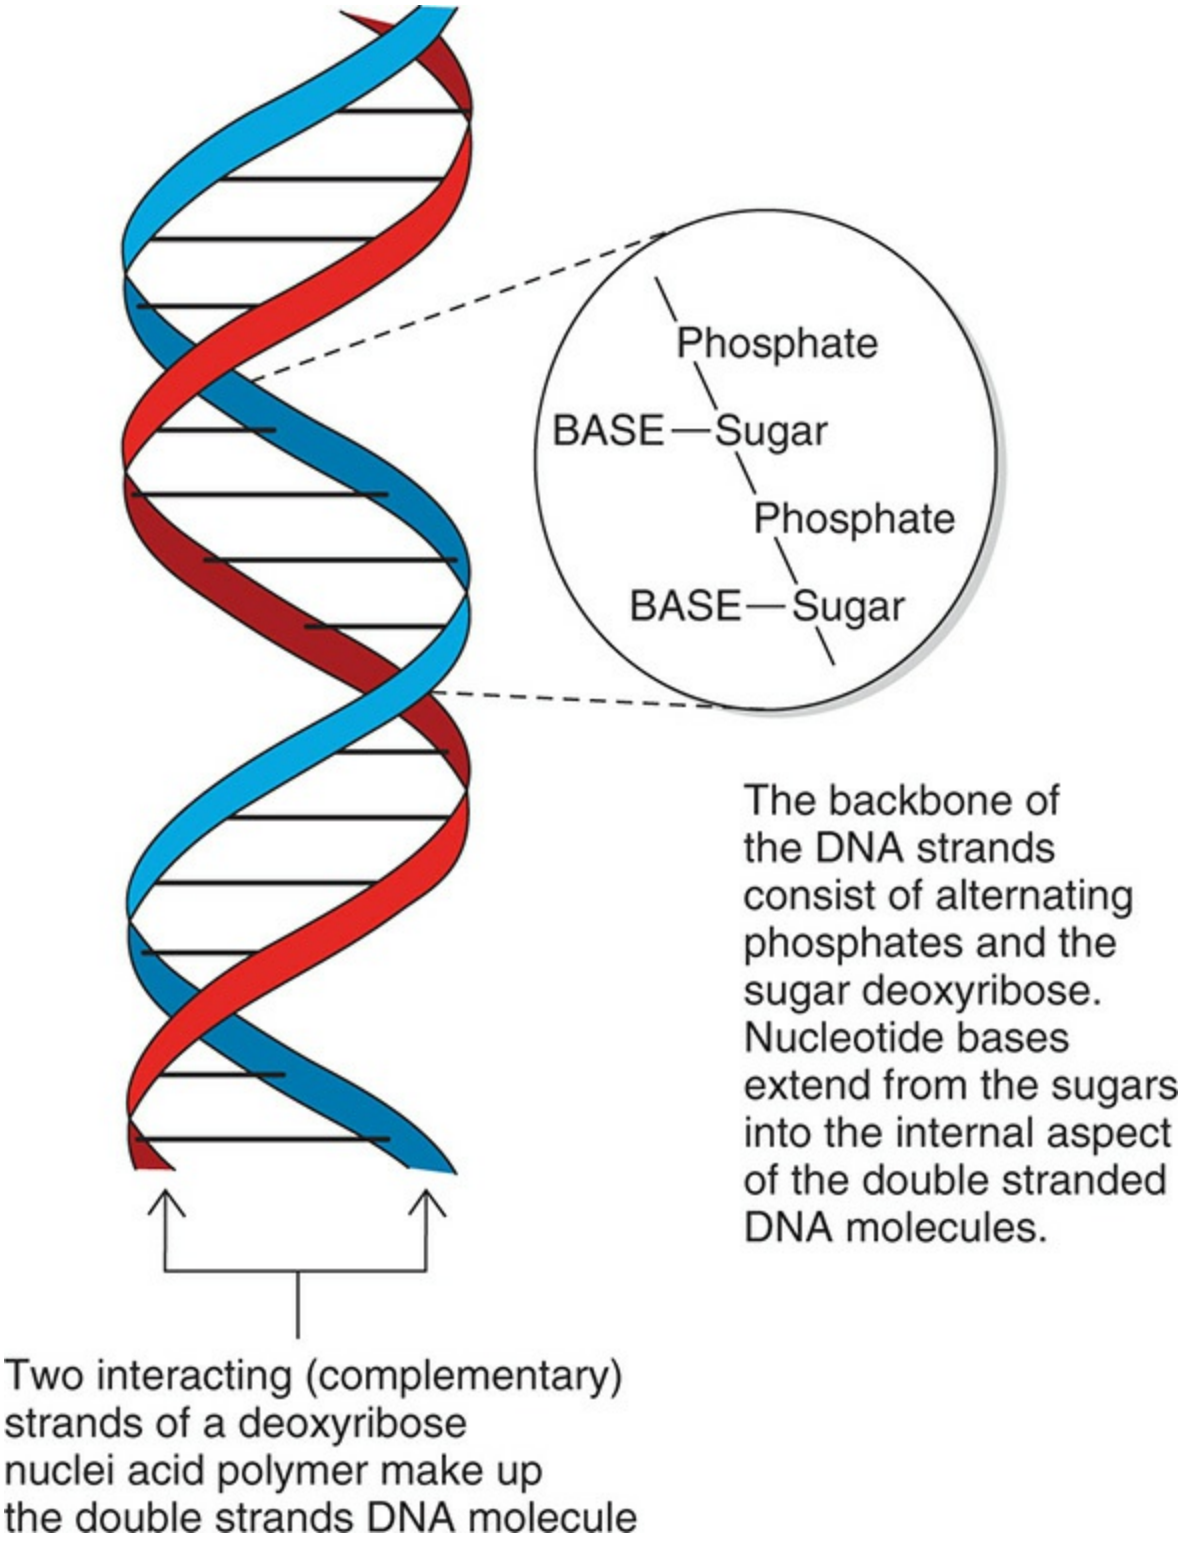
available, and some newer assays that hold particular promise are covered in greater detail. There are now many different types of nucleic acid amplification available. The *polymerase chain reaction* (PCR), which is the forerunner of the other types of nucleic acid amplification assays and may on occasion be used in a generic sense in this textbook, is a surrogate term for nucleic acid amplification. This is done for practicality and for the flow of the text, but the reader should know that the use of other types of nucleic acid amplification chemistries is also feasible.

Finally, since the last edition of this text, matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry has become commercially available and is becoming widely distributed. The basics of this technology and pertinent clinical applications are reviewed.

Nucleic Acids—The Basics of DNA and RNA

Structure of DNA

DNA is a long molecule composed of two strands. Each strand of DNA is a polymer, which means that each strand is composed of repeating similar subunits. The repeating subunits, or the building blocks, of DNA are nucleotide monophosphates. The two strands that compose the DNA molecule have direction determined by their organic chemistry, and they are oriented in directions opposite to one another. The two strands of an intact DNA molecule interact through hydrogen bonds and are termed *complementary*. The basic configuration of DNA is depicted in Figure 4-1.



■ **FIGURE 4-1** Structure of DNA. The structure of DNA has been described as a double helix. DNA is a double-stranded polymer that consists of nucleotides as the basic repetitive unit; nucleotides, in turn, consist of a sugar (deoxyribose), a phosphate, and one of four bases.

There are four kinds of nucleotide monophosphates that make up DNA; they are named according to the type of base they contain. Each nucleotide monophosphate contains a sugar (i.e., deoxyribose), a phosphate, and a nucleotide base (Fig. 4-2). The backbone of each of the two strands of the DNA molecule consists of alternating deoxyribose sugar and phosphate molecules, which are covalently bonded to one another. The nucleotide bases extend from the sugar molecule into the central aspect of the double-stranded DNA molecule. The positions and the orientation of nucleic acids are determined by convention according to the numbering of the carbon molecules of the sugar. The nucleotide base is attached to the sugar at the 1′ carbon position. The bridging phosphate molecules are attached at the 3′ and 5′ carbons, which gives the strand its particular orientation, the importance of which will become clear later in the text. The four nucleotide bases present in DNA are adenine (A) and guanine (G), both of which are purine molecules, and thymine (T) and cytosine (C), both of which are pyrimidine molecules. The purine adenine present on one strand of DNA forms two hydrogen bonds with the pyrimidine thymine on the opposite strand of DNA. These nucleotides are said to be complementary. Similarly, the guanine on one DNA strand forms three hydrogen bonds with the complementary cytosine on the opposite strand of DNA.

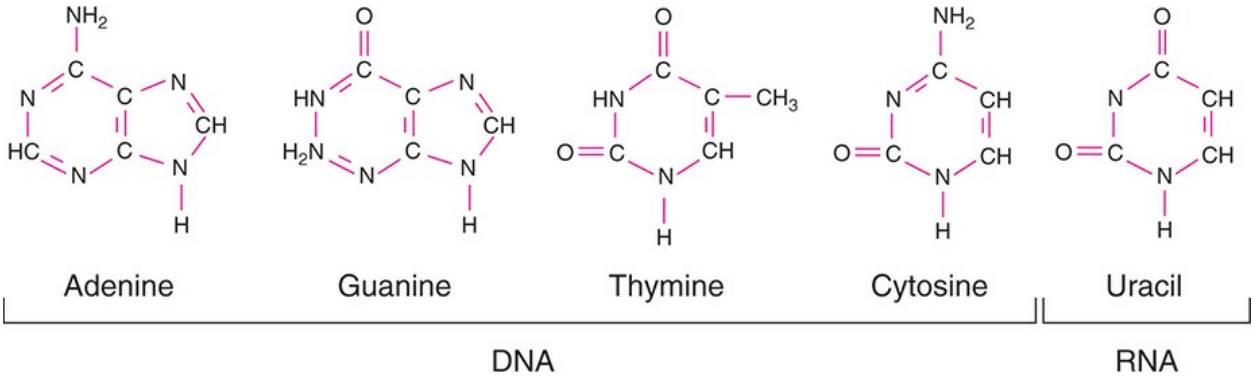
The structure of DNA is often depicted as a ladder, for simplicity, wherein the rungs of the ladder are the complementary bases of the two strands of DNA and the sides of the ladder are understood to represent the alternating sugar phosphate molecules (Fig. 4-3). In life, DNA does not exist, except perhaps temporarily, as a linear molecule. Rather, it is supercoiled; the entire length of the DNA molecule is often greater than the length of the cell that contains it. DNA, therefore, must be supercoiled so that its extensive length can be packed into very small spaces. The actual structure of DNA is the classic double helix described by James Watson and Francis Crick in 1953 (http://nobelprize.org/medicine/laureates/1962/). The two strands of DNA held together by hydrogen bonds, as previously described, exist as a left-handed, helical molecule with major and minor grooves. A knowledge of the basic structure of DNA and the replication of this molecule was pivotal in the development of what are now commonly used nucleic acid amplification-based tests.

Structure of RNA

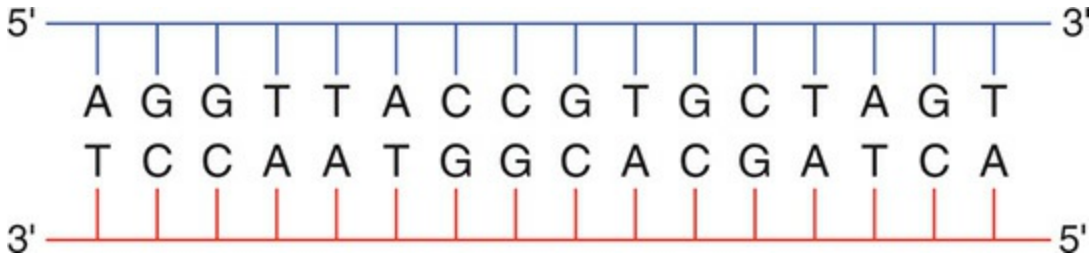
There are many types of RNA molecules in the cell, but we will confine this discussion to the most commonly described forms, which are messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA). The building blocks of RNA are similar to those of DNA. RNA is also a polymer, but it is single stranded. The backbone of this molecule also consists of alternative sugar and phosphate molecules, but for RNA the sugar is ribose. Like DNA, nucleotide bases are covalently bonded to the sugar molecule. In RNA, however, the nucleotide base thymine is replaced by the base

uracil.

139



■ **FIGURE 4-2** Nucleotide bases of DNA and RNA. The four nucleotide bases present in DNA are adenine (A) and guanine (G), both of which are purines, and thymine (T) and cytosine (C), both of which are pyrimidines. Uracil (U) is present in RNA in place of thymine.



■ **FIGURE 4-3** A simplified drawing of DNA. The complex structure of DNA is often simplified to that of a ladder-like structure, wherein the rungs of the ladder are depicted as the complementary nucleotide bases. This is often simplified even further, wherein only the one strand of DNA is depicted in a 5′ to 3′ direction and the presence of the complementary strand is understood.

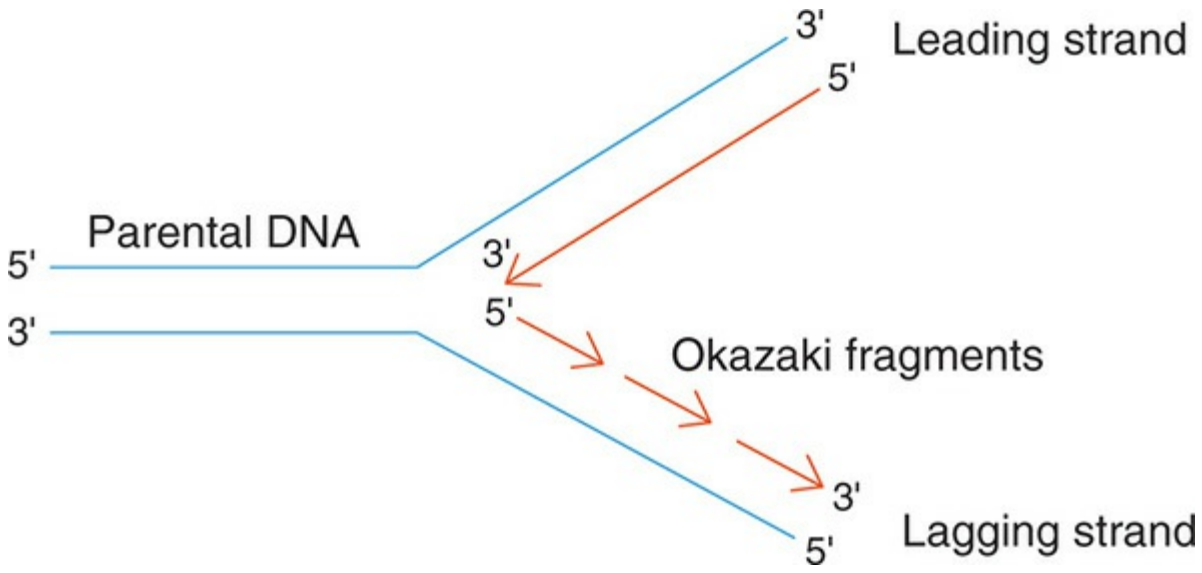
Although most RNA molecules are single stranded, they may fold back on themselves and form complementary hydrogen bonds, thereby creating a secondary structure.

Function of DNA—Information Storage

The genes that encode for the vast majority of the structural and functional proteins of the cell are contained in the chromosomal DNA of the cell. If the cell requires more protein for its cytoskeleton or if it needs more of an enzyme to metabolize a sugar, it

can make more by opening, reading, and using the message in the DNA (see the next section). The DNA has, therefore, been referred to as the blueprint of the cell, which is an apt analogy. When a cell divides, the new cell must also have a copy of the DNA blueprint in order to preserve its structure and perform its functions.

It is important to understand the basics of DNA replication, since many of these principles are used in the PCR and in some other methods of nucleic acid amplification. DNA replication begins with the relaxation of the supercoiled DNA molecule. Then, the more linearized portion of the double helix is at least partially separated into its two component strands. It is as if the rungs of the schematic DNA ladder were sawed down the middle and the two sides of the ladder pulled apart (Fig. 4-4). DNA helicase is an enzyme important in separating the two strands of DNA. One limitation in DNA synthesis, which is performed by DNA polymerase, is that it occurs only from the 5′ to 3′ direction. Therefore, only one strand of DNA can be made in a continuous manner in the 5′ to 3′ direction. This strand, because it is synthesized continuously and more rapidly than the opposing strand, is termed the *leading strand*. The lagging strand is replicated in sections, since the 5′ end becomes available for synthesis only after DNA helicase has performed its function. The discontinuous portions of DNA that are synthesized on the lagging strand are ligated or annealed one to another by DNA ligase, which makes that final lagging strand a continuous strand of DNA. The end result in the replication of DNA is the creation of two daughter strands of DNA from one parent DNA molecule (Fig. 4-5). Each of the new daughter molecules of DNA consists of one strand from the parent DNA molecule and one newly synthesized strand that is complementary to the parent strand. Each of the newly synthesized double-stranded DNA molecules is a perfect match of the parent DNA molecule, unless an error occurs in replication. DNA replication must precede cell division so that each new cell formed has a full complement of DNA.



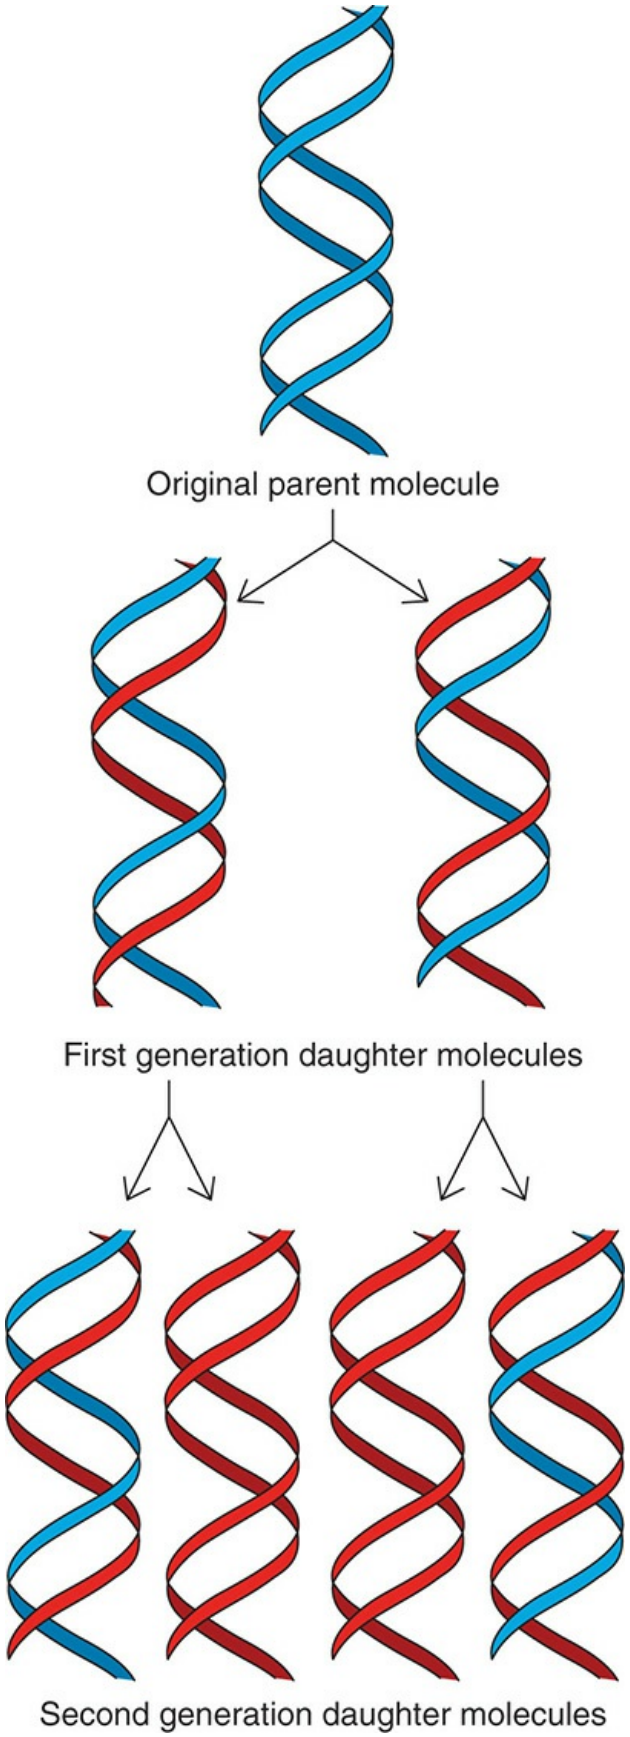
■ **FIGURE 4-4** DNA replication. DNA replication occurs in a 5′ to 3′ direction. Therefore, one strand, the leading strand, is continuously synthesized, whereas the opposite strand is segmentally synthesized in Okazaki fragments.

Of practical interest, each of the enzymes described above has been utilized in current or former methods of nucleic acid amplification. Helicase has been used for helicase-dependent amplification (HDA), DNA polymerase for the PCR, and ligase for the ligase chain reaction (LCR).

Function of RNA—Information Transfer

Reading (Transcription) and Interpretation (Translation) of the Genetic Code. The nucleic acids and proteins of the cell interact in the formation of new proteins, which form the structure and perform the functions of the cell. The first step in protein synthesis is the "rewriting," or transcription, of the genetic message so that it can be transported to the ribosome. The message, which is encoded by the DNA, is transcribed in the form of an RNA molecule, which is aptly termed *messenger RNA*. This occurs in a manner similar to DNA synthesis, but uses a different set of enzymes. Briefly, the DNA strand is unwound and a single-stranded RNA molecule is created that is complementary to the gene being transcribed. This may or may not undergo additional processing (transcriptional processing). The message is then read, or the genetic code is translated by the cellular machinery. This involves other types of RNA molecules, such as tRNA, rRNA, and a variety of proteins.

140



Original parent molecule
First generation daughter molecules
Second generation daughter molecules

■ **FIGURE 4-5** Products of DNA replication. Each of the first-generation daughter molecules of DNA contains one strand from the parent molecule and one newly synthesized strand. Two of the daughter molecules of the second generation of DNA replication contain one of the original parent strands and two consist of entirely newly synthesized DNA.

The translation of the message into a protein occurs on a complicated superstructure composed of proteins and rRNA termed the *ribosome*. The mRNA becomes associated with the ribosome and is processed three bases at a time. These three-base-pair segments are called **codons**, and they encode for particular amino acids. The codons on the mRNA are complementary to anticodons on a portion of the tRNA. Particular tRNAs transport or transfer particular amino acids to the ribosome, the site of protein synthesis. The amino acid molecules are situated so that peptide bonds may be enzymatically formed between them. Eventually, a chain of amino acids is formed (i.e., a peptide), which through continued extension, secondary structure folding, and posttranslational modifications becomes a protein (Fig. 4-6). The reader who is interested in obtaining a more thorough understanding of these processes is directed to textbooks of biochemistry and molecular biology.[5,345]

Signal Amplification Methods

The signal amplification methods described combine some type of nucleic acid, usually a probe, with a generation of a signal. The signal is often amplified through an enzymatic reaction. The signal from fluorescence in situ hybridization (FISH), however, may be directly observed, following the hybridization of the fluorescently labeled probe to its complementary nucleic acid target. A variety of chemical and enzymatic modifications may be applied to FISH or chromogenic in situ hybridization (CISH), if further amplification of the signal is necessary, but are beyond the scope of this book. We will discuss four types of signal amplification in this section: nucleic acid probes, Hybrid Capture (HC), branched-chain DNA, and in situ hybridization (ISH).

Signal amplification is usually considered to be less sensitive than nucleic acid amplification methods. One exception may be FISH, wherein a single copy of a target molecule may be identified in a large population of other cells. This application of FISH is more useful in anatomic pathology specimens or research, wherein a minor subpopulation of cells may be of clinical importance. Signal amplification technologies have several advantages over nucleic acid amplification methods. These procedures are far less likely to produce false-positive results secondary to contamination compared with traditional nucleic acid amplification assays. However, signal contamination or the bleed over of a strong signal from one reaction chamber into an

adjacent well has been reported.

Nucleic Acid Probes

Nucleic acid probes were the first molecular assays to become commonplace in many laboratories. The probes, termed *AccuProbes*, are commercially available for the detection of numerous microorganisms (Hologics, San Diego, CA). These are DNA probes that contain a chemiluminescent label and target the rRNA of the microorganism of interest, which is a useful target since the rRNA is present in greater quantities than the rDNA genes that encode for it. This is an example of biologic amplification, or the amplification of a nucleic acid that occurs during the normal course of cellular events or secondary to microorganism growth. This proprietary chemistry allows for the differentiation of the hybridized from the nonhybridized probe. When the stable DNA–RNA hybrid is treated with the detection reagents provided, light is produced secondary to a chemical reaction. The presence of a certain amount of light that exceeds a predetermined threshold value is considered a positive reaction and indicates the presence of the microorganism to which the probe was designed to hybridize.

Clinical Applications. AccuProbe genetic probes are available for the direct detection of bacteria in clinical specimens or as a rapid and specific method of identifying microorganisms in culture. When used on direct specimens, these probes are less sensitive than enhanced culture for Group A *Streptococcus* and is distinctly less sensitive than PCR.[41] Former products utilizing this technology for *Neisseria gonorrhoeae*

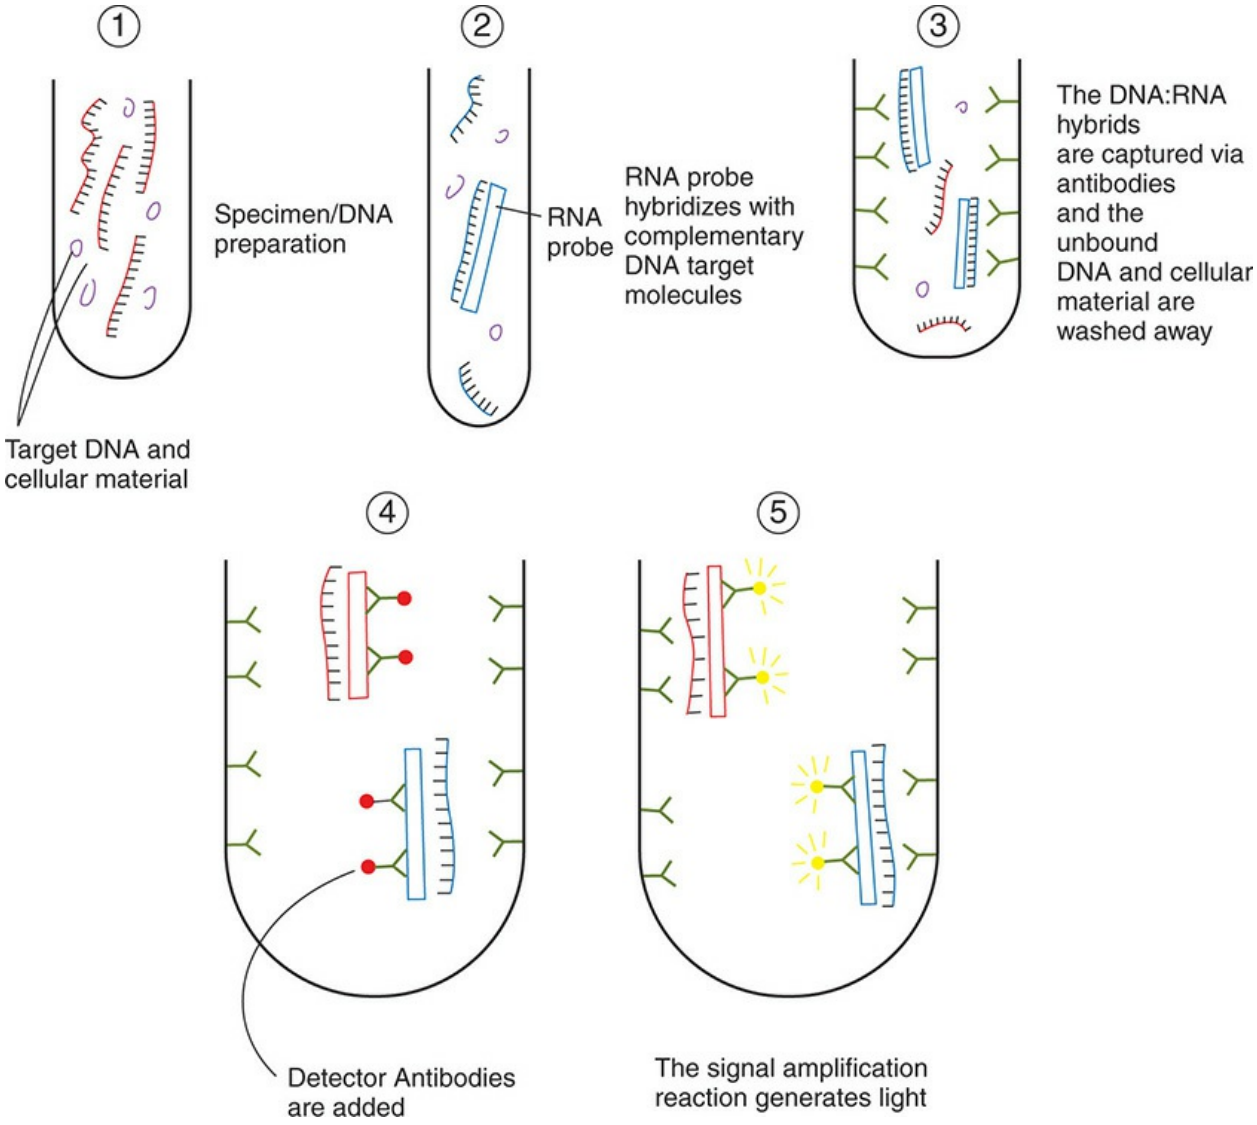
and *Chlamydia trachomatis* represented a significant advance in sensitivity compared with culture for these fastidious pathogens, but have subsequently been replaced by nucleic acid amplification methods.[41,48,119,202]

Today, genetic probes remain a useful option for the rapid identification of a variety of microorganisms in culture, many of which would otherwise require complicated and time-consuming tests for identification. The most useful of these are assays for the identification of mycobacteria and the dimorphic fungi. Genetic probes are commercially available for the *Mycobacterium tuberculosis* complex, *M. kansasii*, *M. gordonae*, and the *M. avium/M. intracellulare* complex.[75,115,243] Genetic probes are also available for *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides* spp.[131,156] The use of these probes for the characterization of cultures that contain mycobacteria or fungi suspected to be dimorphic fungi significantly diminishes the time to identification for the clinical laboratory when compared with routine, traditional methods. Although more expensive, these have overall cost savings, when cost of both materials and labor is considered.

A variety of AccuProbes are also available for the identification of certain bacteria in culture. These include assays for *Campylobacter*, group A and group B *Streptococcus*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Listeria monocytogenes*, and *N. gonorrhoeae*.[63] These assays, when performed from cultures, have sensitivities and specificities in the high 90s to 100%. The advantage of using these assays is time savings. The disadvantage is higher cost.

Hybrid Capture

Hybrid Capture (Qiagen, Gaithersburg, MD) is a signal amplification technology that consists of the retention (capture) of a DNA–RNA molecular complex (a hybrid) in a microtiter plate (Fig. 4-7). Initially, the specimen is processed to prepare the



■ **FIGURE 4-7** HC technology. HC technology is a signal amplification assay. It has become a popular way to detect high-risk HPV subtypes.

DNA. The RNA probes used are complementary to the DNA molecule from the microorganism of interest. The detection of a DNA–RNA hybrid complex is useful, since this complex exists only transiently in nature, primarily during transcription. If the complex is not present, the specimen is considered negative. The DNA–RNA hybrid, if present, is introduced into a tube or the well of a microtiter plate, the walls of which have been coated with a monoclonal antibody that recognizes a DNA–RNA hybrid. This antibody captures and immobilizes the complex and allows the other constituents of the processed clinical specimen to be washed away. Next, another antibody is added and that also recognizes the DNA–RNA complex, but this antibody is labeled with a reporter molecule and able to generate a signal in the form of light.

Light above a certain threshold is considered a positive reaction.

Clinical Applications. There are HC assays commercially available for the detection of high-risk human papillomavirus (HPV) subtypes, a subtyping product to determine if HPV types 16 or 18 are present, *N. gonorrhoeae* and *C. trachomatis.* In the past, an assay for cytomegalovirus (CMV) was an option, but this has been discontinued with the migration of users to quantitative PCR for CMV. The high-risk HPV assay has become standard of care in monitoring women for the cervical dysplasia and carcinoma. A meta-analysis showed that the HCII assay had a greater sensitivity and equivalent specificity compared with a repeat Pap smear for the detection of women with cervical intraepithelial neoplasia type 2 (CIN 2) lesions or higher, when the initial Pap smear was interpreted as atypical squamous cells of undetermined significance (ASCUS).[9] In addition, it has been added to the recommendations of the American College of Obstetricians and Gynecologists as an adjunct to cytologic screening for women 30 to 65 years old; updated guidelines can be found at http://www.uspreventiveservicestaskforce.org.[2,8] The strength of this assay is its high sensitivity and its high negative predictive value.[154] It has been found by some to even be comparable to PCR; however, others have found it slightly less sensitive than nucleic acid amplification-based methods.[30,49] Although this is a highly useful assay, both the sensitivity and the specificity have been questioned.[68,283] de Cremoux et al. showed that some of the false-positive reactions with this assay were due to probe cross-reactivity with low-risk HPV subtypes, while others were likely due to "signal contamination" or bleed over of the fluorescent signal from strongly positive wells into an adjacent wells

that contained negative specimens.[68] Although this technology is time tested, more recently released nucleic acid amplification-based assays are available, which are more automated and have excellent sensitivity and specificity.

The HC has also been used successfully for the detection of *N. gonorrhoeae* and *C. trachomatis.*[64,65,236,316,362] This assay has been reported to be more sensitive than culture, which is not surprising given the fastidious nature of these pathogens, and more sensitive than genetic probe analysis.[65] It has also been used to detect CMV and hepatitis B virus (HBV).[257,361,379] When CMV HC was compared with PCR, the HC technology was 1.5 to 2.0 log less sensitive than PCR; the specificities of PCR and HC in this comparison were 100% and 93.8%, respectively.[34] These uses of HC have essentially been replaced by more sensitive nucleic acid amplification assays.

Branched DNA

Branched-DNA (bDNA) technology is or has been used for the detection and quantitation of pathogens such as HIV, HBV, and hepatitis C virus (HCV). This technology consists of a variety of bDNA probes and signal amplification reporter molecules. In brief, the organism-specific bDNA oligonucleotide probes hybridize to the target nucleic acid molecule, and this complex is captured onto a solid substrate. bDNA oligonucleotide reporter molecules, which are conjugated to reporter enzymes, are added. These, in turn, generate a chemiluminescent signal after the addition of the appropriate substrate. The amount of signal, as with the HC assay, is proportional to the amount of target nucleic acid, which means quantitative results can be generated when this assay is performed with quantitative standards.[312,360]

Clinical Applications. Although a very useful and highly reproducible technology, a large number of clinical assays that use this technology have not been developed. This technology has been used most successfully for the detection and quantification of the HIV, HBV, and HCV.[45,84,265,387] It has been used to monitor the viral loads of patients infected with HIV. The VERSANT HIV-1 RNA 3.0 (Siemens, Malvern, PA) has been found to be a highly reproducible assay with wide linear range (75 to 500 copies of HIV-1 RNA) that is useful for quantitative HIV-1 viral load measurements, even when compared with reverse transcriptase (RT)-PCR.[83,113] Similarly, multicenter evaluations of the VERSANT hepatitis B DNA 3.0 assay and the VERSANT HCV RNA 3.0 assay found that these assays and this technology were reproducible, had a wide dynamic range, and demonstrated results comparable with other commonly used assays.[82,265,387] Although the sensitivity of the bDNA assays may be slightly less than that for PCR, there is overall a good correlation between viral loads generated by these different assays.[62,240] Although useful, the applications of this technology too are being steadily replaced by nucleic acid amplification methods.

In Situ Hybridization

In situ hybridization has been used in the molecular pathology for many years to detect chromosomal translocations (i.e., t9;22) and gene amplifications (i.e., Her2) and to identify infectious agents.[224] These once complex methods are becoming easier to use, and semiautomated platforms are available. ISH may be separated into FISH, wherein the oligonucleotide probe is labeled with a fluorophore that is detected by direct fluorescence microscopy, and CISH, wherein the oligonucleotide probe is labeled in such a way that an enzymatic reaction generates a color that can be viewed using traditional light microscopy. Several studies have demonstrated the feasibility and potential advantages of in situ assays in the clinical microbiology laboratory.[152,164,177,249,250,296]

Some of the first ISH assays used were for the detection of viruses through direct hybridization of an oligonucleotide probe and the viral nucleic acids. These have been used to identify the particular virus associated with a certain cytopathic effect (i.e., CMV as a cause of a Cowdry type A intranuclear inclusion), as well as to differentiate viruses that produce identical cytopathic effects (i.e., herpes simplex virus [HSV] and varicella zoster virus).[28] This technology may also be used to differentiate the high-risk and low-risk HPV subtypes, which is important in the assessment of squamous cell carcinomas of the head and neck.[334]

ISH has also proven useful as a technology that allows for the demonstration of the certain viruses with neoplasia, such as HPV with dysplasia/squamous cell carcinoma of the uterine cervix, Epstein–Barr virus (EBV) with posttransplantation lymphoproliferative disorders and Burkitt's lymphoma, and human herpesvirus 8 (HHV-8) with Kaposi's sarcoma.[39,203,334,367,] The direct visualization of the virally infected cells in the focus of pathology helps support the etiologic role of the detected organism with the disease. Although the detection of viruses using ISH has proven useful in the molecular pathology laboratory, these are often replaced by immunohistochemical methods; it is uncommon to find these technologies used in clinical virology laboratories.

ISH may also be used for the detection of bacteria, mycobacteria, fungi, and parasites. When ISH is used to detect these organisms, the microbial rRNA may be used as the target for the hybridization probe. This is advantageous over a DNA target for two reasons. First, there are many more copies of rRNA in the cell than there are copies of the genes that encode for the ribosomes (rDNA), which increases the sensitivity of the assay. Second, the presence of rRNA helps denote the presence of a viable organism, wherein the detection of DNA, particularly by methods such as PCR, may occur even after the organism is nonviable (i.e., killed by antimicrobial therapy).

Prior to the introduction of FISH into the clinical microbiology laboratory, these technologies have been used by environmental microbiologists to identify and enumerate *Legionella*, *Escherichia coli*, and other bacteria in water samples and biofilms.[215,216,274] Veterinary microbiologists have also used these techniques to study a variety of diseases.[192,207] The molecular pathologist has used the ISH to study *Helicobacter pylori* in gastric biopsies, *Chlamydia* in a variety of disease states, and *Legionella pneumophila* in fixed respiratory specimens.[16,18,23,109,127,165]

The ability to rapidly characterize mycobacteria as tuberculosis or nontuberculous mycobacteria has been the goal of many assays. The mycobacteria are excellent candidates for identification by molecular methods, since some of these cause severe disease and are slow-growing in culture (i.e.,

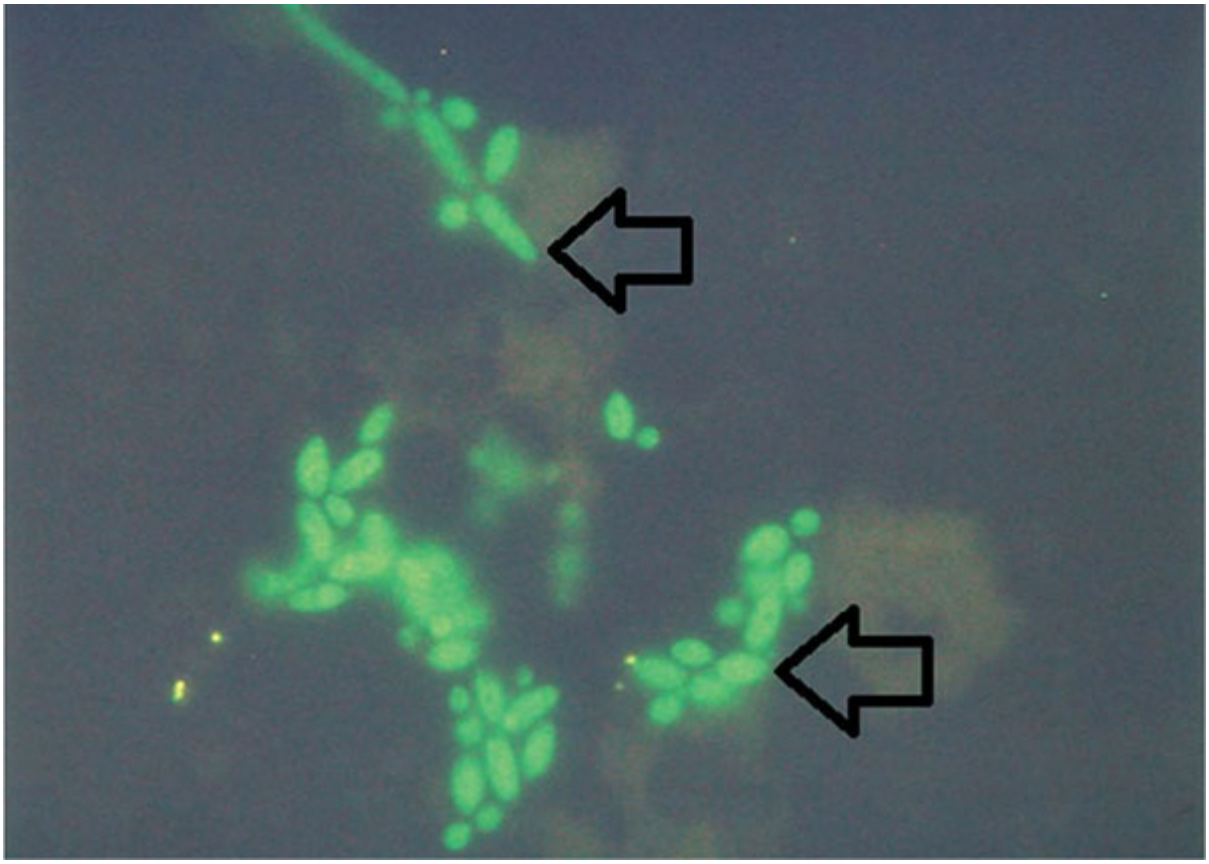
M. tuberculosis), and some are fastidious (i.e., *M. genavense* and *M. haemophilum*) or cannot be cultivated on artificial media (i.e., *M. leprae*). FISH using peptide nucleic acid (PNA) probes has been used successfully for the rapid identification of *M. tuberculosis* in smears from mycobacterial cultures and directly in respiratory samples that contained acid-fast bacilli.[254,342,343] Traditional in situ applications have also been used in histologic sections to definitely identify *M. leprae*.[10]

Fungi and parasites have also been characterized by ISH. ISH assays have been described for the identification of *Aspergillus* species, which is important given the increasing importance of non- *Aspergillus* hyaline septate molds, such as *Fusarium* and *Pseudallescheria*, that are pathogenic to humans and have antifungal susceptibility profiles that are different from most *Aspergillus* species.[138,258,393] These methods are especially important when the excised material was not submitted for culture or if the mold fails to grow in culture. CISH, using a tyramide signal amplification method, has also been applied to the difficult histologic differential diagnosis of morphologically similar yeast and yeast-like forms in human tissues.[145] These methods were less sensitive than the methenamine silver stain for the detection of some of the fungi, but they demonstrated 100% specificity with species-specific identification.[145] Another fungus that has been studied using ISH is *Pneumocystis jiroveci*.[144] The use of ISH for the detection of this fungus may hold some advantages, since both the trophozoite and cyst forms may be detected, rather than only the cyst form, which is the case with some histochemical stains, such as Gomori's methenamine silver (GMS) stain.

Clinical Applications. The use of ISH in clinical microbiology has predominantly focused on the rapid identification of microorganisms in positive blood cultures. Jansen et al.[164] and Kempf et al.[177] simultaneously published articles investigating the use of ISH for the rapid identification of organisms present in positive blood culture bottles. A variety of probes were used, all of which were directed against specific target sequences present in bacterial rRNA. Some probes were genus- and family-inclusive probes (i.e., all staphylococci or all *Enterobacteriaceae*, respectively), whereas others were specific for particular species (i.e., *S. aureus* or *E. coli*). The majority of these probes were highly accurate for the identification of the bacteria responsible for the positive blood cultures. One attractive feature of these assays was that the selection of the ISH probes to be used could be directed based on the findings of the Gram's stain. Another attractive feature was the time to detection, which may be as little as 2 to 3 hours. Kempf et al. compared the time to identification for ISH with traditional methods for 115 positive blood cultures they examined. They found an approximate time savings of 26 hours for the identification of staphylococci (62 of 62 identified by ISH), 46 hours for streptococci (19 of 20 identified by ISH), and 40 hours for gram-negative bacilli (28 of 30 identified by ISH).[177] Overall, they concluded that with a

limited number of ISH probes, the cause of 96.5% of positive blood cultures could be identified within 2.5 hours, whereas conventional culture took between 1 and 3 days.[177]

ISH has also been used for the direct detection of pathogenic bacteria directly in clinical specimens. Hogardt et al. used ISH to detect and identify the bacteria likely to be present in the respiratory specimens of patients with cystic fibrosis.[152] They tested for *Pseudomonas aeruginosa*, *Burkholderia cepacia*, *Stenotrophomonas maltophilia*, *H. influenzae*, and *S. aureus* using ISH. The ISH assays performed directly on the clinical specimen demonstrated 90% sensitivity and 100% specificity compared with culture, even in the complicated milieu of respiratory specimens from patients with cystic fibrosis.[152] It is conceivable that a battery of ISH probes may be useful for the detection of pathogens that are commonly associated with particular diseases, such as bacterial meningitis and community-acquired pneumonia.



■ **FIGURE 4-8** *Candida albicans* PNA FISH. The yeast and pseudohyphae *(arrows)* fluoresce apple green and are easily detected against the red background using the *Candida albicans* PNA FISH (AdvanDx).

Another method of ISH, which uses a PNA probe rather than a DNA probe, has been developed and is commercially available. PNA probes have properties that may be advantageous over DNA probes with regard to penetration, when hybridization is performed on intact organisms, and for greater differentiation, particularly of single nucleotide polymorphisms (SNPs).[341] AdvanDx (Woburn, MA) is a supplier of PNA ISH kits for the rapid detection of *S. aureus* or coagulase-negative staphylococci, *E. faecium* and other *Enterococcus* species, and a number of gram-negative bacilli. Several studies have examined these assays and found them to be useful for identifying and differentiating morphologically similar bacteria in positive blood cultures.[42,249,250]

ISH has also been shown to be useful for the rapid identification and differentiation of clinically important yeast in positive blood cultures. Kempf et al. differentiated *Candida albicans*, *C. glabrata*, *C. krusei*, and *C. parapsilosis* using four ISH probes.[177]Similarly, the *C. albicans* PNA FISH assay (AdvanDx) has been shown to differentiate *C. albicans* from non- *C. albicans* yeast in positive blood cultures[251,296] (Fig. 4-8). The original *C. albicans* only assay has been changed to a two-color assay, using a green fluorophore for *C. albicans* and a red fluorophore for *C. glabrata.* Interestingly, this company subsequently created what could be viewed as a fungal pharmacogenomics assay. It is a three-color probe set marketed as a "traffic light." Green fluorophores are used for *C. albicans* and *C. parapsilosis,* indicating that it is acceptable to "go" ahead and use fluconazole. A yellow fluorophore

is used for *C. tropicalis.* Red fluorophore-labeled probes are used to hybridize with *C. glabrata* and *C. krusei*. The red color is to provide a warning concerning the use of fluconazole, since the susceptibility of *C. glabrata* to this drug is not predictable and many isolates are resistant, and *C. krusei* is innately resistant.[355]

Traditional and PNA ISH has also been used for the rapid differentiation of mycobacteria. The mycobacteria are obvious targets for differentiation by molecular methods, since members of this group cause severe disease (i.e., *M. tuberculosis*), many are slow-growing, and one at least, *M. leprae*, has not been cultivated on artificial media. ISH has been used to differentiate *M. tuberculosis* from nontuberculous mycobacteria in cultures that become positive, as well as directly from positive acid-fast smears and in histologic sections.[343,392] The confirmation of *M. leprae* in histologic sections has also been achieved with ISH.[10]

There has been limited use of ISH when studying parasites and parasitic diseases, but some uses have been described.[162,261,358,394] There has been even less use in the clinical parasitology laboratory. ISH has been used to detect the most common

microsporidia, *Enterocytozoon bieneusi*, which causes gastroenteritis in patients with AIDS.[368] PNA FISH has been used to detect circulating trypanosomes of patients with African sleeping sickness.[285]

ISH is a molecular diagnostic tool that has been integrated into many clinical microbiology laboratories. The rapid time to detection and the ability to selectively choose probes to be used based on the findings of the Gram's stain or the characteristics of the patient population under consideration makes this technology attractive as a diagnostic tool. However, there are new technologies (see Microarrays) that may replace the FISH tests that are commonly used in clinical microbiology.

Nucleic Acid Amplification

Basics of the PCR

The PCR, first described by Kary Mullis in 1983, exploits the basic biochemistry of DNA replication, with the end goal of amplification of a particular portion of DNA.[241,242] The portion of DNA that is amplified usually contains diagnostically or therapeutically useful information. The PCR reaction mixture consists of the target DNA for amplification and the master mix. The master mix, in turn, consists of oligonucleotide DNA primers, the four nucleotide triphosphates, thermostable DNA polymerase, magnesium chloride, and water or buffers. The traditional PCR consists of three phases, which are repetitive, which is the basis for the "chain reaction" portion of the name. These three phases are (1) DNA denaturation—or the separation of the two strands of DNA, (2) primer annealing, and (3) primer extension—the portion of the reaction wherein DNA synthesis occurs.

Denaturation of the template DNA molecule or separation of the two individual strands that compose the parent double-stranded DNA molecule is the first step of PCR. This is accomplished by elevating the temperature of the reaction mixture to approximately 95°C. At this temperature, the double-stranded DNA is physically separated into single strands. This occurs because the elevated thermal energy breaks the hydrogen bonds that hold the two strands of DNA together at lower temperatures. Thermal denaturation of DNA is favored over chemical denaturation, since it is readily reversible by cooling.

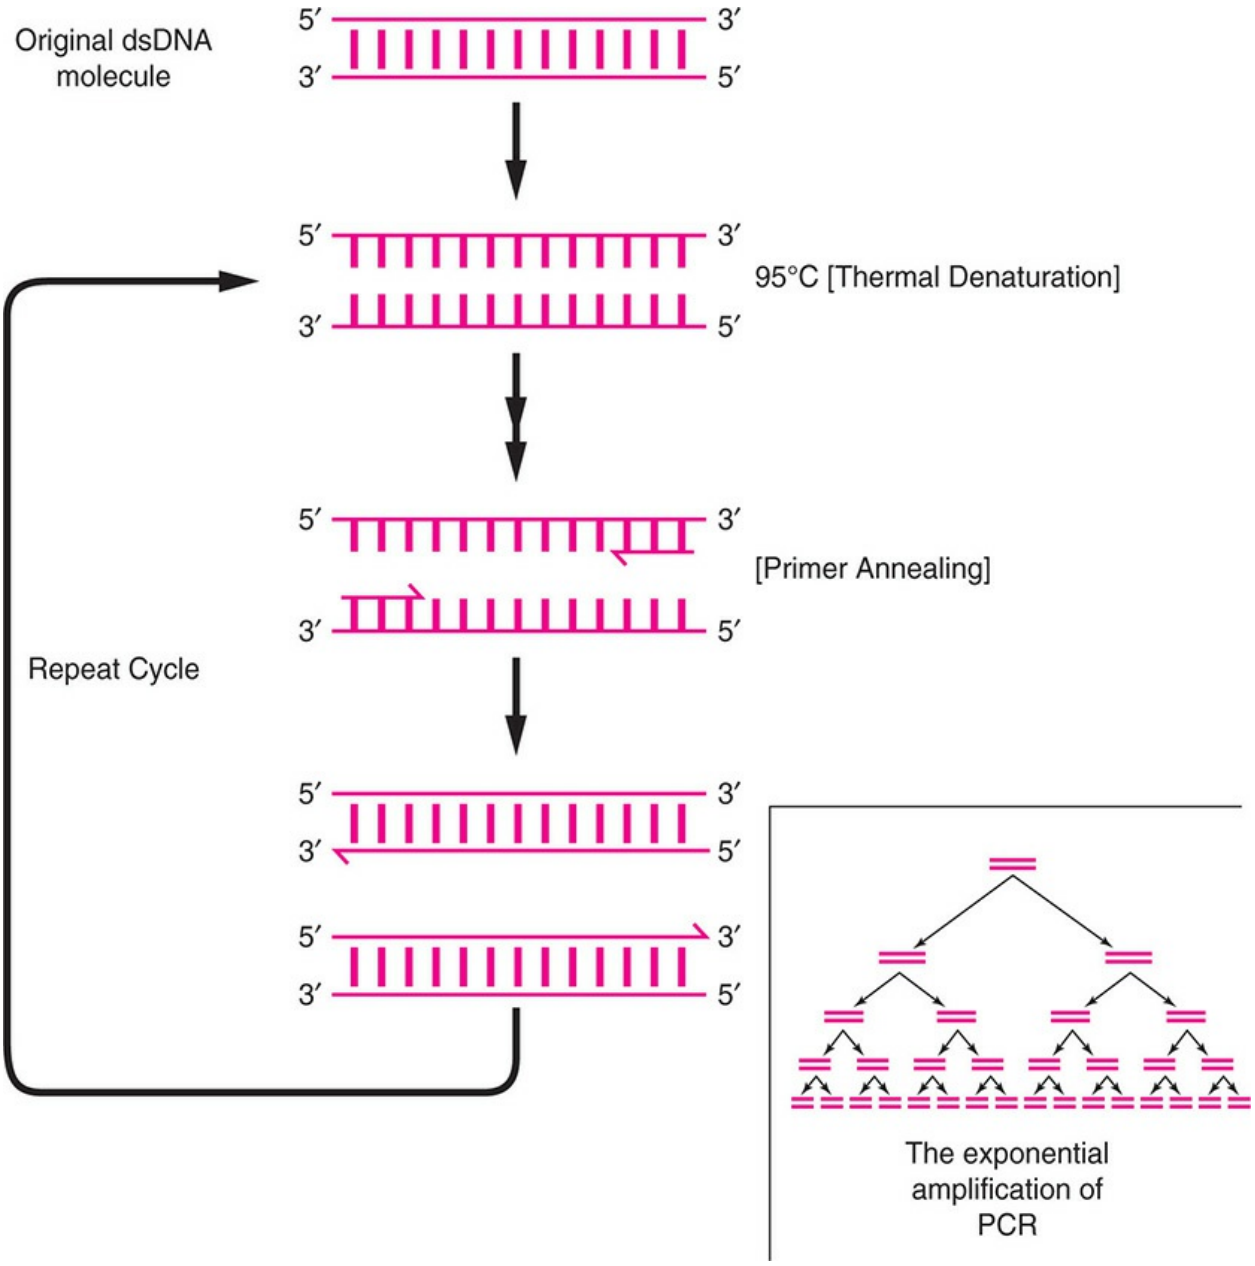
The next step in PCR, primer annealing, begins when the reaction mixture is cooled and the oligonucleotide primers, which flank the area to be amplified, hybridize with the single strands of the template DNA molecule. The oligonucleotide primers are short pieces of DNA, usually between 12 and 20 nucleotides in length, which are necessary to start or prime the DNA synthesis reaction. One primer is the same sense as the upper strand of DNA and is termed the *forward primer*, as denoted (Fig. 4-9);

the other is the same sense as the opposite strand of DNA and is termed the *reverse primer*. The primers hybridize to the target through traditional Watson and Crick base pairing; so the primer annealing temperature should be less than or equal to the T_M, or melting temperature, of the primers used; for simplicity, the T_M is the temperature at which the primers anneal.

When choosing a set of primers, number of technical factors must be considered, many of which are now included in primer design software programs. These are dealt with by industrial scientists when we purchase commercially available PCR kits. Most of the details of primer design are beyond the scope of this text; however, a few points deserve mention. If a single DNA-amplification product, also known as an amplicon, is desired, then the primers should be chosen to hybridize with a single region of the DNA molecule of interest. It is important that the primers do not hybridize with other areas of the molecule from the same organism, or with the DNA of another species that may be present in the specimen preparation. For example, if the molecular microbiologist is attempting to detect *L. pneumophila* in clinical specimens, then he or she should choose a region unique to this microorganism that is not present in the human genome. This has been done successfully by targeting the macrophage infectivity potentiator (*mip*) gene, which contains regions unique enough to differentiate *L. pneumophila* from other bacteria, and is not a constituent of the human genome.[295,382] Cross-reactivity with the human genome would, at best, nonspecifically exhaust the primers and nucleotide triphosphate bases in the reaction mixture, and could, at worst, result in a false-positive PCR reaction, depending on the detection system used.

The presence of the products of PCR amplification is often first assessed by examining the products following gel electrophoresis and staining with ethidium bromide. The presence of a single band in the gel is good preliminary evidence of the specificity of the reaction. The presence of multiple bands suggests that the primers are nonspecific and/or the stringency conditions of the reaction are not optimal (Fig. 4-10). In some instances, the specificity may be improved by changing the reaction conditions, such as salt concentration or primer annealing temperature. The easiest of these to change is the primer annealing temperature. The specificity of the binding of the primers to the target DNA molecule will increase as the annealing temperature used approaches the T_M of the primers (i.e., a more stringent condition).

The synthesis of a new strand of DNA that is complementary to the parent strand of DNA is accomplished by DNA polymerase after primer annealing is complete. The



■ **FIGURE 4-9** PCR. The PCR is a repetitive cycling of thermal denaturation, primer annealing, and extension of the primers through the action of DNA polymerase (not shown here). The reaction results in the exponential production of new DNA molecules; the beginning and end of which are determined by the positions of the forward and reverse primers.

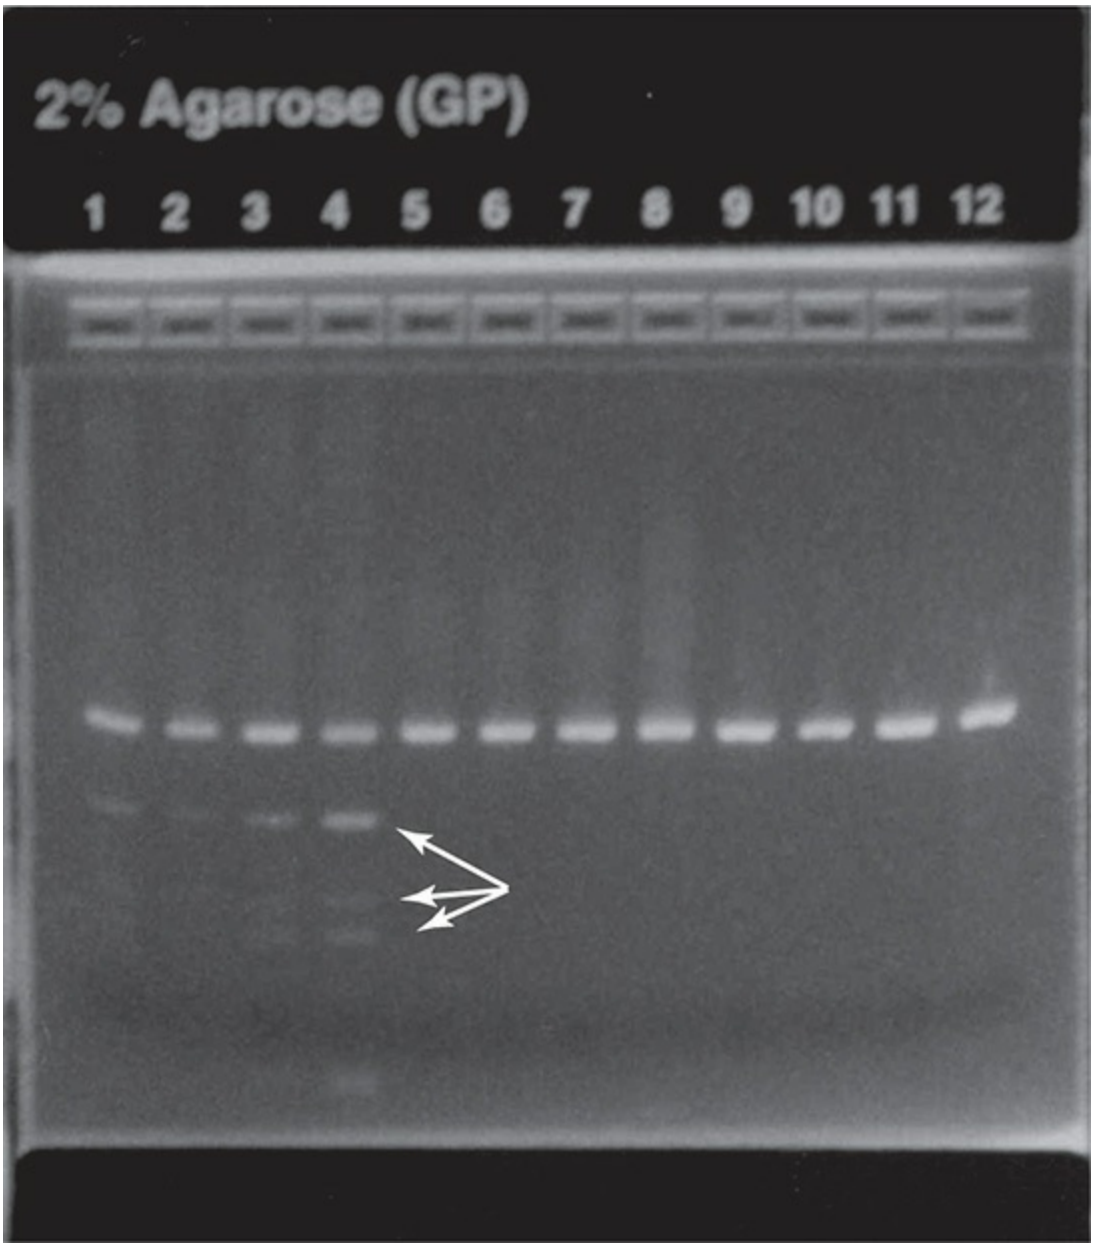
discovery of a thermostable DNA polymerase enzyme afforded the cycling of this reaction in a closed tube, without the need to add new enzyme after each thermal nucleic acid denaturation step. DNA polymerase synthesizes the new complementary strand at a rate of approximately 25 bp/sec. This is important to determine how long

the extension phase of the reaction should last, which is based on the length of the amplicon. After the appropriate amount of time has elapsed to allow for complete extension of the amplicon, the reaction mixture is again cycled to 95°C for another cycle of the PCR.

In this manner, the target portion from one molecule of DNA is amplified exponentially to form millions of amplicons. This exponential increase of the target region of DNA explains the exquisite sensitivity of the PCR reaction and the ability of diagnostic tests that use such methods to detect a very low number of pathogens. This extreme sensitivity also explains the great caution that must be taken when working with amplified DNA, since each of the amplified molecules, if released into the environment, could contaminate a clinical specimen (i.e., amplicon contamination) and result in a false-positive reaction. Although PCR sounds as if a single copy of target DNA should be detectable, in practice, there are numerous PCR inhibitors in clinical specimens that limit the sensitivity of these assays. Although nucleic acid extraction is not covered in detail here, the preamplification processing of clinical specimens, to purge them of inhibitors and prepare them for nucleic acid amplification, is likely as important as the amplification reaction itself.

Clinical Applications. The introduction of PCR into the diagnostic laboratory represented a significant advance in medicine. PCR-based assays have allowed laboratory workers to detect organisms that could not be cultured, as well as those that were fastidious and/or slow-growing. The early methods of detecting the products of PCR, however, were laborious and time-consuming (see Postamplification Analysis). Early PCR-based assays, therefore, were reserved for only the most significant of pathogens. The development of automated and semiautomated PCR platforms and easier, more rapid methods of detection increased the use of these technologies, which continues today, for a wider variety of pathogens. Almost every microorganism of clinical interest has been detected and studied by PCR.

147



■ **FIGURE 4-10** Nonspecific nucleic acid amplification. Nonspecific nucleic acid amplification may occur during the PCR or other nucleic acid amplification assays if the primers hybridize to an alternative site or bind with one another and form primer dimers. Nonspecific amplification and primer dimers may be minimized through careful assay design and optimization of the reaction conditions. Lanes 1 to 5 all demonstrate nonspecific amplification bands, but these are most prominent in lane 5 *(arrows)*. The solid band in all lanes represents the intended amplification target.

Apart from detection, PCR provided researcher with a tool to examine the presence or absence of particular genetic elements within populations, and, when coupled with

DNA sequencing, allowed researchers to examine the composition and variability of genes of interest. RT-PCR (see below) allowed researchers to detect RNA viruses and to measure the genetic response (i.e., the mRNA) of organisms and eukaryotic cells to a variety of stimuli.

Most PCR assays require nucleic acid extraction prior to amplification, although some assays are so robust that the amplification reaction can be performed following a simple lysis. There are many extraction options available from manual to semiautomated to highly automated (Image Plates 4-1A and B). Because of the possibility of amplicon and specimen contamination, the PCR master mix is prepared in a dead-air box (Image Plate 4-1C). There are now a wide variety of commercial assays that have received Food and Drug Administration (FDA) approval. Some of the first of these targeted two of the most common sexually transmitted bacteria, *N. gonorrhoeae* and *C. trachomatis*.[183,200] Although extremely useful because of an exquisite sensitivity that far exceeds culture, these assays are not perfect.[135] The specificity of these assays, although extremely high, is not 100%, which means in a population of low prevalence the positive predictive value is suboptimal and false-positive results may occur, and confirmatory testing has been recommended.[73,349,363] Furthermore, one of the first *N. gonorrhoeae* PCR assays, as well as an early assay that used strand displacement amplification (SDA) (see below), was shown to have the capacity to cross-react with certain nongonococcal *Neisseria* species, which could cause a false-positive reaction.[4,87,89] This demonstrates that just because an assay is FDA approved and just because it is "molecular" does not make it perfect. The laboratory director and team must still vigorously validate these assays and use them in the most appropriate manner for their patient population.

FDA-approved PCR assays are commercially available for the rapid identification of *M. tuberculosis* in acid-fast bacillus smear–positive respiratory specimens.[101,293] Most recently, the Xpert MTB/RIF assay (Cepheid, Sunnyvale, CA), which detects the presence/absence of *M. tuberculosis* and, if present, the genetic elements responsible for rifampin resistance, has been FDA approved[38] (Image Plate 4-1D).

There are a number of FDA-approved assays that use rapid-cycle PCR or loop-mediated amplification (LAMP) available for the rapid detection of group B *Streptococcus* (Image Plate 4-1D and E). Similarly, there are a number of commercial assays that detect methicillin-resistant and/or methicillin-susceptible *S. aureus* (see Real-Time Nucleic Acid Amplification).

FDA-approved assays that use RT-PCR (see below) are available for the detection and quantification of RNA viruses, such as HIV and HCV (Image Plate 4-1F). Additionally, RT-PCR is available in many commercially available assays for the detection of influenza A and B viruses, respiratory syncytial virus (RSV), and other RNA respiratory viruses. There are also FDA-approved assays for CMV, HSV, and other important pathogens.

In addition to FDA-approved assays, there are a wide variety of commercially available analyte-specific reagent and research-use-only products that are available for the study of a variety of human pathogens. These assays may be performed on a variety of rapid-cycle PCR instruments (Image Plates 4-1G and H).

Other Methods of Nucleic Acid Amplification

There are several different methods of nucleic acid amplification that have been devised, many originally devised to avoid licensing fees associated with PCR. Commercial diagnostic kits that utilize some of these technologies are available for several microbial pathogens. One of the first of these to be marketed, which is no longer available, used the LCR. This method was the first commercially available nucleic acid amplification assay to become available and widely used for the detection of *N. gonorrhoeae* and *C. trachomatis*. The non-PCR methods that have been marketed include the nucleic acid sequence-based amplification (NASBA) (bioMérieux, Durham, NC) and transcription-mediated amplification (TMA) (Hologic, San Diego, CA), which are basically the same technology, and SDA (BD Diagnostic Systems, Sparks, MD).

The LCR in its purest form is really a signal amplification reaction that relies on the ligation or connection of two probes that anneal contiguously on the template DNA strand. This technology, when combined with limited extension by DNA polymerase, was the basis of the Abbott products (LCx *Neisseria gonorrhoeae* or LCx *Chlamydia trachomatis* assays,

148

Abbott Park, IL) for the detection of *N. gonorrhoeae* and *C. trachomatis*. The use of the two-probe system necessary for the ligase contributed to its excellent sensitivity. The drawback of this assay was the lack of an internal control. Given the absence of this technology from the commercial market, it will not be discussed further.

Both NASBA and TMA are examples of TMA. These isothermal assays use three enzymes: RT, RNase H, and T7 DNA-dependent RNA polymerase. In short, the RT enzyme makes a cDNA copy of the target molecule, which is usually RNA. The primer that is used to create the strand of complementary DNA to the target RNA molecule contains the T7 RNA polymerase binding sequence on the 5′ end of the molecule. The RNA portion of the DNA–RNA hybrid is then hydrolyzed by RNase H. The second primer then binds and creates the complementary strand of the DNA molecule, thereby completing the cDNA molecule. This cDNA molecule has the T7 RNA polymerase binding sequence incorporated into it and serves as the template for T7 RNA polymerase, which transcribes numerous copies of RNA, which may be detected by a variety of methods.

SDA is an isothermal reaction that relies on the ability of the DNA polymerase to displace one strand of DNA at the site of a single-strand nick and proceed with DNA replication or amplification in this assay. This technology, although efficient, requires special conditions and endonucleases that will generate a nick in only one of the strands of the double-stranded DNA molecule, rather than producing a cutting through both strands of DNA, which is the mode of action for most restriction endonucleases.

Rolling circle amplification (RCA) is a method of unidirectional, isothermal nucleic acid amplification. This method has both a linear phase and an exponential phase of amplification. There are a variety of applications demonstrated or proposed for RCA.[8] Loop-mediated isothermal amplification is another method of isothermal amplification. This chemistry uses multiple primers and a DNA polymerase with strand displacement activity. After the initial phases of linear amplification, a double stem-looped structure is formed through the incorporation of primers with specially incorporated complementary sequences. Complex exponential amplification ensues through a variety of intermediate structures. A by-product of amplification, pyrophosphate, binds with magnesium ions in the reaction mixture, which precipitate and afford detection. This technology has been commercialized in a user-friendly, cost-effective format, which is discussed later.

Clinical Applications. There are FDA-approved commercial assays available for the detection of *N. gonorrhoeae* and *C. trachomatis* that use TMA and SDA.[4] Akduman et al. examined over 3,500 urine specimens using the BDProbeTec-SDA assay (BD Bioscience) and reported a sensitivity of 99.2%, a specificity of 99.3%, a positive predictive value of 84.9%, and a negative predictive value of 99.9%. With regard to different amplification assays, these authors, like others, recommend the need to confirm positive results, given the positive predictive value. The BDProbeTec-SDA assay has an internal amplification control, which is useful for identifying potentially false-negative reactions secondary to amplification inhibition.

The APTIMA (Hologic) line of products is FDA approved, commercially available TMA assays for the detection of *N. gonorrhoeae* and/or *C. trachomatis*. These are now available on the newer, smaller, random-access Panther instrument, as well as on the traditional Tigris. Gaydos et al. studied the APTIMA II combo (GenProbe) and compared the sensitivity and specificity of this assay from endocervical swabs versus urine specimens.[107] For *C. trachomatis*, they found a sensitivity and specificity from endocervical swabs of 94.2% and 97.6%, respectively, compared with a sensitivity and specificity from the first-catch urine of 94.7% and 98.9%, respectively. For *N. gonorrhoeae*, they found a sensitivity and specificity from endocervical swabs of 99.2% and 98.7%, respectively, and a sensitivity and specificity from first-catch urine specimens of 91.3% and 99.3%, respectively. The APTIMA assays do not have an internal control for amplification, but rather use a target capture system, which they

claim virtually eliminates inhibition and negates the need for an internal control. In short, these assays are significantly more sensitive than culture-based methods for the detection of these fastidious pathogens.

The Nuclisens HIV-1 QT assay was an FDA-approved assay that used the NASBA technology for measuring HIV viral loads. Similarly, the Nuclisens CMV pp67 has been compared with a CMV antigenemia in a study of bone marrow transplant recipients, and found to be a suitable replacement for the more labor-intensive antigenemia assay.[111] This technology was particularly useful for the detection of RNA viruses, such as enteroviruses and the West Nile virus, but like TMA, NASBA has also been used to detect bacteria, by directly targeting rRNA or other specific mRNAs.[13,78,193,206] Landry et al., in a comparison with RT-PCR for the detection of enterovirus from clinical specimens, found the NASBA assay to be slightly more sensitive and that it had a shorter turnaround time.[194]

This technology is covered largely for completeness and historical purpose, as NASBA is no longer in common use.

LAMP has been commercialized by Meridian Biosciences, Inc. in the form of *Illumigene*. These assays are easy to use and require only a simple, inexpensive instrument. These assays represent a cost-effective solution to community hospital laboratories with limited experience with molecular diagnostics. There are assays available for *Clostridium difficile,* group A *Streptococcus* and group B *Streptococcus.*

Modifications of PCR

A number of modifications have been made to the standard PCR reaction, which have expanded the use of this test, and broadened the spectrum of the microorganisms that may be detected using these molecular methods.[85,264,373] Several of these modifications are well standardized and have been introduced as routinely used techniques in the clinical laboratory. Of the modifications, the techniques that will be described here are RT-PCR, broad-range PCR, multiplex PCR, and nested PCR. Many of these modifications are performed in a real-time PCR format, which will be covered under a separate heading.

Reverse Transcription-PCR. Retroviruses are RNA viruses that as a part of their life cycle make a DNA copy of their RNA genome. This feat is accomplished by the RT

enzyme. The addition of an RT step prior to PCR makes it possible to amplify and detect RNA targets. This may be accomplished in either a two-step or single-step reaction. A separate RT enzyme has been used prior to the addition of the DNA

polymerase in the two-step RT-PCR reaction, whereas it is now far more common to use a single thermostable DNA polymerase that also possesses significant RT activity and is used in the single-step reaction.[244] The cDNA created by RT is most commonly formed using specific oligonucleotide primers, but random oligonucleotide hexamers have also been used. The PCR portion of the reaction then proceeds as previously described.

RT-PCR is particularly useful for detecting RNA viruses, but it may also be used to detect other microorganisms by targeting the rRNA.[26,173,388] The detection of mRNA is useful for studying the genetic expression of both microorganisms and human host cells. As with PCR, quantitative results may be obtained with RT-PCR, which forms the basis for HIV and HCV viral load testing with this technology.[310] Other nucleic acid amplification technologies that preferentially amplify RNA, such as NASBA and TMA, are technologies competitive with RT-PCR.

Clinical Applications. The detection of RNA viruses has likely been the most important of the clinical applications for RT-PCR to date. Quantitative RT-PCR assays have become commonplace for the detection of HCV and HIV, and there are several FDA-approved assays.[110,265] The quantitative nature of nucleic acid amplification, when used in conjunction with external quantitative standards, is commonly used to determine the amount of these viruses present in the blood of a patient, which is commonly known as the "viral load." Viral load data are important for monitoring the response of the individual patient to therapy. For instance, a patient infected with the HIV virus should demonstrate an increasing CD4 T-lymphocyte count and a diminishing HIV viral load, when treated with appropriate antiretroviral therapy.

RT-PCR has also been used for the detection of the viral causes of meningitis and meningoencephalitis, such as enteroviruses and the West Nile virus.[130,149,155,161,176,370] Several studies have demonstrated the advantages of the rapid detection of enteroviruses from the cerebrospinal fluid (CSF) of patients with meningitis.[286,340] These have examined the advantages of performing these assays in a rapid manner to avoid unnecessary hospitalizations, unnecessary antibiotic use, and unnecessary ancillary procedures—to improve patient care and reduce costs.

The dengue viruses, the Hanta virus, human metapneumovirus, and the severe acute respiratory syndrome (SARS) coronavirus among others have been detected using RT-PCR.[80,175,270,313] The use of RNA-based amplification techniques for the detection of rRNA in bacteria, parasites, and fungi may be advantageous over detection of the rDNA gene by traditional PCR, since the presence of RNA is more likely associated with the presence of viable organisms.

Broad-Range PCR. The specificity of a primer set is determined by a variety of factors. Some of these factors are technical, such as the degree to which the primers

hybridize with their target (i.e., avidity), which is determined by the composition of the reaction mixture (i.e., salt concentration) and the complementarity of the primers with respect to their target sequence (i.e., 100% complementarity = a perfect match). The specificity of a PCR may also reflect the uniqueness of the complementary sequence with which the primers hybridize. In many instances, it is desirable to choose a highly unique (signature) sequence, if one is attempting to detect a single microorganism. For example, it has been shown that the gene that encodes for the *Coccidioides*- specific antigen is a useful target for the detection of *Coccidioides* and the differentiation of this organism from other fungi.[256] Failure to produce a species-specific assay may result in undesired cross-reactivity with closely related species. This is the case with two of the FDA-approved, commercially available nucleic acid amplification assays designed to detect *N. gonorrhoeae*, which are known to be capable of cross-reacting with certain commensal *Neisseria* species.[87,89]

Alternatively, there may be interest in detecting the presence of a larger group of microorganisms, rather than a single species. The primers of such an assay are designed to detect all the organisms in the group of interest while attempting to exclude as many organisms as possible that are not in this group. This would be considered a "broad-range" PCR assay. For example, a primer set that detected only one of the many enteroviruses capable of causing meningitis would be of little value for diagnosing or excluding enteroviral meningitis. In this case, the regions that are conserved among all the clinically relevant enteroviruses would be potential sites for primer and probe annealing. Both specific and broad-range primers are useful, with their utility being dictated by the particular clinical question that is being addressed by the assay. There are many advantages of using broad-range primers, but there are limitations too.

The main reason and principal advantage of using a set of broad-range PCR primers is that any of the members of a large group may be detected in a single reaction. When a positive reaction is obtained, the amplicon may be assessed by multiple methods to determine which member of the particular group is present. This may be done by the use of multiple probes in a Southern blot or enzyme immunoassay (EIA) format, by sequencing of the amplicon or by microarray analysis.[100,134,221]

Postamplification melt-curve analysis is a means of achieving limited differentiation following a broad-range real-time PCR (see Real-Time Nucleic Acid Amplification).[325] The limitation of this technology is that the larger the group the assay is designed to detect, the more likely it is that the reaction will also detect organisms that are phylogenetically related to, but not necessarily part of, the group of interest. For example, we have used a broad-range PCR for the detection of all clinically relevant mycobacteria, but it will also amplify the same segment of DNA from many other G-C (guanine-cytosine)–rich bacteria that are closely related to this group (e.g., *Corynebacterium* spp.). These limitations can be dealt with successfully by using

highly specific probes, but some limitations of this type of application remain. When multiple microorganisms are amplified (i.e., desired targets and undesired targets), there is an early exhaustion of the PCR primers. In addition, it is often difficult to obtain useful information from DNA sequencing because a meaningless mixed sequence will result, unless one is able to identify a sequence that is conserved in the group of interest but is not present in the contaminating organisms.

150

Clinical Applications. Any group of related microorganisms, the members of which are of clinical interest, is a candidate for broad-range PCR. As previously mentioned, broad-range primers have proven useful for detecting the enteroviruses that cause aseptic meningitis.[282,286,340] One limitation of some broad-range assays for the detection of enterovirus is cross-reactivity with rhinovirus.[194] This should not be a significant problem if only CSF is examined, but may result in false-positive reactions if respiratory specimens are examined. This, in fact, was an issue in the recent enterovirus D68 outbreak in the United States; one commercial assay, which was claimed to not cross-react with enteroviruses, was found to cross-react in practice.[223]

Possibly the most commonly used targets for broad-range PCRs have been the genes that encode for the bacterial, mycobacterial, fungal, and parasite ribosomal subunits (rDNA).[131,141,320] These genes are particularly useful for both broad-range PCR and taxonomic categorization of microorganisms because they possess both highly conserved and variable regions. The highly conserved regions are excellent sites for broad-range primers, whereas the variable regions that lie between the primer sites may be used as target sites for species-specific probes or may be assessed by DNA sequencing. These applications have been used to help determine the cause of bacterial meningitis, infective endocarditis, bacteremia in patients with infective endocarditis, and other bacterial infections.[106,278,290,306,320] As with culture, the presence of contaminating bacteria is an issue for the interpretation of the results from a broad-range PCR.[19,118]

Not surprisingly, this type of approach has been used by many different groups for the identification of mycobacteria.[52,132,137] The most common type of postamplification analysis has been DNA sequencing, but multiple probes and DNA microarray analysis have also been used successfully for identification.

The rDNA target sites form the basis of many of the sequence-based identification systems currently used. The MicroSeq Microbial Identification System is a commercially available microbial identification system that uses broad-range primers to target the bacterial 16S rDNA and fungal D2 rDNA region (Thermo Fisher, Scientific, Inc., Foster City, CA). After PCR amplification of the unknown bacterium or fungus,

the sequence is obtained and submitted and matched against a database that is maintained and updated by the provider. This database has been evaluated by a number of groups regarding its usefulness in the molecular identification of a variety of pathogens from bacteria to dermatophytes.[52,132,134,228,246,278,384]

A number of other genetic targets, which like the 16S rDNA gene contain both highly conserved and variable regions, have been used for microorganism identification. These alternative targets for identification via broad-range PCR include the RNA polymerase (*rpoB*), heat-shock protein (*hsp*), the elongation factor Tu (*tuf*), and a translocating ATPase (*secA*).[76,180,221,391] Characterization of microorganisms, particularly mycobacteria, by the *rpoB* gene is particularly of interest, since analysis of this gene also provides information regarding the resistance of mycobacteria to rifampin.[12,69,237,324]

Multiplex PCR. Multiplex PCR is an alternative method to broad-range PCR for the detection of multiple pathogens.[21,108,299] In the simplest of multiplex assays, there are multiple primer sets used in a multiplex PCR reaction, each of which usually targets a particular pathogen. More complex multiplex assays could use combinations of broad-range and species-specific primer sets, for example. The advantage of multiplex reactions is that numerous pathogens may be detected in a single reaction, even if these pathogens are from taxonomically different groups. In some instances, one of the primer sets included in the amplification reactions may be directed against a human gene, such as β-globin, or a nucleic acid construct that has been added to the specimen; these are internal amplification controls for the reaction.[238] The amplification of an internal control is important to ensure that the amplification reaction was not inhibited, which helps to ensure the accuracy of the negative results. The quantitative competitive PCR assay is one method of obtaining a quantitative result and is a type of multiplex reaction.[268,386] The limitations of multiplex PCR reactions are largely secondary to interactions between the different oligonucleotides, which compromises the sensitivity of the reaction, particularly when compared with the individual amplification reactions. The design of highly efficient multiplex assays that have minimal oligonucleotide interactions is a complicated endeavor.

Clinical Applications. Multiple multiplex assays are usually designed to detect different microorganisms that cause the same types of diseases (i.e., a syndromic approach to diagnosis). For example, multiplex assays have been developed to detect *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*, the most common causes of bacterial meningitis.[15,331] A number of multiplex assays have been described for the detection of the viral agents of meningitis and meningoencephalitis.[217,280,292] Multiplex PCR reactions are particularly useful when the number of possible pathogens is limited. Multiplex assays have also been used to detect and differentiate the

polyomaviruses that infect humans, the bacteria that cause middle ear infection, the agents of atypical and typical bacterial pneumonia, and causes of viral respiratory tract infections.[56,91,124,147,271,353]

A number of multiplex assays are commercially available. The first of these were available through Prodesse (Waukesha, WI), now owned by Hologic (Bedford, MA). Their products include the ProFlu+ for influenza A and B viruses and RSV; an assay to determine the type of select influenza A virus strains (ProFast+) and an assay to detect a myriad of medically important Adenoviruses (ProAdeno+).[328]

Two or the newest and most innovative products available use a combination of multiplex PCR/RT-PCR with other methods. The BioFire FilmArray (bioMérieux, Durham, NC) uses a combination of nested, multiplex, and individual PCR reactions to detect a variety of pathogens (see Nested PCR) (Image Plates 4-2A and B). The eSensor technology from GenMark Dx utilizes multiplex PCR and/or RT-PCR to amplify a variety of nucleic acid targets. These are then added to a bioelectric microarray, which is used for detection (see Microarrays).

Nested PCR. Nested PCR is a modification of PCR designed to increase the sensitivity of the assay reaction. This modification consists of two primer sets directed against the same target.[85,139] The first set of primers is developed in the usual manner, whereas the second set of primers is

situated internally or nested with respect to the first set of primers. The traditional approach to nested PCR was to perform a number of PCR cycles, usually less than a full PCR run would contain, and then open the reaction vessel and add the second, nested, set of primers.[93,139,299] As one may imagine, the major problem with this approach is amplicon contamination in the laboratory and a consequential loss of specificity of the assay as a clinical test. More recently, assays described as single-step nested PCR reactions have been reported, wherein both sets of primers are added to the initial reaction vessel and an extended PCR is performed. These have been performed in a real-time or homogeneous format (see below) and have demonstrated an increased sensitivity without amplicon contamination.[389] The advantages of these types of applications are being realized, as FDA-approved, commercially available assays have been introduced. These are constructed in a closed system, which essentially negates the issue of amplicon contamination.

Clinical Applications. Nested PCR has been used in many PCR assays in an attempt to improve the sensitivity of the assay. Nested PCRs have proven valuable for the detection of microorganisms that may be in low quantity in the blood and tissues, such as *Rickettsia*, *Bartonella*, and similar organisms.[222,389] Not surprisingly, these

have also been designed for the detection of herpesvirus and enterovirus from the CSF and have been used in the direct examination of the blood as a means of determining the cause of bacteremia.[72,99,128,181,333] Nested PCR primers may also be used in a multiplex reaction and have been used in this manner to detect different herpesviruses, such as HSV and CMV.[252] This approach has also been used to detect *M. tuberculosis*, which may be an advantageous approach when the bacilli are present in very low quantities.[253]

The BioFire FilmArray (bioMérieux) is a commercially available system that employs nested, multiplex, and singleplex PCR reactions for the detection of a variety of pathogens. The FilmArray pouch, wherein amplification and detection occur, includes all the necessary reagents and materials in a self-contained pouch in a freeze-dried format. All that must be added is the specimen and a hydration solution. The solution will be moved throughout the pouch once it is placed within the instrument. Different areas of the pouch will be activated and fluids mobilized at select times, moving them through the system.

The first step in the system, after the specimen has been added, is nucleic acid purification. This is followed by the performance of a nested, multiplex PCR for the microbial targets within each particular assay. It should be noted that this is performed in a closed system, which minimizes the risk of amplicon contamination secondary to nested PCR. The products from this first reaction are then mobilized into secondary chambers wherein a number of singleplex reactions occur designed to detect select agents of disease using end-point melt-curve analysis (see Real-Time PCR) (Image Plates 4-2 A and B).

A number of panels are commercially available for this easy-to-use system, which brings the capability of molecular diagnostics into laboratories of all sizes. The gastrointestinal panel detects all of the common and several of the less common bacterial causes of gastroenteritis, as well as four parasites and five types of viruses. Similarly, the respiratory panel includes not only the viral respiratory pathogens, but also *Bordetella pertussis*, *Chlamydophila pneumoniae*, and *Mycoplasma pneumoniae.* The blood culture identification panel detects the most commonly occurring and medically important causes of bloodstream infections, as well as select genetic markers of resistance. These three products are all FDA cleared. In development is a meningitis panel that similarly will detect the most important causes of bacterial, viral, and fungal meningitis/meningoencephalitis.

The FilmArray is a clear advance in the syndromic approach to the molecular diagnosis of infectious diseases. It has proven reliable in a number of clinical studies.[287,335] The limitations to this approach are the higher cost of the individual assays. However, when compared with the cost per test for performing each test contained within the assay individually, the cost is quite reasonable and possibly less expensive than traditional methods. The most significant limitation is the throughput,

since each instrument can only process one pouch at a time. This may be ideal for smaller laboratories, but becomes a challenge for larger operations, which may need multiple instruments.

Postamplification Analysis

After completion of the traditional nucleic acid amplification reaction, the amplified product must be analyzed. The methods of analyzing the amplified product range from simply determining the size of the amplicon and the presence of any other products of amplification through gel electrophoresis to determine each nucleotide that composes the amplicon through DNA sequencing. Some methods of postamplification analysis such as hybridization protection assays and single-stranded conformational polymorphisms are not covered here, whereas others such as restriction fragment length polymorphism (RFLP) analysis are covered below in the section on microbial typing.

Traditional Methods of Detection

Gel Electrophoresis/Southern Blot Analysis. Gel electrophoresis is one of the simplest ways of gaining information about the amplicon. Different types of gels may be used for gel electrophoresis, but a simple agarose gel is often used. The agarose gel is rectangular and has wells near one end. The gel is placed into a gel box and covered with buffer; newer, single-use gel electrophoresis systems are available that do not require the addition of buffer. To perform gel electrophoresis, the products of amplification are mixed with a loading dye, which is a dense, viscous, and colored liquid. This helps the user visualize the placement of the mixture into the well when pipetting. After loading, an electrical current is passed through the contents of the gel box and the negatively charged DNA migrates toward the anode. The larger pieces of DNA are retarded by the gel matrix, compared with the smaller pieces of DNA. Therefore, the separation of DNA in gel electrophoresis is largely due to size. A set of DNA molecules of different known sizes, which is a commonly referred to as a ladder, is often placed in the first lane and run in concert with the samples. Through visual comparison of the migration of the amplicon(s) in the

sample lanes (the area beneath the well) and the migration of the DNA molecules of varying sizes in the ladder, the user can estimate the size of the DNA molecule(s) amplified.

The presence of a single band of the expected size is good preliminary evidence of

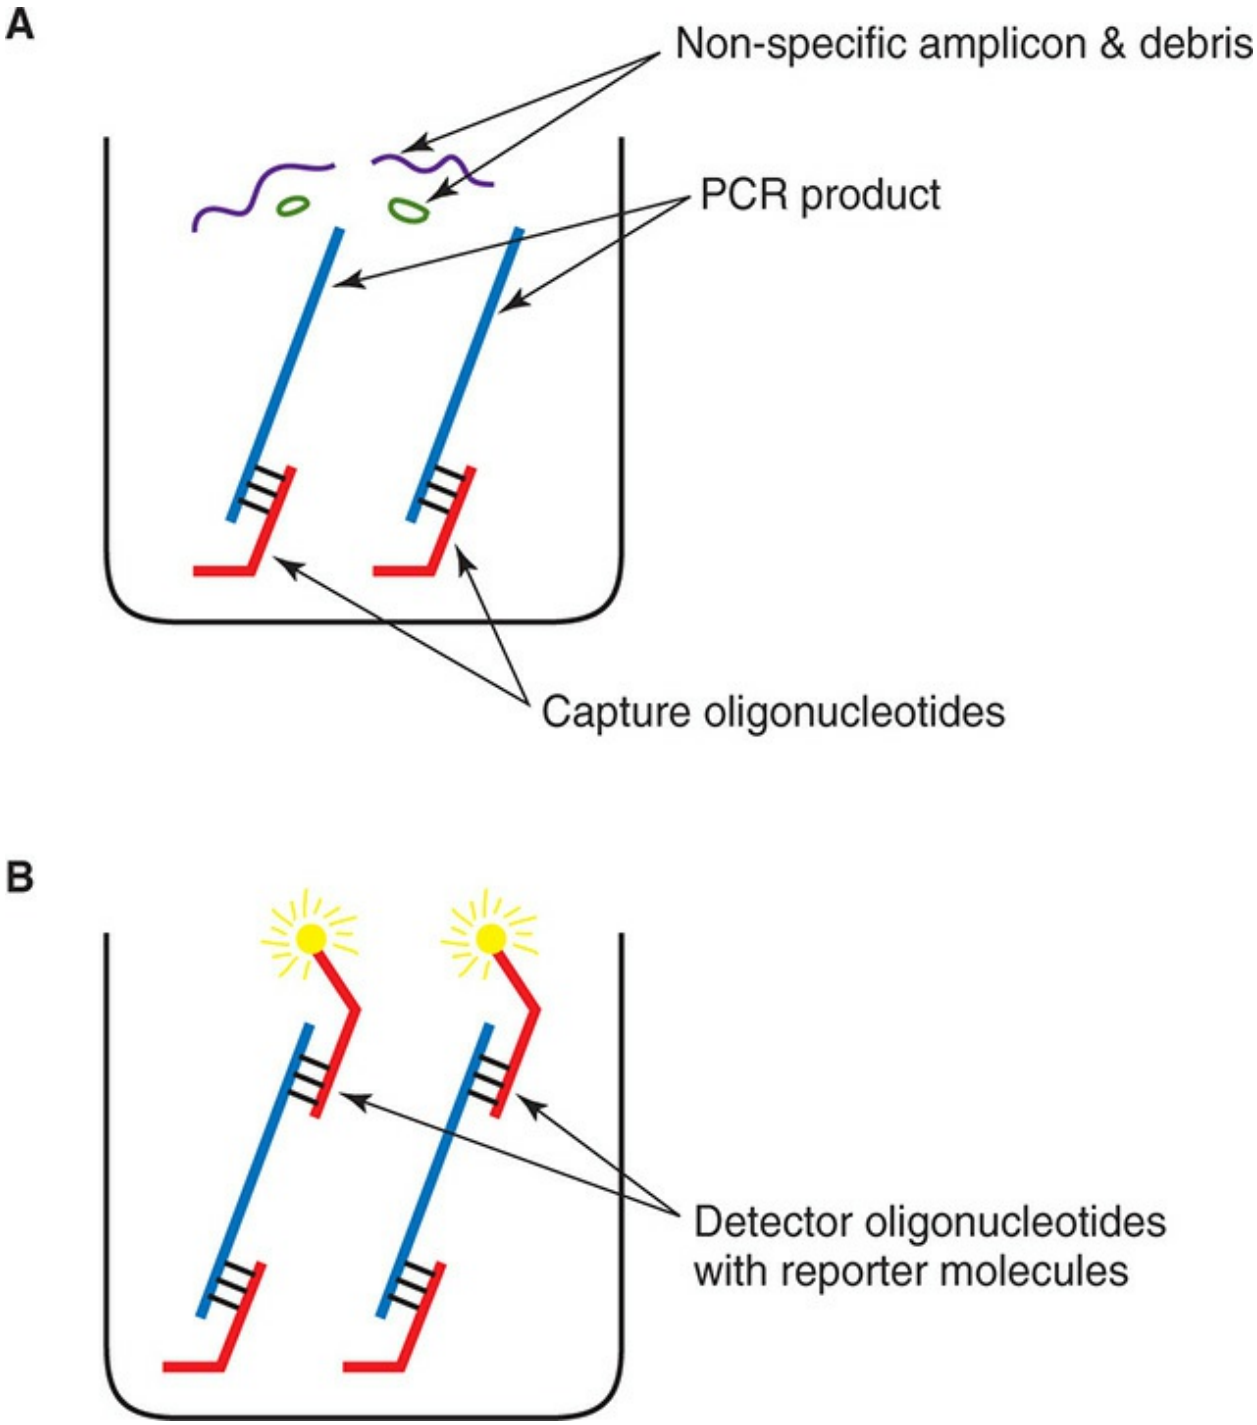
the specificity of the amplification reaction, but the question remains: How can one actually be sure that the amplified product is the desired product and not the product of nonspecific amplification that just happened to be of or near the same size? The answer to this question using traditional methods was achieved by using specific oligonucleotide probes and performing a Southern blot.

In short, after gel electrophoresis, the amplified product was transferred to nitrocellulose paper and a radiolabeled oligonucleotide probe was added. After an appropriate amount of hybridization time and subsequent wash steps to remove unbound probe, the nitrocellulose paper was exposed to x-ray film. If the expected amplicon was present, the radiolabeled probe would hybridize to its complementary sequence on the amplicon, producing an area of exposure on the x-ray film. If the amplicon was the result of nonspecific amplification, the probe would not hybridize and would be washed away, and the x-ray film would not contain an area of exposure on development. This procedure often took 2 to 3 days to complete, was technically complicated, and did not fit well into the clinical laboratory.

Enzymatic Detection of Amplified Products. The use of EIA technology as a method to detect the product of amplification represented a major advance in the rapid detection of specific amplified products.[350] The enzymatic reaction for the detection of the amplified products was often performed in a 96-well plate. Different methods of labeling and detecting the hybridized oligonucleotide probe may be used. The end result, however, is that the hybridized probe that has not been removed by washing generates a signal of either light or, more commonly, color[214] (Fig. 4-11). The use of an oligonucleotide probe increases the specificity of the reaction, whereas linkage with an enzymatic reaction increases the sensitivity of the reaction.[350] The amount of signal generated is proportional to the amount of amplicon present. When used with calibrated standards, quantitative information may be obtained. This methodology was used for an extended period, prior to the introduction of real-time PCR. It is no longer widely used in clinical laboratories.

Reverse Hybridization

The Southern blot, although effective, is time-consuming and labor intensive. In addition, multiple probes or sequencing of the amplicon would be necessary if the product of amplification was secondary to a broad-range PCR. An alternative, highly effective approach is to immobilize all the probes of interest on a nitrocellulose strip and then apply the amplicon to the strip and determine which probe hybridized with the amplicon. This is termed *reverse hybridization*, since the amplicon is applied to the probe that is immobilized in the nitrocellulose strip, which is opposite to how a Southern blot is performed. The assay also has the advantage of using a chromogenic reaction, rather than using radioactivity to detect hybridization (Fig. 4-12).



■ **FIGURE 4-11** There are many methods of detecting an amplicon using enzymes, although this approach is uncommonly used in the era of real-time PCR. **A.** Here, a capture probe is used to retain the specific amplicon so that any nonspecific amplified material and cellular debris may be removed by washing. **B.** The retained amplicon is then detected with another oligonucleotide, and a signal is generated using one of many signal amplification systems.

Clinical Applications. Reverse-hybridization technology is commercially available as line probe assays (LiPAs) (Fujirebio [formerly Innogenetics], Gent, Belgium). This type of technology has been used to differentiate the various genetic subtypes of HCV (i.e., HCV genotyping), a test that provides important prognostic and therapeutic information.[54,66,262,277] The INNO-LiPA HCV II was found to be comparable to DNA sequencing in a direct comparison.[247] Reverse hybridization has also proven useful for screening for the most common mutations present in the HIV genome that confer resistance to antiretroviral agents.[32,70,317,346] The LiPA is technically much easier to perform than DNA sequencing, with simpler posttest analysis. However, unlike sequencing, the use of reverse hybridization allows for an assessment of only the sequences for which there are probes, and does not afford the opportunity to evaluate new mutations, which may be either silent or clinically relevant.[291] Reverse hybridization has also been used to detect HPV and identify the subtypes that are associated with a high risk of dysplasia and subsequent carcinoma.[182,201,225,263,281,365] In addition to virologic applications, reverse-hybridization technology has been used to identify mycobacteria, medically important fungi, and mutations associated with mycobacterial resistance to rifampin.[1,17,37,69,151,220,226,230,233,305,315,347,354] Although highly accurate, the mycobacterial, fungal, and rifampin LiPAs are expensive and are not available in the United States.

DNA Sequencing

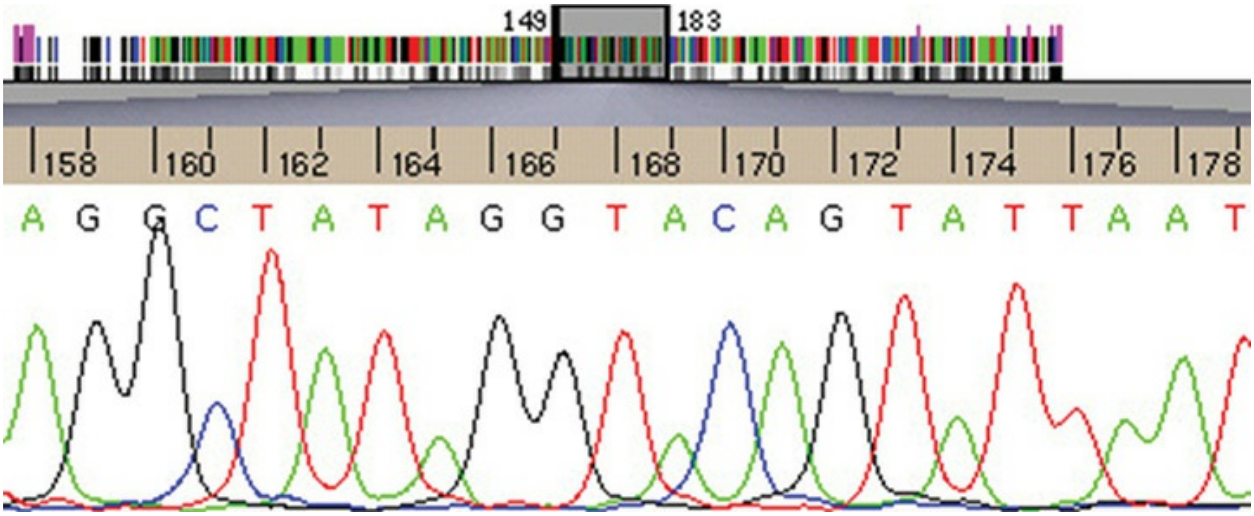
DNA sequencing for the analysis of an amplified product is now a common method of postamplification analysis. Although useful, this technology is more complicated than simple probe hybridization and often requires the user to have experience with sequence alignment and editing software, and genetic databases. DNA sequencing is particularly useful when analyzing a group of microorganisms to determine the areas of conservation and variability within the amplicon obtained by broad-range PCR. Analysis of these variable regions then becomes a powerful tool for the identification of microorganisms.[29,106,114,122,195,205,289,320,371,380,385] It has also proven critically useful for the analysis of genetic mutations within viral genomes, which may often be SNPs and may confer resistance to antiviral drugs.[53,136,186,209] Finally, it may be used for strain typing, by comparing the sequence of genes that contain stain-level variations (e.g., *Spa* typing).

Traditional DNA Sequencing. Traditional DNA sequencing, once a tool used solely in research laboratories, has also become commonplace in many molecular pathology and molecular microbiology laboratories (Image Plates 4-2C). This technology, which uses traditional Sanger sequencing or sequencing by termination, works through the incorporation of dideoxynucleotides into a growing strand of DNA. When a dideoxynucleotide is incorporated into the DNA strand, it can be extended no further. The analysis of the DNA fragments that result, which are as numerous as the nucleotides that compose the strand, provides the sequence information. In the past, this was accomplished with large gels poured between two glass plates and the use of radioactive reporter molecules. Today, these methods have been modified to use fluorescently labeled reporter molecules, with either a more user-friendly gel system or more commonly with capillary electrophoresis (Fig. 4-13). The sequence of long regions of DNA, up to hundreds of base pairs in length, may be readily determined by these methods.

Clinical Applications. HIV genotyping is one of the principal applications of DNA sequencing in the molecular microbiology laboratory.[47,301] This is done to determine the presence of acquired mutations in the genome of HIV for a particular patient that may confer resistance to antiretroviral agents. This assay is complicated and consists of extraction of the HIV RNA, followed by four-to-five RT-PCR assays, each of

which is followed by Sanger sequencing. Although nucleotide determination is largely automated in many of these systems, some manual sequence analysis of the generated sequences is still required. DNA sequencing has also been used to demonstrate resistance-associated mutations in CMV and to determine the HCV genotype.[136,143,186,209,247]

DNA sequencing has also been used successfully for the identification of bacteria, mycobacteria, *Nocardia*, and fungi. The genes that encode for the ribosomal subunits of these organisms are the most commonly used genetic targets of sequence-based identification. One of the most common uses of this approach has been for the identification of the causes



■ **FIGURE 4-13** Sequence from HIV. A DNA sequence from the HIV following RT-PCR is demonstrated here and was obtained by using sequencing by termination (i.e., traditional Sanger sequencing). The most commonly used methods of sequencing by termination utilize capillary electrophoresis rather than gel-based methods.

of bacterial endocarditis.[106,114,123,179,231,279] Sequence-based identification, however, has also been used to determine the causative agent of infection in a variety of other infections, including sinusitis and urinary tract infections.[40,125] This technology has revolutionized the way in which we identify slow-growing microorganisms such as mycobacteria and nocardiae.[51,132,178,228,260,266] It has also been used for the identification of fungal pathogens.[133,134,275] Although rDNA genes are commonly used as the genetic targets for sequence-based identification, other genes that have proven useful for characterizing microorganisms include the *rpoB, hsp*, and *tuf* genes, among

others.[76,77,97,178,191,259,298]

Sequencing by Synthesis (Pyrosequencing). Pyrosequencing is an alternative method of DNA sequencing, which is sequencing by synthesis, in contrast to sequencing by dideoxynucleotide termination or Sanger sequencing[248,302,303] (Image Plate 4-2D). This technology has been used extensively in the analysis of SNPs associated with genetic diseases and neoplasia; it has also been used for the identification and differentiation of microorganisms.[3,6,103,248] Unlike traditional sequencing by termination, this sequencing technology is based on nucleotide incorporation into the newly synthesized strand of DNA.

In short, the PCR-amplified DNA molecule, one strand of which contains a terminal biotin that was covalently bonded to the primer, is immobilized in the well of a microtiter plate. Processing with sodium hydroxide creates a single-stranded molecule. The sequencing primer and reagents are added, followed by the automated addition of each of the four nucleotides. If the nucleotide added is the next appropriate nucleotide and incorporated in the growing strand, then pyrophosphate—a natural by-product of nucleotide incorporation—is generated. The pyrophosphate is then converted into light by enzymatic reactions. The light generated is recorded by the instrument, and the sequence is thereby determined (Fig. 4-14).

The primary limitations of sequencing by synthesis are its ability to generate only relatively short sequences, problems generating a sequence when extensive secondary structure is present, and an inability to accurately characterize regions that contain more than four of the same nucleotide in tandem (i.e., homopolymers). The advantages are ease of use (i.e., the sequencing reaction occurs in a commonly used 96-well plate) and the sequence generated is present in context, which means surrounding, known sequences may be used as a sequencing control. The key to successfully using pyrosequencing for microorganism identification is knowledge of focal genetic targets that provide information sufficient for the differentiation of the microorganisms of interest.

Clinical Applications. Applications that use sequencing by synthesis have been introduced into some clinical microbiology laboratory. A major limitation has been the lack of FDA-approved products and an apparent lack of interest in supporting this technology by the company of ownership.

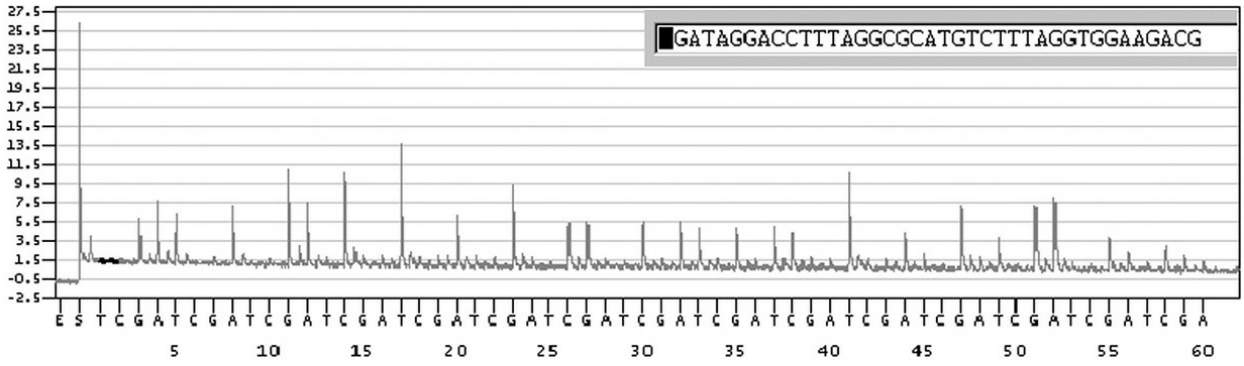
Research applications have included the identification and typing of bacteria, such as *H. pylori* and *L. monocytogenes*, and the differentiation of bacteria into clinically relevant groups.[118,239,359] It has also been used to study linezolid resistance in the enterococci.[327] Additional uses that would likely prove useful for the clinician may include the rapid identification of bacteria that cause infections in neonates and the rapid identification of the bacteria that cause meningitis.[172]

Pyrosequencing has also been used to identify clinically relevant fungi, nocardiae,

and mycobacteria.[112] We have used a broad-range PCR that targets the portion of the 16S rDNA that contains the hypervariable region A and have demonstrated excellent differentiation of the vast majority of the clinically relevant mycobacteria with pyrosequencing; this was achieved with the analysis of a region consisting of only 30 bp.[357] We chose this target because the hypervariable region A had been shown by several groups to be useful for the genetic differentiation of mycobacteria.[74,137,337] Similarly, we have targeted portions of the 16S rDNA gene that confer taxonomic information for *Nocardia* species and have achieved excellent results.[90,219]

The differentiation of viruses has also been demonstrated using this technology. An assay has been developed to determine the HCV genotype using pyrosequencing.[81] We have also used this method to differentiate the human polyomaviruses that may be recovered from human tissues and body fluids.[20]

Many of the pyrosequencing applications described for clinical microbiology laboratories use a broad-range PCR



■ **FIGURE 4-14** DNA sequence by pyrosequencing. This pyrogram was generated from a clinical specimen that contained acid-fast bacilli. Real-time PCR followed by pyrosequencing was performed because of the possibility of tuberculosis. The sequence generated, which is from the hypervariable region A of the 16S rDNA gene, identified the isolate as *M. intracellulare*.

for the microorganisms of interest, followed by the investigation of a compact variable region that confers the genetic information of interest. There are many additional potential applications for sequencing by synthesis for the diagnosis of infectious disease and for the characterization of the infecting microorganisms and the host. These applications may include the identification of the causative agents of infection and the detection of resistance-associated genetic mutations. Furthermore, the

characterization of SNPs or other genetic polymorphisms that may increase the risk of infection in the host could also be determined by this technology. To this end, we have used this technology to perform human toll receptor genotyping to study the effect of this mutation on human susceptibility to infection. Unfortunately, commercially available kits are not yet available; so users must rely on laboratory-developed assays, which has limited the widespread use of this technology.

Next-Generation Sequencing. Next-generation sequencing (NGS) may be performed using a variety of sequencing methods that have been developed to perform massive parallel sequencing (Image Plates 4-2E and F). These methods afford the opportunity to perform DNA sequencing of a large number of amplified products simultaneously and to sort this extensive amount of data using bioinformatics tools. Alternately, there are applications that afford long-read, single-molecule sequencing.

There are numerous potential applications in the area of microbiology. There is an entire subsection of our discipline that is utilizing this technology to study the microbiome. The human, microbiome, environmental interactions will prove to be a rich area of research and discovery for many years to come. Other groups have used a method termed *shotgun* NGS for pathogen discovery, which may have more immediate applications in clinical medicine. Finally, it is now possible to sequence entire bacterial genomes within a day using this technology. Such applications have been used in the ultimate strain typing assays to study epidemics. A detailed discussion of this technology, which is still in the early stages, is beyond the scope of this text, but select references are provided.

Microarray Analysis. A wide variety of microarrays have been used for many years in the basic sciences for many purposes, including infectious diseases.[14,26,33] These devices detect a multitude of signals simultaneously and may be used to detect genetic (DNA) targets, alterations in genetic targets, or differences in expression (mRNA).[33] They are useful in determining which genes are expressed and which genes are silenced in response to different stimuli. These discovery tools have proven useful when studying everything from infections to cancer. Briefly, products of nucleic acid amplification, which may be the result of broad-range PCR or RT-PCR, are applied to the microarray. The microarray consists of often thousands of hybridization sites, each of which provides information regarding the nucleotide composition of the amplicon. The signal generated from the microarray may be fluorescent or electrical. The major advantage of the microarray is its ability to examine thousands of hybridization reactions simultaneously. This feature also contributes to one of its major limitations, namely the amount of data generated from a single microarray may be overwhelming to the user and usually requires computers and advanced software packages for data analysis.

There have been modifications to this technology wherein only a very limited

number of hybridization sites are used. This approach affords the detection of a variety of different pathogens responsible for a particular type of disease (i.e., a syndromic approach to diagnostics). Some groups have employed microarray hybridization technology after organisms have grown in culture (i.e., blood culture). They have found that the growth (i.e., biologic amplification) is sufficient for the detection of the target organisms and a PCR step is not needed prior to amplification.

Clinical Applications. Microarray formats have been used extensively in discovery. They have been used to identify bacteria, mycobacteria, fungi, and viruses, to detect the genetic determinants of resistance, to study host response to infection, and to discover new drugs that may be useful to cure infections.[36,44,46,60,94,100,235,314] Regarding HIV, this technology has proven very useful for studying viral gene expression and the changes in the host cell expression profile after infection.[163,322,348,366,375]

There has been some realization to predictions made regarding the potential utility of microarrays in the clinical microbiology laboratory, with the introduction of two microarray platforms.[33] The GenMark eSensor system, which uses a bioelectric array following multiplex PCR/RT-PCR for the detection of respiratory viruses, was described earlier (Image Plates 4-2G and H). The Verigene system (Nanosphere, Northbrook, IL) is a limited microarray system that may be used with or without nucleic acid amplification (Image Plates 4-3A and B). One of the most exciting applications of this technology is the use of this system on blood culture bottles that signal positive. The Gram's stain is used to select the type of assay to be performed, a gram-positive panel, a gram-negative panel, and in the near future a yeast panel. These panels do not require PCR prior to hybridization with the microarray, since the growth or biologic amplification of the bacteria in the blood culture bottle provides sufficient target for detection. These panels contain an expanded group of organisms that are identified, as well as key genetic indicators of resistance.

The Verigene system may also be used to detect and differentiate the products of a multiplex PCR reaction, and thereby may be used to detect microbial pathogens directly in clinical specimens. The Verigene Enteric Pathogens Test, which is FDA approved, detects the common bacterial and viral pathogens that cause enterocolitis. This group also offers a *C. difficile* assay that detects both toxin genes as well as the ribotype 027 marker of hypervirulence. The Respiratory Virus Plus test detects influenza A and B viruses, identifies some viral subtypes, and detects the H275Y genetic marker of oseltamivir resistance. The Respiratory Pathogens Flex test is an expanded respiratory panel, which in addition to detecting influenza A and B and viruses RSV also detects adenovirus, human metapneumovirus, parainfluenza viruses 1–4, rhinovirus, and *Bordetella.* These and similar tests represent a major advance in the molecular syndromic approach to the diagnosis of infectious diseases.

156

Real-Time Nucleic Acid Amplification

Real-Time PCR, which is also commonly called **rapid-cycle PCR**, has evolved from a "new" technique into the manner in which almost all PCR assays are performed in the clinical laboratories. It is incorrect to abbreviate this as RT-PCR, as that designation has traditionally been used for RT-PCR. This section reviews that basics and select applications of this technology.

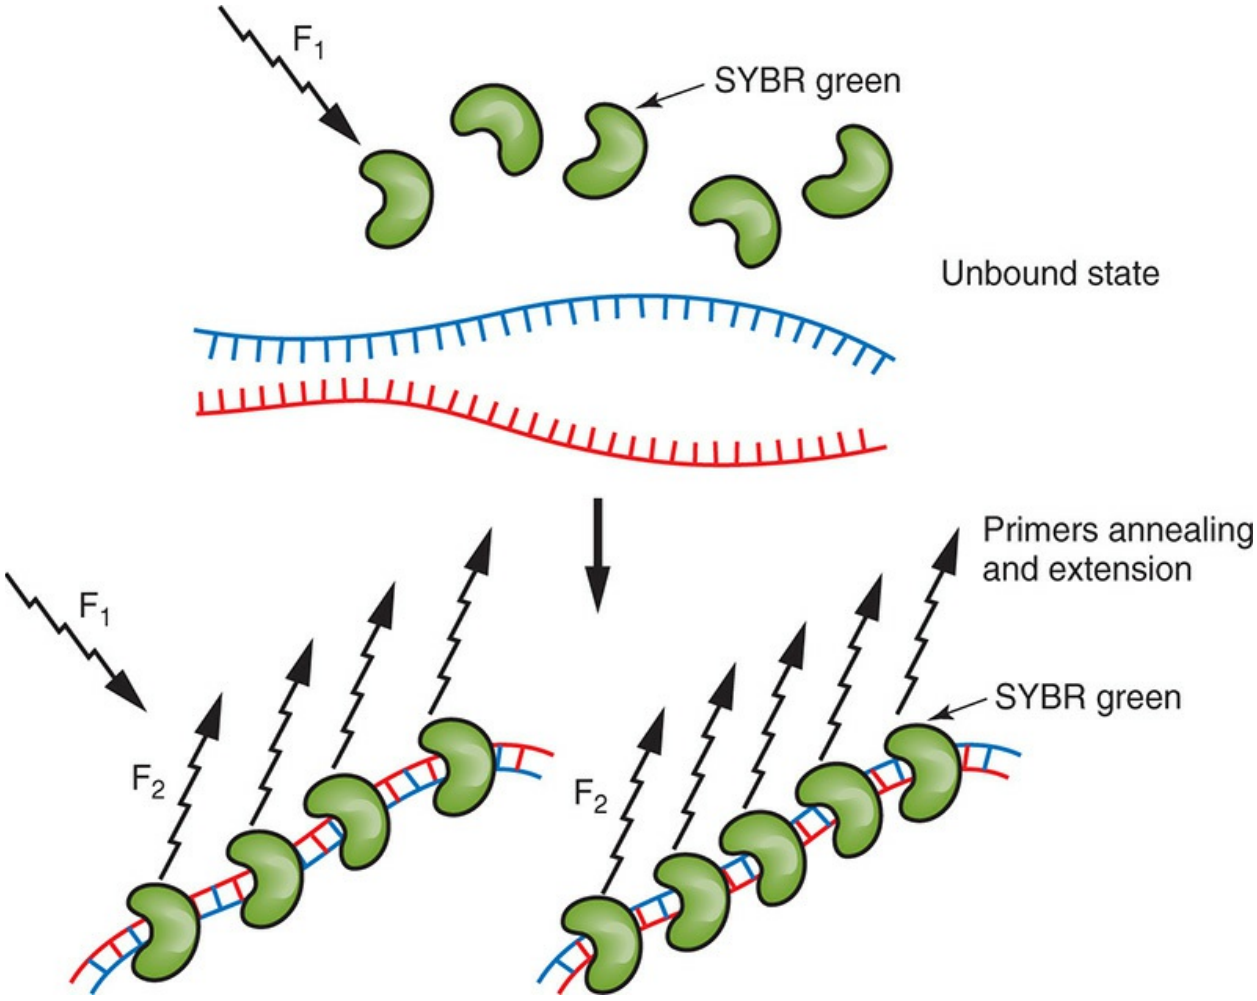
Two technologic advances resulted in the development of real-time nucleic acid amplification. The first was the development of methods of more rapid heat exchange (i.e., rapid heating and cooling) of the reaction chamber.[211] Traditional PCR, for example, occurs in a block cycler, in which the block consists of metal or some other solid material. The rate at which the solid block can be heated and cooled to the temperatures needed for PCR limits the rate at which the cycling may proceed. The rapid introduction of heated air and the removal of the heated air (cooling), which may be achieved through fans in real-time instruments, allows the cycling reaction to proceed more rapidly. The use of smaller reaction volumes also assists in the more rapid exchange of thermal energy. The second technical advance was in the development of a homogeneous reaction mixture.[211] This is a mixture in which the fluorogenic molecules that are used for the detection of the amplified products are present within the same reaction vessel in which amplification occurs. Furthermore, an assessment of the fluorescence from these molecules is usually obtained by the instrument once per amplification cycle. Evidence of amplification occurs during the PCR reaction in "real-time," which is why these assays are commonly referred to as real-time PCR. This type of amplicon detection represented a significant advance in nucleic acid chemistry, since it was more rapid than traditional methods of amplicon detection. In addition, this closed-tube system results in a significant reduction in the chance of amplicon contamination of the laboratory, since the reaction vessel does not have to be opened to analyze the amplicon. There are a variety of platforms available for real-time nucleic acid amplification[98] (Image Plates 4-1G and H). In addition to real-time PCR, the NASBA reaction, in the past, has been modified to a real-time format with detection using molecular beacons (see below). There is the possibility of modifying any nucleic acid amplification technology to a real-time format.

Methods of Detecting the Products of Real-Time Amplification

There are a variety of fluorogenic molecules that may be used for the detection of amplified nucleic acids in a homogeneous or real-time reaction. These may be

nonspecific, detecting any amplified nucleic acid, or specific, such as oligonucleotide probes, which hybridize with a specific sequence present in the amplicon. The nonspecific detection of amplicon using SYBR green and the use of third-generation binding dyes, as well as the three most commonly used types of oligonucleotide probes methods used for specific amplicon detection, will be covered. The specific fluorophore-labeled oligonucleotide probes that will be discussed are the hydrolysis probe (i.e., TaqMan) fluorescence resonance energy transfer (FRET) probes, and molecular beacons. Other types of detector molecules are also available, but a discussion of these is beyond the scope of this text.

SYBR Green. SYBR Green I is a dye that binds to the minor groove of double-stranded DNA. This dye emits very little fluorescence when in the unbound state, but generates considerably more fluorescence when bound to double-stranded DNA (Fig. 4-15). This property makes it useful for determining the presence of an amplified DNA product.



■ **FIGURE 4-15** SYBR green chemistry. SYBR Green I dye binds to the minor groove of double-stranded DNA. When DNA is single stranded, there is no minor groove; so SYBR green does not bind to DNA. However, after primer annealing and extension, SYBR green can bind and emit light (F_2) in response to the appropriate excitation wavelength (F_1). SYBR green is an excellent method of measuring nonspecific amplicon generation, since the more DNA is produced by PCR the more binding sites there are available for binding and the more fluorescence is generated.

157

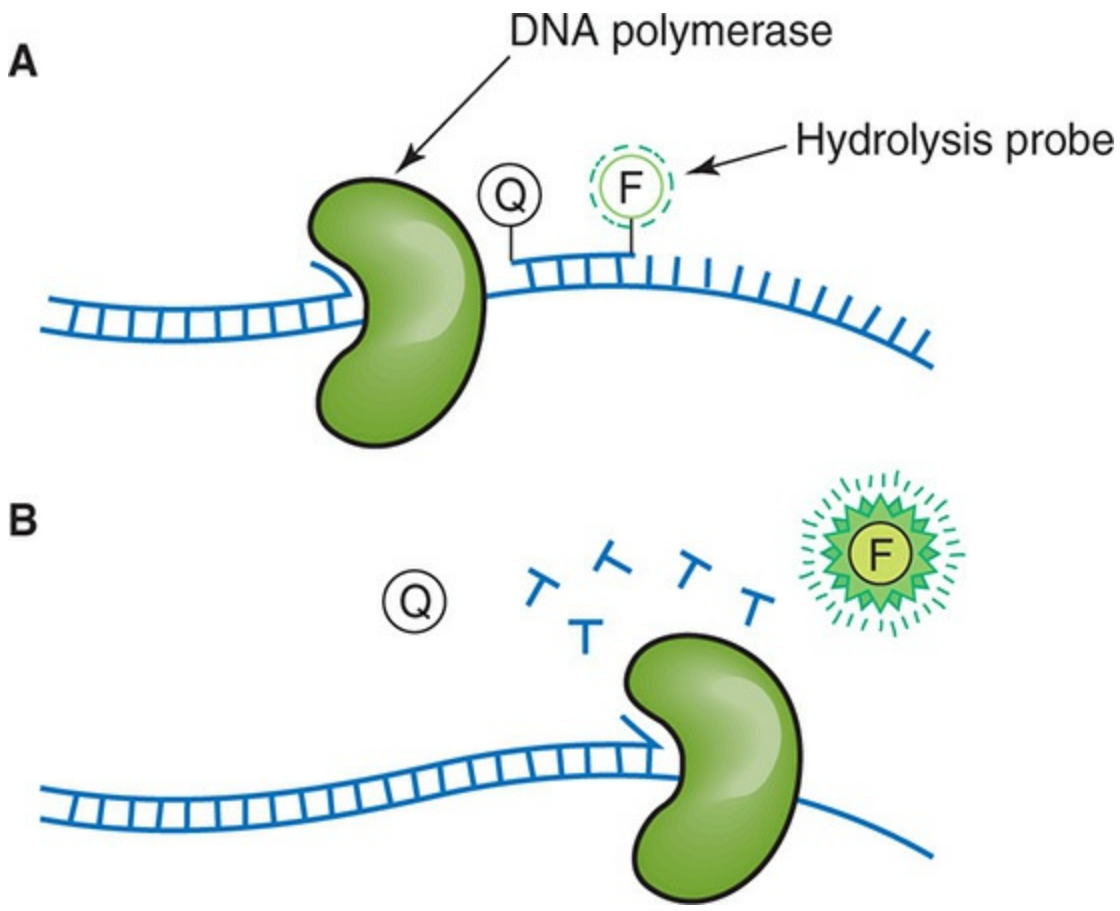
Multiple molecules of SYBR green may bind to a single amplicon, thereby making it a sensitive method of amplicon detection. Also, this dye is much less expensive than specific oligonucleotide probes that are labeled with fluorophores. The detection of amplicons using SYBR green is useful for optimizing the PCR reaction (i.e., determining the optimal concentrations of the primers and $MgCl_2$). It is also useful to determine if amplification has occurred prior to a definitive method of postamplification analysis, such as DNA sequencing or microarray analysis. The main disadvantage of SYBR green detection is that it is nonspecific and these detector molecules will bind to any double-stranded DNA, including the products of nonspecific amplification and primer dimers. This method of detection lacks the specificity achieved with the use of an oligonucleotide probe (described below). It is for this reason that SYBR green detection should never be used as the sole method of detection in a clinical assay.

Third-Generation DNA-Binding Dyes. Advances in double-stranded DNA-binding dyes have resulted in what has been termed *third-generation binging dyes*. These dyes more fully saturate the amplified DNA molecule, so much so that upon melt-curve analysis it is possible to differentiate even SNP. This is an inexpensive, sensitive means of assessing for a SNP, and when this SNP is located in an important location of deriving meaningful information. Although commercially available assays have not been developed, we commonly utilize this methodology to differentiate *M. abscessus* from *M. chelonae,* and use it to identify inducible clarithromycin susceptibility. We have also developed assays to detect the SNP responsible for a toll receptor mutation (discussed earlier) and to differentiate *Plasmodium falciparum* from other *Plasmodium* species.

Hybridization Probes. There are many different types of fluorescently labeled oligonucleotide probes that may be used for amplicon detection in a real-time PCR assay. The three that will be discussed are the most commonly used and cover the most important aspects of real-time detection chemistry. These are the hydrolysis

probes (i.e., Taqman probes), the FRET probes, and molecular beacons.

Hydrolysis or Taqman Probes. The hydrolysis probe detection chemistry relies on the 5′ to 3′ exonuclease activity of DNA polymerase. This function of DNA polymerase hydrolyzes any oligonucleotide that may bind to the single-stranded portion of the DNA molecule for which the complementary strand is being synthesized. In nature, this helps to ensure that only the appropriate nucleotides are incorporated into the newly synthesized strand of DNA. The hydrolysis probe chemistry exploits this property of DNA polymerase to generate a detectable signal. The hydrolysis oligonucleotide probe is labeled with both a fluorophore and a quencher molecule. In the absence of specific target, this molecule folds up to a certain degree, which places the quencher molecule in close enough proximity to the fluorophore so that the majority of any fluorescent signal emitted is immediately absorbed. When this probe binds to the complementary portion of DNA that has been generated by the previous cycles of PCR, it is hydrolyzed by DNA polymerase (Fig. 4-16). This hydrolysis affords the diffusion of the fluorophore away from the quencher molecule and the generation of light that is not quenched and, therefore, detectable.

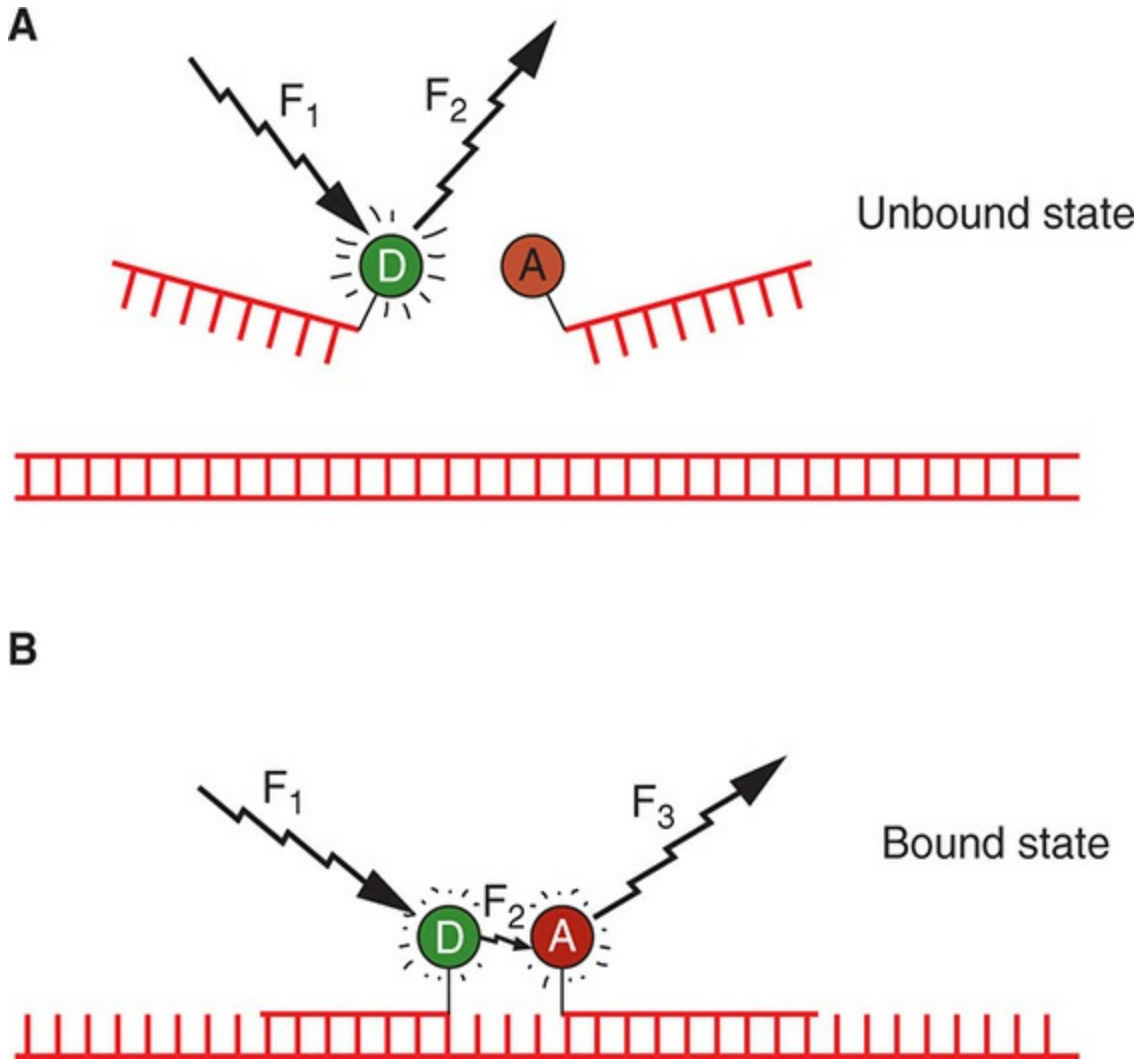


■ **FIGURE 4-16** Hydrolysis probe chemistry. **A.** The close proximity of the quencher

molecule (*Q*) to the fluorescent molecule (*F*), both of which are attached to the intact hydrolysis probe, results in only minimal background fluorescence. **B.** The hydrolysis of this probe by the exonuclease activity of DNA polymerase as extension occurs results in diffusion of the fluorophore from the quencher molecule, so that fluorescence may occur when the fluorophore is appropriately excited.

FRET Probes. FRET probes function through the transfer of energy. In this system, there are two detector probes used instead of one. These probes hybridize in close proximity to one another on the amplicon, with a two- to five-nucleotide gap between the two probes. The probe on the upstream side of the pair has a fluorescein molecule attached to the 3′ end of the probe, and may be termed the *donor molecule*. The second probe in the FRET set is situated downstream in relation to the first probe, has an acceptor molecule, usually LC640 or LC705 when used with the LightCycler system, on the 5′ end of molecule; this has been termed the *acceptor molecule*. Other acceptor molecules may be used, but they must have the property of being excited by the wavelength of light that is emitted by the fluorescein or another donor molecule and, in turn, to emit light of another, detectable wavelength. In addition, the label on the 5′ end of the acceptor probe, this probe must be phosphorylated to prevent probe extension during PCR. Detection with the FRET probes works as follows: if the appropriate probe hybridization sequence is present in the amplicon, the FRET probes will hybridize. At this time, the donor molecule (the fluorescein) is excited by light energy introduced into the system by the instrument. When the excited donor molecule returns to its base energy state, it releases light of a particular wavelength. This released light excites the nearby acceptor molecule (LC640 or LC705), completing resonance energy transfer. The acceptor molecule is in turn excited to a heightened energy state. When the acceptor molecule returns to its base energy state, it releases light energy that is detected by the system (Fig. 4-17). Detection using FRET-based chemistry is by its nature highly specific, since the only way to receive the final energy signal is for four independent reactions occur. These independent reactions are the hybridization of the two individual primers that afford amplification and the hybridization of each of the probes that afford detection (Fig. 4-18).

158



■ **FIGURE 4-17** FRET. Two probes, both of which are labeled with a fluorophore, are necessary to achieve FRET. **A.** The excitation wavelength (F_1) of the donor fluorophore (D) raises the energy state of the molecule and an emission occurs (F_2). This does not affect the acceptor fluorophore (A) when the probes are not hybridized, because they are not in close proximity to one another. **B.** When the two probes are hybridized and near to one another, then the emitted light from the excited donor fluorophore (F_2) acts as the excitation energy for the acceptor fluorophore, which in turn emits an particular wavelength of light of its own (F_3). The presence of the emission (F_3) from the acceptor molecule is evidence that probe hybridization has occurred.

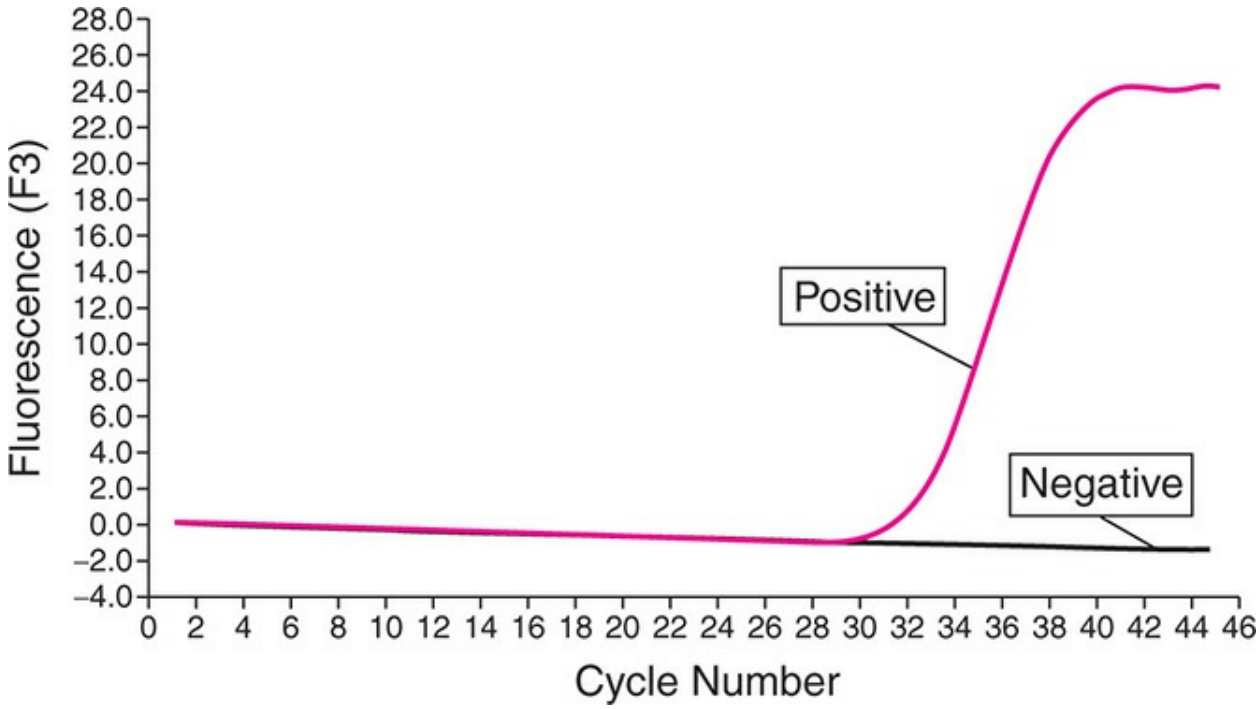
The use of FRET probes also allows the user to perform a postamplification melt-curve analysis. This is possible because of the nature of FRET probe interactions and the fact that unlike hydrolysis probes these probes are not hydrolyzed during detection. The reader will recall that the hydrogen bonds are responsible for the

hybridization between the oligonucleotide probes to the complementary DNA strand. When thermal energy is added to the system that exceeds the energy of these bonds, the bonds will be broken and the probe will "melt off" the complementary DNA target. The point at which half the probe molecules are bound and half are unbound is the melting point or T_M of the oligonucleotide.

Melting-curve analysis is performed after the PCR reaction is complete. Initially, the reaction mixture is cooled to a point well below the T_M of the individual FRET probes so that both will hybridize if the appropriate amplified DNA is present. At this point, an excitation wavelength of light is introduced into the instrument and a signal will be generated from the FRET reaction that occurs between the juxtaposed probes. Next, the reaction mixture is then slowly heated while continuous fluorescence measurements are taken. When the reaction mixture reaches and finally exceeds the T_M of the FRET probes, there will be a precipitous loss in the fluorescence signal. The first derivative of the slope of this curve results in a peak (Fig. 4-19). The perpendicular line that may be drawn through the center of this peak represents the experimentally derived T_M.

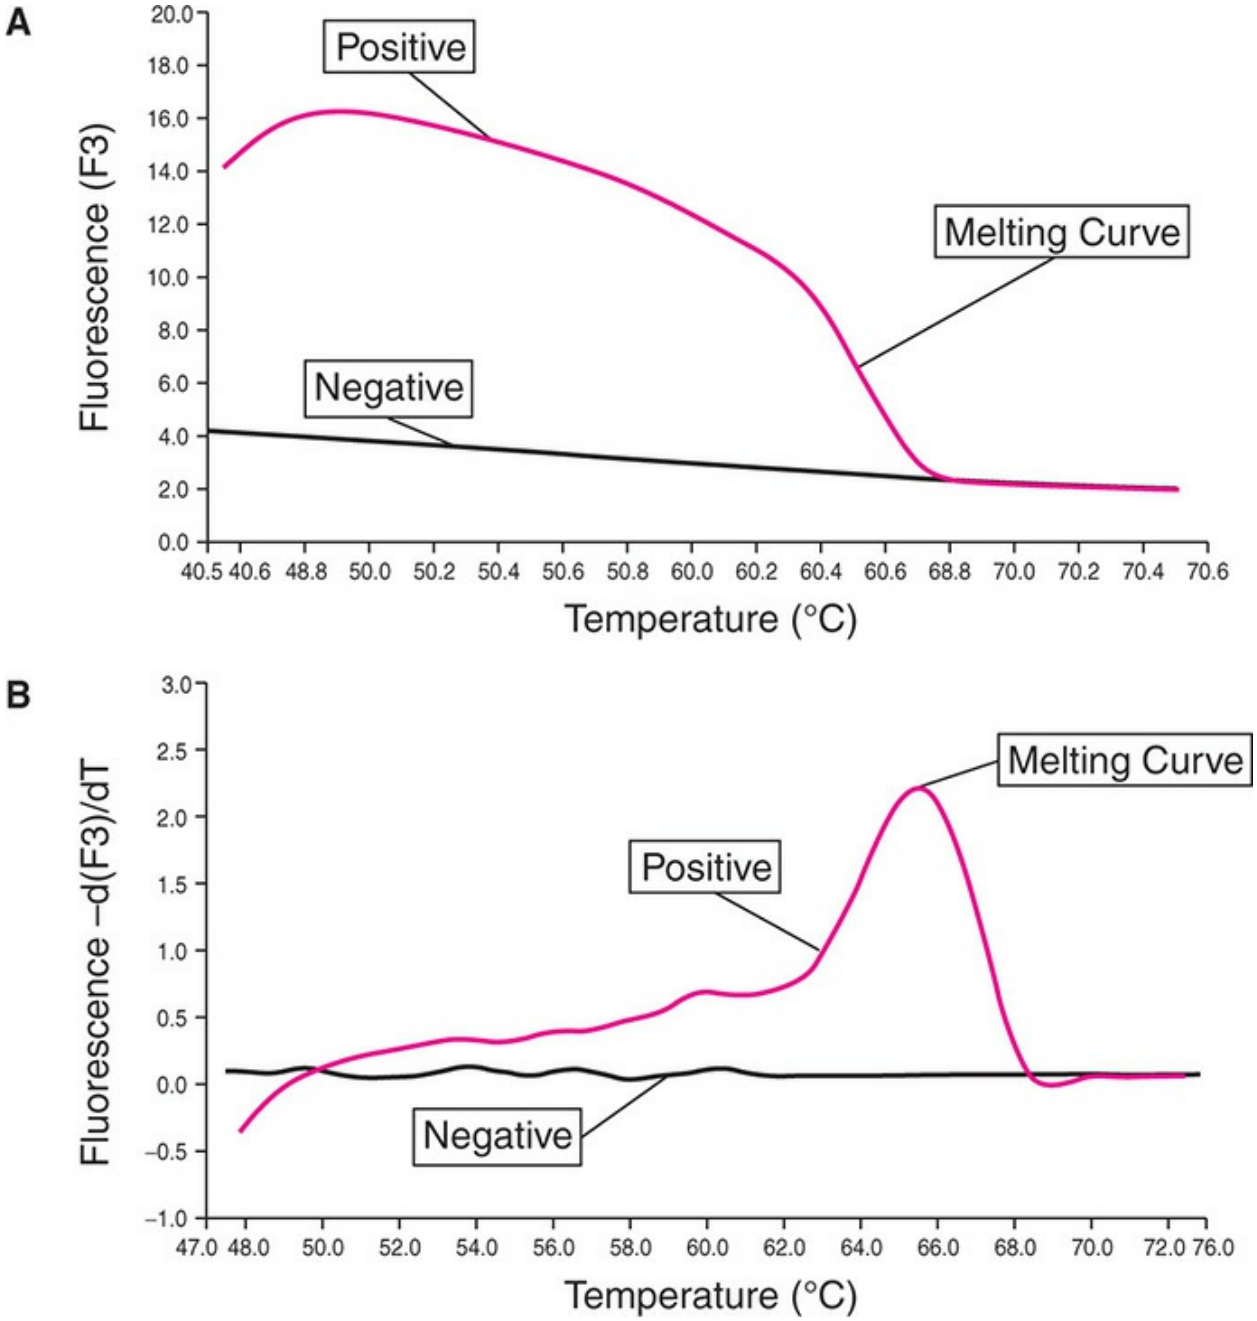
There are at least three important uses for melt-curve analysis. First, there should be a relatively predictable melting temperature for the expected amplicon, which may be confirmed using known standards. The demonstration of the appropriate melting temperature helps assure the user that the identification is correct, rather than a misidentification potentially obtained through the amplification and detection of a taxonomically related organism. Secondly, postamplification melt-curve analysis may be used to differentiate closely related organisms, where the probe hybridizes to an target area wherein there is a small degree of genetic variability that separates the species. Finally, the detection of nucleotide mismatches between the FRET probes and their corresponding probe hybridization site, just like that used for organism differentiation, may be used to detect other clinically important SNPs, such as those that may confer resistance to antimicrobials or those in the host that may denote relative susceptibility to infection.

Molecular Beacons. The next type of detector molecule to be discussed is the molecular beacon. This molecule, like the hydrolysis probe, contains both a fluorophore and a quencher molecule. The molecular beacon, however, is larger than typical hydrolysis probes and is not hydrolyzed by the DNA polymerase in order to achieve fluorescence in the presence of the appropriate amplicon. This molecule has a loop-and-stem configuration (Fig. 4-20). The loop portion of the molecule is the part of the molecule that is complementary to a specific part of the amplicon. The stem is a construct of complementary nucleic acids designed to keep the

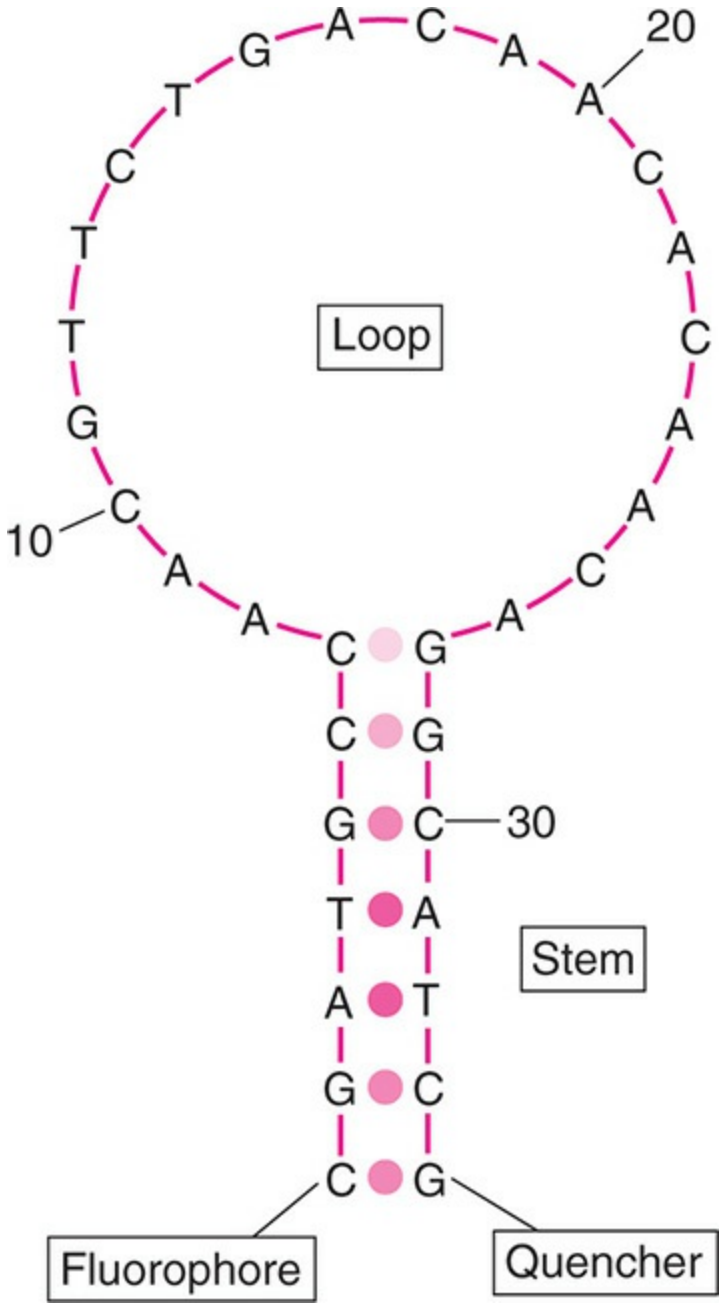


■ **FIGURE 4-18** Positive and negative real-time PCR reactions. Positive real-time PCR reactions demonstrate an exponential increase in fluorescence, whereas the negative reactions retain only low, basal levels of fluorescence.

159



■ **FIGURE 4-19** The melting curves (**A**) and the first derivative of the curve the melting peaks (**B**) are demonstrated for one positive and one negative specimen in a real-time PCR that specifically detects *Staphylococcus aureus*.



■ **FIGURE 4-20** This molecular beacon was designed to detect the amplified product of a broad-range *Salmonella* PCR. It consists of 34 nucleotides and has a stem-loop configuration. This structure places the fluorophore in close proximity to the fluorescence-quenching molecule when the molecular beacon is not hybridized with its genetic target (i.e., the PCR is negative). When the appropriate amplicon is present, the thermodynamics favor hybridization over the stem-loop configuration, the molecule opens and hybridizes, and fluorescence is discernible, as the fluorophore is spatially separated from the quencher.

molecule closed, in the absence of a specific amplicon. The two respective ends of the

molecular beacon probe molecule are the sites of attachment for the fluorophore and quencher molecules. The fluorophore is juxtaposed with the quencher molecule when the beacon is closed (i.e., when it is not in the presence of the appropriate amplicon). When the beacon is in the presence of the appropriate amplicon, the thermodynamics favor hybridization with the amplicon over the closed, semi-self-hybridized state. When the molecular beacon is hybridized, the fluorophore is spatially separated from the quencher, and fluorescence can be detected by the instrument. Melting curves can be achieved with molecular beacons, but it is much more difficult to achieve the same quality of melt-curve results as those achieved with FRET probes.

It may seem difficult for the molecular microbiologist to choose which type of detector molecule to use for a real-time nucleic acid amplification assay. In part, this may be dictated by the type of instrumentation present in the laboratory. For example, if a SmartCycler is purchased, a molecular beacon or hydrolysis would be favored, whereas for the LightCycler, FRET-probe chemistry is favored. The ABI 7500 series (Applied Biosystems, Foster City, CA) and Roche (COBAS) TaqMan (Roche Diagnostics, Indianapolis, IN) platforms use hydrolysis probes. Some platforms, such as the RotorGene (Qiagen), are biochemically agnostic and support any type of probe chemistry. For the most part, the same ends (i.e., detection of the microorganism of interest) can be achieved by a variety of different means. The other major factor in determining the type of probe to use on a particular segment of DNA is the nucleotide composition of that segment. Factors that may influence probe selection include the G-C content of the region and the presence of secondary structure, among others.

160

Clinical Applications. There are far too many applications to completely review here. In short, anything previously detected by traditional PCR has been migrated to a real-time PCR platform. The relative ease of this migration has contributed significantly to the implementation of real-time assays for a wide variety of clinically important microorganisms. The commercial availability of a wide variety of assays, the ease of use, the rapid turnaround time, the availability of assay design software for the development of laboratory-developed tests, and the closed-tube nature of these systems has facilitated the implementation of this testing in the clinical laboratory. These assays are not only used for the detection of the fastidious pathogens that have traditionally been approached using PCR, but also for common microorganisms that have been traditionally detected by culture (e.g., *S. aureus*) or EIA (e.g., *C. difficile*). Real-time assays for DNA viruses include assays for the herpesviruses, adenovirus, smallpox virus, and parvovirus B19, among others.[126,140,146,168,184,318,332,344] Postamplification melt-curve analysis has been used to differentiate HSV type 1 from HSV type 2, and such assays are commercially available and some are FDA

approved.[381] The quantitative nature of these assays has also been used to predict disease and monitor the viral load in response to therapy.[11,116,121,168,311,374] Quantitative PCR for the detection and monitoring of HIV, HCV, CMV, EBV, and the BK virus has become the standard of care. Real-time RT-PCR and similar technologies for RNA viruses include broad-range assays for enteroviruses that cause viral encephalitis and individual and multiplex assays for the detection of respiratory viruses.[27,55,129,176,284,330,369,370,376,378] RT-PCR for influenza A and B viruses and RSV has essentially replaced cell culture for the detection of these viruses. Real-time assays have also been used to rapidly more recently recognized and emerging viral pathogens, such as human metapneumovirus and the SARS coronavirus.[59,120,198,212,213,269,270] There are several FDA-approved respiratory viral panels that include essentially all respiratory viruses of medical importance.

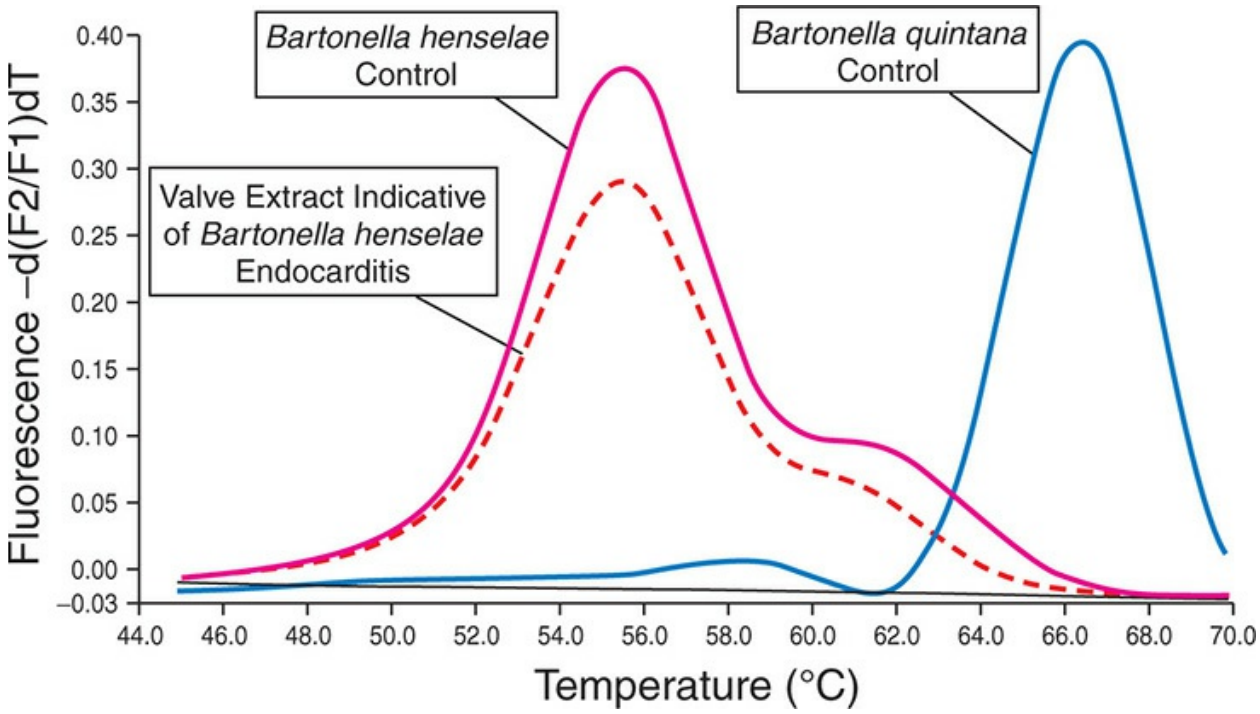
Numerous assays have been described that detect bacteria and the genes associated with resistance. There are several assays for the detection of group B *Streptococcus* for prenatal screening during pregnancy. There are also several platforms to choose from for the detection of methicillin-susceptible and methicillin-resistant *S. aureus*. These applications include the detection of nasal colonization, use on positive blood cultures that contain gram-positive cocci in clusters and wounds. There are assays for the detection of group A *Streptococcus,* which are primarily used as a more sensitive replacement for culture. A major change has been the virtual replacement of toxin-detecting immunoassays for *C. difficile* with rapid-cycle PCR. There is, however, some controversy surrounding this test, as it is so sensitive that it also likely detects patients with colonization; therefore, only detecting patients with the appropriate clinical presentation is very important.

In addition, the literature is replete with examples of real-time amplification assays for the detection and differentiation of a variety of microorganisms and resistance-associated genes. Many of these assays target the traditional microorganisms that do not grow on artificial media or are extremely difficult to culture, such as *Tropheryma whippelii*, *Rickettsia*, and *Bartonella* species.[92,170,389] Postamplification melt-curve analysis also has been used to differentiate the most common *Bartonella* species (Fig. 4-21). In addition to these applications, as PCR in the real-time formats has become widespread and more user-friendly, it is being applied to commonly encountered bacteria and their mechanisms of resistance. For example, real-time PCR and other molecular methods have been shown to be a reliable and more timely method for the differentiation of *S. aureus* from coagulase-negative staphylococci in blood culture bottles that signal positive and contain gram-positive cocci, and is a reliable method for determining oxacillin resistance in these *S. aureus* isolates.[326]

Real-time assays for fungi include assays for organisms that cannot be cultivated in the routine clinical microbiology laboratory, such as *P. jiroveci*, and for slow-growing

organisms, such as *H. capsulatum*.[158,174,197,218,227,255] We have demonstrated a greater than twofold increase in the sensitivity of PCR for *Pneumocystis* over a morphologic assessment of stained respiratory smears. Other applications have included the detection of invasive mold and yeast infection in immunocompromised patients and the detection of other systemic dimorphic fungal pathogens, such as *Coccidioides* and *Penicillium marneffei*.[24,158,267,272,276,288,336]

Another important application for these assays has been the rapid detection of mycobacteria, particularly *M. tuberculosis*. Mycobacteria are excellent candidates for detection



■ **FIGURE 4-21** Postamplification melt-curve analysis. Postamplification melt-curve analysis may be used to differentiate closely related species. In this example, the causative agent of the culture-negative endocarditis, *Bartonella henselae*, is distinguished from *Bartonella quintana* using this technique.

161

and identification by molecular methods, since these microorganisms are slow-growing, some cause severe disease and death, and tuberculosis is a communicable disease for which transmission-control measures may be instituted. Several real-time assays have been developed for the rapid detection of *M. tuberculosis* directly from clinical specimens. Shrestha et al. describe a LightCycler assay that detects and

differentiates *M. tuberculosis* from nontuberculous mycobacteria using postamplification melt-curve analysis.[325] Excellent assays for the detection of *M. tuberculosis* are also available for SmartCycler and TaqMan users.[50,71,304] Assays have also been developed for the rapid detection of resistance to commonly used drugs, such as isoniazid and rifampin.[297,308,364] The Cepheid Xpert MTB/RIF is the only FDA-approved assay that detects *M. tuberculosis* and genetic targets of rifampin resistance.[38] This is performed in the standard Cepheid cartridge, which is easy to use and produces results in about an hour. This assay represents a significant advance in the detection of multidrug-resistant *M. tuberculosis.*

The detection and identification of parasites has also been approached using real-time nucleic acid amplification assays. A number of assays have been described for the rapid detection of otherwise difficult to detect parasite *Toxoplasma gondii*.[57,167,204] Other applications include the detection of stool parasites, such as *Cryptosporidium* and microsporidia, the identification of tissue parasites, such as *Leishmania* and *Trypanosoma*, and the detection and differentiation of the *Plasmodium* species, among many other applications.[22,31,43,61,86,96,150,229,319,377,383] Likely, the greatest advance in commercially available molecular parasitology was the release of the FDA-approved APTIMA *Trichomonas vaginalis* assay (Hologics, San Diego, CA). This assay, like many of the others from this company, uses TMA amplification. This assay is more sensitive than microscopy; in some studies the sensitivity was better than lateral flow EIA, whereas in other studies the sensitivities were equivalent.[157,245] The cost-effectiveness of screening all asymptomatic women has been called into question by Hathorn et al., because of the low prevalence of disease in this population; they offer an alternative suggestion of screening asymptomatic individuals in high-risk groups.[142] The precise way in which this assay fits into women's health programs remains to be determined.

Strain Typing

Hospital microbiologists and epidemiologists may need to determine relatedness among bacteria or fungi of the same species to determine if transmission of the organism of interest has taken place in a manner that may be addressed by infection control. For example, if *P. aeruginosa* has been isolated from four babies in a neonatal intensive care unit, the hospital epidemiologist may wonder if these are the same bacterial strain that has been transferred from a point source or if they are different strains and the infection has occurred merely by chance. The determination that the bacteria are all of the same strain strengthens the evidence that there is a point source of transmission of the bacteria and that there is a breakdown in techniques or personal hygiene, all of

which may be corrected.

Phenotypic methods of strain typing preceded genotypic methods, but many of these lack the high degree of discrimination that may be achieved by genotypic strain typing. Some others, such as bacteriophage typing, require a high degree of specialized expertise and the maintenance of considerable resources (i.e., libraries of bacteriophages). Antimicrobial susceptibility profiling, although not as definitive as some of the genotypic methods of profiling, is valuable, and uses information that is often already available because of susceptibility testing performed to guide therapy. Bacteria that have very different antimicrobial susceptibility profiles are likely not identical and therefore probably do not warrant more expensive genotypic strain typing.

The earliest molecular attempts at demonstrating relatedness among different groups of bacteria were accomplished with simple DNA–DNA hybridization studies. Groups of bacteria with high degrees of DNA homology, as determined through DNA–DNA hybridization studies, were considered to be more closely related, compared with groups that had poor DNA homology when compared with one another. For the most part, these studies confirmed what was considered to be true from phenotypic testing. For example, the DNA–DNA hybridization studies between *Staphylococcus* and *Micrococcus*, which are in the same family, would demonstrate greater homology than would a comparison between *Staphylococcus* and *Pseudomonas*.

Plasmids are small, circular DNA molecules that are present in many bacteria and exist separately from the chromosomal DNA. Plasmids are important because they may contain genes important for virulence, including genes that impart resistance to antimicrobial agents. Plasmids may also spread from one bacterium to another via conjugation and thereby disseminate these genes. Developments in electrophoresis that allowed for the separation of plasmids from the chromosomal DNA, and the differentiation of plasmids from one another, made possible plasmid profiling as an early means of strain typing. Plasmid profiling was one of the earliest genetic methods used to determine strain relatedness.

There have been many genetic methods described for analyzing the relationship of microorganisms. Methods that are not discussed here but that have proven useful include ribotyping, random amplified polymorphic DNA (RAPD) analysis, spoligotyping, and most recently applications of NGS.

Molecular typing methods may be categorized as those that require nucleic acid amplification for the typing process (amplification-based methods) and those that do not (non–amplification-based methods). This chapter will discuss one non–amplification-based method, pulsed-field gel electrophoresis (PFGE), which has been considered by many to be the standard for microbial typing. Two amplification-based typing methods will be discussed, PCR-RFLP, which combines the strengths of PCR with the typing of RFLP, and Rep-PCR, a typing method that targets repetitive genetic elements that occur naturally in bacteria.

Non–Amplification-Based Typing

Pulsed-Field Gel Electrophoresis. There are many strain typing methods that vary in the degree of separation that may be detected, cost and ease of use. Many of the

current methods of molecular strain typing rely on the use of a group of enzymes called **restriction endonucleases**. These enzymes are naturally occurring enzymes that cleave double-stranded DNA based on particular sequences termed *restriction sites*. Different enzymes cleave based on different sequences, and a variety of restriction endonucleases are commercially available. When the enzymes cleave the DNA, the two ends of the DNA produced may be either blunt or may have overhanging nucleotide (i.e., so-called sticky ends). When microbial chromosomal or plasmid DNA is extracted from the organisms and exposed to one or more restriction endonucleases, it will be cleaved depending on the restriction endonucleases used and the number of restriction sites present in the DNA. The fragments of DNA that result will vary in size, and may be separated from one another by gel electrophoresis and visualized by staining with ethidium bromide. This is a RFLP analysis. Microorganisms with the same RFLP pattern are likely to be closely related, whereas those with very different RFLP patterns are less likely to be closely related. Although RFLP patterns are highly reproducible and very accurate, problems may arise in assessing the hundreds of DNA fragments that may arise following restriction enzyme digestion. PFGE was devised as a means to simplify RFLP typing.

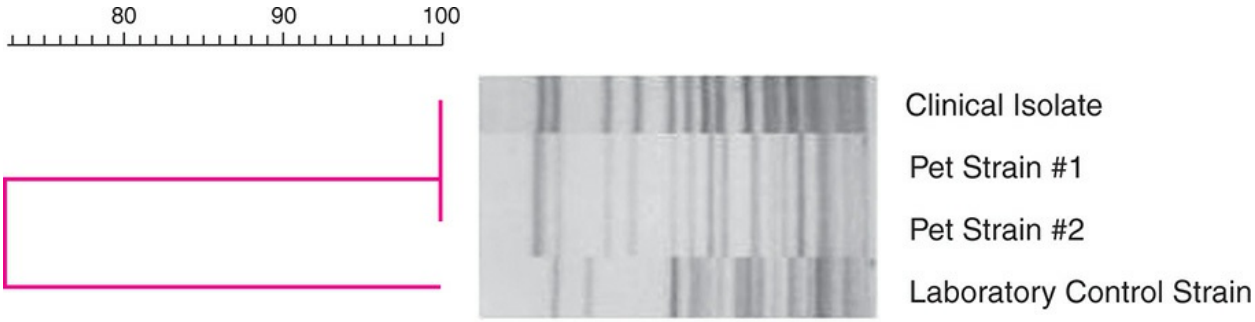
PFGE is considered by many to be the standard form of strain typing, to which newer methods should be compared. In short, this technique begins with the extraction of the chromosomal bacterial DNA of the strains of interest, which are exposed to a variety of restriction endonucleases. The type of restriction endonucleases used is usually determined by the type of bacteria under analysis, based on previous research that has demonstrated the efficacy of these enzymes. As above, the restriction endonucleases cut the chromosomal DNA into a variety of pieces, depending on the number of restriction sites present in that particular strain. The fragments of chromosomal DNA are then separated using a specialized type of electrophoresis. The chromosomal restriction profile resulting from PFGE usually results in 5 to 20 fragments that range in size from 10 to 800 kb[350,352] (Fig. 4-22). These are visualized, photographed, and submitted for image analysis. Computer programs are then used to determine if the strains under analysis are indistinguishable or distinguishable and the degree to which these may be distinguished. The process has been termed *DNA fingerprinting* when the process of RFLP is combined with Southern blot transfer and probe hybridization.[350]

Amplification-Based Typing

There are a number of postamplification methods of analysis that may be used for microbial typing. The newest and most powerful are being developed using NGS. The standard amplification-based typing methods include single-stranded conformation polymorphism analysis, amplified fragment length polymorphisms, arbitrarily primed PCR, RFLP analysis of the PCR product (PCR-RFLP), and analysis of PCR products of repetitive elements present in bacterial genomes (rep-PCR). The discussion of all these methods is beyond the scope of this text. We will briefly describe the latter two types of analysis, PCR-RFLP and rep-PCR, as examples of amplification-based methods of microbial typing

PCR-RFLP. Just as restriction endonucleases may be used to ligate the chromosomal DNA of bacteria, these enzymes may also be used to cleave an amplicon. The selection of the endonuclease(s) used with PCR-RFLP must be chosen with care, since the amplicon is orders of magnitude smaller than the bacterial chromosome and is less likely to randomly contain restriction sites. The enzymes are often chosen based on previous knowledge of restriction sites that are variably present in the amplicons and, therefore, may be useful for the comparison of strains. The size of the amplicon and the number of potential restriction sites that it may contain imposes limitations on the differentiating capabilities of this technology.

RFLP analysis of the PCR product is commonly performed on assays directed against the rDNA. When the PCR product of an assay that targets the rDNA is analyzed by RFLP, it may be referred to as PCR ribotyping. Even when the rDNA is analyzed, it is important to target particular areas, to achieve type-specific information.[169,185] PCR-RFLP has been used to type all different kinds of microorganisms, including bacteria such as *Campylobacter* and *Borrelia* species and atypical fungi such as *P. jiroveci*.[58,160,199] In addition to strain comparisons, PCR-RFLP patterns may be used for organism identification. The use of this technology in this manner relies on the use of highly specific PCR primers. This technique, for example, has been used to identify fastidious bacteria, such as *Bartonella* species, and difficult-to-identify parasites, such as hookworms and filarial worms.[104,105,171,294] This technology has also proven very useful for the differentiation of *Nocardia* species, which is clinically important given the differences in antimicrobial susceptibilities within this group.[208,338] The nonribosomal genes that are used for



■ **FIGURE 4-22** Pathogenic isolate of *Pasteurella multocida*. The analysis of a pathogenic isolate of *Pasteurella multocida* (clinical isolate) was genetically indistinguishable from two phenotypically different *P. multocida* isolates obtained from the patient's cat, but is clearly distinguishable from the laboratory control strain.

163

PCR-RFLP include either housekeeping genes, such as *rpoB*, or any gene that may contain strain-specific information for a particular group of organisms (i.e., the genes that encode for the enzymes responsible for hippurate hydrolysis for *Campylobacter jejuni*).[166,294,339]

REP-PCR. Repetitive DNA elements in prokaryotic genomes form the basis for rep-PCR. These repetitive elements are the hybridization sites for the primers used in rep-PCR. These primers, which are complementary to the interspersed repetitive sequences, generate through PCR amplification variably sized DNA fragments, which may be separated by gel electrophoresis (Fig. 4-23). The electrophoretic patterns may be used to determine the relatedness of bacterial strains that are being compared. A single primer set may be used for a variety of gram-positive and gram-negative bacteria, or more than one primer set may be used to target different repetitive elements. Rep-PCR has been used to type enterohemorrhagic *E. coli* isolates to investigate animal-to-human transmission.[95,102,321] It, like other typing techniques, has been used to track both gram-positive and gram-negative bacteria that are resistant to antimicrobial agents and those of importance to the hospital epidemiologist.[25,67,323,356] The information generated through rep-PCR may also be used for microorganism identification. This technology, for example, has been used to identify organisms and examine diversity with the *Streptomyces* genus and to identify *Bartonella* species.[196,300]

Clinical Applications of Microbial Typing. Genetic comparisons of microorganisms have been used to investigate outbreaks in hospitals, in cities, and even across the nation.[35,117,190,210,232,273,390] It is common for potential nosocomial outbreaks to be

investigated using genetic typing methods. A possibility of an outbreak is often suspected when the frequency of isolation of a pathogenic microorganism exceeds its usual baseline recovery rate. This may be in a particular place, such as the number of methicillin-resistant *S. aureus* blood isolates in the hospital in general or a ward in particular, or it may be the number of *Salmonella* isolates reported to a county health department.

Given the fragility of premature babies, these techniques are commonly used to investigate outbreaks in neonatal intensive care units.[188,234,309] Molecular typing methods are also commonly used to investigate infections caused by bacteria that are resistant to antimicrobial agents.[88,148,159,309] In some instances, genetic typing methods have been used to successfully determine the point source of an outbreak. Outbreaks and the transmission of *M. tuberculosis* are often studied using molecular typing methods.[79,189,307,329,351,372]

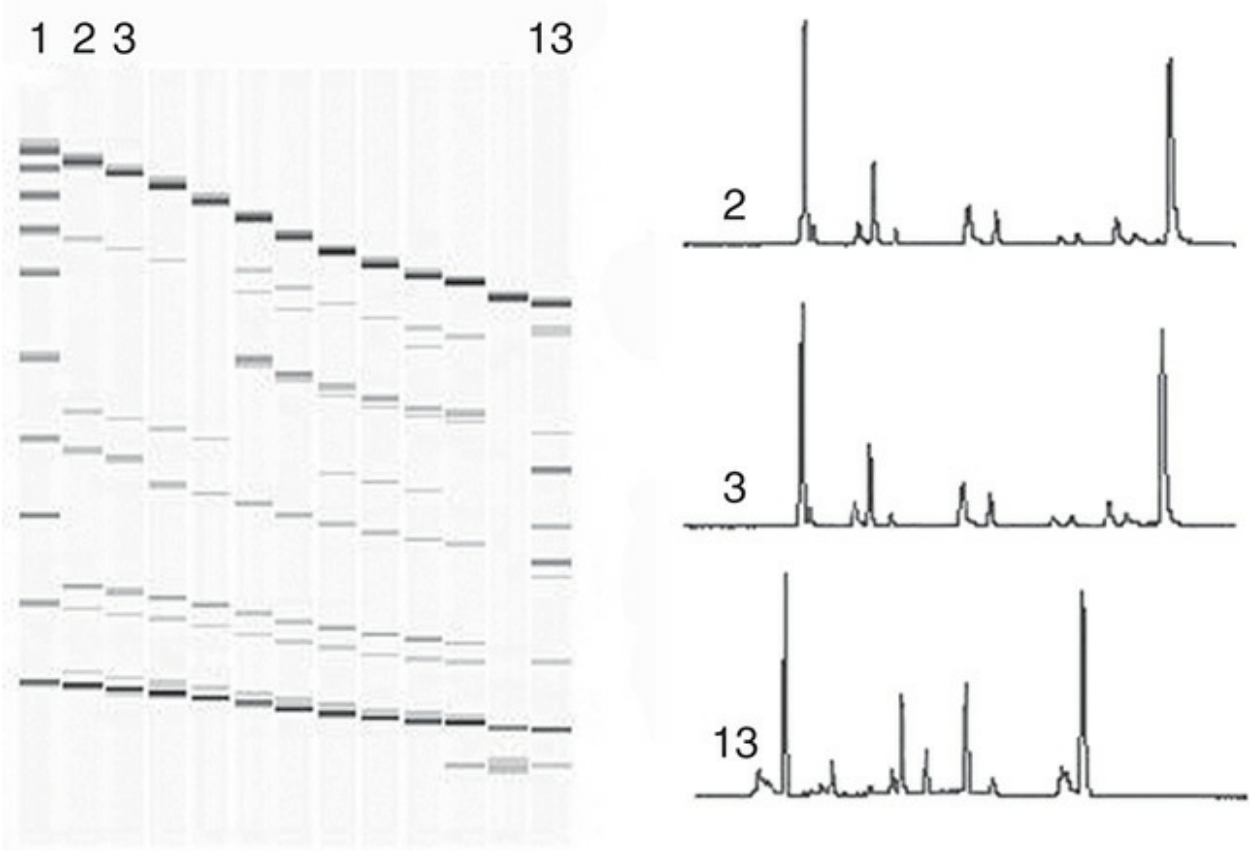
Public health epidemiologists from across the country have for many years now been collaborating by submitting standardized typing information obtained from strains of bacteria that cause foodborne disease into a national public database in a program called PulseNet. The PFGE fingerprint patterns are submitted from participants in all 50 states. PulseNet is designed as an early warning system for foodborne diseases. More information about this national effort to track and rapidly curtail bacterial foodborne illnesses may be obtained at www.cdc.gov/pulsenet.

Mass Spectrometry

A variety of different types of mass spectrometry have been used by clinical and environmental chemists for the detection and characterization of molecules. It has been demonstrated that this type of technology is useful for the identification of microorganisms by a mass spectrometric profile of the proteins, largely rRNA proteins, of the organism.

MALDI-TOF mass spectrometry is the type of mass spectrometry used in clinical microbiology.[153,187] Currently, two FDA-approved, commercially available mass spectrometers are available for use in clinical microbiology laboratories. These include the MALDI Biotyper (Bruker, Billerica, MA) and the Vitek MS (bioMérieux, Durham, NC) (Image Plates 4-3C and D).

In brief, bacteria or yeast from a colony is mixed with matrix supplied by the manufacturer on a position on the test slide. This is placed into the mass spectrometer, wherein this spot will be activated by a laser. The matrix absorbs much of the energy from the laser and converts it into heat. The heat vaporizes the outer portion of the specimen. The molecules move through a vacuum space at a different rate based on the mass-to-charge (m/z) ratio, and this “time of flight” is



■ **FIGURE 4-23** Rep-PCR of *Staphylococcus* isolates. The fragment analysis *(right)* reflects the patterns of the bands in the gel that is performed following rep-PCR. The ladder (Lane *1*) is used as a comparative standard. The fragments from the isolates represented in Lanes *2* and *3* are indistinguishable, whereas these are clearly different from those produced by the isolate represented in Lane *13*.

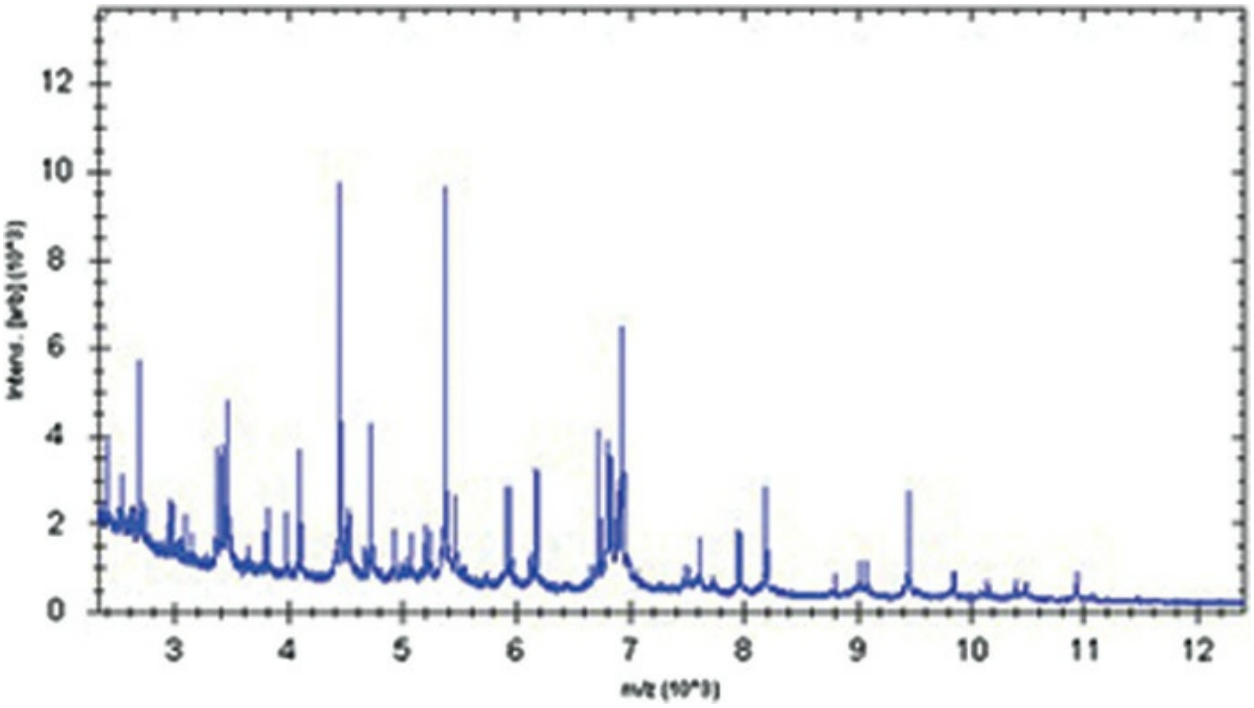
164

determined by the arrival of the different molecules at the detector. A summation of the time of flight for all molecules present will produce a spectrum (Fig. 4-24). This spectrum is then electronically compared with all the spectra in the library to determine the best match (Fig. 4-25) and subsequently the identification of the microbe (Fig. 4-26).

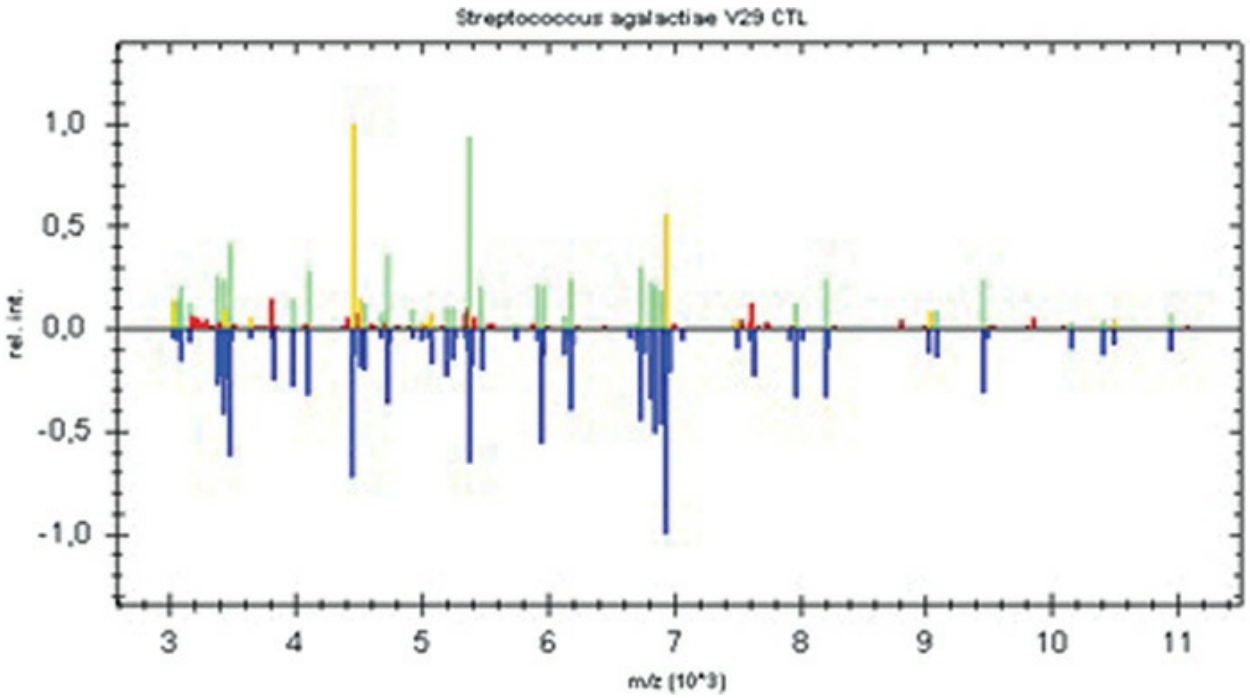
The literature is replete with manuscripts demonstrating the overall excellent ability of these mass spectrometers to identify a wide variety of microorganisms. Upon initial assessment, acquisition of these instruments may appear prohibitive because of a high capital cost. However, when one assesses the materials used, labor, and time to identification, then the return on investment for these instruments is excellent. Although these factors are important to justify the purchase of these instruments, the

greatest advantages are in the clinical impact. These instruments identify a wide variety of organisms within minutes with a high degree of accuracy. The delivery of accurate organism identification information early to treating physicians affords the opportunity for providers to assure appropriate therapeutic coverage. In addition to the direct identification of cultivated microorganisms, others have processed the sediment of blood culture bottles that signal positive as a means to more rapidly identify the causes of bloodstream infections.

There are, of course, some limitations, but these are few. For example, this technology cannot differentiate *Shigella* from *E. coli*. As with any assay, it is important to appropriately validate every assay and determine means to handle



■ **FIGURE 4-24** The MALDI-TOF spectrum produced by a microorganism.



■ **FIGURE 4-25** The comparison of the MALDI-TOF spectrum produced by that test microorganism with the library.

Mb	Detected Species	Log(Score)
	Streptococcus agalactiae V29 CTL	2,361
	Streptococcus agalactiae DSM 6784 DSM	2,352

165

any shortcomings. Overall, MALDI-TOF is a cost-effective significant advance in the identification of a wide variety of microorganisms in clinical microbiology.

Conclusion

The molecular revolution continues and is stronger than ever. Industrial microbiologists and engineers are delivering innovative solutions to improve the laboratory-based diagnosis of infectious diseases. The number of molecular applications for the detection and characterization of all types of microorganisms, many of which are easy-to-use, FDA-approved assays. Many of these are taking a syndromic approach to testing, with assays targeting a broader ranges of organisms that cause a particular type of disease (e.g., gastroenteritis), even if these organisms are taxonomically unrelated (e.g., bacteria, viruses, and/or parasites or fungi targeted by the same assay). Simultaneously, clinical microbiologists for the first time are utilizing mass spectrometry to more quickly identify common microorganisms and, in many instances, more accurately identify less commonly encountered microorganisms. Finally, the use of genetic typing of microbes remains needed to demonstrate relatedness among microorganisms continues to provide useful information regarding the transmission of infectious diseases. Although a variety of molecular methods are available, the use of NGS promises yet another powerful tool for the molecular epidemiologist.

Bacterial Superantigens

Over the three centuries that have passed since Leeuwenhoek first observed bacteria and protozoa with his primitive microscope, a vast amount of knowledge has been accumulated about the microbial world. Microorganisms are found in all environments, including the soil, water, and air. They are able to participate in all vital life functions that are observed in higher, more complex life forms and are found in association with the nonliving environment and with all other living things. By their activities in these environments, microorganisms are an integral part of the balance of life. Using microorganisms, biochemical and genetic processes that occur in all forms of life have been elucidated, and the innumerable roles of microorganisms in environmental cycles are only now beginning to be fully appreciated. By necessity, subsequent chapters in this textbook deal with a relatively small number of microorganisms that are capable of causing disease in humans.

By the end of the 19th century, Louis Pasteur had experimentally dispelled the myth of spontaneous generation, and Robert Koch, among others, had shown that microorganisms were able to cause infectious diseases, such as anthrax and tuberculosis. Although current techniques allow more direct assessments of microbial virulence and pathogenicity, making Koch's original postulates somewhat inapplicable, these fundamental principles still serve as the basis for the unequivocal link between microorganisms and infectious diseases. **Koch's postulates** are outlined in Box 5-1.

Taxonomy: Classification, Nomenclature, and Identification of Bacteria

The taxonomy of bacteria specifically refers to three basic concepts: classification, nomenclature, and identification. **Classification** is the process of systematically dividing organisms into groups, with the species being the smallest and most definitive level of division. Classification also refers to the grouping of described species into genera, and on through the levels of families, orders, classes, and phyla. Historically, new species have evolved from the recognition of isolates that have phenotypic characteristics that differ from similar organisms (e.g., other members of the family *Enterobacteriaceae*). These isolates are then compared with other organisms using a large battery of phenotypic tests. Present-day applications of molecular techniques (e.g., DNA hybridization, DNA sequencing, and polymerase chain reaction [PCR]-based amplification) have enabled taxonomists to identify microbial "signature sequences" and other genetic elements that establish genetic relatedness between and among different microorganisms. Based on systematic comparisons of genetic, chemotaxonomic, and phenotypic traits, new taxa would be proposed and named via publication. The process of naming organisms is delineated by rules of nomenclature.

BOX 5-1

Koch's Postulates

1. A given organism must be present in every case of a given disease;
2. The microorganism can be isolated from (or demonstrated in) specimens associated with that disease state;
3. Inoculation of the isolate into susceptible animals produces a similar disease; and
4. The same organism that is associated with the initial disease state can be

recovered from representative specimens from the experimentally infected animal.

The Naming of Bacteria

Efforts to codify the taxonomy and nomenclature of bacteria started in earnest at the beginning of the 20th century with the work of Chester, Buchanan, and others.[12,13,20,64] During the early 20th century, committees of interested microbiologists were convened to organize bacterial taxonomy, to promulgate rules regarding the validation of new bacterial names, and to establish procedures for changes in nomenclature (Box 5-2). These discussions resulted in the publication of the International Code of Nomenclature of Bacteria in 1948. Sequential revisions of this document were published by the International Committee of Systematic Bacteriology in 1958, 1973, and 1992.[83,84] Priorities and rules for the naming of bacteria were established beginning on May 1, 1953, and on January 1, 1980, the first "Approved List of Bacterial Names" was published in the *International Journal of Systematic Bacteriology* (IJSB).[80] This list was subsequently amended and republished in 1989.[81] Quarterly issues of IJSB (now called the *International Journal of Systematic and Evolutionary Microbiology*, IJSEM) routinely list the names of new species (i.e., Validation Lists). Descriptions of new species can be published either in IJSEM or in a variety of other American and foreign journals. If the description is published in a journal other than IJSEM, the name and the literature reference containing its description must subsequently appear in an IJSEM Validation List. As of the beginning of the new millennium, 4,314 validly named prokaryotic species names have appeared either in the "Approved List of Bacterial Names," in IJSEM, or in IJSEM Validation Lists.[80,81] More recently, provisions for proposed species names that are currently nonculturable but that have been characterized by molecular methods (see below) have also been established.[59,60] New or revised species designations can be proposed by any investigator; the criteria for publication, including the naming of the new species are cited in Box 5-2. A detailed description of the morphologic, biochemical, and genetic characteristics of the organism is given, and there is designation of a living culture of the organism as the "type strain" of the species. This type strain is deposited in reference type culture collections (e.g., the **American Type Culture Collection [ATCC]** and the **National Type Culture Collection [NTCC]**); so the new species will be available to other investigators. Challenges to the validity of new species names are made by publishing a "request for an opinion" from the Judicial Commission of the International Union of Microbiological Societies. This commission usually refers the request to smaller

committees that deal with specific groups of organisms, such as the *Enterobacteriaceae* or the *Pasteurellaceae*.

BOX 5-2

Rules for the Nomenclature of Bacteria

1. There is only one correct name for an organism. When more than one name exists for the same specimen, the oldest legitimate name for that organism has precedence. Occasionally, proposed and accepted names may be changed to reflect proper latinized endings (e.g., the name *Alloiococcus otitis* being changed to *Alloiococcus otitidis*).
2. Names that cause errors or confusion should be rejected.
3. All names that are in Latin or are "Latinized" (i.e., given endings that agree in terms of proper usage and gender [masculine, feminine, neuter]), regardless of origin.
4. The first word of the name (genus name) is always capitalized.
5. The second word (species or specific epithet) is not capitalized.
6. Both the genus and the species name, together referred to as the species, are either underlined or italicized when appearing in print.
7. The correct name or a species or higher taxonomic designations is determined by valid publication, legitimacy of the name with regard to the rules of nomenclature, and priority of publication.
8. Genus and species names appearing in the IJSEM can be changed according to the following rules:
   a. In transferring a species from one genus to another, the species epithet is retained (e.g., *Campylobacter pylori* became *Helicobacter pylori*);
   b. If a type strain is found to actually belong to another genus, the type strain genus is considered invalid; and
   c. If an organism is included in two or more genera or has two or more species designations, the name of the genus/species containing the correct type strain is considered the valid name.

175

Phenotypic Identification of Bacteria

Phenotypic identification procedures remain the principal method for identification of most isolates in the clinical microbiology laboratory (Box 5-3). The focus of identification efforts is at the genus and species level, with no attempt to describe the

hierarchy to which a given organism belongs. At present, taxonomic schemes, such as those published in the four-volume 1984-to-1989 edition of *Bergey's Manual of Systematic Bacteriology*, the 1994 edition of *Bergey's Manual of Determinative Bacteriology*, and various laboratory manuals and journals, reflect groupings of bacteria in nonhierarchical schemes based strictly on phenotypic characteristics. In the preface to the 1994 edition of *Bergey's Manual of Determinative Bacteriology*, J.G. Holt, the editor in chief, states that "the arrangement of the book is strictly phenotypic; no attempt has been made to offer a natural classification. The arrangement chosen is utilitarian and

BOX 5-3

Methods for Characterization of Microorganisms in the Clinical Microbiology Laboratory

1. **Cellular morphology**—This includes cell size, cell shape, and the arrangement of cells with respect to one another.
2. **Staining characteristics**—This usually refers to the Gram's and acid-fast stains, but may include the description of other microscopic characteristics, such as the presence of spores, metachromatic granules, vacuoles, etc.
3. **Motility**—Motility may be observed microscopically with a wet preparation, or by inoculation of semi-solid motility medium.
4. **Presence/absence of spores**—The presence of spores is particularly useful for identifying *Clostridium*, *Bacillus,* and related species. Spores can generally be discerned on Gram's stains, but occasionally specific spore stains may be helpful.
5. **Growth characteristics:**
   a. **Rapidity of growth**—Most organisms isolated in the clinical laboratory grow within 1 to 2 days. However, certain bacteria (e.g., actinomycetes, mycobacteria) may take considerably longer.
   b. **Morphology of colonies on growth media**—Bacteria vary in their appearance on solid culture media. With experience, colony morphology on various media coupled with a few rapid tests (e.g., oxidase, catalase) is often sufficient for genus-level characterization of organisms growing from clinical specimens.
   c. **Optimal atmospheric conditions for growth**—Microorganisms can be characterized by their requirements for oxygen and, depending on this requirement, can be classified as **aerobic** (requires O_2), **facultative** (can grow in the presence or absence of O_2), or **anaerobic** (optimal growth/any growth in the absence of O_2). The growth of most organisms is also

stimulated by CO_2, and, for **capnophilic** bacteria, $CO_2$is required for growth (e.g., *Neisseria gonorrhoeae*). Other organisms, such as *Campylobacter jejuni*, may require atmospheres with slightly decreased O_2tension; these organisms are termed *microaerophilic.*

d. Optimal temperature for growth—Most organisms isolated in clinical laboratories grow optimally at 35°C to 37°C. Ability to grow at various temperatures may be helpful in characterizing some isolates (e.g., campylobacters, certain nontuberculous mycobacteria).

e. Colony morphology on nonselective, selective, and differential media—Clinical laboratories routinely inoculate specimens onto both nonselective and selective media in order to provide optimal conditions for recovery of organisms in a specimen. Selective media use antimicrobial agents (e.g., colistin and nalidixic acid in colistin–nalidixic acid [CNA] agar) or dyes and bile salts (e.g., MacConkey agar; eosin–methylene blue [EMB] agar) to inhibit the growth of some organisms and allow the growth of others. In addition, some selective media are also differential, which means that the colonies growing on a given medium have an appearance that discloses information about a phenotypic characteristic or characteristics. These features may suggest the possible identity of the organism (e.g., the colorless colonies of lactose-nonfermenting *Shigella* species versus the pink/red colonies of lactose-fermenting *E. coli* on MacConkey agar).

6. **Biochemical characteristics**—Along with cellular and colonial morphology and the appearance of colonies on selective and differential media, biochemical and enzymatic tests form the basis for most identification procedures performed in clinical microbiology laboratories. In general, biochemical (phenotypic) characteristics refer to the formation of distinct biochemical end products from defined substrates, the production of acid from various carbohydrates, and the presence of certain bacterial enzymes as determined by chromogenic substrates or other methods.

7. **Serologic tests**—Serologic tests for bacterial identification usually involve the detection of antigens by enzyme or fluorescence immunoassays, or agglutination assays (see Chapter 3). Serologic identification methods may also be used to confirm identifications

176

obtained by other methods. For example, *Salmonella* species can be identified by phenotypic methods, but serotyping of *Salmonella* isolates

for somatic and flagellar antigens is usually performed by slide agglutination with group- or type-specific antisera.

8. **Analysis of metabolic end products or structural components of organisms**—Metabolic end product analysis is performed indirectly with virtually all microbial identification systems, in which a metabolic end product produces a visually detectable change in an indicator of some kind. However, these analyses may also be performed by other methods, such as gas chromatographic analysis of a sampling of broth culture after extraction with various organic solvents. This technique is especially helpful for genus and species identification of anaerobic bacteria. Chemotaxonomic approaches (e.g., cell wall outer membrane and peptidoglycan analysis, cell wall composition, detection of electron transport components such as cytochromes and menaquinones by gas–liquid or high-pressure liquid chromatography) are also helpful, but are not used in most laboratories. Cell wall analysis has enjoyed success in some hospital laboratories as a method for differentiation and identification of mycobacteria and related organisms.
9. **Molecular genetic analysis**—Molecular methods include G+C% content, DNA–DNA hybridization, PCR, and DNA base sequencing. Although these methods are not used routinely in many hospital laboratories, they enabled the development of molecular assays that are now used in many laboratories for detection and identification of mycobacteria, chlamydiae, systemic fungi, and some bacteria. Amplification techniques (e.g., PCR, ligase chain reaction, strand-displacement amplification, nucleic acid sequence-based identification, and transcription-mediated amplification) are also being used in many clinical laboratories for direct detection of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* in urogenital specimens, the detection and differentiation of respiratory viruses, the detection of *C. difficile* and for viral load determinations in patients with HIV-1, transplant-associated viral infections (e.g., CMV, BK, and EBV), and hepatitis C infections.
10. **Proteomic analysis—** Matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) is a type of mass spectrometry that is commercially available and has become commonly used in the clinical microbiology laboratory, in many instances replacing traditional biochemical identification. Microorganisms, most commonly bacteria and yeasts, are placed on a test slide and mixed with matrix material. The specimen is submitted for laser desorption/ionization and the molecules of the microorganisms are separated largely by mass and their "time of flight." The spectrum formed based largely on the protein content of the organisms is compared with a library of spectra of known microorganisms and thereby identification can be achieved in minutes at a very low cost per test.

is intended to aid in the identification of bacteria."[13,46] In this context, an operational definition of a **species** is a collection of strains that share many common phenotypic characteristics. A bacterial **strain** is derived from a single culture isolate, and a species **type strain** represents the permanent example of the species that carries the reference name and is part of a culture collection (e.g., ATCC). Species are assigned to morphologically and biochemically defined **genera**, which, in turn, are assigned to **families**, each of which also has certain morphologic, physiologic, and biochemical features. Since taxonomic decisions and controversies are arbitrated by committee, individual knowledge and bias introduced at this level make phenotypic classification above the species level somewhat arbitrary.[87] Nomenclature rules that imply a hierarchical classification have been accepted for years, however, as taxonomic convention for these nonhierarchical classification schemes. Consequently, family names have the latinized ending ***-aceae*** (e.g., the family *Enterobacteriaceae*, the family *Neisseriaceae*), order names have the ending ***-ales*** (i.e., Order *Eubacteriales*), and tribe names end in ***-eae*** (e.g., the Tribe *Proteae*). The incorporation of phenotypic data into computer-assisted databases of commercially available identification systems has provided systematic organization for the vast amount of phenotypic data that has accumulated. These data will no doubt continue to serve the clinical laboratory as the principal method for bacterial identification. The development of elegant and powerful genetic techniques, however, has made hierarchical bacterial classification not just a possibility but an inevitability.

Phylogenetic Criteria for Classification of Bacteria

Because the nucleotide sequence of DNA is unique to individual species of microorganisms, analysis of nucleic acid relatedness between and among microbes was recognized as a potential tool for unraveling bacterial taxonomy and nomenclature. Initially DNA was analyzed for its **G + C% (guanine plus cytosine percent)** content. This analysis is limited, however, by the fact that two organisms with divergent DNA sequences can have similar G+C% contents. Subsequently, it was found that **DNA–DNA hybridization** yielded more useful information. Double-stranded DNA can be separated into its two component strands by heat or high salt concentrations. On cooling or on lowering the salt concentration, the two single strands will reanneal or hybridize into the double-stranded forms by specific base-pairing (see below). The extent to which two single strands of DNA reanneal with one another is an indirect assessment of their relatedness.[86] Using this technique, it was found that organisms with about 15% or more sequence mismatches do not reanneal under ideal conditions; so DNA from distantly related organisms will not hybridize. Consequently, DNA–DNA hybridization

has been most useful for comparing organisms at or below the species level. In this context, a **bacterial species** can be defined as a group of bacteria that exhibit greater than 70% to 75% DNA relatedness, with 5% or less divergence in related nucleotide sequences.[86,96]

In the 1970s, geneticists began to examine ribosomal RNA sequences as a method for demonstrating microbial relatedness. This work centered on the **16S rRNA molecule**, which is a part of the 30S subunit of the bacterial ribosome (see below). This molecule is 1,500 to 1,800 nucleotides in length, is easily isolated from bacterial organisms, and has the same structural and functional roles in all bacterial cells. Small-subunit ribosomal RNAs have remained highly conserved during evolution; mutations in these highly conserved base sequences are usually lethal, and organisms with such mutations do not survive and propagate. In addition, since these molecules are an integral part of a complex, protein-containing structure (i.e., the bacterial ribosome), horizontal transfer of rRNAs to other organisms is rare. By examining the nucleotide sequences of the 16S rRNA, phylogenetic relationships and evolution of organisms from common ancestral types can be ascertained. Ribosomal RNA sequence analysis is most useful for determining the relatedness of microorganisms above the genus level, although this technique has been used to validate existing phenotypic differences between closely related genera and species. Strains of the same species usually show greater than 97% similarity in the rRNA sequences.[86]

Since its inception, sequencing studies of small-subunit RNA has had a tremendous impact on bacterial systematics. In the late 1970s, analysis of 16S rRNA from diverse bacterial groups (i.e., methanogenic [methane-producing] bacteria, halophilic bacteria, thermoacidophilic bacteria, etc.) revealed that these organisms were completely divergent from other bacteria and from eukaryotic organisms and heralded the division of the microbial world into two domains—the *Archaea* and the *Bacteria*—and reinforced the phylogenetic separation of eukaryotic organisms into a third domain, the *Eukaryota*. The development of DNA sequencing in the late 1970s and reverse transcription PCR (RT-PCR) technology in the early to mid-1980s enabled the amplification and sequencing of small-subunit rDNA. Extensive study and cataloging of these sequences in the 1980s and 1990s form the basis of the proposed phylogenetic classification scheme. The second edition of *Bergey's Manual of Systematic Bacteriology* reflects a complete departure from the first edition in its phylogenetic classification scheme. The second edition of *Bergey's Manual of Systematic Bacteriology* began publication in 2001 with volume 1, covering the *Archea* and the phototrophic bacteria. Subsequent years have seen the publication of volume 2 (the *Proteobacteria*) in 2005, volume 3 (the *Firmicutes*) in 2009, and volume 4 (*Bacteroidetes*, *Spirochaetes*, *Tenericutes* [*Mollicutes*], *Acidobacteria*,

Fibrobacteres, *Fusobacteria*, *Dictyoglomi*, *Gemmatimonadetes*, *Lentisphaerae*, *Verrucomicrobia*, *Chlamydiae*, *Planctomycetes*) in 2011.

The prokaryotic world is divided into two domains—the ***Archaea*** and the ***Eubacteria***.[99] Eukaryotic organisms are placed in Domain ***Eukaryota***. *Archaea* and *Bacteria* probably evolved from an ancestral organism, as evidenced by similarities in amino acid sequences of large structural and regulatory molecules and enzymes, including adenosine triphosphatases and elongation factors that function in protein synthesis. The *Archaea* include two major branches—the ***Euryarchaeota*** and the ***Crenarchaeota***. The *Euryarchaeota* include the methanogenic bacteria, the sulfate-reducing bacteria, aerobic **halophilic** (salt-requiring) and **thermoacidophilic** (optimal growth at 50°C to 60°C at pH less than 5) bacteria, and anaerobic **hyperthermophilic** bacteria. The *Crenarchaeota* are all **thermophilic** (optimal growth at 50°C to 60°C), organisms that are either sulfur-reducing heterotrophs or aerobic organisms capable of oxidizing sulfur or other inorganic and organic substrates. Although *Archaea* are similar to the *Eubacteria* in size, nucleoid structure, cell growth, and division, they also differ in several respects. The genome size of the *Eubacteria* ($0.6–12 \times 10^6$ base-pairs) can be up to three times larger than that of the *Archaea* ($1–4 \times 10^6$ base-pairs). The *Archaea* have cell walls composed primarily of protein and lack the murein peptidoglycan found in the *Eubacteria*. Although both groups have 70S ribosomes, those of the *Archaea* are insensitive to inhibition of protein synthesis by streptomycin or chloramphenicol, but, like the *Eukaryota*, they are sensitive to inhibition by diphtheria toxin. The opposite characteristics are present in the *Eubacteria*. In short, the *Archaea* encompasses bacteria that are environmental "extremophiles"; this group contains no human pathogens.

Organisms in the Domain *Eubacteria* (or Domain *Bacteria*, as addressed in *Bergey's Manual*) are divided into divisions or phyla. Most of these phyla are composed of environmental species, such as the thermophilic and/or photosynthetic bacteria. Human pathogens are distributed among eight different phyla. Most of the clinically significant gram-negative bacteria belong to the **Phylum *Proteobacteria***, which is divided into five classes, designated **α-, β-, γ-, δ-,** and **ε- *Proteobacteria***. All of the enteric bacteria, most of the nonfermentative species, fastidious gram-negative coccobacilli and cocci, and the campylobacters belong to the various classes within the Phylum *Proteobacteria.* **Phylum *Firmicutes*** includes the clostridia, eubacteria, peptococci, aerobic spore-forming gram-positive bacilli (e.g., *Bacillus* and related genera), the staphylococci, streptococci, and enterococci. **Phylum *Actinobacteria*** includes the aerobic and anaerobic actinomycetes and related organisms, the aerobic gram-positive cocci, and several other genera of facultative gram-positive bacilli. **Phylum *Bacteroidetes*** contains *Bacteroides* group organisms (*Bacteroides*, *Porphyromonas*, and *Prevotella*), flavobacteria, sphingobacteria, and related nonfermentative gram-negative bacilli. **Phylum *Fusobacteria*** is comprised of the

fusobacteria and the genus *Streptobacillus*. **Phylum *Spirochaetes*** and **Phylum *Chlamydiae*** include the spiral-shaped bacteria (e.g., *Borrelia, Treponema*, and *Leptospira*) and the *Chlamydia* and *Chlamydophila* genera, respectively. **Phylum *Tenericutes*** includes the mycoplasmas and ureaplasmas. Box 5-4 provides a complete outline of the classification scheme for organisms associated with humans and human disease that appears in the new edition of *Bergey's Manual of Systematic Bacteriology*.

Despite the current emphasis on molecular methods for classification, phenotypic criteria continue to be the mainstay of bacterial identification in the clinical microbiology laboratory. With the methods outlined in Box 5-3, along

with various identification schemes and computer-assisted databases, most bacteria isolated in the clinical laboratory can be placed in a taxonomic framework that allows a genus and species name to be determined. This approach fulfills the role of the clinical microbiology laboratory in providing physicians with accurate and timely organism identifications and determining the susceptibility of these organisms to antimicrobial agents. Physicians, in turn, use this information to guide their selection of appropriate therapeutic interventions, to monitor the clinical response of the patient, and to evaluate the patient's clinical course.

In order to provide the reader with sufficient background information for understanding subsequent chapters regarding specific bacterial pathogens and the diseases that they cause, the next section of this chapter deals with the general morphology, physiology, and virulence mechanisms of bacteria. This discussion will provide the information necessary for understanding the nuances of morphology, staining properties, growth, metabolic features, and biochemical characteristics of the organisms discussed in subsequent chapters. The basic morphology and physiology of fungi, parasites, and viruses are presented in Chapters 21, 22, and 23, respectively.

Basic Bacterial Anatomy and Physiology

Bacteria are prokaryotic, while fungi, protozoa, and other organisms are eukaryotic. Eukaryotic cells contain a nucleus with a nuclear membrane enclosing multiple chromosomes, while prokaryotic cells have a single chromosome (nucleoid) that is not enclosed in a nuclear membrane. Eukaryotic cells also possess a variety of subcellular organelles with specialized functions, such as mitochondria (sites of aerobic respiration) and chloroplasts (sites of photosynthesis in green plants). In fact, these subcellular organelles probably evolved from prokaryotic organisms that entered the eukaryotic cells and developed symbiotic relationships with them over time by losing metabolic functions associated with a free-living existence and developing features or attributes that benefitted the "host" organism. Prokaryotic and eukaryotic cells differ substantially in many other characteristics; these are briefly described in Table 5-1.

Bacterial Size and Shape

Bacterial cells have a wide variety of sizes and shapes. Most bacteria are generally 0.2 to 2 µm in diameter and 1 to 6 µm in length, although many environmental organisms may be as long as 100 µm. Bacteria exist in four basic morphologies: spherical cells, or **cocci**; rod-shaped cells, or **bacilli**; spiral-shaped cells, or **spirilla**; and comma-shaped cells, or **vibrios**. Arrangements of coccal cells in pairs, chains, or clusters define groups of organisms called **diplococci**, **streptococci**, and **staphylococci**, respectively (Fig. 5-1). Rod-shaped organisms may be regular in morphology, may be somewhat shorter (i.e., "**coccobacillary**"), or may appear club- or dumbbell-shaped ("**coryneform**"). Comma-shaped cells generally define a basic characteristic of certain species (e.g.,

TABLE 5-1 Properties of Prokaryotic and Eukaryotic Cells

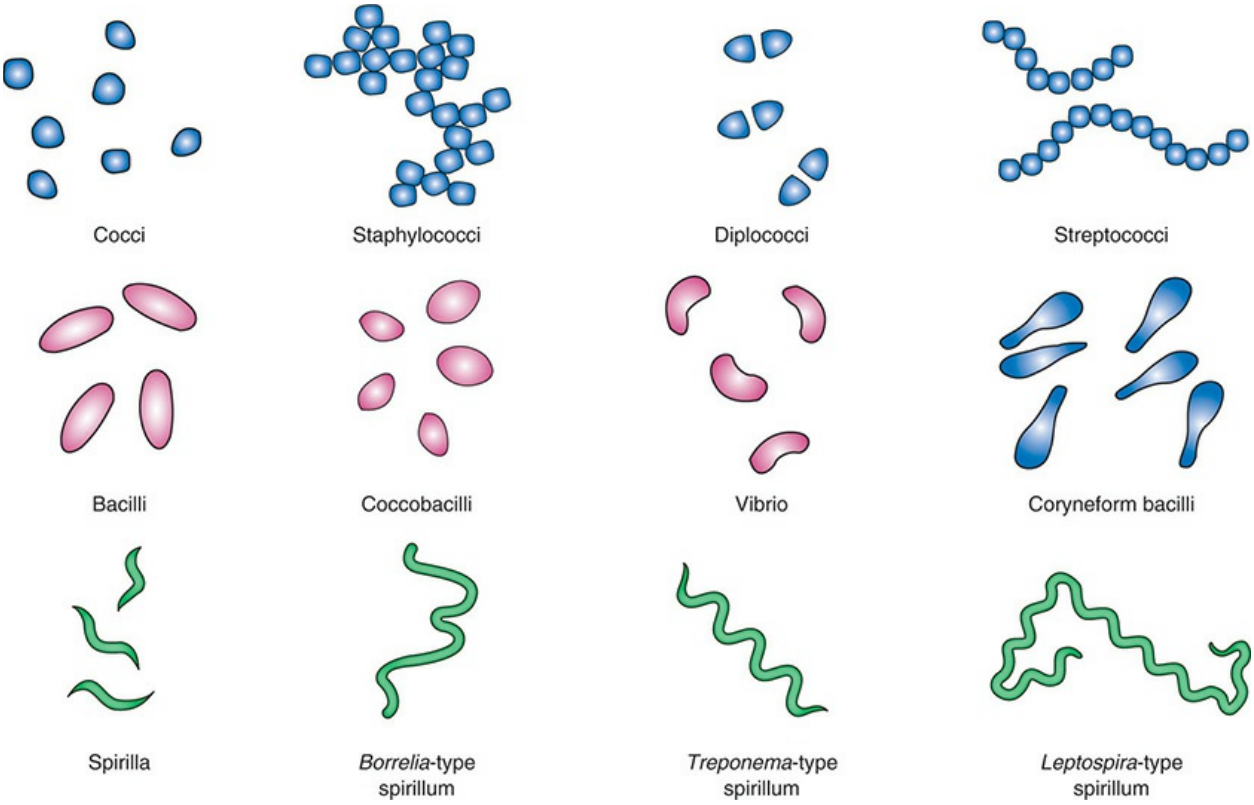
Characteristic	Prokaryotic (Eubacterial) Cells	Eukaryotic Cells
Major groups	Bacteria, blue-green algae	Algae, fungi, protozoa, plants, animals
Cell wall	Contains peptidoglycan, lipid, protein	Variable; when present, contains chitin (fungi) or cellulose (green plants)
Nuclear structure		
Nuclear membrane	Absent	Present

Chromosomes	Single, closed, circular double-stranded DNA	Multiple, linear chromosomes
Ploidy	Haploid	Most are diploid; haploid (fungi)
Transcription/translation	Continuous, with short-lived mRNA and polyribosome (polysome) formation	Discontinuous; long-lived mRNA transcribed in nucleus and translated in cytoplasm
Histones	Absent	Present
Cytoplasm		
Ribosomes	Present: 70S (50S + 30S)	Present: 80S (60S + 40S)
Mitochondria	Absent	Present
Golgi complex	Absent	Present
Endoplasmic reticulum	Absent	Present
Cytoplasmic membrane	Present: phospholipids, no sterols (except for *Mycoplasma* species)	Present: phospholipids and sterols (cholesterol, ergosterol)
Triglycerides	Absent	Present
Motility	Flagella (simple)	Flagella (complex); pseudopodia; cilia and other complex locomotor organelles)

183

Energy generation	Cytoplasmic membrane-associated	Mitochondria
Sexual reproduction	Absent (unnecessary)	Present in most; may be evolutionarily lost in some fungi and absent in some protozoa
Recombination/gene exchange	Chromosomal or plasmid gene exchange via transformation, transduction, or conjugation)	Diploid zygote formed from haploid germ cells; meiosis results in genetic recombination

Vibrio species). The same is true for certain other spiral-shaped bacteria (e.g., *Campylobacter*, *Helicobacter*, *Borrelia*, and *Treponema* species), in which spiral formation may be loose (about 4 coils per organism) or tight (14 to 20 coils per organism). In addition to their size, shape, and cellular arrangement, bacteria can be further differentiated on the basis of their staining characteristics with the **Gram's stain**. Using this staining technique, most bacteria can be classified as gram-positive or gram-negative. The Gram's stain helps to differentiate bacteria based on their cell wall structure, which is discussed later in this chapter. The structure of a generalized bacterial cell (both gram-positive and gram-negative) is depicted in Figure 5-2.



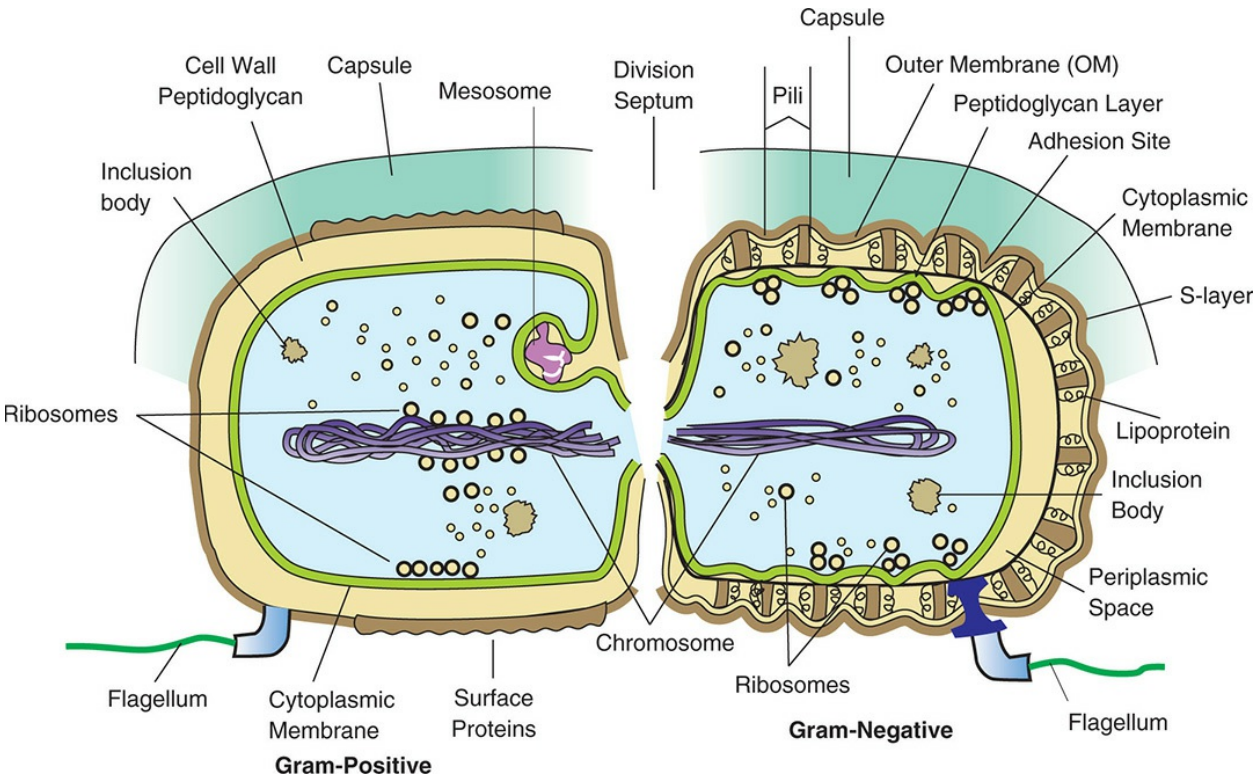
■ **FIGURE 5-1** Basic morphologies of various bacteria.

Nuclear Structure, DNA Replication, Transcription, and Translation

The inheritable characteristics of all living organisms are determined by the structure of the genetic material. The genetic material of an individual cell is composed of **DNA** organized into single or multiple chromosomes. Collectively, the genetic material is referred to as the genome of the organism. In the vast majority of prokaryotic

organisms, the **genome** is composed of a single, covalently closed, circular chromosome of double-stranded DNA (dsDNA); in some organisms (e.g., *Borrelia burgdorferi*, the streptomycetes) linear DNA is present. In the *Archaea* and the *Bacteria*, this circular chromosome is not bounded by a membrane, but is free in the cytoplasm in a discrete central portion of the bacterial cell called the **nucleoid**. Bacterial cellular DNA has a molecular weight of about 106 kDa, measures 300 to 1,400 μm in length, and is present in the cell in a **supercoiled** state (i.e., the double-stranded molecule is twisted up on itself like a "twisted" rubber band). Individual genes are arranged linearly on the chromosome. The nucleoid represents about 10% of the cell volume, although DNA is only 2% to 3% of the dry weight of the cell. In *Escherichia coli*, the chromosome contains about 5×10^6 base-pairs, and its length is

184



■ **FIGURE 5-2** Cross-section through a generalized bacterial cell. The left half of this figure depicts the structure of a gram-positive bacterium; the right half shows the structure of a gram-negative bacterium.

about 1,000 times the length of the bacterial cell in which it is contained. Unlike similar processes in eukaryotic cells, DNA replication and transcription of the DNA into

messenger ribonucleic acid (mRNA) occur continually. The chromosome also appears to be attached to the inner aspect of the cell membrane at certain points. In **eukaryotic** organisms, the genetic material is organized into several **chromosomes** within the nucleus. The chromosomes are, in turn, associated with several basic proteins called histones, which help to stabilize chromosomal structure. The chromosomes of eukaryotic organisms are separated from the rest of the cellular material by a **nuclear membrane**, which is composed of a lipid bilayer that is similar in composition to the cell membrane. The nuclear membrane also contains pores that allow passage of small molecules into and out of the nucleus.

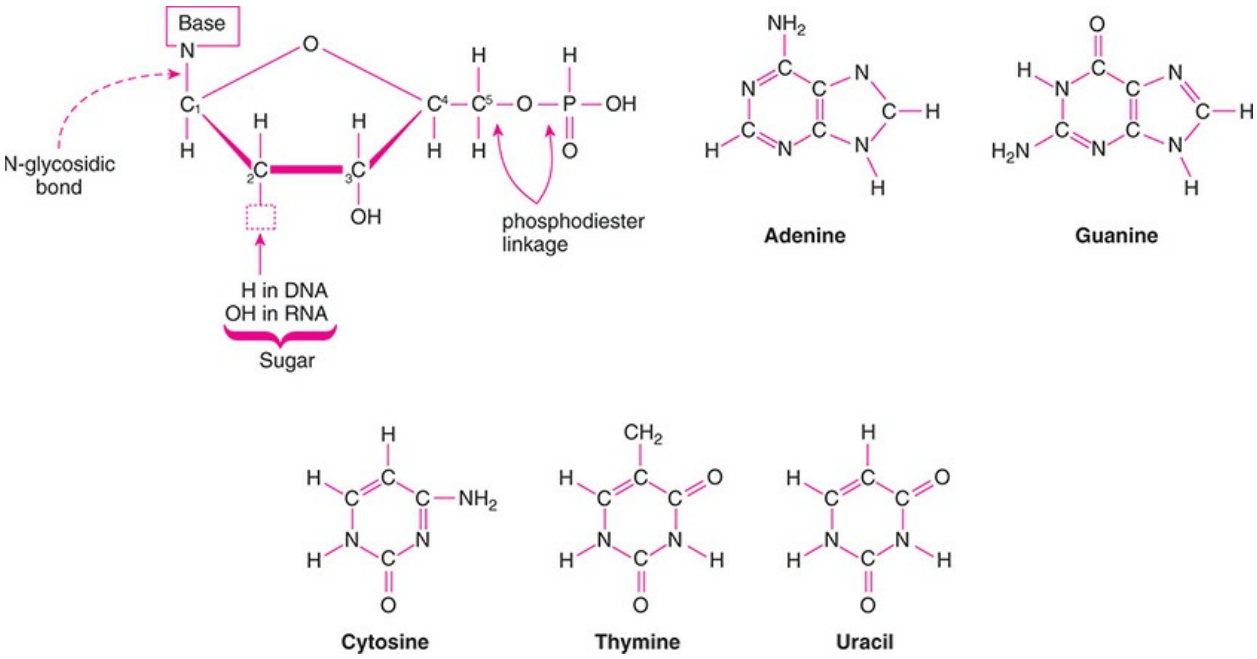
Nucleic acids of all bacteria, like other organisms, are composed of **polynucleotides** (a polymer consisting of nucleotides) that are comprised of the following three components (Fig. 5-3): (1) a cyclic, 5-carbon sugar (ribose in RNA; deoxyribose in DNA), (2) a purine (adenine, guanine) or pyrimidine (cytosine, thymine, uracil) base attached to the 1′ carbon atom of the pentose by an *N*-glycosidic bond, and (3) a phosphate (PO_3) attached to the 5′ carbon of the pentose by a phosphodiester linkage. Deoxyribose moieties are linked together via alternating phosphate groups to form a chain that has a characteristic helical coil, and the bases are directed toward the central axis of the coil. Such a structure composes a single strand of nucleic acid (ssDNA).

The double-helix structure of DNA, specifically, results from the interaction between two complementary single strands of nucleic acid. Complementarity is associated with the sequence of bases on a single strand and the hydrogen bonding that occurs between specific bases on the complementary strand (Fig. 5-4). The **purine** bases are **adenine** (**A**) and **guanine** (**G**), and the **pyrimidine** bases are **cytosine** (**C**), **thymine** (**T**), and **uracil** (**U**) (Fig. 5-3). The purine adenine will specifically base-pair only with the pyrimidine thymine, while the purine guanosine will specifically base-pair only with the pyrimidine cytosine. Antiparallel chains of ssDNA are held together by three hydrogen bonds between C and G and two hydrogen bonds between A and T (Fig. 5-4). Native DNA exists as a double-stranded helix, while RNA exists primarily in a single-stranded form as **messenger RNA** (**mRNA**) and in partially double-stranded forms in **ribosomal RNA** (**rRNA**) and **transfer RNA** (**tRNA**) molecules. In all RNA species, uracil is present in place of thymine (see Fig. 5-3). The sequence of purine and pyrimidine bases in DNA constitutes the genetic code, with specific codons (three base-pair sequences) coding for specific amino acids. Single-stranded mRNA is synthesized from double-stranded DNA during the process of **transcription** by a **DNA-dependent RNA polymerase**, in which a complementary strand of mRNA is synthesized with the "sense" strand of dsDNA as the template. The mRNA then becomes associated with **ribosomes**, which are the sites of protein synthesis.

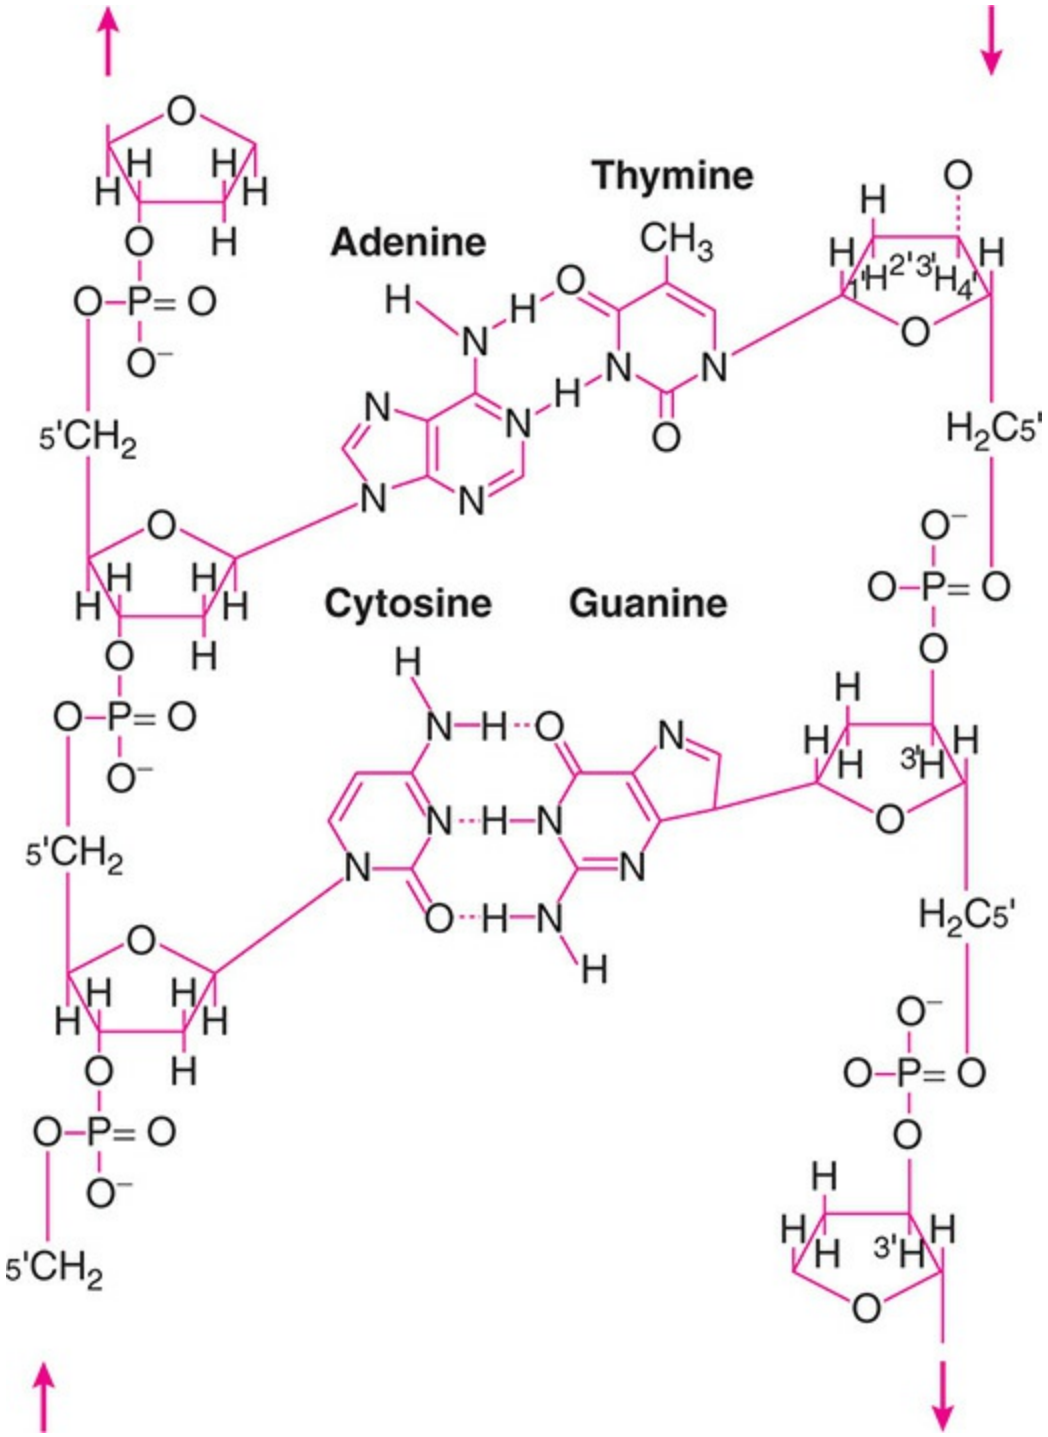
Both prokaryotic and eukaryotic organisms harbor large numbers of ribosomes. In prokaryotic organisms, the ribosomes are 70S; in eukaryotic organisms, the ribosomes

are 80S. The "S" refers to a Svedberg unit, which is an indirect measure of the size of the ribosome as determined by its rate of sedimentation when subjected to ultracentrifugal force. The 70S bacterial ribosome has a molecular weight of about 80 kDa and exists in a dissociated state as two subunits termed the *30S* and the *50S subunits*. The 30S subunit contains the 16S RNA species, while the 50S subunit contains both 23S and 5S RNA; together, the subunits also contain

185



■ **FIGURE 5-3** Molecular structure of polynucleotides and nucleic acid bases. Polynucleotides consist of a cyclic, 5-carbon sugar (ribose or deoxyribose), a purine or pyrimidine base attached to the 1′ carbon atom of the sugar by an *N*-glycosidic bond, and a phosphate group linked to the 5′ carbon of the sugar by a phosphodiester linkage. The structures of the two purine (adenine and guanine) and the three pyrimidine (cytosine, thymine, and uracil) bases are also shown.



■ **FIGURE 5-4** In the DNA molecule, the two polynucleotide strands of the DNA double helix are "antiparallel," that is, the 3′-OH terminus of one strand is adjacent to the 5′-P terminus of the complementary strand. The bases, which are directed toward the central axis of the helix, hold the two polynucleotide strands together by relatively weak hydrogen bonds. Adenine pairs with thymine via two hydrogen bonds, while cytosine pairs with guanine via three hydrogen bonds. These interactive forces between the polynucleotide

strands can be overcome by thermal energy (heat) or by strong alkali in the process of denaturation.

about 50 ribosomal proteins. rRNA comprises 70% of the total cellular RNA. The remaining cellular RNA is found as tRNA (16%) and mRNA (14%).

When complexed with an mRNA transcript from the DNA, the 50S and 30S ribosomal subunits form the intact 70S ribosome found in bacterial cells. Ribosome–mRNA aggregates, termed *polyribosomes* or *polysomes*, contain all components of the protein-synthesizing system; polysomes are essentially chains of 70S ribosomes (monomers) attached to mRNA. Histone or histone-like proteins that serve to stabilize the nascent polypeptides synthesized by the polysomes have only recently been found in small amounts in association with *E. coli* DNA, whereas the occurrence of polyamine proteins (e.g., putrescine and spermidine) associated with bacterial DNA is well known. The mRNA is "decoded" in association with several ribosomes in a polysome–mRNA complex, where the **codon–anticodon base-pairing** occurs through molecules of tRNA during the process of **translation**. tRNA molecules bear the **specific anticodons** corresponding to the codons of the mRNA and also carry the corresponding, covalently linked amino acid. The tRNA–amino acid complex interacts with the ribosome such that a peptide bond is formed between the amino acid on the tRNA and the nascent peptidyl–tRNA. Interaction of tRNA–amino acid, ribosomes, adenosine triphosphate (ATP) and several cofactors result in the formation of a specific polypeptide chain. Thus, the genetic code present in the DNA is translated into structural protein molecules (i.e., "building blocks") or enzymes that, in turn, catalyze the synthesis and degradation of all the other cellular components. The synthesis of new DNA molecules, called **replication**, occurs by the uncoiling and "unzipping" of the dsDNA molecule by a **DNA gyrase** enzyme, and the synthesis of complementary strands of DNA by a DNA-dependent DNA polymerase.

186

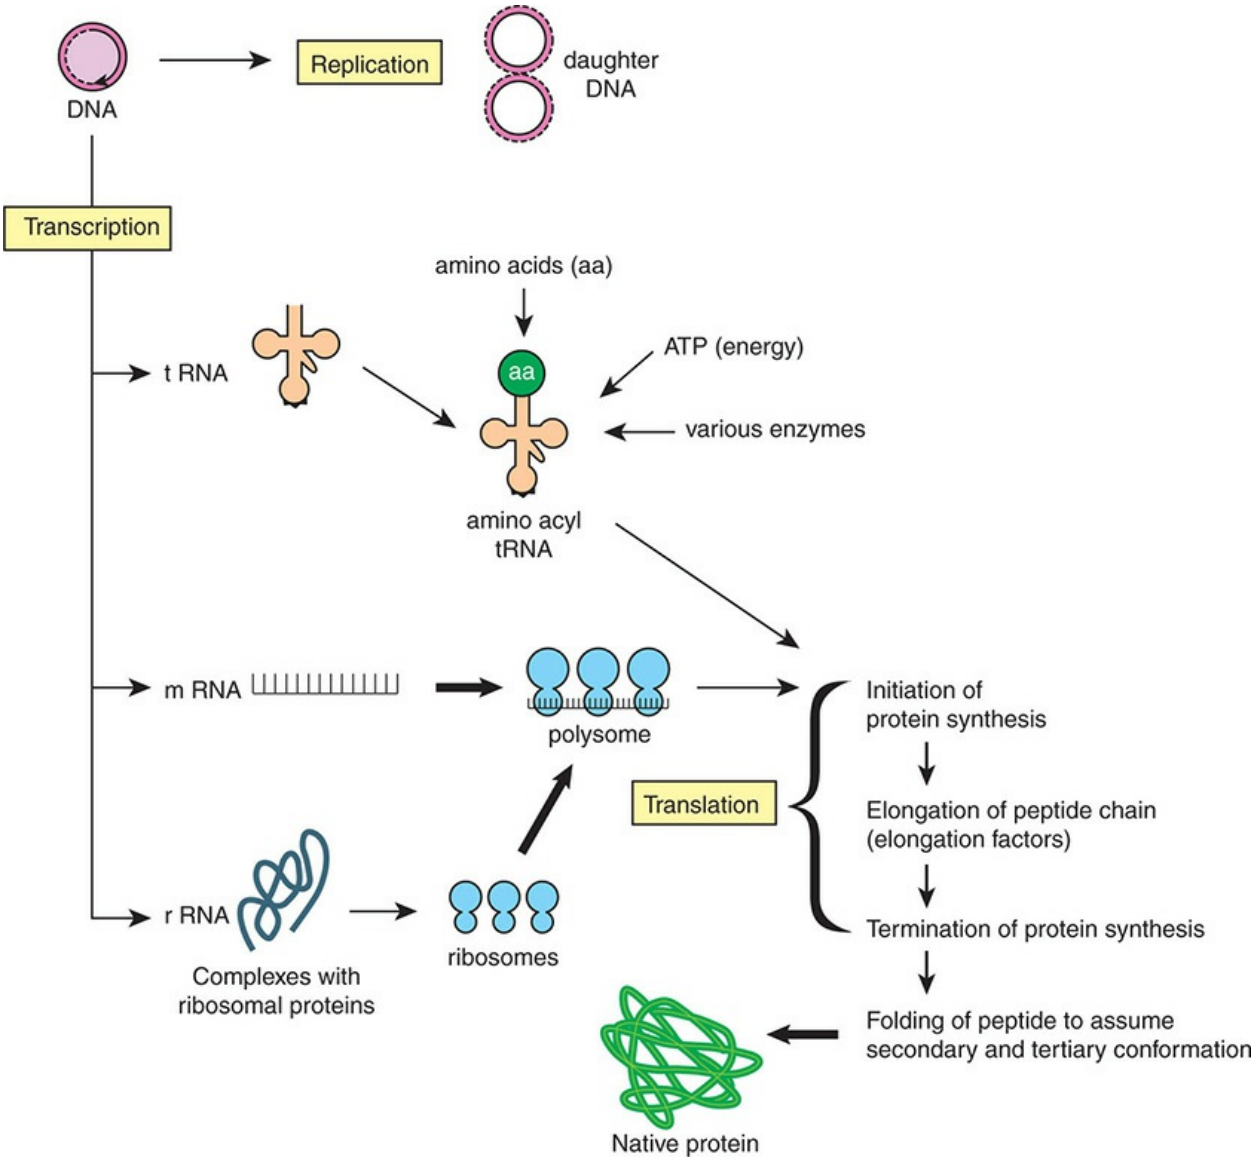
Each new dsDNA molecule contains a single strand of the parent DNA. The relationship among DNA replication, RNA transcription, and translation of the genetic code into proteins is summarized in Figure 5-5.

In addition to its utility for determining genetic relatedness among bacteria (see above), sequencing of rRNA molecules has revealed nucleotide sequences that are unique to individual species. Since these unique RNA sequences are also highly conserved and exist in multiple copies within the ribosomes of a bacterial cell, synthetic oligonucleotides that can hybridize with these unique sequences can be used to both detect and identify bacteria. Such an approach forms the basis for nucleic acid probe technology for direct detection of microorganisms in clinical specimens or for

identification of microorganisms recovered in culture.

Cytoplasm

The cytoplasm is an amorphous gel containing enzymes, ions, and a variety of granules, many of which represent food and energy reserves. The cytoplasmic enzymes of prokaryotic cells function in both anabolic and catabolic processes, and many of these enzymes are associated with the inner aspect of the cell membrane (see below). Prokaryotic cells lack separate, membrane-bounded subcellular organelles, while eukaryotic cells contain a variety of subcellular structures (e.g., mitochondria, endoplasmic reticula, etc.) composed of or bounded by phospholipid bilayer membranes. Intracellular, cytoplasmic inclusions or granules represent accumulations of food reserves (polysaccharides, lipids, or polyphosphates). The numbers and types of storage granules



■ **FIGURE 5-5** Replication, transcription, and translation of the genetic code in prokaryotic organisms. DNA is replicated by DNA-dependent DNA polymerase to produce two double-stranded DNA (dsDNA) molecules. The genetic code in the dsDNA is copied to produce a single-stranded RNA called messenger RNA (mRNA) during the process of transcription. Transfer RNA (tRNA) and ribosomal RNA (rRNA) are also transcribed. rRNA becomes complexed with specific proteins to form part of the structure of the ribosome. The mRNA becomes complexed with ribosomes to form polysomes, which are the site of protein synthesis. On the polysome, codons specific for individual amino acids are recognized by anticodons on tRNA molecules by specific base-pairing. Specific codons correspond to different amino acids attached to aminoacyl tRNA molecules. During the stages of translation, protein synthesis is initiated, polypeptide chains are elongated, and synthesis is eventually terminated with the release of a protein molecule.

vary with the medium and the functional state of the cells. Starch is the principal storage product among the *Neisseria* and *Clostridium* species, while glycogen is the major storage material of enteric bacteria. *Bacillus* and *Pseudomonas* species accumulate 30% or more of their dry weight as a high-molecular-weight lipid called **poly- β-hydroxybutyrate**. High-molecular-weight polymers of polyphosphate known as **metachromatic granules** or **volutin** occur in *Corynebacterium* species, *Yersinia pestis*, and *Mycobacterium* species. These volutin granules appear reddish-pink when stained with methylene blue. Intracytoplasmic inclusions that are found mostly among environmental bacteria include magnetosomes and gas vesicles. **Magnetosomes** are composed of various forms of iron and impart a magnetic axis to the organism that allows it to orient itself in relation to the earth's magnetic field. **Gas vesicles** permit the organism to maintain buoyancy at a certain level in an aqueous environment. Both of these inclusions enable the organisms to adjust locations in response to growth conditions and nutrient concentrations.

Extrachromosomal DNA is frequently present in the cytoplasm of prokaryotic organisms in the form of **plasmids**. Plasmids exist as covalently closed circles of dsDNA that range in size from about 1 kilobase (kb) to greater than 400 kb, which is equivalent to about 10% of the size of the *E. coli* chromosome. They are generally not found in eukaryotic organisms, although some subcellular organelles in eukaryotic organisms (e.g., mitochondria) do contain DNA molecules that resemble bacterial plasmids. Plasmids are capable of autonomous replication, are inherited by progeny bacterial cells, and may contain the genetic information for a variety of structures or functions related to bacterial virulence, including genes for antimicrobial resistance, virulence-related adhesins, toxin production, and resistance to heavy metal ions. Some plasmids, termed *conjugative plasmids*, encode for enzymes that facilitate transmission of plasmids to other bacterial cells. Some bacteria may also possess **transposons** and **insertion sequences**, which are sequences of DNA that are able to insert into different, unrelated sites on either the chromosome or a plasmid. Insertion of these elements into DNA does not require that the transposon base sequence be homologous with its insertion site (see below).

Cytoplasmic Membrane

The cytoplasm of all bacterial cells is surrounded by a cytoplasmic membrane. The bacterial cytoplasmic membrane lies immediately within the cell wall peptidoglycan layer in gram-positive bacteria, and adjacent to the periplasmic space in gram-negative bacteria (discussed below). The basic structure of the cytoplasmic membrane is a phospholipid bilayer in which various constituent proteins are embedded. The membrane is comprised of 30% to 60% phospholipid and 50% to 70% protein by

weight. Most bacterial cell membranes contain phosphatidyl glycerol, phosphatidyl ethanolamine, and diphosphatidyl glycerol; they do not contain sterols (e.g., cholesterol or ergosterol). The only prokaryotic exceptions to this are the mycoplasmas and ureaplasmas, which incorporate sterols from the growth medium into their cell membranes. The fatty acids that compose the lipid portion of the phospholipid bilayer generally contain 15 to 18 carbon backbones and are usually saturated or monounsaturated.

The cell membrane of prokaryotes possesses several functions that are relegated to specialized intracytoplasmic organelles in eukaryotic organisms. The bacterial cell membrane contains enzymes that are active in cellular respiration and oxidative phosphorylation, peptidoglycan and complex lipid biosynthesis, DNA replication, and outer membrane biosynthesis in gram-negative bacteria. In phototrophic bacteria, the early events associated with light harvesting also occur at the cell membrane level. The cell membrane contains the machinery for the synthesis and secretion of enzymes and bacterial toxins and provides an insulating barrier across which there may form an ion gradient or membrane potential that is used for energy production; such energy may be used for flagellar movement, chromosomal mobilization, etc. The membrane structure allows the retention of metabolites and exclusion of many external compounds. Some membrane proteins are involved in the active transport of materials (e.g., certain monosaccharides and disaccharides) into the cytoplasm. Such specific membrane-associated carrier proteins are termed *permeases*. **Mesosomes**, which are invaginations of the cytoplasmic membrane that extend into the cytoplasm, may function to increase the available membrane surface area for catabolic and anabolic cellular enzymes. They may also function in DNA replication and DNA duplex separation in actively growing cells. However, there is also evidence suggesting that mesosomes may actually be artifacts that result from the fixation techniques used for electron microscopy.

Bacterial Cell Wall Structure

The bacterial cell wall provides structural rigidity, confers shape to the cell, and forms a physical barrier against the outside environment. The rigid component of the cell wall of all bacteria is composed of **peptidoglycan**. Peptidoglycan is found in all bacterial species except for the cell wall–deficient mycoplasmas and ureaplasmas. This structure is composed of a backbone of alternating carbohydrate moieties of ***N*-acetylglucosamine and *N*-acetylmuramic acid** in β-1,4 linkage (Fig. 5-6). Short tetrapeptides, generally composed of identical short chains of D- and L-amino acids, are attached to the *N*-acetylmuramic acid residues via a peptide bond to the lactyl group on C3. These short chains contain unusual amino acids not generally found in proteins, including D-isomers of alanine and D-glutamic acid (gram-positive bacteria), *meso*-diaminopimelic acid (*meso*-DAP) or lysine (gram-negative bacteria). Some of

these tetrapeptides are, in turn, linked to one another by short peptides forming cross-bridges between adjacent peptidoglycan strands (Fig. 5-7). The types of amino acids found and the degrees of cross-linkage are variable components of the peptidoglycan structure. For example, in *Staphylococcus aureus*, most of the *N*-acetylmuramic acid residues are cross-linked to adjacent peptidoglycan strands by five glycine residues, thereby providing a rather tight, rigid cell wall structure (Fig. 5-7A). In gram-negative bacteria such as *E. coli*, the cross-linkage is directly between the *meso*-DAP of one peptidoglycan "chain" and the terminal D-alanyl residue on an adjacent strand (Fig. 5-7B). The degree of such cross-linking determines whether a cell wall structure is termed *tight* (highly cross-linked) or *loose*. Among the gram-positive bacteria, there are

over 100 different peptidoglycan chemotypes that differ by having various amino acid substituents attached to the lactyl group of *N*-acetylmuramic acid or that have different linkage units comprising the interpeptide bridges. Slight changes in the cell wall chemotype may occur on exposure to high salt concentrations or cell wall–active antimicrobial agents such as methicillin.

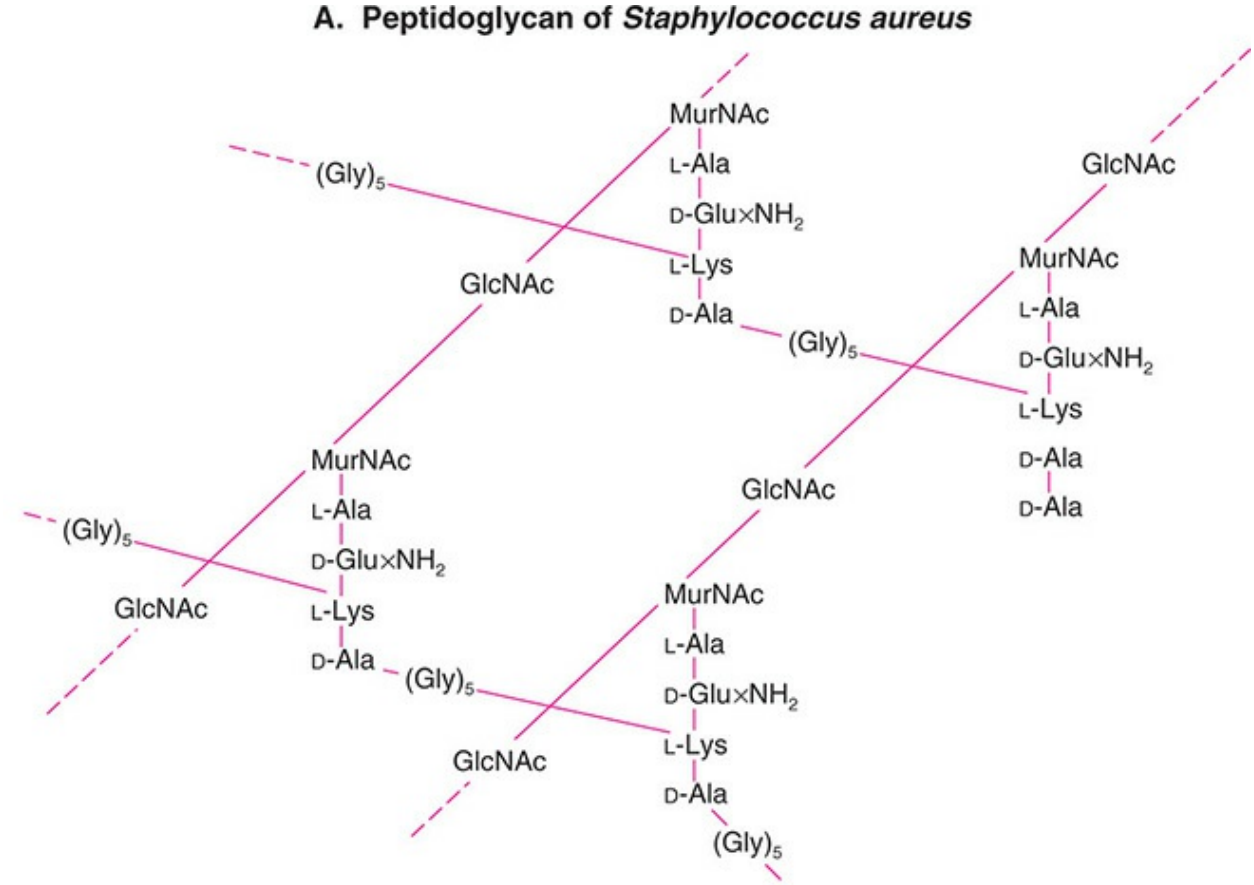
Bacterial cell wall biosynthesis is a continual process. New peptidoglycan polymers are exported from the cell and linked to preexisting cell wall polymers at the inner aspect of the cell wall by **penicillin-binding proteins**. At the same time, older peptidoglycan material overlying the newly synthesized structures is continually being removed by cell wall autolysins. Antimicrobial agents such as penicillins and cephalosporins inhibit bacterial cell growth by binding to the penicillin-binding proteins, thereby inhibiting polymer renewal at the inner aspect of the wall. Continuous autolytic hydrolysis of older peptidoglycan materials causes a thinning of the wall, eventually resulting in cell lysis.

Gram-Positive Bacterial Cell Walls. The gram-positive bacterial cell wall (Fig. 5-8A) is almost 80 nm thick and is composed mostly of several layers of peptidoglycan; in fact, anywhere from 40% to greater than 80% of the dry weight of some gram-positive cell walls may be peptidoglycan. Trapped within this peptidoglycan matrix are a variety of proteins, polysaccharides, and unique molecules called teichoic acids. Teichoic acids are polymers of either ribitol (5-carbon) or glycerol (3-carbon) units joined together by phosphodiester linkages (Fig. 5-9). Ribitol teichoic acids are associated with the cell wall, while glycerol teichoic acids are associated with the inner aspect of the bacterial cell membrane. Ribitol teichoic acids are covalently linked to the peptidoglycan via the C6 hydroxyl group of *N*-acetylmuramic acid, while the glycerol teichoic acids are linked to glycolipids of the cytoplasmic membrane. The latter molecules are termed *lipoteichoic acids*. They are linked to the outer lipid layer of the cell membrane and extend into the cell wall. Teichoic acids of different bacteria are further modified by addition of "R" groups including ester-linked D-alanine or D-lysine residues or *O*-glycoside-linked glucose, galactose, or *N*-acetylglucosamine. Teichoic acids stabilize the cell wall, maintain the association of the wall with the cell membrane, chelate small ions necessary for cell function and cell wall integrity, and participate in cellular interaction and adherence to mucosal or other surfaces. Teichoic acids may also function in peptidoglycan synthesis and septum formation during growth and reproduction and may also play a role in the competence of some gram-positive bacteria to undergo transformation. In some organisms, the teichoic acids are antigenic and form the basis for antigenic grouping (e.g., the group D antigen in group D streptococci and members of the genus *Enterococcus*).

In the various groups of pathogenic gram-positive bacteria, other cell wall structures that are important virulence determinants may also be present. For example, M protein, a well-recognized virulence factor of group A β-hemolytic streptococci, is associated with lipoteichoic acids in the streptococcal cell wall and extends out of the wall as a fimbrial protein (see Chapter 13).[45] The group antigens of the group A, B, C, F, and G β-hemolytic streptococci are also nonteichoic acid polysaccharides that are found in the cell wall. The C polysaccharide found in the cell walls of *Streptococcus pneumoniae* is a complex lipoteichoic acid composed of ribitol and phosphate substituted at various points with *N*-acetyl-D-galactosamine, D-glucose, *N*-acetyl-2,4-diamino-2,4,6-trideoxyhexose in *O*-glycosidic linkage and choline in diester linkage.[49]

Gram-positive (and some gram-negative) bacterial cell walls also possess a cell wall component called the **S-layer**. S-layers consist of protein or glycoprotein molecules of 50 to 120 kDa molecular weight that self-assemble on the outer surface of the organism in oblique, square or hexagonal, packed lattice-like structures.[7,82] S-layer material may constitute up to 20% of the total cell protein. On electron microscopy, the S-layer appears as an extra "layer" on top of the cell wall. S-layer proteins are poorly conserved and can differ markedly even between related species. Depending on the species, the S-layers have a thickness between 5 and 25 nm and possess identical pores 2 to 8 nm in diameter. S-layers exhibit either an oblique, square, or hexagonal lattice symmetry. Depending on the lattice symmetry, the S-layer is composed of one (P1), two (P2), three (P3), four (P4), or six (P6) identical protein subunits, respectively. For many bacteria, the S-layer represents the outermost interaction zone with the environment and its functions are diverse and vary from species to species. In *Archaea,* the S-layer is the only cell

189

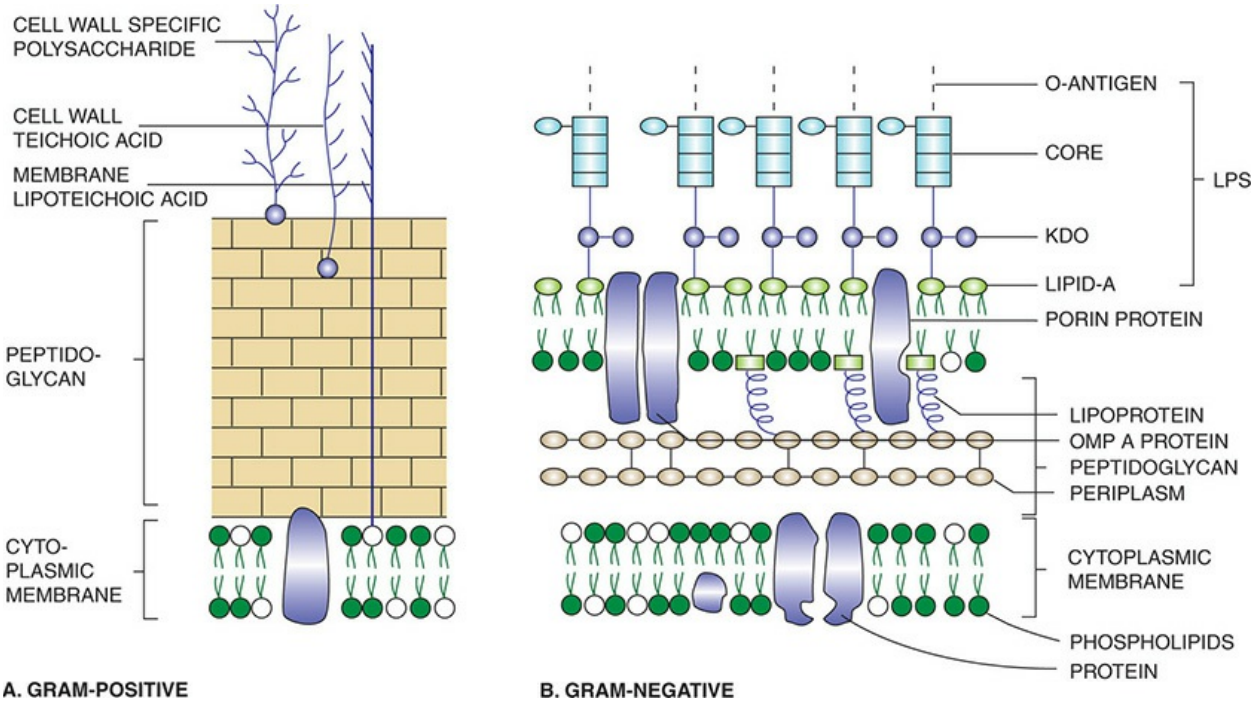


■ **FIGURE 5-7** Structure of the peptidoglycan in *Staphylococcus aureus* and *Escherichia coli*.

wall component and, therefore, is important for mechanical stabilization. Additional functions associated with S-layers include protection against bacteriophages and resistance against low pH. The S-layer may act as a barrier against high-molecular-weight substances (e.g., lytic enzymes) and may function as an adhesin in the case of glycosylated S-layers. S-layers may act to stabilize the cell membrane and to provide attachment sites for periplasmic proteins. In pathogenic microorganisms, the S-layer may inhibit phagocytosis and/or prevent the binding of immunoglobulin and complement. Freeze-etch electron microscopic techniques have demonstrated S-layers in *Bacillus*, *Lactobacillus*, *Clostridium*, *Campylobacter*, and *Aeromonas* species. In *Bacillus anthracis*, it is now thought that the S-layer is this organism's major cell wall antigen and, along with the capsule and the two toxins, may contribute to virulence.[57]

Gram-Negative Bacterial Cell Walls. The cell wall of gram-negative bacteria (Fig. 5-8B) is thinner than that of gram-positive bacteria but is structurally more complex.

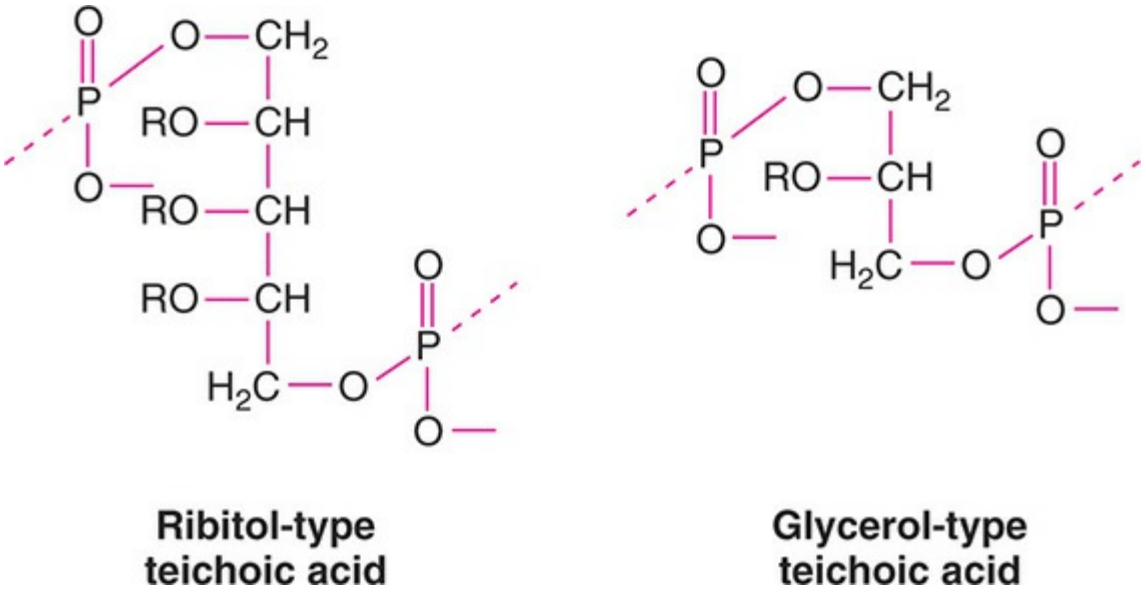
190



■ **FIGURE 5-8** Structure of the cell wall of gram-positive (**A**) and gram-negative (**B**) bacteria. KDO, keto-deoxy-octulonate; LPS, lipopolysaccharide.

Immediately outside of the cytoplasmic membrane is the **periplasmic space**. The periplasmic space contains degradative enzymes (alkaline phosphatase, proteases,

nucleosidases, β-lactamases, and aminoglycoside phosphorylases) and specific binding and transport proteins for vitamins, amino acids, and ions. A **single-unit-thick peptidoglycan layer** forms the outer border of the periplasmic space. Because the peptidoglycan layer is only one layer thick, cross-linking occurs only to adjacent peptidoglycan strands rather than to layers of peptidoglycan either closer to or more external to the individual cell surface. Cross-links are formed from the carboxyl group of the terminal D-alanine residue on one chain to the free amino group of a *meso*-DAP residue on an adjacent chain (Fig. 5-7B). The peptidoglycan layer of gram-negative bacteria is fairly "loose"; that is only about half of the peptide chains attached to the *N*-acetylmuramic acid residues are actually involved in cross-linking. Moreover, cross-linking within the peptidoglycan occurs directly from the muramyl tetrapeptide on one peptidoglycan chain to the muramyl tetrapeptide of an adjacent peptidoglycan chain (i.e., no interpeptide bridges as in Fig. 5-7A).

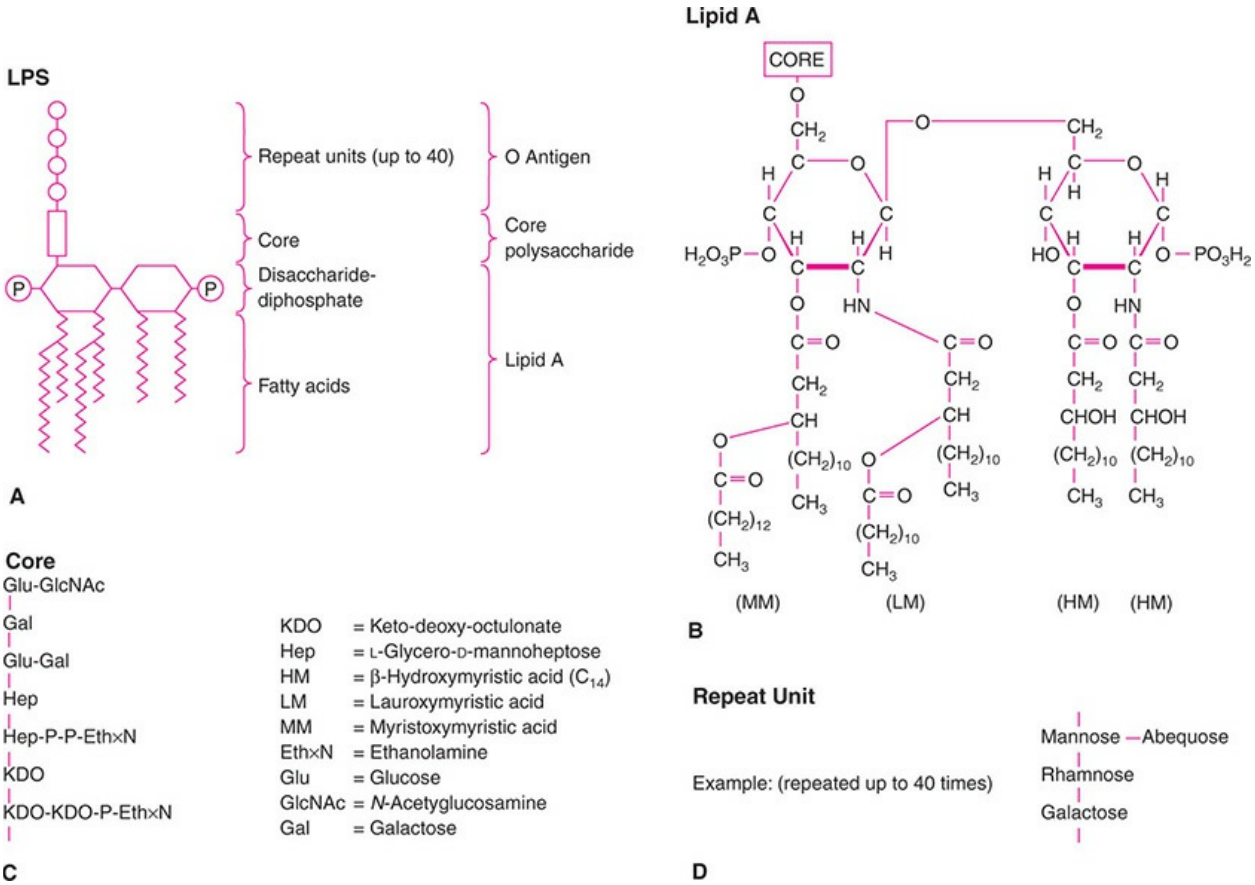


■ **FIGURE 5-9** Structure of teichoic acids of gram-positive bacteria. Ribotol teichoic acid is shown on the left; glycerol teichoic acid is shown on the right. "R" group substitutions may include ester-linked D-alanine or D-lysine or *O*-glycosidic links to glucose, galactose, or *N*-acetylglucosamine.

Outside of the thin peptidoglycan layer is the **outer membrane**. This outer membrane has a basic structure similar to the cytoplasmic membrane; that is, a phospholipid bilayer in which various other large molecules are embedded. The outer membrane is anchored to the peptidoglycan layer by small, strongly lipophilic **murein lipoproteins** that are attached covalently to the amino group of diaminopimelic acid in the peptidoglycan and extend across the periplasmic space as an α-helical structure.

The other end of this lipoprotein is noncovalently embedded in the lipid structure of the outer membrane.

A structural component that is unique to the gram-negative outer membrane is **lipopolysaccharide (LPS)** (Fig. 5-10A). LPS molecules are the major surface antigenic determinants (called **somatic** or **O antigens**) in gram-negative bacteria and are responsible for the endotoxin activity of gram-negative cells. LPS molecules are high-molecular-weight, complex glycolipids consisting of three components: a complex, hydrophobic, lipid portion called **lipid A**, a **core polysaccharide region** that links lipid A to the more external structures of the molecule and that is generally similar in structure within a given bacterial genus or species, and **O-specific (somatic antigen) polysaccharide side chains**, which are regions of variable biochemical structure that impart unique



■ **FIGURE 5-10** The lipopolysaccharide (LPS) of the gram-negative cell envelope. **A.** Segment of the polymer showing the arrangements of the major constituents. **B.** Structure of lipid A of *Salmonella typhimurium*. **C.** Polysaccharide core. **D.** Typical repeat unit (*Salmonella typhimurium*). Melnick, and Adelberg's Medical Microbiology. 19th Ed. Norwalk, CT: Appleton & Lange, 1991.)

serologic identity to gram-negative species. The lipid A moiety of the LPS is embedded in the outer leaflet of the outer membrane, with the core polysaccharide and the O-specific side chains projecting from the outer membrane surface like whiskers. Each *Salmonella* serotype, for example, has characteristic O-specific side chains that allow serologic confirmation of biochemical identifications and afford strain typing when possible foodborne *Salmonella* outbreaks are being investigated. The structure of LPS has been studied most extensively in *Salmonella* species and *E. coli*.

Lipid A is composed of a glucosamine disaccharide in which the hydroxyl groups are esterified to uncommon β-hydroxy fatty acids like β-hydroxymyristic acid (C14), myristomyristic acid, and lauromyristic acid (Fig. 5-10B). Additional fatty acids may be attached via hydroxyl groups to other unsubstituted locations on the myristic acid molecule; these additional substitutions differ among the various genera of gram-negative bacteria. Attached to the lipid A portion of the LPS is the core polysaccharide. The core polysaccharide contains two unique carbohydrates: **3-deoxy-D-mannooctulosonate** (formerly called **2-keto-3-deoxyoctonoic acid [KDO]**), an 8-carbon sugar, and **heptose**, a 7-carbon sugar. Core KDO forms covalent connections between lipid A and heptose moieties in the core polysaccharide. Additional sugars (e.g., *N*-acetylglucosamine, glucose, and galactose) may also be found in the core polysaccharide. The core polysaccharide structure is fairly conserved within a given genus, but may vary from species to species. The O-specific side chains are attached to the core polysaccharide and are responsible for the antigenic specificity of individual isolates. These side chains contain a variable number (up to about 40) of repeating oligosaccharide units comprised of three to five monosaccharides each. These antigenically specific side chains often contain unusual or uncommon carbohydrate residues, including aminohexuronic acid, 6-deoxyhexoses, and 2,6-dideoxyhexoses. The lipid A moiety appears to be the principal component responsible for the manifestations of endotoxin activity in patients with gram-negative bacterial sepsis (e.g., fever, shock, vascular collapse, and hemorrhage). Endotoxin can also activate complement and can cause disseminated intravascular coagulation. The generalized structure of the LPS of *Salmonella* species is shown in Figure 5-10A, while the structure of lipid A, the core polysaccharides, and somatic antigens are shown in Figure 5-10B, C, and D, respectively.

Dissociation of the outer membrane LPS can be partially accomplished by treatment of cell suspensions with ethylenediamine tetraacetic acid (EDTA), which chelates the divalent cations of the outer membrane. Subsequent treatment with lysozyme hydrolyzes the peptidoglycan layer of gram-negative bacteria, and the cells may be lysed. The dependence of the integrity of the outer membrane on calcium

and magnesium ions is one of the principal reasons for the inclusion of these ions in media that is used for antimicrobial susceptibility testing.

Some gram-negative bacteria (e.g., *Haemophilus influenzae*, *Neisseria gonorrhoeae*, and *Bordetella pertussis*) have **lipo-oligosaccharides (LOS)** rather than LPS in their cell walls.[11,42,102] LOS contains lipid A and an oligosaccharide core containing KDO, but it does not have a long-chain polysaccharide O antigen as is found in the LPS of enteric bacteria. These molecules, like endotoxin, possess a range of biologic activity, including general toxicity, pyrogenicity, and the unique ability to induce B-cell mitogenicity and polyclonal B-cell activation. Antigenic variation seen in *N. gonorrhoeae* is partially due to high-frequency structural modulation of the LOS, which has also been shown to affect gonococcal adherence to mucosal surfaces and susceptibility to the bactericidal action of normal human serum.[77,78]

The gram-negative outer membrane also contains phospholipids and proteins. The phospholipids are similar to those found in the cytoplasmic membrane and include phosphatidyl ethanolamine and phosphatidyl glycerol. Proteins also constitute a significant portion of the outer membrane. Those that are present in greatest concentrations are called **principal or major outer membrane proteins** (**OMPs**). These proteins fall into three major groups. **Porin proteins** are proteins that form trans-outer membrane channels through which lower-molecular-weight materials (e.g., amino acids, sugars, ions) are allowed into the periplasmic space. Many of these porin proteins are composed of three identical proteins that form a "doughnut-shaped" pore. Porins also help to limit passage of many antimicrobial agents into the cell. **Transmembrane proteins** are nonporin proteins that span the outer membrane, extend through the periplasm, and are associated with the peptidoglycan layer of the cell wall. They may function in exoenzyme production and secretion, transport of specific proteins, attachment to surfaces, or in binding of antimicrobial agents to their cell-surface targets (e.g., penicillin-binding proteins). **Peripheral proteins** are responsible for transmembrane transport of molecules that are also too large for porin entry. Most of these proteins are components of substrate-specific permease systems (e.g., siderophore binding and transport of iron into the cell). Lipoproteins (see above) are the smallest of the OMPs and serve to stabilize the cell wall via covalent linkage with the peptidoglycan.

The structure of the bacterial cell wall has direct, practical importance to the microbiologist because the type of cell wall structure is largely responsible for the **Gram's stain** reaction. This differential stain divides the majority of bacteria into two groups—**the gram-positive** and the **gram-negative bacteria**. In the Gram's stain procedure, cells are (1) stained with **crystal violet**; (2) treated with i**odine** to form a crystal violet–iodine complex within the cell; (3) washed with an **organic solvent**

(acetone–alcohol); and (4) stained again with the red counterstain **safranin**. In gram-positive bacteria, the purple crystal violet–iodine complex is retained within the cell after washing with acid–alcohol because the thick peptidoglycan layer does not allow the crystal violet–iodine complex to be washed out of the cell. In gram-negative bacteria, the crystal violet–iodine complex is leached from the cell (i.e., the cells become colorless) because of disruption of the lipid-rich outer membrane by the acetone–alcohol organic solvent. These colorless cells must be counterstained in order to be seen under the light microscope; this counterstain is provided by safranin. Gram-positive bacteria appear blue-purple under the microscope, while gram-negative bacteria are stained red by the safranin counterstain.

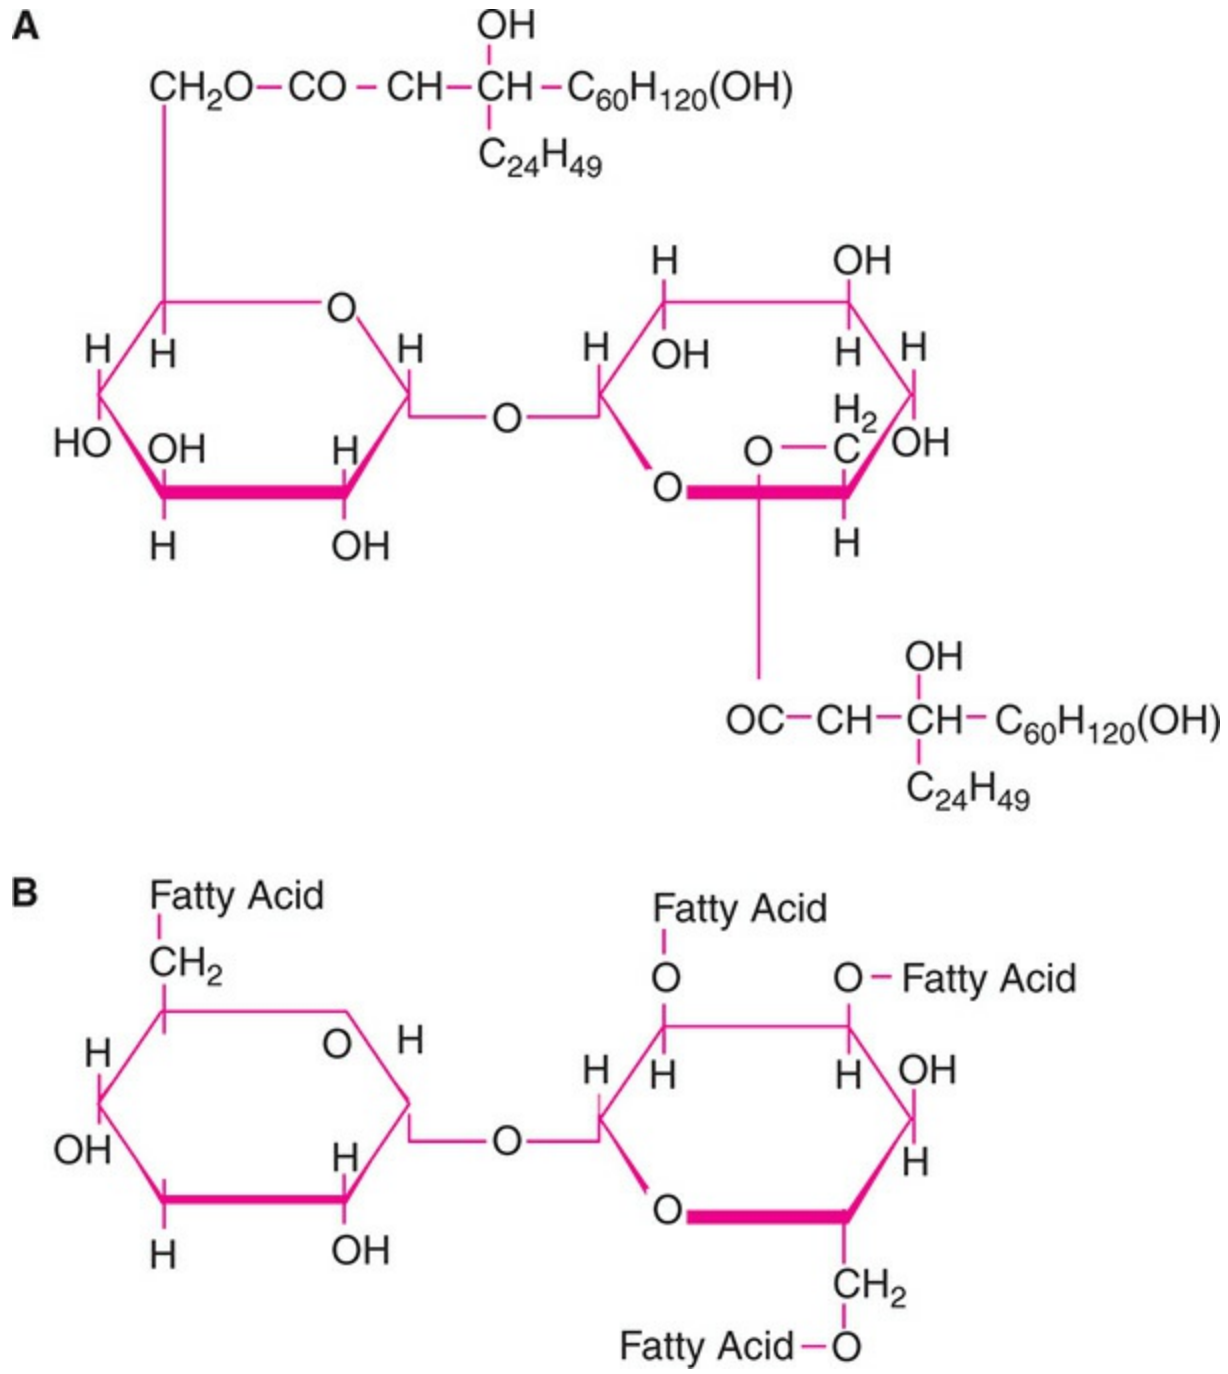
Some gram-negative bacteria do not have the complex cell wall structure described above. Organisms in the *Cytophaga–Flexibacter–Flavobacterium* group have outer membranes containing ornithine-aminolipids and sulfonolipids as their principal components, along with large amounts of branched-chain fatty acids with odd-numbered carbon side chains. Organisms in *Archaea* lack a peptidoglycan structure and have instead a "pseudopeptidoglycan" composed of proteins, glycerol esters, and *N*-acetyltalosaminuronic acid (i.e., *meso*-DAP and *N*-acetylmuramic acid are absent). Some *Archaea* lack even this rudimentary peptidoglycan, having instead a thin cell wall consisting of proteins or sulfated polysaccharides.

"Acid-Fast" Bacterial Cell Walls. A modification of the gram-positive cell wall is seen in organisms belonging to the genera *Mycobacterium*, *Nocardia,* and *Corynebacterium*. In these organisms, lipids account for as much as 60% of the dry weight of the cell wall. These organisms contain molecules called **mycolic acids** in their cell walls. Mycolic acids are large, α-substituted, β-hydroxy fatty acids that occur as esters attached to cell wall polysaccharides. Mycolic acids vary in the number of carbon atoms; those with 30 carbons (C30) are found among the corynebacteria (corynemycolenic acids), those with C50 are found in *Nocardia* species (nocardic acids), and those with C90 or more constitute the mycolic acids found in the genus *Mycobacterium*. In *Mycobacterium tuberculosis*, the unique mycolic acid **6,6 ′-dimycolyltrehalose** is known as **cord factor** (Fig. 5-11A). This molecule is associated with virulence of *M. tuberculosis* and has a wide range of biologic activities, including cell membrane cytotoxicity, inhibition of polymorphonuclear cell migration, induction of granuloma formation, adjuvanticity, antitumor activity, and ability to activate the alternative complement pathway.

The cell membrane of mycobacteria is similar to other bacterial unit membranes except that it contains **phosphatidylinositol mannosides** and **lipoarabinomannan**. External to the membrane is the peptidoglycan layer which is composed of *N*-acetylglucosamine in β-1,4 linkage to *N*-glycolylmuramic acid. The murein layer is cross-linked by tetrapeptide bridges containing L-alanine, D-glutamate, and *meso*-DAP residues. Some of the *N*-glycolylmuramic acid residues are linked by phosphodiester

bonds to an overlying layer of branched-chain polysaccharide macromolecules called **arabinogalactans** (containing arabinose and galactose moieties). The distal arabinose residues of this layer are linked to the overlying mycolic acids. The hydrocarbon chains of the mycolic acids are intercalated with those of numerous other wall-associated lipids and glycolipids. These cell wall-associated lipids include those with medium (C24 to C36) and short (C12 to C20) fatty acyl groups. These wall-associated lipids include trehalose sulfolipids (Fig. 5-11B). The trehalose sulfolipids, typified by the principal sulfolipid of *M. tuberculosis* **2,3,6,6′-tetraacyltrehalose-2′-sulfate**, are associated with mycobacterial virulence

193



■ **FIGURE 5-11** Molecular structure of specialized lipids found in the cell wall of *Mycobacterium tuberculosis*. **A.** Molecular structure of cord factor (6,6′-dimycolyltrehalose) produced by *Mycobacterium tuberculosis*. **B.** Molecular structure of the principal sulfolipid (2,3,6,6′-tetraacyltrehalose-2′-sulfate) of *M. tuberculosis*.

in that these molecules may act to prevent phagosome–lysozyme fusion following phagocytosis of the mycobacterial cells, thereby allowing the organisms to survive as

facultative intracellular parasites. Protruding from the plasma membrane through the peptidoglycan, arabinogalactan, and mycolic acid layers of the wall are substituted phospholipids (phosphatidylinositol mannosides) and lipopolysaccharides (lipoarabinomannans) that are attached to the outer leaflet of the mycobacterial cell membrane. These molecules provide a noncovalent link between the cell membrane and the cell wall. Proteins that are embedded in the mycobacterial cell wall are involved in biosynthesis and construction of the cell wall polymers and some apparently also function as porins.

Organisms that are acid-fast are stained red with the basic dye carbol fuchsin and are resistant to decolorization with acid–alcohol. Because of the hydrophobicity of the mycobacterial cell wall, penetration of the dye into the cell is enhanced by heat treatment (i.e., the Ziehl–Neelsen method) or incorporation of detergent into the dye (i.e., the Kinyoun method). Resistance to decolorization by acid–alcohol (i.e., "acid-fastness") is associated with the mycolic acid–arabinogalactan moieties that constitute the bulk of cell wall materials external to the peptidoglycan layer. The soluble lipids contribute to but do not determine the acid-fast properties of mycobacterial cells, since extraction of these lipids diminishes but does not destroy the ability of the cells to retain carbol fuchsin (i.e., their acid-fastness). Mechanical disruption of the cell wall and extraction of the cell wall lipids with ethanolic alkalis that remove both free and esterified lipids destroys the acid-fast properties of these organisms, indicating that the total lipid content of the cell wall is responsible for the acid-fast staining property.

Bacterial Endospores

Endospores are spherical or oval structures formed within certain bacterial species that represent a dormant or "resting" stage in the growth cycle of the organism. Among clinically significant bacteria, endospores are formed by aerobic gram-positive bacilli belonging to genus *Bacillus* and other related genera, and by the anaerobic gram-positive bacilli in the genus *Clostridium.* In these genera, endospores are formed in response to nutritional deprivation within the vegetative bacterial cell. They are highly resistant to the injurious effects of heat, drying, pressure, and many chemical disinfectants. Sterilization temperatures (i.e., 120°C for 15 to 20 minutes) are required to kill spores. The heat resistance of bacterial endospores is believed to be due to reduced amounts of water in the core of the spore itself. The size, shape, and location of incipient endospores in stationary-phase cells of *Clostridium*, *Bacillus,* and related species are helpful for characterization and identification of certain species within these two genera (see Chapters 14 and 16). The endospores may be spherical, subspherical or oval in shape, they may differ in their location within the cell (i.e., central, terminal, or subterminal), and they may or may not swell the cell. Endospores generally do not stain with routine staining methods like the Gram's stain, and appear as refractile, nonstaining bodies in smears.

Under the stimulus of certain environmental conditions such as the exhaustion of nutrients (i.e., glucose, nitrogen, or phosphate) or exposure to suboptimal temperatures or redox potentials, the nuclear material divides into two nucleoids, and one becomes separated from the other by a membranous septum. The septum then grows together and the spore core becomes engulfed in a double membrane. Between the two

membranes, a cortex layer is deposited by the membranes. This cortex consists primarily of peptidoglycan material. The cortex layer thickens and accumulates calcium ions because of the chelating activity of a unique molecule called **dipicolinic acid**. The core becomes protected by the high concentration of calcium ions tightly cross-linking the peptidoglycan material and all available water in the spore is expelled. Several layers of the spore coat (a keratin-like substance that is rich in disulfide bonds) are laid down, and the endospore is liberated on the death and lysis of the mother vegetative cell. Endospores may remain viable for prolonged periods. When the spore is placed in a favorable environment in the presence of particular stimuli (e.g., the presence of particular amino acids or carbohydrates and water), spore outgrowth occurs. Upon this stimulus, enzymes are activated which degrade the spore cortex and release the peptidoglycan material, calcium ions, and dipicolinic acid. RNA synthesis begins, followed by protein synthesis and, eventually, DNA synthesis. A new vegetative cell results.

Bacterial Surface Structures

Capsules. Some bacteria possess a capsule external to the outer layer of the cell wall. The capsule may be thick or thin, and may be closely or loosely associated with the external aspect of the cell wall. Loosely associated capsular material may also be referred to as a **slime layer** or **glycocalyx**. Capsular material is usually polysaccharide in nature; these polysaccharides may be polymers of single monosaccharides (glucans, dextrans, levans) or heteropolysaccharides containing both hexose and pentose sugars, plus ribitol, glycerol, or other sugar alcohols. Phosphates are also frequently present. In most cases, the capsule is synthesized at the level of the cell membrane; components are synthesized and exported out of the cell by an isoprenoid lipid "carrier" system, in which the components become attached to "primer" capsular material already present on the surface of the cell. In some cases, such as the glucan capsule of *Streptococcus mutans*, the capsule is synthesized by a class of extracellular and cell wall-associated enzymes called **glucosyltransferases**.[9] The action of these enzymes on dietary sucrose creates a branched, **insoluble glucan** matrix that specifically interacts with the tooth surface and with receptors on the *S. mutans* cell. Subsequent formation of acids from dietary sucrose and from intracellular glycogen

stores in *S. mutans* and other organisms leads to formation of dental caries.

The bacterial capsule serves several functions. It protects the cell from desiccation and from toxic materials in the environment (e.g., heavy metal ions, free radicals) and promotes the concentration of nutrients at the bacterial cell surface because of its polyanionic nature. In addition, the capsule also plays a role in the adherence of bacteria to cells and mucosal surfaces. This adherence is necessary for many organisms to establish infections in appropriate hosts (discussed below). Some bacterial capsules function to protect cells from phagocytosis (in the absence of anticapsular antibodies) by polymorphonuclear leukocytes. Capsular material is usually antigenic, and the serologic detection of the capsule forms the basis of the **Quellung test** (see Chapter 12), which can be used to identify and/or subtype several important human pathogenic bacteria, including *S. pneumoniae*, *H. influenzae* type b, *Klebsiella pneumoniae*, and *Neisseria meningitidis* serogroups. The capsular material of many microorganisms is synthesized in abundance and is shed into the surrounding fluid both in vivo and in vitro.

In recent years, the capsular structure of *Staphylococcus aureus* has been an area of interest to both basic scientists and clinical microbiologists. More than 90% of *S. aureus* strains isolated in the clinical laboratory are encapsulated, and these capsules have been divided serologically into 11 types.[63] The types that have been characterized thus far (types 1, 2, 5, and 8) are complex *N*- and *O*-acetylated carbohydrates in β-1,4 and β-1,3 linkages. Capsular types 5 and 8 predominate among clinical isolates, and a predominant number of oxacillin-resistant strains express the type 5 capsular polysaccharide.[2,39] Of interest to the bench microbiologist is that capsular type 5 *S. aureus* strains also may not be reliably identified by latex agglutination coagulase tests used in clinical laboratories.[38] For this reason, latex beads coated with antibodies to type 5 and 8 capsular polysaccharides are now included in some formulations of the coagulase latex agglutination test.[40]

In some bacterial species, such as *Bacillus* and related species, the capsule is polypeptide in nature. *B. anthracis*, the cause of anthrax, is encapsulated in both infected tissue and when grown on media containing bicarbonate or in a >5% CO_2environment. Both capsule formation and toxin production are specifically "turned on" by these cultural conditions, which, interestingly, reflect the same bicarbonate and CO_2 concentrations found in tissues infected with *B. anthracis*.[91] The *B. anthracis* capsule is composed of linked, β-peptide chains of D-glutamic acid ranging from 50 to 100 residues per chain.[91] The presence of the capsule renders *B. anthracis* resistant to phagocytosis.[54]

Flagella. Bacterial flagella are long, filamentous appendages that arise at the level of the cytoplasmic membrane and extend through the cell wall into the surrounding

medium. They are responsible for cellular motility. Flagella are usually found in rod-shaped, gram-negative bacteria, although motile, gram-positive rods (e.g., *Listeria* species) and cocci (some *Enterococcus* species, *Vagococcus* species) are also found. Flagella differ in their numbers and their arrangements on cells. Bacteria with a single polar flagellum are termed **monotrichous**; those with two or more flagella originating at one pole or point are **lophotrichous;** those with a single flagellum located at two different points or poles are called **amphitrichous;** and those with two or more (a tuft) flagellae at two points or poles of the cell are called **amphi-lophotrichous.** Organisms that have flagella arising over the entire cell surface are termed **peritrichous**.

In gram-negative bacteria, flagella have been demonstrated to have a complex structure consisting of three parts: the **filament**, the **hook**, and the **basal body** (Fig. 5-12). The flagellar filament is 13 to 17 nm in diameter and is variable in length. The filament is composed of parallel subfibrils of the 30- to 40-kDa subunit protein **flagellin,** which interact to form a hollow cylinder. The filament is semirigid and forms a left-handed helix as it exits the cell. Flagellin has the capacity to self-assemble. Monomers of the protein are synthesized and passed through the lumen of the cylinder. At the growing tip of the flagellum helix, the monomer undergoes a conformational change and becomes added to the

distal end of the flagellum. The hook is composed of another distinct protein and acts as a "sleeve" from which the flagellar filament emerges. The hook permits the transmission of a rotary motion from the basal body to the filament. The **basal body** is composed of complex rings connected by a rod-shaped structure. The **M, S, P, and L rings** are anchored in the membrane, the periplasmic space, the peptidoglycan, and the lipopolysaccharide outer membrane, respectively. At least 10 proteins comprise the outer ring structure in gram-negative bacteria. The ring structure attached to the cell membrane rotates as a part of an energy-dependent reaction, causing the rigid flagellar helix to turn like a propeller. The energy for this reaction is derived by the passage of protons from the outside into the cytoplasm via the basal body. The outer rings (L and P rings) evidently function as bearings, minimizing friction and leakage of materials from the cell at the points of flagellar insertion. In gram-positive bacteria, the flagellar structure is less complex and is composed of two rings. One ring structure anchors the flagellum to the plasma membrane, while the second ring structure is embedded in the thick peptidoglycan layer.

Several species of flagellated organisms are also able to alter the expressed antigenic type of flagella that they produce; this process is known as **phase variation**. This refers to the ability of organisms to express two types of flagella alternately. Phase variation occurs by the differential expression of chromosomal genes that code for two variously structured flagellin proteins. This phenomenon was first recognized in enteric gram-negative bacteria such as *Salmonella* species, but also occurs in other species, such as *N. gonorrhoeae* (see below). Flagellar antigens in gram-negative bacilli are referred to as H antigens, from the German word "hauch," meaning "breath." Some organisms have slightly modified flagellar structures. *Vibrio* species have the typical flagellar morphology, but the flagellum is encased in a sheath derived from the outer membrane of the cell wall. In the spirochetes, the flagellum does not protrude into the environment, but lies within a sheath that is exterior to the protoplasmic cylinder of the cell body of the organism. This endoflagellum or **axial filament** arises from one pole of the cell and wraps around the cell body internal to the sheath.

Other Locomotor Organelles. Some gram-negative bacteria exhibit what is known as "gliding motility." This type of motility is most apparent when organisms are in contact with a surface. In clinical microbiology, gliding motility is seen among the *Capnocytophaga* species, which are part of the normal microbiota of the human oropharynx and are occasionally isolated from infectious processes (see Chapter 9). Studies with *Flavobacterium johnsonii* and other organisms in the *Cytophaga–Flavobacterium–Bacteroides* group have suggested that proteins or glycoproteins located within the outer membrane adhere to the substratum and that

other proteins within the cell membrane harvest proton-motive forces that cause the surface proteins to move along "tracks" within the peptidoglycan layer.[56] Other studies have also shown the presence of unique sulfonolipids in the outer membrane of gliding bacteria that are absent in nonmotile mutants of the same species. Using spontaneous, chemically induced, and transposon-induced nonmotile mutants, several unlinked genes and operons involved with gliding motility have been identified.[47]

Fimbriae (Pili). Fimbriae or pili are smaller appendages found on the surface of many gram-negative and some gram-positive bacteria. Although the terms *pili* and *fimbriae* have been used interchangeably, the latter term is now used to describe any nonflagellar hairlike appendages, while the former term is used to denote the fimbriae of gram-negative bacteria that function specifically in the transfer of DNA from one cell to another during the process of conjugation (i.e., sex pili). Fimbriae are composed of a protein called **fimbrillin** (or **pilin**), are 3 to 25 nm in diameter, and are 10 to 20 mm in length. Fimbrillin produced in gram-negative bacteria is a subunit protein of 17 to 20 kDa molecular weight. The proteins form hollow tubes that originate in the cell membrane, but that lack the basal body and hook structures of flagella. Fimbrial subunit proteins are added at the base of the structure, rather than at the tip as is seen with flagellar synthesis. Sex pili are involved in specific pair formation for exchange of genetic material during conjugation and also serve as attachment sites for bacteriophages.

Fimbriae also function as cellular organelles for attachment to cells and/or mucosal surfaces; fimbriae that serve

this attachment function are often referred to as **adhesins.** Most adhesins display lectin-like binding to terminal carbohydrate residues (e.g., mannose)—for instance, the adherence of enteric bacteria to mucosal surfaces that is mediated by type 1 (type-specific) or common pili that can be inhibited by preincubation of the bacteria with mannose. Mannose attaches to the terminal portion of the adhesin and blocks adherence; therefore, type 1 pili are termed *mannose-sensitive*. Adhesins that are not affected by mannose are termed *mannose-resistant* or *type 2 pili*. Differing lectin-like specificities are partly responsible for the tissue tropisms observed with a variety of bacterial species.

The role of fimbriae as virulence factors in gram-negative bacteria has been studied extensively in *N. gonorrhoeae* and *N. meningitidis*.[43,62] These pathogenic *Neisseria* species produce antigenically and structurally similar fimbriae that are composed of 16.5 to 21.5 kDa fimbrial subunit proteins. Virulent strains of *N. gonorrhoeae* express these surface fimbriae and are able to adhere avidly to mucosal cells in the genital

tract.[95] Fimbriated organisms are also responsible for the domed type 1 and type 2 colonies produced by freshly isolated gonococci on agar media. The loss of fimbriae on repeated subculture in vitro renders these organisms unable to initiate urogenital infection because of lack of mucosal adherence. Colonies composed of nonpiliated gonococci are larger and flatter. Gonococci possess a large number of genes that code for structurally and antigenically distinct fimbrial proteins, and these proteins undergo both **phase variation** and **antigenic variation** (see Chapter 11). In phase variation between the piliated and the nonpiliated state, the *pil* genes (fimbrial structural genes) are either not expressed or the fimbrial proteins cannot be assembled into functional fimbriae. In antigenic variation, new fimbrial types may emerge because of recombinational events among the 20 or so fimbrial genes present in the bacterial genome. Because of the ability of a single gonococcal strain to produce multiple, antigenically distinct fimbrial antigens, the use of fimbriae as candidate antigens for antigonococcal vaccines has been largely unsuccessful.

Among the gram-positive bacteria, only a limited number of species express cell-surface fimbriae, including some streptococci, corynebacteria, and *Actinomyces* species. *Actinomyces viscosus* and *Actinomyces naeslundii*, facultative gram-positive bacilli found in the oral cavity, express two types of fimbriae. Type 1 fimbriae mediate bacterial adherence to tooth surfaces via interaction with salivary acidic proline-rich proteins, while type 2 fimbriae mediate bacterial adherence to oral streptococci and various mammalian cell types, including polymorphonuclear leukocytes and erythrocytes.[21,74] These type 2 fimbriae bind to either galactose or *N*-acetylgalactosamine residues on the surface of coaggregating oral streptococci or with the oligosaccharides of mammalian cell membrane glycoproteins.[74] Unlike the fimbriae from gram-negative bacteria, fimbriae of *Actinomyces* species are covalently linked to the cell wall peptidoglycan layer.[100] The ability of oral *Actinomyces* species to adhere to buccal mucosal cells and to coaggregate with cariogenic oral streptococci facilitates biofilm formation and the initiation of dental plaque. Fimbrial coaggregates of *Actinomyces* and oral streptococci have been shown to resist phagocytosis and killing by polymorphonuclear cells, and binding of *Actinomyces* to PMNs results in the release of mediators of inflammation. Fimbria clearly play a key role in the ability of these periodontal pathogens to colonize and initiate infection.

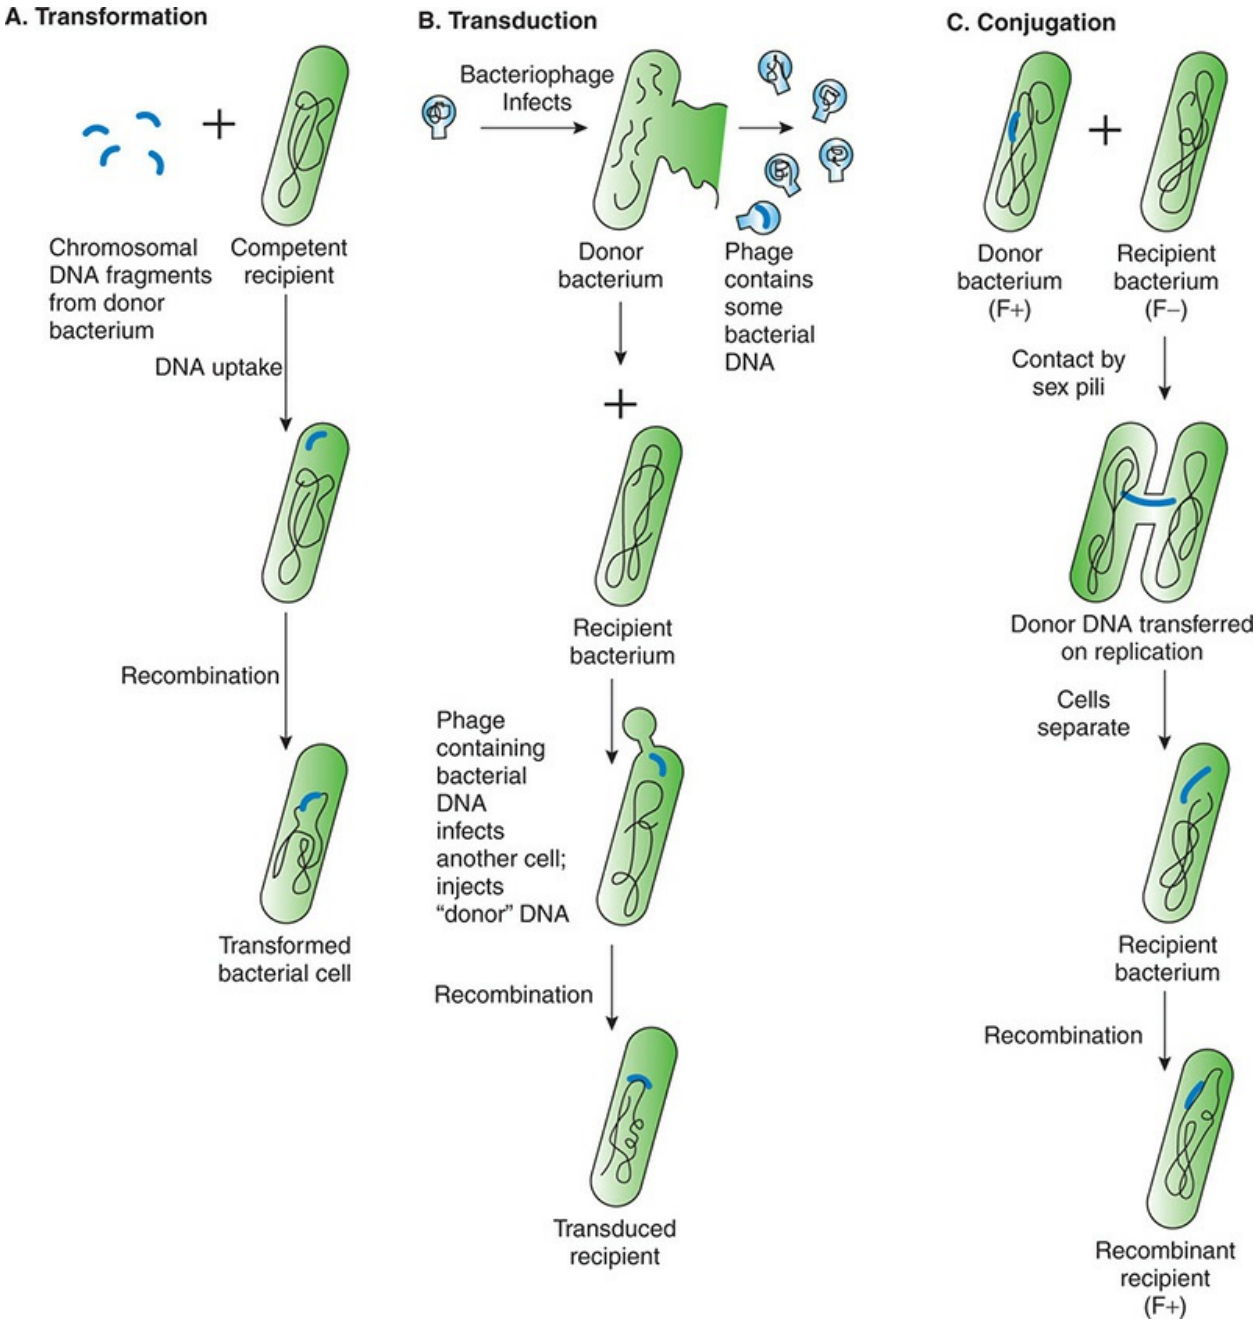
Genetic Exchange and Recombination in Bacteria

Bacterial replication occurs by binary fission, an asexual process that does not involve recombinational events and results in the generation of two daughter cells that are identical to the parent cell. Several groups of bacteria, however, do have the ability to undergo genetic exchange and recombination with other organisms. Genetic exchange between bacteria occurs by one of three general mechanisms: transformation,

transduction, and conjugation (Fig. 5-13).

Transformation involves the uptake of free DNA from the surrounding environment (Fig. 5-13A). Cells that are physiologically capable of taking up and incorporating free DNA into their genomes are termed *competent*. Competence is usually a transient state that occurs toward the late exponential phase of growth, although some organisms may be competent at all times. In competent gram-positive cells (e.g., *Bacillus subtilis*, *S. pneumoniae*), small pieces of double-stranded DNA become bound to the cell via a cell-surface receptor that is expressed during the competent period. As the DNA enters the cell, one strand is hydrolyzed by a surface-bound nuclease. Recombinational events between the single-stranded DNA and homologous regions of the bacterial chromosome result in integration of the transformed DNA into the bacterial genome. If homologous regions for the transforming DNA are lacking, the DNA strand does not integrate, genes on the particular DNA strand are not expressed, and the single-stranded DNA is degraded by endogenous restriction endonucleases. *H. influenzae*, a transformation-competent gram-negative bacterium, also possess receptors for DNA on the cell surface; DNA binding occurs via the recognition of a 10- to 14-base-pair surface-expressed nucleotide sequence that allows DNA only from closely related species to bind and enter the competent cell. Double-stranded DNA then enters the cell, but only one strand participates in the recombinational events that incorporate the transforming DNA into the genome of the recipient. Cells that normally do not express competence for genetic transformation can be made permeable to extracellular DNA ("artificially competent") by treatment with $CaCl_2$ or other salt solutions at 0°C or by **electroporation,** in which cell suspensions are exposed to an electric current that induces DNA entrance into bacterial cells.

Transduction refers to the exchange of genetic information via bacteriophages (Fig. 5-13B). Bacteriophages (or simply "phages") are viruses that infect bacteria. Some bacteriophages are **lytic;** that is, after infecting the bacterial cell, the bacteriophage regulatory genes "take over" the cellular biosynthetic machinery, resulting in the expression of phage structural genes and the production of new phage particles that are released on lysis and death of the host bacterium. With temperate bacteriophages, the genetic material of the bacteriophage becomes incorporated into the host-cell DNA as a "prophage" and replicates along with the bacterial chromosome. Such bacteriophages are also termed *lysogenic bacteriophages*, and the bacterial cell infected with this phage is



■ **FIGURE 5-13** Mechanisms of gene transfer in bacteria. Microorganisms may exchange genetic material by any of three processes: transformation (**A**), transduction via bacteriophage (**B**), and conjugation (**C**).

said to be **lysogenized.** On induction by exposure to certain chemicals (e.g., mitomycin C) or to ultraviolet irradiation, a lysogenic bacteriophage may be induced to begin production of new phages (i.e., the phage becomes "lytic"). Excision of the bacteriophage DNA from the bacterial cell genome results in some bacteriophages

containing not only "phage-specific" genes, but also host-cell genes that were located adjacent to the site of phage DNA integration in the bacterial chromosome.

The transfer of genetic information during transduction may be generalized or specialized. **Generalized transduction** refers to the accidental, random packaging of host-cell DNA into the capsid or "head" of the phage particle. Release of the mature phage particle on cell lysis and subsequent infection of another bacterial cell results in the introduction of "donor DNA" from the original host bacterium into the "recipient." Recombination of the transduced DNA with a homologous region on the chromosome of the recipient cell results in integration and subsequent expression of the transduced genes. Generalized transduction occurs with a frequency of 1 transducing phage out of 10^5 to 10^8 phage particles produced on induction from the lysogenized state, and about 1% to 2% of the total length of the host-cell genome may be transferred by this mechanism. **Specialized transduction** refers to the packaging of specific host-cell genes into the transducing prophage. This type of transduction occurs with temperate phages that have specific chromosomal integration sites, such as bacteriophage λ. Only host-cell genes that flank the integrated phage genome have the opportunity to become incorporated into the bacteriophage genome on induction from the lysogenic state. One specialized transducing phage is produced out of 10^5 to 10^6 new phage particles following induction.

Conjugation is the only mechanism of genetic exchange between bacteria that requires cell-to-cell contact

198

(Fig. 5-13C). Gram-negative bacteria that are able to participate in conjugation possess a plasmid called the **F plasmid** ("fertility plasmid"). This plasmid contains an operon of genes called the *tra* region that codes for the sex pilus (or conjugative pilus) and other molecules involved in conjugation.[34] The specialized pilus functions as a vehicle for establishing contact with another bacterial cell. Once contact is established, the sex pilus apparently is retracted, thereby drawing the other cell closer. The pilus may also act as a "tube" through which DNA is passed during the conjugative process. Cells that possess F plasmids are termed F^+, while cells that lack this plasmid are termed F^-. Once contact of an F^+ cell with an F^- cell is established by the sex pilus, the circular F plasmid begins to be replicated. During this process, one of the single strands of the plasmid DNA is transferred into the recipient cell. This single strand is replicated as it enters the recipient cell, and the end result are two cells that contain complete conjugative plasmids (i.e., both become F^+ cells).

In some organisms, the F plasmid becomes integrated into the host-cell genome at specific integration sites in which homologous nucleotide sequences are present.

Establishment of a connection via the F pilus and subsequent conjugation results in the transfer of some F-plasmid genes plus genetic material from the host cell that is adjacent to the integration site of the F plasmid. Cells possessing an integrated F plasmid are termed *Hfr cells* (high-frequency recombinations). Mating between Hfr cells and F^- cells results in transfer of part of the F genome plus some host-cell genes from the donor. Recipient F^- cells usually remain F^- following conjugation since only part of the F plasmid from the donor Hfr cell is transferred to the recipient cell during the conjugative process. Therefore, these recipient cells will not possess the complete operon that is necessary for subsequent conjugation to occur. Recombination between the genetic material from the donor cell and homologous regions in the F^- recipient enables the donor DNA to become expressed in the recipient cell. The donor cell remains Hfr, since the host-cell chromosome (containing the integrated F plasmid) is replicated during the transfer of the genomic ssDNA from the Hfr to the F^- cell.

Among the gram-positive bacteria, *Enterococcus faecalis* is also able to exchange plasmids via a conjugative process. However, gene transfer is not accomplished via a pilus, but by a **coaggregation** of the organisms in response to **pheromones** produced by the donor bacterium.[65] When exposed to plasmid-free cells (or culture filtrates from plasmid-free cells), plasmid containing cells produce plasmid-encoded pheromones called **aggregation substances.** These aggregation substances are small (seven to eight amino acids) peptides. The pheromones bind to sites that are present on both recipient and donor cells, causing bacterial aggregation. Aggregation results in the establishment of the cell-to-cell connections necessary for plasmid mobilization to occur. Interestingly, enterococcal cells that contain like plasmids and similar aggregation substances respond only to pheromones from cells that have different plasmids and, therefore, produce different aggregation substances.

In addition to the mechanisms of gene transfer just described, other genetic elements also may participate in recombinational events that affect the characteristics and pathogenicity of microorganisms. **Transposable genetic elements** are pieces of DNA that can insert into different, unrelated sites on a bacterial chromosome or plasmid. Because these insertions occur randomly, mutations may be generated because of the disruption of gene sequence continuity. They have been described in *E. coli* and a wide variety of other bacteria. Unlike the mechanisms described above, regions of nucleic acid sequence homology are not required for recombination with these genetic elements to occur. Transposable genetic elements fall into two groups: insertion sequences and transposons. **Insertion sequences** (ISs) are usually small pieces of DNA that carry genes coding only for their own transposition; expression of these genes is not recognized and the insertion is usually phenotypically "silent." ISs have two major characteristics: they are small relative to other transposable elements (generally around 700 to 2,500 base-pairs in length) and only code for proteins implicated in the transposition activity (they are thus different from other transposons,

which also carry accessory genes such as antibiotic resistance genes). These proteins are usually the transposase which catalyzes the enzymatic reaction allowing the IS to move, and also one regulatory protein which either stimulates or inhibits the transposition activity. **Transposons** are larger and encode for at least one function that is recognizable as a phenotypic alteration, such as acquisition of antimicrobial resistance. Transposons described in enteric gram-negative bacteria contain genes for resistance to antimicrobial agents (e.g., aminoglycosides, tetracycline, chloramphenicol) and, among clinically significant gram-positive bacteria, transposons carrying resistance genes for macrolides and tetracycline have been described in group A β-hemolytic streptococci.[14,33]

Requirements for Bacterial Growth and Metabolism

Carbon. Bacteria can be divided into two large groups on the basis of their carbon requirement—the **lithotrophic** (or **autotrophic**) bacteria and the **organotrophic** (or **heterotrophic**) bacteria. The lithotrophic bacteria can use carbon dioxide as the sole source of carbon and synthesize from it the carbon "skeletons" for all their organic metabolites. They require only water, inorganic salts, and CO_2 for growth, and their energy is derived either from light (photolithotrophic bacteria) or from the oxidation of one or more inorganic substances (chemolithotrophic bacteria). Organotrophic bacteria are unable to use CO_2 as their sole source of carbon but require it in an organic form, such as glucose. For these heterotrophic bacteria, a portion of the organic compound that serves as an energy source is also used for the synthesis of organic compounds required by the organism. A wide variety of other substances can also be used as exclusive or partial sources of carbon by different bacterial species. Among the most versatile bacteria are *Pseudomonas* species, some of which can use more than 100 different organic compounds as their sole source of carbon and energy. The relationships among energy sources, carbon sources, and electron donors for generation of energy are summarized in Table 5-2.

Carbon Dioxide. Some bacteria are able to use atmospheric carbon dioxide as a principal source of carbon for biosynthetic reactions. The energy for catalyzing this utilization may come from light energy (**photolithotrophic bacteria**) or from oxidation of inorganic molecules (**chemolithotrophic**

TABLE 5-2 Energy and Carbon Sources of Bacteria

Type/Examples	Energy Source(s)	Carbon Source(s)	Electron Donors
Photolithotrophs Green sulfur bacteria Purple sulfur bacteria	Light	CO_2	Inorganic compounds (H_2S, S)
Photoorgano-trophs Purple nonsulfur bacteria	Light	Organic compounds (and CO_2)	Organic compounds
Chemolithotrophs Hydrogen-, sulfur, and denitrifying bacteria	Oxidation–reduction reactions	CO_2	Inorganic compounds (H_2, S, H_2S, Fe, NH_3)
Chemoorgano-trophs	Oxidation–reduction reactions	Organic compounds	Organic compounds (glucose and other carbohydrates)

bacteria). Organisms that require an organic source of carbon also require some CO_2 for certain macromolecular synthetic pathways, such as fatty acid biosynthesis. Carbon dioxide for these reactions is usually obtained from the breakdown of organic substrates occurring at the same time as the biosynthetic reactions.

Oxygen. The oxygen requirement of a particular bacterium reflects the mechanism used for energy derivation. On the basis of their oxygen requirements, bacteria may be divided into five groups. **Obligate anaerobes** grow only under condition of high reducing intensity and for which oxygen is toxic. **Aerotolerant anaerobes** are anaerobic bacteria that are not killed by exposure to oxygen. **Facultative anaerobes** are capable of growth under both aerobic and anaerobic conditions. **Obligate aerobes** have an absolute requirement for oxygen in order to grow. **Microaerophilic organisms** grow the best under lower oxygen tension; higher oxygen tensions may be

inhibitory. In obligate and facultative aerobes, the assimilation of glucose results in the terminal generation of the free radical superoxide (O_2^-). The superoxide is reduced by the enzyme superoxide dismutase to oxygen gas (O_2) and hydrogen peroxide (H_2O_2). Subsequently, the toxic hydrogen peroxide generated in this reaction is converted to water and oxygen gas by the enzyme catalase, which is found in aerobic and facultative bacteria, or by various peroxidases, which are found in several aerotolerant anaerobes.

Nitrogen. The nitrogen atoms of important biomolecules (i.e., amino acids, purines, pyrimidines) come from ammonium ions (NH_4^+). The generation of ammonium ions starts with the reduction of atmospheric N_2 to NH_4^+ (ammonium ion or ammonia, NH_3). NH_4^+ is then assimilated into more complex macromolecules by way of the key compounds **glutamate** and **glutamine**. Certain species of bacteria (*Rhizobium* species, *Azotobacter* species) and blue-green algae are able to achieve this conversion or "fix" atmospheric N_2 into a more readily usable organic form. Because of the strength of the triple bonds in N_2, nitrogen fixation requires cellular energy in the form of ATP and a powerful reductant. The process is catalyzed by a complex multienzyme system called the nitrogenase complex. In most nitrogen-fixing organisms, reduced ferredoxin is the source of electrons:

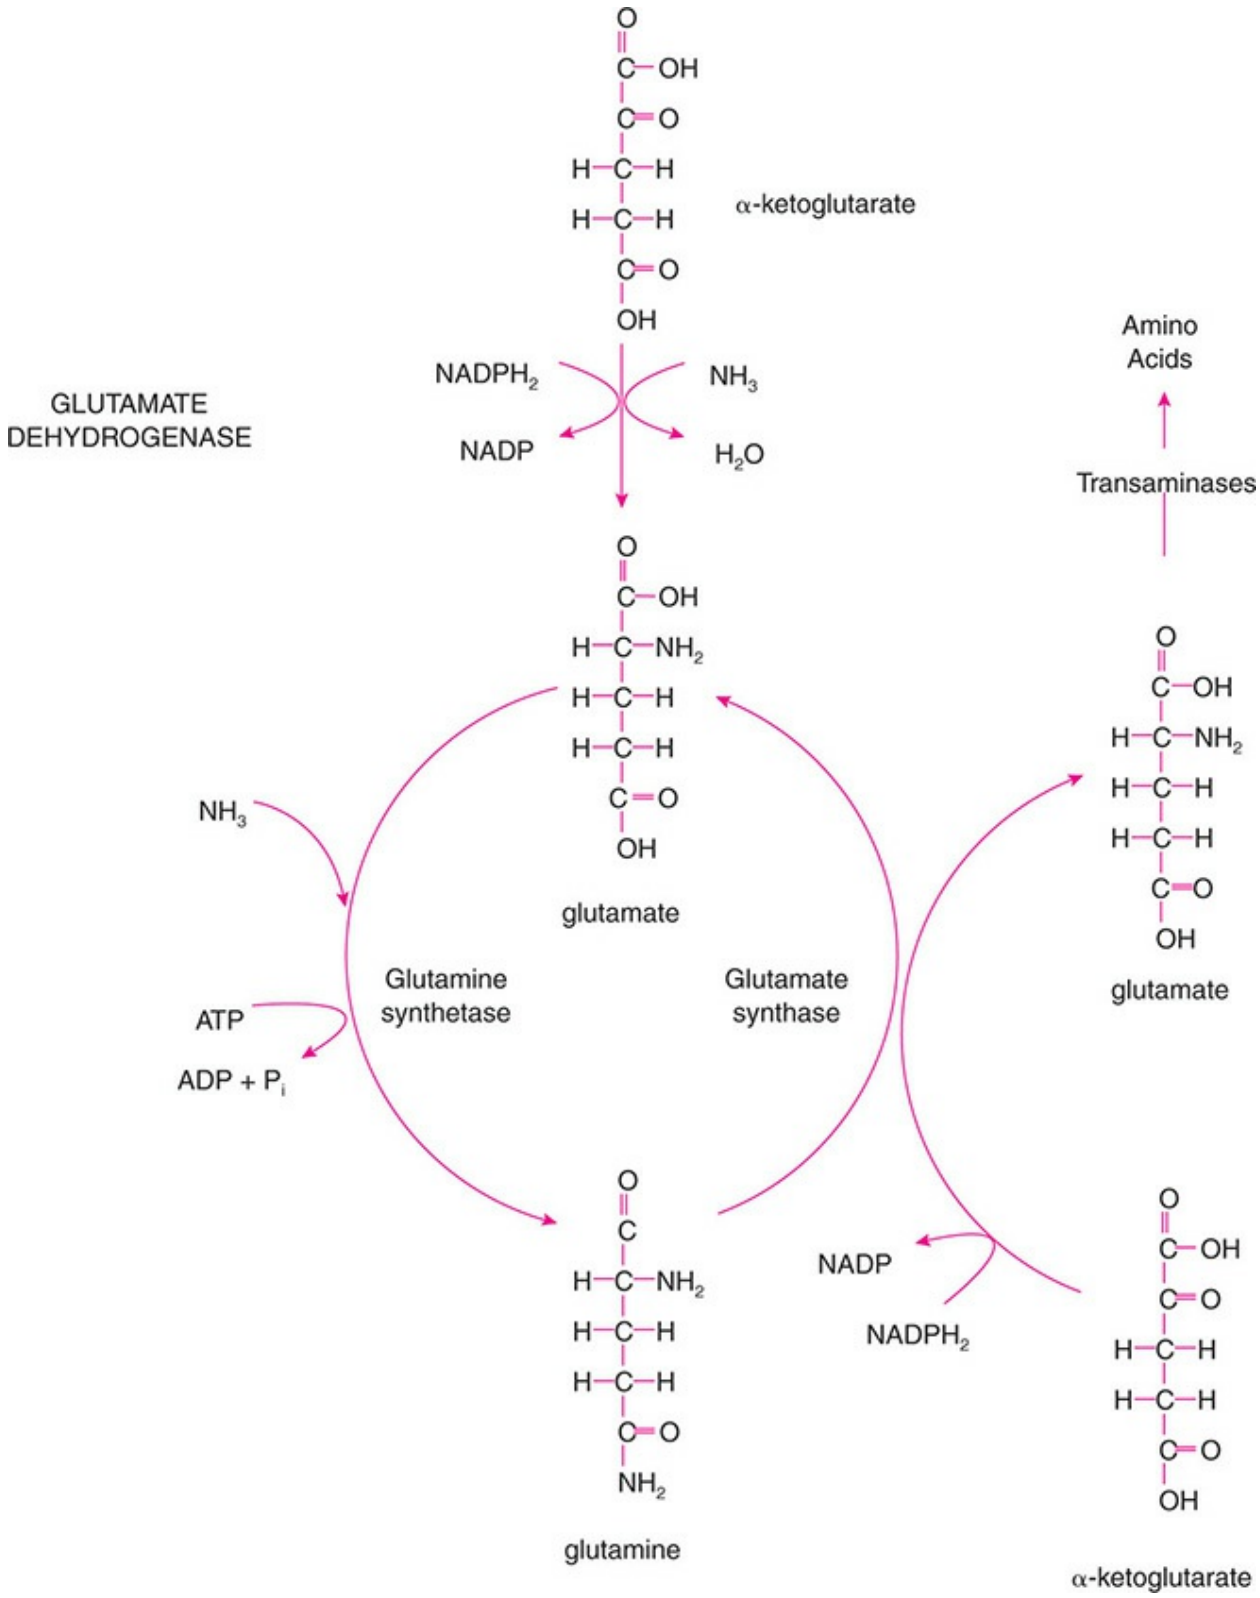
$$N_2 + 6e^- + 12\ ATP + 12\ H_2O \rightarrow 2\ NH_4^+ + 12\ ADP + 12\ Pi + 4H^+$$

The ability to fix nitrogen is accomplished primarily by the soil-dwelling bacteria mentioned above. However, some bacterial species that are involved in human disease, such as *K. pneumoniae* and certain environmental clostridia (e.g., *Clostridium pasteurianicum*) are also able to fix atmospheric nitrogen. Ammonium ions may also be generated by nitrate reduction. This is accomplished by two distinct physiologic mechanisms.**Assimilatory nitrate reduction** is a process in which nitrate is reduced to nitrite and hydroxylamine, which are then converted to ammonia for assimilation. **Dissimilatory nitrate reduction** is when nitrate serves as an alternative electron acceptor to oxygen (anaerobic respiration), with NO_2 or N_2 being the usual products. Nitrate assimilation is quite widespread in microorganisms and requires both nitrate and nitrite reductases, while dissimilatory nitrate reduction occurs only in anaerobic bacteria and facultative anaerobic bacteria growing at low oxygen tension (i.e., in a broth, for example). Ammonia generated by these mechanisms becomes incorporated into organic molecules by the action of the enzymes **glutamate dehydrogenase**, **glutamine synthetase,** and **glutamic acid synthase** (Fig. 5-14). The final products of these reactions are glutamine and glutamic acid, which then become the building blocks used in other biosynthetic reactions for the synthesis of several

amino acids, purines, pyrimidines, and other necessary nitrogenous compounds.

Growth Factors. These substances promote growth of the organism and are provided by various body fluids and tissues in vivo and in the form of yeast extract and blood and/or blood products in vitro. These factors include B-complex vitamins, minerals, certain amino acids, purines, and pyrimidines. The B-complex vitamins play a catalytic role within the cell, acting either as components of coenzymes or as prosthetic groups of enzymes. Organisms that do not require an exogenous source of a given growth factor because they are capable of synthesizing their own are referred to as **prototrophic. Auxotrophic** organisms require the addition of the growth factor to culture media before growth can occur. Small amounts of a number of inorganic ions also are required by all bacteria. In addition to nitrogen, sulfur, and phosphorus, which are present as constituents of important biologic compounds, potassium, magnesium, and calcium are often functionally associated with certain anionic polymers. Magnesium divalent cations stabilize ribosomes, cell membranes, the cell wall, and nucleic acids, and are also required for the activity of many enzymes. Potassium is also necessary for the activity of a number of enzymes, and in gram-positive bacteria the intracellular potassium concentration is influenced by the teichoic acid content of the cell wall. Most organisms also need zinc, iron, manganese, copper, and cobalt. Certain physical requirements for growth

200



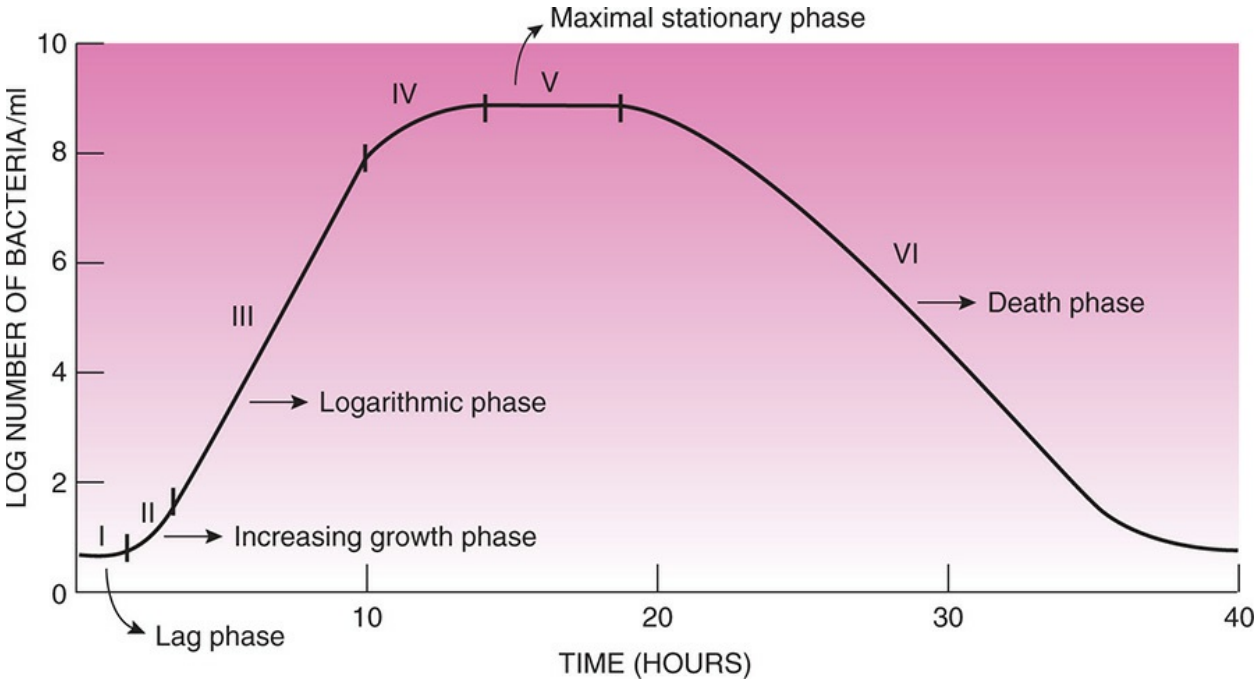
■ **FIGURE 5-14** Nitrogen assimilation and metabolism via the enzymes glutamine synthetase, glutamate dehydrogenase, and glutamate synthase. This enzymatic system results in the formation of amino acids and other compounds.

include optimal growth temperature, pH, and oxidation/reduction potential.

Kinetics of Bacterial Cell Growth

During growth in fluid culture medium, bacteria display a uniform growth curve, as expressed in logarithmic numbers of bacteria over time. A typical bacterial growth curve is shown in Figure 5-15. The lag phase is a period of physiologic adjustment and cellular preparation wherein the cell synthesizes new enzymes, cofactors, and essential metabolic intermediates, and the intracellular pools of nutrients are established. During the increasing growth phase, cell growth begins as enzymatic reaction rates begin to approach their steady-state rates. During the exponential or logarithmic growth phase, cell growth and cell division are occurring at their maximal rates. This rate is influenced by temperature, the type of carbon source being used, the rate-limiting concentrations of various essential nutrients, the types of nutrients available, and the oxygen tension or redox potential. During the declining growth phase, growth eventually ceases because of exhaustion of essential nutrients from the medium or from the accumulation of substances that are inhibitory or toxic. During the stationary phase, the number of viable cells has plateaued and the numbers of new organisms produced is equal to the numbers of cells that die

201



■ **FIGURE 5-15** Kinetics of bacterial growth.

because of lack of nutrients. During the death phase, cells begin to lyse and die.

Clinical laboratories most often deal with bacteria growing on solid media such as blood or chocolate agars. In general, organisms are able to grow to high numbers on solid media because the acid and other inhibitory products diffuse away from the bacterial colonies during growth, and the depletion of nutrients in the vicinity of the colonies is countered by diffusion of fresh nutrients into growth areas on the agar media. However, some organisms are extremely sensitive to slight pH shifts or metabolic by-products that cause cell lysis by themselves or that activate cellular autolysins. Periodic or frequent subculture to fresh agar media is usually sufficient for short-term preservation of organism viability on solid culture media.

General Bacterial Metabolism and Energy Generation

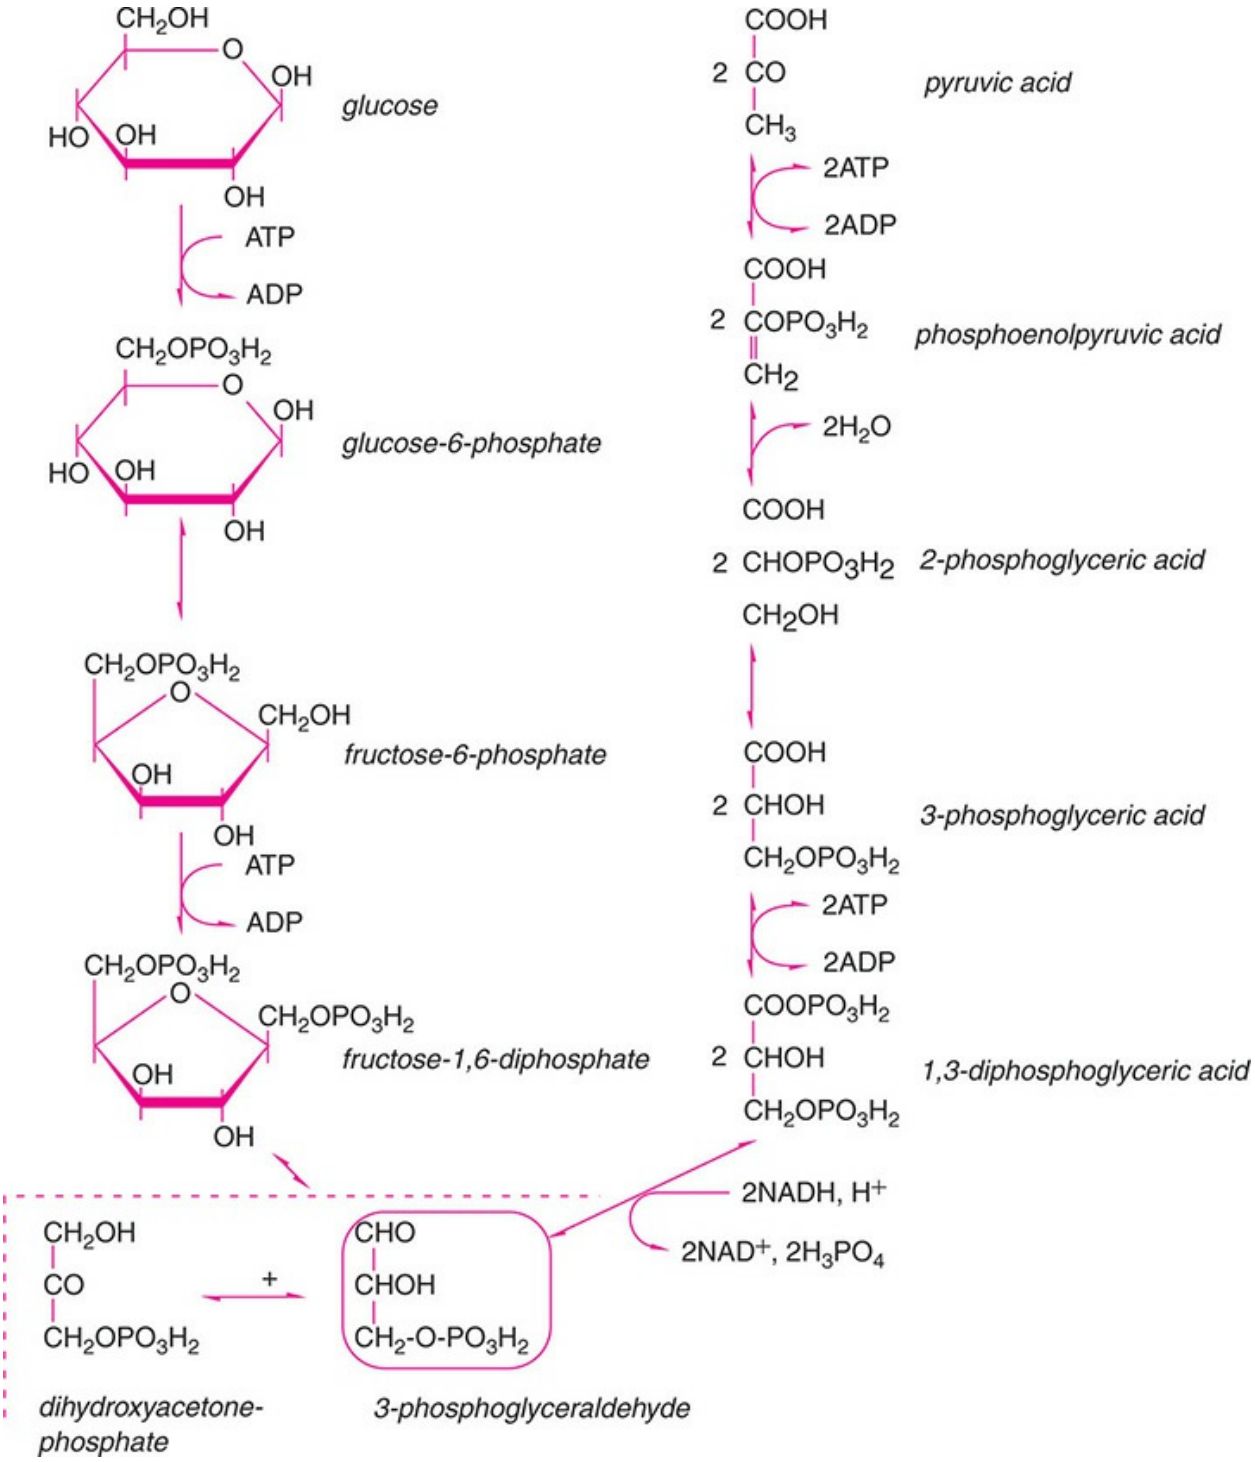
Fermentation. Bacterial metabolism is a dynamic balance between biosynthesis (anabolic reactions) and degradation (catabolic reactions). Catabolic reactions, in addition to providing smaller building blocks for subsequent biosynthetic processes, provide the energy necessary for biosynthetic reactions. In these processes, energy from the hydrolysis of chemical bonds is captured in the high-energy phosphate bonds of **ATP**. These bonds provide for the activation and continuation of other biochemical events. Using this energy, the bacterial cell wall, proteins, nucleic acids, and other structural and regulatory macromolecules are synthesized. Utilization of carbohydrates by bacteria and the conditions under which this utilization occurs are key characteristics for broadly characterizing bacteria. In general, many tests performed in the clinical microbiology laboratory involve the detection of the end products of bacterial metabolism in liquid culture after sufficient incubation times, either by pH indicators in the medium or by gas–liquid chromatography. The ability of a given microorganism to produce acid from a variety of carbohydrates (e.g., maltose, sucrose, mannitol, mannose, etc.) reflects the enzymatic capabilities of these organisms to initially convert such carbohydrates to glucose, which is the starting point for both aerobic and anaerobic carbohydrate catabolism.

Utilization of glucose under anaerobic conditions is termed *fermentation*. Fermentation occurs via glycolysis (also called the **hexose diphosphate** and the **Embden–Meyerhof–Parnas pathway**), with the end product being pyruvic acid or pyruvate. The glycolytic pathway from glucose to pyruvate is shown in Figure 5-16. This pathway requires two ATP molecules for initial phosphorylation of glucose to glucose-6-phosphate and subsequent phosphorylation of fructose-6-phosphate to fructose-1,6-diphosphate. During glycolysis, ATP is generated at two points in the pathway. As a result of the conversion of 1,3-diphosphoglyceric acid to 3-phosphoglyceric acid, the energy derived from the oxidation of an aldehyde group is conserved as a high-energy phosphate bond in ATP. The conversion of phosphoenolpyruvate to pyruvate results in the generation of another ATP molecule.

Therefore, four ATP molecules are produced from every molecule of glucose during glycolysis by a process called **substrate level phosphorylation,** resulting in a net gain of two molecules of ATP. In addition to ATP, reducing power is also produced by the generation of $NADH_2$ from the cofactor NAD (nicotinamide adenine dinucleotide).

Glycolysis is not the sole pathway for carbohydrate metabolism in most organisms. Many strictly aerobic bacteria use the Entner–Doudoroff pathway, which begins with glucose being converted to 6-phosphogluconic acid. This molecule is dehydrated to form 2-keto-3-deoxy-6-gluconate, and then hydrolyzed to pyruvate and glyceraldehyde-3-phosphate (Fig. 5-17). Pyruvate then enters the **Krebs tricarboxylic acid cycle** (see below), and the glyceraldehyde-3-phosphate is converted to pyruvate via the glycolytic cycle. Many bacteria use the pentose phosphate pathway, in which glucose-6-phosphate is oxidized to 6-phosphogluconic acid, which is then further oxidized to ribulose-5-phosphate (5-carbon), CO_2, and NADH (Fig. 5-18). Five-carbon monosaccharides are used in the biosynthesis of nucleic acids. Some bacteria

202



■ **FIGURE 5-16** Glycolytic pathway.

are able to metabolize 5-carbon (pentose) sugars such as xylose and arabinose. In the metabolism of 5-carbon sugars, enzymes known as transketolases and transaldolases convert these simple carbohydrates to various 3-, 4-, and 5-carbon intermediates,

which, in turn, are used as building blocks for the biosynthesis of nucleic acid precursors.

Utilization of Pyruvate. Pyruvate may enter a variety of pathways, resulting in several different end products. It is these end products that are often useful in categorizing the organisms isolated in the clinical microbiology laboratory. The metabolic pathways shown in Figures 5-19 and 5-20 include:

Pathway 1—Homolactic Fermentation (Homofermentative). In this pathway, the simplest of fermentations, the primary product of glucose fermentation is lactic acid. Some organisms that are considered homolactic fermenters also make small amounts of acetate, ethanol, and formate. The relative amounts of the latter products are dependent on the initial pH and the buffering capacity of the medium. Generally, no gas is formed. Homolactic fermentation of glucose is characteristic of the streptococci, enterococci, pediococci, and lactobacilli.[64]

Pathway 2—Heterolactic Fermentation. Pyruvate is decarboxylated to yield acetaldehyde and CO_2. The acetaldehyde is then reduced by $NADH_2$ and alcohol dehydrogenase to form ethanol. This type of pathway is seen in *Leuconostoc* species, some lactobacilli, and yeasts.

Pathway 3—Mixed Acid Fermentation. In this metabolic pathway, pyruvate is metabolized to a number of different products (acetic acid, ethanol, succinic acid, formic acid). Initially, pyruvate is cleaved in the presence of coenzyme A (CoA) to form formic acid and acetyl-CoA. Some of the acetyl-CoA is reduced to acetaldehyde and then to ethanol. The acetyl group of some acetyl-CoA is transferred to phosphate, yielding acetylphosphate, which

203

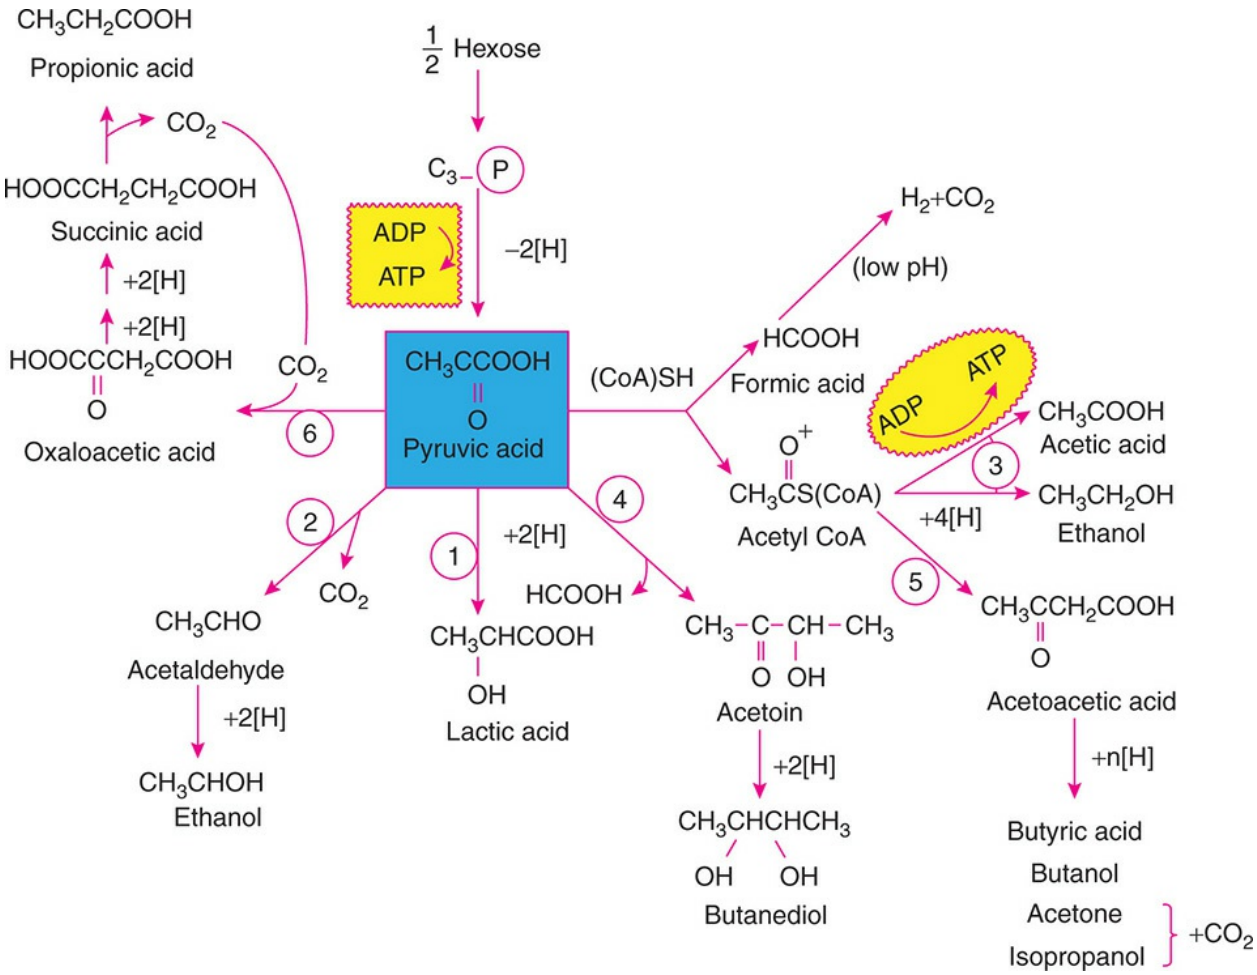
■ **FIGURE 5-18** The pentose phosphate pathway.

204



■ **FIGURE 5-19** Utilization of pyruvate formed during anaerobic fermentation.

then yields its high-energy bond to ADP, producing one ATP and acetic acid. Some bacteria are able to oxidize formate directly to hydrogen gas and CO_2. The nature and amounts of these acid products depend on the organism.

Pathway 4—Butanediol Fermentation. Bacteria that use this pathway have an enzyme that condenses two pyruvate molecules (each with 3 carbons) to CO_2 and a 5-carbon intermediate called α-acetolactate. The α-acetolactate is then enzymatically decarboxylated, resulting in acetoin (acetylmethylcarbinol) formation. In the presence of hydrogen ions, acetoin is further reduced to 2,3-butanediol. This reduction reaction is slowly reversible in air under alkaline conditions; the acetoin that is synthesized can be detected by the addition of α-naphthol. This is the basis of the **Voges–Proskauer (VP) test**, which uses α-naphthol in the presence of alkali to detect acetoin. This pathway is seen in the *Klebsiella–Enterobacter–Serratia–Hafnia* group of the family *Enterobacteriaceae*. The conversion of some of the pyruvate to 2, 3-butanediol reduces the amount of acid

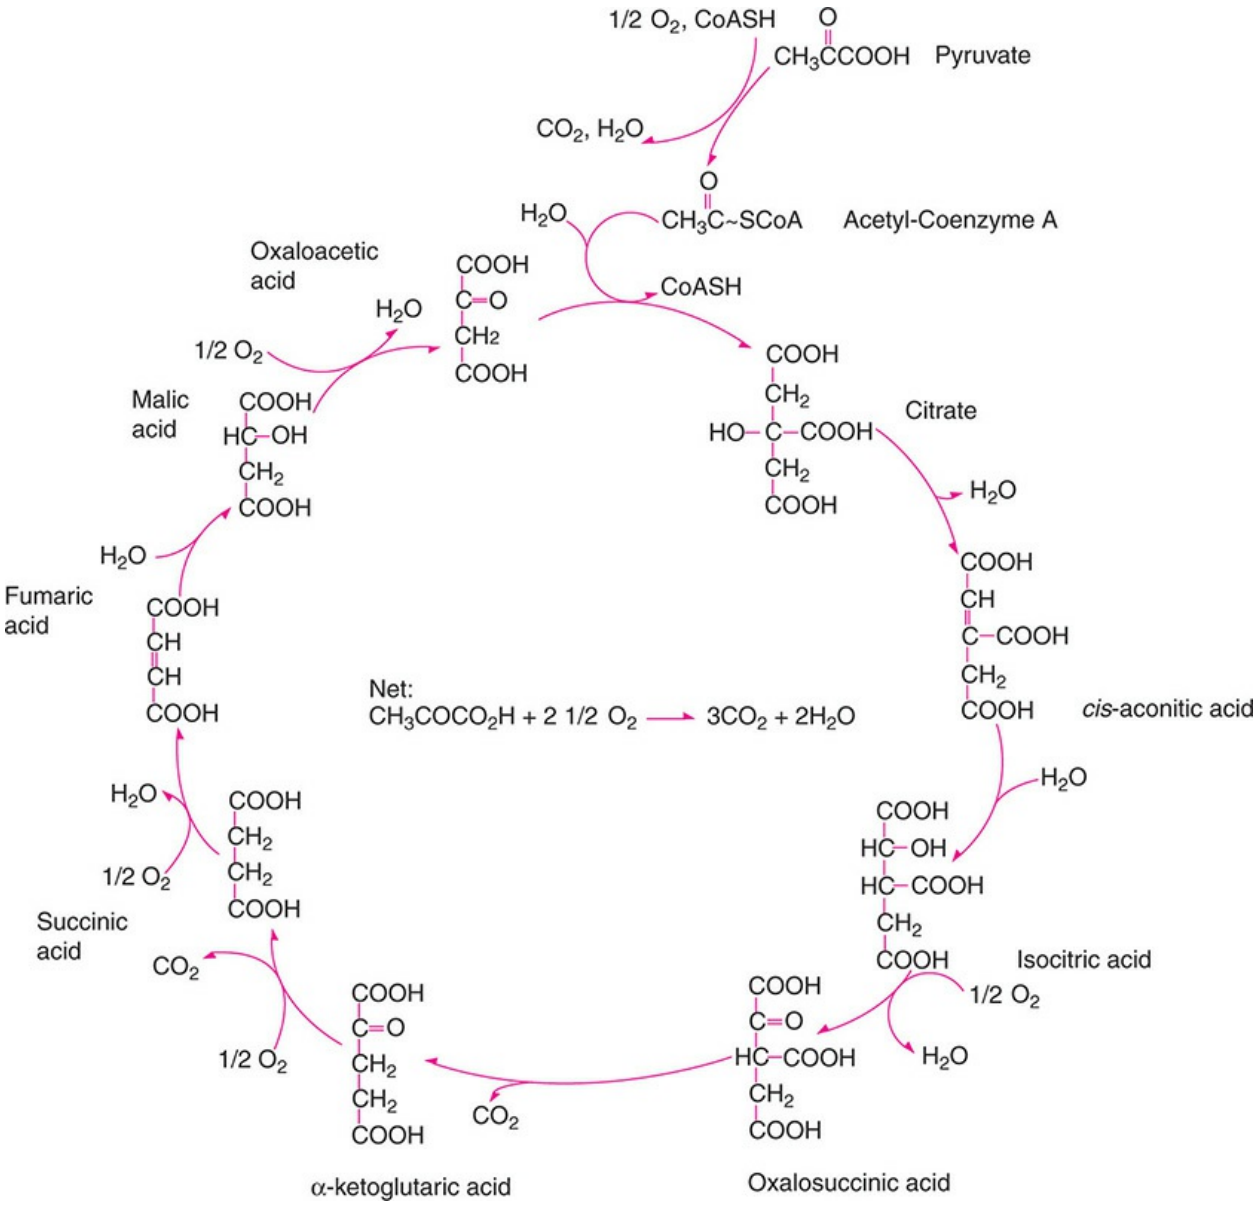
relative to the mixed acid pathway described above and is responsible for **methyl-red (MR)** reaction used to separate *E. coli* and related organisms (**MR** + **/VP–**) from the *Klebsiella–Enterobacter–Serratia–Hafnia* group (**MR–/VP** +).

Pathway 5—Butanol Fermentation. This fermentation pathway is seen among members of the genus *Clostridium*. These organisms possess an enzyme that condenses two molecules of acetyl-CoA formed from pyruvate to form acetoacetyl-CoA. This molecule is reduced to in a stepwise fashion to butyryl-CoA, which can be subsequently hydrolyzed to butyric acid and ATP. Alternatively, free acetoacetate is released and decarboxylated to produce CO_2 and acetone, which may be reduced to isopropyl alcohol. In clinical microbiology laboratories performing reference work on clostridia, volatile and nonvolatile fermentation products are detected by gas–liquid chromatographic analysis of derivatives prepared from broth cultures. Detection of these metabolic end products is helpful for genus- or species-level identification of these anaerobic bacteria.

Pathway 6—Propionic Acid Fermentation. This is a cyclic-type of reaction in which oxaloacetate is formed from carbon dioxide, pyruvate, and ATP using a biotin containing coenzyme. Oxaloacetate is reduced to malate, converted to fumarate and then reduced to succinic acid (succinate). Decarboxylation of succinate results in the formation of propionic acid (propionate). This pathway is seen in anaerobic gram-negative bacilli in the genus *Bacteroides* and in *Propionibacterium* species, which are gram-positive, anaerobic, non–spore-forming bacilli.

Utilization of glucose under aerobic conditions is called respiration (Fig. 5-20). Pyruvate formed during fermentation enters the Krebs cycle, during which it is broken down to CO_2 and H_2O with the generation of ATP. Oxidative decarboxylation of pyruvate yields the high-energy intermediate called acetyl-coenzyme A (acetyl-CoA), which condenses with a molecule of oxaloacetate to form citrate and free CoA. A series of oxidative reactions ensues with the regeneration of oxaloacetate and the generation of reducing power in the forms of reduced NAD (NADH) and reduced flavin adenine dinucleotide (FADH). These high-energy compounds

205



■ **FIGURE 5-20** Krebs tricarboxylic acid cycle.

subsequently enter the **electron transport chain,** which consists of alternating hydrogen and electron carriers located in sequence across the cell membrane. Transfer of protons down the electron transport chain creates a membrane potential. The energy of this potential is harnessed by a membrane-associated multienzyme system called **ATP synthase.** The subunit enzyme catalyzes the phosphorylation of ADP with inorganic phosphate. The final electron acceptor in the electron transport chain is oxygen (O_2), with the final product being H_2O. Complete oxidation of glucose via anaerobic glycolysis and the aerobic Krebs cycle results in a net gain of 38 ATP molecules per mole of glucose, as compared with the net generation of only 2 ATP

molecules per mole of glucose via the glycolytic (fermentative) pathway alone. In addition to the generation of ATP during aerobic metabolism, the Krebs cycle also provides the cell with precursors or intermediate compounds used in the biosynthesis of several other cellular components, such as purines, pyrimidines, amino acids, and lipids. The cycle also serves a catabolic function by providing a venue for the oxidative breakdown of these same macromolecules.

Bacterial Virulence Factors and Pathogenicity

Definitions and Concepts

Pathogenicity refers to the ability of an organism to cause disease. Organisms that are capable of causing disease under the appropriate circumstances are called **pathogens. Virulence** usually refers to the degree of pathogenicity within a group or species of microorganisms. The virulence of a microorganism is not generally attributable to a single factor, but is dependent on several parameters that relate to the organism, the host, and the dynamic interaction between them. This balance between the host and the "potential pathogen"

206

is an area of increasing interest among microbiologists. In general, virulence encompasses two features of a pathogenic microorganism: the **infectivity** (i.e., the ability to initiate an infection) and the **severity** of the condition produced. Highly virulent, moderately virulent, and/or avirulent strains may occur within a species or group of organisms that are generally considered to be pathogenic. Infection of the host by an organism is a necessary step in the production of disease. It is important to differentiate colonization from infection. Colonization of a host with normal microbiota occurs most commonly on surfaces (e.g., skin and mucous membranes) and within luminal organs, such as the gastrointestinal tract. The colonization factors present on the surfaces of organisms that comprise the microbiota (e.g., fimbriae, lipoteichoic acids, capsules, and OMPs) are operationally the same as those used by pathogenic microorganisms. The organisms of the normal microbiota become established in and on the host early in life and persist in a dynamic state throughout the lifetime of the host. Infection with exogenous bacteria may be aborted by the presence of normal microbiota that already occupies the ecologic niche of the potential pathogen. If it does occur, infection may only be apparent by the demonstration of an antibody response with elimination of the exogenous organism. In some cases, an asymptomatic carrier state may result, or overt disease may develop.

The ability of an organism to cause disease involves both microbial and host factors.

There is currently a great deal of interest in the variety of **adaptive responses** of bacteria that result in the expression of characteristics involved in disease pathogenesis. For example, *Pseudomonas aeruginosa* is a ubiquitous soil and water organism that, because of its genetic versatility, has successfully adapted to human environments, such as hospitals, to create its own nosocomial niche. Over the years of its coexistence with humans, *P. aeruginosa* has emerged as a nosocomial and opportunistic pathogen that expresses a range of genetically determined virulence factors, including several exotoxins, hemolysins, lipases, elastases, and proteases, highly mucoid alginate capsular polysaccharides, and plasmid and transposon-mediated mechanisms of antimicrobial resistance.[93] These genetically determined adaptive responses have provided *P. aeruginosa* with the versatility to survive and actually thrive in potentially hostile environments, including the human body. Medical progress has also enabled us to appreciate the adaptive responses of organisms that are part of the normal human microbiota. When host defense mechanisms are abrogated by underlying noninfectious causes or various interventions (e.g., malignancy, diabetes mellitus, immunosuppressive therapy), endogenous organisms may also cause disease because of the phenotypic expression of characteristics that reflect a new adaptive response of the organism to its host.

In recent years, **bacterial sensing mechanisms** have become a focus of research in medical microbiology. Bacteria have developed sophisticated methods for sensing their environment and regulating the expression of genes involved in virulence.[27] **Two-component signal transduction** refers to regulatory protein pairs that function sequentially in detecting alterations in the external environment and in effecting adaptive responses in the organism. At the molecular level, this occurs by transfer of phosphate groups from sensor to effector proteins; the phosphorylation state of the effector proteins regulates the strength and duration of the response by binding to promoters in the nucleic acid that allow the expression (i.e., transcription and subsequent translation) of bacterial genes that code for virulence factors. Two-component signal transduction sensing systems have been described in enteric gram-negative bacteria, *B. fragilis*, *B. pertussis*, *M. tuberculosis*, *Vibrio* species, and *Clostridium perfringens*, among others.[27,94] Some organisms express certain virulence genes in response to threshold levels of autoinducers. These autoinducers are *N*-acylhomoserine or *N*- butyrylhomoserine lactones that are produced continually.[41] When the bacterial population reaches a certain threshold, enough autoinducer is present to activate transcription factors within the cells that coordinate the expression of virulence genes. This complex signaling mechanism, called **"quorum sensing,"** has been demonstrated in environmental bacteria (e.g., *Vibrio fischeri*, *Rhizobium leguminosarum*) and in human pathogens (i.e., *P. aeruginosa*, *Salmonella* species).[15,16,68,85] The transcription activators that respond to quorum sensing in these diverse microbial groups show significant amino acid sequence homology, suggesting

that sensing mechanisms evolved early and were disseminated widely among microorganisms that occupy various ecologic niches.

Requirements for Pathogenicity

The first step in the establishment of an infectious process resides in the ability of a microorganism to enter the host and to initiate infection. The initial contact depends on the ability of the organism to attach to and survive on the surfaces of the host. Attachment occurs via interaction of various bacterial adhesins with cell-surface receptors (see below). Some organisms will attach to epithelial cells without invasion of the deeper tissues. In such cases (e.g., *Corynebacterium diphtheriae*), toxins or enzymes elaborated by the organisms are usually responsible for the disease, which may be local or systemic. Deeper infection occurs when certain organisms attach to the mucosal epithelial cells and subsequently penetrate this barrier. Further multiplication of the organisms in the subepithelial tissues results in tissue destruction from bacterial factors (e.g., proteases, collagenases, hyaluronidases) and from the immune response (i.e., complement-mediated cytolysis, cell-mediated immune reactions). More invasive organisms may attach, penetrate the epithelial cell surfaces, multiply, and extend into the deeper tissues; eventually gaining access to the bloodstream and causing disseminated infection. Organisms such as mycobacteria and brucellae, attach, invade, multiply, and subsequently adapt themselves to a continued existence within the host, usually by inhibiting killing within the phagolysosome and living intracellularly, usually within histiocytes of the reticuloendothelial system.

Many organisms are highly specific in the types of tissues that they may infect. For example, *N. meningitidis* can be a normal inhabitant of the throat, and the asymptomatic carrier state is well characterized. Under the appropriate circumstances, these organisms may invade, causing infections of the meninges and the bloodstream. *S. pneumoniae* may also inhabit the throat and nasopharynx, yet virulent strains preferentially invade the lower respiratory tract and the bloodstream, causing pneumonia, pneumococcal sepsis

207

and/or meningitis. Tissue specificities may reflect the presence of cellular receptors for bacterial surface antigens or the presence of nutrients that serve as chemoattractants for the microorganisms (e.g., certain amino acids, ions, or carbohydrates). A classic example of this nutritional dependence is seen with *Brucella abortus*, the cause of contagious abortion in cattle. This organism has a specific growth requirement for the sugar alcohol erythritol, which is present in high concentrations in the bovine uterus and placental tissue. Hence, this organism may actually “home in” on the bovine genital tract because of this nutritional predilection.

Virulence Factors of Bacteria

Bacterial virulence factors are structural components or products produced by bacteria that allow the organism to harm the host in some manner. Some virulence factors are cell-associated, while others may be extracellular. In addition, some of the factors involved in disease production are part of the anatomic or physiologic composition of the cell, and their roles as virulence factors are incidental to the life cycle of the organism.

Adhesins. In order to infect a host, microorganisms must first adhere to the mucosal surface. Bacterial adherence is usually a specific process involving bacterial cell-surface structures that are generally known as adhesins and complementary receptors on the surface of susceptible cells. Bacterial adhesins may include fimbriae, components of the bacterial capsule, lipoteichoic acids that project outside the peptidoglycan of the cell wall of gram-positive bacteria, OMPs, or other cell-surface antigens. Specific examples of well-characterized adhesins in pathogenic microorganisms have been discussed previously and include the adherence fimbriae of *N. gonorrhoeae*, mannose-sensitive (type 1) and mannose-resistant (type 2) fimbriae of uropathogenic and enteropathogenic *E. coli*, and lipoteichoic acids of β-hemolytic streptococci.[29,55,62] The human cell-surface protein fibronectin is a host receptor for some bacterial pathogens.

Aggressins. In order to survive and multiply within the host, many organisms produce a variety of substances that allow them to avoid or circumvent host defense mechanisms. These substances, termed *aggressins*, include capsules and extracellular slime substances, surface proteins and carbohydrates, enzymes, toxins, and other small molecules. The capsular structures of some bacteria enable the organisms to avoid phagocytosis by preventing interaction between the bacterial cell surface and phagocytic cells or by concealing bacterial cell-surface components that would otherwise interact with phagocytic cells or complement and lead to their ingestion.[25,58,97] Specific antibodies directed against capsular material lead to opsonization of the microorganisms. Following opsonization, encapsulated bacteria are readily and rapidly ingested and killed by phagocytic cells. Some organisms produce capsules that are structurally similar to host tissues and, therefore, are not recognized as foreign by immunosurveillance. In this manner, such organisms can evade host defenses. For example, the capsules of *E. coli* K1 and group B meningococci are composed of partially O-acetylated, α-2,8-linked, *N*- acetylneuraminic acid, which is structurally similar to the neuraminic acid found in tissue of the central nervous system. Organisms that possess capsules that behave as aggressins include *S. aureus*, *S. pneumoniae*, *N. meningitidis*, *H. influenzae* type b, *K. pneumoniae*, group A and group B β-hemolytic streptococci, and *B. anthracis*.[25,36,48,58,90,97]

Some bacteria possess surface proteins that play roles in adherence and other virulence-associated functions. For example, the M protein of group A streptococci plays many roles in the pathogenesis of infection with this organism, including adherence, resistance to phagocytosis, intracellular invasion, impairment of complement function, and lytic effects on polymorphonuclear leukocytes.[5,6,17,28,44,71,72] Protein A, a cell wall protein of *S. aureus*, is able to bind immunoglobulin (IgG) molecules by their Fc region. Since antibody-mediated phagocytosis (i.e., opsonization) is Fc receptor-dependent, protein A may interfere with this process. The presence of protein A may also inhibit the activation of complement by the staphylococcal cell wall by masking the peptidoglycan moieties that are known to have complement-activating activity. Some bacteria are able to produce proteases that are able to hydrolyze and inactivate secretory immunoglobulins (IgA).[69] This immunoglobulin acts locally to prevent bacterial adherence; hydrolysis of IgA by bacterial proteases therefore fosters mucosal colonization (see Chapter 3).

Some aggressins act after phagocytosis has occurred by interfering with phagosome/lysosome fusion and with the activity of the myeloperoxidase system. The mycobacteria and brucellae are able to adapt to an intracellular existence within host cells by elaborating substances that prevent intracellular destruction of organisms. In the mycobacteria, this may be due to the presence of cell wall–associated mycosides and sulfolipids that become incorporated into the inner aspect of the phagosome and prevent lysosome/phagosome fusion.[3,22,30] *Listeria monocytogenes* expresses a surface protein called **internalin** that binds to glycoprotein receptors on epithelial cells and allows the organism to become internalized in a membrane-bound vacuole.[66] The organism then produces a hemolysin called **listeriolysin O**, which intercalates into the membrane of the vacuole and causes the formation of pores.[53] *L. monocytogenes* then enters the cytoplasm of the cell, where it continues to grow, thereby escaping the toxic environment with the phagolysosome. *S. aureus* secretes **catalase** and **superoxide dismutase**, which inhibit organism destruction by the myeloperoxidase system of phagocytic cells. Taking up residence within phagocytic cells by these mechanisms also contributes to virulence by protecting the organisms from destruction by specific antibodies and complement. Intracellular existence also has a significant influence on therapy. Infections with organisms such as *Brucella* species and *Francisella tularensis* must be treated with antibiotics that are able to penetrate into the phagocyte and act intracellularly (e.g., tetracyclines, aminoglycosides) in order to affect these "protected" organisms.[35]

Many bacteria produce enzymes or toxins or possess cellular constituents that have direct toxic or necrotizing effects on host inflammatory cells and other components of the immune system. Leukocidin and γ-hemolysin produced by *S. aureus* cause rounding and swelling of exposed polymorphonuclear cells and macrophages, followed

by degranulation, nuclear rupture, and cell lysis.[70] The lipopolysaccharide of gram-negative bacteria may delay or attenuate the acute inflammatory

response, allowing the organism to establish itself within the host with relative ease. The lipid A portion of endotoxin, in particular, can activate complement and stimulate the release of various cytokines (i.e., interleukin [IL]-2, IL-6, IL-8, tumor necrosis factor α [TNF-α]) that lead to the clinical manifestations of endotoxic shock, which includes hypotension, disseminated intravascular coagulation, and death. Gram-positive bacteria possess cell wall peptidoglycan polymers and membrane teichoic acids that can cause a similar release of cytokines and can precipitate symptoms similar to septic shock. Some organisms have other cell-surface properties, such as the LOS and certain surface proteins that render them resistant to the bactericidal effects of normal human serum (e.g., *N. gonorrhoeae*).[67] This property may facilitate dissemination of the bacteria via the bloodstream and lymphatics, leading to systemic infection or to the establishment of infected foci at sites distant from the site of the initial infection.

The invasive properties of some bacteria are attributed to the elaboration of enzymes that act extracellularly. *S. aureus*, *S. pneumoniae*, group B streptococci, and *Propionibacterium acnes* produce an enzyme called **hyaluronate lyase** (or hyaluronidase) during the exponential growth phase. This enzyme promotes the spread of the organism through the connective tissues by depolymerizing hyaluronic acid, the ground substance responsible for cell-to-cell adhesion.[32] Group A streptococci and staphylococci also elaborate enzymes that hydrolyze fibrin clots (**streptokinase** and **staphylokinase**), which also facilitate the spread of organisms in the tissues.[23,50] *C. perfringens* and other clostridia (e.g., *C. histolyticum*, *C. septicum*, *C. sordellii*, *C. novyi*, and *C. fallax*) produce cytotoxins, cytolysins, collagenases, phospholipases, hyaluronidases, and deoxyribonucleases that allow these organisms to colonize devitalized tissue, break down the collagen matrix of muscle and connective tissue, and facilitate the extension of the organisms into these tissues to cause necrotizing fasciitis and gas gangrene.[61]

Iron has been shown to be an essential nutrient for many organisms, and a requirement for virulence in some bacterial pathogens. In this regard, successful pathogenic bacteria have evolved ways to obtain iron from the environment or from the iron-restricted milieu of host tissues, in which free iron is maintained at low concentrations by binding to transferrin and lactoferrin proteins. Microorganisms scavenge this iron by the production of **siderophores**, which are small molecules that function as high-affinity iron chelators. The production of siderophores is, therefore,

considered a virulence factor.[10] Some organisms have evolved lactoferrin- or transferrin-binding proteins, from which the iron is removed and transported into the cell.[4,31] Both *N. gonorrhoeae* and *N. meningitidis* possess outer membrane receptors for binding human transferrin, lactoferrin, and hemoglobin and periplasmic binding proteins for removal of iron from the bound carriers and transport into the cell.[1,8,51,52,88] In addition, the production of many extracellular microbial products, including **toxins**, is partially regulated at the transcriptional level by the concentrations of iron in the surrounding medium. For example, expression of the β-phage structural gene for diphtheria toxin in lysogenized *C. diphtheriae* only occurs when iron becomes the growth-limiting substrate (see below).[75]

Although plasmids themselves are not virulence factors, the genes that code for many of the bacterial cell products responsible for virulence frequently reside on bacterial plasmids. **R factors** (plasmids that contain genes coding for resistance to antimicrobial agents) may be considered virulence factors because the acquisition of resistance to antimicrobial agents fosters continued growth and spread of bacterial infections in spite of therapeutic interventions. Some bacteria also contain plasmids that code for sex pili and chromosomal mobilization. These two factors enable a microorganism to transfer genetic material (either plasmid-borne, chromosomal, or both) to other organisms. Plasmids may also bear the genes that code for colonization antigens, serum resistance, iron chelation and transport, toxin and hemolysin production, and undefined intracellular survival functions. Plasmids containing resistance genes have been described in many medically-important gram-negative (i.e., all genera of the *Enterobacteriaceae*, *Pseudomonas*, *Vibrio*, *Pasteurella*, *Campylobacter*, *Haemophilus*, *Neisseria*, and *Bacteroides*) and gram-positive (e.g., *Staphylococcus*, *Streptococcus*, *Enterococcus*, *Bacillus*, *Clostridium*, and *Corynebacterium*) genera.

Exotoxins and Endotoxins. Toxins of microbial origin fall into two groups: exotoxins and endotoxins. **Bacterial exotoxins** are the most potent biologic toxins known and are produced predominantly by gram-positive bacteria, although some gram-negative bacteria also elaborate them. Exotoxins are usually protein in nature and are heat-labile. Because they are proteins, many can be inactivated or destroyed by proteolytic enzymes. Conversely, some exotoxins become activated only after partial hydrolysis ("nicking") by proteolytic enzymes (see below). The toxic activity of many exotoxins can be destroyed by formaldehyde treatment (toxoid development) and neutralized by specific antibodies. Exploitation of these properties led to the development of the diphtheria and tetanus toxoids that are used for active immunization against diphtheria and tetanus, respectively.

In general, bacterial exotoxins fall into two groups. The first group consists of **cytolytic toxins**, which act on cell membranes to cause pore formation and

subsequent lysis of the cell. Examples of these toxins include the seven enterotoxins of *S. aureus*, and streptolysins O and S produced by group A streptococci. The second group consists of two-subunit, A–B, or **bipartite toxins**. These toxins contain a B (or binding) subunit that attaches to a specific host-cell receptor, and an A (or active) subunit, that passes into the cell and interacts with the target. These toxins include the cholera toxin of *Vibrio cholerae*, the Shiga toxin of *Shigella dysenteriae*, pertussis toxin produced by *B. pertussis*, and diphtheria toxin produced by lysogenized *C. diphtheriae*. Certain diseases, such as tetanus, botulism, diphtheria, and cholera, are due almost entirely to the effects of the toxins on target organs and tissues.

Tetanus is caused by the systemic effects of tetanus neurotoxin, the toxin produced by *Clostridium tetani*. Tetanus usually occurs as a result of a wound infection by *C. tetani* or, rarely, from injection of materials contaminated with *C. tetani* vegetative cells or spores. Tetanus neurotoxin is released upon cell lysis after bacterial growth under anaerobic conditions (e.g., in deep puncture wounds). The toxin is translated initially as a single peptide of about 150 kDa. On release from the bacterial cell, the toxin peptide is cleaved by proteolytic enzymes to form a light (L, 50 kDa) and a heavy (H, 100 kDa) chain that are connected by a disulfide bond; under reducing

209

conditions, the two peptides are split into separate L and H chains. The receptor-binding site of the intact toxin molecule resides in the H chain. The L chain is internalized and moves from the peripheral nerves to the central nervous system by retrograde axonal transport. When tetanus toxin reaches the neurons in the spinal cord, brain stem, and cerebellum, it binds to its receptor, a ganglioside containing stearic acid, sphingosine, glucose, galactose, *N*- acetylglucosamine, and *N*- acetyl neuraminic acid (sialic acid). The spasmogenic effect of the toxin is due to its action on presynaptic reflexes involving interneurons in the spinal cord. The toxin blocks the normal postsynaptic inhibition of spinal motor neurons following afferent impulses by preventing the release of inhibitory neurotransmitters (i.e., γ-aminobutyric acid, glycine). This presynaptic blockage of central neurons results in elevated muscle tone and hyperactive reflexes. Resulting sensitivity to excitatory impulses, unchecked by inhibitory mechanisms, produces the generalized spastic paralysis characteristic of tetanus.

Botulism results from the ingestion of toxins formed by *Clostridium botulinum* growing in food, the principal vehicles being improperly canned fruits and vegetables (generally home canned), condiments, and fish products. Wound botulism is a systemic intoxication resulting from growth of *C. botulinum* and toxin production in wounds, and was reported during the 1980s and 1990s as a complication of wound infections in parenteral-drug users.[18,101] *C. botulinum* can also colonize the intestinal

tract of infants and produce toxin at that site (infant botulism).[92] Toxin accumulates in cells of *C. botulinum* during spore germination and active vegetative cell growth, but is released only upon cell lysis. Organisms within *C. botulinum* cluster into three groups depending on their 16S rRNA gene sequences: *C. botulinum* types B, E, and F, *C. botulinum* types C and D, and *C. botulinum* types A, F, and B. *C. botulinum* type G clusters independently from the others and is also called *Clostridium argentinense*.[24] These groups correspond to seven serologic types of *C. botulinum* toxins (types A, B, C-1, D, E, F, and G [associated with *C. argentinense*]), and each produces an immunologically type-specific toxin.[89] Toxin types A, B, E, and F are the types known to affect humans.

Native botulinum toxins are labile proteins and are complexed with nontoxin proteins to stabilize the molecules.[73] Botulinum toxin is produced as a progenitor protein with a molecular weight of about 150 kDa. These toxins are produced as inert molecules that become activated after proteolysis, but proteolytic cleavage is internal to the peptide molecules and the toxins do not change in molecular weight following activation. The active toxin, therefore, consists of a 50-kDa light (L) chain and a 100-kDa heavy (H) chain connected by a disulfide bond. After absorption from the gastrointestinal tract, the toxin reaches susceptible neurons (at neuromuscular junctions and peripheral autonomic synapses) via the bloodstream. There it becomes bound to presynaptic terminals, where it blocks the release of acetylcholine from cholinergic motor nerve endings. The hallmark of botulism includes cranial nerve involvement, bilateral and descending weakening, and paralysis of skeletal muscles and is characterized by fatigue, dizziness, nausea, blurring of vision, slurring of speech, dilatation of pupils, urinary retention, general flaccid paralysis of skeletal muscles, and respiratory paralysis.[19]

Diphtheria is another example of an illness that is primarily due to the action of a toxin.[26] Interestingly, only strains of *C. diphtheriae* that contain a lysogenic bacteriophage (β-corynephage) are able to produce diphtheria toxin. The structural genes for the toxin (called the *tox* gene) is part of the bacteriophage genome. The expression of the *tox* gene is regulated by an iron-activated repressor and toxin production occurs only when iron becomes the growth-limiting substrate.[76] In the presence of iron (Fe^{2+}), the repressor forms active dimers with Fe^{2+}, which bind to the *tox* gene promoter and inhibit *tox* gene expression. When Fe^{2+} becomes limiting, the Fe^{2+}/repressor dimer dissociates, allowing the *tox* gene to be transcribed and translated.[37,98]

The toxin molecule is formed by *C. diphtheriae* in association with the cell membrane and is secreted from the cell as a single peptide consisting of 535 amino acids with a molecular weight of about 58 kDa. Through proteolysis, the single peptide is cleaved into two major chains, designated as A and B, that are connected by

disulfide bonds. Peptide A is a 21-kDa peptide that contains the enzymatic activity of the molecule that inhibits protein synthesis, while peptide B is a 37-kDa fragment that contains a C-terminal receptor-binding domain and an internal translocating domain. Peptide B is responsible for binding of the toxin molecule to its target receptor. On binding to the target cell via peptide B, the toxin enters the cell via receptor-mediated endocytosis. The low pH within the endosome triggers the translocation of peptide A (via interaction with the peptide B translocating domain) into the cytosol; at this time the disulfide bonds are reduced, peptide B is released, and peptide A becomes enzymatically active. Peptide A inhibits protein synthesis by the adenoribosylation of elongation factor-2, an enzyme that is required for translocation of the polypeptidyl–tRNA from the acceptor site to the donor site on the eucaryotic ribosome. The adenoribosyl group is transferred from NAD to elongation factor-2 by the peptide A toxin subunit, rendering EF-2 inactive:

$$\mathrm{NAD^+ + EF\text{–}2} \xrightarrow[\text{A}]{\text{toxin peptide}} \text{adenoribosyl phosphate:}$$

$$\text{EF-2 complex} + \text{nicotinamide} + \mathrm{H^+}$$

Treatment of the intact toxin with formalin renders a toxoid that cannot be split into A and B subunits. Therefore, the toxoid lacks the ability to catalyze its toxic intracellular effects, yet it retains antigenicity. Immunity to diphtheria is generally mediated by the presence of antibodies against the toxin.

All the signs and symptoms of cholera caused by *V. cholerae* result from the rapid loss of fluid from the gastrointestinal tract. Increased electrolyte secretion is caused by a protein enterotoxin. The 84-Da enterotoxin consists of a binding subunit (subunit B) composed of five identical 11.5-kDa monomers and a biologically active 27-kDa subunit (subunit A). The mode of action of cholera toxin is described in Chapter 8.

Endotoxins on the other hand, are produced only by gram-negative bacteria and consist primarily of LPS. LPS, as described earlier, is a structural component of the gram-negative outer membrane, containing the somatic (O) antigenic determinants. Endotoxins are heat-stable, are not detoxified by formaldehyde treatment, and are only partially neutralized by specific antibodies. Compared with many of

the exotoxins, endotoxins are of relatively low toxicity. Although endotoxin may escape into the surrounding fluids (as “blebs” on the surface of gram-negative bacteria), the whole cell generally retains the major portion of the toxic activity. The biologic and toxic activities of endotoxin are broad. Nanogram amounts of endotoxin cause fever in humans and the release of endogenous pyrogen. Larger doses cause hypotension,

lowered polymorphonuclear leukocyte and platelet counts from increased margination of these cells toward the walls of small blood vessels, hemorrhage, and sometimes disseminated intravascular coagulation due to the activation of clotting mechanisms. Endotoxin is also mitogenic for B lymphocytes and stimulates the release of several cytokines from macrophages.

Bacterial Superantigens. Another group of extracellular protein toxins, such as those produced by *S. aureus* or group A β-hemolytic streptococci are able to bind to structural peptides on host T-lymphocyte receptors and macrophage class II histocompatibility antigens. This binding induces the release of cytokines. Various *S. aureus* extracellular proteins, such as toxic shock syndrome toxin 1 (TSST-1), staphylococcal enterotoxins A and B, and group A streptococcal toxins act as "superantigens" and induce high levels of T-cell proliferation, prompt IL-2 and TNF-α release and cause a shock syndrome.[79] Superantigens produced by various bacteria will be discussed further in subsequent chapters dealing with specific bacterial genera.

Gram-negative bacilli belonging to the *Enterobacteriaceae* are the most frequently encountered bacterial isolates recovered from clinical specimens. Widely dispersed in nature, these organisms are found in soil and water, on plants, and, as the family name indicates, within the intestinal tracts of humans and animals. Before the advent of antibiotics, chemotherapy, and immunosuppressive measures, the infectious diseases caused by the *Enterobacteriaceae* were relatively well defined. Diarrheal and dysenteric syndromes, accompanied by fever and septicemia in classic cases of typhoid fever, were known to be caused by *Salmonella* and *Shigella* species. Classic cases of pneumonia, characterized by the production of brick-red or "currant jelly" sputum, were known to be caused by Friedlander's bacillus (*Klebsiella pneumoniae*). *Escherichia coli*, *Proteus* species, and various members of the *Klebsiella–Enterobacter* group were commonly recovered from traumatic wounds contaminated with soil or vegetative matter or from abdominal wound incisions following gastrointestinal surgery.

214

Thus, members of the *Enterobacteriaceae* may be incriminated in virtually any type of infectious disease and recovered from any specimen received in the laboratory. Immunocompromised or debilitated patients are highly susceptible to hospital-acquired infections, either after colonization with environmental strains or following invasive procedures, such as catheterization, bronchoscopy, colposcopy, or surgical biopsies, in which mucous membranes are traumatized or transected.

Endotoxic shock is one potentially lethal manifestation of infection with gram-negative bacteria, including the *Enterobacteriaceae*. Endotoxin is a complex pharmacologically active lipopolysaccharide that is contained within the cell wall of gram-negative species. This lipopolysaccharide is structured in three layers: (1) an outer variable carbohydrate portion that determines O-antigenic specificity (e.g., various *Salmonella* serotypes), (2) a middle core polysaccharide that is structurally similar among species, and (3) a central, highly conserved lipid moiety called lipid-A. The biologic effects of endotoxin have been demonstrated experimentally: small quantities injected intravenously into animals produce fever, leukopenia, capillary hemorrhage, hypotension, and circulatory collapse—symptoms that are, to a large extent, the same as those seen in humans with gram-negative sepsis.

The limulus lysate assay, which uses a reagent prepared from the amebocytes of the horseshoe crab (*Limulus polyphemus*), has been used with varying success in the diagnosis of endotoxic shock.[206] The lysate undergoes gelation when in contact with even trace amounts of endotoxin. More promising in the diagnosis of gram-negative sepsis is the development of monoclonal antibodies that can be used in enzyme-linked immunoassay or other techniques for the detection of lipid-A. The pharmacologic effects of endotoxin can be attributed primarily to lipid-A. It is highly antigenic and has determinants common to all strains of gram-negative bacilli. Thus, the detection of circulating lipid-A in patients with gram-negative sepsis, using a monoclonal antibody, could establish a diagnosis so that presumptive therapy could be started before the causative organism is recovered and identified.

Microbiologists must be alert to the emergence of any *Enterobacteriaceae* that are resistant to multiple antibiotics. Virtually all resistance seen to β-lactam antibiotics in *Enterobacteriaceae* is mediated by acquired or chromosomal β-lactamases. Certain members of the *Enterobacteriaceae* possess chromosomally determined inducible AmpC β-lactamases. These include the so-called MYSPACE organisms: *Morganella morgannii, Yersinia enterocolitica, Serratia marcescens, Providencia* spp., *Aeromonas* spp. *Citrobacter freundii* complex, and *Enterobacter* spp.[315] Antibiotic resistance may also evolve in formerly susceptible clinical isolates through the transfer of plasmids known as R factors or R plasmids. These large R plasmids encode for genes that produce β-lactamase enzymes capable of hydrolyzing penicillins, first-, second-, and third-generation cephalosporins and aztreonnam, and have therefore been designated extendedspectrum β-lactamases or ESBLs.[507] Detecting these

resistant strains is not only important in treating the patient from whom the isolate is recovered but also has important implications for surveillance of nosocomial infections. The mechanisms by which resistance may develop and methods used for detection of resistance mechanisms are discussed in more detail in Chapter 17. Specific clinical syndromes of individual genera and species are discussed in later sections of this chapter.

Characteristics for Presumptive Identification

What are the initial clues that an unknown isolate recovered from a clinical specimen may belong to the *Enterobacteriaceae*? In specimens other than feces, a Gram-stained preparation may reveal short, plump, gram-negative bacillary or coccobacillary cells, ranging from 0.5 to 2 fm wide to 2 to 4 fm long (see Image Plate 6-1A). However, species differentiation cannot be made on the basis of only Gram stain morphology.

Characteristic colonial morphology of an organism growing on a solid medium may provide a second clue. Typically, members of the *Enterobacteriaceae* produce relatively large, dull gray, dry, or mucoid colonies on sheep blood agar, the latter suggesting encapsulated strains of *K. pneumoniae* (see Image Plate 6-1B and C). Hemolysis on blood agar is variable and indistinctive. Colonies appearing as a thin film or as waves (a phenomenon known as **swarming**) suggest that the organism is motile and probably a *Proteus* species (see Image Plate 6-1D). Colonies that appear red on MacConkey agar or have a green sheen on eosin methylene blue (EMB) agar (see Image Plate 6-2) indicate that the organism is capable of forming acid from lactose in the medium.

Differentiation of the *Enterobacteriaceae*, however, is based primarily on the presence or absence of different enzymes coded by the genetic material of the bacterial chromosome. These enzymes direct the metabolism of bacteria along one of several pathways that can be detected by special media used in in vitro culture techniques. Substrates on which these enzymes can react are incorporated into the culture medium, together with an indicator that can detect either the utilization of the substrate or the presence of specific metabolic products. By selecting a series of media that measure different metabolic characteristics of the microorganisms to be tested, a biochemical profile can be determined for making a species identification.

Screening Characteristics

Definitive identification of the members of the *Enterobacteriaceae* may require a battery of biochemical tests. Considerable time loss and possible misidentification can be avoided if a few preliminary observations are made to ensure that the organism being tested belongs to this group. If the organism is a gram-negative organism of

another group, it may be necessary to use a different set of characteristics than that commonly used for the identification of the *Enterobacteriaceae.* With few exceptions, all members of the *Enterobacteriaceae* demonstrate the following characteristics:

- Glucose is fermented (see Image Plate 6-1E and F)
- Cytochrome oxidase is negative (see Image Plate 6-1G)
- Nitrate is reduced to nitrite (see Image Plate 6-1H).

215

Carbohydrate Utilization. It is common for laboratory microbiologists to refer to all carbohydrates as sugars. This is convenient in an operational sense, although it is understood that polyhedral alcohols, such as dulcitol and mannitol, or cationic salts of acetate or tartrate are not carbohydrates and thus are not truly sugars in a chemical sense.

The term **fermentation** is also used somewhat loosely in reference to the utilization of carbohydrates by bacteria, with terms such as **lactose-fermenters** and **non–lactosefermenters**. By definition, fermentation is an oxidation–reduction metabolic process that takes place in an anaerobic environment, and instead of oxygen, an organic substrate serves as the final hydrogen (electron) acceptor. In bacteriologic test systems, this process is detected by observing color changes in pH indicators as acid products are formed. Acidification of a test medium may occur through the degradation of carbohydrates by pathways other than fermentation, or there may be ingredients other than carbohydrates in some media that result in acid end products. Although most bacteria that metabolize carbohydrates are facultative anaerobes, the utilization may not always be under strictly anaerobic conditions, as is observed in the production of acid products by bacterial colonies growing on the surface of agar media. Even though all tests used to measure an organism's ability to enzymatically degrade a "sugar" into acid products may not be "fermentative," these terms will be used in this textbook for convenience.

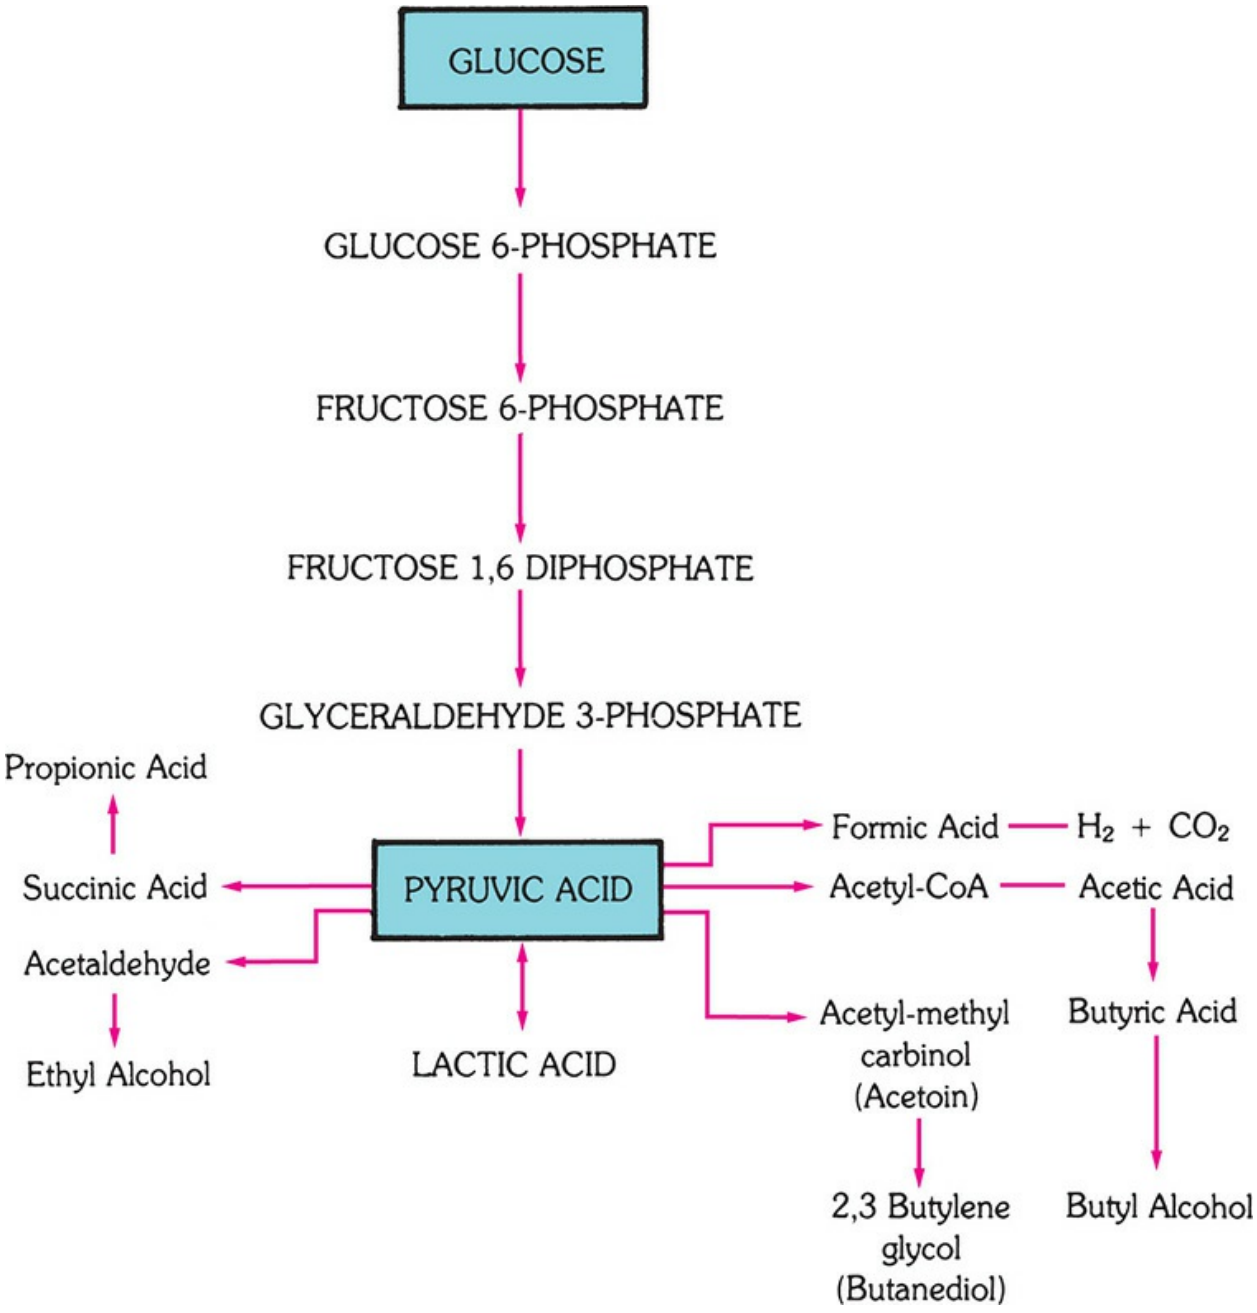
Basic Principles of Fermentation. Pasteur's mid-19th century studies of the action of yeasts on wine provide the basis for our present understanding of carbohydrate fermentation. Pasteur observed that certain contaminating bacterial species produced a drop in the pH of wine (a carbohydrate substrate) from the production of a variety of acids. Full descriptions of the fermentative pathways by which a monosaccharide such as glucose is degraded evolved soon thereafter. Through a series of enzymatic glycolytic cleavages and transformations, the glucose molecule is split into a series of three carbon compounds, the most important of which is pyruvic acid. The chemical sequence by which glucose is converted to pyruvic acid is known as the **Embden–Meyerhof pathway** (EMP; Fig. 6-1). Many bacteria, including all *Enterobacteriaceae*, ferment glucose through the EMP to form pyruvic acid; the

manner in which pyruvic acid is further used, however, varies among bacterial species. The alternative fates of pyruvic acid are the result of a variety of fermentation pathways, yielding quite different products (Fig. 6-1).

Bacteria are differentiated by the carbohydrates they metabolize and the types and quantities of acids produced. These differences in enzymatic activity serve as one of the important characteristics by which the different species are recognized. It is important for students of microbiology to understand that in the glycolytic formation of pyruvic acid, adenosine triphosphate (ATP) is generated at the expense of the reduction of nicotinamide adenine dinucleotide (NAD) to $NADH_2$. For each glucose molecule that is fermented to form pyruvic acid, four hydrogen ions are consumed through the reduction of two NAD to two $NADH_2$. Because the total NAD in the cell is very limited, fermentation would cease

216

very rapidly if the $NADH_2$ were not reoxidized in the further metabolism of pyruvic acid. Figure 6-2 depicts the fermentation of three molecules of glucose by means of two alternative pathways. For example, glucose fermentation by *E. coli* occurs by means of the mixed acid fermentation pathway and results in the production of large quantities of acetic, lactic, and formic acids, with a marked drop in the pH of the test medium. This is detected by a positive methyl red test (Fig. 6-2). On the other hand, the *Klebsiella–Enterobacter–Hafnia–Serratia* group metabolizes pyruvic acid primarily through the butylene glycol pathway, producing acetyl methyl carbinol (acetoin) and a positive Voges–Proskauer (VP) test (Fig. 6-2). Note that the principal end products in this latter pathway are alcohols, with only a small amount of acid produced; thus the methyl red test is usually negative for this group of organisms.



■ **FIGURE 6-1** Fermentation of glucose to form pyruvate (EMP) and the alternative fates of pyruvic acid.

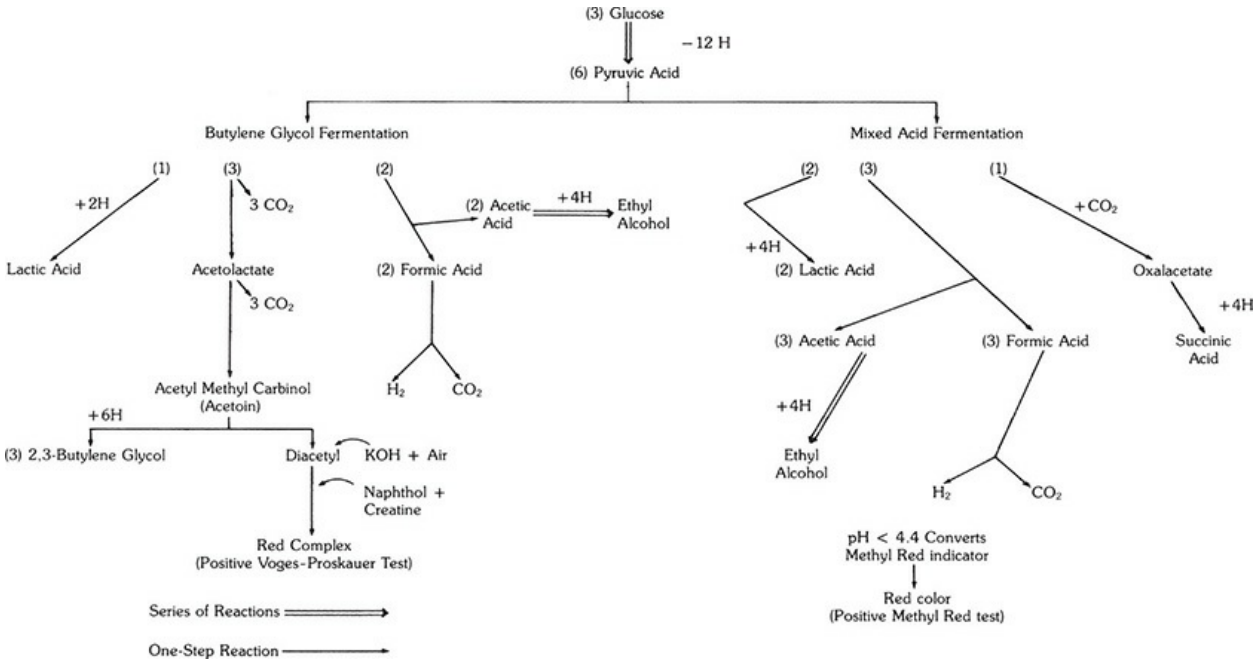
The gas resulting from fermenting bacteria is primarily a mixture of hydrogen and carbon dioxide formed through the cleavage of formic acid. It is an accepted rule of thumb that any bacterium that forms gas in carbohydrate test medium must first form acid, which is self-evident from the EMP scheme shown in Figure 6-1. Gas is best detected by using a broth carbohydrate-fermentation medium into which small inverted Durham tubes have been placed (see Image Plate 6-1F). Even trace amounts

of gas, which collect as bubbles under the Durham tubes, can be detected. Some species of *Enterobacteriaceae* lack the enzyme formic dehydrogenase and cannot cleave formic acid and, as a result, do not form even trace amounts of CO_2 (e.g., most species of *Shigella*). Conversely, organisms that use the butylene glycol pathway (i.e., are VP-positive) produce copious amounts of CO_2 (Fig. 6-2). Therefore, when a large amount of gas is observed, one should consider members of the *Klebsiella–Enterobacter–Hafnia–Serratia* group as the likely identification. The formation of ethyl alcohol by microorganisms is of utmost commercial importance in the manufacture of alcoholic beverages and organic reagents; however, it is of limited usefulness in the laboratory identification of bacteria.

The bacterial fermentation of lactose is more complex than that of glucose. Lactose is a disaccharide composed of glucose and galactose, connected through an oxygen linkage known as a **galactoside bond.** On hydrolysis, this bond is severed, releasing glucose and galactose. For a bacterium to metabolize lactose, two enzymes must be present: (1) β-galactoside permease, permitting the transport of a β-galactoside, such as lactose, through the bacterial cell wall; and (2) β-galactosidase, the enzyme required to hydrolyze the β-galactoside bond once the disaccharide has entered the cell. The final acid reaction results from the degradation of glucose as shown in Figure 6-3.

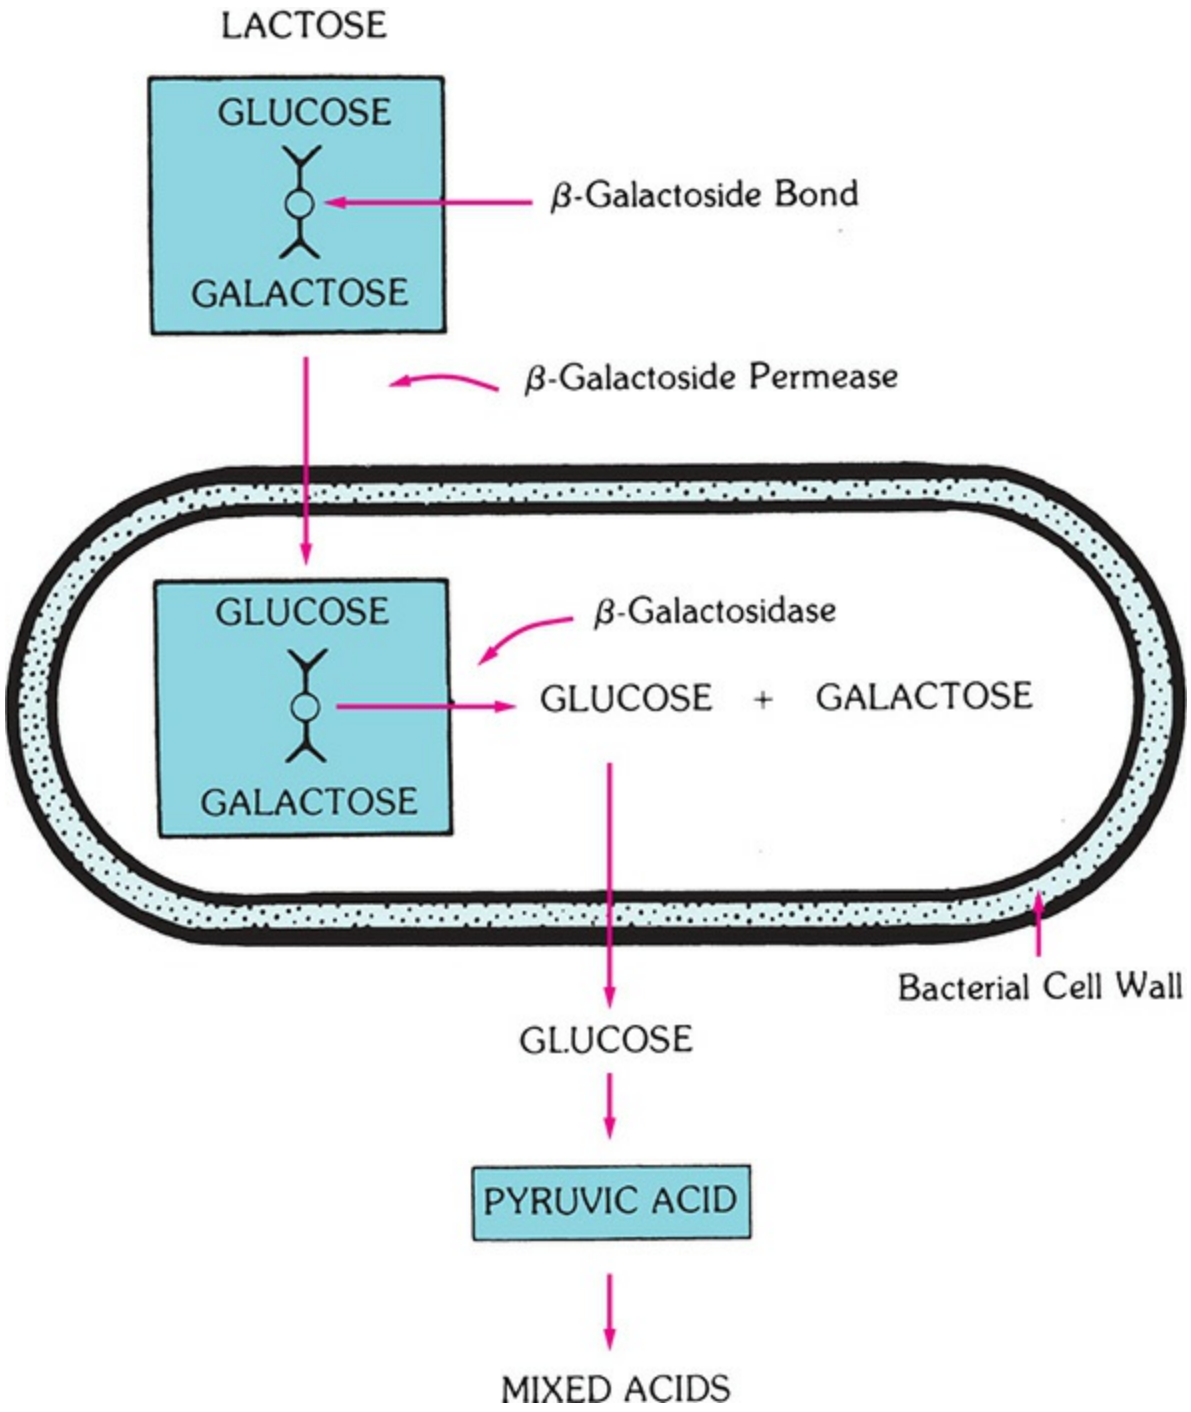
Because lactose fermentation ultimately proceeds by way of glucose degradation through the EMP, it follows that any organism incapable of metabolizing glucose cannot form acid from lactose. This explains why glucose is omitted from the formulas of primary isolation media such as MacConkey agar and EMB agar: if it is not omitted, the ability to detect the lactose-fermenting capability of the test bacteria would be lost. In the test medium, the end point of lactose fermentation is the detection of acid production. A non–lactose-fermenting organism is one that lacks either one or both of the two enzymes required for lactose metabolism or lacks the ability to attack glucose. So-called late lactose-fermenters are believed to be organisms that exhibit β-galactosidase activity but show sluggish β-galactoside permease activity.

β-Galactosidase and the ONPG Test. *o*-Nitrophenyl-β-D-galactopyranoside (ONPG) is a compound structurally



■ **FIGURE 6-2** Mixed acid and butylene glycol pathways of glucose fermentation.

217



■ **FIGURE 6-3** Bacterial fermentation of lactose: Lactose, a disaccharide composed of molecules of glucose and galactose joined by a β-galactoside bond, diffuses through the bacterial cell wall under the action of β-galactoside permease. If the bacterium produces β-galactosidase, the lactose is hydrolyzed to produce glucose and galactose. The glucose is then metabolized as illustrated in Figure 6-1.

similar to lactose except that the glucose has been replaced by an *o*-nitrophenyl group.

This rather ingenious manipulation of the molecule forms the basis for the ONPG test, which is outlined in Chart 6-1. This test detects the enzyme β-galactosidase far more quickly than does the test for lactose fermentation previously described. This is helpful in identifying late lactose-fermenters that are deficient in β-galactoside permease. ONPG permeates the bacterial cell more readily than lactose and, under the action of β-galactosidase, is hydrolyzed into galactose and *o*-nitrophenol (see Chart 6-1). *o*-Nitrophenol is a chromophore that is colorless when bound to D-galactopyranoside but is yellow in its free (unbound) form (see Image Plate 6-4A).

ONPG test tablets that can be easily reconstituted by adding a small amount of water are available commercially and are convenient for use in the laboratory. Organisms with strong β-galactosidase activity may produce a positive test within a few minutes after inoculation of the medium. The ONPG test is most helpful for detection of β-galactosidase activity in late lactose-fermenters, such as some strains of *E. coli*, in which differentiation from species of *Shigella* (except certain strains of *Shigella sonnei*) may otherwise be difficult. The test is also helpful in distinguishing some strains of *Citrobacter* species and *Salmonella* ser. Arizonae (ONPG-positive) from most *Salmonella* species (ONPG-negative). The ONPG test is not a substitute for the determination of lactose fermentation because only the enzyme β-galactosidase is measured.

Cytochrome Oxidase Activity. Any organism that displays cytochrome oxidase activity following the procedure and test conditions outlined in Chart 1-5 is excluded from the *Enterobacteriaceae*. The developing color reaction must be interpreted within 10 to 20 seconds because many organisms, including selected members of the *Enterobacteriaceae*, may produce delayed false-positive reactions. Both oxidase-positive and oxidase-negative control organisms should be tested if there is difficulty in interpreting the cytochrome oxidase reaction. The commercial cytochrome oxidase droppers are used most often because of their convenience. The color reactions are clearly visible within 10 seconds. If metal inoculating loops or wires are used in the laboratory for transferring bacteria to the oxidase reagent, those made from stainless steel or Nichrome may produce false-positive reactions, owing to trace amounts of iron oxide on the flamed surface of the metal. This problem can be circumvented by using plastic or platinum inoculating loops or by using wooden applicator sticks or cotton swabs to perform the oxidase test. Tetramethyl- *p*-phenylenediamine, rather than the dimethyl derivative, is most commonly used because the reagent is more stable, more sensitive, and less toxic (see Chart 1-5 and Image Plate 6-1G).

Nitrate Reduction. All *Enterobacteriaceae*, with the exception of certain biotypes of *Pantoea agglomerans* and certain species of *Serratia* and *Yersinia*, reduce nitrate to nitrite. Because a variable period of incubation (3 to 24 hours, depending on the system used) is required to perform the nitrate reduction test, it is not commonly used

to prescreen unknown bacterial isolates. Rather, the test is used in most laboratories either to confirm the correct classification of an unknown microorganism or as an aid in determining the identification of bacterial species. Details of the nitrate reduction test are presented in Chart 6-2.

Any basal medium that supports the growth of the organism and contains a 0.1% concentration of potassium nitrate (KNO_3) is suitable for performing this test. Nitrate broth and nitrate agar in a slant are the media forms most commonly used in clinical laboratories. Because the enzyme nitrate reductase is maximally active under anaerobic conditions, Zobell[688] has recommended the use of semisolid agar. Semisolid media also enhance the growth of many bacterial species and provide the anaerobic environment needed for enzyme activation. The addition of zinc dust to all negative reactions, as shown in Chart 6-2, should be a routine procedure. Most organisms capable of reducing nitrates will do so within 24 hours; some may produce detectable quantities within 2 hours. A rapid nitrate test has been described by Schreckenberger and Blazevic.[586] Both α-naphthylamine and sulfanilic acid are relatively unstable, so their reactivity should be determined at frequent intervals by testing with positiveand negative control organisms. The diazonium compound that forms from the reaction of the reduced nitrate and reagents is also relatively unstable, and the color tends to fade; accordingly, readings should be made soon after the reagents are added (see Image Plate 6-1H).

218

Culture Media Used for Detection of Carbohydrate Fermentation

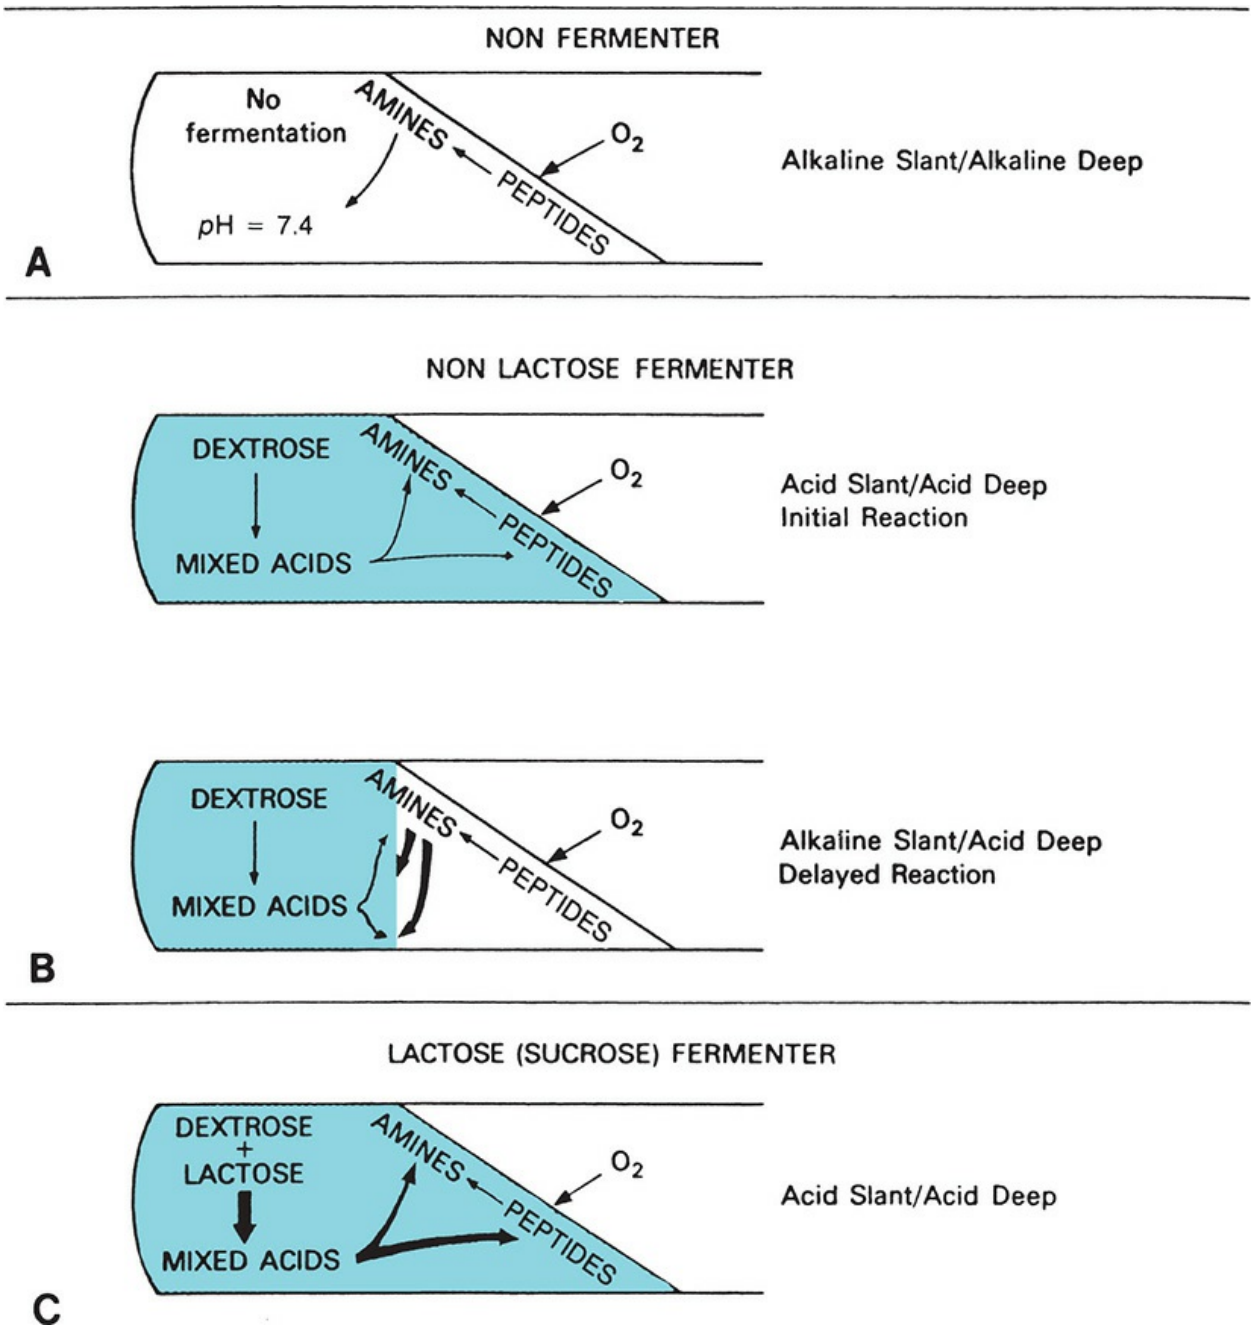
A variety of liquid or agar media can be used to measure the ability of a test organism to fermentatively utilize carbohydrates. The carbohydrate to be tested, such as glucose, is filter-sterilized and added aseptically to a basal medium to a final concentration of 0.5% to 1.0%. The formula of a typical basal fermentation medium contains trypticase (BBL), 10 g; sodium chloride, 5 g; phenol red, 0.018 g; and distilled water to equal 1 L. Trypticase is a hydrolysate of casein that serves as a source for carbon and nitrogen; sodium chloride is an osmotic stabilizer; and phenol red is a pH indicator that turns yellow when the pH of the medium drops below 6.8. Image Plate 6-1F illustrates acid fermentation reactions in purple broth medium. All of the *Enterobacteriaceae* grow well in this type of medium, and the base formula used is a matter of personal preference. In addition to producing a pH color shift in fermentation culture media, the production of mixed acids, notably butyric acid, often

results in a pungent, foul odor from the culture medium. When such an odor is detected, one should immediately be suspicious of the presence of one of the *Enterobacteriaceae* (in addition, the anaerobic bacteria produce characteristic metabolic products with distinctive odors).

Use of Kligler's Iron Agar and Triple Sugar Iron Agar

In practice, microorganisms that are capable of fermenting glucose are commonly detected by observing the reactions they produce when grown on Kligler's iron agar (KIA) or triple sugar iron (TSI) agar (Fig. 6-4; see Image Plate 6-1E). If an organism cannot ferment glucose, then an alkalineslant–alkaline-butt (no change) reaction is observed (see Fig. 6-4A), indicating a lack of acid production and failure of the test organism to ferment any of the sugars present. This reaction alone is sufficient to exclude an organism from the *Enterobacteriaceae*. The formula for KIA is listed in Box 6-1 (the formula for TSI is identical except that 10 g of sucrose is added).

Several observations are important in studying the formulas of KIA and TSI. The incorporation of four protein derivatives—beef extract, yeast extract, peptone, and proteose peptone—makes KIA and TSI nutritionally very rich. The lack of inhibitors permits the growth of all but the most fastidious bacterial species (excluding the obligate anaerobes). For this reason, KIA and TSI agar can be used only when testing a bacterial species selected from a single colony recovered on primary or selective agar plates. Glucose and lactose (and sucrose in TSI medium) are evenly distributed throughout both the slant and butt (deep) portion of the tube. However, lactose is present in a concentration 10 times



■ **FIGURE 6-4** Three general types of reactions produced by bacteria growing on KIA: **A.** Nonfermentative bacilli that are unable to produce acids from the fermentation of glucose or lactose; there is no change in the medium (represented by *white*). **B.** Initial acidification of both the deep and the slant of the medium (*shaded area*) by bacteria that ferment glucose, but the slant reverts back to alkaline pH as alkaline amines are formed from the oxidative decarboxylation of peptides (derived from protein in the medium) near the surface. **C.** Complete permanent acidification of both the deep and the slant of the tube by lactose-fermenting bacteria.

BOX 6-1

Kligler's Iron Agar

Beef extract, 3 g
Yeast extract, 3 g
Peptone, 15 g
Proteose peptone, 5 g
Lactose, 10 g
Glucose, 1 g
Ferrous sulfate, 0.2 g
Sodium chloride, 5 g
Sodium thiosulfate, 0.3 g
Agar, 12 g
Phenol red, 0.024 g
Distilled water to equal 1 L
Final pH, 7.4

that of glucose (similarly, the ratio of sucrose to glucose is 10:1 in TSI medium). This 10:1 ratio is important to the understanding of the biochemical principles discussed later. Ferrous sulfate as a hydrogen sulfide detector is somewhat less sensitive than other ferric or ferrous salts; therefore, there may be discrepancies in the hydrogen sulfide readings between KIA and TSI and other test media (see Image Plate 6-4B). The phenol red indicator is yellow below a pH of 6.8. Because the pH of the uninoculated medium is buffered at 7.4, relatively small quantities of acid production result in a visible color change.

Biochemical Principles

The biochemical principles underlying the reactions observed in KIA or TSI agar are illustrated in Figure 6-4. Note that the molten agar is allowed to solidify in a slant. This configuration results in essentially two reaction chambers within the same tube. The **slant** portion, exposed throughout its surface to atmospheric oxygen, is aerobic; the lower portion, called the **butt** or the **deep,** is protected from the air and is relatively anaerobic. It is important when preparing the media that the slant and the deep are kept equal in length, approximately 3 cm (1.5 in.) each, so that this two-chamber effect is preserved.

KIA and TSI tubes are inoculated with a long, straight wire. The well-isolated test colony recovered from an agar plate is touched with the end of the inoculating needle, which is then stabbed into the deep of the tube, extending to within 3 to 5 mm of its bottom. When the inoculating wire is removed from the deep of the tube, the slant surface is streaked with a back-and-forth motion. Inoculated tubes are placed into an incubator at 35°C for 18 to 24 hours. The color photographs shown in Image Plates 6-1E and 7-1A reveal the reactions that are described in Box 6-2. Thus, as shown in Figure 6-4A and in Plate 7-1A, without carbohydrate fermentation, no acids are formed, and the amine production in the slant together with the alkaline buffers produce a red color throughout the medium. The bacteria that produce this type of reaction are known as **nonfermenters** (see Chapter 7).

BOX 6-2

Reactions on KIA

Alkaline Slant/Alkaline Deep (K/K)

No carbohydrate fermentation. This is characteristic of nonfermentative bacteria, such as *Pseudomonas aeruginosa*.

Alkaline Slant/Acid Deep (K/A)

Glucose fermented; lactose (or sucrose for TSI medium) not fermented. This is characteristic of non–lactose-fermenting bacteria, such as *Shigella* species.

Alkaline Slant/Acid (Black) Deep (K/A/H_2S)

Glucose fermented; lactose not fermented, hydrogen sulfide produced. This is characteristic of non–lactose-fermenting, hydrogen sulfide-producing bacteria, such as *Salmonella* species, *Citrobacter* species, and *Proteus* species.

Acid Slant/Acid Deep (A/A)

Glucose and lactose (or sucrose with TSI) fermented. This is characteristic of lactose-fermenting coliforms, such as *Escherichia coli* and the *Klebsiella–Enterobacter* species.

If the KIA tube is inoculated with a glucose-fermenting organism that cannot utilize lactose, only a relatively small quantity of acid can be obtained from the 0.1% concentration of glucose in the medium. Initially, during the first 8 to 12 hours of incubation, even this amount of acid may be sufficient to convert both the deep and

the slant color to yellow. Within the next few hours, however, the glucose supply is completely exhausted, and the bacteria begin oxidative degradation of the amino acids within the slant portion of the tube where oxygen is present. This results in the release of amines that soon counteract the small quantities of acid present in the slant; by 18 to 24 hours, the entire slant reverts to an alkaline pH, and the color returns to red. In the deep (anaerobic portion) of the tube, however, amino acid degradation is insufficient to counteract the acid formed, and the medium remains yellow. Thus, the alkaline-slant–acid-deep reaction on KIA (or TSI) is an important initial indicator that the test organism is a non–lactose-fermenter (see Fig. 6-4B and Image Plate 6-1E).

If the KIA tube is inoculated with a lactose-fermenting organism, then, even though the glucose is completely used up after the first 8 to 12 hours, fermentation continues as the organism is able to use lactose (present in 10 times the concentration of glucose). Consequently, when the tube is examined at the end of 18 to 24 hours, acid production from fermentation of lactose is still occurring, and both the slant and the deep appear yellow, resulting in an acid-slant–aciddeep reaction (see Fig. 6-4 *C* and Image Plate 6-1E).

Many microbiologists prefer TSI over KIA because the addition of sucrose to the formula helps screen for *Salmonella*

and *Shigella* species, because neither of these (except rare strains) metabolizes either lactose or sucrose. Therefore, any acid–acid reaction of TSI indicates that either lactose, sucrose, or both have been fermented, excluding *Salmonella* and *Shigella.* It should also be remembered that *Y. enterocolitica* ferments sucrose, but not lactose; thus, on TSI, the reaction will be acid–acid (similar to coliforms such as *E. coli*), but on KIA, the reaction will be alkaline–acid (similar to a non–lactose-fermenter). Consequently, when screening stool specimens for *Salmonella*, *Shigella*, and *Yersinia*, some might argue that KIA is preferable to TSI.

For the detection of hydrogen sulfide, which is colorless, the medium must include an indicator. Sodium thiosulfate is the source of sulfur atoms in most media used for hydrogen sulfide production. Iron salts (ferrous sulfate and ferric ammonium citrate) incorporated in the culture media then react with hydrogen sulfide to produce an insoluble black precipitate (ferrous sulfide). An acid environment is required for an organism to produce hydrogen sulfide and, therefore, a source of hydrogen ions must be provided. Because the deep of the KIA and TSI tubes becomes acidic with glucose fermentation (hydrogen ions increase), the blackening is often first seen or confined there, particularly with non–lactosefermenting bacteria (see Image Plate 6-1E). Thus, it follows that a black deep should be read as acid even if the usual yellow color is obscured by the black precipitate. KIA and TSI are less sensitive in the detection of hydrogen sulfide than other iron-containing media, such as sulfide indole motility

(SIM) medium (see Image Plate 6-4B).

If an organism can be excluded from the *Enterobacteriaceae* before an extended battery of biochemical tests is set up, considerable time and labor will be saved. It is recommended that either a KIA or a TSI slant be set up on all isolates suspected of being one of the *Enterobacteriaceae* at the same time that differential test media of kit systems are set up. Even if an organism is a fermenter and is suspected of being one of the *Enterobacteriaceae*, a cytochrome oxidase test should be performed to exclude organisms belonging to other genera of fermenting bacteria, such as *Aeromonas, Plesiomonas, Vibrio*, and *Pasteurella* species, that are oxidase-positive.

Selection of Primary Isolation Media

Selective culture media must be used to recover the significant species of bacteria from specimens that may harbor a mixture of microorganisms. To make rational selections, microbiologists must know the composition of each formula and the purpose and relative concentration of each chemical or compound that is included. For example, it is not sufficient to know that bile salts are included in the formulas of a number of selective media to inhibit the growth of grampositive and some of the more fastidious gram-negative bacteria species. For example, *Salmonella–Shigella* (SS) agar contains about five times the concentration of bile salts compared with MacConkey agar and is more inhibitory to *E. coli* and more selective for the recovery of *Salmonella* species from stool cultures.

For the recovery of the *Enterobacteriaceae* from clinical specimens that potentially harbor mixed bacteria, three general types of media are available: (1) nonselective media for primary isolation (e.g., blood agar); (2) selective or differential agars (e.g., MacConkey and Hektoen enteric agars); and (3) enrichment broths. Tables 6-1 and 6-2 compare different media commonly used in clinical practice. The formulas are complex and include ingredients that not only inhibit the growth of certain bacterial species (selective), but also detect several biochemical characteristics that are important in making a preliminary identification of the microorganisms present in the specimen (differential).

Chemicals and Compounds Used in Selective Media

Box 6-3 lists the general types of chemicals and compounds used in selective media, including brief comments on the function of each.

Selective Isolation Media

In 1905, MacConkey[403] first described a selective differential medium (neutral red–

bile salt agar) that he used to isolate gram-negative enteric bacilli from specimens containing mixtures of bacterial species. He incorporated lactose and the indicator neutral red into this medium to provide a visual means for detecting lactose utilization by the test organism. At that time, all non–spore-forming, gram-negative bacilli were still referred to as enteric organisms; however, microbiologists had recognized that certain species were more pathogenic to humans than others. The carbohydrate-utilization patterns of several species of bacteria were already known by the turn of the century, and the fermentation of lactose, in particular, was recognized as an important marker for differentiating certain enteric pathogens. Holt–Harris and Teague[297] in 1916 described a medium with eosin and methylene blue as indicators for differentiating between lactose-fermenting and non–lactosefermenting colonies. Sucrose was included in the medium to detect members of the coliform group that ferment sucrose more readily than lactose.

MacConkey and EMB agars are only moderately inhibitory and are designed primarily to prevent growth of gram-positive bacteria from mixed cultures. Many species of fastidious gram-negative organisms are inhibited as well; however, all *Enterobacteriaceae* grow well. Table 6-1 compares the formulas, inhibitory ingredients, and key differential characteristics for MacConkey and EMB agars. A new formulation of MacConkey agar, MacConkey III, was developed by researchers at Becton–Dickinson to improve recovery of CO_2-sensitive *Enterobacteriaceae*. Although aerobic incubation is recommended for MacConkey agar, it has become common in many clinical microbiology laboratories to incubate all primary plates including MacConkey agar in a 5% CO_2 incubator in order to keep all plates together. The problem with this is that some strains of *Enterobacteriaceae* may fail to grow or show partial inhibition when incubated in CO_2 because of a decrease in pH of the medium. In one study, MacConkey III was shown to

221

TABLE 6-1 Selective Differential Media for Recovery of *Enterobacteriaceae*

Medium	Formulation		Purpose and Differential Ingredients	Reactions and Interpretation
MacConkey agar (see Image Plates 6-2*A* and *B*)	Peptone Polypeptone Lactose Bile salts Sodium chloride Agar Neutral red Crystal violet Distilled water to Final pH, 7.1	17 g 3 g 10 g 1.5 g 5 g 13.5 g 0.03 g 0.001 g 1 L	MacConkey agar is a differential-plating medium for the selection and recovery of the *Enterobacteriaceae* and related enteric gram-negative bacilli. The bile salts and crystal violet inhibit the growth of gram-positive bacteria and some fastidious gram-negative bacteria. Lactose is the sole carbohydrate. Lactose-fermenting bacteria produce colonies that are in varying shades of red, owing to the conversion of the neutral red indicator dye (red below pH 6.8) from the production of mixed acids. Colonies of non–lactose-fermenting bacteria appear colorless or transparent.	Typical strong lactose fermenters, such as species of *Escherichia, Klebsiella,* and *Enterobacter*, produce red colonies surrounded by a zone of precipitated bile. Slow or weak lactose fermenters, such as *Citrobacter, Providencia, Serratia,* and *Hafnia*, may appear colorless after 24 hours or slightly pink in 24–48 hours. Species of *Proteus, Edwardsiella, Salmonella*, and *Shigella*, with rare exceptions, produce colorless or transparent colonies. Representative colonies, showing these various reactions, are shown in Image Plate 6-2.
Eosin methylene blue (EMB) agar (see Image Plates 6-2*C* through *F*)	Peptone Lactose Sucrose[a] Dipotassium, PO_4 Agar Eosin Y Methylene blue Distilled water to Final pH, 7.2	10 g 5 g 5 g 2 g 13.5 g 0.4 g 0.065 g 1 L	EMB agar is a differential-plating medium that can be used in place of MacConkey agar in the isolation and detection of the *Enterobacteriaceae* or related coliform bacilli from specimens with mixed bacteria. The aniline dyes (eosin and methylene blue) inhibit gram-positive and fastidious gram-negative bacteria. They combine to form a precipitate at acid pH, thus also serving as indicators of acid production. Levine EMB, with only lactose, gives reactions more in parallel with MacConkey agar; the modified formula also detects sucrose fermenters.	Typical strong lactose-fermenting colonies, notably *Escherichia coli*, produce colonies that are green-black with a metallic sheen. Weak fermenters, including *Klebsiella, Enterobacter, Serratia*, and *Hafnia*, produce purple colonies within 24–48 hours. Non–lactose-fermenters, including *Proteus, Salmonella*, and *Shigella*, produce transparent colonies. *Yersinia enterocolitica*, a nonlactose, sucrose fermenter, produces transparent colonies on Levine EMB and purple-to-black colonies on the modified formula. See Image Plate 6-2.

[a]Modified Holt–Harris–Teague formula. Sucrose is not contained in Levine EMB agar.

TABLE 6-2 Highly Selective Media for Recovery of *Enterobacteriaceae* From Gastrointestinal Specimens

Medium	Formulation		Purpose and Differential Ingredients	Reactions and Interpretation
Salmonella–Shigella (SS) agar (see Image Plates 6-3*G* and *H*)	Beef extract Peptone Lactose Bile salts Sodium citrate Sodium thiosulfate Ferric citrate Agar Neutral red Brilliant green Distilled water to Final pH, 7.4	5 g 5 g 10 g 8.5 g 8.5 g 8.5 g 1 g 12.5 g 0.025 g 0.033 g 1 L	SS agar is a highly selective medium formulated to inhibit the growth of most coliform organisms and permit the growth of species of *Salmonella* and *Shigella* from environmental and clinical specimens. The high bile salts concentration and sodium citrate inhibit all gram-positive bacteria and many gram-negative organisms, including coliforms. Lactose is the sole carbohydrate and neutral red is the indicator for acid detection. Sodium thiosulfate is a source of sulfur. Any bacteria that produce hydrogen sulfide gas are detected by the black precipitate formed with ferric citrate (relatively insensitive).High selectivity of SS agar permits use of heavy inoculum.	Any lactose-fermenting colonies that appear are colored red by the neutral red. Rare strains of *Salmonella arizonae* are lactose fermenting, and colonies may simulate *Escherichia coli.* Growth of species of *Salmonella* is uninhibited, and colonies appear colorless with black centers, owing to hydrogen sulfide gas production. Species of *Shigella* show varying inhibition and colorless colonies with no blackening. Motile strains of *Proteus* that appear on SS agar do not swarm. See Image Plate 6-3

Hektoen enteric (HE) agar (see Image Plates 6-3E and F)	Peptone Yeast extract Bile salts Lactose Sucrose Salicin Sodium chloride Sodium thiosulfate Ferric ammonium citrate Acid fuchsin Thymol blue Agar Distilled water to Final pH, 7.6	12 g 3 g 9 g 12 g 12 g 2 g 5 g 5 g 1.5 g 0.1 g 0.04 g 14 g 1 L	HE agar is a recent formulation devised as a direct-plating medium for fecal specimens to increase the yield of species of *Salmonella* and *Shigella* from the heavy numbers of normal flora. The high bile salt concentration inhibits growth of all gram-positive bacteria and retards the growth of many strains of coliforms. Acids may be produced from the carbohydrates, and acid fuchsin reacting with thymol blue produces a yellow color when the pH is lowered. Sodium thiosulfate is a sulfur source, and hydrogen sulfide gas is detected by ferric ammonium citrate (relatively sensitive).	Rapid lactose fermenters (such as *E. coli*) are moderately inhibited and produce bright-orange to salmon-pink colonies. *Salmonella* colonies are blue-green, typically with black centers from hydrogen sulfide gas. *Shigella* appear greener than *Salmonella*, with the color fading to the periphery of the colony. *Proteus* strains are somewhat inhibited; colonies that develop are small, transparent, and more glistening or watery in appearance than species of *Salmonella* or *Shigella*. See Image Plate 6-3.
Xylose lysine deoxycholate (XLD) agar (see Image Plates 6-3A through D)	Xylose Lysine Lactose Sucrose Sodium chloride Yeast extract Phenol red Agar Sodium deoxycholate Sodium thiosulfate Ferric ammonium citrate Distilled water to Final pH, 7.4	3.5 g 5 g 7.5 g 7.5 g 5 g 3 g 0.08 g 13.5 g 2.5 g 6.8 g 0.8 g 1 L	XLD agar is less inhibitory to growth of coliform bacilli than HE agar and was designed to detect shigellae in feces after enrichment in gram-negative broth. Bile salts in relatively low concentration make this medium less selective than the other two included in this table. Three carbohydrates are available for acid production, and phenol red is the pH indicator. Lysine-positive organisms, such as most *Salmonella* species, produce initial yellow colonies from xylose utilization and delayed red colonies from lysine decarboxylation. Hydrogen sulfide detection system is similar to that of HE agar.	Organisms such as *E. coli* and *Klebsiella–Enterobacter* species may use more than one carbohydrate and produce bright yellow colonies. Colonies of many species of *Proteus* are also yellow. Most species of *Salmonella* produce red colonies, most with black centers from hydrogen sulfide gas. *Shigella*, *Providencia*, and many *Proteus* species use none of the carbohydrates and produce translucent colonies. *Citrobacter* colonies are yellow with black centers; many *Proteus* species are yellow or translucent with black centers; salmonellae are red with black centers. See Image Plate 6-3.

provide superior recovery and colony size in both air and CO_2 incubation to a comparator MacConkey agar.[355]

Deciding whether to use MacConkey or EMB agar is largely a matter of personal preference, because bacterial species that use lactose can be differentiated on both. MacConkey agar contains neutral red as the pH indicator and, as a result, lactose-metabolizing colonies appear pink from the production of mixed acids (see Image Plate 6-2A and B). Strong acid-producing bacteria, such as *E. coli*, form deep red colonies with a diffuse pink precipitate in the agar surrounding the colonies caused by precipitation of the bile salts in the medium that occurs at a low pH (see Image Plate 6-2A). Weaker acid-producing bacteria form light-pink colonies or colonies that are clear at the periphery and have pink centers, with the agar surrounding the colonies remaining clear (see Image Plate 6-1C). On EMB agar, strong acid-producing bacteria form colonies that have a metallic sheen (see Image Plate 6-2C and D). The appearance of the sheen, caused by precipitation of dye in the colonies, is highly suggestive of *E. coli*, although other strong acid producers, such as *Y. enterocolitica*, may have a similar appearance.

Highly Selective Isolation Media Used Primarily for Gastrointestinal Specimens

Media are made highly selective by the addition of a variety of inhibitors to their formulas, generally in higher concentrations than in MacConkey and EMB agars. These media are used primarily to inhibit the growth of *E. coli* and other "coliforms," but they allow *Salmonella* and *Shigella* species to grow out from stool specimens.

Several selective media formulated for use in clinical laboratories are discussed here. The most commonly used are SS agar, xylose lysine deoxycholate (XLD) agar, and HE agar. These are described in Table 6-2.

Deciding which of these selective media to use for the recovery of enteric pathogens from fecal specimens depends both on personal preference and on the species to be selected. In general, these media are used in the clinical laboratory for the recovery of *Salmonella* and *Shigella* species from diarrheal stool specimens, or in public health laboratories to investigate possible fecal contamination of food and water supplies. Virtually all species of *Salmonella* grow well in the presence of bile salts, which explains why the gallbladder often serves as one reservoir for human carriers. Bile

223

BOX 6-3

Chemicals and Compounds Used in Selective Media

Protein hydrolysates (e.g., peptones, meat infusion, tryptones, and casein): Proteins are cleaved by acids or enzymes into amino acids and peptides that can be used by bacteria to provide the carbon and nitrogen needed for bacterial metabolism.

Carbohydrates: A variety of disaccharides (e.g., lactose, sucrose, and maltose), hexoses (dextrose), and pentoses (xylose) are included in selective media for two purposes: (1) to provide a ready source of carbon for energy and (2) to serve as substrates in biochemical reactions for identification of unknown organisms.

Buffers: Balanced monosodium and disodium or potassium phosphates are most commonly used. Buffers provide (1) a stable pH for optimal growth of microorganisms and (2) a standard reference pH for those media in which acid or alkaline reactions are used to identify microorganisms.

Enrichments (e.g., blood, serum, vitamin supplements, and yeast extracts): Growth supplements are added to media to recover fastidious organisms. Enrichments are less commonly used for the recovery of the *Enterobacteriaceae* because most members of this group grow without them.

Inhibitors: Various compounds may serve to inhibit the growth of certain undesired bacterial species, thus making the medium selective: (1) aniline dyes (e.g., brilliant green and eosin), (2) heavy metals (e.g., bismuth), (3) chemicals (e.g., azide, citrate, deoxycholate, selenite, and phenylethyl alcohol), and (4) antimicrobial agents (e.g., neomycin, colistin, vancomycin, and chloramphenicol). Their relative

concentrations are important in determining the selectivity of the medium in which they are contained.

pH indicators: Fuchsin, methylene blue, neutral red, phenol red, and bromcresol purple are commonly used indicators in test media to measure pH shifts resulting from bacterial metabolism of given substrates.

Miscellaneous indicators: Other indicators may be included to detect specific bacterial products (e.g., ferric and ferrous ions for the detection of hydrogen sulfide).

Miscellaneous compounds and chemicals: Agar, a gelatinous extract of red seaweed, is commonly added to a medium, in varying concentrations, as a solidifying agent. Concentrations of 1% to 2% are used for plating media; concentrations of 0.05% to 0.3% are used for semisolid motility media; and trace amounts are added to anaerobic broth media to prevent convection currents and oxygen penetration. Sodium thiosulfate is commonly added to provide a source of sulfur.

salts are added to selective media because other species of enteric bacilli, including some of the more fastidious strains of *Shigella,* grow poorly or not at all. SS and HE agars contain relatively high concentrations of bile salts and are well adapted for recovering *Salmonella* species from specimens heavily contaminated with other coliform bacilli. However, because of its inhibitory effect on the recovery of certain strains of *Shigella* species, the routine use of SS agar as a single selective medium for isolation of enteric pathogens from stool specimens is not recommended.

XLD agar contains lactose, sucrose, and xylose[627]; thus, microorganisms that ferment these carbohydrates form yellow colonies (see Image Plate 6-3A). Bacteria incapable of fermenting these carbohydrates do not produce acids and form colorless colonies (see Image Plate 6-3B). Organisms that produce hydrogen sulfide form black pigment beginning in the center of the colonies (see Image Plate 6-3C). XLD agar also contains lysine. This is important because many species of *Salmonella* will ferment xylose and, therefore, will initially produce yellow colonies on XLD, but because these same species also decarboxylate lysine, the colonies will revert to pink after the small amount of xylose in the medium is used up. Lactose and sucrose, added in excess, prevent lysine-positive coliforms from similarly reverting. Because the decarboxylation of lysine results in the formation of strongly alkaline amines, a light-pink halo may appear around the colonies on XLD agar (see Image Plate 6-3C). Black colonies without a pink halo are more suggestive of a hydrogen sulfideproducing strain of *Proteus* species (see Image Plate 6-3D).

The carbohydrates in HE agar are lactose, sucrose, and salicin.[354] Microorganisms capable of fermenting these carbohydrates also form yellow colonies (see Image Plate 6-3E); asaccharolytic strains produce colonies that are translucent or light green (see

Image Plate 6-3F). Lactoseand sucrosenegative bacteria that acidify salicin may produce orange colonies. HE agar also contains ferric salts; thus hydrogen sulfide-producing colonies appear black.

Bismuth sulfite and brilliant green agars are highly selective media that are not commonly used in clinical laboratories. They are difficult to prepare, and their shelf life is very short (48 to 72 hours). These media are specifically designed to recover *Salmonella typhi* from fecal specimens and are particularly useful when screening numerous patients in endemic areas or during an epidemic. *Salmonella* species (*S. typhi* in particular) can be suspected on these media because of the propensity to produce colonies with a black sheen.

Enrichment Media

As the name indicates, an enrichment medium is used to enhance the growth of certain bacterial species and inhibit

224

the development of unwanted microorganisms. Enrichment media are most commonly used in clinical laboratories for the recovery of *Salmonella* and *Shigella* species from fecal specimens. Enrichment broths are particularly helpful in the recovery of organisms from the stools of *Salmonella* carriers or from patients with light *Shigella* infections in whom the number of organisms may be as low as 200 per gram of feces. (*E. coli* and other enteric bacilli may reach massive concentrations, as high as 10^9 per gram of feces.)

Enrichment media work on the principle that *E. coli* and other gram-negative organisms, which constitute the normal fecal flora, are maintained in a prolonged **lag** phase by the inhibitory chemicals in the broth. *Salmonella* and *Shigella* species are far less inhibited, enter into a log phase of growth, and are more readily recovered from fecal samples. However, after several hours, the enrichment media no longer suppress the growth of *E. coli* and other enteric organisms, which will ultimately overgrow the culture. Thus, for maximal recovery of *Salmonella* and *Shigella* species from fecal samples, it is recommended that the enrichment broth be subcultured within 8 hours.

The two most commonly used enrichment media are selenite broth and gram-negative broth. Selenite broth is more inhibitory to the growth of *E. coli* and other enteric gramnegative bacilli than is gram-negative broth. Thus, selenite broth is best adapted for the recovery of *Salmonella* or *Shigella* species from heavily contaminated specimens, such as feces or sewage. However, gram-negative broth is used with greater frequency in clinical laboratories because it is less inhibitory to the growth of many of the more fastidious strains of *Shigella* species. Enrichment of fecal specimens in gramnegative broth for 4 to 6 hours and then subculturing to HE or XLD

agar is the optimal technique for the recovery of *Shigella* species in suspected cases of bacillary dysentery. The formulas and salient characteristics of these two enrichment media are summarized in Table 6-3.

Guidelines for Choosing Selective Isolation Media

The media listed in Tables 6-1 through 6-3 and the several combinations in which they can be used may be somewhat confusing. The following is a guide for selecting media that may be optimal in the recovery of the *Enterobacteriaceae* from clinical specimens.

For specimens other than feces or rectal swabs, a combination of MacConkey or EMB agar and a blood agar is usually sufficient. Media with greater inhibitory properties are not routinely required because the concentration of commensal flora or contaminating organisms is relatively low in most nonenteric specimens. Subculturing to a more inhibitory medium can be done in instances in which it appears necessary.

For fecal specimens or rectal swabs, it is necessary to select only one medium from each of the groups listed in Tables 6-1 and 6-2. The approach outlined in Box 6-4 is suggested.

Differential Identification Characteristics

Although a preliminary identification of the *Enterobacteriaceae* is possible based on colony characteristics and biochemical reactions on primary isolation media, further species identification requires the determination of additional phenotypic characteristics that reflect the genetic code and unique identity of the organism being tested. It is the purpose of this discussion to review the salient features of the tests that measure these phenotypic characteristics and are commonly used in clinical laboratories. This orientation is necessary so that laboratory personnel can develop a fundamental understanding of the principles behind these procedures in order to recognize and correct any biochemical inconsistencies, problems with mixed cultures, or faulty techniques. It is not possible to discuss the variety of differential tests and numerous schemes available for the final species identification of the *Enterobacteriaceae*. However, several of the tests widely used in clinical laboratories to measure the metabolic characteristics by which all but a few rare or atypical species of the *Enterobacteriaceae* can be identified are listed in Box 6-5. Carbohydrate utilization and ONPG activity have been discussed previously.

TABLE 6-3 Enrichment Broths for Recovery of *Enterobacteriaceae*

Broth	Formulation		Purpose and Differential Ingredients	Reactions and Interpretation
Selenite broth	Peptone Lactose Sodium selenite Sodium phosphate Distilled water to Final pH, 7.0	5 g 4 g 4 g 10 g 1 L	Selenite F broth is recommended for the isolation of salmonellae from specimens—such as feces, urine, or sewage—that have heavy concentrations of mixed bacteria. Sodium selenite is inhibitory to *Escherichia coli* and other coliform bacilli, including many strains of *Shigella*. The medium functions best under anaerobic conditions, and a pour depth of at least 5 cm (2 in.) is recommended.	Within a few hours after inoculation with the specimen, the broth becomes cloudy. Because coliforms or other intestinal flora may overgrow the pathogens within a few hours, subculture to *Salmonella–Shigella* (SS) agar or bismuth sulfite is recommended within 8–12 hours. Overheating of the broth during preparation may produce a visible precipitate, making it unsatisfactory for use.
Gram-negative (GN) broth	Polypeptone peptone Glucose D-mannitol Sodium citrate Sodium deoxycholate Dipotassium phosphate Monopotassium phosphate Sodium chloride Distilled water to Final pH, 7.0	20 g 1 g 2 g 5 g 0.5 g 4 g 1.5 g 5 g 1 L	Because of the relatively low concentration of deoxycholate, GN broth is less inhibitory to *E. coli* and other coliforms. Most strains of *Shigella* grow well. The deoxycholate and citrate are inhibitory to gram-positive bacteria. The increased concentration of mannitol over glucose limits the growth of *Proteus* species, nonetheless encouraging growth of *Salmonella and Shigella* species, both of which are capable of fermenting mannitol.	GN broth is designed for the recovery of *Salmonella* and *Shigella* species when they are in small numbers in fecal specimens. The broth may become cloudy within 4–6 hours of inoculation, and subculture to HE agar or XLD agar within that time is recommended.

BOX 6-4

Selecting a Medium for Fecal Specimen or Rectal Swab

1. Inoculate the specimen directly to a MacConkey or EMB agar plate for primary isolation of all species of enteric gram-negative bacilli.
2. Directly inoculate either an XLD or an HE agar plate for the selective screening of *Salmonella* or *Shigella* species.
3. Enrich a small portion of the specimen by heavily inoculating either selenite or GN broth. If selenite is used, subculture to HE agar within 8 to 12 hours; if GN is used, subculture within 4 hours. *Note*: In the author's laboratory, this step is not routinely performed unless screening asymptomatic patients for presence of a carrier state.
4. Incubate all plate cultures at 35°C for 24 to 48 hours. Select suspicious colonies for definitive biochemical or serologic testing.

BOX 6-5

Tests Used to Measure

Metabolic Characteristics of *Enterobacteriaceae*

Carbohydrate utilization
o-Nitrophenyl-β-D-galactopyranoside (ONPG) activity
Indole production

Voges–Proskauer test (production of acetyl methyl carbinol [acetoin])
Citrate utilization
Urease production
Decarboxylation of lysine, ornithine, and arginine
Phenylalanine deaminase production
Hydrogen sulfide production
Motility

Indole Production

Indole is one of the degradation products from the metabolism of the amino acid tryptophan. Bacteria that possess the enzyme tryptophanase are capable of cleaving tryptophan, thereby producing indole, pyruvic acid, and ammonia. Indole can be detected in tryptophan test medium by observing the development of a red color after adding a solution containing *p*-dimethylaminobenzaldehyde (e.g., Ehrlich's or Kovac's reagent). The biochemistry and details of the indole test are schematically illustrated in Figure 6-5 and Chart 1-4, respectively. A color reproduction is shown in Image Plate 6-4C.

The choice between Ehrlich's and Kovac's reagents is one of personal preference. Ehrlich's reagent is more sensitive and is preferred when testing nonfermentative bacilli or anaerobes in which indole production is minimal. Because indole is soluble in organic compounds, xylene or chloroform should be added to the test medium before adding Ehrlich's reagent. This extraction step is less critical for Kovac's reagent because amyl alcohol is used for the diluent (ethyl alcohol is used with Ehrlich's reagent).

BACTERIA

■ **FIGURE 6-5** Formation of indole by tryptophanaseproducing bacteria growing on a culture medium containing tryptophan. Indole is one of the immediate degradation products (in addition to pyruvic acid and ammonia) resulting from the deamination of tryptophan. Indole can be extracted from the aqueous phase of the medium by chloroform and detected by the addition of Ehrlich's reagent (dimethylaminobenzaldehyde).

Methyl Red Test

A simplified schema showing only two alternative pathways (mixed acid and butylene glycol) for the metabolism of the pyruvate formed from the fermentation of glucose is shown in Figure 6-2. Bacteria that follow primarily the mixed acid fermentation route often produce sufficient acid to maintain a pH below 4.4 (the acid color breakpoint of the methyl red indicator). The methyl red test provides a valuable characteristic for identifying bacterial species that produce strong acids from glucose.

The details of the methyl red test are shown in Chart 6-3. The test, as originally described, requires 48 to 72 hours of incubation before a valid result can be obtained, an amount of time unacceptable to most clinical microbiology laboratories. Barry and coworkers[38] have described a modification that can be read in 18 to 24 hours. A 0.5-mL aliquot of broth is used with a relatively heavy inoculum of the test organism. One or two drops of methyl red reagent are added after 18 to 24 hours of incubation at 35°C, and the development of red color indicates a positive test (see Image Plate 6-4C). The Barry modification is as accurate as the test originally described and saves a significant amount of time.

Voges–Proskauer Test

The details of the VP test, shown in Chart 6-4, are based on the conversion of acetyl methyl carbinol (acetoin) to diacetyl through the action of potassium hydroxide and atmospheric oxygen. Diacetyl is converted into a red complex under the catalytic action of α-naphthol and creatine (see Image Plate 6-4D).

Note, in Figure 6-2, that the formation of acetoin and butylene glycol is an alternative pathway for the metabolism of pyruvic acid. Bacteria that use this pathway, such as certain strains within the *Klebsiella–Enterobacter–Serratia–Hafnia* group, produce only small quantities of mixed acids that may be insufficient to lower the pH of the methyl red medium enough to produce a color change. Consequently, most species of the *Enterobacteriaceae* that are VP-positive, with rare exceptions, are methyl red-negative and vice versa (see Image Plate 6-4C and D).

Citrate Utilization

The principle of the citrate-utilization test (Chart 6-5) is to determine the ability of an organism to use sodium citrate as the sole source of carbon for metabolism and growth. The original formula, described by Koser[365] in 1923, was a broth medium containing sodium ammonium phosphate, monopotassium phosphate, magnesium sulfate, and sodium citrate. Proteins and carbohydrates were omitted as carbon and nitrogen sources. The end point of the Koser test was either the presence or lack of visible turbidity after incubation of the test organism: this end point was actually a measure of the organism's ability to use carbon from sodium citrate to produce sufficient growth to become visible. It was soon recognized, however, that nonspecific turbidity could occur in Koser's medium. Simmons[597] resolved this problem by adding agar and bromthymol blue to the Koser formula, which provided a more sensitive color end point. Simmon's citrate agar medium is poured into a test tube and slanted. A light inoculum from a colony of growth of the test organism is streaked onto the surface of the agar slant. If the inoculum is too heavy, preformed organic compounds within the cell walls of dying bacteria may release sufficient carbon and nitrogen to produce a false-positive test result. When inoculating a series of tubes of differential culture media with an unknown organism, it is important that the citrate medium be streaked first to prevent carryover of proteins or carbohydrates from the other media.

The production of a blue color in the test medium after 24 hours of incubation at 35°C indicates the presence of alkaline products and a positive citrate-utilization test result (see Image Plate 6-4D). If carbon is used from sodium citrate, nitrogen is also extracted from the ammonium phosphate contained in the medium, releasing ammonia. Occasionally, visible growth is detected along the streak line before conversion of the medium to a blue color. This visible growth also indicates a positive test result. Malonate, acetate, and mucate are other anionic radicals commonly used to determine the ability of bacteria to use these simple compounds as a sole source of carbon.

The acronym IMViC (indole, methyl red, VP, and citrate) was once used by sanitarians and epidemiologists to refer to the tests needed to detect fecal contamination of food and water. Public health officials have used *E. coli* for many years to indicate fecal contamination. *Enterobacter aerogenes* produces colonies on primary isolation media that often cannot be distinguished from *E. coli*. However, the recovery of *E. aerogenes* from food and potable water does not necessarily signify fecal contamination because the organism is widespread in soil, grasses, and vegetative matter. Therefore, a set of biochemical characteristics was needed to differentiate the two organisms. The IMViC tests were adopted to serve this purpose. Most strains of *E. coli* are indoleand methyl red-positive, with VP and citrate being negative. *E. aerogenes* typically produces exactly opposite reactions (see Image Plates 6-4C and D). Although the individual characteristics included in the IMViC battery are still used

in bacterial identification systems, they are used only infrequently as a specific test set.

In view of the complexity of differentiating over 100 species of *Enterobacteriaceae* presented in the next section, it is interesting that there was a time when the major decisions in microbiology were relatively simple and could be made on the basis of only four easy-to-perform biochemical tests.

Urease Production

Microorganisms that possess the enzyme urease hydrolyze urea, releasing ammonia and producing a pink–red color change in the medium (see Image Plate 6-4E). The details of the urease test are shown in Chart 6-6.

Important differences between Stuart's urea broth and Christensen's urea agar should be noted. Stuart's broth is heavily buffered with phosphate salts at a pH of 6.8. Relatively large quantities of ammonia must be formed by the test organism before the buffer system is overcome and the medium's pH is elevated above 8.0 to produce a color change in the indicator. Stuart's broth, therefore, is virtually selective for *Proteus* species.

Christensen's urea agar[142] is less buffered than Stuart's urea broth and contains peptones and glucose. This enriched

medium supports the growth of many species of bacteria that cannot grow in Stuart's broth, and the decreased buffer capacity permits the detection of smaller amounts of ammonia. Organisms that produce less urease, such as certain species of *Klebsiella, Enterobacter, Brucella*, and *Bordetella bronchiseptica*, can be tested with Christensen's urea agar. For many of these species, a positive urease reaction is first detected by a pink-to-red color change in the slant portion of the agar (see Image Plate 6-4E). The slant initially turns red because the alkaline reaction, resulting from the splitting of small quantities of urea, is augmented by the amines formed from the oxidative decarboxylation of the amino acids in the airexposed portion of the medium.

Decarboxylation of Lysine, Ornithine, and Arginine

Many species of bacteria possess enzymes capable of decarboxylating specific amino acids in the test medium. The decarboxylase enzymes remove a molecule of CO_2 from an amino acid to form alkaline-reacting amines. The following are the amino acids most commonly tested and their amine degradation products:

Lysine → cadaverine

Ornithine → putrescine

Arginine → citrulline

A number of test systems have been described to measure this property, based on either detection of an alkaline pH shift in the test medium or direct measurement of the reaction products. For example, the amines resulting from the decarboxylation reaction can be detected with Ninhydrin reagent after extraction from the broth culture with chloroform. This is the relatively sensitive Carlquist reaction,[89] most commonly used for detecting the weak decarboxylase activity of many of the nonfermentative gram-negative bacilli and certain species of anaerobic bacteria.

The decarboxylase activity of the *Enterobacteriaceae* is most commonly measured in clinical microbiology laboratories with Møller decarboxylase broth.[443] The details of this test are shown in Chart 6-7. The end point of the reaction is the production of an alkaline pH shift in the medium and the development of a blue–purple color after incubation with the test organism (see Image Plate 6-4F). Note, in the Møller formula, included in Chart 6-7, that the medium is buffered at pH 6.0. This is more acidic than most culture media. This low pH is necessary because the decarboxylase enzymes are not optimally active until the pH of the medium drops below 5.5. The drop from 6.0 to 5.5 results from the growing bacteria that metabolize the small amount of glucose in the medium to produce mixed acids. A control tube, devoid of amino acid, must always be included when performing the decarboxylase test to ensure that this initial drop in pH has occurred. A yellow color change in the bromcresol purple indicator of the control tube shows acidification. Pyridoxal phosphate is included in the medium and acts as a coenzyme to further enhance the decarboxylase activity.

Many microbiologists prefer Falkow lysine broth[217] over the Møller medium because the Falkow test depends on only an alkaline shift in pH indicator, and neither an anaerobic nor an acid environment is required. However, this medium cannot be used to detect lysine decarboxylase activity in certain members of the *Klebsiella–Enterobacter–Serratia–Hafnia* group. They produce acetyl methyl carbinol, which interferes with the final alkaline pH shift, leading to false-negative interpretations. Modifications in this medium form the basis of the motility indole ornithine (MIO)[199] semisolid agar used in clinical microbiology laboratories. Rapid methods for detecting ornithine[226] and lysine[76] decarboxylase activity in members of the *Enterobacteriaceae* have also been described.

Edwards and Fife[201] described a solid lysine decarboxylase medium based on the Falkow formula, which includes ferric ammonium citrate and thiosulfate for the detection of hydrogen sulfide. This medium is lysine iron agar (LIA), used in many laboratories as an aid in the identification of *Salmonella* species, most of which are both hydrogen sulfidepositive and lysine decarboxylase-positive. A black deep and a purple slant with LIA are virtually indicative of *Salmonella* species. Another advantage of LIA is that *Proteus* and *Providencia* species, both of which deaminate, rather than

decarboxylate, amino acids, can be detected by the development of a red color in the slant of the tube (see Image Plate 6-4G).

The lysine decarboxylase test is useful in differentiating lactose-negative *Citrobacter* species (0% positive) from *Salmonella* species (98% positive). Almost all strains of *S. sonnei* (more than 98%) possess ornithine decarboxylase activity, whereas only a few strains of *S. boydii* (2.5%) show such activity; *S. dysenteriae* and *S. flexneri* are ornithine-negative. The ornithine decarboxylase test is perhaps most useful in differentiating *Klebsiella* species (most species are negative) from *Enterobacter* species (most strains are positive).

Phenylalanine Deaminase Production

The phenylalanine deaminase determination is useful in the initial differentiation of *Proteus, Morganella*, and *Providencia* species from other gram-negative bacilli. Only members of these genera, and a few relatively rare isolates of the *Enterobacter* group, possess the enzyme responsible for the oxidative deamination of phenylalanine. The test is easily performed, as outlined in Chart 6-8. Phenylpyruvic acid may be detected in as little as 4 hours if a heavy inoculum is used; however, 18 to 24 hours of incubation are generally recommended. The phenylalanine test medium uses yeast extract as the source for carbon and nitrogen. Meat extracts or protein hydrolysates contain varying amounts of naturally occurring phenylalanine that can lead to inconsistent results. The development of a green color after addition of the ferric chloride reagent is immediate and easy to visualize (see Image Plate 6-4E).

Hydrogen Sulfide Production

The ability of certain bacterial species to liberate sulfur from sulfur-containing amino acids or other compounds in the form of H_2S is an important characteristic for their identification. The media most commonly used for the detection of H_2S and the sources for sulfur and the sulfide indicators are listed in Table 6-4. The sequence of steps leading to the production and detection of H_2S in a test system is outlined in Box 6-6.

228

TABLE 6-4 Media for the Detection of Hydrogen Sulfide (H_2S)

Media	Sulfur Source	H_2S Indicator
Bismuth sulfite	Peptones plus sulfite	Ferrous sulfate

Citrate sulfide agar	Sodium thiosulfate	Ferric ammonium citrate
Deoxycholate citrate agar	Peptones	Ferric citrate
Lysine iron agar	Sodium thiosulfate	Ferric ammonium citrate
Kligler's iron agar	Sodium thiosulfate	Ferrous sulfate
Triple sugar iron agar	Sodium thiosulfate	Ferrous sulfate
Lead acetate agar	Sodium thiosulfate	Lead acetate
Salmonella–Shigella agar	Sodium thiosulfate	Ferric citrate
Sulfide–indole–motility medium	Sodium thiosulfate	Peptonized iron
Xylose–lysine–deoxycholate or Hektoen enteric	Sodium thiosulfate	Ferric ammonium citrate

The differences in detecting H_2S production in the different media result from alteration in one or more of these conditions. H_2S detected in one medium may not be detected in another, and it is necessary to know the test system used when interpreting identification charts. SIM medium is more sensitive than KIA for the detection of H_2S, presumably because of KIA's semisolid consistency, lack of carbohydrates to suppress H_2S formation, and use of peptonized iron as the indicator (see Image Plate 6-4B). KIA, on the other hand, is more sensitive than TSI agar because sucrose is believed to suppress the enzyme mechanisms responsible for H_2S production. Lead acetate is the most sensitive indicator and should be used whenever bacteria that produce only trace amounts of H_2S are tested. Unfortunately, lead acetate, when incorporated in culture media, also inhibits the growth of many fastidious bacteria, specifically the ones that may require a sensitive detection system. These organisms can be tested for production of H_2S by draping a lead acetate-impregnated filter paper strip under the cap of a culture tube of KIA medium. In this way, the extreme sensitivity of the lead acetate indicator can be used without incorporating it directly into the medium.

With all H_2S detection systems, the end point is an insoluble, heavy metal sulfide, which produces a black precipitate in the medium or on the filter paper strip. Because hydrogen ions must be available for H_2S formation, the blackening is first seen in test media in which acid formation is maximal, that is, along the inoculation line, within the

deeps of slanted agar media, or in the centers of colonies growing on agar surfaces.

BOX 6-6

How H_2S Is Produced

1. Release of sulfide from cysteine or thiosulfate by bacterial enzymatic action
2. Coupling of sulfide (S^{2-}) with a hydrogen ion (H^1) to form H_2S
3. Detection of H_2S by iron, bismuth, or lead to produce insoluble, heavy metal sulfides that appear as a black precipitate

Motility

Bacterial motility is another important determinant in making a final species identification. Bacteria move by means of flagella, the number and location of which vary among the different species. Flagellar stains are available for this determination (see Chapter 7).

Bacterial motility can be observed directly by placing a drop of culture broth medium on a microscope slide, adding a coverslip and viewing it under a microscope using a high-dry objective (40×). This technique is used primarily for detecting the motility of bacteria species that do not grow well in semisolid agar media. However, *Enterobacteriaceae* do grow well, and tubes containing semisolid agar are most commonly used.

Motility media have agar concentrations of 0.4% or less. At higher concentrations, the gel is too firm to allow the organisms to spread freely. Combination media, such as SIM medium[404] or MIO agar[199] have found wide use in clinical microbiology laboratories because more than one characteristic can be measured in the same tube. The motility test must be interpreted first because the addition of an indole reagent may obscure the results. Because SIM medium and MIO agar have a slightly turbid background, interpretations may be somewhat difficult with bacterial species that grow slowly in these media. In these cases, a motility test medium (Box 6-7) is recommended because it supports the growth of most fastidious bacteria and has a crystal-clear appearance.

229

BOX 6-7

Motility Test Medium (Edwards and Ewing)

Beef extract, 3 g
Peptone, 10 g
Sodium chloride, 5 g
Agar, 4 g
Distilled water to equal 1 L
Final pH, 7.3

The motility test is interpreted by making a macroscopic examination of the medium for a diffuse zone of growth flaring out from the line of inoculation (see Image Plate 6-4H). The use of tetrazolium salts in motility medium has been advocated as an aid in the visual detection of bacterial growth. Tetrazolium salts are colorless but are converted into insoluble red formazan complexes by the reducing properties of growing bacteria. In a motility test medium containing tetrazolium, the development of this red color helps trace the spread of bacteria from the inoculation line. However, these salts may inhibit certain fastidious bacteria and cannot be

Taxonomy of the *Enterobacteriaceae*

The application of new technologies to study the taxonomy of microorganisms has led to a rapid increase in the number of genera and species of bacteria that fit the general criteria for *Enterobacteriaceae*. In 1972, Edwards and Ewing[200] described 11 genera and 26 species belonging to the *Enterobacteriaceae*. In 1985, Farmer and associates[220] described 22 genera comprising 69 species and 29 enteric groups. In this chapter, 37 genera and 148 species, biogroups, and unnamed enteric groups of *Enterobacteriaceae* are described.

Classification of Enterobacteriaceae by Tribes

The division of the *Enterobacteriaceae* into tribes is not used in the current edition of *Bergey's Manual* or in the Centers for Disease Control and Prevention (CDC) classification because the authors believe that the use of tribes is of no diagnostic significance and of questionable taxonomic significance. This argument has validity from the perspective of pure classification. Yet, for the users of this book who are new to the field of microbiology and who must orient themselves to the complex and confusing *Enterobacteriaceae*, the tribe concept proposed by Ewing[212] has certain

teaching and learning advantages. We agree with Ewing that his scheme, although imperfect, represents a good compromise between practical and ideal taxonomies.

The tribe concept provides both students and practitioners with a convenient method of grouping together the major genera within the family that share similar biochemical reactions and are of similar diagnostic importance. We believe it is important that practicing microbiologists maintain a base of knowledge that is firmly grounded in the morphology, physiology, and biochemistry of medically important bacteria. Furthermore, certain phenotypic patterns that allow easy subgrouping and clustering of related species must be committed to memory. This orientation is especially important if microbiologists use semiautomated and automated commercial systems with computer-assisted identification, because it serves as a quality control to validate instrument-generated information. The use of the tribe concept as an approach to learning the *Enterobacteriaceae* serves these goals well, and is the approach chosen for use in this textbook for teaching the key features of the established genera of the *Enterobacteriaceae*. The current species included in the established genera, sorted by tribes, are listed in Table 6-5.

Key Identification Characteristics for the Most Common Species

Table 6-6 shows the key identification characteristics used in separating the established genera of the *Enterobacteriaceae* into seven tribes. Students should study this table and learn to categorize an unknown isolate into one of these tribes on the basis of reactions seen with these key tests. The following observations are made to assist students in identifying the most common species.

The members of the *Escherichieae* have the following key reactions: indole-positive, methyl red-positive, VP-negative, citrate-negative (the classic example of mixed acid fermenters). They are negative for all the other key biochemical tests: hydrogen sulfide, phenylalanine deaminase, and urea. Note from Table 6-6 that *Shigella* species are similar to *Escherichia* species except that they are negative for CO_2 gas and motility.

The *Edwardsielleae* are similar to *Escherichieae* except for the property of being hydrogen sulfide-positive. Students may wish to think of *Edwardsiella tarda* as hydrogen sulfidepositive *E. coli*. *Salmonelleae* resemble *Edwardsielleae* except that they are indole-negative and citrate-positive. *Citrobacter freundii* is similar to *Salmonella* except for being lysinenegative. *C. koseri* differs from *C. freundii* by being hydrogen sulfide-negative and indole-positive.

The *Klebsielleae* are composed of the VP-positive members of the *Enterobacteriaceae.* As shown in Table 6-6 and illustrated in Figure 6-2, most members of this tribe produce copious amounts of CO_2, so much so that the deep portion of KIA and TSI slants is often pushed halfway up the tube. Notice that the *Klebsiella* species are nonmotile and that *Pantoea* is triple-decarboxylase-negative

(lysine-negative, arginine-negative, and ornithine-negative).

The *Proteeae* are separated from all others by virtue of being phenylalanine deaminase-positive, a feature unique to this tribe. The urea reaction for the species in the genus *Proteus* and *Morganella* as well as one of the *Providencia* species (*P. rettgeri*) is strongly positive. Both species of *Proteus* listed in Table 6-6 are hydrogen sulfide-positive and exhibit swarming motility.

The *Yersinieae* represented here by the most commonly isolated species, *Y. enterocolitica*, are very similar to members

230

TABLE 6-5 Important Recent Changes in the Established Genera of the *Enterobacteriaceae*

New Designation	Previous Designation	Comments
Tribe I: *Escherichieae*		
Escherichia coli		Sorbitol (+) except for serotype 0157:H7. All other species are sorbitol (−).
Escherichia coli inactive	Alkalescens-Dispar	Anaerogenic, lactose-negative (or delayed), and nonmotile.
Escherichia albertii	New species	Associated with diarrheal disease in Bangladeshi children. Indole-negative, ferments D-mannitol but not D-xylose. Separated from *H. alvei* by negative VP test.
Escherichia fergusonii	Enteric Group 10	Found in blood, urine, and feces. Indole (+), Sorbitol (−), LAO (+, −, +), lactose (−) but ONPG (+).
Escherichia hermannii	Enteric Group 11	Wounds and feces most common sources. Yellow pigmented, indole (+), sorbitol (−), LAO (−, −, +).
Escherichia vulneris	Enteric Group 1 API group 2 Alma group 1	Most strains from human wounds. Over half the strains are yellow pigmented.
Shigella		The four species of *Shigella* and *E. coli* form a single species on the basis of DNA hybridization. *S. dysenteriae* (Group A), *S. flexneri* (Group B), and *S. boydii* (Group C) are biochemically similar and must be separated by serologic methods. *S. sonnei* is ornithine (+).
Tribe II: *Edwardsielleae*		
Edwardsiella tarda	*Edwardsiella anguillimortifera* Asakusa Group	Produce indole and abundant H_2S, ferment glucose and maltose but not mannitol, lactose, sucrose, or arabinose. Found in cold-blooded animals. Opportunistic human pathogen. May cause wound infections and diarrhea.
Edwardsiella tarda biogroup 1		Indole (+), H_2S (−), mannitol, sucrose, and arabinose positive. Found in snakes, not a human clinical isolate.
Edwardsiella hoshinae		Indole (−), H2S (−), isolated from birds, reptiles, and water. Several isolates from human feces.
Edwarsiella ictaluri		No human isolates, causes enteric septicemia in catfish.
Tribe III: *Salmonelleae*		
Salmonella	*S. cholerae-suis* *S. typhi* *S. enteritidis*	All subgroups (subgenera) of *Salmonella* and *Arizona* are considered to belong to the same species. Organisms are now reported by genus and serotype, omitting reference to species.
Tribe IV: Citrobactereae		
Citrobacter amalonaticus	*Levinea amalonaticus*	H_2S (−), indole (+), adonitol (−), malonate (−). Primarily found in human feces, very rarely isolated from blood.
Citrobacter braakii	*Citrobacter* genomospecies 6	H_2S and indole are variable, adonitol (−), malonate (−). Isolated from human stools, urine, wounds, and from animals and food.
Citrobacter farmeri	Citrobacter amalonaticus biogroup 1	Found primarily in human feces. Stains of biogroup 1 ferment sucrose, raffinose, alpha-methyl-D-glucoside, and melibiose and are citrate (−). *C. amalonaticus* usually have the opposite reactions.
Citrobacter freundii		H_2S (+), indole (−), adonitol (−), malonate (−). Found in urine, throat, sputum, blood, and wounds.
Citrobacter gillenii	*Citrobacter* genomonspecies 10	H_2S is variable, indole (−), adonitol (−), malonate (+). Found in human stool and food.
Citrobacter koseri	*Levinea malonatica* *Citrobacter diversus*	H_2S (−), indole (+), adonitol (+), malonate (+). Found in urine, throat, nose, sputum, and wounds. Rare cause of neonatal meningitis.
Citrobacter murliniae	*Citrobacter* genomospecies 11	H_2S is variable, indole (+), adonitol (−), malonate (−). Found in human stools and blood.
Citrobacter rodentium	*Citrobacter* genomospecies 9	H_2S (−), indole (−), adonitol (−), malonate (+). This organism has been isolated only from rodents.

Citrobacter sedlakii	*Citrobacter* genomonspecies 8	H_2S (−), indole (+), adonitol (−), malonate (+). Found in human stools, blood, and wounds.
Citrobacter werkmanii	*Citrobacter* genomospecies 7	H_2S (+), indole (−), adonitol (−), malonate (+). Found in human stools and urine and from food.
Citrobacter youngae	*Citrobacter* genomonspecies 5	H_2S and indole are variable, adonitol (−), malonate (−). Isolated from human stools and blood and from animals and food.
Tribe V: Klebsielleae		
Klebsiella granulomatis	*Calymmatobacterium granulomatis*	Cannot be cultured on conventional culture media. Causative agent of granuloma inguinale.
Klebsiella pneumoniae subsp. *ozaenae*	*Klebsiella ozaenae*	Biochemically inactive strain of *K. pneumoniae*. Causes atrophic rhinitis, a condition called ozena.
Klebsiella pneumoniae subsp. *rhinoscleromatis*	Klebsiella rhinoscleromatis	Biochemically inactive strain of *K. pneumoniae*. Causes a granulomatous disease known as rhinoscleroma.
Klebsiella alba	New species	Plant and soil isolates
Klebsiella singaporensis	New species	Plant and soil isolates
Klebsiella variicola	New species	Plant and soil isolates
Raoultella ornithinolytica	*Klebsiella* Group 47 *Klebsiella ornithinolytica*	MIO (−, +, +). Isolated from blood, urine, sputum, and wounds.
Raoultella planticola	*Klebsiella* Species 2 *Klebsiella trevisanii Klebsiella planticola*	Water and plant isolates. Rare human clinical isolates. May be difficult to separate from ornithine-negative strains of *R. ornithinolytica*.
Raoultella terrigena	*Klebsiella terrigena*	Soil and water isolates
Cronobacter sakazakii	Yellow-pigmented *Enterobacter cloacae* *Enterobacter sakazakii*	LAO (−, +, +). Bright yellow pigment at 35°C. May cause meningitis, brain abscesses, and bacteremia in neonates.
"*Enterobacter agglomerans* complex"	*Erwinia herbicola* *Erwinia milletiae*	Heterogeneous group of organisms representing over 13 DNA hybridization groups (HG). HG XIII has been transferred to the new genus Pantoea as *Pantoea agglomerans*. Organisms that are LAO negative (referred to as "triple decarboxylase negative") and are yellow pigmented were usually identified as *E. agglomerans* in the past.
Enterobacter asburiae	Enteric Group 17 atypical *Citrobacter*	Biochemically similar to *E. cloacae*. Nonmotile, VP (−), (79% + after 2 days), urea (+) (delayed). Isolated from variety of human sources: blood, urine, wounds, respiratory tract, feces.
Enterobacter aerogenes		LAO (+, −, +). Common clinical isolate.
Enterobacter cancerogenus	*Erwinia cancerogena* *Enterobacter taylorae* Enteric Group 19	Includes organisms formerly classified as *E. taylorae*. LAO (−, +, +), adonitol, inositol, sorbitol, raffinose, and melibiose all negative. Isolated from a variety of clinical sources including blood and spinal fluid. Majority of strains isolated from clinical specimens.
Enterobacter cloacae subsp. *cloacae*	*Enterobacter cloacae*	LAO (−, +, +). Common clinical isolate.
Enterobacter cloacae subsp. *dissolvens*	Enterobacter dissolvens Erwinia dissolvens	Separation of these subspecies by phenotypic testing is challenging, and separation using MALDI-TOF is not yet possible. Laboratories should report as "*E. cloacae* complex."
Enterobacter hormaechei	Enteric Group 75	LAO (−, +, +). Biochemically closest to *E. cancerogenus* except is urea (+), sucrose (+), and esculin (−). Isolates reported from blood, wounds, and sputum.
Enterobacter kobei	Enteric Group 69 Japanese NIH Group 21	Closely related to *E. cloacae*. Majority isolated from clinical specimens.
Kosakonia cowanii	Japanese NIH Group 42 *Enterobacter cowanii*	LAO (−, −, −): phenotypically resemble *P. agglomerans*

Lelliottia nimipressuralis	*Erwinia nimipressuralis* *Enterobacter nimipressuralis*	Closely related to *E. cloacae*. Not found in human clinical specimens.
Pluralibacter gergoviae	atypical *Enterobacter aerogenes* *Enterobacter gergoviae*	LAO (+, −, +). Strong urease (+). Found in environment and urine and respiratory tract of humans. Rare isolates have been recovered from blood.
Pluralibacter pyrinus	*Erwinia pirina* *Enterobacter pyrinus*	Urease (+), most closely resembling *P. gergoviae*, is differentiated by its growth in KCN broth, acid production from myoinositol, and lack of acid production from raffinose. Causes brown leaf spot disease of pear trees.
Hafnia alvei	*Enterobacter hafniae*	Lactose (−), LAO (+, −, +), grows at 35°C but biochemically more active at 25°C. Found in clinical specimens, especially feces, occasionally from blood, sputum, urine, and wounds.
Hafnia alvei biogroup 1	"*Hafnia protea*" *Obesumbacterium proteus* biogroup 1	Not a human clinical isolate. Occurs in breweries, where it grows in beer wort.
Pantoea agglomerans	*Enterobacter agglomerans* HG XIII *Erwinia herbicola* *Erwinia milletiae*	LAO (−, −, −) some may be yellow pigmented. Isolated from plant surfaces, seeds, and water, as well as from humans (wound, blood, urine, internal organs) and animals.
Pantoea ananatis	*Pantoea ananas* *Enterobacter agglomerans* HG VI *Erwinia ananas* *Erwinia uredovora*	Plant pathogen, causes pineapple rot
Pantoea citrea	New species	Isolated from Mandarin oranges in Japan
Pantoea dispersa	*Enterobacter agglomerans* HG III	Isolated from plant surfaces, seeds, humans, and the environment. Separated from *P. agglomerans* by negative salicin reaction.
Pantoea punctata	New species	Isolated from Mandarin oranges in Japan
Pantoea stewartii subsp. *indologenes*	*Erwinia stewartii*	Cause of leaf spot on foxtail millet and pearl millet
Pantoea stewartii subsp. *stewartii*	*Erwinia stewartii*	Causative agent of Stewart's bacterial wilt of corn
Pantoea terrea	New species	Isolated from soil in Japan
Serratia entomophila		Resembles *S. marcescens* (arabinose −). Insect pathogen, no human isolates reported.
Serratia ficaria		Natural habitat is figs and fig wasps. Has been very rarely reported from human clinical specimens.
"*Serratia*" *fonticola*		Not really a species of *Serratia*. A water organism, rarely isolated from human specimens, mostly wounds.
Serratia grimesii	see *Serratia liquefaciens* group	Isolated from environment and human clinical specimens. Cannot be differentiated from other members of "*S. liquefaciens* group" by commonly used tests.
"*Serratia liquefaciens* group"	*Enterobacter liquefaciens*, Different biogroups within the species *S. liquefaciens*	Consists of several DNA hybridization groups including species now named *Serratia proteamaculans*, and *S. grimesii*. Cannot be separated by currently utilized biochemical tests. Differ from *S. marcescens* by being L-arabinose (+). Report as "*S. liquefaciens* group."
Serratia marcescens		DNase (+), gelatin (+), L-arabinose (−) (other species are positive). Common clinical isolate. Red pigment produced by some strains.
Serratia odorifera biogroup 1 *Serratia odorifera* biogroup 2		Dirty, musty odor like potatoes. Two biogroups. Biogroup 1 is ornithine, sucrose, and raffinose positive, and is predominantly isolated from sputum. Biogroup 2 is negative for these three reactions and has been recovered from blood and CSF.
Serratia plymuthica	*Bacterium plymuthica*	May have red pigment. Isolated from soil, water, sputum. Extremely rare in clinical specimens.

Serratia proteamaculans subsp. *proteamaculans*	see *Serratia liquefaciens* group	Cannot be separated from other members of "*S. liquefaciens* group" by currently utilized biochemical tests. Differ from *S. marcescens* by being L-arabinose (+).
Serratia quinivorans	*Serratia proteamaculans* subsp. *quinovora* see *Serratia liquefaciens* group	Isolated from plants, wild rodents, insects, and water, but not yet from human clinical specimens.
Serratia rubidaea		Red pigment produced. Rarely isolated in humans.
Tribe VI: *Proteeae*		
Proteus hauseri	*Proteus vulgaris* biogroup 3, DNA group 3	H_2S (+), indole (+), salicin and esculin are (−).
Proteus mirabilis		H_2S (+), indole (−), ornithine (+). Common clinical isolate.
Proteus myxofaciens		No human isolates reported. Isolated only from living and dead gypsy moths.
Proteus penneri	*Proteus vulgaris* biogroup 1	Closely related to *P. vulgaris*, except that indole (−), salicin (−), esculin (−), and chloramphenicol resistant.
Proteus vulgaris	*Proteus vulgaris* biogroup 2	H_2S (+), indole (+), ornithine (−) Common clinical isolate. Indole, salicin, and esculin are positive.
Proteus vulgaris biogroup 3		Consists of four separate genetic species and are designated DNA groups 3, 4, 5, and 6. Indole (+), but salicin and esculin are (−). DNA group 3 has recently been named *Proteus hauseri*.
Morganella morganii subsp. *morganii*	*Proteus morganii*	H_2S (−), lysine, ornithine and motility all variable, trehalose (−). Causes urinary tract infections and is cultured from many other body sites. Contains four biogroups designated A through D.
Morganella morganii subsp. *sibonii*	*Morganella morganii* biogroup 1	H_2S (−), lysine, ornithine variable, trehalose and motility (+). Contains three biogroups designated E through G.
Morganella morganii subsp. 3		
Providencia alcalifaciens	*Providencia alcalifaciens* biogroup 1,2	Urea (−), adonitol (+), inositol (−). Generally isolated from diarrheic stools, particularly children.
Providencia heimbachae		Not a human clinical isolate. Found in penguin feces and an aborted cow fetus.
Providencia rettgeri	*Proteus rettgeri*	Urea (+), adonitol (+), inositol (+). Mostly isolated from urine of hospitalized and catheterized specimens.
Providencia rustigianii	*Providencia alcalifaciens* biogroup 3, *Providencia friedericiana*	Urea (−), adonitol (−), inositol (−). Rarely found in clinical specimens, mostly from human feces.
Providencia stuartii	*Providencia alcalifaciens* biogroup 4	Urea (v), adonitol (−), inositol (+). Isolated most often from urine, less often from wounds, burns, and bacteremias. May cause nosocomial outbreaks.
Tribe VII: *Yersinieae*		
Yersinia aldovae	*Yersinia enterocolitica*-like Group X2	Biochemically similar to *Y. enterocolitica*. Isolated from surface water, drinking water, and fish
Yersinia bercovieri	*Yersinia enterocolitica* biogroup 3B	Biochemically similar to *Y. enterocolitica*. Isolated from human feces, water, soil, and raw vegetables.
Yersinia enterocolitica		May cause diarrhea, terminal ileitis, mesenteric lymphadenitis, arthritis, and septicemia in humans.
Yersinia frederiksenii	Biogroup of *Y. enterocolitica*	Mainly found in water, sewage, and fish. Occasionally found in human feces, blood, and sputum. Rarely associated with gastrointestinal illness.
Yersinia intermedia	Biogroup of *Y. enterocolitica*	Found in fresh water, sewage, and aquatic animals. Human isolates have been from stool, blood, wounds, and urine. Probably not a cause of gastrointestinal illness.
Yersinia kristensenii	Biogroup of *Y. enterocolitica*	Found in water, soil, and animals. Human isolates have been from stool, blood, and urine. No evidence that it can cause gastrointestinal illness.

Yersinia mollaretii	*Yersinia enterocolitica* biogroup 3A	Biochemically similar to *Y. enterocolitica*. Isolated from human feces, drinking water, meat, and raw vegetables.
Yersinia pestis	*Pasteurella pestis* *Yersinia pseudotuberculosis* subsp. *pestis*	Causative agent of plague.
Yersinia pseudotuberculosis		May cause mesenteric lymphadenitis, diarrhea, and septicemia in humans.
Yersinia rohdei		Biochemically similar to *Y. enterocolitica*. Isolated from dog feces, water, and human feces.
"Yersinia" ruckeri	"Red mouth bacterium"	Will probably be moved to a new genus. Fish pathogen. Human isolates are extremely rare.

IMViC, indole, methyl red, Voges–Proskauer, citrate; LAO, lysine, arginine, ornithine; MIO, motility, indole, ornithine; PAD, phenylalanine deaminase; HG, hybridization group; (+), >90% of strains positive; (−), >90% of strains negative; (v), variable.

TABLE 6-6 Key Identification Characteristics for the Most Common *Enterobacteriaceae*

[a]Swarming motility demonstrated on noninhibitory media.
[b]Nonmotile at 36°C, motile at 22°C.
KIA, Kligler's iron agar; H_2S, hydrogen sulfide; MR, methyl red; VP, Voges–Proskauer; IND, indole; CIT, citrate; PAD, phenylalanine deaminase; URE, urease; MOT, motility; LYS, lysine; ARG, arginine; ORN, ornithine; ONPG, o-nitrophenyl-β-D-galactopyranoside; ++, strong positive reaction; +, 90% or more strains positive; −, 90% or more strains negative; +/−, 50% to 90% of strains positive; −/+, 50% to 90% of strains negative; shaded areas indicate key reactions; A/A, acid slant/acid butt; Alk/A, alkaline slant, acid butt.

of the *Escherichieae*, except that *Y. enterocolitica* is usually urea-positive. Students may wish to think of *Y. enterocolitica* as urea-positive *E. coli*. Note that the motility for *Y. enterocolitica* is negative at 36°C but positive at 22°C.

Key reactions for students to remember are found in Box 6-8. When it is necessary to confirm the identification of a common *Enterobacteriaceae* with an unusual biochemical pattern or when an uncommon species is suspected, it will be necessary to consult Table 6-7, which gives the reactions of all named species of *Enterobacteriaceae* to 48 biochemical substrates.

Tribe *Escherichieae*. The two genera within this tribe are *Escherichia* and *Shigella*. On first reflection, these two groups of bacteria would not appear to be related because of differences in growth characteristics and appearance on the enteric isolation media (*E. coli* characteristically ferments lactose, *Shigella* species do not). *E. coli* is generally biochemically active compared with Shigella species, which tend to be inert. However, *E. coli* and *Shigella* species are closely related genetically; in fact, all four species of *Shigella* and *E. coli* form a single species on the basis of DNA hybridization studies.[64] However, because *Shigella* species are associated with a specific disease spectrum (bacillary dysentery) and because specific typing antisera for separating *E. coli* from *Shigella* are commercially available, *Shigella* species will continue to be classified in a separate genus, at least for now. Students should note,

however, that certain late lactose-fermenting, nonmotile, and biochemically inactive strains of *E. coli* can be difficult to differentiate from *Shigella* species, and rare strains of *Shigella*

BOX 6-8

Key Facts to Remember for Identifying *Enterobacteriaceae*

Hydrogen Sulfide-Positive

Edwardsiella tarda
Salmonella species
Citrobacter freundii
Proteus vulgaris
Proteus mirabilis

Voges–Proskauer-Positive

Klebsiella species
Enterobacter species
Hafnia species
Pantoea species
Serratia species

Phenylalanine Deaminase-Positive

Proteus species
Providencia species
Morganella species

Nonmotile at 36°C

Shigella species
Klebsiella species
Yersinia species (motile at 22°C)

TABLE 6-7 Biochemical Reactions of the Named Species and Unnamed Groups of the Family *Enterobacteriaceae*[a,b]

Organism	Indole production	Methyl red	Voges–Proskauer	Citrate (Simmons)	Hydrogen sulfide (TSI)	Urea hydrolysis	Phenylalanine deaminase	Lysine decarboxylase	Arginine dihydrolase	Ornithine decarboxylase	Motility	Gelatin hydrolysis (22°C)	Growth in KCN	Malonate utilization	D–Glucose, acid	D–Glucose, gas	Lactose fermentation	Sucrose fermentation	D–Mannitol fermentation	Dulcitol fermentation	Salicin fermentation	Adonitol fermentation	myo–Inositol fermentation

[a] Data provide by Brent Barrett using CDC Enterobacteriaceae Tables originally developed by J.J. Farmer, PhD, retired from CDC with revision by Caroline O'Hara, and updated with results published in the International Journal of Systemic Bacteriology added by A.P. Schreckenberger.
[b] Each number is the percentage of positive reactions after 2 days of incubation at 36°C unless otherwise indicated (gelatin hydrolysis and DNASE and all reactions of *Xenorhabdus* species, *P. luminescens* and *Y. ruckeri*). Reactions that become positive after 2 days are not considered. TSI, triple sugar iron agar; ONPG, o-nitrophenyl-β-D-galactopyrannoside; NA, not available.

species (*S. flexneri*) also can produce gas from the fermentation of glucose. The pathogenic spectrum of *E. coli* is much broader than that of *Shigella* species, and toxigenic strains of *E. coli* can produce dysentery-like diarrheal syndromes indistinguishable from shigellosis. Serologic testing may be required in some instances to differentiate certain closely related strains. The key characteristics of the Escherichieae are given in Table 6-6.

Genus *Escherichia*. The genus *Escherichia* contains five species: *E. albertii*, *E. coli*, *E. fergusonii*, *E. hermannii*, and *E. vulneris*. A former member of the genus, *E. adecarboxylata*, has been assigned to a new genus as *Leclercia adecarboxylata* and is discussed elsewhere in this chapter.[622]

Another former member of the genus, *E. blattae,* has been transferred to a new genus, *Shimwellia,* as *S. blattae.*[541] It has been recovered from the intestinal tract of cockroaches, is indole-negative, does not ferment lactose, and has not been associated with human infections.[541] The different biochemical

[a]Strains of *E. coli* belonging to serotype 0157:H7 are sorbitol negative.

reactions for the recognized species of *Escherichia* are shown in Table 6-8.

E. coli is the bacterial species most commonly recovered in the clinical laboratories and has been incriminated in infectious diseases involving virtually every human tissue and organ system. *E. coli* is one of the common organisms involved in gram-negative sepsis and endotoxin-induced shock. Urinary tract and wound infections, pneumonia in immunosuppressed hospitalized patients, and meningitis in neonates are other common infections caused by *E. coli*. *E. coli* are serotyped on the basis of their O (somatic), H (flagellar), and K (capsular) surface antigens. More than 170 different O antigen serogroups are currently recognized.[457] The combination of O and H antigens defines a "serotype" of an isolate; for example, *E. coli* O157:H7 is a serotype of a virulent strain of *E. coli* associated with hemorrhagic colitis and hemolytic–uremic syndrome (HUS).

Carbon dioxide-dependent strains of *E. coli* have been reported from urine and empyema fluid specimens.[398,630] We have also observed such strains in our

laboratory. It is possible that the incidence of infections associated with capnophilic *E. coli* is higher than currently thought because culture plates from urine and wound specimens are not routinely incubated in CO_2.

E. coli *That Causes Gastroenteritis.* Certain strains of *E. coli* can cause enteritis or gastroenteritis by six distinct mechanisms, resulting in six different clinical syndromes. These include enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enteroinvasive *E. coli* (EIEC), enterohemorrhagic *E. coli* (EHEC), enteroaggregative *E. coli* (EAEC), and diffusely adherent *E. coli* (DAEC)[457] (Table 6-9). EPEC, EAEC, and DAEC isolates are characterized by their distinct patterns of adherence to epithelial cells in vitro. EPEC strains bind to host cells in a pattern called localized adherence, in which microcolonies form on the surfaces of the cells. EAEC isolates bind in an aggregative adherence pattern that is characterized by a stacked-brick-like arrangement on the surfaces of the cells. DAEC strains are defined by a pattern of diffuse adherence in which the bacteria uniformly cover the entire cell surface.[457] In addition to the six classes of diarrheagenic *E. coli* mentioned above, there are other potential classes, such as cytolethal distending toxin (CDT)-producing *E. coli* and cell-detaching *E. coli* (CDEC) that have yet to be fully characterized.[457]

Although assays to identify all categories of *E. coli* that cause gastroenteritis are available, in most cases it is not necessary to identify a specific *E. coli* pathogen in a particular patient. Most patients with gastroenteritis due to *E. coli* will resolve their diarrhea before seeking medical attention or their diarrhea resolves following treatment with empirical antibiotics given for other bacterial diarrheas. Therefore, with the exception of assays for the detection of EHEC (discussed below), phenotypic assays or serotyping of *E. coli* for diagnosis of diarrheagenic strains is not routinely performed in the clinical laboratory.

***Pathophysiology of Enterohemorrhagic* E. coli.** The clinical significance of EHEC was not known until 1982, when these organisms were associated with two conditions of previously unknown etiology: hemorrhagic colitis[564] and hemolytic–uremic syndrome.[339] (see Clinical Correlation Box 6-1.) *E. coli* O157:H7 was the first of several Shigatoxin-producing serotypes known to cause human illness. *E. coli* O157:H7 is so named because it expresses the 157th somatic (O) antigen identified and the 7th flagellar (H) antigen. Among the most important virulence characteristics of *E. coli* O157:H7 is its ability to produced one or more Shiga toxins (Stxs) (also called verocytotoxins, and formerly known as Shiga-like toxins). Stx1 is indistinguishable from Stx

255

TABLE 6-9 Key Features of Diarrheagenic *E. coli*[191,457]

Term	Abbreviation	Pathogenic Phenotype	Signs and Symptoms
Enterotoxigenic *E. coli*	ETEC	Elaboration of secretory heat-labile (LT) and/or heat-stable (ST) enterotoxins that do not damage the mucosal epithelium. Toxin production is plasmid mediated and most commonly involves *E. coli* serogroups 06, 08, 015, 020, 025, 027, 063, 078, 080, 085, 092, 0115, 0128ac, 0139, 0148, 0153, 0159, and 0167.[547] From 1996 to 2003, 16 outbreaks of ETEC infections occurred in the US and on cruise ships. *E. coli* O169:H41 was identified in 10 outbreaks. This serotype was identified in 1 of 21 confirmed ETEC outbreaks before 1996.[41]	Associated with two major clinical syndromes: "weanling diarrhea" among children in the developing world and "Traveler's diarrhea." Typically abrupt in onset with short incubation period (14–50 hours). Profuse watery diarrhea is predominant symptom (similar to *Vibrio cholerae*), usually without blood, mucus, or pus. Often accompanied by mild abdominal cramps. Dehydration and vomiting occur in some cases.
Enteropathogenic *E. coli*	EPEC	Adhere to intestinal epithelial cells in localized microcolonies producing characteristic histopathologic lesions known as "attaching and effacing lesions" (A/E lesions). Serogroups 055, 086, 0111, 0119, 0126, 0127, 0128ab, and 0142 are most commonly involved.[547]	Usually occurs in infants. Characterized by low-grade fever, malaise, vomiting, and profuse, watery diarrhea, with a prominent amount of mucus, but with no gross blood. Fecal leukocytes are seen only occasionally.
Enteroinvasive *E. coli*	EIEC	Invade colonic epithelial cells. Pathogenesis virtually identical to *Shigella* species. As with *Shigella*, most strains are nonmotile, late– or non–lactose-fermenters, and anaerogenic. The most commonly involved serogroups are 028ac, 029, 0112ac, 0124, 0136, 0143, 0144, 0152, and 0164.[547]	Infection presents most commonly as watery diarrhea, indistinguishable from ETEC. Some patients present with a dysentery syndrome; hallmarks are fever and colitis. Symptoms are urgency and tenesmus; blood, mucus, and many leukocytes in stool.
Enterohemorrhagic *E. coli*	EHEC	Elaboration of Stxs, an enterohemolysin, and like EPEC produce A/E lesions. Most commonly involved serogroup is O157:H7.	Bloody diarrhea without WBCs. Often no fever. Abdominal pain is common. May progress to HUS.
Enteroaggregative *E. coli*	EAEC	Adhere to epithelial cells in a pattern resembling a pile of stacked bricks and produce an ST-like toxin (EAST1), an LT toxin, and fimbrial colonization factors called "AAFs" (aggregative adherence fimbriae).	Watery, mucoid, secretory diarrheal illness with low-grade fever and little or no vomiting. Stools usually without gross blood or fecal leukocytes. Recovered principally from children with chronic diarrhea.[458,499]
Diffusely adherent *E. coli*	DAEC	Adhere to epithelial cells in a diffuse pattern and carry a gene encoding surface fimbria designated *F1845*.	Majority of patients have watery diarrhea without blood or fecal leukocytes.

CLINICAL CORRELATION BOX 6-1 Hemorrhagic Colitis and Hemolytic–Uremic Syndrome

Hemolytic–uremic syndrome (HUS) is a thrombotic disease of the kidney microvasculature in which the endothelial cell is the primary site of damage. HUS is defined by a triad of features: (1) the appearance of fragmented red cells (microangiopathic hemolytic anemia), (2) reduced platelet count (thrombocytopenia), and (3) acute renal failure, evidenced by a reduced glomerular filtration rate and low urine output. HUS is the leading cause of acute renal failure in children. In its most common form, this syndrome is preceded by a diarrheal illness that presents with severe abdominal pain, vomiting, and watery diarrhea. The diarrhea subsequently becomes blood-streaked or grossly bloody, and despite evidence of colitis, the children typically have little or no fever. This constellation of signs and symptoms is called **hemorrhagic colitis.** In the most severe infections, ischemic colitis and perforation can occur. In some patients, colonic stenosis can develop following

ischemic colitis. EHEC organisms colonize the large intestine via the formation of distinctive attaching and effacing lesions that provide a tight junction between the EHEC and the surface of the intestinal epithelial cells. Development of attaching and effacing lesions (A/E lesions) requires numerous genes that are located on a 35-kb chromosome pathogenicity island termed the locus on enterocyte effacement (LEE). Following colonization, EHEC produce Stxs that translocate into the circulation, probably facilitated by the influx (transmigration) of neutrophils. Once in the circulation, Stx travels to the kidneys, where it is transferred and bound via the B subunit of the toxin to neutral glycolipid globotriaosylceramide (Gb_3) receptors on target cells (i.e., glomerular endothelial and tubular epithelial cells). The toxin is then internalized and routed to the endoplasmic reticulum, where the single A subunit enzymatically inactivates the ribosomes, causing inhibition of protein synthesis and cell damage. This leads to glomerular endothelial cell swelling and detachment from the underlying basement membrane with secondary activation of both platelets and the coagulation cascade.

256

This sequence of events results in the classic signs of Stx-mediated HUS. The coagulation cascade results in fibrin deposition, causing narrowing of the capillaries and shearing of red cells as they are pushed through the damaged vessels. The shearing and tearing of red blood cells result in the fragmented erythrocytes typical of microangiopathic hemolytic anemia. The consumption of platelets leads to thrombocytopenia, and the anemia in addition to restricted blood flow to the kidneys, which consequently leads to renal failure.[352,594,675] There are no treatments of proven value other than supportive care for patients with HUS. Antibiotic treatment of children with *E. coli* O157:H7 infection increases the risk of HUS and therefore should be avoided.[509] Research is currently underway to develop specific Stx antibodies to block the binding of Stx to endothelial cells as well as synthetic Gb3 receptor analogues that can be given orally to entrap Stx in the gut and prevent the entry of the toxin into the circulation.[338,657]

produced by *S. dysenteriae* type 1. Stx2 is a more divergent molecule that has multiple variants (Stx2, Stx2c, Stx2d, Stx2e, Stx2f) that are closely related to each other but more distantly related to Stx1. Some *E. coli* O157 strains produce only Stx1, some only Stx2, and others produce both. The toxins do not carry equivalent risks of causing HUS. Strains that produce only Stx2 have the highest risk; strains that produce only Stx1 have the lowest risk, and strains that make both toxins carry an intermediate

risk. Both toxins are composed of five B subunits and a single A subunit. The B subunit binds to globotriaosylceramide (Gb3), a glycolipid found in varying degrees in membranes of eukaryotic cells. The A subunit is a potent cytotoxin and is responsible for cell injury. Production of Stx is not in itself sufficient to cause disease. Other virulence factors identified in *E. coli* O157 include a 60-MDa-virulence plasmid (pO157) and the locus of enterocyte effacement (LEE). The 60-MDa plasmid encodes an enterohemolysin (designated EHEC-Hly) that may allow *E. coli* O157 to use hemoglobin released by the action of EHEC-Hly as a source of iron, thereby stimulating the growth of *E. coli* O157 in the gut.[509] The LEE contains genes for an adhesion molecule (intimin) and for other factors important for the production of attaching–effacing lesions. The clinical manifestations of *E. coli* O157 infection range from asymptomatic carriage to nonbloody diarrhea, hemorrhagic colitis, HUS, and death. The incubation period varies from 1 to 8 days, with an average interval of 3 days between exposure and illness. Most patients with hemorrhagic colitis recover within 7 days. Illness typically begins with abdominal cramps and nonbloody diarrhea. Stool may become bloody after the first 1 to 2 days, with the amount of blood varying from a few small streaks to stools that are almost entirely blood. Vomiting occurs in 30% to 60% of cases, and fever is usually low-grade or absent.[426] HUS following urinary tract infection with EHEC has been reported[436,608]; however, because of the low prevalence, routine testing of sorbitol-negative *E. coli* urinary isolates for the presence of Stx does not seem warranted.[634,671] Currently, antibiotics are not recommended for treatment of *E. coli* O157 infections because of the concern that antibiotic use will increase the production of Stxs. Stx genes are bacteriophageencoded, and antibiotics that cause bacteriophage induction (e.g., fluoroquinolones, trimethoprim–sulfamethoxazole, and furazolidone) may increase Stx expression. In view of these issues, it is recommended that clinical laboratories do not report antimicrobial susceptibility results for O157 or other Stx *E. coli* isolates.[352,675]

***Epidemiology of enterohemorrhagic* E. coli.** In early 1993, the largest *E. coli* food-poisoning outbreak to date caused by *E. coli* O157:H7 occurred in the states of Washington, Idaho, California, and Nevada. Altogether, 582 culture-confirmed cases were reported, causing 171 hospitalizations, 41 cases of HUS, and 4 deaths. Hamburgers from a single fast-food restaurant chain were implicated. The source of most cases of *E. coli*-related illnesses in the United States is considered to be ground beef. Hamburgers, in particular, have been the cause of multiple outbreaks of disease. This is because of the high prevalence of *E. coli* O157:H7 colonization in cows. For a summary of risk factors during all the steps of industrial scale beef production from farm to fork see the review by Meyer–Broseta and colleagues.[433] According to recent market-basket surveys, *E. coli* O157:H7 is present in 1.0% to 2.5% of meat and poultry samples. It also turns up less frequently in supermarket samples of lamb and pork, although such isolates could arise from secondary contamination in the

butchering area. In the United States, cases have tended to occur in the last two-thirds of the year and in states bordering Canada. Infection persists in animal reservoirs in part because the organism survives in soil for long periods. Other animals, including pigs, sheep, deer, and rabbits, can also carry EHEC, and many other foods and water can be contaminated with the feces of infected animals.[245,473] The result has been outbreaks involving municipal water supplies,[491] venison,[546] uncooked vegetables, cheese curd,[119] apple cider,[113] alfalfa sprouts.[75,442] spinach,[265] and raw prepackaged cookie dough.[460] In addition, because incredibly low numbers of these organisms can cause illness, personto-person spread has occurred within families and in daycare centers, among children during visits to dairy farms,[120] and petting zoos,[285] and among persons exposed to sawdust and other surfaces in county fair buildings used for showing animals.[645] Although O157:H7 is the prototypic serotype of EHEC in the United States, several other EHEC serotypes, such as O26:H11, O48:H21, O103:H2, O111:NM (nonmotile), and O145:NM, have been recognized in other countries.[204, 331,399] Although non-O157 serotypes of EHEC are rare in the United States, one outbreak of hemorrhagic colitis caused by EHEC serotype O104:H21 was reported among 11 patients in Helena, Montana, in 1994.[112] Another outbreak occurred among teenage campers in Texas in June 1999, caused by EHEC serotype O111:H8, in which 55 campers became ill and HUS developed in two.[77,118] *E. coli* O111 is the second most common non-O157 Shiga toxin-producing *E. coli* (STEC) reported in the United States,[78] and it is among the most common reported in Europe.[86] A large outbreak of HUS caused by STEC O104:H4 occurred in Germany in May 2011. There were 3,469 confirmed cases of STEC and 852 cases of HUS. A unique feature of this outbreak was that 90% of affected cases were adults and more than two-thirds of

case subjects with HUS were female. The outbreak was traced to contaminated fenugreek sprouts served at several restaurants.[82] To learn more about infections caused by EHEC, the reviews by Kaper and O'Brien,[335] Mead and Griffin,[426] Nataro and Kaper,[457] Paton and Paton,[509] and Tarr[625] may be consulted.

***Detection of Enterohemorrhagic* E. coli.** Isolation of *E. coli* O157:H7 is possible only during the acute phase of illness, and the organisms may not be detectable 5 to 7 days after onset. Because the majority of EHEC infections are caused by *E. coli* serotype O157:H7, the current laboratory approaches to detection are based on either detection of Shiga-toxin-producing strains or detection of the O157:H7 serotype. The currently accepted methods for detection can be summarized as follows: (1) assays for the detection of the O157 serotype[406,503,607] or Stxs[341,406,468] directly from stool; (2)

direct plating on sorbitol–MacConkey agar (SMAC),[414] cefixime–SMAC,[135] SMAC supplemented with cefixime and tellurite (CT-SMAC),[686] or media containing either 5-bromo-5-chloro-3-indoxyl-β-D-glucuronide[490] or 4-methylumbelliferyl-β-D-glucuronide[633]; and (3) immunomagnetic separation (IMS) using O157-specific, antibodycoated beads, followed by bacteriologic culture.[136,337] Many laboratories in the United States and elsewhere use SMAC agar to identify the slow sorbitol fermentation phenotype (i.e., sorbitol-negative at 24 hour) of O157:H7. SMAC agar contains 1% D-sorbitol rather than lactose to differentiate sorbitol-negative *E. coli* strains (colonies appear colorless, similar to lactose-negative colonies on regular MacConkey agar). Suspected isolates are then confirmed with specific O157:H7 antisera. This medium, however, does not detect other, sorbitol-positive EHEC serotypes. Other detection methods such as chromogenic medium and enzyme-linked immunosorbent assay (ELISA) methods for detection of Stx are more sensitive and specific, but are considerably more expensive than SMAC.[468,503] Incorporation of this testing into the routine microbiology laboratory comes at a significant additional cost, and laboratories may want to limit testing to patients at highest risk. One of the recommendations published by the CDC for diagnosis of STEC infections by clinical laboratories is that all stools submitted for routine testing from patients with acute community-acquired diarrhea (regardless of patient age, season of the year, or presence or absence of blood in the stool) be simultaneously cultured for *E. coli* O157:H7 and tested with an assay that detects Stxs to detect non-O157 STEC.[127] A mini-review on the role of the laboratory in the diagnosis of EHEC infections has been provided by Kehl.[342]

***Species Other Than* E. coli.** Strains designated in the CDC classification as *E. coli*-inactive are anaerogenic (non–gasproducing), lactose-negative (or delayed), and nonmotile. These strains were previously known as the Alkalescens–Dispar serotype.

Escherichia albertii is a newly described species of indole-, D-sorbitol-, and lactose-negative enterobacterial isolates recovered from diarrheal stools of children.[306] Because these strains are not included in the databases of commercial systems at present, they are most often identified as *Hafnia*, *Salmonella*, *E. coli*, or *Yersinia ruckeri*.[5] *E. albertii* most closely resemble inactive *E. coli*, although they do not resemble the Alkalescens–Dispar group because of their ability to produce gas from D-glucose. They can be separated from *H. alvei* based on acetate assimilation, negative VP test, and failure to grow in potassium cyanide (KCN). In addition, *E. albertii* show weak-to-moderate L-prolineaminopeptidase (PYR) reactions, whereas *H. alvei* express strong PYR activity.[5] Laboratory workers should be advised that isolates recovered from stool specimens that give an unacceptable first-choice identification of *H. alvei* for an isolate that is L-rhamnose-, D-xylose-, and VP-negative should be further tested

to rule out *E. albertii*.

E. albertii has recently been identified as the cause of two food-borne outbreaks of gastroenteritis in Japan.[361,496] The clinical significance of *E. albertii* has been studied by Ooka and colleagues who examined 278 *eae*-positive strains that were originally identified by routine diagnostic protocols as EPEC or EHEC. They were isolated from humans, animals, and the environment in Japan, Belgium, Brazil, and Germany during 1993 to 2009. From this group, 26 strains (14 humans, 11 birds, and 1 cat) were identified as *E. albertii*.[495] Because discriminating *E. albertii* from other *Enterobacteriaceae* is difficult and because *E. albertii* possesses the *eae* gene, many strains identified as enterohemorrhagic or enteropathogenic *E. coli* might in fact be strains of *E. albertii*.[495]

E. fergusonii (formerly CDC enteric group 10) has been recovered from blood, gallbladder, urine, and feces; however, its clinical significance has not been establi shed.[220,221,239,240,371,372,560] It is differentiated from *E. coli* by being sorbitoland lactose-negative, but adonitoland cellobiose-positive. One case of cystitis caused by an ESBL-producing strain of *E. fergusonii* has been reported.[371]

E. hermannii (formerly CDC enteric group 11) has been most commonly found in human wounds, sputum, and feces.[525] Of eight strains recovered at the University of Illinois Medical Center, five have been from wound specimens, including four leg wounds in patients with cellulitis and one finger wound, and one strain each has been recovered from urine, maxillary sinus, and blood. The isolates recovered from wounds were mixed with other pathogenic species; however, the blood, urine, and sinus isolates were present as the only isolates. Ginsberg and Daum[254] reported recovery of *E. hermannii* from blood, cerebrospinal fluid (CSF), and peritoneal fluid of a septic neonate with bowel perforation; however, other organisms were recovered from the blood, and the pathogenic role in this patient was uncertain. *E. hermannii* has been reported as the sole pathogen in a catheter-related bloodstream infection,[334] and from a patient with acute purulent conjunctivitis after a minor ocular injury.[538] The only documented case of invasive disease caused by *E. hermannii* is from a neonate with bacterial infection of a cephalohematoma with meningitis documented by culture from multiple CSF specimens and fluid aspirated from an enlarging cephalohematoma.[161] *E. hermannii* strains are yellow pigmented, indole-positive, and sorbitol-negative.[66] Because *E. hermannii* are sorbitol-negative, they appear biochemically similar to the O157 serotype of *E. coli*.

E. vulneris (formerly CDC enteric group 1) has a high propensity for causing human wound infections, particularly of the arms and legs,[70,525] which may lead to osteomyelitis.[383] In addition, there have been reports of urosepsis, peritonitis in patients receiving continuous ambulatory peritoneal dialysis (CAPD), intravenous

catheter-related bacteremia, and meningitis caused by *E. vulneris*.[22,27,299,441,589,603] One case of *E. vulneris* bacteremia in a 40-day-old infant and another case of *E. vulneris* bacteremia traced to an infected

258

right chest wall permacath have been seen in the author's laboratory (P. Schreckenberger, Personal communication). *E. vulneris* bacteremia secondary to a subcutaneous abscess in a patient with chronic lymphocytic leukemia has also been reported.[348] Over half of the strains of *E. vulneris* are yellow pigmented, and they are both indoleand sorbitol-negative.

Genus *Shigella*. *Shigella* species can be suspected in cultures because they are non–lactose-fermenters and tend to be biochemically inert. They typically do not produce gas from carbohydrates, with the exception of certain biogroups of *S. flexneri* that are aerogenic. Rare strains of *S. sonnei* can slowly ferment lactose (2%) and sucrose (1%), and most strains can decarboxylate ornithine—characteristics not shared by other *Shigella* species.

There are 4 major subgroups and 43 recognized serotypes of *Shigella*, as shown in Box 6-9.[100] The CDC classification combines *S. dysenteriae* (group A), *S. flexneri* (group B), and *S. boydii* (group C) as "*Shigella* serogroups A, B, and C" because of their biochemical similarities. The presence of ornithine decarboxylase activity and β-galactosidase make most strains of *S. sonnei* biochemically distinct from the other *Shigella* species. The inability to ferment mannitol and a negative catalase reaction distinguish *S. dysenteriae*. *S. dysenteriae* types 1, 3, 4, 6, 9, 11, and 12 and *S. boydii* type 12 are catalase-negative, whereas other species of *Shigella* as well as EIEC and STEC are catalase-positive.[336] The differential characteristics for the four species of *Shigella* are included in Table 6-10. Isolates recovered from stool specimens from patients with diarrheal disease that are suspected of being *Shigella* species should be biochemically categorized and the species confirmed by serologic testing. In the near future, it may be possible to detect *Shigella* species and enteroinvasive strains of *E. coli* using DNA probes selected to detect the virulence plasmids responsible for coding the gene products that initiate intracellular penetration and bowel wall invasion.[55]

BOX 6-9

Subgroups, Serotypes, and Subtypes of *Shigella*

Subgroup	Serotypes and Subtypes

Group A: *Shigella*	15 serotypes (type 1 pro- *dysenteriae* duces Stx)
Group B: *Shigella flexneri*	8 serotypes and 9 subtypes
Group C: *Shigella boydii*	19 serotypes
Group D: *Shigella sonnei*	1 serotype

Pathogenicity. All species of *Shigella* cause acute bloody diarrhea by invading and causing patchy destruction of the colonic epithelium. This leads to the formation of microulcers and inflammatory exudates, and causes inflammatory cells (polymorphonuclear leukocytes, PMNs) and blood to appear in the stool. The diarrheal stool contains 10^6 to 10^8 shigellae per gram. Once excreted, the organism is very sensitive to environmental conditions and dies rapidly, especially when dried or exposed to direct sunlight.[678] For this reason, stool specimens submitted for culture should be processed rapidly (within 2 hours) or placed in a stool preservative such as Cary–Blair Transport Medium.

Incidence and Sources of* Shigella *Infections. Shigellosis is the most communicable of the bacterial diarrheas, and worldwide are responsible for greater than 80 million cases of bloody diarrhea and 700,000 deaths each year.[678] Humans serve as the natural host, and disease is transmitted by the fecal–oral route, with as few as 200 viable organisms being able to cause disease (see Clinical Correlation Box 6-2). Between 20,000 and 30,000 cases of shigellosis are reported annually in the United States.[125] *S. sonnei* is the serotype most commonly associated with diarrheal disease in the United States, accounting for 77% of the *Shigella* serogroups reported to the CDC in 2001.[100] Symptoms associated with *S. sonnei* infection tend to be mild, and some patients may be asymptomatic. *S. dysenteriae* is the least commonly recovered species in

CLINICAL CORRELATION BOX 6-2 *Shigella* Infection (Bacillary Dysentery)

The term "dysentery" was used by Hippocrates to indicate a condition characterized by frequent passage of stool containing blood and mucus accompanied by straining and painful defecation.[193] Humans are the only natural host for *Shigella*, and infection occurs by ingestion. Bacillary dysentery is the most communicable of the bacterial diarrheas, with an infective dose as low as 10 to 100 bacteria producing disease in healthy adults.[194] Fever, watery diarrhea with cramping abdominal pain, and generalized myalgias are the most common early symptoms suggesting shigellosis.[91] Fluid and electrolyte losses may also be noted early in the illness, owing to the action of enterotoxin on the intestinal epithelial cells. After 2 or 3 days, bowel movements become less frequent, and the quantity of stool decreases, but the presence of bright red blood and mucus in the feces and the onset of tenesmus (a distressing urge to defecate) indicate the dysenteric phase of illness, suggesting that bacterial penetration of the bowel has probably occurred. *Shigella* infections should be suspected in community-wide outbreaks of diarrheal illness that disproportionately affect young children. Outbreaks can occur at any time of the year, but are most common in summer.

the United States, but it is the most virulent serotype and the most common serotype isolated in developing countries. The belief that *Shigella* species remain confined to

the bowel and neither invade the bowel lymphatics nor extend to other organs may no longer pertain. Drow and associates[188] reported the recovery of *S. flexneri* from a splenic abscess in a patient with diabetes, indicating that extraintestinal sites of infection may be encountered. Specimens other than stool from which *Shigella* spp. have been recovered include liver, mesenteric lymph nodes, CSF, synovial fluid, vaginal lesions, lungs, conjunctival sacs, corneal scrapings, blood, cutaneous lesions of the penile shaft, and urine.[192,502] Urinary tract infections due to *Shigella* spp. in adults are extremely rare. *Shigella* vaginitis with or without accompanying UTI has been reported in prepubertal girls.[33] Some patients experience a bloody vaginal discharge that may be confused with gonorrhea.[600] Most cases of *Shigella* vulvovaginitis are caused by *S. flexneri*.[451]

Treatment. The World Health Organization has recommended ciprofloxacin as a first-line antimicrobial drug for shigellosis treatment, and third-generation cephalosporins are considered as alternative drug treatmens.[678] Unfortunately, resistance of *Shigella* to ampicillin, trimethoprimsulfamethoxazole, and nalidixic acid has become widespread, and these are no longer recommended. Strains of *S. flexneri* that are resistant to ciprofloxacin and cefotaxime have been reported, thus raising serious questions about the effective treatment of shigellosis in the future.[545]

Tribe *Edwardsielleae*. The Edwardsielleae were initially called the Asakusa group by Sakazaki and Murata in 1963,[573] and the Bartholomew group by King and Adler in 1964.[353] Ewing and associates suggested the name *Edwardsielleae* in 1965,[213] in honor of the prominent American microbiologist, P.R. Edwards. The *Edwardsielleae* consists of one genus, *Edwardsiella*.

Genus *Edwardsiella*. The genus *Edwardsiella* has three species, but only one species, *E. tarda*, is of medical importance. The chief reservoirs in nature are reptiles (especially snakes, toads, and turtles) and freshwater fish. The key characteristics that suggest *E. tarda* are listed in Table 6-6.

A key feature of *E. tarda* is the production of abundant amounts of hydrogen sulfide. Except for this feature, the biochemical properties of the bacterium are similar to those of *E. coli*. The organism also resembles some *Citrobacter* and *Salmonella* species by its production of hydrogen sulfide in TSI agar and its failure to use lactose. This failure to ferment lactose and many other carbohydrates is the basis for the species name *tarda.* A species similar to *E. tarda,* which is hydrogen sulfide-negative, but mannitol-, sucrose-, and arabinose-positive, has been designated "*E. tarda* biogroup 1."[224] This biotype is rarely encountered in laboratory practice and does not yet appear to have clinical significance.

E. tarda has been cited as the cause of a variety of extraintestinal infections.[147,598] The most common are wound infections resulting from trauma, often related to

aquatic accidents. Also common are abscesses that may lead to bacteremia or myonecrosis.[598] Seven patients in one study had typhoidal illnesses, an important differential consideration because *E. tarda* can simulate *S. typhi* in culture.[147] Most reports of enteric illness describe a mild gastroenteritis that improves without therapy in 2 to 3 days. However, Vandepitte and associates[642] reported one case of protracted diarrhea in a 2-month-old infant in whom *E. tarda* (of the same biogroup isolated from tropical aquarium fish in the home of the patient) was the only potential pathogen recovered. Marsh and Gorbach[415] reported the isolation of *E. tarda* from the stool of a patient with bloody diarrhea, and sigmoidoscopic findings of multiple colonic ulcers and mucosal thickening consistent with Crohn's disease. The patient became asymptomatic after 2 days of antibiotic therapy. Iron availability has been thought to regulate the seriousness of *E. tarda* infection.[318,319] Iron overload, caused by such conditions as red cell sickling, leukemia, and cirrhosis, is associated with *E. tarda* septicemia.[318, 672,679] Infection with *E. tarda* related to vascular prostheses has also been reported.[152,462] Clusters of asymptomatic *E. tarda* infections are believed to occur in humans, and at least one such cluster has been reported among seven children and a teacher in a Florida day-care center.[179]

Two other species in the genus *Edwardsiella* have been described. Grimont and associates[269] described *E. hoshinae*, initially recovered from birds, reptiles, and water. This species has also been recovered from human feces; however, it is not known to cause diarrhea. Hawke and coworkers[281] described *E. ictaluri*, an organism that has been recovered only from fish and, at present, has no clinical significance. The biochemical characterization of *Edwardsiella* species is shown in Table 6-11.

Tribe *Salmonelleae*. The *Salmonelleae* contain a single genus, *Salmonella*, and are named after the American microbiologist, D.E. Salmon.

Genus *Salmonella*. Salmonellae have somatic (O) antigens that are lipopolysaccharides, and flagellar (H) antigens that are proteins. *S. typhi* also has a capsular or virulence (Vi) antigen. Biochemically, they are usually both lactoseand sucrose-negative. The key characteristics by which the genus *Salmonella* can be suspected are presented in Table 6-6.

***Classification of* Salmonellae.** From the time of the first isolation of microorganisms of the *Salmonella* group, reported in 1884 by Gaffky (*Bacterium typhosum*) and in 1886 by Salmon and Smith (*Salmonella choleraesuis*), the development of *Salmonella* nomenclature has been very complex and a matter of dispute (Box 6-10). The salmonellae are the

BOX 6-10

Salmonella Taxonomy and Nomenclature

The antigenic formulae of *Salmonella* serotypes are defined and maintained by the World Health Organization (WHO) Collaborating Centre for Reference and Research on *Salmonella* at the Pasteur Institute, Paris, France, and new serotypes are listed in annual updates of the Kauffmann–White scheme.[534,535] In this scheme, the salmonellae are grouped (A, B, C, etc.) on the basis of somatic O antigens and are subdivided into serotypes (1, 2, 3, etc.) by their flagellar H antigens, resulting in serogroups designated A, B, C_1, C_2, C_3, etc. Each unique serotype is given a name. The first salmonellae were given names that indicated the disease and/or the animal from which the organism was isolated (e.g., *S.* ser. Typhi, *S.* ser. Choleraesuis, etc.). New serotypes are now given the name of the geographic location where they were first isolated (*Salmonella* ser. Canada, *Salmonella* ser. Cleveland, etc.). Initially, each serotype was considered a separate species (for example, *S. canada*, *S. cleveland*); however, today this would result in over 2400 species of Salmonella. DNA relatedness studies have demonstrated that all *Salmonella* strains and all serotypes of

"*Arizona*" form a single DNA hybridization group with seven subgroups, with the exception of *S. bongori* (subgroup V) that has been shown by DNA–DNA hybridization to form a distinct species.[156,381,382,551] Since *S. choleraesuis* was already recognized as the type species of *Salmonella*, it had priority as the species designation for the six subgroups considered to comprise a single hybridization group. The name "choleraesuis," however, can lead to confusion because the name refers to both a species and a serotype. So, in 1986, the Subcommittee on *Enterobacteriaceae* of the International Committee on Systematic Bacteriology at the XIV International Congress on Microbiology unanimously recommended that the type species for *Salmonella* be changed to *S. enterica*, a name that had not been used previously as a serovar.[514] In 1987, Le Minor and Popoff[380] made a proposal as a "Request for an Opinion" to the Judicial Commission of the International Committee of Systematic Bacteriology that the genus *Salmonella* consist of only one species "*Salmonella enterica*" to include seven subspecies. *S. typhi*, *S. typhimurium,* and *S. enteritidis* were included in *S. enterica*. This recommendation was adopted by the CDC and many other laboratories. However, after a long delay, the Judicial Commission denied the request based on the fact that the status of *Salmonella* ser. Typhi was not adequately addressed in the Le Minor and Popoff proposal.[661,662] They were concerned that if *S. enterica* were adopted, then *Salmonella* ser. Typhi would be referred to as *S. enterica* subsp. *enterica* ser. Typhi and might be missed or overlooked by physicians.[74] The Judicial Committee therefore ruled that *S. choleraesuis* be retained as the legitimate type species pending an amended request for an opinion.[661,662] In 1987, Le Minor and Popoff[380] also proposed that the seven subgenera of *Salmonella* be referred to as subspecies (subspecies I, II, IIIa, IIIb, IV, V, and VI). Most recently, Euzéby[211] proposed that the genus *Salmonella* consists of three species named *S. bongori*, *S. enterica*, and *S. typhi*. He further proposed that *S. enterica* be divided into six subspecies: *S. enterica* subsp. *enterica, S. enterica* subsp. *arizonae,* S. *enterica* subsp. *diarizonae, S. enterica* subsp. *houtenae, S. enterica* subsp. *indica*, and *S. enterica* subsp. *salamae*. As of this writing, the Judicial Committee has not acted on this latest proposal.

261

most complex of all the *Enterobacteriaceae*, with more than 2,400 serotypes described in the current Kauffmann–White scheme.[534] Prior to July 1, 1983, three species of *Salmonella* were used to report positive results: *S. choleraesuis, S. typhi*, and *S. enteritidis*, with most of the serotypes belonging to the last species, *S. enteritidis*. Presently, all former species and subgroups of *Salmonella* and *Arizona* are considered to be the same species, but can be separated into seven taxa representing

six distinct subgroups. The only exception is *Salmonella bongori*, previously known as subgenera V, which by DNA–DNA hybridization is a distinct species.[551] Thus, there are two species and six subspecies of *Salmonella enterica* in the current system used by the CDC (Box 6-11). The differential characteristics of *Salmonella* species and subspecies are given in Table 6-12.

BOX 6-11

Classification of *Salmonella* Species and Subspecies

There are two species of *Salmonella*: *S. enterica,* which encompasses six subspecies, and *S. bongori*

S. enterica subsp. *enterica* (I): includes most serotypes
S. enterica subsp. *salamae* (II)
S. enterica subsp. *arizonae* (IIIa)
S. enterica subsp. *diarizonae* (IIIb)
S. enterica subsp. *houtenae* (IV)
S. enterica subsp. *indica* (VI)
Salmonella bongori (formerly subspecies V)

Salmonellae *Nomenclature.* Beginning in 1966, the World Health Organization (WHO) began naming serotypes only in subspecies I and dropped all existing serotype names in the other subspecies. The CDC follows this practice and uses names for serotypes in subspecies I and uses antigenic formulas for unnamed serotypes described after 1966 in subspecies II, IV, and VI, and *S. bongori*. For named serotypes, to emphasize that they are not separate species, the serotype name is not italicized, and the first letter is capitalized. At the first citation of a serotype, the genus name is given followed by the word "serotype" or the abbreviation "ser." and then the serotype name (*Salmonella* serotype or ser. Typhimurium). Subsequently, the name may be written with the genus followed directly by the serotype name *Salmonella* Typhimurium or *S.* Typhimurium (Box 6-12).[74]

In day-to-day practice, unknown isolates from clinical specimens that are biochemically suggestive of *Salmonella* species are confirmed using polyclonal antisera containing antibodies to all the major subgroups. Subcultures of confirmed isolates are forwarded to public health laboratories, where serotype designations (e.g., *S.* serotype Typhimurium) are made on the basis of serologic reactions to O and H determinants.

***Identification of* Salmonella typhi.** Although most *Salmonella* serotypes cannot be

distinguished by biochemical reactions, one serotype, namely *S. typhi*, does possess some unique biochemical characteristics that will allow it to be differentiated from other serotypes. First and foremost is the observation that strains of *S. typhi* produce only a trace amount of hydrogen sulfide, which is usually observed as a crescent-shaped wedge of black precipitate forming at the interface of the slant and butt in KIA or TSI media (Image Plate 6-4B). In addition, *S. typhi* strains are noted to be less active biochemically than

the more common serotypes and specifically are negative in the following reactions: Simmon's citrate; ornithine decarboxylase; gas from glucose; fermentation of dulcitol, arabinose, and rhamnose; and mucate and acetate utilization. Consequently, the authors believe that it is within the capabilities of most clinical laboratories to make a preliminary report of *S. typhi* or *Salmonella* species, not *S. typhi,* while the laboratory awaits specific serotype confirmation from their local public health laboratory.

BOX 6-12

Salmonella Nomenclature in Use at CDC[74]

Taxonomic Current	Nomenclature Position
Genus (italics)	*Salmonella*
Species (italics)	*enterica*, which includes subspecies I, II, IIIa, IIIb, IV, and VI *bongori* (formerly subspecies V)
Serotype (capitalized, not italicized)	—The first time a serotype is mentioned in the text, the name should be preceded by the word "serotype" or "ser."
	—Serotypes are named in subspecies I and designated by antigenic formulae in subspecies II, III, IV, VI, and *S. bongori* (e.g., *Salmonella* serotype (ser.) Typhimurium, *Salmonella* II 50:b:z_6, *Salmonella* IIIb 60:k:z)
	—Members of subspecies II, IV, VI, and *S. bongori* retain their names if named before 1966 (e.g., *Salmonella* ser. Marina [IV 48: g, z_{51}])

Incidence and Sources of Salmonelloses. Salmonellosis is a major cause of bacterial enteric illness in both humans and animals (see Clinical Correlation Box 6-3). Each year, an estimated 1.2 million cases of salmonellosis occur among humans in the United States, resulting in 23,000 hospitalizations, and nearly 450 deaths.[128] Approximately 35,000 of these cases are serotyped by public health laboratories, and the results are electronically transmitted to the CDC. Human infections with salmonellae are most commonly caused by ingestion of food, water, or milk contaminated by human or animal excreta. Salmonellae are primary pathogens of lower animals (e.g., poultry, cows, pigs, pets, birds, sheep, seals, donkeys, lizards, and snakes), which are the principal source of nontyphoidal salmonellosis in humans. Interestingly, humans are the only known reservoir for *S. typhi*. Although the incidence of typhoid fever has declined in developed countries, sporadic outbreaks continue to occur. About 400 cases are reported annually in the United States.[99] About half the salmonellosis epidemics are the result of contaminated poultry and poultry products. Salmonellae in the feces of hens contaminate the surface of eggs or penetrate internally through hairline cracks. In hens with ovarian infection, the organisms may gain access to the yolk. The Egg Products Inspection Act of 1970 requires pasteurization of all bulk egg products and federally supervised inspection of shell eggs for cracks.

CLINICAL CORRELATION BOX 6-3 *Salmonella* Infection

Five clinical types of *Salmonella* infection may be distinguished[596]: (1) gastroenteritis, the most frequent manifestation, ranging from mild to fulminant diarrhea, accompanied by low-grade fever and varying degrees of nausea and vomiting; (2) bacteremia or septicemia without major gastrointestinal symptoms (*S. choleraesuis* is particularly invasive) characterized by high, spiking fever and positive blood cultures; (3) enteric fever, potentially caused by any strain of *Salmonella* species, usually manifested as mild fever and diarrhea, except for classical cases of typhoid fever (*S.* Typhi), in which the disease progresses through a bimodal course, characterized by an early period (lasting 1 to 2 weeks) of fever and constipation, during which blood cultures are positive and stool cultures remain negative, followed by a second (diarrheic) phase during which blood cultures become negative and stool cultures positive; (4) a carrier state in which persons with previous infection, especially with *S.* Typhi, may continue to excrete the organism in their feces for up to 1 year following remission of symptoms; and (5) focal infections, e.g., osteomyelitis, meningitis, brain abscess, endocarditis. Of some concern are reports of lactose-positive strains of *S. virchow* causing bacteremia and meningitis.[569] Although detection of lactose-positive strains in the blood or cerebrospinal fluid would not be difficult, finding such strains in stool would pose a problem for most laboratories owing to the similarity in appearance to other lactosepositive coliforms present in stool specimens.

Historically, *S.* Typhimurium has been the most frequently reported serotype, accounting for slightly more than 20% of isolates reported to the CDC annually. The three most common serotypes of *Salmonella* in 2001 were Typhimurium (22%), Enteritidis (18%), and Newport (10%), which accounted for 50% of all isolates. The largest single source outbreak of salmonellosis in U.S. history (16,000 culture-confirmed cases with epidemiologic data indicating that 150,000 to 200,000 persons were actually infected) occurred in 1985 in Illinois and surrounding states and was traced to a faulty valve in a major commercial milk supply firm.[104] Several *S.* Enteritidis outbreaks

have occurred in the United States since 1990 that were associated with shell eggs.[105,107,109,117] An estimated 0.01% of all shell eggs contain *S.* Enteritidis.

Consequently, foods containing raw or undercooked eggs (e.g., homemade eggnog or ice cream, hollandaise sauce, Caesar salad dressing, homemade mayonnaise, and runny omelets) pose a slight risk of infection with *S.* Enteritidis.[107,109] In 1994, an outbreak of *S.* Enteritidis infection was linked to a nationally distributed ice cream brand. Illnesses were documented in 41 states, and more than 200,000 persons were estimated to have been ill.[110] The incidence of *S.* Enteritidis illness and the number of such outbreaks in the United States have decreased by almost 50% between the mid-1990s and 1999.[510] To meet the challenge of further reducing the incidence of such infections, the President's Council on Food Safety announced an Egg Safety Action Plan on December 10, 1999, with the interim goal of reducing egg-associated *S.* Enteritidis illnesses by half by 2005 and eliminating them by 2010.[540] These outbreaks serve as a constant reminder that modern technology cannot always protect against the ravages of infectious diseases that may occur in explosive and widespread epidemics.

Salmonellosis has also been associated with direct or indirect contact with reptiles (i.e., lizards, snakes, turtles). Reptiles are commonly colonized with *Salmonella* and shed the organism intermittently in their feces.[116] During the early 1970s, small pet turtles were an important source of *Salmonella* infection in the United States. In 1975, the Food and Drug Administration (FDA) prohibited the distribution and sale of small turtles, resulting in the prevention of 100,000 cases of salmonellosis annually.[150] However, since 1986, the popularity of iguanas and other reptiles that can transmit infection to humans has given rise to an increased incidence of *Salmonella* infections caused by reptileassociated serotypes.[111,116,124] Increasing evidence now suggests that amphibians (e.g., frogs, toads, newts, and salamanders) can also pose risks for salmonellosis in humans.[430] Overall, reptile and amphibian contacts are estimated to account for 74,000 (6%) of the *Salmonella* infections that occur each year in the United States.[430] Because young children are at increased risk for reptileand amphibian-associated salmonellosis with potentially severe complications (e.g., septicemia and meningitis), reducing exposure of infants or children younger than 5 years of age to reptiles is particularly important. For this reason, reptiles and amphibians should be kept out of households that include children <5 years old or immunocompromised persons, and should not be allowed in child-care centers.[124] For a review of recent *Salmonella* outbreaks, go to: http://www.cdc.gov/salmonella/outbreaks.html.

***Treatment and Emergence of Multidrug-Resistant* Salmonellae.** *Salmonella* gastrointestinal infections usually resolve in 5 to 7 days, and most do not require treatment other than oral fluids. Persons with severe diarrhea may require rehydration with intravenous fluids. Antibiotic therapy can prolong the duration of excretion of nontyphoidal *Salmonella* and is recommended only for patients with severe illness (e.g., those with severe diarrhea, high fever, bloodstream infection, or who need

hospitalization) or those at risk of severe disease or complications, including young infants, older adults (over 65 years old), and immunocompromised persons. Choices for antibiotic therapy for severe infections include fluoroquinolones, third-generation cephalosporins, and ampicillin (for susceptible infections).[129]

A multidrug-resistant (MDR) strain of *S.* Typhimurium definitive type 104 (DT104) that is resistant to five antibiotics (ampicillin, chloramphenicol, streptomycin, sulfamethoxazole, and tetracycline) emerged across the United States during the 1990s.[257] In a national survey conducted by the CDC in 2000, 50% of the *S.* Typhimurium isolates were resistant to one or more drugs, and 28% had a five-drug resistance pattern characteristic of the phage type DT104.[99] Similarly, since 1998, *S.* Newport has emerged as a major MDR pathogen.[273] In 2013, CDC reported that about 3% of nontyphoidal *Salmonella* are resistant to ceftriaxone, with another 3% showing some level of resistance to ciprofloxacin. Five percent of nontyphoidal *Salmonella* tested by CDC are resistant to five or more types of drugs.[129]

***Infections due to* Salmonella enterica *Subspecies* arizonae.** *S. enterica* subsp. *arizonae* resembles salmonellae antigenically, clinically, and epidemiologically. It was first recovered in 1939 from diseased reptiles in Arizona, and was initially called "*Salmonella* sp. Dar-es-salaam type, variety from Arizona."[83] It was later distinguished from *Salmonella* and placed in the new genus *Arizona*, with a single species *A. hinshawii*. However, in 1983, it was again reclassified as a serotype of the genus *Salmonella* based on DNA homology studies. Although most *Salmonella* serotypes cannot be distinguished by biochemical reactions, *S. enterica* subsp. *arizonae* can be easily differentiated on the basis of having positive malonate and negative dulcitol reactions. In addition, some strains ferment lactose, and all strains are ONPG-positive. As a result of these unique biochemical reactions, a correct serotype designation can be easily made by most of the commercially available identification systems. For clinical significance, see Clinical Correlation Box 6-4.

***New Methods for Recovery and Characterization of* Salmonellae.** In addition to the classic media discussed previously (see Tables 6-1 through 6-3), new media have been described that are intended to improve the isolation of *Salmonella* species from stool samples.

Selective and Differential Media. These include novobiocin–brilliant green–glucose agar (NBG),[181] novobiocin–brilliant green–glycerol–lactose agar (NBGL),[533,568] xylose–lysine–Tergitol 4 (XLT4) medium,[440] and modified semisolid Rappaport Vassiliadis medium (MSRV).[26,180,259] The formulations and differential properties of these media are displayed in Table 6-13.

Chromogenic Media. Chromogenic enzyme substrates are compounds that act as the substrate for specific enzymes and change color due to the action of the enzyme on the chromogenic substrate (Fig. 6-6). The first medium of this type was Rambach

agar. It uses a chromogenic substrate for β-galactosidase (X-Gal, 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside) in conjunction with propylene glycol, which is fermented by *Salmonella* spp. to generate acid.[548] Rambach agar is highly specific; however, it does not detect *S.* Typhi and *S.* Paratyphi A.[195,196,526] SM-ID agar is similar to Rambach except that it incorporates two chromogenic substrates, X-Gal, for β-galactosidase, and X-GLU, for β-glucosidase. SM-ID medium detects both Typhi and Paratyphi A serotypes.[195,196,444,515,526,568] *Salmonella* chromogenic

CLINICAL CORRELATION BOX 6-4 *Salmonella arizonae*

Reptiles, particularly snakes, are the main natural reservoir of *S. arizonae*, but humans, poultry, and other animals have also contracted disease from this organism. Human infection should trigger inquiries of a possible connection with reptiles as well as poultry and egg products. *S. arizonae* infection in cancer patients and HIV-positive patients following consumption of snake powder capsules as a folk remedy have been reported by several investigators.[28,102,216,658] A fatal infection of *S. arizonae* gastroenteritis has been reported in a child with microcephaly born to a family of snake charmers in New Delhi, India.[409]

The clinical spectrum of disease varies from benign gastroenteritis to enteric fever and septicemia with localized infection, and is similar to that caused by other *Salmonella* serotypes. Keren et al. reported that gastroenteritis may be seen in any age group and is characterized by cramping abdominal pain, diarrhea (often watery), nausea, vomiting, and low-grade fever.[344] Diarrhea is usually self-limited and lasts from 1 to 5 days. Septicemia may follow, but has also been reported in the absence of gastroenteritis. Localized infection in diverse organ sites, such as brain, bone, liver, lung, joints, and gallbladder, is presumed, although not always documented, to occur following bacteremia. Instances of osteomyelitis caused by this organism have been well-documented.[344] The prevalence of human infections caused by *S. arizonae* is probably underreported because the gastrointestinal symptoms are usually mild. However, this pathogen should be considered in the differential diagnoses of patients with sepsis and severe gastroenteritis who have a history of contact with reptiles, especially snakes. Ownership of reptiles should be discouraged, especially in households with children under 5 years of age.[409]

TABLE 6-13 New Media for Recovery of *Salmonella* Species From Stool

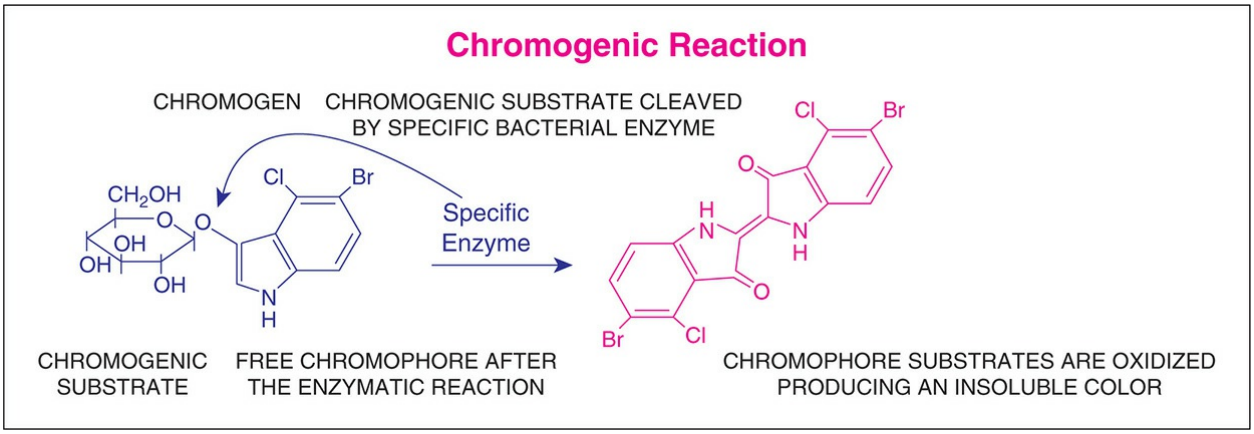
Medium	Formulation	Principle and Interpretation
Novobiocin–brilliant green–glucose agar (NBG)	Tryptic soy agar, 40 g Ferric ammonium citrate, 1.5 g Sodium thiosulfate pentahydrate, 5 g Phenol red (sodium salt), 80 mg Glucose, 1 g Brilliant green, 7 mg Novobiocin, 10 mg Distilled water to1 L Final pH 7.3	*Salmonella* colonies appear smooth and entire with medium- to large-sized, dark black, nucleated centers owing to H_2S production. In addition, reddening and a visible zone of clearing occur in the medium around each colony. Coliforms are either inhibited or fail to produce black-centered colonies. Some *Citrobacter freundii* strains produce colonies indistinguishable from *Salmonella* species.
Novobiocin–brilliant green–glycerol lactose agar (NBGL)	Trypticase soy agar, 40 g Ferric ammonium citrate, 1.5 g Sodium thiosulfate, 5 g Lactose, 10 g Glycerol, 10 mL Brilliant green, 7 mg Novobiocin, 10 mg Distilled water to 1 L	The detection of *Salmonella* spp. is based on the production of H_2S resulting in black colonies. Sufficient H_2S formation is achieved only by colonies that do not produce acid from glycerol or lactose, because a low pH interferes with H_2S formation. This results in colorless colonies for most *Proteus* and *Citrobacter* species.
Rambach agar	Propylene glycol, 10 g Peptone, 5 g Yeast extract, 2 g Sodium desoxycholate, 1 g Neutral red, 0.03 g 5-Bromo-4-chloro-3-indolyl-β-D-Galactopyranoside, 0.1 g Agar, 15 g Distilled water to 1 L	Detects ability of *Salmonella* spp. to metabolize propylene glycol. Suspect colonies on this medium are usually bright red. Contains moderate amount of bile salts to inhibit coliforms.
SM–ID agar	Beef extract, 3 g Bio-Polytone, 6 g Yeast extract, 2 g Bile salts, 4 g Neutral red, 0.025 g Tris buffer, 0.65 g Brilliant green, 0.3 mg Chromogen substrate 1 (galactopyranoside), 0.17 g Sodium glucuronate, 12 g Chromogen substrate 2 (glucopyranoside), 0.026 g Sorbitol, 8 g Agar, 3.5 g Distilled water to 1 L Final pH 7.6 ± 0.2	Detection of *Salmonella* spp. is based on the formation of acid from the glucuronate and on the absence of β-galactosidase. *Salmonella* serotypes produce pinkish red colonies (sometimes with a colorless rim), whereas coliforms form other colors (green, blue, or violet) if they are positive for β-galactosidase, or remain colorless. Contains moderate amount of bile salts to inhibit coliforms.

265

Modified Semisolid Rappaport–Vassiliadis Medium (MSRV)	Tryptose, 4.59 g Casein hydrolysate acid, 4.59 g Sodium chloride, 7.34 g Potassium dihydrogen phosphate, 1.47 g Magnesium chloride (anhydrous), 10.93 g Malachite green oxalate, 0.037 g Agar, 2.7 g Distilled water to1 L Novobiocin (2% solution) added after sterilization, 1 mL Final pH 5.2 ± 0.2	Based on the swarming phenomenon of motile bacteria (*Salmonella* spp. and others) at reduced agar concentrations. After incubation, the plates are checked for motile bacteria that appear as a halo of growth spreading out from the original inoculation point. Subcultures are taken from the edge of migration to check for purity and for further biochemical and serologic tests. Coliforms are inhibited by a combination of increased osmotic pressure, malachite green, and incubation at 41°C–43°C.
Xylose–Lysine–Tergitol 4 (XLT4)	Bacto proteose peptone No. 3, 1.6 g Bacto yeast extract, 3.0 g L-lysine, 5.0 g Bacto xylose, 3.75 g Bacto lactose, 7.5 g Bacto saccharose, 7.5 g Ferric ammonium citrate, 0.8 g Sodium thiosulfate, 6.8 g Sodium chloride, 5 g Bacto agar, 18 g Bacto phenol red, 0.08 g Distilled water to 1 L Final pH 7.4 ± 0.2	This is a highly selective medium that substitutes the anionic surfactant Tergitol 4 for sodium desoxycholate found in XLD agar. The XLT4 agar completely inhibits the growth of all gram-positive bacteria and fungi, and either completely or strongly inhibits the growth of numerous gram-negative bacteria including *Proteus*, *Providence*, and *Pseudomonas*. In addition, *Citrobacter* species are somewhat inhibited and very rarely produce colonies with black centers after overnight incubation. *Salmonella* colonies (H_2S-positive) appear black or black centered with a yellow periphery after 18–24 hours' incubation. After continued incubation, the colonies become entirely black or pink to red with black centers. Rare strains of *Salmonella* that produce no H_2S display pink to pinkish yellow colonies that can be differentiated from bright yellow non–salmonellae colonies.
Modified ABC medium (αβ-chromogenic medium with alafosfalin)	Bacteriologic agar, 10 g L-arginine, 0.1 g L-aspartic acid, 0.1 g L-cysteine, 0.005g Glycine, 0.1g L-histidine, 0.1g L-isoleucine, 0.1g L-leucine, 0.1g L-lysine, 0.1g L-methionine, 0.005g L-phenylalanine, 0.1g L-proline, 0.1g L-serine, 0.1g L-threonine, 0.1g L-tryptophan, 0.1g L-tyrosine, 0.1g L-valine, 0 .1g Guanine, 0.01g Uracil, 0.01g Cytosine, 0.01g Adenine, 0.01g Sodium citrate, 6.5g Magnesium sulfate, 0.1g Ammonium sulfate, 1g Yeast extract, 0.1g Dipotassium hydrogen phosphate, 7g Potassium dihydrogen phosphate, 2g Chromogen Mix: Ferric ammonium citrate, 0.5g X-α-Gal, 0.08g CHE-Gal, 0.3g IPTG, 0.03g Distilled water to 1L Ingredients added after sterilization: Sodium deoxycholate, 0.5g Alafosfalin final concentration range in agar of 32–0.125 mg/L (Perry et al.[518])	*Salmonella* yield blue colonies; other *Enterobacteriaceae* yield black colonies. Alafosfalin is taken up by bacteria at different rates via a stereospecific permease and may be cleaved intracellularly by an aminopeptidase to yield fosfalin. This released compound interferes with bacterial metabolism via interaction with the alanine racemase enzyme responsible for generating D-alanine. This interaction may result in growth inhibition.[518]

BBL CHROMagar Salmonella (sold by BD under a licensing agreement with CHROMagar, Paris, France)	Chromopeptone, 22.0 g Chromogen mix, 0.34 g Inhibitory Agents, 0.02 g Agar, 15.0 g Distilled water to 1 L	*Salmonella* spp. appear as light mauve to mauve-colored colonies. *Citrobacter freundii* and other coliforms appear as light blue-green to blue-green colored colonies. Some organisms that do not hydrolyze any of the chromogenic compounds may appear as colorless colonies (Image Plates 6-5E through H).

Note: Rambach, XLT4, MSRV, NBG, and NBGL are not suitable for use in the isolation of Typhoid *Salmonella* serotypes.



■ **FIGURE 6-6** Chromogenic reaction: artificial substrates (chromogens) release differently colored compounds upon degradation by specific bacterial enzymes.

medium (SCM; Oxoid, Basingstoke, United Kingdom) contains two chromogenic substrates. The first is Magenta-cap (5-bromo-6-chloro-3-indolylcaprylate), which is hydrolyzed by *Salmonella* species to yield magenta colonies. The second substrate is X-Gal, which causes β-D-galactosidaseproducing organisms to turn blue. Other colonies that do not utilize the chromogens grow as colorless colonies.[97] ABC medium (α, β-chromogenic medium) uses two chromogenic substrates. The first substrate, 3,4-cyclohexenoesculetin-β-D-galactoside (CHE-GAL), is used to detect β-galactosidaseproducing organisms that appear as black colonies in the presence of iron. The second substrate, 5-bromo-4-chloro-3-indolyl-α-D-galactopyranoside (X-α-Gal), is hydrolyzed by *Salmonella* spp., which appear as green colonies.[472,515,517] Perry and colleagues subsequently modified ABC medium with the incorporation of alafosfalin (L-alanyl-1-aminoethylphosphonic acid), a "suicide substrate," that aids in the recovery of *Salmonella* spp. by inhibiting the growth of a wide range of gram-negative bacteria.[518] COMPASS Salmonella agar (Biokar Diagnostics, Beauvais, France) utilizes two chromogenic substrates—5-bromo-6-chloro-3-indolylcaprylate, which detects esterase activity from *Salmonella* spp. yielding magenta colonies, and 5-bromo-4-chloro-3-indolyl-glucopyranoside, which detects β-glucosidase activity from other *Enterobacteriaceae* yielding blue colonies.[515] CHROMagar Salmonella (CHROMagar Microbiology, Paris, France; also sold by BD under the name BBL

CHROMagar Salmonella, BD Diagnostics Sparks, MD) is a newer selective chromogenic medium that uses a chromogen mixture (patented substrates) that detects esterase activity of *Salmonella* spp. and β-galactosidase activity of other *Enterobacteriaceae*.[203,244,407,515] The formulas, principles, and interpretations of the chromogenic agars are given in Table 6-13. Pictures of colonies growing on CHROMagar can be found in Image Plates 6-5E through H)

Evaluations. In a study by Ruiz and associates[568] comparing five plating media for isolation of *Salmonella*, NBGL media had the highest sensitivity (78.4%) and positive predictive value (61%) for direct recovery of *Salmonella* from stool. These authors recommend the use of SM-ID for recovery of *S.* Typhi, which is not detected on NBGL agar. Monnery and colleagues found SM-ID and Rambach agars to be considerably more specific than SS agar and Hektoen agar.[444] Dusch and Altwegg compared six media (HE agar, Rambach agar, SM-ID medium, XLT4 agar, NBGL agar, and MSRV medium) and concluded that MSRV was the most sensitive medium tested for the isolation of nontyphoid salmonellae from stool; however, these authors noted that the semisolid nature of the medium was a disadvantage and requires careful handling in the laboratory. They noted that XLT4 had sensitivity comparable with HE and nearly 100% specificity and can be considered an alternative for the isolation of salmonellae from stools.[196] Perez and colleagues[515] compared four chromogenic media (ABC medium, COMPASS Salmonella agar, CHROMagar Salmonella agar, and SM-ID agar) with conventional Hektoen agar on 916 stool samples from

267

inpatients at three hospitals. After 48 hours of incubation, the sensitivity before and after enrichment in selenite broth was 62.5% and 89.1% with ABC medium, 77.1% and 93.8% with COMPASS agar, 66.7% and 89.1% with CHROMagar, 68.8% and 85.9% with SM-ID agar, and 85.4% and 98.4% with Hektoen agar, respectively. Without enrichment, after 24 hours of incubation, between 45.8% and 62.5% of all the *Salmonella* isolates were detected, according to the medium used. Hektoen was significantly more sensitive than the four chromogenic media, whereas the sensitivities of the four chromogenic media were not significantly different from each other. With enrichment and a 48-hour incubation period, Hektoen agar again had the highest sensitivity (98.4%), whereas the sensitivities of COMPASS, ABC, CHROMagar, and SM-ID were 93.8%, 89.1%, 89.1%, and 85.9%, respectively.[515]

Other Rapid Detection Methods. The 4-methylumbelliferyl caprylate test (MUCAP test; Biolife, Milan, Italy) is a fluorescence test for rapid identification of *Salmonella* strains directly from agar plates. The test consists of an eight-carbon-atom ester conjugated with methylumbelliferone (MEU). This substrate interacts with the *Salmonella* C8 esterase, leading to release of umbelliferone, which is strongly

fluorescent at 365 nm. The test is performed by applying a drop of the reagent directly onto suspect colonies on the agar surface and then observing for the appearance of blue fluorescence of the colony under a Wood's lamp within 5 minutes. Several studies have shown this test to provide nearly 100% sensitivity and specificity in detecting *Salmonella* strains and to offer a useful and rapid adjunct to routine biochemical characterization of *Salmonella* strains.[12,493,570,571] The Oxoid Biochemical Identification System (O.B.I.S.) Salmonella Test (Oxoid) is a rapid colorimetric spot test for the determination of pyroglutamyl aminopeptidase (PYRase) and nitrophenylalanine deaminase (NPA) activity. A sample is taken from a colony growing on an agar plate and applied to the PYR and NPA test areas on the card. A drop of buffer solution is added to both test areas, and after 5 minutes, one drop of PYR developing solution is added to the PYR test area, and one drop of NPA developing solution is added to the NPA test area. The PYRase area on the Test Card is impregnated with L-pyroglutamic acid 7-amino-4-methylcourmarin (7AMC). The enzymatic hydrolysis of the substrate produces a purple color on addition of the PYR developing solution (dimethylaminocinnamaldehyde). The NPA area on the Test Card is impregnated with nitrophenylalanine. Deamination of the reagent is shown by an orange–brown color when the NPA developing solution (0.25M sodium hydroxide) is added. The lack of PYRase and NPA activity in *Salmonella* spp. can be used to differentiate them from *Citrobacter* spp., which possess PYRase activity,[131,307,448] and *Proteus*, *Morganella,* and *Providencia* spp., which have NPA activity.[252]

Molecular Detection Methods. Molecular methods performed directly on stool specimens collected in stool transport media can increase sensitivity and specificity for detection of *Salmonella* and other enteric pathogens compared to stool culture.[271,497,527] Several real-time polymerase chain reaction (PCR) assays have been evaluated and reported to offer reliable detection of enteric pathogens at concentrations 1-to 2-$\log_{10}$ lower than those needed for culture detection.[19,80,159,391,392]

Other new techniques are being introduced that may significantly alter the future identification of *Salmonella* species, both in the clinical laboratory and in epidemiologic field studies. As an example of new applications, Olsvik and associates[494] traced the transmission of *S.* Typhimurium strains from diseased cattle in four separate herds in Norway to human farm workers, by demonstrating identical cryptic plasmid profiles for the various isolates by using restriction endonuclease digestion techniques. As these authors point out, conventional serotyping and biotyping techniques are often not sufficiently specific to determine definitively that two or more isolates from different sources are, in fact, identical. Matrix-assisted laser desorption/ionization time-offlight (MALDI-TOF)–based intact cell mass spectrometry (ICMS) has been used to identify salmonellae at the species and subspecies level[183]

and for rapid discrimination of *S.* Typhi from other *Salmonella* serovars when performed on isolates recovered from blood cultures.[369] Techniques such as MALDI-TOF, restriction endonuclease analysis, or genetic probes will make epidemiologic and diagnostic work in microbiology much more exacting in the future. These techniques are discussed in more detail in Chapter 4.

Tribe *Citrobactereae.* The *Citrobactereae* contains a single genus—*Citrobacter*—and 11 species.

Genus *Citrobacter.* The genus *Citrobacter* and the species *C. freundii* were designated in 1932 by Werkman and Gillen. In 1970, Frederiksen described a new species that he named *C. koseri*. In 1971, Young and coworkers proposed the name *Levinea malonatica* for a similar group of organisms, and in 1972, Ewing and Davis described *Citrobacter diversus*. Frederiksen examined all three strains and determined that they were phenotypically alike, and proposed that the name *C. koseri* be restored as the valid name for this taxon.[236] In 1993, Brenner and colleagues, using DNA relatedness studies, showed that organisms identified as *C. freundii* consisted of a heterogeneous group representing several genetic species.[67] This work led to the establishment of 11 genomospecies within the genus *Citrobacter*, as shown in Table 6-14.

The characteristics that suggest that an isolate may belong to the genus *Citrobacter* are listed in Table 6-6. The key characteristics that differentiate *C. freundii* and other H_2S-positive Citrobacters from salmonellae are growth in KCN (*Salmonella* species are negative), absence of lysine decarboxylase activity (*Salmonella* species are positive), and the hydrolysis of ONPG (*Salmonella* species are negative). The biochemical differentiation among the *Citrobacter* species is shown in Table 6-15. Human isolates of all genomospecies except *C. koseri* have been obtained predominantly from stools.[67] Farmer and coworkers,[220] who reviewed strains referred to the CDC, cited *C. freundii* as a possible cause of diarrhea (although most fecal isolates do not appear to be associated with disease) and as a cause of isolated cases of extraintestinal infections. They also cite a possible association between *C. koseri* and outbreaks of meningitis and brain abscesses in neonates, and report the recovery of *C. amalonaticus* from a few blood cultures. Janda and colleagues at the Microbial Diseases Laboratory in Berkeley, California, reported that *C. freundii* was the most common species identified from all body sites except feces. In gastrointestinal specimens, *C. freundii* ranked fourth behind *C. youngae, C. braakii*, and *C. werkmanii*.[324]

C. freundii (complex) has been reported as a cause of gastrointestinal illness

associated with imported Brie cheese,[103] and isolation of a *C. freundii* strain that carries the *E. coli* O157 antigen has been reported.[46] *C. koseri* has been isolated most often from urine and respiratory tract specimens.[291,400] *C. koseri* has also been reported with increasing frequency as a cause of sporadic and epidemic meningitis in neonates and young infants.[261,358,359,506,649] Brain abscesses are found in 75% of infants with *C. koseri* meningitis, a prevalence far higher than that reported for other bacteria that cause meningitis.[262,358] One-third of infants with *C. koseri* meningitis die, and at least 75% of survivors have severe neurologic impairment.[262] Other reports corroborate the tendency for *C. koseri* to cause meningitis and brain abscesses, particularly in association with the anaerobic gram-negative bacillus *Prevotella melaninogenica*.[23,160,384] *C. sedlakii* was isolated from the blood and cerebrospinal fluid of a 5-day-old premature infant seen with sepsis, meningitis, and a brain abscess at the University of Illinois Medical Center.[197] The child was treated with ampicillin, piperacillin, and cefotaxime. By day 14, the infant was clinically stable, and the therapy was changed to intravenous cefotaxime and oral cotrimoxazole. The child was discharged after 8 weeks to complete 2 more weeks of oral cotrimoxazole therapy at home. At 5½ months of age, a computed tomographic scan of the brain showed resolution of all abscess cavities. Additional isolates of *C. sedlakii* at the University of Illinois have been from urine and an infected arteriovenous graft of the leg. Of 13 *C. braakii* identified at the University of Illinois Medical Center, 5 were recovered from urines, 4 from peritoneal fluids, 1 from an abdominal wound, 2 from endotracheal specimens, and 1 from a bronchial specimen. *C. farmeri* isolates at the University of Illinois have been from stool, urine, abdominal wall tissue, and aqueous fluid. Bruckner and colleagues reported a case of *C. farmeri* bacteremia in a child with short-bowel syndrome in whom a septic episode developed shortly after commencement of a total parenteral nutrition (TPN) infusion.[79] Only three *C. gillenii* isolates have been recovered at

the University of Illinois from three separate sources: urine, peritoneal fluid, and a central venous catheter tip. Most *C. youngae* isolates have been recovered from urine. *C. rodentium* has been isolated only from rodents and causes a disease in laboratory mice known as transmissible murine colonic hyperplasia.[401,581]

Identification of *Citrobacter* species is hampered because the new species are not yet included in the databases of most commercial identification systems. To assist laboratories in speciating the new *Citrobacter* species, O'Hara and colleagues[481] have published a dichotomous key using conventional biochemical tests. The susceptibility pattern of isolates also offers an aid to identification. *C. koseri* has an antibiotic

susceptibility pattern similar to *Klebsiella* (i.e., resistant to ampicillin and ticarcillin), whereas *C. freundii* has a pattern more typical of *Enterobacter* species (i.e., resistant to ampicillin and first-generation cephalosporins).

Tribe *Klebsielleae*. The tribe *Klebsielleae* includes four major genera—*Klebsiella, Enterobacter, Hafnia, and Serratia*—each of which includes several species that are overt and opportunistic pathogens in humans. A new, fifth genus, *Pantoea*, has been added to accommodate the reclassification of the organism formerly named *Enterobacter agglomerans* biotype XIII and now called *Pantoea agglomerans*.[248] The key characteristics suggesting that an unknown isolate belongs to the *Klebsielleae* are listed in Table 6-6. The biochemical differences between the major genera and species within the tribe are presented in Table 6-16.

Genus *Klebsiella*. The genus *Klebsiella* was named after Edwin Klebs, a late–19th-century German microbiologist. The bacillus, now known as *Klebsiella,* was also described by Carl Friedlander, and for many years the "Friedlander bacillus" was well known as a cause of severe, often fatal, pneumonia. The genus includes six species: *K. pneumoniae, K. oxytoca, K. granulomatis, K. variicola, K. singaporensis*, and *K. alba*. *K. pneumoniae* is the type species of this genus.

***Taxonomic Changes in the Genus* Klebsiella.** In 2001, Drancourt and colleagues[187] performed a comparative analysis of the sequences of the 16S rRNA and *rpoB* genes (encoding the bacterial RNA polymerase β-subunit) of the type stains of nine *Klebsiella* species. Their findings confirmed that *Klebsiella* is heterogeneous and composed of species that form three phyletic clusters. Cluster I comprises *K. pneumoniae* subspecies *pneumoniae*, *rhinoscleromatis*, and *ozaenae*, and *K. granulomatis*; cluster II contains *K. ornithinolytica*, *K. planticola*, *K. trevisanii*, and *K. terrigena*; and cluster III contains *K. oxytoca*.[187] On the basis of this evidence, they proposed that the genus *Klebsiella* be divided into two genera, *Klebsiella* and *Raoultella* (named after the French bacteriologist Didier Raoult), and that *K. oxytoca* should be left as a monophyletic taxon. Species included in cluster I are retained in the genus *Klebsiella*, whereas species included in cluster II are transferred to the new genus *Raoultella*.[187] Granier et al.[263] have further shown that the *K. oxytoca* taxon is divided into two clades, which correspond to two genetic groups, called oxy-1 and oxy-2.[264] In 1999, *Calymmatobacterium granulomatis*, the presumed causative agent of donovanosis, was reclassified as *K. granulomatis* on the basis of phylogenetic data.[95,346] Finally, three novel environmental species have been added to the genus, namely, *K. variicola,*[566] *K. singaporensis,*[385]and *K. alba*[680] that have been isolated from plants and soil samples.

Klebsiella and *Raoultella* species are widely distributed in nature and in the gastrointestinal tracts of humans and animals. A *Klebsiella* species should be

suspected when

large colonies with a mucoid consistency are recovered on primary isolation plates. On MacConkey agar, the colonies typically appear large, mucoid, and purple, indicating fermentation of lactose and acid production (see Image Plate 6-1E). Not all strains, however, are mucoid, and certain species of *Enterobacter* can closely simulate the *Klebsiella* species in screening tests. All *Klebsiella* and *Raoultella* species are nonmotile, and most do not decarboxylate ornithine (*R. ornithinolytica* is ornithine-positive)—characteristics that are positive for most *Enterobacter* species. Many strains of *Klebsiella* and *Raoultella* hydrolyze urea slowly, producing a lightpink color in the slant of Christensen's urea agar. Production of indole from tryptophan can be used to separate the two principal species. *K. pneumoniae* is indole-negative, and *K. oxytoca* is indole-positive. Certain strains do not produce these classic reactions, which led to the naming of several additional species. See Table 6-17 for a listing of the characteristics by which these various species can be differentiated.

K. pneumoniae is most frequently recovered from clinical specimens and can cause a classic form of primary pneumonia. It is infrequently found in the oropharynx of normal persons (1% to 6% carrier rate)[557]; however, a prevalence as high as 20% may

occur in hospitalized patients. This colonization may prove to be the source of lung infections that generally occur in patients with debilitating conditions such as alcoholism, diabetes mellitus, and chronic obstructive pulmonary disease.[557] The pneumonia tends to be destructive, with extensive necrosis and hemorrhage, resulting in the production of sputum that may be thick, mucoid, and brickred, or thin and "currant jelly-like" in appearance. Lung abscesses, chronic cavitary disease, internal hemorrhage, and hemoptysis may be seen in severe cases. Pleuritis is commonly present, which explains why pleuritic pain is found in about 80% of patients. *K. pneumoniae* can also cause a variety of extrapulmonary infections, including enteritis and meningitis (in infants), urinary tract infections (in children and adults), and septicemia.

A new, hypervirulent clinical variant of *K. pneumonia* (hvKP) has emerged over the last two decades. Initial reports were from countries in the Asian Pacific Rim (e.g., Taiwan, Korea, Vietnam, and Japan) describing a unique clinical syndrome of community-acquired *K. pneumonia* infections presenting as pyogenic liver abscesses with a propensity for metastatic spread to distant sites.[139,393,655] Subsequently, an increasing number of cases are now being reported in North America,[235,345,377,421,454] South America,[647] the Carribbean,[185] and other continents around the world.[175,208,272,601,637,685] A combination of clinical and bacterial phenotypic features defined this new hvKP strain: (1) its ability to cause infection in ambulatory, healthy patients, (2) unusual sites of infection (e.g., liver, eye, CSF), (3) ability for metastatic spread, and (4) production of hypermucoviscous colonies when grown on agar plates.[593] The hypermucoviscous colonies are demonstrated by a positive "string test." The string test is positive when a bacteriology inoculation loop or needle is able to generate a viscous string >5 mm in length by touching the bacterial colony and raising the loop above the rim of the agar plate, creating a string of bacteria (see Image Plate 6-2H). Because of the unique and severe clinical features of these hvKP strains, laboratories should consider reporting *K. pneumoniae* strains that demonstrate a positive string test as "hypervirulent *K. pneumoniae*." For more on this topic, see review by Shon and colleagues.[593]

K. pneumoniae *Carbapenemase.* *K. pneumoniae* that produce *K. pneumoniae* carbapenemase (KPC) have rapidly spread across hospitals worldwide in the past decade.[61,466,677] KPC-producing *K. pneumoniae* isolates are typically resistant to carbapenems (ertapenem, doripenem, imipenem,

meropenem) as well as penicillins, cephalosporins, fluoroquinolones, and frequently also aminoglycosides. Because carbapenemase resistance can occur in species of *Enterobacteriaceae* other than *K. pneumoniae*, the phrase "Carbapenem-Resistant *Enterobacteriaceae* (CRE)" has been coined as the preferred term when referring to these multidrugresistant strains. Detection of CRE-producing bacteria may be difficult based on routine antibiotic susceptibility testing. It is therefore crucial to implement efficient infection control measures to limit the spread of these pathogens.[130] Surveillance cultures have been applied effectively as part of the multifaceted nationwide interventional strategy to decrease the spread of CREs using either selective broth or agar plates containing carbapenems or carbapenem disks[9,375,396] or selective chromogenic media such as CHROMagar KPC-Colorex KPC (CHROMagar, Paris, France),[9,255,574,669] Brilliance CRE (Oxoid, Thermofisher Scientific, Lenexa KS),[171,255] chrom ID CARBA (bioMerieux, Marcy l'Etoile, FR),[651,669] and SUPRA-CARBA.[255,467] For more on CREs, refer to Chapter 17.

K. ozaenae and *K. rhinoscleromatis* are infrequent isolates that are now considered to be subspecies of *K. pneumoniae*; however, each is associated with a unique spectrum of disease. *K. ozaenae* is associated with atrophic rhinitis, a condition called ozena, and purulent infections of the nasal mucous membranes. Janda and colleagues[326] have also reported a case of corneal abscess caused by *K. ozaenae*. Reports of the isolation of *K. ozaenae* from blood, urine, and soft tissue suggest that the spectrum of disease caused by this organism is more extensive than had been

thought previously.[258] *K. rhinoscleromatis* causes the granulomatous disease rhinoscleroma, an infection of the respiratory mucosa, oropharynx, nose, and paranasal sinuses. Clinical correlations should be made when these species are recovered in cultures to determine their medical significance in individual cases. Even though these two species are no longer considered to be true species but, rather, biochemically inactive strains of *K. pneumoniae*,[64] we believe that there is medical relevance in reporting the names *K. ozaenae* and *K. rhinoscleromatis* because of the specific disease association of these two strains.

Nearly half of the isolates of *K. oxytoca* submitted to the CDC have been from feces, with the next most common source being blood.[220] *K. oxytoca* has now been shown to be the causative agent of antibiotic-associated hemorrhagic colitis (AAHC).[294] AAHC is a distinct form of antibioticassociated diarrhea, in which *C. difficile* is absent and patients experience a sudden onset of bloody diarrhea often in combination with severe abdominal cramps. AAHC is most commonly associated with the use of penicillins, quinolones, and cephalosporins.[294,522] Colonoscopy usually reveals extensive hemorrhage and inflammation in the lamina propria, with lack of pseudomembranes. Spontaneous resolution usually occurs shortly after cessation of the antibiotic.[522] For unknown reasons, *K. oxytoca* AAHC has been associated with concurrent use of nonsteroidal anti-inflammatory drugs.[294,522]

Because of the role of *K. oxytoca* in the pathogenesis of AAHC, laboratories should report *K. oxytoca* from stool cultures when present in significant amounts. For the majority of patients with AAHC, stool testing reveals *K. oxytoca* in significant amounts ($>10^6$ CFU/mL)[689] In our experience, patients with this condition present with nearly pure cultures of *K. oxytoca* in their stool. When reporting *K. oxytoca* from stool cultures, laboratories may want to consider adding a comment to the laboratory report as follows: "Toxigenic strains of *K. oxytoca* have been reported to cause AAHC. Patients usually respond to withdrawal of antimicrobial agents." *K. oxytoca* is not a cause of nonhemorrhagic colitis.[689] Therefore, testing for *K. oxytoca* is warranted only for patients experiencing bloody diarrhea during antibiotic therapy with significant quantities of *K. oxytoca* in their stool culture.

Genus *Raoultella*. In 2001, based on 16S rRNA gene and rpoB sequence analysis, the new genus *Raoultella* was created to accommodate three members of the genus *Klebsiella* Cluster II that were renamed: *Raoultella ornithinolytica, Raoultella terrigena,* and *Raoultella planticola*.[187]

R. ornithinolytica is found in aquatic environments, fish, and ticks[445] and is a rare human pathogen; however, several cases of *R. ornithinolytica* bacteremia have been reported.[275,279,417,445,576] The more recently named species, *R. terrigena*[311] and *R. planticola*,[32] reflect their sources in nature. *R. terrigena* closely resembles *K.*

pneumoniae and has been isolated mainly from soil and water. Human isolates have been recovered from the feces of healthy humans[530] and the respiratory tract[528]; however, their capacity to cause human infection has not been shown. *R. planticola* (synonym *K. trevisanii*)[227,247] has been isolated primarily from botanical and aquatic environments. Early reports of human isolates were from the respiratory tract, urine, cerebrospinal fluid, and blood,[237,238] with the majority of isolates representing colonization, rather than infection. More recent reports suggest that *R. planticola* may be the cause of severe pancreatitis,[17] cholangitis with septic shock,[682] bacteremia,[303] urinary tract infection,[492] acute prostatitis,[366] chronic conjunctivitis,[690] and may be regarded as an emerging pathogen.[210]

Studies from France and Germany suggest that up to 19% of *Klebsiella/Raoultella* species are actually *R. planticola*[446,529,531]; however, the occurrence of *R. planticola* in the United States appears to be less frequent.[668] One problem might be the separation of *R. planticola* from *R. ornithinolytica,* which are closely related species that can be distinguished from each other by very few biochemical tests. *R. planticola* are ornithine decarboxylase (ODC) negative and indole variable, whereas *R. ornithinolytica* are positive for ODC and indole-negative. ODC-negative strains of *R. ornithinolytica* have been described, and these would likely be identified as *R. planticola* or *K. oxytoca* by phenotypic methods.[504,653] In a comparison of three phenotypic identification systems, Park et al.[504] reported that 27/27 *R. ornithinolytica* clinical isolates were identified as *R. ornithinolytica* by Vitek 2; however, MicroScan identified 25/27 (92.6%) as *K. oxytoca,* and API 20E identified 24/27 (88.9%) as *K. oxytoca* using sequence-specific primer PCR as the reference identification method. Similarly, de Jong et al.[177] reported difficulty in separating *Raoultella* species by MALDI-TOF mass spectrometry (MALDI-TOF MS) because mass spectra from *R. planticola* and *R. ornithinolytica* are highly similar and resemble those from *K. oxytoca*.

The higher incidence of infections due to *Klebsiella* species during the past decade probably reflects both an increase in nosocomial infections in debilitated or immunosuppressed patients and a trend toward greater antibiotic resistance. In

the United States, *Klebsiella* accounts for 3% to 7% of all nosocomial bacterial infections, placing them among the eight most important infectious pathogens in hospitals.[532] *Klebsielleae* have a tendency to harbor antibiotic-resistant plasmids; thus, infections with multiple antibiotic-resistant strains can be anticipated. Virtually all clinical strains are resistant to ampicillin, carbenicillin, and ticarcillin. Of particular

concern is the recent appearance of *Klebsiella* strains that possess plasmids that mediate resistance to extended-spectrum β-lactam drugs. This form of resistance is due to the production of unique β-lactamase enzymes, referred to as ES-BLs.[327,394] These enzymes have been seen mostly in strains of *K. pneumoniae* and *E. coli,* and cause them to be resistant to most β-lactam drugs, including the third-generation cephalosporins. A unique feature of ESBLs is their ability to escape detection with most of the commonly used susceptibility tests and the resultant concern that organisms possessing ESBLs are reported to be susceptible to antibiotics to which they are, in fact, resistant.[316,432] In addition, carbapenem resistance among *K. pneumoniae* strains has become widespread in the United States and throughout the world due to the dissemination of strains that carry bla_{KPC} plasmid.[61,677,466] This subject is discussed earlier in this chapter and in more detail in Chapter 17.

K. granulomatis (formerly *C. granulomatis*)[95] is a fastidious gram-negative encapsulated bacillus found intracytoplasmically within macrophages. It is the etiologic agent of granuloma inguinale (also known as Donovanosis), a sexually transmitted disease involving the genitalia and surrounding sites.[561] It is found in specific geographic foci, namely, New Guinea, northwest Australia, southeast India, the Caribbean, parts of South America, parts of central Africa, and the Kwa-Zulu/Natal region of South Africa.[347] *K. granulomatis* cannot be cultured on conventional agar media, although it has been successfully grown in embryonated eggs and in a monocyte coculture system.[347] Currently, the laboratory diagnosis of granuloma inguinale relies on the observation of "Donovan bodies" in tissue smears or biopsy specimens examined by Giemsa and Wright stains. To increase the specificity of the diagnosis, Dieterle's, Warthin–Starry,[266] and rapid Giemsa (Diff Quick)[475] stains have been used. A PCR for detection of donovanosis in genital specimens has been reported.[94,96] Azithromycin has emerged as the drug of choice and should be used if the diagnosis is confirmed or suspected.[474]

Genus *Enterobacter*. Because large amounts of gas are produced by many strains of the genus *Enterobacter*, for many years the type species was called *Aerobacter aerogenes*. The genus designation was changed to *Enterobacter* by Hormaeche and Edwards in 1960.[300]

The taxonomy of Enterobacter has a complicated history, with several species transferred to other genera. There were 29 species and subspecies originally included in the genus *Enterobacter*. However, recent polyphasic taxonomic analysis has determined that the nucleotide sequences of some species are not aligned with the genus *Enterobacter,* and as a result, several species have been transferred to 8 different new genera (Table 6-18). As a genus, *Enterobacter* has the general characteristics of the *Klebsielleae*, but can be differentiated from most *Klebsiella* species because they are motile and ornithine-positive. The biochemical characteristics

by which the medically important species can be differentiated are included in Table 6-19.

[a]Table includes only those *Enterobacter* species that have been isolated from human clinical specimens. Isolates that are triple decarboxylase negative may be *Pantoea* species, and isolates that are both lactose- and sucrose-negative but are lysine-positive may be *Hafnia alvei* (Table 6-16).
+, 90% or more strains are positive; −, 90% or more strains are negative; V, 11%–89% of strains are positive; NA, not available.

274

Enterobacter aerogenes and *Enterobacter cloacae* are the species most commonly encountered in clinical specimens. They are widely distributed in water, in sewage, in soil, and on vegetables. They are part of the commensal enteric flora and are not believed to cause diarrhea, although a Shiga-like toxin-producing strain of *E. cloacae* has been isolated from the feces of an infant with hemolytic–uremic syndrome.[508] They are also associated with a variety of opportunistic infections involving the urinary tract, respiratory tract, and cutaneous wounds, and, on occasion, cause septicemia and meningitis.[505] *E. cloacae* is closely aligned with five other *Enterobacter* species namely: *E. asburiae, E. hormaechei, E. kobei, E. ludwigii*, and *Lelliottia [Enterobacter] nimipressuralis.* These six species are collectively referred to as the *E. cloacae* complex. Furthermore, *E. cloacae* is divided into two subspecies: *E. cloacae* subsp. *cloacae* and *E. cloacae* subsp. *dissolvens* (formerly *E. dissolvens*).[293]

Separation of these species and subspecies by phenotypic testing is challenging, and separation using MALDI-TOF MS is not yet possible. As a result, laboratories may wish to report the identification of these species as the "*E. cloacae* complex." The clinical significance of the species in the *E. cloacae* complex has been reviewed by Mezzatesta and colleagues.[434]

E. asburiae (formerly called CDC enteric group 17, or atypical *Citrobacter*) is biochemically similar to *E. cloacae;* however, it is unique among the *Enterobacter* species by being nonmotile and VP-negative. It has been reported from a variety of human sources, including blood, urine, wounds, respiratory tract, and feces.[69] One case of community-acquired pneumonia caused by *E. asburiae* has been reported.[614] We have found considerable variation in the ability of commercial identification systems to correctly identify this species.

E. cancerogenus (formerly called *Erwinia cancerogena*, *Enterobacter taylorae*, and CDC enteric group 19)[221,585] has been reported to cause a variety of clinical infections, including osteomyelitis after an open fracture,[666] wound infection,[552] especially after severe trauma or crush injuries,[2] urinary tract infection,[555,567] and bacteremia and pneumonia.[567] The key biochemical features are lysine-negative, arginine-positive, and ornithine-positive and -negative reactions in adonitol, inositol, sorbitol, raffinose, and melibiose. They are lactosenegative but ONPG-positive, and we have noted that colonies growing on MacConkey agar will develop purple centers after extended incubation.

E. hormaechei was a new species of *Enterobacter* named in 1989 after Estenio Hormaeche, a Uruguayan microbiologist who (with P.R. Edwards) proposed and defined the genus *Enterobacter*.[484] Formerly known as enteric group 75, it is biochemically closest to *E. taylorae* (now *E. cancerogenus*) except it is urea-positive, sucrose-positive, and esculinnegative. Isolates have been reported from blood, sputum, wounds, ear, gallbladder, and stool. In March 1993, CDC investigators identified a nosocomial outbreak of *E. hormaechei* septicemia in a neonatal intensive care unit. Five infants had positive blood cultures with *E. hormaechei*, and another infant had *E. hormaechei* tracheitis. Four additional infants were identified with *E. hormaechei* colonization. No deaths were reported. Environmental cultures showed the organism to be present on three isolettes and one doorknob.[101,664] An outbreak of *E. hormaechei* bloodstream infections were reported in three neonatal intensive care units in Rio de Janeiro. Chart review for previous procedures revealed parenteral nutrition as the only common procedure.[169] A case of recurrent bacteremia caused by *E. hormaechei* has been seen at the University of Illinois Medical Center in a 2-year-old patient with a neuroblastoma involving a left supraclavicular lymph node, an adrenal gland, and a perinavel lymph node.

In 1981, CDC enteric group 69 was defined for a group of yellow-pigmented strains

that resembled *E. cloacae* biochemically. In 1996, *Enterobacter kobei* was described as a new species of *Enterobacteriaceae* resembling *Enterobacter cloacae*,[364] and similar to enteric group 69, but which were negative in tests for VP, fermentation of adonitol, and yellow pigment production. DNA hybridization studies performed at the CDC and the National Institute of Health (NIH), Tokyo, have led to the conclusion that enteric group 69 species are yellow-pigmented biochemical variants of *E. kobei*.[364,482] The majority of strains of *E. kobei* were isolated from clinical specimens including blood, sputum, throat, and urine.[364,602] A case of nosocomial urosepsis has also been reported in a patient with a history of urinary bladder operation.[292]

Enterobacter species together with certain other members of the family *Enterobacteriaceae* (namely, *C. freundii, Serratia* species, *Morganella morganii*, *Providence* species, and *Y. enterocolitica*) carry a gene for chromosomally encoded β-lactamase that can be induced by certain antibiotics, amino acids, or body fluids.[315,394] Unlike plasmid-mediated β-lactamases, these enzymes are not normally expressed. Only under the influence of an inducer or following mutation does the gene become activated and the enzyme expressed. It is a concern, therefore, that organisms harboring genes for inducible β-lactamases may show false susceptibility if tested in the uninduced state. Recently, methods for the detection of resistance owing to inducible β-lactamases have been described.[304] This topic is discussed further in Chapter 17.

Genus *Cronobacter*. *Cronobacter [Enterobacter] sakazakii* was defined as a novel species by Farmer et al.[218] in 1980; however, the existence of divergent biogroups suggested that these organisms represented multiple species. Using a polyphasic taxonomic approach, Iversen et al.[309] showed that these organisms comprise at least five genomospecies and proposed that these species should be moved to a novel genus, *Cronobacter* gen. nov. within the *Enterobacteriaceae*, initially comprising four named species. The taxonomy was expanded to five named species in 2008,[310] seven named species in 2011, nine species in 2012,[333] and ten named species in 2013.[62] In 2014, *C. helveticus* and *C. pulveris* were reclassified into the genus *Franconibacter* and *C. zurichensis* was reclassified into the new genus *Siccibacter* and renamed *S. turicensis*.[612] (Box 6-13, Table 6-18).

C. sakazakii, known as yellow-pigmented *E. cloacae*,[218] has been found in several cases of neonatal meningitis and sepsis.[47,145,332,357,452,638] Fatality rates as high as 75% have been reported,[373,459] indicating that this organism can be highly virulent. Recent reports have linked *C. sakazakii* infection in neonates with contaminated powdered-milk formulas.[121,126,641] The bright yellow pigment (particularly intense if cultures are incubated at 25°C) and "tough" nature of the colonies are the initial clues that this organism is present (*Pantoea agglomerans* also produces a yellow pigment,

usually less intense, and often only after delayed incubation at room temperature). The decarboxylase pattern of *C. sakazakii* (lysine-negative, arginine-positive, and ornithine-positive) helps to differentiate it from *E. aerogenes* (lysine-positive, arginine-negative, and ornithine-positive) and *P. agglomerans* (lysine-, arginine-,

C. pulveris (syn. *Franconibacter pulveris*)
C. sakazakii
C. turicensis
C. universalis
C. zurichensis (syn. *Siccibacter turicensis*)

All *Cronobacter* species, except *C. condimenti*, have been linked to clinical cases of infection in either adults or infants.

and ornithine-negative); and *E. sakazakii* does not ferment sorbitol, in contrast to *E. cloacae*, which does. *C. sakazakii* are naturally resistant to all macrolides, lincomycin, clindamycin, streptogramins, rifampicin, fusidic acid, and fosfomycin, but are susceptible to tetracyclines, aminoglycosides, numerous β-lactams, chloramphenicol, antifolates, and quinolones.[618]

Genus *Hafnia*. Members of the genus *Hafnia* are commonly isolated from the gastrointestinal tract of humans and animals and from foods including meat and dairy products.[321] *Hafnia alvei*, formerly *Enterobacter hafnia*, was originally thought to be the only species in the genus *Hafnia.* However, DNA–DNA hybridization studies conducted at the CDC in the 1970s revealed that *H. alvei* is genetically heterogeneous and consists of at least two DNA hybridization groups (HGs) designated HG 1 and HG

2. Huys et al.,[305] using molecular techniques and phenotypic data, confirmed that *H. alvei* comprises at least two taxa at the species level, of which HG 1 corresponds to *H. alvei* and HG 2 represents a novel species, for which the name *Hafnia paralvei* was proposed.

The biochemical characteristics of *Hafnia* species are similar to those of *Enterobacter* species except that *Hafnia species* do not produce acids from the following carbohydrates: lactose, sucrose, melibiose, raffinose, adonitol, sorbitol, dulcitol, and inositol (see Table 6-16). *Hafnia* species can be distinguished from *Serratia* species because they do not produce lipase, gelatinase, or deoxyribonuclease. We have also noted that, unlike other species of *Enterobacteriaceae*, *Hafnia* species give off a strong scent of human feces. Abbott and colleagues reported that the two *Hafnia* species could be separated unambiguously based upon a battery of four tests. *H. alvei* strains are typically malonate-, salicin-, and β-glucosidase-positive and D-arabinose-negative, whereas *H. paralvei* have the opposite reactions.[4]

The clinical significance of *Hafnia* species is not well defined. Both species have been recovered from clinical samples with almost identical distribution,[323] but little is known regarding their relative frequency or disease distribution. *Hafnia* species have been recovered from human feces in the absence of symptoms, although isolated cases of infection have been reported from persons in whom *Hafnia* species have been recovered from wounds, abscesses, sputum, urine, blood, and other sites. *Hafnia* species have been reported in cases of hemolytic–uremic syndrome,[154] graft-versus-host disease,[578] and sepsis following stem-cell and tissue transplantation.[42,84] There is also evidence to suggest that *Hafnia* species may be an emerging cause of acute bacterial gastroenteritis.[15,549,550,554,563,667] However, Janda et al. have subsequently shown that the prototypal diarrheagenic stains of *Hafnia alvei* that were reported to contain the *eae* gene of enteropathogenic *E. coli* are in fact a category of diarrheagenic isolates belonging to the genus *Escherichia* that were misidentified as *Hafnia alvei* by the API 20E system.[306,322] These strains have been designated as the new species *E. albertii* discussed previously.[306]

Hafnia strains are reported to be uniformly susceptible to amikacin, gentamicin, ciprofloxacin, gatifloxacin, ofloxacin, trimethoprim–sulfamethoxazole, imipenem, meropenem, and cefepime. Resistance is often noted with β-lactams, β-lactam inhibitor combinations, and cephalosporins owing to the presence of chromosomal AmpC β-lactamases.[4]

Genus *Kosakonia*. Five former *Enterobacter* species are included in the genus *Kosakonia*: *K. arachidis*, *K. cowanii*, *K. oryzae*, *K. radicincitans,* and *K. sacchari*.[270]

K. [*Enterobacter] cowanii* was originally proposed for a group of organisms referred to as NIH Group 42.[308] *K. cowanii* strains are negative for lysine and

ornithine decarboxylases and arginine dihydrolase; therefore, phenotypically, they most closely resemble *Pantoea agglomerans*. Tests useful for differentiation from *P. agglomerans* are negative malonate utilization and fermentation of dulcitol and sorbitol (both negative for *P. agglomerans*). Of the nine strains studied, eight were isolated from clinical specimens: urine (four), sputum (two), blood (one), and pus (one), but their clinical significance is unknown.[308]

Genus *Lelliottia*. The genus *Lelliottia* contains two species, *Lelliottia [Enterobacter] amnigena* and *Lelliottia [Enterobacter] nimipressuralis*.[62]

L. amnigena is primarily a water organism that has been isolated from human specimens.[313] A case of posttransfusion septicemia caused by *L. amnigena* has been reported in France.[317]

L. amnigena has been reported to have caused sepsis following blood transfusion[317] and heart transplantation.[56] Other site infections (cholecystitis, cystitis, lymphadenitis, osteomyelitis) have also been reported to be caused by this microorganism.[85]

L. nimipressuralis has been reported as a cause of pseudobacteremia due to contaminated salined cotton used before applying iodine to collect blood for culture.[351]

Genus *Pantoea*. The genus *Pantoea* was created in 1989 with the type species being *Pantoea agglomerans*.[248] This taxon includes the former type strains of *Enterobacter agglomerans, Erwinia herbicola*, and *Erwinia milletiae*. *Pantoea* is derived from a Greek word meaning "of all sorts and sources," thus describing these bacteria that come from diverse geographic and ecologic sources. There are currently 22 named species in the genus *Pantoea*, most of which are plant pathogens and rarely associated with human disease. Only seven species have been reported to cause human infection, with *P. agglomerans* being the most common. In the early 1970s, *P. agglomerans* (then called *Enterobacter agglomerans*) was responsible for a nationwide outbreak of septicemia caused by contaminated intravenous fluids.[405,410] Subsequently,

multiple cases of *P. agglomerans* sepsis have been reported, usually in neonates with significant prematurity, comorbidity, or indwelling catheters,[45,158,374] but also in adult patients with comorbidity associated with immune suppression.[138,386] *P. agglomerans* has also been associated with cases of septic arthritis or synovitis,[368] osteitis,[376] colelithiasis,[232] occupational respiratory infections and skin allergy,[437] peritonitis,[387] and an outbreak secondary to contaminated parental nutrition.[274] *P. ananatis* (originally named *P. ananas*) has been isolated from a corneal infiltrate following a rice husk injury[412] and from the blood of an elderly man following a colonoscopy for anal

hemorrhage.[172] *P. dispersa* has been isolated from plant surfaces, seeds, humans, and the environment. Two cases of neonatal sepsis due to *P. dispersa* have been reported.[427] Four newly named *Pantoea* species have also been recovered from human clinical specimens: *P. septica* from blood and skin; *P. eucrina* from trachea, cyst, urine, and CSF; *P. brenneri* from urethra and sputum; and *P. conspicua* from blood; however, the clinical significance of these isolates was not reported.[63] *P. gaviniae* and *P. calida* were isolated from infant formula and an infant formula production environment, but no human infections have been reported.[536] *Pantoea* species are tripledecarboxylase-negative (lysine-negative, arginine-negative, and ornithine-negative), and often yellow-pigmented.[248] See Tables 6-7 and 6-16 for additional phenotypic characteristics.

Genus *Pluralibacter*. The genus *Pluralibacter* contains two genera, *Pluralibacter [Enterobacter] gergoviae* and *Pluralibacter [Enterobacter] pyrinus*.[62]

P. gergoviae causes urinary tract infections, and additional isolates have been recovered from the respiratory tract and blood.[72] Biochemically, it is closest to *E. aerogenes* (lysine-positive, arginine-negative, ornithine-positive), but is strongly urease-positive. It can be further differentiated by negative reactions in adonitol, inositol, and sorbitol, whereas *E. aerogenes* is positive for all three reactions.

Genus *Serratia*. *Serratia* species are unique among the *Enterobacteriaceae* in producing three hydrolytic enzymes: lipase, gelatinase, and DNase. Resistance to colistin and cephalothin are additional distinguishing features. There are currently 10 species recognized, 7 of which have been recovered from human clinical specimens. The biochemical differentiation of *Serratia* species of clinical importance is shown in Table 6-20.

S. marcescens is the most important member of the genus *Serratia* and is often associated with a variety of human infections, particularly pneumonia and septicemia in patients with reticuloendothelial malignancies who are receiving chemotherapeutic agents. At one time, the organism was used as a harmless commensal to trace environmental contamination, primarily because the characteristic red pigmentation of some strains was easy to spot in culture media (see Image Plate 6-2G). However, the organism is now recognized as an important pathogen with invasive properties and a tendency to resist many commonly used antibiotics. *S. marcescens* can be a significant nosocomial opportunist, as evidenced by a recent case of childhood meningitis following the use of contaminated benzalkonium chloride disinfectant solution.[577] The species referred to as *S. liquefaciens* is now known to be not a single species but a collection of several DNA HGs, including species named *S. proteamaculans* and

[a]Data obtained from reference 253 and Table 6-7.

277

S. grimesii. They are found on the surfaces of plants and belong to the "*Serratia liquefaciens–proteamaculans–grimesii*" complex. Strains of these species produce plant-growthpromoting chemicals, have antifungal properties, encourage the establishment of nitrogen-fixing symbionts, and act as insect pathogens.[24] Because the species that make up this HG cannot be separated by currently used biochemical tests, it is suggested that members of this species be reported as "*Serratia liquefaciens* group." This group is differentiated from *S. marcescens* by virtue of its ability to ferment L-arabinose.

S. rubidaea, as its name would imply, produces colonies that are red-pigmented but is rarely isolated from human clinical specimens. Ursua and associates[640] reported a case of *S. rubidaea* isolated from the bile and blood of a patient with a bile tract carcinoma who underwent invasive procedures. *S. rubidaea* bacteremia has also been reported in a patient with an arterial catheter.[588] *S. odorifera* produces a dirty, musty odor, similar to unpeeled potatoes. Two biogroups are described. Biogroup 1 is ornithine-, sucrose-, and raffinose-positive and is isolated predominantly from sputum; however, it has been reported to cause severe sepsis in elderly, compromised patients,[141,429] and catheter-associated sepsis in an adolescent patient with thalassemia

major who had been splenectomized.[256] Biogroup 2 is negative for these three reactions and has been recovered from blood and cerebrospinal fluid.[220] Strains of *S. plymuthica* may be redpigmented and have been isolated from soil, water, and human sputum specimens. Although *S. plymuthica* is generally not considered to be a cause of serious human infections, recent reports have shown that it can be a significant pathogen causing chronic osteomyelitis,[687] wound infections,[92,146] and community-acquired[553] and nosocomial bacteremia[92,184,301] and has been isolated from the peritoneal fluid of a patient with cholecystitis.[92] *S. ficaria* has a natural habitat in figs and the fig wasp.[253] Isolation of this species from human specimens is extremely rare and is usually accompanied by a history of ingestion of figs.[18,29,168] There is a single report of the isolation of *S. ficaria* from blood and wound following a dog bite.[166] *S. entomophila* is an insect pathogen, and no human isolates have been reported. "*S.*" *fonticola* is not really a species of *Serratia* and is likely to be reclassified. It is a water organism that has been isolated rarely from human clinical specimens, mostly wounds.[57,220,521] *S. fonticola* has been recovered from the blood of a patient with a digestive neoplasm at the University of Illinois Medical Center. The natural antimicrobial susceptibilities of strains of the less commonly isolated *Serratia* species: *S. ficaria, S. fonticola, S. odorifera, S. plymuthica,* and *S. rubidaea* have been reported by Stock and colleagues.[615]

Tribe *Proteeae*. The *Proteeae* comprise three genera: *Proteus, Morganella, and Providencia*. The characteristics suggesting that an organism belongs to this tribe are given in Table 6-6. The classification, identification, and clinical significance of the Proteeae has been reviewed by O'Hara et al.[477]

Genus *Proteus*. DNA relatedness studies have clarified the classification of organisms within the *Proteeae*. The genus *Proteus* now includes five named species: *P. vulgaris*, *P. mirabilis*, *P. myxofaciens*, *P. penneri*, and *P. hauseri*, and three unnamed genomospecies that were formerly identified as members of biogroup 3 of *P. vulgaris*.[68] Strains of *P. vulgaris* have traditionally been placed into three biogroups as follows:

Proteus biogroup 1: indole-, salicin-, esculin-negative; chloramphenicol-resistant
Proteus biogroup 2: indole-, salicin-, esculin-positive
Proteus biogroup 3: indole-positive, salicinand esculin-negative

Proteus biogroup 1 is a single genetic species and is now known as *P. penneri*.[286] *Proteus* biogroup 2 is a single genetic species and will retain the name *P. vulgaris*. *Proteus* biogroup 3 consists of four separate genetic species that are designated DNA groups (genomovars) 3, 4, 5, and 6. DNA group 3 can be distinguished from *Proteus*

DNA groups 4, 5, and 6 because it is negative for Jordan's tartrate, lipase, and DNase (Table 6-21). Because DNA group 3 can be phenotypically separated from the other *Proteus* genomospecies, it has been officially named *Proteus hauseri* to honor Gustav Hauser, the

German microbiologist, who proposed the genus *Proteus* in 1885.[478] *Proteus* genomospecies 4, 5, and 6 will remain unnamed until better phenotypic differentiation can be accomplished. Biochemical separation of the *Proteus* species and DNA groups is given in Table 6-21.

The genus *Proteus* is found in soil, water, and fecally contaminated materials. *Proteus* species exhibit the characteristic feature of swarming motility, which is observed on noninhibitory agar (e.g., blood agar plate) as a wavelike spreading of the organism across the entire surface of the agar (see Image Plate 6-1D). Whenever swarming is observed, *Proteus* species should be suspected. *P. mirabilis* is the species most frequently recovered from humans, particularly as the causative agent of both urinary tract and wound infections. *P. vulgaris* is more commonly recovered from infected sites in immunosuppressed hosts, particularly those receiving prolonged regimens of antibiotics. As noted in Table 6-21, *P. vulgaris* is indole-positive, whereas *P. mirabilis* is indolenegative. Thus, by performing a rapid spot indole test on a characteristic swarming colony, a rapid presumptive identification of *P. mirabilis* or *P. vulgaris* can be made. The species *P. penneri*[286] and *P. myxofaciens* are also indole-negative but are rarely encountered in clinical laboratories (the latter is a pathogen of

gypsy moth larvae and has not been recovered from human specimens). Therefore, for practical purposes, the recovery of an indole-negative *Proteus* species can be presumptively identified as *P. mirabilis*. Virtually all strains of *P. mirabilis* are sensitive to ampicillin and cephalosporins, whereas *P. vulgaris* is resistant; therefore, most patients with clinical infection, from whom an indole-negative *Proteus* species is recovered, can be treated with one of the broadspectrum penicillins or cephalosporins.

P. penneri closely resembles *P. vulgaris* but differs from *P. vulgaris* by being indole-, salicin-, and esculin-negative and by failing to produce hydrogen sulfide in TSI. When *P. penneri* is suspected, a chloramphenicol susceptibility test should be performed for identification purposes. *P. penneri* is chloramphenicol-resistant, whereas other indole-negative *Proteus* species are chloramphenicol-susceptible (see Table 6-21).[286] Documented human infections with *P. penneri* have been limited mainly to the urinary tract and wounds of the abdomen, groin, neck, and ankle.[286,367] In one report, a patient with leukemia was described, in whom a *P. penneri* bacteremia developed with a concomitant subcutaneous thigh abscess, demonstrating the invasive potential of this bacterium.[209] Microbiologists are advised to be suspicious of any *P. vulgaris* isolates that are indole-negative and hydrogen sulfide-negative because these may possibly be isolates of *P. penneri*.

Genus *Morganella*. On the basis of genetic studies performed by Brenner and colleagues in 1978, the organism previously designated *Proteus morganii* was reassigned to the new genus *Morganella* as *M. morganii*.[64] Studies by Jensen and colleagues have shown that *M. morganii* can be further separated into three DNA relatedness groups and seven biogroups.[328] DNA relatedness group 1 contains biogroups A through D. DNA relatedness group 2 contains biogroups E and F and two-thirds of biogroup G (termed biogroup G-2). DNA relatedness group 3 contains the remaining one-third of biogroup G (termed biogroup G-1). Because G-1 and G-2 are phenotypically indistinguishable, Jensen and associates[328] have proposed dividing *M. morganii* into just two subspecies based on trehalose fermentation. *M. morganii* that are unable to ferment trehalose are designated *M. morganii* subsp. *morganii*, and those that are able to utilize trehalose are designated *M. morganii* subsp. *sibonii*.

M. morganii is a cause of both urinary tract and wound infections and has been implicated as a cause of diarrhea. Serious infections reportedly caused by *M. morganii* include a case of meningitis in a patient with AIDS[416] and a case of meningitis and brain abscess in an 8-day-old infant.[646] *M. psychrotolerans* is a psychrotolerant strain of a *Morganella* capable of growing at temperatures of 2°C to 35°C. It has been isolated from cold-smoked tuna involved in an outbreak of histamine poisoning in Denmark; however, no human infections with this organism have been reported to date.[207] As shown in Table 6-6, the pattern of Simmon's citrate–negative, hydrogen sulfide-negative, and ornithine decarboxylase-positive is characteristic of this genus.

The biochemical differentiation of the subspecies and biogroups is given in Table 6-22.

Genus *Providencia*. *Providencia* of clinical importance are: *Providencia alcalifaciens*, *Providencia stuartii*, *Providencia rettgeri*, and the newly described species *Providencia rustigianii*[287] and *Providencia heimbachae*.[450] All species of the genus *Providencia* deaminate phenylalanine, but only *P. rettgeri* consistently hydrolyzes urea. The biochemical differences of the species are shown in Table 6-23.

Except for causing urinary tract infections, for which Penner has cited several nosocomial outbreaks,[513] infections with *Providencia* species are uncommon and are limited to isolated case reports. All species may be recovered from feces; however, only *P. alcalifaciens* may be associated with diarrheal illness, usually in children.[325]

Hickman–Brenner and associates[287] designated *P. rustigianii* to what was previously known as *P. alcalifaciens* biogroup 3. This organism has also been recovered from feces; however, its role in diarrheal disease is still questionable. A new species, *P. heimbachae*, has been reported from penguin feces and an aborted cow fetus.[450] There has been only one report of human *P. heimbachae* infection, from the stool of a 23-year-old woman with idiopathic diarrhea.[483] Chamberland and colleagues have reported a case of *Providencia stuartii* from a renal abscess that was misidentified using the Vitek 2 GN ID card (bioMerieux) as *Pasteurella canis* (99% probability). The same isolate was identified on the API 20 E system (bioM-erieux) to the genus level of *Pasteurella multocida* (86.1%) versus *Pasteurella pneumotropica/Mannheimia haemolytica* (13.5%). The isolate was identified by MALDI-TOF MS as *Providencia stuartii* using the Biotyper system (software version 3.0; Bruker–Daltonics, Billerica, MA) and Vitek MS (database version 2.0 bioMerieux). Following this, 16S rRNA gene sequencing yielded a definitive result for *Providencia stuartii*.[132]

Tribe *Yersinieae*. Three species of Pasteurella, including the causative agent of human plague, Pasteurella pestis, were formally assigned to a new genus, Yersinia, in the eighth edition of Bergey's Manual and placed in the Enterobacteriaceae. The name for the genus Yersinia was derived from the French bacteriologist Alexander Yersin, who in 1894, first identified the organism now called Yersinia pestis. The key characteristics of the Yersinieae are given in Table 6-6.

Although *Yersinia* species qualify biochemically for inclusion in the *Enterobacteriaceae*, the cells appear small and coccobacillary in Gram-stained smears, and may be small and pinpoint on MacConkey agar, particularly for certain strains of *Y. pestis* and *Y. pseudotuberculosis*. Optimal growth occurs from 25°C to 32°C. Colonies tend to be pinpoint in size after 24 hours of incubation on sheep blood agar. If incubation is continued at room temperature, after 48 hours, gray–white, convex colonies measuring 1 to 2 mm in diameter may be observed.

Genus *Yersinia*. *Yersinia* is the only genus in the *Yersinieae*. Three species, *Y. pestis*, *Y. pseudotuberculosis*, and *Y. enterocolitica*, were included when the genus was transferred to the *Enterobacteriaceae*. In 1980, three new species were proposed for strains that were former subgroups of *Y. enterocolitica*:[44,65,73,639] *Y. frederiksenii* is the name given to the rhamnose-positive biogroup[639]; *Y. intermedia* is the designation for those atypical strains that ferment rhamnose, raffinose, and melibiose[65]; and *Y. kristensenii* is the name for the previous sucrose-negative, trehalose-positive biogroup of *Y. enterocolitica*.[44] Presently, 17 species are included in the genus *Yersinia*; however, only three (*Y. pestis*, *Y. pseudotuberculosis*, and *Y. enterocolitica*) have been unquestionably shown to be human pathogens. One species,

Y. ruckeri, a fish pathogen not known to cause human infection, will probably be moved to a new genus.[214] The differential characteristics for these various species of clinical importance are included in Table 6-24.

***Plague*—Y. pestis.** Plague is an infectious disease of antiquity that persists in modern times. *Y. pestis*, which undergoes an obligate flea–rodent–flea life cycle, causes bubonic plague, a rapid and highly fatal zoonotic disease that was responsible for at least three pandemics occurring in the 5th–6th, 8th–14th, and 19th–21st centuries (Box 6-14).[519]

Epidemiology. *Y. pestis* is endemic in various rodents, including rats, ground squirrels, prairie dogs, mice, and rabbits. Two epidemic forms of disease occur: urban plague, which is maintained in the urban rat population, and sylvatic plague, which is endemic in 17 Western states (Fig. 6-7) and is carried by prairie dogs, mice, rabbits, and rats. The organism is transferred from rodent to rodent or from rodent to human by fleas. Human cases have been concentrated in two principal regions in the United States: (1) a

BOX 6-14

History of Plague

Three major plague pandemics have occurred at intervals of 600 years, each occurring at the end of a major historical epoch: Justinian Plague at the end of Antiquity, Black Death at the end of the Middle Ages, and the Modern Pandemic at the end of the

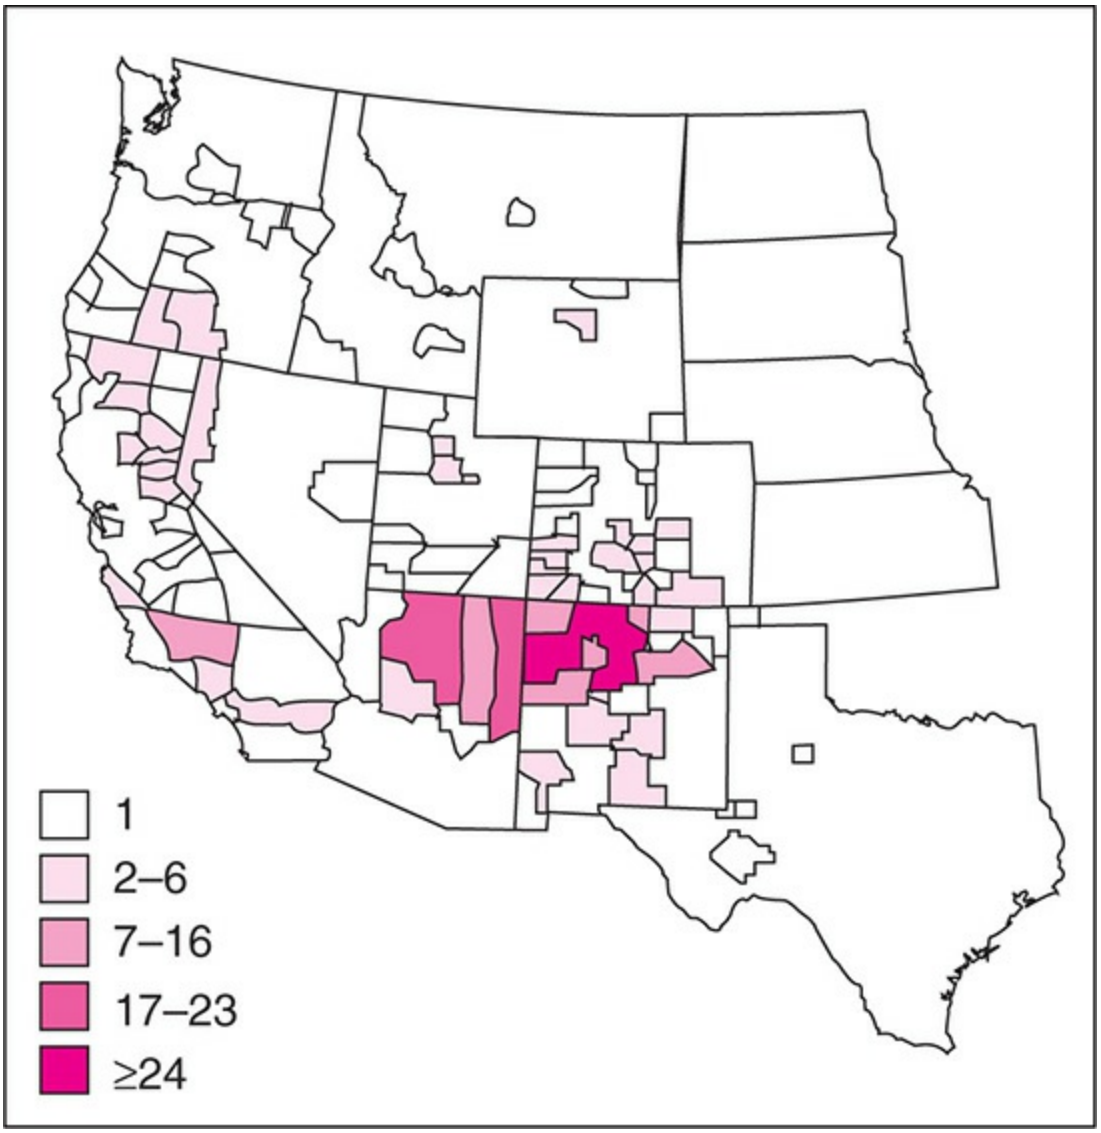
current era.

First Pandemic—The Justinian Plague: (A.D. 541–544) named after the Roman emperor of the 6th century, affected the Mediterranean countries from 532 to 595 and resulted in 100+ million deaths. It began in Egypt and spread through the Middle East and Mediterranean Europe. After that, the 2nd–11th epidemics (A.D. 558–654) occurred in 8- to 12-year cycles, eventually affecting all the "known world."

Second Pandemic—The Black Death: (A.D. 1347–1351) originated in the area of the Black Sea, spread to Sicily, and eventually affected the entire area of Europe up to Great Britain, Scandinavia, and Western Russia. About 17 to 28 million Europeans died from the disease, which represented 30% to 40% of the European population. Epidemics continued in 2- to 5-year cycles from 1361 to 1480, and in less frequent cycles into the 17th century. The second pandemic again encompassed all the "known world."

Third Pandemic—The Modern Pandemic: started in 1855 in Yunnan, a Southwestern province of China. Hong Kong was affected in May 1894; Bombay in 1896; Madagascar in 1898; Egypt, Portugal, Japan, Paraguay, and Eastern Africa in 1899; and Manila, Glasgow, Sydney, and San Francisco in 1900. The outbreaks in India affected more than 10+ million victims between 1896 and 1918, causing the majority of the deaths that occurred during this pandemic. Local epidemics subsequently broke out all over the world until the 1950s, when the pandemic ended.

Plague in the United States—After plague appeared in Hong Kong in 1894, it spread rapidly, reaching the port of San Francisco by boat in 1900. At approximately the same time, it also appeared in Brazil, New Orleans, and New York. Reluctance of California health officials to admit that plague existed in Chinatown resulted in initiation of sylvatic infection. Through sylvatic infection (primarily in the ground squirrel), the infection eventually covered much of the western US (17 States), with the majority of cases occurring in Arizona, California, Colorado, New Mexico, and Oregon. Between 1947 and 1996, 390 cases of plague occurred in the US, resulting in 60 (15.4%) deaths. The most common form was bubonic plague: 327 (84%) cases resulting in 44 (14%) deaths, followed by primary septicemic plague: 49 (13%) cases and 11 (22%) deaths, and primary pneumonic plague: 7 (2%) cases and 4 (57%) deaths. Seven cases and one death were unclassified.[115]



■ **FIGURE 6-7** Number of plague cases, by county—western United States, 1970 to 2002. (Centers for Disease Control and Prevention. Imported plague—New York City, 2002, MMWR Morb Mortal Wkly Rep 2003;52:725–728.)

southwestern area that includes New Mexico, northeastern Arizona, southern Colorado, and southern Utah; and (2) a Pacific Coast region located in California, Oregon, and western Nevada (Fig. 6-7).[108] During 1988 to 2002, a total of 112 human cases of plague were reported from 11 Western states. The majority (97) were exposed in four states (New Mexico, Colorado, Arizona, and California).[122] Approximately 80% of these exposures occurred in peridomestic environments, particularly those that provided abundant food and harbor for flea-infested, plague-susceptible rodents. Household infections occur when people, domestic animals (especially cats), and peridomestic rodents bring fleas into the house, exposing more

persons. Domestic cats permitted to roam freely in areas where plague occurs in rodents are at increased risk for infection and, therefore, increase the risk for peridomestic transmission to humans. Mouth abscesses develop in infected cats, by which they pass the plague directly to people through licking, scratching, or biting.[537] Between 1977 and 1998, 23 human cases of cat-transmitted plague were reported in Western states, and five of those who were ill died.[243]

Travelers can acquire plague in one area and become ill in another area where plague is not endemic (i.e., peripatetic plague). Although rare, peripatetic plague is more likely to

result in fatal outcomes because of delays in seeking treatment or misdiagnosis in areas where healthcare providers might be less familiar with the disease.[122] In the current state of heightened awareness of possible terrorism, peripatetic cases also might be confused with those arising from an intentional release of plague bacteria (Box 6-15).

Clinical Syndromes. Three clinical forms of plague are recognized: bubonic, septicemic, and pneumonic. The septicemic and pneumonic forms are usually secondary to the bubonic form, and the bubonic form is the most common in the United States (see Box 6-14). Bubonic plague is characterized by swelling of cervical, axillary, and inguinal lymph nodes, depending on the location of the portal of entry of the bacteria. Hematogenous dissemination of the bacteria to other organs and tissues may cause intravascular coagulation and endotoxic shock, producing dark discoloration in the extremities (Image Plate 6-5A; Clinical Correlation Box 6-5).

Laboratory Diagnosis. Laboratory confirmation of all forms of plague is performed either by microbiologic methods or by serologic demonstration of antigen or antibody titers. Our colleagues at the Colorado Department of Health have noted that blood cultures are positive in approximately 80% of patients with bubonic plague and 100% of patients with septicemic plague. Gram's stains (Image Plate 6-5B) of bubo aspirates show gram-negative rods in about two-thirds of cases, and Wright–Giemsa stains (Image Plate 6-5C) of peripheral blood smears often reveal the characteristic bipolar staining typical of *Yersinia*. The colonies are slow-growing on ordinary media and are said to have the appearance of beaten copper when viewed under the stereoscope (Image Plate 6-5D). The reaction observed on TSI agar in 24 hours is similar to that seen with *Pasteurella* species (i.e., weak acid production on the slant, with little or no change in the butt). A rapid diagnostic test has been developed that uses a simple dipstick test using monoclonal antibodies to detect the F1 antigen, a protein that is specific to *Y. pestis*. The test produces reliable results within 15 minutes and could help control the disease in developing countries and perhaps speed detection and treatment of the infection during a bioterrorist attack.[134]

BOX 6-15

Epidemiology, Diagnosis, Treatment, and Prevention and Reporting of Plague (*Yersinia pestis*)

Epidemiology

- Plague is usually transmitted to humans by the bite of an infected rodent flea
- Incubation period is 1–7 days for bubonic plague and 1–4 days for pneumonic plague
- Case-fatality rate for untreated bubonic plague is ≥50%
- Domestic pets (i.e., cats and dogs) can carry plague-infected fleas
- Risks include hunting, trapping, cat ownership, and rural residence in areas where plague is endemic
- Person-to-person transmission can occur after contact with a suppurating lesion (bubonic plague) or via respiratory droplets (pneumonic plague)
- Naturally acquired plague typically begins as bubonic plague; intentional release (i.e., terrorism) would manifest chiefly as pneumonic plague

Clinical Findings

- Signs and symptoms include fever, chills, malaise, sore throat, and headache
- A lymphadenitis (bubo) commonly develops; inguinal lymph nodes are affected in 90% of cases
- Infection can progress to shock (septicemic plague) and pneumonia (pneumonic plague)

Laboratory Testing

- Biopolar staining, "safety pin" ovoid, gram-negative organisms are suggestive of plague infection
- Direct fluorescent antibody testing or antigen capture enzyme-linked immunosorbent assay are specific tests
- Confirmatory testing includes culture or a fourfold or greater change in antibody titer

Recommended Treatment

- Primary therapy: streptomycin; alternatively use gentamicin, tetracyclines, or chloramphenicol
- Mortality from bubonic plague is reduced markedly by appropriate therapy
- Patients with primary pneumonic plague are not likely to survive if they do not receive adequate therapy within 18 hours after onset of respiratory symptoms

Prevention and Reporting

- Educate the public about plague symptoms, mode of transmission, and prevention

methods
- Use insect repellents
- Rodent-proof buildings
- Avoid handling rodents or camping near rodent burrows
- Treat dogs and cats in rural areas where plague is endemic with insecticides
- Report plague cases and sick or dead animals to health authorities

See Image Plates 6-5A–D
From reference 122.

283

CLINICAL CORRELATION BOX 6-5 Human Plague

When plague bacilli are introduced into a human host, the microorganisms replicate at the initial site of infection, which may be the site of the flea bite, the bloodstream, or the lung, and consequently, three clinical forms of human plague may occur:

1. **Bubonic:** Incubation period of bubonic plague is 7 days or less after a bite from an infected flea. The infecting bacteria spread to regional lymph nodes, usually in the groin (most common), axilla, or neck. An early sign of lymph node infection is the appearance of large, painful swellings called buboes. There is often a sudden onset of fever, chills, weakness, and headache. Within hours, patients may notice intense pain in the anatomic regions with buboes. Patients become prostrate and lethargic and may exhibit agitation, particularly when the bubo is disturbed. Bubonic plague is the mildest form of plague; however, the fatality rate in untreated cases is approximately 75%.
2. **Pneumonic:** This form is usually secondary to the bubonic process, although it may also result from direct exposure to respiratory droplets from another patient with pneumonic plague or from an infected cat.[202,665] There is a shorter (2 to 3 days) incubation period with pneumonic plague. Patients initially have fever and malaise, and then pulmonary signs develop within 1 day. In such patients, cough, chest pain, and hemoptysis are seen, with the sputum usually purulent and containing plague bacilli (Image Plate 6-5B, 6-5C). Pneumonic plague is quickly followed by sepsis and death unless antimicrobial therapy is initiated within the first day. The fatality rate exceeds 90% if the patient is not treated. Persons suspected of having pneumonic plague should be placed in respiratory isolation and reported immediately to public health authorities so that rapid diagnosis, environmental assessments, and control measures can be initiated.

3. **Septicemic:** Direct infection of the bloodstream by the flea bite, or spread of the plague bacillus from lymph nodes to the bloodstream can result in septicemic plague. These patients have positive blood cultures uniformly. Disease is characterized by high fever, delirium, seizures in children, septic shock, and disseminated intravascular coagulation (DIC). Black hemorrhagic splotches (Image Plate 6-5A) develop that gave plague the name "Black Death."

Diagnosis: Plague should be suspected in febrile patients who have been exposed to rodents or other mammals in known endemic areas (Fig. 6-7). The differential diagnosis of plague includes Reye's syndrome, tularemia, bacterial pneumonia, and an acute surgical abdomen. A febrile course in a prostrate patient with a bubo should suggest either plague or tularemia: a bacteriologic diagnosis in such a patient can be made readily with a smear and culture of a bubo aspirate.
Treatment: Primary therapy: streptomycin; alternatively use gentamicin, tetracyclines, or chloramphenicol.[122]

Modified from reference 619.

***Infections Caused by* Y. pseudotuberculosis.** *Y. pseudotuberculosis* is also endemic in a wide variety of animals, including fowl, and is responsible for mesenteric lymphadenitis, particularly in children in whom a clinical disease simulating appendicitis is manifested.[631] A septicemic form of *Y. pseudotuberculosis* infection occurs rarely and has been described mainly in patients with an underlying disorder, such as hepatic cirrhosis, hemochromatosis, or diabetes, with mortality rates as high as 75% despite antibiotic treatment.[395] Rare cases of urinary tract infection and chronic prostatitis due to *Y. pseudotuberculosis* have also been reported.[155,456] The vehicles and sources of *Y. pseudotuberculosis* infection are unknown. By virtue of its similarity to *Y. enterocolitica*, it has been presumed to be a possible food-borne pathogen, but the evidence for this is limited to a few suggestive outbreaks and two larger outbreaks, one in Canada linked to pasteurized milk[469] and one in Finland due to contaminated iceberg lettuce traced to a farm that used untreated water for spray irrigation of the fields.[471] The major biochemical tests that differentiate *Y. pseudotuberculosis* from *Y. enterocolitica* are ornithine decarboxylase, sucrose, and sorbitol. *Y. pseudotuberculosis* is negative for all three, whereas *Y. enterocolitica* is positive (Table 6-24).

***Infections Caused by* Y. enterocolitica.** *Y. enterocolitica* is widely distributed in aquatic and animal reservoirs, with swine serving as the major reservoir for human pathogenic strains.[59] It is the most common species of *Yersinia* recovered from clinical specimens. The portal of entry in humans is the oral digestive route, with

infection occurring in the terminal ileum that anatomically is adjacent to the appendix. The organism adheres to and penetrates the ileum, causing terminal ileitis, lymphadenitis, and acute enterocolitis, with secondary manifestations of erythema nodosum, polyarthritis,[643] and, less commonly, septicemia,[153,233] and endocarditis.[251] Septicemia with *Y. enterocolitica* is almost exclusively associated with patients in iron overload or those being treated with the iron-chelating agent deferoxamine.[59] Ironloaded patients with β-thalassemia are at greatly increased risk for severe yersiniosis even when their body iron burden (as indicated by the serum ferritin level) is only moderately

284

elevated and they are not receiving iron-chelating therapy.[8] There are six biovars (1A, 1B, 2, 3, 4, and 5) and over 50 serogroups of *Y. enterocolitica;* however, only five, designated O:1,2a,3; O:3; O:5,27; O:8; and O:9, are generally considered pathogenic for humans.[48] Biogroup 1A lacks the virulence determinants of invasive isolates and is considered to be nonpathogenic.[59] The remaining biogroups are of human origin and can be divided into biogroup 1B, found mainly in the United States, and biogroups 2 to 5, found in Europe and elsewhere. Neubauer et al.[463] have proposed division of *Y. enterocolitica* into two subspecies: *Y. enterocolitica* subsp. *enterocolitica* for biogroup 1B and *Y. enterocolitica* subsp. *palaearctica* for European bioserovars.

Association of* Y. enterocolitica *With Transfusion Reactions. *Y. enterocolitica* was recovered from a unit of donor blood submitted to the University of Illinois Hospital Microbiology Laboratory for culture following a transfusion reaction. Shaking chills and a shock-like syndrome developed in the recipient of a contaminated unit of blood after about 50 mL had been transfused. Similar cases have also been reported elsewhere, illustrating this organism's ability to grow at cold temperatures.[50,106,114,314,611,620,635] Between November 1985 and November 1996, the CDC reported 21 cases of sepsis associated with receipt of transfused *Y. enterocolitica*- contaminated red cells.[114] Investigation of these cases has led to the conclusion that blood contamination resulted from asymptomatic *Y. enterocolitica* bacteremia in the blood donors at the time of donation. Arduino and colleagues[21] have demonstrated that *Y. enterocolitica*, when inoculated into units of packed erythrocytes and stored at 4°C, can proliferate and produce endotoxin after a lag phase of 2 to 3 weeks. It is clear from these reports that *Y. enterocolitica* should be looked for whenever transfusion-associated bacteremia or endotoxemia is suspected. To learn more, the reader is referred to the review article by Wagner and coauthors.[652]

Association of* Y. enterocolitica *With Household Preparation of Chitterlings. In countries where *Y. enterocolitica* has become an important cause of diarrhea, 0:3 is

the predominant serotype, and pigs appear to be the major reservoir for infection.[626] A review of clinical isolates of *Y. enterocolitica* submitted to the Yersinia Reference Laboratory of the CDC from 1970 to 1980 and from 1986 to 1988 showed a shift in the preponderant serotype of *Y. enterocolitica* in the United States from 0:8 to 0:3. This shift coincides with an outbreak of gastroenteritis caused by *Y. enterocolitica* serotype 0:3 in Atlanta from November 1988 to January 1989. The outbreak involved 15 patients (all African American), of which 14 were infants (median age, 3 months). A febrile, diarrheal illness developed in all of them, which was strongly associated with the household preparation of chitterlings (the large intestines of pigs). Although none of the infants had direct contact with the raw chitterlings, in nearly all cases, the persons caring for the infants gave a history of cleaning chitterlings.[378] *Y. enterocolitica* was cultured from unopened containers of chitterlings, from the case households as well as from containers of chitterlings purchased from local supermarkets. In 10 of the 12 exposed households, the chitterlings were prepared for a Thanksgiving, Christmas, or New Year's meal. A survey of a grocery store chain in Atlanta revealed that the sale of chitterlings is largely restricted to the period from October through January, and peaks in November. Data from other surveys support the association between chitterling preparation during the Thanksgiving to Christmas holiday period and cases of *Y. enterocolitica* infection, and suggest that routine screening for *Y. enterocolitica* is warranted at certain hospitals, particularly in Black communities, and especially for children less than 1 year of age.[6,123,379,431] Information on the safe preparation of chitterlings is available at http://www.ph.dhr.state.ga.us/epi/news/oct02/103102.shtml.[123]

Recovery of* Y. enterocolitica *From Clinical Specimens. Most strains of *Y. enterocolitica* will grow on selective enteric agars and will appear as small, lactose-negative colonies on MacConkey and SS agars in 48 hours. In some laboratories, plates of MacConkey agar inoculated with stool specimens suspected of harboring *Yersinia* species are routinely incubated at room temperature. *Y. enterocolitica*, in particular, can best be recovered from stool specimens that are incubated at 25°C. Cold enrichment of highly contaminated specimens, such as feces, by incubating cultures at 4°C for 1 to 3 weeks in phosphate-buffered saline before subculture onto enteric media, also enhances the recovery of *Y. enterocolitica*.[501] Weissfeld and Sonnenwirth[663] reported that pretreatment of stool with 0.5% potassium hydroxide at a ratio of 1:2 for 2 minutes, followed by plating onto enteric agar, resulted in the recovery of the highest number of *Yersinia* isolates. The superiority of cefsulodin–irgasan–novobiocin (CIN) agar for recovery of *Y. enterocolitica* from stool suspensions containing 102 colony-forming units or fewer has been reported by Head and colleagues.[282] The use of coldenrichment methods and specialized culture media, such as CIN agar, for the recovery of *Yersinia* is usually not required because, in

cases of enterocolitis, the organisms are usually found in relatively high concentrations. The use of EMB agar is not recommended because *Y. enterocolitica* is sucrose-positive and will appear as a coliform on this medium. A similar problem may also be encountered with the use of TSI, which also contains sucrose.

***Identification of* Y. enterocolitica.** *Y. enterocolitica* is more biochemically reactive at room temperature than at 37°C. It has been our experience that isolates of *Y. enterocolitica* generally do not give an acceptable identification when set up on the Vitek system or the API 20E at an incubation temperature of 37°C. However, API 20E strips incubated at room temperature do provide an acceptable identification. This finding has been confirmed in recent published reports.[20,592] Neubauer and colleagues compared the API 20E, API Rapid 32 IDE, and PCR-based tests and found that the API 20E provided the highest sensitivity at both the genus and the species level.[464] A later study by the same group found that the Vitek GNI card identified *Yersinia* with 96.3% accuracy to the genus level and 57.4% accuracy to the species level.[388] Although antisera that can actually be used to serotype strains of *Y. enterocolitica* are not readily available, Farmer and colleagues have described four simple tests that can be used to screen for pathogenic serotypes. These tests include the pyrazinamidase test, salicin fermentation–esculin hydrolysis, D-xylose fermentation, and Congo red–magnesium oxalate (CR–MOX) agar used to determine Congo red dye uptake, and calcium-dependent growth at 36°C.[219]

***Antibiotic Susceptibility of* Y. enterocolitica.** *Y. enterocolitica* serogroups 0:3 and 0:9 are able to produce two chromosomally mediated β-lactamases, resulting in resistance

to ampicillin, cephalothin, and carbenicillin. Serotype 0:8 strains are susceptible to ampicillin and variable for carbenicillin and cephalosporins. In vitro testing is not reliable, and the administration of broad-spectrum cephalosporins in combination with an aminoglycoside appears effective for most extraintestinal infections, including septicemia.[249] Fluoroquinolones, alone or with aminoglycosides or extended-spectrum cephalosporins, also appear effective.[249,580] Trimethoprim–sulfamethoxazole shows in vitro efficacy, but has little effect on the clinical course (duration) of *Y. enterocolitica* gastroenteritis.[6,500]

Other* Yersinia *Species. *Y. frederiksenii* is most commonly recovered from fresh water, foods, and nonirrigated soil and has only infrequently been recovered from human specimens. This organism can be recovered from stool specimens using MacConkey or SS agar incubated at 25°C for 48 hours, and cold-enrichment techniques are rarely required. *Y. frederiksenii* is believed to be part of the commensal

flora and does not cause diarrhea. Farmer and coworkers[220] cite a few human isolates, referred to the CDC, that were obtained from wound and respiratory samples.

Y. intermedia may also be recovered by cold enrichment from human fecal specimens, but it is probably not related to intestinal disease. Bottone[58] reviewed the medical literature to 1976, noting 21 case histories of extraintestinal infections with these atypical rhamnose-positive species. Of these cases, eight were from conjunctivitis, and three were from urinary tract infections. Bottone added three more cases, representing urinary tract, conjunctival, and auxiliary abscess infections.

Farmer and coworkers[220] cite six specimens received at the CDC from which *Y. kristensenii* was recovered: four from stools, one from blood, and one from urine. Its pathogenic role has not yet been determined. *Y. aleksiciae* is phenotypically similar to *Y. kristensenii* except for being lysine decarboxylase-positive. Strains have been isolated from the feces of humans, rats, moles, reindeer, and pigs and from dairy products. Their clinical significance is unknown.[604] Four species of *Yersinia* have been described that are all biochemically similar to *Y. enterocolitica*. All are very rare human isolates. *Y. rohdei* has been isolated from dog feces, water, and human feces.[16] *Y. aldovae* (formerly *Y. enterocolitica*-like group X2) has been found in surface water, drinking water, and fish.[43] *Y. mollaretii* (formerly *Y. enterocolitica* biogroup 3A) has been isolated from human feces, drinking water, meat, and raw vegetables.[660] *Y. bercovieri* (formerly *Y. enterocolitica* biogroup 3B) has been reported from human feces, water, soil, and vegetables.[660] Five additional species of *Yersinia* (*Y. entomophaga, Y. massiliensis, Y. nurmii, Y. pekkanenii, Y. similis*) have been described that have been recovered from nonhuman reservoirs and are not associated with human infections.

Tribe *Erwinieae*. The *Erwinieae* are primarily pathogens in plants and only saprophytic in humans. The species of the genus *Erwinia* may be divided into three phylogenetic groups. Cluster I represents the true erwinias and comprises *E. amylovora, E. mallotivora, E. persicinus, E. psidii, E. rhapontici*, and *E. tracheiphila*. The species of cluster II have been transferred to the genus *Pectobacterium* as *P. carotovorum* subsp. *atrosepticum*, *P. carotovorum* subsp. *betavasculorum, P. carotovorum* subsp. *carotovorum, P. carotovorum* subsp. *odoriferum, P. carotovorum* subsp. *wasabiae, P. cacticidum, P. chrysanthemi*, and *P. cypripedii*. The members of cluster III have been classified in a new genus *Brenneria* as *B. alni, B. nigrifluens, B. paradisiaca, B. quercina, B. rubrifaciens,* and *B. salicis*.[280] *Erwinia, Pectobacterium*, and *Brenneria* species cause wilt and rotting diseases on plants, food crops, and trees or are part of the epiphytic flora. There has been one report of a urinary tract infection in an 88-year-old woman caused by *Erwinia persicinus*, which previously had been isolated only from a variety of fruits and vegetables.[485] Recently, a new phytopathogenic species isolated from diseased Erythrina trees was determined to be sufficiently different from *Erwinia, Brenneria,* and *Pectobacterium* to warrant placement in a new genus and has been designated *Samsonia erythrinae*.[621]

Miscellaneous New Genera of Enterobacteriaceae

Table 6-25 is a listing of the more recently described and less common species of *Enterobacteriaceae*. New genus-andspecies designations have evolved from DNA hybridization studies and biochemical characterizations performed on atypical strains referred to the CDC and other reference laboratories for identification and classification. Many of these new genus names have been applied to bacterial strains that, at one time, were designated atypical enteric groups at the CDC. Several enteric groups remain unnamed, but will probably achieve genus status in the future when a sufficient number of strains are gathered.

Identification Characteristics of Newer *Enterobacteriaceae*. The key identifying characteristics of several of the new genera are listed in Table 6-26. Learning the new genera need not be overly difficult if one remembers that most of these bacteria represent atypical strains closely related to well-established groups. For example, the closely related genera *Buttiauxella*[228] and *Kluyvera*[222] will phenotypically present as "citrate-positive *E. coli*"; the specific characteristics by which they can be differentiated are included in Table 6-26. Bacteria belonging to *Cedecea*[225,268] resemble *Serratia* because they are lipase-positive and are resistant to cephalothin and colistin; however, unlike *Serratia*, they do not hydrolyze gelatin or DNA.

Ewingella,[267] *Rahnella*,[312] and *Tatumella*[295] will initially be grouped with *Pantoea agglomerans* because they are lysine-, ornithine-, and arginine decarboxylasenegative. The genera *Yokenella*[363] and *Obesumbacterium*[541,542] are similar to *Hafnia alvei*; *Moellerella*[289] can be considered phenylalanine-negative, lactose-positive *Providencia;* and *Leminorella*[290] can be thought of as phenylalanineand urease-negative *Proteus* species. By using this orientation, identification is made somewhat easier.

The reaction patterns of these new genera and species have been incorporated into the numerical code files of most computer-assisted identification systems. Thus, the names of these genera and species may appear in the computer-generated reports of many commercial systems. In these instances, it may be necessary to visually check the individual reactions for accuracy and assess additional characteristics using Table 6-26 or the expanded Table 6-7. Careful correlation of the

TABLE 6-25 New Genera and Species in the Family *Enterobacteriaceae*

New Designation	Previous Designation	Comments
Arsenophonus nasoniae	New species	Not isolated from humans. Cause of the sun-killer trait in the parasitic wasp, *Nasonia vitripennis*.
Averyella dalhousiensis	Enteric group 58	Clinical isolates have been from wounds and feces.
Budvicia aquatica	"HG group"	H_2S (+). Frequently found in drinking and surface water. Has been isolated from human feces, but is not associated with human disease.
Buttiauxella agrestis	"Group F"	Biochemically closest to *Kluyvera*. Key reactions are IMViC (−, +, −, +), LAO (−, −, +), Sucrose (−). Isolated from water. No human isolates reported.
Buttiauxella brennerae	New species	Isolated from mollusks, water, soil, and humans
Buttiauxella ferragutiae	"Group F" Enteric group 63	Isolated from water and soil.
Buttiauxella gaviniae	"Group F" Enteric group 64	Isolated from mollusks.
Buttiauxella izardii	New species	Isolated from mollusks.
Buttiauxella noackiae	Enteric group 59	Like Pantoea agglomerans except arginine positive. Isolated from mollusks, human sputum and wounds, and food.
Buttiauxella warmboldiae	New species	Isolated from snails.
Cedecea davisae	"Enteric group 15-Davis subgroup"	*Cedecea* resemble *Serratia* because they are lipase (+), and resistant to colistin and cephalothin, but unlike *Serratia* are gelatin and DNase (−). *C. davisae* is most common species. Sputum is the most common source.
Cedecea lapagei	"*Cedecea* species 4"	Isolated from human respiratory tract specimens.
Cedecea neteri	"*Cedecea* sp. strain 002" "*Cedecea* sp. strain 001"	Isolated from blood cultures of patient with valvular heart disease. Isolated from sputum and heart blood at autopsy.
Cedecea sp. 3	"*Cedecea* sp. strain 012"	Toe wound.
Cedecea sp. 5		
Cedecea sp. 6		
Ewingella americana	Enteric Group 40	IMViC (−, +, +, +), LAO (−, −, −). Strains may formerly have been classified as *Enterobacter agglomerans*, but differ by being arabinose (−). Isolated from sputa, wounds, and blood cultures.
Kluyvera ascorbata	Enteric Group 8	Looks like *E. coli* except malonate, esculin, and citrate (+). Dark purple pigment on non–blood-containing media. Most common source is sputum followed by urine, stool, and blood.
Kluyvera cochleae	New species	Isolated from mollusks.
Kluyvera cryocrescens	Enteric Group 8	Similar to *K. ascorbata* except grows and ferments glucose at 5°C.
Kluyvera georgiana	Enteric Group 8 *Kluyvera* sp. group 3	Isolated from human sputum and throat.
Kluyvera intermedia	*Enterobacter intermedium*	Isolated from foot wound, blood, stool, and bile.
Leclercia adecarboxylata	Enteric Group 41 *Escherichia adecarboxylata* *Enterobacter agglomerans* HG XI	IMViC (+, +, −, −), LAO (−, −, −). Yellow pigmented. Resembles E. coli on MacConkey and EMB agars. Isolated from a variety of clinical specimens, food, water, and the environment.
Leminorella grimontii	Enteric Group 57	H_2S (+), TDA (−), LAO (−, −, −), IMViC (−, +, −, +). Isolated from human feces and urine.
Leminorella richardii	Enteric Group 57	Same as *L. grimontii* except for IMViC (−, −, −, −).
Leminorella species 3	Enteric Group 57	
Moellerella wisconsensis	Enteric Group 46	Looks like *E. coli* on enteric media. IMViC (−, +, −, +), LAO (−, −, −), lactose and sucrose (+). Originally isolated from stool cultures in Wisconsin.

Photorhabdus luminescens subsp. *luminescens* *Photohabdus luminescens* subsp. *akhurstii* *Photohabdus luminescens* subsp. *laumondii* *Photohabdus temperata* subsp. *temperata* *Photohabdus asymbiotica*	*Xenorhabdus luminescens* New subspecies New subspecies New species and subspecies New species	Bioluminescent and biochemically inactive. Optimum growth at 25°C. All human clinical isolates belong to *P. asymbiotica*. Colonies are yellow pigmented, produce an unusual hemolytic reaction, and are negative for nitrate reduction. Isolates have been from human wounds and blood.
Pragia fontium		H_2S (+), biochemically similar to *Budvicia*. Most strains from drinking water in Czechoslovakia.
Rahnella aquatilis *Rahnella* species 2 *Rahnella* species 3	Group H2	LAO (−, −, −), nonmotile at 36°C, but motile at 25°C, PAD (wk +), no yellow pigment. May have been identified as *E. agglomerans* in the past. Isolates have been from water, foods, and various human sources.
Shimwellia pseudoproteus	*Flavobacterium proteus* *Obesumbacterium proteus* biogroup 2	No human isolates reported. Common brewery contaminant. Grows slowly when incubated at 36° C, making it difficult to identify.[541,542]
Tatumella ptyseos	Group EF-9	Pinpoint colonies, slow growing, relatively inert. Motile at 25°C, but nonmotile at 35°C. Flagella are polar, lateral, or subpolar rather than peritrichous. Large zones of inhibition are formed around disks containing penicillin (10 U). PAD very slow (wk +). Isolated from human clinical specimens, particularly sputum.
Trabulsiella guamensis	Enteric Group 90	H_2S (+) and biochemically similar to *Salmonella*. IMViC (−, +, −, +), Lysine (+), Arginine (50% +), Ornithine (+). Isolates have been from soil and human feces. No evidence that it causes diarrhea.
Xenorhabdus beddingii *Xenorhabdus bovienii* *Xenorhabdus japonicus* *Xenorhabdus nematophilus* *Xenorhabdus poinarii*	*Xenorhabdus nematophilus* subsp. *beddingii* *Xenorhabdus nematophilus* subsp. *bovienii* *Achromobacter nematophilus* *Xenorhabdus nematophilus* subsp. *poinarii*	Has been isolated only from nematodes.
Yokenella regensburgei	*Koserella trabulsii* Enteric Group 45 Japanese NIH biogroup 9 atypical Hafnia *Hafnia* species 3	Biochemically similar to *Hafnia alvei*. Differs by being colistin-resistant and VP (−). Isolated from blood, wounds, throat, sputum, feces, and water.
Enteric group 60 Enteric group 68 Enteric group 137		Biochemically inactive. Recovered from urine and sputum. DNase (+) but otherwise biochemically different from *Serratia*. Clinical isolates have been from urine. Closely related to *Citrobacter farmeri* and *Citrobacter amalonaticus*. Isolated from sputum, urine, and wounds.[656]

IMViC, indole, methyl red, Voges–Proskauer, citrate; LAO, lysine, arginine, ornithine; MIO, motility, indole, ornithine; PAD, phenylalanine deaminase; HG, hybridization group; (+), >90% of strains positive; (−), >90% of strains negative; (v), variable.

biochemical activity with the growth patterns and appearance of colonies on agar media is usually enough to make accurate identifications. It cannot be overemphasized that students and microbiologists must retain a fundamental orientation to the morphology, physiology, and biochemistry of bacteria if accurate identifications are to be made.

Clinical Significance of Newer *Enterobacteriaceae.*

The seemingly endless reclassification and changes in bacterial taxonomy and the

frequent addition of new genera and species might be discouraging for microbiology students and instructors alike. However, Farmer and associates conducted a study of scores of unclassified biogroups submitted for identification at the CDC and have brought order out of disarray in a landmark report that summarizes all of the old and new genera of *Enterobacteriaceae* known as of January 1985.[220] As these investigators point out, up to 95% of all *Enterobacteriaceae* recovered in clinical laboratories are *E. coli, K. pneumoniae*, and *Proteus mirabilis;* over 99% of the isolates belong to only 23 species, leaving less

than 1% as the incidence of recovery for the several newly designated species. Thus, the bacteria listed in Table 6-25 are rarely encountered in most clinical laboratories; however, as Dr. Farmer has also stated, there are at least three reasons why these new species of *Enterobacteriaceae* are important to clinical microbiologists: (1) Some species cause serious human infections; (2) others occur in clinical specimens, but their causative role in disease is uncertain; and (3) many are biochemically similar to well-established species and thus can cause problems in identification. The clinical significance of the newer species that have been recovered from human clinical

specimens is summarized as follows:

Averyella dalhousiensis is the proposed name for CDC enteric group 58.[330] *A. dalhousiensis* has been most frequently isolated from traumatic injuries, fractures, and wounds and rarely from feces.[220] One case of septicemia associated with infection of a central venous catheter has been described.[330] *A. dalhousiensis* is not included in the databases of commercial identification systems and is most commonly misidentified as *Enterobacter* spp., *Salmonella* spp., *Serratia* spp., *Kluyvera* spp., or *Escherichia* spp.[330] There is little known about the epidemiology, pathogenesis, or clinical significance of this organism. Phenotypic reactions are listed in Table 6-7.

290

The genus *Buttiauxella* now contains seven species (see Table 6-25) that occur frequently and abundantly in the intestines of snails, slugs, and other mollusks.[449] A few strains have been isolated from unpolluted soil and drinking water, surface water, sewage, soil, and fecal samples, but have not been isolated from primary sterile clinical specimens.[449] Two clinical isolates of *B. gaviniae*-like organisms have been reported from urine and leg wound specimens in Belgium. The isolates were biochemically indistinguishable from *B. gaviniae,* but 16S rRNA gene sequencing was indecisive.[174]

Cedecea davisae has been isolated from respiratory specimens,[31] blood,[1,13,165,411,516] a scrotal abscess,[30] cutaneous ulcer,[277] and an oral ulcer.[418] *C. neteri* has been reported as a cause of bacteremia.[11,225] *C. lapagei* has been reported to cause lung tissue infection,[151] peritonitis,[170] pneumonia,[681] and bacteremia.[162]

Ewingella americana was described in 1983 and named in honor of the American bacteriologist, William Ewing.[267] The original strains were from human clinical specimens, including sputum, blood, throat, toe and thumb wounds, urine, and stool.[220,267] *E. americana* has been implicated in bacteremia,[182,524] catheter-related bacteremia,[408] an outbreak of nosocomial bacteremia,[523] and an outbreak of pseudobacteremia associated with nonsterile blood collection tubes.[422,423,424] It has also been associated with wound colonization,[40] conjunctivitis,[283] and peritonitis in a patient undergoing peritoneal dialysis.[340]

The genus *Kluyvera* presently contains four species (see Table 6-25).[449,511] The original isolates of *Kluyvera* species were from human clinical specimens and the environment. The most common human sources have been sputum, followed by urine, stool, throat, and blood.[222] Environmental sources noted have been sewage, soil, kitchen food, water, milk, and a hospital sink.[222] There are only a few reports of serious infections with *Kluyvera* species that involved the urinary tract,[636] the

gallbladder,[632] the gastrointestinal tract,[10,215] and soft tissue of the forearm following a cut from a garbage can.[402] In addition, cases of catheter-related bacteremia[676] and mediastinitis and bacteremia following openheart surgery[595] have been reported. *K. intermedia* (formerly *E. intermedius* and Group H1)[650] had not been known to occur in humans until 1987 when Prats et al.[539] reported four strains of *K. intermedia* (*E. intermedius*) that had been isolated from a foot wound, blood, stool, and bile. More recently, O'Hara et al.[486] reported the isolation of *K. intermedia* from the gallbladder of a patient with cholecystitis that also grew group D *Streptococcus*, and coagulase-negative *Staphylococcus*.

The clinical significance of *L. adecarboxylata* is uncertain, but human isolates from blood, sputum, urine, stool, and wounds have been reported.[164,167,173,178,234,397,420,435,498,560,591,622,629] There have been at least two reports of *L. adecarboxylata* bacteremia in premature infants.[453,461] At the University of Illinois Hospital, *L. adecarboxylata* was found colonizing the endotrachea of a neonate and in a cystoscopic urine specimen from a patient in renal failure. In both cases, the organism was isolated along with other pathogen species; therefore, an etiologic role could not be established. In a third patient, *L. adecarboxylata* was recovered in pure culture from the blood of a patient in chronic renal failure receiving hemodialysis. Stock and colleagues studied the natural antimicrobial susceptibility patterns and biochemical profiles of *L. decarboxylata,* and reported that strains were naturally sensitive to tetracyclines, aminoglycosides, all but two β-lactams, quinolones, folate-pathway inhibitors, chloramphenicol, nitrofurantoin, and azithromycin. They were naturally resistant to penicillin G, oxacillin, erythromycin, clarithromycin, ketolides, lincosamides, streptogramins, linezolid, glycopeptides, rifampicin, and fosfomycin.[616]

Leminorella has been isolated primarily from stool and urine.[290] One case of spontaneous peritonitis caused by *L. grimontii* has been reported.[163] Blekher and associates[51] reviewed the medical records of 14 patients from which *Leminorella* spp. were isolated and classified 43% of the cases as definite pathogens, 29% as probable pathogens, and 21% as possible pathogens. Clinical syndromes included urinary tract infections (six patients), surgical site infection (three), and primary bacteremia, peritonitis, respiratory tract infection, and soft tissue infection in one patient each. In one case of asymptomatic bacteriuria, the isolate had no clinical significance.[51] *Leminorella* spp. appear as lactose-negative colonies on primary plating media and gives an alkaline slant and a weak acid reaction with H_2S in the butt of TSI after 48 hours. Similar to *Proteus, Leminorella* species are H_2S-positive, D-mannose-negative, and tyrosine-positive, but unlike *Proteus*, they are ureaand phenylalanine-negative and L-arabinose-positive.

Moellerella wisconsensis was originally found in human stool samples, mainly from the state of Wisconsin.[289] It has also been isolated from water and animals and from clinical specimens other than stool, such as the gallbladder[476,674] and a bronchial aspirate.[654] However, the majority of isolates have been from human feces, and there is evidence that *M. wisconsensis* is associated with human diarrhea.[320] On MacConkey agar, colonies appear bright red with precipitated bile around them; thus, they are indistinguishable from *E. coli* colonies.[289] Stock and colleagues report that *M. wisconsensis* is naturally sensitive to doxycycline, minocycline, all aminoglycosides, numerous β-lactams, all fluoroquinolones, folatepathway inhibitors, chloramphenicol, and nitrofurantoin.[617]

Photorhabdus species are the only terrestrial bioluminescent bacteria (bacterial bioluminescence is seen primarily in marine species). The classification within the genus is complex, with three currently recognized species: *P. luminescens* (formerly, *Xenorhabdus luminescens*), *P. temperata*, and *P. asymbiotica*.[54,231] Several subspecies are recognized (Table 6-25). *Photorhabdus* spp. inhabit the gut of some insectpathogenic nematodes, where they form a symbiotic relationship. Nematode species of this type are able to invade the larvae of susceptible insects and release *Photorhabdus* spp. The bacteria proliferate and kill the insect larvae.[250] Insectpathogenic nematodes harboring *Photorhabdus* spp. are used as biopesticides in a number of countries, including the United States and Australia. A total of 12 human infections with *Photorhabdus* spp. have been reported from the United States and Australia, most often causing skin and soft tissue infections and rarely bacteremia.[223,250,512] Colonies are formed on blood agar plates (BAP) after 24 to 48 hours at both 35°C and at room temperature, with a tendency to "swarm."[250] The defining characteristic is the presence of faint luminescence, which can be seen with the naked eye under conditions of total darkness. Gerrard and colleagues have observed that it is

291

critical to allow the observer's eyes to adjust to the darkness for 10 minutes.[250] *Photorhabdus* spp. do not currently appear in the databases for either the MicroScan Rapid or overnight panels, or the Vitek GNI+ cards, which leads to misidentifications when using these systems.[250]

The genus *Rahnella* consists of three closely related species, *R. aquatilis* and two genomospecies that cannot be phenotypically differentiated from *R. aquatilis* and therefore are given the vernacular names *Rahnella* genomospecies 2 and *Rahnella* genomospecies 3.[71] The natural habitat of *Rahnella aquatilis*, as its name implies, is

water, and most isolates in the original CDC collection were from water, except two isolates from humans (one from a burn wound and the other from the bronchial washing of a patient with HIV).[278] Of the few case reports of *R. aquatilis* in the literature, most describe infections in immunocompromised patients. In addition to the CDC isolates, others have reported the isolation of this organism from sputum (in a patient with chronic lymphocytic leukemia and emphysema),[143] the urinary tract (in a patient with a renal transplant),[14] from a surgical wound possibly due to a nosocomial source,[413] and from blood of immunocompromised[88,90,242,260,298] and immunocompetent[133] patients. *R. aquatilis* has also been isolated from vegetables (primarily carrots) purchased in supermarkets[276] and has been identified as the causative agent of a smoky/phenolic odor (due to the formation of guaiacol) in spoiled, refrigerated chocolate milk.[329]

Of the original strains of *Tatumella ptyseos* studied at the CDC, 30 were from sputum, 6 from throat cultures, 3 from blood, and 1 each from a tracheal aspirate, a feeding tube, a pharynx, a stool, and urine.[295] One case of *T. ptyseos* obtained from the blood culture of a neonate with presumed sepsis has been reported.[624] There are three striking differences between *T. ptyseos* and other members of the *Enterobacteriaceae*: (1) strains produce a large zone of inhibition around penicillin; (2) it has a tendency to die on some laboratory media, such as blood agar, within 7 days; and (3) usually only one flagellum (either polar, subpolar, or lateral) is observed per cell.[295]

Trabulsiella guamensis, formerly known as enteric group 90, is H_2S-positive and biochemically resembles *Salmonella* subgroups 4 and 5.[425] Strains have been isolated from vacuum cleaner dust, soil, and human feces; however, there is no evidence that it causes diarrhea. Its main interest to clinical microbiologist may be its possible misidentification as a strain of *Salmonella* (see Table 6-26).

Yokenella regensburgei was originally identified as NIH biogroup 9 by the NIH in Japan[363] and later found to be identical to "*Koserella trabulsii*" (enteric group 45) named by workers from the CDC.[288,362] Because the name *Y. regensburgei* has priority over "*K trabulsii*" by virtue of prior publication, the use of the later name has been discontinued. In the original reports, *Y. regensburgei* had been recovered from the intestinal tracts of insects and well water, as well as human clinical specimens, including wounds of the limbs, the upper respiratory tract, urine, feces, and knee fluid.[288,363] More recently, Abbott and Janda have reported the recovery of *Y. regensburgei* from the blood of a patient with a transient bacteremia and from a knee wound of a patient with a diagnosis of septic knee.[3] The organism most closely resembles *H. alvei,* from which it must be differentiated (see Table 6-26).

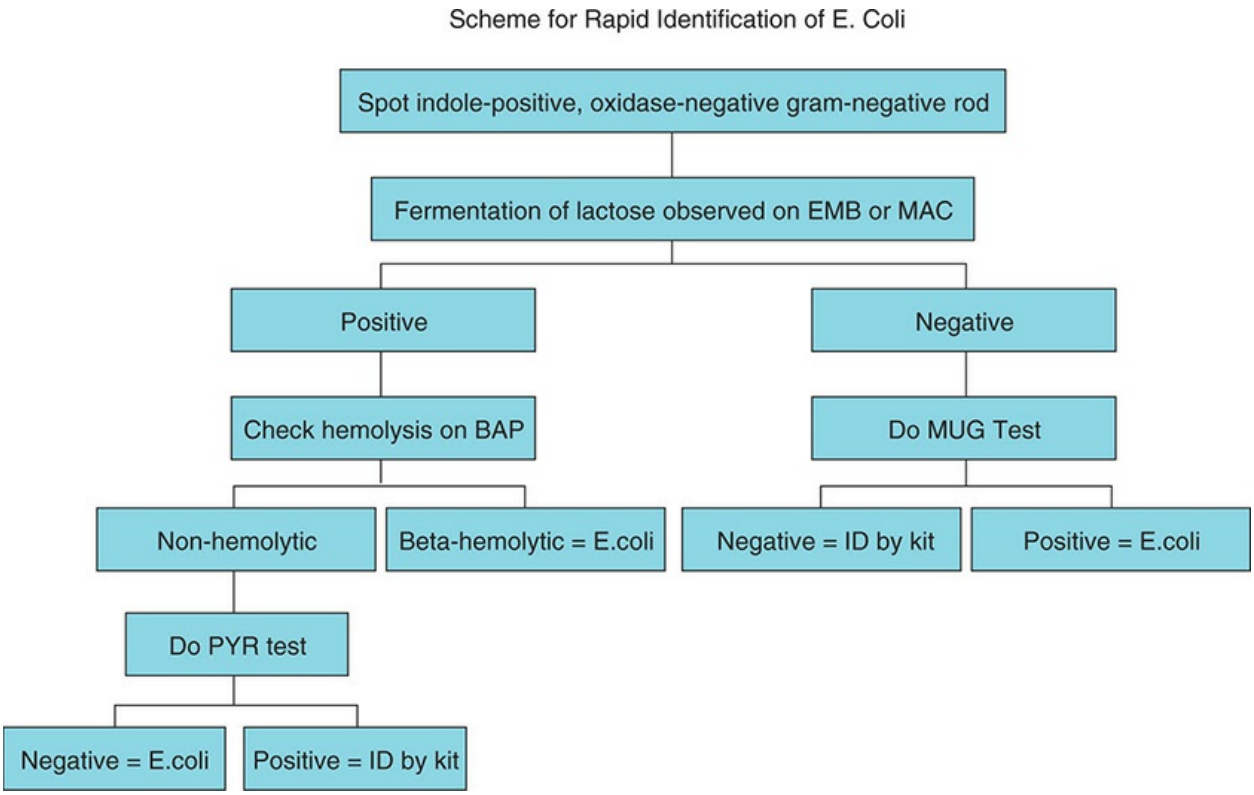
Quick Screening Methods for Rapid Identification

E. coli, the bacterial isolate most frequently recovered in clinical laboratories, is often presumptively identified if an oxidase-negative, lactose-fermenting, dry colony on Mac-Conkey agar gives a positive spot indole reaction (when tested on a colony growing on noninhibitory media, such as blood agar), particularly if the organism has been recovered in pure culture.[34] The spot indole test is also used in many laboratories for rapid speciation of swarming *Proteus* from primary isolation plates.[35] A rapid (2-minute) spot urease test has been described by Qadri and colleagues.[544] This test might be used to separate possible stool pathogens that require further biochemical testing from the nonpathogenic *Proteus–Providencia–Morganella* group. Taylor and Achanzar have reported using the catalase test (with 3% H_2O_2) as an aid in the identification of *Enterobacteriaceae*.[628] They observed vigorous catalase reactions with *Serratia, Proteus*, and *Providencia;* moderate reactions with *Salmonella, Enterobacter*, *Klebsiella*, and rare *Escherichia;* and weak reactions with *Shigella* and most *Escherichia*. They report using the rapid catalase test for screening suspicious colonies on enteric media that mimic stool pathogens. Colonies of *Serratia, Proteus, Providencia*, or *Pseudomonas* are quickly eliminated by vigorous catalase reactions, in contrast to salmonellae, which give weak-to-moderate reactions, or shigellae, which are negative and, therefore, are flagged for further workup. Chester and Moskowitz[140] have reported on the catalase activity of many of the newer members of the *Enterobacteriaceae* and further advocate the use of catalase activity as a rapid supplemental test. Mulczyk and Szewczuk[448] suggested that the test for L-pyrrolidonyl peptidase (PYR) is of great value in differentiating between *Salmonella* and *C. freundii* complex strains. Other authors have also noted the value of using the PYR test for separating *Salmonella* and *E. coli* strains (both negative from *Citrobacter* spp. (PYR+).[131,307] York and colleagues[683] have proposed an algorithm for rapid identification of *E. coli* based on spot tests for oxidase, indole, and PYR and observation of lactose fermentation on MacConkey or EMB and presence or absences of β-hemolysis on BAP (Fig. 6-8). Their algorithm permitted identification of the majority of suspected *E. coli* strains with an accuracy of greater than 99% and a 75% reduction in cost of reagents and technologist time, as well as a decrease in the time to reporting. Clearly, any of these approaches has validity in an era of cost-containment and the desire to receive test results quickly.

Commercial Screening Kits

Several commercial companies have marketed rapid detection kits for the identification of *E. coli*: E.COLI SCREEN, MUG Disk, and BactiCard *E. coli* (Remel, Lenexa,

KS); Lyfo-Kwik OMI (MicroBioLogics, St. Cloud, MN); and ColiScreen (Hardy Diagnostics, Santa Maria CA). These test systems are based on the finding that the majority of strains of *E. coli* are rapidly indole-, ONPG-, and MUG (4-methylumbelliferyl-β-D-glucuronide)-positive.[198,349] The hydrolysis of MUG releases 4-MEU, which is highly fluorescent when viewed under long-wave ultraviolet (UV) light. An interesting use of



■ **FIGURE 6-8** Identification scheme for the separation of *E. coli* from other indole-positive, oxidase-negative rods. BAP, blood agar plate; EMB, eosin methylene blue; MAC, MacConkey agar; MUG, 4-methylumbelliferyl-β-D-glucuronide; PYR, L-pyrrolidonyl-β-naphthylamide; ID, identification. (Modified from York MK, Baron EJ, Clarridge JE, et al. Multilaboratory validation of rapid spot tests for identification of *Escherichia coli*. J Clin Microbiol 2000;38:3394–3398.)

the MUG test is to screen isolates of *E. coli* for the detection of serotype O157:H7 strains, which are the Shiga-like, toxinproducing strains associated with hemorrhagic colitis. This specific serotype is both sorbitoland MUG-negative.

Also available is the RapID SS/u System (Remel), consisting of a set of 12 single-substrate chromogenic tests selected to identify rapidly the bacteria most commonly encountered in urinary tract infections (*E. coli, Proteus* species, *Klebsiella* species, *Serratia* species, *Enterobacter* species, *Pseudomonas* species, coagulase-negative staphylococci, enterococci, and others). Answers are available in 30 minutes to 2 hours, depending on the system used and the biochemical activity of the strain being tested. Another system called OMP and NGP Wee-Tabs (KEY Scientific Products, Round Rock, TX) consists of two substrate tablets that together provide eight enzymatic tests, which, combined with urease, will identify approximately 95% of the *Enterobacteriaceae*. The tablets are rehydrated in a bacterial suspension, with results available in 2 to 4 hours. Hardy Diagnostics (Santa Maria, CA) offers the EnteroScreen4, which is a single tube screening system for use in screening stools for *Salmonella* and *Shigella* species. This system detects lysine deaminase, lysine decarboxylase, H_2S, and urea in a single inoculation onetube configuration.

Chromogenic Agar Media

Chromogenic agar contains artificial substrates (chromogens) that when hydrolyzed by specific microbial enzymes produce colored compounds (Fig. 6-6). The appearance of various colony types on chromogenic agar are illustrated in Image Plates 6-5E through H. Kilian and Bülow were the first to use selective chromogenic medium for the direct identification of *E. coli* in primary culture of urine.[350] Currently, several chromogenic media allowing the direct identification of *E. coli*, *P. mirabilis*, and *Enterococcus* spp. are marketed: CPS ID2 (bioMérieux, Hazelwood, MO),[25,93,137,284,419,470,556,579,670] CHROMagar Orientation (BD Diagnostics, Sparks, MD; Hardy Diagnostics, Santa Maria, CA),[25,93,189,284,302,428,489,575,579] Rainbow UTI (Biolog, Hayward, CA),[53,93,582] and Chromogenic UTI (Oxoid, Basingstoke, United Kingdom).[25,93,137] In evaluations of multiple formulations of these media, the detection rates and identification rates are very similar.[25,93,137] In one study, the use of chromogenic agar allowed a >50% reduction in inoculation time and a >20% reduction in workup time.[189] To extend identification to additional species, colony characteristics on chromogenic agar can be combined with easy-to-use confirmatory spot tests that can be performed in seconds either on paper strips or directly on the agar medium.[489] One cautionary note, however, is that inocula taken from chromogenic agar plates may not be suitable for susceptibility testing with certain automated test systems. Reisner and Austin showed that susceptibility testing directly from CPS ID2 medium resulted in low error rates for all antimicrobial agents tested using the Vitek Legacy System (bioMérieux, Hazelwood, MO).[556] Laboratories using chromogenic media should check with their instrument manufacturer to determine the compatibility of using

inocula from chromogenic agar for antibiotic susceptibility testing on the system in use in their laboratory.

293

Classic Identification Systems

Systems for the identification and naming of microorganisms are either computer-assisted or manual. Before discussing the derivation and applications of numeric coding systems, two manual bacterial identification schemes that are still in use will be reviewed: (1) the cross-hatch or checkerboard matrix, and (2) the branching or dichotomous flow charts.

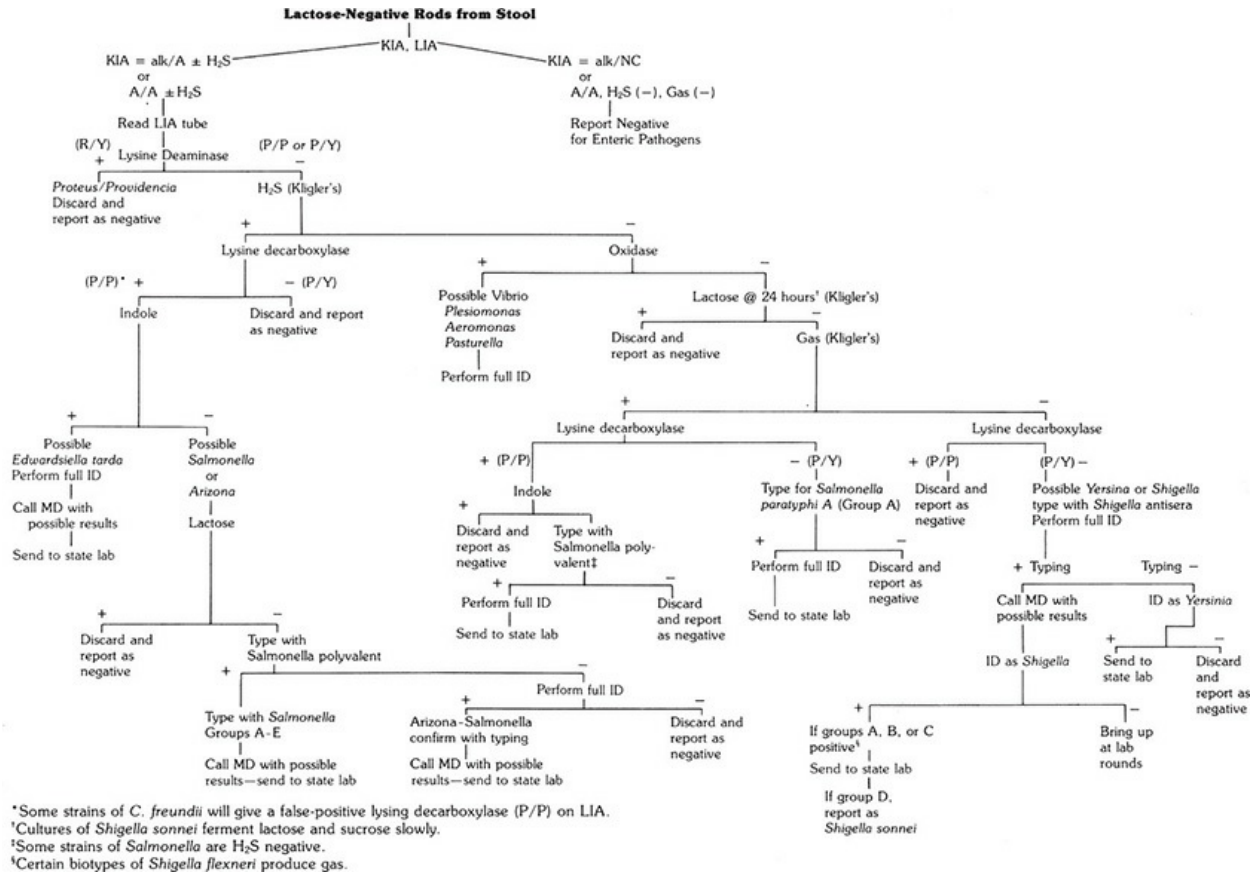
Checkerboard Matrix

Table 6-7 is a comprehensive identification table originally formulated by Farmer and colleagues for use at the CDC to identify all named species, biogroups, and unnamed enteric groups of the *Enterobacteriaceae*. This table is a classic example of the checkerboard matrix and demonstrates its advantages and disadvantages. The matrix is large, with 48 biochemical characteristics for 37 genera, 148 species, biogroups, and unnamed enteric groups. The numbers in the intersecting squares represent the percentage of strains that are positive or reactive against the various biochemical tests (listed in the vertical columns). A reaction is generally considered positive if 90% or more of the strains are reactive, negative if 10% or fewer of the strains fail to produce a result, and variable if 11% to 89% of reactions are positive. The ability to determine both the positive and negative reactions for the various characteristics being measured in this type of identification system results in a high degree of diagnostic accuracy. The major disadvantage of the checkerboard matrix is the tedium involved in matching point by point the various reactions against those derived from the test media and constructing the patterns that best match with a specific genus, species, or biogroup.

Branching Flow Diagrams

Flow diagrams were designed to reduce the tedium of reading the checkerboard matrices and to facilitate the likely bacterial identification by tracing a series of positive and negative branch points in a dichotomous algorithm (Fig. 6-8, 6-9). With the advent of automated instruments and packaged identification systems that rely on computer-assisted analyses of the various reactions of the characteristics being measured, flow diagrams are now used less frequently in clinical laboratories. One problem with flow diagrams has been the potential for inaccuracy if the reaction at a given branch point is

either aberrant (i.e., not typical for the species), misinterpreted, or the result of the reactions of a mixed culture. Many flow diagrams are constructed to repeat some species names at several junctures to accommodate reactions that may be less than 100% or in the variable category (Fig. 6-9). However, this built-in protection



■ **FIGURE 6-9** Schematic for screening of enteric pathogens from stool using KIA and modified LIA.

does not always apply for reactions that are misinterpreted, either by an automated instrument's detection system or by the human eye.

A modification of this approach is being used in many microbiology laboratories for the preliminary screening of commonly encountered bacterial species that are associated with specific infectious disease syndromes. York and colleagues[683] have presented a simple scheme for the rapid identification of *E. coli* from EMB or MacConkey agar (Fig. 6-8). To validate this scheme, five laboratories sequentially collected 1,064 fresh, clinically significant strains with the core criteria of indole-

positive, oxidase-negative, nonspreading organisms on BAP. Of the 1,064 strains tested, 1,000 were *E. coli* and 64 were non–*E. coli*. Using the scheme, three non–*E. coli* isolates were identified as *E. coli,* for an error rate of 0.3%. A total of 13 kit identifications, 657 PYR tests, and 113 MUG tests were needed to identify 1,000 *E. coli* strains with the algorithm.[683] The authors showed that the use of this rapid system saves laboratory resources, provides timely identifications, and yields rare misidentifications. The Clinical and Laboratory Standards Institute (CLSI) has produced a guideline (M35-A2, *Abbreviated Identification of Bacteria and Yeast: Approved Guideline–Second Edition*) that describes tests that can be used to identify a number of aerobic gram-negative rods and gram-positive cocci, a number of commonly isolated anaerobes, and three species of yeast.[149] Because all methods described in the guideline yield results that are highly accurate—attaining a level of reliability equal to or better than current conventional biochemical tests, multitest systems, and automated systems—the resulting identification does not require the adjective "presumptive" qualifying the resulting identification. The genus and species (or genus only, as designated by the algorithm) can be reported without any qualifying wording.[36] Laboratory workers are referred to the CLSI document for methodologic details about the tests chosen and for more information than is presented here.[149]

An algorithm using a KIA and LIA tube (supplemented with tryptophan for detection of indole) has been used for many years in one of our laboratories for the screening of enteric pathogens from stool (Fig. 6-9). Definitive biochemical and serologic procedures are performed only on isolates with reactions that are presumed to be positive, saving the cost of performing more expensive kit identifications.

In addition to saving the cost of setting up commercial test panels, these dichotomous schemes coupled with a few inexpensive biochemical tests and observations offer an additional advantage over automated systems in that they require thought, reasoning, and knowledge on the part of the student or microbiologist, who is not reduced to being a passive observer.

Computer-Aided Schemes

WIP (Web ID Program) is a free online program (developed by Adam Schreckenberger © 2014) that can be used to identify bacteria without the use of downloaded software. The WIP application works on any PC, Apple, or smartphone system with an active Internet connection. Because the program runs within an Internet browser, it requires no additional downloads. One merely needs to enter available phenotypic characteristics into the online Web form to calculate a likelihood probability and modal score. If the likelihood score is less than 95%, a list of phenotypic tests that distinguish the top two candidates will be displayed; likewise, if the modal score is poor, a list of input results that do not match well to the top

candidate prediction will be shown. The program provides statistical selection of unknown bacterial isolates through comparisons to phenotypic characteristic matrices of known strains. The program has three major functions: (1) the identification of an unknown isolate, (2) the selection of additional tests to distinguish between possible strains if identification is not achieved, and (3) the storage and retrieval of results. An assortment of WIPs, each of which targets a specific subset of gram-negative bacteria, is available on www.pschreck.com by clicking the appropriate WIP tab of choice on the site toolbar. This collection is referred to as the AID (App Identification) Cloud. Each WIP references a specific characteristic matrix that was created either from a published table in the literature or from the author's own data. References for each of the four tables are as follows:

Enterics WIP—Enterobacteriaceae courtesy of Brent Barrett using CDC *Enterobacteriaceae* Tables originally developed by J.J. Farmer, PhD, retired from CDC with revision by Caroline O'Hara, and updated with results published in the International Journal of Systemic Bacteriology, & A.P. Schreckenberger.

Vibrio WIP—Vibrio species courtesy of Brent Barrett using Tables developed by J.J. Farmer, PhD, retired from CDC (c)2005, & A.P. Schreckenberger.

Salmonella WIP—Salmonella species CDC Biochemical Tables 4-6-2009 Rev 1 (c)2009, courtesy of Brent Barrett, & WIP dev courtesy of A.P. Schreckenberger.

The table associated with the ASHEX Non-Fermenter WIP is available as a downloadable Excel spreadsheet. This file includes the characteristic matrix as well as the raw phenotypic reaction results used to compute each probability. The complete table is reproduced in Chapter 7 of this text. To access the WIP, go to www.pschreck.com and click the WIP tab of your choice in the toolbar and enter your reactions on the worksheet.

BioBASE 8.0 (BioBASE, Boston, 1994 to 2014 by Peter Alachi) is a computer-enhanced numeric identification software package for use on personal computers that allows the user to create, update, and manipulate unlimited numbers of microbial databases. The current version of BioBASE runs on any Windows-based machine, including Windows 7/Vista and 8.0. It is equipped with several database frequency files, which are used for the identification of unknown bacteria such as the *Enterobacteriaceae*. Conventional biochemical reactions on an unknown isolate are entered into the appropriate database whereby the program compares the unknown profile with that of any taxon in the database. To reach an identification verdict, BioBASE calculates identification scores, modal scores, and similarity indices of each taxon and compares them with the unknown's input data. The topscoring microorganisms are then analyzed and weighted for a decision on identification,

ranging from unacceptable to

295

excellent. Miller and Alachi evaluated this program and report it to be user-friendly, rapid, and accurate, and state that it would be of value to any laboratory that uses conventional biochemicals.[438]

Numeric Coding Systems

The identification of the *Enterobacteriaceae* and many other families and groups of bacteria has been facilitated by the use of automated and packaged kit systems, by which organisms are identified with computer-assisted numeric codes. A numeric code is a system by which the several identifying characteristics of bacteria are translated into a sequence of numbers that represent one or more bacterial species. The fact that the identification of microorganisms is based on a series of positive and negative biochemical reactions makes computer programming easy because computer logic is also constructed on a sequence of positive and negative entries, using a binary numeric system. In binary logic there are only two numbers: "0" (or off) and "1" (or on). As can quickly be surmised, the identification characteristics of microorganisms can be easily translated into binary numbers by assigning a "1" to all positive reactions and a "0" to all negative reactions. This approach can be illustrated using the sequence of characteristics in the API 20E strip (bioMérieux) as a point of reference and converting the positive and negative reactions into binary numbers (Table 6-27). If the binary numbers shown in Table 6-27 are read from top to bottom and rearranged horizontally, the following 21-digit binary number is derived:

10101000011111011100

Although computers are constructed to receive 1/0 bits of data from which to calculate meaningful results, the human mind cannot efficiently manipulate binary logic; therefore, binary codes must be converted into simpler mathematic systems to become usable. Conversion of the two-digit (binary) system into an eight-digit (octal) system serves this purpose. To understand the conversion of binary into octal numbers, visualize a series of three light bulbs. By turning different lights on and off, a total of eight combinations is possible, each of which can be represented by one of eight numbers ranging from 0 to 7. If all lights are off (–), the combination—is equivalent to octal 0. If only the left bulb is turned on (+), the combination +– – is equivalent to octal 1. Octal 2 is represented by the binary pattern –+–, and octal 3 by

the pattern + +−. The octal equivalents of the eight combinations of a three-digit binary number are shown in Table 6-28.

To illustrate how binary numbers longer than three digits can be converted into their octal equivalents, use the binary number that was derived from the API 20E reactions:

10101000011111011100

Beginning from the right, because binary numbers are read from right to left, divide the binary numbers into subsets of three:

101 010 000 111 111 011 100

TABLE 6-27 Binary Conversion of Reactions of Unknown Organism on API 20-E Strip

Characteristic	Reaction	Binary Conversion
ONPG	+	1
Arginine	−	0
Lysine	+	1
Ornithine	−	0
Citrate	+	1
Hydrogen sulfide	−	0
Urease	−	0
Tryptophan deaminase	−	0
Indole	−	0
Voges–Proskauer	+	1
Gelatin	+	1
Glucose	+	1
Mannitol	+	1
Inositol	+	1
Sorbitol	+	1

Rhamnose	−	0
Sucrose	+	1
Melibiose	+	1
Amygdalin	+	1
Arabinose	−	0
Oxidase	−	0

TABLE 6-28 Octal Conversion of Binary Code

Binary	Conversion Formula	Octal
− − −	0 + 0 + 0 =	0
+− −	1 + 0 + 0 =	1
− + −	0 + 2 + 0 =	2
+ + −	1 + 2 + 0 =	3
− − +	0 + 0 + 4 =	4
+ − +	1 + 0 + 4 =	5
− + +	0 + 2 + 4 =	6
+ + +	1 + 2 + 4 =	7

Now convert each three-digit subset into its octal equivalent using the formula given in Table 6-28.

101 010 000 111 111 011 100

5 2 0 7 7 6 1

The number 5207761 is far easier to remember and simpler to enter into a computer than the binary number 10101000111111011100.

296

A simpler way of remembering how to convert each binary triplet into its corresponding octal equivalent is to assign the following values (again reading from right to left): A value of 4 to a positive reaction for the first test in each triplet, a value of 2 to a positive reaction for the second test in each triplet, a value of 1 to a positive reaction for the third test in each triplet, and a value of 0 to any negative reactions (see Table 6-28).

These octal derivatives are known as **biotype numbers,** that is, a numeric representative of a series of phenotypic characteristics expressed by and unique to a particular bacterial species. It is important that everyone using biotype numbers, particularly those who are teaching students, understand that each number in the octal system is representative of three biochemical characteristics and that the number itself represents a pattern of positive and negative reactions. There is great danger that modern microbiologists consider biotype numbers as magic figures that can be read from charts or put into computers to derive automatic organism identification, thus losing sight not only of the biochemical reactions that they represent, but also of the biochemical principles on which the discipline of microbiology is based.

Reading Octal Codes in Numeric Code Registers

All manufacturers who have packaged identification kits on the market publish numeric code registers in which hundreds of biotype numbers are matched with one or more bacterial species that are unique for that number. For example, for the biotype number 5207761, derived from the API 20E set of reactions used in the previous example, the following species are listed in the API 20E Profile Index: *Serratia marcescens*: acceptable identification; *S. marcescens*: 1/243; and *S. rubidaea*: 1/2,859.

The message in the API Profile Index for biotype number 5207761 for *S. marcescens* "Acceptable Identification" indicates that *S. marcescens* can be reported. This assessment is based on a computer-derived calculation of the percentage likelihood that *S. marcescens* is the correct identification compared with all the other organisms entered into the database.

Estimated Frequency of Occurrence

The frequency figures listed with each individual species name (in the previous example, 1/243 for *S. marcescens*) indicate the number of strains selected at random that would have a biotype number similar to the strain being studied. In other words, if one were to randomly test 243 *S. marcescens*, there is a chance of 1 in 243 that you will encounter this exact biochemical pattern, whereas if you tested 2,859 randomly selected *S. rubidaea*, you would have a 1 in 2,859 chance of finding a strain of this exact biotype. This figure does not directly indicate the percentage likelihood that one of these species is the correct one, so the user cannot determine from this statistic how viable one of the choices might be.

Calculation of Likelihood

The identification of an unknown organism with a given biotype number is based on the calculation of percentage likelihood between the unknown biotype number and each taxon stored in the memory of the computer. Code registers that list percentage likelihood figures are more useful for everyday decision making in the laboratory. Any identification that has a likelihood of 90% or greater can be reported, those that are near 90% may be easily identified with one or two additional tests, and those with very low likelihood percentages can probably be discounted. The use of messages such as "excellent identification," "acceptable identification," and "very good identification" in the API system implies that there is a percentage likelihood of 90% or greater. However, when the message describes an identification as "questionable" or "doubtful" and the percentage likelihood is not given, the user is unable to make any assessments concerning the likelihood that an unknown represents a certain species. For students and microbiologists who may be trying to understand this concept for the first time, an example for calculating percentage likelihood and frequency of occurrence is given in Table 6-29.

Resolving Discrepancies

It must be pointed out that all answers derived from computer-based identification systems, whether or not they represent 90% or more confidence, must be interpreted in conjunction with other information available on the unknown organism—the colony morphology, reactions on various isolation media, cellular morphology on Gram's stain, results of presumptive biochemical reactions, antibiotic susceptibility patterns, and clinical setting.

When discrepancies occur, visualization of the tubes, reaction chambers, or microcupules, in which the reactions have taken place, may be necessary. In many instances, the visual interpretation of certain reactions may differ from that detected by instruments. When recalculated, the new biotype number may indicate an alternative bacterial identification that is much more in keeping with preliminary and supplemental observations.

Also, any given species may have several biotype numbers because one or more individual reactions may be variable. Consequently, designating bacterial species by biotype numbers may have epidemiologic value in recognizing the emergence of clusters of similar isolates in a given practice setting. For example, recovery of many *E. coli* from a given environment or series of cultures may be of limited value; however, knowing that all of the organisms have the same biotype number may be invaluable. In this way, it may be possible to trace the agents causing hospital nosocomial outbreaks or communitywide epidemics to a common source. Biotype analysis may also lead to a better understanding of the relation between virulence of bacterial variants and the presence or absence of certain biochemical characteristics.

Packaged Kit Identification Systems

The concept of combining a series of differential media or substrates in a single package, selected to aid in identifying members of a group of bacteria, is a logical development. In

297

TABLE 6-29 Calculation of Frequency of Occurrence and Percentage Likelihood

The identification of an unknown profile is based on the calculation of likelihood between the unknown profile and each species of organism stored in the memory of the computer. To test your understanding of frequency of occurrence and percentage likelihood, work through the following example. For ease in explaining the calculations, this example is based on only four biochemical tests and three species.

Step 1. An unknown organism gives the following profile:

	IND	MR	VP	CIT
Unknown	+	−	+	−

Step 2. Known biochemical reactions of three species of *Enterobacteriaceae* for the four tests (shown as percentage of positive reactions).

	IND	MR	VP	CIT
Serratia marcescens	1	20	98	98
Enterobacter agglomerans	20	50	70	50
Klebsiella oxytoca	99	20	95	95

Step 3. Frequencies of occurrence of observed reactions (+ − + −) for each species.

Note: When a test result of the unknown is positive (IND and VP in this example), the probability of the positive reaction of the test listed in the database is used for the calculation. When the test result of the unknown is negative (MR and CIT), the probability of the negative reaction is 1 minus the probability of positive reactions.

	IND	MR	VP	CIT
Serratia marcescens	0.01	0.80	0.98	0.02
Enterobacter agglomerans	0.20	0.50	0.70	0.50
Klebsiella oxytoca	0.99	0.80	0.95	0.05

Step 4. Calculation of frequencies of occurrence of observed profile (+ − + −) for each species. The frequency of occurrence is calculated by multiplying together all the frequencies of occurrence of the reactions.

Serratia marcescens	$= 0.01 \times 0.80 \times 0.98 \times 0.02 =$	0.0001568
Enterobacter agglomerans	$= 0.20 \times 0.50 \times 0.70 \times 0.50 =$	0.0350000
Klebsiella oxytoca	$= 0.99 \times 0.80 \times 0.95 \times 0.05 =$	0.0376200
		0.0727768

Step 5. Identification percentages. Each frequency is divided by the sum of all the frequencies, and then multiplied by 100 to give the %ID. The sum of the percentages of identification is equal to 100.

Serratia marcescens	$\%ID = (0.001568/0.0727768) \times 100 = 0.21\%$
Enterobacter agglomerans	$\%ID = (0.0350000/0.0727768) \times 100 = 48.1\%$
Klebsiella oxytoca	$\%ID = (0.0376200/0.0727768) \times 100 = 51.7\%$

Step 6. Order of likelihood.

1. *Klebsiella oxytoca*	%ID = 51.7
2. *Enterobacter agglomerans*	%ID = 48.1
3. *Serratia marcescens*	%ID = 0.21

What is the likelihood that Klebsiella oxytoca is the correct answer among the three species in the database?

(*Answer:* From step 5, the answer is 51.7%; however, there is a 48.1% likelihood that the unknown organism is *Enterobacter agglomerans;* therefore, additional tests would have to be set up to correctly identify this unknown organism.)

How frequently will Klebsiella oxytoca give this particular reaction profile?

(*Answer:* From step 4, 3.8% of the time; in other words, not very often.)

IND, indole; MR, methyl red; VP, Voges–Proskauer; CIT, growth on citrate.

fact, the availability of packaged identification systems evolved naturally, almost as a practical necessity. The microorganisms currently known to cause infectious diseases are not only legion, but also are often fastidious and require a large battery of biochemical tests for identification. It is beyond the capability of many laboratories to maintain the diversity of conventional media required. The compact construction (requiring little storage space), easily visible chemical reactions, long shelf life, and standardized quality control provided by the manufacturers of these kits make them

very convenient for use in microbiology laboratories. They are especially useful in lowvolume laboratories, where there may not be the time or the technical expertise to make many of these identifications, and where quality control is more difficult to maintain.

298

Overview of Packaged Systems

It has now become almost standard practice in many clinical laboratories to use one or more available packaged systems for the identification of certain groups of microorganisms. Extensive testing in diagnostic and research laboratories has demonstrated a 95% or greater agreement between most packaged identification systems and conventional methods in the identification of microorganisms. Thus, packaged systems have found wide acceptance in clinical laboratories for the following reasons:

1. Their accuracy has proved to be comparable with that of conventional identification systems. Evaluations of several systems have been made at the CDC by Smith and associates.[599] In all evaluations, two criteria were used for measuring the performance of a product: (1) a comparison of each test in the product with its conventional counterpart and (2) the accuracy of identification made using the product.
2. Several of the systems have a long shelf life—6 months to 1 year—so that outdating of media, a problem particularly with conventional systems, is minimized.
3. The systems require only a minimum of space for storage and incubation.
4. Some of the systems are as easy to use as conventional methods, or even easier. Inoculation is simple, reactions are generally clear-cut within 24 hours, and the availability of computer-assisted file registers makes final identification easy and accurate.

Whether to use one of the packaged identification systems and which one to select is largely a matter of personal preference. The ease of inoculation, the ability to select only the characteristics to be measured, the manipulation required in adding reagents after incubation, and the availability of interpretive charts or computer databases are the main items that potential users should consider before selecting a system. If strict attention is paid to the instructions provided by the manufacturer, essentially the same degree of accuracy and reliability of performance can be attained, with only minor differences in the sensitivity of individual tests.

Specific Identification Systems

API 20E. The API 20E identification system (bioMérieux) has become the reference method against which the accuracy of other systems is compared. The 21 characteristics that can be determined by the API 20E system make it among the largest test sets of the packaged kits. The system identifies a high percentage of bacterial species within 24 hours, without the need to determine additional physiologic characteristics (Image Plate 6-6A). This system is among the most frequently used in clinical laboratories and has a large database that includes common and atypical strains. The API Profile Index, which can be used manually or with computer assistance, provides the frequency probability of several strains that must be considered for each biotype number. Thus, the accuracy of identification of the members of the *Enterobacteriaceae* is maximized. Castillo and Bruckner found that the API 20E system correctly identified 97.7% of 339 clinical and stock isolates.[98] The system is somewhat cumbersome to inoculate—a problem, however, that is overcome quickly with practice. After inoculation, the strips must be handled carefully so that the bacterial suspensions do not spill and contaminate the surrounding environment. Practice is required to interpret occasional borderline reactions, which can affect the biotype number and the final identification. Occasionally, biotype numbers may not appear in the profile register; however, the manufacturer maintains a telephone number for consultation. The design of the system, the operating procedures, substrates included, and evaluation studies are shown in Table 6-30 (Image Plate 6-6A).

BBL Crystal Enteric/Nonfermenter ID System. The BBL Crystal E/NF identification system (Becton Dickinson Microbiology Systems, Sparks, MD) is a miniaturized identification method using modified conventional and chromogenic substrates. It is intended for the identification of clinically significant aerobic gram-negative bacteria that belong to the family *Enterobacteriaceae,* as well as some of the more frequently isolated glucose-fermenting and nonfermenting gram-negative bacilli of human origin. The E/NF kit comprises (1) BBL Crystal E/NF lids, (2) BBL Crystal bases, and (3) BBL Crystal Enteric/Stool ID inoculum fluid tubes (see Image Plate 6-6B). The BBL Crystal lid contains 30 dehydrated substrates on tips of plastic prongs. The BBL Crystal base has 30 reaction wells. Test inoculum is prepared with the BBL Crystal Enteric/Stool ID inoculum fluid and is used to fill all 30 wells in the BBL Crystal base. When the lid is aligned with the base and snapped into place, the test inoculum rehydrates the dried substrates and initiates test reactions. The tests used in the Crystal system include tests for fermentation, oxidation, degradation, and hydrolysis of various substrates, including chromogen-linked substrates.

Following inoculation, panels are incubated upside down in a non-CO_2 incubator with 40% to 60% humidity for 18 to 20 hours at 35°C to 37°C. After incubation,

panels are read upside down using the BBL Crystal light box. The wells are examined for color changes, and a 10-digit profile number is generated. The profile number and off-line test results for indole and oxidase are entered on a PC in which the BBL Crystal ID System Electronic Codebook has been installed to obtain the identification.

In an external study involving three clinical laboratories, the reproducibility of the 30 individual E/NF substrates ranged from 96.3% to 100%. The performance of the E/NF was evaluated with both fresh clinical isolates and challenge test strains. Of 299 fresh clinical isolates tested by the laboratories' current identification methods, the BBL Crystal ID System correctly reported 96.7%, including 16 instances in which two or three organisms were reported and required supplemental testing to resolve. Of 291 previously identified challenge strains confirmed by the laboratories' current identification methods, the BBL Crystal ID System correctly reported 96.9%, including eight instances in which two or three organisms were reported and required supplemental testing to resolve (BBL Crystal Package Insert, May 1994). In two independent evaluations of the Crystal system with fermentative organisms largely from the family *Enterobacteriaceae*, correct identification without supplemental testing was reported to be 91.6%[565] and 92.9%,[659] respectively. In a study using 626 stock challenge isolates conducted at the CDC, the Crystal system correctly identified 71.1% of the total isolates tested, which improved to 87.9% (88.8% for enterics; 84.3%

299

TABLE 6-30 Construction, Use, and Evaluation of the API 20E Identification System

Functional Design	Operating Procedure	Substrates Included	Evaluation Studies
The system consists of a plastic strip with 20 miniaturized cupules containing dehydrated substrates and a plastic incubation chamber with a loosely fitting lid (see Image Plate 6-6*A*). Each cupule has a small hole at the top through which the bacterial suspension can be inoculated with a pipette. Bacterial action on the substrates produces color changes that are interpreted visually.	Add 5 mL of tap water to an incubation tray to provide a humid atmosphere during incubation. Place an API 20E strip into the incubation tray. Prepare a bacterial suspension of the test organism by suspending the cells from a well-isolated colony in 5 mL of sterile 0.85% saline. The turbidity of the suspension is compared with a McFarland 0.5 standard, except for same-day identifications of the *Enterobacteriaceae*, when the suspension is matched to a 1 standard. Using a Pasteur pipette, fill each cupule with the bacterial suspension through the inoculating hole. Overlay the three decarboxylase and the urease cupules with sterile mineral oil. The unit is incubated at 35°C for 5 hours (same-day identification) or for 24–48 hours before reading results.	ONPG Arginine dihydrolase Lysine decarboxylase Ornithine decarboxylase Citrate Hydrogen sulfide Urease Tryptophan deaminase (add 10% $FeCl_3$) Indole Voges–Proskauer (add KOH and α-naphthol) Gelatin Glucose Mannitol Inositol Sorbitol Rhamnose Sucrose Melibiose Amygdalin Arabinose	Aldridge and Hodges, International Clinical Laboratories, Nashville, TN: 90.5% of stock cultures and 96.6% of clinical isolates identified. Overall accuracy 92%.[a] Gooch and Hill, University of Utah, 415 cultures, same-day identification 90.2%.[b]

[a]Aldridge KE, Hodges RL. Correlation studies of Entero-Set 20, API 20E, and conventional media systems for *Enterobacteriaceae* identification. J Clin Microbiol 1981;13:120–125.

for nonenterics) after additional tests suggested by the software program were included.[488]

RapID onE System. The RapID onE system (Thermo Fisher Scientific Inc., Waltham, MA USA) is a qualitative micromethod using conventional and chromogenic substrates for the identification of medically important *Enterobacteriaceae* and other selected oxidase-negative, gram-negative bacteria isolated from human clinical specimens. The system comprises (1) RapID onE panels and (2) RapID onE reagent. Each RapID onE panel has 18 reaction cavities molded into the periphery of a plastic disposable tray. Reaction cavities contain dehydrated reactants, and the tray allows the simultaneous inoculation of each cavity with a predetermined amount of inoculum (see Image Plate 6-6C). A suspension of the test organism in RapID inoculation Fluid (2 mL) is used as the test inoculum, which rehydrates and initiates test reactions. Inoculated panels are placed into the chipboard incubation trays provided in the package and incubated at 35°C to 37°C in a non-CO_2 incubator for 4 hours.

RapID onE panels contain 18 reaction cavities that provide 19 test scores. Tests labeled PRO, GGT, and PYR (cavities 15, 16, and 17) require RapID onE Reagent and are designated with a box drawn around the tests. Test 18 is bifunctional, containing two separate tests in the same cavity. This test is scored **before** the addition of reagent, providing the first test result, which is adonitol; then two drops of INOVA Spot Indole reagent are added to cavity 18 and the same cavity is scored again **after** the addition of reagent to provide the second test result, which is indole. The 19 test

results plus oxidase are scored in the appropriate boxes of the report form, and a seven-digit profile code is generated. The organism ID is obtained by finding the profile code in the RapID onE Code Compendium.

In a study by Schreckenberger and colleagues, 302 of 344 (87.8%) oxidase-negative, gram-negative bacilli tested were correctly identified to the species level, with an additional 24 (7%) organisms correctly identified to the genus or group level. Six organisms gave unacceptable or no ID, eight gave questionable IDs, and four organisms (1.1%) gave incorrect IDs.[587] Kitch and colleagues reported similar findings with an overall identification rate to species or to genus level of 95.8%, with a misidentification rate of 1.3%.[356]

Biolog GN2 Microplate. Biolog GN2 MicroPlate (Biolog, Hayward, CA) consists of a 96-well microtiter plate that tests for the ability of a microorganism to utilize (oxidize) one or more of 95 different carbon sources in the presence of a redox indicator (tetrazolium dye). One well contains no carbon and serves as a negative control or reference well. All the necessary nutrients and biochemicals are prefilled and dried into the 96 wells of the plate. Tetrazolium violet is used to colorimetrically detect the increased respiration that occurs in a cell when it is oxidizing a carbon source (see Image Plate 6-6D). Regardless of its structure, virtually any chemical substrate that is oxidized by the cell will result in formation of NADH, leading to a flow of electrons along a pathway of electron transport. Redox dyes, such as tetrazolium, tap electrons from this flow, converting the tetrazolium to a highly colored formazan. Thus, if a cell is presented with a chemical that it can oxidize, its

respiration increases and the colorless dye is irreversibly reduced to a formazan, forming a purple color. If the cell is given a chemical that it cannot oxidize, no respiratory burst occurs, and no color is formed. The test yields a pattern of purple wells that constitutes a "metabolic fingerprint" of the capacities of the inoculated organism. Bochner has published a description and overview of the system.[52] Miller and Rhoden, at the CDC, have published a preliminary evaluation on the Biolog in which they report that the system performed well with many genera, but that problems were encountered with some strains of *Klebsiella*, *Enterobacter*, and *Serratia*.[439] Holmes and colleagues[296] studied 789 strains, including 55 gram-negative taxa encountered in the clinical laboratory. They reported significantly better results when plates were read manually, rather than when they were read by the automated reader. Plates read manually gave the following performances: oxidase-positive fermenters, five taxa, 64 strains, 92% correct, 3% not identified, and 5% incorrect; biochemically active nonfermenters, eight taxa, 122 strains, 88% correct, 6% not identified, and 6%

incorrect; *Enterobacteriaceae*, 35 taxa, 511 strains, 77% correct, 8% not identified, and 15% incorrect; unreactive nonfermenters, seven taxa, 92 strains, 38% correct, 24% not identified, and 38% incorrect. These authors reported problems with identification of encapsulated strains of some *Enterobacter* and *Klebsiella* taxa, as well as the least biochemically active *Moraxella* and *Neisseria* strains.[296] The Biolog system is now available in a fully automated platform and is described in the next section on automated instruments.

Microscan System. The MicroScan System (Beckman Coulter, West Sacramento, CA) consists of plastic, standard-sized, 96-well microtiter trays in which up to 32 reagent substrates are included for the identification of the *Enterobacteriaceae* and other bacterial species (grampositive, gram-negative, and urinary tract panels are available). Some trays, called Combo trays, also include broth microdilutions of various antibiotics in certain of the microtubes for performing susceptibility tests.[176] MicroScan panels are supplied either in a frozen state or contain dehydrated substrates that make shipping more convenient and allow for room-temperature storage and a longer shelf life. Schieven and associates[583] found that both the frozen and dehydrated microdilution trays provided comparable organism identification and antimicrobial susceptibility results (only 1.3% and 4.2% discrepancy rates, respectively).

The microtubes are inoculated with a heavy suspension of the organism to be identified and incubated at 35°C for 15 to 18 hours. The panels can be interpreted visually (see Image Plate 6-6E), after which the biochemical results are converted into a sevenor eight-digit biotype number that can be translated into an identification with a code book supplied by the manufacturer. Alternatively, an automated tray reader can be used to detect bacterial growth or color changes by differences in light transmission. Differences in electronic pulses are automatically analyzed by a microcomputer that compares reaction patterns with an internal program to determine the likelihood of identifications. Rhoden and associates[559] found that the AutoScan-4, an automatic reader in the MicroScan system, correctly identified 95.4% of members of the *Enterobacteriaceae* (occasional false-negative readings for hydrogen sulfide and arginine dihydrolase reactions were the only problems resulting in misidentification). One disadvantage cited by the authors was that the instrument occasionally reports "very rare biotype," leaving the user unclear as to what rare biotype was indicated.

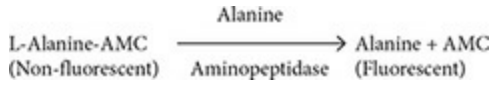
Sensititre System. The Sensititre System (Thermo Fisher Scientific Inc., Waltham, MA) may be purchased as either a manual enteric identification system or in the form of an autoidentification system. The manual plate contains media for performing 23 standard biochemical tests, plus a control, which are dried in the wells of a standard-sized 96-well microtiter tray. Each tray contains four duplicate sets of biochemical wells, permitting simultaneous identification of four organisms per tray. The system

contains conventional biochemical tests and is inoculated and read manually. Staneck and associates[606] reported that agreement between Sensititre and API 20E for 1415 isolates of *Enterobacteriaceae* was 94.6% at the species level.

Semiautomated and Automated Identification Systems

MicroScan Walkaway

The Walkaway (Beckman Coulter, West Sacramento, CA) is a fully automated instrument that incubates any combination of up to 96 conventional or Rapid MicroScan panels simultaneously, automatically adds reagents to conventional panels when required, reads and interprets panel results, and prints results, all without operator intervention (Image Plate 6-6F).[343,479,487,520,558,684] Rapid fluorescence panels in addition to the conventional MicroScan panels are available for use with the Walkaway instrument. The rapid panels use fluorescent labeled compounds and require only a 2-hour incubation for bacterial identification. Each fluorescent substrate consists of a fluorophore, either MEU or 7AMC attached to a phosphate, sugar, or amino acid compound. Two types of reactions occur: fluorogenic and fluorometric. In fluorogenic reactions, a specific enzyme, if present in the bacterial suspension, cleaves the fluorescent compound, releasing the fluorophore, which then fluoresces. For example:



Fluorometric reactions detect changes in pH such as occurs with carbohydrate fermentation. The resultant acid production causes a drop in pH and a decrease in fluorescence. In addition, eight fluorogenic rate reactions are used. These reactions measure the rate of release of the fluorophore and are used in differentiating phenotypically similar species. Results of the ID reactions are converted into 15-digit biocodes for interpretation by the computer. The Walkaway colorimetric optical system has 97 photometers illuminated

by a single tungsten-halogen source through 97 optical fibers. Light from the source passes through interference filters on a color wheel and is focused on the fiberoptics, 96 of which mirror the configuration of a 96-well panel. The 97th photometer

provides a baseline reading to which all photometer signals are ratioed. During each read cycle, the rotating color wheel provides readings at six different wavelengths through the visible spectrum. For biochemical reactions, the computer selects the wavelength reading that best discriminates the reaction occurring in each well. A review of the Walkaway technology has been published by Clayland and colleagues.[148] Several studies have shown that the Walkaway provides accurate identification of organisms belonging to the family Enterobacteriaceae.343,479,487,520,558,684

MicroScan's fluorogenic 2-hour Rapid Negative Identification Panel has been updated to significantly increase accuracy of identification and expand the number of taxa in the database. The updated panel (Rapid Gram Negative Identification Panel 3, RNID3) consists of 36 newly formulated tests and a new database consisting of 119 taxa, covering a total of 150 species. Achondo and associates reported that the RNID3 has an accuracy of 98.4% (92.5% correct to species, 1.6% correct to genus, and 4.3% correct to species with additional tests as recommended by the manufacturer) and 99.3% accuracy for clinically significant isolates.[7]

Alanine5. The accuracy and performance of the Rapid Gram-Negative Identification Type 3 (RNID3) panel were examined in a multicenter evaluation in which a total of 405 isolates comprising 54 species were tested; 96.8% of these species were identified correctly. In the same study, 465 isolates were examined for intraand interlaboratory identification reproducibility and gave an agreement of 99.8%.[39]

Vitek System

The Vitek system (Legacy) (bioMérieux) was first introduced in the early 1980s to perform automated antimicrobial susceptibility tests, with subsequent modifications to improve accuracy.[37,60,455,488] The Vitek Legacy System found wide use in clinical microbiology laboratories and has generally been accepted as a reliable approach to the rapid identification of commonly encountered gram-negative bacilli.[487,520,558] The construction and operating procedures of earlier versions of the Vitek system, initially designed to perform automated antibiotic susceptibility tests, were described in some detail in the second edition of this book (Table 15-10, pages 668–670).

The Vitek 2 system (bioMérieux) is an integrated modular system that consists of a filling-sealer unit, a reader-incubator, a computer control module, a data terminal, and a multicopy printer (see Image Plate 6-6G). In addition, the Vitek 2 system incorporates several technical improvements that automates many procedures that are performed manually with the Vitek Legacy System. The system detects bacterial growth and metabolic changes in the microwells of thin plastic cards by using a fluorescence-based technology (a colorimetric-based instrument was introduced in late 2004). The identification card for gram-negative bacilli (ID-GNB card) for the Vitek 2 is a 64-well plastic card containing 41 fluorescent biochemical tests, including 18

enzymatic tests for aminopeptidases and -oxidases. Substrates used for detection of aminopeptidases are usually coupled with 7AMC; substrates for detection of -oxidases are usually coupled with 4MEU. In addition, there are 18 fermentation tests, 2 decarboxylase tests, and 3 miscellaneous tests. There are two negative control wells, and the remaining wells are empty. Results are interpreted by the ID-GNB database after a 3-hour incubation period. In a study by Funke and colleagues, the Vitek 2 system was shown to correctly identify 84.7% of selected species representing 70 different taxa of *Enterobacteriaceae* and nonenteric bacteria within 3 hours.[241] Ling and colleagues in a much smaller study representing 31 different taxa of the most commonly recovered *Enterobacteriaceae* and nonfermenter species, obtained 95% correct identification to the species level with the Vitek 2.[390] These same researchers evaluated the Vitek 2 for rapid direct identification of gram-negative bacilli from positive blood culture bottles and reported that 97 (82.2%) of strains were correctly identified to species level and 21 (17.8%) strains were not identified. There were no misidentifications.[389] In two additional studies, O'Hara and Miller[480] reported an accuracy of 93.0% for the identification of 482 enteric stock cultures and Gavin et al.[246] reported 95.3% accuracy (*Enterobacteriaceae*, 95.9%; non-*Enterobacteriaceae*, 92.5%) with the Vitek 2.

Sensititre Gram-Negative AutoIdentification System

The Sensititre Automated Reading and Incubation System (ARIS) (Thermo Fisher Scientific Inc., Waltham, MA) is an automated system that uses fluorescence technology to detect bacterial growth and enzyme activity. The system consists of 32 newly formulated biochemical tests, including selected classic biochemical media reformulated to yield a fluorescence signal, along with newly developed fluorescence tests. Each biochemical test medium along with an appropriate fluorescence indicator is dried into the individual wells of the Sensititre plate. Each plate is designed to test three separate organisms. Because these are dried plates, they may be stored at room temperature. All autoidentification tests are read on the Sensititre AutoReader for the presence or absence of fluorescence. The results are transmitted to a computer for analysis and identification. Results may be read after 5 hours of incubation. If a satisfactory level of identification cannot be obtained at 5 hours, the plate may simply be reincubated and read after overnight incubation. Owing to the use of fluorescence technology, these plates cannot be read manually and can be read only on a correctly standardized Sensititre AutoReader. Company in-house data for 1,084 isolates of *Enterobacteriaceae* show overall agreement at 5 hours to be 92.4% and at 18 hours to be 93.4% when compared with standard methods (Sensititre Technical Product Information).

The Phoenix System

The Phoenix Automated Microbiology System (Becton Dickinson Microbiology Systems, Sparks, MD) is a newly developed, fully automated, identification and antimicrobial susceptibility test system. The system is comprised of disposable panels that combine both identification and antimicrobial susceptibility testing, and an instrument that

performs automatic reading at 20-minute intervals during incubation (Image Plate 6-6H). The gram-negative identification segment uses 45 biochemical substrates, including 16 fluorogenic, 14 fermentation, 8 carbon source, 5 chromogenic, and 2 miscellaneous substrates (urea and ornithine) to identify aerobic gram-negative bacilli in 2 to 12 hours, with the vast majority of results provided in 4 hours or less. The instrument monitors both visible spectral changes and fluorescence intensity levels, depending on the type of substrate, interprets the results, and provides an answer when the system is confident of the identification. In a study by Stefaniuk and colleagues, the Phoenix showed a high rate of agreement with conventional identification methods, ranging from 100% for gram-positive cocci to 96% for gram-negative nonfermenters and 92.5% for *Enterobacteriaceae*.[610]

The OmniLog ID System

The OmniLog ID System (Biolog, Hayward, CA) is a fully automated platform for use with Biolog's proprietary carbon source utilization test method (See description of Biolog GN2 MicroPlate in previous section). The OmniLog System simultaneously incubates, reads, and interprets the Biolog MicroPlates. It continuously processes samples but allows the user complete access at any time during a sample run. A unique feature of the OmniLog System is user-defined incubation temperature, allowing organisms to be incubated at their optimal temperature to obtain maximum growth for accurate identification. The instrument begins reading the MicroPlates 4 hours after they have been placed into the reader. The pattern is compared to the identification database, and an ID is called for if enough positive reactions have developed. If no result is obtained after 6 hours, the instrument automatically continues to incubate the Micro-Plate and begins reading again after 16 hours up to 24 hours. Biolog's databases contain over 1,400 different organisms including 501 gram-negative species, representing those important in both clinical and nonclinical microbiology. Many of these species cannot be identified with other identification systems.

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrophotometry

MALDI-TOF spectra are used for the identification of microorganisms such as bacteria or fungi. A colony of the microbe in question is smeared directly on the sample target, which is a plastic or glass plate and overlaid with matrix. The matrix consists of crystallized molecules, of which the three most commonly used are 3,5-dimethoxy-4-hydroxycinnamic acid (sinapinic acid), α-cyano-4-hydroxycinnamic acid (alphacyano or alpha-matrix) and 2,5-dihydroxybenzoic acid (DHB). A solution of one of these molecules is made, often in a mixture of highly purified water and an organic solvent (normally acetonitrile (ACN) or ethanol). Trifluoroacetic acid (TFA) may also be added.

A laser is fired at the matrix crystals in the dried-droplet spot. The matrix absorbs the laser energy and the matrix is desorbed and ionized (by addition of a proton) by this event. The matrix is then thought to transfer proton to the analyte molecules (e.g., bacteria or fungi), thus charging the analyte. Ions observed after this process consist of a neutral molecule [M] and an added or removed ion. The mass spectra travels through a column which separates the ionized matrix based on charge and mass and eventually reaches a detector that generates a unique signal pattern.

The type of mass spectrometer most widely used with MALDI is the TOF (time-of-flight mass spectrometer), mainly due to its large mass range. The TOF measurement procedure is also ideally suited to the MALDI ionization process because the pulsed laser takes individual "shots" rather than working in continuous operation.

The mass spectra generated are analyzed by dedicated software and compared with stored profiles. Species diagnosis by this procedure is much faster, more accurate and cheaper than other procedures based on immunologic or biochemical tests. MALDI-TOF MS has created a revolution in microorganism identification and will likely become the standard method for bacterial identification in medical microbiologic laboratories over the next few years.[87,590,609] Overall performance of MALDI-TOF MS has been reported to be significantly better than conventional biochemical systems for identification of the *Enterobacteriaceae*.[49,157,190,465,562,572,644] One drawback is the inability to separate *E. coli* from *Shigella* using MALDI-TOF thus requiring additional confirmatory testing when *Shigella* species are being ruled out. However, in spite of this drawback laboratories will find that MALDI-TOF MS can reduce reagentand labor-costs considerably and provide identifications 1 to 2 days earlier than conventional phenotypic testing methods.[205,623]

More recently, MALDI-TOF MS has been applied directly to positive blood culture bottles,[144,186,229,370,447,543,584,613] and urine specimens[230,360] leading to reductions in turnaround time and potentially beneficial patient impacts.[648] In one study, the

application of MALDI-TOF from positive blood culture bottles resulted in a 23- to 83-hour faster time to identification for gram-positive isolates and 34- to 51-hour faster identification time for gram-negative isolates.[81] When rapid identification with MALDI-TOF MS is coupled with rapid antimicrobial susceptibility testing performed directly from the blood culture broth, results can be generated a full day earlier.[673]

In summary, commercial manufacturers continue to provide new systems and modifications of existing systems for the identification of microorganisms. To pass FDA standards, all of these systems must perform with accuracy equal to or better than reference methods. Therefore, each system can be used in clinical laboratories, but the choice depends on several variables, including volume of testing, experience of the technical staff, need for definitive identifications, and cost of operation. The *Enterobacteriaceae*, as a group, are rapidly expanding and, for the most part, are biochemically very active; therefore, they are well suited for processing by automated and semiautomated systems. Space has allowed for only a brief overview of these systems in this book. To learn more, the reader is referred to the review of automated systems written by Stager and Davis.[605] The cited references may be consulted for more detailed descriptions and evaluations of performance.

Introduction to Nonfermenting Gram-Negative Bacilli

The nonfermentative gram-negative bacilli are a group of aerobic, non–spore-forming bacilli that do not either use carbohydrates as a source of energy or degrade them through metabolic pathways other than fermentation. Within this group are several genera and species of bacteria with special growth requirements that are not discussed in this chapter. The dividing line between what is a "nonfermenter" and what may otherwise be designated a "fastidious," "unusual," or "miscellaneous" non–glucose-fermenting, gram-negative bacillus (discussed in Chapter 9) is based more on convention than on well-defined genetic or phenotypic characteristics. The term *nonfermentative gram-negative bacilli* is used in this chapter to mean all aerobic gram-negative rods that show abundant growth within 24 hours on the surface of Kligler's iron agar (KIA) or triple sugar iron (TSI) medium, but neither grow in nor acidify the butt of these media.

The genera of nonfermenters to be discussed in this chapter include *Acetobacter, Achromobacter, Acidomonas, Acidovorax, Acinetobacter, Advenella, Agrobacterium, Alcaligenes, Alishewanella, Asaia, Azospirillum, Balneatrix, Bergeyella, Bordetella, Brevundimonas, Burkholderia, Caulobacter, Chryseobacterium, Comamonas, Cupriavidus, Delftia, Elizabethkingia, Empedobacter, Flavobacterium,*

Gluconobacter, Granulibacter, Haematobacter, Herbaspirillum, Inquilinus, Kerstersia, Laribacter, Lautropia, Massilia, Methylobacterium, Moraxella, Myroides, Naxibacter, Neisseria, Ochrobactrum, Oligella, Pandoraea, Pannonibacter, Parococcus, Pseudomonas, Psychrobacter, Ralstonia, Rhizobium, Roseomonas, Shewanella, Sphingobacterium, Sphingomonas, Stenotrophomonas, Weeksella, *Wohlfahrtiimonas*, and a few organisms that currently carry only Centers for Disease Control and Prevention (CDC) alphanumeric designations. Also included in this chapter are a few species of *Neisseria* that appear as gram-negative rods and must be differentiated from similar-appearing nonfermenting bacilli. The genera *Eikenella*, *Brucella*, and *Francisella*, although they possess the general characteristics of nonfermenters, are grouped in this book with the fastidious, gram-negative bacilli and are discussed in Chapter 9. The currently accepted organism nomenclature and a listing of previous designations are presented in Table 7-1. The synonyms for several bacterial species either previously or currently having CDC alphanumeric designations are presented in Table 7-2.

318

TABLE 7-1 Nomenclature for Gram-Negative Nonfermentative Bacilli

Current Usage	Previous Designations	Comments
Achromobacter Groups B, E, and F		Unnamed *Achromobacter* species
Achromobacter denitrificans	*Alcaligenes xylosoxidans* subsp. *denitrificans* *Alcaligenes denitrificans* subsp. *denitrificans* CDC Vc	Subspecies designation no longer used
Achromobacter piechaudii	*Alcaligenes piechaudii*	Isolated primarily from human clinical specimens, but some strains from the environment. Clinical significance not known. Has been recovered from patients with bloodstream infection and chronic ear drainage.
Achromobacter xylosoxidans	*Alcaligenes xylosoxidans* subsp. *xylosoxidans* *Alcaligenes denitrificans* subsp. *xylosoxidans* CDC IIIa and IIIb	Subspecies designation no longer used
Acinetobacter baumannii	*Acinetobacter calcoaceticus* var. *anitratus* *Achromobacter anitratus* *Bacterium anitratum* *Herellea vaginicola* Morax-Axenfeld bacillus *Moraxella glucidolytica* var. *nonliquefaciens* *Pseudomonas calcoacetica*	Species name given to *Acinetobacter* genomospecies 2. Produces acid from glucose. Can be separated from *Acinetobacter calcoaceticus* (genomospecies1) by growth at 41°C and 44°C, production of β-xylosidase, and utilization of malate (*A. baumannii* positive and *A. calcoaceticus* negative). Laboratories that do not perform these tests may choose to report these organisms as *A. baumannii* complex. Most *Acinetobacter* strains isolated from human clinical specimens belong to this species.
Acinetobacter lwoffii	*Acinetobacter calcoaceticus* var. *lwoffi* *Achromobacter lwoffi* *Mima polymorpha* *Moraxella lwoffi*	Species name given to *Acinetobacter* genomospecies 8. Non–glucose-oxidizing strain found in human clinical specimens.
Alcaligenes faecalis	*Alcaligenes odorans* CDC VI	*Alcaligenes odorans* was proposed at a later date for an organism which is a strain of the earlier named *Alcaligenes faecalis*. Fruity odor.
Bergeyella zoohelcum	*Weeksella zoohelcum* CDC IIj	Rapid urea positive. Associated with dog and cat bites.
Bordetella bronchiseptica	*Alcaligenes bronchicanis* *Alcaligenes bronchiseptica* *Bordetella bronchicanis* *Brucella bronchiseptica* *Haemophilus bronchiseptica*	Rapid urea positive
Bordetella hinzii	*Bordetella avium*-like *Alcaligenes faecalis* type II TC (turkey coryza) bacterium type II *Alcaligenes* sp. strain C_2T_2	Isolated from respiratory tracts of chickens and turkeys. Human isolates reported from respiratory tract, ear discharge, and feces.
Bordetella holmesii	CDC nonoxidizer group 2 (NO-2)	Isolated from blood cultures. Oxidase negative, nonmotile; brown soluble pigment produced on heart infusion tyrosine agar. Brown diffusible pigment can also be observed on MacConkey agar.
Bordetella trematum		Isolated from wounds and ear discharge. Oxidase negative, motile.
Brevundimonas diminuta	*Pseudomonas diminuta* CDC Ia	
Brevundimonas vesicularis	*Pseudomonas vesicularis* *Corynebacterium vesiculare*	
Burkholderia cepacia	*Pseudomonas cepacia* *Pseudomonas multivorans* *Pseudomonas kingae* CDC EO-1	Yellow pigment. Recovered from numerous water sources and wet surfaces. Respiratory pathogen in CF patients. Phenotypically similar to at least 17 other species collectively referred to as the *Burkholderia cepacia* complex (Bcc).
Burkholderia gladioli	*Pseudomonas gladioli* *Pseudomonas marginata*	Primarily plant pathogen. Has been reported from sputum of patients with CF.

Burkholderia pseudomallei	*Pseudomonas pseudomallei*	Cause of melioidosis in humans.
Chryseobacterium indologenes	*Flavobacterium indologenes* CDC IIb	Phenotypically similar to *Chryseobacterium gleum*. Indole positive.
Comamonas terrigena	Various species of *Vibrio* E. Falsen group 10 *Aquasprillum aquaticum*	
Comamonas testosteroni	*Pseudomonas testosteroni* *Pseudomonas desmolytica* *Pseudomonas dacunhae* *Pseudomonas cruciviae*	
Cupriavidus pauculus	*Wautersia paucula* *Ralstonia paucula* CDC group IVc-2	Rapid urease positive
Delftia acidovorans	*Comamonas acidovorans* *Pseudomonas acidovorans* *Pseudomonas desmolytica* *Pseudomonas indoloxidans* *Achromobacter cystinovorum*	Orange indole reaction with Kovac's reagent due to production of anthranilic acid from tryptone.
Elizabethkingia meningoseptica	*Chryseobacterium meningosepticum* *Flavobacterium meningosepticum* CDC IIa	Highly pathogenic for premature infants. Indole positive
Empedobacter brevis	*Flavobacterium breve*	
Flavobacterium species		Human species previously included in the genus *Flavobacterium* have been reclassified as members of new or other genera. Remaining species widely distributed in soil and fresh water habitats. Not found in human clinical specimens. All are indole negative.
Methylobacterium mesophilicum	*Pseudomonas mesophilica* *Pseudomonas methanica* *Vibrio extorquens* *Mycoplana rubra* *Protaminobacter* sp. *Chromobacterium* sp. *Beijerinckia* sp.	Slow-growing, pink-pigmented rods. Do not stain well, appear amorphous with many nonstaining vacuoles.
Moraxella atlantae	CDC M-3	
Moraxella lacunata	*Moraxella liquefaciens*	
Moraxella nonliquefaciens	*Bacillus duplex nonliquefaciens*	
Moraxella osloensis	*Mima polymorpha* var. *oxidans*	
Myroides odoratus *Myroides odoratimimus*	*Flavobacterium odoratum* CDC M-4F	Large colonies with a tendency to spread. Indole negative, fruity odor.
Neisseria elongata subsp. *nitroreducens*	*Moraxella* sp. M-6 CDC M-6	Catalase negative. Clinical isolates associated with endocarditis.
Neisseria weaveri	*Moraxella* sp. M-5 CDC M-5	Clinical isolates associated with dog bites
Neisseria zoodegmatis	CDC EF-4b	Human infections associated with dog and cat bites
Ochrobactrum anthropi	CDC Vd-1, Vd-2 *Achromobacter* spp. biotypes 1 and 2. *Achromobacter* groups A, C, D	Only isolates have been from human clinical specimens.
Oligella ureolytica	CDC IVe	Rapid urea positive and phenylalanine deaminase positive
Oligella urethralis	CDC M-4	Clinical isolates have been from ear and urinary tract infections.
Pandoraea	New genus comprising 5 species	Isolated from human clinical samples (mostly CF patients), environment

Paracoccus yeei	CDC EO-2	Forms O-shaped cells on Gram stain
Pseudomonas aeruginosa	*Pseudomonas pyocyanea* *Bacterium aeruginosa*	Belongs to Fluorescent group, grows at 42°C. Most common clinical isolate. Grapelike odor.
Pseudomonas fluorescens		Belongs to Fluorescent group, gelatin positive. Does not grow at 42°C.
Pseudomonas luteola	CDC Ve-1 *Chryseomonas luteola* *Chryseomonas polytricha*	Yellow pigmented, oxidase negative, esculin positive.
Pseudomonas mendocina	CDC Vb-2	
Pseudomonas oryzihabitans	CDC Ve-2 *Flavimonas oryzihabitans* *Pseudomonas lacunogenes*	May cause septicemia and prosthetic valve endocarditis. Yellow pigment, oxidase negative, esculin negative.
Pseudomonas putida		Belongs to Fluorescent group, gelatin negative. Does not grow at 42°C.
Pseudomonas stutzeri	CDC Vb-1	Wrinkled colonies. Ubiquitous in soil and water.
Psychrobacter phenylpyruvicus	*Psychrobacter phenylpyruvica* *Moraxella phenylpyruvica* CDC group M-2	Phenylalanine deaminase positive, grows at 4°C, tolerates NaCl concentrations up to 9%
Ralstonia pickettii	*Burkholderia pickettii* *Pseudomonas pickettii* CDC Va-1, Va-2	Slow growing, pinpoint colonies after 24 hours on blood agar (BAP). Rarely associated with infection. Urea positive, some strains catalase negative.
Ralstonia mannitolilytica	*Pseudomonas thomasii* (Va-3)	Mannitol positive
Rhizobium radiobacter	*Agrobacterium radiobacter* *Agrobacterium tumefaciens* *Agrobacterium biovar 1* CDC Vd-3	
Roseomonas sp.	CDC "pink coccoid group"	Pink, often mucoid colonies, weakly staining gram-negative, plump, coccoid rods
Shewanella putrefaciens *Shewanella algae*	*Pseudomonas putrefaciens* *Alteromonas putrefaciens* *Achromobacter putrefaciens* CDC Ib-1, Ib-2	H_2S-positive. *S. algae* is the predominant human clinical isolate and requires NaCl for growth.
Sphingobacterium multivorum	*Flavobacterium multivorum* CDC IIk-2	Yellow pigment, oxidase positive, esculin positive, mannitol negative, rarely associated with serious infection
Sphingobacterium spiritivorum	*Flavobacterium spiritivorum* *Flavobacterium yabuuchiae* *Sphingobacterium versatilis* CDC IIk-3	Yellow pigment, oxidase positive, esculin positive, mannitol positive. Most common sources for isolation have been blood and urine.
Sphingomonas paucimobilis	*Pseudomonas paucimobilis* CDC IIk-1	Yellow pigment, oxidase positive, esculin positive, slow growing. Found in a variety of clinical specimens.
Stenotrophomonas maltophilia	*Xanthomonas maltophilia* *Pseudomonas maltophilia* CDC group I	Oxidase negative, lysine and DNase positive, can be recovered from almost any clinical site. May cause opportunistic infections.
Weeksella virosa	*Flavobacterium genitale* CDC IIf	Mucoid and sticky. Difficult to remove from agar. Clinical isolates have been associated with urinary and vaginal infections.

321

TABLE 7-2 CDC Lettered and Numbered Bacterial Groups: Synonyms

CDC Designations	Current Usage
I	*Stenotrophomonas maltophilia*

Ia	*Brevundimonas diminuta*
Ib-1	*Shewanella putrefaciens*
Ib-2	*Shewanella algae*
IIa	*Elizabethkingia meningoseptica*
IIb	*Chryseobacterium indologenes*
IIc	CDC group IIc
IId	*Cardiobacterium hominis*
IIe	CDC Group IIe
IIf	*Weeksella virosa*
IIg	CDC group IIg
IIh	CDC group IIh
IIi	CDC group IIi
IIj	*Bergeyella zoohelcum*
IIk-1	*Sphingomonas paucimobilis*
IIk-2	*Sphingobacterium multivorum*
IIk-3	*Sphingobacterium spiritivorum*
IIIa, IIIb	*Achromobacter xylosoxidans*
IVa	*Bordetella bronchiseptica*
IVb	*Bordetella parapertussis*
IVc	Unnamed
IVc-2	*Cupriavidus pauculus*
IVd	*Pseudomonas*-like group 2
IVe	*Oligella ureolytica*
Va-1	*Ralstonia pickettii*
Va-2	*Ralstonia pickettii*

Va-3	*Ralstonia mannitolilytica*
Vb-1	*Pseudomonas stutzeri*
Vb-2	*Pseudomonas mendocina*
Vb-3	*Pseudomonas stutzeri*- like
Vc	*Achromobacter denitrificans*
Vd-1	*Ochrobactrum anthropi*
Vd-2	*Ochrobactrum anthropi*
Vd-3	*Rhizobium radiobacter*
Ve-1	*Pseudomonas luteola*
Ve-2	*Pseudomonas oryzihabitans*
VI	*Alcaligenes faecalis*
HB-1	*Eikenella corrodens*
HB-2	*Aggregatibacter aphrophilus*
HB-3,4	*Aggregatibacter actinomycetemcomitans*
HB-5	*Pasteurella bettyae*
M-1	*Kingella kingae*
M-2	*Psychrobacter phenylpyruvicus*
M-3	*Moraxella atlantae*
M-4	*Oligella urethralis*
M-4f	*Myroides odoratus/odoratimimus*
M-5	*Neisseria weaveri*
M-6	*Neisseria elongata* subsp. *nitroreducens*
TM-1	*Kingella denitrificans*
DF	Dysgonic fermenter
DF-1	*Capnocytophaga ochracea*

	Capnocytophaga gingivalis
	Capnocytophaga sputigena
DF-2	*Capnocytophaga canimorsus*
DF-2-like	*Capnocytophaga cynodegmi*
DF-3	*Dysgonomonas capnocytophagoides*
EO	Eugonic oxidizer
EO-1	*Burkholderia cepacia*
EO-2	*Paracoccus yeei*
EO-3	Unnamed
EO-4	Unnamed
EO-5	Unnamed
EF	Eugonic fermenter
EF-1	*Pseudomonas*-like group 2
EF-3	*Vibrio vulnificus*
EF-4a	*Neisseria animaloris*
EF-4b	*Neisseria zoodegmatis*
EF-5	*Photobacterium damsela*
EF-6	*Vibrio fluvialis*
EF-9	*Tatumella ptyseos*
EF-13	*Vibrio hollisae*
EF-19	*Comamonas terrigena*
EF-26	*Bordetella*-like species
NO	Nonoxidizer
NO-1	CDC Group NO-1
NO-2	*Bordetella holmesii*

WO	Weak oxidizer
WO-1	Unnamed
WO-2	*Pandoraea* spp.

322

As more information accumulates, reclassification of bacteria between genera and species and the creation of new designations must be accepted as part of scientific progress. DNA homology studies often play a larger role in the ultimate classification of bacteria than does a scheme based on phenotypic characteristics alone. For example, within the genus *Pseudomonas,* several biovars and pathovars are now recognized, arranged according to ribosomal RNA (rRNA) and DNA homologies.[814] Full and partial 16S rRNA gene sequencing methods have emerged as useful tools for identifying phenotypically aberrant microorganisms.[207] Because of the increasing microbial diversity and emergence of common pathogens having rare or unique phenotypic characteristics and the identification of new pathogens with incompletely defined phenotypes, more laboratories are relying on a combination of phenotypic and genotypic methods to report an accurate identification of many bacteria.[843] More recently, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) has been adapted for use in microbiology laboratories, where it serves as a paradigm-shifting, rapid, and robust method for accurate microbial identification.[200,828,1028] However, the initial capital required to purchase a mass spectrometry unit will delay the implementation of this technology, and therefore phenotypic profiles including Gram's stain results, colony morphologies, growth requirements, and enzymatic and/or metabolic activities using phenotypic-based tests such as those described in this chapter will likely continue to be used during the next decade. Microbiologists must also keep abreast of changes in bacterial nomenclature so that current names can be used in everyday practice and research data gathered from various investigations using previous designations will not be misinterpreted.

PART I: METABOLISM OF THE NONFERMENTERS

Bacteria that derive their energy from organic compounds are known as **chemoorganotrophs.** Most of the bacteria encountered in clinical medicine derive energy from the utilization of carbohydrates by one of several metabolic pathways.

Detection and measurement of various metabolic products are necessary to identify bacterial species that may be the cause of infectious disease. Some bacteria, such as members of the genus *Moraxella*, do not metabolize carbohydrates but rather derive energy from the degradation of other organic compounds, such as amino acids, alcohols, and organic acids. Some free-living bacteria, such as the nitrogen-fixing groups or those capable of oxidizing sulfur or iron, can derive energy from simple inorganic chemicals. These so-called **chemolithotrophs** are seldom implicated as causes of disease in humans.

Space in this textbook permits only a brief summary of the metabolic pathways used by the nonfermenters, enough to gain a working understanding of terms such as *aerobic, anaerobic, fermentation,* and *oxidation.* These metabolic processes not only define the taxonomic niche of bacteria, but also determine the tests and procedures used in the laboratory identification of microorganisms. Textbooks by Doelle[288] and Thimann[1070] should be consulted for a more detailed discussion of bacterial metabolism and physiology, and the text by MacFaddin[674] provides a review of the biochemistry of the various tests and reactions used in making identifications.

Fermentative and Oxidative Metabolism

The bacterial degradation of carbohydrates proceeds by several metabolic pathways in which hydrogen ions (electrons) are successively transferred to compounds of higher redox potential, with the ultimate release of energy in the form of adenosine triphosphate (ATP). All six-, five-, and four-carbon carbohydrates are initially degraded to pyruvic acid, an initial intermediate. Glucose is the main carbohydrate source of carbon for bacteria, and degradation proceeds by three major pathways: the Embden–Meyerhof–Parnas, the Entner–Doudoroff, and the Warburg–Dickins (hexose monophosphate) pathways. As shown in Figure 7-1, glucose is converted to pyruvic acid in each of these three pathways by a different set of degradation steps. Bacteria use one or more of these pathways for glucose metabolism depending on their enzymatic composition and the presence or lack of oxygen.

The Embden–Meyerhof–Parnas Pathway

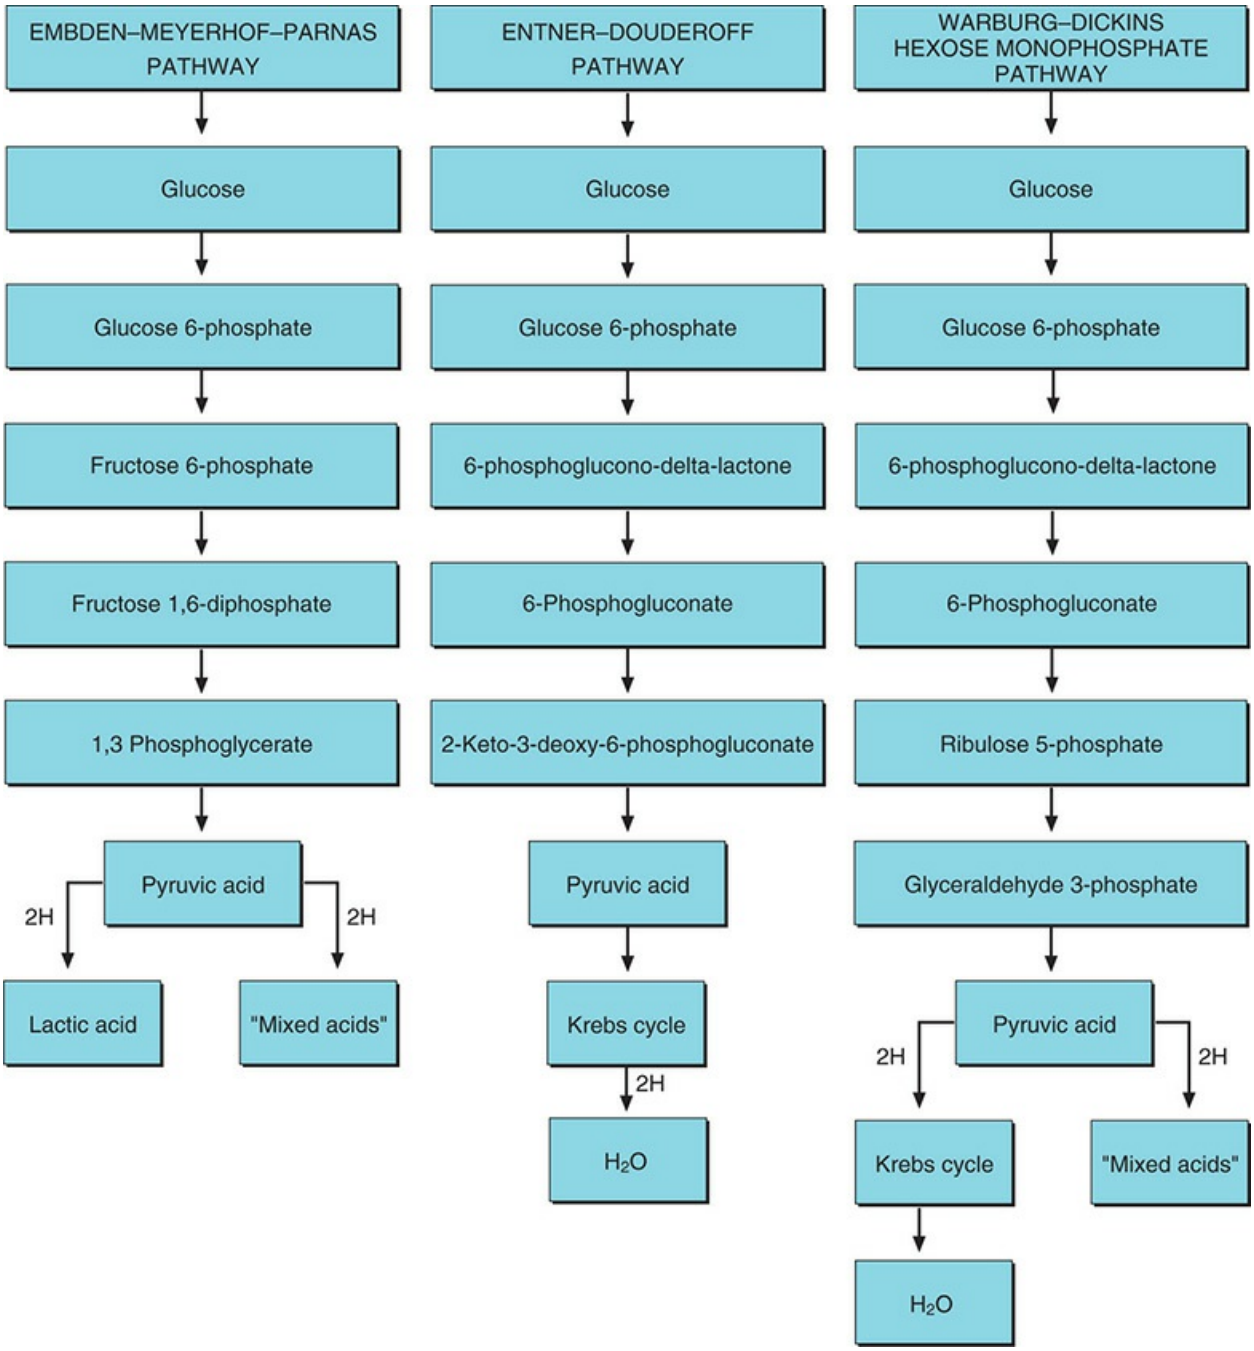
Because glucose is degraded without oxygen, the Embden–Meyerhof–Parnas (EMP) pathway has also been called the **glycolytic** or **anaerobic** pathway, used primarily by anaerobic bacteria and, to some degree, by facultatively anaerobic bacteria as well. The intermediate steps in the EMP pathway include the initial phosphorylation of glucose, conversion to fructose phosphate, and cleavage to form two molecules of glyceraldehyde phosphate, which, through a series of intermediate steps (not shown in

Fig. 7-1), forms pyruvic acid. The EMP pathway is discussed more thoroughly in Chapter 6.

Historically, the EMP pathway has also been termed the *fermentative pathway*. Fermentation and anaerobic metabolism have been considered synonymous ever since Pasteur demonstrated that acids and alcohols are the major end products of carbohydrate degradation when oxygen is excluded from the system. According to a current concept, fermentative metabolism is said to exist in a glycolytic system when organic compounds serve as the final hydrogen (electron) acceptor. Thus, as shown in the EMP pathway outlined in the left column of Figure 7-1, pyruvic acid acts as an intermediate hydrogen acceptor, but is then oxidized by giving up its hydrogen ions to sodium lactate to form lactic acid or to other organic salts to form one of several so-called mixed acids. These acids are the end products of glucose metabolism by the EMP pathway, accounting for the drop in pH in fermentation tests used for identifying bacteria. Bacteria that possess the appropriate enzyme systems can further degrade these mixed acids into alcohols, CO_2, or other organic compounds.

Although these biochemical principles seem somewhat removed from the daily work in the laboratory, microbiologists must have a basic understanding of bacterial metabolism when designing or interpreting test procedures that compare fermentation with oxidation. Fermentation must be determined in test systems that exclude oxygen. The

glycolytic products formed by fermentation have relatively strong acidity, which is easily detected by pH indicators, and large amounts of gas may be produced. This is not true for the Entner–Doudoroff pathway.



■ **FIGURE 7-1** Metabolic pathways for the bacterial degradation of glucose.

The Entner–Doudoroff Pathway

The Entner–Doudoroff (ED) pathway is also termed the *aerobic pathway* because oxygen is required for glycolysis to occur. Note in the center column of Figure 7-1 that glucose is not converted into two triose carbon molecules as in the EMP pathway; rather, it is oxidized to 6-phosphogluconate and 2-keto-3-deoxy-6-phosphogluconate

before forming pyruvic acid. Some bacteria use shunt pathways through which glucose is oxidized directly into glucuronic and ketoglucuronic acid without an initial phosphorylation step. In either event, the intermediate pyruvic acid is formed. "Oxidation" refers more to the manner in which pyruvic acid transfers its hydrogen ions than to the pathway by which it is formed. Lacking the dehydrogenase enzymes necessary to oxidize pyruvic

acid to lactic acid or other "mixed acids," oxidative bacteria transfer the available hydrogen ions from pyruvic acid into the Krebs cycle, where the ions ultimately link with elemental oxygen to form water. Thus, the **oxidative metabolism of carbohydrates** is presently defined as the energy-yielding reactions that require molecular oxygen (or other nonorganic elements) as the terminal hydrogen (electron) acceptor.

This difference in metabolism necessitates alternative, practical approaches to the identification of oxidative and fermentative bacteria. The acids that are formed in the ED pathway (glucuronic acid and its derivatives) and those produced in the Krebs cycle (citric acid and its derivatives) are extremely weak compared with the mixed acids resulting from fermentation. Because the end product of oxidative metabolism is water, gas is not formed from carbohydrates by oxidative organisms. Therefore, test systems with more sensitive detectors of acid production must be used when studying oxidative bacteria, which are discussed in detail later in this chapter. Test systems designed to detect acid production from fermentative bacteria often cannot be applied to oxidative organisms that produce insufficient acids to convert the pH indicator.

The Warburg–Dickens Hexose Monophosphate Pathway

Facultatively anaerobic bacteria have the capacity to grow on the surface of an agar plate in the presence of oxygen or in an anaerobic environment. Just because a microorganism can grow in an aerobic environment does not necessarily mean that oxygen is metabolically used. That is, not all aerobes are oxidative. The term *aerotolerant* is more appropriate for nonoxidative bacteria that are capable of growing in the presence of oxygen but grow better in an anaerobic environment.

Many of the facultative anaerobes can use either the EMP or the ED pathway, depending on the environmental conditions in which they are growing. The hexose monophosphate pathway (HMP), as shown in the right-hand column of Figure 7-1, is actually a hybrid of the EMP and ED pathways. Note that the initial steps in the degradation of glucose in the HMP pathway parallel those of the ED pathway; however, later in the HMP scheme, glyceraldehyde 3-phosphate is formed as the precursor of pyruvic acid, similar to the EMP pathway. These organisms appear

fermentative in test systems, even though the EMP pathway is not strictly used.

Note in Figure 7-1 that ribulose 5-phosphate is the precursor to the formation of glyceraldehyde 3-phosphate in the HMP pathway. Ribulose is a pentose and, for this reason, the HMP pathway has also been referred to as the pentose cycle. It provides the major avenue by which pentoses are metabolized by a number of bacterial species.

Initial Clues That an Unknown Isolate Is a Nonfermenter

The microbiologist may suspect that an unknown gram-negative bacillus is a member of the nonfermenter group by observing one or more of the following characteristics:

1. Lack of evidence for glucose fermentation (Image Plate 7-1A)
2. Positive cytochrome oxidase reaction (Image Plate 7-1B)
3. Failure to grow on MacConkey agar (Image Plate 7-1C)

Additional characteristics used to make preliminary identification of the nonfermenters are presented in Image Plate 7-1.

Lack of Evidence for Glucose Fermentation

Acids produced by nonfermenters are considerably weaker than the mixed acids derived from fermentative bacteria; thus, the pH in fermentation test media in which a nonfermenter is growing may not drop sufficiently to convert the pH indicator. The initial clue that an unknown organism is a nonfermenter is usually the lack of acid production in either KIA or TSI medium, manifested in each instance as an alkaline (red) slant and an alkaline deep (Image Plate 7-1A). Initially, it is important that an unknown organism be classified by its mode of glucose utilization to select the correct set of biochemical characteristics to make a definitive identification. Microbiologists who use packaged commercial identification kits and bypass inoculation of the unknown organism to KIA or TSI tubes may not know whether to select a fermentative or oxidative system. Therefore, before setting up differential systems, it is recommended that the oxidative-fermentative (OF) characteristic of all unknown isolates of gram-negative bacilli be assessed by inoculating a KIA or TSI slant.

Positive Cytochrome Oxidase Reaction

Any colony of a gram-negative bacillus growing on blood agar or other primary isolation media that is cytochrome oxidase positive can be suspected of belonging to the nonfermentative group (Image Plate 7-1B). However, not all oxidase-positive,

gram-negative bacilli are nonfermenters. Therefore, the mode of glucose utilization must still be measured (again demonstrating the importance of setting up a KIA or TSI tube). Cultures of oxidase-positive fermenters, such as *Pasteurella* species, *Aeromonas* species, *Plesiomonas* species, *Vibrio* species, and others, may be mistaken for nonfermenters, making identification more difficult. The procedure for performing the cytochrome oxidase test is given in Chart 1-5. To test the oxidase activity of nonfermenters, the CDC recommends using a 0.5% aqueous solution of tetramethyl- *p*-phenylenediamine hydrochloride. This solution is good for 1 week if stored in a dark bottle in the refrigerator at 4°C to 10°C. A few drops of reagent can be used to flood the surface of agar medium on which bacterial colonies are growing. The development of a blue color within a few seconds indicates a positive test. Negative reactions can be confirmed using the more sensitive Kovac's method, in which a loopful of organisms is mixed with a few drops of reagent on a piece of filter paper (Image Plate 7-1B). The development of a dark blue color within 10 seconds indicates a positive test result.

325

Failure to Grow on MacConkey Agar

Although all members of the *Enterobacteriaceae* grow on MacConkey agar, some nonfermenters do not grow on MacConkey agar. Therefore, a gram-negative bacillus that grows on blood agar but grows poorly or not at all on MacConkey agar should be suspected of belonging to the nonfermentative group. This guideline, however, is far from absolute, because many of the fastidious gram-negative bacilli also do not grow on MacConkey agar. The ability of bacteria to grow on MacConkey agar is determined by inspecting with reflected light the surface of plates that have been inoculated and then incubated for 24 to 48 hours. Organisms that grow well produce colonies that are 3 mm or more in diameter and easy to see. Poorly growing strains produce either widely scattered, tiny pinpoint colonies or absolutely no growth (Image Plate 7-1C).

Tests Used in the Identification of Nonfermenters

Utilization of Glucose

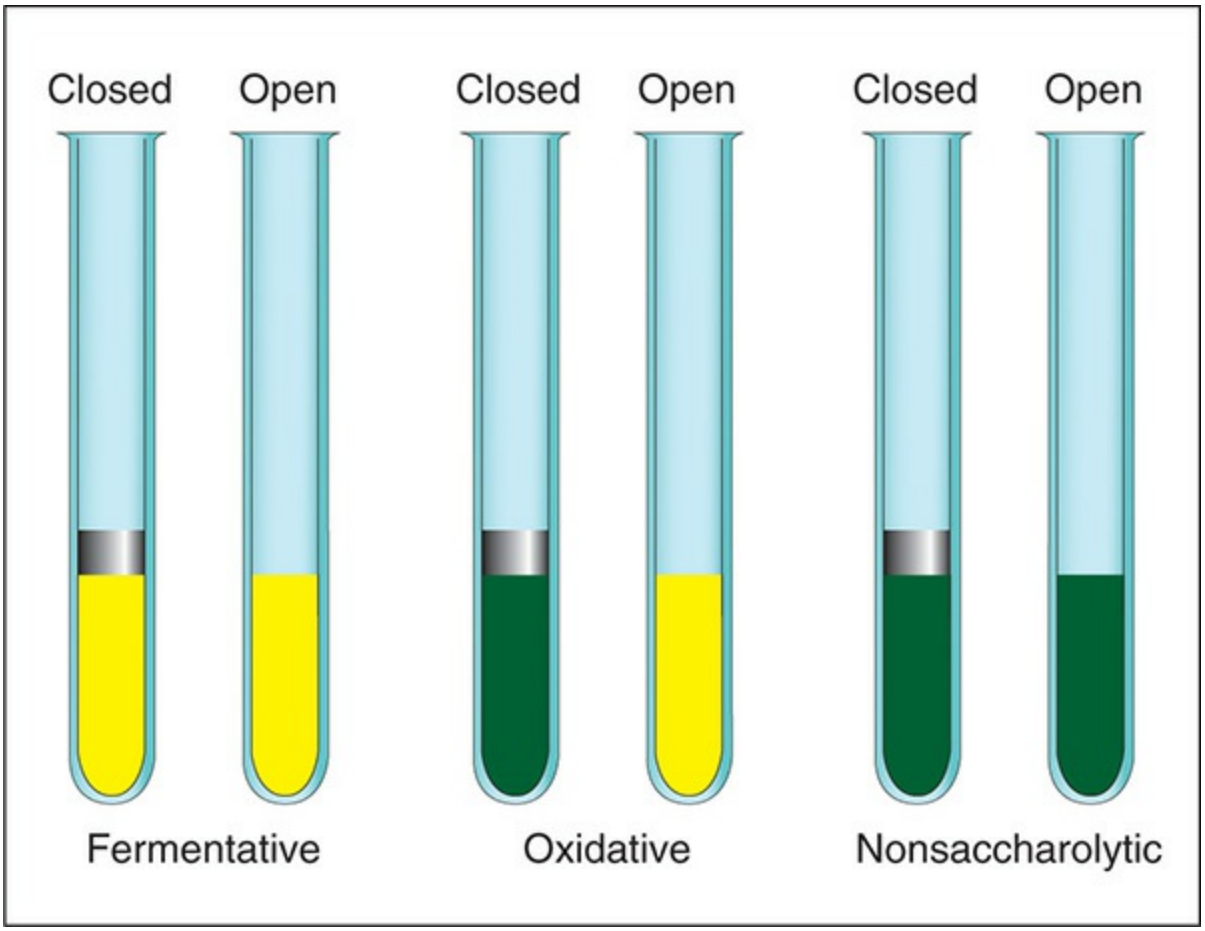
Most conventional culture media designed to detect acid production from fermentative bacteria, such as the *Enterobacteriaceae*, are not suitable for the study of nonfermentative bacilli. They do not support the growth of many strains, and the acids produced are often too weak to convert the pH indicator. Hugh and Leifson[494] were

the first to design an OF medium that accommodated the metabolic properties of the nonfermentative bacilli, as outlined in Chart 7-1.

Note that the Hugh–Leifson OF medium contains 0.2% peptone and 1.0% carbohydrate, so that the ratio of peptone to carbohydrate is 1:5, in contrast with the 2:1 ratio found in media used for carbohydrate fermentation. The decrease in peptone minimizes the formation of oxidative products from amino acids, which tend to raise the pH of the medium and may neutralize the weak acids produced by the nonfermentative bacilli. Conversely, the increase in carbohydrate concentration enhances acid production by the microorganism. The semisolid consistency of the agar, the use of bromthymol blue as the pH indicator, and the inclusion of a small quantity of diphosphate buffer are all designed to enhance the detection of acid.

Two tubes of each carbohydrate medium are required for the test. The medium in one tube is exposed to air; the other is overlaid with sterile mineral oil or melted paraffin (Fig. 7-2). Oxidative microorganisms produce acid only in the open tube exposed to atmospheric oxygen; fermenting organisms produce acid in both tubes; and nonsaccharolytic bacteria are inert in this medium, which remains at an alkaline pH after incubation. Image Plate 7-1D shows the OF reaction of an oxidative nonfermenter, with only the open tube showing the yellow color of acid production.

The OF test has limitations. Slow-growing nonfermentative bacilli may not produce color changes for several days, and species that produce amides from amino acids may cause weak acid reactions that reverse with time, thereby confusing the final interpretation. It is important that the Hugh–Leifson formula be strictly followed when performing the OF test (Chart 7-1).



■ **FIGURE 7-2** The oxidative-fermentative (OF) test. Fermentative organisms produce acid in both the closed and open tubes *(yellow)*; oxidative organisms produce acid only in the open tube. Asaccharolytic organisms that do not use carbohydrates produce no change in either tube.

Motility

A semisolid agar medium for detecting motility of fermentative organisms may not be suitable for nonfermenting species that grow only on the surface of the agar. If a semisolid agar medium is used for nonfermentative bacilli, stab-inoculate only the upper 4 mm of the medium and make an initial reading within 4 to 6 hours. Many motile strains of nonfermentative bacilli show only an early, faint haziness near the surface of the agar, which tends to disappear with prolonged incubation. Readings should again be made at 24 and 48 hours to detect the motility of slowly growing strains. Incubation at 25°C enhances the motility of some strains. We have found that Remel Motility B Medium with tetrazolium (Thermo Scientific, Lenexa, KS) works particularly well for demonstrating motility with the nonfermenting bacilli (Image Plate 7-1E).

The hanging-drop preparation may be more accurate in detecting motility of many species of nonfermentative bacilli. In this technique, a loopful of a 6- to 24-hour, actively growing broth culture that has been incubated at 25°C is placed in the center of a No. 1 coverslip that is inverted and suspended over the concavity of a depression slide. A more practical approach (preferred by the author) is to remove a small amount of growth from the surface of an 18- to 24-hour blood agar plate (BAP) and apply to the surface of a dry glass slide. A drop of saline is added to the inoculum on the slide, and a coverslip is placed over the drop. In either method, the organisms are viewed under a 40× objective with reduced light for the presence of motility. True motility must be differentiated from Brownian movement or the flow of fluid beneath the coverslip. Motile bacteria show

directional movement and change in position relative to each other; when Brownian movement is the cause of the motion, they maintain the same relative positions. The use of flagellar stains (Chart 7-2), discussed later in this chapter, is also helpful in differentiating certain motile species (Fig. 7-3).[202,623]

Pigment Production

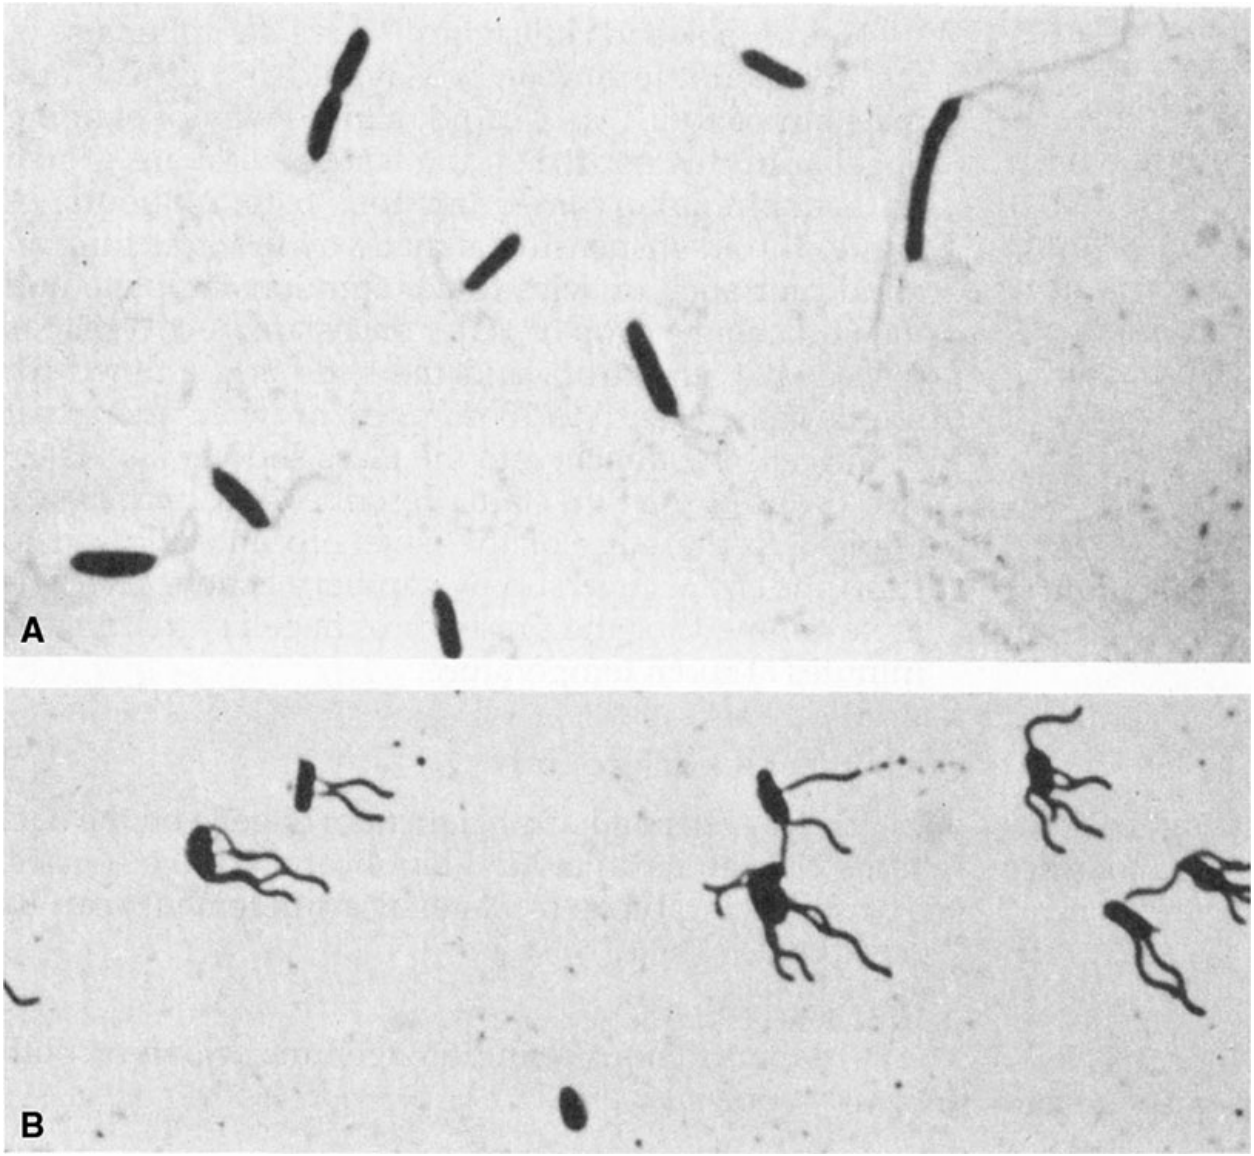
A number of pigments are produced by nonfermenters, some of which are helpful in making a species identification (Image Plate 7-1F). Water-insoluble pigments include carotenoids (yellow-orange), violacein (violet or purple), and phenazines (red, maroon, yellow) that impart distinctive colors to the colonies. Water-soluble and diffusible pigments include fluorescein (pyoverdin), pyocyanin, pyorubin, melanin, and miscellaneous other pigmented by-products that discolor the culture medium. "Tech" and "Flo" media[569] were developed to enhance formation of the water-soluble pigments pyocyanin and pyoverdin (Image Plate 7-1G). These media have special peptones and an increased concentration of magnesium and sulfate ions to enhance pigment production. King and coworkers[569] found that the kind of peptone used in the basal medium markedly affected pigment production. Bacto peptone (Difco Laboratories, Detroit, MI) proved to be superior for the production of pyocyanin but had an inhibitory effect on the elaboration of fluorescein, whereas proteose peptone 3 (Difco) enhanced the production of fluorescein and inhibited the formation of pyocyanin. An increase in phosphate concentration causes enhanced production of fluorescein but decreases pyocyanin production. Pigment production can also be enhanced by growing organisms in gelatin, potato, or milk-containing media and by incubating them at 25°C to 30°C. Pyoverdin may be demonstrated on Flo agar by observing fluorescence under ultraviolet light (using a Wood's lamp) or by the appearance of a yellow pigment in the media in visible light (Image Plate 7-1G and H).

Hydrolysis of Urea

Urea hydrolysis is presented in detail in Chart 6-6. Because many of the urea-splitting nonfermenters require enriched media for growth, Christensen's urea agar slants are used. Positive results may be achieved more rapidly by using a heavy inoculum. Bacterial species, such as *Bordetella bronchiseptica*, that avidly split urea may produce a red color change within 4 hours; weak reactors may require up to 48 hours before a positive reaction can be visualized. The appearance of a faint, delayed, pink tinge in the upper slant portion of the medium probably indicates nonspecific amino acid degradation and should be read as a negative test result (Image Plate 7-2A).

Nitrate Reduction

The basic principles and procedures for performing the nitrate reduction test are presented in Chart 6-2. The reduction of nitrate to nitrite is only the first step in a biochemical process used by some microorganisms to release oxygen—a final hydrogen acceptor at the end point of oxidative metabolism. The nitrate reduction test for nonfermenters is performed in a similar manner to that for other organisms, the end point being the appearance of a red color upon addition of sulfanilic acid and α-naphthylamine to an overnight culture in nitrate-containing media. If a red color does not develop, either



■ **FIGURE 7-3** Bacteria stained with flagellar stains. **A.** Positive flagellar stain of bacilli with polar flagella (original magnification,×900). **B.** Positive flagellar stain of bacilli with peritrichous flagella (original magnification, ×900).

327

nitrate has not been reduced or reduction has proceeded beyond the nitrite stage to the formation of other compounds or to nitrogen gas (denitrification). The appearance of a red color on the addition of a small quantity of zinc dust indicates the residual presence of nitrates, denoting a negative test result; the absence of color indicates that the nitrate has been reduced to compounds other than nitrites (usually nitrogen gas), indicating that the original test was positive.

Denitrification of Nitrates and Nitrites

Certain nonfermenters have the capability of reducing either nitrate or nitrite (or both) to gaseous nitrogen (Chart 7-3). Nitrate–nitrite broth, with an inverted Durham tube or an agar slant, may be used. Because the media contain no carbohydrates, any gas that forms is derived from the nitrate or the nitrite, indicating a positive denitrification test. The broth test is easier to interpret because the collection of gas within the inverted Durham tube is readily visualized. In agar slants, the collection of gas bubbles, usually in the depths of the butt, indicates a positive test result. Most denitrifying media contain both nitrates and nitrites. In rare instances (e.g., in the identification of *Alcaligenes faecalis*, which denitrifies nitrites but not nitrates), separate denitrification tests may be in order. Combination fluorescence–denitrification or fluorescence–lactose–denitrification media are available; however, the reactions may vary from those produced in the media recommended by the CDC (Image Plate 7-2B).

Indole Production

The basic principles and procedure for determination of indole production are presented in Chart 1-4. Minor modifications may be required when detecting indole production by certain weak-reacting nonfermenters. An enriched tryptophan-containing medium, usually heart infusion broth, may be required. Because only small quantities of indole are formed by some nonfermenters, extraction of the culture media by layering a small quantity of xylene or chloroform on the surface may be helpful. Care should be taken to add only a small quantity of extractant because even minimal dilution may lower the concentration of indole below the sensitivity of detection by either Ehrlich's or Kovac's reagent. The appearance of a fuchsia color at the interface of the surface of the medium (or the extractant) with the reagent indicates indole formation and constitutes a positive test result. One organism, *Delftia (Comamonas) acidovorans*, produces a distinctive "pumpkin orange" indole reaction owing to the formation of anthranilic acid, rather than indole, from tryptophan (Image Plate 7-2C).[705]

Decarboxylation

The Møller method for detecting decarboxylation of an amino acid (described in Chapter 6) is based on a change in pH. The development of an alkaline purple color in the test medium, following inoculation with the test organism and incubation at 35°C for 24 to 48 hours, constitutes a positive test result (Chart 6-7). Many nonfermenters display only weak decarboxylase activity and may produce insufficient amines to convert the pH indicator system. This potential shortcoming in the Møller method can be overcome by using only small quantities of substrates (1 to 2 mL) and a heavy inoculum of pregrown organisms in which a high concentration of enzymes has

already accumulated. The sensitivity of detection is also increased by overlaying the culture medium with 4 mm of petrolatum. It is essential that uninoculated, amino acid-free substrate controls be used to compare the color reactions. The initial conversion of the medium to a yellow color as acids accumulate from the small amount of glucose in the medium is not seen with nonfermenters; rather, the end-point reactions are read comparing the strong alkaline purple color reactions with the lighter blue-green hue of the controls (Image Plate 7-2D). Tubes should be incubated at 35°C for up to 5 days before interpreting the reaction as negative. Other systems that use Ninhydrin reagent as an indicator may be more sensitive in detecting decarboxylase activity because the compound reacts directly with the amines to form a purple color.

Esculin Hydrolysis

Esculin hydrolysis is used primarily as a differential characteristic to distinguish between the two *Brevundimonas* species and some of the yellow-pigmented pseudomonads. An esculin medium without bile is recommended for testing of the nonfermenters, because some nonfermenter species are inhibited by bile. Esculin agar slants are inoculated with the unknown isolate and incubated at 35°C for 24 to 48 hours. Esculin in the medium fluoresces when observed with a Wood's lamp. When esculin is hydrolyzed, the medium turns reddish black and fluorescence is lost, indicating a positive test result (Image Plate 7-2E and Chart 7-4).

Flagella Stains

Although usually not required, flagellar stains are occasionally useful in identifying certain motile nonfermentative bacilli, particularly when biochemical reactions are weak or equivocal.

Leifson Method. Reliable results may be obtained using Leifson's staining technique, described in Chart 7-2, if the considerations described in Box 7-1 are given strict attention.[202,623]

Ryu Method. The use of the Ryu flagella stain, which is easy to perform and gives good results, is also recommended.[582,936] The procedure for this method is given in Chart 7-2.

Wet-Mount Technique. Heimbrook and colleagues[432] have described use of the wet-mount technique of Mayfield and Innis[716] and the stain of Ryu[936] as a rapid, simple way of staining flagella. In this approach, the test bacteria are grown on a noninhibitory medium for 16 to 24 hours. A faintly turbid suspension is made by first touching an applicator stick or wire to a colony on the plate and then touching a drop

of water on a slide. A coverslip is placed over the drop, and the slide is examined for motile cells. After 5 to 10 minutes, or when about half of the cells are attached to the glass slide or coverslip, two drops of the Ryu stain (Chart 7-2) are applied to the edge of the coverslip and allowed to

flow under the coverslip by capillary action. The cells are examined for the presence of flagella after 5 to 15 minutes at room temperature.

BOX 7-1

Considerations When Preparing a Leifson Stain

1. The slides must be scrupulously clean. Slides should be soaked in acid dichromate or acid alcohol (3% concentrated hydrochloric acid in 95% ethyl alcohol) for 3–4 days. Final cleaning can be done immediately before use by heating the slides in the blue flame of a Bunsen burner.
2. Bacteria must be grown in a carbohydrate-free medium. A low pH may inhibit formation of flagella, and any acid formation in the medium may be detrimental. The pH of the staining solution should be maintained at 5.0 or higher.
3. Bacteria should be stained during the active log phase of growth, usually within 24 or 48 hours. Room-temperature incubation for 24–48 hours may be required to promote full development of flagella in some species.
4. Care should be taken not to transfer agar to the slide because it may interfere with the staining reaction. Washing the bacteria to be stained two or three times in water (lightly centrifuging between washes) before adding to the slides may help remove surface-staining inhibitors.

Flagellar Morphology. The number and arrangement of flagella on the bacterial cell can be an aid in identification of the species. The following types of flagellar arrangements can be observed:

- Polar
  - Monotrichous—single flagellum at one or both poles
  - Multitrichous—two or more flagella at one or both poles
- Subpolar—flagella near pole with base of flagella at right angle to long axis
- Lateral—flagella projecting from the middle of bacterial cell
- Peritrichous—flagella haphazardly arranged all around bacterial cell

Representative bacteria stained with flagellar stains are shown in Figure 7-3.

PART II: TAXONOMY, BIOCHEMICAL CHARACTERISTICS, AND CLINICAL SIGNIFICANCE OF MEDICALLY IMPORTANT GENERA OF NONFERMENTERS

In the space available here, it is possible to provide only a brief summary of the medically important nonfermenters. Several references can be consulted for an in-depth discussion of the identifying features and clinical syndromes caused by this group of organisms.[439,649,958,1118,1172]

Unlike the *Enterobacteriaceae* the nonfermenting gram-negative bacilli do not fit conveniently into a single family of well-characterized genera, and the correct taxonomic placement of many nonfermentative, gram-negative bacilli (NFBs) remains unresolved. Consequently, the study of nonfermenters is often confusing for the beginning microbiologist. The major genera of nonfermenting, gram-negative bacilli have been classified into at least 22 families including: *Acetobacteraceae (Acetobacter, Acidomonas, Asaia, Gluconobacter, Granulibacter, Roseomonas), Alcaligenaceae (Achromobacter, Advenella, Alcaligenes, Bordetella, Kerstersia, Oligella), Alteromonadaceae (Alishewanella), Brucellaceae (Ochrobactrum), Burkholderiaceae (Burkholderia, Cupriavidus, Lautropia, Pandoraea, Ralstonia), Caulobacteraceae (Brevundimonas, Caulobacter), Comamonadaceae (Comamonas, Acidovorax, Delftia), Flavobacteriaceae (Bergeyella, Chryseobacterium, Elizabethkingia, Empedobacter, Flavobacterium, Myroides, Weeksella), Halomonadaceae (Halomonas), Methylobacteriaceae (Methylobacterium), Moraxellaceae (Acinetobacter, Moraxella, Psychrobacter), Neisseriaceae (Laribacter, Neisseria), Oceanospirillaceae (Balneatrix), Oxalobacteraceae (Herbaspirillum, Massilia, Naxibacter), Pseudomonadaceae (Pseudomonas), Rhizobiaceae (Agrobacterium, Rhizobium), Rhodobacteriaceae (Haematobacter, Pannonibacter, Paracoccus), Rhodospirillaceae (Azospirillum, Inquilinus), Shewanellaceae (Shewanella), Sphingobacteriaceae (Sphingobacterium), Sphingomonadaceae (Sphingomonas), and Xanthomonadaceae (Stenotrophomonas, Wohlfahrtiimonas)* (see http://www.bacterio.net/-classifgenerafamilies.html). In addition, there are a number of clinically important nonfermenters that are not yet assigned to a family and whose taxonomic position is still uncertain.

One approach to studying the nonfermenters is to group them on the basis of the presence or absence of motility and on the type of flagella present in strains that are motile. With this approach, the medically important nonfermenters can be grouped as

in Box 7-2. The biochemical characteristics of the NFBs of clinical relevance are given in Table 7-3.

Organisms That Are Motile With Polar Flagella

Pseudomonads

The genus *Pseudomonas* and some closely related genera, many of which were formerly placed in the genus *Pseudomonas*, make up a group often referred to as the pseudomonads.

BOX 7-2

Medically Important Nonfermenters

Motile with Polar Flagella

Family *Pseudomonadaceae*
(rRNA group I)
Genus *Pseudomonas*

Family *Burkholderiaceae*
(rRNA group II)
Genus *Burkholderia*
Genus *Cupriavidus*
Genus *Lautropia*
Genus *Pandoraea*
Genus *Ralstonia*

Family *Comamonadaceae*
(rRNA group III)
Genus *Comamonas*
Genus *Acidovorax*
Genus *Delftia*

Family *Caulobacteraceae*
(rRNA Group IV)
Genus *Brevundimonas*
Genus *Caulobacter*

Family *Xanthomonadaceae*
(rRNA Group V)
Genus *Stenotrophomonas*
Genus *Wohlfahrtiimonas*

Family *Acetobacteraceae*
Genus *Acetobacter*
Genus *Acidomonas*
Genus *Asaia*
Genus *Gluconobacter*
Genus *Granulibacter*
Genus *Roseomonas*

Family *Alteromonadaceae*
Genus *Alishewanella*

Family *Halomonadaceae*
Genus *Halomonas*

Family *Methylobacteriaceae*
Genus *Methylobacterium*

Family *Neisseriaceae*
Genus *Laribacter*
Genus *Neisseria*

Family *Oceanospirillaceae*
Genus *Balneatrix*

Family *Oxalobacteraceae*
Genus *Herbaspirillum*
Genus *Massilia*
Genus *Naxibacter*

Family *Rhodospirillaceae*
Genus *Azospirillum*
Genus *Inquilinus*

Family *Sphingomonadaceae*
Genus *Sphingomonas*

Family *Shewanellaceae*
Genus *Shewanella*

Organisms Whose Taxonomic Position Is Uncertain

CDC Groups 1c, O-1, O-2, O-3, Vb-3,
WO-1, *Pseudomonas*-like Group 2, OFBA-1

Motile with Peritrichous Flagella

Family *Alcaligenaceae*

Genus *Achromobacter*
Genus *Advenella*
Genus *Alcaligenes*
Genus *Bordetella* (*B. ansorpii, B. avium, B. bronchiseptica, B. hinzii, B. petrii,* and *B. trematum*)
Genus *Kerstersia*
Genus *Oligella* (*O. ureolytica*)

Family *Burkholderiaceae*

Genus *Cupriavidus* (*C. pauculus*)

Family *Rhodobacteraceae*

Genus *Pannonibacter*

Family *Rhizobiaceae*

Genus *Rhizobium*

Family *Brucellaceae*

Genus *Ochrobactrum*

Nonmotile, Oxidase-Positive

Family *Flavobacteriaceae*

Genus *Bergeyella*
Genus *Chryseobacterium*
Genus *Elizabethkingia*
Genus *Empedobacter*
Genus *Flavobacterium*
Genus *Myroides*
Genus *Weeksella*

Family *Sphingobacteriaceae*

Genus *Sphingobacterium*

Family *Moraxellaceae*

Genus *Moraxella*
Genus *Psychrobacter*

Family *Neisseriaceae*

Genus *Neisseria* (*N. zoodegmatis, N. elongata,* and *N. weaveri*)

Family *Alcaligenaceae*
Genus *Oligella* (*O. urethralis*)

Family *Rhodobacteraceae*
Genus *Haematobacter*
Genus *Paracoccus* (EO-2)

Organisms Whose Taxonomic Position Is Uncertain
CDC groups EO-3, EO-4, CDC groups IIc, IIe, IIg, IIh, IIi, Gilardi rod group 1

Nonmotile, Oxidase-Negative

Family *Moraxellaceae*
Genus *Acinetobacter*

Family *Alcaligenaceae*
Genus *Bordetella* (*B. holmesii* and *B. parapertussis*)

Organisms Whose Taxonomic Position Is Uncertain

[a]Data from clinical isolates identified using the methods described in reference 958.
[b]Numbers are percentages of strains giving positive reaction.
PYR, pyrrolidonyl arylamidase test; LAP, leucine amino peptidase test; ESC spot test, esculin hydrolysis; H_2S, hydrogen sulfide; PAD, phenylalanine deaminase; ONPG, *o*-nitrophenyl-β-D-galactopyranoside.

340

Members of this group share the characteristics of being straight or slightly curved gram-negative bacilli that are strict aerobes; most strains are motile by means of one or

more polar flagella; they utilize glucose and other carbohydrates oxidatively; and are usually cytochrome oxidase positive. The key differentiating features of the pseudomonad group are given in Table 7-4.

Palleroni[814] separated the pseudomonads into five rRNA homology groups based on rRNA–DNA homology studies. Gilardi, however, separated the pseudomonads into seven major groups based on phenotypic characteristics: fluorescent, stutzeri, alcaligenes, pseudomallei, acidovorans, facilis–delafieldii, and diminuta.[368] An updated scheme that combines some of the features of both the genotypic and phenotypic classification is outlined in Box 7-3.

Family Pseudomonadaceae—rRNA Group I

Genus *Pseudomonas*. Although most of the pseudomonads were originally classified in the genus *Pseudomonas*, it is now known that each of the five rRNA groups represents taxonomically distinct genetic groups, and as a result different genus names have been assigned to each of the rRNA groups. Only the members of rRNA group I retain the genus designation of *Pseudomonas*.

Fluorescent Group. The species within this group are all characterized by the production of a water-soluble pyoverdin pigment that fluoresces white to blue-green under long-wavelength (400-nm) ultraviolet light. Production of fluorescent pigments is particularly enhanced in media with a high phosphate concentration.[569] Although all three members of this group produce pyoverdin, only one species, *P. aeruginosa*, produces the distinctive blue, water-soluble pigment pyocyanin (Image Plate 7-1G). The key biochemical features that separate the members of the fluorescent group are given in Table 7-5.

Pseudomonas aeruginosa. *P. aeruginosa* produces a characteristic appearance when grown on BAP. It appears as large gray colonies with a spreading periphery and exhibits β-hemolysis. Colonies often have an alligator skin appearance and exhibit a metallic sheen (Image Plate 7-2F). Rapid identification of *P. aeruginosa* in culture can be made whenever the following characteristics are observed: typical colony morphology (Image Plate 7-2F), production of diffusible pigments (Image Plate 7-2G), the presence of a fruity odor, and oxidase positivity (Box 7-4).[208] We have occasionally observed strains that produce a pungent, "rotten-potato" odor. There has been at least one report of a nosocomial outbreak caused by strains of malodorous *P. aeruginosa*.[595]

Pseudomonas aeruginosa is the pseudomonad most frequently recovered from clinical specimens. *P. aeruginosa* infection is especially prevalent among patients with burn wounds, cystic fibrosis (CF), acute leukemia, organ transplants, and intravenous drug addiction.[106] Infections commonly occur at any site where moisture tends to accumulate—tracheostomies, indwelling catheters, burns, the external ear (i.e.,

"swimmer's ear"), and weeping cutaneous wounds. The exudation of bluish pus, with a grapelike odor from the production of pyocyanin, is characteristic of an infection caused by this organism. *P. aeruginosa* also causes urinary tract and lower respiratory tract infections; the latter can be severe and even life-threatening in immunocompromised hosts. The organism can also cause devastating infections of the eye. *Pseudomonas* keratitis, infection of corneal ulcers, and endophthalmitis must be approached as a medical emergency that can be fulminant and threaten permanent loss of vision. Individual case reports of endocarditis, meningitis, brain abscess and infections of bones and joints from hematogenous spread appear with regular frequency in the literature.[106] Most patients with endocarditis caused by *P. aeruginosa* require valve replacement because the infection is difficult to eradicate.[900] *P. aeruginosa* dermatitis and otitis externa outbreaks associated with swimming-pool and hot-tub use are well described.[71] Sporadic *P. aeruginosa* infections following ear piercing have also been reported.[548]

P. aeruginosa produces several substances that are thought to enhance the colonization and infection of host tissue.[106] These substances, together with a variety of virulence factors, including lipopolysaccharide (LPS), exotoxin A, leukocidin, extracellular slime, proteases, phospholipase, and several other enzymes (Box 7-5), make *P. aeruginosa* the most clinically significant bacteria among the NFBs. An unusual mucoid morphotype of *P. aeruginosa* is frequently recovered from respiratory secretions of patients with CF who are chronically infected with *P. aeruginosa* (Image Plate 7-2H). The mucoid morphotype is due to the production of large amounts of a polysaccharide (called alginate) that surrounds the cell. The production of alginate is ultimately responsible for the poor prognosis and high mortality rates among patients with CF. Comprehensive reviews of this subject are available.[373,715,757,1032]

The accuracy of antimicrobial susceptibility testing of *P. aeruginosa* has been evaluated in several studies.[509,528,938] Sader et al.[938] evaluated the MicroScan WalkAway, Vitek, and Vitek 2 and found that all systems exhibited an unacceptable level of very major (false-susceptible) errors for piperacillin-tazobactam, unacceptable minor error rates for cefepime (Vitek 2 and Vitek) and for aztreonam (all three systems). Jekarl and colleagues evaluated Vitek 2 and BD Phoenix for susceptibility testing of *P. aeruginosa* and reported that both systems showed unacceptable overall categoric agreement for imipenem and cefepime and for ceftazidime with Vitek 2.[509] The accuracy of β-lactam susceptibility testing of *P. aeruginosa* was evaluated with four automated systems (BD Phoenix, MicroScan WalkAway, Vitek, and Vitek 2) by Juretschko et al.[528] They found unacceptable levels of error (minor, major, and very major) with aztreonam, cefepime and ceftazidime, piperacillin–taxobactam, and imipenem with all four automated systems and recommended that laboratories seek alternative methods when testing *P. aeruginosa*. Agar diffusion methods (disk

diffusion and Etest) were the most accurate when compared to reference minimal inhibitory concentration (MIC) testing of *P. aeruginosa*.[528]

Treatment of *P. aeruginosa* infections can be difficult. A relatively narrow spectrum of antimicrobials is effective against *P. aeruginosa*, including the carboxypenicillins (carbenicillin, ticarcillin), the ureidopenicillins (mezlocillin, piperacillin), the antipseudomonal cephalosporins (ceftazidime), monobactams (aztreonam), carbapenems (imipenem, meropenem), quinolones (ciprofloxacin, levofloxacin) and aminoglycosides (gentamicin, tobramycin,

amikacin). Almost all strains are resistant to other penicillins and cephalosporins, including ampicillin, cefuroxime, and cefotaxime.[348,656]

P. aeruginosa has the capacity to carry multiresistance plasmids, and this feature has led to the appearance of some *P. aeruginosa* strains that are resistant to all reliable antibiotics.[656] Klebsiella pneumoniae carbapenemase (KPC)-producing *P. aeruginosa* isolates have now been reported in several countries including the United States.[9,501,863,1139] More recently, pan-resistant *P. aeruginosa* isolates harboring both KPC and metallo-β-lactamase (MBL) carbapenemases have emerged.[230,711] The extent to which KPC and MBL carbapenemases-producing *P. aeruginosa* has spread throughout the world is difficult to gage since phenotypic detection

BOX 7-4

Minimum Requirements for Definitive Identification of *P. aeruginosa*

Identification based on all of the following:

1. Gram-negative rod
2. Oxidase-positive
3. Typical smell (fruity grapelike odor or corn tortilla)
4. Recognizable colony morphology
   a. On blood or chocolate agar, appear as large colonies with metallic sheen, mucoid, rough, or pigmented (pyocyanin) and oftenβ-hemolytic (Image Plate 7-2F)
   b. On MacConkey, appear as lactose negative with green pigmentation, or metallic sheen (Image Plate 7-2G)

Limitations:

1. Rare *Aeromonas* isolates may resemble *P. aeruginosa* (lacking the typical smell) but will be spot indole positive (*P. aeruginosa* are indole negative).

2. Some *Burkholderia cepacia* isolates from patients with CF may exhibit morphotypes that resemble *P. aeruginosa*.

From reference 208.

of carbapenemases in *P. aeruginosa* is difficult. The use of molecular techniques may be the only way to determine the extent to which carbapenemase-producing *P. aeruginosa* isolates have disseminated. If undetected by the laboratory, KPC-producing *P. aeruginosa* may become a reservoir for the transmission of this resistance mechanism.[910]

BOX 7-5

Virulence Factors of *Pseudomonas aeruginosa*

Virulence Factor	Biologic Activity
Alginate	Capsular polysaccharide that allows infecting bacteria to adhere to lung epithelial cell surfaces and form biofilms which, in turn, protect the bacteria from antibiotics and the body's immune system
Pili	Surface appendages that allow adherence of organism to GM-1 ganglioside receptors on host epithelial cell surfaces
Neuraminidase	Removes sialic acid residues from GM-1 ganglioside receptors, facilitating binding of pili
Lipopolysaccharide	Produces endotoxin, causes sepsis syndrome: fever, shock, oliguria, leukopenia or leukocytosis, disseminated intravascular coagulation, metabolic abnormalities
Exotoxin A	Tissue destruction, inhibition of protein synthesis; interrupts cell activity and macrophage response
Enterotoxin	Interrupts normal gastrointestinal activity, leading to diarrhea
Exoenzyme S	Inhibits protein synthesis
Phospholipase C	Destroys cytoplasmic membrane; destroys pulmonary surfactant; inactivates opsonins

Elastase	Cleaves immunoglobulins and complement components, disrupts neutrophil activity
Leukocidin	Inhibits neutrophil and lymphocyte function
Pyocyanins	Suppress other bacteria and disrupt respiratory ciliary activity; cause oxidative damage to tissues, particularly oxygenated tissues such as lung

Pseudomonas fluorescens* and *Pseudomonas putida. *P. fluorescens* and *P. putida* both include complexes of closely related species that are difficult to separate phenotypically and with MALDI-TOF MS. For this reason, laboratories are advised to report any organisms included in the *P. fluorescens* or *P. putida* complex as "*Pseudomonas fluorescens* complex," or "*Pseudomonas putida* complex." A list of organisms included in the *P. fluorescens* and *P. putida* complexes are shown in Box 7-6. Organisms included in the *P. fluorescens* and *P. putida* complexes occur in water and soil and may exist in water sources in the hospital environment. For practical purposes, if an isolate is encountered that produces fluorescein (pyoverdin) pigment and does not produce pyocyanin or grow at 42°C, laboratories may wish to report the isolate as "*P. fluorescens/putida* complex," with no further testing, since most laboratory isolates are not considered clinically significant. Both *P. fluorescens* and *P. putida* may exist as normal pharyngeal flora and in only rare occasions have been reported to cause infection in humans. *P. putida* has

been reported to cause catheter-related sepsis in patients with cancer[26,712] and septic arthritis.[675,679] Both groups have been associated with bacteremia from transfused blood.[557,763,870,962,1050,1061] *P. fluorescens* was reported to cause bloodstream infections associated with the use of syringes preloaded with heparin IV catheter flush in 36 patients in 4 states in 2004 to 2005. Twenty-eight additional patients developed delayed-onset bloodstream infections 84 to 421 days after last potential exposure to

the contaminated flush solution.[164] Of increasing importance are reports of *P. fluorescens* pseudobacteremias, the presence of positive blood cultures in the absence of true bacteremia and any related symptoms, most often attributed to contaminated catheters and catheter-related devices.[770,1003]

Stutzeri Group. The organisms in the stutzeri group are all soil denitrifiers and can grow anaerobically in nitrate-containing media, with production of nitrogen gas. Strains are motile by way of polar monotrichous flagella. They can grow with NH_4 as the sole source of nitrogen and acetate as the sole source of carbon for energy. Characteristics

that differentiate members of the stutzeri group are given in Table 7-6.

Pseudomonas stutzeri. *P. stutzeri* (formerly CDC group Vb-1) is ubiquitous in soil and water and has been recovered from humus, manure, straw, sewage, stagnant water, baby formula, hospital equipment, eye cosmetics, and various clinical specimens.[366,368,829] It has only rarely been associated with infections, such as otitis media,[366] conjunctivitis,[684,829] pneumonia,[146,151,806] septic arthritis,[678] endocarditis,[407,921] meningitis in an HIV-positive patient,[915] infections of synthetic vascular grafts,[357]infections of traumatic wounds,[366,371] and vertebral osteomyelitis.[897] It is susceptible to most antibiotics. Freshly isolated colonies are adherent and have a characteristic wrinkled appearance (Image Plate 7-3A), which may be lost after repeated laboratory subculture. *P. stutzeri* comprises a heterogeneous set of strains that includes at least 18 genomic groups without taxonomic status called genomovars.[199,352,927,930,973,993] However, the *P. stutzeri* genomovars are characterized by a high level of heterogeneity of phenotypic properties, which does not allow the taxa to be further categorized into different species.[927–929,993] Only one of the described *P. stutzeri* genomovars has been reclassified and validly published, as the new species, *Pseudomonas balearica*.[88] No human clinical isolates of *P. balearica* have yet been reported.

345

Pseudomonas mendocina. *P. mendocina* (formerly CDC group Vb-2) and the unnamed species CDC group Vb-3 are rarely isolated from clinical specimens. *P. mendocina* colonies are smooth and have the appearance and consistency of butter. Rare but serious infections have been reported because of *P. mendocina*, including four reports of infective endocarditis,[38,517,726,1041] one report of sepsis,[792] and one patient with spondylodiscitis.[186] CDC group Vb-3 isolates resemble *P. stutzeri* except they are arginine positive. Potvliege and colleagues[866] have reported a patient with Vb-3 septicemia in a patient with multiple myeloma.

***Alcaligenes* Group.** Organisms in the alcaligenes group are characterized by being asaccharolytic or only weakly saccharolytic in OF glucose medium. Members of this group include *P. alcaligenes*, *P. pseudoalcaligenes*, and *Pseudomonas* species CDC group 1. The latter unnamed species is similar to *P. alcaligenes*, except that *Pseudomonas* species group 1 strains reduce both nitrate and nitrite to gas.[368] Two former subspecies of *P. pseudoalcaligenes, P. pseudoalcaligenes* subsp. *citrulli* and *P. pseudoalcaligenes* subsp. *konjaci* have been tranfered to the genus *Acidovorax* as *A. citrulli* and *A. konjaci,* respectively.[31] Characteristics that differentiate this group from other similar alkaline pseudomonads are given in Table 7-7. Although members

of this group are recovered from clinical specimens, their ability to act as human pathogens has only rarely been documented. There have been reports of *P. alcaligenes* causing eye infections, empyema, and one patient with fatal endocarditis.[1095]

Other Clinically Relevant *Pseudomonas* Species

Pseudomonas andersonii. *"P. andersonii"* is the name proposed for a new species of *Pseudomonas* associated with granulomatous lung lesions.[419,996] The five isolates described to date have all been recovered from surgically resected lung nodules. *Mycobacterium avium* complex was concomitantly isolated in two of the patients and fungal structures were identified histopathologically in two of the other patients.[996] All organisms grew overnight as on sheep blood agar as small, smooth, opaque, and light-brown colonies. They were positive for oxidase, catalase, and urease. All were negative for bile–esculin hydrolysis and citrate utilization and failed to assimilate most substrates tested. The isolates did not grow at 42°C and did not produce pyocyanin or pyoverdin pigments.[996] All five isolates were susceptible to most antibiotics that are active against gram-negative bacteria.[419,996] The relatively slow growth rate and absence of profiles in most identification system databases will likely lead to underrecognition of this organism.

Pseudomonas fulva. *P. fulva* is included in the *Pseudomonas putida* complex. Colonies are smooth, entire, flat to convex, and pale brownish yellow on nutrient agar. Smooth, yellow-pigmented colonies appear on sheep blood agar after overnight incubation.[886] Fluorescein (pyoverdin) and pyocyanin pigments are not produced and growth does not occur at 42°C.[1089] It is a strict aerobe, weak oxidase positive, catalase positive, nitrate negative, arginine dihydrolase positive, starch and casein hydrolysis negative.[1089] It can be identified reliably by MALDI-TOF MS using the MicroFlex LT instrument and BioTyper (version 3.1) software (Bruker Daltonics, Billerica, MA).[886] *P. fulva* has been reported to cause bloodstream infections,[655,972] and meningitis in patients with external ventricular drains.[19,886] In all instances, the isolates were incorrectly identified as *P. putida* by commercially available identification systems. Laboratories are alerted to conduct further testing, either MALDI-TOF MS or 16S rRNA sequencing on yellow-pigmented isolates that identify as *P. putida* on commercial identification systems.

Pseudomonas otitidis. *P. otitidis* is a novel *Pseudomonas* species recovered exclusively from infected human ears.[201] Cells are motile, gram-negative rods that appear as circular, concave, nonpigmented and nonhemolytic colonies on trypticase soy agar supplemented with blood.[201] Growth occurs at 7°C to 45°C. Colonies typically do not produce fluorescent pigment, and all strains are positive for oxidase and catalase, but negative for urease. Tween 80 and gelatin are hydrolyzed, but casein

and esculin are not.[201] Isolates oxidize glucose, but not mannose, mannitol, or xylose.[618] Roland and Stroman were the first to report *Pseudomonas "otitidis"* otic infections in the United States in 2002.[917] Subsequently, Motoshima et al. reported two isolates of *P. otitidis* from otic infections in Japan,[758] and Lee and colleagues[618] reported isolation of *P. otitidis* from a 53-year-old Korean man with purulent ear discharge. All strains appear to be susceptible to aminoglycosides, fluoroquinolones, polymyxin B, piperacillin, cefotaxime, ceftazidime, and aztreonam, while showing resistance or decreased susceptibility to carbapenems.[201,618,1067] All strains have been found to express MBL activity and to carry a new subclass B3 MBL gene, named $bla_{\text{POM-1}}$.[1067] As such, *P. otitidis* MBL-1 (POM-1) represents the first example of a resident MBL found in a pathogenic *Pseudomonas* species.[1067] Isolates are most often misidentified as *P. aeruginosa* on commercial identification systems; therefore, laboratories are advised that *Psedomonas* isolates that are oxidase positive and grow at 42°C but do not produce a blue-green pigment and demonstrate unusual β-lactam susceptibility patten including testing nonsusceptible to carbapenems should be identified further by 16S rRNA gene sequencing.

Family Burkholderiaceae—rRNA Group II

rRNA Group II consists of organisms that have been referred to in the past as the *Pseudomallei* group. Most species in this group have the unique property of exhibiting resistance to the polymyxin group of antibiotics (polymyxin B and colistin). The biochemical characteristics used to distinguish the members of this group are given in Tables 7-8, 7-9, and 7-10. This group comprises many species, including several plant-associated species. Only those that have been associated with human disease are included in this textbook. Two of the pathogenic species, *B. pseudomallei* and *B. mallei* are listed as category B biothreat agents by the CDC's Strategic Planning Workgroup because of their availability and potential to cause illnesses with high morbidity and mortality.[932]

Genus *Burkholderia*—*Pseudomallei* Group. At the time of this writing, there were 87 species recognized in the genus *Burkholderia*. *Burkholderia* species are human and plant pathogens as well as environmentally important bacteria. They are gram-negative, rod-shaped, motile, and generally obligately aerobic.

Burkholderia mallei. *B. mallei* is an obligate parasite of animals (primarily horses, mules, and donkeys) causing a respiratory tract infection known as glanders. The acute form

of the disease can kill a horse in a couple of weeks. In rare instances, it can be transmitted to humans, usually through an abrasion of the skin.[1146] A patient with laboratory-acquired glanders occurred in the year 2000.[163] Glanders shares with anthrax and plague the distinction of use in war. There is documentation that *B. mallei* was used as a biowarfare agent in World War I.[1173] *B. mallei* is a small gram-negative coccobacillus. On sheep blood agar, it appears as smooth, gray, translucent colonies in 2 days, without pigment or distinctive odor. It is the only nonmotile species in the genus. Other differentiating features are given in Table 7-8.

Burkholderia pseudomallei. *B. pseudomallei* causes melioidosis, a glanders-like disease in animals and humans (Box 7-7). From the rRNA and DNA–DNA results of Yabuuchi et al.,[1197] it is evident the *B. mallei* and *B. pseudomallei* belong to a single genomospecies, but it has been proposed that these two species be kept separate for epidemiologic and zoonotic reasons.

Epidemiology. *B. pseudomallei* has a specific ecologic niche, existing in soil and stagnant water in an area of latitudes 20 degrees north and south of the equator, primarily in Thailand, Vietnam, and parts of northern Australia.[237,244] Other reports confirm that it is endemic in China, Taiwan, and Laos as well, but the true incidence in most countries is unknown.[242,488] Very few patients with melioidosis have been reported from the Indian subcontinent despite similarities in environmental conditions with Southeast Asian countries, although, a patient with melioidosis brain and lung abscess after travel to Sri Lanka was reported in 1999.[831] Most melioidosis cases

reported in other regions arise from travel to areas endemic for *B. pseudomallei*. In the United States, patients with locally acquired melioidosis have been reported in the states of Oklahoma and Georgia.[718,794] The first Oklahoma strain was isolated in 1973 from a 27-year-old farmer with a deep leg wound heavily contaminated with soil as a result of a farming accident. Similar isolates were recovered from the soil near the accident site.[718] The Georgia isolate was recovered in 1977 from a patient that was involved in an automobile accident that resulted in the individual being propelled into a clay embankment. The patient sustained multiple facial fractures and lacerations and developed ulcers in the left eye leading to enucleation. Cultures from the noninfected anophthalmic orbit 8 weeks after enucleation yielded *B. pseudomallei*.[794] Because molecular studies of the Oklahoma strain suggested that it may be a separate species, Glass and colleagues reexamined the Oklahoma and Georgia isolates using standard microbiologic procedures, 16S rRNA gene sequencing, multilocus sequence typing (MLST), and DNA–DNA hybridization and determined that the isolates comprised a novel *Burkholderia* species and in 2006, proposed the name *Burkholderia oklahomensis* for these isolates.[378]

Clinical syndromes. Most infections are asymptomatic or present as a self-limited, short-term, flu-like illness and can be diagnosed only by serology.[49] It is estimated that thousands of US military personnel became infected with *B. pseudomallei* while serving in Southeast Asia in the 1960s and 1970s. Serologic surveys have revealed positive titers for this organism in 1% to 9% of US soldiers returning from Vietnam.[204,574,1024] Thus, with an estimated 3 million military

BOX 7-7

Epidemiology, Diagnosis, Treatment, and Prevention and Reporting of Melioidosis (*Burkholderia pseudomallei*)

Epidemiology

- Melioidosis is an infectious disease caused by the bacterium *Burkholderia pseudomallei.*
- It is clinically and pathologically similar to glanders disease caused by *Burkholderia mallei.*
- Melioidosis is predominantly a disease of tropical climates, especially in Southeast Asia, where it is endemic, with the greatest concentration of cases reported in

Vietnam, Cambodia, Laos, Thailand, Malaysia, Myanmar (Burma), and northern Australia.
- The bacteria causing melioidosis are found in contaminated water and soil. Infection is acquired by inhalation of dust, ingestion of contaminated water, and contact with contaminated soil especially through skin abrasions, and for military troops, by contamination of war wounds. Person-to-person transmission can occur.
- Glanders is contracted by humans from infected domestic animals.
- *Burkholderia pseudomallei* and *Burkholderia mallei* are considered potential agents for biologic warfare and biologic terrorism.

Clinical Findings

- Four clinical presentations of melioidosis are described:
  - *Acute, localized infection*: This form of infection is generally localized as a nodule and results from inoculation through a break in the skin. The acute form of melioidosis can produce fever and general muscle aches, and may progress rapidly to infect the bloodstream.
  - *Pulmonary infection*: This form of the disease can produce a clinical picture of mild bronchitis to severe pneumonia. The onset of pulmonary melioidosis is typically accompanied by high fever, headache, anorexia, and general muscle soreness. Chest pain is common, but a nonproductive or productive cough with normal sputum is the hallmark of this form of melioidosis.
  - *Acute bloodstream infection*: Patients with underlying illness such as HIV, renal failure, and diabetes are affected by this type of the disease, which usually results in septic shock. The symptoms generally include respiratory distress, severe headache, fever, diarrhea, development of pus-filled lesions on the skin, muscle tenderness, and disorientation. This is typically an infection of short duration, and abscesses will be found throughout the body.
  - *Chronic suppurative infection*: Chronic melioidosis is an infection that involves the organs of the body. These typically include the joints, viscera, lymph nodes, skin, brain, liver, lung, bones, and spleen.
- The incubation period (time between exposure and appearance of clinical symptoms) is not clearly defined, but may range from 2 days to many years.

Laboratory Testing

- Organisms appearing as small gram-negative rods may be observed in direct Gram stain from respiratory specimens or abscess materials.
- *Burkholderia pseudomallei* can be recovered from the blood, urine, sputum, or skin lesions using standard laboratory media incubated at 35°C–37°C in ambient atmosphere.
- Detecting and measuring antibodies to the bacteria in the blood is another means of diagnosis.

Recommended Treatment

- For acute or chronic infections, parenteral administration of imipenem or ceftazidime for 2–4 weeks followed by oral therapy with amoxicillin-clavulanate or a combination of doxycycline and trimethoprim-sulfamethoxazole for 3–6 months is recommended.[488]
- Treatment should be initiated early in the course of the disease. Although bloodstream infection with melioidosis can be fatal, the other types of the disease are nonfatal.

Prevention and Reporting

- There is no vaccine for melioidosis.
- Prevention of the infection in endemic-disease areas can be difficult, since contact with contaminated soil is so common. Persons with diabetes and skin lesions should avoid contact with soil and standing water in these areas. Wearing boots during agricultural work can prevent infection through the feet and lower legs.
- Laboratory-acquired infections have been documented. In healthcare settings, using common precautions while handling blood and body fluids can prevent transmission.
- All patient specimens and culture isolates should be handled while wearing gloves and gowns in a biosafety cabinet. Plates should be taped shut when incubating. "Sniffing" of plates containing *B. pseudomallei* is dangerous and should not be done.
- Report possible cases of melioidosis to health authorities.

From the CDC (http://www.cdc.gov/melioidosis/index.html) and the American Society for Microbiology (http://www.asm.org/images/PSAB/Burkholderia101714.pdf).

351

personnel serving in Vietnam from 1965 to 1973, as many as 250,000 may have become infected with *B. pseudomallei*.[752] An important feature of this disease is its ability to produce latent infection that can reactivate many years after primary exposure. For this reason, melioidosis has been dubbed the "Vietnamese time bomb" because the disease may still be incubating in American veterans of the Vietnam conflict.[387,752]

Infections are acquired by contact with the organism either by inhalation of dust or direct contact through breaks in the skin. Three forms of melioidosis have been described: (1) acute disease, presenting as septicemia with metastatic lesions; (2) subacute disease, presenting as a tuberculosis-like pneumonia with cellulitis and lymphangitis; and (3) chronic disease, presenting as a localized chronic cellulitis (Box 7-7). Fifty percent of patients with culture-confirmed melioidosis present with

pneumonia and another 20% of patients with other primary melioidosis presentations develop secondary pneumonia, especially those with positive blood cultures.[730] There has been one report of *B. pseudomallei* lymphadenitis and mediastinitis in a patient with chronic granulomatous disease.[295] Diabetes mellitus has been shown to be a risk factor for the development of bacteremic melioidosis.[1046] It is important to treat suspected cases with antibiotics before any additional treatment of patients, such as draining lesions, in order to avoid sepsis. The mortality rate is 95% in patients with acute disease who are not treated. *B. pseudomallei* is intrinsically resistant to many antibiotics, including the penicillins, first- and second-generation cephalosporins, macrolides, rifamycins, colistin, and the aminoglycosides.[245,513] It is generally susceptible to chloramphenicol, the tetracyclines, trimethoprim-sulfamethoxazole, ureidopenicillins, third-generation cephalosporins, carbapenems, and (unusual for a pseudomonad) amoxicillin-clavulanate.[1175,1204] The fluoroquinolones have only weak activity, and have proved very disappointing in clinical trials.[48,170] This unusual antibiotic profile (i.e., gentamicin- and colistin-resistant and amoxicillin-clavulanate–susceptible) in an oxidase-positive gram-negative rod is useful for confirming the identification of *B. pseudomallei* in the microbiology laboratory.[246] Ceftazidime has been the treatment of choice for treating severe melioidosis, but response to high-dose parenteral treatment is slow.[1175] Carbapenem antibiotics have been shown to be highly active against *B. pseudomallei* in vitro,[245,1008] and in one study, imipenem alone was shown to be an effective treatment for acute severe melioidosis, resulting in fewer treatment failures than ceftazidime alone.[999] In another study, the use of combination therapy with cefoperazone-sulbactam plus trimethoprim-sulfamethoxazole or ceftazidime plus trimethoprim-sulfamethoxazole appeared to be equally efficacious for treatment of severe melioidosis.[183]

Laboratory diagnosis. Definitive diagnosis of melioidosis, which has been called "the great mimicker," depends on the isolation and identification of *B. pseudomallei* from clinical specimens. *B. pseudomallei* grows well on standard laboratory media and often produces wrinkled colonies and thus morphologically may resemble *P. stutzeri*. It can be recovered from blood using standard blood-culture techniques.[1193] Selective agars, either Ashdown's selective agar (ASA)[46] or *Burkholderia pseudomallei* selective agar (BPSA)[482] or selective broths[1155] are recommended for isolation of *B. pseudomallei* from nonsterile body sites, particularly sputum from patients clinically suspected to have melioidosis, and for follow-up during treatment of the disease.[1194]The biochemical properties useful in identifying this organism are given in Table 7-8. Two biotypes of *B. pseudomallei* are categorized by their ability to assimilate L-arabinose.[1004] The arabinose nonassimilators (Ara–) are virulent and can be isolated from both clinical specimens and the environment, whereas the arabinose

assimilators (Ara+) are usually avirulent and with rare exceptions are found only in the environment.[627,1004] Identification of *B. pseudomallei* is usually not difficult in laboratories in areas where the organism is endemic. However, with the increase in international travel and the threat of bioterrorism, it has become more likely that laboratories in areas where *B. pseudomallei* is not endemic could encounter this organism. As many laboratories rely on commercial identification systems, Lowe and colleagues compared the accuracy of four systems, the manual APE 20NE and 20E, and the automated Vitek 1 and 2 systems (bioMérieux Inc. Hazelwood, MO) for their ability to correctly identify 103 strains of *B. pseudomallei*. The API 20NE, API 20E, and Vitek 1 systems gave the correct identification in 98%, 99%, and 99% of the isolates, respectively. The Vitek 2 failed to identify a large number of the *B. pseudomallei* strains largely because of differences in the biochemical reactions achieved compared to expected values in the database.[668] Koh and colleagues, using 47 strains of *B. pseudomallei,* tested what was then a relatively new automated identification system, the BD Phoenix System. Although *B. pseudomallei* is not in the Phoenix database, only four strains were read as no identification. The remaining strains were all incorrectly identified with high confidence as *B. cepacia* (34), *Burkholderia/Ralstonia* spp. (6), or another nonfermenter species (3).[583]

Rapid latex agglutination tests for detection of *B. pseudomallei* antigen in urine[279,1006,1007] have been developed that offer a simple, rapid and highly specific method for diagnosing melioidosis and are particularly useful in areas with limited laboratory facilities.

Laboratory workers are advised to use biologic safety hoods when working with this organism because laboratory-acquired infection with *B. pseudomallei* has been reported.[47,401,856,954] Additional information on the clinical and laboratory features of melioidosis can be found in other published reviews.[242–244,622,1175]

***Burkholderia cepacia* Complex.** *Burkholderia cepacia* is a phytopathogen that causes onion bulb rot in plants and foot rot (i.e., jungle rot) in humans.[1059] Since the early 1980s, *B. cepacia* has emerged as a cause of opportunistic human infections, particularly in patients with chronic granulomatous disease[114,597,802] and CF.[381,499,997,1071] Recent taxonomic advances have demonstrated that *B. cepacia* is actually a cluster of at least 18 closely related genomic species (or genomovars) now called the *B. cepacia* complex (Bcc) which can be differentiated on the basis of molecular and biochemical tests.[213,215,219,375,438,1100,1104,1107,1108,1110,1134] See Box 7-8 for a list of species included in the Bcc. Although all genomovars of Bcc have been cultured from the sputa of patients with CF, *B. cenocepacia* (genomovar III) and *B. multivorans* (genomovar II) account for the majority of the isolates recovered from patients in North America[302,652,826,888,1019] and Europe.[7,281,302,692] A recent study conducted at two CF centers in Argentina showed that *B. contaminans* was the

species

BOX 7-8

Species Included in the *Burkholderia cepacia* Complex (Bcc)[a]

B. ambifaria (VII)[b]
B. anthina (VIII)
B. arboris
B. cenocepacia (III)
B. cepacia (I)
B. contaminans
B. diffusa
B. dolosa (VI)
B. lata
B. latens
B. metallica
B. multivorans (II)
B. pseudomultivorans
B. pyrrocinia (IX)
B. seminalis
B. stabilis (IV)
B. ubonensis
B. vietnamiensis (V)

[a] Data from references 832 and 1100.

[b] Roman numerals in parentheses indicate original genomovar designations.

most frequently recovered from CF patients (57.6%) followed by *B. cenocepacia* (15%).[710] Patients with CF who are colonized with *B. cepacia* have a higher mortality in the year following colonization and have a more precipitous decline in overall pulmonary function following colonization.[635] These bacteria are also those most frequently associated with epidemic spread and with "cepacia syndrome," which is manifested by severe progressive respiratory failure and bacteremia.[43,219,280,390,648,682,1190] Jones et al.[519] reported that genomovar status of Bcc may influence both the likelihood of progression from initial to chronic infection

and the overall survival of the patients. In their study, patients with either *B. multivorans* or *B. cenocepacia* developed chronic infection with deaths from "cepacia syndrome" occurring in both groups.[519] Chaparro et al.[171] found a poorer outcome for CF patients with *B. cepacia* infection following lung transplantation, and De Soyza et al.[280] reported a worse outcome following transplantation with *B. cenocepacia* than with other Bcc species. Aris et al.[43] also found that decreased survival after lung transplantation was linked to genomovar status with a worse outcome for CF patients with *B. cenocepacia* infection. Although the evidence suggests that access to lung transplantation should not be denied to all Bcc-infected CF patients, both the short- and long-term survival are significantly lower when *B. cenocepacia*-infected patients are compared to those infected with other Bcc genomovars.[800]

In addition, several epidemiologic studies have indicated that certain Bcc strains are transmissible between patients and that cross-infection probably occurs by direct person-to-person spread.[161,389,650,651,1002] Virulence markers such as the cable (cbl) pilus encoded by the cable pilin subunit gene (*cblA*) that mediates adherence to mucus glycoproteins and enhances adherence to epithelial cells,[302,382,943,944,1043] and the *B. cepacia* epidemic strain marker (BCESM)[681] designated such because of its association with *B. cepacia* strain types infecting multiple patients with CF, occur almost exclusively in *B. cenocepacia*.

B. cepacia complex has been isolated from numerous water sources and wet surfaces, including detergent solutions and intravenous fluids. Hospital outbreaks of *B. cepacia* infection are usually due to a single contaminated source such as anesthetics,[111] disinfectants,[821,1011] intravenous solutions,[290,1125] nebulizer solutions,[417,495] mouthwash,[162,708,1222] and medical devices, including respiratory therapy equipment.[667,1162] Disinfectants in which *B. cepacia* will grow include povidone–iodine, quaternary ammonium compounds, and chlorhexidine.[91,234,1011] Pseudobacteremias (false-positive blood cultures) have been reported following the use of *B. cepacia*-contaminated disinfectant solutions.[91,234,813,821] *B. cepacia* can also grow in distilled water with a nitrogen source owing to the ability of this organism to fix CO_2 from air. Clinical infections include pneumonia and pneumonitis in patients receiving contaminated anesthetics, urinary tract infection in patients receiving contaminated irrigation fluids following catheterization or cystoscopy, septicemia following heart surgery, endocarditis caused by contaminated heart valves, conjunctivitis, and septic arthritis.[813] Peritonitis following peritoneal dialysis has been associated with povidone–iodine solution contaminated with *B. cepacia*.[821] Infections involving the central nervous system include one child with congenital hydrocephalus who developed bacteremia secondary to a contaminated Holter ventriculoatrial shunt[73] and an adult who developed a brain abscesses secondary to chronic suppurative otitis

media.[445]

Selective media with bacteriostatic dyes, antibiotics, or low pH have been described for the selective isolation of *B. cepacia*. These include *Pseudomonas cepacia* medium (PCM) containing crystal violet, polymyxin B, and ticarcillin[374]; oxidation-fermentation basal medium containing polymyxin B, bacitracin, and lactose (OFPBL)[1164]; and *Burkholderia cepacia*- selective agar (BCSA) containing lactose, sucrose, polymyxin B, gentamicin, and vancomycin.[436] Comparative evaluations of these media have shown that the recovery of *B. cepacia* from patients with CF is enhanced with the use of such media.[437,1128,1135,1192] Overall, BCSA (predominantly used in the United States) and Mast *B. cepacia* medium (predominantly used in Europe) have been found to be the most suitable for growth of all *B. cepacia* complex isolates.[1135,1192]

Identification of *B. cepacia* in the clinical laboratory is problematic because *B. cepacia* is not a single phenotype but a complex of at least 18 separate genetic species (Box 7-8).[722,1100] Commercial identification systems have performed poorly in identifying these organisms. Kiska et al.[575] compared four commercial systems, including the RapID NF Plus (Remel), API Rapid NFT (renamed API 20NE (bioMérieux), Vitek GNI (bioMérieux), and Uni-N/F Tek (Remel). Correct identification for *B. cepacia* was 86% for Uni-N/F Tek, 81% for RapID NF Plus, 50% for Vitek GNI and 43% for API 20NE. Van Pelt and colleagues reported that 90% of *B. cepacia* strains were identified correctly with the API 20NE and Vitek GNI, with 68% identified correctly with the MicroScan WalkAway overnight urine combo type 1 panels.[1128] Shelly et al.[977] evaluated the performance of nine

different commercial systems used in 108 clinical microbiology laboratories from 91 US cities that referred isolates to a CF reference laboratory for confirmatory testing using a polyphasic approach that included genus and species-specific rRNA-based polymerase chain reaction (PCR) assays. Positive predictive values ranged from 71% to 98%, negative predictive values ranged from 50% to 82%, and all systems gave misidentifications for *B. cepacia* complex. The species most frequently misidentified as *B. cepacia* was *Burkholderia gladioli*. Brisse et al.[132] compared the BD Phoenix and Vitek 2 automated instruments for identification of isolates of the *B. cepacia* complex. Rates of correct identification were 50% for BD Phoenix and 53% for Vitek 2 when all *B. cepacia* complex isolates were considered, but differed markedly for *B. cenocepacia* (genomovar III) (71% for Phoenix and 38% for Vitek 2) and *B. multivorans* (genomovar II) (58% for Phoenix and 89% for Vitek 2). Correct identification to the species level has been reported to be as low as 33.3% for *B.*

cepacia using the Vitek MS v2.0 system.[691] The results of these studies support the recommendation that when using commercial systems for identification of *B. cepacia* complex isolates, results should be confirmed by performing supplemental biochemical tests (Table 7-9) or by molecular methods.

MALDI-TOF MS of intact cells has also emerged as a powerful and rapid method for the identification of NFBs including members of the Bcc. However, even though genus-level identifications are reported to be in the 90th percentile, identification to species level for the Bcc is often less than 80%.[100,270,278,328,477,604,691,701,719,1126] Laboratories are advised that when using MALDI-TOF for identification, any organisms listed in Box 7-8 should be reported as *B. cepacia* complex.

Unlike other common pseudomonads, *B. cepacia* is resistant to aminoglycoside antibiotics but is usually susceptible to trimethoprim-sulfamethoxazole, which has become the drug of choice in treating *B. cepacia* infections. Daniel et al.[253] performed in vitro susceptibility studies on 36 *B. cepacia* blood isolates and found that most strains were susceptible to minocycline (94.4%), ceftazidime (86.1%), ciprofloxacin (83.3%), and trimethoprim–sulfamethoxazole (83.3%). In two- and three-drug synergy studies performed by Bonacorsi and colleagues,[109] the addition of ciprofloxacin significantly enhanced the killing activities of piperacillin, imipenem, and meropenem, while the three-drug combination of β-lactam–ciprofloxacin–tobramycin gave the most consistently synergistic effect. Aaron and colleagues[1] also performed in vitro testing using multiple antibiotic combinations for *B. cepacia* isolates. They reported that using double-antibiotic combinations improved bactericidal activity for the following drug combinations: meropenem–minocycline, meropenem–amikacin, and meropenem–ceftazidime. Triple-antibiotic combinations that contained tobramycin, meropenem, and an additional antibiotic were most effective and were bactericidal against 81% and 93% of isolates.[1] In another study, Nzula and colleagues showed that antibiotic MICs vary widely for the different strains of the *B. cepacia* complex.[795] Although all strains were resistant to polymyxin B, MICs for chloramphenicol ranged from 4 to 128 mg/L and those for trimethoprim from 0.25 to 64 mg/L, with the majority of strains exhibiting resistance. Similarly, the MIC ranges for tobramycin, ciprofloxacin, and ceftazidime varied widely, suggesting the need for laboratories to perform susceptibility testing on individual isolates. Vermis et al.[1135] noted that the MICs of clinical isolates originating from patients with CF were higher than those isolated from patients who did not have CF and that in general, *B. cepacia* complex isolates were more susceptible to rifampicin, trimethoprim–sulfamethoxazole, and imipenem and were most resistant to polymyxin B.

For further information on the biology, taxonomy, mechanisms of virulence, and epidemiology of *B. cepacia*, several excellent reviews can be consulted.[219,373,390,520,648,680,1100,1135]

Burkholderia gladioli. *B. gladioli* (formerly named *P. marginata*) is primarily a plant pathogen causing "flower rot" in gladiolus and other plants. It is one of the few pseudomonads that is negative for cytochrome oxidase, and it produces nonfluorescent yellow colonies after 48 to 72 hours of incubation. It has been reported to cause human pulmonary disease and sometimes bacteremia and soft tissue infections in patients with CF,[66,195,395,521,538,558,753] chronic granulomatous disease,[444,924] diabetes,[983] and other immunologic deficiencies.[395] *B. gladioli* has also been reported to cause keratitis, endophthalmitis, and corneal ulcers,[629,909] as well as osteomyelitis in association with chronic granulomatous disease.[126]

B. gladioli usually grows as yellow colonies because of production of a diffusible, nonfluorescent yellow pigment. Biochemical tests that enable differentiation from *B. cepacia* complex include negative reactions for lysine, maltose, and lactose. Most strains are oxidase negative or weakly oxidase positive and catalase positive. Further differentiating characteristics are given in Table 7-9. Laboratory workers should be aware that phenotypic methods for differentiation of *B. gladioli* from the organisms of the *B. cepacia* complex are unreliable and may lead to misidentification.[205] Commercial identification systems often fail to discriminate *B. gladioli* from related species.[977,1128] Therefore, molecular-based methods should be used when confirmation of an isolate as *B. gladioli* is deemed necessary.[76,205,1174] The antibiotic susceptibility pattern may also serve as a clue that an organism might be *B. gladioli,* if it tends to be susceptible to aminoglycosides, imipenem, ciprofloxacin, and trimethoprim–sulfamethoxazole and resistant to aztreonam and cephalosporins.[924]

Genus *Ralstonia* and Genus *Cupriavidus.* Palleroni[814] and later Li et al.[638] demonstrated two DNA homology groups within the *Pseudomonas* RNA homology group II. In 1992, Yabuuchi proposed the generic name *Burkholderia* for seven species but noted that *B. pickettii* and *B. solanacearum* were similar to each other and different from the other five *Burkholderia* species named at the time.[1197] In 1995, Yabuuchi et al.[1198] proposed the transfer of *B. pickettii, B. solanacearum,* and *Alcaligenes eutrophus* to the new genus *Ralstonia* with *R. pickettii* serving as the type species. Subsequently, several new species or new combinations were added to the genus *Ralstonia*. Comparative 16S rRNA sequence analysis now indicates that two distinct sublineages exist within the genus *Ralstonia*. The first, which is called the *Ralstonia eutropha* lineage, is composed of *R. basilensis, R. campinensis, R. eutropha, R. gilardii, R. metallidurans, R. oxalatica, R. paucula, R. repiraculi,* and *R. taiwanensis*. The second is the *Ralstonia pickettii* lineage, which is composed of *R. insidiosa, R. mannitolilytica, R. pickettii, R. solanacearum,* and *R. syzygii*. This separation is supported

BOX 7-9

Characteristics for Differentiation of *Ralstonia* and *Cupriavidus*

Characteristic	*Ralstonia*	*Cupriavidus*
Flagellation	Polar, 1–4	Peritrichous
Colistin (10-µg disks)	Resistant	Susceptible
Acid from carbohydrates	Positive	Negative

by phenotypic differences. Members of the *R. eutropha* lineage have peritrichous flagella, do not produce acids from glucose and are colistin-susceptible, in contrast members of the *R. pickettii* lineage have one or more polar flagella, produce acid from several carbohydrates and are colistin resistant (Box 7-9).[262,1122] Vaneechoutte and colleagues proposed that the species of the *R. eutropa* lineage be reclassified into the new genus *Wautersia*.[1122] Subsequently, DNA–DNA hybridization experiments and an evaluation of phenotypic characteristics, DNA base ratios, and 16S rRNA gene sequences demonstrated that *Wautersia eutropha*, the type species of the genus *Wautersia*, is a later synonym of *Cupriavidus necator*, the type species of the genus *Cupriavidus*. Therefore, all members of the genus *Wautersia* have been reclassified into the genus *Cupriavidus*.[1099]

Ralstonia pickettii. *Ralstonia pickettii* was created for a group of clinical isolates[876] and also turned out to include strains of CDC groups Va-1 and Va-2, which were regarded as two different biovars of *R. pickettii*.[851] Shortly before this, King et al.[567]reported that *R.* ("*Pseudomonas*") *pickettii* contained several biovars, including the strains originally isolated from St. Thomas Hospital, London,[845,846] which had been designated "*Pseudomonas thomasii*," although the name was never validly published. In 1994, Pickett[848] noted that *R. pickettii* should be recognized as having three biovars designated biovar Va-1, biovar Va-2, and biovar 3/*thomasii*. De Baere et al.[262] subsequently confirmed by DNA–DNA hybridization that *R. pickettii* biovar 3/*thomasii* was a separate species and proposed the name *Ralstonia mannitolytica,* later corrected to *Ralstonia mannitolilytica*.[653]

R. pickettii is rarely associated with human infections, but it has been reported to cause nosocomial infections, including bacteremia and urinary tract infections. Nosocomial outbreaks have occurred with contaminated respiratory care solutions,[596] heparin solutions,[706] "sterile" saline solutions,[160,184] distilled water[549,703] and a contaminated water irrigation system.[1209] Pseudo-outbreaks have also been reported because of contaminated blood-culture bottle caps[116] and water splashed from a sink.[431] There have been several reports of primary infection caused by *R. pickettii* including vertebral osteomyelitis and diskitis in a patient receiving long-term hemodialysis,[1169] community-acquired pneumonia,[816,880] bacteremia in a cord-blood-transplant recipient,[1187] bacteremia in cancer patients,[734,835] sepsis in a hemodialysis patient,[1035] neonatal sepsis in a premature infant[1142] and meningitis in a presumably healthy rancher[430] and a child with hydrocephalus.[110]

R. pickettii is slow-growing and produces only pinpoint colonies on BAPs after 24 hours. All strains are urease positive and some strains may be catalase negative. Motility is weak or delayed and may not be detectable. Biovar Va-1 can be separated from Va-2 by the oxidation of lactose and maltose. For additional biochemical characteristics see Table 7-10.

Ralstonia mannitolilytica. *R. mannitolilytica* is the name given to organisms formerly classified as *R. pickettii* biovar 3/*thomasii* (see discussion above).[262] It has been recovered from the sputum of patients with CF[216,220,329] and one patient each with recurrent meningitis and hemoperitoneum,[1117] peritoneal fluid in patients undergoing peritoneal dialysis,[297,1221] bloodstream infection in a premature infant associated with a humidifying respiratory therapy device[103] and catheter-related bacteremia in five patients on a hematology-oncology ward.[409] A national outbreak of *R. mannitolilytica* colonization or infection in pediatric patients associated with use of a contaminated oxygen delivery device (Vapotherm 2000i, Vapotherm Inc., Stevensville, MD) was reported in the period of December 2004 through August 2005. Pulse-field gel electrophoresis showed related strains of *R. mannitolilytica* were recovered from 38 patients at 18 hospitals in 12 states in the United States.[514] *R. mannitolilytica* can be distinguished from other *Ralstonia* species by its acidification of D-arabitol and mannitol, its lack of nitrate reduction and alkalinization of tartrate. Other characteristics are given in Table 7-10.

Ralstonia insidiosa. *R. insidiosa* strains have been isolated from the environment as well as human clinical samples, including respiratory secretions of patients with CF.[211,1122] Strains of *R. solanacearum* and *R. syzygii* have not been isolated from human clinical specimens. Characteristics for identification of *Ralstonia* species of human origin are given in Table 7-10.

Antibiotic susceptibility of *R. pickettii* and *R. insidiosa* has been reported by Ryan

and Adley.[935] The majority of isolates tested showed susceptibility to most antibiotics. The most effective were found to be quinolones and sulfamethoxazole/trimethoprim.[935]

The genus *Cupriavidus* is composed of former *Ralstonia* species that are asaccharolytic, colistin-susceptible, and motile, with peritrichous flagella, except for *C. gilardii*, which has a single polar flagellum (Box 7-9). At the time of this writing, the genus included 14 species: *C. alkaliphilus*, *C. basilensis, C. campinensis, C. gilardii, C. laharis, C. metallidurans, C. necator* (type species formerly *Ralstonia eutropha*), *C. numazuensis, C. oxalaticus, C. pampae, C. pauculus, C. pinatubonensis, C. respiraculi,* and *C. taiwanensis*.[1099] Selected species that have been associated with human infection are discussed in more detail below.

Cupriavidus gilardii. *C. gilardii* (formerly *Ralstonia gilardii*) was named in honor of G.L. Gilardi, an American microbiologist who contributed much to our knowledge of NFBs. It is phenotypically similar to *Alcaligenes faecalis,* and was referred to as *A. faecalis*–like by Gilardi. It is a gram-negative, nonfermenting, asaccharolytic bacillus that is motile by means of peritrichous flagella,[1159] although in the original description by Coenye et al.[210] they were described as being motile by means of a single polar flagellum. Catalase and oxidase are positive. Nitrate and nitrite are not reduced. It can be differentiated from *A. faecalis* by the absence of nitrite reduction and failure to grow on acetamide and in 6.5% NaCl. Human isolates have been from the respiratory tract,

355

a furuncle, cerebrospinal fluid (CSF), bone marrow, thigh muscle abscess,[1062] and blood.[210,541,1159] Coenye et al.[216] reported *C. gilardii* in the respiratory secretions of 10 patients with CF, which represented 9% of the *Ralstonia/Cupriavidus* species isolated from CF patients.

Cupriavidus metallidurans. *C. metallidurans* (formerly *Ralstonia metallidurans*) is known for its ability to survive in high concentrations of toxic heavy metals: metallidurans literally translates to "metal-enduring."[386] Coenye et al.[216] reported *C. metallidurans* in the bronchial secretions of two patients with CF, but its pathogenic or colonizing role could not be determined. There have been two reports of nosocomial septicemia,[607,742] and one report of catheter-related bacteremia[286] caused by *C. metallidurans.* At one of our hospitals, *C. metallidurans* >100,000 CFU/mL was isolated from the urine of an 80-year-old renal transplant patient who was admitted due to respiratory distress caused by fluid overload. The identification was obtained using the Bruker MALDI-TOF MS with a value score of 2.537 and was confirmed with 16S rRNA sequencing. The isolate was susceptible to ampicillin, cefepime,

ceftazidime, ceftriaxone, ciprofloxacin, ertapenem, imipenem, meropenem, and piperacillin/tazobactam, trimethoprim/sulfamethoxazole and resistant to amikacin, cefazolin, gentamicin, nitrofurantoin, and tobramycin using the Clinical and Laboratory Standards Institute (CLSI) non- *Enterobacteriaceae* interpretive breakpoints (Schreckenberger P, personal communication).

Cupriavidus pauculus. *C. pauculus* (formerly *Ralstonia paucula* and CDC group IV c-2) is an oxidase-positive, nonsaccharolytic gram-negative rod that is motile by means of peritrichous flagella and is strongly urease positive. It therefore phenotypically resembles *Alcaligenes*, *Bordetella,* and *Oligella ureolytica*, from which it must be differentiated (Table 7-10). Most reports of human infection have been immunocompromised patients with bacteremia.[30,39,41,235,240,713,738,789,881,945,1069,1213] There have also been two reports of peritonitis following continuous ambulatory peritoneal dialysis, one with accompanying septicemia[1213] and one with a mixed infection with IVc-2 and *Alcaligenes faecalis*[422]; and one patient with tenosynovitis of the hand following a cat bite.[764] In the latter case, it is not clear whether the source of the infectious agent was the cat bite or the tap water used to rinse the lesion. *C. pauculus* has also been reported to cause bacteremia in a child on extracorporeal membrane oxygenation (ECMO),[1092] concomitant meningitis and septicemia in a neonate,[303] and community-acquired pneumonia in a newborn.[55]

Cupriavidus respiraculi. *C. respiraculi* (formerly *Ralstonia respiraculi*) has been recovered from the respiratory tract of patients with CF, although the isolates did not grow on BCSA.[221] Characteristics that differentiate *C. respiraculi* from other *Cupriavidus* species are given in Table 7-10.

Cupriavidus taiwanensis. *C. taiwanensis* (formerly *Ralstonia taiwanensis*) has also been isolated from the sputum of a patient with CF.[180] It is a nonsaccharolytic gram-negative rod that is oxidase, catalase, nitrate, and esculin positive. Additional biochemical characteristics are given in Table 7-10.

Genus *Lautropia*

Lautropia mirabilis. *L. mirabilis* is a motile facultatively anaerobic gram-negative coccus that ferments glucose, fructose, sucrose, and mannitol; reduces nitrate and nitrite; and produces positive reactions for oxidase, urease, and, sometimes weakly, catalase.[361] Phylogenetic characterization based on 16S rRNA gene sequence analysis places this species in the β-subgroup of the *Proteobacteria*, separate from all other described genera, but most closely related to *Burkholderia*.[361] Interestingly, the cellular fatty acid composition of *L. mirabilis* is most similar to the cellular fatty acid of *Acidovorax delafieldii*, *Comamonas terrigena,* and CDC weak oxidizer group 1 (WO-1).[247] Coccoid morphology and the ability to ferment glucose separates *L.*

mirabilis from *C. terrigena*, *A. delafieldii*, WO-1 and members of the *Burkholderia* group. *L. mirabilis* displays extremely polymorphic cell morphology. At least three colony morphologies are seen: (1) flat, dry, circular colonies in young cultures, (2) larger, wrinkled, crisp, and crater forms on prolonged incubation and (3) smooth, glistening, raised, round, mucoid colonies. The colony diameter varies between pinpoint and more than 5 mm, and colonies are usually adherent to the agar.[361] *L. mirabilis* has been recovered from oral and upper respiratory sites,[361] the sputum of a patient with CF,[86] and the oral cavities of children infected with HIV.[931] Its pathogenic potential is unknown.

Genus *Pandoraea*. In 2000, Coenye et al.[209] described a new genus, *Pandoraea* (referring to Pandora's box in Greek mythology) of gram-negative nonfermenters isolated primarily from sputa of patients with CF and from soil. Originally, this genus contained five named species (*P. apista*, *P. norimbergensis*, *P. pnomenusa*, *P. pulmonicola,* and *P. sputorum*) and one unnamed genomic species.[209] Daneshvar et al.[250] described three additional unnamed genomospecies, previously classified as CDC weak oxidizer group 2 (WO-2). More recently four additional named species (*P. thiooxydans, P. oxalativorans, P. faecigallinarum, P. vervacti*) from environmental or animal sources have been added bringing the total of named species to nine.[27,939] *Pandoraea* spp. have been isolated mainly from the respiratory secretions of patients with CF, but have also been found in other clinical samples, including blood and lung tissue.[53,231,524,746,1038] Epidemic spread of *P. apista* from an index patient to five other patients with CF participating in winter camps and/or who had been hospitalized has been reported.[524] At present, the prevalence, patient-to-patient transmissibility, and clinical impact of *Pandoraea* organisms in patients with CF are unknown because the usual manual and automated phenotypic identification methods used in most clinical laboratories are not satisfactory in identifying *Pandoraea* spp.[214,746] *Pandoraea* species will usually grow well on *B. cepacia*-selective medium and therefore, can be misidentified as members of the *B. cepacia* complex. *Pandoraea* species grow well on BAP after overnight incubation at 35°C. Isolated colonies appear circular, convex, semiopaque, entire, and smooth and are 0.5 to 1 mm in diameter. Hemolysis is variable. All species are motile, with polar flagella, and are positive for growth on MacConkey agar, production of catalase, and alkalinization of citrate. All species are negative for reduction of nitrite; denitrification; indole production; gelatin, esculin, and tween hydrolysis; lysine and ornithine decarboxylase; and arginine dihydrolase, β-galactosidase, and DNase activity. No acid is

produced from OF base mannitol, lactose, sucrose, maltose, or fructose. Strains produce weak acid or are negative in OF glucose.[209,250] For features that differentiate *Pandoraea* from phenotypically similar organisms, see Table 7-9.

Family Rhodospirillaceae

Genus *Inquilinus*. The genus *Inquilinus* belongs to the family *Rhodospirillaceae* and includes two species, *I. ginsengisoli* and *I. limosus*. Only *I. limosus* has been associated with infection in humans. *I. limosus* is a rod-shaped gram-negative bacterium that measures 1.5 to 2 mm in width by 3.5 mm in length. It grows at 35°C and 42°C, but poorly at 25°C. It forms very slimy, nonpigmented colonies on nonselective media. Growth on MacConkey agar is very slight after 3 days. Some strains are motile with one or two polar flagella, but motility is difficult to demonstrate because of the mucoid nature of the colonies. It is polymyxin B resistant and lipase positive, making it appear phenotypically similar to the *B. cepacia* complex (Table 7-9).[212,857] All strains are positive for oxidase, catalase, β-glucosidase, phosphatase, proline aminopeptidase, pyrrolidonyl aminopeptidase, esculin hydrolysis, and acetoin production and negative for lysine, arginine, ornithine, denitrification, gelatinase, indole production, and citrate utilization.[189,212] Acid is formed in OF fructose, dextrose, and mannitol (Table 7-3). H_2S is positive by the lead acetate paper strip test but not in TSI agar (Christopher Doern, personal communication). *I. limosus* has been recovered from respiratory secretions of patients with CF in the USA,[212,429,857] Germany,[956,1165] France,[98,189,270] Italy,[197] Spain,[948] and the UK.[227] There is one report of *Inquilinus* sp. being recovered from blood samples of a patient without CF who had prosthetic valve endocarditis.[570] Definitive identification is difficult because it is not contained in the databases of commercial identification kits and its mucoid appearance may lead to confusion with mucoid *P. aeruginosa* strains.[857,1165] Isolates can be recovered on colistin containing *B. cepacia*- selective media, but are inhibited on BCSA, which contains gentamicin.[189] The mucoid nature of *I. limosus* may contribute to its colonization and resistance to many antimicrobial agents.[98,440] All isolates are reported to be resistant to penicillins and cephalosporins, kanamycin, tobramycin, colistin, doxycycline, and co-trimoxazole, but susceptibile to imipenem and ciprofloxacin.[189,1165] There has been no patient-to-patient transmission reported.

Family Comamonadaceae—*rRNA Group III*

Willems and colleagues have proposed that the organisms belonging to rRNA group III be recognized as a new bacterial family, the *Comamonadaceae*.[1176]

***Acidovorans* Group.** This group consists of the organisms formerly named

Pseudomonas acidovorans, Pseudomonas testosteroni and *Comamonas terrigena*. In 1987 Tamaoka[1055] proposed that the organisms known as *Pseudomonas acidovorans* and *P. testosteroni* be placed in the genus *Comamonas,* along with the species *C. terrigena*. Subsequently, *C. acidovorans* was placed into a new genus *Delftia* as the type species *D. acidovorans*.[1166] All are motile by way of a polar tuft of up to six flagella, with the distinctive feature of having a long wavelength (3.0 mm between the top of adjacent waves). Acid is not produced in OF glucose medium, and thus these organisms are grouped among the alkaline pseudomonads (Table 7-7). As a group, the comamonads have a wide geographical distribution and are common soil and water saprophytes. They have been isolated from animal sources, foodstuffs, hospital equipment and human clinical specimens, but they are rarely clinically significant.

Genus *Delftia*

Delftia acidovorans. The genus *Delftia* consists of four speciens: *D. acidovorans, D. lacustris, D. litopenaei,* and *D. tsuruhatensis. D. acidovorans* is the most common of this group to be isolated from clinical specimens. It can be easily distinguished from other alkaline pseudomonads because of the production of a weak acid or neutral reaction in OF fructose and OF mannitol. It is acetamide positive and reduces nitrate without gas formation. It is indole negative, but most strains produce an orange color in the medium on the addition of Kovacs' reagent (so-called orange indole) because of the production of anthranilic acid from tryptone (Image Plate 7-2C).[705] The orange indole reaction can also be demonstrated by adding a drop of Kovacs' reagent to colonies growing on the surface of BAPs. When the indole test is performed with xylene extraction and the addition of Ehrlich's reagent, these same strains produce a vivid yellow reaction in the test medium. *D. acidovorans* has been isolated from a variety of clinical specimens and is usually considered to be nonpathogenic. Isolates have been recovered from sputum, urine, the right and left ureters of a transplanted kidney, renal preservation fluid, corneal scrapings from a patient who had undergone multiple previous eye surgeries, and the blood of a patient with tuberculosis (Schreckenberger P, personal communication). There are reports in the literature of *D. acidovorans* associated with catheter-related bacteremia,[155,156,192,313,545,602,606] suppurative otitis,[894] urinary tract infection,[274] ocular infections,[131,621,625,884,1033] and peritonitis in a patient who had undergone continuous ambulatory peritoneal dialysis.[663] *D. acidovorans* endocarditis has also been described in a 42-year-old intravenous drug abuser.[480] One patient with AIDS developed pneumonia caused by this organism,[334] and an infected immunocompetent man developed a chronic empyema in the pleural cavity.[196] Camargo and colleagues reported isolating *D. acidovorans* isolates in pure cultures at counts above 1,000,000 CFU/mL from tracheal aspirates of 21 patients hospitalized in an intensive care unit,

indicating a common, but undetermined source responsible for the colonization.[145] Characteristic for identification of *D. acidovorans* are given in Table 7-7.

D. lacustris, D. litopenaei,* and *D. tsuruhatensis. These three new species of *Delftia* that have been isolated from mesotrophic lake water in Denmark,[525] a freshwater shrimp culture pond in Taiwan,[181] and sludge collected from a wastewater treatment plant in Japan.[982] Two of these species have subsequently been reported to cause human infection. *D. tsuruhatensis* has been reported to cause catheter-related bloodstream infections in patients with long-term indwelling central venous catheters.[556,869,1049] *D. lacustris* has been reported to cause septicemia in a patient with

pheochromocytoma[1012] and was cultured from bile fluid of a patient with hepatocellular carcinoma, from empyema fluid of a chest cavity following chest trauma and from blood cultures of two patients with renal disease.[984]

Genus *Comamonas*. *Comamonas* species are all motile, oxidase positive, and produce alkaline reactions in OF sugars. They phenotypically resemble *Delftia* species, *P. alacaligenes, P. pseudoalcaligenes,* and *Brevundimonas* species from which they must be differentiated. The phenotypic characteristics for this group of organisms are given in Table 7-7.

Comamonas testosteroni. *C. testosteroni* is an uncommon isolate in the clinical laboratory, despite its wide environmental distribution. Eighteen *C. testosteroni* infections have been reviewed by Barbaro and colleagues.[63] They report that the organism was most often found in association with anatomic abnormalities of the gastrointestinal tract, with perforation of the appendix being the most common. Other previously published reports describe *C. testosteroni* as a cause of sepsis,[52,410,1005,1085] central venous catheter-related infection,[626,791] endocarditis,[229] pseudo-bacteremia traced to contaminated disinfectant used for disinfecting blood-culture bottles before use,[988] pneumonia in a patient with AIDS,[334] endophthalmitis,[887] and meningitis in a patient with recurrent cholesteatoma.[40] Coenye reported isolation of *C. testosteroni* from the respiratory secretions of two patients with CF.[212]

Comamonas terrigena. *C. terrigena* actually comprises three genotypically separate groups. *C. terrigena* DNA group 1 retains the name *C. terrigena*, while *C. terrigena* DNA group 2 (containing *Aquaspirillum aquaticum* and some E. Falsen [EF] group 10 strains) has been renamed *C. aquatica* and *C. terrigena* DNA group 3

(containing some former EF group 10 strains) has been renamed *C. kerstersii*.[1160] *C. terrigena* is not considered a human pathogen, although Sonnenwirth reported the isolation of *C. terrigena* from two blood cultures of a patient with endocarditis; however, the role of the organism as a pathogen in this patient was uncertain.[1014]

Comamonas kerstersia. *C. kerstersia* can be differentiated from other *Comamonas* species by its ability to grow at 42°C. Other phenotypic characteristics are shown in Table 7-7. *C. kerstersia* has been reported to cause intra-abdominal infections[16,97] and bacteremia in a patient with diverticulosis.[804]

Facilis–Delafieldii Group

Genus *Acidovorax*. Willems and colleagues proposed a new genus, *Acidovorax*, which contained three species: *Acidovorax facilis* (formerly *Pseudomonas facilis*), *Acidovorax delafieldii* (formerly *Pseudomonas delafieldii*), and *Acidovorax temperans* (for several former *Pseudomonas* and *Alcaligenes* strains).[1177] These three species form a separate group within the rRNA group III complex. Two of the species, *A. delafieldii* and *A. temperans*, have been isolated from clinical specimens; however, no information regarding the clinical significance of these organisms is available.[368,1177] *A. delafieldii* is probably the same as CDC group WO-1 and *A. temperans* is probably the same as CDC group WO-1A.[1172] Subsequently, the genus has been expanded and now includes 18 species and subspecies that have been isolated from plants and the environment. Three new species have been recovered from human clinical specimens. *A. avenae* and *A. oryzae* have both been reported in patients with catheter-associated bloodstream infection[685,805,980] and *A. wautersii* has been reported in two human infections although the clinical context was not clearly described.[1120] *Acidovorax* species are oxidase positive, motile and utilize carbohydrates oxidatively. For additional differentiating features, see Table 7-3 and the published report by Willems and colleagues.[1177]

Family Caulobacteraceae—rRNA Group IV

All species in rRNA group IV have been transferred to the new genus *Brevundimonas* (meaning bacterium with short-wavelength flagella).[967]

Genus *Brevundimonas*. The genus *Brevundimonas* includes 25 species of which only two, *B. diminuta* and *B. vesicularis,* are found in human clinical specimens. They are grouped with the alkaline pseudomonads because they are nonreactive or only weakly reactive in most carbohydrates (Table 7-7). This group is characterized by the presence of a single, tightly coiled (wavelength of 0.6 to 1.0 mm) polar flagellum. *B. vesicularis* is slow-growing and usually requires 48 hours of incubation for colonies to

be observed on sheep blood agar, producing dark-yellow to orange-pigmented colonies (Image Plate 7-3C). Most strains fail to grow on MacConkey agar. *B. vesicularis* can be separated from all other species of alkaline pseudomonads by virtue of a strong esculin hydrolysis reaction. We have isolated *B. vesicularis* from peritoneal dialysate fluid, a renal dialysis machine, an oral abscess and a scalp wound. Others have reported isolating this species from cervical specimens,[807] blood,[185,365,620,796,858,1123] and a patient with botryomycosis, a rare, chronic suppurative, granulomatous condition affecting the skin.[143] *B. vesicularis* has also been recovered from hospital environmental samples including a shower hose[584] and a hydrotherapy pool.[51] *B. diminuta* has been isolated in patients with bacteremia,[185,620] keratitis,[819] and pleuritis.[669] *B. diminuta* has also been isolated from a sputum of a patient with CF and pneumonia.[725] An extensively drug-resistant VIM-2 MBL-producing *B. diminuta* has been isolated from a thigh biopsy specimen.[13] *B. vesicularis* can be separated from *B. diminuta* by hydrolysis of starch and esculin (both positive with *B. vesicularis*). Moss and Kaltenbach have reported that glutaric acid is produced by *B. diminuta* but not by *B. vesicularis* when the organisms are grown on trypticase soy agar.[755]

Family Xanthomonadaceae—rRNA Group V

Genus *Stenotrophomonas.* The genus *Stenotrophomonas* was created in 1993 to accommodate *Xanthomonas maltophilia* (formerly *Pseudomonas maltophilia*).[815] Several recent studies have shown that there is considerable genetic diversity within *S. maltophilia* and that this species consists of at least nine genomic groups.[223,426] In addition, 12 new *Stenotrophomonas* species have been described that have been recovered from sewage, sludge and soil. (http://www.bacterio.net/stenotrophomonas.html). *S. africana* was proposed for a single isolate recovered from CSF. Phenotypically, it was determined to be almost identical to *S. maltophilia,* except for

TABLE 7-11 Key Characteristics of *S. maltophilia* and *B. cepacia* complex[a]

Test	*S. maltophilia*	*B. cepacia* Complex
Oxidase	–	+ (93)

NO_3 to gas	–	–
Arginine	–	–
Lysine	+	V
Esculin hydrolysis	+	V (67)
ONPG	+ (93)	V (79)
DNase	+	–
Polymyxin B	S	R
Pigment	gray, slight yellow, lavender	gray, chartreuse, yellow

a Data from reference 1172.
+, 90% or more strains positive; −, 90% or more strains negative; V, 11%–89% of strains positive; A, acid reaction; Wk, weak acid; S, susceptible; R, resistant; NA, not available. Numbers in parentheses are percentage of strains giving positive reaction.

the property of being *cis*-aconitate assimilation negative.[301] However, based on extensive molecular analyses, Coenye and colleagues have determined that *S. africana* is a strain of the species *S. maltophilia;* therefore, the species name *S. africana* is disallowed.[222] Of the remaining species, only *S. maltophilia* is associated with human infection.

Stenotrophomonas maltophilia. *S. maltophilia* is a motile rod, possesses polar

multitrichous flagella, and can be easily distinguished from other pseudomonads by virtue of being lysine and DNase positive, but oxidase negative (Table 7- 11). Most strains of *S. maltophilia* are susceptible to colistin and polymyxin B. This property can be used to distinguish *S. maltophilia* from *B. cepacia,* which is also lysine positive but is resistant to colistin and polymyxin B and DNase negative. *S. maltophilia* vigorously utilizes OF maltose, but is usually negative or only weakly positive in OF glucose in 24 hours. Colonies may appear pale yellow or lavender gray on blood agar medium (Image Plate 7-3D). We have noted rare strains of *S. maltophilia* that will be slowly oxidase positive but have all the other biochemical features characteristic of *S. maltophilia.* Carmody and colleagues reported that 20% of *S. maltophilia* isolates derived primarily from cultures of respiratory specimens from persons with CF were oxidase positive.[150] Laboratorians should be aware that rare strains possessing aberrant characteristics may be recovered from clinical specimens.

S. maltophilia is ubiquitous and can be recovered from almost any clinical site. It occasionally causes opportunistic infections and is emerging as an important hospital-acquired pathogen.[559,707,760] The most common site for recovery of *S. maltophilia* is the respiratory tract, although in most patients these isolates do not appear to be clinically significant. An increasing incidence of *S. maltophilia* has been reported in some CF centers in recent years,[61,138,377,542,1094] and an association between *S. maltophilia* colonization and lung damage has been observed.[61,542] The use of selective media increases the isolation rates of *S. maltophilia* from the sputa of patients with CF.[276,551] In patients who do not have CF, *S. maltophilia* has been reported to cause a wide spectrum of disease, including pneumonia,[859] bacteremia,[34,339,578,594,732,759,859,971] endocarditis,[412] catheter-related infections,[312] cholangitis,[822] urinary tract infection,[1130] meningitis,[823,859] and serious wound infections, particularly in patients with cancer.[1131] Morrison and colleagues[750] have studied the spectrum of clinical disease in patients with hospital-acquired *S. maltophilia* infections and report both an increasing rate of nosocomial isolation and a crude mortality rate of 43% in all patients from whom the organism was cultured. Risk factors associated with death for patients with an *S. maltophilia* isolate included the following: patient in intensive care unit, age older than 40 years, and a pulmonary source for the *S. maltophilia* isolate.[750] A comprehensive review of infections associated with *S. maltophilia* has been written by Denton and Kerr.[277]

Another important feature in the rising incidence of *S. maltophilia* infections may be the unique antibiotic susceptibility profile of the organism. *S. maltophilia* is inherently resistant to most of the commonly used antipseudomonal drugs, including aminoglycosides and many β-lactam agents, including those effective against *P. aeruginosa*.[781,820,1129] Thus, colonization may be favored by the use of broad-

spectrum antipseudomonal therapy. Interestingly, *S. maltophilia* is inherently susceptible to trimethoprim-sulfamethoxazole, a drug that has no activity against *P. aeruginosa* or most other *Pseudomonas* species.[193,326] In addition to the problem of inherent resistance, there are problems related to susceptibility testing of *S. maltophilia*. Some automated methods (i.e., Vitek Legacy; bioMérieux, Hazelwood, MO) have programmed software that will prevent the reporting of susceptibility results if the test organism is known to be *S. maltophilia*. Trailing end points can be observed in agar dilution and microdilution tests, and false-susceptible readings with disk diffusion assays have occurred with aminoglycosides (i.e., these should be uniformly resistant) and ciprofloxacin.[448,820] Studies on the use of the Etest (discussed in Chapter 17) for antimicrobial susceptibility testing of *S. maltophilia* have noted the presence of tiny microcolonies or a haze of translucent growth within the area of inhibition that if missed could lead to false susceptibility results.[820,1206] To learn more, the reader is referred to the review written by Robin and Janda.[911]

Genus *Wohlfahrtiimonas.* The genus *Wohlfahrtiimonas* consists of two species *W. chitiniclastica* and *W. larvae*. Both species were first isolated from the larvae of parasitic flies. *Wohlfahrtiimonas* derives its name from the fact that the

first isolates were recovered from the 3rd stage fly larvae of the parasitic fly *Wohlfahrtia magnifica*.[1076] *W. chitiniclastica* has been reported to be the cause of fulminant sepsis in two elderly patients in France and Argentina.[18,885] Both patients were homeless, had a history of alcoholism and were in poor sanitary condition. The source of the infection in both patients was attributed to flies. One patient was described as being covered with thousands of body and hair lice, with dozens of insect larvae in her hair.[885] A third reported patient was a 64-year-old man from the Czech Republic with a 4-year history of gangrene in the distal part of the legs and amputations of the toes on both feet, which was associated with this organism.[585] *Wohlfahrtiimonas* are straight, short, gram-negative rods that are nonmotile, non–glucose-fermenting, strictly aerobic, and both catalase and oxidase positive. Complete phenotypic characteristics for *W. chitiniclastica* have been described by Toth et al.[1076] The organism is not in the databases for the commercially available phenotypic identification systems but can be identified using 16S rRNA sequencing and MALDI-TOF MS.[585] *W. chitiniclastica* was reported to be susceptible to all antibiotics tested in three separate reports.[18,585,885]

Family Acetobacteraceae

At the time of this writing the family *Acetobacteraceae* included 33 genera of Acetic Acid Bacteria (AAB) (http://www.bacterio.net/-classifgenerafamilies.html#Acetobacteraceae). A typical feature of most species of AAB is the ability to oxidize ethanol and sugars to acetic acid. AAB are found throughout the world and have been isolated from diverse vegetables, fruits, and flowers. The AAB have many industrial applications, including the production of vinegar and various drugs.[940,1203] The first report of AAB in humans was in 2004, when Snyder et al.[1010] reported a patient with peritonitis associated with *Asaia borgorensis*; the patient had a peritoneal dialysis catheter. This was followed 2 years later with a second AAB infection due to *Granulibacter bethesdensis* in two patients from separate locations with chronic granulomatous disease (CGD).[402,403] Since then, AAB have been increasingly reported as agents of disease in humans. Only those genera known to cause human infection, namely *Acetobacter, Acidomonas, Asaia, Gluconobacter, Granulibacter,* and *Roseomonas,* will be covered further in this chapter. Two genera of AAB produce pink colonies on solid agar, namely, *Asaia,* and *Roseomonas,* and are covered under the heading Pink-Pigmented Group. The remaining species associated with human disease are described below.

Genus *Acetobacter*. *Acetobacter* species are ellipsoidal to rod shaped, straight or slight curved gram-negative bacilli. Motility is variable; if motile, they are peritrichously flagellated. They are obligately aerobic and form pale colonies that are nonpigmented on solid media.[990] A minority of strains produce brown water-soluble pigments or show pink colonies because of the production of porphyrins. They are usually catalase positive and oxidase negative. Optimal growth temperature is 30°C. They are negative for gelatin hydrolysis, indole, and H_2S production.[990] They occur naturally in a variety of flowers and fruits. *Acetobacter* bacteremia has been reported in a 40-year-old HIV-positive man who for 1 year had been receiving chronic hemodialysis for end-stage renal disease. He was admitted because fever and a large inflammatory skin lesion that followed the course of an arteriovenous fistula. Two blood samples drawn through a sublavian catheter and the arteriovenous fistula both grew a very small polymorphic gram-variable rod on blood and chocolate agars that was identified by 16S rRNA sequencing as *Acetobacter cibinongensis*.[388] *A. indonesiensis* was isolated from successive sputum cultures of a 31-year-old man with CF following a lung transplant.[99]

Genus *Acidomonas*

Acidomonas methanolica. The genus *Acidomonas* is phylogenetically located within the *Acetobacteraceae* and contains a single species, *A. methanolica*, which

shares characteristics with AAB; however, methanol utilization and a unique ecologic niche are characteristics unique to this species.[1205] Cells are gram-negative, non–spore-forming, and rod-shaped, occurring singly or rarely in pairs. They are obligately aerobic and grow best at 30°C.[991] Colonies on peptone-yeast extract–malt extract (PYM) nutrient medium are shinny, smooth, entire and beige to pink after 5 days at 30°C,[1205] although other authors have described the colonies as white to yellow on PYM medium.[991] Cells are usually motile by a single polar flagellum (or occasionally polar tuft).[1205] Strains produce catalase but are negative for oxidase, nitrate reduction, and urease.[991,1205] Other phenotypic characteristics can be found in the reference by Yamashita et al.[1205] The natural habitat for *A. methanolica* is activated sludge which differs from other Acetobacteraceae that are isolated from fruits and vegetables. *A. methanolica*-associated necrotizing lymphadenitis has been reported in a 10-year-old patient with CGD.[173]

Genus *Gluconobacter*. *Gluconobacter* species are gram-negative, ellipsoidal to rod-shaped cells occurring singly and/or in pairs, rarely in chains. They may be motile or nonmotile; if motile, they produce three to eight polar flagella. They are obligately aerobic and grow optimally at 25°C to 30°C.[992] They are catalase positive, but oxidase negative. They are negative for nitrate reduction, gelatin hydrolysis, indole, and H_2S production.[992] These bacteria are found naturally occurring in sugar-rich environments such as fruits and flowers. Alauzet et al. have reported isolating *Gluconobacter* species from three patients. One was an HIV-negative man and known to be an intravenous drug abuser who was hospitalized with decreased visual acuity and suspected fungal endophthalmitis. A central venous catheter (CVC) was in place for amphotericin B administration. Fever appeared after 3 days and two peripheral blood samples yielded growth of a gram-negative rod that grew as tiny colonies after 48 hours of incubation at 37°C. The isolate was catalase positive, oxidase negative, and was identified as *Gluconobacter* species by molecular means.[10] Two other patients, a 2-year-old and a 3-year-old, with CF both had positive sputum cultures for *Gluconobacter*, which was recovered on *Burkholderia cepacia*-selective medium.[10] *Gluconobacter* was misidentified in both incidence as either *Acinetobacter* species (low discrimination) using API 20 E, or *Shigella* species (good identification) using the Vitek2 GN system.[10] A *Gluconobacter* bloodstream infection associated with endocarditis was reported in a patient with a history of

intravenous drug abuse.[74] Laboratories are advised that none of the current

commercial systems for bacterial identification are able to recognize AAB. Organisms that show unusual growth characteristics should be further evaluated using molecular testing methods.

Genus *Granulibacter*

Granulibacter bethesdensis. *G. bethesdensis* is an emerging pathogen in patients with CGD and is characterized by frequent infections that cause fever and necrotizing lymphadenitis, and can relapse after periods of clinical quiescence.[404] CGD is a rare inherited disease caused by mutations in genes encoding any of the four subunits that make up nicotinamide adenine dinucleotide phosphate oxidase (NADPH oxidase) that leads to defective production of superoxide and hydrogen peroxide.[966] Patients suffer from recurrent life-threatening infections with catalase-producing organisms and also develop tissue granulomas.[1179] A novel gram-negative rod was isolated from cervical and supraclavicular lymph nodes of a CGD patient in 2003 and from the same patient, three more times through 2005. A similar organism was isolated from two other CGD patients in 2005 and 2006. Phenotypic and geotypic analyses determined that the novel isolates represented a previous undescribed AAB, which was named *Granulibacter bethesdensis*.[402,403] Additional isoates of *G. bethesdensis* have been reported in patients with CGD from North and Central America[404] and Spain.[662] Cells are gram negative, nonmotile, and coccobacillus to rod-shaped. They produce a yellow pigment on solid media and grow optimally at 35°C to 37°C.[403] They are strictly aerobic, catalase positive, oxidase negative, and urease variable. Acid is produced from glucose but not from mannitol, sorbitol, dulcitol, lactose, sucrose, maltose, or xylose.[403] Biochemical differentiation of *G. bethesdensis* from similar nonfermenting species that appear as coccobacili and are oxidase-negative and nonmotile can be found in Table 7-18. Laboratorians are advised that isolation of *G. bethesdensis* is time-consuming, growth is consistently sparse, and definitive identification requires sequencing the 16S rRNA gene.[404] Strains of *G. bethesdensis* are reported to be multidrug resistant, and therapy requires surgery and combination antimicrobial drugs, including long-term ceftriaxone.[404] Antibiotic susceptibility data are provided in the report by Greenberg et al.[402]

Yellow-Pigmented Group

Family Pseudomonadaceae

Genus *Pseudomonas*

Pseudomonas luteola. This species has been previously known as

Chromobacterium typhiflavum, CDC group Ve-1, *Pseudomonas luteola*, *Pseudomonas polytricha,* and *Chryseomonas luteola*.[472] The taxonomic placement was resolved in 1997 when the species was placed back into the genus *Pseudomonas*.[32] *P. luteola* is motile by means of multitrichous polar flagella, is oxidase negative, and grows on both MacConkey and blood agar media, producing yellow-pigmented colonies that are often wrinkled and become adherent to the agar (Image Plate 7-3B). The biochemical features that differentiate *P. luteola* from other yellow-pigmented pseudomonads are given in Table 7-12. It is a rare clinical isolate and has been recovered from a variety of clinical specimens, including wound, cervix, urine, and throat specimens.[368] It is often isolated with other organisms and judged not to be clinically significant. In one study, only 14 strains of *P. luteola* were found among 565 clinical isolates of nonfermenters over a 2-year period.[829] Reports of serious infections caused by *P. luteola* include bacteremia,[80,89,188,238,314,337,808,809,874,878,883,1167] endocarditis,[153,799] meningitis,[188,587] leg ulceration,[1083] osteomyelitis,[874] brain abscess,[356] and peritonitis.[226,346,874,1039]

Pseudomonas oryzihabitans. This organism has been described formerly as *Chromobacterium typhiflavum*, *Pseudomonas oryzihabitans*, CDC group Ve-2 and *Flavimonas oryzihabitans*.[472] The taxonomic placement was resolved in 1997 when the species was placed back into the genus *Pseudomonas*.[32] *P. oryzihabitans* has characteristics similar to *Chryseomonas luteola* in that these organisms are also motile and oxidase negative and form yellow-pigmented colonies on blood agar medium. Like *P. luteola*, colonies of *P. oryzihabitans* form rough or wrinkled colonies. This organism can be differentiated from *P. luteola* by negative reactions for esculin hydrolysis and orthonitrophenyl-β-D-galactopyranoside (ONPG) and the feature of having a single polar flagellum. Additional differential characteristics are given in Table 7-12. *P. oryzihabitans* has been recovered from a variety of clinical sites, including wounds, sputum, ear, eye, urine, peritoneal fluid, inhalation-therapy equipment, and blood.[95,337,370,572,624,641,642,855,874,1082] More recently, infections with this organism have been related to the presence of an intravascular catheter in immunocompromised patients.[671, 698,918,1133] In our clinical laboratory, this organism has been recovered from sputum, urine, prostatic secretion, skin, and blood. *P. oryzihabitans* also appears to be an emerging pathogen in peritonitis related to continuous ambulatory peritoneal dialysis, with several cases now reported in the literature.[24,87,318,319,633,824,994] Other predisposing factors for *P. oryzihabitans* infections include indwelling intravascular catheters, artificial grafts, intravenous drug abuse, severe head trauma requiring surgery, and bone marrow transplantation.[174]

Family Sphingomonadaceae[586]

Genus *Sphingomonas*. The genus *Sphingomonas* was described by Yabuuchi et al. in 1990[1200] and was emended by Takeuchi et al. in 1993.[1053] Organisms in this genus are gram-negative, non–spore-forming rods that have a single polar flagellum when they are motile. They are yellow, obligately aerobic, and produce catalase. Bacteria belonging to the genus *Sphingomonas* are ubiquitous in soil, water, and sediments, and strains isolated from these environments are known to be decomposers of aromatic compounds and, therefore, are expected to be used for bioremediation of the environment.[60] It is now known that members of the genus *Sphingomonas* can be divided into four phylogenetic groups, each representing a different genus. Consequently, three new genera, *Sphingobium*, *Novosphingobium,* and *Sphingopyxis*, in addition to the genus *Sphingomonas* have been created to accommodate the four phylogenetic

362

groups.[1052] The emended genus *Sphingomonas* contains at least 90 species, of which

only *S. paucimobilis*, designated the type species, and *S. parapaucimobilis* are thought to be important clinically.

Sphingomonas paucimobilis. This organism, formerly known as *Pseudomonas paucimobilis* and as CDC group IIk-1, is the most common species found in human clinical specimens. It is a gram-negative, motile rod with a polar flagellum. However, few cells are actively motile in broth culture, thus making motility a difficult characteristic to demonstrate. Motility occurs at 18°C to 22°C, but not at 37°C.[814] The oxidase reaction is weak positive or negative. Colonies grown on blood agar medium are yellow-pigmented; however, this species is slow-growing, and only small colonies may be observed after 24 hours of incubation. Growth occurs at 37°C, but not at 42°C, with optimal growth occurring at 30°C.[814] Isolates are strongly esculin hydrolysis positive and produce a zone of inhibited growth around a vancomycin disk (30 mg) placed on BAP (Schreckenberger P, personal observation). Additional biochemical features are given in Table 7-12. *S. paucimobilis* has been isolated from a variety of clinical specimens, including blood, CSF, urine, wounds, vagina, and cervix and from the hospital environment.[460,890,1051] Community-acquired bacteremia and peritonitis have also been reported in patients receiving long-term ambulatory peritoneal dialysis.[751]There have been a few reports of nosocomially acquired *S. paucimobilis* infections from contamination of hemodialysis fluids,[144] contamination of a hospital water system,[840] contamination during *in vitro* processing of bone marrow for transplantation[614]and catheter-related sepsis.[266,489,946,947] There has also been a report of *S. paucimobilis* bacteremia that was accompanied by septic shock in a burn patient.[152] Toh and colleagues reviewed the risk factors associated with *S. paucimobilis* infection and found that community-acquired infections, diabetes mellitus and alcoholism were significant risk factors for primary bacteremia.[1074] Bayram et al.[81] reviewed the clinical features of *S. paucimobilis* infections in children. Most strains are susceptible to tetracycline, chloramphenicol, trimethoprim–sulfamethoxazole, and aminoglycosides; their susceptibility to other antimicrobial agents, including fluoroquinolones, varies.[324,489,890]

The cellular and colonial characteristics of *S. parapaucimobilis* are similar to those of *S. paucimobilis*. It is differentiated from *S. paucimobilis* by blackening of lead acetate paper suspended over KIA, ability to grow and alkalinize Simmons' citrate medium and a negative extracellular deoxyribonuclease reaction.[1200] Clinical isolates have been obtained from the sputum, urine, and vaginal specimens.[1200]

Family Oceanospirillaceae

Genus *Balneatrix*

Balneatrix alpaca. *Balneatrix* is a new genus consisting of a single species, *B.*

alpica.[255] This bacterium was first isolated in 1987 during an outbreak of pneumonia and meningitis among persons who attended a hot (37°C) spring spa in Southern France.[154,255,492] Thirty-five patients with pneumonia and two with meningitis occurred. Isolates from eight patients were recovered from blood, CSF, and sputum; one was also recovered from water. The bacterium is described as gram-negative, straight or curved rods, motile by a single polar flagellum, strictly aerobic, and growing at a wide range of temperatures (20°C to 46°C). Colonies are 2 to 3 mm in diameter, convex, and smooth. The center of the colonies is pale yellow after 2 to 3 days and pale brown after 4 days. The organism grows on chocolate and tryptic soy agars, but not on MacConkey agar. It is oxidase positive and nonfermentative but oxidatively utilizes glucose, mannose, fructose, maltose, sorbitol, mannitol, glycerol, and inositol. Indole is produced, and nitrate is reduced to nitrite. Gelatin is weakly hydrolyzed, and lecithinase is positive. The following substrates are not utilized: arginine, lysine, ornithine, urease, esculin, acetamide, starch, and ONPG (Table 7-12).[154,255] *B. alpica* is reported to be susceptible to penicillin G and to all other β-lactam antibiotics and to all aminoglycosides, chloramphenicol, tetracycline, erythromycin, sulfonamides, trimethoprim, ofloxacin, and nalidixic acid. It is resistant to clindamycin and vancomycin.[154]

Family Oxalobacteraceae

Genus *Massilia*. The genus *Massilia* consists of 25 species isolated mainly from sewage, sludge and soil. The species of the genera *Massilia* and *Naxibacter* are often grouped together on the basis of 16S rRNA gene sequence comparisons. For this reason Kampfer and colleagues proposed the transfer of all species of the genus *Naxibacter* to the genus *Massilia*.[534]

Massilia timonae. *M. timonae* is the most frequently reported species to cause human infection. *M. timonae* is an actively motile (with lateral as well as a single polar flagellum), strictly aerobic gram-negative rod. The original description by La Scola and colleagues[608] described the type strain as being oxidase negative and arginine dihydrolase positive; however, Lindquist et al.[645] reported that the type strain as well as four additional human isolates tested oxidase positive and arginine negative. Colonies appear pale yellow and are distinctly tenacious on agar media and have a tendency to form pellicles on the surface of liquid medium.[608] Acid is produced oxidatively from some carbohydrates. Lindquist and colleagues reported that when grown in OF medium without added carbohydrate, the strains produced a distinctly alkaline reaction. Consequently, a neutral reaction in a tube with carbohydrate was interpreted as weakly positive for acid production.[645] Additional biochemical reactions are given in Table 7-12. Isolates have been recovered from a surgical wound, CSF, the

femur of a 29-year-old with osteomyelitis, biopsy of a cervical lymph node in a patient with lymphadenopathy, and from the blood of three other patients.[608,645,1000,1097] *M. timonae* is susceptible to most antibiotics, with resistance reported to ampicillin, amoxicillin-clavulanate, cefuroxime, cephalothin, and aztreonam.[608,1000,1097]

Massilia oculi. This organism was described in 2012 as a novel species isolated from the eye of a patient with endophthalmitis.[535] The organism was described as producing colonies that are beige, translucent, and shiny with entire edges within 24 hours on blood agar and nutrient agar. They have an oxidative metabolism and are positive for esculin hydrolysis, but negative for nitrate reduction, urease, and oxidase.[535]

Massilia haematophilus. *M. haematophilus* (formerly *Naxibacter haematophilus*) is described as nonmotile, oxidase-positive, gram-negative rods with an oxidative metabolism. Colonies are beige, translucent, and shiny with entire

363

edges and are negative for esculin and ONPG.[533] The type strain was isolated from human blood of a 23-year-old Swedish man with multiple health problems. *M. haematophilus* has also been isolated from a neck vertebrae bone of an Israeli patient who had vertebral osteomyelitis. Identification was confirmed with 16S rRNA sequencing (Orna Schwartz, personal communication).

Unnamed Species

CDC Groups O-1, O-2. CDC groups O-1 and O-2 are phenotypically similar, motile, and usually oxidase-positive, gram-negative rods. Both groups are yellow-pigmented and most closely resemble *Agrobacterium* yellow group and *Sphingomonas* species (Table 7-12). These organisms grow poorly or not at all on MacConkey agar, usually hydrolyze esculin, but are otherwise inactive. They are motile, although motility may be difficult to demonstrate. On Gram's stain, O-1 appears as uniformly short gram-negative rods, and O-2 appears as slightly pleomorphic rods, with some cells appearing thin in the central portion with thickened ends. Isolates have been from a variety of clinical sources. One patient with group O-1-associated pneumonia complicated by bronchopulmonary fistula and bacteremia has been reported.[872]

***Agrobacterium* Yellow Group.** Organisms in this group are represented by slender, medium-to-long gram-negative rods that produce a yellow insoluble growth pigment and most closely resemble *Sphingomonas paucimobilis* and CDC group O-1 and O-2 organisms. Growth on MacConkey agar is variable, motility occurs via a single polar flagellum, and oxidase and catalase are positive; glucose, xylose, lactose, sucrose, and maltose are oxidized, but not mannitol. Carbohydrate reactions may be weak or late.[1172] A positive 3-ketolactonate reaction and negative lipase and DNase reactions differentiate this organism from *S. paucimobilis* (Table 7-12). Isolates have been from blood and peritoneal fluid.[166,1047,1172]

Curved Rod Group

Family Caulobacteraceae

Genus *Caulobacter*. The genus *Caulobacter* is composed of dimorphic, prosthecate bacteria that at the time of this writing includes16 species. Reproduction in *Caulobacter* results in the separation of two cells that are morphologically different from each other. One cell is nonmotile, sessile by virtue of adhesive material and prosthecate, possessing at least one elongated cylindrical appendage (called a prostheca). The other cell is flagellated, bearing one polar flagellum, by which it is motile.[4] *Caulobacter* species stain gram negative and appear distinctly curved, but may be straight in some isolates and have a fusiform shape. The cells are arranged frequently in typical rosettes in which the stalks originate from a common point or region and the cells become arranged symmetrically around this point. The rosettes are especially numerous and large in preparations from agar colonies.[124] In the laboratory,

rosette formation is often observed in wet mounts.[529] A picture of rosette formation from a wet mount of *Caulobacter* can be seen in a photo appearing in the publication by Justesen et al.[529] The organism grows well on most common culture media at temperatures between 15°C to 35°C with optimal temperature of 20°C to 25°C for most isolates.[4] Colonies are circular, convex and glistening. and may be colorless or yellow upon aging.[355] The organism is reported to be oxidase positive and catalase negative.[529] Phenotypic identification is usually carried out using carbon source utilization studies.[355] In one report, biochemical identification with API ID 32 GN and Vitek 2 GN systems (bioMèrieux, Marcy l'Etoile, France) resulted in incorrect identifications as *Brevundimonas vesicularis* (probability, 90.6%) and *Sphingomonas paucimobilis* (probability, 97.24%), respectively.[529] *Caulobacter* are ubiquitous in water and have been isolated from distilled, tap, and commercially bottles drinking water; river, canal, and pond water and sewage (activated slidge during secondary treatment).[4,124,676] There have been three reports of of *Caulobacter* causing human infection. Bridger et al.[129] reported a pediatric patient with *Caulobacter* meningitis following neurosurgery. Justesen et al.[529] described a 64-year-old man who developed peritonitis because of *Caulobacter* while undergoing intermittent peritoneal dialysis for chronic renal insufficiency. Drancourt et al.[300] conducted 16S rRNA sequencing on clinical isolates that could not be identified by conventional phenotypic methods and found one isolate of *Caulobacter intermedius,* although no details were provided about the clinical significance of the isolate. Laboratorians are advised to suspect *Caulobacter* species when cresent shaped bacteria with rosette formation are observed in microscopic examination. Final identification would be confirmed by 16S rRNA sequencing.

Family Oxalobacteraceae

Genus *Herbaspirillum*. This genus consists of small spiral-shaped bacteria from herbaceous seed-bearing plants. *Herbaspirillum* species are gram negative, generally curved and sometimes helical bacilli. Individual cells are 0.6 to 0.7 mm wide and 1.5 to 5.0 mm in length and have one to three or more flagella on one or both poles.[59] A group of clinical isolates previously described as EF-1, has been shown by molecular hybridization to belong to the genus *Herbaspirillum* and is designated as a new unnamed species, *Herbaspirillum* species 3.[59] The organism is oxidase and urease positive; catalase is weak or variable. Other reactions are given in Table 7-13. Isolates in the original description were recovered from the respiratory tract, feces, urine, ear, eye, and wound sites, but clinical significance was not reported.[59] Subsequently, clinical isolates have been recovered from sputum of patients with CF.[212,1021] It has

also been recovered from the blood of one patient with CF who had a chronic (3-year) respiratory tract infection,[1021] two patients with leukemia,[177,1218] and one patient with cellulitis and bacteremia who had jumped into a freshwater canal in central Florida.[1056] *Herbaspirillum* species has also been found in the arterial walls of aortic aneurysms.[704] Antibiotic susceptibility data are not available.

Family Neisseriaceae

Genus *Laribacter*

Laribacter hongkongensis. Based on phylogenetic affiliation, this bacterium belongs to the *Neisseriaceae* family and

is a facultatively anaerobic, nonsporulating, nonfermentative bacillus. On Gram's stain, the organisms appear as gram-negative, seagull-shaped or spiral rods (Image Plate 7-5D). Good growth occurs on sheep blood agar as nonhemolytic, gray colonies 1 mm in diameter after 24 hours of incubation at 37°C in ambient air. On MacConkey agar,

colonies are small and lactose negative, but take on a cornflower-blue appearance similar to colonies of *Acinetobacter* (Schreckenberger, personal observation; Image Plate 7-5E). Most strains are motile with bipolar flagella. All strains are oxidase, catalase, urease and arginine dihydrolase positive; these organisms reduce nitrate, but do not ferment, oxidize, or assimilate any carbohydrates (Table 7-13).[1185,1212] *L. hongkongensis* was first discovered in Hong Kong from the blood and empyema fluid of a 54-year-old patient with cirrhosis[1212] and from the stools of patients with community-acquired diarrhea.[611,1185,1186] Two additional patients with *L. hongkongensis* bacteremia including one fatal case have been reported from Korea[564] and Hong Kong.[1084] *L. hongkongensis* has been found in drinking water reservoirs in Hong Kong[610] and in up to 60% of intestines from commonly consumed freshwater fish of the carp family.[1063,1186] Woo and colleagues reported an association between *L. hongkongensis* and community-acquired diarrhea, eating fish, and travel[1186]; however, a causative role was not shown.[322] Isolation of *L. hongkongensis* from stool was subsequently reported from countries in Asia (China and Japan), Europe (Switzerland), Africa (Tunisia), and Central America (Cuba), suggesting that the bacterium is found worldwide.[783,1186] Beilfuss and colleagues recently reported the first isolation of *L. hongkongensis* from the stool of a patient with no travel outside of the United States.[83] A review of the microbiologic characteristics and pathogenicity of *L. hongkongensis* has been published by Raja and Ghosh.[875]

Isolation of *Laribacter* from stool specimens requires the use of selective media. *L. hongkongensis* grows poorly or not at all on *Campylobacter* BAP (CAMPY BAP) and Hektoen agars (Schreckenberger, personal observation). Others have reported isolation of *L. hongkongensis* from stools using Charcoal Cefoperazone Deoxycholate Agar (CCDA) under microaerophilic conditions[611,1185] or Cefoperazone MacConkey agar in ambient air.[327,611] Growth also occurs on MacConkey agar in a microaerophilic or anaerobic environment, and at 25°C and 42°C, but not a 4°C, 44°C, or 50°C. No enhancement of growth is observed with 5% CO_2.[1212] The failure to recognize *L. hongkongensis* from human stools is likely due to a combination of the organisms not being sought, or misidentification by phenotypic methods. Commercial identification kits do not include *L. hongkongensis* in their databases, and isolates set up on these systems are either given a low probability ID or are misidentified as *Acinetobacter lwoffii*.[83,564] *L. hongkongensis* can be identified correctly by MALDI-TOF MS using the Bruker Biotyper 3.1 and reference library v3.1.2.0 software (Bruker Daltonik, Billerica, MA).[83,1057,1084]

L. hongkongensis is generally resistant to β-lactam antibiotics, including broad-spectrum penicillins and cephalosporins, but is susceptible to carbapenems,

amoxicillin-clavulanate, quinolones, and aminoglycosides.[609, 611,1185,1186,1212] Lau and colleagues have demonstrated that all isolates of *L. hongkongensis* possess a chromosomally encoded AmpC β-lactamase which they have named LHK-5 (gene, *bla* LHK-5),[609] Antibiotic treatment is usually not necessary in patients with *Laribacter* gastroenteritis; however, for serious infections, susceptibility testing of individual isolates is recommended.

CDC Group O-3

CDC group O-3 cells are motile, oxidase positive, gram-negative rods. They grow poorly or not at all on MacConkey agar, usually hydrolyze esculin, oxidize OF glucose and OF xylose, but are otherwise inactive (Table 7-13). Unlike Groups O-1 and O-2, they do not produce a yellow pigment. On Gram's stain, O-3 cells appear as thin, medium to slightly long curved rods with tapered ends (sickle-like) that sometimes form rosettes.[248,1172] Most isolates of O-3 grow well on CAMPY CVA (*Campylobacter* agar with cefoperazone, vancomycin, and amphotericin B) plates under microaerophilic conditions, thus creating the potential for misidentification of O-3 organisms as *Campylobacter*.[248] Isolates have been recovered from a variety of clinical sources. Group O-3 isolates have been reported to be susceptible to the aminoglycosides, trimethoprim–sulfamethoxazole, and imipenem. Resistance was noted to most β-lactams, and variable susceptibility was noted for chloramphenicol, tetracycline, ciprofloxacin, and amoxicillin-clavulanate.[248]

Halophilic and/or Hydrogen Sulfide-Positive Pseudomonads

Family Shewanellaceae

Genus *Shewanella*. In 1985, MacDonell and Colwell proposed the new genus *Shewanella,* composed of three species: *S. putrefaciens* (formerly *Pseudomonas putrefaciens*, *Alteromonas putrefaciens,* and CDC group Ib), *S. hanedai,* and *S. benthica*.[673] Currently, there are at least 62 species included in the genus *Shewanella* most of which are associated with aquatic and marine habitats; however, the type species, *S. putrefaciens*, has been recovered from human clinical specimens. The CDC recognizes two biotypes of *S. putrefaciens* based on the requirement of NaCl for growth, oxidation of sucrose and maltose, and the ability to grow on *Salmonella*–

Shigella (SS) agar.[1172] Owen et al.[810] have shown that organisms identified as *S. putrefaciens* comprise at least four clearly separated genomic groups (I–IV). Based on the taxonomic proposals of Nozue and colleagues[790] and Simidu et al.,[995] strains belonging to Owen's genomic group IV (synonymous with CDC biotype 2) should be identified as *S. alga* (corrected to *S. algae*).[1081] Khashe and Janda[560] have reported that *S. algae* is the predominant human clinical isolate (77%), while *S. putrefaciens* (CDC biotype 1) represents the majority of nonhuman isolates (89%). *S. algae* requires NaCl for growth, while *S. putrefaciens* does not (Table 7-14). Strains of *S. putrefaciens* and *S. algae* are oxidase positive and motile by means of polar flagella. They are easily distinguished because they are the only nonfermenters that produce hydrogen sulfide in KIA and TSI media. All strains are positive for ornithine decarboxylase, nitrate reductase, and DNase. Colonies produce an orange-tan pigment on blood agar medium. Although they are infrequent clinical isolates, *S. putrefaciens* and *S. algae* have been associated with skin ulcers,[35,182,264,271,292,812,1208] ear infections,[366, 474,1150] eye infections,[140] arthritis and osteomyelitis,[634,864] bacteremia,[130,292,500,565,702,812,955,1113] infective endocarditis,[283] and peritonitis in patients undergoing continuous ambulatory peritoneal dialysis.[241] Many of the infections reported to be caused by *S. putrefaciens* were probably caused by *S. algae*.[292,1143] A review of human infection with *S. putrefaciens* and *S. algae* has been provided by Vignier et al.[1136] Shewanellae are generally susceptible to most antimicrobial agents effective against gram-negative rods, except penicillin and cephalothin.[324,1146] Recent investigations have noted that the mean MICs of *S. algae* to penicillin, ampicillin and tetracycline were higher than the corresponding MICs of *S. putrefaciens*.[560,1143] For a review of the epidemiology, disease spectrum, and identification of *Shewanella* species, see the review by Janda and Abbott.[504]

Family Alteromonadaceae—Halophilic Group

Genus *Alishewanella*

Alishewanella fetalis. *A. fetalis* is a halophilic gram-negative rod that grows at temperatures between 25°C and 42°C, with optimal growth at 37°C. NaCl is required for growth. It can withstand NaCl concentrations up to 8%, but it does not grow at 10% NaCl, which helps differentiate this species from *S. algae,* which can grow in 10% NaCl.[1144] Also, unlike *S. algae,* it is esculin hydrolysis positive. It is oxidase and catalase positive and asaccharolytic. It does not produce H_2S in the butt of TSI and KIA. Other reactions are given in Table 7-14. It has been isolated from a human fetus at autopsy; however, its association with clinical infection is unknown.[1144]

Family Halomonadaceae

Genus *Halomonas.* *Halomonas* species are halophilic and alkaliphilic microbes belonging to the family *Halomonadaceae*, that are typically isolated from high-salt environments. *Halomonas venusta* was originally described as *Alcaligenes venustus*,[77] but later transferred to the new genus *Deleya*, as *Deleya venusta*, by Baumann and colleagues.[78] In 1996 Dobson and Franzmann proposed combining the genus *Deleya* into a more broadly defined genus, *Halomonas*.[287] von Graevenitz and colleagues were the first to report a human infection caused by *H. venusta* in a wound that originated from a fish bite.[1147] They reported that the organism grew on BAP and MacConkey agars and appeared as mucoid, colorless colonies. Positive reactions occurred with nitrate, urea, and esculin. Additional biochemical reactions are given in Table 7-14. *H. venusta* are reported to be susceptible to most antibiotics.[1147]

CDC Halophilic Nonfermenter Group 1 consists of six phenotypically similar isolates received by the CDC between 1971 and 1998 that were similar to *H. venusta,* except for

366

esculin hydrolysis and cellular fatty acid composition. Five of these were from human blood cultures, the sixth was from a hip wound culture (CDC, unpublished data). Three novel species of *Halomonas* were reported by Stevens and colleagues to cause bacteremia in two patients undergoing renal dialysis at a renal care center. A subsequent investigation of the renal dialysis equipment resulted in the isolation of three novel species of *Halomonas* traced to contaminated bicarbonate used to prepare dialysis fluid.[1030]

Pink-Pigmented Group

The pink-pigmented, nonfermentive, gram-negative bacilli associated with human infection include *Methylobacterium* species, *Rosemonas* species, *Azospirillum brasilense,* and *Asaia bogorensis*. These bacteria are slow-growing and present multiple diagnostic challenges to the microbiology laboratory, including culture, isolation, and identification to the species level. A review of the disease spectrum,

taxonomy, and laboratory identification of the pink-pigmented group of NFBs has been published by Hogue and colleagues.[447]

Family Methylobacteriaceae

Genus *Methylobacterium*. *Methylobacterium* species are gram-negative, pink-pigmented bacteria that have the ability to facultatively utilize methane.[399] Fifty-one species of *Methylobacterium* are currently recognized and additional unassigned biovars are recognized on the basis of carbon assimilation type, electrophoretic type, and DNA–DNA homology grouping.[354,399,400,1090] *M. mesophilicum*, formerly classified as *Pseudomonas mesophilica* and *Vibrio extorquens*, is the species most often isolated from human clinical specimens. Isolates are reported to be oxidase positive and motile; however, the oxidase reaction may be weak, and motility may be difficult to demonstrate. In our experience, all isolates seen have appeared nonmotile. Other key reactions include positive tests for catalase, urease, and amylase (Table 7-15). Additional differentiating characteristics can be found in the report by Urakami and colleagues.[1090]Isolates are slow-growing on ordinary media, with the best growth occurring on Sabouraud's agar, buffered charcoal–yeast extract agar, or Middlebrook 7H11 agar.[368] Optimal growth occurs from 25°C to 30°C. Colonies are dry and appear pink or coral in incandescent light (Image Plate 7-3E). Under UV

light, colonies appear dark, owing to the absorption of UV light. Although classified as a gram-negative rod, this species often does not stain well, or it may show variable results on Gram's staining. Individual cells contain large, nonstaining vacuoles that give this organism a unique microscopic appearance[1009] (Image Plate 7-3F). *M. mesophilicum* has been reported to cause chronic skin ulcers,[603] central catheter infection,[949] bacteremia in immunocompromised patients,[134,369,372,547,1009] synovitis[654] and peritonitis in a patient undergoing continuous ambulatory peritoneal dialysis.[934] Isolates have also been reported from bronchial washings[331] and from the cornea of a patient receiving corticosteroids.[310] One patient with meningitis caused by *M. mesophilicum* has been reported.[1219] Bloodstream infections caused by *M. radiotolerans, M. thiocyanatum, M. aminovorans, M. lusitanum,* and *M. zatmanii* have also been reported.[479,599] Tap water has been implicated as a possible mode of transmission for methylobacteria in the hospital environment because they have been reported to exhibit resistance to chlorination.[442,902] To learn more, see the review by Kaye,[547] Sanders,[949] Truant,[1080] and Kovaleva.[588]

Family Acetobacteraceae

Genus *Roseomonas* and Genus *Azospirillum*. *Roseomonas* are pink-pigmented bacteria that phenotypically and genotypically resemble *Methylobacterium* species but are separable from the latter by their inability to oxidize methanol, to assimilate acetamide and by lack of absorption of long-wave UV light.[906] Members of the genus are nonfermentative, weakly staining, gram-negative, plump coccoid rods, appearing in pairs or short chains, to mainly cocci with only an occasional rod (Image Plate 7-3G). They grow on 5% sheep blood agar, chocolate agar, buffered charcoal yeast extract (BCYE) agar, Sabouraud's agar, and almost always (91%) on MacConkey agar. Growth occurs at 25°C, 35°C and usually 42°C. Growth appears as pinpoint, pale-pink, shiny, raised, entire and often mucoid colonies after 2 to 3 days of incubation at 35°C (Image Plate 7-3H). We have noted that the *Roseomonas* grow very well on Sabouraud's agar, producing light pink mucoid (sometimes runny) colonies. The organisms do not appear black when viewed under UV light which helps to differentiate *Roseomonas* from *Methylobacterium* which do appear black under UV light.[906]

All strains are weakly oxidase positive (often after 30 seconds) or oxidase negative, catalase positive, and urease positive (Table 7-15).

The genus *Roseomonas* was first described in 1993 to include three named species, *R. gilardii* (genomospecies 1), *R. cervicalis* (genomospecies 2), and *R. fauriae* (genomospecies 3), and three unnamed genomospecies (genomospecies

4, 5, and 6).[906] Han et al.[420] sequenced the 16S rRNA of all 6 *Roseomonas* genomospecies and reported that *Roseomonas* genomospecies 1, 2, 4, and 5 were valid taxa, but that genomospecies 3 and 6 are not and indicated that the invalid *Roseomonas* species belong to the genus *Azospirillum*. Han and colleagues also proposed a new species, *Roseomonas mucosa*, and a new subspecies, *R. gilardii* subspecies *rosea* (in differentiation from *R. gilardii* subspecies *gilardii*).[420] *Roseomonas* genomospecies 3 (named *R. fauriae*) was then found to be a later synonym of *Azospirillum brasilense* and so the earlier name for this species has taxonomic preference.[433,1060] As of this writing, there are 21 named species in the genus *Roseomonas* and 17 named species in the genus *Azospirillum.*

Roseomonas species have been reported in several single-case reports from blood or catheter-related infections,[11,64,260,699,731,903,985,1040] vertebral osteomyelitis,[768] postoperative endophthalmitis,[178] and spinal epidural abscess.[694] Peritonitis, caused by *R. gilardii,*[950] *R. fauriae* (now *A. brasilense*),[96] and *R. mucosa*[127] in patients undergoing continuous ambulatory peritoneal dialysis have also been reported. In

multiple-case reports, about 60% of the isolates recovered have been from blood, with about 20% from wounds, exudates, and abscesses, and about 10% from genitourinary sites.[260,636,1037] The clinical characteristics of infections caused by *Roseomonas* species and antimicrobial susceptibilities of the isolates have been reviewed by Wang and colleagues.[1156]

Genus *Asaia*. *Asaia* are gram-negative obligately aerobic environmental bacteria belonging to the AAB and are assigned to the family *Acetobacteraceae*. The genus currently contains eight species. The natural habitats of *Asaia* spp. are reported to be in the flowers of the orchid tree, plumbago and fermented glutinous rice, all originating in hot tropical climates, particularly in Indonesia and Thailand.[1202] *Asaia bogorensis* has been reported as a cause of peritonitis in a patient on automated peritoneal dialysis.[1010] Daneshvar and colleagues identified 14 isolates of a novel *Asaia* species, of which 3 were from a dialysis-associated outbreak.[252] An *Asaia* species was isolated from the sputum of a 2-year-old boy with CF using *Burkholderia cepacia*-selective medium in a French hospital.[10] *A. bogorensis* has been recovered from the blood of two unrelated episodes of bacteremia in patients with a history of intravenous drug abuse.[1087,1088] Another species, *A. lannensis,* has been reported to cause bacteremia in two children with idiopathic dilated cardiomyopathy awaiting cardiac transplantation[527] and in a child with cancer and bone marrow transplantation.[2] *Asaia* species have also been isolated in two separate incidences from fruit-flavored bottled water that had spoiled as a result of bacterial overgrowth.[590,745] Isolates characterized at CDC are pink-pigmented, oxidase-negative, motile rods that are oxidative in OF glucose, xylose, and mannitol (Daneshvar MI, personal communication). Additional characteristics are given in Table 7-15. Moore reported that *Asaia* spp. were resistant to ceftazidime, meropenem, imipenem, trimethoprim, amikacin, vancomycin, aztreonam, penicillin, and ampicillin by disk diffusion.[745] The *A. bogorensis* strain reported by Snyder et al.[1010] was susceptible to aminoglycosides (amikacin, tobramycin, gentamicin) and resistant to ceftazidime and meropenem by disk diffusion.

Unnamed Species

Some organisms possessing characteristics of the Pseudomonads have not been officially named. These are included below.

***Pseudomonas*-Like Group 2.** This is an unclassified group of *Pseudomonas*-like organisms that previously had been included in CDC group IVd. Strains are oxidase positive and motile. Colonies on blood agar are reported to have a sticky consistency

and are difficult to remove.[368] Other identifying characteristics include growth on MacConkey agar; oxidation of glucose, xylose, mannitol, and lactose; hydrolysis of urea; and negative reactions for indole, nitrate, esculin hydrolysis, and oxidation of sucrose and maltose.[268] Isolates are similar to *B. gladioli* but do not oxidize dulcitol or inositol.[1172] The majority of strains (66%) are colistin resistant.[367] Human clinical isolates have been recovered from the respiratory tract, blood, spinal fluid, feces, urine, and dialysate.[368,391,567,579]

CDC Group 1c. CDC group 1c is a *Pseudomonas*-like organism that on Gram's stain appears as a gram-negative slender rod of variable length. It is motile with one or two polar flagella, grows on MacConkey agar, and oxidizes glucose and maltose, but not xylose, mannitol, lactose, or sucrose. It reduces nitrate to nitrite without gas formation, is arginine dihydolase positive, but negative for lysine and ornithine decarboxylase, esculin hydrolysis, and gelatin hydrolysis. Urease and citrate are variable. The organism grows well at 25°C, 35°C, and usually 42°C.[1172] Additional reactions are given in Table 7-3. Most isolates have come from human sources, including urine, sputum, blood, bronchial wash, wound, bile, and other sites.[1172] Their ability to cause human infection is not reported and antibiotic susceptibility data are not available.

CDC Group WO-1. This is the designation given to a group of weakly oxidative (WO) gram-negative rods isolated primarily from clinical specimens. They oxidize mannitol and glucose, often weakly and sometimes delayed (3 to 7 days), and reduce nitrate. Most strains are motile, with one or two polar flagella; however, motility is usually delayed in motility medium or is detected only by wet preparation. Strains are usually oxidase and catalase positive. Some strains produce soluble pigment (yellow, tan, amber, olive green, or brown). Other differentiating characteristics can be found in the article by Hollis and colleagues.[452] CDC WO-1 strains that oxidize xylose and are citrate positive are probably *Acidovorax delafieldii*, whereas strains WO-1 that are xylose negative and citrate negative are probably *Acidovorax temperans*.[1172] Isolates characterized at the CDC have been from blood (33%), CSF (10%), urine, lung, wound, and some environmental sources.[452]

OFBA-1. OFBA-1 is an unclassified medium-to-long gram-negative, motile rod with one or two polar flagella that has the unusual property of producing acid in OF base medium without carbohydrate; thus the acronym "OFBA," meaning "OF Base Acid." The organism most closely resembles *P. aeruginosa* biochemically because of β-hemolysis, growth at 42°C, presence of arginine dihydrolase, nitrate reduction

to gas, and utilization of most carbohydrates.[1149,1172] Unlike *P. aeruginosa,* it is negative for pyocyanin and pyoverdin production and acetamide hydrolysis. Isolates have been recovered from blood, leg ulcer, abdominal wound, bronchial wash, and a catheter tunnel infection in a patient on continuous ambulatory peritoneal dialysis.[1149,1172]

Organisms That Are Motile With Peritrichous Flagella

Family Alcaligenaceae

This family includes the clinically relevant genera *Achromobacter*, *Advenella, Alcaligenes*, *Bordetella*, *Kerstersia,* and *Oligella*.[273,354] Members of the family *Alcaligenaceae* are gram-negative rods that are usually oxidase positive, grow on MacConkey agar, and are motile by means of peritrichous flagella. The biochemical features that differentiate the members of this family, as well as certain other nonfermenters with similar biochemical characteristics, are given in Tables 7-16 and 7-17.

Genus *Alcaligenes*. The taxonomy of the genus *Alcaligenes* is closely intertwined with the taxonomy of the genus *Achromobacter*, and several *Alcaligenes* species have now been reclassified as *Achromobacter* species.[1196]

Alcaligenes faecalis. *A. faecalis* is the most frequently isolated member of the *Alcaligenaceae* in the clinical laboratory. Members of this species produce strong alkaline reactions in all carbohydrate media. Most strains form characteristic colonies with a thin, spreading irregular edge (Image Plate 7-4A). Some strains (previously named "*A. odorans*") produce a characteristic fruity odor (sometimes described as the odor of green apples) and cause a greenish discoloration of blood agar medium. A key biochemical feature of this species is its ability to reduce nitrite but not nitrate. *A. faecalis* exists in the soil and water and has been isolated from many types of clinical specimens. It is a rare cause of acute otitis, urinary tract infection and bacteremia.[8,102] Most infections are opportunistic and are acquired from moist items, such as nebulizers, respirators, and lavage fluids. It is often found in mixed cultures, particularly in samples of diabetic ulcers of the feet and lower extremities, and its clinical significance is difficult to determine.

Genus *Achromobacter*. The genus *Achromobacter* was described in 1981 by Yabuuchi and Yano[1199] and originally contained a single species, *Achromobacter*

xylosoxidans. Based on taxonomic studies, Yabuuchi et al.[1196] transferred the species *Alcaligenes ruhlandii* and *Alcaligenes piechaudii* to the genus *Achromobacter* and proposed the transfer of *Alcaligenes denitrificans* to the genus *Achromobacter* as *Achromobacter xylosoxidans* subsp. *denitrificans*, thus automatically creating a second subspecies, *Achromobacter xylosoxidans* subsp. *xylosoxidans*. However, the reclassification of *Alcaligenes denitrificans* as a subspecies of *Achromobacter xylosoxidans* contradicted previous work that showed that the two taxa are distinct species.[1105] Accordingly, Coenye and colleagues have proposed that *Alcaligenes denitrificans* be reclassified as *Achromobacter denitrificans*.[217] In this textbook, we treat these organisms as separate species, referring to them as *Achromobacter xylosoxidans* and *Achromobacter denitrificans*, respectively. For identification purposes, the *Achromobacter* species can be divided into the asaccharolytic and saccharolytic species based on their ability to oxidize OF glucose (Tables 7-16 and 7-17). The in vitro susceptibility of *Achromobacter* spp. and a comparison of disk diffusion, Etest, and agar dilution methods have been provided by Almuzara and colleagues.[17]

Asaccharolytic *Achromobacter* Species. *A. piechaudii* was first described in 1986.[571] It can be distinguished from *Alcaligenes* and other asaccharolytic *Achromobacter* species by its ability to reduce nitrate but not nitrite and grow in 6.5% sodium chloride (Table 7-16). Although this species is reported to have been isolated mainly from human clinical material, there are only rare reports of a possible pathogenic role for this species. One patient with diabetes developed a chronic ear discharge associated with this organism,[830] an immunocompromised elderly man developed recurrent bacteremia in association with an intravenous catheter in,[546] and a patient with previous malignancy but no known immunosuppression developed bacteremia with this organism.[589]

A. denitrificans strains are found predominantly in the soil but can occasionally be found in human clinical specimens. Isolates have been reported from blood collection tubes, blood, ear, CSF, and urine.[1146] Serious infections attributed to *A. denitrificans* include community-acquired pneumonia,[54] peritoneal dialysis-related peritonitis,[147] and a patient with a renal abscess and a nephro-cutaneous fistula.[974] An organism that is biochemically similar to *A. denitrificans*, known as *Alcaligenes*-like group 1, has been recovered from blood, brain abscess, urine, bronchial wash, knee joint and water, suggesting that it may have greater potential to cause human infection. It can be differentiated from *A. denitrificans* by cellular fatty acid composition, failure to grow on SS agar, failure to alkalinize tartrate and acetamide, and a positive urease reaction (Table 7-16).[1172]

Two novel asaccharolytic *Achromobacter* species, *A. insolitus* and *A. spanius,* have

been recently described by Coenye et al.[218] These two species are found rarely in human clinical specimens. They are both oxidase and catalase positive and reduce nitrate without the formation of gas. They are both asaccharolytic and are biochemically difficult to separate from each other and from other asaccharolytic *Achromobacter* species and from *Alcaligenes faecalis*.[218]

Recently Vandamme and colleagues have named four new asaccharolytic species of *Achromobacter* representing different MLST genogroups. The new species are *A. mucicolens* (genogroup 4), *A. animicus* (genogroup 6), *A. spiritinus* (genogroup 10) and *A. pulmonis* (genogroup 11). All have been isolated from human sputum, some from patients with CF.[1111]

Saccharolytic *Achromobacter* Species. *A. xylosoxidans* is easily distinguished from the genus *Alcaligenes* and the asaccharolytic *Achromobacter* species by acidification of OF glucose and xylose (thus, the species name). It has been isolated from many types of specimens, most frequently blood,[8,304,384,1163] but also from CSF, bronchial washings, urine, pus, and wounds.[497,1145,1146] It may be an opportunistic pathogen that has been reported to cause nosocomial infections, including pneumonia, bacteremia, and meningitis,
